Table 2: Results for accuracy and execution time on the test data sets

$\mathbf{t_c}$ we used an Apache Spark cluster with 3 executor nodes of 10 cores and 30Gb of memory each. The same code was executed on both platforms. This is, actually, one of the advantages of the library presented here. In Table 2, we show the accuracy and execution time (in seconds) obtained for four data sets of increasing size by the three libraries (the documentation of the package contains the details for these data sets). Regarding accuracy, all the packages achieved comparable results, as should be expected. Regarding the execution time, the results obtained by our package are significantly better, especially in the last two data sets. Against `Ceka`, our implementation obtained a slight speedup even in the smallest data set for both algorithms. For the second data set, `spark-crowd` obtained speedups of several orders of magnitude. It was not possible to obtain results for the last two instances in a reasonable amount of time with `Ceka`. However, `spark-crowd` solved these cases in few minutes. `Truth-Inf` obtained better results in terms of execution time in comparison to Ceka. As the algorithms chosen in this comparison are quite simple in terms of time complexity, the benefits of parallelization are less apparent, especially in the first two instances for the MajorityVoting algorithm, where the implementation in `Truth-Inf` obtained better results in terms of execution time. However, as the data and the complexity of the algorithm increases, the cost of parallelization is less noticeable. In the MajorityVoting algorithm one can see good results in the last two data sets. For the DawidSkene algorithm, the benefits of parallelization can be seen from the second data set, with a significant speedup especially in the third. `Truth-Inf` was not able to complete the execution for the last data set, due to a memory error.

5. Future Plans and Conclusions

As this is a field of recent interest, new algorithms may appear. Thus, it is in our plans to add the most interesting algorithms to the package. We also expect to develop new features and algorithms that scale even better for this problem using this library as the base of further developments. Finally, we hope that the community contributes with new implementations, which we will be delighted to integrate into the library.

Abstract

We study robust PCA for the fully observed setting, which is about separating a low rank matrix $\boldsymbol{L}$ and a sparse matrix $\boldsymbol{S}$ from their sum $\boldsymbol{D} = \boldsymbol{L} + \boldsymbol{S}$. In this paper, a new algorithm, dubbed accelerated alternating projections, is introduced for robust PCA which significantly improves the computational efficiency of the existing alternating projections proposed in (Netrapalli et al., 2014) when updating the low rank factor. The acceleration is achieved by first projecting a matrix onto some low dimensional subspace before obtaining a new estimate of the low rank matrix via truncated SVD. Exact recovery guarantee has been established which shows linear convergence of the proposed algorithm. Empirical performance evaluations establish the advantage of our algorithm over other state-of-the-art algorithms for robust PCA.

Keywords: Robust PCA, Alternating Projections, Matrix Manifold, Tangent Space, Subspace Projection

1. Introduction

Robust principal component analysis (RPCA) appears in a wide range of applications, including video and voice background subtraction (Li et al., 2004; Huang et al., 2012), sparse graphs clustering (Chen et al., 2012), 3D reconstruction (Mobahi et al., 2011), and fault isolation (Tharrault et al., 2008). Suppose we are given a sum of a low rank matrix and a sparse matrix, denoted $\boldsymbol{D} = \boldsymbol{L} + \boldsymbol{S}$. The goal of RPCA is to reconstruct $\boldsymbol{L}$ and $\boldsymbol{S}$ simultaneously from $\boldsymbol{D}$. As a concrete example, for foreground-background separation in video processing, $\boldsymbol{L}$ represents static background through all the frames of a video which should be low rank while $\boldsymbol{S}$ represents moving objects which can be assumed to be sparse since typically they will not block a large portion of the screen for a long time.

RPCA can be achieved by seeking a low rank matrix $\boldsymbol{L}'$ and a sparse matrix $\boldsymbol{S}'$ such that their sum fits the measurement matrix $\boldsymbol{D}$ as well as possible:

$$\min_{\boldsymbol{L}',\boldsymbol{S}'\in\mathbb{R}^{m\times n}} \|\boldsymbol{D}-\boldsymbol{L}'-\boldsymbol{S}'\|_F \quad \text{subject to } rank(\boldsymbol{L}')\le r \text{ and } \|\boldsymbol{S}'\|_0\le|\Omega|, \tag{1}$$

where r denotes the rank of the underlying low rank matrix, Ω denotes the support set of the underlying sparse matrix, and $\|\boldsymbol{S}'\|_0$ counts the number of non-zero entries in $\boldsymbol{S}'$. Compared to the traditional principal component analysis (PCA) which computes a low rank approximation of a data matrix, RPCA is less sensitive to outliers since it includes a sparse part in the formulation.

Since the seminal works of (Wright et al., 2009; Candès et al., 2011; Chandrasekaran et al., 2011), RPCA has received intensive investigations both from theoretical and algorithmic aspects. Noticing that (1) is a non-convex problem, some of the earlier works focus on the following convex relaxation of RPCA:

$$\min_{\boldsymbol{L}',\boldsymbol{S}'\in\mathbb{R}^{m\times n}} \|\boldsymbol{L}'\|_*+\lambda\|\boldsymbol{S}'\|_1 \quad \text{subject to } \boldsymbol{L}'+\boldsymbol{S}'=\boldsymbol{D}, \tag{2}$$

where $\|\cdot\|_*$ is the nuclear norm (*viz.* trace norm) of matrices, λ is the regularization parameter, and $\|\cdot\|_1$ denotes the ℓ_1-norm of the vectors obtained by stacking the columns of associated matrices. Under some mild conditions, it has been proven that the RPCA problem can be solved exactly by the aforementioned convex relaxation Candès et al. (2011); Chandrasekaran et al. (2011). However, a limitation of the convex relaxation based approach is that the resulting semidefinite programming is computationally rather expensive to solve, even for medium size matrices. Alternative to the convex relaxation, many non-convex algorithms have been designed to target (1) directly. This line of research will be reviewed in more detail in Section 2.3 after our approach has been introduced.

This paper targets the non-convex optimization for RPCA directly. The main contributions of this work are two-fold. Firstly, we propose a new algorithm, accelerated alternating projections (AccAltProj), for RPCA, which is substantially faster than other state-of-the-art algorithms. Secondly, exact recovery of accelerated alternating projections has been established for the fixed sparsity model, where we assume the ratio of the number of non-zero entries in each row and column of $\boldsymbol{S}$ is less than a threshold.

1.1. Assumptions

It is clear that the RPCA problem is ill-posed without any additional conditions. Common assumptions are that $\boldsymbol{L}$ cannot be too sparse and $\boldsymbol{S}$ cannot be locally too dense, which are formalized in A1 and A2, respectively.

A1 *The underlying low rank matrix $\boldsymbol{L}\in\mathbb{R}^{m\times n}$ is a rank-r matrix with μ-incoherence, that is*

$$\max_i \|\boldsymbol{e}_i^T\boldsymbol{U}\|_2\le\sqrt{\frac{\mu r}{m}}, \quad \text{and} \quad \max_j \|\boldsymbol{e}_j^T\boldsymbol{V}\|_2\le\sqrt{\frac{\mu r}{n}}$$

hold for a positive numerical constant $1\le\mu\le\frac{\min\{m,n\}}{r}$, where $\boldsymbol{L}=\boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$ is the SVD of $\boldsymbol{L}$.

Assumption A1 was first introduced in (Candès and Recht, 2009) for low rank matrix completion, and now it is a very standard assumption for related low rank reconstruction problems. It basically states that the left and right singular vectors of $\boldsymbol{L}$ are weakly correlated with the canonical basis, which implies $\boldsymbol{L}$ cannot be a very sparse matrix.

A2 *The underlying sparse matrix $\boldsymbol{S} \in \mathbb{R}^{m\times n}$ is α-sparse. That is, $\boldsymbol{S}$ has at most αn non-zero entries in each row, and at most αm non-zero entries in each column. In the other words, for all $1 \le i \le m, 1 \le j \le n$,*

$$\|\boldsymbol{e}_i^T \boldsymbol{S}\|_0 \le \alpha n \quad \textit{and} \quad \|\boldsymbol{S}\boldsymbol{e}_j\|_0 \le \alpha m. \tag{3}$$

In this paper, we assume[1]

$$\alpha \lesssim \min\left\{\frac{1}{\mu r^2\kappa^3}, \frac{1}{\mu^{1.5} r^2 \kappa}, \frac{1}{\mu^2 r^2}\right\}, \tag{4}$$

where κ is the condition number of $\boldsymbol{L}$.

Assumption A2 states that the non-zero entries of the sparse matrix $\boldsymbol{S}$ cannot concentrate in a few rows or columns, so there does not exist a low rank component in $\boldsymbol{S}$. If the indices of the support set Ω are sampled independently from the Bernoulli distribution with the associated parameter being slightly smaller than α, by the Chernoff inequality, one can easily show that (3) holds with high probability.

1.2. Organization and Notation of the Paper

The rest of the paper is organized as follows. In the remainder of this section, we introduce standard notation that is used throughout the paper. Section 2.1 presents the proposed algorithm and discusses how to implement it efficiently. The theoretical recovery guarantee of the proposed algorithm is presented in Section 2.2, followed by a review of prior art for RPCA. In Section 3, we present the numerical simulations of our algorithm. Section 4 contains all the mathematical proofs of our main theoretical result. We conclude this paper with future directions in Section 5.

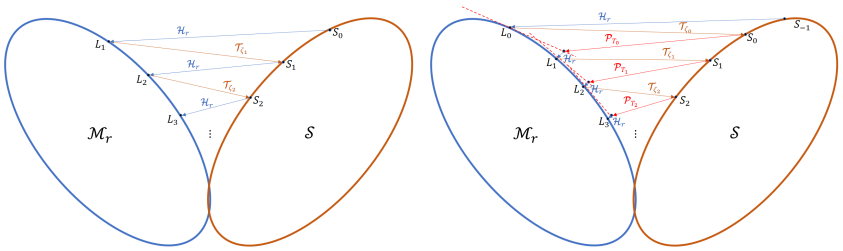
In this paper, vectors are denoted by bold lowercase letters (e.g., $\boldsymbol{x}$), matrices are denoted by bold capital letters (e.g., $\boldsymbol{X}$), and operators are denoted by calligraphic letters (e.g., $\mathcal{H}$). In particular, $\boldsymbol{e}_i$ denotes the i^{th} canonical basis vector, $\boldsymbol{I}$ denotes the identity matrix, and $\mathcal{I}$ denotes the identity operator. For a vector $\boldsymbol{x}$, $\|\boldsymbol{x}\|_0$ counts the number of non-zero entries in $\boldsymbol{x}$, and $\|\boldsymbol{x}\|_2$ denotes the ℓ_2 norm of $\boldsymbol{x}$. For a matrix $\boldsymbol{X}$, $[\boldsymbol{X}]_{ij}$ denotes its $(i,j)^{th}$ entry, $\sigma_i(\boldsymbol{X})$ denotes its i^{th} singular value, $\|\boldsymbol{X}\|_\infty = \max_{ij} |[\boldsymbol{X}]_{ij}|$ denotes the maximum magnitude of its entries, $\|\boldsymbol{X}\|_2 = \sigma_1(\boldsymbol{X})$ denotes its spectral norm, $\|\boldsymbol{X}\|_F = \sqrt{\sum_i \sigma_i^2(\boldsymbol{X})}$ denotes its Frobenius norm, and $\|\boldsymbol{X}\|_* = \sum_i \sigma_i(\boldsymbol{X})$ denotes its nuclear norm. The inner product of two real valued vectors is defined as $\langle \boldsymbol{x}, \boldsymbol{y}\rangle = \boldsymbol{x}^T\boldsymbol{y}$, and the inner product of two real valued matrices is defined as $\langle \boldsymbol{X}, \boldsymbol{Y}\rangle = Trace(\boldsymbol{X}^T\boldsymbol{Y})$, where $(\cdot)^T$ represents the transpose of a vector or matrix.

Additionally, we sometimes use the shorthand σ_i^A to denote the i^{th} singular value of a matrix $\boldsymbol{A}$. Note that $\kappa = \sigma_1^L/\sigma_r^L$ always denotes the condition number of the underlying rank-r matrix $\boldsymbol{L}$, and $\Omega = supp(\boldsymbol{S})$ is always referred to as the support of the underlying sparse matrix $\boldsymbol{S}$. At the k^{th} iteration of the proposed algorithm, the estimates of the low rank matrix and the sparse matrix are denoted by $\boldsymbol{L}_k$ and $\boldsymbol{S}_k$, respectively.

1. The standard notion "$\lesssim$" in (4) means there exists an absolute numerical constant $C > 0$ such that α can be upper bounded by C times the right hand side.

2. Algorithm and Theoretical Results

In this section, we present the new algorithm and its recovery guarantee. For ease of exposition, we assume all matrices are square (i.e., $m = n$), but emphasize that nothing is special about this assumption and all the results can be easily extended to rectangular matrices.



2.1. Proposed Algorithm

Alternating projections is a minimization approach that has been successfully used in many fields, including image processing (Wang et al., 2008; Chan and Wong, 2000; O'Sullivan and Benac, 2007), matrix completion (Keshavan et al., 2012; Jain et al., 2013; Hardt, 2013; Tanner and Wei, 2016), phase retrieval (Netrapalli et al., 2013; Cai et al., 2017; Zhang, 2017), and many others (Peters and Heath, 2009; Agarwal et al., 2014; Yu et al., 2016; Pu et al., 2017). A non-convex algorithm based on alternating projections, namely AltProj, is presented in (Netrapalli et al., 2014) for RPCA accompanied with a theoretical recovery guarantee. In each iteration, AltProj first updates $\boldsymbol{L}$ by projecting $\boldsymbol{D}-\boldsymbol{S}$ onto the space of rank-r matrices, denoted $\mathcal{M}_r$, and then updates $\boldsymbol{S}$ by projecting $\boldsymbol{D}-\boldsymbol{L}$ onto the space of sparse matrices, denoted $\mathcal{S}$; see the left plot of Figure 1 for an illustration. Regarding to the implementation of AltProj, the projection of a matrix onto the space of low rank matrices can be computed by the singular value decomposition (SVD) followed by truncating out small singular values, while the projection of a matrix onto the space of sparse matrices can be computed by the hard thresholding operator. As a non-convex algorithm which targets (1) directly, AltProj is computationally much more efficient than solving the convex relaxation problem (2) using semidefinite programming (SDP). However, when projecting $\boldsymbol{D}-\boldsymbol{S}$ onto the low rank matrix manifold, AltProj requires to compute the SVD of a full size matrix, which is computationally expensive. Inspired by the work in (Vandereycken, 2013; Wei et al., 2016a,b), we propose an accelerated algorithm for RPCA, coined accelerated alternating projections (AccAltProj), to circumvent the high computational cost of the SVD. The new algorithm is able to reduce the per-iteration computational cost of AltProj significantly, while a theoretical guarantee can be similarly established.

Our algorithm consists of two phases: initialization and projections onto $\mathcal{M}_r$ and $\mathcal{S}$ alternatively. We begin our discussion with the second phase, which is described in Algorithm 1. For geometric comparison between AltProj and AccAltProj, see Figure 1.

Let $(\boldsymbol{L}_k, \boldsymbol{S}_k)$ be a pair of current estimates. At the $(k+1)^{th}$ iteration, AccAltProj first trims $\boldsymbol{L}_k$ into an incoherent matrix $\widetilde{\boldsymbol{L}}_k$ using Algorithm 2. Noting that $\widetilde{\boldsymbol{L}}_k$ is still a rank-r matrix, so its left and right singular vectors define an $(2n-r)r$-dimensional subspace (Vandereycken, 2013),

$$\widetilde{T}_k = \{\widetilde{\boldsymbol{U}}_k\boldsymbol{A}^T + \boldsymbol{B}\widetilde{\boldsymbol{V}}_k^T \mid \boldsymbol{A}, \boldsymbol{B} \in \mathbb{R}^{n\times r}\}, \tag{5}$$

(i) Illustration of AltProj (ii) Illustration of AccAltProj

Figure 1: Visual comparison between AltProj and AccAltProj, where $\mathcal{M}_r$ denotes the manifold of rank-r matrices and $\mathcal{S}$ denotes the set of sparse matrices. The red dash line in (ii) represents the tangent space of $\mathcal{M}_r$ at $\boldsymbol{L}_k$. In fact, each circle represents a sum of a low rank matrix and a sparse matrix, but with the component on one circle fixed when projecting onto the other circle. For conciseness, the trim stage, i.e., $\widetilde{\boldsymbol{L}}_k$, is not included in the plot for AccAltProj.

Algorithm 1 Robust PCA by Accelerated Alternating Projections (AccAltProj)

Input: $\boldsymbol{D} = \boldsymbol{L} + \boldsymbol{S}$: matrix to be split; r: rank of $\boldsymbol{L}$; ϵ: target precision level; β: thresholding parameter; γ: target converge rate; μ: incoherence parameter of $\boldsymbol{L}$.
Initialization
$k = 0$
while $\|\boldsymbol{D} - \boldsymbol{L}_k - \boldsymbol{S}_k\|_F / \|\boldsymbol{D}\|_F \geq \epsilon$ **do**
  $\widetilde{\boldsymbol{L}}_k = \mathrm{Trim}(\boldsymbol{L}_k, \mu)$
  $\boldsymbol{L}_{k+1} = \mathcal{H}_r(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D} - \boldsymbol{S}_k))$
  $\zeta_{k+1} = \beta\left(\sigma_{r+1}\left(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D} - \boldsymbol{S}_k)\right) + \gamma^{k+1}\sigma_1\left(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D} - \boldsymbol{S}_k)\right)\right)$
  $\boldsymbol{S}_{k+1} = \mathcal{T}_{\zeta_{k+1}}(\boldsymbol{D} - \boldsymbol{L}_{k+1})$
  $k = k + 1$
end while
Output: $\boldsymbol{L}_k$, $\boldsymbol{S}_k$

where $\widetilde{\boldsymbol{L}}_k = \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{\Sigma}}_k\widetilde{\boldsymbol{V}}_k^T$ is the SVD of $\widetilde{\boldsymbol{L}}_k$[2]. Given a matrix $\boldsymbol{Z} \in \mathbb{R}^{n\times n}$, it can be easily verified that the projections of $\boldsymbol{Z}$ onto the subspace $\widetilde{T}_k$ and its orthogonal complement are given by

$$\mathcal{P}_{\widetilde{T}_k}\boldsymbol{Z} = \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{Z} + \boldsymbol{Z}\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{Z}\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T \tag{6}$$

and

$$(\mathcal{I} - \mathcal{P}_{\widetilde{T}_k})\boldsymbol{Z} = (\boldsymbol{I} - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\boldsymbol{Z}(\boldsymbol{I} - \widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T). \tag{7}$$

2. In practice, we only need the trimmed orthogonal matrices $\widetilde{\boldsymbol{U}}_k$ and $\widetilde{\boldsymbol{V}}_k$ for the projection $\mathcal{P}_{\widetilde{T}_k}$, and they can be computed efficiently via a QR decomposition. The entire matrix $\widetilde{\boldsymbol{L}}_k$ should never be formed in an efficient implementation of AccAltProj.

Algorithm 2 Trim

Input: $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$: matrix to be trimmed; μ: target incoherence level.
$c_\mu = \sqrt{\frac{\mu r}{n}}$
for $i = 1$ `to` m **do**
  $\boldsymbol{A}^{(i)} = \min\{1, \frac{c_\mu}{\|\boldsymbol{U}^{(i)}\|}\}\boldsymbol{U}^{(i)}$
end for
for $j = 1$ `to` n **do**
  $\boldsymbol{B}^{(j)} = \min\{1, \frac{c_\mu}{\|\boldsymbol{V}^{(j)}\|}\}\boldsymbol{V}^{(i)}$
end for
Output: $\widetilde{\boldsymbol{L}} = \boldsymbol{A}\boldsymbol{\Sigma}\boldsymbol{B}$

As stated previously, AltProj truncates the SVD of $\boldsymbol{D} - \boldsymbol{S}_k$ directly to get a new estimate of $\boldsymbol{L}$. In contrast, AccAltProj first projects $\boldsymbol{D} - \boldsymbol{S}_k$ onto the low dimensional subspace $\widetilde{T}_k$, and then projects the intermediate matrix onto the rank-r matrix manifold $\mathcal{M}_r$ using the truncated SVD. That is,

$$\boldsymbol{L}_{k+1} = \mathcal{H}_r(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D} - \boldsymbol{S}_k)),$$

where $\mathcal{H}_r$ computes the best rank-r approximation of a matrix,

$$\mathcal{H}_r(\boldsymbol{Z}) := \boldsymbol{Q}\boldsymbol{\Lambda}_r\boldsymbol{P}^T \text{ where } \boldsymbol{Z} = \boldsymbol{Q}\boldsymbol{\Lambda}\boldsymbol{P}^T \text{ is its SVD and } [\boldsymbol{\Lambda}_r]_{ii} := \begin{cases} [\boldsymbol{\Lambda}]_{ii} & i \leq r \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

Before proceeding, it is worth noting that the set of rank-r matrices $\mathcal{M}_r$ form a smooth manifold of dimension $(2n - r)r$, and $\widetilde{T}_k$ is indeed the tangent space of $\mathcal{M}_r$ at $\widetilde{\boldsymbol{L}}_k$ (Vandereycken, 2013). Matrix manifold algorithms based on the tangent space of low dimensional spaces have been widely studied in the literature, see for example (Ngo and Saad, 2012; Mishra et al., 2012; Vandereycken, 2013; Mishra and Sepulchre, 2014; Mishra et al., 2014; Wei et al., 2016a,b) and references therein. In particular, we invite readers to explore the book (Absil et al., 2009) for more details about the differential geometry ideas behind manifold algorithms.

One can see that a SVD is still needed to obtain the new estimate $\boldsymbol{L}_{k+1}$. Nevertheless, it can be computed in a very efficient way (Vandereycken, 2013; Wei et al., 2016a,b). Let $(\boldsymbol{I} - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k = \boldsymbol{Q}_1\boldsymbol{R}_1$ and $(\boldsymbol{I} - \widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{U}}_k = \boldsymbol{Q}_2\boldsymbol{R}_2$ be the QR decompositions of $(\boldsymbol{I} - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k$ and $(\boldsymbol{I} - \widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{U}}_k$, respectively. Note that $(\boldsymbol{I} - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k$ and $(\boldsymbol{I} - \widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{U}}_k$ can be computed by one matrix-matrix subtraction between an $n \times n$ matrix and an $n \times n$ matrix, two matrix-matrix multiplications between an $n \times n$ matrix and an $n \times r$ matrix, and a few matrix-matrix multiplications between a $r \times n$ and an $n \times r$ or between an $n \times r$ matrix and a $r \times r$ matrix. Moreover, A little algebra gives

$$\begin{aligned}
\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D} - \boldsymbol{S}_k) &= \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T(\boldsymbol{D} - \boldsymbol{S}_k) + (\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T \\
&= \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T(\boldsymbol{D} - \boldsymbol{S}_k)(\boldsymbol{I} - \widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T) + (\boldsymbol{I} - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T + \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T \\
&= \widetilde{\boldsymbol{U}}_k\boldsymbol{R}_2^T\boldsymbol{Q}_2^T + \boldsymbol{Q}_1\boldsymbol{R}_1\widetilde{\boldsymbol{V}}_k^T + \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T(\boldsymbol{D} - \boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T
\end{aligned}$$

$$= \begin{bmatrix} \widetilde{\boldsymbol{U}}_k & \boldsymbol{Q}_1 \end{bmatrix} \begin{bmatrix} \widetilde{\boldsymbol{U}}_k^T(\boldsymbol{D}-\boldsymbol{S}_k)\widetilde{\boldsymbol{V}}_k & \boldsymbol{R}_2^T \\ \boldsymbol{R}_1 & \boldsymbol{0} \end{bmatrix} \begin{bmatrix} \widetilde{\boldsymbol{V}}_k^T \\ \boldsymbol{Q}_2^T \end{bmatrix}$$
$$:= \begin{bmatrix} \widetilde{\boldsymbol{U}}_k & \boldsymbol{Q}_1 \end{bmatrix} \boldsymbol{M}_k \begin{bmatrix} \widetilde{\boldsymbol{V}}_k^T \\ \boldsymbol{Q}_2^T \end{bmatrix},$$

where the fourth line follows from the fact $\widetilde{\boldsymbol{U}}_k^T\boldsymbol{Q}_1 = \widetilde{\boldsymbol{V}}_k^T\boldsymbol{Q}_2 = \boldsymbol{0}$. Let $\boldsymbol{M}_k = \boldsymbol{U}_{M_k}\boldsymbol{\Sigma}_{M_k}\boldsymbol{V}_{M_k}^T$ be the SVD of $\boldsymbol{M}_k$, which can be computed using $O(r^3)$ flops since $\boldsymbol{M}_k$ is a $2r \times 2r$ matrix. Then the SVD of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k) = \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{\Sigma}}_k\widetilde{\boldsymbol{V}}_k^T$ can be computed by

$$\widetilde{\boldsymbol{U}}_{k+1} = \begin{bmatrix} \widetilde{\boldsymbol{U}}_k & \boldsymbol{Q}_1 \end{bmatrix} \boldsymbol{U}_{M_k}, \quad \widetilde{\boldsymbol{\Sigma}}_{k+1} = \boldsymbol{\Sigma}_{M_k}, \quad \text{and} \quad \widetilde{\boldsymbol{V}}_{k+1} = \begin{bmatrix} \widetilde{\boldsymbol{V}}_k & \boldsymbol{Q}_2 \end{bmatrix} \boldsymbol{V}_{M_k} \tag{9}$$

since both the matrices $\begin{bmatrix} \widetilde{\boldsymbol{U}}_k & \boldsymbol{Q}_1 \end{bmatrix}$ and $\begin{bmatrix} \widetilde{\boldsymbol{V}}_k & \boldsymbol{Q}_2 \end{bmatrix}$ are orthogonal. In summary, the overall computational costs of $\mathcal{H}_r(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k))$ lie in one matrix-matrix subtraction between an $n \times n$ matrix and an $n \times n$ matrix, two matrix-matrix multiplications between an $n \times n$ matrix and an $n \times r$ matrix, the QR decomposition of two $n \times r$ matrices, an SVD of a $2r \times 2r$ matrix, and a few matrix-matrix multiplications between a $r \times n$ matrix and an $n \times r$ matrix or between an $n \times r$ matrix and a $r \times r$ matrix, leading to a total of $4n^2r + n^2 + O(nr^2 + r^3)$ flops. Thus, the dominant per iteration computational complexity of AccAltProj for updating the estimate of $\boldsymbol{L}$ is the same as the novel gradient descent based approach introduced in (Yi et al., 2016). In contrast, computing the best rank-r approximation of a non-structured $n \times n$ matrix $\boldsymbol{D}-\boldsymbol{S}_k$ typically costs $O(n^2r) + n^2$ flops with a large hidden constant in front of n^2r.

After $\boldsymbol{L}_{k+1}$ is obtained, following the approach in (Netrapalli et al., 2014), we apply the hard thresholding operator to update the estimate of the sparse matrix,

$$\boldsymbol{S}_{k+1} = \mathcal{T}_{\zeta_{k+1}}(\boldsymbol{D}-\boldsymbol{L}_{k+1}),$$

where the thresholding operator $\mathcal{T}_{\zeta_{k+1}}$ is defined as

$$[\mathcal{T}_{\zeta_{k+1}}\boldsymbol{Z}]_{ij} = \begin{cases} [\boldsymbol{Z}]_{ij} & |[\boldsymbol{Z}]_{ij}| > \zeta_{k+1} \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

for any matrix $\boldsymbol{Z} \in \mathbb{R}^{m\times n}$. Notice that the thresholding value of ζ_{k+1} in Algorithm 1 is chosen as

$$\zeta_{k+1} = \beta\left(\sigma_{r+1}\left(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)\right) + \gamma^{k+1}\sigma_1\left(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)\right)\right),$$

which relies on a tuning parameter $\beta > 0$, a convergence rate parameter $0 \le \gamma < 1$, and the singular values of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$. Since we have already obtained all the singular values of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$ when computing $\boldsymbol{L}_{k+1}$, the extra cost of computing ζ_{k+1} is very marginal. Therefore, the cost of updating the estimate of $\boldsymbol{S}$ is very low and insensitive to the sparsity of $\boldsymbol{S}$.

In this paper, a good initialization is achieved by two steps of modified AltProj when setting the input rank to r, see Algorithm 3. With this initialization scheme, we can construct an initial guess that is sufficiently close to the ground truth and is inside the "basin of attraction" as detailed in the next subsection. Note that the thresholding parameter β_{init} used in Algorithm 3 is different from that in Algorithm 1.

Algorithm 3 Initialization by Two Steps of AltProj

Input: $\boldsymbol{D} = \boldsymbol{L} + \boldsymbol{S}$: matrix to be split; r: rank of $\boldsymbol{L}$; β_{init}, β: thresholding parameters.
$\boldsymbol{L}_{-1} = \boldsymbol{0}$
$\zeta_{-1} = \beta_{init} \cdot \sigma_1^D$
$\boldsymbol{S}_{-1} = \mathcal{T}_{\zeta_{-1}}(\boldsymbol{D}-\boldsymbol{L}_{-1})$
$\boldsymbol{L}_0 = \mathcal{H}_r(\boldsymbol{D}-\boldsymbol{S}_{-1})$
$\zeta_0 = \beta \cdot \sigma_1(\boldsymbol{D}-\boldsymbol{S}_{-1})$
$\boldsymbol{S}_0 = \mathcal{T}_{\zeta_0}(\boldsymbol{D}-\boldsymbol{L}_0)$
Output: $\boldsymbol{L}_0$, $\boldsymbol{S}_0$

2.2. Theoretical Guarantee

In this subsection, we present the theoretical recovery guarantee of AccAltProj (Algorithm 1 together with Algorithm 3). The following theorem establishes the local convergence of AccAltProj.

Theorem 1 (Local Convergence of AccAltProj) *Let $\boldsymbol{L} \in \mathbb{R}^{n\times n}$ and $\boldsymbol{S} \in \mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2. If the initial guesses $\boldsymbol{L}_0$ and $\boldsymbol{S}_0$ obey the following conditions:*

$$\|\boldsymbol{L}-\boldsymbol{L}_0\|_2 \le 8\alpha\mu r\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_0\|_\infty \le \frac{\mu r}{n}\sigma_1^L, \quad \text{and} \quad supp(\boldsymbol{S}_0) \subset \Omega,$$

then the iterates of Algorithm 1 with parameters $\beta = \frac{\mu r}{2n}$ and $\gamma \in \left(\frac{1}{\sqrt{12}}, 1\right)$ satisfy

$$\|\boldsymbol{L}-\boldsymbol{L}_k\|_2 \le 8\alpha\mu r\gamma^k\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty \le \frac{\mu r}{n}\gamma^k\sigma_1^L, \quad \text{and} \quad supp(\boldsymbol{S}_k) \subset \Omega.$$

The next theorem states that the initial guesses obtained from Algorithm 3 fulfill the conditions required in Theorem 1.

Theorem 2 (Guaranteed Initialization) *Let $\boldsymbol{L} \in \mathbb{R}^{n\times n}$ and $\boldsymbol{S} \in \mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2, respectively. If the thresholding parameters obey $\frac{\mu r\sigma_1^L}{n\sigma_1^D} \le \beta_{init} \le \frac{3\mu r\sigma_1^L}{n\sigma_1^D}$ and $\beta = \frac{\mu r}{2n}$, then the outputs of Algorithm 3 satisfy*

$$\|\boldsymbol{L}-\boldsymbol{L}_0\|_2 \le 8\alpha\mu r\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_0\|_\infty \le \frac{\mu r}{n}\sigma_1^L, \quad \text{and} \quad supp(\boldsymbol{S}_0) \subset \Omega.$$

The proofs of Theorems 1 and 2 are presented in Section 4. The convergence of AccAltProj follows immediately by combining the above two theorems together.

For conciseness, the main theorems are stated for symmetric matrices. However, similar results can be established for nonsymmetric matrix recovery problems as they can be cast as problems with respect to symmetric augmented matrices, as suggested in (Netrapalli et al., 2014). Without loss of generality, assume $dm \le n < (d+1)m$ for some $d \ge 1$ and construct

$\overline{\boldsymbol{L}}$ and $\overline{\boldsymbol{S}}$ as

$$\overline{\boldsymbol{L}} := \begin{bmatrix} \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{L} \\ \vdots & \ddots & \vdots & \vdots \\ \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{L} \\ \underbrace{\boldsymbol{L}^T \quad \cdots \quad \boldsymbol{L}^T}_{d \text{ times}} & & & \mathbf{0} \end{bmatrix} \Bigg\} d \text{ times}, \qquad \overline{\boldsymbol{S}} := \begin{bmatrix} \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{S} \\ \vdots & \ddots & \vdots & \vdots \\ \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{S} \\ \underbrace{\boldsymbol{S}^T \quad \cdots \quad \boldsymbol{S}^T}_{d \text{ times}} & & & \mathbf{0} \end{bmatrix} \Bigg\} d \text{ times}.$$

Then it is not hard to see that $\overline{\boldsymbol{L}}$ is $O(\mu)$-incoherent, and $\overline{\boldsymbol{S}}$ is $O(\alpha)$-sparse, with the hidden constants being independent of d. Moreover, based on the connection between the SVD of the augmented matrix and that of the original one, it can be easily verified that at the k^{th} iteration the estimates returned by AccAltProj with input $\overline{\boldsymbol{D}} = \overline{\boldsymbol{L}} + \overline{\boldsymbol{S}}$ have the form

$$\overline{\boldsymbol{L}}_k = \begin{bmatrix} \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{L}_k \\ \vdots & \ddots & \vdots & \vdots \\ \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{L}_k \\ \underbrace{\boldsymbol{L}_k^T \quad \cdots \quad \boldsymbol{L}_k^T}_{d \text{ times}} & & & \mathbf{0} \end{bmatrix} \Bigg\} d \text{ times}, \qquad \overline{\boldsymbol{S}}_k = \begin{bmatrix} \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{S}_k \\ \vdots & \ddots & \vdots & \vdots \\ \mathbf{0} & \cdots & \mathbf{0} & \boldsymbol{S}_k \\ \underbrace{\boldsymbol{S}_k^T \quad \cdots \quad \boldsymbol{S}_k^T}_{d \text{ times}} & & & \mathbf{0} \end{bmatrix} \Bigg\} d \text{ times},$$

where $\boldsymbol{L}_k, \boldsymbol{S}_k$ are the the k^{th} estimates returned by AccAltProj with input $\boldsymbol{D} = \boldsymbol{L} + \boldsymbol{S}$.

2.3. Related Work

As mentioned earlier, convex relaxation based methods for RPCA have higher computational complexity and slower convergence rate which are not applicable for high dimensional problems. In fact, the convergence rate of the algorithm for computing the solution to the SDP formulation of RPCA (Candès et al., 2011; Chandrasekaran et al., 2011; Xu et al., 2010) is sub-linear with the per iteration computational complexity being $O(n^3)$. By contrast, AccAltProj only requires $O(\log(1/\epsilon))$ iterations to achieve an accuracy of ϵ, and the dominant per iteration computational cost is $O(rn^2)$.

There have been many other algorithms which are designed to solve the non-convex RPCA problem directly. In (Wang et al., 2013), an alternating minimization algorithm was proposed for (1) based on the factorization model of low rank matrices. However, only convergence to fixed points was established there. In (Gu et al., 2016), the authors developed an alternating minimization algorithm for RPCA, which allows the sparsity level α to be $O(1/(\mu^{2/3}r^{2/3}n))$ for successful recovery, which is more stringent than our result when $r \ll n$. A projected gradient descent algorithm was proposed in Chen and Wainwright (2015) for the special case of positive semidefinite matrices based on the ℓ_1-norm of each row of the underlying sparse matrix, which is not very practical.

In Table 1, we compare AccAltProj with the other two competitive non-convex algorithms for RPCA: AltProj from (Netrapalli et al., 2014) and non-convex gradient descent

(GD) from (Yi et al., 2016). GD attempts to reconstruct the low rank matrix by minimizing an objective function which contains the prior knowledge of the sparse matrix. The table displays the computational complexity of each algorithm for updating the estimates of the low rank matrix and the sparse matrix, as well as the convergence rate and the theoretical tolerance for the number of non-zero entries in the sparse matrix.

From the table, we can see that AccAltProj achieves the same linear convergence rate as AltProj, which is faster than GD. Moreover, AccAltProj has the lowest per iteration computational complexity for updating both the estimates of $\boldsymbol{L}$ and $\boldsymbol{S}$ (ties with AltProj for updating the sparse part). It is worth emphasizing that the acceleration stage in AccAltProj which first projects $\boldsymbol{D} - \boldsymbol{S}_k$ onto a low dimensional subspace reduces the computational cost of the SVD in AltProj dramatically. Overall, AccAltProj will be substantially faster than AltProj and GD, as confirmed by our numerical simulations in next section. The table also shows that the theoretical sparsity level that can be tolerated by AccAltProj is lower than that of GD and AltProj. Our result looses an order in r because we have replaced the spectral norm by the Frobenius norm when considering the reduction of the reconstruction error in terms of the spectral norm. In addition, the condition number of the target matrix appears in the theoretical result because the current version of AccAltProj deals with the fixed rank case which requires the initial guess is sufficiently close to the target matrix for the theoretical analysis. Nevertheless, we note that the sufficient condition regarding to α to guarantee the exact recovery of AccAltProj is highly pessimistic when compared with its empirical performance. Numerical investigations in next section show that AccAltProj can tolerate as large α as AltProj does under different energy levels.

Table 1: Comparison of AccAltProj, AltProj and GD.

Algorithm	AccAltProj	AltProj	GD
Updating $\boldsymbol{S}$	$\boldsymbol{O}\left(\boldsymbol{n^2}\right)$	$O\left(rn^2\right)$	$O\left(n^2 + \alpha n^2 \log(\alpha n)\right)$
Updating $\boldsymbol{L}$	$\boldsymbol{O}\left(\boldsymbol{rn^2}\right)$	$O\left(r^2n^2\right)$	$\boldsymbol{O}\left(\boldsymbol{rn^2}\right)$
Tolerance of α	$O\left(\frac{1}{\max\{\mu r^2\kappa^3, \mu^{1.5}r^2\kappa, \mu^2r^2\}}\right)$	$\boldsymbol{O}\left(\frac{\mathbf{1}}{\boldsymbol{\mu r}}\right)$	$O\left(\frac{1}{\max\{\mu r^{1.5}\kappa^{1.5}, \mu r\kappa^2\}}\right)$
Iterations needed	$\boldsymbol{O}\left(\mathbf{log}\left(\frac{\mathbf{1}}{\boldsymbol{\epsilon}}\right)\right)$	$\boldsymbol{O}\left(\mathbf{log}\left(\frac{\mathbf{1}}{\boldsymbol{\epsilon}}\right)\right)$	$O\left(\kappa \log(\frac{1}{\epsilon})\right)$

3. Numerical Expierments

In this section, we present the empirical performance of our AccAltProj algorithm and compare it with the state-of-the-art AltProj algorithm from (Netrapalli et al., 2014) and the leading gradient descent based algorithm (GD) from (Yi et al., 2016). The tests are conducted on a laptop equipped with 64-bit Windows 7, Intel i7-4712HQ (4 Cores at 2.3 GHz) and 16GB DDR3L-1600 RAM, and executed from MATLAB R2017a. We implement AltProj by ourselves, while the codes for GD are downloaded from the author's website[3]. Hand tuned parameters are used for these algorithms to achieve the best performance in the numerical comparison. The codes for AccAltProj can be found online:

3. Website: `www.yixinyang.org/code/RPCA_GD.zip`.

https://github.com/caesarcai/AccAltProj_for_RPCA.

Notice that the computation of an initial guess by Algorithm 3 requires the truncated SVD on a full size matrix. As is typical in the literature, we used the PROPACK library[4] for this task when the size of $\boldsymbol{D}$ is large and r is relatively small. To reduce the dependence of the theoretical result on the condition number of the underlying low rank matrix, AltProj was originally designed to loop r stages for the input rank increasing from 1 to r and each stage contains a few number of iterations for a fixed rank. However, when the condition number is medium large which is the case in our tests, we have observed that AltProj achieves the best computational efficiency when fixing the rank to r. Thus, to make fair comparison, we test AltProj when input rank is fixed, the same as the other two algorithms.

Synthetic Datasets We follow the setup in (Netrapalli et al., 2014) and (Yi et al., 2016) for the random tests on synthetic data. An $n \times n$ rank r matrix $\boldsymbol{L}$ is formed via $\boldsymbol{L} = \boldsymbol{P}\boldsymbol{Q}^T$, where $\boldsymbol{P}, \boldsymbol{Q} \in \mathbb{R}^{n\times r}$ are two random matrices having their entries drawn i.i.d from the standard normal distribution. The locations of the non-zero entries of the underlying sparse matrix $\boldsymbol{S}$ are sampled uniformly and independently without replacement, while the values of the non-zero entries are drawn i.i.d from the uniform distribution over the interval $[-c \cdot \mathbb{E}(|[\boldsymbol{L}]_{ij}|), c \cdot \mathbb{E}(|[\boldsymbol{L}]_{ij}|)]$ for some constant $c > 0$. The relative computing error at the k^{th} iteration of a single test is defined as

$$err_k = \frac{\|\boldsymbol{D} - \boldsymbol{L}_k - \boldsymbol{S}_k\|_F}{\|\boldsymbol{D}\|_F}. \tag{11}$$

The test algorithms are terminated when either the relative computing error is smaller than a tolerance, $err_k < tol$, or a maximum number of 100 iterations is reached. Recall that μ is the incoherence parameter of the low rank matrix $\boldsymbol{L}$ and α is the sparsity parameter of the sparse matrix $\boldsymbol{S}$. In the random tests, we use 1.1μ in AltProj and AccAltProj, and use 1.1α in GD.

Though we are only able to provide a theoretical guarantee for AccAltProj with trim in this paper, it can be easily seen that AccAltProj can also be implemented without the trim step. Thus, both AccAltProj with and without trim are tested. The parameters β and β_{init} are set to be $\beta = \frac{1.1\mu r}{2\sqrt{mn}}$ and $\beta_{init} = \frac{1.1\mu r}{\sqrt{mn}}$ in our experiments, and $\gamma = 0.5$ is used when $\alpha < 0.55$ and $\gamma = 0.65$ is used when $\alpha \geq 0.55$.

We first test the performance of the algorithms under different values of α for fixed $n = 2500$ and $r = 5$. Three different values of c are investigated: $c \in \{0.2, 1, 5\}$, which represent three different signal levels of $\boldsymbol{S}$. For each value of c, 10 different values of α from 0.3 to 0.75 are tested. We set $tol = 10^{-6}$ in the stopping condition for all the test algorithms. The backtracking line search has been used in GD which can improve its recovery performance substantially in our tests. An algorithm is considered to have successfully reconstructed $\boldsymbol{L}$ (or equivalently, $\boldsymbol{S}$) if the low rank output of the algorithm $\boldsymbol{L}_k$ satisfies

$$\frac{\|\boldsymbol{L}_k - \boldsymbol{L}\|_F}{\|\boldsymbol{L}\|_F} \leq 10^{-4}.$$

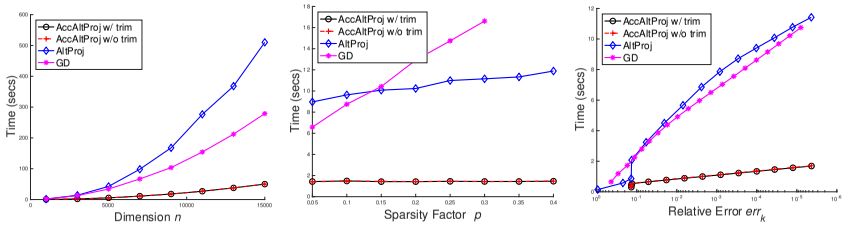
Table 2: Rate of success for AccAltProj with and without trim, AltProj, and GD for different values of α.

$c = 0.2$	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65	0.7	0.75
AccAltProj w/ trim	10	10	10	10	10	10	10	10	4	0
AccAltProj w/o trim	10	10	10	10	10	10	10	10	4	0
AltProj	10	10	10	10	10	10	10	10	0	0
GD	10	10	10	0	0	0	0	0	0	0

$c = 1$	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65	0.7	0.75
AccAltProj w/ trim	10	10	10	10	10	10	10	9	0	0
AccAltProj w/o trim	10	10	10	10	10	10	10	9	0	0
AltProj	10	10	10	10	10	10	10	8	0	0
GD	10	10	10	10	9	0	0	0	0	0



$c = 5$	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65	0.7	0.75
AccAltProj w/ trim	10	10	10	10	10	10	10	5	0	0
AccAltProj w/o trim	10	10	10	10	10	10	10	5	0	0
AltProj	10	10	10	10	10	10	10	3	0	0
GD	10	10	10	10	10	10	7	0	0	0

The number of successful reconstructions for each algorithm out of 10 random tests are presented in Table 2. It is clear that AccAltProj (with and without trim) and AltProj exhibit similar behavior even though the theoretical requirement of AccAltProj with trim is a bit more stringent than that of AltProj, and they can tolerate larger values of α than GD when c is small.

Next, we evaluate the runtime of the test algorithms. The computational results are plotted in Figure 2 together with the setup corresponding to each plot. Figure 2(i) shows that AccAltProj is substantially faster than AltProj and GD. In particular, when n is large, it achieves about 10× speedup. Figure 2(ii) shows that AccAltProj and AltProj are less sensitive to the sparsity of $\boldsymbol{S}$. Notice that we have used a well-tuned fixed stepsize for GD here so that it can achieve the best computational efficiency. Thus, GD fails to converge when $\alpha \geq 0.35$ which is smaller than the largest value of α for successful recovery corresponding to $c = 1$ in Table 2. Lastly, Figure 2(iii) shows the lowest computational time of AccAltProj against the relative computing error.

Video Background Subtraction In this section, we compare the performance of AccAltProj with and without trim, AltProj and GD on video background subtraction, a real world benchmark problem for RPCA. The task in background subtraction is to separate moving foreground objects from a static background. The two videos we have used for this test are *Shoppingmall* and *Restaurant* which can be found online[5].The size of each frame of *Shoppingmall* is 256×320 and that of *Restaurant* is 120×160. The total number of frames are 1000 and 3055 in *Shoppingmall* and *Restaurant*, respectively. Each video can be represented by a matrix, where each column of the matrix is a vectorized frame of the

5. Website: perception.i2r.a-star.edu.sg/bk_model/bk_index.html.

(i) Varying Dimension vs Runtime (ii) Varying Sparsity vs Runtime (iii) Relative Error vs Runtime

Figure 2: Runtime for synthetic datasets: (i) Varying dimension n vs runtime, where $r = 5$, $\alpha = 0.1$, $c = 1$, and n varies from 1000 to 15000. The algorithms are terminated after $err_k < 10^{-4}$ is satisfied. (ii) Varying sparsity factor α vs runtime, where $r = 5$, $c = 1$ and $n = 2500$. The algorithms are terminated when either $err_k < 10^{-4}$ or 100 number of iterations is reached, whichever comes first. (iii) Relative error err_k vs runtime, where $r = 5$, $\alpha = 0.1$, $c = 1$, and $n = 2500$. The algorithms are terminated after $err_k < 10^{-5}$ is satisfied so that we can observe more iterations.

Table 3: Computational results for video background subtraction. Here "S" represents *Shoppingmall*, "R" represents *Restaurant*, and μ is the incoherence parameter of the output low rank matrices along the time axis (i.e., among different frames).

	AccAltProj w/ trim		AccAltProj w/o trim		AltProj		GD	
	runtime	μ	runtime	μ	runtime	μ	runtime	μ
S	38.98s	2.12	38.79s	2.26	82.97s	2.13	161.1s	2.85
R	28.09s	5.16	27.94s	5.25	69.12s	5.28	107.3s	6.07

video. Then, we apply each algorithm to decompose the matrix into a low rank part which represents the static background of the video and a sparse part which represents the moving objects in the video. Since there is no ground truth for the incoherence parameter and the sparsity parameter, their values are estimated by trial-and-error in the tests. We set $\gamma = 0.7$ and $r = 2$ in the decomposition of both videos, and *tol* is set to 10^{-4} in the stopping criteria. All the four algorithms can achieve desirable visual performance for the two tested videos and we only present the decomposition results of three selected frames for both AccAltProj with trim and without trim in Figure 3.

Table 3 contains the runtime of each algorithm. We can see that AccAltProj with and without trim are also faster than AltProj and GD for the background subtraction experiments conducted here. We also include the incoherence values of the output low rank matrices along the time axis. It is worth noting that the incoherence parameter value of the low rank output from AccAltProj with trim are smaller than that from AccAltProj without trim, which suggests the output backgrounds from AccAltProj with trim are more consistent through all the frames. Additionally, AccAltProj and AltProj have comparable output incoherence.

Figure 3: Video background subtraction: The top three rows correspond to three different frames from the video *Shoppingmall*, while the bottom three rows are frames from the video *Restaurant*. The first column contains the original frames, the middle two columns are the separated background and foreground outputs of AccAltProj with trim, and the right two columns are the separated background and foreground outputs of AccAltProj without trim.

4. Proofs

4.1. Proof of Theorem 1

The proof of Theorem 1 follows a route established in (Netrapalli et al., 2014). Despite this, the details of the proof itself are nevertheless quite involved because there are two more operations (i.e., projection onto a tangent space and trim) in AccAltProj than in AltProj. Overall, the proof consists of two steps:

- When $\|\boldsymbol{L}-\boldsymbol{L}_k\|_2$ and $\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty$ are sufficiently small, and $supp(\boldsymbol{S}_k)\subset\Omega$, then $\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_2$ deceases in some sense by a constant factor (see Lemma 12) and $\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_\infty$ is small (see Lemma 13).
- When $\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_\infty$ is sufficiently small, we can choose ζ_{k+1} such that $supp(\boldsymbol{S}_{k+1})\subset\Omega$ and $\|\boldsymbol{S}-\boldsymbol{S}_{k+1}\|_\infty$ is small (see Lemma 14).

These results will be presented in a set of lemmas. For ease of notation we define $\tau:=4\alpha\mu r\kappa$ and $\upsilon:=\tau(48\sqrt{\mu r}\kappa+\mu r)$ in the sequel.

Lemma 3 ***(Weyl's inequality)*** *Let $\boldsymbol{A},\boldsymbol{B},\boldsymbol{C}\in\mathbb{R}^{n\times n}$ be the symmetric matrices such that $\boldsymbol{A}=\boldsymbol{B}+\boldsymbol{C}$. Then the inequality*

$$|\sigma_i^A-\sigma_i^B|\le\|\boldsymbol{C}\|_2$$

holds for all i, where σ_i^A and σ_i^B represent the i^{th} singular values of $\boldsymbol{A}$ and $\boldsymbol{B}$ respectively.

Proof This is a well-known result and the proof can be found in many standard textbooks, see for example Bhatia (2013). ■

Lemma 4 *Let $\boldsymbol{S}\in\mathbb{R}^{n\times n}$ be a symmetric sparse matrix which satisfies Assumption A2. Then, the inequality*

$$\|\boldsymbol{S}\|_2\le\alpha n\|\boldsymbol{S}\|_\infty$$

holds, where α is the sparsity level of $\boldsymbol{S}$.

Proof The proof can be found in (Netrapalli et al., 2014, Lemma 4). ■

Lemma 5 *Let* Trim *be the algorithm defined by Algorithm 2. If $\boldsymbol{L}_k\in\mathbb{R}^{n\times n}$ is a rank-r matrix with*

$$\|\boldsymbol{L}_k-\boldsymbol{L}\|_2\le\frac{\sigma_r^L}{20\sqrt{r}},$$

then the trim output with the level $\sqrt{\frac{\mu r}{n}}$ satisfies

$$\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_F\le 8\kappa\|\boldsymbol{L}_k-\boldsymbol{L}\|_F, \tag{12}$$

$$\max_i\|\boldsymbol{e}_i^T\widetilde{\boldsymbol{U}}_k\|_2\le\frac{10}{9}\sqrt{\frac{\mu r}{n}},\quad\text{and}\quad\max_j\|\boldsymbol{e}_j^T\widetilde{\boldsymbol{V}}_k\|_2\le\frac{10}{9}\sqrt{\frac{\mu r}{n}}, \tag{13}$$

where $\widetilde{\boldsymbol{L}}_k=\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{\Sigma}}_k\widetilde{\boldsymbol{V}}_k^T$ is the SVD of $\widetilde{\boldsymbol{L}}_k$. Furthermore, it follows that

$$\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_2\le 8\sqrt{2r}\kappa\|\boldsymbol{L}_k-\boldsymbol{L}\|_2. \tag{14}$$

Proof Since both $\boldsymbol{L}$ and $\boldsymbol{L}_k$ are rank-r matrices, $\boldsymbol{L}_k-\boldsymbol{L}$ is rank at most $2r$. So

$$\|\boldsymbol{L}_k-\boldsymbol{L}\|_F\le\sqrt{2r}\|\boldsymbol{L}_k-\boldsymbol{L}\|_2\le\sqrt{2r}\frac{\sigma_r^L}{20\sqrt{r}}=\frac{\sigma_r^L}{10\sqrt{2}}.$$

Then, the first two parts of the lemma, i.e., (12) and (13), follow from (Wei et al., 2016a, Lemma 4.10). Noting that $\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_2\le\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_F$, (14) follows immediately. ■

Lemma 6 *Let $\boldsymbol{L}=\boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$ and $\widetilde{\boldsymbol{L}}_k=\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{\Sigma}}_k\widetilde{\boldsymbol{V}}_k^T$ be the SVD of two rank-r matrices, then*

$$\|\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}\widetilde{\boldsymbol{U}}^T\|_2\le\frac{\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_2}{\sigma_r^L},\qquad\|\boldsymbol{V}\boldsymbol{V}^T-\widetilde{\boldsymbol{V}}\widetilde{\boldsymbol{V}}^T\|_2\le\frac{\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_2}{\sigma_r^L}, \tag{15}$$

and

$$\|(\mathcal{I}-\mathcal{P}_{\widetilde{T}_k})\boldsymbol{L}\|_2\le\frac{\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_2^2}{\sigma_r^L}. \tag{16}$$

Proof The proof of (15) can be found in (Wei et al., 2016b, Lemma 4.2). The Frobenius norm version of (16) can also be found in (Wei et al., 2016a,b). Here we only need to prove the spectral norm version, i.e., (16). Since $\boldsymbol{L}=\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{L}$ and $\widetilde{\boldsymbol{L}}_k(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)=\boldsymbol{0}$, we have

$$\begin{aligned}
\|(\mathcal{I}-\mathcal{P}_{\widetilde{T}_k})\boldsymbol{L}\|_2&=\|(\boldsymbol{I}-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\boldsymbol{L}(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)\|_2\\
&=\|(\boldsymbol{I}-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{L}(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)\|_2\\
&=\|(\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{L}(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)\|_2\\
&=\|(\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\boldsymbol{L}(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)\|_2\\
&=\|(\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)(\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k)(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)\|_2\\
&\le\|(\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\|_2\|(\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k)\|_2\|(\boldsymbol{I}-\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T)\|_2\\
&\le\frac{\|\widetilde{\boldsymbol{L}}_k-\boldsymbol{L}\|_2^2}{\sigma_r^L},
\end{aligned}$$

where the last inequality follows from (15). ■

Lemma 7 *Let $\boldsymbol{S}\in\mathbb{R}^{n\times n}$ be a symmetric matrix satisfying Assumption A2. Let $\widetilde{\boldsymbol{L}}_k\in\mathbb{R}^{n\times n}$ be a rank-r matrix with $\frac{100}{81}\mu$-incoherence. That is,*

$$\max_i\|\boldsymbol{e}_i^T\widetilde{\boldsymbol{U}}_k\|_2\le\frac{10}{9}\sqrt{\frac{\mu r}{n}}\quad\text{and}\quad\max_j\|\boldsymbol{e}_j^T\widetilde{\boldsymbol{V}}_k\|_2\le\frac{10}{9}\sqrt{\frac{\mu r}{n}},$$

where $\widetilde{\boldsymbol{L}}=\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{\Sigma}}_k\widetilde{\boldsymbol{V}}_k^T$ is the SVD of $\widetilde{\boldsymbol{L}}_k$. If $supp(\boldsymbol{S}_k)\subset\Omega$, then

$$\|\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_\infty\le 4\alpha\mu r\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty. \tag{17}$$

Proof By the incoherence assumption of $\widetilde{\boldsymbol{L}}_k$ and the sparsity assumption of $\boldsymbol{S}-\boldsymbol{S}_k$, we have

$$\begin{aligned}
[\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)]_{ab} &= \langle \mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k), \boldsymbol{e}_a\boldsymbol{e}_b^T\rangle \\
&= \langle \boldsymbol{S}-\boldsymbol{S}_k, \mathcal{P}_{\widetilde{T}_k}(\boldsymbol{e}_a\boldsymbol{e}_b^T)\rangle \\
&= \langle \boldsymbol{S}-\boldsymbol{S}_k, \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\boldsymbol{e}_b^T + \boldsymbol{e}_a\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T - \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T\rangle \\
&= \langle (\boldsymbol{S}-\boldsymbol{S}_k)\boldsymbol{e}_b, \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\rangle + \langle \boldsymbol{e}_a^T(\boldsymbol{S}-\boldsymbol{S}_k), \boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T\rangle - \langle \boldsymbol{S}-\boldsymbol{S}_k, \widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T\rangle \\
&\le \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\left(\sum_{i|(i,b)\in\Omega}|\boldsymbol{e}_i^T\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a| + \sum_{j|(a,j)\in\Omega}|\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T\boldsymbol{e}_j|\right) \\
&\quad + \|\boldsymbol{S}-\boldsymbol{S}_k\|_2\,\|\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T\|_* \\
&\le 2\alpha n\frac{100\mu r}{81n}\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty + \alpha n\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\|\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T\|_F \\
&\le \frac{200}{81}\alpha\mu r\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty + \alpha n\frac{\mu r}{n}\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty \\
&= 4\alpha\mu r\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty,
\end{aligned}$$

where the first inequality uses Hölder's inequality and the second inequality uses Lemma 4. We also use the fact $\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\boldsymbol{e}_a\boldsymbol{e}_b^T\widetilde{\boldsymbol{V}}_k\widetilde{\boldsymbol{V}}_k^T$ is a rank-1 matrix to bound its nuclear norm. ■

Lemma 8 *Under the symmetric setting, i.e., $\boldsymbol{U}\boldsymbol{U}^T = \boldsymbol{V}\boldsymbol{V}^T$ where $\boldsymbol{U}\in\mathbb{R}^{n\times r}$ and $\boldsymbol{V}\in\mathbb{R}^{n\times r}$ are two orthogonal matrices, we have*

$$\|\mathcal{P}_T\boldsymbol{Z}\|_2 \le \sqrt{\frac{4}{3}}\|\boldsymbol{Z}\|_2$$

for any symmetric matrix $\boldsymbol{Z}\in\mathbb{R}^{n\times n}$. Moreover, the upper bound is tight.

Proof First notice that

$$\mathcal{P}_T\boldsymbol{Z} = \boldsymbol{U}\boldsymbol{U}^T\boldsymbol{Z} + \boldsymbol{Z}\boldsymbol{U}\boldsymbol{U}^T - \boldsymbol{U}\boldsymbol{U}^T\boldsymbol{Z}\boldsymbol{U}\boldsymbol{U}^T$$

is symmetric. Let $\boldsymbol{y}\in\mathbb{R}^n$ be a unit vector such that $\|\mathcal{P}_T\boldsymbol{Z}\|_2 = |\boldsymbol{y}^T(\mathcal{P}_T\boldsymbol{Z})\boldsymbol{y}|$. Denote $\boldsymbol{y}_1 = \boldsymbol{U}\boldsymbol{U}^T\boldsymbol{y}$ and $\boldsymbol{y}_2 = (\boldsymbol{I}-\boldsymbol{U}\boldsymbol{U}^T)\boldsymbol{y}$. Then,

$$\begin{aligned}
\|\mathcal{P}_T\boldsymbol{Z}\|_2 &= |\boldsymbol{y}^T(\mathcal{P}_T\boldsymbol{Z})\boldsymbol{y}| \\
&= |\boldsymbol{y}_1^T\boldsymbol{Z}\boldsymbol{y} + \boldsymbol{y}^T\boldsymbol{Z}\boldsymbol{y}_1 - \boldsymbol{y}_1^T\boldsymbol{Z}\boldsymbol{y}_1| \\
&= |\boldsymbol{y}_1^T\boldsymbol{Z}\boldsymbol{y}_1 + \boldsymbol{y}_1^T\boldsymbol{Z}\boldsymbol{y}_2 + \boldsymbol{y}_2^T\boldsymbol{Z}\boldsymbol{y}_1| \\
&= |\langle \boldsymbol{y}_1\boldsymbol{y}_1^T + \boldsymbol{y}_1\boldsymbol{y}_2^T + \boldsymbol{y}_2\boldsymbol{y}_1^T, \boldsymbol{Z}\rangle| \\
&\le \|\boldsymbol{y}_1\boldsymbol{y}_1^T + \boldsymbol{y}_1\boldsymbol{y}_2^T + \boldsymbol{y}_2\boldsymbol{y}_1^T\|_*\|\boldsymbol{Z}\|_2.
\end{aligned}$$

Let $a = \|\boldsymbol{y}_1\|_2^2$. Since $\boldsymbol{y}_1\perp\boldsymbol{y}_2$, we have $\|\boldsymbol{y}_1\|_2^2 + \|\boldsymbol{y}_2\|_2^2 = 1$, which implies $\|\boldsymbol{y}_2\|_2^2 = 1-a$ and

$$\boldsymbol{y}_1\boldsymbol{y}_1^T + \boldsymbol{y}_1\boldsymbol{y}_2^T + \boldsymbol{y}_2\boldsymbol{y}_1^T = \begin{bmatrix}\boldsymbol{y}_1 & \boldsymbol{y}_2\end{bmatrix}\begin{bmatrix}1 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}\boldsymbol{y}_1 & \boldsymbol{y}_2\end{bmatrix}^T$$

$$= \begin{bmatrix}\frac{\boldsymbol{y}_1}{\sqrt{a}} & \frac{\boldsymbol{y}_2}{\sqrt{1-a}}\end{bmatrix}\begin{bmatrix}a & \sqrt{a(1-a)}\\ \sqrt{a(1-a)} & 0\end{bmatrix}\begin{bmatrix}\frac{\boldsymbol{y}_1}{\sqrt{a}} & \frac{\boldsymbol{y}_2}{\sqrt{1-a}}\end{bmatrix}^T.$$

Since $\begin{bmatrix}\frac{\boldsymbol{y}_1}{\sqrt{a}} & \frac{\boldsymbol{y}_2}{\sqrt{1-a}}\end{bmatrix}$ is an orthogonal matrix, one has

$$\begin{aligned}
\|\boldsymbol{y}_1\boldsymbol{y}_1^T + \boldsymbol{y}_1\boldsymbol{y}_2^T + \boldsymbol{y}_2\boldsymbol{y}_1^T\|_* &= \left\|\begin{bmatrix}a & \sqrt{a(1-a)}\\ \sqrt{a(1-a)} & 0\end{bmatrix}\right\|_* \\
&= \sqrt{a^2+4a(1-a)} \\
&= \sqrt{\frac{4}{3} - 3\left(a-\frac{2}{3}\right)^2} \\
&\le \sqrt{\frac{4}{3}},
\end{aligned}$$

which complete the proof for the upper bound.

To show the tightness of the bound, let $\boldsymbol{U} = \boldsymbol{V} = \begin{bmatrix}1\\0\end{bmatrix}$ and $\boldsymbol{Z} = \begin{bmatrix}1 & \sqrt{2}\\ \sqrt{2} & -1\end{bmatrix}$. It can be easily verified that $\|\mathcal{P}_T\boldsymbol{Z}\|_2 = \sqrt{\frac{4}{3}}\|\boldsymbol{Z}\|_2$. ■

Lemma 9 *Let $\boldsymbol{U}\in\mathbb{R}^{n\times r}$ be an orthogonal matrix with μ-incoherence, i.e., $\|\boldsymbol{e}_i^T\boldsymbol{U}\|_2 \le \sqrt{\frac{\mu r}{n}}$ for all i. Then, for any $\boldsymbol{Z}\in\mathbb{R}^{n\times n}$, the inequality*

$$\|\boldsymbol{e}_i^T\boldsymbol{Z}^a\boldsymbol{U}\|_2 \le \max_l\sqrt{\frac{\mu r}{n}}(\sqrt{n}\|\boldsymbol{e}_l^T\boldsymbol{Z}\|_2)^a$$

holds for all i and $a\ge 0$.

Proof This proof is done by mathematical induction.
Base case: When $a=0$, $\|\boldsymbol{e}_i^T\boldsymbol{U}\| \le \sqrt{\frac{\mu r}{n}}$ is satisfied following from the assumption.
Induction Hypothesis: $\|\boldsymbol{e}_i^T(\boldsymbol{Z})^a\boldsymbol{U}\|_2 \le \max_l\sqrt{\frac{\mu r}{n}}(\sqrt{n}\|\boldsymbol{e}_l^T\boldsymbol{Z}\|_2)^a$ for all i at the a^{th} power.
Induction Step: We have

$$\begin{aligned}
\|\boldsymbol{e}_i^T\boldsymbol{Z}^{a+1}\boldsymbol{U}\|_2^2 &= \|\boldsymbol{e}_i^T\boldsymbol{Z}\boldsymbol{Z}^a\boldsymbol{U}\|_2^2 \\
&= \sum_j\left(\sum_k[\boldsymbol{Z}]_{ik}[\boldsymbol{Z}^a\boldsymbol{U}]_{kj}\right)^2 \\
&= \sum_{k_1k_2}[\boldsymbol{Z}]_{ik_1}[\boldsymbol{Z}]_{ik_2}\sum_j[\boldsymbol{Z}^a\boldsymbol{U}]_{k_1j}[\boldsymbol{Z}^a\boldsymbol{U}]_{k_2j} \\
&= \sum_{k_1k_2}[\boldsymbol{Z}]_{ik_1}[\boldsymbol{Z}]_{ik_2}\langle \boldsymbol{e}_{k_1}^T\boldsymbol{Z}^a\boldsymbol{U}, \boldsymbol{e}_{k_2}^T\boldsymbol{Z}^a\boldsymbol{U}\rangle \\
&\le \sum_{k_1k_2}|[\boldsymbol{Z}]_{ik_1}[\boldsymbol{Z}]_{ik_2}|\|\boldsymbol{e}_{k_1}^T\boldsymbol{Z}^a\boldsymbol{U}\|_2\,\|\boldsymbol{e}_{k_2}^T\boldsymbol{Z}^a\boldsymbol{U}\|_2
\end{aligned}$$

$$\leq \max_l \frac{\mu r}{n}(\sqrt{n}\|\boldsymbol{e}_l^T\boldsymbol{Z}\|_2)^{2a}\sum_{k_1k_2}|[\boldsymbol{Z}]_{ik_1}[\boldsymbol{Z}]_{ik_2}|$$
$$\leq \max_l \frac{\mu r}{n}(\sqrt{n}\|\boldsymbol{e}_l^T\boldsymbol{Z}\|_2)^{2a}(\sqrt{n}\|\boldsymbol{e}_i^T\boldsymbol{Z}\|_2)^2$$
$$\leq \max_l \frac{\mu r}{n}(\sqrt{n}\|\boldsymbol{e}_l^T\boldsymbol{Z}\|_2)^{2a+2}.$$

The proof is complete by taking a square root from both sides. ■

Lemma 10 *Let $\boldsymbol{L}\in\mathbb{R}^{n\times n}$ and $\boldsymbol{S}\in\mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2, respectively. Let $\widetilde{\boldsymbol{L}}_k\in\mathbb{R}^{n\times n}$ be the trim output of $\boldsymbol{L}_k$. If*

$$\|\boldsymbol{L}-\boldsymbol{L}_k\|_2\leq 8\alpha\mu r\gamma^k\sigma_1^L,\quad \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\leq\frac{\mu r}{n}\gamma^k\sigma_1^L,\text{ and } supp(\boldsymbol{S}_k)\subset\Omega,$$

then

$$\|(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_2\leq\tau\gamma^{k+1}\sigma_r^L \tag{18}$$

and

$$\max_l\sqrt{n}\|\boldsymbol{e}_l^T[(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)]\|_2\leq\upsilon\gamma^k\sigma_r^L \tag{19}$$

hold for all $k\geq 0$, provided $1>\gamma\geq 512\tau r\kappa^2+\frac{1}{\sqrt{12}}$. Here recall that $\tau=4\alpha\mu r\kappa$ and $\upsilon=\tau(48\sqrt{\mu}r\kappa+\mu r)$.

Proof For all $k\geq 0$, we get

$$\begin{aligned}\|(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_2&\leq\|(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}\|_2+\|\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_2\\&\leq\frac{\|\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k\|_2^2}{\sigma_r^L}+\sqrt{\frac{4}{3}}\|\boldsymbol{S}-\boldsymbol{S}_k\|_2\\&\leq\frac{(8\sqrt{2r}\kappa)^2\|\boldsymbol{L}-\boldsymbol{L}_k\|_2^2}{\sigma_r^L}+\sqrt{\frac{4}{3}}\alpha n\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\\&\leq 128\cdot 8\alpha\mu r^2\kappa^3\|\boldsymbol{L}-\boldsymbol{L}_k\|_2+\sqrt{\frac{4}{3}}\alpha n\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\\&\leq\left(512\tau r\kappa^2+\frac{1}{4}\sqrt{\frac{4}{3}}\right)4\alpha\mu r\gamma^k\sigma_1^L\\&\leq 4\alpha\mu r\gamma^{k+1}\sigma_1^L,\\&=\tau\gamma^{k+1}\sigma_r^L\end{aligned}$$

where the second inequality uses Lemma 6 and 8, the third inequality uses Lemma 4 and 5, the fourth inequality follows from $\frac{\|\boldsymbol{L}-\boldsymbol{L}_k\|_2}{\sigma_r^L}\leq 8\alpha\mu r\kappa$, and the last inequality uses the bound of γ.

To compute the bound of $\max_l\sqrt{n}\|\boldsymbol{e}_l^T[(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)]\|_2$, first note that

$$\max_l\|\boldsymbol{e}_l^T(\mathcal{I}-\mathcal{P}_{\widetilde{T}_k})\boldsymbol{L}\|_2=\max_l\|\boldsymbol{e}_l^T(\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)(\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k)(\boldsymbol{I}-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\|_2$$

$$\begin{aligned}&\leq\max_l\|\boldsymbol{e}_l^T(\boldsymbol{U}\boldsymbol{U}^T-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T)\|_2\|\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k\|_2\|\boldsymbol{I}-\widetilde{\boldsymbol{U}}_k\widetilde{\boldsymbol{U}}_k^T\|_2\\&\leq\left(\frac{19}{9}\sqrt{\frac{\mu r}{n}}\right)\|\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k\|_2,\end{aligned}$$

where the last inequality follows from the fact $\boldsymbol{L}$ is μ-incoherent and $\widetilde{\boldsymbol{L}}_k$ is $\frac{100}{81}\mu$-incoherent. Hence, for all $k\geq 0$, we have

$$\begin{aligned}\max_l\sqrt{n}\|\boldsymbol{e}_l^T((\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k))\|_2&\leq\max_l\sqrt{n}\|\boldsymbol{e}_l^T(\mathcal{I}-\mathcal{P}_{\widetilde{T}_k})\boldsymbol{L}\|_2+\sqrt{n}\|\boldsymbol{e}_l^T\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_2\\&\leq\frac{19\sqrt{n}}{9}\sqrt{\frac{\mu r}{n}}\|\boldsymbol{L}-\widetilde{\boldsymbol{L}}_k\|_2+n\|\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_\infty\\&\leq\frac{19}{9}8\sqrt{2\mu}r\kappa\|\boldsymbol{L}-\boldsymbol{L}_k\|_2+4n\alpha\mu r\|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\\&\leq 24\sqrt{\mu}r\kappa\cdot 8\alpha\mu r\gamma^k\sigma_1^L+4n\alpha\mu r\cdot\frac{\mu r}{n}\gamma^k\sigma_1^L\\&=\upsilon\gamma^k\sigma_r^L,\end{aligned}$$

where the third inequality uses Lemma 5 and 7. ■

Lemma 11 *Let $\boldsymbol{L}\in\mathbb{R}^{n\times n}$ and $\boldsymbol{S}\in\mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2, respectively. Let $\widetilde{\boldsymbol{L}}_k\in\mathbb{R}^{n\times n}$ be the trim output of $\boldsymbol{L}_k$. If*

$$\|\boldsymbol{L}-\boldsymbol{L}_k\|_2\leq 8\alpha\mu r\gamma^k\sigma_1^L,\quad \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty\leq\frac{\mu r}{n}\gamma^k\sigma_1^L,\text{ and } supp(\boldsymbol{S}_k)\subset\Omega,$$

then

$$|\sigma_i^L-|\lambda_i^{(k)}||\leq\tau\sigma_r^L \tag{20}$$

and

$$(1-2\tau)\gamma^j\sigma_1^L\leq|\lambda_{r+1}^{(k)}|+\gamma^j|\lambda_1^{(k)}|\leq(1+2\tau)\gamma^j\sigma_1^L \tag{21}$$

hold for all $k\geq 0$ and $j\leq k+1$, provided $1>\gamma\geq 512\tau r\kappa^2+\frac{1}{\sqrt{12}}$. Here $|\lambda_i^{(k)}|$ is the i^{th} singular value of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$.

Proof Since $\boldsymbol{D}=\boldsymbol{L}+\boldsymbol{S}$, we have

$$\begin{aligned}\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)&=\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{L}+\boldsymbol{S}-\boldsymbol{S}_k)\\&=\boldsymbol{L}+(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k).\end{aligned}$$

Hence, by Weyl's inequality and (18) in Lemma 10, we can see that

$$\begin{aligned}|\sigma_i^L-|\lambda_i^{(k)}||&\leq\|(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_2\\&\leq\tau\gamma^{k+1}\sigma_r^L\end{aligned}$$

hold for all i and $k\geq 0$. So the first claim is proved since $\gamma<1$.

Notice that $\boldsymbol{L}$ is a rank-r matrix, which implies $\sigma_{r+1}^L = 0$, so we have

$$\begin{aligned}||\lambda_{r+1}^{(k)}| + \gamma^j|\lambda_1^{(k)}| - \gamma^j\sigma_1^L| &= ||\lambda_{r+1}^{(k)}| - \sigma_{r+1}^L + \gamma^j|\lambda_1^{(k)}| - \gamma^j\sigma_1^L| \\ &\le \tau\gamma^{k+1}\sigma_r^L + \tau\gamma^{j+k+1}\sigma_r^L \\ &\le \left(1+\gamma^{k+1}\right)\tau\gamma^j\sigma_r^L \\ &\le 2\tau\gamma^j\sigma_1^L\end{aligned}$$

for all $j \le k+1$. This completes the proof of the second claim. ■

Lemma 12 *Let $\boldsymbol{L} \in \mathbb{R}^{n\times n}$ and $\boldsymbol{S} \in \mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2, respectively. Let $\widetilde{\boldsymbol{L}}_k \in \mathbb{R}^{n\times n}$ be the trim output of $\boldsymbol{L}_k$. If*

$$\|\boldsymbol{L}-\boldsymbol{L}_k\|_2 \le 8\alpha\mu r\gamma^k\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty \le \frac{\mu r}{n}\gamma^k\sigma_1^L, \text{ and } supp(\boldsymbol{S}_k) \subset \Omega,$$

then we have

$$\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_2 \le 8\alpha\mu r\gamma^{k+1}\sigma_1^L,$$

provided $1 > \gamma \ge 512\tau r\kappa^2 + \frac{1}{\sqrt{12}}$.

Proof A direct calculation yields

$$\begin{aligned}\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_2 &\le \|\boldsymbol{L}-\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)\|_2 + \|\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)-\boldsymbol{L}_{k+1}\|_2 \\ &\le 2\|\boldsymbol{L}-\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)\|_2 \\ &= 2\|\boldsymbol{L}-\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{L}+\boldsymbol{S}-\boldsymbol{S}_k)\|_2 \\ &= 2\|(\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)\|_2 \\ &\le 2\cdot\tau\gamma^{k+1}\sigma_r^L \\ &= 8\alpha\mu r\gamma^{k+1}\sigma_1^L,\end{aligned}$$

where the second inequality follows from the fact $\boldsymbol{L}_{k+1} = \mathcal{H}_r(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k))$ is the best rank-r approximation of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$, and the last inequality uses (18) in Lemma 10. ■

Lemma 13 *Let $\boldsymbol{L} \in \mathbb{R}^{n\times n}$ and $\boldsymbol{S} \in \mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2, respectively. Let $\widetilde{\boldsymbol{L}}_k \in \mathbb{R}^{n\times n}$ be the trim output of $\boldsymbol{L}_k$. If*

$$\|\boldsymbol{L}-\boldsymbol{L}_k\|_2 \le 8\alpha\mu r\gamma^k\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty \le \frac{\mu r}{n}\gamma^k\sigma_1^L, \text{ and } supp(\boldsymbol{S}_k) \subset \Omega,$$

then we have

$$\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_\infty \le \left(\frac{1}{2}-\tau\right)\frac{\mu r}{n}\gamma^{k+1}\sigma_1^L,$$

provided $1 > \gamma \ge \max\{512\tau r\kappa^2 + \frac{1}{\sqrt{12}}, \frac{2\upsilon}{(1-12\tau)(1-\tau-\upsilon)^2}\}$ *and* $\tau < \frac{1}{12}$.

Proof Let $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k) = \begin{bmatrix}\boldsymbol{U}_{k+1} & \ddot{\boldsymbol{U}}_{k+1}\end{bmatrix}\begin{bmatrix}\boldsymbol{\Lambda} & \boldsymbol{0}\\ \boldsymbol{0} & \ddot{\boldsymbol{\Lambda}}\end{bmatrix}\begin{bmatrix}\boldsymbol{U}_{k+1}^T\\ \ddot{\boldsymbol{U}}_{k+1}^T\end{bmatrix} = \boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T$ be its eigenvalue decomposition. We use the lighter notation λ_i $(1 \le i \le n)$ for the eigenvalues of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$ at the k-th iteration and assume they are ordered by $|\lambda_1| \ge |\lambda_2| \ge \cdots \ge |\lambda_n|$. Moreover, $\boldsymbol{\Lambda}$ has its r largest eigenvalues in magnitude, $\boldsymbol{U}_{k+1}$ contains the first r eigenvectors, and $\ddot{\boldsymbol{U}}_{k+1}$ has the rest. It follows that $\boldsymbol{L}_{k+1} = \mathcal{H}_r(\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)) = \boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T$.

Denote $\boldsymbol{Z} = \mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)-\boldsymbol{L} = (\mathcal{P}_{\widetilde{T}_k}-\mathcal{I})\boldsymbol{L}+\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{S}-\boldsymbol{S}_k)$. Let $\boldsymbol{u}_i$ be the i^{th} eigenvector of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$. Noting that $(\lambda_i\boldsymbol{I}-\boldsymbol{Z})\boldsymbol{u}_i = \boldsymbol{L}\boldsymbol{u}_i$, we have

$$\boldsymbol{u}_i = \left(\boldsymbol{I}-\frac{\boldsymbol{Z}}{\lambda_i}\right)^{-1}\frac{\boldsymbol{L}}{\lambda_i}\boldsymbol{u}_i = \left(\boldsymbol{I}+\frac{\boldsymbol{Z}}{\lambda_i}+\left(\frac{\boldsymbol{Z}}{\lambda_i}\right)^2+\cdots\right)\frac{\boldsymbol{L}}{\lambda_i}\boldsymbol{u}_i$$

for all $\boldsymbol{u}_i$ with $1 \le i \le r$, where the expansion is valid because

$$\frac{\|\boldsymbol{Z}\|_2}{\lambda_i} \le \frac{\|\boldsymbol{Z}\|_2}{\lambda_r} \le \frac{\tau}{1-\tau} < 1$$

following from (18) in Lemma 10 and (20) in Lemma 11. This implies

$$\begin{aligned}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T &= \sum_{i=1}^r \boldsymbol{u}_i\lambda_i\boldsymbol{u}_i^T \\ &= \sum_{i=1}^r\left(\sum_{a\ge0}\left(\frac{\boldsymbol{Z}}{\lambda_i}\right)^a\frac{\boldsymbol{L}}{\lambda_i}\right)\boldsymbol{u}_i\lambda_i\boldsymbol{u}_i^T\left(\sum_{b\ge0}\left(\frac{\boldsymbol{Z}}{\lambda_i}\right)^b\frac{\boldsymbol{L}}{\lambda_i}\right)^T \\ &= \sum_{a\ge0}\boldsymbol{Z}^a\boldsymbol{L}\sum_{i=1}^r\left(\boldsymbol{u}_i\frac{1}{\lambda_i^{a+b+1}}\boldsymbol{u}_i^T\right)\boldsymbol{L}\sum_{b\ge0}\boldsymbol{Z}^b \\ &= \sum_{a,b\ge0}\boldsymbol{Z}^a\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\boldsymbol{Z}^b.\end{aligned}$$

Thus, we have

$$\begin{aligned}\|\boldsymbol{L}_{k+1}-\boldsymbol{L}\|_\infty &= \|\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T-\boldsymbol{L}\|_\infty \\ &= \|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L}-\boldsymbol{L}+\sum_{a+b>0}\boldsymbol{Z}^a\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\boldsymbol{Z}^b\|_\infty \\ &\le \|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L}-\boldsymbol{L}\|_\infty+\sum_{a+b>0}\|\boldsymbol{Z}^a\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\boldsymbol{Z}^b\|_\infty \\ &:= \boldsymbol{Y}_0+\sum_{a+b>0}\boldsymbol{Y}_{ab}.\end{aligned}$$

We will handle $\boldsymbol{Y}_0$ first. Recall that $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$ is the SVD of the symmetric matrix $\boldsymbol{L}$ which obeys μ-incoherence, i.e., $\boldsymbol{U}\boldsymbol{U}^T = \boldsymbol{V}\boldsymbol{V}^T$ and $\|\boldsymbol{e}_i^T\boldsymbol{U}\boldsymbol{U}^T\|_2 \le \sqrt{\frac{\mu r}{n}}$ for all i. So, for each (i,j) entry of $\boldsymbol{Y}_0$, one has

$$\boldsymbol{Y}_0 = \max_{ij}|\boldsymbol{e}_i^T(\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L}-\boldsymbol{L})\boldsymbol{e}_j|$$

$$
\begin{aligned}
&= \max_{ij} |\boldsymbol{e}_i^T \boldsymbol{U}\boldsymbol{U}^T(\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L} - \boldsymbol{L})\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{e}_j| \\
&\le \max_{ij} \|\boldsymbol{e}_i^T\boldsymbol{U}\boldsymbol{U}^T\|_2 \, \|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L} - \boldsymbol{L}\|_2 \, \|\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{e}_j\|_2 \\
&\le \frac{\mu r}{n}\|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L} - \boldsymbol{L}\|_2,
\end{aligned}
$$

where the second equation follows from the fact $\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{L} = \boldsymbol{L}\boldsymbol{U}\boldsymbol{U}^T = \boldsymbol{L}$. Since $\boldsymbol{L} = \boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T - \boldsymbol{Z}$, there hold

$$
\begin{aligned}
&\|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{L} - \boldsymbol{L}\|_2 \\
&= \|(\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T - \boldsymbol{Z})\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T(\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T - \boldsymbol{Z}) - \boldsymbol{L}\|_2 \\
&= \|\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T - \boldsymbol{L} - \boldsymbol{U}_{k+1}\boldsymbol{U}_{k+1}^T\boldsymbol{Z} - \boldsymbol{Z}\boldsymbol{U}_{k+1}\boldsymbol{U}_{k+1}^T - \boldsymbol{Z}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_{k+1}^T\boldsymbol{Z}\|_2 \\
&\le \|\boldsymbol{Z} - \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T\|_2 + 2\|\boldsymbol{Z}\|_2 + \frac{\|\boldsymbol{Z}\|_2^2}{|\lambda_r|} \\
&\le \|\ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T\|_2 + 4\|\boldsymbol{Z}\|_2 \\
&\le |\lambda_{r+1}| + 4\|\boldsymbol{Z}\|_2 \\
&\le 5\|\boldsymbol{Z}\|_2 \\
&\le 5\tau\gamma^{k+1}\sigma_1^L,
\end{aligned}
$$

where the fifth inequality uses (18) in Lemma 10, and notice that $\frac{\|\boldsymbol{Z}\|_2}{|\lambda_r|} \le \frac{\tau}{1-\tau} < 1$ since $\tau < \frac{1}{2}$ and $|\lambda_{r+1}| \le \|\boldsymbol{Z}\|_2$ since $\boldsymbol{L}$ is a rank-r matrix. Thus, we have

$$
\boldsymbol{Y}_0 \le \frac{\mu r}{n} 5\tau\gamma^{k+1}\sigma_1^L. \tag{22}
$$

Next, we derive an upper bound for the rest part. Note that

$$
\begin{aligned}
\boldsymbol{Y}_{ab} &= \max_{ij} |\boldsymbol{e}_i^T\boldsymbol{Z}^a\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\boldsymbol{Z}^b\boldsymbol{e}_j| \\
&= \max_{ij} |(\boldsymbol{e}_i^T\boldsymbol{Z}^a\boldsymbol{U}\boldsymbol{U}^T)\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}(\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{Z}^b\boldsymbol{e}_j)| \\
&\le \max_{ij} \|\boldsymbol{e}_i^T\boldsymbol{Z}^a\boldsymbol{U}\|_2 \, \|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\|_2 \, \|\boldsymbol{U}^T\boldsymbol{Z}^b\boldsymbol{e}_j\|_2 \\
&\le \max_{l} \frac{\mu r}{n}(\sqrt{n}\|\boldsymbol{e}_l^T\boldsymbol{Z}\|_2)^{a+b}\|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\|_2,
\end{aligned}
$$

where the last inequality uses Lemma 9. Furthermore, by using $\boldsymbol{L} = \boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T - \boldsymbol{Z}$ again, we get

$$
\begin{aligned}
&\|\boldsymbol{L}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{L}\|_2 \\
&= \|(\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T - \boldsymbol{Z})\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T(\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}\boldsymbol{U}_{k+1}^T + \ddot{\boldsymbol{U}}_{k+1}\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_{k+1}^T - \boldsymbol{Z})\|_2 \\
&= \|\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b-1)}\boldsymbol{U}_{k+1}^T - \boldsymbol{Z}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b)}\boldsymbol{U}_{k+1}^T - \boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b)}\boldsymbol{U}_{k+1}^T\boldsymbol{Z} + \boldsymbol{Z}\boldsymbol{U}_{k+1}\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_{k+1}^T\boldsymbol{Z}\|_2 \\
&\le |\lambda_r|^{-(a+b-1)} + |\lambda_r|^{-(a+b)}\|\boldsymbol{Z}\|_2 + |\lambda_r|^{-(a+b)}\|\boldsymbol{Z}\|_2 + |\lambda_r|^{-(a+b+1)}\|\boldsymbol{Z}\|_2^2 \\
&= |\lambda_r|^{-(a+b-1)}\left(1 + \frac{2\|\boldsymbol{Z}\|_2}{|\lambda_r|} + \left(\frac{\|\boldsymbol{Z}\|_2}{|\lambda_r|}\right)^2\right)
\end{aligned}
$$

$$
\begin{aligned}
&= |\lambda_r|^{-(a+b-1)}\left(1 + \frac{\|\boldsymbol{Z}\|_2}{|\lambda_r|}\right)^2 \\
&\le |\lambda_r|^{-(a+b-1)}\left(\frac{1}{1-\tau}\right)^2 \\
&\le \left(\frac{1}{1-\tau}\right)^2\left((1-\tau)\sigma_r^L\right)^{-(a+b-1)},
\end{aligned}
$$

where the second inequality follows from $\frac{\|\boldsymbol{Z}\|_2}{|\lambda_r|} \le \frac{\tau}{1-\tau}$, and the last inequality follows from Lemma 11. Together with (19) in Lemma 10, we have

$$
\begin{aligned}
\sum_{a+b>0}\boldsymbol{Y}_{ab} &\le \sum_{a+b>0}\frac{\mu r}{n}\left(\frac{1}{1-\tau}\right)^2\upsilon\gamma^k\sigma_r^L\left(\frac{\upsilon\gamma^k\sigma_r^L}{(1-\tau)\sigma_r^L}\right)^{a+b-1} \\
&\le \frac{\mu r}{n}\left(\frac{1}{1-\tau}\right)^2\upsilon\gamma^k\sigma_1^L\sum_{a+b>0}\left(\frac{\upsilon}{1-\tau}\right)^{a+b-1} \\
&\le \frac{\mu r}{n}\left(\frac{1}{1-\tau}\right)^2\upsilon\gamma^k\sigma_1^L\left(\frac{1}{1-\frac{\upsilon}{1-\tau}}\right)^2 \\
&\le \frac{\mu r}{n}\left(\frac{1}{1-\tau-\upsilon}\right)^2\upsilon\gamma^k\sigma_1^L.
\end{aligned} \tag{23}
$$

Finally, combining (22) and (23) together gives

$$
\begin{aligned}
\|\boldsymbol{L}_{k+1} - \boldsymbol{L}\|_\infty &= \boldsymbol{Y}_0 + \sum_{a+b>0}\boldsymbol{Y}_{ab} \\
&\le \frac{\mu r}{n}5\tau\gamma^{k+1}\sigma_1^L + \frac{\mu r}{n}\left(\frac{1}{1-\tau-\upsilon}\right)^2\upsilon\gamma^k\sigma_1^L \\
&\le \left(\frac{1}{2} - \tau\right)\frac{\mu r}{n}\gamma^{k+1}\sigma_1^L,
\end{aligned}
$$

where the last inequality follows from $\gamma \ge \frac{2\upsilon}{(1-12\tau)(1-\tau-\upsilon)^2}$. ■

Lemma 14 *Let $\boldsymbol{L} \in \mathbb{R}^{n\times n}$ and $\boldsymbol{S} \in \mathbb{R}^{n\times n}$ be two symmetric matrices satisfying Assumptions A1 and A2, respectively. Let $\widetilde{\boldsymbol{L}}_k \in \mathbb{R}^{n\times n}$ be the trim output of $\boldsymbol{L}_k$. Recall that $\beta = \frac{\mu r}{2n}$. If*

$$
\|\boldsymbol{L} - \boldsymbol{L}_k\|_2 \le 8\alpha\mu r\gamma^k\sigma_1^L, \quad \|\boldsymbol{S} - \boldsymbol{S}_k\|_\infty \le \frac{\mu r}{n}\gamma^k\sigma_1^L, \text{ and } supp(\boldsymbol{S}_k) \subset \Omega
$$

then we have

$$
supp(\boldsymbol{S}_{k+1}) \subset \Omega \quad \textit{and} \quad \|\boldsymbol{S} - \boldsymbol{S}_{k+1}\|_\infty \le \frac{\mu r}{n}\gamma^{k+1}\sigma_1^L,
$$

provided $1 > \gamma \ge \max\{512\tau r\kappa^2 + \frac{1}{\sqrt{12}}, \frac{2\upsilon}{(1-12\tau)(1-\tau-\upsilon)^2}\}$ *and* $\tau < \frac{1}{12}$.

Proof We first notice that

$$[\boldsymbol{S}_{k+1}]_{ij} = [\mathcal{T}_{\zeta_{k+1}}(\boldsymbol{D}-\boldsymbol{L}_{k+1})]_{ij} = [\mathcal{T}_{\zeta_{k+1}}(\boldsymbol{S}+\boldsymbol{L}-\boldsymbol{L}_{k+1})]_{ij} = \begin{cases} \mathcal{T}_{\zeta_{k+1}}([\boldsymbol{S}+\boldsymbol{L}-\boldsymbol{L}_{k+1}]_{ij}) & (i,j)\in\Omega \\ \mathcal{T}_{\zeta_{k+1}}([\boldsymbol{L}-\boldsymbol{L}_{k+1}]_{ij}) & (i,j)\in\Omega^c \end{cases}.$$

Let $|\lambda_i^{(k)}|$ denote i^{th} singular value of $\mathcal{P}_{\widetilde{T}_k}(\boldsymbol{D}-\boldsymbol{S}_k)$. By Lemmas 11 and 13, we have

$$\begin{aligned} |[\boldsymbol{L}-\boldsymbol{L}_{k+1}]_{ij}| &\le \|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_\infty \le \left(\frac{1}{2}-\tau\right)\frac{\mu r}{n}\gamma^{k+1}\sigma_1^L \\ &\le \left(\frac{1}{2}-\tau\right)\frac{\mu r}{n}\frac{1}{1-2\tau}\left(|\lambda_{r+1}^{(k)}|+\gamma^{k+1}|\lambda_1^{(k)}|\right) \\ &= \zeta_{k+1} \end{aligned}$$

for any entry of $\boldsymbol{L}-\boldsymbol{L}_{k+1}$. Hence, $[\boldsymbol{S}_{k+1}]_{ij}=0$ for all $(i,j)\in\Omega^c$, i.e., $supp(\boldsymbol{S}_{k+1})\subset\Omega$.

Denote $\Omega_{k+1} := supp(\boldsymbol{S}_{k+1}) = \{(i,j) \mid [(\boldsymbol{D}-\boldsymbol{L}_{k+1})]_{ij} > \zeta_k\}$. Then, for any entry of $\boldsymbol{S}-\boldsymbol{S}_{k+1}$, there hold

$$[\boldsymbol{S}-\boldsymbol{S}_{k+1}]_{ij} = \begin{cases} 0 \\ [\boldsymbol{L}_{k+1}-\boldsymbol{L}]_{ij} \\ [\boldsymbol{S}]_{ij} \end{cases} \le \begin{cases} 0 \\ \|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_\infty \\ \|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_\infty+\zeta_{k+1} \end{cases} \le \begin{cases} 0 & (i,j)\in\Omega^c \\ \left(\frac{1}{2}-\tau\right)\frac{\mu r}{n}\gamma^{k+1}\sigma_1^L & (i,j)\in\Omega_{k+1} \\ \frac{\mu r}{n}\gamma^{k+1}\sigma_1^L & (i,j)\in\Omega\backslash\Omega_{k+1}. \end{cases}$$

Here the last step follows from Lemma 11 which implies $\zeta_{k+1} = \frac{\mu r}{2n}(|\lambda_{r+1}^{(k)}| + \gamma^{k+1}|\lambda_1^{(k)}|) \le \left(\frac{1}{2}+\tau\right)\frac{\mu r}{n}\gamma^{k+1}\sigma_1^L$. Therefore, $\|\boldsymbol{S}-\boldsymbol{S}_{k+1}\|_\infty \le \frac{\mu r}{n}\gamma^{k+1}\sigma_1^L$. ■

Now, we have all the ingredients for the proof of Theorem 1.

Proof [Proof of Theorem 1] This theorem will be proved by mathematical induction.
Base Case: When $k=0$, the base case is satisfied by the assumption on the intialization.
Induction Step: Assume we have

$$\|\boldsymbol{L}-\boldsymbol{L}_k\|_2 \le 8\alpha\mu r\gamma^k\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_k\|_\infty \le \frac{\mu r}{n}\gamma^k\sigma_1^L, \quad \text{and} \quad supp(\boldsymbol{S}_k)\subset\Omega$$

at the k^{th} iteration. At the $(k+1)^{th}$ iteration. If follows directly from Lemmas 12 and 14 that

$$\|\boldsymbol{L}-\boldsymbol{L}_{k+1}\|_2 \le 8\alpha\mu r\gamma^{k+1}\sigma_1^L, \quad \|\boldsymbol{S}-\boldsymbol{S}_{k+1}\|_\infty \le \frac{\mu r}{n}\gamma^{k+1}\sigma_1^L \quad \text{and} \quad supp(\boldsymbol{S}_{k+1})\subset\Omega,$$

which completes the proof.

Additionally, notice that we overall require $1>\gamma\ge\max\{512\tau r\kappa^2+\frac{1}{\sqrt{12}}, \frac{2\upsilon}{(1-12\tau)(1-\tau-\upsilon)^2}\}$. By the definition of τ and υ, one can easily see that the lower bound approaches $\frac{1}{\sqrt{12}}$ when the constant hidden in (4) is sufficiently large. Therefore, the theorem can be proved for any $\gamma\in\left(\frac{1}{\sqrt{12}},1\right)$. ■

4.2. Proof of Theorem 2

We first present a lemma which is a variant of Lemma 9 and also appears in (Netrapalli et al., 2014, Lemma 5). The lemma can be similarly proved by mathematical induction.

Lemma 15 *Let $\boldsymbol{S}\in\mathbb{R}^{n\times n}$ be a sparse matrix satisfying Assumption A2. Let $\boldsymbol{U}\in\mathbb{R}^{n\times r}$ be an orthogonal matrix with μ-incoherence, i.e., $\|\boldsymbol{e}_i^T\boldsymbol{U}\|_2\le\sqrt{\frac{\mu r}{n}}$ for all i. Then*

$$\|\boldsymbol{e}_i^T\boldsymbol{S}^a\boldsymbol{U}\|_2 \le \sqrt{\frac{\mu r}{n}}(\alpha n\|\boldsymbol{S}\|_\infty)^a$$

for all i and $a\ge 0$.

Though the proposed initialization scheme (i.e., Algorithms 3) basically consists of two steps of AltProj (Netrapalli et al., 2014), we provide an independent proof for Theorem 2 here because we bound the approximation errors of the low rank matrices using the spectral norm rather than the infinity norm. The proof of Theorem 2 follows a similar structure to that of Theorem 1, but without the projection onto a low dimensional tangent space. Instead of first presenting several auxiliary lemmas, we give a single proof by putting all the elements together.

Proof [Proof of Theorem 2] The proof can be partitioned into several parts.

(i) Note that $\boldsymbol{L}_{-1}=0$ and

$$\|\boldsymbol{L}-\boldsymbol{L}_{-1}\|_\infty = \|\boldsymbol{L}\|_\infty = \max_{ij}\left|\boldsymbol{e}_i^T\boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{U}^T\boldsymbol{e}_j\right| \le \max_{ij}\|\boldsymbol{e}_i^T\boldsymbol{U}\|_2\|\boldsymbol{\Sigma}\|_2\|\boldsymbol{U}^T\boldsymbol{e}_j\|_2 \le \frac{\mu r}{n}\sigma_1^L,$$

where the last inequality follows from Assumption A1, i.e., $\boldsymbol{L}$ is μ-incoherent. Thus, with the choice of $\beta_{init}\ge\frac{\mu r\sigma_1^L}{n\sigma_1^D}$, we have

$$\|\boldsymbol{L}-\boldsymbol{L}_{-1}\|_\infty \le \beta_{init}\sigma_1^D = \zeta_{-1}. \tag{24}$$

Since

$$[\boldsymbol{S}_{-1}]_{ij} = [\mathcal{T}_{\zeta_{-1}}(\boldsymbol{S}+\boldsymbol{L}-\boldsymbol{L}_{-1})]_{ij} = \begin{cases} \mathcal{T}_{\zeta_{-1}}([\boldsymbol{S}+\boldsymbol{L}-\boldsymbol{L}_{-1}]_{ij}) & (i,j)\in\Omega \\ \mathcal{T}_{\zeta_{-1}}([\boldsymbol{L}-\boldsymbol{L}_{-1}]_{ij}) & (i,j)\in\Omega^c, \end{cases}$$

it follows that $[\boldsymbol{S}_{-1}]_{ij}=0$ for all $(i,j)\in\Omega^c$, i.e. $\Omega_{-1} := supp(\boldsymbol{S}_{-1})\subset\Omega$. Moreover, for any entries of $\boldsymbol{S}-\boldsymbol{S}_{-1}$, we have

$$[\boldsymbol{S}-\boldsymbol{S}_{-1}]_{ij} = \begin{cases} 0 \\ [\boldsymbol{L}_{-1}-\boldsymbol{L}]_{ij} \\ [\boldsymbol{S}]_{ij} \end{cases} \le \begin{cases} 0 \\ \|\boldsymbol{L}-\boldsymbol{L}_{-1}\|_\infty \\ \|\boldsymbol{L}-\boldsymbol{L}_{-1}\|_\infty+\zeta_{-1} \end{cases} \le \begin{cases} 0 & (i,j)\in\Omega^c \\ \frac{\mu r}{n}\sigma_1^L & (i,j)\in\Omega_{-1} \\ \frac{4\mu r}{n}\sigma_1^L & (i,j)\in\Omega\backslash\Omega_{-1} \end{cases},$$

where the last inequality follows from $\beta_{init}\le\frac{3\mu r\sigma_1^L}{n\sigma_1^D}$, so that $\zeta_{-1}\le\frac{3\mu r}{n}\sigma_1^L$. Therefore, if follows that

$$supp(\boldsymbol{S}_{-1})\subset\Omega \quad \text{and} \quad \|\boldsymbol{S}-\boldsymbol{S}_{-1}\|_\infty \le \frac{4\mu r}{n}\sigma_1^L. \tag{25}$$

By Lemma 4, we also have

$$\|\boldsymbol{S}-\boldsymbol{S}_{-1}\|_2 \le \alpha n\|\boldsymbol{S}-\boldsymbol{S}_{-1}\|_\infty \le 4\alpha\mu r\sigma_1^L.$$

(ii) To bound the approximation error of $\boldsymbol{L}_0$ to $\boldsymbol{L}$ in terms of the spectral norm, note that

$$\begin{aligned}\|\boldsymbol{L}-\boldsymbol{L}_0\|_2 &\le \|\boldsymbol{L}-(\boldsymbol{D}-\boldsymbol{S}_{-1})\|_2 + \|(\boldsymbol{D}-\boldsymbol{S}_{-1})-\boldsymbol{L}_0\|_2\\ &\le 2\|\boldsymbol{L}-(\boldsymbol{D}-\boldsymbol{S}_{-1})\|_2\\ &= 2\|\boldsymbol{L}-(\boldsymbol{L}+\boldsymbol{S}-\boldsymbol{S}_{-1})\|_2\\ &= 2\|\boldsymbol{S}-\boldsymbol{S}_{-1}\|_2,\end{aligned}$$

where the second inequality follows from the fact $\boldsymbol{L}_0 = \mathcal{H}_r(\boldsymbol{D}-\boldsymbol{S}_{-1})$ is the best rank-r approximation of $\boldsymbol{D}-\boldsymbol{S}_{-1}$. It follows immediately that

$$\|\boldsymbol{L}-\boldsymbol{L}_0\|_2 \le 8\alpha\mu r\sigma_1^L. \tag{26}$$

(iii) Since $\boldsymbol{D}=\boldsymbol{L}+\boldsymbol{S}$, we have $\boldsymbol{D}-\boldsymbol{S}_{-1} = \boldsymbol{L}+\boldsymbol{S}-\boldsymbol{S}_{-1}$. Let λ_i denotes the i^{th} eigenvalue of $\boldsymbol{D}-\boldsymbol{S}_{-1}$ ordered by $|\lambda_1|\ge|\lambda_2|\ge\cdots\ge|\lambda_n|$. The application of Weyl's inequality together with the bound of α in Assumption A2 implies that

$$|\sigma_i^L - |\lambda_i|| \le \|\boldsymbol{S}-\boldsymbol{S}_{-1}\|_2 \le \frac{\sigma_r^L}{8} \tag{27}$$

holds for all i. Consequently, we have

$$\frac{7}{8}\sigma_i^L \le |\lambda_i| \le \frac{9}{8}\sigma_i^L, \qquad \forall 1\le i\le r, \tag{28}$$

$$\frac{\|\boldsymbol{S}-\boldsymbol{S}_{-1}\|_2}{|\lambda_r|} \le \frac{\frac{\sigma_r^L}{8}}{\frac{7\sigma_r^L}{8}} = \frac{1}{7}. \tag{29}$$

Let $\boldsymbol{D}-\boldsymbol{S}_{-1} = [\boldsymbol{U}_0,\ddot{\boldsymbol{U}}_0]\begin{bmatrix}\boldsymbol{\Lambda} & \boldsymbol{0}\\ \boldsymbol{0} & \ddot{\boldsymbol{\Lambda}}\end{bmatrix}[\boldsymbol{U}_0,\ddot{\boldsymbol{U}}_0]^T = \boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T + \ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T$ be its eigenvalue decomposition, where $\boldsymbol{\Lambda}$ has the r largest eigenvalues in magnitude and $\ddot{\boldsymbol{\Lambda}}$ contains the rest eigenvalues. Also, $\boldsymbol{U}_0$ contains the first r eigenvectors, and $\ddot{\boldsymbol{U}}_0$ has the rest. Notice that $\boldsymbol{L}_0 = \mathcal{H}_r(\boldsymbol{D}-\boldsymbol{S}_{-1}) = \boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T$ due to the symmetric setting. Denote $\boldsymbol{E} = \boldsymbol{D}-\boldsymbol{S_{-1}}-\boldsymbol{L} = \boldsymbol{S}-\boldsymbol{S}_{-1}$. Let $\boldsymbol{u}_i$ be the i^{th} eigenvector of $\boldsymbol{D}-\boldsymbol{S}_{-1} = \boldsymbol{L}+\boldsymbol{E}$. For $1\le i\le r$, since $(\boldsymbol{L}+\boldsymbol{E})\boldsymbol{u}_i = \lambda_i\boldsymbol{u}_i$, we have

$$\boldsymbol{u}_i = \left(\boldsymbol{I}-\frac{\boldsymbol{E}}{\lambda_i}\right)^{-1}\frac{\boldsymbol{L}}{\lambda_i}\boldsymbol{u}_i = \left(\boldsymbol{I}+\frac{\boldsymbol{E}}{\lambda_i}+\left(\frac{\boldsymbol{E}}{\lambda_i}\right)^2+\cdots\right)\frac{\boldsymbol{L}}{\lambda_i}\boldsymbol{u}_i$$

for each $\boldsymbol{u}_i$, where the expansion in the last equality is valid because $\frac{\|\boldsymbol{E}\|_2}{|\lambda_i|} \le \frac{1}{7}$ for all $1\le i\le r$ following from (29). Therefore,

$$\begin{aligned}\|\boldsymbol{L}_0-\boldsymbol{L}\|_\infty &= \|\boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T-\boldsymbol{L}\|_\infty\\ &= \|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L}+\sum_{a+b>0}\boldsymbol{E}^a\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\boldsymbol{E}^b\|_\infty\\ &\le \|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L}\|_\infty + \sum_{a+b>0}\|\boldsymbol{E}^a\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\boldsymbol{E}^b\|_\infty\\ &:= \boldsymbol{Y}_0 + \sum_{a+b>0}\boldsymbol{Y}_{ab}.\end{aligned}$$

We will handle $\boldsymbol{Y}_0$ first. Recall that $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$ is the SVD of the symmetric matrix $\boldsymbol{L}$ which is μ-incoherence, i.e., $\boldsymbol{U}\boldsymbol{U}^T = \boldsymbol{V}\boldsymbol{V}^T$ and $\|\boldsymbol{e}_i^T\boldsymbol{U}\boldsymbol{U}^T\|_2 \le \sqrt{\frac{\mu r}{n}}$ for all i. For each (i,j) entry of $\boldsymbol{Y}_0$, we have

$$\begin{aligned}\boldsymbol{Y}_0 &= \max_{ij}|\boldsymbol{e}_i^T(\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L})\boldsymbol{e}_j|\\ &= \max_{ij}|\boldsymbol{e}_i^T\boldsymbol{U}\boldsymbol{U}^T(\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L})\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{e}_j|\\ &\le \max_{ij}\|\boldsymbol{e}_i^T\boldsymbol{U}\boldsymbol{U}^T\|_2\ \|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L}\|_2\ \|\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{e}_j\|_2\\ &\le \frac{\mu r}{n}\|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L}\|_2,\end{aligned}$$

where the second equation follows from the fact $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{U}^T\boldsymbol{L} = \boldsymbol{L}\boldsymbol{U}\boldsymbol{U}^T$. Since $\boldsymbol{L} = \boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T + \ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T - \boldsymbol{E}$,

$$\begin{aligned}&\|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{L}-\boldsymbol{L}\|_2\\ &= \|(\boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T+\ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T-\boldsymbol{E})\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T(\boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T+\ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T-\boldsymbol{E})-\boldsymbol{L}\|_2\\ &= \|\boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T-\boldsymbol{L}-\boldsymbol{U}_0\boldsymbol{U}_0^T\boldsymbol{E}-\boldsymbol{E}\boldsymbol{U}_0\boldsymbol{U}_0^T-\boldsymbol{E}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-1}\boldsymbol{U}_0^T\boldsymbol{E}\|_2\\ &\le \|\boldsymbol{E}-\ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T\|_2 + 2\|\boldsymbol{E}\|_2 + \frac{\|\boldsymbol{E}\|_2^2}{|\lambda_r|}\\ &\le \|\ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T\|_2 + 4\|\boldsymbol{E}\|_2\\ &\le |\lambda_{r+1}| + 4\|\boldsymbol{E}\|_2\\ &\le 5\|\boldsymbol{E}\|_2,\end{aligned}$$

where the first and fourth inequality follow from (27) and (29), and $|\lambda_{r+1}| \le \|\boldsymbol{E}\|_2$ since $\sigma_{r+1}^L = 0$. Together, we have

$$\boldsymbol{Y}_0 \le \frac{5\mu r}{n}\|\boldsymbol{E}\|_2 \le 5\alpha\mu r\|\boldsymbol{E}\|_\infty, \tag{30}$$

where the last inequality follows from Lemma 4.

Next, we will find an upper bound for the rest part. Note that

$$\begin{aligned}\boldsymbol{Y}_{ab} &= \max_{ij}|\boldsymbol{e}_i^T\boldsymbol{E}^a\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\boldsymbol{E}^b\boldsymbol{e}_j|\\ &= \max_{ij}|(\boldsymbol{e}_i^T\boldsymbol{E}^a\boldsymbol{U}\boldsymbol{U}^T)\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}(\boldsymbol{U}\boldsymbol{U}^T\boldsymbol{E}^b\boldsymbol{e}_j)|\\ &\le \max_{ij}\|\boldsymbol{e}_i^T\boldsymbol{E}^a\boldsymbol{U}\|_2\ \|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\|_2\ \|\boldsymbol{U}^T\boldsymbol{E}^b\boldsymbol{e}_j\|_2\end{aligned}$$

$$\leq \frac{\mu r}{n}(\alpha n\|\boldsymbol{E}\|_\infty)^{a+b}\|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\|_2$$
$$\leq \alpha\mu r\|\boldsymbol{E}\|_\infty\left(\frac{\sigma_r^L}{8}\right)^{a+b-1}\|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\|_2,$$

where the second inequality uses Lemma 15. Furthermore, by using $\boldsymbol{L} = \boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T + \ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T - \boldsymbol{E}$ again, we have

$$\begin{aligned}
&\|\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{L}\|_2\\
&= \|(\boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T + \ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T - \boldsymbol{E})\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T(\boldsymbol{U}_0\boldsymbol{\Lambda}\boldsymbol{U}_0^T + \ddot{\boldsymbol{U}}_0\ddot{\boldsymbol{\Lambda}}\ddot{\boldsymbol{U}}_0^T - \boldsymbol{E})\|_2\\
&= \|\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b-1)}\boldsymbol{U}_0^T - \boldsymbol{E}\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b)}\boldsymbol{U}_0^T - \boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b)}\boldsymbol{U}_0^T\boldsymbol{E} + \boldsymbol{E}\boldsymbol{L}\boldsymbol{U}_0\boldsymbol{\Lambda}^{-(a+b+1)}\boldsymbol{U}_0^T\boldsymbol{E}\|_2\\
&\leq |\lambda_r|^{-(a+b-1)} + |\lambda_r|^{-(a+b)}\|\boldsymbol{E}\|_2 + |\lambda_r|^{-(a+b)}\|\boldsymbol{E}\|_2 + |\lambda_r|^{-(a+b+1)}\|\boldsymbol{E}\|_2^2\\
&= |\lambda_r|^{-(a+b-1)}\left(1 + \frac{2\|\boldsymbol{E}\|_2}{|\lambda_r|} + \left(\frac{\|\boldsymbol{E}\|_2}{|\lambda_r|}\right)^2\right)\\
&= |\lambda_r|^{-(a+b-1)}\left(1 + \frac{\|\boldsymbol{E}\|_2}{|\lambda_r|}\right)^2\\
&\leq 2|\lambda_r|^{-(a+b-1)}\\
&\leq 2\left(\frac{7}{8}\sigma_r^L\right)^{-(a+b-1)},
\end{aligned}$$

where the second inequality follows from (29) and the last inequality follows from (28). Together, we have

$$\begin{aligned}
\sum_{a+b>0}\boldsymbol{Y}_{ab} &\leq \sum_{a+b>0} 2\alpha\mu r\|\boldsymbol{E}\|_\infty\left(\frac{\frac{1}{8}\sigma_r^L}{\frac{7}{8}\sigma_r^L}\right)^{a+b-1}\\
&\leq 2\alpha\mu r\|\boldsymbol{E}\|_\infty\sum_{a+b>0}\left(\frac{1}{7}\right)^{a+b-1}\\
&\leq 2\alpha\mu r\|\boldsymbol{E}\|_\infty\left(\frac{1}{1-\frac{1}{7}}\right)^2\\
&\leq 3\alpha\mu r\|\boldsymbol{E}\|_\infty. \qquad (31)
\end{aligned}$$

Finally, combining (30)) and (31)) together yields

$$\begin{aligned}
\|\boldsymbol{L}_0 - \boldsymbol{L}\|_\infty &= \boldsymbol{Y}_0 + \sum_{a+b>0}\boldsymbol{Y}_{ab}\\
&\leq 5\alpha\mu r\|\boldsymbol{E}\|_\infty + 3\alpha\mu r\|\boldsymbol{E}\|_\infty\\
&\leq \frac{\mu r}{4n}\sigma_1^L, \qquad (32)
\end{aligned}$$

where the last step uses (25) and the bound of α in Assumption A2.

(iv) From the thresholding rule, we know that

$$[\boldsymbol{S}_0]_{ij} = [\mathcal{T}_{\zeta_0}(\boldsymbol{S}+\boldsymbol{L}-\boldsymbol{L}_0)]_{ij} = \begin{cases}\mathcal{T}_{\zeta_0}([\boldsymbol{S}+\boldsymbol{L}-\boldsymbol{L}_0]_{ij}) & (i,j)\in\Omega\\ \mathcal{T}_{\zeta_0}([\boldsymbol{L}-\boldsymbol{L}_0]_{ij}) & (i,j)\in\Omega^c\end{cases}.$$

So (28), (32) and $\zeta_0 = \frac{\mu r}{2n}\lambda_1$ imply $[\boldsymbol{S}_0]_{ij} = 0$ for all $(i,j)\in\Omega^c$, i.e., $supp(\boldsymbol{S}_0) := \Omega_0 \subset \Omega$. Also, for any entries of $\boldsymbol{S}-\boldsymbol{S}_0$, there hold

$$[\boldsymbol{S}-\boldsymbol{S}_0]_{ij} = \begin{cases}0\\ [\boldsymbol{L}_0-\boldsymbol{L}]_{ij}\\ [\boldsymbol{S}]_{ij}\end{cases} \leq \begin{cases}0\\ \|\boldsymbol{L}-\boldsymbol{L}_0\|_\infty\\ \|\boldsymbol{L}-\boldsymbol{L}_0\|_\infty+\zeta_0\end{cases} \leq \begin{cases}0 & (i,j)\in\Omega^c\\ \frac{\mu r}{4n}\sigma_1^L & (i,j)\in\Omega_0\\ \frac{\mu r}{n}\sigma_1^L & (i,j)\in\Omega\backslash\Omega_0.\end{cases}$$

Here the last inequality follows from (28) which implies $\zeta_0 = \frac{\mu r}{2n}\lambda_1 \leq \frac{3\mu r}{4n}\sigma_1^L$. Therefore, we have

$$supp(\boldsymbol{S}_0)\subset\Omega \quad\text{and}\quad \|\boldsymbol{S}-\boldsymbol{S}_0\|_\infty \leq \frac{\mu r}{n}\sigma_1^L.$$

The proof is compete by noting (26) and the above results. ■

5. Discussion and Future Direction

We have presented a highly efficient algorithm AccAltProj for robust principal component analysis. The algorithm is developed by introducing a novel subspace projection step before the SVD truncation, which reduces the per iteration computational complexity of the algorithm of alternating projections significantly. Theoretical recovery guarantee has been established for the new algorithm, while numerical simulations show that our algorithm is superior to other state-of-the-art algorithms.

There are three lines of research for future work. Firstly, the theoretical number of the non-zero entries in a sparse matrix below which AccAltProj can achieve successful recovery is highly pessimistic compared with our numerical findings. This suggests the possibility of improving the theoretical result. Secondly, recovery stability of the proposed algorithm to additive noise will be investigated in the future. Finally, this paper focuses on the fully observed setting. The proposed algorithm might be similarly extended to the partially observed setting where only partial entries of a matrix are observed. It is also interesting to study the recovery guarantee of the proposed algorithm under this partial observed setting.

Abstract

Singular values of a data in a matrix form provide insights on the structure of the data, the effective dimensionality, and the choice of hyper-parameters on higher-level data analysis tools. However, in many practical applications such as collaborative filtering and network analysis, we only get a partial observation. Under such scenarios, we consider the fundamental problem of recovering spectral properties of the underlying matrix from a sampling of its entries. In this paper, we address the problem of directly recovering the spectrum, which is the set of singular values, and also in sample-efficient approaches for recovering a spectral sum function, which is an aggregate sum of a fixed function applied to each of the singular values. Our approach is to first estimate the Schatten k-norms of a matrix for a small set of values of k, and then apply Chebyshev approximation when estimating a spectral sum function or apply moment matching in Wasserstein distance when estimating the singular values directly. The main technical challenge is in accurately estimating the Schatten norms from a sampling of a matrix. We introduce a novel unbiased estimator based on counting small structures called network motifs in a graph and provide guarantees that match its empirical performance. Our theoretical analysis shows that Schatten norms can be recovered accurately from strictly smaller number of samples compared to what is needed to recover the underlying low-rank matrix. Numerical experiments suggest that we significantly improve upon a competing approach of using matrix completion methods, below the matrix completion threshold, above which matrix completion algorithms recover the underlying low-rank matrix exactly.

Keywords: spectrum estimation, matrix completion, counting subgraphs.

1. Introduction

Computing and analyzing the set of singular values of a data in a matrix form, which is called the spectrum, provide insights into the geometry and topology of the data. Such a spectral analysis is routinely a first step in general data analysis with the goal of checking if there exists a lower dimensional subspace explaining the important aspects of the data, which itself might be high dimensional. Concretely, it is a first step in dimensionality reduction methods such as principal component analysis or canonical correlation analysis.

However, spectral analysis becomes challenging in practical scenarios where the data is only partially observed. We commonly observe pairwise relations of randomly chosen pairs: each user only rates a few movies in recommendation systems, each player/team only plays against a few opponents in sports leagues, each word appears in the same sentence with a small number of other words in word count matrices, and each worker answers a few questions in crowdsourcing. In other applications, we have more structured samples. For example, in a network analysis we might be interested in the spectrum of a large network, but only get to see the connections within a small subset of nodes corresponding to sampling a sub-matrix of the adjacency matrix. Whatever the sampling pattern is, typical number of paired relations we observe is significantly smaller than the dimension of the data matrix.

We study all such variations in sampling patterns for partially observed data matrices, and ask the following fundamental question: *can we estimate spectral properties of a data matrix from partial observations?* We propose a novel approach that allows us to estimate the spectrum, i.e. the singular values. A crucial building block in our approach is that spectral properties can be accurately approximated from the first few moments of the spectrum known as the Schatten k-norms defined as

$$\|M\|_k \;=\; \Big(\sum_{i=1}^{d} \sigma_i(M)^k\Big)^{1/k} ,$$

where $\sigma_1(M) \geq \sigma_2(M) \geq \cdots \geq \sigma_d(M) \geq 0$ are the singular values of the data matrix $M \in \mathbb{R}^{d\times d}$. Once we obtain accurate estimates of Schatten k-norms, these estimates, as well as corresponding performance guarantees, can readily be translated into accurate estimates of the spectrum of the matrix. Further, if we are interested in estimating a class of functions known as spectral sum functions of the form (4), our estimates of the Schatten norms can be used to estimate any spectral sum function using Chebyshev expansions.

1.1. Setup

We want to estimate the Schatten k-norm of a positive semidefinite matrix $M \in \mathbb{R}^{d\times d}$ from a subset of its entries. The restriction to positive semidefinite matrices is primarily for notational convenience, and our analyses, the estimator, and the efficient algorithms naturally generalize to any non-square matrices. Namely, we can extend our framework to bipartite graphs and estimate Schatten k-norm of any matrix for any even k. Let Ω denote the set of indices of samples we are given and let $\mathcal{P}_\Omega(M) = \{(i,j,M_{ij})\}_{(i,j)\in\Omega}$ denote the samples. With a slight abuse of notation, we used $\mathcal{P}_\Omega(M)$ to also denote the $d\times d$ sampled matrix:

$$\mathcal{P}_\Omega(M)_{ij} = \begin{cases} M_{ij} & \text{if } (i,j)\in\Omega\,, \\ 0 & \text{otherwise}\,, \end{cases}$$

and it should be clear from the context which one we refer to. Although we propose a framework that generally applies to any probabilistic sampling, it is necessary to propose specific sampling scenarios to provide tight analyses on the performance. Hence, we focus on *Erdös-Rényi sampling*.

There is an extensive line of research in low-rank matrix completion problems (Candès and Recht, 2009; Keshavan et al., 2010a), which addresses a fundamental question of how many samples are required to *complete* a matrix (i.e. estimate all the missing entries) from a small subset of sampled entries. It is typically assumed that each entry of the matrix is sampled independently with a probability $p \in (0,1]$. We refer to this scenario as *Erdös-Rényi sampling*, as the resulting pattern of the samples encoded as a graph is distributed

as an Erdös-Rényi random graph. The spectral properties of such an sampled matrix have been well studied in the literature (Friedman et al., 1989; Achlioptas and McSherry, 2001; Feige and Ofek, 2005; Keshavan et al., 2010a; Le et al., 2015). In particular, it is known that the original matrix is close in spectral norm to the sampled one where the missing entries are filled in with zeros and properly rescaled under certain incoherence assumptions. This suggests using the singular values of the sampled and rescaled matrix $(d^2/|\Omega|)\mathcal{P}(M)$ directly for estimating the Schatten norms. However, in the sub-linear regime in which the number of samples $|\Omega| = d^2p$ is comparable to or significantly smaller than the degrees of freedom in representing a symmetric rank-r matrix, which is $dr - r^2$, the spectrum of the sampled matrix is significantly different from the spectrum of the original matrix as shown in Figure 1. We need to design novel estimators that are more sample efficient in the sub-linear regime where $d^2p \ll dr$.

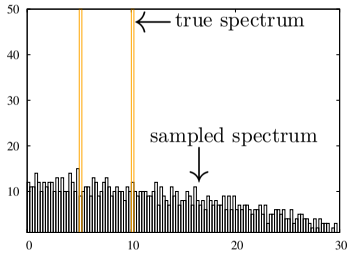

Figure 1: In yellow, we show the histogram of the singular values of a positive semi-definite matrix $M \in \mathbb{R}^{d\times d}$ of size $d = 1000$ with rank $r = 100$, with $\sigma_1 = \cdots = \sigma_{50} = 10$, $\sigma_{51} = \cdots = \sigma_{100} = 5$, and the rest at zero (we omit zero singular values in the plot for illustration). In comparison, we show in black the histogram of the singular values of the sampled matrix where each entry of M is sampled with probability $p = (1/d)r^{1-2/7}$ (properly rescaled by $1/p$ to best match the original spectrum).

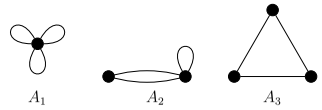
1.2. Summary of the approach and preview of results



We propose first estimating one or a few Scahtten norms, which can be accurately estimated from samples, and using these estimated Schatten norms to approximate the spectral properties of interest: spectral sum functions and the spectrum. We use an alternative expression of the Schatten k-norm for positive semidefinite matrices as the trace of the k-th power of M, i.e. $(\|M\|_k)^k = \mathrm{Tr}(M^k)$. This sum of the entries along the diagonal of M^k is the sum of total weights of all the closed walks of length k. Consider the entries of M as weights on a complete graph K_d over d nodes (with self-loops). A closed walk of length k is defined as a sequence of nodes $w = (w_1, w_2, \ldots, w_{k+1})$ with $w_1 = w_{k+1}$, where we allow repeated nodes and repeated edges. The *weight* of a closed walk $w = (w_1, \ldots, w_k, w_1)$ is defined as

$\omega_M(w) \equiv \prod_{i=1}^{k} M_{w_i w_{i+1}}$, which is the product of the weights along the walk. It follows that

$$\|M\|_k^k \;=\; \sum_{w:\text{ all length } k \text{ closed walks}} \omega_M(w)\,. \tag{1}$$

Following the notations from enumeration of small simple cycles in a graph by Alon et al. (1997), we partition this summation into those with the same pattern H that we call a *k-cyclic pseudograph*. Let $C_k = (V_k, E_k)$ denote the undirected simple cycle graph with k nodes, e.g. A_3 in Figure 2 is C_3. We expand the standard notion of simple k-cyclic graphs to include multi-edges and loops, hence the name *pseudograph*.

Definition 1 We define an unlabelled and undirected pseudograph $H = (V_H, E_H)$ to be a *k-cyclic pseudograph* for $k \geq 3$ if there exists an onto node-mapping from $C_k = (V_k, E_k)$, i.e. $f : V_k \to V_H$, and a one-to-one edge-mapping $g : E_k \to E_H$ such that $g(e) = (f(u_e), f(v_e))$ for all $e = (u_e, v_e) \in E_k$. We use $\mathcal{H}_k$ to denote the set of all k-cyclic pseudographs. We use $c(H)$ to the number of different node mappings f from C_k to a k-cyclic pseudograph H.

$c(A_1) = 1 \quad c(A_2) = 3 \quad c(A_3) = 6$

Figure 2: The 3-cyclic pseudographs $\mathcal{H}_3 = \{A_1, A_2, A_3\}$.

In the above example, each member of $\mathcal{H}_3$ is a distinct pattern that can be mapped from C_3. For A_1, it is clear that there is only one mapping from C_3 to A_1 (i.e. $c(A_1) = 1$). For A_2, one can map any of the three nodes to the left-node of A_2, hence $c(A_2) = 3$. For A_3, any of the three nodes can be mapped to the bottom-left-node of A_3 and also one can map the rest of the nodes clockwise or counter-clockwise, resulting in $c(A_3) = 6$. For $k \leq 7$, all the k-cyclic pseudo graphs are given in the Section 9 (See Figures 10–15).

Each closed walk w of length k is associated with one of the graphs in $\mathcal{H}_k$, as there is a unique H that the walk is an Eulerian cycle of (under a one-to-one mapping of the nodes). We denote this graph by $H(w) \in \mathcal{H}_k$. Considering the weight of a walk $\omega_M(w)$, there are multiple distinct walks with the same weight. For example, a length-3 walk $w = (v_1, v_2, v_2, v_1)$ has $H(w) = A_2$ and there are 3 walks with the same weight $\omega(w) = (M_{v_1v_2})^2 M_{v_2v_2}$, i.e. (v_1, v_2, v_2, v_1), (v_2, v_2, v_1, v_2), and (v_2, v_1, v_2, v_2). This multiplicity of the weight depends only on the structure $H(w)$ of a walk, and it is exactly $c(H(w))$ the number of mappings from C_k to $H(w)$ in Definition 1. The total sum of the weights of closed walks of length k can be partitioned into their respective pattern, which will make computation of such terms more efficient (see Section 2) and also de-biasing straight forward (see Equation (3)):

$$\|M\|_k^k \;=\; \sum_{H\in\mathcal{H}_k} \omega_M(H)\, c(H)\,, \tag{2}$$

where with a slight abuse of a notation, we let $\omega_M(H)$ for $H \in \mathcal{H}_k$ be the sum of all *distinct* weights of walks w with $H(w) = H$, and $c(H)$ is the multiplicity of each of those distinct weights. This gives an alternative tool for computing the Schatten k-norm without explicitly computing the singular values.

Given only the access to a subset of sampled entries, one might be tempted to apply the above formula to the sampled matrix with an appropriate scaling, i.e.

$$\left\| \frac{d^2}{|\Omega|} \mathcal{P}_\Omega(M) \right\|_k^k = \frac{d^2}{|\Omega|} \sum_{H \in \mathcal{H}_k} \omega_{\mathcal{P}_\Omega(M)}(H)\, c(H)\,,$$

to estimate $\|M\|_k^k$. However, this is significantly biased. To eliminate the bias, we propose rescaling each term in (1) by the inverse of the probability of sampling that particular walk w (i.e. the probability that all edges in w are sampled). A crucial observation is that, for any sampling model that is invariant under a relabelling of the nodes, this probability only depends on the pattern $H(w)$. In particular, this is true for the Erdös-Rényi sampling. Based on this observation, we introduce a novel estimator that de-biases each group separately:

$$\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) = \sum_{H \in \mathcal{H}_k} \frac{1}{p(H)}\, \omega_{\mathcal{P}_\Omega(M)}(H)\, c(H)\,, \tag{3}$$

where $p(H)$ is the probability a pattern H is sampled, i.e. all edges traversed in a walk w with $H(w) = H$ is sampled. It immediately follows that this estimator is unbiased, i.e. $\mathbb{E}_\Omega[\widehat{\Theta}_k(\mathcal{P}_\Omega(M))] = \|M\|_k^k$, where the randomness is in Ω. However, computing this estimate can be challenging. Naive enumeration over all closed walks of length k takes time scaling as $O(d\,\Delta^{k-1})$, where Δ is the maximum degree of the graph. Except for extremely sparse graphs, this is impractical. Inspired by the work of Alon et al. (1997) in counting short cycles in a graph, we introduce a novel and efficient method for computing the proposed estimate for small values of k.

Proposition 2 *For a positive semidefinite matrix M and any sampling pattern Ω, the proposed estimate $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ in (3) can be computed in time $O(d^\alpha)$ for $k \in \{3, 4, 5, 6, 7\}$, where $\alpha < 2.373$ is the exponent of matrix multiplication. For $k = 1$ or 2, $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ can be computed in time $O(d)$ and $O(d^2)$, respectively.*

This bound holds regardless of the degree, and the complexity can be even smaller for sparse graphs as matrix multiplications are more efficient. We give a constructive proof by introducing a novel algorithm achieving this complexity in Section 2. For $k \geq 8$, our approach can potentially be extended, but the complexity of the problem fundamentally changes as it is at least as hard as counting K_4 in a graph, for which the best known run time is $O(d^{\alpha+1})$ for general graphs (Kloks et al., 2000).

We make the following contributions in this paper:

- We give in (3) an unbiased estimator of the Schatten k-norm of a positive semidefinite matrix M, from a random sampling of its entries. In general, the complexity of computing the estimate scales as $O(d\Delta^{k-1})$ where Δ is the maximum degree (number of sampled entries in a column) in the sampled matrix. We propose a novel efficient algorithm for computing the estimate in (3) exactly for small $k \leq 7$, which involves only matrix operations. This algorithm is significantly more efficient and has run-time scaling as $O(d^\alpha)$ independent of the degree and for all $k \leq 7$ (see Proposition 2) .

- Under the typical Erdös-Rényi sampling, we show that the Schatten k-norm of an incoherent rank-r matrix can be approximated within any constant multiplicative error, with number of samples scaling as $O(dr^{1-2/k})$ (see Theorem 3). In particular, this is strictly smaller than the number of samples necessary to complete the matrix, which scales as $O(dr \log d)$. Below this matrix completion threshold, numerical experiments confirm that the proposed estimator significantly outperforms simple heuristics of using singular values of the sampled matrices directly or applying state-of-the-art matrix completion methods (see Figure 4).

- Given the estimation of first K Schatten norms, it is straight forward to approximate spectral sum functions of the form (4) using Chebyshev's expansion, and also estimate the spectrum itself using moment matching in Wasserstein distance. We apply our Schatten norm estimates to the applications of estimating the generalized rank studied in Zhang et al. (2015) and estimating the spectrum studied in Kong and Valiant (2016). We provide performance guarantees for both applications and provide experimental results suggesting we improve upon other competing methods.

- We propose a new sampling model, which we call *graph sampling*, that preserves the structural properties of the pattern of the samples. We identify a fundamental property of the structure of the pattern ($\lambda^*_{G,r}$ in Eq.(14)) that captures the difficulty of estimating the Schatten k-norm from such graph sampling (see Theorem 11). Under this graph sampling, we show that there are sampling patterns that are significantly more efficient, for estimating the spectral properties, than Erdös-Rényi sampling.

In the remainder of this section, we review existing works in Schatten norm approximation, and provide an efficient implementation of the estimator (3) for small k in Section 2. In Section 3, we provide a theoretical analysis of our estimator under the Erdös-Rényi sampling scenario. In Section 4, we provide a theoretical analysis under the graph sampling scenario. We conclude with a discussion on interesting observations and remaining challenges in Section 5.

1.3. Related work

We review the existing methods in approximating the Schatten norms, counting small structures in graphs, and various applications of Schatten norms.

Estimating k-Schatten norms of a data matrix. The proposed Schatten norm estimator can be used as a black box in various applications where we want to test the property of a data matrix or a network but limited to observe only a small portion of the data. These include, for example, network forensics, matrix spectral property testing, and testing for graph isospectral properties. Relatively little is known under the matrix completion setting studied in this paper. However, Schatten norm estimation under different resource constrained scenarios have been studied. Hutchinson (1990) propose a randomized algorithm

for approximating the trace of any large matrix, where the constraint is on the computational complexity. The goal is to design a random rank-one linear mapping such that the trace is preserved in expectation and the variance is small (Avron and Toledo, 2011; Roosta-Khorasani and Ascher, 2015). Li et al. (2014) propose an optimal bilinear sketching of a data matrix, where the constraint is on the memory, i.e. the size of the resulting sketch. The goal is to design a sketch of a data matrix M using minimal storage and a corresponding approximate reconstruction method for $\|M\|_k^k$. Li and Woodruff (2016) propose an optimal streaming algorithm where only one-pass on the data is allowed in a data stream model and the constraint is on the space complexity of the algorithm. The goal is to design a streaming algorithm using minimal space to estimate $\|M\|_k^k$. Zhang et al. (2015) propose an estimator under a distributed setting where columns of the data are store in distributed storage and the constraint is on the communication complexity. The goal is to design a distributed protocol minimizing the communication to estimate $\|M\|_k^k$. Given a random vector X, Kong and Valiant (2016) propose an optimal estimator for the Schatten k-norm of the covariance matrix, where the constraint is on the number of samples n. The goal is to design an estimator using minimum number of samples to estimate $\|\mathbb{E}[XX^T]\|_k^k$.

One of our contributions is that we propose an efficient algorithm for computing the weighted counts of small structures in Section 2, which can significantly improve upon less sample-efficient counterpart in, for example, (Kong and Valiant, 2016). Under the setting of (Kong and Valiant, 2016) (and also (Li et al., 2014)), the main idea of the estimator is that the weight of each length-k cycle in the observed empirical covariance matrix $(1/n)\sum_{i=1}^n X_i X_i^T$ provides an unbiased estimator of $\|\mathbb{E}[XX^T]\|_k^k$. One prefers to sum over the weights of as many cycles as computationally allowed in order to reduce the variance. As counting all cycles is in general computationally hard, they propose counting only increasing cycles (which only accounts for only $1/k!$ fraction of all the cycles), which can be computed in time $O(d^\alpha)$. If one has an efficient method to count all the (weighted) cycles, then the variance of the estimator could potentially decrease by an order of $k!$. For $k \le 7$, our proposed algorithm in Section 2 provides exactly such an estimator. We replace (Kong and Valiant, 2016, Algorithm 1) with ours, and run the same experiment to showcase the improvement in Figure 3, for dimension $d = 2048$ and various values of number of samples n comparing the multiplicative error in estimating $\|\mathbb{E}[XX^T]\|_k^k$, for $k = 7$. With the same run-time, significant gain is achieved by simply substituting our proposed algorithm for counting small structures, in the sub-routine. In general, the efficient algorithm we propose might be of independent interest to various applications, and can directly replace (and significantly improve upon) other popular but less efficient counterparts.

One of the main challenges under the sampling scenario considered in this paper is that existing counting methods like that of (Kong and Valiant, 2016) cannot be applied, regardless of how much computational power we have. Under the matrix completion scenario, we need to (a) sum over all small structures $H \in \mathcal{H}_k$ and not just C_k as in (Kong and Valiant, 2016); and (b) for each structure we need to sum over all subgraphs with the same structure and not just those walks whose labels form a monotonically increasing sequence as in (Kong and Valiant, 2016).

Algorithms for counting structures. An important problem in graph theory is to count the number of small structures, also called network motifs, in a given graph. This has many

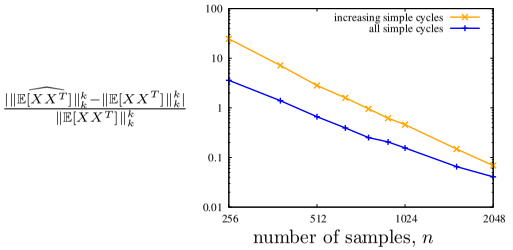


Figure 3: By replacing Algorithm 1 in (Kong and Valiant, 2016) that only counts increasing cycles with our proposed algorithm that counts all cycles, significant gain is acheived in estimating $\|\mathbb{E}[XX^T]\|_k^k$, for $k = 7$.

practical applications in designing good LDPC codes (Tian et al., 2004), understanding the properties of social networks (Ugander et al., 2013), and explaining gene regulation networks (Shen-Orr et al., 2002). Exact and approximate algorithms have been proposed in (Alon et al., 1997; Kloks et al., 2000; Liu and Wang, 2006; Halford and Chugg, 2006; Karimi and Banihashemi, 2013; Wang et al., 2014). The most relevant one is the work of Alon et al. (1997) on counting the number of cycles C_k, where counts of various small structures called k-cyclic graphs are used as sub-routines and efficient approaches are proposed for $k \le 7$. These are similar to k-cyclic pseudographs, but with multi-edges condensed to a single edge. When counting cycles in a simple (unweighted) graph, k-cyclic graphs are sufficient as all the edges have weight one. Hence, one does not need to track how many times an edge has been traversed; the weight of that walk is always one. In our setting, the weight of a walk depends on how many times an edge has been traversed, which we track using multiedges. It is therefore crucial to introduce the class of k-cyclic pseudographs in our estimator.

In a distributed environment, fast algorithms for counting small structures have been proposed by Elenberg et al. (2015) and Elenberg et al. (2016) for small values of $k \in \{3, 4\}$. However, the main strength of their approach is in distributed computing, and under the typical centralized setting we study, this approach can be slower by a factor exponential in k for, say $k \le 7$.

From Schatten norms to spectral sum functions. A dominant application of Schatten norms is in approximating a family of functions of a matrix, which are called *spectral sum functions* (Han et al., 2016) of the form

$$F(M; f) \equiv \sum_{i=1}^{d} f(\sigma_i(M)) \simeq \sum_{k=0}^{K} a_k \Big\{ \sum_{i=1}^{d} \sigma_i(M)^k \Big\} . \tag{4}$$

A typical approach is to compute the coefficients of a Chebyshev approximation of f, which immediately leads to an approximation of the spectral sum function of interest as the weighted sum of Schatten k-norms. This follows from the approximation of $f(x) \simeq$

$\sum_{k=0}^{K} a_k x^k$. This approach has been widely used in fast methods for approximating the log-determinant (Pace and LeSage, 2004; Zhang and Leithead, 2007; Boutsidis et al., 2015; Aune et al., 2014; Han et al., 2015), corresponding to $f(x) = \log x$. Practically, log-determinant computations are routinely (approximately) required in applications including Gaussian graphical models (Rue and Held, 2005), minimum-volume ellipsoids (Van Aelst and Rousseeuw, 2009), and metric learning (Davis et al., 2007). Fast methods for approximating trace of matrix inverse has been studied in (Wu et al., 2016; Chen, 2016), corresponding to $f(x) = x^{-1}$, motivated by applications in lattice quantum chromodynamics (Stathopoulos et al., 2013). Fast methods for approximating the Estarada index has been studied in (Han et al., 2016), corresponding to $f(x) = \exp(x)$. Practically, it is used in characterizing 3-dimensional molecular structure (Estrada, 2000) and measuring graph centrality (Estrada and Hatano, 2007), the entropy of a graph (Carbó-Dorca, 2008), and the bipartivity of a graph (Estrada and Rodriguez-Velázquez, 2005). Approximating the generalized rank under communication constraints has been studied in (Zhang et al., 2015), corresponding to $f(x; c_1) = \mathbb{I}(x \leq c_1)$. The generalized rank approximates a necessary tuning parameter in a number of problems where low-rank solutions are sought including robust PCA (Candès et al., 2011; Netrapalli et al., 2014) and matrix completion (Keshavan et al., 2010b,a; Jain et al., 2013), and also is required in sampling based methods in numerical analysis (Mahoney et al., 2011; Halko et al., 2011). Similarly, (Saade et al., 2015) studied the number of singular values in an interval, corresponding to $f(x; c_1, c_2) = \mathbb{I}(c_1 \leq x \leq c_2)$. In practice, a number of eigensolvers (Polizzi, 2009; Sakurai and Sugiura, 2003; Schofield et al., 2012) require the number of eigenvalues in a given interval. For more comprehensive list of references and applications of this framework, we refer to the related work section in (Han et al., 2016).

In a recent work, Kong and Valiant (2016) provide a novel approach to tackle the challenging problem of estimating the singular values themselves. Considering the histogram of the singular values as a one-dimensional distribution and the Schatten k-norm as the k-th moment of this distribution, the authors provide an innovative algorithm to estimate the histogram that best matches the moments in Wasserstein distance.

Matrix completion. Low-rank matrix completion addresses the problem of recovering a low-rank matrix from its sampled entries. Tight lower and upper bounds on the sample complexity is well studied in both cases where you want exact recovery when samples are noiseless (Candès and Recht, 2009; Keshavan et al., 2010a; Bhojanapalli and Jain, 2014), and also when samples are noisy and where you want approximate recovery (Keshavan et al., 2010b; Negahban and Wainwright, 2012). In practical applications, one might not have enough samples to estimate all the missing entries with sufficient accuracy. However, one might still be able to infer important spectral properties of the data, such as the singular values or the rank. Such spectral properties can also assist in making decisions on how many more samples to collect in order to make accurate inference on the quantity of interest. In this paper, one of the fundamental question we ask and answer affirmatively is: Can we accurately recover the spectral properties of a low-rank matrix from sampling of its entries, below the matrix completion threshold?

2. Efficient Algorithm

In this section we give a constructive proof of Proposition 2, inspired by the seminal work of Alon et al. (1997) and generalize their counting algorithm for k-cyclic graphs to counting (weighted) k-cyclic pseudographs. In computing the estimate in (3), $c(H)$ can be computed in time $O(k!)$. Suppose $p(H)$ has been computed. We will explain how to compute $p(H)$ for Erös-Rényi sampling and graph sampling in Sections 3 and 4. The bottleneck then is computing the weights $\omega_{\mathcal{P}_\Omega(M)}(H)$ for each $H \in \mathcal{H}_k$. Let $\gamma_M(H) \equiv \omega_M(H)c(H)$. We give matrix-multiplication-based equations to compute $\gamma_M(H)$ for every $H \in \mathcal{H}_k$ for $k \in \{3, 4, 5, 6, 7\}$. This establishes that $\gamma_M(H)$, and hence $\omega_M(H)$, can be computed in time $O(d^\alpha)$, proving Proposition 2.

For any matrix $A \in \mathbb{R}^{d\times d}$, let $\mathrm{diag}(A)$ to be a diagonal matrix such that $(\mathrm{diag}(A))_{ii} = A_{ii}$, for all $i \in [d]$ and $(\mathrm{diag}(A))_{i,j} = 0$, for all $i \neq j \in [d]$. For a given matrix $M \in \mathbb{R}^{d\times d}$, define O_M to be matrix of off-diagonal entries of M that is $O_M \equiv M - \mathrm{diag}(M)$ and $D_M \equiv \mathrm{diag}(M)$. Let $\mathrm{tr}(A)$ denote the trace of A, that is, $\mathrm{tr}(A) = \sum_{i\in[d]} A_{ii}$. Let $A*B$ denote the standard matrix multiplication of two matrices A and B. Consider computing $\gamma_M(H)$ for $H \in \mathcal{H}_3$ as labeled in Figure 2:

$$\gamma_M(A_1) = \mathrm{tr}(D_M{*}D_M{*}D_M) \quad (5)$$

$$\gamma_M(A_2) = 3\,\mathrm{tr}(D_M{*}O_M{*}O_M) \quad (6)$$

$$\gamma_M(A_3) = \mathrm{tr}(O_M{*}O_M{*}O_M) \quad (7)$$

The first weighted sum $\gamma_M(A_1)$ is the sum of all weights of walks of length 3 that consist of three self-loops. One can show that $\gamma_M(A_1) = \sum_{i\in[d]} M_{ii}^3$, which is (5) in our matrix operation notations. Similarly, $\gamma_M(A_3)$ is the sum of weights of length 3 walks with no self-loop, which leads to (7) and, $\gamma_M(A_2)$ is the sum of weights of length 3 walks with a single self-loop, which leads to (6). The factor 3 accounts for the fact that the self loop could have been placed at the first, second or the third in the walk.

Similarly, for each k-cyclic pseudographs in $\mathcal{H}_k$ for $k \leq 7$, computing $\gamma_M(H)$ involves a few matrix operations with run-time $O(d^\alpha)$. We provide the complete set of explicit expressions in Section 10. A MATLAB implementation of the estimator (3), that includes as its sub-routines the computation of the weights of all k-cyclic pseudographs, is available for download at `https://github.com/khetan2/Schatten_norm_estimation`. The explicit formulae in Section 10 together with the implementation in the above url might be of interest to other problems involving counting small structures in graphs.

For $k = 1$, the estimator simplifies to $\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) = (1/p)\sum_i \mathcal{P}_\Omega(M)_{ii}$, which can be computed in time $O(d)$. For $k = 2$, the estimator simplifies to $\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) = (1/p)\sum_{i,j} \mathcal{P}_\Omega(M)_{ij}^2$, which can be computed in time $O(|\Omega|)$. However, for $k \geq 8$, there exist walks over K_4, a clique over 4 nodes, that cannot be decomposed into simple computations involving matrix operations. The best known algorithm for a simpler task of counting K_4 has run-time scaling as $O(d^{\alpha+1})$, which is fundamentally different. We refer to Section 5 for further discussions on the computational complexity beyond $k = 7$.

Algorithm 1 Schatten k-norm estimator

Require: $\mathcal{P}_\Omega(M)$, k, $\mathcal{H}_k$, $p(H)$ for all $H \in \mathcal{H}_k$
Ensure: $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$
1: **if** $k \leq 7$ **then**
2: For each $H \in \mathcal{H}_k$, compute $\gamma_{\mathcal{P}_\Omega(M)}(H)$ using the formula from Eq. (5)–(7) for $k = 3$ and Eq. (60) – (203) for $k \in \{4, 5, 6, 7\}$
3: $\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) \leftarrow \sum_{H \in \mathcal{H}_k} \frac{1}{p(H)} \gamma_{\mathcal{P}_\Omega(M)}(H)$
4: **else**
5: $\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) \leftarrow$ Algorithm 4$[\mathcal{P}_\Omega(M)$, k, $\mathcal{H}_k$, $p(H)$ for all $H \in \mathcal{H}_k]$ [Section 6]
6: **end if**

3. Erdös-Rényi sampling

Under the stylized but canonical Erdös-Rényi sampling, notice that the probability $p(H)$ that we observe all edges in a walk with pattern H is

$$p(H) \;=\; p^{m(H)}\,,$$

where p is the probability an edge is sampled and $m(H)$ is the number of distinct edges in a k-cyclic pseudograph H. Plugging in this value of $p(H)$, which can be computed in time linear in k, into the estimator (3), we get an estimate customized for Erdös-Rényi sampling.

Given a rank-r matrix M, the difficulty of estimating properties of M from sampled entries is captured by the *incoherence* of the original matrix M, which we denote by $\mu(M) \in \mathbb{R}$ (Candès and Recht, 2009). Formally, let $M \equiv U\Sigma U^\top$ be the singular value decomposition of a positive definite matrix where U is a $d \times r$ orthonormal matrix and $\Sigma \equiv \mathrm{diag}(\sigma_1, \cdots, \sigma_r)$ with singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$. Let $U_{i,r}$ denote the i-th row and j-th column entry of matrix U. The incoherence $\mu(M)$ is defined as the smallest positive value μ such that the following holds:

A1. For all $i \in [d]$, we have $\sum_{a=1}^r U_{ia}^2(\sigma_a/\sigma_1) \leq \mu r/d$.

A2. For all $i \neq j \in [d]$, we have $|\sum_{a=1}^r U_{ia}U_{ja}(\sigma_a/\sigma_1)| \leq \mu\sqrt{r}/d$.

The incoherence measures how well the matrix is spread out and is a common measure of difficulty in completing a matrix from random samples (Candès and Recht, 2009; Keshavan et al., 2010a). We note that our incoherence condition depends upon singular values unlike the one given in (Candès and Recht, 2009) which only depends upon row and column spaces. The lower the incoherence, the more spread out the entries are, and estimation is easier. On the other hand, if there are a few entries that are much larger than the rest, estimating a property of the matrix (such as the Schatten k-norm) from uniformly sampled entries can be extremely challenging.

3.1. Performance guarantee

For any $d \times d$ positive semidefinite matrix M of rank r with incoherence $\mu(M) = \mu$ and the effective condition number $\kappa = \sigma_{\max}(M)/\sigma_{\min}(M)$, we define

$$\rho^2 \;\equiv\; (\kappa\mu)^{2k} g(k) \max\left\{1, \frac{(dp)^{k-1}}{d}, \frac{r^k p^{k-1}}{d^{k-1}}\right\},$$

such that the variance of our estimator is bounded by $\mathrm{Var}(\widehat{\Theta}(\mathcal{P}_\Omega(M))/\|M\|_k^k) \leq \rho^2(r^{1-2/k}/dp)^k$ as we show in the proof of Theorem 3 in Section 8.1. Here, $g(k) = O(k!)$ is a function depending only on k. Note that for $k \geq 3$, ρ^2 simplifies to $\rho^2 = (\kappa\mu)^{2k} g(k) \max\left\{1, \frac{(dp)^{k-1}}{d}\right\}$.

Theorem 3 (Upper bound under the Erdös-Rényi sampling) *For any integer $k \in [3, \infty)$, any $\delta > 0$, any rank-r positive semidefinite matrix $M \in \mathbb{R}^{d\times d}$, and given i.i.d. samples of the entries of M with probability p, the proposed estimate of* (3) *achieves normalized error δ with probability bounded by*

$$\mathbb{P}\left(\frac{|\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) - \|M\|_k^k|}{\|M\|_k^k} \;\geq\; \delta\right) \;\leq\; \frac{\rho^2}{\delta^2}\Big(\frac{r^{1-2/k}}{dp}\Big)^k. \tag{8}$$

Consider a typical scenario where μ, κ, and k are finite with respect to d and r, and rank is sufficiently small, $r = O(d^{k/((k-1)(k-2))})$. Then the Chebyshev's bound in (8) implies that the sample complexity of $d^2p = O(dr^{1-2/k})$ is sufficient to recover $\|M\|_k^k$ up to arbitrarily small multiplicative error and arbitrarily small (but strictly positive) error probability. This is strictly less than the known minimax sample complexity for recovering the entire low-rank matrix, which scales is $\Theta(rd\log d)$. As we seek to estimate only a property of the matrix (i.e. the Schatten k-norm) and not the whole matrix itself, we can be more efficient on the sample complexity by a factor of $r^{2/k}$ in rank and a factor of $\log d$ in the dimension. We emphasize here that such a gain can only be established using the proposed estimator based on the structure of the k-cyclic pseudographs. We will show empirically that the standard matrix completion approaches fail in the critical regime of samples below the recovery threshold of $O(rd\log d)$.

Figure 4 is a scatter plot of the absolute relative error in estimated Schatten k-norm, $\big|\|M\|_k^k - \widehat{\|M\|_k^k}\big|/\|M\|_k^k$, for $k = 5$, for three approaches: the proposed estimator, Schatten norm of the scaled sampled matrix (after rank-r projection), and Schatten norm of the completed matrix, using state-of-the-art alternating minimization algorithm (Jain et al., 2013). All the three estimators are evaluated 20 times for each value of p. M is a symmetric positive semi-definite matrix of size $d = 500$, and rank $r = 100$ (left panel) and $r = 500$ (right panel). Singular vectors U of $M = U\Sigma U^\top$, are generated by QR decomposition of $\mathcal{N}(0, \mathbb{I}_{d\times d})$ and $\Sigma_{i,i}$ is uniformly distributed over $[1, 2]$. For a low rank matrix on the left, there is a clear critical value of $p \simeq 0.45$, above which matrix completion is exact with high probability. However, this algorithm knows the underlying rank and crucially exploits the fact that the underlying matrix is exactly low-rank. In comparison, our approach is agnostic to the low-rank assumption but finds the accurate estimate that is adaptive to the actual rank in a data-driven manner. Using the first r singular values of the (rescaled) sampled matrix fails miserably for all regimes (we truncate the error at one for illustration purposes). In this paper, we are interested in the regime where exact matrix completion is impossible as we do not have enough samples to exactly recover the underlying matrix: $p \leq 0.45$ in the left panel and all regimes in the right panel.

The sufficient condition of $d^2p = O(dr^{1-2/k})$ in Theorem 3 holds for a broad range of parameters where the rank is sufficiently small $r = O(d^{k/((k-1)(k-2))})$ (to ensure that

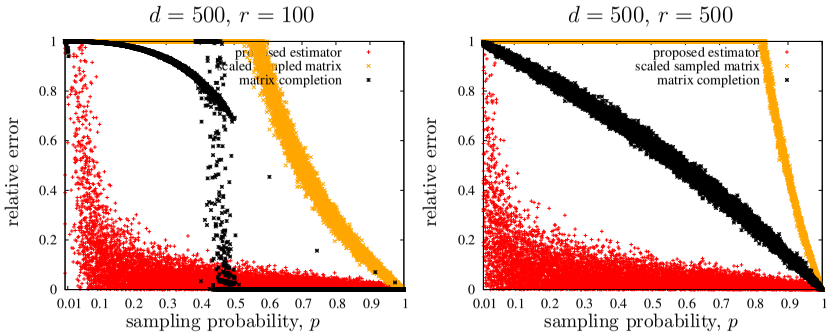

Figure 4: The proposed estimator outperforms both baseline approaches below the matrix completion threshold. For $k = 5$, comparison of the absolute relative error in estimated Schatten norm that is $\big|\|M\|_k^k - \widehat{\|M\|_k^k}\big|/\|M\|_k^k$ for the three algorithms: (1) the proposed estimator, $\widehat{\|M\|_k^k} = \widehat{\Theta}_k(\mathcal{P}_\Omega(M))$, (2) Schatten norm of the scaled sampled matrix, $\widehat{\|M\|_k^k} = \|(1/p)\mathcal{P}_r(\mathcal{P}_\Omega(M))\|_k^k$, (3) Schatten norm of the completed matrix, $\widetilde{M} = \text{AltMin}(\mathcal{P}_\Omega(M))$ from (Jain et al., 2013), $\widehat{\|M\|_k^k} = \|\widetilde{M}\|_k^k$, where $\mathcal{P}_r(\cdot)$ is the standard best rank-r projection of a matrix. Ω is generated by Erdös-Rényi sampling of matrix M with probability p.

the first term in ρ^2 dominates). However, the following results in Figure 5 on numerical experiments suggest that our analysis holds more generally for all regimes of the rank r, even those close to d. M is generated using settings similar to that of Figure 4. Empirical probabilities are computed by averaging over 100 instances.

One might hope to tighten the Chebyshev bound by exploiting the fact that the correlation among the summands in our estimator (3) is weak. This can be made precise using the recent result from Schudy and Sviridenko (2011), where a Bernstein-type bound was proved for the sum of polynomials of independent random variables that are weakly correlated. The first term in the bound (9) is the natural Bernstein-type bound corresponding to the Chebyshev's bound in (8). However, under the regime where k is large or p is large, the correlation among the summands becomes stronger, and the second and third term in the bound (9) start to dominate. In the typical regime of interest where μ, κ, k are finite, rank is sufficiently small $r = O(d^{k/((k-1)(k-2))})$, and sample complexity $d^2p = O(dr^{1-2/k})$, the error probability is dominated by the first term on the right-hand side of (9). Neither one of the two bounds in (8) and (9) dominates the other, and depending on the values of the problem parameters, we might want to apply the one that is tighter. We provide a proof in Section 8.2.

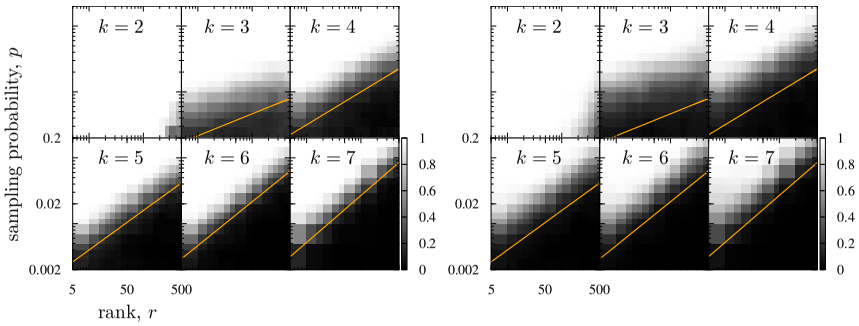

Figure 5: Each colormap in each block for $k \in \{2, 3, 4, 5, 6, 7\}$ show empirical probability of the event $\big\{\big|\|M\|_k^k - \widehat{\Theta}_k(\mathcal{P}_\Omega(M))\big|/\|M\|_k^k \le \delta\big\}$, for $\delta = 0.5$ (left panel) and $\delta = 0.2$ (right panel). Ω is generated by Erdös-Rényi sampling of matrix M with probability p (vertical axis). M is a symmetric positive semi-definite matrix of size $d = 1000$. The solid lines correspond to our theoretical prediction $p = (1/d)r^{1-2/k}$.

Theorem 4 *Under the hypotheses of Theorem 3, the error probability is upper bounded by*

$$\mathbb{P}\left(\frac{\big|\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) - \|M\|_k^k\big|}{\|M\|_k^k} \ge \delta\right) \le$$
$$e^2 \max\left\{e^{-\frac{\delta^2}{\rho^2}\left(\frac{dp}{r^{1-2/k}}\right)^k}, e^{-(dp)\left(\frac{\delta d}{\rho r^{k-1}}\right)^{1/k}}, e^{-(dp)\left(\frac{\delta d}{\rho r^{k-1}}\right)}, e^{-\frac{\delta dp}{\rho}}\right\}. \quad (9)$$

These two results show that the sample size of $d^2p = O(dr^{1-2/k})$ is sufficient to estimate a Schatten k-norm accurately when μ, κ, k are finite and rank is sufficiently small $r = O(d^{k/((k-1)(k-2))})$. In general, we do not expect to get a universal upper bound that is significantly tighter for all r, because for a special case of $r = d$, the following corollary of (Li et al., 2014, Theorem 3.2) provides a lower bound; it is necessary to have sample size $d^2p = O(d^{2-4/k})$ when $r = d$. Hence, the gap is at most a factor of $r^{2/k}$ in the sample complexity.

Corollary 5 *Consider any linear observation $X \in \mathbb{R}^n$ of a matrix $M \in \mathbb{R}^{d\times d}$ and any estimate $\theta(X)$ satisfying $(1-\delta_k)\|M\|_k^k \le \theta(X) \le (1+\delta_k)\|M\|_k^k$ for any M with probability at least $3/4$, where $\delta_k = (1.2^k - 1)/(1.2^k + 1)$. Then, $n = \Omega(d^{2-4/k})$.*

For $k \in \{1, 2\}$, precise bounds can be obtained with simpler analyses. In particular, we have the following remarks, whose proof follows immediately by applying Chebyshev's inequality and Bernstien's inequality along with the incoherence assumptions.

Remark 6 *For $k = 1$, the probability of error in* (8) *is upper bounded by* $\min\{\nu_1, \nu_2\}$, *where*

$$\nu_1 \equiv \frac{1}{\delta^2}\frac{(\kappa\mu)^2}{dp}\,, \quad \textit{and} \quad \nu_2 \equiv 2\exp\Big(\frac{-\delta^2}{2}\Big(\frac{(\kappa\mu)^2}{dp} + \delta\frac{(\kappa\mu)}{3dp}\Big)^{-1}\Big)\,.$$

Remark 7 *For $k = 2$, the probability of error in* (8) *is upper bounded by* $\min\{\nu_1, \nu_2\}$, *where*

$$\nu_1 \equiv \frac{1}{\delta^2}\frac{(\kappa\mu)^4}{d^2p}\big(2 + \frac{r^2}{d}\big) \;\; \textit{, and} \quad \nu_2 \equiv 2\exp\Big(-\frac{\delta^2}{2}\Big(\frac{(\kappa\mu)^4}{d^2p}\big(2+\frac{r^2}{d}\big) + \delta\frac{(\kappa\mu)^2 r}{3d^2p}\Big)^{-1}\Big)\,.$$

When $k = 2$, for rank small $r \le C\sqrt{d}$, only we only need $d^2p = O(1)$ samples for recovery up to any arbitrary small multiplicative error. When rank r is large, our estimator requires $d^2p = O(d)$ for both $k \in \{1, 2\}$.

3.2. From Schatten norms to spectrum and spectral sum functions

Schatten norms by themselves are rarely of practical interest in real applications, but they provide a popular means to approximate functions of singular values, which are often of great practical interest (Di Napoli et al., 2016; Zhang et al., 2015; Kong and Valiant, 2016). In this section, we consider two such applications using the first few Schatten norms explicitly: estimating the generalized rank in Section 3.2.1 and estimating the singular values in Section 3.2.2.

3.2.1. Estimating the generalized rank

For a matrix $M \in \mathbb{R}^{d\times d}$ and a given constant $c \ge 0$, its *generalized rank* of order c is given by

$$\operatorname{rank}(M, c) = \sum_{i=1}^{d} \mathbb{I}\big[\sigma_i(M) > c\big]\,.$$

This recovers the standard rank as a special case when $c = 0$. Without loss of generality, we assume that $\sigma_{\max}(M) \le 1$. For any given $0 \le c_2 < c_1 \le 1$, and $\delta \in [0, 1)$, our goal is to get an estimate $\widehat{r}(\mathcal{P}_\Omega(M))$ from sampled entries $\mathcal{P}_\Omega(M)$ such that

$$(1-\delta)\operatorname{rank}(M, c_1) \;\le\; \widehat{r}(\mathcal{P}_\Omega(M)) \;\le\; (1+\delta)\operatorname{rank}(M, c_2)\,.$$

The reason we take two different constants c_1, c_2 is to handle the ambiguous case when the matrix M has many eigenvalues smaller than but very close to c_1. If we were to set $c_2 = c_1$, then any estimator $\widehat{r}(M)$ would be strictly prohibited from counting these eigenvalues. However, since these eigenvalues are so close to the threshold, distinguishing them from other eigenvalues just above the threshold is difficult. Setting $c_2 < c_1$ allows us to avoid this difficulty and focus on the more fundamental challenges of the problem.

Consider the function $H_{c_1,c_2} : \mathbb{R} \to [0, 1]$ given by

$$H_{c_1,c_2}(x) = \begin{cases} 1 & \text{if } x > c_1 \\ 0 & \text{if } x < c_2 \\ \frac{x-c_2}{c_1-c_2} & \text{otherwise.} \end{cases}$$

It is a piecewise linear approximation of a step function and satisfies the following:

$$\operatorname{rank}(M, c_1) \;\le\; \textstyle\sum_{i=1}^{d} H_{c_1,c_2}(\sigma_i(M)) \;\le\; \operatorname{rank}(M, c_2)\,. \tag{10}$$

We exploit this sandwich relation and estimate the generalized rank. Given a polynomial function $f : \mathbb{R} \to \mathbb{R}$ of finite degree m such that $f(x) \approx H_{c_1,c_2}(x)$ for all x, such that $f(x) = a_0 + a_1x + \cdots + a_mx^m$, we immediately have the following relation, which extends to a function on the cone of PSD matrices in the standard way:

$$\sum_{i=1}^{d} f(\sigma_i(M)) \;=\; a_0 d + \sum_{k=1}^{m} a_k \|M\|_k^k\,. \tag{11}$$

Using this equality, we propose the estimator:

$$\widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2) \;\equiv\; a_0 d + \sum_{k=1}^{m} a_k \widehat{\Theta}_k(\mathcal{P}_\Omega(M))\,, \tag{12}$$

where we use the first several $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$'s obtained by the estimator (3). Note that function f depends upon c_1, c_2. The remaining task is to obtain the coefficients of the polynomials in f that is a suitable approximation of the function H_{c_1,c_2}. In a similar context of estimating the generalized rank from approximate Schatten norms, Zhang et al. (2015) propose to use a composite function $f = q_s \circ q$ where q is a finite-degree Chebyshev polynomial of the first kind such that $\sup_{x\in[0,1]} |q(x) - H_{c_1,c_2}(x)| \le 0.1$, and q_s is a polynomial of degree $2s + 1$ given by

$$q_s(x) \;=\; \frac{1}{B(s+1, s+1)}\int_0^x t^s(1-t)^s dt\,, \qquad \text{where } B(\cdot,\cdot) \text{ is the Beta function.}$$

Note that, since H_{c_1,c_2} is a continuous function with bounded variation, classical theory in (Mason and Handscomb, 2002, Theorem 5.7), guarantees existence of the Chebyshev polynomial q of a finite constant degree, say C_b, that depends upon c_1 and c_2. Specifically, for a given choice of thresholds $0 \le c_1 < c_2 \le 1$ and the degree of the beta approximation s, the estimator $\widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2)$ in (12) can be computed as follows.

The approximation of H_{c_1,c_2} with $f = q_s \circ q$ and our upper bound on estimated Schatten norms $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ translate into the following guarantee on generalized rank estimator $\widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2)$ given in (12).

Corollary 8 *Suppose $\|M\|_2 \le 1$. Under the hypotheses of Theorem 3, for any given $1 \ge c_1 > c_2 \ge 0$, there exists a constant C_b, such that for any $s \ge 0$ and any $\gamma > 0$, the estimate in* (12) *with the choice of $f = q_s \circ q$ satisfies*

$$(1-\delta)(\operatorname{rank}(M, c_1) - 2^{-s}d) \;\le\; \widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2) \;\le\; (1+\delta)(\operatorname{rank}(M, c_2) + 2^{-s}d)\,,$$

with probability at least $1 - \gamma C_b(2s+1)$, where $\delta \equiv \max_{1\le k\le C_b(2s+1)}\Big\{\sqrt{\frac{\rho^2}{\gamma}(\frac{\max\{1, r^{1-2/k}\}}{dp})^k}\Big\}$.

Algorithm 2 Generalized rank estimator (a variation of Zhang et al. (2015))

Require: $\mathcal{P}_\Omega(M)$, c_1, c_2, s
Ensure: $\widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2)$
1: For given c_1 and c_2, find a Chebyshev polynomial of the first kind $q(x)$ satisfying

$$\sup_{x\in[0,1]} |q(x) - H_{c_1,c_2}(x)| < 0.1$$

[Algorithm 7]
2: Let C_b denote the degree of $q(x)$
3: Find the degree $(2s+1)C_b$ polynomial expansion of $q_s \circ q(x) = \sum_{k=0}^{(2s+1)C_b} a_k x^k$
4: $\widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2) \leftarrow a_0 d + \sum_{k=1}^{(2s+1)C_b} a_k \widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ [Algorithm 1]

The proof follows immediately from Theorem 3 and the following lemma which gives a uniform bound on the approximation error between H_{c_1,c_2} and $f = q_s \circ q$. Lemma 9, together with Equations (10) and (11), provides a (deterministic) functional approximation guarantee of

$$\operatorname{rank}(M, c_1) - d\,2^{-s} \;\le\; \sum_{i=1}^{d} f(\sigma_i(M)) \;\le\; \operatorname{rank}(M, c_1) + d\,2^{-s}\,,$$

for any $c_1 < c_2$ and any choice of s, as long as C_b is large enough to guarantee a 0.1 uniform error bound on the Chebyshev polynomial approximation. Since we can achieve $1 \pm \delta$ approximation on each polynomial in $f(\sigma_i(x))$, Theorem 3 implies the desired Corollary 8. Note that using Remarks 6 and 7, the bounds in (9) hold for $k \in [1, \infty)$ with $r^{1-2/k}$ replaced by $\max\{1, r^{1-2/k}\}$.

Lemma 9 (Zhang et al. (2015), Lemma 1) *Consider the composite polynomial $f(x) = q_s(q(x))$. Then $f(x) \in [0,1]$ for all $x \in [0,1]$, and moreover*

$$|f(x) - H_{c_1,c_2}(x)| \le 2^{-s}\,, \qquad \text{for all } x \in [0, c_2] \cup [c_1, 1]\,.$$

In Figure 6, we evaluate the performance of estimator (12) numerically. We construct a symmetric matrix M of size $d = 1000$ and rank $r = 200$, $\sigma_i \sim \text{Uni}(0, 0.4)$ for $1 \le i \le r/2$, and $\sigma_i \sim \text{Uni}(0.6, 1)$ for $r/2 + 1 \le i \le r$. We estimate $\widehat{r}(\mathcal{P}_\Omega(M); c_1, c_2)$ for Erdös-Rényi sampling Ω, and a choice of $c_2 = 0.5$ and $c_1 = 0.6$, which is motivated by the distribution of σ_i. We use Chebyshev polynomial of degree $C_b = 2$, and $s = 1$ for q_s. That is function f is of degree 6. Accuracy of the estimator can be improved by increasing C_b and s, however that would require estimating higher Schatten norms.

3.2.2. Estimating the spectrum

Given accurate estimates of first K Schatten norms of a matrix M, we can estimate singular values of M using a linear programming based algorithm given in (Kong and Valiant, 2016). In particular, we get the following guarantees on the estimated singular values, whose proof follows directly using the analysis techniques in the proof of (Kong and Valiant, 2016,

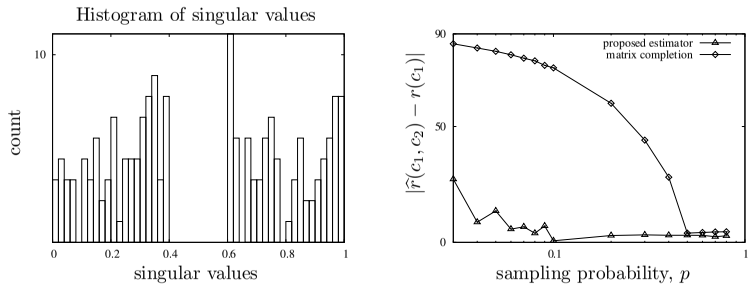

Figure 6: The left panel shows a histogram of singular values of M chosen for the experiment. The right panel compares absolute error in estimation $\widehat{r}(\mathcal{P}_\Omega(M); c_1 = 0.5, c_2 = 0.6)$ for two choices of the Schatten norm estimates $\widehat{\|M\|_k^k}$: first the proposed estimator $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ in (3), and second the Schatten norm of the completed matrix, $\widetilde{M} = \text{AltMin}(\mathcal{P}_\Omega(M))$ from (Jain et al., 2013).

Theorem 2). The main idea is that given the rank, the maximum support size of the true spectrum, and an estimate of its first K moments, one can find r singular values whose K first moments are close to the estimated Schatten norms.

Algorithm 3 Spectrum estimator (a variation of Kong and Valiant (2016))

Require: $\mathcal{P}_\Omega(M)$, K, ϵ, target rank r, lower bound a and upper bound b on the positive singular values
Ensure: estimated singular values $(\widehat{\sigma}_1, \widehat{\sigma}_2, \ldots, \widehat{\sigma}_r)$
1: $L \in \mathbb{R}^K : L_k = \widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ for $k \in [K]$ [Algorithm 1]
2: $t = \lceil (b-a)/\epsilon \rceil + 1$, $x \in \mathbb{R}^t$: $x_i = a + \epsilon(i-1)$, for $i \in [t]$,
3: $V \in \mathbb{R}^{K \times t} : V_{ij} = x_j^i$ for $i \in [K], j \in [t]$
4: $p^* \equiv \{\min_{p \in \mathbb{R}^t} |Vp - L|_1 : \mathbb{1}_t^\top p = 1, p \ge 0\}$
5: $\widehat{\sigma}_i = \min\{x_j : \sum_{\ell \le j} p_\ell^* \ge \frac{i}{r+1}\}$, ith $(r+1)$st-quantile of distribution corresponding to p^*

Further, our upper bound on the first K moments can be translated into an upper bound on the Wasserstein distance between those two distributions, which in turn gives the following bound on the singular values. With small enough ϵ and large enough K and r, we need sample size $d^2 p > C_{r,K,\epsilon,\gamma} d r^{1-2/k}$ to achieve arbitrary small error.

Corollary 10 *Under the hypotheses of Theorem 3, given rank r, constants $0 \le a < b$ such that $\sigma_{\min} \ge a$, $\sigma_{\max} \le b$, and estimates of the first K Schatten norms of M, $\{\widehat{\Theta}_k(\mathcal{P}_\Omega(M))\}_{k\in[K]}$ obtained by the estimator (3), for any $0 < \epsilon \ll (b-a)$, and $\gamma > 0$, Algo-*

rithm 3 runs in time $\mathrm{poly}(r, K, (b-a)/\epsilon)$ *and returns* $\{\widehat{\sigma}_i\}_{i\in[r]}$ *an estimate of* $\{\sigma_i(M)\}_{i\in[r]}$ *such that*

$$\frac{1}{r}\sum_{i=1}^{r}|\widehat{\sigma}_i - \sigma_i| \quad \leq$$
$$\frac{C(b-a)}{K} + \frac{b-a}{r} + g(K)(b-a)\left(\epsilon K b^{K-1} + \sum_{k=1}^{K}\sigma_{\max}^k\sqrt{\frac{\rho^2}{\gamma}\left(\frac{\max\{1, r^{1-2/k}\}}{dp}\right)^k}\right),$$

with probability at least $1-\gamma K$*, where* C *is an absolute constant and* $g(K)$ *only depends on* K*.*

In Figure 7, we evaluate the performance of the proposed estimator (3), in recovering the true spectrum using Algorithm 3. We compare the results with the case when Schatten norms are estimated using matrix completion. We consider two distributions on singular values, one peak and two peaks. More general distributions of spectrum can be recovered accurately, however that would require estimating higher Schatten norms. For both cases, the proposed estimator outperforms matrix completion approaches, and achieves better accuracy as sample size increases with α. In each graph, the black solid line depicts the empirical Cumulative Distribution Function (CDF) of the ground truths $\{\sigma_i\}_{i\in[r]}$ for those r strictly positive singular values. In the first experiment (the top panel), there are r singular values at one peak $\sigma_i = 1$, and in the second experiment (the bottom pannel) there are $r/2$ singular values at each of the two peaks at $\sigma_i = 1$ and $\sigma_i = 2$. Each cell shows the result of a choice of rank $r \in \{50, 200, 500\}$ and a parameter $\alpha \in \{3, 5, 8, 10\}$, where Ω is generated using Erdös-Rényi sampling with probability $p = (\alpha/d)r^{1-2/7}$. Matrix M is a symmetric matrix of size $d = 1000$ and rank r with singular values $\{\sigma_i\}_{i\in[d]}$. In each cell, there are one black line, three blue lines, and three orange lines. Each blue line corresponds to the empirical CDF of $\{\widehat{\sigma}_i\}_{i\in[d]}$ for each trial, over three independent trials. Each orange line corresponds to the empirical CDF of $\{\widetilde{\sigma}_i\}_{i\in[d]}$. Here, $\widehat{\sigma}_i$'s are estimated using $\{\widehat{\Theta}_k(\mathcal{P}_\Omega(M))\}_{k\in[K]}$ obtained by the estimator (3), and $\widetilde{\sigma}_i$'s are estimated using $\{\|\widetilde{M}\|_k^k\}_{k\in[K]}$ where $\widetilde{M} = \mathrm{AltMin}(\mathcal{P}_\Omega(M))$, along with Algorithm 2 in (Kong and Valiant, 2016), for $K = 7$.

4. Graph sampling

Our framework for estimating the Schatten k-norms can be applied more generally to any random sampling, as long as the distribution is permutation invariant. In practice, we typically observe one instance of a sampled matrix and do not know how the samples were generated. Under a mild assumption that the probability of sampling an entry is independent of the value of that entry, the only information about the sampling model that we have is the *pattern*, i.e. an unlabelled graph $G = (V, E)$ capturing the pattern of sampled indices by the edges. This naturally suggests a novel sampling scenario that we call *graph sampling*.

The Erdös-Rényi sampling has been criticized as being too strict for explaining how real-world datasets are sampled. When working with natural data, we typically only get

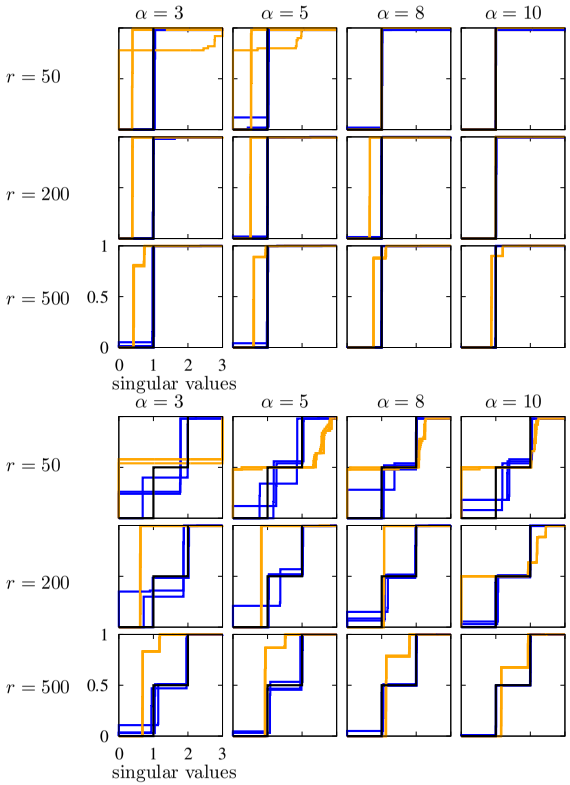

Figure 7: The proposed estimator (in blue solid lines) outperforms matrix completion approaches (in orange solid lines) in estimating the ground truths empirical cumulative distribution function of the r strictly positive singular values (in black solid line) for two examples: one peak at $\sigma_i = 1$ on the top and two peaks at $\sigma_i = 1$ or $\sigma_i = 2$ on the bottom.

one instance of a sampled matrix without the knowledge of how those entries are sampled. In this section, we propose a new sampling model that we call *graph sampling* that makes minimal assumptions about how the data was sampled. We assume that the *pattern* has been determined a priori, which is represented by a deterministic graph $G = (V, E)$ with d nodes denoted by V and undirected edges denoted by E. The random sampling Ω is chosen uniformly at random over all relabeling of the nodes in G. Formally, for a given $G = (V, E)$, a permutation $\pi : [d] \to V$ is drawn uniformly at random and samples are drawn according

to

$$\mathcal{P}_\Omega(M) \;=\; \{(i,j,M_{ij})\}_{(\pi(i),\pi(j))\in E}\,.$$

As the sampling pattern G is completely known to the statistician who only has one instance of a random sampling, we are only imposing that the samples are drawn uniformly at random from all instances that share the same pattern. Further, understanding this graph sampling model has a potential to reveal the subtle dependence of the estimation problem on the underlying pattern, which is known to be hard even for an established area of matrix completion.

In this section, we provide an estimator under graph sampling, and characterize the fundamental limit on the achievable error. This crucially depends on the original pattern G via a fundamental property $\lambda^*_{G,r}$, which is generally challenging to compute. However, we provide a bound on $\lambda^*_{G,r}$ for two extreme cases of varying difficulty: a clique sampling that requires only $O(r^{2-4/k})$ samples and a clique-star sampling that requires as many as $O(dr^{1-4/k})$ samples. This is made formal by showing a lower bound on the minimax sample complexity. Comparing the two necessary conditions on sample complexity, $O(r^{2-4/k})$ for clique sampling and $O(dr^{1-4/k})$ for clique-star sampling, it follows that depending on the pattern of the samples, the sample complexity can vary drastically, especially for low-rank matrices where $r \ll d$.

Under the *graph sampling*, the probability $p(H)$ that we observe all edges in a walk with pattern H is

$$p(H) \;=\; \frac{\omega_{\mathcal{P}_\Omega(\mathbb{1}_d\mathbb{1}_d^T)}(H)}{\omega_{\mathbb{1}_d\mathbb{1}_d^T}(H)}\,,$$

where $\mathbb{1}_d\mathbb{1}_d^T$ is the all ones matrix, and by permutation invariance, the probability is the ratio between total (unweighted) number of walks with $H(w)=H$ in the original pattern Ω and that of the complete graph K_d. Note that although Ω is a random quantity, $\omega_{\mathcal{P}_\Omega(\mathbb{1}\mathbb{1}^T)}(H)$ only depends on the structure and not the labelling of the nodes and hence is a deterministic quantity. Plugging in this value of $p(H)$, which can be computed in time $O(d^\alpha)$ for $k \le 7$ as shown in Proposition 2 (and in general only increases the computational complexity of the estimate by a factor of two), into the estimator (3), we get an estimate customized for graph sampling.

4.1. Performance Guarantees

Recall the graph sampling defined in Section 1.1, where we relabel the nodes of a pattern graph $G(V,E)$ according to a random uniform permutation, and sample the entries of the matrix M on the edges. We prove a fundamental lower bound on the sample complexity that crucially depends on the following property of the pattern G. Let $G_\pi(\widetilde{V},\Omega)$ denote the graph after relabeling the nodes of $G=(V,E)$ with permutation $\pi:[d]\to[d]$. For independent Rademacher variables u_i for $i\in[r]$

$$f_{G,r}(\lambda) \;\equiv\; \max_{\pi}\left\{\mathbb{E}_u\left[\exp\left((5/d)^2\lambda^2\sum_{(i,j)\in\mathcal{P}^{(r)}(G_\pi)}u_iu_j\right)\right]\right\}, \tag{13}$$

where $\mathcal{P}^{(r)}(G_\pi)\subseteq[r]\times[r]$ is a projection of the edges Ω over d nodes to a set of edges over r nodes by mapping a node $i\in[d]$ to a node $1+(i-1 \bmod r)\in[r]$. Precisely, $(i,j)\in\mathcal{P}^{(r)}(G_\pi)$ if there exists an edge $(i',j')\in\Omega$ such that $i=1+(i'-1 \bmod r)$ and $j=1+(j'-1 \bmod r)$. Observe that $f_{G,r}(\lambda)$ is a non-decreasing function of λ. It follows from the fact that for any positive λ and random variable x and any $\epsilon>0$, we have $\mathbb{E}[e^{\lambda(1+\epsilon)x}]\ge\mathbb{E}[e^{\lambda x}](\mathbb{E}[e^{\lambda x}])^\epsilon\ge\mathbb{E}[e^{\lambda x}]e^{\epsilon\lambda\mathbb{E}[x]}\ge\mathbb{E}[e^{\lambda x}]$. The first and the second inequalities use Jensen's inequality and the third one holds when $\mathbb{E}[x]\ge 0$. Note that $\mathbb{E}_u[\sum_{(i,j)\in\mathcal{P}^{(r)}(G_\pi)}u_iu_j]\ge 0$, since u_i's are i.i.d. Rademacher variables.

This function measures the distance between a particular low-rank matrix with Gaussian entries and its rank one perturbation, which is used in our constructive lower bound (see Eq. (35)). Intuitively, smaller $f_{G,r}(\lambda)$ implies that two rank-r matrices with separated Schatten norms look similar after graph sampling w.r.t. G. Hence, when this function is small, say less than $26/25$, then it is hard to distinguish which of the two (distributions of) matrices we are observing. This is captured by the largest value of λ that still maintains $f_{G,r}(\lambda)$ sufficiently small:

$$\lambda^*_{G,r} \;\equiv\; \max_{\{\lambda>0:f_{G,r}(\lambda)\le 26/25\}}\lambda\,. \tag{14}$$

One can choose any number not necessarily $26/25$ as long as it is strictly larger than one and strictly smaller than two, and this will only change the probability upper bound in (15). If we sample from a graph G with large $\lambda^*_{G,r}$, then we cannot distinguish two distributions even if they have a large Schatten norm separation. We do not have enough samples and/or our pattern is not sample efficient. The dependence of the fundamental lower bound on the graph G is captured by this quantity $\lambda^*_{G,r}$, which is made precise in the following theorem. We provide a lower bound that captures how sample complexity depends on the pattern G and also on the underlying matrix, by providing analysis customized for each family of matrices $\mathcal{M}_{r,\mu}$ parametrized by its rank and incoherence:

$$\mathcal{M}_{r,\mu}\equiv\big\{M\in\mathbb{R}^{d\times d}: M=M^\top, \mathrm{rank}(M)\le r\,,\ \mu(M)\le\mu\big\}.$$

Theorem 11 (General lower bound under graph sampling) *For any $k\in[3,\infty)$ suppose we observe samples under the graph sampling defined in Section 1.1 with respect to a pattern graph $G=(V,E)$. Then there exist universal constants $C>0$, $C'>0$ and $C''>0$ such that for any $r\ge e^{C''k}$ and $\mu\ge C'\sqrt{\log r}$, if $\lambda^*_{G,r}\ge Cdr^{1/k-1/2}$ then*

$$\inf_{M\in\mathcal{M}_{r,\mu}}\sup_{\widetilde{\Theta}}\;\mathbb{P}\left(\frac{1}{2}\|M\|_k\le\widetilde{\Theta}(\mathcal{P}_{\Omega(M)})\le 2\|M\|_k\right)\;\le\;\frac{3}{4}\,, \tag{15}$$

where the supremum is over any measurable function of $\mathcal{P}_{\Omega(M)}$ and the probability is with respect to the random sampling Ω.

A proof of Theorem 11 is given in Section 8.3. It is in general challenging to evaluate $\lambda^*_{G,r}$ for a given graph. For a special case of *clique sampling*, where the pattern $G(V,E)$ is a clique over a subset of ℓ nodes among d, we provide a sharp upper bound on $\lambda^*_{G,r}$.

Lemma 12 (Lower bound for clique sampling) *If the pattern graph $G(V,E)$ is a clique over a subset of ℓ nodes, then $\lambda^*_{G,r}\ge 2^{-4}d(\min\{\ell,r\})^{-1/2}$.*

Therefore, if $\ell \le 2^{-8}C^{-2}r^{1-2/k}$ then $\lambda^*_{G,r} \ge Cdr^{1/k-1/2}$, which together with Theorem 11 implies that with probability at least $1/4$ any estimator makes a multiplicative error larger than two. Hence, sample size of $\ell(\ell+1)/2 = O(r^{2-4/k})$ is necessary to achieve multiplicative error less than two with high probability. We show that our estimator is optimal for $k = 3$, by providing a matching upper bound on the sample complexity. For any positive semidefinite matrix $M \in \mathbb{R}^{d\times d}$ of rank r with incoherence $\mu(M) = \mu$, $\kappa = \sigma_{\max}(M)/\sigma_{\min}(M)$, and some function $g(k) = O(k!)$, we define

$$\tilde{\rho}^2 \;\equiv\; (\kappa\mu)^{2k} g(k) \max\left\{1\,,\, \frac{\ell^{k-1}}{r^{k-2}}\,,\, \frac{\ell}{r}\,,\, \frac{r^{1/2}\ell^k}{d}\right\},$$

such that the variance of our estimator is bounded by $\mathrm{Var}(\widehat{\Theta}(\mathcal{P}_\Omega(M))/\|M\|_k^k) \le \rho^2(r^{1-2/k}/\ell)^k$ as we show for $k = 3$ in the proof of Theorem 13 in Section 8.6. Here, $g(k) = O(k!)$ is a function of k only.

Theorem 13 (Upper bound for clique sampling) *For $k = 3$, any $\delta > 0$, and any rank-r matrix $M \succeq 0$, the proposed estimator* (3) *achieves a multiplicative error δ with probability of error bounded by*

$$\mathbb{P}\left(\frac{\big|\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) - \|M\|_k^k\big|}{\|M\|_k^k} \;\ge\; \delta\right) \;\le\; \frac{\tilde{\rho}^2}{\delta^2}\Big(\frac{r^{1-2/k}}{\ell}\Big)^k,$$

under the graph sampling with the pattern graph G that is a clique over ℓ nodes.

For a typical scenario with finite μ and κ, this upper bound shows that sample size of $\ell(\ell+1)/2 = O(r^{2-4/k})$ is sufficient to achieve any arbitrarily small multiplicative error for $k = 3$ and sufficiently small rank $r \le d^{2k/(3k-2)}$ and $\ell \le r^{(k-2)/(k-1)}$, to ensure that the first term dominates in $\tilde{\rho}^2$. However, the numerical experiments suggest that our analysis holds more generally for all regimes of the rank r. This matches the previous lower bound, proving optimality of the proposed estimator for $k = 3$. Although the current analysis holds only for $k = 3$, we are intentionally writing the guarantee in general form as we expect the bound to hold more generally. In particular, we believe that Lemma 19 holds for all $k \ge 3$, and thereby Theorem 13 holds for any fixed integer $k \in [3, \infty)$. In the numerical experiments in Figure 8, M is generated using settings similar to that of Figure 4. Empirical probabilities are computed by averaging over 100 instances.

Although our analysis does not give a tight lower bound for Erdös-Rényi sampling, there exists graph patterns such that the sample complexity is large, i.e. scales linearly in d. Consider a *clique-star sampling* where the pattern graph $G(V, E)$ has a clique on a small subset of nodes V_1, $|V_1| = \ell$, and the remaining nodes $V \setminus V_1$ are disconnected among themselves and are fully connected with the clique in V_1. Precisely, $G = (V, E)$ with $(i, j) \in E$ if $i \in V_1$ or $j \in V_1$.

Lemma 14 (Lower bound for clique-star sampling) *Under the clique-star sampling over a clique of size ℓ, there exists an absolute constant c such that $\lambda^*_{G,r} \ge cd(r(\min\{\ell, r\}))^{-1/4}$.*

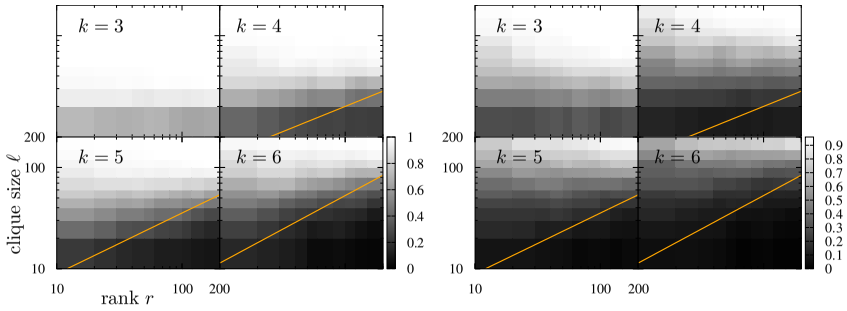

Figure 8: Each colormap in each block for $k \in \{3, 4, 5, 6\}$ show empirical probability of the event $\big\{\big|\|M\|_k^k - \widehat{\Theta}_k(\mathcal{P}_\Omega(M))\big|/\|M\|_k^k \le \delta\big\}$, for $\delta = 0.5$ (left panel) and $\delta = 0.2$ (right panel). Ω is generated by clique sampling of matrix M with a clique of size ℓ (vertical axis). M is a positive semi-definite matrix of size $d = 1000$. The solid lines correspond to our theoretical prediction $\ell = \sqrt{k}r^{1-2/k}$.

Together with Theorem 11, this implies that if $\ell \le c^4C^{-4}r^{1-4/k}$, then with probability at least $1/4$, any estimator makes an multiplicative error larger than two. This implies that the total number of edges in the pattern graph should be $O(dr^{1-4/k})$ for accurate estimation. Together with the upper bound on clique sampling in Theorem 13, this shows that the sample complexity can drastically change based on the pattern of your sampling model. Clique sampling requires only $O(r^{2-4/k})$ samples (for $k = 3$) whereas clique-star sampling requires at least $O(dr^{1-4/k})$. A proof of Lemma 12 and Lemma 14 is given in Section 8.4 and 8.5 respectively.

5. Discussion

We list some observations and future research directions.

Complexity of the estimator beyond $k = 7$. For $k \ge 8$, our approach of using matrix operations to count (the weights of) walks for each pattern $H \in \mathcal{H}_k$ can potentially be extended. However, the complexity of the problem fundamentally changes for $k \ge 8$. As our estimator is at least as hard as counting small structures in a simple (unweighted) graph, we can borrow known complexity results to get a lower bound. For instance, for $k \ge 8$, we need to count K_4 in a graph. There is no known simple matrix computation to count K_4 in a general graph. The best known run time for counting all K_4 is $O(d^{\alpha+1})$ for general graphs (Kloks et al., 2000). For general k, under standard hardness assumptions, Flum and Grohe (2004) show that there is no algorithm with run time $O(f(k)d^c)$ for counting cycles of length k, for any function $f(k)$ and a constant c that does not depend on k. In comparison, finding *one cycle* of length k can be done in time $2^{O(k)}d^\alpha$ (Alon et al., 1997). This implies that the complexity should scale as $O(d^{f(k)})$, and we believe $f(k)$ should be larger than $(\alpha\sqrt{2k}/3)$. The reason is that for $k \ge \binom{\ell}{2}$ for an odd ℓ, our estimator needs to count the

number of cliques K_ℓ of size ℓ and, for $k \geq (1/2)\ell^2$ for an even ℓ, we require counting K_ℓ. The best known algorithm for counting K_ℓ takes time $O(\min\{d^{1+\alpha\lceil(\ell-1)/3\rceil}, d^{2+\alpha\lceil(\ell-2)/3\rceil}\})$ for general graphs (Alon et al., 1997, Theorem 6.4). Putting these bounds together, we believe that the estimator take time at least $d^{\alpha\sqrt{2k}/3}$.

Sufficiency of $k \leq 7$ for practical applications. There are many practical applications where $k \leq 7$ is sufficient for estimating spectral sum function of a matrix from its partial observations. In the two applications we discuss in this paper, generalized rank estimation and spectrum estimation, we show by numerical experiments that $k \leq 7$ is sufficient. In Figure 6, we show that the generalized rank of a matrix can be estimated within 0.05 multiplicative error, for the case when the eigenvalues of the matrix are uniformly distributed in an interval. In Figure 7, we show that $k = 7$ is sufficient for estimating the spectrum for one peak and two peak distributions of eigenvalues. Further, for uniform distribution of eigenvalues, Kong and Valiant (2016) use only first $k = 7$ Schatten norms for estimating the spectrum. They note that considering higher Schatten norms beyond $k = 7$ did not significantly improve the results.

Graph sampling. Typical guarantees known for matrix completion assumes the Erdös-Rényi sampling. One exception is the deterministic sampling studied by Bhojanapalli and Jain (2014), but such generalization in sampling comes at a price of requiring more strict assumptions on the matrix M. We propose graph sampling, which can potentially capture how estimation guarantees depend explicitly on the pattern G, and still remain analytically tractable. We give such examples for special graphs in Section 4, and graph sampling model can potentially be used to bridge the gap in sampling models between theory and practice.

(Standard) rank estimation. As several popular matrix completion approaches require the knowledge of the rank of the original matrix, it is of great practical interest to estimate the standard rank of a matrix from sampled entries. Our framework in Section 3.2.1 provides a way to estimate the standard rank from samples. However, there are a few parameters that need to be tuned, such as the thresholds c_1 and c_2, and the degree of the polynomial approximation and the order of the Schatten norm. For rank estimation, Keshavan and Oh (2009) give an estimator that is provably correct in the regime where matrix completion works, justifying the requirement that popular matrix completion algorithms (Keshavan et al., 2010a; Jain et al., 2013) need to know the underlying rank. However, in the regime of our interest, which is below the standard matrix completion threshold, the algorithm fails miserably and there are no guarantees. In a more recent work, Saade et al. (2015) propose a novel rank estimator of counting the negative eigenvalues of Bethe Hessian matrix. It is an interesting future direction to build upon our framework to provide a guideline for choosing the parameters for the standard rank estimation, and compare its performance to existing methods.

The effect of the effective rank. One property of the Schatten norm is that as k gets large and as the singular values have small effective rank (meaning that they decay fast), the summation is dominated by the largest few singular values. In such scenarios, in the estimation problem, any algorithm that tracks the first few singular values correctly would achieve small error. Hence, the gap get smaller as the effective rank gets smaller, between

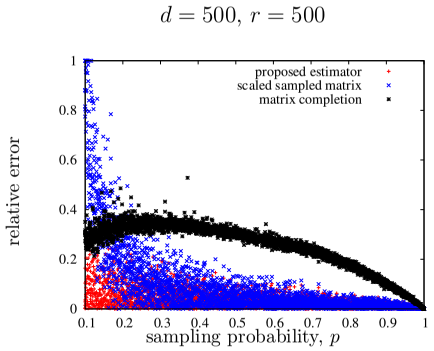

Figure 9: For a matrix with a very small effective rank, the gap between the proposed estimator and the simple scaled sampled matrix approach is smaller.

the proposed estimator and the simple Schatten k-norm of the rescaled sampled matrix, as depicted in Figure 9. We are using the same setting as those in Figure 4 with a full rank matrix M with $r = d = 500$, but the effective rank is relatively small as the singular values are decaying as $\sigma_i = 1/i^2$. For the current choice of $k = 5$, notice that the contribution in $\|M\|_k^k$ of the second singular value is a factor of 2^{10} smaller than the top singular value, making it effectively a rank one matrix.

Technical challenges. The technical challenge in proving bounds on the necessary number of samples needed to estimate Schatten k-norms lies in getting tight bounds on the variance of the estimator. Variance is a function of weighted counts of each pseudograph of $2k$-closed walks, in the complete matrix. As the weight of each walk can be positive or negative, significant cancellation occurs when we sum all the weights. However, this stochastic cancellation is hard to capture in the analysis and we assume the worst case where all the weights are positive, which cannot occur for incoherent and well-conditioned matrices. This weakness of the analysis leads to the requirement of the rank being sufficiently small in the case of Erdös-Rényi sampling and k small in the case of clique sampling. We believe these bounds can be tightened and the same is reflected in the numerical simulations which show the same scaling holds for all small values of k and rank close to the dimension of the matrix.

6. Algorithm for estimating Schatten k-norm for $k \geq 8$

The collection of pseudographs $\mathcal{H}_k$ is partitioned into sets $\{\mathcal{H}_{k,i}^{\text{iso}}\}_{1\leq i\leq r}$, for some $r \leq k!$. The partitions $\mathcal{H}_{k,i}^{\text{iso}}$ are defined such that the pseudographs in one partition are isomorphic to each other when multi-edges are condensed into one. This is useful since all the pseudographs in one partition are observed together in $G([d], \Omega)$ for any fixed subgraph in G. The underlying simple graph (including self loops) for each partition $\mathcal{H}_{k,i}^{\text{iso}}$ is denoted by $F_{k,i}$.

The main idea is to enumerate a list $\mathcal{L}_\ell$ of all connected ℓ-vertex induced subgraphs (possibly with loops) of the graph $G([d], \Omega)$, for each $1 \le \ell \le k$. The unbiased weighted count of all pseudographs $\mathcal{H}_k$ for each of these vertex-induced subgraphs $g \in \mathcal{L}_\ell$ is computed. This is achieved by further enumerating a list $\mathcal{S}_{g,\ell}$ of all ℓ-vertex subgraphs for each g. Then the unbiased weight of all pseudographs $H \in \mathcal{H}_k$ that exist in the subgraph h is computed and is summed over to get the estimate of the k-th Schatten norm. Recall the notation $\mathcal{P}_\Omega(M)$ which is used to denote the partially observed matrix corresponding to the index set Ω with the unobserved entries being replaced by zero. We abuse this notation and use $h(M)$ to represent the matrix M restricted to the subgraph h of the observed graph $G([d], \Omega)$.

Each connected induced subgraphs of size k in a graph can be enumerated in time polynomial in d and k (Elbassioni, 2015). The number of connected induced subgraphs of size k in a graph is upper bounded by $(e\Delta)^k/((\Delta-1)k)$, where Δ is the maximum degree of the graph (Uehara et al., 1999). Therefore, Algorithm 4 runs in time that is super exponential in k, polynomial in d and the number of k-connected induced subgraphs in the observed graph $G([d], \Omega)$.

Algorithm 4 Schatten k-norm estimator

Require: $\mathcal{P}_\Omega(M)$, k, $\mathcal{H}_k$, $p(H)$ for all $H \in \mathcal{H}_k$
Ensure: $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$
$\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) \leftarrow 0$
for $1 \le \ell \le k$ **do**
  Enumerate a list, $\mathcal{L}_\ell$, of all connected ℓ-vertex induced subgraphs (possibly with loops) of the graph $G([d], \Omega)$
  for all $g \in \mathcal{L}_\ell$ **do**
    Enumerate a list $\mathcal{S}_{g,\ell}$ of all connected ℓ-vertex subgraphs of the graph g by removing one or more edges
    for all $h \in \mathcal{S}_{g,\ell}$ **do**
      for $1 \le i \le r$ **do**
        if h is isomorphic to $F_{k,i}$ **then**
          $\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) \leftarrow \widehat{\Theta}_k(\mathcal{P}_\Omega(M)) + \sum_{H \in \mathcal{H}_{k,i}^{\text{iso}}} \frac{1}{p(H)} \omega_{h(M)}(H) c(H)$
        end if

7. Algorithm for computing the Chebyshev polynomial

8. Proofs

We provide proofs for the main results and the technical lemmas.

Algorithm 5 Chebyshev polynomial of the first kind approximating $H_{c_1,c_2}(x)$

Require: H_{c_1,c_2}, c_1, c_2, and target accuracy $\delta = 0.1$
Ensure: Chebyshev polynomial $q(x)$ of first kind
$g(x) \equiv \frac{x-c_2}{c_1-c_2}$
$T_0(x) \equiv 1$, $T_1(x) \equiv x$
$q(x) \leftarrow \frac{1}{\pi}\int_{c_2}^{c_1}(1-x^2)^{-1/2} g(x) T_0(x) dx + \frac{1}{\pi}\int_{c_1}^{1}(1-x^2)^{-1/2} T_0(x) dx$
$i = 1$
while $\sup_{x\in[0,1]} |q(x) - H_{c_1,c_2}(x)| \ge \delta$ **do**
  $q(x) \leftarrow q(x) + \frac{2T_i(x)}{\pi}\int_{c_2}^{c_1}(1-x^2)^{-1/2} g(x) T_i(x) dx + \frac{2T_i(x)}{\pi}\int_{c_1}^{1}(1-x^2)^{-1/2} T_i(x) dx$
  $i \leftarrow i + 1$
  $T_i(x) \equiv 2xT_{i-1}(x) - T_{i-2}(x)$
end while

8.1. Proof of Theorem 3

Consider $\widetilde{W}$ to be the collection of all length k closed walks on a complete graph of d vertices. Here we slightly overload the notion of complete graph to refer to an undirected graph with not only all the $d(d-1)/2$ simple edges but also with d self loops as well. Construct the largest possible collection W from $\widetilde{W}$ wherein each walk has distinct weights that is $\omega(w) \neq \omega(w')$ for all $w, w' \in W$. We partition W according to the pattern among k-cyclic pseudographs, which are further partitioned into four groups. The estimator (3) can be re-written as

$$\begin{aligned}
\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) &= \sum_{w\in W} \frac{c(H(w))}{p(H(w))} \omega_{\mathcal{P}_\Omega(M)}(w) \\
&= \sum_{H\in\mathcal{H}_k} \Big\{ \frac{c(H)}{p(H)} \sum_{w: H(w)=H} \omega_M(w)\, \mathbb{I}(w \subseteq \Omega) \Big\} \\
&= \sum_{i=1}^{4} \sum_{H\in\mathcal{H}_{k,i}} \Big\{ \frac{c(H)}{p(H)} \sum_{w: H(w)=H} \omega_M(w)\, \mathbb{I}(w \subseteq \Omega) \Big\},
\end{aligned}$$

where we write $w \subseteq \Omega$ to denote the event that all the edges in the walk w are sampled, and we define

- $\mathcal{H}_{k,1} \equiv \{C_k\}$ is just a (set of a) simple cycle of length k and there are total $|\{w \in W : H(w) \in \mathcal{H}_{k,1}\}| = \binom{d}{k}(k!/2k) \le (d^k/2k)$ corresponding walks to this set, and $c(C_k) = 2k$.
- $\mathcal{H}_{k,2} \equiv \{H(V_H, E_H) \in \mathcal{H}_k : |V_H| \le k-1$ and no self loops$\}$, and there are total $|\{w \in W : H(w) \in \mathcal{H}_{k,2}| \le d^{k-1}$ corresponding walks to this set.
- $\mathcal{H}_{k,3} \equiv \bigcup_{s=1}^{k-1} \mathcal{H}_{k,3,s}$ where $\mathcal{H}_{k,3,s} = \{H \in \mathcal{H}_k$ with s self loops$\}$, and there are total $|\{w \in W : H(w) \in \mathcal{H}_{k,3}\}| \le d^{k-s}$ corresponding walks in this set.
- $\mathcal{H}_{k,4} \equiv \{H(V_H, E_H) \in \mathcal{H}_k : |V_H| = 1\}$ is a (set of a) graph with k self loops and there are total $|\{w \in W : H(w) \in \mathcal{H}_{k,4}\}| = d$ corresponding walks to this set.

Given this unbiased estimator, we provide an upper bound on the variance of each of the partitions to prove concentration with Chebyshev's inequality. For any walk $w \in W$, let $|w|$ denote the number of unique edges (including self loops) that the walk w traverses. Let $|w \cap w'|$ denote the number of unique overlapping edges (including self loops) of walks w and w'. We have,

$$\begin{aligned}
&\mathrm{Var}\big(\widehat{\Theta}_k(\mathcal{P}_\Omega(M))\big) \\
&= 2\sum_{\ell=1}^{k-1} \sum_{\substack{w\neq w'\in \widetilde{W} \\ |w\cap w'|=\ell}} \mathrm{cov}\left(\frac{\mathbb{I}(w\subseteq\Omega)\omega_M(w)c(H(w))}{p(H(w))}, \frac{\mathbb{I}(w'\subseteq\Omega)\omega_M(w')c(H(w'))}{p(H(w'))}\right) \\
&\quad + \sum_{i=1}^{4} \sum_{H\in\mathcal{H}_{k,i}} \left\{\frac{c(H)^2}{p(H)^2} \sum_{w:H(w)=H} \omega_M(w)^2 \mathrm{Var}\Big(\mathbb{I}(w\subseteq\Omega)\Big)\right\} \\
&< 4\sum_{\ell=1}^{k-1} \sum_{\substack{w\neq w'\in W \\ |w\cap w'|=\ell}} \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\mathbb{I}(w'\subseteq\Omega)\Big]\left(\frac{\big|\omega_M(w)\,\omega_M(w')\big|c(H(w))c(H(w'))}{p(H(w))\,p(H(w'))}\right) \\
&\quad + \sum_{i=1}^{4} \sum_{H\in\mathcal{H}_{k,i}} \sum_{w:H(w)=H} \frac{c(H)^2\omega_M(w)^2}{p(H)^2} \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big]. \qquad (16)
\end{aligned}$$

Recall from the definition of incoherence that $|M_{ii}| \le \sigma_1(M)\mu r/d$ and $|M_{ij}| = \sigma_1(M)\mu r^{1/2}/d$, and let $\alpha = \sigma_1(M)\mu r^{1/2}/d$ denote the maximum off-diagonal entry, such that $|M_{ij}| \le \alpha$ and $|M_{ii}| \le \alpha\sqrt{r}$ for all $i,j \in [d]$. Let $A_{p,k,\alpha,d} = d^k\alpha^{2k}/p^k$ denote the target scaling of the variance, then

$$\sum_{H\in\mathcal{H}_{k,i}} \sum_{w:H(w)=H} \frac{c(H)^2\,\omega_M(w)^2}{p(H)^2} \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big] \;\le$$

$$\begin{cases}
\dfrac{d^k}{2k}\dfrac{(2k)^2\alpha^{2k}}{p^k} = 2kA_{p,k,\alpha,d}\,, & \text{for } i=1\ , \qquad (17)\\
d^{k-1}\dfrac{f(k)^2\alpha^{2k}}{p^k} = \dfrac{f(k)^2}{d}A_{p,k,\alpha,d}\,, & \text{for } i=2\ , \qquad (18)\\
d\dfrac{r^k\alpha^{2k}}{p} = \dfrac{r^kp^{k-1}}{d^{k-1}}A_{p,k,\alpha,d}\,, & \text{for } i=4\,, \qquad (19)
\end{cases}$$

and for $i=3$ and for $1\le s\le k-1$, we have

$$\sum_{H\in\mathcal{H}_{k,3,s}} \sum_{w:H(w)=H} \frac{c(H)^2\,\omega_M(w)^2}{p(H)^2} \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big] \;\le\; d^{k-s}\frac{f(k)^2\alpha^{2k}r^s}{p^k} = \frac{f(k)^2r^s}{d^s}A_{p,k,\alpha,d}\,, \quad (20)$$

where $c(H)$ is defined as the multiplicity of walks with the same weight satisfying $c(H) \le f(k)$. For $w \neq w'$ and $|w\cap w'| = \ell$, where the range of ℓ varies across equations depending upon the set to which w, w' belongs, we have the following:

$$\sum_{\substack{w\neq w'\in W \\ |w\cap w'|=\ell, H(w)\in\mathcal{H}_{k,i,s}, H(w')\in\mathcal{H}_{k,i',s'}}} \mathbb{E}\Big[\mathbb{I}(w\in\Omega)\mathbb{I}(w'\in\Omega)\Big] \frac{\big|\omega_M(H(w))\omega_M(H(w'))\big|\,c(H(w))c(H(w'))}{p(H(w))p(H(w'))} \;\le$$

$$\begin{cases}
\dfrac{d^kd^{k-(\ell+1)}}{2k}\dfrac{\alpha^{2k}(2k)^2}{p^\ell} = \dfrac{(dp)^{k-\ell}}{d}\,2kA_{p,k,\alpha,d}, & \text{for } i=i'=1 \quad (21)\\
\dfrac{f(k)^2d^{k-1}d^{k-1-(\ell+1)}\alpha^{2k}}{p^\ell} \le \dfrac{f(k)^2(dp)^{k-\ell}}{d^3}A_{p,k,\alpha,d} & \text{for } i=i'=2 \quad (22)\\
\dfrac{f(k)^2d^{k-s}d^{k-s'-\ell}\alpha^{2k-s-s'}(\alpha\sqrt{r})^{s+s'}}{p^\ell} \le \dfrac{f(k)^2(dp)^{k-\ell}}{(d/\sqrt{r})^{s+s'}}A_{p,k,\alpha,d}\,, & \text{for } i=i'=3 \quad (23)\\
\dfrac{f(k)^2d^kd^{k-1-(\ell+1)}\alpha^{2k}}{p^\ell} \le \dfrac{f(k)^2(dp)^{k-\ell}}{d^2}A_{p,k,\alpha,d} & \text{for } i=1, i'=2 (24)\\
\dfrac{f(k)^2d^kd^{k-s-(\ell+1)}\alpha^{2k-s}(\alpha\sqrt{r})^s}{p^\ell} \le \dfrac{f(k)^2(dp)^{k-\ell}}{d(d/\sqrt{r})^s}A_{p,k,\alpha,d} & \text{for } i=1, i'=3 (25)\\
\dfrac{f(k)^2d^{k-1}d^{k-s-(\ell+1)}\alpha^{2k-s}(\alpha\sqrt{r})^s}{p^\ell} \le \dfrac{f(k)^2(dp)^{k-\ell}}{d^2(d/\sqrt{r})^s}A_{p,k,\alpha,d} & \text{for } i=2, i'=3 (26)\\
\dfrac{f(k)^2dd^{k-s-\ell}\alpha^{k-s}(\alpha\sqrt{r})^{k+s}}{p^\ell} \le \dfrac{f(k)^2(dp)^{k-\ell}}{d^{k-1}(d/\sqrt{r})^{k+s}}A_{p,k,\alpha,d} & \text{for } i=3, i'=4 (27)
\end{cases}$$

where (27) is valid only for $\ell = 1$. Note that for any w with $H(w) \in \mathcal{H}_{k,1}\bigcup\mathcal{H}_{k,2}$, it has no overlap with w' such that $H(w') \in \mathcal{H}_{k,4}$.

Observe that $\mathrm{Var}\big(\widehat{\Theta}_k(\mathcal{P}_\Omega(M))\big)$ as bounded in (16) is upper bounded by the sum of quantities in (17)-(27), summating over all possible values of $1\le\ell\le k-1$, and $1\le s,s'\le k-1$. Let $h(k) \equiv f(k)^2A_{p,k,\alpha,d}$. Observe that quantities in (17),(18), and (20) are upper bounded by $h(k)$. Quantities in (21)-(27) are upper bounded by $h_1(k) \equiv h(k)(dp)^{k-1}/d$. Quantity in (19) is upper bounded by $h_2(k) \equiv h(k)r^kp^{k-1}/d^{k-1}$.

Given $\|M\|_k^k \ge r(\sigma_{\min})^k$, recall a bound on off diagonals of matrix M by $|M_{ij}| \le \alpha = \mu\sigma_{\max}\sqrt{r}/d$ and $A_{p,k,\alpha,d} = d^k\alpha^{2k}/p^k$. This gives

$$\frac{A_{p,k,\alpha,d}}{\|M\|_k^{2k}} \;\le\; \frac{\kappa^{2k}\mu^{2k}r^{k-2}}{d^kp^k}\,.$$

Using Chebyshev's inequality and collecting all terms in the upper bound on the variance, we have for sufficiently large d the following bound:

$$\mathbb{P}\left(\frac{\big|\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) - \|M\|_k^k\big|}{\|M\|_k^k} \;\ge\; \delta\right) \;\le\; \frac{(\kappa\mu)^{2k}f(k)^2r^{k-2}}{\delta^2(dp)^k}\max\left\{1, \frac{(dp)^{k-1}}{d}, \frac{r^kp^{k-1}}{d^{k-1}}\right\},$$

where the second and the third term in the max expression follow from evaluating $h_1(k)$ and $h_2(k)$. If sampling probability p is small enough such that $dp \le Cd^{1/(k-1)}$ for some constant C, then the second and the third terms are smaller than the first term. Hence, the desired result in Theorem 3 follows.

8.2. Proof of Theorem 4

We can prove a Bernstein-type bound on accuracy of the estimator. The estimator (3) can be rewritten as a multi-linear polynomial function of $d(d+1)/2$ i.i.d. Bernoulli(p) random variables.

$$\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) \;=\; \sum_{w\in W}\left\{\frac{c(H(w))}{p(H(w))}\,\omega_M(w) \prod_{(i,j)\in\mathrm{unique}(w)} \mathbb{I}((i,j)\in\Omega)\right\},$$

where $\mathbb{I}((i,j) \subseteq \Omega)$ is a random variable that takes value 1 if the $(i,j)_{\text{th}}$ entry of the matrix M is sampled, and unique(w) denotes the set of the unique edges (and self loops) that the walk w traverses. Let q denote the power of the polynomial function that is the maximum number of unique edges in the walk w, that is $q = k$.

We use the following Bernstien-type concentration results of Schudy and Sviridenko (2011) for the polynomials of independent random variables.

Lemma 15 (Schudy and Sviridenko (2011),Theorem 1.3) *We are given $d(d+1)/2$ independent central moment bounded random variables $\{\mathbb{I}((i,j) \in \Omega)\}_{1 \le i \le j \le d}$ with the same parameter L. We are given a multilinear polynomial $\widehat{\Theta}_k(\mathcal{P}_\Omega(M))$ of power q, then*

$$\mathbb{P}\Big[\Big|\widehat{\Theta}_k(\mathcal{P}_\Omega(M)) - \mathbb{E}\big[\widehat{\Theta}_k(\mathcal{P}_\Omega(M))\big]\Big| \ge \lambda\Big] \;\le\; e^2 \max\left\{ e^{\frac{-\lambda^2}{\mathrm{Var}[\widehat{\Theta}_k(\mathcal{P}_\Omega(M))]R^q}}, \max_{t\in[q]} e^{-(\frac{\lambda}{\mu_t L^t R^q})^{1/t}} \right\},$$

where R is some absolute constant and μ_t is defined as follows:

$$\mu_t \;=\; \max_{\substack{S\subseteq\{(i,j):i,j\in[d]\}\\ |S|=t}} \left(\sum_{w\in W | w\supseteq S} \frac{c(H(w))}{p(H(w))} \, |\omega_M(w)| \prod_{(i,j)\in \text{unique}(w)\setminus S} \mathbb{E}[\mathbb{I}((i,j)\in\Omega)] \right) \quad (28)$$

where $w \supseteq S$ denotes that the walk w comprises edges(and self loops) contained in the set S. The parameter L is defined as follows: A random variable Z is called central moment bounded with real parameter $L > 0$, if for any integer $i \ge 1$ we have

$$E\big[|Z - \mathbb{E}[Z]|^i\big] \;\le\; i\,L\,\mathbb{E}[|Z-\mathbb{E}[Z]|^{i-1}]\,.$$

For each of the Bernoulli random variables $\{\mathbb{I}((i,j)\in\Omega)\}_{1\le i\le j\le d}$, L is contained in $[1/4, 1]$. In the following, we show that $\mu_t \le (\mu\sigma_{\max})^k g(k) r^k/(d(dp)^t)$, for $t \in [k]$. Using Lemma 15, along with $\|M\|_k^k \ge r(\sigma_{\min})^k$, the bound in (9) follows immediately.

To compute μ_t, define a set of walks $W_{\ell,s,\hat{s}}$ such that $w \in W_{\ell,s,\hat{s}}$ has $0 \le \ell \le k$ unique edges and $0 \le s \le k$ unique self loops, and $\hat{s}$ total self loops with $\ell + \hat{s} \le k$. For the set S as required in (28), let $S_{\tilde{\ell},\tilde{s}}$ be a set of $\tilde{\ell}$ unique edges and $\tilde{s}$ unique self loops, with $|S_{\tilde{\ell},\tilde{s}}| = \tilde{\ell}+\tilde{s}$

where $1 \le \tilde{\ell} + \tilde{s} \le k$. Therefore, we have

$$\begin{aligned}
\mu_t &= \max_{\substack{S_{\tilde{\ell},\tilde{s}}\\ :\tilde{\ell}+\tilde{s}=t}} \left(\sum_{\substack{0\le s\le\hat{s}\le k\\ \ell\in[k]:\ell+\hat{s}\le k}} \sum_{\substack{w\in W_{\ell,s,\hat{s}}\\ :w\supseteq S_{\tilde{\ell},\tilde{s}}}} \frac{c(H(w))}{p(H(w))} \, |\omega_M(w)| \prod_{(i,j)\in\text{unique}(w)\setminus S_{\tilde{\ell},\tilde{s}}} \mathbb{E}[\mathbb{I}((i,j)\subseteq\Omega)] \right) \\
&\le \max_{\substack{S_{\tilde{\ell},\tilde{s}}\\ :\tilde{\ell}+\tilde{s}=t}} \left(\sum_{\substack{0\le s\le\hat{s}\le k\\ \ell\in[k]:\ell+\hat{s}\le k}} \sum_{\substack{w\in W_{\ell,s,\hat{s}}\\ :w\supseteq S_{\tilde{\ell},\tilde{s}}}} \frac{f(k)}{p^{\ell+s}} \, \alpha^k r^{\hat{s}/2} p^{\ell+s-(\tilde{\ell}+\tilde{s})} \right) \\
&\le \max_{\substack{S_{\tilde{\ell},\tilde{s}}\\ :\tilde{\ell}+\tilde{s}=t}} \left(\sum_{\substack{0\le s\le\hat{s}\le k\\ \ell\in[k]:\ell+\hat{s}\le k,\tilde{s}\le s}} \frac{d^{\ell-(1+\tilde{\ell})} f(k)}{p^{\ell+s}} \, \frac{(\mu\sigma_{\max})^k r^{(k+\hat{s})/2}}{d^k} p^{\ell+s-(\tilde{\ell}+\tilde{s})} \right) \\
&= \max_{\substack{S_{\tilde{\ell},\tilde{s}}\\ :\tilde{\ell}+\tilde{s}=t}} \left(\sum_{\substack{0\le s\le\hat{s}\le k\\ \ell\in[k]:\ell+\hat{s}\le k,\tilde{s}\le s}} \frac{f(k)(\mu\sigma_{\max})^k r^{(k+\hat{s})/2}}{d d^{(k-\ell-\tilde{s})}(dp)^{(\tilde{\ell}+\tilde{s})}} \right) \\
&\le \max_{\substack{S_{\tilde{\ell},\tilde{s}}\\ :\tilde{\ell}+\tilde{s}=t}} \left(\frac{k^3 f(k)(\mu\sigma_{\max})^k r^{(k+\hat{s})/2}}{d d^{(k-\ell-\tilde{s})}(dp)^{(\tilde{\ell}+\tilde{s})}} \right) \;\le\; \frac{(\mu\sigma_{\max})^k g(k) r^k}{d(dp)^t}\,.
\end{aligned}$$

8.3. Proof of Theorem 11

The proof technique is a generalization to a rank-r symmetric matrix of the proof given by Li et al. (2014) for deriving lower bound on the size of a random bi-linear sketch needed for approximating Schatten norm of any matrix. It also draws on the techniques used in Andoni et al. (2013) for proving a lower bound on the size of the linear sketches of moments.

We prove Theorem 11 for an arbitrary fixed relabeling permutation π of the graph nodes. Indeed, by Yao's minimax principle, it suffices to give two distributions on matrix $M \in \mathcal{M}_r$ for which the $\|M\|_k$ values differ by a constant factor with high probability, but for any relabeling permutation π of the nodes of the pattern graph G, the induced distributions on the sampled entries $\mathcal{P}_\Omega(M)$ corresponding to the relabeled graph $G_\pi(\widetilde{V}, \Omega)$, have low total variation distance.

For positive $C > 0$ to be specified later, define $\lambda \equiv C d r^{1/k - 1/2}$. We construct distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ for $M \in \mathcal{M}_{r,\mu}$ with $\mu = C'\sqrt{\log r}$, for some absolute constant C', such that the following holds:

1. $\|M\|_k \le \lambda$ on the entire support of $\mathcal{D}_1$, and $\|M\|_k \ge 4\lambda$ on the entire support of $\mathcal{D}_2$.

2. Let $\mathcal{E}_1$ and $\mathcal{E}_2$ denote the distribution of the sampled matrix $\mathcal{P}_\Omega(M)$ when M is drawn from $\mathcal{D}_1$ and $\mathcal{D}_2$ respectively. Recall that Ω is the set of edges of the relabeled graph $G_\pi(\widetilde{V}, \Omega)$ as defined in Section 4.1. If $\lambda^*_{G,r} \ge \lambda$ then, the total variation distance between $\mathcal{E}_1$ and $\mathcal{E}_2$ is bounded by $\mathrm{TV}(\mathcal{E}_1, \mathcal{E}_2) \le 1/2$.

The desired result (15) follows from the above claims and the following relationship between statistical tests and estimators:

$$\begin{aligned}
&\mathop{\mathbb{P}}_{M\sim\frac{1}{2}(\mathcal{D}_1+\mathcal{D}_2)}\left(\frac{1}{2}\|M\|_k \le \widetilde{\Theta}(\mathcal{P}_{\Omega(M)}) \le 2\|M\|_k\right)\\
&\le \frac{1}{2}\mathop{\mathbb{P}}_{M\sim\mathcal{D}_2}\left(\widetilde{\Theta}(\mathcal{P}_{\Omega(M)}) \ge 2\lambda\right) + \frac{1}{2}\mathop{\mathbb{P}}_{M\sim\mathcal{D}_1}\left(\widetilde{\Theta}(\mathcal{P}_{\Omega(M)}) \le 2\lambda\right)\\
&\le \frac{1}{2}\big(1+\mathrm{TV}(\mathcal{E}_1,\mathcal{E}_2)\big) \;\le\; \frac{3}{4}\,,
\end{aligned}$$

where the last inequality follows from the following characterization of the total variation distance $\mathrm{TV}(\mathcal{E}_1,\mathcal{E}_2) \equiv \sup_A |\mathcal{E}_1(A) - \mathcal{E}_2(A)|$.

To prove the two claims, we construct one of the desired rank-r random matrix via tiling, i.e. covering the matrix with copies of a single $r\times r$ sub-matrix from the *Gaussian Wigner Ensemble*, where diagonals and off-diagonals(upper triangle) are both distributed as i.i.d. standard Gaussians. Another one is constructed by adding a rank one perturbation. Precisely, we define a random matrix drawn from $\mathcal{D}_1$ as follows.

A random $r\times r$ matrix Z chosen from Gaussian Wigner Ensemble, $\mathcal{G}(r,r)$, is a symmetric matrix whose entries $Z_{i,i}$ and $Z_{i,j}$ for $i<j$ are independent with $N(0,1)$ distribution. Define $B \equiv \mathbb{1}_{\lceil d/r\rceil}\mathbb{1}_{\lceil d/r\rceil}^\top$ to be an all-ones matrix of size $\lceil d/r\rceil \times \lceil d/r\rceil$. Let $\bar{\mathcal{D}}_1$ denote the distribution of $M_1 = Y\otimes B$ where $Y\sim\mathcal{G}(r,r)$, and $\otimes$ denotes the standard Kronecker product of two matrices. Note that the matrix norm of M_1 and Y are related by $\|M_1\|_k = \lceil d/r\rceil\|Y\|_k$. Since the Schatten norm of $Y\sim\mathcal{G}(r,r)$ takes value on the entire $\mathbb{R}_+$, we need to truncate it. We set $\mathcal{D}_1$ to be $\bar{\mathcal{D}}_1$ conditioned on the event $S_1 = \{M_1 : \|M_1\|_k \le \lambda, \mu(M_1) \le C'\sqrt{\log r}\}$, i.e. $\mathcal{D}_1(A) = \bar{\mathcal{D}}_1(A\cap S_1)/\bar{\mathcal{D}}_1(S_1)$.

We define $\bar{\mathcal{D}}_2$ by adding a rank one perturbation. Precisely, let $M_2 = M_1 + (5/d)\lambda U$, where $M_1\sim\bar{\mathcal{D}}_1$ and $U = uu^\top\otimes B$. Here a random vector $u\in\{\pm1\}^r$ is a vector of i.i.d. Rademacher random variables. Note that U is a rank one matrix and $\|U\|_k = \lceil d/r\rceil\|uu^\top\|_k = d$. We set $\mathcal{D}_2$ to be $\bar{\mathcal{D}}_2$ conditioned on the event $S_2 = \{M_2 : \|M_2\|_k \ge 4\lambda, \mu(M_2) \le C'\sqrt{\log r}\}$. Observe that $M_1\sim\bar{\mathcal{D}}_1$ and $M_2\sim\bar{\mathcal{D}}_2$ belong to $\mathbb{R}^{d\times d}$, are symmetric and both are rank at most $r+1$.

Let $\bar{\mathcal{E}}_1$ and $\bar{\mathcal{E}}_2$ denote the distribution of $\mathcal{P}_\Omega(M)$ when M is drawn from $\bar{\mathcal{D}}_1$ and $\bar{\mathcal{D}}_2$ respectively. We first show that their total variation distance is not too large. Using the triangle inequality, we have

$$\begin{aligned}
\mathrm{TV}(\mathcal{E}_1,\mathcal{E}_2) &\le \mathrm{TV}(\bar{\mathcal{E}}_1,\bar{\mathcal{E}}_2) + \mathrm{TV}(\bar{\mathcal{E}}_1,\mathcal{E}_1) + \mathrm{TV}(\bar{\mathcal{E}}_2,\mathcal{E}_2)\\
&\le \mathrm{TV}(\bar{\mathcal{E}}_1,\bar{\mathcal{E}}_2) + \mathrm{TV}(\bar{\mathcal{D}}_1,\mathcal{D}_1) + \mathrm{TV}(\bar{\mathcal{D}}_2,\mathcal{D}_2) \qquad (29)\\
&= \mathrm{TV}(\bar{\mathcal{E}}_1,\bar{\mathcal{E}}_2) + \mathop{\mathbb{P}}_{M_1\sim D_1}\big((\|M_1\|_k \ge \lambda)\cup(\mu(M_1)\ge C'\sqrt{\log r})\big)\\
&\quad + \mathop{\mathbb{P}}_{M_2\sim\mathcal{D}_2}\big((\|M_2\|_k \le 4\lambda)\cup(\mu(M_2)\ge C'\sqrt{\log r})\big)\,, \qquad (30)
\end{aligned}$$

where (29) follows from the data processing inequality and (30) follows from $\mathrm{TV}(\mathcal{E}_1,\mathcal{E}_2)\equiv\sup_A|\mathcal{E}_1(A)-\mathcal{E}_2(A)|$. We next show that the three terms in (30) are sufficiently small.

We first provide an upper bound on $\mathrm{TV}(\bar{\mathcal{E}}_1,\bar{\mathcal{E}}_2)$. As per our construction, only the upper triangular (including diagonals) of the upper-left submatrix of size $r\times r$ of $M_1\sim\mathcal{D}_1$ and $M_2\sim\mathcal{D}_2$ has unique entries and the rest are copies of these. Observe that the set of unique

entries of M_1(or M_2) corresponding to any pattern graph $G(V,E)$ are precisely the following entries of the projection graph $\mathcal{P}^{(r)}(G)$ that is defined in Section 4.1:

$$E(\mathcal{P}^{(r)}(G)) \;\equiv\; \Big\{(i,j) : i\le j\in[r], (i,j)\in\mathcal{P}^{(r)}(G(V,E))\Big\}\,. \qquad (31)$$

For the purpose of computing the total variation distance $\mathrm{TV}(\bar{\mathcal{E}}_1,\bar{\mathcal{E}}_2)$, it is sufficient to consider only $E(\mathcal{P}^{(r)}(G_\pi))$ entries of M_1 distributed as i.i.d. standard Gaussians $N(0,I_{\ell_1\times\ell_1})$, and the entries of M_2 distributed as $N(W,I_{\ell_1\times\ell_1})$), where $\ell_1 = |E(\mathcal{P}^{(r)}(G_\pi))|$. The random vector W represents the rank one perturbation and is distributed as

$$W_{i,j} = (5/d)\lambda\, u_i u_j\,, \qquad (i,j)\in E(\mathcal{P}^{(r)}(G_\pi))\,.$$

To bound total variation distance between $\bar{\mathcal{E}}_1$ and $\bar{\mathcal{E}}_2$, we use the following lemma and the fact that for any two distributions μ and ν, $\mathrm{TV}(\mu,\nu)\le\sqrt{\chi^2(\mu\,\|\,\nu)}$. Let $\mu*\nu$ denote the convolution of the density (or equivalently addition of the two random variables).

Lemma 16 (Ingster and Suslina (2012), p97) *It holds that $\chi^2(N(0,I_n)*\mu\,\|\,N(0,I_n)) \le \mathbb{E}\exp(\langle z,z'\rangle) - 1$, where $z,z'\sim\mu$ are independent.*

It follows that

$$\mathrm{TV}(\bar{\mathcal{E}}_1,\bar{\mathcal{E}}_2) \;\le\; \sqrt{\mathbb{E}e^{\langle W,W'\rangle}-1} \;\le\; 1/5\,,$$

for $\lambda^*_G\ge\lambda$ where the expectation is taken over independent W and W' which are identically distributed. We show that if $\lambda^*_G\ge\lambda$ the last inequality holds, as following:

$$\begin{aligned}
&\mathbb{E}_{W,W'}\exp\big(\langle W,W'\rangle\big)\\
&= \mathbb{E}_{u,u'}\exp\left((5/d)^2\lambda^2\sum_{(i,j)\in E(\mathcal{P}^{(r)}(G_\pi))} u_iu'_iu_ju'_j\right)\\
&= \mathbb{E}_u\exp\left((5/d)^2\lambda^2\sum_{(i,j)\in E(\mathcal{P}^{(r)}(G_\pi))} u_iu_j\right) \qquad (32)\\
&= \mathbb{E}_u\left[\exp\left((5/d)^2\lambda^2\sum_{\substack{(i,j)\in E(\mathcal{P}^{(r)}(G_\pi))\\ :i\ne j}} u_iu_j\right)\right]\exp\left((5/d)^2\lambda^2\sum_{\substack{(i,j)\in E(\mathcal{P}^{(r)}(G_\pi))\\ :i=j}} u_iu_j\right)\\
&\le \mathbb{E}_u\left[\exp\left((5/d)^2\lambda^2\sum_{\substack{(i,j)\in E(\mathcal{P}^{(r)}(G_\pi))\\ :i\ne j}} 2u_iu_j\right)\right]\exp\left((5/d)^2\lambda^2\sum_{\substack{(i,j)\in E(\mathcal{P}^{(r)}(G_\pi))\\ :i=j}} u_iu_j\right) \qquad (33)\\
&= \mathbb{E}_u\left[\exp\left((5/d)^2\lambda^2\sum_{\substack{(i,j)\in\mathcal{P}^{(r)}(G_\pi)\\ :i\ne j}} u_iu_j\right)\right]\exp\left((5/d)^2\lambda^2\sum_{\substack{(i,j)\in\mathcal{P}^{(r)}(G_\pi)\\ :i=j}} u_iu_j\right) \qquad (34)\\
&= \mathbb{E}_u\left[\exp\left((5/d)^2\lambda^2\sum_{(i,j)\in\mathcal{P}^{(r)}(G_\pi)} u_iu_j\right)\right]\\
&\le 1+1/25\,, \qquad (35)
\end{aligned}$$

where (32) follows from the fact that u, u' are i.i.d. Rademacher variables, (33) follows from the fact that $f_{G,r}(\lambda)$ defined in (13) is non-decreasing in λ, (34) follows from the definition of $E(\mathcal{P}^{(r)}(G_\pi))$ in (31),and (35) follows from the definition of λ^*_G in (14).

To bound the other two terms in (30), we use Wigner's semicircular law and its rate of convergence for Gaussian Wigner Ensemble, $\mathcal{G}(r,r)$ as defined above. Consider the empirical spectral distribution of $Z \in \mathbb{R}^{r\times r}$ as

$$F_Z(x) = \frac{1}{r}|\{i : \lambda_i(Z) \le x\}|.$$

Lemma 17 (Wigner (1955)) *Define $Z = (1/\sqrt{r})Y$ for $Y \sim \mathcal{G}(r,r)$. Then as $r \to \infty$ the empirical distribution $F_Z(x)$ of Z converges weakly to the distribution $G(x)$ with density*

$$g(t) = \frac{\sqrt{4-t^2}}{2\pi} \quad t \in [-2,2]\,.$$

Lemma 18 (Götze and Tikhomirov (2003)) *For any positive constant $\alpha > 0$, let $\ell_{r,\alpha} = \log r(\log\log r)^\alpha$. There exists an absolute positive constant C and c such that for r large enough,*

$$\mathbb{P}\Big\{ \sup_x \big|F_Z(x) - G(x)\big| \ge r^{-1}\log r \ell^6_{r,\alpha}\Big\} \;\le\; C\exp\big\{-c\ell_{r,\alpha}\big\}\,.$$

To bound the schatten norm of a matrix $Y \sim \mathcal{G}(r,r)$, along with Lemma 17 and Lemma 18 we use the following. If $F(x)$ and $G(x)$ are cumulative distribution functions of densities μ, ν then for any continuous and bounded function f, we have

$$\left|\int f d\mu - \int f d\nu\right| \;\le\; \|f\|_\infty \sup_x \big|F(x) - G(x)\big|\,.$$

Choosing $f(x) = x^k$ for $x \in [-2,2]$, we can see that for $k = O(\log r)$ there exists a constant $C > 2$ such that with probability $1 - 1/80$ it holds that

$$\|(1/\sqrt{r})Y\|_k^k = \left(\int_{-2}^{2} x^k \frac{\sqrt{4-x^2}}{2\pi}dx + o(1)\right)r \;\le\; (2^k + o(1))r \;\le\; C^k r\,. \tag{36}$$

Hence $\|Y\|_k \le Cr^{(1/k+1/2)}$. By construction of distribution $\bar{\mathcal{D}}_1$, for $M_1 \sim \bar{\mathcal{D}}_1$, $\|M_1\|_k = (d/r)\|Y\|_k \le Cdr^{(1/k-1/2)} = \lambda$. Also, by construction $M_2 \sim \bar{\mathcal{D}}_2$ is $M_2 = M_1 + (5/d)\lambda U$ where $\|U\|_k = d$. Using triangle inequality, we have

$$\begin{aligned}\|M_2\|_k &\ge \|(5/d)\lambda U\|_k - \|M_1\|_k \\ &\ge 5\lambda - Cdr^{1/k-1/2} \;=\; 4\lambda\,,\end{aligned}$$

Recall that, incoherence parameter $\mu(M)$ is defined as $\mu(M) = \max_{i\neq j\in[d]} M_{i,j}/(|\sigma_{\max}(M)|\sqrt{r}/d)$. From (36), there exists a constant $0 < C' < 1$ such that with probability $1 - 1/160$ it holds that $\|Y\|_2 \ge C'r$. The integral evaluates to 1 for $k = 2$. Therefore, the largest singular value of M_1 is lower bounded: $|\sigma_{\max}(M_1)| \ge C'd/\sqrt{r}$. Using the fact that there exists a constant C'' such that $\max_{i,j\in[r]}\{Y_{i,j}\} \le C''\sqrt{\log r}$ with probability at least $1 - 1/160$, we have, $\mu(M_1) \le (C''/C')\sqrt{\log r}$. The same $\mu(M_1)$ satisfies the upper bound on diagonals as well. Therefore, using union bound, the second and the third term in (30) are upper bounded by $1/40$.

8.4. Proof of Lemma 12

Observe that for any given permutation π, $\mathcal{P}^{(r)}(G_\pi)$ as defined in Section 4.1 is a clique over a subset of nodes $\widetilde{V}_\pi$, where $|\widetilde{V}_\pi| \le \min\{\ell, r\}$. From the definition of $f_{G,r}(\lambda)$, (13), we have the following:

$$\begin{aligned} & f_{G,r}(\lambda) \\ = \;& \max_\pi \left\{\mathbb{E}_u \exp\left((5/d)^2\lambda^2 \sum_{(i,j)\in\mathcal{P}^{(r)}(G_\pi)} u_i u_j\right)\right\} = \max_\pi \left\{\mathbb{E}_u \exp\left((5/d)^2\lambda^2\big(\sum_{i\in\widetilde{V}_\pi} u_i\big)^2\right)\right\} \\ = \;& \max_\pi \left\{\sum_{t=0}^{\infty} \frac{(5/d)^{2t}\lambda^{2t}\mathbb{E}_u\big[\big(\sum_{i\in\widetilde{V}_\pi} u_i\big)^{2t}\big]}{t!}\right\} \;\le\; \max_\pi \left\{\left(1 + 2\sum_{t=1}^{\infty}\big((5/d)^2\lambda^2|\widetilde{V}_\pi|\big)^t\right)\right\}, \end{aligned}$$

where the inequality follows from the bound in (37). Therefore, from the definition of $\lambda^*_{G,r}$, we have that $\lambda^*_{G,r}$ is lower bounded by $2^{-4}d(\min\{\ell, r\})^{-1/2}$.

To bound $\mathbb{E}(\sum_{i\in\widetilde{V}_\pi} u_i)^{2t}$, for $t \in [1,\infty)$, using Hoeffding bound we have that

$$\mathbb{E}\left|\sum_{i\in\widetilde{V}_\pi} u_i\right|^{2t} \;=\; \int_0^{|\widetilde{V}_\pi|^{2t}} \mathbb{P}\left(\left|\sum_{i\in\widetilde{V}_\pi} u_i\right|^{2t} \ge z\right)dz \;\le\; 2\int_0^{|\widetilde{V}_\pi|^{2t}} \exp\left(\frac{-z^{1/t}}{2|\widetilde{V}_\pi|}\right)dz \;\le\; 2(2|\widetilde{V}_\pi|)^t t!\,, \tag{37}$$

where the integral is evaluated by variable substitution.

8.5. Proof of Lemma 14

For the given pattern graph G and any given permutation π, let $\widetilde{A}_\pi \in \{0,1\}^{r\times r}$ be the adjacency matrix of the graph $\mathcal{P}^{(r)}(G_\pi)$ that is defined in Section 4.1. Observe that for a permutation π, ℓ_π rows of $\widetilde{A}_\pi$ are all-ones and the remaining are all-zeros, where $\ell_\pi \le \min\{\ell, r\}$. Let A_π be a copy of $\widetilde{A}_\pi$ where all the diagonal entries are replaced with zero. Note that $\mathbb{E}_u(u^\top A_\pi u)^{2t+1} = 0$ for all $t \ge 0$, where u_i's are i.i.d. Rademacher random variables. Define $C_\pi \equiv \exp((5/d)^2\lambda^2\ell_\pi)$.

From the definition of $f_{G,r}(\lambda)$, (13), we have the following:

$$\begin{aligned} & f_{G,r}(\lambda) \\ = \;& \max_\pi \left\{\mathbb{E}_u \exp\left((5/d)^2\lambda^2 \sum_{(i,j)\in\mathcal{P}^{(r)}(G_\pi)} u_i u_j\right)\right\} = \max_\pi \left\{C_\pi\mathbb{E}_u \exp\left((5/d)^2\lambda^2(u^\top A_\pi u)\right)\right\} \\ = \;& \max_\pi \left\{C_\pi\sum_{t=0}^{\infty} \frac{(5/d)^{4t}\lambda^{4t}\mathbb{E}_u\big[(u^\top A_\pi u)^{2t}\big]}{(2t)!}\right\} \;\le\; \max_\pi \left\{C_\pi\left(1 + 4\sum_{t=1}^{\infty}\big(2c(5/d)^2\lambda^2\sqrt{\ell_\pi r}\big)^{2t}\right)\right\}, \end{aligned}$$

where the inequality follows from the bound in (38), and c is some absolute constant. Therefore, from the definition of $\lambda^*_{G,r}$, we have that $\lambda^*_{G,r}$ is lower bounded by $cd((\min\{\ell, r\})r)^{-1/4}$.

To bound $\mathbb{E}_u\big[(u^\top A_\pi u)^{2t}\big]$, for $t \in [1,\infty)$, we use Hanson-Wright Inequality. Observe that $\|A_\pi\|_2 \le \sqrt{\ell_\pi r}$, and $\|A_\pi\|_{\rm F}^2 = (r-1)\ell_\pi < \ell_\pi r$.

$$\begin{aligned}
\mathbb{E}_u\big[(u^\top A_\pi u)^{2t}\big] &= \int_0^{(2\sqrt{r\ell_\pi})^{2t}} \mathbb{P}\big((u^\top A_\pi u)^{2t} \ge z\big)dz \;+\; \int_{(2\sqrt{r\ell_\pi})^{2t}}^{(\ell_\pi r)^{2t}} \mathbb{P}\big((u^\top A_\pi u)^{2t} \ge z\big)dz \\
&\le \int_0^{(2\sqrt{r\ell_\pi})^{2t}} \exp\left(\frac{-cz^{1/t}}{4\ell_\pi r}\right)dz + \int_{(2\sqrt{r\ell_\pi})^{2t}}^{(\ell_\pi r)^{2t}} \exp\left(\frac{-cz^{1/(2t)}}{2\sqrt{\ell_\pi r}}\right)dz \\
&\le 2(4\ell_\pi r/c)^t t! + 2(2\sqrt{\ell_\pi r}/c)^{2t}(2t)! \;\le\; 4(2\sqrt{\ell_\pi r}/c)^{2t}(2t)!\,, \qquad (38)
\end{aligned}$$

where the integral is evaluated by variable substitution.

8.6. Proof of Theorem 13

For a clique of size m selected uniformly at random, we derive an upper bound on the variance of our estimator. Following the notations defined in the proof of Theorem 3, we have the following bound on the variance.

$$\begin{aligned}
&\mathrm{Var}\big(\widehat{\Theta}_k(\mathcal{P}_\Omega(M))\big) \\
=\;& 2\sum_{\ell=0}^{k} \sum_{\substack{w\neq w'\in\widetilde{W}\\ |w\cap w'|=\ell}} \mathrm{Covar}\left(\frac{\mathbb{I}(w\subseteq\Omega)\omega_M(w)c(H(w))}{p(H(w))}, \frac{\mathbb{I}(w'\subseteq\Omega)\omega_M(w')c(H(w'))}{p(H(w'))}\right) \\
&+ \sum_{i=1}^{4}\sum_{H\in\mathcal{H}_{k,i}} \left\{\frac{c(H)^2}{p(H)^2} \sum_{w:H(w)=H} \omega_M(w)^2 \mathrm{Var}\Big(\mathbb{I}(w\subseteq\Omega)\Big)\right\} \\
<\;& 2\sum_{\ell=0}^{k} \sum_{\substack{w\neq w'\in W\\ |w\cap w'|=\ell}} \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\mathbb{I}(w'\subseteq\Omega)\Big]\left(\frac{\omega_M(w)\,\omega_M(w')c(H(w))c(H(w'))}{p(H(w))\,p(H(w'))}\right) \\
&-2\sum_{\ell=0}^{k} \sum_{\substack{w\neq w'\in W\\ |w\cap w'|=\ell}} \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big]\mathbb{E}\Big[\mathbb{I}(w'\subseteq\Omega)\Big]\left(\frac{\omega_M(w)\,\omega_M(w')c(H(w))c(H(w'))}{p(H(w))\,p(H(w'))}\right) \\
&+ \sum_{i=1}^{4}\sum_{H\in\mathcal{H}_{k,i}} \sum_{w:H(w)=H} \frac{c(H)^2\omega_M(w)^2}{p(H)^2}\mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big]\,. \qquad (39)
\end{aligned}$$

where we abuse the earlier defined notation $|w\cap w'|$ to denote the number of overlapping nodes in the two walks $w, w' \in W$ instead of number of overlapping edges. Note that in pattern sampling, covariance term for two walks that do not have any overlapping node is not zero. As earlier, we provide bound on each of the terms in (39).

Probability of any walk w being sampled is $\mathbb{P}[w\in\Omega] = \binom{m}{\ell}/\binom{d}{\ell} \le f(\ell)m^\ell/d^\ell$, where ℓ is the number of unique nodes that the walk traverses and $f(\ell)$ is an exponential function in ℓ. Recall that off diagonals of matrix M are bounded by $|M_{ij}| \le \alpha = \mu\sigma_{\max}\sqrt{r}/d$ and the diagonals are bounded by $|M_{ii}| \le \mu\sigma_{\max} r/d$. We have,

$$\sum_{H\in\mathcal{H}_{k,i}} \sum_{w:H(w)=H} \frac{c(H)^2\,\omega_M(w)^2}{p(H)^2}\mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big] \;\le$$

$$\begin{cases}
\dfrac{d^k}{2k}\dfrac{f(k)^2\alpha^{2k}d^k}{m^k} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^k}\,, & \text{for } i=1\;, \qquad (40)\\
\left(\dfrac{d^2}{m}\right)^{k-1} f(k)^2\alpha^{2k} = \dfrac{m}{d^2}\dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^k}\,, & \text{for } i=2\;, \qquad (41)\\
\dfrac{d^2}{m}r^k\alpha^{2k} = \dfrac{r^k m^{k-1}}{d^{2k-2}}\dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^k}\,, & \text{for } i=4\,, \qquad (42)
\end{cases}$$

and for $i=3$ and for $1\le s\le k-1$, we have

$$\begin{aligned}
&\sum_{H\in\mathcal{H}_{k,3,s}}\sum_{w:H(w)=H} \frac{c(H)^2\,\omega_M(w)^2}{p(H)^2}\mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big] \\
&\le \left(\frac{d^2}{m}\right)^{k-s} f(k)^2\alpha^{2k}r^s = \frac{m^s r^s}{d^{2s}}\frac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^k}\,, \qquad (43)
\end{aligned}$$

For any two walks w, w' with $\ell \ge 0$ overlapping nodes, $\mathbb{P}[w,w'\in\Omega]/(\mathbb{P}[w\in\Omega]\mathbb{P}[w'\in\Omega]) \le f(k)d^\ell/m^\ell$. For $w\neq w'$ and $|w\cap w'| = \ell$, where the range of ℓ varies across equations depending upon the set to which w, w' belongs, we have the following:

$$\sum_{\substack{w\neq w'\in W\\ |w\cap w'|=\ell\\ H(w)\in\mathcal{H}_{k,i,s}\\ H(w')\in\mathcal{H}_{k,i',s'}}} \Big(\mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\mathbb{I}(w'\subseteq\Omega)\Big] - \mathbb{E}\Big[\mathbb{I}(w\subseteq\Omega)\Big]\mathbb{E}\Big[\mathbb{I}(w'\subseteq\Omega)\Big]\Big)\left(\frac{\omega_M(w)\,\omega_M(w')c(H(w))c(H(w'))}{p(H(w))\,p(H(w'))}\right) \;\le$$

$$\begin{cases}
\dfrac{f(k)^2 d^\ell}{m^\ell}\dfrac{(\mu\sigma_{\max})^{2k}r^2}{d^\ell} = \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}\max\{r^2,r^\ell\}}{m^\ell}, & \text{for } i=i'=1, \ell\ge 1 \quad (44)\\
\dfrac{m^{2k-1}}{d^{2k}}\dfrac{d^{2k}f(k)^2(\mu\sigma_{\max})^{2k}r^2}{m^{2k}} = \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^2}{m}, & \text{for } i=i'=1, \ell=0 \quad (45)\\
\dfrac{f(k)^2 d^\ell d^{2k-2-\ell}\alpha^{2k}}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d^2}, & \text{for } i=i'=2 \quad (46)\\
\dfrac{f(k)^2 d^\ell d^{2k-s-s'-\ell}\alpha^{2k}(\sqrt{r})^{s+s'}}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d}, & \text{for } i=i'=3 \quad (47)\\
f(k)^2 d^2\alpha^{2k}(\sqrt{r})^{2k} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{d^{2k-2}/r^k}, & \text{for } i=i'=4 \quad (48)\\
\dfrac{f(k)^2 d^\ell d^{2k-1-\ell}\alpha^{2k}}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d}, & \text{for } i=1, i'=2 \quad (49)\\
\dfrac{f(k)^2 d^\ell d^{2k-s-\ell}\alpha^{2k}(\sqrt{r})^s}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d/\sqrt{r}}, & \text{for } i=1, i'=3 \quad (50)\\
\dfrac{f(k)^2 d^\ell d^{k+1-\ell}\alpha^{2k}(\sqrt{r})^k}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d^{k-1}/(\sqrt{r})^k}, & \text{for } i=1, i'=4\,, \quad (51)\\
\dfrac{f(k)^2 d^\ell d^{2k-1-s-\ell}\alpha^{2k}(\sqrt{r})^s}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d^2/\sqrt{r}}, & \text{for } i=2, i'=3 \quad (52)\\
\dfrac{f(k)^2 d^\ell d^{k-\ell}\alpha^{2k}(\sqrt{r})^k}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d^k(\sqrt{r})^k}, & \text{for } i=2, i'=4\,, \quad (53)\\
\dfrac{f(k)^2 d^\ell d^{k+1-s-\ell}\alpha^{2k}(\sqrt{r})^{s+k}}{m^\ell} \le \dfrac{f(k)^2(\mu\sigma_{\max})^{2k}r^k}{m^\ell d^{k-1}/(\sqrt{r})^k}, & \text{for } i=3, i'=4\,, \quad (54)
\end{cases}$$

Where (44) and (45) both use (56), and (45) also uses (55). Note that ℓ is zero in (48). Collecting all the terms, and using Chebyshev's inequality, along with $\|M\|_k^k \geq r(\sigma_{\min})^k$, we get the desired result.

For any two disjoint simple cycles $w \neq w' \in \mathcal{H}_{k,1}$ with $|w \cap w'| = 0$, we have the following

$$\begin{aligned} \mathbb{P}\big[w \in \Omega\big] - \mathbb{P}\big[w \in \Omega \;\big|\; w' \in \Omega\big] &= \frac{\binom{m}{k}}{\binom{d}{k}} - \frac{\binom{m-k}{k}}{\binom{d-k}{k}} \\ &\leq \frac{m^k}{(d-k+1)^k} - \frac{(m-2k+1)^k}{(d-k)^k} \leq \frac{f(k)m^{k-1}}{d^k}, \end{aligned} \quad (55)$$

where the last inequality assumes that $k < d/2$.

Lemma 19 *For $k = 3$, and any $0 \leq \ell \leq k$*

$$\sum_{w \neq w' \in \mathcal{H}_{k,1} : |w \cap w'| = \ell} \omega_M(w)\omega_M(w') \;\leq\; \frac{f(k)(\mu\sigma_{\max})^{2k} \max\{r^2, r^\ell\}}{d^\ell}. \quad (56)$$

Although we give a proof for $k = 3$ only, we are intentionally writing the lemma for general k as we expect the lemma holds for all $k \geq 3$. The joint walk $w \neq w' \in \mathcal{H}_{k,1} : |w \cap w'| = \ell$ corresponds to $H(w) = D_{27}$, for $\ell = 1$; and $H(w) = D_{23}$, for $\ell = 2$ in Figure 12. Define $\tilde{M} \equiv M - \mathrm{diag}(M)$, and let $\odot$ denote the Hadamard product of two matrices. We have,

$$\sum_{w \neq w' \in \mathcal{H}_{k,1} : |w \cap w'| = 2} \omega_M(w)\omega_M(w') \;=\; (1/4) \sum_{i,j \in [d]} \Big(\big(\tilde{M}^2 \odot \tilde{M}^2 - (\tilde{M} \odot \tilde{M})^2\big) \odot (\tilde{M} \odot \tilde{M}) \Big)_{i,j} \quad (57)$$

Let's denote the quantity in (57) by C_1, we have,

$$\begin{aligned} &\sum_{w \neq w' \in \mathcal{H}_{k,1} : |w \cap w'| = 1} \omega_M(w)\omega_M(w') \\ &= \; (1/8) \sum_{i \in [d]} \Big(\mathrm{diag}(\tilde{M}^3) \odot \mathrm{diag}(\tilde{M}^3) - 2\mathrm{diag}((\tilde{M} \odot \tilde{M})^3) \Big)_i - 2C_1 \,. \end{aligned} \quad (58)$$

It is easy to verify Equation (56) for $k = 3$ and $\ell \in \{1, 2\}$ using the fact that M is a μ incoherent symmetric matrix with its off-diagonals bounded by $\mu\sigma_{\max}(\sqrt{r}/d)$. For $\ell = 0$, quantity in (56) is the sum of each pair of disjoint triangles. For sum of all triangles, we have,

$$\sum_{w \in \mathcal{H}_{k,1}} \omega_M(w) = (1/6) \sum_{i \in [d]} \Big(\mathrm{diag}(\tilde{M}^3) \Big)_i \;\leq\; (\mu\sigma_{\max})^3 r \,. \quad (59)$$

Using Equations (57), (58) and (59), bound for $\ell = 0$ follows immediately. Bound for $\ell = k$, follows by using the fact that $M_{i,j} \leq \mu\sigma_{\max}(\sqrt{r}/d)$ for $i \neq j \in [d]$.

9. k-cyclic pseudographs

We provide an enumeration of all k-cyclic psuedographs for $k \in \{4, 5, 6, 7\}$ in Figures (10–15).

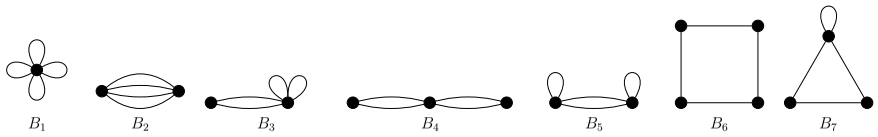

Figure 10: The 4-cyclic pseudographs $\mathcal{H}_4$.

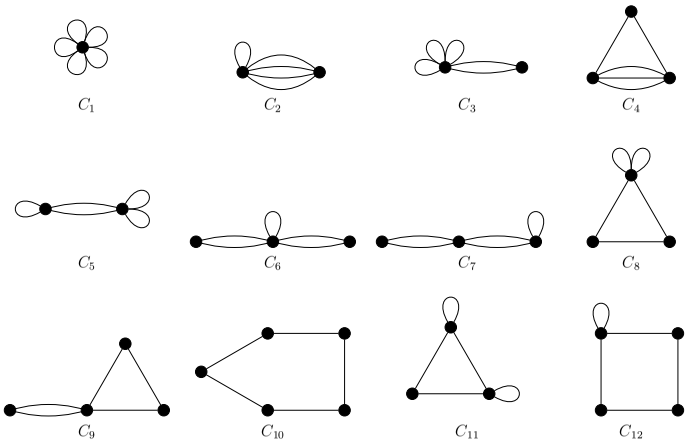

Figure 11: The 5-cyclic pseudographs $\mathcal{H}_5$.

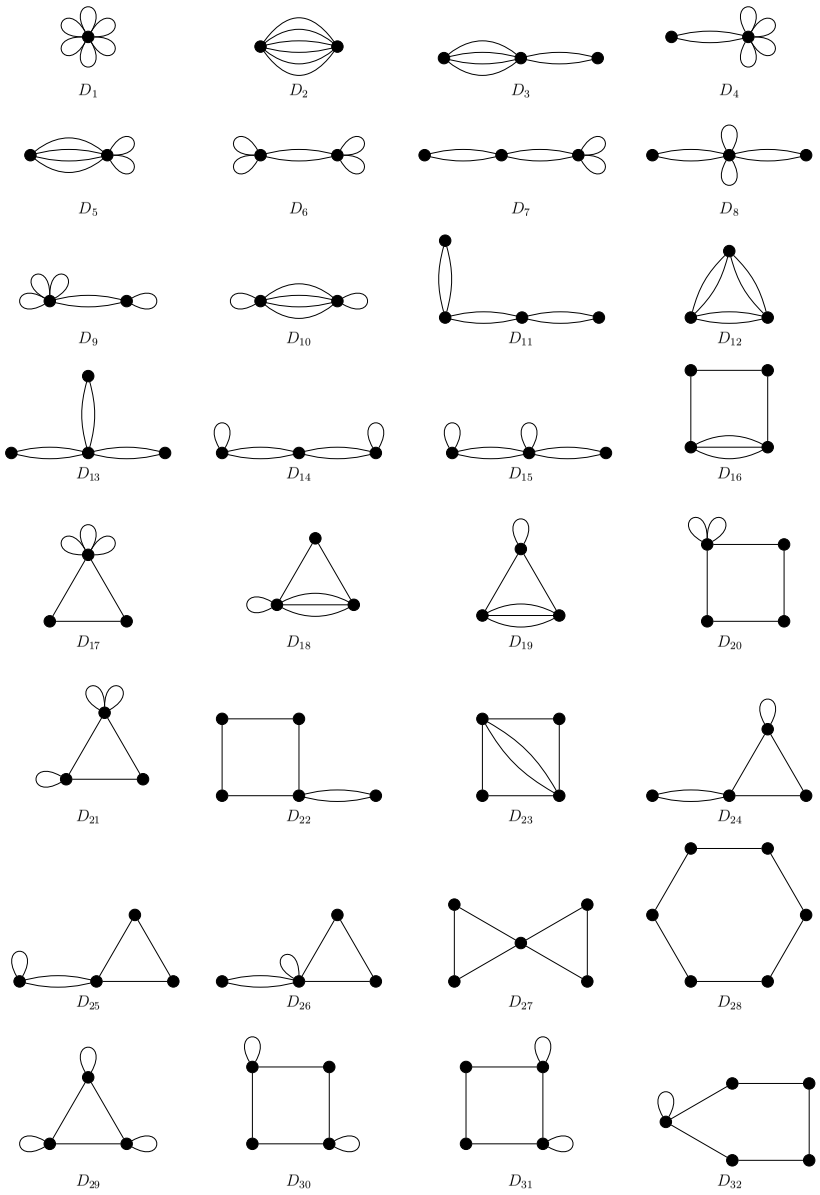

Figure 12: The 6-cyclic pseudographs $\mathcal{H}_6$.

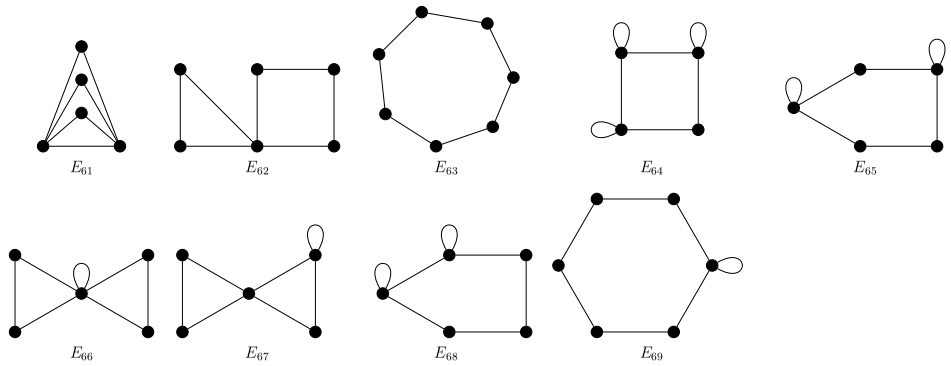

Figure 15: The 7-cyclic pseudographs $\mathcal{H}_7$.

10. Efficient computation of $\omega_M(H)$ for $k \in \{4,5,6,7\}$

In this section we provide the complete matrix oeprations for copmuting $\gamma_M(H)$'s. Equations (60) - (66) give expressions to compute $\gamma_M(H)$ for $H \in \mathcal{H}_4$ as labeled in Figure 10. Equations (67) - (78) give expressions to compute $\gamma_M(H)$ for $H \in \mathcal{H}_5$ as labeled in Figure 11. Equations (79) - (110) give expressions to compute $\gamma_M(H)$ for $H \in \mathcal{H}_6$ as labeled in Figure 12. Equations (111) - (203) give expressions to compute $\gamma_M(H)$ for $H \in \mathcal{H}_7$ as labeled in Figure 15.

For brevity of notations and readability, we define the following additional notations. Let $A \odot B$ denote the Hadamard product. For $A \in \mathbb{R}^{d\times d}$, let $\mathrm{sum}(A)$ denote a vector $v \in \mathbb{R}^d$ such that $v_i = \sum_{j\in[d]} A_{i,j}$. With a slight abuse of notation, for $v \in \mathbb{R}^d$, let $\mathrm{sum}(v)$ denote sum of all elements of v that is $\mathrm{sum}(v) = \sum_{i\in[d]} v_i$. Let $\mathrm{sum}(\gamma_M(H_i) : \gamma_M(H_j)) \equiv \sum_{i'=i}^{j} \gamma_M(H_{i'})$. Define $R \equiv \mathbb{1}_{d\times d} - \mathrm{diag}(\mathbb{1}_{d\times d})$, that is R is an all-ones matrix except on diagonals which are zeros. Further, for brevity, we omit the subscript M from the notations $\gamma_M(H), O_M$ and D_M.

$$\gamma(B_1) = \mathrm{sum}(\mathrm{sum}(D \odot D \odot D \odot D)) \tag{60}$$
$$\gamma(B_2) = \mathrm{sum}(\mathrm{sum}(O \odot O \odot O \odot O)) \tag{61}$$
$$\gamma(B_3) = 4\,\mathrm{tr}(O*O*D*D) \tag{62}$$
$$\gamma(B_4) = 2\,\mathrm{sum}(\mathrm{sum}((O \odot O)*(O \odot O) \odot R)) \tag{63}$$
$$\gamma(B_5) = 2\,\mathrm{tr}(O*D*O*D) \tag{64}$$
$$\gamma(B_6) = \mathrm{tr}(O*O*O*O) - \mathrm{sum}(\gamma(B_2) : \gamma(B_4)) \tag{65}$$
$$\gamma(B_7) = \mathrm{tr}(M*M*M*M) - \mathrm{sum}(\gamma(B_1) : \gamma(B_6)) \tag{66}$$

$$\gamma(C_1) = \operatorname{tr}(D \odot D \odot D \odot D \odot D) \tag{67}$$
$$\gamma(C_2) = 5\ \operatorname{sum}(\operatorname{sum}(D * O \odot O \odot O \odot O)) \tag{68}$$
$$\gamma(C_3) = 5\ \operatorname{sum}(\operatorname{sum}((D \odot D \odot D) * (O \odot O))) \tag{69}$$
$$\gamma(C_4) = 5\ \operatorname{tr}((O \odot O \odot O) * O * O) \tag{70}$$
$$\gamma(C_5) = 5\ \operatorname{sum}(\operatorname{sum}(D * (O \odot O) * (D \odot D))) \tag{71}$$
$$\gamma(C_6) = 5\ \operatorname{sum}(\operatorname{sum}(((O \odot O) * D * (O \odot O)) \odot R)) \tag{72}$$
$$\gamma(C_7) = 5\ \operatorname{sum}(\operatorname{sum}((D * (O \odot O) * (O \odot O)) \odot R)) \tag{73}$$
$$\gamma(C_8) = 5\ \operatorname{tr}(O * O * O * (D \odot D)) \tag{74}$$
$$\gamma(C_9) = 5\ \operatorname{sum}(\operatorname{diag}(O \odot O \odot O) \odot \operatorname{sum}(O \odot O)) - 10\ \operatorname{tr}((O \odot O \odot O) * O * O)) \tag{75}$$
$$\gamma(C_{10}) = \operatorname{tr}(O * O * O * O * O) - \gamma(C_4) - \gamma(C_9) \tag{76}$$
$$\gamma(C_{11}) = 5\ \operatorname{tr}(O * D * O * D * O) \tag{77}$$

Abstract

Kernel-based methods exhibit well-documented performance in various nonlinear learning tasks. Most of them rely on a preselected kernel, whose prudent choice presumes task-specific prior information. Especially when the latter is not available, multi-kernel learning has gained popularity thanks to its flexibility in choosing kernels from a prescribed kernel dictionary. Leveraging the random feature approximation and its recent orthogonality-promoting variant, the present contribution develops a scalable multi-kernel learning scheme (termed Raker) to obtain the sought nonlinear learning function 'on the fly,' first for static environments. To further boost performance in dynamic environments, an adaptive multi-kernel learning scheme (termed AdaRaker) is developed. AdaRaker accounts not only for data-driven learning of kernel combination, but also for the unknown dynamics. Performance is analyzed in terms of both static and dynamic regrets. AdaRaker is uniquely capable of tracking nonlinear learning functions in environments with unknown dynamics, and with with analytic performance guarantees. Tests with synthetic and real datasets are carried out to showcase the effectiveness of the novel algorithms.[1]

Keywords: Online learning, reproducing kernel Hilbert space, multi-kernel learning, random features, dynamic and adversarial environments.

1. Introduction

Function approximation emerges in various learning tasks such as regression, classification, clustering, dimensionality reduction, as well as reinforcement learning (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004; Dai et al., 2017). Among them, the emphasis here is placed on supervised functional learning tasks: given samples $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)\}_{t=1}^T$ with $\mathbf{x}_t \in \mathbb{R}^d$ and $y_t \in \mathbb{R}$, the goal is to find a function $f(\cdot)$ such that the discrepancy between each pair of y_t and $f(\mathbf{x}_t)$ is minimized. Typically, such discrepancy is measured by a cost function $\mathcal{C}(f(\mathbf{x}_t), y_t)$, which requires to find $f(\cdot)$ minimizing $\sum_{t=1}^T \mathcal{C}(f(\mathbf{x}_t), y_t)$. While this goal is too ambitious to achieve in general, the problem becomes tractable when $f(\cdot)$ is assumed to belong to a reproducing kernel Hilbert space (RKHS) induced by a kernel (Schölkopf and Smola, 2002). Comparable to deep neural networks, functions defined in RKHS can model highly nonlinear relationship, and thus kernel-based methods have well-documented merits for principled function approximation. Despite their popularity, most kernel methods rely on a single pre-selected kernel. Yet, multi-kernel learning (MKL) is more powerful, thanks to its data-driven kernel selection from a given dictionary; see e.g., (Shawe-Taylor and Cristianini, 2004; Rakotomamonjy et al., 2008; Cortes et al., 2009; Gönen and Alpaydın, 2011), and (Bazerque and Giannakis, 2013).

In addition to the attractive representation power that can be afforded by kernel methods, several learning tasks are also expected to be performed in an online fashion. Such a need naturally arises when the data arrive sequentially, such as those in online spam detection (Ma et al., 2009), and time series prediction (Richard et al., 2009); or, when the sheer volume of data makes it impossible to carry out data analytics in batch form (Kivinen et al., 2004). This motivates well online kernel-based learning methods that inherit the merits of their batch counterparts, while at the same time allowing efficient online implementation. Taking a step further, the optimal function may itself change over time in environments with *unknown dynamics*. This is the case when the function of interest e.g., represents the state in brain graphs, or, captures the temporal processes propagating over time-varying networks. Especially when variations are due to adversarial interventions, the underlying dynamics are unknown. Online kernel-based learning in such environments remains a largely uncharted territory (Kivinen et al., 2004; Hoi et al., 2013).

In accordance with these needs and desiderata, the *goal* of this paper is an algorithmic pursuit of scalable online MKL in environments with unknown dynamics, along with their associated performance guarantees. Major challenges come from two sources: i) the well-known "curse" of dimensionality in kernel-based learning; and, ii) the defiance of tracking unknown time-varying functions without future information. Regarding i), the representer theorem renders the size of kernel matrices to grow quadratically with the number of data (Wahba, 1990), thus the computational complexity to find even a *single* kernel-based predictor is cubic. Furthermore, storage of past data causes memory overflow in large-scale learning tasks such as those emerging in e.g., topology identification of social and brain networks (Shen et al., 2016, 2017; Shen and Giannakis, 2018), which makes kernel-based methods less scalable relative to their linear counterparts. For ii), most online learning settings presume time invariance or slow dynamics, where an algorithm achieving sub-linear regret incurs on average "no-regret" relative to the *best static* benchmark. Clearly, designing online schemes that are comparable to the *best dynamic* solution is appealing though formidably challenging without knowledge of the dynamics (Kivinen et al., 2004).

1.1. Related works

To put our work in context, we review prior art from the following two aspects.

Batch kernel methods. Kernel methods are known to suffer from the growing dimensionality in large-scale learning tasks (Shawe-Taylor and Cristianini, 2004). Major efforts have been devoted to scaling up kernel methods in batch settings. Those include approaches to approximating the kernel matrix using low-rank factorizations (Williams and Seeger, 2001; Sheikholeslami et al., 2018), whose performance was analyzed in (Cortes et al., 2010). Recently, random feature (RF) based function estimators have gained popularity since the work of (Rahimi and Recht, 2007) and (Dai et al., 2014), whose variance has been con-

1. Preliminary results in this paper were presented in part at the 2018 International Conference on Artificial Intelligence and Statistics (Shen et al., 2018).

siderably reduced through an *orthogonality promoting* RF modification (Yu et al., 2016). These approaches assume that the kernel is known, a choice crucially dependent on domain knowledge. Enabling kernel selection, several MKL-based approaches have emerged, see e.g., (Lanckriet et al., 2004; Rakotomamonjy et al., 2008; Bach, 2008; Cortes et al., 2009; Gönen and Alpaydm, 2011), and their performance gain has been documented relative to their single kernel counterparts. However, the aforementioned methods are designed for batch settings, and are either intractable or become less efficient in online setups. When the sought functions vary over time and especially when the dynamics are unknown (as in adversarial settings), batch schemes fall short in tracking the optimal function estimators.

Online (multi-)kernel learning. Tailored for streaming large-scale datasets, online kernel-based learning methods have gained due popularity. To deal with the growing complexity of online kernel learning, successful attempts have been made to design *budgeted* kernel learning algorithms, including techniques such as support vector removal (Kivinen et al., 2004; Dekel et al., 2008), and support vector merging (Wang et al., 2012). Maintaining an affordable budget, online multi-kernel learning (OMKL) methods have been reported for online classification (Jin et al., 2010; Hoi et al., 2013; Sahoo et al., 2016), and regression (Sahoo et al., 2014; Lu et al., 2018). Devoid of the need for budget maintenance, online kernel-based learning algorithms based on RF approximation (Rahimi and Recht, 2007) have been developed in (Lu et al., 2016; Bouboulis et al., 2018; Ding et al., 2017), but only with a single pre-selected kernel. More importantly, existing kernel-based learning approaches implicitly presume a *static* environment, where the benchmark is provided through the best static function (a.k.a. static regret) (Shalev-Shwartz, 2011). However, static regret is not a comprehensive metric for dynamic settings, where the optimal kernel also varies over time and the dynamics are generally unknown as with adversarial settings.

1.2. Our contributions

The present paper develops an adaptive online MKL algorithm, capable of learning a nonlinear function from sequentially arriving data samples. Relative to prior art, our contributions can be summarized as follows.

c1) For the first time, RFs are employed for scalable online MKL tackled by a weighted combination of advices from an ensemble of experts - an innovative cross-fertilization of online learning to MKL. Performance of the resultant algorithm (abbreviated as **Raker**) is benchmarked by the best time-invariant function approximant via static regret analysis.

c2) A novel adaptive approach (termed **AdaRaker**) is introduced for scalable online MKL in environments with unknown dynamics. AdaRaker is a hierarchical ensemble learner with scalable RF-based modules that provably yields sub-linear dynamic regret, so long as the accumulated variation grows sub-linearly with time.

c3) The novel algorithms are compared with competing alternatives for online nonlinear regression on both synthetic and real datasets. The tests corroborate that Raker and AdaRaker exhibit attractive performance in both accuracy and scalability.

Outline. Section 2 presents preliminaries, and states the problem. Section 3 develops the Raker for online MKL in static environments, and Section 4 develops its adaptive version for online MKL in environments with unknown dynamics. Section 5 reports numerical tests with both synthetic and real datasets, while conclusions are drawn in Section 6.

Notation. Bold uppercase (lowercase) letters will denote matrices (column vectors), while $(\cdot)^\top$ stands for vector and matrix transposition, and $\|\mathbf{x}\|$ denotes the ℓ_2-norm of a vector $\mathbf{x}$. Inequalities for vectors $\mathbf{x} > \mathbf{0}$, and the projection operator $[\mathbf{a}]^+ := \max\{\mathbf{a}, \mathbf{0}\}$ are defined entrywise. Symbol † represents the Hermitian operator, while the indicator function $\mathbb{1}_{\{A\}}$ takes value 1 when the event A happens, and 0 otherwise. $\mathbb{E}$ denotes the expectation, while $\langle\cdot,\cdot\rangle$ and $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ the vector inner product in Euclidian and Hilbert space respectively.

2. Preliminaries and Problem Statement

This section reviews briefly basics of kernel-based learning, to introduce notation and the needed background for our novel online MKL schemes.

Given samples $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)\}_{t=1}^T$ with $\mathbf{x}_t \in \mathbb{R}^d$ and $y_t \in \mathbb{R}$, the function approximation task is to find a function $f(\cdot)$ such that $y_t = f(\mathbf{x}_t) + e_t$, where e_t denotes an error term representing noise or un-modeled dynamics. It is supposed that $f(\cdot)$ belongs to a reproducing kernel Hilbert space (RKHS), namely $\mathcal{H} := \{f | f(\mathbf{x}) = \sum_{t=1}^\infty \alpha_t \kappa(\mathbf{x}, \mathbf{x}_t)\}$, where $\kappa(\mathbf{x}, \mathbf{x}_t) : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ is a symmetric positive semidefinite basis (so-termed kernel) function, which measures the similarity between $\mathbf{x}$ and $\mathbf{x}_t$. Among the choices of κ specifying different bases, a popular one is the Gaussian given by $\kappa(\mathbf{x}, \mathbf{x}_t) := \exp[-\|\mathbf{x}-\mathbf{x}_t\|^2/(2\sigma^2)]$. A kernel is reproducing if it satisfies $\langle \kappa(\mathbf{x}, \mathbf{x}_t), \kappa(\mathbf{x}, \mathbf{x}_{t'})\rangle_{\mathcal{H}} = \kappa(\mathbf{x}_t, \mathbf{x}_{t'})$, which in turn induces the RKHS norm $\|f\|_{\mathcal{H}}^2 := \sum_t \sum_{t'} \alpha_t \alpha_{t'} \kappa(\mathbf{x}_t, \mathbf{x}_{t'})$. Consider the optimization problem

$$\min_{f \in \mathcal{H}} \ \frac{1}{T} \sum_{t=1}^T \mathcal{C}(f(\mathbf{x}_t), y_t) + \lambda \Omega\left(\|f\|_{\mathcal{H}}^2\right) \tag{1}$$

where depending on the application, the cost function $\mathcal{C}(\cdot,\cdot)$ can be selected to be, e.g., the least-squares (LS), the logistic or the hinge loss; $\Omega(\cdot)$ is an increasing function; and, $\lambda > 0$ is a regularization parameter that controls overfitting. According to the representer theorem, the optimal solution of (1) admits the finite-dimensional form, given by (Wahba, 1990)

$$\hat{f}(\mathbf{x}) = \sum_{t=1}^T \alpha_t \kappa(\mathbf{x}, \mathbf{x}_t) := \boldsymbol{\alpha}^\top \mathbf{k}(\mathbf{x}) \tag{2}$$

where $\boldsymbol{\alpha} := [\alpha_1, \ldots, \alpha_T]^\top \in \mathbb{R}^T$ collects the combination coefficients, and the $T \times 1$ kernel vector is $\mathbf{k}(\mathbf{x}) := [\kappa(\mathbf{x}, \mathbf{x}_1), \ldots, \kappa(\mathbf{x}, \mathbf{x}_T)]^\top$. Substituting (2) into the RKHS norm, we find $\|f\|_{\mathcal{H}}^2 := \sum_t \sum_{t'} \alpha_t \alpha_{t'} \kappa(\mathbf{x}_t, \mathbf{x}_{t'}) = \boldsymbol{\alpha}^\top \mathbf{K} \boldsymbol{\alpha}$, where the $T \times T$ kernel matrix $\mathbf{K}$ has entries $[\mathbf{K}]_{t,t'} := \kappa(\mathbf{x}_t, \mathbf{x}_{t'})$; thus, the functional problem (1) boils down to a T-dimensional optimization over $\boldsymbol{\alpha}$, namely

$$\min_{\boldsymbol{\alpha} \in \mathbb{R}^T} \ \frac{1}{T} \sum_{t=1}^T \mathcal{C}(\boldsymbol{\alpha}^\top \mathbf{k}(\mathbf{x}_t), y_t) + \lambda \Omega\left(\boldsymbol{\alpha}^\top \mathbf{K} \boldsymbol{\alpha}\right) \tag{3}$$

where $\mathbf{k}^\top(\mathbf{x}_t)$ is the tth row of the matrix $\mathbf{K}$. While a scalar y_t is used here for brevity, coverage extends readily to vectors $\{\mathbf{y}_t\}$.

Note that (1) relies on: i) a known pre-selected kernel κ; and ii) having $\{\mathbf{x}_t, y_t\}_{t=1}^T$ available in batch form. A key observation here is that the dimension of the variable $\boldsymbol{\alpha}$ in

(3) grows with time T (or, the number of samples in the batch form), making it less scalable in online implementation. In the ensuing section, an online MKL method will be proposed to select κ as a superposition of multiple kernels, when the data become available online.

3. Online MKL in static environments

In this section, we develop an online learning approach that builds on the notion of **ra**ndom features (Rahimi and Recht, 2007; Yu et al., 2016), and leverages in a unique way multi-**ker**nel approximation – two tools justifying our acronym **Raker** used henceforth.

3.1. RF-based single kernel learning

To cope with the curse of dimensionality in optimizing (3), we will reformulate the functional optimization problem (1) as a parametric one with the dimension of optimization variables not growing with time. In this way, powerful toolboxes from convex optimization and online learning in vector spaces can be leveraged. We achieve this goal by judiciously using RFs. Although generalizations will follow, this subsection is devoted to RF-based single kernel learning, where basics of kernels, RFs, and online learning will be revisited.

As in (Rahimi and Recht, 2007), we will approximate κ in (2) using shift-invariant kernels that satisfy $\kappa(\mathbf{x}_t,\mathbf{x}_{t'})=\kappa(\mathbf{x}_t-\mathbf{x}_{t'})$. For $\kappa(\mathbf{x}_t-\mathbf{x}_{t'})$ absolutely integrable, its Fourier transform $\pi_\kappa(\mathbf{v})$ exists and represents the power spectral density, which upon normalizing to ensure $\kappa(\mathbf{0})=1$, can also be viewed as a probability density function (pdf); hence,

$$\kappa(\mathbf{x}_t-\mathbf{x}_{t'})=\int \pi_\kappa(\mathbf{v})e^{j\mathbf{v}^\top(\mathbf{x}_t-\mathbf{x}_{t'})}d\mathbf{v}:=\mathbb{E}_{\mathbf{v}}\left[e^{j\mathbf{v}^\top(\mathbf{x}_t-\mathbf{x}_{t'})}\right] \tag{4}$$

where the last equality is just the definition of the expected value. Drawing a sufficient number of D independent and identically distributed (i.i.d.) samples $\{\mathbf{v}_i\}_{i=1}^D$ from $\pi_\kappa(\mathbf{v})$, the ensemble mean in (4) can be approximated by the sample average

$$\hat{\kappa}_c(\mathbf{x}_t,\mathbf{x}_{t'}):=\frac{1}{D}\sum_{i=1}^{D}e^{j\mathbf{v}_i^\top(\mathbf{x}_t-\mathbf{x}_{t'})}:=\boldsymbol{\zeta}_{\mathbf{V}}^\dagger(\mathbf{x}_t)\boldsymbol{\zeta}_{\mathbf{V}}(\mathbf{x}_{t'}) \tag{5}$$

where $\mathbf{V}:=[\mathbf{v}_1,\ldots,\mathbf{v}_D]^\top\in\mathbb{R}^{D\times d}$, symbol $\dagger$ represents the Hermitian (conjugate-transpose) operator, and $\boldsymbol{\zeta}_{\mathbf{V}}(\mathbf{x})$ the complex RF vector

$$\boldsymbol{\zeta}_{\mathbf{V}}(\mathbf{x}):=\frac{1}{\sqrt{D}}\left[e^{j\mathbf{v}_1^\top\mathbf{x}},\ldots,e^{j\mathbf{v}_D^\top\mathbf{x}}\right]^\top. \tag{6}$$

Taking expected values on both sides of (5) and using (4) yields $\mathbb{E}_{\mathbf{v}}[\hat{\kappa}_c(\mathbf{x}_t,\mathbf{x}_{t'})]=\kappa(\mathbf{x}_t,\mathbf{x}_{t'})$, which means $\hat{\kappa}_c$ is unbiased. Likewise, $\hat{\kappa}_c$ can be shown consistent since $\mathbb{V}\text{ar}[\hat{\kappa}_c(\mathbf{x}_t,\mathbf{x}_{t'})]\propto D^{-1}$ vanishes as $D\to\infty$. Finding $\pi_\kappa(\mathbf{v})$ requires d-dimensional Fourier transform of κ, generally through numerical integration. For a number of popular kernels however, $\pi_\kappa(\mathbf{v})$ is available in closed form. Taking the Gaussian kernel as an example, where $\kappa_G(\mathbf{x}_t,\mathbf{x}_{t'})=\exp\left(\|\mathbf{x}_t-\mathbf{x}_{t'}\|_2^2/(2\sigma^2)\right)$, has Fourier transform corresponding to the pdf $\pi_G(\mathbf{v})=\mathcal{N}(0,\sigma^{-2}\mathbf{I})$.

Instead of the *complex* RFs $\{\boldsymbol{\zeta}_{\mathbf{V}}(\mathbf{x}_t)\}$ in (6) forming the linear kernel estimator $\hat{\kappa}_c$ in (5), one can consider its real part $\hat{\kappa}(\mathbf{x}_t,\mathbf{x}_{t'}):=\Re\{\hat{\kappa}_c(\mathbf{x}_t,\mathbf{x}_{t'})\}$ that is also an unbiased estimator

of κ. Defining the real RF vector $\mathbf{z}_{\mathbf{V}}(\mathbf{x}):=[\Re^\top\{\boldsymbol{\zeta}_{\mathbf{V}}(\mathbf{x}_t)\},\Im^\top\{\boldsymbol{\zeta}_{\mathbf{V}}(\mathbf{x}_t)\}]^\top$, this real kernel estimator becomes (cf. (5))

$$\hat{\kappa}(\mathbf{x}_t,\mathbf{x}_{t'})=\mathbf{z}_{\mathbf{V}}^\top(\mathbf{x}_t)\mathbf{z}_{\mathbf{V}}(\mathbf{x}_{t'}) \tag{7}$$

where the $2D\times 1$ *real* RF vector can be written as

$$\mathbf{z}_{\mathbf{V}}(\mathbf{x})=\frac{1}{\sqrt{D}}\left[\sin(\mathbf{v}_1^\top\mathbf{x}),\ldots,\sin(\mathbf{v}_D^\top\mathbf{x}),\cos(\mathbf{v}_1^\top\mathbf{x}),\ldots,\cos(\mathbf{v}_D^\top\mathbf{x})\right]^\top. \tag{8}$$

Hence, the nonlinear function that is optimal in the sense of (1) can be approximated by a linear one in the new $2D$-dimensional RF space, namely (cf. (2) and (7))

$$\hat{f}^{\text{RF}}(\mathbf{x})=\sum_{t=1}^{T}\alpha_t\mathbf{z}_{\mathbf{V}}^\top(\mathbf{x}_t)\mathbf{z}_{\mathbf{V}}(\mathbf{x}):=\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}) \tag{9}$$

where $\boldsymbol{\theta}^\top:=\sum_{\tau=1}^{T}\alpha_\tau\mathbf{z}_{\mathbf{V}}^\top(\mathbf{x}_\tau)$ is the new weight vector of size $2D$ whose dimension does not increase with number of data samples T.

While the solution $\hat{f}$ in (2) is the superposition of nonlinear functions κ, its RF approximant $\hat{f}^{\text{RF}}$ in (9) is a linear function of $\mathbf{z}_{\mathbf{V}}(\mathbf{x})$. As a result, the loss becomes

$$\mathcal{L}_t\big(f(\mathbf{x}_t)\big):=\mathcal{C}(f(\mathbf{x}_t),y_t)+\lambda\Omega\left(\|f\|_{\mathcal{H}}^2\right)=\mathcal{C}\left(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t\right)+\lambda\Omega\left(\|\boldsymbol{\theta}\|^2\right) \tag{10}$$

where $\|\boldsymbol{\theta}\|^2:=\sum_t\sum_{t'}\alpha_t\alpha_{t'}\mathbf{z}_{\mathbf{V}}^\top(\mathbf{x}_t)\mathbf{z}_{\mathbf{V}}(\mathbf{x}_{t'}):=\|f\|_{\mathcal{H}}^2$; and the online learning task is

$$\min_{\boldsymbol{\theta}\in\mathbb{R}^{2D}}\sum_{t=1}^{T}\mathcal{L}\left(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t\right),\ \text{with}\ \mathcal{L}\big(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t\big):=\mathcal{C}\big(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t\big)+\lambda\Omega\big(\|\boldsymbol{\theta}\|^2\big). \tag{11}$$

Compared with the functional optimization in (1), the reformulated problem (11) is parametric, and more importantly it involves only optimization variables of fixed size $2D$. We can thus solve (11) using the online gradient descent iteration, e.g., (Hazan, 2016). Acquiring $\mathbf{x}_t$ per slot t, its RF $\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t)$ is formed as in (8), and $\boldsymbol{\theta}_{t+1}$ is updated online as

$$\boldsymbol{\theta}_{t+1}=\boldsymbol{\theta}_t-\eta_t\nabla\mathcal{L}(\boldsymbol{\theta}_t^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t) \tag{12}$$

where $\{\eta_t\}$ is the sequence of stepsizes that can tune learning rates, and $\nabla\mathcal{L}(\boldsymbol{\theta}_t^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t)$ the gradient at $\boldsymbol{\theta}=\boldsymbol{\theta}_t$. Iteration (12) provides *a functional update* since $\hat{f}_t^{\text{RF}}(\mathbf{x})=\boldsymbol{\theta}_t^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x})$, but the upshot of involving RFs is that this approximant is in the span of $\{\mathbf{z}_{\mathbf{V}}(\mathbf{x}),\forall\mathbf{x}\in\mathcal{X}\}$. Since $\mathbb{E}[\hat{\kappa}]=\kappa$, we find readily that $\mathbb{E}[\hat{f}^{\text{RF}}]=\hat{f}$; in words, unbiasedness of the kernel approximation ensures that the RF-based function approximant is also unbiased.

Variance-reduced RF. Besides unbiasedness, performance of the RF approximation is also influenced by the variance of RFs. Note that the variance of $\hat{\kappa}$ in (7) is of order $\mathcal{O}(D^{-1})$, but its scale can be reduced if $\mathbf{V}$ is formed to have orthogonal rows (Yu et al., 2016). Specifically for a Gaussian kernel with bandwidth σ^2, recall that $\mathbf{V}=\sigma^{-1}\mathbf{G}$ in (8), where each entry of $\mathbf{G}$ is drawn from $\mathcal{N}(0,1)$. For the variance-reduced orthogonal (O)RF

with $D = d$, one starts with Q-R factorization of $\mathbf{V} = \mathbf{QR}$, and uses the $d \times d$ factor $\mathbf{Q}$ along with a diagonal matrix $\mathbf{\Lambda}$, to form (Yu et al., 2016)

$$\mathbf{V}_{\text{ORF}} = \sigma^{-1}\,\mathbf{\Lambda Q} \tag{13}$$

where the diagonal entries of $\mathbf{\Lambda}$ are drawn i.i.d. from the χ distribution with d degrees of freedom, to ensure unbiasedness of the kernel approximant. For $D > d$, one selects $D = \nu d$ with $\nu > 1$ integer, and generates independently ν matrices each of size $d \times d$ as in (13). The final $\mathbf{V}_{\text{ORF}}$ is formed by concatenating these $d \times d$ sub-matrices. The upshot of ORF is that (Yu et al., 2016) $\mathbb{V}\text{ar}(\hat{\kappa}_{\text{ORF}}(\mathbf{x}_t, \mathbf{x}_{t'})) \leq \mathbb{V}\text{ar}(\hat{\kappa}(\mathbf{x}_t, \mathbf{x}_{t'}))$. As we have also confirmed via simulated tests, ORF-based function approximation can attain a prescribed accuracy with considerably less ORFs than what required by its RF-based counterpart.

The RF-based online single kernel learning scheme in this section presumes that κ is known a priori. Since this is not generally possible, it is prudent to adaptively select kernels by superimposing multiple kernel functions from a prescribed dictionary. This superposition will play a key role in the RF-based online MKL approach presented next.

3.2. Raker for online MKL

Specifying the kernel that "shapes" $\mathcal{H}$ is a critical choice for single kernel learning, since different kernels yield function estimates of variable accuracy. To deal with this, combinations of kernels from a prescribed and sufficiently rich dictionary $\{\kappa_p\}_{p=1}^P$ can be employed in (1). Each combination belongs to the convex hull $\bar{\mathcal{K}} := \{\bar{\kappa} = \sum_{p=1}^P \bar{\alpha}_p \kappa_p,\ \bar{\alpha}_p \geq 0,\ \sum_{p=1}^P \bar{\alpha}_p = 1\}$, and is itself a kernel (Schölkopf and Smola, 2002). With $\bar{\mathcal{H}}$ denoting the RKHS induced by $\bar{\kappa} \in \bar{\mathcal{K}}$, one then solves (1) with $\mathcal{H}$ replaced by $\bar{\mathcal{H}} := \mathcal{H}_1 \bigoplus \cdots \bigoplus \mathcal{H}_P$, where $\{\mathcal{H}_p\}_{p=1}^P$ represent the RKHSs corresponding to $\{\kappa_p\}_{p=1}^P$ (Micchelli and Pontil, 2005).

The candidate function $\bar{f} \in \bar{\mathcal{H}}$ is expressible in a separable form as $\bar{f}(\mathbf{x}) := \sum_{p=1}^P \bar{f}_p(\mathbf{x})$, where $\bar{f}_p(\mathbf{x})$ belongs to $\mathcal{H}_p$, for $p \in \mathcal{P} := \{1, \ldots, P\}$. To add flexibility per kernel in our ensuing online MKL scheme, we let wlog $\{\bar{f}_p = w_p f_p\}_{p=1}^P$, and seek functions of the form

$$f(\mathbf{x}) := \sum_{p=1}^P \bar{w}_p f_p(\mathbf{x}) \in \bar{\mathcal{H}} \tag{14}$$

where $f := \bar{f} / \sum_{p=1}^P w_p$, and the normalized weights $\{\bar{w}_p := w_p / \sum_{p=1}^P w_p\}_{p=1}^P$ satisfy $\bar{w}_p \geq 0$, and $\sum_{p=1}^P \bar{w}_p = 1$. Plugging (14) into (1), MKL solves the nonconvex problem

$$\min_{\{\bar{w}_p\},\{f_p\}} \ \frac{1}{T}\sum_{t=1}^T \mathcal{C}\left(\sum_{p=1}^P \bar{w}_p f_p(\mathbf{x}_t), y_t\right) + \lambda\Omega\left(\left\|\sum_{p=1}^P \bar{w}_p f_p\right\|_{\bar{\mathcal{H}}}^2\right) \tag{15a}$$

$$\text{s. to} \quad \sum_{p=1}^P \bar{w}_p = 1,\ \bar{w}_p \geq 0,\ p \in \mathcal{P} \tag{15b}$$

$$f_p \in \mathcal{H}_p,\ p \in \mathcal{P}. \tag{15c}$$

If Ω is convex over f, then (15a) is biconvex, meaning it is convex wrt $\{f_p\}$ ($\{\bar{w}_p\}$) when $\{\bar{w}_p\}$ ($\{f_p\}$) is given. Leveraging biconvexity, existing batch MKL schemes solve (15) via

alternating minimization that is known not to scale well with P and T (Micchelli and Pontil, 2005; Cortes et al., 2009; Gönen and Alpaydın, 2011).

To deal with scalability, our novel approach will leverage for the first time (O)RFs in a uniquely principled MKL formulation to end up with an efficient online learning approach. To this end, we will minimize a cost that upper bounds that in (15a), namely

$$\min_{\{\bar{w}_p\},\{f_p\}} \ \frac{1}{T}\sum_{t=1}^T\sum_{p=1}^P \bar{w}_p \mathcal{C}\left(f_p(\mathbf{x}_t), y_t\right) + \lambda\sum_{p=1}^P \bar{w}_p\,\Omega\left(\|f_p\|_{\mathcal{H}_p}^2\right) \quad \text{s. to (15b) and (15c)} \tag{16}$$

where Jensen's inequality confirms that under (15b) the cost in (16) upper bounds that of (15a). A key advantage of (16) is that its objective is separable across kernel 'atoms.'

We will exploit this separability jointly with the RF-based function approximation per kernel, to formulate our scalable online MKL task as

$$\min_{\{\bar{w}_p\},\{\hat{f}_p^{\text{RF}}\}} \sum_{t=1}^T\sum_{p=1}^P \bar{w}_p\,\mathcal{L}_t\left(\hat{f}_p^{\text{RF}}(\mathbf{x}_t)\right) \quad \text{s. to (15b) and } \hat{f}_p^{\text{RF}} \in \left\{\hat{f}_p(\mathbf{x}) = \boldsymbol{\theta}^\top \mathbf{z}_{\mathbf{V}_p}(\mathbf{x})\right\} \tag{17}$$

where we interchangeably use $\mathcal{L}_t(\hat{f}(\mathbf{x}_t))$ as defined in (10) and $\mathcal{L}\big(\boldsymbol{\theta}^\top \mathbf{z}_{\mathbf{V}}(\mathbf{x}_t), y_t\big)$ as in (11). We will efficiently solve (17) 'on-the-fly' using our Raker algorithm, and what more, we will provide analytical performance guarantees. Our iterative solution will update separately each $\hat{f}_p^{\text{RF}}$ as in Section 3.1 using the scalable (O)RF-based function approximation scheme. Given $\mathbf{x}_t$, an RF vector $\mathbf{z}_p(\mathbf{x}_t)$ will be generated per p from pdf $\pi_{\kappa_p}(\mathbf{v})$ (cf. (8)), where we let $\mathbf{z}_p(\mathbf{x}_t) := \mathbf{z}_{\mathbf{V}_p}(\mathbf{x}_t)$ for notational brevity. Hence, for each p and slot t, we have

$$\hat{f}_{p,t}^{\text{RF}}(\mathbf{x}_t) = \boldsymbol{\theta}_{p,t}^\top \mathbf{z}_p(\mathbf{x}_t) \tag{18}$$

and as in (12), $\boldsymbol{\theta}_{p,t}$ is updated via

$$\boldsymbol{\theta}_{p,t+1} = \boldsymbol{\theta}_{p,t} - \eta\nabla\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top \mathbf{z}_p(\mathbf{x}_t), y_t). \tag{19}$$

As far as solving for $\bar{w}_{p,t}$, since it resides on a probability simplex (15b), our idea is to employ a multiplicative update (a.k.a. exponentiated gradient descent), e.g., (Hazan, 2016). Specifically, the un-normalized weights are found first as

$$w_{p,t+1} = \arg\min_{w_p}\ \eta\,\mathcal{L}_t\left(\hat{f}_{p,t}^{\text{RF}}(\mathbf{x}_t)\right)(w_p - w_{p,t}) + \mathcal{D}_{\text{KL}}(w_p \| w_{p,t}) \tag{20}$$

where $\mathcal{D}_{\text{KL}}(w_p \| w_{p,t}) := w_p \log(w_p / w_{p,t})$ is the KL-divergence. It can be readily verified that (20) admits the following closed-form update

$$w_{p,t+1} = w_{p,t} \exp\left(-\eta\mathcal{L}_t\left(\hat{f}_{p,t}^{\text{RF}}(\mathbf{x}_t)\right)\right) \tag{21}$$

where $\eta \in (0, 1)$ is a chosen constant that controls the adaptation rate of $\{w_{p,t}\}$. Having found $\{w_{p,t}\}$ as in (21), the normalized weights in (14) are obtained as $\bar{w}_{p,t} := w_{p,t} / \sum_{p=1}^P w_{p,t}$. Update (21) is intuitively pleasing because when $\hat{f}_{p,t}^{\text{RF}}$ contributes a larger loss relative to other $\hat{f}_{p',t}^{\text{RF}}$ with $p' \neq p$ at slot t, the corresponding $w_{p,t+1}$ decreases more than the other

Algorithm 1 Raker for online MKL in static environments

Input: Kernels $\kappa_p,\ p=1,\ldots,P$, step size $\eta>0$, and number of random features D.
Initialization: $\boldsymbol{\theta}_1=\mathbf{0}$.
for $t=1,2,\ldots,T$ **do**
  Receive a streaming datum $\mathbf{x}_t$.
  Construct $\mathbf{z}_p(\mathbf{x}_t)$ via (8) using κ_p for $p=1,\ldots,P$.
  Predict $\hat{f}_t^{\mathrm{RF}}(\mathbf{x}_t):=\sum_{p=1}^P \bar{w}_{p,t}\hat{f}_{p,t}^{\mathrm{RF}}(\mathbf{x}_t)$ with $\hat{f}_{p,t}^{\mathrm{RF}}(\mathbf{x}_t)$ in (18).
  Observe loss function $\mathcal{L}_t$, incur $\mathcal{L}_t(\hat{f}_t^{\mathrm{RF}}(\mathbf{x}_t))$.
  for $p=1,\ldots,P$ **do**
    Obtain loss $\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)$ or $\mathcal{L}_t(\hat{f}_{p,t}^{\mathrm{RF}}(\mathbf{x}_t))$.
    Update $\boldsymbol{\theta}_{p,t+1}$ via (19).
    Update $w_{p,t+1}$ via (21).
  end for
end for

weights in the next time slot. In other words, a more accurate RF-based approximant tends to play more important role in predicting the upcoming data.

Remark 1. The update (21) resembles the online learning paradigm, a.k.a. *online prediction with* (weighted) *expert advices* (Vovk, 1995; Cesa-Bianchi and Lugosi, 2006). Building on but going beyond OMKL in (Sahoo et al., 2014), the idea here is to view MKL with *RF-based function approximants* as a weighted combination of advices from an ensemble of P function approximants (experts). Besides permeating benefits from online learning to MKL, what is distinct here relative to (Vovk, 1995; Cesa-Bianchi and Lugosi, 2006) is that each function approximant also performs online learning for self improvement (cf. (19)).

In summary, our Raker for static (or slow-varying) dynamics is listed as Algorithm 1.

Memory requirement and computational complexity. At the t-th iteration, our Raker in Algorithm 1 needs to store a real $2D$ RF vector, and its corresponding weight vector per κ_p. Hence, the memory required is of order $\mathcal{O}(dDP)$. Regarding computational overhead, the per-iteration complexity (e.g., calculating inner products) is again of order $\mathcal{O}(dDP)$. Compared with the complexity of $\mathcal{O}(tdP)$ for OMKL by (Sahoo et al., 2014), or, $\mathcal{O}(t^3P)$ when matrix inversion required for the batch MKL, e.g., (Bazerque and Giannakis, 2013), the Raker is clearly more scalable, as t grows. Even when OMKL is confined to a budget of B past samples, the corresponding complexity of $\mathcal{O}(dBP)$ is comparable to that of Raker. This speaks for Raker's merits, whose performance guarantees will be proved analytically, and also demonstrated by numerical tests to outperform budgeted schemes.

Application examples: Online MKL regression and classification. To appreciate the usefulness of RF-based online MKL, consider first nonlinear regression, where given samples $\{\mathbf{x}_t\in\mathbb{R}^d, y_t\in\mathbb{R}\}_{t=1}^T$, the goal is to find a nonlinear function $f\in\mathcal{H}$, such that $y_t=f(\mathbf{x}_t)+e_t$. The criterion is to minimize the regularized prediction error of y_t, typically using the LS loss $\mathcal{L}(f(\mathbf{x}_t),y_t):=[y_t-f(\mathbf{x}_t)]^2+\lambda\|f\|_{\mathcal{H}}^2$, whose gradient is (cf. (19))

$$\nabla\mathcal{L}\left(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t\right)=2(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t)-y_t)\mathbf{z}_p(\mathbf{x}_t)+2\lambda\boldsymbol{\theta}_{p,t}. \tag{22}$$

It is clear that the per iteration complexity of Raker is only related to the dimension of $\mathbf{z}_p(\mathbf{x}_t)$, and does not increase over time.

For nonlinear classification, consider kernel-based perceptron and kernel-based logistic regression, which aim at learning a nonlinear classifier that best approximates either y_t or the pdf of y_t conditioned on $\mathbf{x}_t$. With binary labels $\{\pm1\}$, the perceptron solves (1) with $\mathcal{L}(f(\mathbf{x}_t),y_t)=\max(0,1-y_tf(\mathbf{x}_t))+\lambda\|f\|_{\mathcal{H}}^2$, which equals zero if $y_t=f(\mathbf{x}_t)$, otherwise it equals 1. Raker's gradient in this case is (cf. (19))

$$\nabla\mathcal{L}\left(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t\right)=-2y_t\mathcal{C}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\mathbf{z}_p(\mathbf{x}_t)+2\lambda\boldsymbol{\theta}_{p,t}. \tag{23}$$

Accordingly, given $\mathbf{x}_t$, logistic regression postulates that $\Pr(y_t=1|\mathbf{x}_t)=1/(1+\exp(f(\mathbf{x}_t)))$. Here the gradient of Raker takes the form (cf. (19))

$$\nabla\mathcal{L}\left(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t\right)=\frac{2y_t\exp(y_t\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t))}{1+\exp(y_t\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t))}\mathbf{z}_p(\mathbf{x}_t)+2\lambda\boldsymbol{\theta}_{p,t}. \tag{24}$$

To compare alternatives on equal footing, the numerical tests in Section 5 will deal with kernel-based regression and classification.

3.3. Static regret analysis of Raker

To analyze the performance of Raker, we assume that the following conditions are satisfied.

(as1) *Per slot t, the loss function $\mathcal{L}(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t)$ in (11) is convex w.r.t. $\boldsymbol{\theta}$.*

(as2) *For $\boldsymbol{\theta}$ belonging to a bounded set $\boldsymbol{\Theta}$ with $\|\boldsymbol{\theta}\|\leq C_\theta$, the loss is bounded; that is, $\mathcal{L}(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t)\in[-1,1]$, and has bounded gradient, meaning, $\|\nabla\mathcal{L}(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t),y_t)\|\leq L$.*

(as3) *Kernels $\{\kappa_p\}_{p=1}^P$ are shift-invariant, standardized, and bounded, that is, $\kappa_p(\mathbf{x}_i,\mathbf{x}_j)\leq 1,\ \forall\mathbf{x}_i,\mathbf{x}_j$; and w.l.o.g. they also have bounded entries, meaning $\|\mathbf{x}\|\leq 1$.*

Convexity of the loss under (as1) is satisfied by the popular loss functions including the square loss and the hinge loss. As far as (as2), it ensures that the losses, and their gradients are bounded, meaning they are L-Lipschitz continuous. While boundedness of the losses commonly holds since $\|\boldsymbol{\theta}\|$ is bounded, Lipschitz continuity is also not restrictive. Considering kernel-based regression as an example, the gradient is $(\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t)-y_t)\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t)+\lambda\boldsymbol{\theta}$. Since the loss is bounded, e.g., $\|\boldsymbol{\theta}^\top\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t)-y_t\|\leq 1$, and the RF vector in (8) can be bounded as $\|\mathbf{z}_{\mathbf{V}}(\mathbf{x}_t)\|\leq 1$, the constant is $L:=1+\lambda C_\theta$ using the Cauchy-Schwartz inequality. Kernels satisfying conditions in (as3) include Gaussian, Laplacian, and Cauchy (Rahimi and Recht, 2007). In general, (as1)-(as3) are standard in online convex optimization (OCO) (Shalev-Shwartz, 2011; Hazan, 2016), and in kernel-based learning (Micchelli and Pontil, 2005; Rahimi and Recht, 2007; Lu et al., 2016).

With regard to the performance of an online algorithm, static regret is commonly adopted as a metric by most OCO schemes to measure the difference between the aggregate loss of an OCO algorithm, and that of the best fixed function approximant in hindsight, e.g., (Shalev-Shwartz, 2011; Hazan, 2016). Specifically, for a generic sequence $\{\hat{f}_t\}$ generated by an RF-based kernel learning algorithm $\mathcal{A}$, its static regret is

$$\mathrm{Reg}_{\mathcal{A}}^{\mathrm{s}}(T):=\sum_{t=1}^T\mathcal{L}_t(\hat{f}_t(\mathbf{x}_t))-\sum_{t=1}^T\mathcal{L}_t(f^*(\mathbf{x}_t)) \tag{25}$$

where $\hat{f}_t$ will henceforth represent $\hat{f}_t^{\text{RF}}$ without the superscript for notational brevity; and, $f^*(\cdot)$ is obtained as the batch solution

$$f^*(\cdot) \in \arg \min_{\{f_p^*, p\in\mathcal{P}\}} \sum_{t=1}^{T} \mathcal{L}_t(f_p^*(\mathbf{x}_t)) \quad \text{with} \quad f_p^*(\cdot) \in \arg \min_{f\in\mathcal{F}_p} \sum_{t=1}^{T} \mathcal{L}_t(f(\mathbf{x}_t)) \tag{26}$$

with $\mathcal{F}_p := \mathcal{H}_p$, and $\mathcal{H}_p$ representing the RKHS induced by κ_p. Using (25) and (26), we first establish the static regret of our Raker approach in the following lemma.

Lemma 1 *Under (as1), (as2), and with $\hat{f}_p^*$ as in (26) with $\mathcal{F}_p := \{\hat{f}_p | \hat{f}_p(\mathbf{x}) = \boldsymbol{\theta}^\top \mathbf{z}_p(\mathbf{x}), \forall \boldsymbol{\theta} \in \mathbb{R}^{2D}\}$, the sequences $\{\hat{f}_{p,t}\}$ and $\{\bar{w}_{p,t}\}$ generated by Raker satisfy the following bound*

$$\sum_{t=1}^{T} \mathcal{L}_t\Big(\sum_{p=1}^{P} \bar{w}_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\Big) - \sum_{t=1}^{T} \mathcal{L}_t\left(\hat{f}_p^*(\mathbf{x}_t)\right) \leq \frac{\ln P}{\eta} + \frac{\|\boldsymbol{\theta}_p^*\|^2}{2\eta} + \frac{\eta L^2 T}{2} + \eta T \tag{27}$$

where $\boldsymbol{\theta}_p^*$ is associated with the best RF function approximant $\hat{f}_p^*(\mathbf{x}) = \left(\boldsymbol{\theta}_p^*\right)^\top \mathbf{z}_p(\mathbf{x})$.

Proof: See Appendix A. ■

Besides Raker's static regret bound, the next theorem compares the Raker loss relative to that of the best functional estimator in the original RKHS.

Theorem 1 *Under (as1)-(as3) and with f_p^* in (26) belonging to the RKHS $\mathcal{H}_p$, for a fixed $\epsilon > 0$, the following bound holds with probability at least $1 - 2^8\left(\frac{\sigma_p}{\epsilon}\right)^2 \exp\left(\frac{-D\epsilon^2}{4d+8}\right)$*

$$\sum_{t=1}^{T} \mathcal{L}_t\left(\sum_{p=1}^{P} \bar{w}_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\right) - \min_{p\in\{1,\ldots,P\}} \sum_{t=1}^{T} \mathcal{L}_t\left(f_p^*(\mathbf{x}_t)\right) \leq \frac{\ln P}{\eta} + \frac{(1+\epsilon)C^2}{2\eta} + \frac{\eta L^2 T}{2} + \eta T + \epsilon LTC \tag{28}$$

where C is a constant, while $\sigma_p^2 := \mathbb{E}_{\mathbf{v}}^{\pi_{\kappa_p}}[\|\mathbf{v}\|^2]$ is the second-order moment of the RF vector norm. Setting $\eta = \epsilon = \mathcal{O}(1/\sqrt{T})$ in (28), the static regret in (25) leads to

$$\text{Reg}_{\text{Raker}}^{\text{s}}(T) = \mathcal{O}(\sqrt{T}). \tag{29}$$

Proof: See Appendix B. ■

Observe that the probability of (28) to hold grows as D increases, and one can always find a D to ensure a positive probability for a given ϵ. Bearing this in mind, we will henceforth use "with high probability" (w.h.p.) to summarize the sense (28) and (29) hold. Theorem 1 establishes that with proper choice of parameters, the Raker achieves sub-linear regret relative to the best static function approximant in (26).

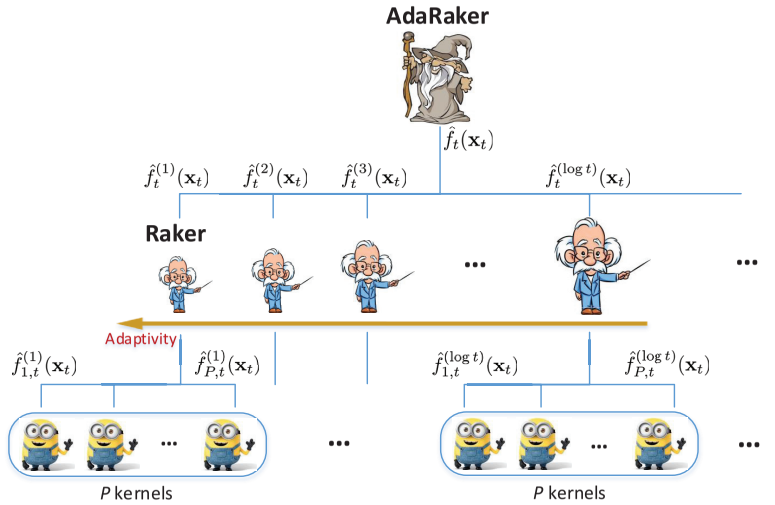

Figure 1: Hierarchical AdaRaker structure. Experienced experts in the middle layer present a Raker instance, where the size of expert cartoons is proportional to the interval length.

4. Online MKL in Environments with Unknown Dynamics

Our Raker in Section 3 combines an ensemble of kernel learners 'on the fly,' and performs on average as the "best" fixed function, thus fulfilling the learning objective in environments with zero (or slow) dynamics. To broaden its scope to environments with unknown dynamics, this section introduces an **ada**ptive **Raker** approach (termed **AdaRaker**).

4.1. AdaRaker with hierarchical ensembles

As with any online learning algorithm, the choice of η in (19) and (21) affects the performance critically. Especially in environments with unknown dynamics, a large η improves the tracking ability of fast-varying functions, while a smaller one allows improved estimation of slow-varying parameters $\{\boldsymbol{\theta}_t, w_{p,t}\}$. The optimal choice of η_t clearly depends on the variability of the optimal function estimator (Kivinen et al., 2004; Besbes et al., 2015). Selecting $\{\eta_t\}$ however, is formidably challenging if the environment dynamics are unknown.

Toward addressing this challenge, our idea here is to hedge between multiple Raker learners with different learning rates. Specifically, we view each Raker instance in Algorithm 1 as a black box algorithm $\mathcal{A}_I$, where the subscript I represents the algorithm running on interval $I := [\underline{I}, \bar{I}]$ starting from slot $\underline{I}$ to slot $\bar{I}$. Let a pre-selected set $\mathcal{I}$ collect all these intervals, the design of which will be specified later. At the beginning of each interval $I \in \mathcal{I}$, a new instance of the online Raker algorithm $\mathcal{A}_I$ is initialized with an interval-specific learning rate $\eta^{(I)} := \min\{1/2, \eta_0/\sqrt{|I|}\}$ with constant $\eta_0 > 0$. Allowing for overlap between intervals, multiple Raker instances $\{\mathcal{A}_I\}$ will be run in parallel. Consider now

Algorithm 2 AdaRaker for online MKL in dynamic environments

Initialization: learner weights $\{h_1^{(I)}\}$, and their learning rates $\{\eta^{(I)}\}$.
for $t = 1, 2, \ldots, T$ **do**
  Obtain $\hat{f}_t^{(I)}(\mathbf{x}_t)$ from each Raker instance $\mathcal{A}_I$, $I \in \mathcal{I}(t)$.
  Predict $\hat{f}_t(\mathbf{x}_t)$ via a weighted combination (33).
  Observe loss function $\mathcal{L}_t$, and incur $\mathcal{L}_t(\hat{f}_t(\mathbf{x}_t))$.
  for $I \in \mathcal{I}(t)$ **do**
    Incur loss $\mathcal{L}_t(\hat{f}_t^{(I)}(\mathbf{x}_t))$.
    Update $\hat{f}_t^{(I)}$ via Raker in Algorithm 1.
    Update weights $h_{t+1}^{(I)}$ via (31).
  end for
end for

collecting all active intervals at the current slot t in the set

$$\mathcal{I}(t) := \{I \in \mathcal{I} \,|\, t \in [\underline{I}, \bar{I}]\},\ \forall t \in \mathcal{T}. \tag{30}$$

For each Raker instance $\mathcal{A}_I$ with $I \in \mathcal{I}(t)$, let $\hat{f}_t^{(I)}(\cdot)$ denote its output at time t that combines multiple kernel-based function estimators, and $\mathcal{L}_t(\hat{f}_t^{(I)}(\mathbf{x}_t))$ represent the associated instantaneous loss. The output of the ensemble learner $\mathcal{A}$ at time t is the weighted combination of outputs from all learners, namely $\{\hat{f}_t^{(I)}, \forall I \in \mathcal{I}(t)\}$. With $h_t^{(I)}$ denoting the weight of the Raker instance $\mathcal{A}_I$, we will update it online via

$$h_{t+1}^{(I)} = \begin{cases} 0, & \text{if } t \notin I \\ \eta^{(I)}, & \text{if } t = \underline{I} \\ h_t^{(I)} \exp\left(-\eta^{(I)} r_t^{(I)}\right), & \text{else} \end{cases} \tag{31}$$

where $\underline{I}$ is the first time slot of interval I, and the loss of $\mathcal{A}_I$ *relative* to the overall loss is

$$r_t^{(I)} = \mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \mathcal{L}_t(\hat{f}_t^{(I)}(\mathbf{x}_t)),\ \forall I \in \mathcal{I}(t). \tag{32}$$

Intuitively thinking, one would wish to decrease (increase) the weights of those instances with small (large) losses in future rounds. Using update (31), and defining the normalized weight as $\bar{h}_t^{(I)} := h_t^{(I)} / \sum_{J \in \mathcal{I}(t)} h_t^{(J)}$, the overall output is given by

$$\hat{f}_t(\mathbf{x}) := \sum_{I \in \mathcal{I}} \bar{h}_t^{(I)} \hat{f}_t^{(I)}(\mathbf{x}) \quad \text{with} \quad \hat{f}_t^{(I)}(\mathbf{x}) := \sum_{p \in \mathcal{P}} \bar{w}_{p,t}^{(I)} \hat{f}_{p,t}^{(I)}(\mathbf{x}) \tag{33}$$

where $\{\bar{w}_{p,t}^{(I)}\}$ are the kernel combination weights generated by Raker $\mathcal{A}_I$ (cf. (21)).

The AdaRaker scheme is summarized in Algorithm 2, and depicted in Figure 1.

Selecting judiciously variable-length intervals in $\mathcal{I}$ can affect performance critically. Such a selection criterion for achieving interval regret has been reported in (Daniely et al., 2015). Instead, our pursuit is a hierarchical ensemble design for online MKL in environments with unknown dynamics using scalable RF-based function approximants. This hierarchical

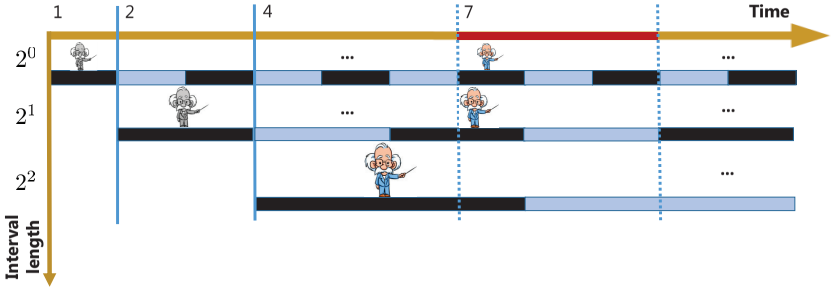

Figure 2: AdaRaker as an ensemble of Rakers with different learning rates: Each light/dark black interval initiates a Raker learner. At slot 7, colored experts are active, and gray ones are inactive.

design is well motivated because with long intervals, the Raker loss per interval is relatively low in slow-varying settings, but higher as the dynamics become more pronounced. On the other hand, a short interval can hedge against a possibly rapid change, but its performance on each interval could suffer if the objective stays nearly static. Bearing these tradeoffs in mind, we present next a simple yet efficient interval partitioning scheme.

Illustration of interval sets: *Consider partitioning the entire horizon into intervals of length* $2^0, 2^1, 2^2, \ldots$. *Intervals of length* 2^j *with a given* $j \in \mathbb{N}$ *are consecutively assigned without overlap starting from* $t = 2^j$. *In the non-overlapping case, define a set of intervals* $\mathcal{I}_j = [\underline{I}_j, \bar{I}_j]$ *such that each interval's length is* $|\mathcal{I}_j| = \bar{I}_j - \underline{I}_j + 1 = 2^j$, $j \in \mathbb{N}$. *For this selection of intervals, each time slot* t *is covered by a set of at most* $\lceil \log_2 t \rceil$ *intervals, which forms the active set of intervals* $\mathcal{I}(t)$ *at time* t. *See the diagram in Fig. 2.*

4.2. Dynamic regret analysis of AdaRaker

The static regret in Theorem 1 is with respect to a time-invariant optimal function estimator benchmark. In dynamic environments however, this optimal function benchmark may change over time - what justifies this subsection's performance analysis of AdaRaker.

Our analysis will rely on the *dynamic regret* that is related to tracking regret, and has been introduced in (Besbes et al., 2015; Jadbabaie et al., 2015) to quantify the performance of online algorithms. The dynamic regret is defined as (cf. (25))

$$\mathrm{Reg}_{\mathcal{A}}^{\mathrm{d}}(T) := \sum_{t=1}^{T} \mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \sum_{t=1}^{T} \mathcal{L}_t(f_t^*(\mathbf{x}_t)) \tag{34}$$

where the benchmark is the aggregate loss incurred by a sequence of the best dynamic functions$\{f_t^*\}$ from $\mathcal{F}$ formed by the union of function spaces $\mathcal{H}_p$ induced by $\{\kappa_p\}$, given by

$$f_t^*(\cdot) \in \arg \min_{\{f_{p,t}^* , p \in \mathcal{P}\}} \mathcal{L}_t(f_p^*(\mathbf{x}_t)) \quad \text{with} \quad f_{p,t}^*(\cdot) \in \arg \min_{f \in \mathcal{H}_p} \mathcal{L}_t(f(\mathbf{x}_t)) \tag{35}$$

Comparing (26) with (35) we deduce that the dynamic regret is always larger than the static regret in (25). Thus, a sub-linear dynamic regret implies a sub-linear static regret, but not vice versa. Given $\{\mathcal{L}_t\}$, AdaRaker generates functions $\{\hat{f}_t\}$ to minimize the dynamic regret.

To assess the AdaRaker performance, we will start with an *intermediate* result on the static regret associated with any sub-interval $I \subseteq \mathcal{T}$.

Lemma 2 *Under (as1)-(as3), the static regret on any interval $I \subseteq \mathcal{T}$ is given by*

$$\mathrm{Reg}^{\mathrm{s}}_{\mathcal{A}}(|I|) := \sum_{t\in I} \mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \sum_{t\in I} \mathcal{L}_t(f_I^*(\mathbf{x}_t)) \tag{36}$$

where $|I|$ denotes the length of interval I, and the best time-invariant function approximant is $f_I^* \in \arg\min_{f\in\bigcup_{p\in\mathcal{P}}\mathcal{H}_p} \sum_{t\in I}\mathcal{L}_t(f(\mathbf{x}_t))$, with $\mathcal{H}_p$ denoting the RKHS induced by κ_p. Then for any interval $I \subseteq \mathcal{T}$ and fixed positive constants C_0, C_1, the following bound holds

$$\mathrm{Reg}^{\mathrm{s}}_{\mathrm{AdaRaker}}(|I|) \leq C_0\sqrt{|I|} + C_1 \ln T\sqrt{|I|}, \text{ w.h.p.} \tag{37}$$

Proof: See Appendix C. ■

Lemma 2 establishes that by combining Raker learners with different learning rates, AdaRaker can achieve sub-linear static regret over *any* interval I with arbitrary interval length. This also holds for intervals overlapping with multiple intervals; see e.g., the red interval in Fig. 2. Clearly, the best fixed solution in (36) is interval specific, which can vary over different intervals. This is qualitatively why the function approximants generated by AdaRaker can cope with a *time-varying* benchmark. Such an intuition will in fact become quantitative in the next theorem, which establishes the dynamic regret for AdaRaker.

Theorem 2 *Suppose (as1)-(as3) are satisfied, and define the accumulated variation of online loss functions as*

$$\mathcal{V}(\{\mathcal{L}_t\}_{t=1}^T) := \sum_{t=1}^{T} \max_{f\in\mathcal{F}} \left|\mathcal{L}_{t+1}(f(\mathbf{x}_{t+1})) - \mathcal{L}_t(f(\mathbf{x}_t))\right| \tag{38}$$

where $\mathcal{F} := \bigcup_{p\in\mathcal{P}}\mathcal{H}_p$. Then AdaRaker can afford a dynamic regret in (34) *bounded by*

$$\begin{aligned}\mathrm{Reg}^{\mathrm{d}}_{\mathrm{AdaRaker}}(T) \leq& (2 + C_0 + C_1 \ln T) T^{\frac{2}{3}} \mathcal{V}^{\frac{1}{3}}(\{\mathcal{L}_t\}_{t=1}^T) \\ =& \tilde{\mathcal{O}}\left(T^{\frac{2}{3}}\mathcal{V}^{\frac{1}{3}}(\{\mathcal{L}_t\}_{t=1}^T)\right), \text{ w.h.p.}\end{aligned} \tag{39}$$

where $\tilde{\mathcal{O}}$ neglects the lower-order terms with a polynomial $\log T$ rate.

Proof: See Appendix D. ■

Theorem 2 asserts that AdaRaker's dynamic regret depends on the variation of loss functions in (38), and on the horizon T. Interesting enough, whenever the loss functions *do not vary on average*, meaning $\mathcal{V}(\{\mathcal{L}_t\}_{t=1}^T) = \mathbf{o}(T)$, AdaRaker achieves sub-linear dynamic regret. To this end, it is useful to present an example where this argument holds.

Intermittent switches: With $\mathcal{L}_t \neq \mathcal{L}_{t+1}$ defining a switch, consider that the number of switches is sub-linear over T; that is, $\sum_{t=1}^T \mathbb{1}(\mathcal{L}_t \neq \mathcal{L}_{t+1}) = T^\gamma$, $\forall\gamma \in [0,1)$. Then it follows that $\mathcal{V}(\{\mathcal{L}_t\}_{t=1}^T) = \mathcal{O}(T^\gamma)$, since the one-slot variation of the loss functions is bounded.

Other setups with sub-linear accumulated variation emerge, e.g., when the per-slot variation decreases as $\mathcal{V}(\mathcal{L}_t) = \mathcal{O}(t^{\gamma-1})$, $\forall\gamma \in [0,1)$. Besides dynamic losses, sub-linear dynamic regrets can be also effected by confining the variability of optimal function estimators.

Theorem 3 *Suppose the conditions of Theorem 2 hold, and define the regret relative to an m-switching dynamic benchmark as $\mathrm{Reg}^m_{\mathcal{A}}(T) := \sum_{t=1}^T \mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \sum_{t=1}^T \mathcal{L}_t(\check{f}_t^*(\mathbf{x}_t))$, where $\{\check{f}_t^*\}$ is any trajectory from*

$$\left\{\{\check{f}_t^*\}_{t=1}^T \in \bigcup\nolimits_{p\in\mathcal{P}} \mathcal{H}_p \middle| \sum\nolimits_{t=1}^T \mathbb{1}(\check{f}_t^* \neq \check{f}_{t-1}^*) \leq m\right\}. \tag{40}$$

With C_0 and C_1 denoting some universal constants, it then holds w.h.p. that

$$\mathrm{Reg}^m_{\mathrm{AdaRaker}}(T) \leq (C_0 + C_1 \ln T)\sqrt{Tm} = \tilde{\mathcal{O}}\left(\sqrt{Tm}\right). \tag{41}$$

Proof: See Appendix E. ■

Theorem 3 asserts that without prior knowledge of the environment dynamics, the dynamic regret of AdaRaker is sub-linearly growing with time, provided that the number of changes of the optimal function estimators is sub-linear in T; that is, $\mathrm{Reg}^m_{\mathrm{AdaRaker}}(T) = \mathbf{o}(T)$ given $m = \mathbf{o}(T)$. Therefore, our AdaRaker can track the optimal dynamic functions, if the optimal function *varies slowly* over time; e.g., it does not change in the long-term average sense. While the conditions to guarantee optimality in dynamic settings may appear restrictive, they are practically relevant, since abrupt changes or adversarial samples will likely not happen at each and every slot in practice.

5. Numerical Tests

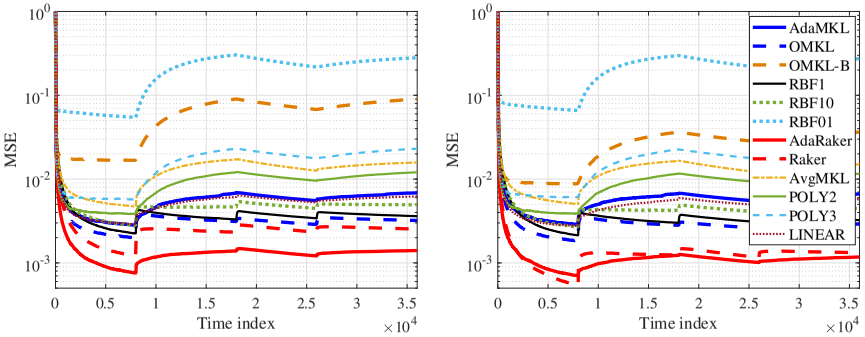
This section evaluates the performance of our novel algorithms in online regression tasks using both synthetic and real-world datasets.

In the subsequent tests, we use the following benchmarks.

RBF: the online *single* kernel learning method using Gaussian kernels, a.k.a. radial basis functions (RBFs), with bandwidth $\sigma^2 = \{0.1, 1, 10\}$ (cf. RBF01, RBF1, RBF10);
POLY: the online *single* kernel method using polynomial kernels, with degree $d = \{2, 3\}$ (cf. POLY2, POLY3);
LINEAR: the online *single* kernel learning method using a linear kernel;
AvgMKL: the online *single* kernel learning method using the average of candidate kernels without updating the weights;
OMKL: the popular online (O)MKL algorithm without a budget (Sahoo et al., 2014);
OMKL-B: the OMKL algorithm on a budget for regression modified from its single kernel version (Kivinen et al., 2004), with the kernel combination weights updated as (21);
M-Forgetron: the online multi-kernel based Forgetron modified from its single kernel version (Dekel et al., 2008), with the kernel combination weights updated as in (21);

Time index	$[1, 200]$	$[201, 1000]$	$[1001, 2000]$	$[2001, 2300]$	$[2301, 3000]$
σ^2	0.01	1	10	0.01	1
Time index	$[3001, 3500]$	$[3501, 4300]$	$[4301, 5100]$	$[5101, 5900]$	$5901, 6500$
σ^2	10	0.01	1	0.01	0.1

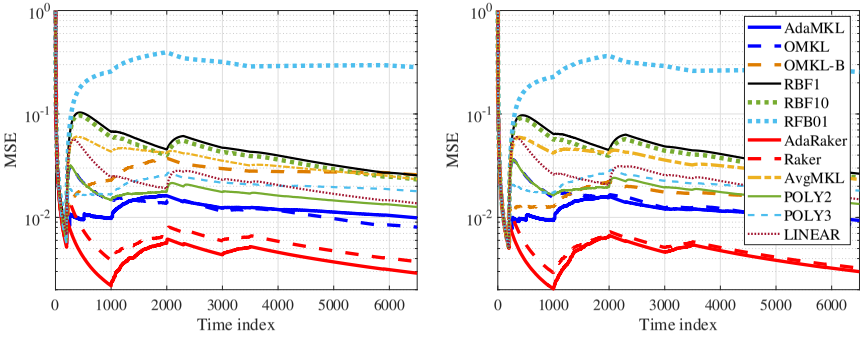
Table 1: Intervals and $\{\sigma^2\}$ for synthetic dataset.



AdaMKL: the adaptive version of OMKL that operates in a similar fashion as Algorithm 2, but instead of using our Raker as an ensemble, it adopts OMKL as an instance $\mathcal{A}_I$.

Note that AdaMKL, OMKL-B, and M-Forgetron have not been formally proposed in existing works, but we introduced them here only for comparison purposes. All the considered MKL approaches use a dictionary of Gaussian kernels with $\sigma^2 = \{0.1, 1, 10\}$, and AvgMKL, OMKL, AdaMKL, OMKL-B, and M-Forgetron also include a linear, and a polynomial kernel with order of 2 into their kernel dictionary. For all MKL approaches, the stepsize for updating kernel combination weights in (21) is chosen as 0.5 uniformly, while the stepsize for updating per-kernel function estimators will be specified later in each test. The regularization parameter is set equal to $\lambda = 0.01$ for all approaches. Entries of $\{\mathbf{x}_t\}$ and $\{y_t\}$ are normalized to lie in $[0, 1]$. Regarding AdaMKL and AdaRaker, multiple instances are initialized on intervals with length $|I| := 2^0, 2^1, 2^2, \ldots$, along with the corresponding learning rate on the interval I as $\eta^{(I)} := \min\{1/2, 10/\sqrt{|I|}\}$; see the example in Figure 2. All the results in the tables were reported using the performance at the last time index.

5.1. Synthetic data tests for regression



This subsection presents the synthetic data tests for regression.

Data generation. In this test, two synthetic datasets were generated as follows.
For *Dataset 1*, the feature vectors $\{\mathbf{x}_t \in \mathbb{R}^{10}\}_{t=1}^{14,000}$ are generated from the standardized Gaussian distribution, while y_t is generated as $y_t = \sum_{\tau=1}^{t} \alpha_\tau \kappa_\tau(\mathbf{x}_t, \mathbf{x}_\tau)$, where $\{\alpha_t\}$ is generated as $\alpha_t = 1 + e_t$ with $e_t \sim \mathcal{N}(0, \sigma_\alpha^2)$ and $\sigma_\alpha = 0.01$, while $\{\kappa_t\}$ are kernel functions that change overtime: for $t \in [1, 8000] \bigcup [18001, 26000]$, κ_t is a Gaussian kernel with $\sigma^2 = 1$, while for $t \in [8001, 18000] \bigcup [26001, 36000]$ the Gaussian kernel has $\sigma^2 = 10$. Therefore, the underlying nonlinear relationship between $\mathbf{x}_t$ and y_t undergoes intermittent changes, which come from corresponding changes in the optimal kernel combinations.
Dataset 2 is generated with more variance and switching points. Specifically, the feature vectors are generated from the standardized Gaussian distribution, while y_t is generated as $y_t = \sum_{\tau=1}^{t} \alpha_\tau \kappa_\tau(\mathbf{x}_t, \mathbf{x}_\tau)$, where $\{\kappa_t\}$ change over 10 intervals with different σ^2; see Table 1.
Testing performance. The performance of all schemes is tested in terms of the mean-square (prediction) error $\text{MSE}(t) := (1/t) \sum_{\tau=1}^{t} (y_\tau - \hat{y}_\tau)^2$ in Figure 3 and Figure 4, and their CPU time is listed in Table 2. For OMKL-B, $B = 20$ and 50 most recent data samples were kept in the budget; and for RF-based Raker and AdaRaker approaches, $D = 20$ and 50 orthogonal random features were used by default. The default stepsize is chosen as $1/\sqrt{T}$ for RBF, POLY, LINEAR, AvgMKL, OMKL, OMKL-B and Raker. In both tests, AdaRaker outperforms the alternatives in terms of MSE, especially when the true nonlinear relationship between $\mathbf{x}_t$ and y_t changes; e.g., compare the MSE of KL-RBF and Raker with that of AdaRaker at $t = 8000, 18000, 26000$ in Figure 3, and $t = 200, 2000, 3000, 3500$

(a) (b)

Figure 3: MSE performance on synthetic Dataset 1: a) $D = B = 20$; b) $D = B = 50$.

(a) (b)

Figure 4: MSE performance on synthetic Dataset 2: a) $D = B = 20$; b) $D = B = 50$.

in Figure 4. This corroborates the effectiveness of the novel AdaRacker method that can flexibly select learning rates according to the variability of the environments, and adaptively combine multiple kernels when the optimal underlying nonlinear relationship is varying over time. In addition, MKL approaches including our Raker approach enjoy lower MSE than that of the single-kernel approaches as well as the simple AvgMKL approach, which is also aligned with our design principle of developing MKL schemes that broaden generalizability of a kernel-based learner over a larger function space.

Table 2 records the CPU time of all benchmark algorithms running tests on two different datasets. It can be observed that leveraging the RF-based approximation, the proposed AdaRaker and Raker algorithms are much faster than AdaMKL and OMKL; hence, they are preferable especially for large-scale datasets. Although the CPU time of OMKL-B with

	Dataset 1		Dataset 2	
Setting	$D = B = 20$	$D = B = 50$	$D = B = 20$	$D = B = 50$
AdaMKL	318.52		27.29

Air quality	13	9,358	real

Table 3: A summary of real datasets used in the tests.

a budget size $B = 20$ or $B = 50$ is relatively low, OMKL-B does not perform as well as AdaRaker and Raker algorithms. Therefore, the AdaRaker and Raker approaches attain a sweet-spot in the performance-complexity tradeoff.

5.2. Real data tests for online regression

To further evaluate our algorithms in real-world scenarios, the present subsection is devoted to testing and comparing on several popular real datasets.

Datasets description. Performance is tested on benchmark datasets from UCI machine learning repository (Lichman, 2013).

- **Twitter** dataset consists of $T = 14,000$ samples from a popular micro-blogging platform Twitter, where $\mathbf{x}_t \in \mathbb{R}^{77}$ include features such as the number of new interactive authors, and the length of discussion on a given topic, while y_t represents the average number of active discussion (popularity) on a certain topic (Kawala et al., 2013). A larger dataset with $T = 100,000$ is also included for testing only (Ada)Raker and OMKL-B, since other methods do not scale to such a large T.

- **Tom's hardware** dataset contains $T = 10,000$ samples from a worldwide new technology forum, where a 96-dimensional feature vector includes the number of discussions involving a certain topic, while y_t represents the average number of display about a certain topic on Tom's hardware (Kawala et al., 2013).

Table 5: MSE (10^{-3}) performance of different algorithms with optimally chosen stepsizes.

- **energy** dataset consists of $T = 18,600$ samples, with each $\mathbf{x}_t \in \mathbb{R}^{27}$ describing the humidity and temperature indoors and outdoors, while y_t denotes the energy use of light fixtures in the house (Candanedo et al., 2017).

- **air quality** dataset collects $T = 9,358$ instances of hourly averaged responses from five chemical sensors located in a polluted area of Italy. The averaged sensor response $\mathbf{x}_t \in \mathbb{R}^{13}$ contains the hourly concentrations of e.g., CO, Non Metanic Hydrocarbons, and Nitrogen Dioxide (NO2), where the goal is to predict the concentration of polluting chemicals y_t in the air (De Vito et al., 2008).

To highlight the effectiveness of our approaches, the datasets mainly include time series data, where non-stationarity is more likely to happen; see Table 3 for a summary.

MSE performance. The MSE performance of each algorithm on the aforementioned datasets is presented in Table 4. By default, we use the complexity $B = D = 50$ for OMKL-B and (Ada)Raker, and the stepsize $1/\sqrt{T}$ for RBF, POLY, LINEAR, AvgMKL,

MSE	OMKL-B				Raker				AdaRaker
Stepsize	$1/\sqrt{T}$	$0.5/\sqrt{t}$	$0.1/\sqrt{t}$	Tuned	$1/\sqrt{T}$	$0.5/\sqrt{t}$	$0.1/\sqrt{t}$	Tuned	/
Twitter	27.0	27.1	29.6	9.9	3.0	17.9	4.3	2.9	**2.6**

Table 6: MSE (10^{-3}) versus the choice of stepsizes with complexity $B = D = 50$.

OMKL, OMKL-B and Raker. To boost the performance of each algorithm, their MSE when using manually tuned stepsizes is also reported in Table 5, which selects the best stepsize on each dataset among $\{10^{-3}, 10^{-2}, \cdots, 10^{3}\}/\sqrt{T}$. A common observation is that leveraging the flexibility of multiple kernels, MKL methods in most cases outperform the algorithms using only a single kernel. By simply averaging over all the kernels, AvgMKL outperforms most of single kernel methods, but performs worse than the adaptive kernel combination methods. This confirms that relying on a pre-selected kernel function is not sufficient to guarantee low fitting loss, while allowing the MKL approaches to select the best kernel combinations in a data-driven fashion holds the key for improved performance.

In most tested datasets, Raker obtains function approximants with lower MSE relative to MKL alternatives without RF approximation. Furthermore, incorporating multiple Raker instances with variable learning rates, AdaRaker consistently yields the lowest MSE in all the tests. As it has been shown in the synthetic data test, the sizable performance gain of AdaRaker appears when the underlying nonlinear models change in the tested time-series datasets. This observation is aligned with our design principle of AdaRaker; that is, when the optimal function predictor varies slowly (fast), AdaRaker tends to select a Raker instance with small (large) learning rate. Interesting enough, even with adaptive learning rate, AdaMKL does not perform as well as OMKL in some tests. This is partially because unlike AdaRaker with fixed number of RFs, each instance in AdaMKL involves a different *number of support vectors* (samples). The instance operating on the longest interval contains at most $T/2$ support vectors, which may deteriorate performance relative to OMKL with T support vectors.

Table 6 further compares the MSE performance of AdaRaker with OMKL-B and Raker using different stepsizes. Clearly, the performance of OMKL-B and Raker is sensitive to the choice of stepsizes. While the optimal stepsize varies from dataset to dataset, selecting a constant stepsize $1/\sqrt{T}$ generally leads to better performance than a diminishing one of $\mathcal{O}(1/\sqrt{t})$. In the online scenarios however, the choice $1/\sqrt{T}$ may not be feasible if T is unknown ahead of time. In contrast, AdaRaker obtained the best MSE performance without knowing T, and without the need of stepsize selection, which confirms that AdaRaker is capable of adapting its stepsize to variable environments with unknown dynamics.

Computational complexity. The CPU time of all the considered schemes is recorded under all the tests; see Table 7. It is evident that in all tests, our RF-based MKL methods including Raker and AdaRaker are computationally more efficient than other MKL methods except that OMKL-B is faster than AdaRaker. Intuitively speaking, the per-slot complexity of Raker does not grow with time, since it requires computing only one inner product of two

Table 8: MSE (10^{-3}) versus complexity. For OMKL-B, the complexity measure is the data budget B; and for (Ada)Raker, the complexity measure is the number of RFs D.

$2D$-dimensional vectors per kernel learner, while the computational complexity of AdaMKL, OMKL, POLY, LINEAR, AvgMKL, and RBF increases with time at least linearly. With a fixed budget size, OMKL-B enjoys light-weight updates that leads to a lower CPU time than alternatives, but higher than Raker. However, given such a limited budget of data, OMKL-B exhibits higher MSE than AdaRaker and Raker; see MSE in Tables 4 and 6.

Running multiple instances of Raker in parallel, the complexity of AdaRaker is reasonably higher than Raker (roughly $\log T$ times higher), but its runtime is still only around 10% of that of AdaMKL, and significantly lower than other single-kernel alternatives especially when the actual feature dimension d is higher than the number of random features D. The computational advantage of our MKL algorithms in this test also corroborates the quantitative analysis at the end of Section 3.2. Regarding the tradeoff between learning accuracy and complexity, a delicate comparison among OMKL-B, Raker and AdaRaker follows next.

Accuracy versus complexity. To further understand the tradeoff between complexity and learning accuracy, the performance of three scalable methods AdaRaker, Raker and OMKL-B is tested under different parameter settings, e.g., D, the number of random features, and B, the number of budgeted data. The MSE performance is reported in Table 8 after one pass of all data in each dataset, while the corresponding CPU time is in Table 9.

Not surprising, all three algorithms require longer CPU time as the complexity (in terms of B or D) increases. For given complexity (same B and D), Raker requires the lowest CPU time, and its MSE is also markedly lower than that of OMKL-B in all tests. On the other hand, AdaRaker always attains the lowest MSE, and its performance gain is

Time	OMKL-B			Raker			AdaRaker		
Complexity	10	50	100	10	50	100	10	50	100
Twitter	1.42	1.89	2.84	0.42	0.51	0.80	7.58	8.64	11.65

Raker ($D = 50$)	9.74	2.54	0.58	**0.40**	**0.12**	**0.21**
AdaRaker ($D = 50$)	**1.10**	**0.36**	**0.34**	6.76	1.73	3.56

Table 10: Classification error (%) and runtime (second) of different algorithms with the default stepsize $1/\sqrt{T}$ for RBF, OMKL and Raker, and with complexity $B = D = 50$.

remarkable especially in the Energy and Air pollution datasets. For Twitter (Large) dataset, the performance of AdaRaker does not improve as RFs increase from $D = 50$ to $D = 100$, which implies that $D = 50$ is enough to provide reliable kernel approximation in this dataset. Considering that AdaRaker is embedded with concurrent $\log t$ Raker instances at time t, its CPU time is relatively higher. However, one would expect a major reduction in the number of concurrent instances and thus markedly lower CPU time, if a larger basic interval size (instead of base number 2 in Figure 2) is incorporated in AdaRaker real implementation.

At this point, one may wonder how many RFs are enough for Raker and AdaRaker to guarantee the same online learning accuracy as that of OMKL-B with B samples. While this intriguing question has been recently studied in the batch setting with an answer of $D = \mathcal{O}(\sqrt{B})$ RFs (Rudi and Rosasco, 2017), its thorough treatment in the online setting constitutes our future research.

5.3. Real data tests for online classification

In this section, the performance of Raker and AdaRaker is tested on real datasets for the online classification task. We use the logistic loss as the learning objective function with the regularization parameter $\lambda = 0.005$ for all considered approaches except for the perceptron-

	Classification error

Table 11: Classification error (%) of different algorithms with the dataset-specific optimally chosen stepsizes for RBF, OMKL and Raker, and with complexity $B = D = 50$.

based Forgetron algorithm. Kernels and all other parameters such as the default stepsizes, are chosen as those in the regression task.

Datasets description. We test classification performance on the following datasets.

- **Movement** dataset consists of $T = 13,197$ temporal streams of received signal strength (RSS) measured between the nodes of a wireless sensor network, with each $\mathbf{x}_t \in \mathbb{R}^4$ comprising 4 anchor nodes (Bacciu et al., 2014). Data has been collected during user movements at the frequency of 8 Hz (8 samples per second). The RSS samples in the dataset have been rescaled to lie in $[-1, 1]$. The binary label y_t indicates whether the user's trajectory will lead to a change in the spatial context (here a room change) or not.
- **Electronic Device** dataset consists of $T = 3,600$ samples collected as part of a government sponsored study called 'Powering the Nation,' where the feature vectors $\mathbf{x}_t \in \mathbb{R}^{60}$ represent electricity readings from different households over 15 mins, sampled within a month (Lines et al., 2011). Binary label y_t represents the type of electronic devices used at the certain interval of time time: dishwasher or kettle.
- **Human Activity** dataset consists of $T = 7,352$ samples collected from a group of 30 volunteers wearing a smartphone (Samsung Galaxy S II) on their waist to monitor activities (Anguita et al., 2013). Feature vectors $\{\mathbf{x}_t \in \mathbb{R}^{30}\}$ here measure e.g., triaxial acceleration and angular velocity, while binary label y_t represents the activity during a certain period: walking or not walking.

Classification performance. The classification error $(1/T)\sum_{t=1}^{T} \max\{0, \text{sign}(-y_t\hat{y}_t)\}$ and the CPU time of each algorithm on these datasets are summarized in Table 10 when a default stepsize $1/\sqrt{T}$ is used for POLY, LINEAR, RBF, AvgMKL, OMKL and Raker. The budget of M-Forgetron is set at $B = 50$ samples, while Raker and AdaRaker adopt $D = 50$ RFs. As with the regression tests, it is evident that AdaRaker attains the highest

	OMKL				Raker				AdaRaker

Table 13: Classification error (%) and CPU time (second) versus complexity.

classification accuracy and the Raker has the lowest CPU time among all competing algorithms. Without having to tune stepsizes, the performance of AdaMKL and M-Forgetron is also competitive in this case. To explore the best performance of each algorithm, the classification performance under manually tuned stepsizes is reported in Table 11, where each algorithm uses the best stepsize among $\{10^{-3}, 10^{-2}, \cdots, 10^{3}\}/\sqrt{T}$ for each dataset. With the optimally chosen stepsizes, the performance of all algorithms improves, and Raker even achieves slightly lower classification error than AdaRaker in some datasets. This is reasonable since compared to Raker with the offline tuned stepsize, AdaRaker will incur some error due to the online adaptation to several (possibly suboptimal) learning rates.

To corroborate the effectiveness of our algorithms in adapting to unknown dynamics (e.g., unknown time horizon T and variability), Table 12 compares the performance of AdaRaker with OMKL and Raker using default, diminishing and optimally tuned stepsizes. Similar to regression tests, the performance of Raker and OMKL is sensitive to the stepsize choice, while AdaRaker achieves the desired performance by combining learners with different learning rates. By simply averaging over all the kernels, AvgMKL outperforms single kernel methods in most cases, but performs much worse than OMKL and (Ada)Raker methods. Note that the Raker also achieves competitive classification accuracy when the constant stepsize $1/\sqrt{T}$ is used. Such a choice is however not always feasible in practice, since it requires knowledge of how many data samples will be available ahead of time.

Accuracy versus complexity. In this experiment, we test classification performance in terms of both classification error and CPU time for different levels of complexity; see Table 13. We use the number of support vectors B for M-Forgetron, and the number of RFs D for Raker and AdaRaker to represent different levels of complexity, and compare

their performance using the default stepsize. It is expected that CPU time increases as the complexity increases, and the classification error decreases as the complexity grows. For all three datasets, the AdaRaker achieves the lowest classification error, and the Raker outperforms the M-Forgetron while at the same time it is more efficient computationally.

6. Concluding Remarks

This paper dealt with kernel-based learning in environments with unknown dynamics that also include static or slow variations. Uniquely combining advances in random feature based function approximation with online learning from an ensemble of experts, a scalable online multi-kernel learning approach termed Raker, was developed for static environments based on a dictionary of kernels. Endowing Raker with capability of tracking time-varying optimal function estimators, AdaRaker was introduced as an ensemble version of Raker with variable learning rates. The key modules of the novel learning approaches are: i) the random features are for scalability, as they reduce the per-iteration complexity; ii) the preselected kernel dictionary is for flexibility, that is to broaden generalizability of a kernel-based learner over a larger function space; iii) the weighted combination of kernels adjusted online accounts for the reliability of learners; and, iv) the adoption of multiple learning rates is for improved adaptivity to changing environments with unknown dynamics.

Complementing the principled algorithmic design, the performance of Raker is rigorously established using static regret analysis. Furthermore, without a-priori knowledge of dynamics, it is proved that AdaRaker achieves sub-linear dynamic regret, provided that either the loss or the optimal learning function does not change on average. Experiments on synthetic and real datasets validate the effectiveness of the novel methods.

Appendix A. Proof of Lemma 1

To prove Lemma 1, we introduce two intermediate lemmata as follows.

Lemma 3 *Under (as1), (as2), and $\hat{f}_p^*$ as in* (26) *with $\mathcal{F}_p := \{\hat{f}_p | \hat{f}_p(\mathbf{x}) = \boldsymbol{\theta}^\top \mathbf{z}_p(\mathbf{x}), \forall \boldsymbol{\theta} \in \mathbb{R}^{2D}\}$, let $\{\hat{f}_{p,t}(\mathbf{x}_t)\}$ denote the sequence of estimates generated by Raker with a pre-selected kernel κ_p. Then the following bound holds true w.p.1*

$$\sum_{t=1}^{T} \mathcal{L}_t(\hat{f}_{p,t}(\mathbf{x}_t)) - \sum_{t=1}^{T} \mathcal{L}_t(\hat{f}_p^*(\mathbf{x}_t)) \leq \frac{\|\boldsymbol{\theta}_p^*\|^2}{2\eta} + \frac{\eta L^2 T}{2} \tag{42}$$

where η is the learning rate, L is the Lipschitz constant in (as2), and $\boldsymbol{\theta}_p^*$ is the corresponding parameter (or weight) vector supporting the best estimator $\hat{f}_p^*(\mathbf{x}) = (\boldsymbol{\theta}_p^*)^\top \mathbf{z}_p(\mathbf{x})$.

Proof: Similar to the regret analysis of online gradient descent (Shalev-Shwartz, 2011), using (12) for any fixed $\boldsymbol{\theta}$, we find

$$\begin{aligned}\|\boldsymbol{\theta}_{p,t+1}-\boldsymbol{\theta}\|^2 =&\|\boldsymbol{\theta}_{p,t}-\eta\nabla\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)-\boldsymbol{\theta}\|^2 \\ =&\|\boldsymbol{\theta}_{p,t}-\boldsymbol{\theta}\|^2+\eta^2\|\nabla\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\|^2-2\eta\nabla^\top\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)(\boldsymbol{\theta}_{p,t}-\boldsymbol{\theta}).\end{aligned} \tag{43}$$

Meanwhile, the convexity of the loss under (as1) implies that

$$\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)-\mathcal{L}(\boldsymbol{\theta}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\le\nabla^\top\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)(\boldsymbol{\theta}_{p,t}-\boldsymbol{\theta}). \tag{44}$$

Plugging (44) into (43) and rearranging terms yields

$$\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)-\mathcal{L}(\boldsymbol{\theta}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\le\frac{\|\boldsymbol{\theta}_{p,t}-\boldsymbol{\theta}\|^2-\|\boldsymbol{\theta}_{p,t+1}-\boldsymbol{\theta}\|^2}{2\eta}+\frac{\eta}{2}\|\nabla\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\|^2. \tag{45}$$

Summing (45) over $t=1,\ldots,T$, with $\hat{f}_{p,t}(\mathbf{x}_t)=\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t)$, we arrive at

$$\begin{aligned}&\sum_{t=1}^T\Big(\mathcal{L}(\hat{f}_{p,t}(\mathbf{x}_t),y_t)-\mathcal{L}(\boldsymbol{\theta}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\Big)\\ \le&\frac{\|\boldsymbol{\theta}_{p,1}-\boldsymbol{\theta}\|^2-\|\boldsymbol{\theta}_{p,T+1}-\boldsymbol{\theta}\|^2}{2\eta}+\frac{\eta}{2}\sum_{t=1}^T\|\nabla\mathcal{L}(\boldsymbol{\theta}_{p,t}^\top\mathbf{z}_p(\mathbf{x}_t),y_t)\|^2\\ \overset{(a)}{\le}&\frac{\|\boldsymbol{\theta}\|^2}{2\eta}+\frac{\eta L^2T}{2}\end{aligned} \tag{46}$$

where (a) uses the Lipschitz constant in (as2), the non-negativity of $\|\boldsymbol{\theta}_{p,T+1}-\boldsymbol{\theta}\|^2$, and the initial value $\boldsymbol{\theta}_{p,1}=\mathbf{0}$. The proof of Lemma 3 is then complete by choosing $\boldsymbol{\theta}=\boldsymbol{\theta}_p^*=\sum_{t=1}^T\alpha_{p,t}^*\mathbf{z}_p(\mathbf{x}_t)$ such that $\hat{f}_p^*(\mathbf{x}_t)=\boldsymbol{\theta}^\top\mathbf{z}_p(\mathbf{x}_t)$ in (46). ■

Lemma 3 establishes that the static regret of the Raker is upper bounded by some constants, which mainly depend on the stepsize in (19) and the time horizon T.

In addition, we will bound the difference between the loss of the solution obtained from Algorithm 1 and the loss of the best single kernel-based online learning algorithm. Specifically the following lemma holds:

Lemma 4 *Under (as1) and (as2), with $\{\hat{f}_{p,t}\}$ generated from Raker, it holds that*

$$\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t(\hat{f}_{p,t}(\mathbf{x}_t))-\sum_{t=1}^T\mathcal{L}_t(\hat{f}_{p,t}(\mathbf{x}_t))\le\eta T+\frac{\ln P}{\eta} \tag{47}$$

where η is the learning rate in (21)*, and P is the number of kernels in the dictionary.*

Proof: Letting $W_t:=\sum_{p=1}^P w_{p,t}$, the weight recursion in (21) implies that

$$\begin{aligned}W_{t+1}&=\sum_{p=1}^P w_{p,t+1}=\sum_{p=1}^P w_{p,t}\exp\Big(-\eta\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)\Big)\\ &\le\sum_{p=1}^P w_{p,t}\left(1-\eta\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\right)\end{aligned} \tag{48}$$

where the last inequality holds because $\exp(-\eta x)\le 1-\eta x+\eta^2x^2$, for $|\eta|\le 1$. Furthermore, substituting $\bar{w}_{p,t}:=w_{p,t}/\sum_{p=1}^P w_{p,t}=w_{p,t}/W_t$ into (48), it follows that

$$\begin{aligned}W_{t+1}&\le\sum_{p=1}^P W_t\bar{w}_{p,t}\left(1-\eta\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\right)\\ &=W_t\left(1-\eta\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\right).\end{aligned} \tag{49}$$

Using $1+x\le e^x$, $\forall x$, (49) leads to

$$W_{t+1}\le W_t\exp\left(-\eta\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\right). \tag{50}$$

Telescoping (50) from $t=1$ to T, we have ($W_1=1$)

$$W_{T+1}\le\exp\left(-\eta\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\right). \tag{51}$$

On the other hand, for any p, the following holds true

$$\begin{aligned}W_{T+1}\ge w_{p,T+1}&=w_{p,1}\prod_{t=1}^T\exp(-\eta\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big))\\ &=w_{p,1}\exp\left(-\eta\sum_{t=1}^T\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)\right).\end{aligned} \tag{52}$$

Combining (51) with (52), we arrive at

$$\begin{aligned}&\exp\left(-\eta\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\right)\\ \ge& w_{p,1}\exp\left(-\eta\sum_{t=1}^T\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)\right).\end{aligned} \tag{53}$$

Taking the logarithm on both sides of (53), we find that (cf. $w_{p,1}=1/P$)

$$-\eta\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta^2\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2\ge-\eta\sum_{t=1}^T\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)-\ln P \tag{54}$$

which leads to

$$\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)\le\sum_{t=1}^T\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)+\eta\sum_{t=1}^T\sum_{p=1}^P\bar{w}_{p,t}\mathcal{L}_t\Big(\hat{f}_{p,t}(\mathbf{x}_t)\Big)^2+\frac{\ln P}{\eta} \tag{55}$$

and the proof is complete since $\mathcal{L}_t\left(\hat{f}_{p,t}(\mathbf{x}_t)\right)^2 \leq 1$ and $\sum_{p=1}^P \bar{w}_{p,t} = 1$. ■

Moreover, since $\mathcal{L}_t(\cdot)$ is convex under (as1), Jensen's inequality implies that

$$\mathcal{L}_t\Big(\sum_{p=1}^P \bar{w}_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\Big) \leq \sum_{p=1}^P \bar{w}_{p,t}\mathcal{L}_t\left(\hat{f}_{p,t}(\mathbf{x}_t)\right). \tag{56}$$

Plugging (56) into (47) in Lemma 4, we arrive at

$$\begin{aligned}\sum_{t=1}^T \mathcal{L}_t\Big(\sum_{p=1}^P \bar{w}_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\Big) &\leq \sum_{t=1}^T \mathcal{L}_t\left(\hat{f}_{p,t}(\mathbf{x}_t)\right) + \eta T + \frac{\ln P}{\eta} \\ &\overset{(a)}{\leq} \sum_{t=1}^T \mathcal{L}_t\left(\hat{f}_p^*(\mathbf{x}_t)\right) + \frac{\ln P}{\eta} + \frac{\|\boldsymbol{\theta}_p^*\|^2}{2\eta} + \frac{\eta L^2 T}{2} + \eta T \end{aligned} \tag{57}$$

where (a) follows because $\boldsymbol{\theta}_p^*$ is the optimal solution for any given kernel κ_p. This proves the claim in Lemma 1.

Appendix B. Proof of Theorem 1

To derive the performance bound relative to the best function estimator $f^*(\mathbf{x}_t)$ in the RKHS, the key step is to bound the error of approximation. For a given shift-invariant κ_p, the maximum point-wise error of the RF kernel approximant is uniformly bounded with probability at least $1 - 2^8\left(\frac{\sigma_p}{\epsilon}\right)^2 \exp\left(\frac{-D\epsilon^2}{4d+8}\right)$, by (Rahimi and Recht, 2007)

$$\sup_{\mathbf{x}_i,\mathbf{x}_j\in\mathcal{X}} \left|\mathbf{z}_p^\top(\mathbf{x}_i)\mathbf{z}_p(\mathbf{x}_j) - \kappa_p(\mathbf{x}_i,\mathbf{x}_j)\right| < \epsilon \tag{58}$$

where $\epsilon > 0$ is a given constant, D the number of features, while d represents the dimension of $\mathbf{x}$, and $\sigma_p^2 := \mathbb{E}_p[\|\mathbf{v}\|^2]$ is the second-order moments of the RF vector norm. Henceforth, for the optimal function estimator (26) in $\mathcal{H}_p$ denoted by $f_p^*(\mathbf{x}) := \sum_{t=1}^T \alpha_{p,t}^*\kappa_p(\mathbf{x},\mathbf{x}_t)$, and its RF-based approximant $\check{f}_p^* := \sum_{t=1}^T \alpha_{p,t}^*\mathbf{z}_p^\top(\mathbf{x})\mathbf{z}_p(\mathbf{x}_t) \in \mathcal{F}_p$, we have

$$\begin{aligned}\left|\sum_{t=1}^T \mathcal{L}_t\left(\check{f}_p^*(\mathbf{x}_t)\right) - \sum_{t=1}^T \mathcal{L}_t\left(f_p^*(\mathbf{x}_t)\right)\right| &\overset{(a)}{\leq} \sum_{t=1}^T \left|\mathcal{L}_t\left(\check{f}_p^*(\mathbf{x}_t)\right) - \mathcal{L}_t(f_p^*(\mathbf{x}_t))\right| \\ &\overset{(b)}{\leq} \sum_{t=1}^T L\left|\sum_{t'=1}^T \alpha_{p,t'}^*\mathbf{z}_p^\top(\mathbf{x}_{t'})\mathbf{z}_p(\mathbf{x}_t) - \sum_{t'=1}^T \alpha_{p,t'}^*\kappa_p(\mathbf{x}_{t'},\mathbf{x}_t)\right| \\ &\overset{(c)}{\leq} \sum_{t=1}^T L\sum_{t'=1}^T |\alpha_{p,t'}^*|\left|\mathbf{z}_p^\top(\mathbf{x}_{t'})\mathbf{z}_p(\mathbf{x}_t) - \kappa_p(\mathbf{x}_{t'},\mathbf{x}_t)\right| \end{aligned} \tag{59}$$

where (a) follows from the triangle inequality; (b) uses the Lipschitz continuity of the loss, and (c) is due to the Cauchy-Schwarz inequality. Combining with (58), yields

$$\left|\sum_{t=1}^T \mathcal{L}_t(\check{f}_p^*(\mathbf{x}_t)) - \sum_{t=1}^T \mathcal{L}_t(f_p^*(\mathbf{x}_t))\right| \leq \sum_{t=1}^T L\epsilon\sum_{t'=1}^T |\alpha_{p,t'}^*| \leq \epsilon LTC, \text{ w.h.p.} \tag{60}$$

where the equality follows from $C := \max_p \sum_{t=1}^T |\alpha_{p,t}^*|$. Under the kernel bounds in (as3), the uniform convergence in (58) implies that $\sup_{\mathbf{x}_t,\mathbf{x}_{t'}\in\mathcal{X}} \mathbf{z}_p^\top(\mathbf{x}_t)\mathbf{z}_p(\mathbf{x}_{t'}) \leq 1+\epsilon$, w.h.p., which in turn leads to

$$\left\|\boldsymbol{\theta}_p^*\right\|^2 := \left\|\sum_{t=1}^T \alpha_{p,t}^*\mathbf{z}_p(\mathbf{x}_t)\right\|^2 = \left|\sum_{t=1}^T\sum_{t'=1}^T \alpha_{p,t}^*\alpha_{p,t'}^*\mathbf{z}_p^\top(\mathbf{x}_t)\mathbf{z}_p(\mathbf{x}_{t'})\right| \leq (1+\epsilon)C^2 \tag{61}$$

where we again used the definition of C.

Lemma 1 together with (60) and (61) leads to the regret of the proposed Raker algorithm relative to the best static function in $\mathcal{H}_p$, that is given by

$$\begin{aligned}&\sum_{t=1}^T \mathcal{L}_t\Big(\sum_{p=1}^P w_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\Big) - \sum_{t=1}^T \mathcal{L}_t(f_p^*(\mathbf{x}_t)) \\ =&\sum_{t=1}^T \mathcal{L}_t\Big(\sum_{p=1}^P w_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\Big) - \sum_{t=1}^T \mathcal{L}_t\left(\check{f}_p^*(\mathbf{x}_t)\right) + \sum_{t=1}^T \mathcal{L}_t\left(\check{f}_p^*(\mathbf{x}_t)\right) - \sum_{t=1}^T \mathcal{L}_t(f_p^*(\mathbf{x}_t)) \\ \leq&\frac{\ln P}{\eta} + \frac{\eta L^2 T}{2} + \eta T + \frac{(1+\epsilon)C^2}{2\eta} + \epsilon LTC, \text{ w.h.p.} \end{aligned} \tag{62}$$

which completes the proof of Theorem 1.

Appendix C. Proof of Lemma 2

Using Theorem 1 with $\eta = \epsilon = \mathcal{O}(1/\sqrt{T})$, it holds w.h.p. that

$$\sum_{t=1}^T \mathcal{L}_t\Big(\sum_{p=1}^P w_{p,t}\hat{f}_{p,t}(\mathbf{x}_t)\Big) - \sum_{t=1}^T \mathcal{L}_t(f_{p^*}^*(\mathbf{x}_t)) \leq \left(\ln P + \frac{C^2}{2} + \frac{L^2}{2} + LC\right)\sqrt{T} := c_0\sqrt{T} \tag{63}$$

where $p^* := \arg\min_{p\in\mathcal{P}} \sum_{t=1}^T \mathcal{L}_t\left(\hat{f}_p^*(\mathbf{x}_t)\right)$. At the end of interval I, we then deduce that the static regret of the Raker learner $\mathcal{A}_I$ is (cf. (36))

$$\mathrm{Reg}_{\mathcal{A}_I}^{\mathrm{s}}(|I|) = \sum_{t\in I} \mathcal{L}_t\left(\hat{f}_t^{(I)}(\mathbf{x}_t)\right) - \sum_{t\in I} \mathcal{L}_t(f_I^*(\mathbf{x}_t)) \leq c_0\sqrt{|I|}, \text{ w.h.p.} \tag{64}$$

where $\hat{f}_t^{(I)}(\mathbf{x}_t)$ is defined in (33), and $f_I^* \in \arg\min_{f\in\bigcup_{p\in\mathcal{P}}\mathcal{H}_p} \sum_{t\in I} \mathcal{L}_t(f(\mathbf{x}_t))$. To this end, we sketch the main steps leading to Lemma 2 as follows.

For every interval I, the static regret of the AdaRaker can be decomposed as

$$\begin{aligned}\mathrm{Reg}_{\mathrm{AdaRaker}}^{\mathrm{s}}(|I|) &= \sum_{t\in I} \mathcal{L}_t\left(\hat{f}_t(\mathbf{x}_t)\right) - \sum_{t\in I} \mathcal{L}_t\left(\hat{f}_t^{(I)}(\mathbf{x}_t)\right) + \sum_{t\in I} \mathcal{L}_t\left(\hat{f}_t^{(I)}(\mathbf{x}_t)\right) - \sum_{t\in I} \mathcal{L}_t(f_I^*(\mathbf{x}_t)) \\ &:= \mathcal{R}_1 + \mathcal{R}_2 \end{aligned} \tag{65}$$

where the first two sums in (65) represented by $\mathcal{R}_1$ capture the regret of the Ada-Raker learner $\mathcal{A}$ relative to the Raker learner $\mathcal{A}_I$; while the last two sums in (65) forming $\mathcal{R}_2$ denote the static regret of $\mathcal{A}_I$ on this interval. Notice that $\mathcal{R}_2$ directly follows from (64), while $\mathcal{R}_1$

can be bounded following the same steps in Lemma 4. Different from the kernel selections however, the crux is that the number of Raker learners (experts) $|\mathcal{I}(t)|$ is time-varying.

A tight bound can be derived via the *Sleeping Experts* reformulation of (Luo and Schapire, 2015; Daniely et al., 2015), where an expert that has never appeared is thought of as being *asleep* for all previous rounds. For a looser bound, we assume the experts (instances $\{\mathcal{A}_I\}$) ever appeared until t are all active; that is, the total number of experts is upper bounded by $t\log t$, since at most $\log t$ experts are run during time t. Using (48)-(55), we have that

$$\mathcal{R}_1 \leq \eta^{(I)}|I| + \frac{\ln(t\log t)}{\eta^{(I)}} = \sqrt{|I|}\,(1+\ln t+\ln(\log t)) \leq \sqrt{|I|}\,(1+2\ln t) \tag{66}$$

where $\eta^{(I)} := 1/\sqrt{|I|}$, and $\ln(\log t) \leq \ln(t)$. With (64), for any interval $I \in \mathcal{I}$, we have

$$\mathrm{Reg}^{\mathrm{s}}_{\mathrm{AdaRaker}}(|I|) = \sqrt{|I|}\,(1+c_0+2\ln t) \leq \sqrt{|I|}\,(1+c_0+2\ln T)\,. \tag{67}$$

Since the static regret bound (65) holds only at the end of such interval, the bound (67) only holds for those intervals (collected in $\mathcal{I}$) (re)initializing Raker instance $\mathcal{A}_I$.

The next step is to show that (67) holds for any interval $I \subseteq \mathcal{T}$, possibly $I \notin \mathcal{I}$. This is possible whenever the interval set $\mathcal{I}$ is properly designed, e.g., the interval partition given in Section 4.1. For any interval I, define the set of subintervals covered by I as $\mathcal{I}\|I := \{I' \subseteq I, I' \in \mathcal{I}\}$. As argued in (Daniely et al., 2015, Lemma 5), interval I can be partitioned into two sequences of *non-overlapping* but *consecutive* intervals, given by $\{I_{-m},\ldots,I_0\} \subseteq \mathcal{I}\|I$ and $\{I_1,\ldots,I_n\} \subseteq \mathcal{I}\|I$, the lengths of which satisfy $|I_{k+1}|/|I_k| \leq 1/2$, $\forall k \in [1,n-1]$ and $|I_k|/|I_{k+1}| \leq 1/2$, $\forall k \in [-m,-1]$. Therefore, we have (using $\sum_{k=1}^{\infty}\sqrt{2^{-k}T_0} \leq 4\sqrt{T_0}$)

$$\mathrm{Reg}^{\mathrm{s}}_{\mathrm{AdaRaker}}(|I|) = \sum_{k=1}^{n-1}\mathrm{Reg}^{\mathrm{s}}_{\mathrm{Ada}}(|I_k|) + \sum_{k=-m}^{-1}\mathrm{Reg}^{\mathrm{s}}_{\mathrm{Ada}}(|I_k|) \leq C_0\sqrt{|I|} + C_1\ln T\sqrt{|I|} \tag{68}$$

where the inequality follows from (67) with $|I|$ replaced by $|I_k|$ ($\leq |I|$), and C_0, C_1 are constants depending on c_0 defined in (63). This completes the proof of Lemma 2.

Appendix D. Proof of Theorem 2

To start, the dynamic regret in (34) can be decomposed as

$$\mathrm{Reg}^{\mathrm{d}}_{\mathcal{A}}(T) := \sum_{t=1}^{T}\mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \sum_{t=1}^{T}\mathcal{L}_t(f^*(\mathbf{x}_t)) + \sum_{t=1}^{T}\mathcal{L}_t(f^*(\mathbf{x}_t)) - \sum_{t=1}^{T}\mathcal{L}_t(f_t^*(\mathbf{x}_t)) \tag{69}$$

where $f^*(\cdot)$ is the best fixed function in (26), and $f_t^*(\cdot)$ is the best dynamic function in (35), both of which belong to the union of spaces $\bigcup_{p\in\mathcal{P}}\mathcal{H}_p$. In (69), the first difference of sums is the static regret of AdaRaker, while the second difference of sums is the relative loss between the best fixed function and the best dynamic solution in the common space.

Intuitively, if the time horizon T is large, then the average static regret will become small, but the gap between the two benchmarks is large. With the insights gained from (Besbes et al., 2015; Luo et al., 2017), T essentially trades off the values of two terms. Thus,

splitting $\mathcal{T}$ into sub-horizons $\{\mathcal{T}_s\}$, $s = 1,\ldots,\lfloor T/\Delta T\rfloor$, each having length ΔT, the dynamic regret of AdaRaker can be bounded by

$$\begin{aligned}\mathrm{Reg}^{\mathrm{d}}_{\mathrm{AdaRaker}}(T) &= \sum_{s=1}^{\lfloor T/\Delta T\rfloor}\sum_{t\in\mathcal{T}_s}\Big(\mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \mathcal{L}_t(f^*_{\mathcal{T}_s}(\mathbf{x}_t))\Big) + \sum_{s=1}^{\lfloor T/\Delta T\rfloor}\sum_{t\in\mathcal{T}_s}\big(\mathcal{L}_t(f^*_{\mathcal{T}_s}(\mathbf{x}_t)) - \mathcal{L}_t(f_t^*(\mathbf{x}_t))\big)\\ &:= \sum_{s=1}^{\lfloor T/\Delta T\rfloor}\mathcal{R}_1 + \sum_{s=1}^{\lfloor T/\Delta T\rfloor}\mathcal{R}_2\end{aligned} \tag{70}$$

where the first sum over $\mathcal{T}_s$ we define as $\mathcal{R}_1$ can be bounded under AdaRaker from Lemma 2, while the second sum over $\mathcal{T}_s$ that we define as $\mathcal{R}_2$ depends on the variability of the environments $\mathcal{V}(\{\mathcal{L}_t\})$, can be bounded by (Besbes et al., 2015, Prop. 2)

$$\mathcal{R}_2 \leq 2\Delta T\mathcal{V}(\{\mathcal{L}_t\}_{t\in\mathcal{T}_s}). \tag{71}$$

Together with Lemma 2, it follows that

$$\begin{aligned}\mathrm{Reg}^{\mathrm{d}}_{\mathrm{AdaRaker}}(T) &\leq \sum_{s=1}^{\lfloor T/\Delta T\rfloor}\Big((C_0+C_1\ln T)\sqrt{\Delta T} + 2\Delta T\mathcal{V}(\{\mathcal{L}_t\}_{t\in\mathcal{T}_s})\Big)\\ &= (C_0+C_1\ln T)\frac{T}{\sqrt{|\Delta T|}} + 2|\Delta T|\mathcal{V}(\{\mathcal{L}_t\}_{t=1}^{T}),\ \text{w.h.p.}\end{aligned} \tag{72}$$

Since (37) in Lemma 2 holds for any interval $\Delta T \subseteq \mathcal{T}$, after selecting ΔT so that $|\Delta T| = \big(T/\mathcal{V}(\{\mathcal{L}_t\}_{t=1}^{T})\big)^{\frac{2}{3}}$, we arrive at

$$\mathrm{Reg}^{\mathrm{d}}_{\mathrm{AdaRaker}}(T) \leq (C_0+C_1\ln T)T^{\frac{2}{3}}\mathcal{V}^{\frac{1}{3}}(\{\mathcal{L}_t\}_{t=1}^{T}) + 2T^{\frac{2}{3}}\mathcal{V}^{\frac{1}{3}}(\{\mathcal{L}_t\}_{t=1}^{T}),\ \text{w.h.p.} \tag{73}$$

which completes the proof of Theorem 2.

Appendix E. Proof of Theorem 3

Suppose that the m-switching dynamic solution $\{\check{f}_t^*\}$ changes at slots $t_1 = 1,\ldots,t_m$, and define the m sub-intervals that partition $\mathcal{T} := \{1,\ldots,T\}$ as $\mathcal{T}_1 := [1,t_2-1]$, $\mathcal{T}_2 := [t_2,t_3-1],\ldots$, and $\mathcal{T}_m := [t_m,T]$. To use the bound in Lemma 2, we decompose the regret of AdaRaker relative to the m-switching dynamic solution $\{\check{f}_t^*\}$ by

$$\begin{aligned}\mathrm{Reg}^{m}_{\mathrm{AdaRaker}}(T) &\overset{(a)}{=} \sum_{s=1}^{m}\sum_{t\in\mathcal{T}_s}\Big(\mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \mathcal{L}_t(\check{f}^*_{t_s}(\mathbf{x}_t))\Big)\\ &\overset{(b)}{\leq} \sum_{s=1}^{m}\sum_{t\in\mathcal{T}_s}\Big(\mathcal{L}_t(\hat{f}_t(\mathbf{x}_t)) - \mathcal{L}_t(f^*_{\mathcal{T}_s}(\mathbf{x}_t))\Big)\end{aligned} \tag{74}$$

where (a) holds because the definition of $\{\check{f}_t^*\}$ in (40) implies that $\check{f}_t^* = \check{f}^*_{t_s}$, $\forall t \in \mathcal{T}_s$, and (b) because the best fixed function is given by $f^*_{\mathcal{T}_s} \in \arg\min_{f\in f\in\bigcup_{p\in\mathcal{P}}\mathcal{H}_p}\sum_{t\in\mathcal{T}_s}\mathcal{L}_t(f(\mathbf{x}_t))$. Therefore, using the regret bound of Lemma 2 in (37), we have

$$\mathrm{Reg}^{m}_{\mathrm{AdaRaker}}(T) \leq \sum_{s=1}^{m}\mathrm{Reg}^{\mathrm{s}}_{\mathcal{A}}(|\mathcal{T}_s|) \leq (C_0+C_1\ln T)\sum_{s=1}^{m}\sqrt{|\mathcal{T}_s|}. \tag{75}$$

Holder's inequality further implies that

$$\begin{aligned}\mathrm{Reg}^m_{\mathrm{AdaRaker}}(T) &\leq (C_0 + C_1 \ln T)\left(\sum_{s=1}^{m}(1)^2\right)^{\frac{1}{2}}\left(\sum_{s=1}^{m}\left(\sqrt{|\mathcal{T}_s|}\right)^2\right)^{\frac{1}{2}} \\ &\leq (C_0 + C_1 \ln T)\sqrt{Tm}, \text{ w.h.p.} \end{aligned} \tag{76}$$

which completes the proof of Theorem 3.

Abstract

Statistical relational learning is primarily concerned with learning and inferring relationships between entities in large-scale knowledge graphs. Nickel et al. (2011) proposed a RESCAL tensor factorization model for statistical relational learning, which achieves better or at least comparable results on common benchmark data sets when compared to other state-of-the-art methods. Given a positive integer s, RESCAL computes an s-dimensional latent vector for each entity. The latent factors can be further used for solving relational learning tasks, such as collective classification, collective entity resolution and link-based clustering.

The focus of this paper is to determine the number of latent factors in the RESCAL model. Due to the structure of the RESCAL model, its log-likelihood function is not concave. As a result, the corresponding maximum likelihood estimators (MLEs) may not be consistent. Nonetheless, we design a specific pseudometric, prove the consistency of the MLEs under this pseudometric and establish its rate of convergence. Based on these results, we propose a general class of information criteria and prove their model selection consistencies when the number of relations is either bounded or diverges at a proper rate of the number of entities. Simulations and real data examples show that our proposed information criteria have good finite sample properties.

Keywords: Information criteria; Knowledge graph; Model selection consistency; RESCAL model; Statistical relational learning; Tensor factorization.

1. Introduction

Relational data is becoming ubiquitous in artificial intelligence and social network analysis. These data sets are in the form of graphs, with nodes and edges representing entities and relationships, respectively. Recently, a number of companies have developed and released their knowledge graphs, including the Google Knowledge Graph, Microsoft Bing's Satori Knowledge Base, Yandex's Object Answer, the Linkedln Knowledge Graph, etc. These knowledge graphs are graph-structured knowledge bases that store factual information as relationships between entities. They are created via the automatic extraction of semantic relationships from semi-structured or unstructured text (see Section II.C in Nickel et al., 2016). The data may be incomplete, noisy and contain false information. It is therefore of great importance to infer the existence of a particular relationship to improve the quality of these extracted information.

Statistical relational learning is primarily concerned with learning from relational data sets, and solving tasks such as predicting whether two entities are related (link prediction), identifying equivalent entities (entity resolution), and grouping similar entities based on their relationships (link-based clustering). Statistical relational models can be roughly divided into three categories: the relational graphical models, the latent class models and the tensor factorization models. Relational graphical models include probabilistic relational models (Getoor and Mihalkova, 2011) and Markov logic networks (MLN, Richardson and Domingos, 2006). These models are constructed via Bayesian or Markov networks. In latent class models, each entity is assigned to one of the latent classes and the probability of a relationship between entities depends on their corresponding classes. Two important examples include the stochastic block model (SBM, Nowicki and Snijders, 2001) and the infinite relational model (IRM, Kemp et al., 2006). IRM can be viewed as a nonparametric extension of SBM where the total number of clusters is not prespecified. Both models have received considerable attentions in the statistics and machine learning literature for community detection in networks.

Tensors are multidimensional arrays. Tensor factorization methods such as CANDECOMP/PARAFAC (CP, Harshman and Lundy, 1994), Tucker (Tucker, 1966) and their extensions have found applications in a variety of fields. Kolda and Bader (2009) presented a thorough overview of tensor decompositions and their applications. Recently, tensor factorizations are being actively studied in the statistics literature and have becoming an emerging field of statistics. To name a few, Chi and Kolda (2012) developed a Poisson tensor factorization model for sparse count data. Yang and Dunson (2016) proposed a conditional tensor factorization model for high-dimensional classification with categorical predictors. Sun et al. (2017) proposed a sparse tensor decomposition method by incorporating a truncation step into the tensor power iteration step.

Relational data sets are typically expressed as (subject, predicate, object) triples and can be grouped as a third-order tensor. As a result, tensor factorization methods can be naturally applied to these data sets. Nickel (2013) proposed a RESCAL factorization model for statistical relational learning. Compared to other tensor factorization approaches such as CP and Tucker methods, RESCAL is more capable of detecting the correlations produced between multiple interconnected nodes. For relational data consisting of n entities, K types of relations, and a positive integer s, RESCAL computes an $n \times s$ factor matrix and an $s \times s \times K$ core tensor. The factor matrix and the core tensor can be further used for link prediction, entity resolution and link-based clustering. Nickel et al. (2011) showed that a linear RESCAL model achieved better or comparable results on common benchmark data sets when compared to other existing methods such as MLN, DEDICOM (Harshman, 1978), IRM, CP, MRC (Kok and Domingos, 2007), etc. It was shown in Nickel and Tresp (2013) that a logistic RESCAL model could further improve the link prediction results.

Central to the empirical validity of RESCAL is the correct specification of the number of latent factors. Nickel et al. (2011) proposed to select this parameter via cross-validation. As commonly known for cross-validation methods, there's no theoretical guarantee against overestimation. Besides, cross-validation can be computationally expensive, especially for large n and K. In the literature, model selection is less studied for tensor factorization

methods. Allen (2012) and Sun et al. (2017) proposed to use Bayesian information criteria (BIC, Schwarz, 1978) for sparse CP decomposition. However, no theoretical results were provided for BIC. Indeed, we show in this paper that a BIC-type criterion may fail for the RESCAL model.

The contribution of this paper is twofold. First, we propose a general class of information criteria for the RESCAL model and prove their model selection consistency. Although we focus on the RESCAL model, our information criteria can be extended to select models for general tensor factorization methods with slight modification. The problem is nonstandard and challenging since both the factor matrix and the core tensor are not observed and need to be estimated. Besides, the model parameters are non-identifiable. Moreover, the derivation of model/tuning parameter selection consistency of information criteria usually relies on the (uniform) consistency of estimated parameters. For example, Fan and Tang (2013) derived the uniform consistency of the maximum likelihood estimators (MLEs) to prove the consistency of GIC (see Proposition 2 in that paper). Zhang et al. (2016) established the uniform consistency of the support vector machine solutions to prove the consistency of SVMIC$_H$ (see Lemma 2 in that paper). The consistency of these estimators are due to the concavity (convexity) of the likelihood (or the empirical loss) functions. In contrast, for most tensor decomposition models including RESCAL, the likelihood (or the empirical loss) function is usually non-concave (non-convex) and may have multiple local solutions. As a result, the corresponding global maximizer (minimizer) may not be consistent even with the identifiability constraints. It remains unknown how to establish the consistency of the information criterion without consistency of the estimator. A key innovation in our analysis is to design a "proper" pseudometric and show that the global optimum is consistent under this specific pseudometric. We further establish the rate of convergence of the global optimum under this pseudometric as a function of n and K. Based on these results, we establish the consistency of our information criteria when K is either bounded or diverges at a proper rate of n. No parametric assumptions are imposed on the latent factors. Second, we introduce a scalable algorithm for estimating the parameters in the logistic RESCAL model. Despite the fact that a linear RESCAL model can be conveniently solved by an alternating least square algorithm (Nickel et al., 2011), there are lack of optimization algorithms for solving general RESCAL models. The proposed algorithm is based on the alternating direction method of multipliers (ADMM, Boyd et al., 2011) and can be implemented in a parallelized fashion.

The rest of the paper is organized as follows. We formally introduce the RESCAL model and study the parameter identifiability in Section 2. Our information criteria are presented in Section 3 and their model selection properties are investigated. Numerical examples are presented in Section 4 to examine the finite sample performance of the proposed information criteria. Section 5 concludes with a summary and discussion of future extensions. All the proofs are given in the Appendix.

2. The RESCAL Model

This section is structured as follows. We introduce the RESCAL model in Section 2.1. In Section 2.2, we study the identifiability of parameters in the model.

2.1. Model Setup

In knowledge graphs, facts can be expressed in the form of (subject, predicate, object) triples, where subject and object are entities and predicate is the relation between entities. For example, consider the following sentence from Wikipedia:

Jon Snow is a fictional character in the A Song of Ice and Fire series of fantasy novels by American author George R. R. Martin, and its television adaptation Game of Thrones.

The information contained in this message can be summarized into the following set of (subject, predicate, object) triples:

Subject	*Predicate*	*Object*
Jon Snow	*character in*	*A Song of Ice and Fire*
Jon Snow	*character in*	*Game of Thrones*
A Song of Ice and Fire	*genre*	*novel*
Game of Thrones	*genre*	*television series*
George R.R. Martin	*author of*	*A Song of Ice and Fire*
George R.R. Martin	*profession*	*novelist*

In this example, we have a total of 7 entities, 4 types of relations and 6 triples. More generally, let $\mathcal{E} = \{e_1, \ldots, e_n\}$ denote the set of all entities and $\mathcal{R} = \{r_1, \ldots, r_K\}$ denote the set of all relation types. The number of relations K is either bounded or diverges with n. Assuming non-existing triples indicate false relationships, we can construct a third-order binary tensor

$$\boldsymbol{Y} = \{Y_{ijk}\}_{i,j\in\{1,\ldots,n\},k\in\{1,\ldots,K\}},$$

such that

$$Y_{ijk} = \begin{cases} 1, & \text{if a triple } (e_i, r_k, e_j) \text{ exists,} \\ 0, & \text{otherwise.} \end{cases}$$

The RESCAL model is defined as follows. For each entity e_i, a latent vector $\boldsymbol{a}_{i,0} \in \mathbb{R}^{s_0}$ is generated. The Y_{ijk}'s are assumed to be conditionally independent given all latent factors $\{\boldsymbol{a}_{i,0}\}_{i=1}^n$. Besides, it is assumed that

$$\Pr(Y_{ijk} = 1 | \{\boldsymbol{a}_{i,0}\}_{i=1}^n) = \mathrm{g}(\boldsymbol{a}_{i,0}^T \boldsymbol{R}_{k,0} \boldsymbol{a}_{j,0}), \tag{1}$$

for some strictly monotone link function g and $s_0 \times s_0$ matrices $\boldsymbol{R}_{1,0}, \ldots, \boldsymbol{R}_{K,0}$. In the above model, $\boldsymbol{a}_{i,0}$ corresponds to the latent representation of the ith entity and $\boldsymbol{R}_{k,0}$ specifies how these $\boldsymbol{a}_{i,0}$'s interact for the k-th relation. To account for asymmetric relations, we do not restrict $\boldsymbol{R}_{k,0}$'s to symmetric matrices. When the relations are symmetric, i.e.,

$$\Pr(Y_{ijk} = 1 | \{\boldsymbol{a}_{i,0}\}_{i=1}^n) = \Pr(Y_{jik} = 1 | \{\boldsymbol{a}_{i,0}\}_{i=1}^n), \quad \forall i, j, k,$$

one can impose the symmetry constraints and obtain a similar derivation.

For continuous Y_{ijk}, a related tensor factorization model is the TUCKER-2 decomposition, which decomposes the tensor into

$$Y_{ijk} = \boldsymbol{a}_{i,0}^T \boldsymbol{R}_{k,0} \boldsymbol{b}_{j,0} + e_{ijk}, \quad \forall i, j, k, \tag{2}$$

for some $\boldsymbol{a}_{1,0},\ldots,\boldsymbol{a}_{n,0} \in \mathbb{R}^{s_1}$, $\boldsymbol{b}_{1,0},\ldots,\boldsymbol{b}_{n,0} \in \mathbb{R}^{s_2}$, $\boldsymbol{R}_{1,0},\ldots,\boldsymbol{R}_{K,0} \in \mathbb{R}^{s_1\times s_2}$ and some (random) errors $\{e_{ijk}\}_{ijk}$. By Equation 1, RESCAL can be interpreted as a "nonlinear" TUCKER-2 model with the additional constraints that $s_1 = s_2 = s_0$ and $\boldsymbol{a}_{i,0} = \boldsymbol{b}_{i,0}, \forall i$.

CP decomposition is another important tensor factorization method that decomposes a tensor into a sum of rank-1 tensors. It assumes that

$$Y_{ijk} = \sum_{s=1}^{s_0} a_{i,s}b_{j,s}r_{k,s} + e_{ijk},$$

for some $\{a_{i,s}\}_{i,s}$, $\{b_{j,s}\}_{j,s}$, $\{r_{k,s}\}_{k,s}$ and $\{e_{ijk}\}_{ijk}$. Define $\boldsymbol{a}_{i,0} = (a_{i,1},\ldots,a_{i,s_0})^T$ and $\boldsymbol{b}_{i,0} = (b_{i,1},\ldots,b_{i,s_0})^T$. In view of Equation 2, CP is a special TUCKER-2 model with the constraints that $s_1 = s_2 = s_0$ and $\boldsymbol{R}_{k,0} = \mathrm{diag}(r_{k,1},\ldots,r_{k,s_0})$ where $\mathrm{diag}(r_{k,1},\ldots,r_{k,s_0})$ is a diagonal matrix with the sth diagonal elements being $r_{k,s}$.

In this paper, the proposed information criteria are designed in particular for the RESCAL model. However, they can be extended to estimate s_0 in a more general tensor factorization framework including CP and TUCKER-2 models. We discuss this further in Section 5.

2.2. Identifiability

The parameterization in Equation 1 is not identifiable. To see this, for any nonsingular matrix $\boldsymbol{C} \in \mathbb{R}^{s_0\times s_0}$, we define $\boldsymbol{a}_i = \boldsymbol{C}^{-1}\boldsymbol{a}_{i,0}$, $\boldsymbol{R}_k = \boldsymbol{C}^T\boldsymbol{R}_{k,0}\boldsymbol{C}$, $\forall i,k$. Observe that

$$\boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0} = \boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j, \quad \forall i,j,k,$$

and hence we have

$$\Pr(Y_{ijk} = 1) = \mathrm{g}(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j).$$

Let $\boldsymbol{A}_0 = [\boldsymbol{a}_{1,0},\ldots,\boldsymbol{a}_{n,0}]^T$. We impose the following condition.

(A0) (i) Assume $\boldsymbol{A}_0$ has full column rank. (ii) Assume the matrix $[\boldsymbol{R}_{1,0}^T,\ldots,\boldsymbol{R}_{K,0}^T]$ has full row rank.

(A0)(i) requires the latent factors to be linearly independent. (A0)(ii) holds when at least one of the $\boldsymbol{R}_{k,0}$'s has full rank. Under Condition (A0), the following lemma states that the RESCAL model is identifiable up to a nonsingular linear transformation. In Section B.1 of the Appendix, we show (A0) is also necessary to guarantee such identifiability when $\boldsymbol{R}_{1,0},\ldots,\boldsymbol{R}_{K,0}$ are symmetric.

Lemma 1 (Identifiability). *Assume (A0) holds. Assume there exist some $\{\boldsymbol{a}_i\}_i$, $\{\boldsymbol{R}_k\}_k$ such that $\boldsymbol{a}_i \in \mathbb{R}^{s_0}$, $\boldsymbol{R}_k \in \mathbb{R}^{s_0\times s_0}$ and*

$$g(\boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0}) = g(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j), \quad \forall i,j,k.$$

Then, there exists some invertible matrix $\boldsymbol{C} \in \mathbb{R}^{s_0\times s_0}$ such that

$$\boldsymbol{a}_i = \boldsymbol{C}^{-1}\boldsymbol{a}_{i,0} \quad \textit{and} \quad \boldsymbol{R}_k = \boldsymbol{C}^T\boldsymbol{R}_{k,0}\boldsymbol{C}.$$

To fix the nonsingular transformation indeterminacy, we adopt a specific constrained parameterization and focus on estimating $\{\boldsymbol{a}_i^*\}_i$ and $\{\boldsymbol{R}_k^*\}_k$ where

$$\boldsymbol{a}_i^* = (\boldsymbol{A}_{s_0,0}^{-1})^T\boldsymbol{a}_{i,0} \quad \text{and} \quad \boldsymbol{R}_k^* = \boldsymbol{A}_{s_0,0}\boldsymbol{R}_{k,0}\boldsymbol{A}_{s_0,0}^T,$$

where $\boldsymbol{A}_{s_0,0} = [\boldsymbol{a}_{1,0},\ldots,\boldsymbol{a}_{s_0,0}]^T$. Observe that

$$[\boldsymbol{a}_1^*,\ldots,\boldsymbol{a}_{s_0}^*] = (\boldsymbol{A}_{s_0,0}^{-1})^T[\boldsymbol{a}_{1,0},\ldots,\boldsymbol{a}_{s_0,0}] = (\boldsymbol{A}_{s_0,0}^{-1})^T\boldsymbol{A}_{s_0,0}^T = \boldsymbol{I}_{s_0},$$

where $\boldsymbol{I}_{s_0}$ stands for an $s_0\times s_0$ identity matrix. Therefore, the first s_0 $\boldsymbol{a}_i^*$'s are fixed as long as $\boldsymbol{A}_{s_0,0}$ is nonsingular. By Lemma 1, the parameters $\{\boldsymbol{a}_i^*\}_i$ and $\{\boldsymbol{R}_k^*\}_k$ are estimable.

From now on, we only consider the logistic link function for simplicity, i.e, $\mathrm{g}(x) = 1/\{1+\exp(-x)\}$. Results for other link functions can be similarly discussed.

3. Model Selection

Parameters $\{\boldsymbol{a}_i^*\}_{i=1}^n$ and $\{\boldsymbol{R}_k^*\}_{k=1}^K$ can be estimated by maximizing the (conditional) log-likelihood function. Since we use the logistic link function, the log-likelihood is equal to

$$\begin{aligned}
\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i\}_i,\{\boldsymbol{R}_k\}_k) &= \log\left(\prod_{ijk}\mathrm{g}(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)^{Y_{ijk}}\{1-\mathrm{g}(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)\}^{1-Y_{ijk}}\right)\\
&= \sum_{ijk}\left(Y_{ijk}\log\{\mathrm{g}(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)\} + (1-Y_{ijk})\log\{1-\mathrm{g}(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)\}\right)\\
&= \sum_{ijk}\left(Y_{ijk}\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j - \log\{1+\exp(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)\}\right),
\end{aligned}$$

where the first equality is due to the conditional independence assumption.

We assume the number of latent factors s_0 is fixed. For any $s \in \{1,\ldots,s_{\max}\}$ where $s_{\max}$ is allowed to diverge with n and satisfies $s_{\max} \geq s_0$, we define the following constrained maximum likelihood estimator

$$(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) = \underset{\substack{\boldsymbol{a}_1^{(s)},\ldots,\boldsymbol{a}_n^{(s)}\in\Theta_a^{(s)}\\ \mathrm{vec}(\boldsymbol{R}_1^{(s)}),\ldots,\mathrm{vec}(\boldsymbol{R}_K^{(s)})\in\Theta_r^{(s)}}}{\arg\max} \ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k), \tag{3}$$

$$\text{subject to} \quad [\boldsymbol{a}_1^{(s)},\ldots,\boldsymbol{a}_s^{(s)}] = \boldsymbol{I}_s, \tag{4}$$

for some $\Theta_a^{(s)} \subseteq \mathbb{R}^s$, $\Theta_r^{(s)} \subseteq \mathbb{R}^{s^2}$, where the $\mathrm{vec}(\cdot)$ operator stacks the entries of a matrix into a column vector. To estimate the number of latent factors, we define the following likelihood-based information criteria

$$\mathrm{IC}(s) = 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - s\kappa(n,K),$$

for some penalty functions $\kappa(\cdot,\cdot)$. The estimated number of latent factors is given by

$$\hat{s} = \underset{s\in\{1,\ldots,s_{\max}\}}{\arg\max}\ \mathrm{IC}(s). \tag{5}$$

In addition to the constraint in Equation 4, there exist many other constraints that would make the estimators identifiable. The choice of the identifiability constraints might affect the value of IC. However, it wouldn't affect the value of $\hat{s}$. Detailed discussions can be found in Section A of the Appendix.

A major technical difficulty in establishing the consistency of IC is due to the nonconcavity of the objective function given in Equation 3. For any $\{\boldsymbol{a}_j\}_{j\in\{1,\ldots,n\}}$, $\{\boldsymbol{R}_k\}_{k\in\{1,\ldots,K\}}$, let

$$\boldsymbol{\beta} = (\boldsymbol{a}_1^T, \ldots, \boldsymbol{a}_n^T, \mathrm{vec}(\boldsymbol{R}_1)^T, \ldots, \mathrm{vec}(\boldsymbol{R}_K)^T)^T,$$

be the set of parameters.

For any $\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n \in \mathbb{R}^s$, $\boldsymbol{T}_1, \ldots, \boldsymbol{T}_K \in \mathbb{R}^{s\times s}$, we define

$$\boldsymbol{\zeta} = (\boldsymbol{b}_1^T, \ldots, \boldsymbol{b}_n^T, \mathrm{vec}(\boldsymbol{T}_1)^T, \ldots, \mathrm{vec}(\boldsymbol{T}_K)^T)^T.$$

With some calculations, we can show that

$$\begin{aligned} -\boldsymbol{\zeta}^T \frac{\partial^2 \ell_n}{\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}^T}\boldsymbol{\zeta} &= \underbrace{\sum_{ijk} \pi_{ijk}(1-\pi_{ijk})(\boldsymbol{b}_i^T\boldsymbol{R}_k\boldsymbol{a}_j + \boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{b}_j + \boldsymbol{a}_i^T\boldsymbol{T}_k\boldsymbol{a}_j)^2}_{I_1} \\ &+ \underbrace{\sum_{ijk}(\pi_{ijk} - Y_{ijk})(2\boldsymbol{b}_i^T\boldsymbol{R}_k\boldsymbol{b}_j + \boldsymbol{b}_i^T\boldsymbol{T}_k\boldsymbol{a}_j + \boldsymbol{a}_i^T\boldsymbol{T}_k\boldsymbol{b}_j)}_{I_2}, \end{aligned}$$

where $\pi_{ijk} = \exp(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)/\{1+\exp(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)\}$. Here, I_1 is nonnegative. However, I_2 can be negative for some $\boldsymbol{\beta}$ and $\boldsymbol{\zeta}$. Therefore, the negative Hessian matrix is not positive semidefinite and the likelihood function is not concave. As a result, $\widehat{\boldsymbol{a}}_i^{s_0}$ and $\widehat{\boldsymbol{R}}_k^{s_0}$ may not be consistent to $\boldsymbol{a}_i^*$ and $\boldsymbol{R}_k^*$, even with the identifiability constraints in Equation 4. Here, the presence of I_2 is due to the bilinear formulation of the RESCAL model.

Let $\theta_{ijk} = \boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j$. Notice that ℓ_n is concave in θ_{ijk}, $\forall i,j,k$. This motivates us to consider the following pseudometric:

$$\begin{aligned} & d\left(\{\boldsymbol{a}_{i,1}^{(s_1)}\}_i, \{\boldsymbol{R}_{k,1}^{(s_1)}\}_{k_1}; \{\boldsymbol{a}_{i,2}^{(s_2)}\}_i, \{\boldsymbol{R}_{k,2}^{(s_2)}\}_{k_2}\right) \\ = & \left\{\frac{1}{n^2K}\sum_{ijk}\left((\boldsymbol{a}_{i,1}^{(s_1)})^T(\boldsymbol{R}_{k,1}^{(s_1)})^T\boldsymbol{a}_{j,1}^{(s_1)} - (\boldsymbol{a}_{i,2}^{(s_2)})^T(\boldsymbol{R}_{k,2}^{(s_2)})^T\boldsymbol{a}_{j,2}^{(s_2)}\right)^2\right\}^{1/2}, \end{aligned}$$

for any integers $s_1, s_2 > 0$ and $\boldsymbol{a}_{i,1}^{(s_1)} \in \mathbb{R}^{s_1}$, $\boldsymbol{R}_{k,1}^{(s_1)} \in \mathbb{R}^{s_1\times s_1}$, $\boldsymbol{a}_{i,2}^{(s_2)} \in \mathbb{R}^{s_2}$, $\boldsymbol{R}_{k,2}^{(s_2)} \in \mathbb{R}^{s_2\times s_2}$. Apparently, $d(\cdot,\cdot)$ is nonnegative, symmetric and satisfies the triangle inequality. Below, we establish the convergence rate of

$$d\left(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k; \{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k\right).$$

We first introduce some notation. For any $s > s_0$, we define

$$\boldsymbol{a}_{i,0}^{(s)} = \begin{cases} ((\boldsymbol{a}_{i,0})^T, \boldsymbol{0}_{s-s_0}^T)^T, & i \notin \{s_0+1,\ldots,s\}, \\ ((\boldsymbol{a}_{i,0})^T, \underbrace{0,\ldots,0}_{i-s_0-1}, 1, \underbrace{0,\ldots,0}_{s-i})^T, & i \in \{s_0+1,\ldots,s\}, \end{cases}$$

and

$$\boldsymbol{R}_{k,0}^{(s)} = \begin{pmatrix} \boldsymbol{R}_{k,0} & \boldsymbol{O}_{r,s-r} \\ \boldsymbol{O}_{s-r,r} & \boldsymbol{O}_{s-r,s-r} \end{pmatrix},$$

where $\boldsymbol{0}_q$ denotes a q-dimensional zero vector and $\boldsymbol{O}_{p,q}$ is an $p\times q$ zero matrix. With a slight abuse of notation, we write $\boldsymbol{a}_{i,0}^{(s_0)} = \boldsymbol{a}_{i,0}$ and $\boldsymbol{R}_{k,0}^{(s_0)} = \boldsymbol{R}_{k,0}$. Clearly, for any $s \geq s_0$, we have

$$(\boldsymbol{a}_{i,0}^{(s)})^T\boldsymbol{R}_{k,0}^{(s)}\boldsymbol{a}_{j,0}^{(s)} = \boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0}, \quad \forall i,j,k,$$

and hence

$$(\{\boldsymbol{a}_{i,0}^{(s)}\}_i, \{\boldsymbol{R}_{k,0}^{(s)}\}_k) = \underset{\{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k}{\arg\max} \mathrm{E}\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k).$$

Let

$$\boldsymbol{a}_i^{(s)*} = (\boldsymbol{A}_{s,0}^{-1})^T\boldsymbol{a}_{i,0}^{(s)} \quad \text{and} \quad \boldsymbol{R}_k^{(s)*} = \boldsymbol{A}_{s,0}\boldsymbol{R}_{k,0}^{(s)}\boldsymbol{A}_{s,0}^T,$$

where $\boldsymbol{A}_{s,0} = [\boldsymbol{a}_{1,0}^{(s)}, \ldots, \boldsymbol{a}_{s,0}^{(s)}]^T$. When $\boldsymbol{A}_{s_0,0}$ is invertible, $\boldsymbol{A}_{s,0}$'s are invertible for all $s > s_0$. The defined $\{\boldsymbol{a}_i^{(s)*}\}$'s satisfy the identifiability constraints in Equation 4 for all $s \geq s_0$. We make the following assumption.

(A1) Assume $\boldsymbol{a}_i^{(s)*} \in \Theta_a^{(s)}$ and $\mathrm{vec}(\boldsymbol{R}_k^{(s)*}) \in \Theta_r^{(s)}$, $\forall i = 1,\ldots,n$, $k = 1,\ldots,K$ and $s_0 \leq s \leq s_{\max}$. In addition, assume $\sup_{\boldsymbol{x}\in\Theta_a^{(s)}}\|\boldsymbol{x}\|_2 \leq \omega_a$, $\sup_{\boldsymbol{y}\in\Theta_r^{(s)}}\|\boldsymbol{y}\|_2 \leq \omega_r$ for some $\omega_a, \omega_r > 0$.

Lemma 2. *Assume (A1) holds, $s_{\max} = o\{\sqrt{n/\log(nK)}\}$. Then there exists some constant $C_0 > 0$ such that the following event occurs with probability tending to 1,*

$$\max_{s\in\{s_0,\ldots,s_{\max}\}} \frac{1}{s^2}d^2\left(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k; \{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k\right) \leq \frac{\exp(2\omega_a^2\omega_r)(n+K)(\log n + \log K)}{n^2K}.$$

Under the condition $s_{\max} = o\{\sqrt{n/\log(nK)}\}$, we have that

$$\frac{s_{\max}^2(n+K)(\log n + \log K)}{n^2K} \leq \frac{s_{\max}^2(2n\log n + 2K\log K)}{n^2K} \leq \frac{2s_{\max}^2\log n}{n} + \frac{2s_{\max}^2\log K}{n^2} = o(1).$$

When ω_a and ω_r are bounded, it follows that

$$\max_{s\in\{s_0,\ldots,s_{\max}\}} d^2\left(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k; \{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k\right) \leq \frac{s_{\max}^2\exp(2\omega_a^2\omega_r)(n+K)(\log n + \log K)}{n^2K} = o(1).$$

Hence, $\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i$ and $\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k$ are consistent under the pseudometric d for all overfitted models. On the contrary, for underfitted models, we require the following conditions.

(A2) Assume there exists some constant $\bar{c} > 0$ such that $\lambda_{\min}(\boldsymbol{A}_0^T\boldsymbol{A}_0) \geq n\bar{c}$.
(A3) Let $\bar{K} = \lambda_{\min}(\sum_{k=1}^K \boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0})$. Assume $\liminf_n \bar{K} > 0$.

Lemma 3. *Assume (A2) and (A3) hold. The for any $s \in \{1, 2, \ldots, s_0 - 1\}$, we have*

$$d^2\left(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k; \{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k\right) \geq \frac{\bar{c}^2\bar{K}}{K},$$

where $\bar{c}$ and $\bar{K}$ are defined in (A2) and (A3), respectively.

Assumption (A3) holds if there exists some $k_0 \in \{1, \ldots, K\}$ such that

$$\liminf_n \lambda_{\min}(\boldsymbol{R}_{k_0,0}\boldsymbol{R}_{k_0,0}^T) > 0.$$

When $\bar{K} \geq c'K$ for some constant $c' > 0$, it follows from Lemma 3 that

$$\liminf_n d\left(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k; \{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k\right) > 0.$$

Based on these results, we establish the consistency of $\hat{s}$ defined in Equation 5 below. For any sequences $\{a_n\}$ and $\{b_n\}$, we write $a_n \sim b_n$ if there exist some universal constants $c_1, c_2 > 0$ such that $c_1 a_n \leq b_n \leq c_2 a_n$.

Theorem 1. *Assume (A1)-(A3) hold, $K \sim n^{l_0}$ for some $0 \leq l_0 \leq 1$, $s_{\max} = o\{\sqrt{n/\log(nK)}\}$, $\liminf_n n^{(1-l_0)/2}\bar{K} \geq \exp(2\omega_a^2\omega_r)\sqrt{\log n}$. Assume $\kappa(n, K)$ satisfies*

$$s_{\max}\exp(\omega_a^2\omega_r)(n + K)(\log n + \log K) \ll \kappa(n, K) \ll \frac{n^2\bar{K}}{\exp(\omega_a^2\omega_r)}. \tag{6}$$

Then, we have $Pr(\hat{s} = s_0) \to 1$ where $\hat{s}$ is defined in Equation 5.

Let $c(n, K) = \kappa(n, K)(n + K)^{-1}(\log n + \log K)^{-1}$. When $s_{\max}, \omega_a, \omega_r$ are bounded, it follows from Theorem 1 that IC is consistent provided that $c(n, K) \to \infty$ and $c(n, K) = o(n\bar{K}/\log n)$. Define

$$\tau_\alpha(n, K) = \frac{(n + K)^\alpha}{\max^\alpha(n, K)},$$

for some $\alpha \geq 0$. Note that

$$1 \leq \tau_\alpha(n, K) \leq 2^\alpha. \tag{7}$$

Consider the following criteria:

$$\mathrm{IC}_\alpha(s) = 2\ell_n(\boldsymbol{Y}; \{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - s\tau_\alpha(n, K)(n + K)(\log n + \log K)\log\{\log(nK)\}. \tag{8}$$

Note that the term $\log\{\log(nK)\}$ satisfies that $\log\{\log(nK)\} \to \infty$ and $\log\{\log(nK)\} = o(n/\log n)$. It follows from Equation 7 and Theorem 1 that IC_α is consistent for all $\alpha \geq 0$. When $\alpha > 0$, the term $\tau_\alpha(n, K)$ adjust the model complexity penalty upwards. We notice that Bai and Ng (2002) used a similar finite sample correction term in their proposed information criteria for approximate factor models. Our simulation studies show that such adjustment is essential to achieve selection consistency for large K.

Conditions (A1) and (A2) are directly imposed on the realizations of $\boldsymbol{a}_{1,0}, \ldots, \boldsymbol{a}_{n,0}$. In Section B.2 and B.3, we consider an asymptotic framework where $\boldsymbol{a}_{1,0}, \ldots, \boldsymbol{a}_{n,0}$ are i.i.d according to some distribution function and show (A1) and (A2) hold with probability tending to 1. Therefore, under this framework, we still have $\Pr(\hat{s} = s_0) \to 1$. The consistency of our information criterion remains unchanged.

Observe that we have a total of $n \times n \times K = n^2K$ observations. Consider the following BIC-type criterion:

$$\mathrm{BIC}(s) = 2\ell_n(\boldsymbol{Y}; \{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - s\log(n^2K). \tag{9}$$

The model complexity penalty in BIC satisfies

$$\log(n^2K) = 2\log n + \log K \ll (n + K)(\log n + \log K).$$

Hence, it does not meet Condition (6) in Theorem 1. As a result, BIC may fail to identity the true model. As shown in our simulation studies, BIC will choose overfitted models and is not selection consistent.

4. Numerical Experiments

This section is organized as follows. In Section 4.1, we introduce our algorithm for computing the maximum likelihood estimators of a logistic RESCAL model. Simulation studies are presented in Section 4.2. In Section 4.3, we apply the proposed information criteria to a real dataset.

4.1. Implementation

In this section, we propose an algorithm for computing $\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i$ and $\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k$. The algorithm is based upon a 3-block alternating direction method of multipliers (ADMM). Set $\Theta_a^{(s)} = \mathbb{R}^s$, $\Theta_r^{(s)} = \mathbb{R}^{s\times s}$, $[\boldsymbol{a}_1^{(s)}, \ldots, \boldsymbol{a}_s^{(s)}] = \boldsymbol{I}_s$, $\widehat{\boldsymbol{a}}_i^{(s)}$'s and $\widehat{\boldsymbol{R}}_k^{(s)}$'s are defined by

$$(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_{i=(s+1)}^n, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) = \underset{\{\boldsymbol{a}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_k^{(s)}\}_k}{\arg\max} \ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k), \tag{10}$$

where

$$\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k) = \sum_{ijk}\left(Y_{ijk}(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)} - \log[1 + \exp\{(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}]\right).$$

For any $\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n \in \mathbb{R}^s$, define

$$\bar{\ell}_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k, \{\boldsymbol{b}_i^{(s)}\}_i) = \sum_{ijk}\left(Y_{ijk}(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{b}_j^{(s)} - \log[1 + \exp\{(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{b}_j^{(s)}\}]\right).$$

Fix $[\boldsymbol{b}_1^{(s)}, \ldots, \boldsymbol{b}_s^{(s)}] = \boldsymbol{I}_s$, the optimization problem in Equation 10 is equivalent to

$$(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_{i=s+1}^n, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k, \{\widehat{\boldsymbol{b}}_i^{(s)}\}_{i=s+1}^n) = \underset{\substack{\{\boldsymbol{a}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_k^{(s)}\}_k \\ \{\boldsymbol{b}_i^{(s)}\}_{i=s+1}^n}}{\arg\max} \bar{\ell}_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k, \{\boldsymbol{b}_i^{(s)}\}_i),$$
$$\text{subject to} \qquad \boldsymbol{a}_i^{(s)} = \boldsymbol{b}_i^{(s)}, \forall i = s + 1, \ldots, n.$$

We then derive its augmented Lagrangian, which gives us

$$\begin{aligned}&L_\rho(\{\boldsymbol{a}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_k^{(s)}\}_k, \{\boldsymbol{b}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{v}_i^{(s)}\}_{i=s+1}^n)\\ =\ & -\bar{\ell}_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k, \{\boldsymbol{b}_i^{(s)}\}_i) + \sum_{i=s+1}^n \rho(\boldsymbol{a}_i^{(s)} - \boldsymbol{b}_i^{(s)})^T \boldsymbol{v}_i^{(s)} + \sum_{i=s+1}^n \frac{\rho}{2}\|\boldsymbol{a}_i^{(s)} - \boldsymbol{b}_i^{(s)}\|_2^2,\end{aligned}$$

where $\rho > 0$ is a penalty parameter and $\boldsymbol{v}_{s+1}^{(s)}, \ldots, \boldsymbol{v}_n^{(s)} \in \mathbb{R}^s$.

Applying dual descent method yields the following steps, with l denotes the iteration number:

$$\{\boldsymbol{a}_{i,l+1}^{(s)}\}_{i=s+1}^n = \underset{\{\boldsymbol{a}_i^{(s)}\}_{i=s+1}^n}{\arg\min}\ L_\rho(\{\boldsymbol{a}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_{k,l}^{(s)}\}_k, \{\boldsymbol{b}_{i,l}^{(s)}\}_{i=s+1}^n, \{\boldsymbol{v}_{i,l}^{(s)}\}_{i=s+1}^n), \quad (11)$$

$$\{\boldsymbol{R}_{k,l+1}^{(s)}\}_{k=1}^K = \underset{\{\boldsymbol{R}_k^{(s)}\}_{k=1}^K}{\arg\min}\ L_\rho(\{\boldsymbol{a}_{i,l+1}^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_k^{(s)}\}_k, \{\boldsymbol{b}_{i,l}^{(s)}\}_{i=s+1}^n, \{\boldsymbol{v}_{i,l}^{(s)}\}_{i=s+1}^n), \quad (12)$$

$$\{\boldsymbol{b}_{i,l+1}^{(s)}\}_{i=s+1}^n = \underset{\{\boldsymbol{b}_i^{(s)}\}_{i=s+1}^n}{\arg\min}\ L_\rho(\{\boldsymbol{a}_{i,l+1}^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_{k,l+1}^{(s)}\}_k, \{\boldsymbol{b}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{v}_{i,l}^{(s)}\}_{i=s+1}^n), \quad (13)$$

$$\boldsymbol{v}_{i,l+1}^{(s)} = \boldsymbol{v}_{i,l}^{(s)} + \boldsymbol{a}_{i,l}^{(s)} - \boldsymbol{b}_{i,l}^{(s)}, \qquad \forall i = s+1, \ldots, n.$$

Let us examine Equation 11-13 in more details. In Equation 11, we rewrite the objective function as

$$\begin{aligned}&L_\rho(\{\boldsymbol{a}_i^{(s)}\}_{i=s+1}^n, \{\boldsymbol{R}_{k,l}^{(s)}\}_k, \{\boldsymbol{b}_{i,l}^{(s)}\}_{i=s+1}^n, \{\boldsymbol{v}_{i,l}^{(s)}\}_{i=s+1}^n)\\ =\ & \sum_{i=s+1}^n \left\{ \sum_{j,k} \left(\log[1 + \exp\{(\boldsymbol{a}_i^{(s)})^T \boldsymbol{R}_{k,l}^{(s)} \boldsymbol{b}_{j,l}^{(s)}\}] - Y_{ijk} (\boldsymbol{a}_i^{(s)})^T \boldsymbol{R}_{k,l}^{(s)} \boldsymbol{b}_{j,l}^{(s)} \right) \right.\\ +\ & \left. \rho(\boldsymbol{a}_i^{(s)} - \boldsymbol{b}_{i,l}^{(s)})^T \boldsymbol{v}_{i,l}^{(s)} + \frac{\rho}{2}\|\boldsymbol{a}_i^{(s)} - \boldsymbol{b}_{i,l}^{(s)}\|_2^2 \right\}.\end{aligned}$$

Note that L_ρ can be represented as a separable sum of functions. As a result, $\boldsymbol{a}_{i,l+1}^{(s)}$'s can be solved in parallel. More specifically, we have

$$\begin{aligned}\boldsymbol{a}_{i,l+1}^{(s)} =\ & \underset{\boldsymbol{a}^{(s)}}{\arg\min} \left\{ \sum_{j,k} \left(\log[1 + \exp\{(\boldsymbol{a}_i^{(s)})^T \boldsymbol{R}_{k,l}^{(s)} \boldsymbol{b}_{j,l}^{(s)}\}] - Y_{ijk} (\boldsymbol{a}_i^{(s)})^T \boldsymbol{R}_{k,l}^{(s)} \boldsymbol{b}_{j,l}^{(s)} \right) \right.\\ +\ & \left. \rho(\boldsymbol{a}_i^{(s)} - \boldsymbol{b}_{i,l}^{(s)})^T \boldsymbol{v}_{i,l}^{(s)} + \frac{\rho}{2}\|\boldsymbol{a}_i^{(s)} - \boldsymbol{b}_{i,l}^{(s)}\|_2^2 \right\}.\end{aligned}$$

Hence, each $\boldsymbol{a}_{i,l+1}^{(s)}$ can be computed by solving a ridge type logistic regression with responses $\{Y_{ijk}\}_{j,k}$ and covariates $\{\boldsymbol{R}_{k,l}^{(s)} \boldsymbol{b}_{j,l}^{(s)}\}_{j,k}$.

In Equation 12, each $\boldsymbol{R}_{k,l+1}^{(s)}$ can be independently updated by solving a logistic regression with responses $\{Y_{ijk}\}_{i,j}$ and covariates $\boldsymbol{b}_{j,l}^{(s)} \otimes \boldsymbol{a}_{i,l+1}^{(s)}$, i.e,

$$\mathrm{vec}(\boldsymbol{R}_{k,l+1}^{(s)}) = \underset{\boldsymbol{r}_k^{(s)} \in \mathbb{R}^{s^2}}{\arg\min} \sum_{ij} \left\{ \log\left(1 + \exp[\{(\boldsymbol{b}_{j,l}^{(s)})^T \otimes (\boldsymbol{a}_{i,l+1}^{(s)})^T\} \boldsymbol{r}_k^{(s)}]\right) - Y_{ijk} \{(\boldsymbol{b}_{j,l}^{(s)})^T \otimes (\boldsymbol{a}_{i,l+1}^{(s)})^T\} \boldsymbol{r}_k^{(s)} \right\},$$

where $\otimes$ denotes the Kronecker product.

Similar to Equation 11, each $\boldsymbol{b}_{i,l+1}^{(s)}$ in Equation 13 can be independently computed by solving a ridge type regression with responses $\{Y_{ijk}\}_{j,k}$ and covariates $\{(\boldsymbol{R}_{k,l+1}^{(s)})^T \boldsymbol{a}_{j,l+1}^{(s)}\}_{j,k}$.

Using similar arguments in Theorem 2 in Wang et al. (2017), we can show that the proposed 3-block ADMM algorithm converges for any sufficiently large ρ. In our implementation, we set $\rho = nK/2$. To guarantee global convergence, we randomly generate multiple initial estimators and solve the optimization problem multiple times based on these initial values.

4.2. Simulations

We simulate $\{Y_{ijk}\}_{ijk}$ from the following model:

$$\begin{aligned}&\Pr(Y_{ijk} = 1 | \{\boldsymbol{a}_i\}_i, \{\boldsymbol{R}_k\}_k) = \frac{\exp(\boldsymbol{a}_i^T \boldsymbol{R}_k \boldsymbol{a}_j)}{1 + \exp(\boldsymbol{a}_i^T \boldsymbol{R}_k \boldsymbol{a}_j)},\\ &\boldsymbol{a}_1, \boldsymbol{a}_2, \ldots, \boldsymbol{a}_n \overset{iid}{\sim} N(0,1),\\ &\boldsymbol{R}_1 = \boldsymbol{R}_2 = \cdots = \boldsymbol{R}_K = \mathrm{diag}(\underbrace{1, -1, 1, -1, \ldots, 1, -1}_{s_0}),\end{aligned}$$

where $N(0,1)$ stands for a standard normal random variable and $\mathrm{diag}(v_1, \ldots, v_q)$ denotes a $q \times q$ diagonal matrix with the jth element equal to v_j.

We consider six simulation settings. In the first three settings, we fix $K = 3$ and set $n = 100, 150$ and 200, respectively. In the last three settings, we increase K to 10, 20, 50, and set $n = 50$. In each setting, we further consider three scenarios, by setting $s_0 = 2, 4$ and 8. Let $s_{\max} = 12$. The ADMM algorithm proposed in Section 4.1 is implemented in R. Some subroutines of the algorithm are written in C with the GNU Scientific Library (GSL, Galassi et al., 2015) to facilitate the computation. We compare the proposed IC_α (see Equation 8) with the BIC-type criterion (see Equation 9). In IC_α, we set $\alpha = 0, 0.5$ and 1. Note that when $\alpha = 0$, we have

$$\tau_\alpha(n, K) = \frac{(n+K)^\alpha}{\max^\alpha(n, K)} = 1.$$

Reported in Table 1 and 2 are the percentage of selecting the true models (TP) and the average of $\hat{s}$ selected by IC_0, $\mathrm{IC}_{0.5}$, IC_1 and BIC over 100 replications.

It can be seen from Table 1 and 2 that BIC fails in all settings. It always selects overfitted models. On the contrary, the proposed information criteria are consistent for most of the settings. For example, under settings where $s_0 = 2$ or 4, TPs of IC_0, $\mathrm{IC}_{0.5}$ and IC_1 are larger than or equal to 93%. When $s_0 = 8$, expect for the last setting, TPs of the proposed information criteria are no less than 60% for all cases.

IC_0, $\mathrm{IC}_{0.5}$ and IC_1 perform very similarly for small K. In the first three settings, TPs of these three information criteria are nearly the same for all cases. However, $\mathrm{IC}_{0.5}$ and IC_1 are more robust than IC_0 for large K. This can be seen in the last scenario of Setting 6, where the TP of IC_0 is no more than 20%. Besides, in the last two settings, TP of IC_0 is smaller than $\mathrm{IC}_{0.5}$ and IC_1 for all cases. These differences are due to the finite sample

correction term $\tau_\alpha(n, K)$. As commented before, $\tau_{0.5}(n, K)$ and $\tau_1(n, K)$ increase the model complexity penalty term in $\text{IC}_{0.5}$ and IC_1 to avoid overfitting for large K.

In Section D of the Appendix, we examine the performance of our proposed information criteria under the scenario where $\boldsymbol{a}_1, \boldsymbol{a}_2, \ldots, \boldsymbol{a}_n \overset{iid}{\sim} N(0, \{0.5^{|i-j|}\}_{i,j=1,\ldots,s_0})$. Results are similar to those presented at Table 1 and 2.

4.3. Real Data Experiments

In this section, we apply the proposed information criteria to the "Social Evolution" dataset (Madan et al., 2012). This dataset comes from MIT's Human Dynamics Laboratory. It tracks everyday life of a whole undergraduate MIT dormitory from October 2008 to May 2009. We use the survey data, resulting in $n = 84$ participants and $K = 5$ binary relations. The five relations are: close relationship, political discussion, social interaction and two social media interaction.

We compute $\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i$ and $\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k$ for $s = \{1, \ldots, 12\}$ and select the number of latent factors using the proposed information criteria and BIC. It turns out that IC_0, $\text{IC}_{0.5}$ and IC_1 all suggest the presence of 9 factors. In contrast, BIC selects 12 factors. To further evaluate the number of latent factors selected by the proposed information criteria, we consider the following cross-validation procedure. For any $s \in [1, \ldots, 12]$, we randomly select 80% of the observations and estimate $\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i$ and $\{\widehat{\boldsymbol{R}}_k^{(s)}\}$ by maximizing the observed likelihood function based on these training samples. Then we compute

$$\widehat{\pi}_{ijk} = \frac{\exp\{(\widehat{\boldsymbol{a}}_i^{(s)})^T \widehat{\boldsymbol{R}}_k^{(s)} \widehat{\boldsymbol{a}}_j^{(s)}\}}{1 + \exp\{(\widehat{\boldsymbol{a}}_i^{(s)})^T \widehat{\boldsymbol{R}}_k^{(s)} \widehat{\boldsymbol{a}}_j^{(s)}\}}.$$

Based on these predicted probabilities, we calculate the area under the precision-recall curve (AUC) on the remaining 20% testing samples.

Reported in Table 3 are the AUC scores averaged over 100 replications. For any $s \in \{1, \ldots, 12\}$, we denoted by AUC_s the corresponding AUC score. It can be seen from Table 3 that AUC_s first increases and then decreases as s increases. The maximum AUC score is achieved at $s = 10$. Observe that AUC_9 is very close to AUC_{10}, and it is larger than the remaining AUC scores. This demonstrates that the proposed information criteria select less latent factors while achieve better or similar link prediction results when compared to BIC.

5. Discussion

In this paper, we propose information criteria for selecting the number of latent factors in the RESCAL tensor factorization model and prove their model selection consistency. Although we focus on the logistic RESCAL model, the proposed information criteria can be applied to general tensor factorization models. More specifically, consider the following

class of models:

$$Y_{ijk} = \mathrm{g}(\boldsymbol{a}_{i,0}^T \boldsymbol{R}_{k,0} \boldsymbol{b}_{j,0}) + e_{ijk}, \quad \forall i, j \in \{1, \ldots, n\}, k \in \{1, \ldots, K\}, \tag{14}$$

with any of (or without) the following constraints:
(C1) $\boldsymbol{R}_{k,0}$ is diagonal;
(C2) $\boldsymbol{a}_{i,0} = \boldsymbol{b}_{i,0}$ for $i \in \{1, \ldots, n\}$,
for some strictly increasing function g, $\boldsymbol{a}_{i,0}, \boldsymbol{b}_{i,0} \in \mathbb{R}^{s_0}$, $\boldsymbol{R}_{k,0} \in \mathbb{R}^{s_0 \times s_0}$ and some mean zero random errors $\{e_{ijk}\}_{ijk}$.

As commented in Section 2.1, such representation includes the RESCAL, CP and TUCKER-2 models. Specifically, it reduces to the TUCKER-2 model by setting g to be the identity function. If further (C1) holds, then the model in Equation 14 reduces to the CP model. When (C2) holds, it corresponds to the RESCAL model. Consider the following information criteria,

$$\mathrm{IC}(s) = \ell_n(\boldsymbol{Y}; \{\widehat{\boldsymbol{a}}_i\}_i, \{\widehat{\boldsymbol{R}}_k\}_k, \{\widehat{\boldsymbol{b}}_i\}_i) - s\kappa(n, K),$$

where ℓ_n stands for the likelihood function and $\widehat{\boldsymbol{a}}_i$, $\widehat{\boldsymbol{R}}_k$, $\widehat{\boldsymbol{b}}_i$ are the corresponding (constrained) MLEs. Similar to Theorem 1, we can show that with some properly chosen $\kappa(n, K)$, IC is consistent under this general setting.

Currently, we assume the tensor $\boldsymbol{Y}$ is completely observed. When some of the Y_{ijk}'s are missing, we can calculate $\widehat{\boldsymbol{a}}_i^{(s)}$'s and $\widehat{\boldsymbol{R}}_k^{(s)}$'s by maximizing the following observed likelihood function

$$\begin{aligned} \underset{\substack{\boldsymbol{a}_1^{(s)}, \ldots, \boldsymbol{a}_n^{(s)} \in \Theta_a^{(s)} \\ \mathrm{vec}(\boldsymbol{R}_1^{(s)}), \ldots, \mathrm{vec}(\boldsymbol{R}_K^{(s)}) \in \Theta_r^{(s)}}}{\arg\max} & \sum_{(i,j,k) \in N_{obs}} \left(Y_{ijk} (\boldsymbol{a}_i^{(s)})^T \boldsymbol{R}_k^{(s)} \boldsymbol{a}_j^{(s)} - \log[1 + \exp\{(\boldsymbol{a}_i^{(s)})^T \boldsymbol{R}_k^{(s)} \boldsymbol{a}_j^{(s)}\}] \right), \\ \text{subject to} \quad & [\boldsymbol{a}_1^{(s)}, \ldots, \boldsymbol{a}_s^{(s)}] = \boldsymbol{I}_s, \end{aligned}$$

where N_{obs} denotes the set of the observed responses. The above optimization problem can also be solved by a 3-block ADMM algorithm. Define the following class of information criteria,

$$\mathrm{IC}_{obs}(s) = \sum_{(i,j,k) \in N_{obs}} \left(Y_{ijk} (\widehat{\boldsymbol{a}}_i^{(s)})^T \widehat{\boldsymbol{R}}_k^{(s)} \widehat{\boldsymbol{a}}_j^{(s)} - \log[1 + \exp\{(\widehat{\boldsymbol{a}}_i^{(s)})^T \widehat{\boldsymbol{R}}_k^{(s)} \widehat{\boldsymbol{a}}_j^{(s)}\}] \right) - \hat{p} s \kappa(n, K),$$

where $\hat{p} = |N_{obs}|/(n^2 K)$ denotes the percentage of observed responses. Consistency of IC_{obs} can be similarly studied.

Acknowledgments

The authors wish to thank the Associate Editor and anonymous referees for their constructive comments, which lead to significant improvement of this work.

Appendix A. More on the Identifiability Constraint

Let $\pi(\cdot)$ be a permutation function of $\{1, \ldots, n\}$. Alternative to our estimator defined in Equation 3, one may consider

$$\begin{aligned} (\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k) = & \underset{\substack{\boldsymbol{a}_1^{(s)}, \ldots, \boldsymbol{a}_n^{(s)} \in \Theta_a^{(s)} \\ \mathrm{vec}(\boldsymbol{R}_1^{(s)}), \ldots, \mathrm{vec}(\boldsymbol{R}_K^{(s)}) \in \Theta_r^{(s)}}}{\arg\max} \ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k), \\ & \text{subject to} \quad [\boldsymbol{a}_{\pi(1)}^{(s)}, \ldots, \boldsymbol{a}_{\pi(s)}^{(s)}] = \boldsymbol{I}_s, \end{aligned}$$

and the corresponding information criteria

$$\mathrm{IC}_\pi(s) = 2\ell_n(\boldsymbol{Y}; \{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k) - s\kappa(n, K).$$

Since $\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \boldsymbol{R}_k^{(s)}{}_k) = \ell_n(\boldsymbol{Y}; \{\boldsymbol{C}^{-1}\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{C}^T \boldsymbol{R}_k^{(s)} \boldsymbol{C}\}_k)$ for any invertible matrix $\boldsymbol{C} \in \mathbb{R}^{s \times s}$, $(\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k)$ is also the maximizer of $\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k)$ subject to the constraint that $[\boldsymbol{a}_{\pi(1)}^{(s)}, \ldots, \boldsymbol{a}_{\pi(s)}^{(s)}]$ is invertible. Similarly, the estimator $(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)$ is the maximizer of $\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)}\}_i, \{\boldsymbol{R}_k^{(s)}\}_k)$ subject to the constraint that $[\boldsymbol{a}_1^{(s)}, \ldots, \boldsymbol{a}_s^{(s)}]$ is invertible. As a result, we have $\mathrm{IC}(s) = \mathrm{IC}_\pi(s)$ as long as

$$[\widehat{\boldsymbol{a}}_{\pi(1)}^{(s)}, \ldots, \widehat{\boldsymbol{a}}_{\pi(s)}^{(s)}] \text{ is invertible and } [\widehat{\boldsymbol{a}}_{1,\pi}^{(s)}, \ldots, \widehat{\boldsymbol{a}}_{s,\pi}^{(s)}] \text{ is invertible.} \tag{15}$$

However, it remains unknown whether Equation 15 holds or not. Hence, there's no guarantee that $\mathrm{IC}(s) = \mathrm{IC}_\pi(s)$. This means the choice of the identifiability constraint might affect the value of our proposed information criterion.

In the following, we prove

$$\Pr\left(\bigcap_{\substack{\pi: \{1,\ldots,n\} \to \{1,\ldots,n\} \\ |\{\pi(1), \ldots, \pi(n)\}| = n}} \left\{ \underset{s=1,\ldots,s_{\max}}{\arg\max} \{\mathrm{IC}_\pi(s)\} = s_0 \right\} \right) \to 1. \tag{16}$$

This means with probability tending to 1, all the information criteria with different identifiability constraints will select the true model. Therefore, the choice of the identifiability constraint will not affect the performance of our method. For any $s \in \{s_0, \ldots, s_{\max}\}$, let $\boldsymbol{A}_{s,0,\pi} = [\boldsymbol{a}_{\pi(1),0}^{(s)}, \ldots, \boldsymbol{a}_{\pi(s),0}^{(s)}]^T$,

$$\boldsymbol{a}_{i,\pi}^{(s)*} = (\boldsymbol{A}_{s,0,\pi}^{-1})^T \boldsymbol{a}_{i,0}^{(s)} \text{ and } \boldsymbol{R}_{k,\pi}^{(s)*} = \boldsymbol{A}_{s,0,\pi} \boldsymbol{R}_{k,0}^{(s)} \boldsymbol{A}_{s,0,\pi}^T.$$

We need the following condition.
(A4) Assume $\boldsymbol{a}_{i,\pi}^{(s)*} \in \Theta_a^{(s)}$ and $\mathrm{vec}(\boldsymbol{R}_{k,\pi}^{(s)*}) \in \Theta_r^{(s)}$, $\forall i = 1, \ldots, n$, $k = 1, \ldots, K$, $s_0 \le s \le s_{\max}$ and any permutation function $\pi(\cdot)$. In addition, assume $\sup_{\boldsymbol{x} \in \Theta_a^{(s)}} \|\boldsymbol{x}\|_2 \le \omega_a$, $\sup_{\boldsymbol{y} \in \Theta_r^{(s)}} \|\boldsymbol{y}\|_2 \le \omega_r$ for some $\omega_a, \omega_r > 0$.

Corollary 1. *Assume (A2)-(A4) hold,* $K \sim n^{l_0}$ *for some* $0 \le l_0 \le 1$, $s_{\max} = o\{\sqrt{n/\log(nK)}\}$, $\liminf_n n^{(1-l_0)/2} \bar{K} \ge \exp(2\omega_a^2 \omega_r)\sqrt{\log n}$. *Assume* $\kappa(n, K)$ *satisfies Condition* (6). *Then,* (16) *is satisfied.*

Appendix B. More on the Technical Conditions

B.1. Discussion of Condition (A0)

In this section, we show the necessity of (A0) when the matrices $\boldsymbol{R}_{1,0},\ldots,\boldsymbol{R}_{K,0}$ are symmetric. More specifically, when (A0) doesn't hold, we show there exist some $0 \le s < s_0$, $\overline{\boldsymbol{a}}_{1,0},\ldots,\overline{\boldsymbol{a}}_{n,0} \in \mathbb{R}^s$ and $\overline{\boldsymbol{R}}_{1,0},\ldots,\overline{\boldsymbol{R}}_{K,0} \in \mathbb{R}^{s\times s}$ such that

$$\overline{\boldsymbol{a}}_{i,0}^T\overline{\boldsymbol{R}}_{k,0}\overline{\boldsymbol{a}}_{j,0} = \boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0}, \quad \forall 1 \le i,j \le n, 1 \le k \le K. \tag{17}$$

Let's first consider the case where $\mathrm{rank}(\boldsymbol{A}_0) = s$ for some $s < s_0$. Thus, it follows that

$$\boldsymbol{A}_0 = \overline{\boldsymbol{A}}_0\boldsymbol{C},$$

for some $\overline{\boldsymbol{A}}_0 \in \mathbb{R}^{n\times s}$ and $\boldsymbol{C} \in \mathbb{R}^{s\times s_0}$. Set $\overline{\boldsymbol{a}}_{i,0}$ to be the ith row of $\overline{\boldsymbol{A}}_0$ and $\overline{\boldsymbol{R}}_{k,0} = \boldsymbol{C}\boldsymbol{R}_{k,0}\boldsymbol{C}^T$, Equation 17 is thus satisfied. In addition, the new matrix $\overline{\boldsymbol{A}}_0$ shall have full column rank.

Let $\boldsymbol{R}_0 = (\boldsymbol{R}_{1,0}^T,\ldots,\boldsymbol{R}_{K,0}^T)^T$. Consider the case where $\mathrm{rank}(\boldsymbol{R}_0) = s$ for some $s < s_0$. It follows from the singular value decomposition that

$$\boldsymbol{R}_0 = \boldsymbol{U}_0\boldsymbol{\Lambda}_0\boldsymbol{V}_0^T, \tag{18}$$

for some diagonal matrix $\boldsymbol{\Lambda}_0 \in \mathbb{R}^{s\times s}$, and some matrices $\boldsymbol{U}_0 \in \mathbb{R}^{Ks_0\times s}$, $\boldsymbol{V}_0 \in \mathbb{R}^{s_0\times s}$ that satisfy $\boldsymbol{U}_0^T\boldsymbol{U}_0 = \boldsymbol{V}_0^T\boldsymbol{V}_0 = \boldsymbol{I}_s$. Denoted by $\boldsymbol{U}_{k,0}$ the submatrix of $\boldsymbol{U}_0$ formed by rows in $\{(k-1)s_0+1,(k-1)s_0+2,\cdots,ks_0\}$ and columns in $\{1,2,\ldots,s\}$. It follows from Equation 18 that

$$\boldsymbol{R}_{k,0} = \boldsymbol{U}_{k,0}\boldsymbol{\Lambda}_0\boldsymbol{V}_0^T, \quad \forall 1 \le k \le K.$$

Since $\boldsymbol{R}_{k,0}$ is symmetric, we have $\boldsymbol{U}_{k,0}\boldsymbol{\Lambda}_0\boldsymbol{V}_0^T = \boldsymbol{V}_0\boldsymbol{\Lambda}_0\boldsymbol{U}_{k,0}^T = \boldsymbol{R}_{k,0}$. Notice that $\boldsymbol{V}_0^T\boldsymbol{V}_0 = \boldsymbol{I}_s$. It follows that $\boldsymbol{U}_{k,0}\boldsymbol{\Lambda}_0 = \boldsymbol{V}_0\boldsymbol{\Lambda}_0\boldsymbol{U}_{k,0}^T\boldsymbol{V}_0$. Therefore, we have

$$\boldsymbol{R}_{k,0} = \boldsymbol{V}_0\boldsymbol{\Lambda}_0\boldsymbol{U}_{k,0}^T\boldsymbol{V}_0\boldsymbol{V}_0^T. \tag{19}$$

Define $\overline{\boldsymbol{a}}_{i,0} = \boldsymbol{V}_0^T\boldsymbol{a}_{i,0}, \forall 1 \le i \le n$ and $\overline{\boldsymbol{R}}_{k,0} = \boldsymbol{\Lambda}_0\boldsymbol{U}_{k,0}^T\boldsymbol{V}_0$. In view of Equation 19, it is immediate to see that Equation 17 holds. Since $\boldsymbol{V}_0^T\boldsymbol{V}_0 = \boldsymbol{I}_s$, we have $\overline{\boldsymbol{R}}_{k,0} = \boldsymbol{V}_0^T\boldsymbol{V}_0\boldsymbol{\Lambda}_0\boldsymbol{U}_{k,0}^T\boldsymbol{V}_0 = \boldsymbol{V}_0^T\boldsymbol{R}_{k,0}\boldsymbol{V}_0$. As a result, $\overline{\boldsymbol{R}}_{1,0},\ldots,\overline{\boldsymbol{R}}_{K,0}$ are also symmetric. Suppose $\overline{\boldsymbol{R}}_0 = (\overline{\boldsymbol{R}}_{1,0}^T,\cdots,\overline{\boldsymbol{R}}_{K,0}^T)^T$ doesn't have full column rank. Using the same arguments, we can find some $s' < s$, $\widetilde{\boldsymbol{a}}_{1,0},\cdots,\widetilde{\boldsymbol{a}}_{n,0} \in \mathbb{R}^{s'}$, $\widetilde{\boldsymbol{R}}_{1,0},\cdots,\widetilde{\boldsymbol{R}}_{K,0} \in \mathbb{R}^{s'\times s'}$ such that

$$\widetilde{\boldsymbol{a}}_{i,0}^T\widetilde{\boldsymbol{R}}_{k,0}\widetilde{\boldsymbol{a}}_{j,0} = \boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0}, \quad \forall 1 \le i,j \le n, 1 \le k \le K. \tag{20}$$

We may repeat this procedure until we find some $\widetilde{\boldsymbol{a}}_{i,0}$'s, $\widetilde{\boldsymbol{R}}_{k,0}$'s satisfy Equation 20 and that the matrix $(\widetilde{\boldsymbol{R}}_{1,0}^T,\cdots,\widetilde{\boldsymbol{R}}_{K,0}^T)^T$ has full column rank.

B.2. Discussion of Condition (A1)

In this section, we consider an asymptotic framework where $\boldsymbol{a}_{1,0},\ldots,\boldsymbol{a}_{n,0}$ are i.i.d according to some distribution function and show (A1) holds with probability tending to 1. For any q-dimensional vector $\boldsymbol{q}$, let $\|\boldsymbol{q}\|_2$ denote its Euclidean norm. For any $m\times q$ matrix $\boldsymbol{Q}$, $\|\boldsymbol{Q}\|_2$ stands for the spectral norm of $\boldsymbol{Q}$ while $\|\boldsymbol{Q}\|_F$ denotes its Frobenius norm. For simplicity, we assume $\Theta_a = \{\boldsymbol{x} \in \mathbb{R}^{s_0} : \|\boldsymbol{x}\|_2 \le \omega_a\}$ and $\Theta_r = \{\boldsymbol{y} \in \mathbb{R}^{s_0^2} : \|\boldsymbol{y}\|_2 \le \omega_r\}$. Assume $\max_{k=1,\ldots,K}\|\boldsymbol{R}_{k,0}\|_F = O(1)$, $\|\boldsymbol{a}_{1,0}\|_2$ is bounded with probability 1. In addition, assume there exist some constants $c_0, t_0 > 0$ such that

$$\Pr\left(\|[\boldsymbol{a}_{1,0},\ldots,\boldsymbol{a}_{s_0,0}]^{-1}\|_F > t\right) \le c_0t^{-1}, \qquad \forall t \le t_0. \tag{21}$$

When $s_0 = 1$, the above condition is closely related to the margin assumption (Tsybakov, 2004; Audibert and Tsybakov, 2007) in the classification literature. It automatically holds when $a_{1,0}$ has a bounded probability density function.

In the following, we show with proper choice of ω_a and ω_r, (A1) holds with probability tending to 1. By the identifiability constraints, $\|\boldsymbol{a}_i^{(s)*}\|_2 = 1$, $\forall i = 1,\ldots,s$ and $s = s_0,\ldots,s_{\max}$. When $\omega_a,\omega_r \to \infty$, we have for sufficiently large n,

$$\Pr\left(\boldsymbol{a}_i^{(s)*} \in \Omega_a\right) = 1, \qquad \forall 1 \le i \le s, s_0 \le s \le s_{\max}. \tag{22}$$

By the definition of $\boldsymbol{A}_{s,0}$, we have

$$\boldsymbol{A}_{s,0}^{-1} = \begin{pmatrix} \boldsymbol{A}_{s_0,0}^{-1} & \boldsymbol{O}_{s_0\times(s-s_0)} \\ -\boldsymbol{A}_{(s_0+1):s,0}\boldsymbol{A}_{s_0,0}^{-1} & \boldsymbol{I}_{s-s_0} \end{pmatrix}, \tag{23}$$

where $\boldsymbol{A}_{(s_0+1):s,0} = [\boldsymbol{a}_{s_0+1,0},\ldots,\boldsymbol{a}_{s,0}]^T$. It follows that

$$\boldsymbol{a}_i^{(s)*} = \begin{pmatrix} \boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{a}_{i,0} \\ (\underbrace{0,\ldots,0}_{i-s_0-1},1,\underbrace{0,\ldots,0}_{s-i})^T - \boldsymbol{A}_{(s_0+1):s,0}\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{a}_{i,0} \end{pmatrix}, \qquad \forall s < i \le n, s_0 \le s \le s_{\max}.$$

Under the given conditions, we have $\|\boldsymbol{a}_{i,0}\|_2 \le \omega_0$ with probability 1 for some constant $\omega_0 > 0$. Therefore, we have

$$\max_{\substack{s_0\le s\le s_{\max}\\ s<i\le n}}\|\boldsymbol{a}_i^{(s)*}\|_2 \le \omega_0\|\boldsymbol{A}_{s_0,0}^{-1}\|_2 + 1 + \sqrt{s_{\max}}\omega_0^2\|\boldsymbol{A}_{s_0,0}^{-1}\|_2 \le 1 + (1+\sqrt{s_{\max}}\omega_0)\omega_0\|\boldsymbol{A}_{s_0,0}^{-1}\|_F.$$

By (21), it is immediate to see that

$$\Pr\left(\max_{\substack{s_0\le s\le s_{\max}\\ s<i\le n}}\|\boldsymbol{a}_i^{(s)*}\|_2 > \omega_a\right) \to 0,$$

as long as $\omega_a \gg \sqrt{s_{\max}}$. This together with Equation 22 yields

$$\Pr\left(\max_{\substack{s_0\le s\le s_{\max}\\ 1\le i\le n}}\|\boldsymbol{a}_i^{(s)*}\|_2 > \omega_a\right) \to 0.$$

Combining Equation 23 with the definition of $\boldsymbol{R}_k^{(s)*}$ yields

$$\boldsymbol{R}_k^{(s)*} = \begin{pmatrix} \boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T & -\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T\boldsymbol{A}_{(s_0+1):s,0}^T \\ -\boldsymbol{A}_{(s_0+1):s,0}\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T & \boldsymbol{A}_{(s_0+1):s,0}\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T\boldsymbol{A}_{(s_0+1):s,0}^T \end{pmatrix}$$

Since $\max_{1\le k\le K}\|\boldsymbol{R}_{k,0}\|_F = O(1)$, $\max_{1\le i\le n}\|\boldsymbol{a}_{i,0}\|_2 = O(1)$, we have

$$\max_{1\le k\le K}\|\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T\|_F \le \max_{1\le k\le K}\|\boldsymbol{A}_{s_0,0}^{-1}\|_F^2\|\boldsymbol{R}_{k,0}\|_F = O(\|\boldsymbol{A}_{s_0,0}^{-1}\|_F^2),$$

and

$$\begin{aligned} & \max_{\substack{1\le k\le K\\ s_0\le s\le s_{\max}}} \|\boldsymbol{A}_{(s_0+1):s,0}\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T\|_F \\ \le & \max_{\substack{1\le k\le K\\ s_0\le s\le s_{\max}}} \|\boldsymbol{A}_{s_0,0}^{-1}\|_F^2\|\boldsymbol{A}_{(s_0+1):s,0}\|_F\|\boldsymbol{R}_{k,0}\|_F = O(\sqrt{s_{\max}}\|\boldsymbol{A}_{s_0,0}^{-1}\|_F^2), \\ & \max_{\substack{1\le k\le K\\ s_0\le s\le s_{\max}}} \|\boldsymbol{A}_{(s_0+1):s,0}\boldsymbol{A}_{s_0,0}^{-1}\boldsymbol{R}_{k,0}(\boldsymbol{A}_{s_0,0}^{-1})^T\boldsymbol{A}_{(s_0+1):s,0}^T\|_F \\ \le & \max_{\substack{1\le k\le K\\ s_0\le s\le s_{\max}}} \|\boldsymbol{A}_{s_0,0}^{-1}\|_F^2\|\boldsymbol{A}_{(s_0+1):s,0}\|_F^2\|\boldsymbol{R}_{k,0}\|_F = O(s_{\max}\|\boldsymbol{A}_{s_0,0}^{-1}\|_F^2). \end{aligned}$$

By (21), we have $\max_{1\le k\le K, s_0\le s\le s_{\max}}\|\boldsymbol{R}_k^{(s)*}\|_F \le \omega_r$ with probability tending to 1, for any ω_r such that $\omega_r/s_{\max}\to\infty$.

B.3. Discussion of Condition (A2)

Assume the matrix $\mathrm{E}\boldsymbol{a}_{1,0}\boldsymbol{a}_{1,0}^T$ is positive definite. Since s_0 is fixed, it follows from the law of large numbers that

$$\frac{1}{n}\sum_{i=1}^n \boldsymbol{a}_{i,0}\boldsymbol{a}_{i,0}^T \xrightarrow{P} \mathrm{E}\boldsymbol{a}_{1,0}\boldsymbol{a}_{1,0}^T.$$

Therefore, (A2) holds with probability tending to 1.

Appendix C. Proofs

In the following, we provide proofs of Lemma 1, Lemma 2 and Theorem 1. We define

$$\ell_0(\{\boldsymbol{a}_i\}_i,\{\boldsymbol{R}_k\}_k) = \mathrm{E}\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i\}_i,\{\boldsymbol{R}_k\}_k),$$

for any $\boldsymbol{a}_1,\ldots,\boldsymbol{a}_n\in\mathbb{R}^s$, $\boldsymbol{R}_1,\ldots,\boldsymbol{R}_K\in\mathbb{R}^{s\times s}$ and any integer $s\ge 1$. Define $\theta_{ijk} = (\boldsymbol{a}_i^*)^T\boldsymbol{R}_k\boldsymbol{a}_j^*$ and $\hat\theta_{ijk} = \widehat{\boldsymbol{a}}_i^T\widehat{\boldsymbol{R}}_k\widehat{\boldsymbol{a}}_j$.

C.1. Proof of Lemma 1

Assume there exist some $\{\boldsymbol{a}_i\}_i$, $\{\boldsymbol{R}_k\}_k$ such that

$$\mathrm{g}(\boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0}) = \mathrm{g}(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j),\quad \forall i,j,k.$$

Since $\mathrm{g}(\cdot)$ is strictly monotone, we have

$$\boldsymbol{a}_{i,0}^T\boldsymbol{R}_{k,0}\boldsymbol{a}_{j,0} = \boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j,\quad \forall i,j,k,$$

or equivalently,

$$\begin{pmatrix} \boldsymbol{A}\boldsymbol{R}_1 \\ \vdots \\ \boldsymbol{A}\boldsymbol{R}_K \end{pmatrix}\boldsymbol{A}^T = \begin{pmatrix} \boldsymbol{A}_0\boldsymbol{R}_{1,0} \\ \vdots \\ \boldsymbol{A}_0\boldsymbol{R}_{K,0} \end{pmatrix}\boldsymbol{A}_0^T.$$

where $\boldsymbol{A} = [\boldsymbol{a}_1,\boldsymbol{a}_2,\ldots,\boldsymbol{a}_n]^T$. Thus, it follows that

$$\begin{pmatrix} \boldsymbol{A}_0^T\boldsymbol{A}\boldsymbol{R}_1 \\ \vdots \\ \boldsymbol{A}_0^T\boldsymbol{A}\boldsymbol{R}_K \end{pmatrix}\boldsymbol{A}^T = \begin{pmatrix} \boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{1,0} \\ \vdots \\ \boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{K,0} \end{pmatrix}\boldsymbol{A}_0^T.$$

By (A0), the matrix $\boldsymbol{A}_0^T\boldsymbol{A}_0$ is invertible. As a result, we have

$$\begin{pmatrix} (\boldsymbol{A}_0^T\boldsymbol{A}_0)^{-1}\boldsymbol{A}_0^T\boldsymbol{A}\boldsymbol{R}_1 \\ \vdots \\ (\boldsymbol{A}_0^T\boldsymbol{A}_0)^{-1}\boldsymbol{A}_0^T\boldsymbol{A}\boldsymbol{R}_K \end{pmatrix}\boldsymbol{A}^T = \begin{pmatrix} \boldsymbol{R}_{1,0} \\ \vdots \\ \boldsymbol{R}_{K,0} \end{pmatrix}\boldsymbol{A}_0^T.$$

Therefore,

$$\left(\sum_{k=1}^K \boldsymbol{R}_{k,0}^T(\boldsymbol{A}_0^T\boldsymbol{A}_0)^{-1}\boldsymbol{A}_0^T\boldsymbol{A}\boldsymbol{R}_1\right)\boldsymbol{A}^T = \left(\sum_{k=1}^K \boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0}\right)\boldsymbol{A}_0^T.$$

Notice that the matrix $\sum_{k=1}^K \boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0}$ is invertible under Condition (A0). It follows that

$$\underbrace{\left(\sum_{k=1}^K \boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0}\right)^{-1}\left(\sum_{k=1}^K \boldsymbol{R}_{k,0}^T(\boldsymbol{A}_0^T\boldsymbol{A}_0)^{-1}\boldsymbol{A}_0^T\boldsymbol{A}\boldsymbol{R}_k\right)}_{\boldsymbol{C}}\boldsymbol{A}^T = \boldsymbol{A}_0^T.$$

By Lemma 5.1 in Banerjee and Roy (2014), we have $\mathrm{rank}(\boldsymbol{C})\ge\mathrm{rank}(\boldsymbol{A}_0) = s_0$. Therefore, $\boldsymbol{C}$ is invertible. It follows that

$$\boldsymbol{A} = \boldsymbol{A}_0(\boldsymbol{C}^T)^{-1}, \tag{24}$$

or equivalently,

$$\boldsymbol{a}_i = \boldsymbol{C}^{-1}\boldsymbol{a}_{i,0},\quad \forall i = 1,\ldots,n.$$

By Equation 24, we obtain $\boldsymbol{A}_0(\boldsymbol{C}^T)^{-1}\boldsymbol{R}_k\boldsymbol{C}^{-1}\boldsymbol{A}_0^T = \boldsymbol{A}_0\boldsymbol{R}_{k,0}\boldsymbol{A}_0^T, \forall k$, and hence

$$\boldsymbol{A}_0^T\boldsymbol{A}_0(\boldsymbol{C}^T)^{-1}\boldsymbol{R}_k\boldsymbol{C}^{-1}\boldsymbol{A}_0^T\boldsymbol{A}_0 = \boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{k,0}\boldsymbol{A}_0^T\boldsymbol{A}_0,\quad \forall k = 1,\ldots,K.$$

Since $\boldsymbol{A}_0^T\boldsymbol{A}_0$ is invertible, this further implies $(\boldsymbol{C}^T)^{-1}\boldsymbol{R}_k\boldsymbol{C}^{-1} = \boldsymbol{R}_{k,0}, \forall k$, or equivalently,

$$\boldsymbol{R}_k = \boldsymbol{C}^T\boldsymbol{R}_{k,0}\boldsymbol{C},\quad \forall k = 1,\ldots,K.$$

The proof is hence completed.

C.2. Proof of Lemma 2

To prove Lemma 2, we need the following lemma.

Lemma 4 (Mendelson et al. (2008), Lemma 2.3). *Given $d \geq 1$, and $\varepsilon > 0$, we have*

$$N(\varepsilon, B_2^d, \|\cdot\|_2) \leq \left(1 + \frac{2}{\varepsilon}\right)^d,$$

where B_2^d is the unit ball in $\mathbb{R}^d$, and $N(\varepsilon, \cdot, \|\cdot\|_2)$ the covering number with respect to the Euclidean metric (see Definition 2.2.3 in van der Vaart and Wellner (1996) for details).

Under Condition (A1), we have $\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^{(s)*}\}_i, \{\boldsymbol{R}_k^{(s)*}\}_k) \leq \ell_n(\boldsymbol{Y}; \{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)$ and hence

$$\ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k) \leq \ell_n(\boldsymbol{Y}; \{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k). \tag{25}$$

Besides, we have

$$\max_i \|\widehat{\boldsymbol{a}}_i^{(s)}\|_2 \leq \omega_a, \quad \max_k \|\mathrm{vec}(\widehat{\boldsymbol{R}}_k^{(s)})\|_2 \leq \omega_r, \quad \forall s \in \{s_0, \ldots, s_{\max}\}, \tag{26}$$

and

$$\max_i \|\boldsymbol{a}_i^*\|_2 \leq \omega_a, \quad \max_k \|\mathrm{vec}(\boldsymbol{R}_k^*)\|_2 \leq \omega_r. \tag{27}$$

Therefore,

$$\begin{aligned} &\max_{i,j,k} |(\widehat{\boldsymbol{a}}_i^{(s)})^T \widehat{\boldsymbol{R}}_k^{(s)} \widehat{\boldsymbol{a}}_j^{(s)}| \leq \left(\max_i \|\widehat{\boldsymbol{a}}_i^{(s)}\|_2^2 \max_k \|\widehat{\boldsymbol{R}}_k^{(s)}\|_2\right) \leq \left(\max_i \|\widehat{\boldsymbol{a}}_i^{(s)}\|_2^2 \max_k \|\widehat{\boldsymbol{R}}_k^{(s)}\|_F\right) \\ \leq\ & \left(\max_i \|\widehat{\boldsymbol{a}}_i^{(s)}\|_2^2 \max_k \|\mathrm{vec}(\widehat{\boldsymbol{R}}_k^{(s)})\|_2\right) \leq \omega_a^2 \omega_r, \quad \forall s \in \{s_0, \ldots, s_{\max}\}. \end{aligned} \tag{28}$$

Similarly, we can show

$$\max_{i,j,k} \|(\boldsymbol{a}_i^*)^T \boldsymbol{R}_k^* \boldsymbol{a}_j^*\|_2 \leq \omega_a^2 \omega_r. \tag{29}$$

We define $\theta_{ijk}^* = (\boldsymbol{a}_i^*)^T \boldsymbol{R}_k^* \boldsymbol{a}_j^*$ and $\hat{\theta}_{ijk}^{(s)} = (\widehat{\boldsymbol{a}}_i^{(s)})^T \widehat{\boldsymbol{R}}_k^{(s)} \widehat{\boldsymbol{a}}_j^{(s)}$. It follows from a second-order Taylor expansion that

$$\mathrm{g}(\theta_{ijk}^*)(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)}) - \log\{1 + \exp(\theta_{ijk}^*)\} + \log\{1 + \exp(\hat{\theta}_{ijk}^{(s)})\} = \frac{\exp(\tilde{\theta}_{ijk}^{(s)})(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)})^2}{2\{1 + \exp(\tilde{\theta}_{ijk}^{(s)})\}^2}, \tag{30}$$

for some $\tilde{\theta}_{ijk}^{(s)}$ lying on the line segment joining θ_{ijk}^* and $\hat{\theta}_{ijk}^{(s)}$. By (28) and (29), we have for any i, j, k and $s \in \{s_0, \ldots, s_{\max}\}$, $|\tilde{\theta}_{ijk}^{(s)}| \leq \omega_a^2 \omega_r$. This together with Equation 30 gives that

$$\begin{aligned} &\mathrm{g}(\theta_{ijk}^*)\theta_{ijk}^* - \log\{1 + \exp(\theta_{ijk}^*)\} - \mathrm{g}(\theta_{ijk}^*)\hat{\theta}_{ijk}^{(s)} + \log\{1 + \exp(\hat{\theta}_{ijk}^{(s)})\} \\ \geq\ & \frac{(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)})^2 \exp(\omega_a^2 \omega_r)}{2\{1 + \exp(\omega_a^2 \omega_r)\}^2} \geq \frac{(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)})^2 \exp(\omega_a^2 \omega_r)}{8 \exp(2\omega_a^2 \omega_r)} = \frac{(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)})^2}{8 \exp(\omega_a^2 \omega_r)}, \end{aligned}$$

and hence

$$\begin{aligned} &\ell_0(\{\boldsymbol{a}_i^*\}_i, \{\boldsymbol{R}_k^*\}_k) - \ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i, \{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) \\ =\ & \sum_{ijk} \left(\mathrm{g}(\theta_{ijk}^*)(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)}) - \log \frac{\{1 + \exp(\theta_{ijk}^*)\}}{\{1 + \exp(\hat{\theta}_{ijk}^{(s)})\}}\right) \geq \frac{\sum_{ijk}(\theta_{ijk}^* - \hat{\theta}_{ijk}^{(s)})^2}{8 \exp(\omega_a^2 \omega_r)}. \end{aligned} \tag{31}$$

In the following, we provide an upper bound for

$$\begin{aligned} &\max_{s \in \{1, \ldots, s_{\max}\}} \sup_{\substack{\boldsymbol{a}_i \in \mathbb{R}^s, \boldsymbol{R}_k \in \mathbb{R}^{s \times s} \\ \max_i \|\boldsymbol{a}_i\|_2 \leq \omega_a \\ \max_k \|\mathrm{vec}(\boldsymbol{R}_k)\|_2 \leq \omega_r}} |\ell_0(\{\boldsymbol{a}_i\}_i, \{\boldsymbol{R}_k\}_k) - \ell_n(\boldsymbol{Y}; \{\boldsymbol{a}_i\}_i, \{\boldsymbol{R}_k\}_k)| \\ =\ & \max_{s \in \{1, \ldots, s_{\max}\}} \sup_{\substack{\boldsymbol{a}_i \in \mathbb{R}^s, \boldsymbol{R}_k \in \mathbb{R}^{s \times s} \\ \max_i \|\boldsymbol{a}_i\|_2 \leq \omega_a \\ \max_k \|\mathrm{vec}(\boldsymbol{R}_k)\|_2 \leq \omega_r}} \left|\sum_{ijk} (Y_{ijk} - \pi_{ijk}^*) \boldsymbol{a}_i^T \boldsymbol{R}_k \boldsymbol{a}_j\right|, \end{aligned}$$

where $\pi_{ijk}^* = \exp(\theta_{ijk}^*)/\{1 + \exp(\theta_{ijk}^*)\}$, $\forall i, j, k$.

Let $\varepsilon_a = \omega_a/(nK)^2$ and $\{\bar{\boldsymbol{a}}_1^{(s)}, \ldots, \bar{\boldsymbol{a}}_{N_{s,\varepsilon_a}}^{(s)}\}$ be a minimal ε_a-net of the vector space $(\{\boldsymbol{a} \in \mathbb{R}^s : \|\boldsymbol{a}\|_2 \leq \omega_a\}, \|\cdot\|_2)$. It follows from Lemma 4 that

$$\begin{aligned} N_{s,\varepsilon_a} &= N(\varepsilon_a, \{\boldsymbol{a} \in \mathbb{R}^s : \|\boldsymbol{a}\|_2 \leq \omega_a\}, \|\cdot\|_2) = N(1/(nK)^2, B_2^s, \|\cdot\|_2) \\ &\leq \left(1 + 2n^2K^2\right)^s \leq (3nK)^{2s}. \end{aligned} \tag{32}$$

Let $\varepsilon_r = \omega_r/(nK)^2$, and $\{\bar{\boldsymbol{R}}_1^{(s)}, \ldots, \bar{\boldsymbol{R}}_{N_{s^2,\varepsilon_r}}^{(s)}\}$ be a minimal ε_r-net of the vector space $(\{\boldsymbol{R} \in \mathbb{R}^{s \times s} : \|\mathrm{vec}(\boldsymbol{R})\|_2 \leq \omega\}, \|\cdot\|_F)$. For any $s \times s$ matrices $\boldsymbol{Q}$, we have $\|\boldsymbol{Q}\|_F = \|\mathrm{vec}(\boldsymbol{Q})\|_2$. Similar to (32), we can show that

$$N_{s^2,\varepsilon_r} \leq (3nK)^{2s^2}. \tag{33}$$

Hence, for any $\boldsymbol{a}_i, \boldsymbol{a}_j \in \mathbb{R}^s$ and $\boldsymbol{R}_k \in \mathbb{R}^{s \times s}$ satisfying $\|\boldsymbol{a}_i\|_2, \|\boldsymbol{a}_j\|_2 \leq \omega_a, \|\mathrm{vec}(\boldsymbol{R}_k)\|_2 \leq \omega_r$, there exist some $\bar{\boldsymbol{a}}_{l_i}^{(s)}$, $\bar{\boldsymbol{a}}_{l_j}^{(s)}$, $\bar{\boldsymbol{R}}_{t_k}^{(s)}$, such that

$$\|\boldsymbol{a}_i - \bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2 \leq \frac{\omega_a}{(nK)^2}, \quad \|\boldsymbol{a}_j - \bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2 \leq \frac{\omega_a}{(nK)^2}, \quad \|\boldsymbol{R}_k - \bar{\boldsymbol{R}}_{t_k}^{(s)}\|_F \leq \frac{\omega_r}{(nK)^2}. \tag{34}$$

This further implies

$$\begin{aligned} &|(\boldsymbol{a}_i)^T \boldsymbol{R}_k \boldsymbol{a}_j - (\bar{\boldsymbol{a}}_{l_i}^{(s)})^T \bar{\boldsymbol{R}}_{t_k}^{(s)} \bar{\boldsymbol{a}}_{l_j}^{(s)}| \leq |(\boldsymbol{a}_i)^T \boldsymbol{R}_k \boldsymbol{a}_j - (\bar{\boldsymbol{a}}_{l_i}^{(s)})^T \boldsymbol{R}_k \boldsymbol{a}_j| \\ +\ & |(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T \boldsymbol{R}_k \boldsymbol{a}_j - (\bar{\boldsymbol{a}}_{l_i}^{(s)})^T \bar{\boldsymbol{R}}_{t_k}^{(s)} \boldsymbol{a}_j| + |(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T \bar{\boldsymbol{R}}_{t_k}^{(s)} \boldsymbol{a}_j - (\bar{\boldsymbol{a}}_{l_i}^{(s)})^T \bar{\boldsymbol{R}}_{t_k}^{(s)} \bar{\boldsymbol{a}}_{l_j}^{(s)}| \\ \leq\ & \|\boldsymbol{a}_i - \bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2 \|\boldsymbol{R}_k\|_2 \|\boldsymbol{a}_j\|_2 + \|\bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2 \|\boldsymbol{R}_k - \bar{\boldsymbol{R}}_{t_k}^{(s)}\|_2 \|\boldsymbol{a}_j\|_2 + \|\bar{\boldsymbol{a}}_i^{(s)}\|_2 \|\bar{\boldsymbol{R}}_{t_k}^{(s)}\|_2 \|\boldsymbol{a}_j - \bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2 \\ \leq\ & \|\boldsymbol{a}_i - \bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2 \|\boldsymbol{R}_k\|_F \|\boldsymbol{a}_j\|_2 + \|\bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2 \|\boldsymbol{R}_k - \bar{\boldsymbol{R}}_{t_k}^{(s)}\|_F \|\boldsymbol{a}_j\|_2 + \|\bar{\boldsymbol{a}}_i^{(s)}\|_2 \|\bar{\boldsymbol{R}}_{t_k}^{(s)}\|_F \|\boldsymbol{a}_j - \bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2 \\ \leq\ & 2\frac{\omega_a}{(nK)^2} \omega_a \omega_r + \frac{\omega_r}{(nK)^2} \omega_a^2 = \frac{3\omega_a^2 \omega_r}{(nK)^2}. \end{aligned} \tag{35}$$

Therefore, we have

$$\max_{s\in\{1,\ldots,s_{\max}\}}\frac{1}{s}\sup_{\substack{\boldsymbol{a}_i\in\mathbb{R}^s,\boldsymbol{R}_k\in\mathbb{R}^{s\times s}\\ \max_i\|\boldsymbol{a}_i\|_2\le\omega_a\\ \max_k\|\mathrm{vec}(\boldsymbol{R}_k)\|_2\le\omega_r}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j\right| \tag{36}$$

$$\le \max_{s\in\{1,\ldots,s_{\max}\}}\frac{1}{s}\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|+\sum_{ijk}|Y_{ijk}-\pi^*_{ijk}|\frac{3\omega_a^2\omega_r}{n^2K^2}$$

$$\le \max_{s\in\{1,\ldots,s_{\max}\}}\frac{1}{s}\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|+\frac{3\omega_a^2\omega_r}{K}.$$

By Bernstein's inequality (van der Vaart and Wellner, 1996, Lemma 2.2.9), we obtain for any $t>0$,

$$\max_{\substack{s\in\{1,\ldots,s_{\max}\}\\ l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\Pr\left(\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|>t\right)\le 2\exp\left(-\frac{t^2}{2\sigma_0^2+2M_0t/3}\right), \tag{37}$$

where

$$M_0 = \max_{s\in\{1,\ldots,s_{\max}\}}\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\max_{ijk}|Y_{ijk}-\pi^*_{ijk}||(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}|,$$

$$\sigma_0^2 = \max_{s\in\{1,\ldots,s_{\max}\}}\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\sum_{ijk}\mathrm{E}|Y_{ijk}-\pi^*_{ijk}|^2|(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}|^2.$$

With some calculations, we can show that

$$M_0 \le \max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\|\bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2\|\bar{\boldsymbol{R}}_{t_k}^{(s)}\|_2\|\bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2\le\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\|\bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2\|\bar{\boldsymbol{R}}_{t_k}^{(s)}\|_F\|\bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2$$

$$\le \max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\|\bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2\|\mathrm{vec}(\bar{\boldsymbol{R}}_{t_k}^{(s)})\|_2\|\bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2\le\omega_a^2\omega_r, \tag{38}$$

and

$$\sigma_0^2 \le \max_{s\in\{1,\ldots,s_{\max}\}}\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\sum_{ijk}\mathrm{E}|Y_{ijk}-\pi^*_{ijk}|^2\|\bar{\boldsymbol{a}}_{l_i}^{(s)}\|_2^2\|\mathrm{vec}(\bar{\boldsymbol{R}}_{t_k}^{(s)})\|_2^2\|\bar{\boldsymbol{a}}_{l_j}^{(s)}\|_2^2$$

$$\le \omega_a^4\omega_r^2\sum_{ijk}\mathrm{E}|Y_{ijk}-\pi^*_{ijk}|^2\le\omega_a^4\omega_r^2n^2K. \tag{39}$$

Let $t_s=5\omega_a^2\omega_r sn\sqrt{K\max(n,K)\log(nK)}$, we have

$$\max_{s\in\{1,\ldots,s_{\max}\}}\Pr\left(\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|>t_s\right)$$

$$\le \max_{\substack{s\in\{1,\ldots,s_{\max}\}\\ l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}N_{s,\varepsilon_a}^nN_{s^2,\varepsilon_r}^K\Pr\left(\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|>t_s\right)$$

$$\le \max_{\substack{s\in\{1,\ldots,s_{\max}\}\\ l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}(3nK)^{2sn+2s^2K}\Pr\left(\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|>t_s\right)$$

$$\le \max_{s\in\{1,\ldots,s_{\max}\}}2\exp\left(-\frac{25\omega_a^4\omega_r^2s^2n^2K\max(n,K)\log(nK)}{2\omega_a^4\omega_r^2\{n^2K+sn\sqrt{K\max(n,K)\log(nK)}/3\}}+(2sn+2s^2K)\log(3nK)\right)$$

$$= \max_{s\in\{1,\ldots,s_{\max}\}}2\exp\left(-\frac{25s^2\max(n,K)\log(nK)}{2+2s\sqrt{\max(n,K)\log(nK)}/(3n\sqrt{K})}+(2sn+2s^2K)\log(3nK)\right), \tag{40}$$

where the first inequality is due to Bonferroni's inequality, the second inequality follows by (32) and (33), the third inequality is due to (37)-(39).

Under the given conditions, we have $s\le s_{\max}=o\{n/\log(nK)\}$ and hence

$$\frac{s\sqrt{\max(n,K)\log(nK)}}{n\sqrt{K}}\le\frac{s\sqrt{n\log(nK)}}{n\sqrt{K}}+\frac{s\sqrt{K\log(nK)}}{n\sqrt{K}}\le\frac{s_{\max}\sqrt{\log(nK)}}{\sqrt{n}}+\frac{s_{\max}\sqrt{\log(nK)}}{n}\ll 1.$$

It follows that for any $s\in\{1,\ldots,s_{\max}\}$,

$$\Pr\left(\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|>5\omega_a^2\omega_r sn\sqrt{K\max(n,K)\log(nK)}\right)$$

$$\le 2\exp\left(-\frac{25s^2\max(n,K)\log(nK)}{2+1}+4s^2\max(n,K)\log(3nK)\right)$$

$$\le 2\exp\{-4s^2\max(n,K)\log(nK)\}\le 2\exp\{-4s^2n\log(nK)\}.$$

By Bonferroni's inequality, we have

$$\Pr\left(\bigcup_{s\in\{1,\ldots,s_{\max}\}}\left\{\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\right|>t_s\right\}\right)$$

$$\le \sum_{s=1}^{s_{\max}}2\exp\{-4s^2n\log(nK)\}\le\sum_{s=1}^{+\infty}2\exp\{-4sn\log(nK)\}\le\frac{2\exp\{-4n\log(nK)\}}{1-\exp\{-4n\log(nK)\}}\to 0.$$

This together with (36) implies that

$$\max_{s\in\{1,\ldots,s_{\max}\}} \frac{1}{s} \sup_{\substack{\boldsymbol{a}_i\in\mathbb{R}^s,\boldsymbol{R}_k\in\mathbb{R}^{s\times s}\\ \max_i\|\boldsymbol{a}_i\|_2\le\omega_a\\ \max_k\|\mathrm{vec}(\boldsymbol{R}_k)\|_2\le\omega_r}} \left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j\right| \le 6\omega_a^2\omega_r n\sqrt{K\max(n,K)\log(nK)}, \quad (41)$$

with probability tending to 1. Combining this with (26) and (27), we obtain with probability tending to 1,

$$\begin{aligned} &\max\left(\max_s\left|\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)-\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\right|/s,\right. \quad (42)\\ &\left.|\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)-\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)|/s_0\right) \le 6\omega_a^2\omega_r n\sqrt{K\max(n,K)\log(nK)}. \end{aligned}$$

Therefore, it follows from (31) that

$$\begin{aligned} &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s}\sum_{ijk}(\theta^*_{ijk}-\hat\theta^{(s)}_{ijk})^2 \quad (43)\\ \le\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{8\exp(\omega_a^2\omega_r)}{s}\left(\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)-\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\right)\\ \le\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{8\exp(\omega_a^2\omega_r)}{s}\left|\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)-\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\right|\\ +\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{8\exp(\omega_a^2\omega_r)}{s}\left|\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)-\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)\right|\\ +\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{8\exp(\omega_a^2\omega_r)}{s}\left(\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)-\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\right)\\ \le\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{8\exp(\omega_a^2\omega_r)}{s}\left|\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)-\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\right|\\ +\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{8\exp(\omega_a^2\omega_r)}{s}\left|\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)-\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)\right|\\ \le\ &96\omega_a^2\omega_r\exp(\omega_a^2\omega_r)n\sqrt{K\max(n,K)\log(nK)}, \end{aligned}$$

where the third inequality is due to that $\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\ge\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)$, for all $s\in\{s_0,\ldots,s_{\max}\}$.

Let $r_{n,K}=(n+K)^{-1/2}(\log n+\log K)^{-1/2}$. As $n\to\infty$, we have

$$r_{n,K}^2 n\sqrt{K\max(n,K)\log(nK)} \le r_{n,K}^2 n\sqrt{K(n+K)\log(nK)} = \frac{n\sqrt{K}}{\sqrt{(n+K)\log(nK)}} \ll \sqrt{nK}.$$

Since $\omega_a^2\omega_r\le\exp(\omega_a^2\omega_r)$, it follows from (43) that

$$\Pr\left(\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{r_{n,K}^2}{s^2\exp(2\omega_a^2\omega_r)}\sum_{ijk}(\theta^*_{ijk}-\hat\theta^{(s)}_{ijk})^2\ge\sqrt{nK}\right)\to 0. \quad (44)$$

For any integer $m\ge 1$, define

$$\mathbb{S}_m^{(s)} = \left\{(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k): m-1<\frac{r_{n,K}}{s\exp(\omega_a^2\omega_r)}\sqrt{\sum_{ijk}\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}^2}\le m,\right.$$
$$\left.\boldsymbol{a}_i^{(s)}\in\mathbb{R}^s,\forall i,\boldsymbol{R}_k^{(s)}\in\mathbb{R}^{s\times s},\forall k,\max_i\|\boldsymbol{a}_i^{(s)}\|_2\le\omega_a,\max_k\|\mathrm{vec}(\boldsymbol{R}_k^{(s)})\|_2\le\omega_r\right\}.$$

For any $(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}$, similar to (31), we can show that

$$\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)-\ell_0(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\ge\frac{\sum_{ijk}\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}^2}{8\exp(\omega_a^2\omega_r)}\ge\frac{(m-1)^2s^2r_{n,K}^{-2}}{8\exp(-\omega_a^2\omega_r)}. \quad (45)$$

The event $(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}$ implies that

$$\sup_{(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}}\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\ge\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k).$$

It follows from (45) that

$$\sup_{(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}\right|\ge\frac{(m-1)^2s^2\exp(\omega_a^2\omega_r)}{8r_{n,K}^2}. \quad (46)$$

For any $\{l_i\}_i$ and $\{t_k\}_k$ satisfying (34), it follows from (35) that

$$\begin{aligned} &\sum_{ijk}\{\theta^*_{ijk}-(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\}^2\\ \le\ &\sum_{ijk}\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}+(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}-(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\}^2\\ \le\ &2\sum_{ijk}\left(\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}^2+\{(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}-(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\}^2\right)\\ \le\ &\frac{2m^2s^2\exp(2\omega_a^2\omega_r)}{r_{n,K}^2}+\frac{6\omega_a^2\omega_r}{K}\le\frac{3m^2s^2\exp(2\omega_a^2\omega_r)}{r_{n,K}^2}. \end{aligned} \quad (47)$$

Let $\Lambda_m^{(s)}=\{(\{l_i\}_i,\{t_k\}_k):\sum_{ijk}\{\theta^*_{ijk}-(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}\}^2\le 3m^2s^2\exp(2\omega_a^2\omega_r)/r_{n,K}^2\}$. Similar to (36), we can show

$$\begin{aligned} &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s^2}\sup_{(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}\right|\\ \le\ &\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s^2}\max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}\\ (\{l_i\}_i,\{t_k\}_k)\in\Lambda_m^{(s)}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}-\theta^*_{ijk}\}\right|+\frac{3\omega_a^2\omega_r}{K}. \end{aligned}$$

Under the event defined in (46), for any $m \geq 9$, we have

$$\begin{aligned}
&\max_{s\in\{s_0,\ldots,s_{\max}\}} \frac{1}{s^2} \max_{\substack{l_1,\ldots,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,\ldots,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}\\ (\{l_i\}_i,\{t_k\}_k)\in\Lambda_m^{(s)}}} \left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}-\theta^*_{ijk}\}\right| \\
\geq\ & \frac{(m-1)^2\exp(\omega_a^2\omega_r)}{8r_{n,K}^2}-\frac{3\omega_a^2\omega_r}{K} \geq \frac{(m-1)^2\exp(\omega_a^2\omega_r)}{16r_{n,K}^2}+\frac{4\exp(\omega_a^2\omega_r)}{r_{n,K}^2}-\frac{3\omega_a^2\omega_r}{K} \geq \frac{(m-1)^2\exp(\omega_a^2\omega_r)}{16r_{n,K}^2}.
\end{aligned}$$

Define

$$(\sigma_m^{(s)})^2 = \max_{\substack{l_1,..,l_n\in\{1,\ldots,N_{s,\varepsilon_{n,K}}\}\\ t_1,..,t_K\in\{1,\ldots,N_{s^2,\varepsilon_{n,K}}\}\\ (\{l_i\}_i,\{t_k\}_k)\in\Lambda_m^{(s)}}} \sum_{ijk}\mathrm{E}|Y_{ijk}-\pi^*_{ijk}|^2\{(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}-\theta^*_{ijk}\}^2.$$

By (47), it is immediate to see that

$$(\sigma_m^{(s)})^2 \leq 3m^2s^2\exp(2\omega_a^2\omega_r)/r_{n,K}^2. \tag{48}$$

Similar to (37) and (40), we can show there exist some constants $J_0>0$, $K_0>0$ such that for any $m\geq J_0$ and any s such that $s_0\leq s\leq s_{\max}$,

$$\begin{aligned}
&\Pr\left(\frac{1}{s^2}\max_{\substack{l_1,..,l_n\in\{1,\ldots,N_{s,\varepsilon_a}\}\\ t_1,..,t_K\in\{1,\ldots,N_{s^2,\varepsilon_r}\}\\ (\{l_i\}_i,\{t_k\}_k)\in\Lambda_m^{(s)}}}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{(\bar{\boldsymbol{a}}_{l_i}^{(s)})^T\bar{\boldsymbol{R}}_{t_k}^{(s)}\bar{\boldsymbol{a}}_{l_j}^{(s)}-\theta^*_{ijk}\}\right| \geq \frac{(m-1)^2\exp(\omega_a^2\omega_r)}{16r_{n,K}^2}\right) \\
\leq\ & 2\exp\left(-\frac{(m-1)^4s^4\exp(2\omega_a^2\omega_r)/(256r_{n,K}^4)}{2(\sigma_m^{(s)})^2+(m-1)^2s^2\omega_a^2\omega_r\exp(\omega_a\omega_r)M_0/(24r_{n,K}^2)}+(2sn+2s^2K)\log(3nK)\right) \\
\leq\ & 2\exp\left(-\frac{(m-1)^4s^4/(256r_{n,K}^4)}{6m^2s^2/r_{n,K}^2+(m-1)^2s^2/(24r_{n,K}^2)}+(2sn+2s^2K)\log(3nK)\right) \leq 2\exp(-K_0m^2s^2r_{n,K}^{-2}),
\end{aligned}$$

where the second inequality is due to (38), (48) and the fact that $\omega_a^2\omega_r\leq\exp(\omega_a^2\omega_r)$. This yields

$$\Pr\left((\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}\right)\leq 2\exp(-K_0m^2s^2r_{n,K}^{-2}). \tag{49}$$

Let $J_{n,K}$ be the integer such that $J_{n,K}-1\leq(nK)^{1/4}\leq J_{n,K}$. In view of (44), we have for any $m\geq J_0$,

$$\begin{aligned}
&\Pr\left(\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{r_{n,K}}{s\exp(\omega_a^2\omega_r)}\sqrt{\sum_{ijk}(\theta^*_{ijk}-\hat{\theta}^{(s)}_{ijk})^2}>m\right) \leq \sum_{s=s_0}^{s_{\max}}\sum_{l=m}^{J_{n,K}}2\exp(-K_0l^2s^2r_{n,K}^{-2})+o(1) \\
&\leq \sum_{s=1}^{+\infty}\sum_{l=1}^{+\infty}2\exp(-K_0lmss_0r_{n,K}^{-2})+o(1) \leq \frac{2\exp(-s_0mK_0r_{n,K}^{-2})}{1-2\exp(-s_0mK_0r_{n,K}^{-2})}+o(1)=o(1).
\end{aligned}$$

This implies there exists some constant $C_0>0$ such that the following event occurs with probability tending to 1,

$$\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s^2}\sum_{ijk}(\hat{\theta}^{(s)}_{ijk}-\theta^*_{ijk})^2\leq C_0\exp(\omega_a^2\omega_r)r_{n,K}^{-2}, \tag{50}$$

The proof is hence completed.

C.3. Proof of Lemma 3

For any $s<s_0$, we have

$$\begin{aligned}
&\sum_{ijk}\left((\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)}-(\boldsymbol{a}_i^*)^T\boldsymbol{R}_k^*\boldsymbol{a}_j^*\right)^2 \qquad (51)\\
\geq\ & \inf_{\substack{\boldsymbol{a}_1^{(s)},\ldots,\boldsymbol{a}_n^{(s)}\in\mathbb{R}^s\\ \boldsymbol{R}_1^{(s)},\ldots,\boldsymbol{R}_K^{(s)}\in\mathbb{R}^{s\times s}}}\sum_{ijk}\left((\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}-(\boldsymbol{a}_i^*)^T\boldsymbol{R}_k^*\boldsymbol{a}_j^*\right)^2 \\
=\ & \inf_{\substack{\boldsymbol{A}^{(s)}\in\mathbb{R}^{n\times s}\\ \boldsymbol{R}_1^{(s)},\ldots,\boldsymbol{R}_K^{(s)}\in\mathbb{R}^{s\times s}}}\sum_{k=1}^K\|\boldsymbol{A}^{(s)}\boldsymbol{R}_k^{(s)}(\boldsymbol{A}^{(s)})^T-\boldsymbol{A}_0\boldsymbol{R}_{k,0}\boldsymbol{A}_0^T\|_F^2 \\
=\ & \inf_{\substack{\boldsymbol{A}^{(s)}\in\mathbb{R}^{n\times s}\\ \boldsymbol{R}_1^{(s)},\ldots,\boldsymbol{R}_K^{(s)}\in\mathbb{R}^{s\times s}}}\left\|\begin{pmatrix}\boldsymbol{A}^{(s)}\boldsymbol{R}_1^{(s)}\\ \vdots\\ \boldsymbol{A}^{(s)}\boldsymbol{R}_K^{(s)}\end{pmatrix}(\boldsymbol{A}^{(s)})^T-\underbrace{\begin{pmatrix}\boldsymbol{A}_0\boldsymbol{R}_{1,0}\\ \vdots\\ \boldsymbol{A}_0\boldsymbol{R}_{K,0}\end{pmatrix}}_{\boldsymbol{B}_0}\boldsymbol{A}_0^T\right\|_F^2 \\
\geq\ & \inf_{\boldsymbol{A}^{(s)}\in\mathbb{R}^{n\times s},\boldsymbol{B}^{(s)}\in\mathbb{R}^{nK\times s}}\left\|\boldsymbol{B}^{(s)}(\boldsymbol{A}^{(s)})^T-\boldsymbol{B}_0\boldsymbol{A}_0^T\right\|_F^2.
\end{aligned}$$

Define

$$(\widehat{\boldsymbol{A}}^{(s)},\widehat{\boldsymbol{B}}^{(s)})=\arg\min_{\substack{\boldsymbol{A}^{(s)}\in\mathbb{R}^{n\times s}\\ \boldsymbol{B}^{(s)}\in\mathbb{R}^{nK\times s}}}\|\boldsymbol{B}^{(s)}(\boldsymbol{A}^{(s)})^T-\boldsymbol{B}_0\boldsymbol{A}_0^T\|_F^2.$$

The above minimizers are not unique. Notice that $\mathrm{rank}(\boldsymbol{B}_0\boldsymbol{A}_0^T)\leq\mathrm{rank}(\boldsymbol{A}_0^T)\leq s_0$. Assume $\boldsymbol{B}_0\boldsymbol{A}_0^T$ has the following singular value decomposition,

$$\boldsymbol{B}_0\boldsymbol{A}_0^T=n\boldsymbol{U}_n\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T,$$

for some $\boldsymbol{U}_n\in\mathbb{R}^{nK\times s_0},\boldsymbol{V}_n\in\mathbb{R}^{n\times s_0}$ such that $\boldsymbol{U}_n^T\boldsymbol{U}_n=\boldsymbol{V}_n^T\boldsymbol{V}_n=\boldsymbol{I}_{s_0}$, and some diagonal matrix

$$\boldsymbol{\Lambda}_n=\mathrm{diag}(\lambda_n^{(1)},\lambda_n^{(2)},\ldots,\lambda_n^{(s_0)})$$

such that $|\lambda_n^{(1)}|\geq|\lambda_n^{(2)}|\geq\cdots\geq|\lambda_n^{(s_0)}|$. Then one solution is given by

$$\widehat{\boldsymbol{A}}^{(s)}=n\boldsymbol{V}_n\boldsymbol{\Lambda}_n\boldsymbol{U}_n^T\boldsymbol{U}_n^{(s)},\quad \widehat{\boldsymbol{B}}^{(s)}=\boldsymbol{U}_n^{(s)},$$

where $\boldsymbol{U}_n^{(s)}$ is the submatrix of $\boldsymbol{U}_n$ formed by its first s columns.

Since $\boldsymbol{U}_n^T\boldsymbol{U}_n = \boldsymbol{I}_{s_0}$, we have

$$\begin{aligned}\widehat{\boldsymbol{B}}^{(s)}(\widehat{\boldsymbol{A}}^{(s)})^T &= n\boldsymbol{U}_n^{(s)}(\boldsymbol{U}_n^{(s)})^T\boldsymbol{U}_n\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T = n\boldsymbol{U}_n^{(s)}(\boldsymbol{I}_s, \boldsymbol{O}_{s,s_0-s})\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T \\ &= n\boldsymbol{U}_n\begin{pmatrix}\boldsymbol{I}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{O}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T,\end{aligned}$$

and hence

$$\begin{aligned}\widehat{\boldsymbol{B}}^{(s)}(\widehat{\boldsymbol{A}}^{(s)})^T - \boldsymbol{B}_0\boldsymbol{A}_0^T &= n\boldsymbol{U}_n\begin{pmatrix}\boldsymbol{I}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{O}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T - n\boldsymbol{U}_n\boldsymbol{I}_{s_0}\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T \\ &= -n\boldsymbol{U}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T.\end{aligned}$$

This together with (51) implies that

$$\begin{aligned}&\sum_{ijk}\left((\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)} - (\boldsymbol{a}_i^*)^T\boldsymbol{R}_k^*\boldsymbol{a}_j^*\right)^2 \geq \|\widehat{\boldsymbol{B}}^{(s)}(\widehat{\boldsymbol{A}}^{(s)})^T - \boldsymbol{B}_0\boldsymbol{A}_0^T\|_F^2 \\ \geq\ & n^2\text{trace}\left(\boldsymbol{U}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n\boldsymbol{V}_n^T\boldsymbol{V}_n\boldsymbol{\Lambda}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{U}_n^T\right) \\ =\ & n^2\text{trace}\left(\boldsymbol{U}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n^2\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{U}_n^T\right) \qquad (52) \\ =\ & n^2\text{trace}\left(\boldsymbol{\Lambda}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{U}_n^T\boldsymbol{U}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n\right) \\ =\ & n^2\text{trace}\left(\boldsymbol{\Lambda}_n\begin{pmatrix}\boldsymbol{O}_s & \boldsymbol{O}_{s,s_0-s}\\ \boldsymbol{O}_{s_0-s,s} & \boldsymbol{I}_{s_0-s,s_0-s}\end{pmatrix}\boldsymbol{\Lambda}_n\right) \geq n^2(\lambda_n^{(s_0)})^2, \qquad (53)\end{aligned}$$

where (52) is due to that $\boldsymbol{V}_n^T\boldsymbol{V}_n = \boldsymbol{I}_{s_0}$ and the equality in (53) is due to that $\boldsymbol{U}_n^T\boldsymbol{U}_n = \boldsymbol{I}_{s_0}$.

To summarize, we've shown

$$\sum_{ijk}\left((\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)} - (\boldsymbol{a}_i^*)^T\boldsymbol{R}_k^*\boldsymbol{a}_j^*\right)^2 \geq n^2(\lambda_n^{(s_0)})^2. \qquad (54)$$

In the following, we provide a lower bound for $(\lambda_n^{(s_0)})^2$. By definition, $(\lambda_n^{(s_0)})^2$ is the s_0-th largest eigenvalue of

$$\frac{1}{n^2}\boldsymbol{A}_0\boldsymbol{B}_0^T\boldsymbol{B}_0\boldsymbol{A}_0^T = \frac{1}{n^2}\sum_{k=1}^K\boldsymbol{A}_0\boldsymbol{R}_{k,0}^T\boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{k,0}\boldsymbol{A}_0^T.$$

We first provide an lower bound for $\lambda_{\min}(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{k,0}/n)$. Let $\boldsymbol{\Sigma}_A = \boldsymbol{A}_0^T\boldsymbol{A}_0/n$. Consider the following eigenvalue decomposition:

$$\boldsymbol{\Sigma}_A = \boldsymbol{U}_A\boldsymbol{\Lambda}_A\boldsymbol{U}_A^T,$$

for some orthogonal matrix $\boldsymbol{U}_A$ and some diagonal matrix $\boldsymbol{\Lambda}_A$. Under Assumption (A2), the matrix

$$\boldsymbol{\Sigma}_A - \bar{c}\boldsymbol{I}_{s_0}$$

is positive semidefinite. As a result, the matrix

$$\sum_{k=1}^K\boldsymbol{R}_{k,0}^T(\boldsymbol{\Sigma}_A - \bar{c}\boldsymbol{I}_{s_0})\boldsymbol{R}_{k,0}$$

is positive semidefinite. Therefore, we have

$$\begin{aligned}&\lambda_{\min}\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{\Sigma}_A\boldsymbol{R}_{k,0}\right) = \inf_{\boldsymbol{a}_0\in\mathbb{R}^{s_0},\|\boldsymbol{a}_0\|_2=1}\boldsymbol{a}_0^T\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{\Sigma}_A\boldsymbol{R}_{k,0}\right)\boldsymbol{a}_0 \qquad (55) \\ =\ & \inf_{\boldsymbol{a}_0\in\mathbb{R}^{s_0},\|\boldsymbol{a}_0\|_2=1}\left\{\boldsymbol{a}_0^T\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T(\boldsymbol{\Sigma}_A - \bar{c}\boldsymbol{I}_{s_0})\boldsymbol{R}_{k,0}\right)\boldsymbol{a}_0 + \bar{c}\boldsymbol{a}_0^T\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0}\right)\boldsymbol{a}_0\right\} \\ \geq\ & \bar{c}\inf_{\boldsymbol{a}_0\in\mathbb{R}^{s_0},\|\boldsymbol{a}_0\|_2=1}\boldsymbol{a}_0^T\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0}\right)\boldsymbol{a}_0 = \bar{c}\lambda_{\min}\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{R}_{k,0}\right) = \bar{c}\bar{K}.\end{aligned}$$

By the eigenvalue decomposition, we have

$$\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{\Sigma}_A\boldsymbol{R}_{k,0} = \boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}\boldsymbol{U}_{RA},$$

for some orthogonal matrix $\boldsymbol{U}_{RA}\in\mathbb{R}^{s_0\times s_0}$ and some diagonal matrix $\boldsymbol{\Lambda}_{RA}\in\mathbb{R}^{s_0\times s_0}$. It follows from (55) that all the diagonal elements in $\boldsymbol{\Lambda}_{RA}$ are positive. Let $\boldsymbol{\Lambda}_{RA}^{1/2}$ be the diagonal matrix such that $\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{\Lambda}_{RA}^{1/2} = \boldsymbol{\Lambda}_{RA}$. Apparently, the diagonal elements in $\boldsymbol{\Lambda}_{RA}^{1/2}$ are nonzero. Notice that

$$\frac{1}{n^2}\sum_{k=1}^K\boldsymbol{A}_0\boldsymbol{R}_{k,0}^T\boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{k,0}\boldsymbol{A}_0^T = \frac{1}{n}\boldsymbol{A}_0\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\boldsymbol{A}_0^T.$$

The s_0 largest eigenvalues in $\frac{1}{n^2}\sum_{k=1}^K\boldsymbol{A}_0\boldsymbol{R}_{k,0}^T\boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{R}_{k,0}\boldsymbol{A}_0^T$ corresponds to the smallest eigenvalue in

$$\frac{1}{n}\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}.$$

Similar to (55), we can show that

$$\begin{aligned}&\lambda_{\min}\left(\frac{1}{n}\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\boldsymbol{A}_0^T\boldsymbol{A}_0\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\right) \geq \bar{c}\lambda_{\min}\left(\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}^{1/2}\boldsymbol{U}_{RA}\right) \\ =\ & \bar{c}\lambda_{\min}(\boldsymbol{U}_{RA}^T\boldsymbol{\Lambda}_{RA}\boldsymbol{U}_{RA}) \geq \bar{c}^2\lambda_{\min}\left(\sum_{k=1}^K\boldsymbol{R}_{k,0}^T\boldsymbol{\Sigma}_A\boldsymbol{R}_{k,0}\right).\end{aligned}$$

Combining this together with (55), we obtain that

$$(\lambda_{n,k}^{(s_0)})^2 \geq \bar{c}^2\bar{K}.$$

It follows from (54) that

$$\sum_{ijk}\left((\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)} - (\boldsymbol{a}_i^*)^T\boldsymbol{R}_k^*\boldsymbol{a}_j^*\right)^2 \geq n^2\bar{c}^2\bar{K}.$$

This completes the proof.

C.4. Proof of Theorem 1

It suffices to show

$$\Pr\left(\mathrm{IC}(s_0) > \max_{1\le s<s_0} \mathrm{IC}(s)\right) \to 1, \tag{56}$$

and

$$\Pr\left(\mathrm{IC}(s_0) > \max_{s_0\le s\le s_{\max}} \mathrm{IC}(s)\right) \to 1. \tag{57}$$

We first show (56). Combining Lemma 3 with (31), we obtain that

$$2\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k) - 2\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) \ge \frac{\sum_{ijk}(\theta^*_{ijk}-\hat\theta^{(s)}_{ijk})^2}{4\exp(\omega_a^2\omega_r)} \ge \frac{n^2\bar c^2\bar K}{4\exp(\omega_a^2\omega_r)},$$

for any $s\in\{1,\ldots,s_0-1\}$. Combining this with (42), we have that

$$\begin{aligned}
&2\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k) - 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) \ge 2\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k) - 2\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\\
-\ & 2\left|\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k) - \ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)\right| - 2\left|\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - \ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k)\right|\\
\ge\ & \frac{\bar c^2n^2\bar K}{4\exp(\omega_a^2\omega_r)} - 24\omega_a^2\omega_r n\sqrt{K\max(n,K)\log(nK)},
\end{aligned}\tag{58}$$

with probability tending to 1.

Under the given conditions, we have $K\sim n^{l_0}$ for some $0\le l_0\le 1$. This together with the condition $n^{(1-l_0)/2}\bar K \gg \exp(2\omega_a^2\omega_r)\sqrt{\log n}$ yields

$$\omega_a^2\omega_r n\sqrt{K\max(n,K)\log(nK)} = O\left(\exp(\omega_a^2\omega_r)n^{3/2+l_0/2}\sqrt{\log n}\right) \ll \frac{n^2\bar K}{\exp(\omega_a^2\omega_r)}. \tag{59}$$

By (58), we have with probability tending to 1 that

$$2\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k) - 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) \ge \frac{\bar c^2n^2\bar K}{8\exp(\omega_a^2\omega_r)}, \tag{60}$$

for all $1\le s<s_0$. By definition, we have

$$\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s_0)}\}_k) \ge \ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k).$$

This together with (60) gives that for all $1\le s<s_0$,

$$2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s_0)}\}_k) - 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) \ge \frac{\bar c^2n^2\bar K}{8\exp(\omega_a^2\omega_r)}, \tag{61}$$

with probability tending to 1.

Under the given conditions, we have $\kappa(n,K)\ll n^2\bar K/\exp(\omega_a^2\omega_r)$. Under the event defined in (61), we have that

$$\begin{aligned}
\mathrm{IC}(s_0)-\mathrm{IC}(s) &= 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s_0)}\}_k) - 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - (s_0-s)\kappa(n,K)\\
&\ge \frac{\bar c^2n^2\bar K}{8\exp(\omega_a^2\omega_r)} - s_0\kappa(n,K) \gg 0,
\end{aligned}$$

since s_0 is fixed. This proves (56).

Now we show (57). Similar to (37)-(42), we can show the following event occurs with probability tending to 1,

$$\sup_{\substack{s\in\{s_0,\ldots,s_{\max}\}\\ \boldsymbol{a}_1^{(s)},\ldots,\boldsymbol{a}_n^{(s)}\in\Omega_a,\boldsymbol{R}_1^{(s)},\ldots,\boldsymbol{R}_K^{(s)}\in\Omega_r\\ \frac{d(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k;\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)}{s\exp(\omega_a^2\omega_r)}=O\left(\frac{r_{n,K}^{-1}}{n\sqrt{K}}\right)}} \frac{1}{s^2}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{\theta^*_{ijk}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}\right| = O\left(\frac{\exp(\omega_a^2\omega_r)}{r_{n,K}^2}\right). \tag{62}$$

By Lemma 2, we obtain with probability tending to 1,

$$\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s^2}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{\theta^*_{ijk}-(\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)}\}\right| = O\left(\frac{\exp(\omega_a^2\omega_r)}{r_{n,K}^2}\right),$$

and hence

$$\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s}\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{\theta^*_{ijk}-(\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)}\}\right| = O\left(\frac{s_{\max}\exp(\omega_a^2\omega_r)}{r_{n,K}^2}\right). \tag{63}$$

Since $\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)\ge\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)$, under the event defined in (63), we have

$$\begin{aligned}
&2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - 2\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k) \le 2\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - 2\ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k)\\
-\ & 2\left|\sum_{ijk}(Y_{ijk}-\pi^*_{ijk})\{\theta^*_{ijk}-(\widehat{\boldsymbol{a}}_i^{(s)})^T\widehat{\boldsymbol{R}}_k^{(s)}\widehat{\boldsymbol{a}}_j^{(s)}\}\right| = O\left(\frac{ss_{\max}\exp(\omega_a^2\omega_r)}{r_{n,K}^2}\right).
\end{aligned}$$

Notice that

$$\ell_0(\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) \le \ell_0(\{\boldsymbol{a}_i^*\}_i,\{\boldsymbol{R}_k^*\}_k),$$

we have with probability tending to 1 that

$$2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) - 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s_0)}\}_k) \le O\left(\frac{ss_{\max}\exp(\omega_a^2\omega_r)}{r_{n,K}^2}\right), \tag{64}$$

for all $s_0<s\le s_{\max}$. Under the event defined in (64), we have

$$\begin{aligned}
\mathrm{IC}(s_0)-\mathrm{IC}(s) &\ge 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s_0)}\}_k) - 2\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_i^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_k^{(s)}\}_k) + (s-s_0)\kappa(n,K)\\
&\ge (s-s_0)\kappa(n,K) - O\left(ss_{\max}\exp(\omega_a^2\omega_r)r_{n,K}^{-2}\right).
\end{aligned}$$

Under the condition $\kappa(n,K)\gg s_{\max}\exp(\omega_a^2\omega_r)(n+K)(\log n+\log K)$, we have that

$$\Pr\left(\mathrm{IC}(s_0) > \max_{s_0<s\le s_{\max}}\mathrm{IC}(s)\right)\to 1,$$

This proves (57). The proof is hence completed.

C.5. Proof of Corollary 1

Using similar arguments in Lemma 3, we can show for any permutation function $\pi : \{1,\ldots,n\} \to \{1,\ldots,n\}$,

$$\sum_{ijk}\left((\widehat{\boldsymbol{a}}_{i,\pi}^{(s)})^T\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\widehat{\boldsymbol{a}}_{j,\pi}^{(s)}-(\boldsymbol{a}_{i,\pi}^{*})^T\boldsymbol{R}_{k,\pi}^{*}\boldsymbol{a}_{j,\pi}^{*}\right)^2\geq n^2\bar{c}^2\bar{K}. \tag{65}$$

In addition, it follows from (41) and the condition $K=O(n^{l_0})$ that

$$\Pr\left(\max_{\substack{s\in\{1,\ldots,s_{\max}\}\\ \pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}}\frac{1}{s}\left|\sum_{ijk}(Y_{ijk}-\pi_{ijk}^{*})(\widehat{\boldsymbol{a}}_{i,\pi}^{(s)})^T\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\widehat{\boldsymbol{a}}_{j,\pi}^{(s)}\right|\leq C_0\omega_a^2\omega_r n^{3/2+l_0/2}\sqrt{\log n}\right)\to 1,$$

and

$$\Pr\left(\frac{1}{s_0}\left|\sum_{ijk}(Y_{ijk}-\pi_{ijk}^{*})(\boldsymbol{a}_i^{*})^T\boldsymbol{R}_k^{*}\boldsymbol{a}_j^{*}\right|\leq C_0\omega_a^2\omega_r n^{3/2+l_0/2}\sqrt{\log n}\right)\to 1,$$

for some constant $C_0>0$. Hence, the following event occurs with probability tending to 1,

$$\begin{aligned}&\max\left(\max_{s,\pi}\left|\ell_0(\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k)-\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k)\right|/s,\right.\\ &\left.|\ell_0(\{\boldsymbol{a}_i^{*}\}_i,\{\boldsymbol{R}_k^{*}\}_k)-\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^{*}\}_i,\{\boldsymbol{R}_k^{*}\}_k)|/s_0\right)\leq C_0\omega_a^2\omega_r n\sqrt{K\max(n,K)\log(nK)}.\end{aligned} \tag{66}$$

Combining (65) with (31) yields

$$2\ell_0(\{\boldsymbol{a}_i^{*}\}_i,\{\boldsymbol{R}_k^{*}\}_k)-2\max_{\substack{s\in\{1,\ldots,s_0-1\}\\ \pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}}\ell_0(\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k)\geq\frac{n^2\bar{c}^2\bar{K}}{4\exp(\omega_a^2\omega_r)}. \tag{67}$$

Under the given conditions, we have

$$\frac{n^2\bar{c}^2\bar{K}}{4\exp(\omega_a^2\omega_r)}\gg\omega_a^2\omega_r n\sqrt{K\max(n,K)\log(nK)}.$$

This together with (66) and (67) gives

$$2\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^{*}\}_i,\{\boldsymbol{R}_k^{*}\}_k)-2\max_{\substack{s\in\{1,\ldots,s_0-1\}\\ \pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}}\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k)\geq\frac{n^2\bar{c}^2\bar{K}}{8\exp(\omega_a^2\omega_r)},$$

with probability tending to 1.

Under Condition (A4), we have $\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s_0)}\}_k)\geq\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_{i,\pi}^{(s_0)*}\}_i,\{\boldsymbol{R}_{k,\pi}^{(s_0)*}\})=\ell_n(\boldsymbol{Y};\{\boldsymbol{a}_i^{*}\}_i,\{\boldsymbol{R}_k^{*}\}_k)$. Therefore, the following event occurs with probability tending to 1,

$$\min_{\pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}2\left(\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s_0)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s_0)}\}_k)-\max_{s\in\{1,\ldots,s_0-1\}}\ell_n(\boldsymbol{Y};\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k)\right)\geq\frac{n^2\bar{c}^2\bar{K}}{8\exp(\omega_a^2\omega_r)}.$$

Under the given conditions in Corollary 1, we obtain

$$\Pr\left(\bigcap_{\pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}\left\{\mathrm{IC}_\pi(s_0)>\max_{1\leq s\leq s_0-1}\mathrm{IC}_\pi(s)\right\}\right)\to 1. \tag{68}$$

Similar to (46) and (49), we can show

$$\begin{aligned}&\Pr\left(\bigcup_{\pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}\left\{(\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\},\widehat{\boldsymbol{R}}_{k,\pi}^{(s)})\in\mathbb{S}_m^{(s)}\right\}\right)\\ \leq\;&\Pr\left(\sup_{(\{\boldsymbol{a}_i^{(s)}\}_i,\{\boldsymbol{R}_k^{(s)}\}_k)\in\mathbb{S}_m^{(s)}}\left|\sum_{ijk}(Y_{ijk}-\pi_{ijk}^{*})\{\theta_{ijk}^{*}-(\boldsymbol{a}_i^{(s)})^T\boldsymbol{R}_k^{(s)}\boldsymbol{a}_j^{(s)}\}\right|\geq\frac{(m-1)^2s^2\exp(\omega_a^2\omega_r)}{8r_{n,K}^2}\right)\\ \leq\;&2\exp(-K_0m^2s^2r_{n,K}^{-2}),\end{aligned}$$

for some constant $K_0>0$. Using similar arguments in the proof of Lemma 2, this yields with probability tending to 1,

$$\max_{\substack{s\in\{s_0,\ldots,s_{\max}\}\\ \pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}}\frac{1}{s^2}d^2\left(\{\widehat{\boldsymbol{a}}_{i,\pi}^{(s)}\}_i,\{\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\}_k;\{\boldsymbol{a}_i^{*}\}_i,\{\boldsymbol{R}_k^{*}\}_k\right)\leq\frac{\exp(2\omega_a^2\omega_r)(n+K)(\log n+\log K)}{n^2K}.$$

This together with (62) gives

$$\max_{s\in\{s_0,\ldots,s_{\max}\}}\frac{1}{s}\left|\sum_{ijk}(Y_{ijk}-\pi_{ijk}^{*})\{\theta_{ijk}^{*}-(\widehat{\boldsymbol{a}}_{i,\pi}^{(s)})^T\widehat{\boldsymbol{R}}_{k,\pi}^{(s)}\widehat{\boldsymbol{a}}_{j,\pi}^{(s)}\}\right|=O\left(\frac{s_{\max}\exp(\omega_a^2\omega_r)}{r_{n,K}^2}\right),$$

with probability tending to 1. Using similar arguments in the proof of Theorem 1, we can show

$$\Pr\left(\bigcap_{\pi:\{1,\ldots,n\}\to\{1,\ldots,n\}}\left\{\mathrm{IC}_\pi(s_0)>\max_{s_0<s\leq s_{\max}}\mathrm{IC}_\pi(s)\right\}\right)\to 1.$$

This together with (68) yields (16). The proof is hence completed.

Appendix D. Additional Simulation Results

We simulate the response $\{Y_{ijk}\}_{ijk}$ from the following model:

$$\begin{aligned}&\Pr(Y_{ijk}=1|\{\boldsymbol{a}_i\}_i,\{\boldsymbol{R}_k\}_k)=\frac{\exp(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)}{1+\exp(\boldsymbol{a}_i^T\boldsymbol{R}_k\boldsymbol{a}_j)},\\ &\boldsymbol{a}_1,\boldsymbol{a}_2,\ldots,\boldsymbol{a}_n\overset{iid}{\sim}N(0,\{0.5^{|i-j|}\}_{i,j=1,\ldots,s_0}),\\ &\boldsymbol{R}_1=\boldsymbol{R}_2=\cdots=\boldsymbol{R}_K=\mathrm{diag}(\underbrace{1,-1,1,-1,\ldots,1,-1}_{s_0}).\end{aligned}$$

Table 5: Simulation results for Setting IV, V and VI (standard errors in parenthesis)

We use the same six settings as described in Section 4.2. In each setting, we further consider three scenarios, by setting $s_0 = 2, 4$ and 6. Reported in Table 3 and 4 are the percentage of selecting the true models (TP) and the average of $\hat{s}$ selected by IC_0, $IC_{0.5}$, IC_1 and BIC over 100 replications.

It can be seen from Table 4 and 5 that our proposed information criteria are consistent. In contrast, BIC fails in all settings. In addition, in the last two settings, TPs of $IC_{0.5}$ and IC_1 are larger than IC_0 for most of the cases. As commented before, these differences are due to the finite sample correction term $\tau_\alpha(n, K)$.

Abstract

Probabilistic linear discriminant analysis (PLDA) is a method used for biometric problems like speaker or face recognition that models the variability of the samples using two latent variables, one that depends on the class of the sample and another one that is assumed independent across samples and models the within-class variability. In this work, we propose a generalization of PLDA that enables joint modeling of two sample-dependent factors: the class of interest and a nuisance condition. The approach does not change the basic form of PLDA but rather modifies the training procedure to consider the dependency across samples of the latent variable that models within-class variability. While the identity of the nuisance condition is needed during training, it is not needed during testing since we propose a scoring procedure that marginalizes over the corresponding latent variable. We show results on a multilingual speaker-verification task, where the language spoken is considered a nuisance condition. The proposed joint PLDA approach leads to significant performance gains in this task for two different data sets, in particular when the training data contains mostly or only monolingual speakers.

Keywords: Probabilistic linear discriminant analysis, speaker recognition, factor analysis, language variability, robustness to acoustic conditions

1. Introduction

PLDA was proposed by Prince (2007) for doing inferences about the identity of a person from an image of their face. A closely related model had been previously proposed by Ioffe (2006) and also tested on image processing tasks. The technique was later widely adopted by the speaker recognition community, becoming the state-of-the-art scoring technique for this task (Kenny, 2010; Burget et al., 2011; Brümmer, 2010a; Senoussaoui et al., 2011; Matejka et al., 2011). PLDA assumes that each sample[1] is represented by a feature vector of fixed dimension and that this vector is given by a sum of three terms: a term that depends on the class of the sample, a term that models the within-class variability and is assumed independent across samples, and a final term that models any remaining variability and is also independent across samples. These assumptions imply that all samples from the same class are independent of each other and also independent of samples from other classes once the class is known.

In contrast with the assumptions made by PLDA, many training data sets consist of samples that come from a small set of distinct conditions. For example, many speaker recognition data sets contain only a few acoustic conditions (different microphones or noise conditions), speech styles (conversational, monologue, read), and languages. Samples corresponding to the same condition will most likely be statistically dependent.

The literature proposes a few approaches that generalize PLDA to consider metadata about the samples during training. The main motivation for these approaches, though, is not to relax the conditional independence assumption but rather to enable a more flexible model that can adapt to each of the available conditions rather than assuming that samples from all conditions can be modeled with the same linear model. Yet, a side effect of the proposed generalizations is the introduction of a dependency between samples from the same condition. The simplest approach of this family is to train a separate PLDA model for each condition, as proposed by Garcia-Romero et al. (2012). Nevertheless, in this paper, the authors show that pooling the data from all conditions, as proposed by Lei et al. (2012), leads to better performance than training separate models. This result is reasonable, since training separate PLDA models does not allow the overall model to learn how samples from the same class vary across conditions; only within-condition variation is learned.

The tied PLDA model proposed by Li et al. (2012) is designed to tackle this problem. In this approach, one PLDA model is trained for each condition, but these models are tied by forcing the latent variable corresponding to each class to be the same across all conditions. The approach was shown to outperform standard PLDA with pooled training data when each class in the training data is seen under both considered conditions, frontal and profile, in a face recognition task. A similar approach is proposed by Mak et al. (2016), but in this case, the mixture component is not given during training. Instead, the PLDA mixture components depend on a continuous metadata value, which is modeled with a mixture of Gaussians. The approach is tested by adding noise to the training data at different SNR levels. The resulting training data then contains samples for each speaker at different SNR levels. Under these conditions, the authors show gains from the proposed approach compared to pooling all the data to train a single PLDA model.

In this paper, we consider a scenario where each speaker in the training data is seen only under a small subset of the conditions present in the training set (potentially, only one). Further, we expect some conditions to have much less training data than others. Under this scenario, the tied PLDA approach does not work well, since it requires training a PLDA model of the same dimensions for each condition, which may be impossible or suboptimal for the conditions with less data. Further, the tied PLDA model can only learn how the nuisance conditions affect the classes of interest if it is provided samples for each class under different conditions during training.

We propose a novel generalization of the PLDA model that relaxes the conditional independence assumption without increasing the size of the parameter space, keeping the same functional form of the original PLDA model but modifying the training and scoring procedures to consider the dependency across samples originating from the sample's condition. In the proposed approach, which we call Joint PLDA (JPLDA), the condition is assumed to be known during training but not during testing. An expectation-maximization (EM) training

1. Throughout this paper, the word sample is used to refer to an audio signal or recording containing speech.

procedure is formulated that takes into account the condition of each sample. Scoring is performed, as in standard PLDA, by computing a likelihood ratio between the null hypothesis that the two sides of a trial belong to the same speaker versus the alternative hypothesis that the two sides belong to different speakers. The two likelihoods are computed by marginalizing over two hypotheses about the condition in both sides of a trial: that they are the same and that they are different. This way, we expect that the new model will be better at coping with same-condition versus different-condition trials than standard PLDA, since knowledge about the condition is used during training and implicitly considered during scoring. Further, we expect this model to behave better than tied PLDA under a training scenario where the number of samples is highly imbalanced across conditions and each speaker is seen only under one or a small subset of conditions.

The mathematical formulation for the proposed JPLDA approach was first published in arXiv (Ferrer, 2017), without results or analysis. A similar model with a significantly different formulation for the EM and scoring algorithms was later published, also in arXiv, by other authors (Shi et al., 2017). They show significant improvements from this approach on a text-dependent speaker verification task. In this paper, we show results and detailed analysis on two multilingual speaker recognition data sets, one composed of Mixer data (Cieri et al., 2007) from the speaker recognition evaluations organized by NIST and another that uses LASRS data (Beck et al., 2004). We evaluate two training scenarios, one using all available training data from the PRISM data set (Ferrer et al., 2011), which contains a small percentage of speakers speaking two different languages, and one where we subset the training data to contain only one language per speaker. We show that JPLDA significantly outperforms two standard PLDA approaches with different structures and tied PLDA, especially when the training data contains mostly or only a single language per speaker.

2. Standard PLDA Models

In this work, we adopt the nomenclature usually used by the speaker recognition community. Yet, the model proposed can be used for the original image processing task or any other task for which standard PLDA is used.

Standard PLDA (Prince, 2007) assumes that the vector m_i representing a certain sample from speaker s_i is given by

$$m_i = \mu + V y_{s_i} + U x_i + z_i, \tag{1}$$

where μ is a fixed bias; y_{s_i} is a vector of size R_y, the dimension of the speaker subspace; and x_i is a vector of size R_x, the dimension of the subspace corresponding to the nuisance condition or, as usually called in speaker recognition, the channel. The model assumes that

$$\begin{aligned} y_{s_i} &\sim N(0, I), \\ x_i &\sim N(0, I), \\ z_i &\sim N(0, D^{-1}), \end{aligned}$$

where the matrix D is assumed to be diagonal. All these latent variables are assumed independent: speaker variables are independent across speakers, and the nuisance variable x_i and noise variable z_i are independent across samples.

This model is equivalent (Sizov et al., 2014) to assuming the following distributions

$$m_i|\gamma_{s_i} \sim N(\gamma_{s_i}, UU^T + D^{-1}), \tag{2}$$

$$\gamma_{s_i} \sim N(\mu, VV^T). \tag{3}$$

where we can see that VV^T is the between-speaker and $UU^T + D^{-1}$ is the within-speaker covariance matrix of the m_i vectors. Note that, in the general case, the matrix VV^T could be singular. This fact, though, does not cause any theoretical or practical problems for the PLDA model.

The model described above corresponds to the original PLDA formulation, which we will call full PLDA (FPLDA). In speaker recognition, a simplified version of PLDA (SPLDA for the purpose of this paper) is more commonly used, where the nuisance term Ux_i is absorbed into the noise term, which is then assumed to have a full rather than diagonal covariance matrix. Sizov et al. (2014) gives a comprehensive explanation of the usual flavors of PLDA.

The training of PLDA parameters is done using an EM algorithm. The EM formulation for SPLDA and FPLDA can be found in two very detailed documents by Brümmer (2010a,b). For FPLDA, we use a minimum divergence (Kenny, 2010) step after every maximization step. This step is generally used to speed up convergence of the EM algorithm. For SPLDA, this step was not necessary for quick convergence since, as we will see, the smart initialization procedure described below already leads to an excellent model. We will not reproduce the EM formulas here, but we will describe the two initialization procedures we use, since they will be compared in the experimental section.

2.1. EM Initialization Procedure

The EM algorithm requires an initial model to start the iterations. This model can be generated randomly or, in the case of SPLDA, with a "smart" procedure that results in a much better initial model that, in turn, requires many fewer or no EM iterations to converge to the final parameters.

In our experiments, for random initialization, we set D to be an identity matrix, and V and U, when applicable, to be matrices with random elements drawn from a normal distribution with standard deviation 0.01 and mean 0.

For SPLDA, we also try a smart initialization approach that is directly motivated by Equations (2) and (3). Namely, we initialize V and D as follows

$$\begin{aligned} V &= Q\Lambda^{-1/2}, \\ D &= W^{-1}, \end{aligned}$$

where W is the empirical within-speaker covariance matrix of the training data, and Q is a matrix with the eigenvectors corresponding to the R_y largest eigenvalues of the between-speaker covariance matrix of the training data and $\Lambda^{-1/2}$ is a diagonal matrix containing the square roots of those eigenvalues. As will be shown in the experiments, this initialization procedure works quite well, leading to models that are as good as those trained with many iterations of EM.

2.2. Scoring

In this work, we consider a verification task. Two sets of samples, an enrollment set E and a test set T, each corresponding to one or more samples from the same speaker, are compared

to decide whether the two speakers are the same or different. This comparison is usually called a *trial* in speaker verification. In some applications, a hard decision is needed; in others, a soft score is preferable. The PLDA paper (Prince, 2007) showed how to use this model to compute the likelihood ratio (LR) between the two hypotheses, which can be used directly as soft score or thresholded to make hard decisions if required. The LR is given by

$$LR = \frac{p(E,T|H_{SS})}{p(E,T|H_{DS})},$$

where H_{SS} is the hypothesis that the speakers in both sets are the same, while H_{DS} is the hypothesis that the speakers are different. This value can be computed using a closed form using the PLDA model. In our code we use the formulation derived by Cumani et al. (2014), Equation (34). Note, though, that the last term in that equation should not be there (this mistake was confirmed by one coauthor of the paper).

3. Tied PLDA Model

The tied PLDA model was introduced by Li et al. (2012). The model is a mixture of PLDA models where the latent variable corresponding to the speaker is tied across components. The vector representing sample i from speaker s_i is modeled as

$$m_i = \mu_{d_i} + V_{d_i} y_{s_i} + U_{d_i} x_i + z_i, \tag{4}$$

where d_i indicates the mixture component corresponding to sample i, and where

$$\begin{aligned} y_{s_i} &\sim N(0, I), \\ x_i &\sim N(0, I), \\ z_i &\sim N(0, D_{d_i}^{-1}). \end{aligned}$$

Hence, once the mixture component is given, the model reduces to a standard PLDA model. In this work, we assume that the mixture component is known both during training and during testing, as in the original work (Li et al., 2012), though the authors note that this is not a necessary condition. In the simplest case we could take the mixture component to be the nuisance condition of the sample but, as we will see, this might not be feasible if some conditions have too few training samples in which case grouping of samples from different conditions into the same component might be necessary. Note that the latent variable y_{s_i} does not depend on the component. Rather, this variable is tied for all samples from the same speaker across components. This enables the model to properly represent cross-component variability.

As for the original PLDA model, a simple PLDA model can be used instead of the full PLDA model for each component in the mixture. Further, the covariance matrix for the noise term can be either full or diagonal. In this work, each component is described by a SPLDA model for simplicity of implementation, since the difference between SPLDA and FPLDA is very small in practice.

The TPLDA model described by Li et al. (2012) and used here coincides with what Mak et al. (2016) calls SNR-dependent mixture PLDA model if we assume the SNR to be discrete rather than continuous so that the posterior probability for each component is fixed to 1 for the component corresponding to the sample, and to 0 otherwise. The training and scoring procedures for TPLDA can be found in the supplementary material for Mak et al. (2016).

4. Joint PLDA Model

In this work, we propose a generalization of the original PLDA model where the nuisance variable is no longer considered independent across samples, but potentially shared (tied) across samples that correspond to the same nuisance condition. This makes the model symmetric in the two latent variables corresponding to the speaker and the nuisance condition. To represent this dependency, we introduce a condition label for each sample, called c_i. Given this label, and the speaker label s_i, we propose to model vector m_i of dimension R_m for sample i as:

$$m_i = \mu + V y_{s_i} + U x_{c_i} + z_i, \tag{5}$$

where, as before, y_{s_i} is a vector of size R_y and x_{c_i} is a vector of size R_x, and

$$\begin{aligned} y_{s_i} &\sim N(0, I), \\ x_{c_i} &\sim N(0, I), \\ z_i &\sim N(0, D^{-1}). \end{aligned}$$

The model's parameters to estimate are $\lambda = \{\mu, V, U, D\}$, as in the standard PLDA formulation, but the input data for the training algorithm is now required to have a second set of labels indicating the nuisance condition of each sample.

The expectation-maximization equations for training this new model are significantly more involved than for the original PLDA model. This is due to the fact that each speaker cannot be treated separately from the others since samples from one speaker might be dependent on samples from a different speaker. This creates a potential dependency between all training samples, which greatly complicates the formulation, increasing the computation time by orders of magnitude for each EM iteration. Nevertheless, as we will see in the experiments, initializing the model in a smart way basically makes EM unnecessary in our experiments, reducing the training time of the model to the same order of what is required to train standard PLDA on the same data. A detailed derivation of the EM algorithm and scoring procedure for JPLDA is given by Ferrer (2017). In Appendix A we give a summary of the formulation, including all the equations needed to implement these algorithms. We have not implemented a minimum divergence step for this model. We plan to add this step in the future. Yet, given that, as we will see, the smart initialization procedure described below makes EM unnecessary in our experiments, we believe minimum divergence is unlikely to result in better models for this approach, at least for the current experiments.

Note that the matrix D in the JPLDA model can be full or diagonal. If we want D to be diagonal, we simply set D to be the diagonal part of the estimated value for D in each maximization step of the EM algorithm, as done for the standard PLDA EM algorithm (Brümmer, 2010a).

4.1. EM Initialization Procedure

The JPLDA model can be randomly initialized using the same procedure as for standard PLDA described in Section 2.1. We propose an alternative procedure to get the initial values for the PLDA model, U_0, V_0 and D_0. The procedure first estimates the matrix U_0 by training an SPLDA model with condition labels as targets, implicitly absorbing the effect of the speaker term into the noise term. This PLDA model is used to estimate the effect

of the condition in the samples, which is then subtracted to obtain condition-compensated samples. The new training data is then used to estimate another SPLDA model which should now model the effect of the speaker. This second SPLDA model is used obtain V_0 and D_0. Algorithm 1 gives the pseudocode for the proposed initialization algorithm. Note that, as usually done when training PLDA models, we assume an initial step where μ is set to the global mean of the data and subtracted from all training samples. The initialization step, as well as the EM iterations, use the resulting centered samples as input. As we will see this "smart" initialization leads to such a good starting point that EM iterations are unnecessary in our experiments.

Algorithm 1 Smart EM initialization approach for JPLDA. The matrix M, of size $N \times R_m$ contains the centered training vectors. L_c and L_s are vectors of size N containing the condition and speaker labels for the training data, respectively. Function SPLDAtrain returns the parameters of an SPLDA model (the subspace matrix and the noise precision matrix) after running 20 EM iterations, while function SPLDAlatent returns the estimated latent variables for each of the training samples. Note that all samples with the same label have the same latent variable.

procedure JPLDAInitialization(M, L_c, L_s, R_x, R_y)
  U_0, D = SPLDAtrain(M, L_c, R_x)
  X = SPLDAlatent(M, L_c, U_0, D) ▷ X is a matrix of size $N \times R_x$
  $M_c = M - XU_0^T$
  V_0, D_0 = SPLDAtrain(M_c, L_s, R_y)
  return V_0, U_0, D_0

4.2. Scoring

As for standard PLDA, we define the score as the likelihood ratio between the two hypotheses: that the speakers are the same and that the speakers are different. Nevertheless, in this case we need to marginalize both likelihoods over two new hypotheses: that the nuisance conditions are the same and that they are different. This is because, in general, we cannot assume that the nuisance condition is known during testing. Hence, the LR is computed as follows:

$$LR = \frac{p(E,T|H_{SS},H_{SC})P(H_{SC}|H_{SS}) + p(E,T|H_{SS},H_{DC})P(H_{DC}|H_{SS})}{p(E,T|H_{DS},H_{SC})P(H_{SC}|H_{DS}) + p(E,T|H_{DS},H_{DC})P(H_{DC}|H_{DS})} \quad (6)$$

where, as before, H_{SS} is the hypothesis that the speakers for both sets are the same, and H_{DS} is the hypothesis that they are different, while H_{SC} is the hypothesis that the nuisance condition for both sets is the same, and H_{DC} is the hypothesis that they are different. This LR value can be computed using a closed form derived in Appendix A and, in more detail, in (Ferrer, 2017).

Note that here we assume that all samples from the enrollment set come from the same condition and all samples from the test set come from the same condition, which could be the same or different from the enrollment condition. This is trivially true when the sets are composed of a single sample, which is the case we consider in the experiments in this paper. The formulation would become more complex without this assumption since we would need to consider the possibility that each sample in each set could come from different conditions. In

(Ferrer, 2017), we also derive the scoring formula for a multi-enrollment single-test case where the enrollment conditions are known and different from the test condition. This formulation is used when applying JPLDA to language identification (LID). Experiments on LID will be the subject of another paper. Further, the generalization of the scoring formula to multiple enrollment or test samples with unknown conditions will be considered in future work.

Another implicit assumption made in Equation (6) is that the conditions in the test trials have not been seen during training. This assumption is also made with respect to the speakers, both in JPLDA and standard PLDA scoring. While, in many applications, the assumption that test speakers are unseen during training is appropriate, this may not always be the case for nuisance conditions. In particular, in our experiments, where the nuisance condition is given by the language spoken in the signal, this assumption does not hold for some trials, since some of the test languages are seen during training. In the future, we plan to relax this assumption, which may allow for further performance improvements.

The scoring formula above depends on two prior probabilities, the probability that the enrollment and test conditions are the same given that the speakers are the same, $P(H_{SC}|H_{SS})$, and the probability that the conditions are the same given that the speakers are different, $P(H_{SC}|H_{DS})$. The other two prior probabilities are dependent on these two since $P(H_{SC}|H_{SS}) + P(H_{DC}|H_{SS}) = 1$ and $P(H_{SC}|H_{DS}) + P(H_{DC}|H_{DS}) = 1$. These two independent prior probabilities are parameters that could be computed from the training data, tuned using a development set, or set to arbitrary values based on what is known about the test data. In some applications, the nuisance condition might be known also in testing. In that case, the same-condition priors can be set to 1.0 for same-condition trials and to 0 for different-condition trials.

5. Experimental Setup

In this section we describe the task, the performance metrics, the data used for the experiments and the procedure used to convert each audio sample to a fixed-length vector to be modeled by the different PLDA methods.

5.1. Multilanguage Speaker Verification

The task considered for our experiments is speaker verification, which consists of determining whether two sets of samples, an enrollment and a test set, belong to the same speaker or not. Here we consider the simplest case, where both enrollment and test sets each contain a single speech sample. A pair of enrollment and test samples is called a *trial*. A trial is a target trial if the enrollment and test speakers are the same and an impostor trial if the two speakers are different. In this paper we explore the problem of multilanguage speaker verification where test trials can be composed of two samples in the same language (same-language trials) or two samples in different languages (cross-language trials).

Most state-of-the-art speaker verification systems are inherently language-independent in the sense that they do not use information about the language spoken in order to generate the output score. Yet, this does not mean that they are robust to language variation. In fact, speaker verification performance is known to degrade significantly in cross-language trials as well as in same-language trials from languages not found in the training set (Auckenthaler et al., 2001; Misra and Hansen, 2014; Rozi et al., 2016).

Rozi et al. (2016) discusses a problem that occurs when training PLDA models with multilingual data: the distribution of the speaker factors becomes broader to cover the different languages that a speaker might speak, which could result in suboptimal performance on same-language trials. They propose to mitigate this problem by training a standard PLDA model using both language and speaker as targets (i.e., samples from the same speaker but different language are considered as different speakers). This language-aware PLDA model performs significantly better on same-language trials than the model trained with speaker targets, but degrades on cross-language trials, since it cannot model cross-language variation. JPLDA, on the other hand, can simultaneously model language and speaker factors, allowing the speaker factors to keep a sharper distribution, while still modeling the effect of language, resulting in improved performance both in same-language and cross-language trials with respect to standard PLDA.

5.2. Performance Metrics

We compute performance using the equal-error rate (EER) and detection error (DET) curves. The DET curves and the EER measure the performance of a system that uses the scores (in our case, the LRs) to make final decisions on the label of each sample by comparing these scores with a decision threshold. Samples whose scores are above the threshold are labeled as targets and samples whose scores are below the threshold are labeled as impostors. Two types of error are then possible: (1) misses, the true target trials that are labeled as impostors by the system, and (2) false alarms, the impostor trials that are labeled as targets by the system. The EER is given by the miss rate when the decision threshold is set such that the miss rate is equal to the false alarm rate.

DET curves (Martin et al., 1997) are a variation over the traditional receiver operating characteristic (ROC) curves that have been widely used for speaker verification for two decades. A DET curve is a plot of the false alarm rate versus the miss rate obtained while sweeping a decision threshold over a certain range where the axes are transformed to a probit scale. The probit transformation, the inverse of the cumulative distribution function of the standard normal distribution, converts the miss versus false alarm rate curve into a straight line if the score distribution for the two classes is Gaussian with the same standard deviation (Martin et al., 1997), which is a reasonable approximation for many speaker verification systems.

5.3. Training Data

We consider two training conditions, one that includes all our available training data (FULL) and a subset that keeps only one language for each speaker (MONOLING). The second condition is designed to help us analyze performance of the PLDA methods under this extremely challenging scenario where no explicit information is available in the training data of the effect that language has on the vectors representing the samples.

The FULL training set is composed of:

- Switchboard Cellular Part 1 (Graff et al., 2001) and Cellular Part 2 (Graff et al., 2004), consisting of English cellphone conversations
- Switchboard 2 Phase 2 (Graff et al., 1999) and Phase 3 (Graff et al., 2002) samples, consisting of English telephone conversations

- Mixer data (Cieri et al., 2007) from the 2004 to 2008 speaker recognition evaluations organized by the National Institute of Standards and Technology (NIST). This data contains English samples recorded both on telephone and microphone channels and non-English samples recorded on telephone channels. With very few exceptions, speakers that recorded non-English samples also recorded English samples. Only one speaker has data in two non-English languages and no data in English. Only a subset of this data is used for training, leaving some speakers out for testing (Section 5.4). We also discard data from languages for which only one or two speakers are available and samples where the language was unavailable or ambiguous (e.g., more than one language listed in the language key) in NIST's keys.

The MONOLING training set is created by randomly keeping the samples from only one of the languages spoken by each speaker from the FULL training set.

Finally, in Section 6.4, we analyze results when subsetting these two training sets to contain a more balanced representation of channels while keeping all data from bilingual speakers for the FULL training set. Specifically, we subset the FULL training set to discard all the telephone data from speakers that do not have data in both English and another language. This is data that is not adding much new information, since all non-English data is recorded over telephone line, and all speakers with non-English data also have telephone recordings in English. By subsetting the data this way, we achieve a more balanced representation of the telephone data with respect to the microphone data, while emphasizing the data from bilingual speakers, which is a very small minority on the original set including all the data. To create the subset for the MONOLING training set, we simply use the samples that appear in the subset from the FULL training set and also appear in the MONOLING set.

Table 1 shows statistics on the two training sets and their corresponding subsets. The languages included under "Other" are: Arabic (with 440 samples); Bengali (88); French (25); Chinese (868); Farsi (25); Hindi (143); Italian (11); Japanese (124); Korean (78); Russian (478); Spanish (170); Tagalog (26); Thai (185); Vietnamese (169); Chinese Wu (63); and Cantonese (216).

5.4. Test Data

We consider two testing conditions, one composed of Mixer data and used for development and one composed of LASRS data and used as held-out set for final evaluation of the selected methods.

The Mixer test data is composed of telephone samples from Mixer collections (Cieri et al., 2007) from the 2005 to 2010 NIST speaker recognition evaluations, from speakers not used for training. We include 119 samples in Arabic from 21 speakers; 200 samples in Russian from 47 speakers; 309 samples in Thai from 38 speakers; 827 samples in Chinese from 163 speakers; and 5755 samples in English from 701 speakers (including those that also speak one of the other languages). The trials are created by selecting the same number of target and impostor same-language and cross-language trials such that the final set of trials is a balanced union of both types of trials. Further, the same-language trials are created as a balanced union of English versus non-English trials. The final set of trials contains 11,522 target trials and 858,119 impostor trials.

The LASRS test data is composed of samples from a bilingual, multi-modal voice corpus (Beck et al., 2004). The corpus is composed of 100 bilingual speakers from each of

Name	Sel	Sample count				Speaker count			
		Eng Mic	Eng Phn	Other Phn	Total	MonoLing		BiLing	Total
						Eng	Other		
FULL	all	11017	38382	3109	52508	2764	34	495	3293
	subset	11017	3711	2733	17461	207	0	494	701
MONOLING	all	10797	36619	1688	49104	3026	267	0	3293
	subset	10797	1948	1332	14077	468	233	0	701

Table 1: Statistics for the four training sets considered in our experiments. "Eng" refers to English data while "Other" refers to any language other than English. "Phn" refers to telephone or cellphone data, and "Mic" refers to all other microphones in the training set. "Monoling" refers to speakers for which we only have samples in a single language, and "Biling" refers to speakers for which we have samples in two languages (English plus one other language in most cases).

three languages: Arabic, Korean and Spanish. In all cases, the other language of the speakers is English. Each speaker is asked to perform a series of tasks, including talking with a partner on the phone and reading various texts, in English and also in their native language. Each task is recorded using several recording devices and repeated in two separate sessions recorded on different days. The LASRS trials for this work are created by enrolling with data from the first recorded session and testing on the second recorded session in each of the two spoken languages. We use only the conversational data from each session. This results in the same number of same-language and cross-language trials for a total of 848 target trials and 100336 impostor trials for each of seven different microphones: a camcorder microphone (Cm); a Desktop microphone (Dm); a studio microphone (Sm); an omnidirectional microphone (Om); a local telephone microphone (Tm); a remote telephone microphone (Tk); and a telephone earpiece (Ts). For this study, we only consider same-microphone trials for simplicity of analysis. For more details on the collection protocol, see (Beck et al., 2004).

5.5. I-vector Extraction

For validation of the proposed approach, we use a traditional i-vector framework for speaker recognition (Dehak et al., 2011). I-vectors are fixed-dimensional vectors that attempt to represent, as fully as the assumptions allow, the characteristics of the speech in an audio recording. In this framework, each recording is first represented by a sequence of short-term feature vectors $x = \{x_1, \ldots, x_L\}$. The length L of this sequence is variable and depends on the duration of the recording. The i-vector approach then assumes each of these feature vectors x_j is independently drawn from an N-component Gaussian mixture model (GMM) with weights w_i, covariance matrices C_i and means $\mu_i + T_i\omega$, for $i \in \{1, \ldots, N\}$. The parameters of the i-vector model are the set of w_i, C_i, μ_i, and T_i. While weights and covariances are fixed for all recordings, the means vary in a subspace determined by the matrices T_i. Each recording is then modeled by a different GMM, determined by the vector ω. These vectors are assumed

to have a prior normal standard distribution. The mean of the posterior distribution of ω given the sequence of features x is the i-vector, used to represent the recording.

The posterior distribution of the i-vector model is intractable. It cannot be used in an EM algorithm to obtain the model's parameters or even to obtain the i-vectors for a new sample, given the model. A mean-field Variational Bayes (VB) EM approach can be used to estimate the model's parameters and the i-vectors, as described by Brümmer (2015). In this approach, the parameters are iteratively reestimated, along with the posterior distribution for ω and the responsibilities for each recording. The responsibilities are variational parameters that can be interpreted as soft assignments for the frames to each of the N components of the model.

In the classical i-vector approach, though, the parameters w_i, C_i and μ_i are fixed in an initial step. They are given by the weights, covariances and means of a GMM, called the universal background model (UBM), trained using recordings from many different speakers. An approximate posterior distribution of ω is then obtained using a simplifying assumption: the responsibilities are set to be the UBM state posteriors. With the responsibilities and the w_i, C_i and μ_i parameters fixed, the T_i matrices are estimated by maximizing the VB lower bound. Finally, once the parameters of the model have been estimated, i-vectors are extracted as the mean of the approximate posterior distribution of ω given the features for the recording, again fixing the responsibilities to be the UBM state posteriors.

In our experiments, the process for extracting an i-vector to represent a variable-length speech recording is as follows. The first 20 mel-frequency cepstral coefficients (MFCCs) are extracted from the audio signal using a 25ms window every 10ms. MFCCs are an acoustic feature vector that captures information regarding the amplitude of different frequencies in a similar manner to how sounds are perceived by the human ear (Davis and Mermelstein, 1980). The MFCCs are appended with deltas and double deltas to help capture the dynamics of speech over time (e.g., Gales and Young, 2008). This results in a feature vector of 60 dimensions, with 100 frames (of feature vector) per second.

Speech activity detection (SAD) is then applied to remove any frames that do not contain speech. For this purpose we use a deep neural network (DNN)-based model trained on telephone and microphone data from a combination of Fisher (Cieri et al., a,b), Switchboard (Graff et al., 2001, 2004, 1999, 2002) and Mixer data (Cieri et al., 2007), as well as a 30-minute long dual-tone multi-frequency (DTMF) signal without speech, and a set of 3740 signals where speech from the Fisher corpora was corrupted with non-vocal music at different SNR levels. The ground truth labels used to train the DNN were obtained using our previous SAD system which consisted of a speech/non-speech hidden Markov model (HMM) decoder and various duration constraints. This system performed very well but was slow, complex and hard to retrain given new data. The labels for the corrupted data were obtained from the clean signals. As input to the SAD system we use MFCC features, mean and variance normalized over each waveform, except for the C_0 coefficient, for which the maximum rather than the mean is subtracted before dividing by the standard deviation. The normalized features are concatenated over a window of 31 frames. The resulting 620-dimensional feature vector forms the input to a DNN that consists of two hidden layers of sizes 500 and 100. The output layer of the DNN consists of two nodes trained to predict the posteriors for the speech and non-speech classes. These posteriors are converted into likelihood ratios using Bayes rule (assuming a prior of 0.5), and a threshold of 0.5 is applied to obtain the final

speech regions. For a more detailed description of the DNN-based SAD approach, please see (Graciarena et al., 2016).

The UBM is then estimated with an EM algorithm using the speech frames from a random subset of 10,000 samples (full recordings) of the data used to estimate the T_i matrices described next. The subspaces T_i are then estimated using the FULL training data described in Section 5.3, except that samples from languages for which only one or two speakers are available or where the language was unavailable or ambiguous are not discarded for this purpose. Finally, once the model is trained, the i-vectors for any audio sample can be extracted using only the speech frames, as in training.

The i-vectors can then be used for determining speaker similarity between two utterances using PLDA. For the experiments, we process the i-vectors with multiclass linear discriminant analysis (LDA) trained on the same training data used for PLDA, after which we subtract the mean over the training data and perform length normalization (Garcia-Romero and Espy-Wilson, 2011). The length-normalization step serves to better satisfy the Gaussianity assumption behind PLDA.

6. Results

In this section we compare results for different EM initialization techniques, parameter settings and training data for the proposed and the baseline PLDA techniques described in previous sections.

The nuisance condition for JPLDA in these experiments is the language spoken in the sample. During training, this label is known; during scoring, the label is marginalized to compute the LR, unless otherwise indicated. For TPLDA, on the other hand, we cannot take the mixture component to be the language spoken in the sample. This is because we do not have enough training speakers for each language to train a good PLDA model for each component. Hence, we consider a two-component model with a component modeling all English data and another component modeling the non-English data. This, as we will see, turns out to be a good model when matched data is available for training both components. Note that our implementation of TPLDA assumes that the mixture component is given both in training and in scoring. This is possible in our experiments because we have the language spoken during testing.

For SPLDA, FPLDA and JPLDA, the LDA dimension is set to 400; no dimensionality reduction is done in these cases but the data is still transformed by the LDA matrix, centered and length normalized. For TPLDA, on the other hand, we use an LDA dimension of 200, because we found that this value gives significantly better performance than keeping the original dimension of 400.

The speaker and language ranks for all experiments in this section are fixed to 200 and 16, respectively. These values were chosen for being optimal or approximately optimal for all methods under study (FPLDA, SPLDA and JPLDA) when using all available training data. The language rank of 16 is the largest rank that can be used for JPLDA. This value turned out to be optimal for JPLDA. FPLDA is largely insensitive to this parameter, giving very similar performance for language ranks between 5 and 16. Unless otherwise stated, all JPLDA results are obtained using $P(H_{SC}|H_{SS}) = P(H_{SC}|H_{DS}) = 0.5$. For TPLDA we use a diagonal matrix for the covariance of the noise model which proved to be slightly better than a full covariance.

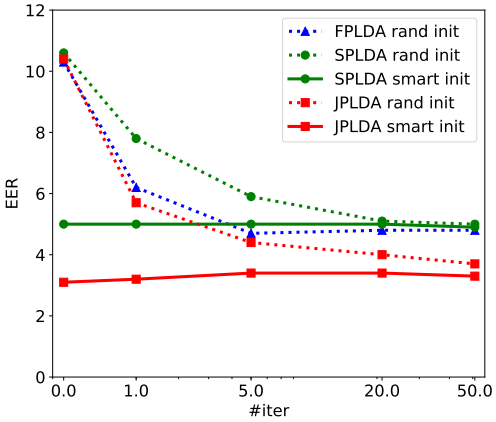

Figure 1: Comparison of performance as a function of the number of EM iterations on the Mixer test data using all available training data, for random and smart initialization for three different PLDA models. Note that a log scale is used for the x-axis.

All tuning decisions above were made based solely on the results on Mixer test data.

6.1. Initialization and Convergence of Training Procedure

We first show results for SPLDA, FPLDA and JPLDA as a function of the number of EM iterations run for the two initialization procedures, random and smart, explained in Sections 2.1 and 4.1. For FPLDA, no standard way exists of which we are aware to smartly initialize all parameters of the model. In this case, we only show results for random initialization. For this section, we use the FULL training data without subsetting and test on the Mixer data.

Results in Figure 1 show that EM iterations are essential when random initialization is used, leading to large gains over the initial random model as the iterations progress and converging to an approximately stable value when reaching 50 iterations. On the other hand, when smart initialization of SPLDA or JPLDA is used, EM iterations are not necessary on this data set. In fact, JPLDA performance with smart initialization slightly degrades for larger number of iterations, probably due to overfitting of the training data. For this reason, for the rest of the experiments we use only one iteration of EM for JPLDA, though zero iterations could also be safely used.

6.2. Prior Probability of Same Language in JPLDA

In this section we show JPLDA results on the Mixer development set when using all available training data as a function of the prior probabilities of same language, $P(H_{SC}|H_{SS})$ and $P(H_{SC}|H_{DS})$ (see Section 4.2). We fix these two parameters to the same value and sweep

this value between 0 and 1 at 0.1 steps. We show results on the full test data but also split the data into same-language and cross-language trials. We compare these results with those we would obtain by knowing the language of each sample a priori and using this knowledge during scoring to set the priors appropriately as explained in Section 4.2.

Figure 2 shows performance as a function of the probability of same language parameter. Values below 0.1 are optimal for the cross-language trials, while values above 0.1 and below 1.0 are optimal for same-language trials. The fact that a probability of same language of 1.0 is not optimal for same-language trials might be due to some samples including code-switching, making trials involving these samples not strictly same-language trials. Further, a value lower than 1.0 for same-language trials may better accommodate the variation in accent that takes place when people speak to different interlocutors. Once all trials are pooled together, values between 0.3 and 0.8 give almost identical performance. For this range of values, we can also see that performance is very close to what we would obtain if the language of the test files was known during scoring (the red dashed line in the plot). This performance is obtained by setting the probability of same language to 1.0 for same-language trials and to 0.0 for cross-language trials. For the remaining experiments, we use a probability of same language of 0.5.

Figure 2 shows that the same-language and different-language subsets have a significantly lower EER than the pooled set of trials. This is due to the fact that the scores for both sets of trials are misaligned with each other. That is, the EER threshold is different for both sets, leading to a larger EER than that for either set once the trials are pooled together. As we will see in Section 6.4, Figure 6, this effect is actually more salient in standard PLDA approaches, with JPLDA mitigating the problem, though not fully solving it.

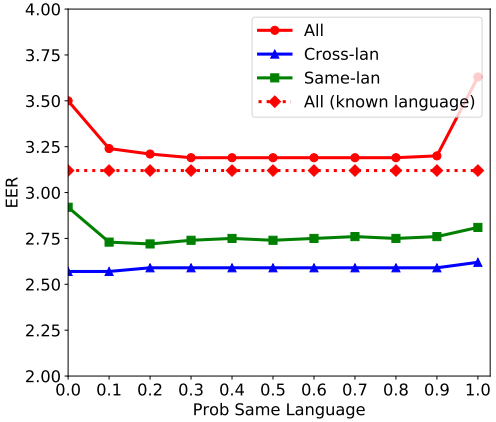
6.3. Method Comparison

We now compare the performance of the four methods on all test sets from Mixer and LASRS divided by microphone type using the two training sets: FULL and MONOLING.

The top plot in Figure 3 shows that FPLDA gives slightly better performance than SPLDA for some channels (mostly the telephone ones) when the FULL training data is used. For this reason, for the remaining experiments in this paper, we use FPLDA as the baseline.

Comparing the two methods that consider language labels during training, TPLDA and JPLDA, on the top plot in Figure 3, we see that they both give significant gains over the baselines on Mixer data, where the channel is matched to the majority of the training data's channel. In this case, both approaches succeed in mitigating the effect of language variability. On the other hand, when the channel is not exactly the same as the one observed most in training, TPLDA fails to generalize, leading to consistently worse performance than JPLDA. This is reasonable: while alternative microphone data is observed for the English training data, only telephone data is observed for the non-English data. This implies that the PLDA mixture corresponding to non-English data in TPLDA was only learned with telephone data, resulting in the poorer performance observed on some of the LASRS channels. On the other hand, JPLDA can leverage the information about alternative microphones learned from English data for all languages, since the matrix that models this variability is shared across languages.

In the bottom plot in Figure 3, we see that when only a single language from each speaker is available for training (that is, the within speaker variation due to language is not



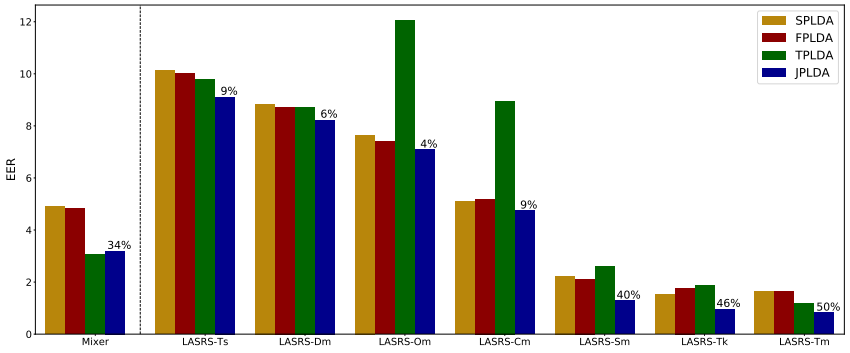


Figure 2: Comparison of JPLDA performance as a function of the prior probability of same language on the Mixer test data using the FULL training data. The known-language line corresponds to the performance on all trials when using the information about the test language during scoring.

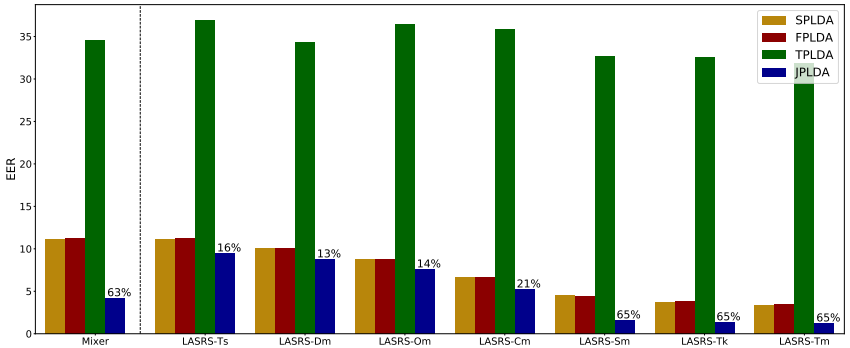
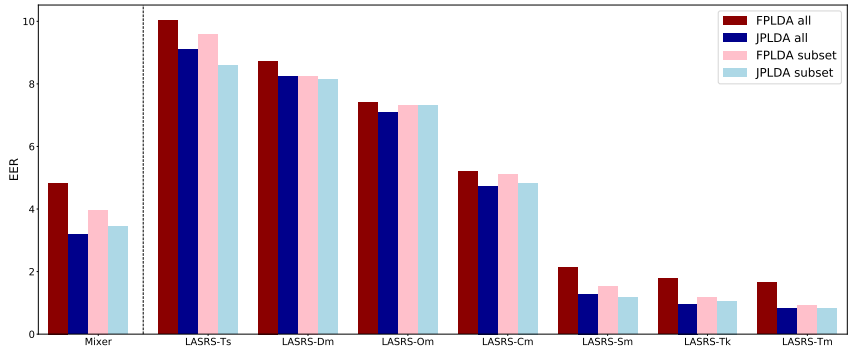
observed in training), TPLDA leads to a large degradation over both baselines. Note that, as far as we know, TPLDA had not been tested under this challenging scenario. Rather, it was tested using training data where each class of interest (e.g., a face) was seen under all possible conditions (front and profile) (Li et al., 2012). When each class is seen under a single condition, the TPLDA model basically degenerates to separate (untied) PLDA models, each learned on the data from its own condition. This implies that the resulting mixture will be unable to model the cross-language variability, which results in extremely degraded performance on the cross-language trials. Indeed, our results indicate that the same-language trials get reasonable TPLDA performance (results not shown here), it is the degradation on the cross-language trials that affects the overall performance as observed in the plot.



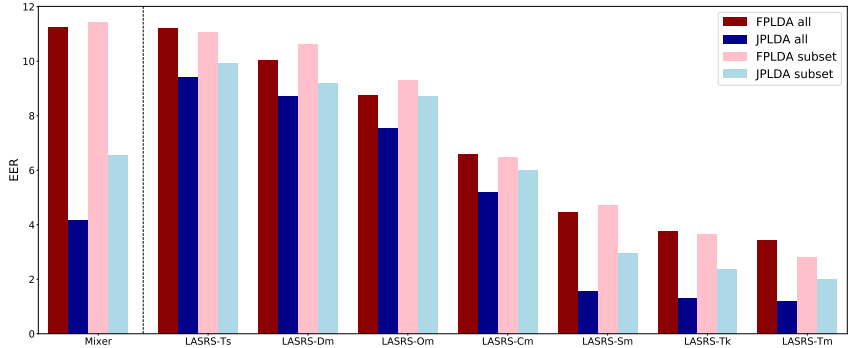
Finally, focusing on JPLDA, we see that significant gains are observed compared to both baselines using both training sets, with larger relative gains when the training data contains only a single language per speaker, in which case we find gains from 13% of up to 65% relative to the FPLDA baseline.

6.4. Training Data Comparison

Finally, in this section we compare the FPLDA baseline and JPLDA using the two training sets defined in Section 5.3 and their subsets, where we discard telephone samples from speakers that only have English samples in an attempt to achieve a better balance between English and non-English samples and telephone and microphone samples.



(a) Training data: FULL



(b) Training data: MONOLING

Figure 3: Comparison of performance for four PLDA methods on all test sets using both training sets, FULL and MONOLING. The numbers on top of the JPLDA bars show the relative gain of JPLDA relative to FPLDA.

Figure 4 shows that, for FPLDA, using the subset is significantly better than using the full training set for both training conditions, FULL and MONOLING, for most test conditions. That is, FPLDA benefits from having a more balanced distribution of conditions within the training data. This is because, in standard PLDA, the samples from all speakers are assumed to follow the same distribution, regardless of whether these samples are all in English, or both in English and some other language. Hence, if a large proportion of speakers only have English samples, the parameters in the PLDA model will be mostly determined by what is optimal for these speakers, degrading the performance on non-English and cross-language trials.

(a) Training data: FULL

(b) Training data: MONOLING

Figure 4: Comparison of performance for FPLDA and JPLDA on all test sets using the two training sets, FULL and MONOLING. For each case, we compare using the full training set and a subset where we discard telephone samples from speakers that only have English samples in the FULL training set.

On the other hand, JPLDA does not seem to require subsetting the data[2]. In fact, for the FULL training condition, JPLDA leads to similar or better performance (using either the full training set or the subset) than FPLDA using the subset. For the MONOLING condition, the advantage of JPLDA over FPLDA is much larger than for the FULL training set, consistently showing significant gains over the best FPLDA result. Further, for this training condition we

2. Note that the EER on the better performing test sets (LASRS-Sm, LASRS-Tk and LASRS-Tm) corresponds to very few misses, making that metric somewhat unreliable on those sets. However, DET curves shown later in the section complement the EER results, supporting the overall conclusions made based on EERs.

see a consistent trend showing that JPLDA benefits from using the full training set, which indicates that, contrary to PLDA, JPLDA can handle the imbalance in the full set of data, successfully leveraging the additional samples missing from the subset.

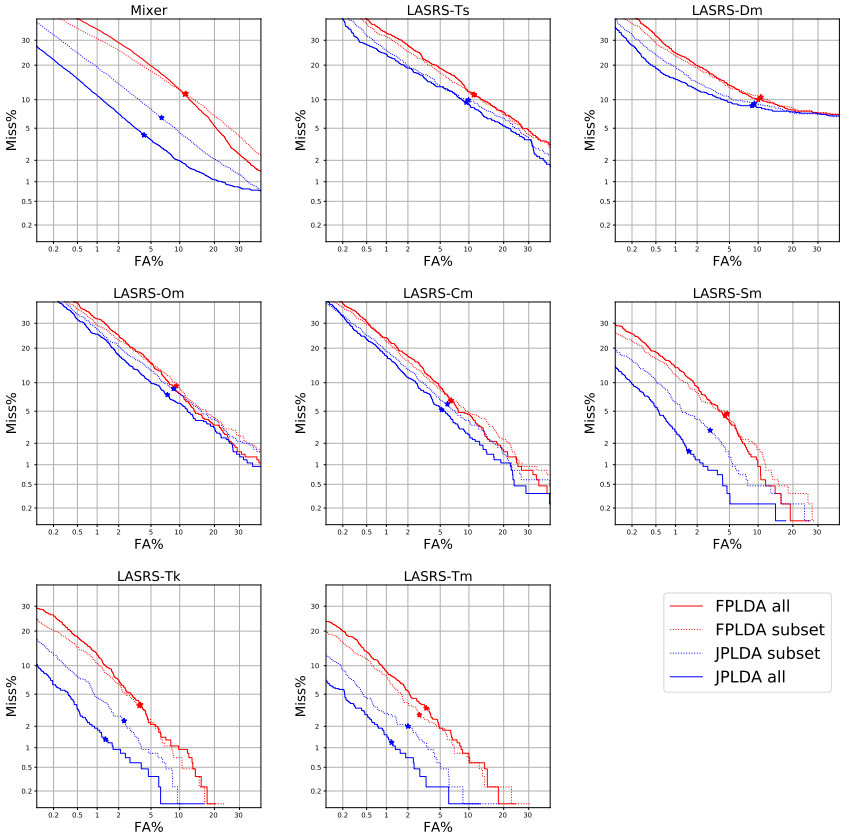
To complement the EER results in the bar plots, Figure 5 shows the DET curves for all test sets. We show these curves for the more challenging training condition, MONOLING, where JPLDA gives the biggest advantage over FPLDA. The plots show that the gains are not specific to the EER operating point. Rather, JPLDA gives a significant gain over FPLDA over a very wide range of operating points corresponding to miss and false alarms rates between 0.01% to 40%. Further, we also see the advantage of using all the available training data rather than just the subset when using JPLDA, while the opposite is true for FPLDA, as already observed in the EER bar plots.

Finally, Figure 6 shows EER results on Mixer test data using the two training sets and their subsets for all trials (as in previous bar plots) as well as for same-language and cross-language trials. The performance on all trials is the same as in Figure 4. These plots show that: (1) Both same-language and cross-language trials benefit from using JPLDA, particularly for the MONOLING training conditions. (2) The JPLDA benefit from using the complete training sets holds for both same-language and cross-language subsets of trials. (3) The FPLDA benefit from using the subset only holds on the same-language trials; cross-language trial performance is degraded or unchanged by subsetting the training data. And (4) the relative gain from JPLDA is larger once same-language and cross-language trials are pooled together. This last observation indicates that JPLDA is not only improving discrimination for each type of trial (same-language and cross-language), but it is also aligning the distributions of these two types of trials such that when they are pooled together, the relative gain from using JPLDA is emphasized. Yet, as we can see, JPLDA does not appear to fully solve the problem, since the pooled performance is still somewhat worse than that of the subsets. We plan to study the source of the remaining misalignment in the near future.

7. Conclusions

We have proposed a generalization of PLDA where within-class variability factors are no longer considered independent across samples. The method assumes that the identity of a nuisance condition is known during training and ties the latent variable corresponding to the within-class variability across all samples with the same nuisance condition label. During scoring, a likelihood ratio is computed as for standard PLDA by marginalizing over the nuisance condition. Hence, the identity of the nuisance condition can be unknown during testing.

We show results on a multilingual speaker recognition task comparing the proposed method with two types of standard PLDA models as well as to a tied PLDA model where the nuisance condition is used to determine the component in a mixture of PLDA models. Our results show that large relative gains are obtained from using JPLDA when the training data contains few or no speakers with data in more than one language. That is, the JPLDA model is able to extrapolate the effect of language from a small proportion or even zero training speakers with data from more than one language. Standard PLDA models are only able to mitigate the effect of language when exposed to a significant proportion of training speakers with data in more than one language.



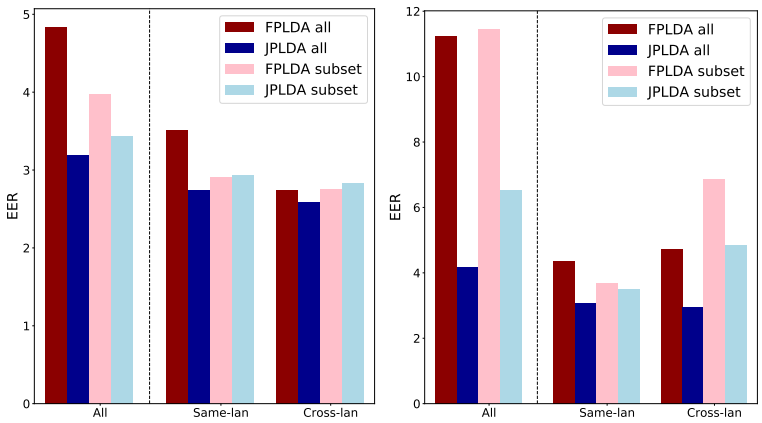


Figure 5: DET curves for FPLDA and JPLDA on all test sets using the MONOLING training set and its subset. The marker over each curve corresponds to the EER point for that system.

The proposed JPLDA method can be used for any task for which standard PLDA is used whenever a discrete nuisance condition is known during training. Examples include speaker recognition using channel, speaking style or language labels, among others, as the sample-dependent nuisance condition, and face recognition using pose as sample-dependent nuisance condition. The strength of JPLDA lies in its ability to extrapolate the effect that

(a) Training data: FULL (b) Training data: MONOLING

Figure 6: Comparison of performance for FPLDA and JPLDA on the Mixer test set on all trials as well as on same-language and cross-language subsets, using the two training sets, FULL and MONOLING, and their subsets.

the nuisance condition has on the samples based on few or even no classes (speakers or faces) seen under several nuisance conditions.

The proposed approach introduces the additional requirement with respect to the original PLDA approach that the identity of the nuisance condition be known during training. In future work, we will explore the possibility of automatically detecting the nuisance conditions, using classifiers trained on data for which the factors are known or using clustering with distance metrics designed to reflect the nuisance of interest. Finally, an interesting generalization of the proposed approach would be to allow for more than one sample-dependent nuisance condition. These are directions we plan to explore in the near future.

Appendix A. JPLDA Formulas

In this appendix we derive the probabilities that are needed during training with the EM algorithm and during scoring with the likelihood ratio for the proposed JPLDA method. The derivations closely follow the ones for standard PLDA in (Brümmer, 2010a) with one main difference: in the new model, most probabilities cannot be formulated by speaker and then multiplied to get the total probabilities, as is usually done for standard PLDA, since the condition introduces dependencies across samples from different speakers. Instead, we formulate all probabilities over all samples.

In the following, we take

$$\begin{aligned} Y &= \{y_1, \ldots, y_S\} \\ X &= \{x_1, \ldots, x_C\} \\ M &= \{m_1, \ldots, m_N\} \end{aligned}$$

where S, C and N are the total number of speakers, conditions, and samples, respectively. Further, we assume that $\mu = 0$. In the general case, as done for standard PLDA, this parameter is set to the global mean of the training data and subtracted from all samples before running EM or scoring.

A.1. Probability Distributions

The joint prior for the hidden variables for all the data is given by

$$p(Y, X) = p(X)p(Y) \propto \exp(-\frac{1}{2}\sum_s y_s^T y_s - \frac{1}{2}\sum_c x_c^T x_c), \tag{7}$$

and the full data likelihood is given by

$$\begin{aligned} p(M|Y, X, \lambda) &= \prod_i N(m_i|Vy_{s_i} + Ux_{c_i}, D^{-1}) \\ &\propto \exp\sum_i \left(-\frac{1}{2}(m_i - Vy_{s_i} - Ux_{c_i})^T D(m_i - Vy_{s_i} - Ux_{c_i}) + \frac{1}{2}\log|D|\right). \end{aligned} \tag{8}$$

The joint probability is proportional, as a function of M, X and Y, to the product of the likelihood and the prior,

$$\begin{aligned} p(M, Y, X|\lambda) \propto \exp\Bigg[&\sum_i \left(-\frac{1}{2}m_i^T Dm_i + m_i^T DVy_{s_i} + m_i^T DUx_{c_i} - x_{c_i}^T Jy_{s_i}\right) \\ &-\frac{1}{2}\sum_s y_s^T L_s y_s - \frac{1}{2}\sum_c x_c^T K_c x_c\Bigg] \end{aligned}$$

where

$$\begin{aligned} J &= U^T DV \\ K_c &= n_c U^T DU + I \\ L_s &= n_s V^T DV + I \end{aligned}$$

where n_c and n_s are the number of samples for condition c and speaker s, respectively.

We can now compute the posterior from two factors:

$$p(Y, X|M, \lambda) = p(Y|X, M, \lambda)p(X|M, \lambda)$$

The outer posterior is proportional, as a function of Y, to the joint probability. Keeping only the terms in the joint probability that depend on Y we get

$$p(Y|X, M, \lambda) \propto \exp\left[\sum_i \left(m_i^T DV y_{s_i} - x_{c_i}^T J y_{s_i}\right) - \frac{1}{2}\sum_s y_s^T L_s y_s\right] \propto \prod_s N(y_s|\hat{y}_s, L_s^{-1}) \quad (9)$$

where

$$\begin{aligned}
\hat{y}_s &= \tilde{y}_s - L_s^{-1} J^T \bar{x}_s \\
\tilde{y}_s &= L_s^{-1} V^T D f_s \\
\bar{x}_s &= \sum_{i|s_i=s} x_{c_i} \\
f_s &= \sum_{i|s_i=s} m_i
\end{aligned}$$

Marginalizing that distribution we can extract the posterior for a single latent variable y_s:

$$p(y_s|X, M, \lambda) = N(y_s|\hat{y}_s, L_s^{-1}) \quad (10)$$

The inner posterior is proportional to the joint probability of X and M:

$$\begin{aligned}
p(X|M, \lambda) &\propto p(M, X|\lambda) = \frac{p(Y, X, M|\lambda)}{p(Y|X, M, \lambda)}\Big|_{Y=0} \\
&\propto \exp\left(\sum_c g_c^T DU x_c - \frac{1}{2}\sum_c x_c^T K_c x_c - \sum_c x_c^T J\bar{\bar{y}}_c + \frac{1}{2}\sum_s \bar{x}_s^T J L_s^{-1} J^T \bar{x}_s\right)
\end{aligned}$$

where we have used the *candidate's formula* (Besag, 1989) to obtain the joint probability and where

$$\begin{aligned}
g_c &= \sum_{i|c_i=c} m_i \\
\bar{\bar{y}}_c &= \sum_{i|c_i=c} \tilde{y}_{s_i} = \sum_{i|c_i=c} L_{s_i}^{-1} V^T D f_{s_i}
\end{aligned}$$

We now define vectors which are the concatenation of all individual latent vectors:

$$\begin{aligned}
\boldsymbol{X} &= [x_1^T \dots x_C^T]^T \\
\boldsymbol{Y} &= [y_1^T \dots y_S^T]^T
\end{aligned}$$

and, similarly, for all other vectors. Converting the sums into matrix form, we get

$$p(\boldsymbol{X}|M, \lambda) \propto \exp\left(\boldsymbol{X}^T \Phi - \frac{1}{2}\boldsymbol{X}(T_2 - H^T T_4 H)\boldsymbol{X}\right) \propto N(\boldsymbol{X}|\hat{\boldsymbol{X}}, \Sigma) \quad (11)$$

where

$$\begin{aligned}
\Sigma &= (T_2 - H^T T_4 H)^{-1} \quad (12) \\
\hat{\boldsymbol{X}} &= \Sigma\Phi \\
\Phi &= T_1 \boldsymbol{G} - T_3 \bar{\bar{\boldsymbol{Y}}} \\
T_1 &= \text{diagn}(U^T D, C) \\
T_2 &= \text{diag}(K_1, \dots, K_C) \\
T_3 &= \text{diagn}(J, C) \\
T_4 &= \text{diag}(JL_1^{-1}J^T, \dots, JL_S^{-1}J^T)
\end{aligned}$$

where $\text{diagn}(M, N)$ is a block diagonal matrix with matrix M in each of N blocks and $\text{diag}(T_1, \dots, T_N)$ is a block diagonal matrix with blocks given by matrices T_i. The matrix H is of size SR_xxCR_x, where block $H_{s,c}$ (R_x rows and columns starting at position (sR_x, cR_x) in H) is given by:

$$H_{s,c} = n_{s,c} I$$

where I is the identity matrix of size R_x and $n_{s,c}$ is the number of times that condition c occurs for speaker s, which could be zero.

As for the outer posterior, we can marginalize the distribution in Equation (11) to get the distribution for an individual x_c

$$p(x_c|M, \lambda) = N(x_c|\hat{x}_c, \Sigma_c) \quad (13)$$

where Σ_c and $\hat{x}_c$ are the blocks corresponding to latent variable c in Σ and $\hat{X}$.

A.2. EM Algorithm

The EM auxiliary function is given by the expected value of the log-likelihood with respect to the posterior probability of the hidden variables given the data and the previously estimated model parameters, λ_{k-1}.

$$\begin{aligned}
Q(\lambda_k|\lambda_{k-1}) &= E_{X,Y|M,\lambda_{k-1}}\left[\log p(M, Y, X|\lambda_k)\right] \\
&= \frac{N}{2}\log|D| - \frac{1}{2}\text{tr}(SD) - \frac{1}{2}\text{tr}(RW^T DW) + \text{tr}(TDW) + \text{const}
\end{aligned}$$

where

$$\begin{aligned}
W &= [UV] \\
S &= \sum_i m_i m_i^T \\
R &= \sum_i \langle z_i z_i^T \rangle \\
T &= \sum_i \langle z_i \rangle m_i^T \\
z_i &= [x_{c_i}^T y_{s_i}^T]^T
\end{aligned}$$

where the $\langle$ and $\rangle$ symbols stand for the expectation with respect to the distribution of z_i given the data M and the previous parameters λ_{k-1}.

A.2.1. M-Step

Now, differentiating Q with respect to D and W and setting to zero, we get that

$$\begin{aligned} D^{-1} &= \frac{1}{N}(S - WT) \\ W^T &= R^{-1}T \end{aligned}$$

So, the matrices are estimated exactly the same way as in the standard PLDA approach (Brümmer, 2010a). The additional complexity of JPLDA lies in the forms that R and T take.

A.2.2. E-Step

To find T and R we use the equations we have obtained for the posterior distributions of x_c and y_s (Equations 10 and 13). The two components of T are given by:

$$\begin{aligned} T_x &= \sum_i \langle x_{c_i} \rangle m_i^T = \sum_c \hat{x}_c g_c^T \\ T_y &= \sum_s \langle y_{s_i} \rangle m_i^T = \sum_s L_s^{-1}(V^T D f_s - J^T \bar{\hat{x}}_s) f_s^T \end{aligned}$$

where we use the law of total expectations to get the expectation of y_s from its conditional expectation and where

$$\bar{\hat{x}}_s = \sum_{i|s_i=s} \hat{x}_{c_i}$$

Finally, we can get the components of R as follows:

$$\begin{aligned} R_{xx} &= \sum_i \langle x_{c_i} x_{c_i}^T \rangle = \sum_c n_c(\Sigma_c + \hat{x}_c \hat{x}_c^T) \\ R_{yx} &= \sum_i \langle y_{s_i} x_{c_i}^T \rangle = \sum_s \left[\tilde{y}_s \bar{\hat{x}}_s^T - \tilde{J}^T \sum_{i|s_i=s} \sum_{j|s_j=s} \left[\hat{x}_{c_i} \hat{x}_{c_j}^T + \Sigma_{c_j,c_i} \right] \right] \\ R_{yy} &= \sum_i \langle y_{s_i} y_{s_i}^T \rangle = \sum_s n_s \left[L_s^{-1} + \tilde{y}_s \tilde{y}_s^T - \tilde{y}_s \bar{\hat{x}}_s^T \tilde{J} - \tilde{J}^T \bar{\hat{x}}_s \tilde{y}_s^T + \tilde{J}^T \langle \bar{x}_s \bar{x}_s^T \rangle \tilde{J} \right] \end{aligned}$$

where $\tilde{J} = JL_s^{-1}$ and Σ_{c_j,c_i} is the block in matrix Σ (Equation 12) corresponding to latent variables c_i and c_j.

A.3. Scoring

In this paper we assume all trials are composed of a single enrollment and a single test sample. That is, the sets E and T in Equation (6) are each composed of a single vector, m_E and m_T, respectively. M is then given by $\{m_E, m_T\}$. We can now use the formulas derived above to obtain the LR in Equation (6) where we need to compute four probabilities for the data given different hypotheses. The probabilities can be obtained using the candidate's formula (Besag, 1989):

$$p(M|h_s, h_c) = \left. \frac{p(M|X_{h_c}, Y_{h_s}) p(X_{h_c}) p(Y_{h_s})}{p(Y_{h_s}|X_{h_c}, M) p(X_{h_c}|M, h_s)} \right|_{X_{h_c}=0, Y_{h_s}=0} \tag{14}$$

where $h_s \in \{H_{SS}, H_{DS}\}$ and $h_c \in \{H_{SC}, H_{DC}\}$, and where

$$X_{h_c} = \begin{cases} \{x\}, & \text{if } h_c = H_{SC} \\ \{x_E, x_T\}, & \text{if } h_c = H_{DC} \end{cases}$$

$$Y_{h_s} = \begin{cases} \{y\}, & \text{if } h_s = H_{SS} \\ \{y_E, y_T\}, & \text{if } h_s = H_{DS} \end{cases}$$

That is, the latent variables are two independent vectors for the different-condition and different-speaker hypotheses and a single vector for the same-condition and same-speaker hypotheses.

The likelihood in the numerator of Equation (14) is the same for all four combination of hypotheses since, regardless of whether the latent variables are tied or not, Equation (8) has the same form. Hence, that term cancels out in the computation of the LR. The priors, on the other hand, will have one factor for the same-speaker or same-condition case and two identical factors, once evaluated at 0, for the different-speaker or different-condition case. All that is left to do is compute the inner and outer posteriors in the denominator of Equation (14) and evaluate them at 0.

The outer posterior $p(Y_{h_s}|X_{h_c}, M)$, given by Equation (9), takes the same value for both values of h_c when the latent variables are set to 0. Its logarithm is given by

$$\log p(Y_{h_s}|X_{h_c}, M)|_0 = \begin{cases} \frac{1}{2}k + \frac{1}{2}\log|L_1| - \frac{1}{2}(\tilde{m}_E + \tilde{m}_T)^T L_1^{-1}(\tilde{m}_E + \tilde{m}_T), & \text{if } h_s = H_{SS} \\ k + \log|L_2| - \frac{1}{2}\tilde{m}_E^T L_2^{-1}\tilde{m}_E - \frac{1}{2}\tilde{m}_T^T L_2^{-1}\tilde{m}_T, & \text{if } h_s = H_{DS} \end{cases}$$

where $L_2 = V^T D V + I$, $L_1 = 2V^T D V + I$, $\tilde{m}_E = V^T D m_E$, $\tilde{m}_T = V^T D m_T$ and $k = -R_y \log(2\pi)$.

The inner posterior is given in Equation (11). For the scoring scenario, its logarithm is given by

$$\log p(X_{h_c}|M, h_s) = \begin{cases} -\frac{1}{2}R_x k - Q_{h_c,h_s}, & \text{if } h_c = H_{SC} \\ -R_x k - Q_{h_c,h_s}, & \text{if } h_c = H_{DC} \end{cases}$$

where $Q_{h_c,h_s} = \frac{1}{2}\log|\Sigma_{h_c,h_s}| + \frac{1}{2}\Phi_{h_c,h_s}^T \Sigma_{h_c,h_s} \Phi_{h_c,h_s}$ with

$$\begin{aligned} \Sigma_{H_{SC},H_{SS}} &= \left[2U^T D U + I - 4JL_S^{-1}J^T\right]^{-1} \\ \Sigma_{H_{SC},H_{DS}} &= \left[2U^T D U + I - 2JL_D^{-1}J^T\right]^{-1} \\ \Sigma_{H_{DC},H_{SS}} &= \left[\text{diagn}(K_D, 2) - [II]^T JL_S^{-1}J^T[II]\right]^{-1} \\ \Sigma_{H_{DC},H_{DS}} &= \left[\text{diagn}(K_D, 2) - \text{diagn}(JL_D^{-1}J^T, 2)\right]^{-1} \\ \Phi_{H_{SC},H_{SS}} &= \left((\hat{m}_E + \hat{m}_T) - 2JL_S^{-1}(\tilde{m}_E + \tilde{m}_T)\right) \\ \Phi_{H_{SC},H_{DS}} &= \left((\hat{m}_E + \hat{m}_T) - JL_D^{-1}(\tilde{m}_E + \tilde{m}_T)\right) \\ \Phi_{H_{DC},H_{SS}} &= \begin{bmatrix} \hat{m}_E - JL_S^{-1}(\tilde{m}_E + \tilde{m}_T) \\ \hat{m}_T - JL_S^{-1}(\tilde{m}_E + \tilde{m}_T) \end{bmatrix} \\ \Phi_{H_{DC},H_{DS}} &= \begin{bmatrix} \hat{m}_E - JL_D^{-1}\tilde{m}_E \\ \hat{m}_T - JL_D^{-1}\tilde{m}_T \end{bmatrix} \end{aligned}$$

where $\hat{m}_E = U^T D m_E$ and $\hat{m}_T = U^T D m_T$.

Finally, since the outer posterior is independent of the condition hypothesis, the logarithm of the LR (LLR) can be written as a sum of terms involving the outer posterior and the inner posteriors

$$\text{LLR} = \text{LLR}_o + \text{LLR}_i$$

where

$$\begin{aligned}
\text{LLR}_o &= \log \frac{p(Y_{H_{DS}}|X_{h_c}, M)}{p(y)p(Y_{H_{SS}}|X_{h_c}, M)}\Big|_0 \\
&= \log|L_2| - \frac{1}{2}\log|L_1| + \frac{1}{2}\tilde{m}_E^T(L_1^{-1} - L_2^{-1})\tilde{m}_E + \frac{1}{2}\tilde{m}_T^T(L_1^{-1} - L_2^{-1})\tilde{m}_T + \tilde{m}_T^T L_1^{-1}\tilde{m}_E \\
\text{LLR}_i &= \log \frac{p(x)p(X_{H_{SC}}|M, H_{SS})^{-1}P_{SS} + p(x)^2 p(X_{H_{DC}}|M, H_{SS})^{-1}P_{DS}}{p(x)p(X_{H_{SC}}|M, H_{DS})^{-1}P_{SD} + p(x)^2 p(X_{H_{DC}}|M, H_{DS})^{-1}P_{DD}}\Big|_0 \\
&= \log\left(\exp(Q_{H_{SC},H_{SS}})P_{SS} + \exp(Q_{H_{DC},H_{SS}})P_{DS}\right) - \\
&\quad \log\left(\exp(Q_{H_{SC},H_{DS}})P_{SD} + \exp(Q_{H_{DC},H_{DS}})P_{DD}\right)
\end{aligned}$$

where we use the fact that $\log p(x)|_0 = -\frac{1}{2}R_x k$ and $\log p(y)|_0 = -\frac{1}{2}R_y k$, and where $P_{SS} = P(H_{SC}|H_{SS})$, $P_{SD} = P(H_{SC}|H_{DS})$, $P_{DS} = P(H_{DC}|H_{SS})$, and $P_{DD} = P(H_{DC}|H_{DS})$.

Abstract

The success of deep convolutional architectures is often attributed in part to their ability to learn multiscale and invariant representations of natural signals. However, a precise study of these properties and how they affect learning guarantees is still missing. In this paper, we consider deep convolutional representations of signals; we study their invariance to translations and to more general groups of transformations, their stability to the action of diffeomorphisms, and their ability to preserve signal information. This analysis is carried by introducing a multilayer kernel based on convolutional kernel networks and by studying the geometry induced by the kernel mapping. We then characterize the corresponding reproducing kernel Hilbert space (RKHS), showing that it contains a large class of convolutional neural networks with homogeneous activation functions. This analysis allows us to separate data representation from learning, and to provide a canonical measure of model complexity, the RKHS norm, which controls both stability and generalization of any learned model. In addition to models in the constructed RKHS, our stability analysis also applies to convolutional networks with generic activations such as rectified linear units, and we discuss its relationship with recent generalization bounds based on spectral norms.

Keywords: invariant representations, deep learning, stability, kernel methods

1. Introduction

The results achieved by deep neural networks for prediction tasks have been impressive in domains where data is structured and available in large amounts. In particular, convolutional neural networks (CNNs, LeCun et al., 1989) have shown to effectively leverage the local stationarity of natural images at multiple scales thanks to convolutional operations, while also providing some translation invariance through pooling operations. Yet, the exact nature of this invariance and the characteristics of functional spaces where convolutional neural networks live are poorly understood; overall, these models are sometimes seen as clever engineering black boxes that have been designed with a lot of insight collected since they were introduced.

Understanding the inductive bias of these models is nevertheless a fundamental question. For instance, a better grasp of the geometry induced by convolutional representations may bring new intuition about their success, and lead to improved measures of model complexity. In turn, the issue of regularization may be solved by providing ways to control the variations of prediction functions in a principled manner. One meaningful way to study such variations is to consider the stability of model predictions to naturally occuring changes of input signals, such as translations and deformations.

Small deformations of natural signals often preserve their main characteristics, such as class labels (*e.g.*, the same digit with different handwritings may correspond to the same images up to small deformations), and provide a much richer class of transformations than translations. The scattering transform (Mallat, 2012; Bruna and Mallat, 2013) is a recent attempt to characterize convolutional multilayer architectures based on wavelets. The theory provides an elegant characterization of invariance and stability properties of signals represented via the scattering operator, through a notion of Lipschitz stability to the action of diffeomorphisms. Nevertheless, these networks do not involve "learning" in the classical sense since the filters of the networks are pre-defined, and the resulting architecture differs significantly from the most used ones, which adapt filters to training data.

In this work, we study these theoretical properties for more standard convolutional architectures, from the point of view of positive definite kernels (Schölkopf and Smola, 2001). Specifically, we consider a functional space derived from a kernel for multi-dimensional signals that admits a multi-layer and convolutional structure based on the construction of convolutional kernel networks (CKNs) introduced by Mairal (2016); Mairal et al. (2014). The kernel representation follows standard convolutional architectures, with patch extraction, non-linear (kernel) mappings, and pooling operations. We show that our functional space contains a large class of CNNs with smooth homogeneous activation functions.

The main motivation for introducing a kernel framework is to study separately data representation and predictive models. On the one hand, we study the translation-invariance properties of the kernel representation and its stability to the action of diffeomorphisms, obtaining similar guarantees as the scattering transform (Mallat, 2012), while preserving signal information. When the kernel is appropriately designed, we also show how to obtain signal representations that are invariant to the action of any locally compact group of transformations, by modifying the construction of the kernel representation to become *equivariant* to the group action. On the other hand, we show that these stability results can be translated to predictive models by controlling their norm in the functional space, or simply the norm of the last layer in the case of CKNs (Mairal, 2016). With our kernel framework, the RKHS norm also acts as a measure of model complexity, thus controlling both stability and generalization, so that stability may lead to improved sample complexity. Finally, our work suggests that explicitly regularizing CNNs with the RKHS norm (or approximations thereof) can help obtain more stable models, a more practical question which we study in follow-up work (Bietti et al., 2019).

A short version of this paper was published at the Neural Information Processing Systems 2017 conference (Bietti and Mairal, 2017).

1.1. Summary of Main Results

Our work characterizes properties of deep convolutional models along two main directions.

- The first goal is to study *representation* properties of such models, independently of training data. Given a deep convolutional architecture, we study signal preservation as well as invariance and stability properties.

- The second goal focuses on *learning* aspects, by studying the complexity of learned models based on our representation. In particular, our construction relies on kernel methods, allowing us to define a corresponding functional space (the RKHS). We show that this functional space contains a class of CNNs with smooth homogeneous activations, and study the complexity of such models by considering their RKHS norm. This directly leads to statements on the generalization of such models, as well as on the invariance and stability properties of their predictions.

- Finally, we show how some of our arguments extend to more traditional CNNs with generic and possibly non-smooth activations (such as ReLU or tanh).

Signal preservation, invariance and stability. We tackle this first goal by defining a deep convolutional representation based on hierarchical kernels. We show that the representation preserves signal information and guarantees near-invariance to translations and stability to deformations in the following sense, defined by Mallat (2012): for signals $x : \mathbb{R}^d \to \mathbb{R}^{p_0}$ defined on the continuous domain $\mathbb{R}^d$, we say that a representation $\Phi(x)$ is *stable* to the action of diffeomorphisms if

$$\|\Phi(L_\tau x) - \Phi(x)\| \leq (C_1\|\nabla\tau\|_\infty + C_2\|\tau\|_\infty)\|x\|,$$

where $\tau : \mathbb{R}^d \to \mathbb{R}^d$ is a C^1-diffeomorphism, $L_\tau x(u) = x(u-\tau(u))$ its action operator, and the norms $\|\tau\|_\infty$ and $\|\nabla\tau\|_\infty$ characterize how large the translation and deformation components are, respectively (see Section 3 for formal definitions). The Jacobian $\nabla\tau$ quantifies the size of local deformations, so that the first term controls the stability of the representation. In the case of translations, the first term vanishes ($\nabla\tau = 0$), hence a small value of C_2 is desirable for translation invariance. We show that such signal preservation and stability properties are valid for the multilayer kernel representation Φ defined in Section 2 by repeated application of patch extraction, kernel mapping, and pooling operators:

- The representation can be discretized with no loss of information, by subsampling at each layer with a factor smaller than the patch size;

- The translation invariance is controlled by a factor $C_2 = C_2'/\sigma_n$, where σ_n represents the "resolution" of the last layer, and typically increases exponentially with depth;

- The deformation stability is controlled by a factor C_1 which increases as κ^{d+1}, where κ corresponds to the patch size at a given layer, that is, the size of the "receptive field" of a patch relative to the resolution of the previous layer.

These results suggest that a good way to obtain a stable representation that preserves signal information is to use the smallest possible patches at each layer (*e.g.*, 3x3 for images) and perform pooling and downsampling at a factor smaller than the patch size, with as many layers as needed in order to reach a desired level of translation invariance σ_n. We show in Section 3.3 that the same invariance and stability guarantees hold when using kernel approximations as in CKNs, at the cost of losing signal information.

In Section 3.5, we show how to go beyond the translation group, by constructing similar representations that are invariant to the action of locally compact groups. This is achieved by modifying patch extraction and pooling operators so that they commute with the group action operator (this is known as *equivariance*).

Model complexity. Our second goal is to analyze the complexity of deep convolutional models by studying the functional space defined by our kernel representation, showing that certain classes of CNNs are contained in this space, and characterizing their norm.

The multi-layer kernel representation defined in Section 2 is constructed by using kernel mappings defined on local signal patches at each scale, which replace the linear mapping followed by a non-linearity in standard convolutional networks. Inspired by Zhang et al. (2017b), we show in Section 4.1 that when these kernel mappings come from a class of dot-product kernels, the corresponding RKHS contains functions of the form

$$z \mapsto \|z\|\sigma(\langle g, z\rangle/\|z\|),$$

for certain types of smooth activation functions σ, where g and z live in a particular Hilbert space. These behave like simple neural network functions on patches, up to homogeneization. Note that if σ was allowed to be homogeneous, such as for rectified linear units $\sigma(\alpha) = \max(\alpha, 0)$, homogeneization would disappear. By considering multiple such functions at each layer, we construct a CNN in the RKHS of the full multi-layer kernel in Section 4.2. Denoting such a CNN by f_σ, we show that its RKHS norm can be bounded as

$$\|f_\sigma\|^2 \leq \|w_{n+1}\|^2\, C_\sigma^2(\|W_n\|_2^2\, C_\sigma^2(\|W_{n-1}\|_2^2 \ldots C_\sigma^2(\|W_2\|_2^2\, C_\sigma^2(\|W_1\|_F^2))\ldots)),$$

where W_k are convolutional filter parameters at layer k, w_{n+1} carries the parameters of a final linear fully connected layer, C_σ^2 is a function quantifying the complexity of the simple functions defined above depending on the choice of activation σ, and $\|W_k\|_2$, $\|W_k\|_F$ denote spectral and Frobenius norms, respectively, (see Section 4.2 for details). This norm can then control generalization aspects through classical margin bounds, as well as the invariance and stability of model predictions. Indeed, by using the reproducing property $f(x) = \langle f, \Phi(x)\rangle$, this "linearization" lets us control stability properties of model predictions through $\|f\|$:

$$\text{for all signals } x \text{ and } x', \quad |f(x) - f(x')| \leq \|f\| \cdot \|\Phi(x) - \Phi(x')\|,$$

meaning that the prediction function f will inherit the stability of Φ when $\|f\|$ is small.

The case of standard CNNs with generic activations. When considering CNNs with generic, possibly non-smooth activations such as rectified linear units (ReLUs), the separation between a data-independent representation and a learned model is not always achievable in contrast to our kernel approach. In particular, the "representation" given by the last layer of a learned CNN is often considered by practitioners, but such a representation is data-dependent in that it is typically trained on a specific task and dataset, and does not preserve signal information.

Nevertheless, we obtain similar invariance and stability properties for the predictions of such models in Section 4.3, by considering a complexity measure given by the product of spectral norms of each linear convolutional mapping in a CNN. Unlike our study based on kernel methods, such results do not say anything about generalization; however, relevant generalization bounds based on similar quantities have been derived (though other quantities in addition to the product of spectral norms appear in the bounds, and these bounds do not directly apply to CNNs), *e.g.*, by Bartlett et al. (2017); Neyshabur et al. (2018), making the relationship between generalization and stability clear in this context as well.

1.2. Related Work

Our work relies on image representations introduced in the context of convolutional kernel networks (Mairal, 2016; Mairal et al., 2014), which yield a sequence of spatial maps similar to traditional CNNs, but where each point on the maps is possibly infinite-dimensional and lives in a reproducing kernel Hilbert space (RKHS). The extension to signals with d spatial dimensions is straightforward. Since computing the corresponding Gram matrix as in classical kernel machines is computationally impractical, CKNs provide an approximation scheme consisting of learning finite-dimensional subspaces of each RKHS's layer, where the data is projected. The resulting architecture of CKNs resembles traditional CNNs with a subspace learning interpretation and different unsupervised learning principles.

Another major source of inspiration is the study of group-invariance and stability to the action of diffeomorphisms of scattering networks (Mallat, 2012), which introduced the main formalism and several proof techniques that were keys to our results. Our main effort was to extend them to more general CNN architectures and to the kernel framework, allowing us to provide a clear relationship between stability properties of the representation and generalization of learned CNN models. We note that an extension of scattering networks results to more general convolutional networks was previously given by Wiatowski and Bölcskei (2018); however, their guarantees on deformations do not improve on the inherent stability properties of the considered signal, and their study does not consider learning or generalization, by treating a convolutional architecture with fixed weights as a feature extractor. In contrast, our stability analysis shows the benefits of deep representations with a clear dependence on the choice of network architecture through the size of convolutional patches and pooling layers, and we study the implications for learned CNNs through notions of model complexity.

Invariance to groups of transformations was also studied for more classical convolutional neural networks from methodological and empirical points of view (Bruna et al., 2013; Cohen and Welling, 2016), and for shallow learned representations (Anselmi et al., 2016) or kernel methods (Haasdonk and Burkhardt, 2007; Mroueh et al., 2015; Raj et al., 2017). Our work provides a similar group-equivariant construction to (Cohen and Welling, 2016), while additionally relating it to stability. In particular, we show that in order to achieve group invariance, pooling on the group is only needed at the final layer, while deep architectures with pooling at multiple scales are mainly beneficial for stability. For the specific example of the roto-translation group (Sifre and Mallat, 2013), we show that our construction achieves invariance to rotations while maintaining stability to deformations on the translation group.

Note also that other techniques combining deep neural networks and kernels have been introduced earlier. Multilayer kernel machines were for instance introduced by Cho and Saul (2009); Schölkopf et al. (1998). Shallow kernels for images modeling local regions were also proposed by Schölkopf (1997), and a multilayer construction was proposed by Bo et al. (2011). More recently, different models based on kernels have been introduced by Anselmi et al. (2015); Daniely et al. (2016); Montavon et al. (2011) to gain some theoretical insight about classical multilayer neural networks, while kernels are used by Zhang et al. (2017b) to define convex models for two-layer convolutional networks. Theoretical and practical concerns for learning with multilayer kernels have been studied in Daniely et al. (2017, 2016); Steinwart et al. (2016); Zhang et al. (2016) in addition to CKNs. In particular,

Daniely et al. (2017, 2016) study certain classes of dot-product kernels with random feature approximations, Steinwart et al. (2016) consider hierarchical Gaussian kernels with learned weights, and Zhang et al. (2016) study a convex formulation for learning a certain class of fully connected neural networks using a hierarchical kernel. In contrast to these works, our focus is on the kernel *representation* induced by the specific hierarchical kernel defined in CKNs and the geometry of the RKHS. Our characterization of CNNs and activation functions contained in the RKHS is similar to the work of Zhang et al. (2016, 2017b), but differs in several ways: we consider general *homogeneous* dot-product kernels, which yield desirable properties of kernel mappings for stability; we construct generic multi-layer CNNs with pooling in the RKHS, while Zhang et al. (2016) only considers fully-connected networks and Zhang et al. (2017b) is limited to two-layer convolutional networks with no pooling; we quantify the RKHS norm of a CNN depending on its parameters, in particular matrix norms, as a way to control stability and generalization, while Zhang et al. (2016, 2017b) consider models with constrained parameters, and focus on convex learning procedures.

1.3. Notation and Basic Mathematical Tools

A positive definite kernel K that operates on a set $\mathcal{X}$ implicitly defines a reproducing kernel Hilbert space $\mathcal{H}$ of functions from $\mathcal{X}$ to $\mathbb{R}$, along with a mapping $\varphi : \mathcal{X} \to \mathcal{H}$. A *predictive model* associates to every point z in $\mathcal{X}$ a label in $\mathbb{R}$; it consists of a linear function f in $\mathcal{H}$ such that $f(z) = \langle f, \varphi(z) \rangle_{\mathcal{H}}$, where $\varphi(z)$ is the *data representation*. Given now two points z, z' in $\mathcal{X}$, Cauchy-Schwarz's inequality allows us to control the variation of the predictive model f according to the geometry induced by the Hilbert norm $\|.\|_{\mathcal{H}}$:

$$|f(z) - f(z')| \leq \|f\|_{\mathcal{H}} \|\varphi(z) - \varphi(z')\|_{\mathcal{H}}. \tag{1}$$

This property implies that two points z and z' that are close to each other according to the RKHS norm should lead to similar predictions, when the model f has small norm in $\mathcal{H}$.

Then, we consider notation from signal processing similar to Mallat (2012). We call a signal x a function in $L^2(\mathbb{R}^d, \mathcal{H})$, where the domain $\mathbb{R}^d$ represents spatial coordinates, and $\mathcal{H}$ is a Hilbert space, when $\|x\|_{L^2}^2 := \int_{\mathbb{R}^d} \|x(u)\|_{\mathcal{H}}^2 du < \infty$, where du is the Lebesgue measure on $\mathbb{R}^d$. Given a linear operator $T : L^2(\mathbb{R}^d, \mathcal{H}) \to L^2(\mathbb{R}^d, \mathcal{H}')$, the operator norm is defined as $\|T\|_{L^2(\mathbb{R}^d,\mathcal{H}) \to L^2(\mathbb{R}^d,\mathcal{H}')} := \sup_{\|x\|_{L^2(\mathbb{R}^d,\mathcal{H})} \leq 1} \|Tx\|_{L^2(\mathbb{R}^d,\mathcal{H}')}$. For the sake of clarity, we drop norm subscripts, from now on, using the notation $\|\cdot\|$ for Hilbert space norms, L^2 norms, and $L^2 \to L^2$ operator norms, while $|\cdot|$ denotes the Euclidean norm on $\mathbb{R}^d$. We use cursive capital letters (*e.g.*, $\mathcal{H}, \mathcal{P}$) to denote Hilbert spaces, and non-cursive ones for operators (*e.g.*, P, M, A). Some useful mathematical tools are also presented in Appendix A.

1.4. Organization of the Paper

The rest of the paper is structured as follows:

- In Section 2, we introduce a multilayer convolutional kernel representation for continuous signals, based on a hierarchy of patch extraction, kernel mapping, and pooling operators. We present useful properties of this representation such as signal preservation, as well as ways to make it practical through discretization and kernel approximations in the context of CKNs.

- In Section 3, we present our main results regarding stability and invariance, namely that the kernel representation introduced in Section 2 is near translation-invariant and stable to the action of diffeomorphisms. We then show in Section 3.3 that the same stability results apply in the presence of kernel approximations such as those of CKNs (Mairal, 2016), and describe a generic way to modify the multilayer construction in order to guarantee invariance to the action of any locally compact group of transformations in Section 3.5.
- In Section 4, we study the functional spaces induced by our representation, showing that simple neural-network like functions with certain smooth activations are contained in the RKHS at intermediate layers, and that the RKHS of the full kernel induced by our representation contains a class of generic CNNs with smooth and homogeneous activations. We then present upper bounds on the RKHS norm of such CNNs, which serves as a measure of complexity, controlling both generalization and stability. Section 4.3 studies the stability for CNNs with generic activations such as rectified linear units, and discusses the link with generalization.
- Finally, we discuss in Section 5 how the obtained stability results apply to the practical setting of learning prediction functions. In particular, we explain why the regularization used in CKNs provides a natural way to control stability, while a similar control is harder to achieve with generic CNNs.

2. Construction of the Multilayer Convolutional Kernel

We now present the multilayer convolutional kernel, which operates on signals with d spatial dimensions. The construction follows closely that of convolutional kernel networks but is generalized to input signals defined on the continuous domain $\mathbb{R}^d$. Dealing with continuous signals is indeed useful to characterize the stability properties of signal representations to small deformations, as done by Mallat (2012) in the context of the scattering transform. The issue of discretization on a discrete grid is addressed in Section 2.1.

In what follows, we consider signals x_0 that live in $L^2(\mathbb{R}^d, \mathcal{H}_0)$, where typically $\mathcal{H}_0 = \mathbb{R}^{p_0}$ (*e.g.*, with $p_0 = 3$ and $d = 2$, the vector $x_0(u)$ in $\mathbb{R}^3$ may represent the RGB pixel value at location u in $\mathbb{R}^2$). Then, we build a sequence of reproducing kernel Hilbert spaces $\mathcal{H}_1, \mathcal{H}_2, \ldots$, and transform x_0 into a sequence of "feature maps", respectively denoted by x_1 in $L^2(\mathbb{R}^d, \mathcal{H}_1)$, x_2 in $L^2(\mathbb{R}^d, \mathcal{H}_2)$, *etc...* As depicted in Figure 1, a new map x_k is built from the previous one x_{k-1} by applying successively three operators that perform patch extraction (P_k), kernel mapping (M_k) to a new RKHS $\mathcal{H}_k$, and linear pooling (A_k), respectively. When going up in the hierarchy, the points $x_k(u)$ carry information from larger signal neighborhoods centered at u in $\mathbb{R}^d$ with more invariance, as we formally show in Section 3.

Patch extraction operator. Given the layer x_{k-1}, we consider a patch shape S_k, defined as a compact centered subset of $\mathbb{R}^d$, *e.g.*, a box, and we define the Hilbert space $\mathcal{P}_k := L^2(S_k, \mathcal{H}_{k-1})$ equipped with the norm $\|z\|^2 = \int_{S_k} \|z(u)\|^2 d\nu_k(u)$, where $d\nu_k$ is the normalized uniform measure on S_k for every z in $\mathcal{P}_k$. Specifically, we define the (linear) patch extraction operator $P_k : L^2(\mathbb{R}^d, \mathcal{H}_{k-1}) \to L^2(\mathbb{R}^d, \mathcal{P}_k)$ such that for all u in $\mathbb{R}^d$,

$$P_k x_{k-1}(u) = (v \mapsto x_{k-1}(u+v))_{v \in S_k} \in \mathcal{P}_k.$$

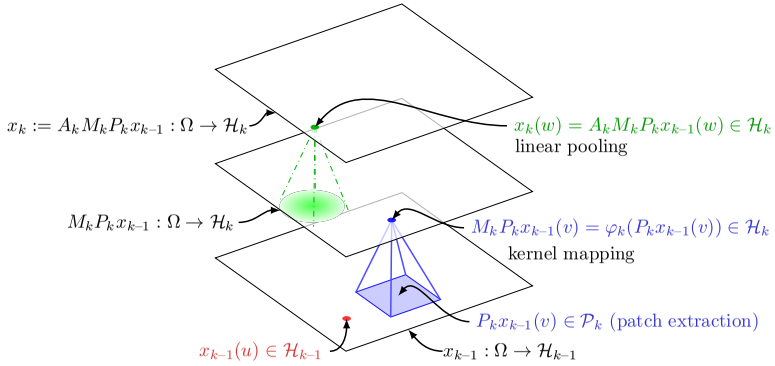

Figure 1: Construction of the k-th signal representation from the k–1-th one. Note that while the domain Ω is depicted as a box in $\mathbb{R}^2$ here, our construction is supported on $\Omega = \mathbb{R}^d$.

Note that by equipping $\mathcal{P}_k$ with a normalized measure, it is easy to show that the operator P_k preserves the norm—that is, $\|P_k x_{k-1}\| = \|x_{k-1}\|$ and hence $P_k x_{k-1}$ is in $L^2(\mathbb{R}^d, \mathcal{P}_k)$.

Kernel mapping operator. Then, we map each patch of x_{k-1} to a RKHS $\mathcal{H}_k$ thanks to the kernel mapping $\varphi_k : \mathcal{P}_k \to \mathcal{H}_k$ associated to a positive definite kernel K_k that operates on patches. It allows us to define the pointwise operator M_k such that for all u in $\mathbb{R}^d$,

$$M_k P_k x_{k-1}(u) := \varphi_k(P_k x_{k-1}(u)) \in \mathcal{H}_k.$$

In this paper, we consider homogeneous dot-product kernels K_k operating on $\mathcal{P}_k$, defined in terms of a function $\kappa_k : [-1, 1] \to \mathbb{R}$ that satisfies the following constraints:

$$\kappa_k(u) = \sum_{j=0}^{+\infty} b_j u^j \quad \text{s.t.} \quad \forall j, b_j \geq 0, \quad \kappa_k(1) = 1, \quad \kappa_k'(1) = 1, \tag{A1}$$

assuming convergence of the series $\sum_j b_j$ and $\sum_j j b_j$. Then, we define the kernel K_k by

$$K_k(z, z') = \|z\| \|z'\| \kappa_k\left(\frac{\langle z, z' \rangle}{\|z\| \|z'\|}\right), \tag{2}$$

if $z, z' \in \mathcal{P}_k \setminus \{0\}$, and $K_k(z, z') = 0$ if $z = 0$ or $z' = 0$. The kernel is positive definite since it admits a Maclaurin expansion with only non-negative coefficients (Schoenberg, 1942; Schölkopf and Smola, 2001). The condition $\kappa_k(1) = 1$ ensures that the RKHS mapping preserves the norm—that is, $\|\varphi_k(z)\| = K_k(z, z)^{1/2} = \|z\|$, and thus $\|M_k P_k x_{k-1}(u)\| = \|P_k x_{k-1}(u)\|$ for all u in $\mathbb{R}^d$; as a consequence, $M_k P_k x_{k-1}$ is always in $L^2(\mathbb{R}^d, \mathcal{H}_k)$. The technical condition $\kappa_k'(1) = 1$, where κ_k' is the first derivative of κ_k, ensures that the kernel mapping φ_k is non-expansive, according to Lemma 1 below.

Lemma 1 (Non-expansiveness of the kernel mappings) *Consider a positive-definite kernel of the form* (2) *satisfying* (A1) *with RKHS mapping* $\varphi_k : \mathcal{P}_k \to \mathcal{H}_k$. *Then,* φ_k *is non-expansive—that is, for all* z, z' *in* $\mathcal{P}_k$,

$$\|\varphi_k(z) - \varphi_k(z')\| \leq \|z - z'\|.$$

Moreover, we remark that the kernel K_k *is lower-bounded by the linear one*

$$K_k(z, z') \geq \langle z, z' \rangle. \tag{3}$$

From the proof of the lemma, given in Appendix B, one may notice that the assumption $\kappa_k'(1) = 1$ is not critical and may be safely replaced by $\kappa_k'(1) \leq 1$. Then, the non-expansiveness property would be preserved. Yet, we have chosen a stronger constraint since it yields a few simplifications in the stability analysis, where we use the relation (3) that requires $\kappa_k'(1) = 1$. More generally, the kernel mapping is Lipschitz continuous with constant $\rho_k = \max(1, \sqrt{\kappa_k'(1)})$. Our stability results hold in a setting with $\rho_k > 1$, but with constants $\prod_k \rho_k$ that may grow exponentially with the number of layers.

Examples of functions κ_k that satisfy the properties (A1) are now given below:

exponential	$\kappa_{\exp}(\langle z, z' \rangle) = e^{\langle z, z' \rangle - 1}$
inverse polynomial	$\kappa_{\text{inv-poly}}(\langle z, z' \rangle) = \frac{1}{2 - \langle z, z' \rangle}$
polynomial, degree p	$\kappa_{\text{poly}}(\langle z, z' \rangle) = \frac{1}{(c+1)^p}(c + \langle z, z' \rangle)^p \quad$ with $\quad c = p - 1$
arc-cosine, degree 1	$\kappa_{\text{acos}}(\langle z, z' \rangle) = \frac{1}{\pi}\left(\sin(\theta) + (\pi - \theta)\cos(\theta)\right)$ with $\theta = \arccos(\langle z, z' \rangle)$
Vovk's, degree 3	$\kappa_{\text{vovk}}(\langle z, z' \rangle) = \frac{1}{3}\left(\frac{1 - \langle z, z' \rangle^3}{1 - \langle z, z' \rangle}\right) = \frac{1}{3}\left(1 + \langle z, z' \rangle + \langle z, z' \rangle^2\right)$

We note that the inverse polynomial kernel was used by Zhang et al. (2016, 2017b) to build convex models of fully connected networks and two-layer convolutional neural networks, while the arc-cosine kernel appears in early deep kernel machines (Cho and Saul, 2009). Note that the homogeneous exponential kernel reduces to the Gaussian kernel for unit-norm vectors. Indeed, for all z, z' such that $\|z\| = \|z'\| = 1$, we have

$$\kappa_{\exp}(\langle z, z' \rangle) = e^{\langle z, z' \rangle - 1} = e^{-\frac{1}{2}\|z - z'\|^2},$$

and thus, we may refer to kernel (2) with the function $\kappa_{\exp}$ as the homogeneous Gaussian kernel. The kernel $\kappa(\langle z, z' \rangle) = e^{\alpha(\langle z, z' \rangle - 1)} = e^{-\frac{\alpha}{2}\|z - z'\|^2}$ with $\alpha \neq 1$ may also be used here, but we choose $\alpha = 1$ for simplicity since $\kappa'(1) = \alpha$ (see discussion above).

Pooling operator. The last step to build the layer x_k consists of pooling neighboring values to achieve local shift-invariance. We apply a linear convolution operator A_k with a Gaussian filter of scale σ_k, $h_{\sigma_k}(u) := \sigma_k^{-d} h(u/\sigma_k)$, where $h(u) = (2\pi)^{-d/2}\exp(-|u|^2/2)$. Then, for all u in $\mathbb{R}^d$,

$$x_k(u) = A_k M_k P_k x_{k-1}(u) = \int_{\mathbb{R}^d} h_{\sigma_k}(u - v) M_k P_k x_{k-1}(v) dv \in \mathcal{H}_k, \tag{4}$$

where the integral is a Bochner integral (see, Diestel and Uhl, 1977; Muandet et al., 2017). By applying Schur's test to the integral operator A_k (see Appendix A), we obtain that the operator norm $\|A_k\|$ is less than 1. Thus, x_k is in $L^2(\mathbb{R}^d, \mathcal{H}_k)$, with $\|x_k\| \leq \|M_k P_k x_{k-1}\|$. Note that a similar pooling operator is used in the scattering transform (Mallat, 2012).

Multilayer construction and prediction layer. Finally, we obtain a multilayer representation by composing multiple times the previous operators. In order to increase invariance with each layer and to increase the size of the receptive fields (that is, the neighborhood of the original signal considered in a given patch), the size of the patch S_k and pooling scale σ_k typically grow exponentially with k, with σ_k and the patch size $\sup_{c \in S_k} |c|$ of the same order. With n layers, the maps x_n may then be written

$$x_n := A_n M_n P_n A_{n-1} M_{n-1} P_{n-1} \cdots A_1 M_1 P_1 x_0 \ \in \ L^2(\mathbb{R}^d, \mathcal{H}_n). \tag{5}$$

It remains to define a kernel from this representation, that will play the same role as the "fully connected" layer of classical convolutional neural networks. For that purpose, we simply consider the following linear kernel defined for all x_0, x_0' in $L^2(\mathbb{R}^d, \mathcal{H}_0)$ by using the corresponding feature maps x_n, x_n' in $L^2(\mathbb{R}^d, \mathcal{H}_n)$ given by our multilayer construction (5):

$$\mathcal{K}_n(x_0, x_0') = \langle x_n, x_n' \rangle = \int_{u \in \mathbb{R}^d} \langle x_n(u), x_n'(u) \rangle du. \tag{6}$$

Then, the RKHS $\mathcal{H}_{\mathcal{K}_n}$ of $\mathcal{K}_n$ contains all functions of the form $f(x_0) = \langle w, x_n \rangle$ with w in $L^2(\mathbb{R}^d, \mathcal{H}_n)$ (see Appendix A).

We note that one may also consider nonlinear kernels, such as a Gaussian kernel:

$$\mathcal{K}_n(x_0, x_0') = e^{-\frac{\alpha}{2}\|x_n - x_n'\|^2}. \tag{7}$$

Such kernels are then associated to a RKHS denoted by $\mathcal{H}_{n+1}$, along with a kernel mapping $\varphi_{n+1} : L^2(\mathbb{R}^d, \mathcal{H}_n) \to \mathcal{H}_{n+1}$ which we call *prediction layer*, so that the final representation is given by $\varphi_{n+1}(x_n)$ in $\mathcal{H}_{n+1}$. We note that φ_{n+1} is non-expansive for the Gaussian kernel when $\alpha \leq 1$ (see Section B.1), and is simply an isometric linear mapping for the linear kernel. Then, we have the relation $\mathcal{K}_n(x_0, x_0') := \langle \varphi_{n+1}(x_n), \varphi_{n+1}(x_n') \rangle$, and in particular, the RKHS $\mathcal{H}_{\mathcal{K}_n}$ of $\mathcal{K}_n$ contains all functions of the form $f(x_0) = \langle w, \varphi_{n+1}(x_n) \rangle$ with w in $\mathcal{H}_{n+1}$, see Appendix A.

2.1. Signal Preservation and Discretization

In this section, we show that the multilayer kernel representation preserves all information about the signal at each layer, and besides, each feature map x_k can be sampled on a discrete set with no loss of information. This suggests a natural approach for discretization which will be discussed after the following lemma, whose proof is given in Appendix C.

Lemma 2 (Signal recovery from sampling) *Assume that* $\mathcal{H}_k$ *contains all linear functions* $z \mapsto \langle g, z \rangle$ *with* g *in* $\mathcal{P}_k$ *(this is true for all kernels* K_k *described in the previous section, according to Corollary 12 in Section 4.1 later); then, the signal* x_{k-1} *can be recovered from a sampling of* x_k *at discrete locations in a set* Ω *as soon as* $\Omega + S_k = \mathbb{R}^d$ (i.e., *the union of patches centered at these points covers* $\mathbb{R}^d$*). It follows that* x_k *can be reconstructed from such a sampling.*

The previous construction defines a kernel representation for general signals in $L^2(\mathbb{R}^d, \mathcal{H}_0)$, which is an abstract object defined for theoretical purposes. In practice, signals are discrete, and it is thus important to discuss the problem of discretization. For clarity, we limit the

presentation to 1-dimensional signals ($d = 1$), but the arguments can easily be extended to higher dimensions d when using box-shaped patches. Notation from the previous section is preserved, but we add a bar on top of all discrete analogues of their continuous counterparts. *e.g.*, $\bar{x}_k$ is a discrete feature map in $\ell^2(\mathbb{Z}, \bar{\mathcal{H}}_k)$ for some RKHS $\bar{\mathcal{H}}_k$.

Input signals x_0 and $\bar{x}_0$. Discrete signals acquired by a physical device may be seen as local integrators of signals defined on a continuous domain (*e.g.*, sensors from digital cameras integrate the pointwise distribution of photons in a spatial and temporal window). Then, consider a signal x_0 in $L^2(\mathbb{R}^d, \mathcal{H}_0)$ and s_0 a sampling interval. By defining $\bar{x}_0$ in $\ell_2(\mathbb{Z}, \mathcal{H}_0)$ such that $\bar{x}_0[n] = x_0(ns_0)$ for all n in $\mathbb{Z}$, it is thus natural to assume that $x_0 = A_0 x$, where A_0 is a pooling operator (local integrator) applied to an original continuous signal x. The role of A_0 is to prevent aliasing and reduce high frequencies; typically, the scale σ_0 of A_0 should be of the same magnitude as s_0, which we choose to be $s_0 = 1$ without loss of generality. This natural assumption is kept later for the stability analysis.

Multilayer construction. We now want to build discrete feature maps $\bar{x}_k$ in $\ell^2(\mathbb{Z}, \bar{\mathcal{H}}_k)$ at each layer k involving subsampling with a factor s_k with respect to $\bar{x}_{k-1}$. We now define the discrete analogues of the operators P_k (patch extraction), M_k (kernel mapping), and A_k (pooling) as follows: for $n \in \mathbb{Z}$,

$$\bar{P}_k \bar{x}_{k-1}[n] := \frac{1}{\sqrt{e_k}}(\bar{x}_{k-1}[n], \bar{x}_{k-1}[n+1], \dots, \bar{x}_{k-1}[n+e_k-1]) \in \bar{\mathcal{P}}_k := \bar{\mathcal{H}}_{k-1}^{e_k}$$
$$\bar{M}_k \bar{P}_k \bar{x}_{k-1}[n] := \bar{\varphi}_k(\bar{P}_k \bar{x}_{k-1}[n]) \in \bar{\mathcal{H}}_k$$
$$\bar{x}_k[n] = \bar{A}_k \bar{M}_k \bar{P}_k \bar{x}_{k-1}[n] := \frac{1}{\sqrt{s_k}} \sum_{m \in \mathbb{Z}} \bar{h}_k[ns_k - m] \bar{M}_k \bar{P}_k \bar{x}_{k-1}[m] = (\bar{h}_k * \bar{M}_k \bar{P}_k \bar{x}_{k-1})[ns_k] \in \bar{\mathcal{H}}_k,$$

where (i) $\bar{P}_k$ extracts a patch of size e_k starting at position n in $\bar{x}_{k-1}[n]$, which lives in the Hilbert space $\bar{\mathcal{P}}_k$ defined as the direct sum of e_k times $\bar{\mathcal{H}}_{k-1}$; (ii) $\bar{M}_k$ is a kernel mapping identical to the continuous case, which preserves the norm, like M_k; (iii) $\bar{A}_k$ performs a convolution with a Gaussian filter and a subsampling operation with factor s_k. The next lemma shows that under mild assumptions, this construction preserves signal information.

Lemma 3 (Signal recovery with subsampling) *Assume that $\bar{\mathcal{H}}_k$ contains the linear functions $z \mapsto \langle w, z \rangle$ for all w in $\bar{\mathcal{P}}_k$ and that $e_k \geq s_k$. Then, $\bar{x}_{k-1}$ can be recovered from $\bar{x}_k$.*

The proof is given in Appendix C. The result relies on recovering patches using linear "measurement" functions and deconvolution of the pooling operation. While such a deconvolution operation can be unstable, it may be possible to obtain more stable recovery mechanisms by also considering non-linear measurements, a question which we leave open.

Links between the parameters of the discrete and continuous models. Due to subsampling, the patch size in the continuous and discrete models are related by a multiplicative factor. Specifically, a patch of size e_k with discretization corresponds to a patch S_k of diameter $e_k s_{k-1} s_{k-2} \dots s_1$ in the continuous case. The same holds true for the scale parameter σ_k of the Gaussian pooling.

2.2. Practical Implementation via Convolutional Kernel Networks

Besides discretization, convolutional kernel networks add two modifications to implement in practice the image representation we have described. First, it uses feature maps with finite spatial support, which introduces border effects that we do not study (like Mallat, 2012), but which are negligible when dealing with large realistic images. Second, CKNs use finite-dimensional approximations of the kernel feature map. Typically, each RKHS's mapping is approximated by performing a projection onto a subspace of finite dimension, which is a classical approach to make kernel methods work at large scale (Fine and Scheinberg, 2001; Smola and Schölkopf, 2000; Williams and Seeger, 2001). If we consider the kernel mapping $\varphi_k : \mathcal{P}_k \to \mathcal{H}_k$ at layer k, the orthogonal projection onto the finite-dimensional subspace $\mathcal{F}_k = \mathrm{span}(\varphi_k(z_1), \dots, \varphi_k(z_{p_k})) \subseteq \mathcal{H}_k$, where the z_i's are p_k anchor points in $\mathcal{P}_k$, is given by the linear operator $\Pi_k : \mathcal{H}_k \to \mathcal{F}_k$ defined for f in $\mathcal{H}_k$ by

$$\Pi_k f := \sum_{1 \leq i,j \leq p_k} (K_{ZZ}^{-1})_{ij} \langle \varphi_k(z_i), f \rangle \varphi_k(z_j), \tag{8}$$

where K_{ZZ}^{-1} is the inverse (or pseudo-inverse) of the $p_k \times p_k$ kernel matrix $[K_k(z_i, z_j)]_{ij}$. As an orthogonal projection operator, Π_k is non-expansive, *i.e.*, $\|\Pi_k\| \leq 1$. We can then define the new approximate version $\tilde{M}_k$ of the kernel mapping operator M_k by

$$\tilde{M}_k P_k x_{k-1}(u) := \Pi_k \varphi_k(P_k x_{k-1}(u)) \in \mathcal{F}_k. \tag{9}$$

Note that all points in the feature map $\tilde{M}_k P_k x_{k-1}$ lie in the p_k-dimensional space $\mathcal{F}_k \subseteq \mathcal{H}_k$, which allows us to represent each point $\tilde{M}_k P_k x_{k-1}(u)$ by the finite dimensional vector

$$\psi_k(P_k x_{k-1}(u)) := K_{ZZ}^{-1/2} K_Z(P_k x_{k-1}(u)) \in \mathbb{R}^{p_k}, \tag{10}$$

with $K_Z(z) := (K_k(z_1, z), \dots, K_k(z_{p_k}, z))^\top$; this finite-dimensional representation preserves the Hilbertian inner product and norm[1] in $\mathcal{F}_k$ so that $\|\psi_k(P_k x_{k-1}(u))\|_2^2 = \|\tilde{M}_k P_k x_{k-1}(u)\|_{\mathcal{H}_k}^2$.

Such a finite-dimensional mapping is compatible with the multilayer construction, which builds $\mathcal{H}_k$ by manipulating points from $\mathcal{H}_{k-1}$. Here, the approximation provides points in $\mathcal{F}_k \subseteq \mathcal{H}_k$, which remain in $\mathcal{F}_k$ after pooling since $\mathcal{F}_k$ is a linear subspace. Eventually, the sequence of RKHSs $\{\mathcal{H}_k\}_{k \geq 0}$ is not affected by the finite-dimensional approximation. Besides, the stability results we will present next are preserved thanks to the non-expansiveness of the projection. In contrast, other kernel approximations such as random Fourier features (Rahimi and Recht, 2007) do not provide points in the RKHS (see Bach, 2017), and their effect on the functional space derived from the multilayer construction is unclear.

It is then possible to derive theoretical results for the CKN model, which appears as a natural implementation of the kernel constructed previously; yet, we will also show in Section 4 that the results apply more broadly to CNNs that are contained in the functional space associated to the kernel. However, the stability of these CNNs depends on their RKHS norm, which is hard to control. In contrast, for CKNs, stability is typically controlled by the norm of the final prediction layer.

1. We have $\langle \psi_k(z), \psi_k(z') \rangle_2 = \langle \Pi_k \varphi_k(z), \Pi_k \varphi_k(z') \rangle_{\mathcal{H}_k}$. See Mairal (2016) for details.

3. Stability to Deformations and Group Invariance

In this section, we study the translation invariance and the stability under the action of diffeomorphisms of the kernel representation described in Section 2 for continuous signals. In addition to translation invariance, it is desirable to have a representation that is stable to small local deformations. We describe such deformations using a C^1-diffeomorphism $\tau : \mathbb{R}^d \to \mathbb{R}^d$, and let L_τ denote the linear operator defined by $L_\tau x(u) = x(u - \tau(u))$. We use a similar characterization of stability to the one introduced by Mallat (2012): the representation $\Phi(\cdot)$ is *stable* under the action of diffeomorphisms if there exist two non-negative constants C_1 and C_2 such that

$$\|\Phi(L_\tau x) - \Phi(x)\| \leq (C_1 \|\nabla\tau\|_\infty + C_2 \|\tau\|_\infty)\|x\|, \tag{11}$$

where $\nabla\tau$ is the Jacobian of τ, $\|\nabla\tau\|_\infty := \sup_{u\in\mathbb{R}^d} \|\nabla\tau(u)\|$, and $\|\tau\|_\infty := \sup_{u\in\mathbb{R}^d} |\tau(u)|$. The quantity $\|\nabla\tau(u)\|$ measures the size of the deformation at a location u, and like Mallat (2012), we assume the regularity condition $\|\nabla\tau\|_\infty \leq 1/2$, which implies that the deformation is invertible (Allassonnière et al., 2007; Trouvé and Younes, 2005) and helps us avoid degenerate situations. In order to have a near-translation-invariant representation, we want C_2 to be small (a translation is a diffeomorphism with $\nabla\tau = 0$), and indeed we will show that C_2 is proportional to $1/\sigma_n$, where σ_n is the scale of the last pooling layer, which typically increases exponentially with the number of layers n. When $\nabla\tau$ is non-zero, the diffeomorphism deviates from a translation, producing local deformations controlled by $\nabla\tau$.

Additional assumptions. In order to study the stability of the representation (5), we assume that the input signal x_0 may be written as $x_0 = A_0 x$, where A_0 is an initial pooling operator at scale σ_0, which allows us to control the high frequencies of the signal in the first layer. As discussed previously in Section 2.1, this assumption is natural and compatible with any physical acquisition device. Note that σ_0 can be taken arbitrarily small, so that this assumption does not limit the generality of our results. Then, we are interested in understanding the stability of the representation

$$\Phi_n(x) := A_n M_n P_n A_{n-1} M_{n-1} P_{n-1} \cdots A_1 M_1 P_1 A_0 x.$$

We do not consider a prediction layer φ_{n+1} here for simplicity, but note that if we add one on top of Φ_n, based on a linear of Gaussian kernel, then the stability of the full representation $\varphi_{n+1} \circ \Phi_n$ immediately follows from that of Φ_n thanks to the non-expansiveness of φ_{n+1} (see Section 2). Then, we make an assumption that relates the scale of the pooling operator at layer $k-1$ with the diameter of the patch S_k: we assume indeed that there exists $\kappa > 0$ such that for all $k \geq 1$,

$$\sup_{c\in S_k} |c| \leq \kappa\sigma_{k-1}. \tag{A2}$$

The scales σ_k are typically exponentially increasing with the layers k, and characterize the "resolution" of each feature map. This assumption corresponds to considering patch sizes that are adapted to these intermediate resolutions. Moreover, the stability bounds we obtain hereafter increase with κ, which leads us to believe that small patch sizes lead to more stable representations, something which matches well the trend of using small, 3x3 convolution filters at each scale in modern deep architectures (*e.g.*, Simonyan and Zisserman, 2014).

Finally, before presenting our stability results, we recall a few properties of the operators involved in the representation Φ_n, which are heavily used in the analysis.

1. **Patch extraction operator**: P_k is linear and preserves the norm;
2. **Kernel mapping operator**: M_k preserves the norm and is non-expansive;
3. **Pooling operator**: A_k is linear and non-expansive $\|A_k\| \leq 1$;

The rest of this section is organized into three parts. We present the main stability results in Section 3.1, explain their compatibility with kernel approximations in Section 3.3, and provide numerical experiment for demonstrating the stability of the kernel representation in Section 3.4. Finally, we introduce mechanisms to achieve invariance to any group of transformations in Section 3.5.

3.1. Stability Results and Translation Invariance

Here, we show that our kernel representation Φ_n satisfies the stability property (11), with a constant C_2 inversely proportional to σ_n, thereby achieving near-invariance to translations. The results are then extended to more general transformation groups in Section 3.5.

General bound for stability. The following result gives an upper bound on the quantity of interest, $\|\Phi_n(L_\tau x) - \Phi_n(x)\|$, in terms of the norm of various linear operators which control how τ affects each layer. An important object of study is the commutator of linear operators A and B, which is denoted by $[A, B] = AB - BA$.

Proposition 4 (Bound with operator norms) *For any x in $L^2(\mathbb{R}^d, \mathcal{H}_0)$, we have*

$$\|\Phi_n(L_\tau x) - \Phi_n(x)\| \leq \left(\sum_{k=1}^n \|[P_k A_{k-1}, L_\tau]\| + \|[A_n, L_\tau]\| + \|L_\tau A_n - A_n\|\right)\|x\|. \tag{12}$$

For translations $L_\tau x(u) = L_c x(u) = x(u - c)$, it is easy to see that patch extraction and pooling operators commute with L_c (this is also known as *covariance* or *equivariance* to translations), so that we are left with the term $\|L_c A_n - A_n\|$, which should control translation invariance. For general diffeomorphisms τ, we no longer have exact covariance, but we show below that commutators are stable to τ, in the sense that $\|[P_k A_{k-1}, L_\tau]\|$ is controlled by $\|\nabla\tau\|_\infty$, while $\|L_\tau A_n - A_n\|$ is controlled by $\|\tau\|_\infty$ and decays with the pooling size σ_n.

Bound on $\|[P_k A_{k-1}, L_\tau]\|$. We note that $P_k z$ can be identified with $(L_c z)_{c\in S_k}$ isometrically for all z in $L^2(\mathbb{R}^d, \mathcal{H}_{k-1})$, since $\|P_k z\|^2 = \int_{S_k} \|L_c z\|^2 d\nu_k(c)$ by Fubini's theorem. Then,

$$\begin{aligned}\|P_k A_{k-1} L_\tau z - L_\tau P_k A_{k-1} z\|^2 &= \int_{S_k} \|L_c A_{k-1} L_\tau z - L_\tau L_c A_{k-1} z\|^2 d\nu_k(c) \\ &\leq \sup_{c\in S_k} \|L_c A_{k-1} L_\tau z - L_\tau L_c A_{k-1} z\|^2,\end{aligned}$$

so that $\|[P_k A_{k-1}, L_\tau]\| \leq \sup_{c\in S_k} \|[L_c A_{k-1}, L_\tau]\|$. The following result lets us bound the commutator $\|[L_c A_{k-1}, L_\tau]\|$ when $|c| \leq \kappa\sigma_{k-1}$, which is satisfied under assumption (A2).

Lemma 5 (Stability of shifted pooling) *Consider A_σ the pooling operator with kernel $h_\sigma(u) = \sigma^{-d}h(u/\sigma)$. If $\|\nabla\tau\|_\infty \leq 1/2$, there exists a constant C_1 such that for any σ and $|c| \leq \kappa\sigma$, we have*

$$\|[L_c A_\sigma, L_\tau]\| \leq C_1 \|\nabla\tau\|_\infty,$$

where C_1 depends only on h and κ.

A similar result can be found in Lemma E.1 of Mallat (2012) for commutators of the form $[A_\sigma, L_\tau]$, but we extend it to handle integral operators $L_c A_\sigma$ with a shifted kernel. The proof (given in Appendix C.4) follows closely Mallat (2012) and relies on the fact that $[L_c A_\sigma, L_\tau]$ is an integral operator in order to bound its norm via Schur's test. Note that κ can be made larger, at the cost of an increase of the constant C_1 of the order κ^{d+1}.

Bound on $\|L_\tau A_n - A_n\|$. We bound the operator norm $\|L_\tau A_n - A_n\|$ in terms of $\|\tau\|_\infty$ using the following result due to Mallat (2012, Lemma 2.11), with $\sigma = \sigma_n$:

Lemma 6 (Translation invariance) *If $\|\nabla\tau\|_\infty \leq 1/2$, we have*

$$\|L_\tau A_\sigma - A_\sigma\| \leq \frac{C_2}{\sigma}\|\tau\|_\infty,$$

with $C_2 = 2^d \cdot \|\nabla h\|_1$.

Combining Proposition 4 with Lemmas 5 and 6, we now obtain the following result:

Theorem 7 (Stability bound) *Assume* (A2). *If $\|\nabla\tau\|_\infty \leq 1/2$, we have*

$$\|\Phi_n(L_\tau x) - \Phi_n(x)\| \leq \left(C_1\,(1+n)\,\|\nabla\tau\|_\infty + \frac{C_2}{\sigma_n}\|\tau\|_\infty\right)\|x\|. \tag{13}$$

This result matches the desired notion of stability in Eq. (11), with a translation-invariance factor that decays with σ_n. We discuss implications of our bound, and compare it with related work on stability in Section 3.2. We also note that our bound yields a worst-case guarantee on stability, in the sense that it holds for any signal x. In particular, making additional assumptions on the signal (*e.g.*, smoothness) may lead to improved stability. The predictions for a specific model may also be more stable than applying (1) to our stability bound, for instance if the filters are smooth enough.

Remark 8 (Stability for Lipschitz non-linear mappings) *While the previous results require non-expansive non-linear mappings φ_k, it is easy to extend the result to the following more general condition*

$$\|\varphi_k(z) - \varphi_k(z')\| \leq \rho_k\|z - z'\| \quad \text{and} \quad \|\varphi_k(z)\| \leq \rho_k\|z\|.$$

Indeed, the proof of Proposition 4 easily extends to this setting, giving an additional factor $\prod_k \rho_k$ in the bound (11). *The stability bound* (13) *then becomes*

$$\|\Phi_n(L_\tau x) - \Phi_n(x)\| \leq \left(\prod_{k=1}^{n}\rho_k\right)\left(C_1\,(1+n)\,\|\nabla\tau\|_\infty + \frac{C_2}{\sigma_n}\|\tau\|_\infty\right)\|x\|. \tag{14}$$

This will be useful for obtaining stability of CNNs with generic activations such as ReLU (see Section 4.3), and this also captures the case of kernels with $\kappa_k'(1) > 1$ in Lemma 1.

3.2. Discussion of the Stability Bound (Theorem 7)

In this section, we discuss the implications of our stability bound (13), and compare it to related work on the stability of the scattering transform (Mallat, 2012) as well as the work of (Wiatowski and Bölcskei, 2018) on more general convolutional models.

Role of depth. Our bound displays a linear dependence on the number of layers n in the stability constant $C_1(1+n)$. We note that a dependence on a notion of depth (the number of layers n here) also appears in Mallat (2012), with a factor equal to the maximal length of "scattering paths", and with the same condition $\|\nabla\tau\|_\infty \leq 1/2$. Nevertheless, the number of layers is tightly linked to the patch sizes, and we now show how a deeper architecture can be beneficial for stability. Given a desired level of translation-invariance σ_f and a given initial resolution σ_0, the above bound together with the discretization results of Section 2.1 suggest that one can obtain a stable representation that preserves signal information by taking small patches at each layer and subsampling with a factor equal to the patch size (assuming a patch size greater than one) until the desired level of invariance is reached: in this case we have $\sigma_f/\sigma_0 \approx \kappa^n$, where κ is of the order of the patch size, so that $n = O(\log(\sigma_f/\sigma_0)/\log(\kappa))$, and hence the stability constant $C_1(1+n)$ grows with κ as $\kappa^{d+1}/\log(\kappa)$, explaining the benefit of small patches, and thus of deeper models.

Norm preservation. While the scattering representation preserves the norm of the input signals when the length of scattering paths goes to infinity, in our setting the norm may decrease with depth due to pooling layers. However, we show in Appendix C.5 that a part of the signal norm is still preserved, particularly for signals with high energy in the low frequencies, as is the case for natural images (*e.g.*, Torralba and Oliva, 2003). This justifies that the bounded quantity in (13) is relevant and non-trivial. Nevertheless, we recall that despite a possible loss in norm, our (infinite-dimensional) representation $\Phi(x)$ preserves signal information, as discussed in Section 2.1.

Dependence on signal bandwidth. We note that our stability result crucially relies on the assumption $\sigma_0 > 0$, which effectively limits its applicability to signals with frequencies bounded by $\lambda_0 \approx 1/\sigma_0$. While this assumption is realistic in practice for digital signals, our bound degrades as σ_0 approaches 0, since the number of layers n grows as $\log(1/\sigma_0)$, as explained above. This is in contrast to the stability bound of Mallat (2012), which holds uniformly over any such σ_0, thanks to the use of more powerful tools from harmonic analysis such as the Cotlar-Stein lemma, which allows to control stability simultaneously at all frequencies thanks to the structure of the wavelet transform, something which seems more challenging in our case due to the non-linearities separating different scales.

We note that it may be difficult to obtain meaningful stability results for an unbounded frequency support given a fixed architecture, without making assumptions about the filters of a specific model. In particular, if we consider a model with a high frequency Fourier or cosine filter at the first layer, supported on a large enough patch relative to the corresponding wavelength, this will cause instabilities, particularly if the input signal has isolated high frequencies (see, *e.g.*, Bruna and Mallat, 2013). By the arguments of Section 4, such an unstable model g is in the RKHS, and we then have that the final representation $\Phi(\cdot)$ is

also unstable, since

$$\|\Phi(L_\tau x) - \Phi(x)\| = \sup_{f \in \mathcal{H}_{\mathcal{K}_n}, \|f\| \leq 1} \langle f, \Phi(L_\tau x) - \Phi(x) \rangle$$
$$\geq \frac{1}{\|g\|} \langle g, \Phi(L_\tau x) - \Phi(x) \rangle = \frac{1}{\|g\|} (g(L_\tau x) - g(x)).$$

Comparison with Wiatowski and Bölcskei (2018). The work of Wiatowski and Bölcskei (2018) also studies deformation stability for generic convolutional network models, however their "deformation sensitivity" result only shows that the representation is as sensitive to deformations as the original signal, something which is also applicable here thanks to the non-expansiveness of our representation. Moreover, their bound does not show the dependence on deformation size (the Jacobian norm), and displays a translation invariance part that degrades linearly with $1/\sigma_0$. In contrast, the translation invariance part of our bound is independent of σ_0, and the overall bound only depends logarithmically on $1/\sigma_0$, by exploiting architectural choices such as pooling layers and patch sizes.

3.3. Stability with Kernel Approximations

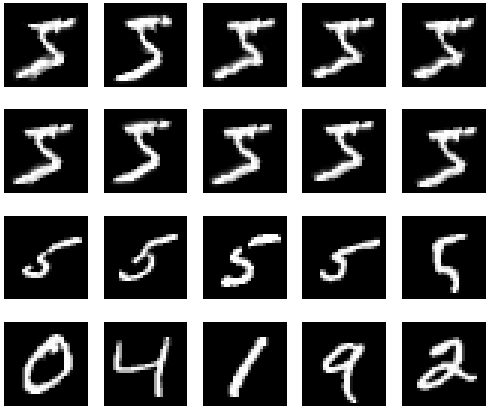
As in the analysis of the scattering transform of Mallat (2012), we have characterized the stability and shift-invariance of the data representation for continuous signals, in order to give some intuition about the properties of the corresponding discrete representation, which we have described in Section 2.1.

Another approximation performed in the CKN model of Mairal (2016) consists of adding projection steps on finite-dimensional subspaces of the RKHS's layers, as discusssed in Section 2.2. Interestingly, the stability properties we have obtained previously are compatible with these steps. We may indeed replace the operator M_k with the operator $\tilde{M}_k z(u) = \Pi_k \varphi_k(z(u))$ for any map z in $L^2(\mathbb{R}^d, \mathcal{P}_k)$, instead of $M_k z(u) = \varphi_k(z(u))$; $\Pi_k : \mathcal{H}_k \to \mathcal{F}_k$ is here an orthogonal projection operator onto a linear subspace, given in (8). Then, $\tilde{M}_k$ does not necessarily preserve the norm anymore, but $\|\tilde{M}_k z\| \leq \|z\|$, with a loss of information equal to $\|M_k z - \tilde{M}_k z\|$ corresponding to the quality of approximation of the kernel K_k on the points $z(u)$. On the other hand, the non-expansiveness of M_k is satisfied thanks to the non-expansiveness of the projection. In summary, it is possible to show that the conclusions of Theorem 7 remain valid when adding the CKN projection steps at each layer, but some signal information is lost in the process.

3.4. Empirical Study of Stability

In this section, we provide numerical experiments to demonstrate the stability properties of the kernel representations defined in Section 2 on discrete images.

We consider images of handwritten digits from the Infinite MNIST dataset of Loosli et al. (2007), which consists of 28x28 grayscale MNIST digits augmented with small translations and deformations. Translations are chosen at random from one of eight possible directions, while deformations are generated by considering small smooth deformations τ, and approximating $L_\tau x$ using a tangent vector field ∇x containing partial derivatives of the signal x along the horizontal and vertical image directions. We introduce a deformation



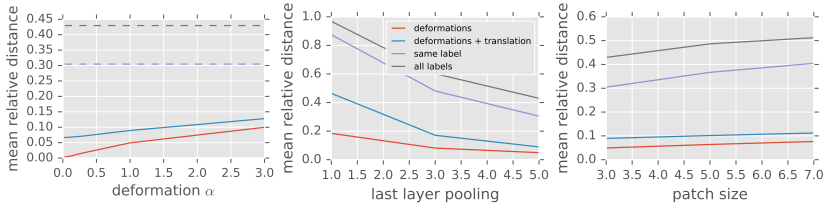


Figure 2: MNIST digits with transformations considered in our numerical study of stability. Each row gives examples of images from a set of digits that are compared to a reference image of a "5". From top to bottom: deformations with $\alpha = 3$; translations and deformations with $\alpha = 1$; digits from the training set with the same label "5" as the reference digit; digits from the training set with any label.

parameter α to control such deformations, which are then given by

$$L_{\alpha\tau} x(u) = x(u - \alpha\tau(u)) \approx x(u) - \alpha\tau(u) \cdot \nabla x(u).$$

Figure 2 shows examples of different deformations, with various values of α, with or without translations, generated from a reference image of the digit "5". In addition, one may consider that a given reference image of a handwritten digit can be deformed into different images of the same digit, and perhaps even into a different digit (*e.g.*, a "1" may be deformed into a "7"). Intuitively, the latter transformation corresponds to a "larger" deformation than the former, so that a prediction function that is stable to deformations should be preferable for a classification task. The aim of our experiments is to quantify this stability, and to study how it is affected by architectural choices such as patch sizes and pooling scales.

We consider a full kernel representation, discretized as described in Section 2.1. We limit ourselves to 2 layers in order to make the computation of the full kernel tractable. Patch extraction is performed with zero padding in order to preserve the size of the previous feature map. We use a homogeneous dot-product kernel as in Eq. (2) with $\kappa(z) = e^{\rho(z-1)}$, $\rho = 1/(0.65)^2$. Note that this choice yields $\kappa'(z) = \rho > 1$, giving an ρ-Lipschitz kernel mapping instead of a non-expansive one as in Lemma 1 which considers $\rho = 1$. However, values of ρ larger than one typically lead to better empirical performance for classification (Mairal, 2016), and the stability results of Section 3 are still valid with an additional factor ρ^n (with $n = 2$ here) in Eq. (13). For a subsampling factor s, we apply a Gaussian filter with scale $\sigma = s/\sqrt{2}$ before downsampling. Our C++ implementation for computing the full kernel given two images is available at `https://github.com/albietz/ckn_kernel`.

(a) (b) (c)

Figure 3: Average relative representation distance for various 2-layer models. Lines in the legend corresponds to rows of images in Figure 2. In (b-c), deformations are obtained with $\alpha = 1$. We show the impact on relative distance of: (a) the value of α in deformations, in $\{0.01, 0.03, 0.1, 0.3, 1, 3\}$; (b) the subsampling factor of the final pooling layer, in $\{1, 3, 5\}$; (c) the patch size, in $\{3, 5, 7\}$.

In Figure 3, we show average relative distance in representation space between a reference image and images from various sets of 20 images (either generated transformations, or images appearing in the training set). For a given architecture A and set S of images, the average relative distance to an image x is given by

$$\frac{1}{|S|}\sum_{x' \in S} \frac{\|\Phi_A(x') - \Phi_A(x)\|}{\|\Phi_A(x)\|} = \frac{1}{|S|}\sum_{x' \in S} \frac{\sqrt{K_A(x,x) + K_A(x',x') - 2K_A(x,x')}}{\sqrt{K_A(x,x)}},$$

where Φ_A denotes the kernel representation for architecture A and $K_A(x, x')$ the corresponding kernel. We normalize by $\|\Phi_A(x)\|$ in order to reduce sensitivity to the choice of architecture. We start with a $(3, 2)$-layer followed by a $(3, 5)$-layer, where (p, s) indicates a layer with patch size p and subsampling s. In Figure 3b, we vary the subsampling factor of the second layer, and in Figure 3c we vary the patch size of both layers.

Each row of Figure 2 shows digits and deformed versions. Intuitively, it should be easier to deform an image of a handwritten 5 into a different image of a 5, than into a different digit. Indeed, Figure 3 shows that the average relative distance for images with different labels is always larger than for images with the same label, which in turn is larger than for small deformations and translations of the reference image.

Adding translations on top of deformations increases distance in all cases, and Figure 3b shows that this gap is smaller when using larger subsampling factors in the last layer. This agrees with the stability bound (13), which shows that a larger pooling scale at the last layer increases translation invariance. Figure 3a highlights the dependence of the distance on the deformation size α, which is near-linear as in Eq. (13) (note that α controls the Jacobian of the deformation). Finally, Figure 3c shows that larger patch sizes can make the representations less stable, as discussed in Section 3.

3.5. Global Invariance to Group Actions

In Section 3.1, we have seen how the kernel representation of Section 2 creates invariance to translations by commuting with the action of translations at intermediate layers, and how

the last pooling layer on the translation group governs the final level of invariance. It is often useful to encode invariances to different groups of transformations, such as rotations or reflections (see, *e.g.*, Cohen and Welling, 2016; Mallat, 2012; Raj et al., 2017; Sifre and Mallat, 2013). Here, we show how this can be achieved by defining adapted patch extraction and pooling operators that commute with the action of a transformation group G (this is known as group covariance or equivariance). We assume that G is locally compact such that we can define a left-invariant Haar measure μ—that is, a measure on G that satisfies $\mu(gS) = \mu(S)$ for any Borel set $S \subseteq G$ and g in G. We assume the initial signal $x(u)$ is defined on G, and we define subsequent feature maps on the same domain. The action of an element g in G is denoted by L_g, where $L_g x(u) = x(g^{-1}u)$. In order to keep the presentation simple, we ignore some issues related to the general construction in $L^2(G)$ of our signals and operators, which can be made more precise using tools from abstract harmonic analysis (*e.g.*, Folland, 2016).

Extending a signal on G. We note that the original signal is defined on a domain $\mathbb{R}^d$ which may be different from the transformation group G that acts on $\mathbb{R}^d$ (*e.g.*, for 2D images the domain is $\mathbb{R}^2$ but G may also include a rotation angle). The action of g in G on the original signal defined on $\mathbb{R}^d$, denoted $\tilde{x}(\omega)$ yields a transformed signal $L_g\tilde{x}(\omega) = \tilde{x}(g^{-1} \cdot \omega)$, where $\cdot$ denotes group action. This requires an appropriate extension of the signal to G that preserves the meaning of signal transformations. We make the following assumption: every element ω in $\mathbb{R}^d$ can be reached with a transformation u_ω in G from a neutral element ϵ in $\mathbb{R}^d$ (*e.g.*, $\epsilon = 0$), as $\omega = u_\omega \cdot \epsilon$. Note that for 2D images ($d = 2$), this typically requires a group G that is "larger" than translations, such as the roto-translation group, while it is not satisfied, for instance, for rotations only. A similar assumption is made by Kondor and Trivedi (2018). Then, one can extend the original signal $\tilde{x}$ by defining $x(u) := \tilde{x}(u \cdot \epsilon)$. Indeed, we then have

$$L_g x(u_\omega) = x(g^{-1}u_\omega) = \tilde{x}((g^{-1}u_\omega) \cdot \epsilon) = \tilde{x}(g^{-1} \cdot \omega),$$

so that the signal $(x(u_\omega))_{\omega \in \mathbb{R}^d}$ preserves the structure of $\tilde{x}$. We detail this below for the example of roto-translations on 2D images. Then, we are interested in defining a layer—that is, a succession of patch extraction, kernel mapping, and pooling operators—that commutes with L_g, in order to achieve equivariance to G.

Patch extraction. We define patch extraction as follows

$$Px(u) = (x(uv))_{v \in S} \quad \text{for all} \quad u \in G,$$

where $S \subset G$ is a patch shape centered at the identity element. P commutes with L_g since

$$PL_g x(u) = (L_g x(uv))_{v \in S} = (x(g^{-1}uv))_{v \in S} = Px(g^{-1}u) = L_g Px(u).$$

Kernel mapping. The pointwise operator M is defined exactly as in Section 2, and thus commutes with L_g.

Pooling. The pooling operator on the group G is defined by

$$Ax(u) = \int_G x(uv)h(v)d\mu(v) = \int_G x(v)h(u^{-1}v)d\mu(v),$$

where h is a pooling filter typically localized around the identity element. The construction is similar to Raj et al. (2017) and it is easy to see from the first expression of $Ax(u)$ that $AL_g x(u) = L_g Ax(u)$, making the pooling operator G-equivariant. One may also pool on a subset of the group by only integrating over the subset in the first expression, an operation which is also G-equivariant.

In our analysis of stability in Section 3.1, we saw that inner pooling layers are useful to guarantee stability to local deformations, while global invariance is achieved mainly through the last pooling layer. In some cases, one only needs stability to a subgroup of G, while achieving invariance to the whole group, *e.g.*, in the roto-translation group (Oyallon and Mallat, 2015; Sifre and Mallat, 2013), one might want invariance to a global rotation but stability to local translations. Then, one can perform patch extraction and pooling just on the subgroup to stabilize (*e.g.*, translations) in intermediate layers, while pooling on the entire group at the last layer to achieve the global group invariance.

Example with the roto-translation group. We consider a simple example on 2D images where one wants global invariance to rotations in addition to near-invariance and stability to translations as in Section 3.1. For this, we consider the roto-translation group (see, *e.g.*, Sifre and Mallat, 2013), defined as the *semi-direct* product of translations $\mathbb{R}^2$ and rotations $SO(2)$, denoted by $G = \mathbb{R}^2 \rtimes SO(2)$, with the following group operation

$$gg' = (v + R_\theta v', \theta + \theta'),$$

for $g = (v, \theta)$, $g' = (v', \theta')$ in G, where R_θ is a rotation matrix in $SO(2)$. The element $g = (v, \theta)$ in G acts on a location $u \in \mathbb{R}^2$ by combining a rotation and a translation:

$$\begin{aligned} g \cdot u &= v + R_\theta u \\ g^{-1} \cdot u &= (-R_{-\theta} v, -\theta) \cdot u = R_{-\theta}(u - v). \end{aligned}$$

For a given image $\tilde{x}$ in $L^2(\mathbb{R}^2)$, our equivariant construction outlined above requires an extension of the signal to the group G. We consider the Haar measure given by $d\mu((v, \theta)) := dv d\mu_c(\theta)$, where dv is the Lebesgue measure on $\mathbb{R}^2$ and $d\mu_c$ the normalized Haar measure on the unit circle. Note that μ is left-invariant, since the determinant of rotation matrices that appears in the change of variables is 1. We can then define x by $x((u, \eta)) := \tilde{x}(u)$ for any angle η, which is in $L^2(G)$ and preserves the definition of group action on the original signal $\tilde{x}$ since

$$L_g x((u, \eta)) = x(g^{-1}(u, \eta)) = x((g^{-1} \cdot u, \eta - \theta)) = \tilde{x}(g^{-1} \cdot u) = L_g \tilde{x}(u).$$

That is, we can study the action of G on 2D images in $L^2(\mathbb{R}^2)$ by studying the action on the extended signals in $L^2(G)$ defined above.

We can now define patch extraction and pooling operators $P, A : L^2(G) \to L^2(G)$ only on the translation subgroup, by considering a patch shape $S = \{(v, 0)\}_{v \in \tilde{S}} \subset G$ with $\tilde{S} \subset \mathbb{R}^2$ for P, and defining pooling by $Ax(g) = \int_{\mathbb{R}^d} x(g(v, 0))h(v)dv$, where h is a Gaussian pooling filter with scale σ defined on $\mathbb{R}^2$.

The following result, proved in Appendix C, shows analogous results to the stability lemmas of Section 3.1 for the operators P and A. For a diffeomorphism τ, we denote by L_τ the action operator given by $L_\tau x((u, \eta)) = x((\tau(u), 0)^{-1}(u, \eta)) = x((u - \tau(u), \eta))$.

Lemma 9 (Stability with roto-translation patches) *If $\|\nabla\tau\|_\infty \leq 1/2$, and the following condition holds $\sup_{c \in \tilde{S}} |c| \leq \kappa\sigma$, we have*

$$\|[PA, L_\tau]\| \leq C_1 \|\nabla\tau\|_\infty,$$

with the same constant C_1 as in Lemma 5, which depends on h and κ. Similarly, we have

$$\|L_\tau A - A\| \leq \frac{C_2}{\sigma} \|\tau\|_\infty,$$

with C_2 as defined in Lemma 6.

By constructing a multi-layer representation $\Phi_n(x)$ in $L^2(G)$ using similar operators at each layer, we can obtain a similar stability result to Theorem 7. By adding a global pooling operator $A_c : L^2(G) \to L^2(\mathbb{R}^2)$ after the last layer, defined, for $x \in L^2(G)$, as

$$A_c x(u) = \int x((u, \eta)) d\mu_c(\eta),$$

we additionally obtain global invariance to rotations, as shown in the following theorem.

Theorem 10 (Stability and global rotation invariance) *Assume* (A2) *for patches $\tilde{S}$ at each layer. Define the operator $L_{(\tau,\theta)} x((u, \eta)) = x((\tau(u), \theta)^{-1}(u, \eta))$, and define the diffeomorphism $\tau_\theta : u \mapsto R_{-\theta}\tau(u)$. If $\|\nabla\tau\|_\infty \leq 1/2$, we have*

$$\begin{aligned} \|A_c \Phi_n(L_{(\tau,\theta)} x) - A_c \Phi_n(x)\| &\leq \|\Phi_n(L_{R_{\tau_\theta}} x) - \Phi_n(x)\| \\ &\leq \left(C_1 (1 + n) \|\nabla\tau\|_\infty + \frac{C_2}{\sigma_n} \|\tau\|_\infty \right) \|x\|. \end{aligned}$$

We note that a similar result may be obtained when $G = \mathbb{R}^d \rtimes H$, where H is any compact group, with a possible additional dependence on how elements of H affect the size of patches.

4. Link with Existing Convolutional Architectures

In this section, we study the functional spaces (RKHS) that arise from our multilayer kernel representation, and examine the connections with more standard convolutional architectures. The motivation of this study is that if a CNN model f is in the RKHS, then it can be written in a "linearized" form $f(x) = \langle f, \Phi(x) \rangle$, so that our study of stability of the kernel representation Φ extends to predictions using $|f(x) - f(x')| \leq \|f\| \|\Phi(x) - \Phi(x')\|$.

We begin by considering in Section 4.1 the intermediate kernels K_k, showing that their RKHSs contain simple neural-network-like functions defined on patches with smooth activations, while in Section 4.2 we show that a certain class of generic CNNs are contained in the RKHS $\mathcal{H}_{\mathcal{K}_n}$ of the full multilayer kernel $\mathcal{K}_n$ and characterize their norm. This is achieved by considering particular functions in each intermediate RKHS defined in terms of the convolutional filters of the CNN. A consequence of these results is that our stability and invariance properties from Section 3 are valid for this broad class of CNNs.

4.1. Activation Functions and Kernels K_k

Before introducing formal links between our kernel representation and classical convolutional architectures, we study in more details the kernels K_k described in Section 2 and their RKHSs $\mathcal{H}_k$. In particular, we are interested in characterizing which types of functions live in $\mathcal{H}_k$. The next lemma extends some results of Zhang et al. (2016, 2017b), originally developed for the inverse polynomial and Gaussian kernels; it shows that the RKHS may contain simple "neural network" functions with activations σ that are smooth enough.

Lemma 11 (Activation functions and RKHSs $\mathcal{H}_k$) *Let $\sigma : [-1,1] \to \mathbb{R}$ be a function that admits a polynomial expansion $\sigma(u) := \sum_{j=0}^{\infty} a_j u^j$. Consider a kernel K_k from Section 2, given in (2), with $\kappa_k(u) = \sum_{j=0}^{\infty} b_j u^j$, and $b_j \geq 0$ for all j. Assume further that $a_j = 0$ whenever $b_j = 0$, and define the function $C_\sigma^2(\lambda^2) := \sum_{j=0}^{\infty} (a_j^2/b_j)\lambda^{2j}$. Let g in $\mathcal{P}_k$ be such that $C_\sigma^2(\|g\|^2) < \infty$. Then, the RKHS $\mathcal{H}_k$ contains the function*

$$f : z \mapsto \|z\| \sigma(\langle g, z\rangle / \|z\|), \tag{15}$$

and its norm satisfies $\|f\| \leq C_\sigma(\|g\|^2)$.

Noting that for all examples of κ_k given in Section 2, we have $b_1 > 0$, this result implies the next corollary, which was also found to be useful in our analysis.

Corollary 12 (Linear functions and RKHSs) *The RKHSs $\mathcal{H}_k$ for the examples of κ_k given in Section 2 contain all linear functions of the form $z \mapsto \langle g, z\rangle$ with g in $\mathcal{P}_k$.*

The previous lemma shows that for many choices of smooth functions σ, the RKHS $\mathcal{H}_k$ contains the functions of the form (15). While the non-homogeneous functions $z \mapsto \sigma(\langle g, z\rangle)$ are standard in neural networks, the homogeneous variant is not. Yet, we note that (i) the most successful activation function, namely rectified linear units, is homogeneous—that is, $\mathrm{relu}(\langle g, z\rangle) = \|z\| \mathrm{relu}(\langle g, z\rangle / \|z\|)$; (ii) while relu is nonsmooth and thus not in our RKHSs, there exists a smoothed variant that satisfies the conditions of Lemma 11 for useful kernels. As noticed by Zhang et al. (2016, 2017b), this is for instance the case for the inverse polynomial kernel. In Figure 4, we plot and compare these different variants of ReLU.

4.2. Convolutional Neural Networks and their Complexity

We now study the connection between the kernel representation defined in Section 2 and CNNs. Specifically, we show that the RKHS of the final kernel $\mathcal{K}_n$ obtained from our kernel construction contains a set of CNNs on continuous domains with certain types of smooth homogeneous activations. An important consequence is that the stability results of previous sections apply to this class of CNNs, although the stability depends on the RKHS norm, as discussed later in Section 5. This norm also serves as a measure of model complexity, thus controlling both generalization and stability.

CNN maps construction. We now define a CNN function f_σ that takes as input an image z_0 in $L^2(\mathbb{R}^d, \mathbb{R}^{p_0})$ with p_0 channels, and build a sequence of feature maps, represented at layer k as a function z_k in $L^2(\mathbb{R}^d, \mathbb{R}^{p_k})$ with p_k channels; the map z_k is obtained from z_{k-1} by performing linear convolutions with a set of filters $(w_k^i)_{i=1,\dots,p_k}$, followed by a pointwise

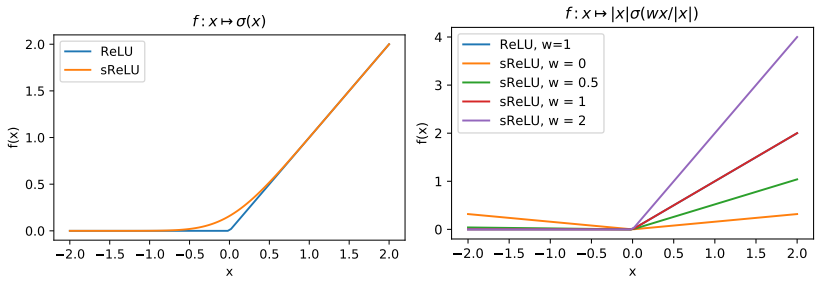

Figure 4: Comparison of one-dimensional functions obtained with relu and smoothed relu (sReLU) activations. (Left) non-homogeneous setting of Zhang et al. (2016, 2017b). (Right) our homogeneous setting, for different values of the parameter w. Note that for $w \geq 0.5$, sReLU and ReLU are indistinguishable.

activation function σ to obtain an intermediate feature map $\tilde{z}_k$, then by applying a linear pooling filter. Note that each w_k^i is in $L^2(S_k, \mathbb{R}^{p_{k-1}})$, with channels denoted by w_k^{ij} in $L^2(S_k, \mathbb{R})$. Formally, the intermediate map $\tilde{z}_k$ in $L^2(\mathbb{R}^d, \mathbb{R}^{p_k})$ is obtained by

$$\tilde{z}_k^i(u) = n_k(u) \sigma\big(\langle w_k^i, P_k z_{k-1}(u)\rangle / n_k(u)\big)\,, \tag{16}$$

where $\tilde{z}_k(u) = (\tilde{z}_k^1(u), \dots, \tilde{z}_k^{p_k}(u))$ is in $\mathbb{R}^{p_k}$, and P_k is a patch extraction operator for finite-dimensional maps. The activation involves a pointwise non-linearity σ along with a quantity $n_k(u) := \|P_k x_{k-1}(u)\|$ in (16), which is due to the homogenization, and which is independent of the filters w_k^i. Finally, the map z_k is obtained by using a pooling operator as in Section 2, with $z_k = A_k \tilde{z}_k$, and $z_0 = x_0$.

Prediction layer. For simplicity, we consider the case of a linear fully connected prediction layer. In this case, the final CNN prediction function f_σ is given by

$$f_\sigma(x_0) = \langle w_{n+1}, z_n\rangle,$$

with parameters w_{n+1} in $L^2(\mathbb{R}^d, \mathbb{R}^{p_n})$. We now show that such a CNN function is contained in the RKHS of the kernel $\mathcal{K}_n$ defined in (6).

Construction in the RKHS. The function f_σ can be constructed recursively from intermediate functions that lie in the RKHSs $\mathcal{H}_k$, of the form (15), for appropriate activations σ. Specifically, we define initial quantities f_1^i in $\mathcal{H}_1$ and g_1^i in $\mathcal{P}_1$ for $i = 1, \dots, p_1$ such that

$$g_1^i = w_1^i \in L^2(S_1, \mathbb{R}^{p_0}) = L^2(S_1, \mathcal{H}_0) = \mathcal{P}_1,$$
$$f_1^i(z) = \|z\| \sigma(\langle g_i^0, z\rangle / \|z\|) \quad \text{for } z \in \mathcal{P}_1,$$

and we define, from layer k–1, the quantities f_k^i in $\mathcal{H}_k$ and g_k^i in $\mathcal{P}_k$ for $i = 1, \dots, p_k$:

$$g_k^i(v) = \sum_{j=1}^{p_{k-1}} w_k^{ij}(v) f_{k-1}^j \quad \text{where} \quad w_k^i(v) = (w_k^{ij}(v))_{j=1,\dots,p_{k-1}},$$
$$f_k^i(z) = \|z\| \sigma(\langle g_k^i, z\rangle / \|z\|) \quad \text{for } z \in \mathcal{P}_k.$$

For the linear prediction layer, we define g_σ in $L^2(\mathbb{R}^d, \mathcal{H}_n)$ by:

$$g_\sigma(u) = \sum_{j=1}^{p_n} w_{n+1}^j(u) f_n^j \quad \text{for all } u \in \mathbb{R}^d,$$

so that the function $f : x_0 \mapsto \langle g_\sigma, x_n \rangle$ is in the RKHS of $\mathcal{K}_n$, where x_n is the final representation given in Eq. (5). In Appendix D.2, we show that $f = f_\sigma$, which implies that the CNN function f_σ is in the RKHS. We note that a similar construction for fully connected multilayer networks with constraints on weights and inputs was given by Zhang et al. (2016).

Norm of the CNN f_σ. We now study the RKHS norm of the CNN constructed above. This quantity is important as it controls the stability and invariance of the predictions of a learned model through (1). Additionally, the RKHS norm provides a way to control model complexity, and can lead to generalization bounds, *e.g.*, through Rademacher complexity and margin bounds (Boucheron et al., 2005; Shalev-Shwartz and Ben-David, 2014). In particular, such results rely on the following upper bound on the empirical Rademacher complexity of a function class with bounded RKHS norm $\mathcal{F}_\lambda = \{f \in \mathcal{H}_{\mathcal{K}_n} : \|f\| \leq \lambda\}$, for a dataset $\{x^{(1)}, \dots, x^{(N)}\}$:

$$R_N(\mathcal{F}_\lambda) \leq \frac{\lambda \sqrt{\frac{1}{N}\sum_{i=1}^N \mathcal{K}_n(x^{(i)}, x^{(i)})}}{\sqrt{N}}. \tag{17}$$

The bound remains valid when only considering CNN functions in $\mathcal{F}_\lambda$ of the form f_σ, since such a function class is contained in $\mathcal{F}_\lambda$. If we consider a binary classification task with training labels $y^{(i)}$ in $\{-1, 1\}$, on can then obtain a margin-based bound for any function f_N in $\mathcal{F}_\lambda$ obtained from the training set and any margin $\gamma > 0$: with probability $1 - \delta$, we have (see, *e.g.*, Boucheron et al., 2005)

$$L(f_N) \leq L_N^\gamma(f_N) + O\left(\frac{\lambda \sqrt{\frac{1}{N}\sum_{i=1}^N \mathcal{K}_n(x^{(i)}, x^{(i)})}}{\gamma \sqrt{N}} + \sqrt{\frac{\log(1/\delta)}{N}} \right), \tag{18}$$

with

$$L(f) = \mathbb{P}_{(x,y)\sim\mathcal{D}}(yf(x) < 0)$$
$$L_N^\gamma(f) = \frac{1}{N}\sum_{i=1}^N \mathbf{1}\{y^{(i)} f(x^{(i)}) < \gamma\},$$

where $\mathcal{D}$ is the distribution of data-label pairs $(x^{(i)}, y^{(i)})$. Intuitively, the margin γ corresponds to a level of confidence, and L_N^γ measures training error when requiring confident predictions. Then, the bound on the gap between this training error and the true expected error $L(f_N)$ becomes larger for small confidence levels, and is controlled by the model complexity λ and the sample size N.

Note that the bound requires a fixed value of λ used during training, but in practice, learning under a constraint $\|f\| \leq \lambda$ can be difficult, especially for CNNs which are typically trained with stochastic gradient descent with little regularization. However, by considering

values of λ on a logarithmic scale and taking a union bound, one can obtain a similar bound with $\|f_N\|$ instead of λ, up to logarithmic factors (see, *e.g.*, Shalev-Shwartz and Ben-David, 2014, Theorem 26.14), where f_N is obtained from the training data. We note that various authors have recently considered other norm-based complexity measures to control the generalization of neural networks with more standard activations (see, *e.g.*, Bartlett et al., 2017; Liang et al., 2018; Neyshabur et al., 2017, 2015). However, their results are typically obtained for fully connected networks on finite-dimensional inputs, while we consider CNNs for input signals defined on continuous domains. The next proposition (proved in Appendix D.2) characterizes the norm of f_σ in terms of the L^2 norms of the filters w_k^{ij}, and follows from the recursive definition of the intermediate RKHS elements f_k^i.

Proposition 13 (RKHS norm of CNNs) *Assume the activation σ satisfies $C_\sigma(a) < \infty$ for all $a \geq 0$, where C_σ is defined for a given kernel in Lemma 11. Then, the CNN function f_σ defined above is in the RKHS $\mathcal{H}_{\mathcal{K}_n}$, with norm*

$$\|f_\sigma\|^2 \leq p_n \sum_{i=1}^{p_n} \|w_{n+1}^i\|_2^2 B_{n,i},$$

where $B_{n,i}$ is defined by $B_{1,i} = C_\sigma^2(\|w_1^i\|_2^2)$ and $B_{k,i} = C_\sigma^2\left(p_{k-1}\sum_{j=1}^{p_{k-1}} \|w_k^{ij}\|_2^2 B_{k-1,j}\right)$.

Note that this upper bound need not grow exponentially with depth when the filters have small norm and C_σ takes small values around zero. However, the dependency of the bound on the number of feature maps p_k of each layer k may not be satisfactory in situations where the number of parameters is very large, which is common in successful deep learning architectures. The following proposition removes this dependence, relying instead on matrix spectral norms. Similar quantities have been used recently to obtain useful generalization bounds for neural networks (Bartlett et al., 2017; Neyshabur et al., 2018).

Proposition 14 (RKHS norm of CNNs using spectral norms) *Assume the activation σ satisfies $C_\sigma(a) < \infty$ for all $a \geq 0$, where C_σ is defined for a given kernel in Lemma 11. Then, the CNN function f_σ defined above is in the RKHS $\mathcal{H}_{\mathcal{K}_n}$, with norm*

$$\|f_\sigma\|^2 \leq \|w_{n+1}\|^2 \; C_\sigma^2(\|W_n\|_2^2 \; C_\sigma^2(\|W_{n-1}\|_2^2 \dots C_\sigma^2(\|W_2\|_2^2 \; C_\sigma^2(\|W_1\|_F^2)) \dots)). \tag{19}$$

The norms are defined as follows:

$$\|W_k\|_2^2 = \int_{S_k} \|W_k(u)\|_2^2 d\nu_k(u), \quad \text{for } k = 2, \dots, n$$
$$\|W_1\|_F^2 = \int_{S_1} \|W_1(u)\|_F^2 d\nu_1(u),$$

where $W_k(u)$ is the matrix $(w_k^{ij}(u))_{ij}$, $\|\cdot\|_2$ the spectral norm, and $\|\cdot\|_F$ the Frobenius norm.

As an example, if we consider $\kappa_1 = \cdots = \kappa_n$ to be one of the kernels introduced in Section 2 and take $\sigma = \kappa_1$ so that $C_\sigma^2(\lambda^2) = \kappa_1(\lambda^2)$, then constraining the norms at each layer to be smaller than 1 ensures $\|f_\sigma\| \leq 1$, since for $\lambda \leq 1$ we have $C_\sigma^2(\lambda^2) \leq C_\sigma^2(1) = \kappa_1(1) = 1$.

If we consider linear kernels and $\sigma(u) = u$, we have $C_\sigma^2(\lambda^2) = \lambda^2$ and the bound becomes $\|f_\sigma\| \leq \|w_{n+1}\|\|W_n\|_2 \cdots \|W_2\|_2\|W_1\|_F$. If we ignore the convolutional structure (*i.e.*, only taking 1x1 patches on a 1x1 image), the norm involves a product of spectral norms at each layer (ignoring the first layer), a quantity which also appears in recent generalization bounds (Bartlett et al., 2017; Neyshabur et al., 2018). While such quantities have proven useful to explain some generalization phenomena, such as the behavior of networks trained on data with random labels (Bartlett et al., 2017; Zhang et al., 2017a), some authors have pointed out that spectral norms may yield overly pessimistic generalization bounds when comparing with simple parameter counting (Arora et al., 2018), and our results may display similar drawbacks. We note, however, that Proposition 14 only gives an upper bound, and the actual RKHS norm may be smaller in practice. It may also be that the norm is not well controlled during training, and that the obtained bounds may not fully explain the generalization behavior observed in practice. Using such quantities to regularize during training may then yield bounds that are less vacuous (Bietti et al., 2019).

Generalization and stability. The results of this section imply that our study of the geometry of the kernel representations, and in particular the stability and invariance properties of Section 3, apply to the generic CNNs defined above, thanks to the Lipschitz smoothness relation (1). The smoothness is then controlled by the RKHS norm of these functions, which sheds light on the links between generalization and stability. In particular, functions with low RKHS norm provide better generalization guarantees on unseen data, as shown by the margin bound in Eq. (18). This implies, for instance, that generalization is harder if the task requires classifying two slightly deformed images with different labels, since separating such predictions by some margin requires a function with large RKHS norm according to our stability analysis. In contrast, if a stable function (*i.e.*, with small RKHS norm) is sufficient to do well on a training set, learning becomes "easier" and few samples may be enough for good generalization.

4.3. Stability and Generalization with Generic Activations

Our study of stability and generalization so far has relied on kernel methods, which allows us to separate learned models from data representations in order to establish tight connections between the stability of representations and statistical properties of learned CNNs through RKHS norms. One important caveat, however, is that our study is limited to CNNs with a class of smooth and homogeneous activations described in Section 4.1, which differ from generic activations used in practice such as ReLU or tanh. Indeed, ReLU is homogeneous but lacks the required smoothness, while tanh is not homogeneous. In this section, we show that our stability results can be extended to the predictions of CNNs with such activations, and that stability is controlled by a quantity based on spectral norms, which plays an important role in recent results on generalization. This confirms a strong connection between stability and generalization in this more general context as well.

Stability bound. We consider an activation function $\sigma : \mathbb{R} \to \mathbb{R}$ that is ρ-Lipschitz and satisfies $\sigma(0) = 0$. Examples include ReLU and tanh activations, for which $\rho = 1$. The CNN construction is similar to Section 4.2 with feature maps z_k in $L^2(\mathbb{R}^d, \mathbb{R}^{p_k})$, and a final prediction function f_σ defined with an inner product $\langle w_{n+1}, z_n \rangle$. The only change is the

non-linear mapping in Eq. (16), which is no longer homogeneized, and can be rewritten as

$$\tilde{z}_k(u) = \varphi_k(P_k z_{k-1}(u)) := \sigma\left(\int_{S_k} W_k(v)(P_k z_{k-1}(u))(v) d\nu_k(v)\right),$$

where σ is applied component-wise. The non-linear mapping φ_k on patches satisfies

$$\|\varphi_k(z) - \varphi_k(z')\| \leq \rho_k \|z - z'\| \quad \text{and} \quad \|\varphi_k(z)\| \leq \rho_k \|z\|,$$

where $\rho_k = \rho\|W_k\|_2$ and $\|W_k\|_2$ is the spectral norm of $W_k : L^2(S_k, \mathbb{R}^{p_k - 1}) \to \mathbb{R}^{p_k}$ defined by

$$\|W_k\|_2 = \sup_{\|z\| \leq 1} \left\| \int_{S_k} W_k(v) z(v) d\nu_k(v) \right\|.$$

We note that this spectral norm is slightly different than the mixed norm used in Proposition 14. By defining an operator M_k that applies φ_k pointwise as in Section 2, the construction of the last feature map takes the same form as that of the multilayer kernel representation, so that the results of Section 3 apply, leading to the following stability bound on the final predictions:

$$|f_\sigma(L_\tau x) - f_\sigma(x)| \leq \rho^n \|w_{n+1}\| \left(\prod_k \|W_k\|_2\right) \left(C_1 (1+n) \|\nabla \tau\|_\infty + \frac{C_2}{\sigma_n} \|\tau\|_\infty\right) \|x\|. \quad (20)$$

Link with generalization. The stability bound (20) takes a similar form to the one obtained for CNNs in the RKHS, with the RKHS norm replaced by the product of spectral norms. In contrast to the RKHS norm, such a quantity does not directly lead to generalization bounds; however, a few recent works have provided meaningful generalization bounds for deep neural networks that involve the product of spectral norms (Bartlett et al., 2017; Neyshabur et al., 2018). Thus, this suggests that stable CNNs have better generalization properties, even when considering generic CNNs with ReLU or tanh activations. Nevertheless, these bounds typically involve an additional factor consisting of other matrix norms summed across layers, which may introduce some dependence on the number of parameters, and do not directly support convolutional structure. In contrast, our RKHS norm bound based on spectral norms given in Proposition 14 directly supports convolutional structure, and has no dependence on the number of parameters.

5. Discussion and Concluding Remarks

In this paper, we introduce a multilayer convolutional kernel representation (Section 2); we show that it is stable to the action of diffeomorphisms, and that it can be made invariant to groups of transformations (Section 3); and finally we explain connections between our representation and generic convolutional networks by showing that certain classes of CNNs with smooth activations are contained in the RKHS of the full multilayer kernel (Section 4). A consequence of this last result is that the stability results of Section 3 apply to any CNN function f from that class, by using the relation

$$|f(L_\tau x) - f(x)| \leq \|f\| \|\Phi_n(L_\tau x) - \Phi_n(x)\|,$$

which follows from (1), assuming a linear prediction layer. In the case of CNNs with generic activations such as ReLU, the kernel point of view is not applicable, and the separation between model and representation is not as clear. However, we show in Section 4.3 that a similar stability bound can be obtained, with the product of spectral norms at each layer playing a similar role to the RKHS norm of the CNN. In both cases, a quantity that characterizes complexity of a model appears in the final bound on predicted values — either the RKHS norm or the product of spectral norms —, and this complexity measure is also closely related to generalization. This implies that learning with stable CNNs is "easier" in terms of sample complexity, and that the inductive bias of CNNs is thus suitable to tasks that present some invariance under translation and small local deformation, as well as more general transformation groups, when the architecture is appropriately constructed.

In order to ensure stability, the previous bounds suggest that one should control the RKHS norm $\|f\|$, or the product of spectral norms when using generic activations; however, these quantities are difficult to control with standard approaches to learning CNNs, such as backpropagation. In contrast, traditional kernel methods typically control this norm by using it as an explicit regularizer in the learning process, making such a stability guarantee more useful. In order to avoid the scalability issues of such approaches, convolutional kernel networks approximate the full kernel map Φ_n by taking appropriate projections as explained in Section 2.2, leading to a representation $\tilde{\Phi}_n$ that can be represented with a practical representation ψ_n that preserves the Hilbert space structure isometrically (using the finite-dimensional descriptions of points in the RKHS given in (10)). Section 3.3 shows that such representations satisfy the same stability and invariance results as the full representation, at the cost of losing information. Then, if we consider a CKN function of the form $f_w(x) = \langle w, \psi_n(x) \rangle$, stability is obtained thanks to the relation

$$|f_w(L_\tau x) - f_w(x)| \leq \|w\| \|\psi_n(L_\tau x) - \psi_n(x)\| = \|w\| \|\tilde{\Phi}_n(L_\tau x) - \tilde{\Phi}_n(x)\|.$$

In particular, learning such a function by controlling the norm of w, *e.g.*, with ℓ_2 regularization, provides a natural way to explicitly control stability. In the context of CNNs with generic activations, it has been suggested (see, *e.g.*, Zhang et al., 2017a) that optimization algorithms may play an important role in controlling their generalization ability, and it may be plausible that these impact the RKHS norm of a learned CNN, or its spectral norms. A better understanding of such implicit regularization behavior would be interesting, but falls beyond the scope of this paper. Nevertheless, modern CNNs trained with SGD have been found to be highly unstable to small, additive perturbations known as "adversarial examples" (Szegedy et al., 2014), which suggests that the RKHS norm of these models may be quite large, and that controlling it explicitly during learning might be important to learn more stable models (Bietti et al., 2019; Cisse et al., 2017).

Appendix A. Useful Mathematical Tools

In this section, we present preliminary mathematical tools that are used in our analysis.

Harmonic analysis. We recall a classical result from harmonic analysis (see, *e.g.*, Stein, 1993), which was used many times by Mallat (2012) to prove the stability of the scattering transform to the action of diffeomorphisms.

Lemma A.1 (Schur's test) *Let $\mathcal{H}$ be a Hilbert space and Ω a subset of $\mathbb{R}^d$. Consider T an integral operator with kernel $k : \Omega \times \Omega \to \mathbb{R}$, meaning that for all u in Ω and x in $L^2(\Omega, \mathcal{H})$,*

$$Tx(u) = \int_\Omega k(u, v) x(v) dv, \tag{21}$$

where the integral is a Bochner integral (see, Diestel and Uhl, 1977; Muandet et al., 2017) when $\mathcal{H}$ is infinite-dimensional. If

$$\forall u \in \Omega, \quad \int |k(u, v)| dv \leq C \quad \text{and} \quad \forall v \in \Omega, \quad \int |k(u, v)| du \leq C,$$

for some constant C, then, Tx is always in $L^2(\Omega, \mathcal{H})$ for all x in $L^2(\Omega, \mathcal{H})$ and we have $\|T\| \leq C$.

Note that while the proofs of the lemma above are typically given for real-valued functions in $L^2(\Omega, \mathbb{R})$, the result can easily be extended to Hilbert space-valued functions x in $L^2(\Omega, \mathcal{H})$. In order to prove this, we consider the integral operator $|T|$ with kernel $|k|$ that operates on $L^2(\Omega, \mathbb{R}_+)$, meaning that $|T|$ is defined as in (21) by replacing $k(u, v)$ by the absolute value $|k(u, v)|$. Then, consider x in $L^2(\Omega, \mathcal{H})$ and use the triangle inequality property of Bochner integrals:

$$\|Tx\|^2 = \int_\Omega \|Tx(u)\|^2 du \leq \int_\Omega \left(\int_\Omega |k(u, v)| \|x(v)\| dv \right)^2 du = \||T||x|\|^2,$$

where the function $|x|$ is such that $|x|(u) = \|x(u)\|$ and thus $|x|$ is in $L^2(\Omega, \mathbb{R}_+)$. We may now apply Schur's test to the operator $|T|$ for real-valued functions, which gives $\||T|\| \leq C$. Then, noting that $\||x|\| = \|x\|$, we conclude with the inequality $\|Tx\|^2 \leq \||T||x|\|^2 \leq \||T|\|^2 \|x\|^2 \leq C^2 \|x\|^2$.

The following lemma shows that the pooling operators A_k defined in Section 2 are non-expansive.

Lemma A.2 (Non-expansiveness of pooling operators) *If $h(u) := (2\pi)^{-d/2} \exp(-|u|^2/2)$, then the pooling operator A_σ defined for any $\sigma > 0$ by*

$$A_\sigma x(u) = \int_{\mathbb{R}^d} \sigma^{-d} h\left(\frac{u - v}{\sigma} \right) x(v) dv,$$

has operator norm $\|A_\sigma\| \leq 1$.

Proof With the notations from above, we have $\|A_\sigma x\| \leq \||A_\sigma||x|\| = \|h_\sigma * |x|\|$, where $h_\sigma := \sigma^{-d} h(\cdot/\sigma)$ and $*$ denotes convolution. By Young's inequality, we have $\|h_\sigma * |x|\| \leq \|h_\sigma\|_1 \cdot \||x|\| = 1 \cdot \||x|\| = \|x\|$, which concludes the proof. ∎

Kernel methods. We now recall a classical result that characterizes the reproducing kernel Hilbert space (RKHS) of functions defined from explicit Hilbert space mappings (see, *e.g.*, Saitoh, 1997, §2.1).

Theorem A.1 *Let $\psi : \mathcal{X} \to H$ be a feature map to a Hilbert space H, and let $K(z,z') := \langle \psi(z), \psi(z') \rangle_H$ for $z, z' \in \mathcal{X}$. Let $\mathcal{H}$ be the linear subspace defined by*

$$\mathcal{H} := \{ f_w \ ; \ w \in H \} \quad s.t. \quad f_w : z \mapsto \langle w, \psi(z) \rangle_H,$$

and consider the norm

$$\|f_w\|_{\mathcal{H}}^2 := \inf_{w' \in H} \{ \|w'\|_H^2 \quad s.t. \quad f_w = f_{w'} \}.$$

Then $\mathcal{H}$ is the reproducing kernel Hilbert space associated to kernel K.

A consequence of this result is that the RKHS of the kernel $\mathcal{K}_n(x,x') = \langle \Phi(x), \Phi(x') \rangle$, defined from a given final representation $\Phi(x) \in \mathcal{H}_{n+1}$ such as the one introduced in Section 2, contains functions of the form $f : x \mapsto \langle w, \Phi(x) \rangle$ with $w \in \mathcal{H}_{n+1}$, and the RKHS norm of such a function satisfies $\|f\| \leq \|w\|_{\mathcal{H}_{n+1}}$.

Appendix B. Proofs Related to the Multilayer Kernel Construction

B.1. Proof of Lemma 1 and Non-Expansiveness of the Gaussian Kernel

We begin with the proof of Lemma 1 related to homogeneous dot-product kernels (2).

Proof In this proof, we drop all indices k since there is no ambiguity. We will prove the more general result that φ is ρ_k-Lipschitz with $\rho_k = \max(1, \sqrt{\kappa'(1)})$ for any value of $\kappa'(1)$ (in particular, it is non-expansive when $\kappa'(1) \leq 1$).

Let us consider the Maclaurin expansion $\kappa(u) = \sum_{j=0}^{+\infty} b_j u^j < +\infty$ with $b_j \geq 0$ for all j and all u in $[-1,+1]$. Recall that the condition $b_j \geq 0$ comes from the positive-definiteness of K (Schoenberg, 1942). Then, we have $\kappa'(u) = \sum_{j=1}^{+\infty} j b_j u^{j-1}$. Noting that $j b_j u^{j-1} \leq j b_j$ for $u \in [-1,1]$, we have $\kappa'(u) \leq \kappa'(1)$ on $[-1,1]$. The fundamental theorem of calculus then yields, for $u \in [-1,1]$,

$$\kappa(u) = \kappa(1) - \int_u^1 \kappa'(t) dt \geq \kappa(1) - \kappa'(1)(1-u). \tag{22}$$

Then, if $z, z' \neq 0$,

$$\|\varphi(z) - \varphi(z')\|^2 = K(z,z) + K(z',z') - 2K(z,z') = \|z\|^2 + \|z'\|^2 - 2\|z\|\|z'\|\kappa(u),$$

with $u = \langle z, z' \rangle / (\|z\|\|z'\|)$. Using (22) with $\kappa(1) = 1$, we have

$$\begin{aligned}
\|\varphi(z) - \varphi(z')\|^2 &\leq \|z\|^2 + \|z'\|^2 - 2\|z\|\|z'\| \left(1 - \kappa'(1) + \kappa'(1) u\right) \\
&= (1 - \kappa'(1)) \left(\|z\|^2 + \|z'\|^2 - 2\|z\|\|z'\| \right) + \kappa'(1) \left(\|z\|^2 + \|z'\|^2 - 2\langle z, z' \rangle \right) \\
&= (1 - \kappa'(1)) \left| \|z\| - \|z'\| \right|^2 + \kappa'(1) \|z - z'\|^2 \\
&\leq \begin{cases} \|z - z'\|^2, & \text{if } 0 \leq \kappa'(1) \leq 1 \\ \kappa'(1) \|z - z'\|^2, & \text{if } \kappa'(1) > 1 \end{cases} \\
&= \rho_k^2 \|z - z'\|^2,
\end{aligned}$$

with $\rho_k = \max(1, \sqrt{\kappa'(1)})$, which yields the desired result. Finally, we remark that we have shown the relation $\kappa(u) \geq \kappa(1) - \kappa'(1) + \kappa'(1) u$; when $\kappa'(1) = 1$, this immediately yields (3).

If $z = 0$ or $z' = 0$, the result also holds trivially. For example,

$$\|\varphi(z) - \varphi(0)\|^2 = K(z,z) + K(0,0) - 2K(z,0) = \|z\|^2 = \|z - 0\|^2.$$

■

Non-expansiveness of the Gaussian kernel. We now consider the Gaussian kernel

$$K(z,z') := e^{-\frac{\alpha}{2}\|z - z'\|^2},$$

with feature map φ. We simply use the convexity inequality $e^u \geq 1 + u$ for all u, and

$$\|\varphi(z) - \varphi(z')\|^2 = K(z,z) + K(z',z') - 2K(z,z') = 2 - 2e^{-\frac{\alpha}{2}\|z - z'\|^2} \leq \alpha \|z - z'\|^2.$$

In particular, φ is non-expansive when $\alpha \leq 1$.

Appendix C. Proofs of Recovery and Stability Results

C.1. Proof of Lemma 2

Proof We denote by $\bar{\Omega}$ the discrete set of sampling points considered in this lemma. The assumption on $\bar{\Omega}$ can be written as $\{u + v \ ; \ u \in \bar{\Omega}, v \in S_k\} = \mathbb{R}^d$.

Let B denote an orthonormal basis of the Hilbert space $\mathcal{P}_k = L^2(S_k, \mathcal{H}_{k-1})$, and define the linear function f_w in $\mathcal{H}_k$ such that $f_w : z \mapsto \langle w, z \rangle$ for w in $\mathcal{P}_k$. We thus have

$$\begin{aligned}
P_k x_{k-1}(u) &= \sum_{w \in B} \langle w, P_k x_{k-1}(u) \rangle w \\
&= \sum_{w \in B} f_w(P_k x_{k-1}(u)) w \\
&= \sum_{w \in B} \langle f_w, M_k P_k x_{k-1}(u) \rangle w,
\end{aligned}$$

using the reproducing property in the RKHS $\mathcal{H}_k$. Applying the pooling operator A_k yields

$$\begin{aligned}
A_k P_k x_{k-1}(u) &= \sum_{w \in B} \langle f_w, A_k M_k P_k x_{k-1}(u) \rangle w, \\
&= \sum_{w \in B} \langle f_w, x_k(u) \rangle w.
\end{aligned}$$

Noting that $A_k P_k x_{k-1} = A_k (L_v x_{k-1})_{v \in S_k} = (A_k L_v x_{k-1})_{v \in S_k} = (L_v A_k x_{k-1})_{v \in S_k} = P_k A_k x_{k-1}$, with $L_v x_{k-1}(u) := x_{k-1}(u+v)$, we can choose v in S_k and obtain from the previous relations

$$A_k x_{k-1}(u + v) = \sum_{w \in B} \langle f_w, x_k(u) \rangle w(v).$$

Thus, taking all sampling points $u \in \bar{\Omega}$ and all $v \in S_k$, we have a full view of the signal $A_k x_{k-1}$ on all of $\mathbb{R}^d$ by our assumption on the set $\bar{\Omega}$.

For $f \in \mathcal{H}_{k-1}$, the signal $\langle f, x_{k-1}(u)\rangle$ can then be recovered by deconvolution as follows:

$$\langle f, x_{k-1}(u)\rangle = \mathcal{F}^{-1}\left(\frac{\mathcal{F}(\langle f, A_k x_{k-1}(\cdot)\rangle)}{\mathcal{F}(h_{\sigma_k})}\right)(u),$$

where $\mathcal{F}$ denotes the Fourier transform. Note that the inverse Fourier transform is well-defined here because the signal $\langle f, A_k x_k(\cdot)\rangle$ is itself a convolution with h_{σ_k}, and $\mathcal{F}(h_{\sigma_k})$ is strictly positive as the Fourier transform of a Gaussian is also a Gaussian.

By considering all elements f in an orthonormal basis of $\mathcal{H}_{k-1}$, we can recover x_{k-1}. The map x_k can then be reconstructed trivially by applying operators P_k, M_k and A_k on x_{k-1}. ■

C.2. Proof of Lemma 3

Proof In this proof, we drop the bar notation on all quantities for simplicity; there is indeed no ambiguity since all signals are discrete here. First, we recall that $\mathcal{H}_k$ contains all linear functions on $\mathcal{P}_k = \mathcal{H}_{k-1}^{e_k}$; thus, we may consider in particular functions $f_{j,w}(z) := e_k^{1/2}\langle w, z_j\rangle$ for $j \in \{1, \dots, e_k\}$, $w \in \mathcal{H}_{k-1}$, and $z = (z_1, z_2, \dots, z_{e_k})$ in $\mathcal{P}_k$. Then, we may evaluate

$$\begin{aligned}
\langle f_{j,w}, s_k^{-1/2} x_k[n]\rangle &= \sum_{m\in\mathbb{Z}} h_k[ns_k - m]\langle f_{j,w}, M_k P_k x_{k-1}[m]\rangle \\
&= \sum_{m\in\mathbb{Z}} h_k[ns_k - m]\langle f_{j,w}, \varphi_k(P_k x_{k-1}[m])\rangle \\
&= \sum_{m\in\mathbb{Z}} h_k[ns_k - m] f_{j,w}(P_k x_{k-1}[m]) \\
&= \sum_{m\in\mathbb{Z}} h_k[ns_k - m]\langle w, x_{k-1}[m+j]\rangle \\
&= \sum_{m\in\mathbb{Z}} h_k[ns_k + j - m]\langle w, x_{k-1}[m]\rangle \\
&= (h_k * \langle w, x_{k-1}\rangle)[ns_k + j],
\end{aligned}$$

where, with an abuse of notation, $\langle w, x_{k-1}\rangle$ is the real-valued discrete signal such that $\langle w, x_{k-1}\rangle[n] = \langle w, x_{k-1}[n]\rangle$. Since integers of the form $(ns_k + j)$ cover all of $\mathbb{Z}$ according to the assumption $e_k \geq s_k$, we have a full view of the signal $(h_k * \langle w, x_{k-1}\rangle)$ on $\mathbb{Z}$. We will now follow the same reasoning as in the proof of Lemma 2 to recover $\langle w, x_{k-1}\rangle$:

$$\langle w, x_{k-1}\rangle = \mathcal{F}^{-1}\left(\frac{\mathcal{F}(h_k * \langle w, x_{k-1}\rangle)}{\mathcal{F}(h_k)}\right),$$

where $\mathcal{F}$ is the Fourier transform. Since the signals involved there are discrete, their Fourier transform are periodic with period 2π, and we note that $\mathcal{F}(h_k)$ is strictly positive and bounded away from zero. The signal x_{k-1} is then recovered exactly as in the proof of Lemma 2 by considering for w the elements of an orthonormal basis of $\mathcal{H}_{k-1}$. ■

C.3. Proof of Proposition 4

Proof Define $(MPA)_{k:j} := M_k P_k A_{k-1} M_{k-1} P_{k-1} A_{k-2} \cdots M_j P_j A_{j-1}$. Using the fact that $\|A_k\| \leq 1$, $\|P_k\| = 1$ and M_k is non-expansive, we obtain

$$\begin{aligned}
\|\Phi_n(L_\tau x) - \Phi_n(x)\| &= \|A_n(MPA)_{n:2} M_1 P_1 A_0 L_\tau x - A_n(MPA)_{n:2} M_1 P_1 A_0 x\| \\
&\leq \|A_n(MPA)_{n:2} M_1 P_1 A_0 L_\tau x - A_n(MPA)_{n:2} M_1 L_\tau P_1 A_0 x\| \\
&\quad + \|A_n(MPA)_{n:2} M_1 L_\tau P_1 A_0 x - A_n(MPA)_{n:2} M_1 P_1 A_0 x\| \\
&\leq \|[P_1 A_0, L_\tau]\|\|x\| \\
&\quad + \|A_n(MPA)_{n:2} M_1 L_\tau P_1 A_0 x - A_n(MPA)_{n:2} M_1 P_1 A_0 x\|.
\end{aligned}$$

Note that M_1 is defined point-wise, and thus commutes with L_τ:

$$M_1 L_\tau x(u) = \varphi_1(L_\tau x(u)) = \varphi_1(x(u - \tau(u)) = M_1 x(u - \tau(u)) = L_\tau M_1 x(u).$$

By noticing that $\|M_1 P_1 A_0 x\| \leq \|x\|$, we can expand the second term above in the same way. Repeating this by induction yields

$$\begin{aligned}
\|\Phi_n(L_\tau x) - \Phi_n(x)\| &\leq \sum_{k=1}^{n} \|[P_k A_{k-1}, L_\tau]\|\|x\| + \|A_n L_\tau (MPA)_{n:1} x - A_n (MPA)_{n:1} x\| \\
&\leq \sum_{k=1}^{n} \|[P_k A_{k-1}, L_\tau]\|\|x\| + \|A_n L_\tau - A_n\|\|x\|,
\end{aligned}$$

and the result follows by decomposing $A_n L_\tau = [A_n, L_\tau] + L_\tau A_n$ and applying the triangle inequality. ■

C.4. Proof of Lemma 5

Proof The proof follows in large parts the methodology introduced by Mallat (2012) in the analysis of the stability of the scattering transform. More precisely, we will follow in part the proof of Lemma E.1 of Mallat (2012). The kernel (in the sense of Lemma A.1) of A_σ is $h_\sigma(z - u) = \sigma^{-d} h(\frac{z-u}{\sigma})$. Throughout the proof, we will use the following bounds on the decay of h for simplicity, as in Mallat (2012):[2]

$$\begin{aligned}
|h(u)| &\leq \frac{C_h}{(1 + |u|)^{d+2}} \\
|\nabla h(u)| &\leq \frac{C'_h}{(1 + |u|)^{d+2}},
\end{aligned}$$

which are satisfied for the Gaussian function h thanks to its exponential decay.

We now decompose the commutator

$$[L_c A_\sigma, L_\tau] = L_c A_\sigma L_\tau - L_\tau L_c A_\sigma = L_c(A_\sigma - L_c^{-1} L_\tau L_c A_\sigma L_\tau^{-1}) L_\tau = L_c T L_\tau,$$

2. Note that a more precise analysis may be obtained by using finer decay bounds.

with $T := A_\sigma - L_c^{-1} L_\tau L_c A_\sigma L_\tau^{-1}$. Hence,

$$\|[L_c A_\sigma, L_\tau]\| \leq \|L_c\| \|L_\tau\| \|T\|.$$

We have $\|L_c\| = 1$ since the translation operator L_c preserves the norm. Note that we have

$$2^{-d} \leq (1 - \|\nabla\tau\|_\infty)^d \leq \det(I - \nabla\tau(u)) \leq (1 + \|\nabla\tau\|_\infty)^d \leq 2^d, \tag{23}$$

for all $u \in \mathbb{R}^d$. Thus, for $f \in L^2(\mathbb{R}^d)$,

$$\begin{aligned}\|L_\tau f\|^2 &= \int_{\mathbb{R}^d} |f(z - \tau(z))|^2 dz = \int_{\mathbb{R}^d} |f(u)|^2 \det(I - \nabla\tau(u))^{-1} du \\ &\leq (1 - \|\nabla\tau\|_\infty)^{-d} \|f\|^2,\end{aligned}$$

such that $\|L_\tau\| \leq (1 - \|\nabla\tau\|_\infty)^{-d/2} \leq 2^{d/2}$. This yields

$$\|[L_c A_\sigma, L_\tau]\| \leq 2^{d/2} \|T\|.$$

Kernel of T. We now show that T is an integral operator and describe its kernel. Let $\xi = (I - \tau)^{-1}$, so that $L_\tau^{-1} f(z) = f(\xi(z))$ for any function f in $L^2(\mathbb{R}^d)$. We have

$$\begin{aligned}A_\sigma L_\tau^{-1} f(z) &= \int h_\sigma(z - v) f(\xi(v)) dv \\ &= \int h_\sigma(z - u + \tau(u)) f(u) \det(I - \nabla\tau(u)), du\end{aligned}$$

using the change of variable $v = u - \tau(u)$, giving $\left|\frac{dv}{du}\right| = \det(I - \nabla\tau(u))$. Then note that $L_c^{-1} L_\tau L_c f(z) = L_\tau L_c f(z + c) = L_c f(z + c - \tau(z + c)) = f(z - \tau(z + c))$. This yields the following kernel for the operator T:

$$k(z, u) = h_\sigma(z - u) - h_\sigma(z - \tau(z + c) - u + \tau(u)) \det(I - \nabla\tau(u)). \tag{24}$$

A similar operator appears in Lemma E.1 of Mallat (2012), whose kernel is identical to (24) when $c = 0$.

Like Mallat (2012), we decompose $T = T_1 + T_2$, with kernels

$$\begin{aligned}k_1(z, u) &= h_\sigma(z - u) - h_\sigma((I - \nabla\tau(u))(z - u)) \det(I - \nabla\tau(u)) \\ k_2(z, u) &= \det(I - \nabla\tau(u)) \left(h_\sigma((I - \nabla\tau(u))(z - u)) - h_\sigma(z - \tau(z + c) - u + \tau(u))\right).\end{aligned}$$

The kernel $k_1(z, u)$ appears in (Mallat, 2012), whereas the kernel $k_2(z, u)$ involves a shift c which is not present in (Mallat, 2012). For completeness, we include the proof of the bound for both operators, even though only dealing with k_2 requires slightly new developments.

Bound on $\|T_1\|$. We can write $k_1(z, u) = \sigma^{-d} g(u, (z - u)/\sigma)$ with

$$\begin{aligned}g(u, v) &= h(v) - h((I - \nabla\tau(u))v) \det(I - \nabla\tau(u)) \\ &= (1 - \det(I - \nabla\tau(u)))h((I - \nabla\tau(u))v) + h(v) - h((I - \nabla\tau(u))v).\end{aligned}$$

Using the fundamental theorem of calculus on h, we have

$$h(v) - h((I - \nabla\tau(u))v) = \int_0^1 \langle \nabla h((I + (t - 1)\nabla\tau(u))v), \nabla\tau(u)v \rangle dt.$$

Noticing that

$$|(I + (t - 1)\nabla\tau(u))v| \geq (1 - \|\nabla\tau\|_\infty)|v| \geq (1/2)|v|,$$

and that $\det(I - \nabla\tau(u))) \geq (1 - \|\nabla\tau\|_\infty)^d \geq 1 - d\|\nabla\tau\|_\infty$, we bound each term as follows

$$\begin{aligned}|(1 - \det(I - \nabla\tau(u)))h((I - \nabla\tau(u))v)| &\leq d\|\nabla\tau\|_\infty \frac{C_h}{(1 + \frac{1}{2}|v|)^{d+2}} \\ \left|\int_0^1 \langle \nabla h((I + (t - 1)\nabla\tau(u))v), \nabla\tau(u)v \rangle dt\right| &\leq \|\nabla\tau\|_\infty \frac{C_h' |v|}{(1 + \frac{1}{2}|v|)^{d+2}}.\end{aligned}$$

We thus have

$$|g(u, v)| \leq \|\nabla\tau\|_\infty \frac{C_h d + C_h' |v|}{(1 + \frac{1}{2}|v|)^{d+2}}.$$

Using appropriate changes of variables in order to bound $\int |k_1(z, u)| du$ and $\int |k_1(z, u)| dz$, Schur's test yields

$$\|T_1\| \leq C_1 \|\nabla\tau\|_\infty, \tag{25}$$

with

$$C_1 = \int_{\mathbb{R}^d} \frac{C_h d + C_h' |v|}{(1 + \frac{1}{2}|v|)^{d+2}} dv$$

Bound on $\|T_2\|$. Let $\alpha(z, u) = \tau(z + c) - \tau(u) - \nabla\tau(u)(z - u)$, and note that we have

$$\begin{aligned}|\alpha(z, u)| &\leq |\tau(z + c) - \tau(u)| + |\nabla\tau(u)(z - u)| \\ &\leq \|\nabla\tau\|_\infty |z + c - u| + \|\nabla\tau\|_\infty |z - u| \\ &\leq \|\nabla\tau\|_\infty (|c| + 2|z - u|).\end{aligned} \tag{26}$$

The fundamental theorem of calculus yields

$$k_2(z, u) = -\det(I - \nabla\tau(u)) \int_0^1 \langle \nabla h_\sigma(z - \tau(z + c) - u + \tau(u) - t\alpha(z, u)), \alpha(z, u) \rangle dt.$$

We note that $|\det(I - \nabla\tau(u))| \leq 2^d$, and $\nabla h_\sigma(v) = \sigma^{-d-1} \nabla h(v/\sigma)$. Using the change of variable $z' = (z - u)/\sigma$, we obtain

$$\begin{aligned}&\int |k_2(z, u)| dz \\ &\quad \leq 2^d \int \int_0^1 \left|\nabla h\left(z' + \frac{\tau(u + \sigma z' + c) - \tau(u) - t\alpha(u + \sigma z', u)}{\sigma}\right)\right| \left|\frac{\alpha(u + \sigma z', u)}{\sigma}\right| dt dz'.\end{aligned}$$

We can use the upper bound (26), together with our assumption $|c| \leq \kappa\sigma$:

$$\left|\frac{\alpha(u + \sigma z', u)}{\sigma}\right| \leq \|\nabla\tau\|_\infty (\kappa + 2|z'|). \tag{27}$$

Separately, we have $|\nabla h(v(z'))| \leq C'_h/(1+|v(z')|)^{d+2}$, with

$$v(z') := z' + \frac{\tau(u+\sigma z'+c) - \tau(u) - t\alpha(u+\sigma z', u)}{\sigma}.$$

For $|z'| > 2\kappa$, we have

$$\begin{aligned}\left|\frac{\tau(u+\sigma z'+c) - \tau(u) - t\alpha(u+\sigma z', u)}{\sigma}\right| &= \left|t\nabla\tau(u)z' + (1-t)\frac{\tau(u+\sigma z'+c)-\tau(u)}{\sigma}\right| \\ &\leq t\|\nabla\tau\|_\infty|z'| + (1-t)\|\nabla\tau\|_\infty(|z'|+\kappa) \\ &\leq \frac{3}{2}\|\nabla\tau\|_\infty|z'| \leq \frac{3}{4}|z'|,\end{aligned}$$

and hence, using the reverse triangle inequality, $|v(z')| \geq |z'| - \frac{3}{4}|z'| = \frac{1}{4}|z'|$. This yields the upper bound

$$|\nabla h(v(z'))| \leq \begin{cases} C'_h, & \text{if } |z'| \leq 2\kappa \\ \frac{C'_h}{(1+\frac{1}{4}|z'|)^{d+2}}, & \text{if } |z'| > 2\kappa. \end{cases} \tag{28}$$

Combining these two bounds, we obtain

$$\int |k_2(z,u)|dz \leq C_2\|\nabla\tau\|_\infty,$$

with

$$C_2 := 2^d C'_h\left(\int_{|z'|<2\kappa}(\kappa+2|z'|)dz' + \int_{|z'|>2\kappa}\frac{\kappa+2|z'|}{(1+\frac{1}{4}|z'|)^{d+2}}dz'\right).$$

Note that the dependence of the first integral on κ is of order k^{d+1}. Following the same steps with the change of variable $u' = (z-u)/\sigma$, we obtain the bound $\int|k_2(z,u)|du \leq C_2\|\nabla\tau\|_\infty$. Schur's test then yields

$$\|T_2\| \leq C_2\|\nabla\tau\|_\infty. \tag{29}$$

We have thus proven

$$\|[L_c A_\sigma, L_\tau]\| \leq 2^{d/2}\|T\| \leq 2^{d/2}(C_1+C_2)\|\nabla\tau\|_\infty.$$

■

C.5. Discussion and Proof of Norm Preservation

We now state a result which shows that while the kernel representation may lose some of the energy of the original signal, it preserves a part of it, ensuring that the stability bound in Theorem 7 is non-trivial. We consider in this section the full kernel representation, including a prediction layer, which is given by $\Phi(x) = \varphi_{n+1}(\Phi_n(x))$, where φ_{n+1} is the kernel feature map of either a Gaussian kernel (7) with $\alpha = 1$, or a linear kernel (6). In both cases, φ_{n+1} is non-expansive, which yields

$$\|\Phi(L_\tau x) - \Phi(x)\| \leq \|\Phi_n(L_\tau x) - \Phi_n(x)\|,$$

such that the stability result of Theorem 7 also applies to Φ. For the Gaussian case, we trivially have a representation with norm 1, which trivially shows a preservation of norm, while for the linear case, at least part of the signal energy is preserved, in particular the energy in the low frequencies, which is predominant, for instance, in natural images (Torralba and Oliva, 2003).

Lemma 15 (Norm preservation) *For the two choices of prediction layers, $\Phi(x)$ satisfies*

$$\|\Phi(x)\| = 1 \quad \textit{(Gaussian)}, \qquad \|\Phi(x)\| \geq \|A_n A_{n-1}\dots A_0 x\| \quad \textit{(Linear)}.$$

It follows that the representation Φ is not contractive:

$$\sup_{x,x'\in L^2(\mathbb{R}^d,\mathcal{H}_0)} \frac{\|\Phi(x)-\Phi(x')\|}{\|x-x'\|} = 1. \tag{30}$$

Proof We begin by studying $\|\Phi(x)\|$. The Gaussian case is trivial since the Gaussian kernel mapping φ_{n+1} maps all points to the sphere. In the linear case, we have

$$\begin{aligned}\|\Phi(x)\|^2 = \|\Phi_n(x)\|^2 &= \|A_n M_n P_n x_{n-1}\|^2 \\ &= \int \|A_n M_n P_n x_{n-1}(u)\|^2 du \\ &= \int \langle \int h_{\sigma_n}(u-v) M_n P_n x_{n-1}(v)dv, \int h_{\sigma_n}(u-v') M_n P_n x_{n-1}(v')dv'\rangle du \\ &= \int\int\int h_{\sigma_n}(u-v)h_{\sigma_n}(u-v')\langle\varphi_n(P_n x_{n-1}(v)), \varphi_n(P_n x_{n-1}(v'))\rangle dvdv'du \\ &\geq \int\int\int h_{\sigma_n}(u-v)h_{\sigma_n}(u-v')\langle P_n x_{n-1}(v), P_n x_{n-1}(v')\rangle dvdv'du \\ &= \int \|A_n P_n x_{n-1}(u)\|^2 du = \|A_n P_n x_{n-1}\|^2,\end{aligned}$$

where the inequality follows from $\langle\varphi_n(z), \varphi_n(z')\rangle = K_n(z,z') \geq \langle z, z'\rangle$ (see Lemma 1). Using Fubini's theorem and the fact that A_n commutes with translations, we have

$$\begin{aligned}\|A_n P_n x_{n-1}\|^2 &= \int_{S_n} \|A_n L_v x_{n-1}\|^2 d\nu_n(v) \\ &= \int_{S_n} \|L_v A_n x_{k-1}\|^2 d\nu_n(v) \\ &= \int_{S_n} \|A_n x_{k-1}\|^2 d\nu_n(v) \\ &= \|A_n x_{n-1}\|^2,\end{aligned}$$

where we used the fact that translations L_v preserve the norm. Note that we have

$$A_n x_{n-1} = A_n A_{n-1} M_{n-1} P_{n-1} x_{n-2} = A_{n,n-1} M_{n-1} P_{n-1} x_{n-2},$$

where $A_{n,n-1}$ is an integral operator with positive kernel $h_{\sigma_n} * h_{\sigma_{n-1}}$. Repeating the above relation then yields

$$\|\Phi(x)\|^2 \geq \|A_n x_{n-1}\|^2 \geq \|A_n A_{n-1} x_{n-1}\|^2 \geq \dots \geq \|A_n A_{n-1}\dots A_0 x\|^2,$$

and the result follows.

We now show (30). By our assumptions on φ_{n+1} and on the operators A_k, M_k, P_k, we have that Φ is non-expansive, so that

$$\sup_{x,x' \in L^2(\mathbb{R}^d, \mathcal{H}_0)} \frac{\|\Phi(x) - \Phi(x')\|}{\|x - x'\|} \leq 1.$$

It then suffices to show that one can find x, x' such that the norm ratio $\frac{\|\Phi(x)-\Phi(x')\|}{\|x-x'\|}$ is arbitrarily close to 1. In particular, we begin by showing that for any signal $x \neq 0$ we have

$$\lim_{\lambda \to 1} \frac{\|\Phi(\lambda x) - \Phi(x)\|}{\|\lambda x - x\|} \geq \frac{\|A_\sigma x\|}{\|x\|}, \tag{31}$$

where A_σ is the pooling operator with scale $\sigma = (\sigma_n^2 + \sigma_{n-1}^2 + \ldots + \sigma_1^2)^{1/2}$, and the result will follow by considering appropriate signals x that make this lower bound arbitrarily close to 1.

Note that by homogeneity of the kernels maps φ_k (which follows from the homogeneity of kernels K_k), and by linearity of the operators A_k and P_k, we have $\Phi_n(\lambda x) = \lambda \Phi_n(x)$ for any $\lambda \geq 0$. Taking $\lambda > 0$, we have

$$\|\Phi_n(\lambda x) - \Phi_n(x)\| = (\lambda - 1)\|\Phi_n(x)\| \geq (\lambda - 1)\|A_n A_{n-1} \ldots A_0 x\| = (\lambda - 1)\|A_\sigma x\|,$$

adapting Lemma 15 to the representation Φ_n. Thus,

$$\lim_{\lambda \to 1} \frac{\|\Phi_n(\lambda x) - \Phi_n(x)\|}{\|\lambda x - x\|} \geq \frac{\|A_\sigma x\|}{\|x\|}.$$

When φ_{n+1} is linear, we immediately obtain (31) since $\|\Phi(\lambda x) - \Phi(x)\| = \|\Phi_n(\lambda x) - \Phi_n(x)\|$. For the Gaussian case, we have

$$\begin{aligned}
\|\Phi(\lambda x) - \Phi(x)\|^2 &= 2 - 2e^{-\frac{1}{2}\|\Phi_n(\lambda x) - \Phi_n(x)\|^2} \\
&= 2 - 2e^{-\frac{1}{2}(\lambda-1)^2\|\Phi_n(x)\|^2} \\
&= (\lambda - 1)^2 \|\Phi_n(x)\|^2 + o((\lambda - 1)^2) \\
&= \|\Phi_n(\lambda x) - \Phi_n(x)\|^2 + o((\lambda - 1)^2),
\end{aligned}$$

which yields (31).

By considering a Gaussian signal with scale $\tau \gg \sigma$, we can make $\frac{\|A_\sigma x\|}{\|x\|}$ arbitrarily close to 1 by taking an arbitrarily large τ. It follows that

$$\sup_x \lim_{\lambda \to 1} \frac{\|\Phi(\lambda x) - \Phi(x)\|}{\|\lambda x - x\|} = 1,$$

which yields the result. ■

C.6. Proof of Lemma 9

Proof We have

$$\begin{aligned}
Px((u,\eta)) &= (v \in \tilde{S} \mapsto x((u,\eta)(v,0))) \\
&= (v \in \tilde{S} \mapsto x((u + R_\eta v, \eta))) \\
&= (v \in R_\eta \tilde{S} \mapsto x((u + v, \eta))) \\
Ax((u,\eta)) &= \int_{\mathbb{R}^2} x((u,\eta)(v,0)) h(v) dv \\
&= \int_{\mathbb{R}^2} x((u + R_\eta v, \eta)) h(v) dv \\
&= \int_{\mathbb{R}^2} x((v,\eta)) h(R_{-\eta}(v - u)) dv \\
&= \int_{\mathbb{R}^2} x((v,\eta)) h(u - v) dv,
\end{aligned}$$

where the last equality uses the circular symmetry of a Gaussian around the origin. For a diffeomorphism τ, we denote by L_τ the action operator given by $L_\tau x((u,\eta)) = x((\tau(u), 0)^{-1}(u,\eta)) = x((u - \tau(u), \eta))$. If we denote $x(\cdot, \eta)$ the $L^2(\mathbb{R}^2)$ signal obtained from a signal $x \in L^2(G)$ at a fixed angle, we have shown

$$\begin{aligned}
(Px)(\cdot,\eta) &= \tilde{P}_\eta(x(\cdot,\eta)) \\
(Ax)(\cdot,\eta) &= \tilde{A}(x(\cdot,\eta)) \\
(L_\tau x)(\cdot,\eta) &= \tilde{L}_\tau(x(\cdot,\eta)),
\end{aligned}$$

where $\tilde{P}_\eta, \tilde{A}, \tilde{L}_\tau$ are defined on $L^2(\mathbb{R}^2)$ as in Section 2, with a rotated patch $R_\eta \tilde{S}$ for $\tilde{P}_\eta$. Then, we have, for a signal $x \in L^2(G)$,

$$\begin{aligned}
\|[PA, L_\tau]x\|_{L^2(G)}^2 &= \int \|([PA, L_\tau]x)(\cdot,\eta)\|_{L^2(\mathbb{R}^2)}^2 d\mu_c(\eta) \\
&= \int \|[\tilde{P}_\eta \tilde{A}, \tilde{L}_\tau](x(\cdot,\eta))\|_{L^2(\mathbb{R}^2)}^2 d\mu_c(\eta) \\
&\leq \int \|[\tilde{P}_\eta \tilde{A}, \tilde{L}_\tau]\|^2 \|x(\cdot,\eta)\|_{L^2(\mathbb{R}^2)}^2 d\mu_c(\eta) \\
&\leq \left(\sup_\eta \|[\tilde{P}_\eta \tilde{A}, \tilde{L}_\tau]\|^2 \right) \|x\|_{L^2(G)}^2,
\end{aligned}$$

so that $\|[PA, L_\tau]\|_{L^2(G)} \leq \sup_\eta \|[\tilde{P}_\eta \tilde{A}, \tilde{L}_\tau]\|_{L^2(\mathbb{R}^2)}^2$. Note that we have $\sup_{c \in R_\eta \tilde{S}} |c| = \sup_{c \in \tilde{S}} |c| \leq \kappa\sigma$, since rotations preserve the norm, so that we can bound each $\|[\tilde{P}_\eta \tilde{A}, \tilde{L}_\tau]\|$ as in Section 3.1 to obtain the desired result. Similarly, $\|L_\tau A - A\|$ can be bounded as in Section 3.1. ■

C.7. Proof of Theorem 10

Proof First, note that A_c can be written as an integral operator

$$A_c x(u) = \int x((v,\eta))k(u,(v,\eta))d\mu((v,\eta)),$$

with $k(u,(v,\eta)) = \delta_u(v)$, where δ denotes the Dirac delta function. We have

$$\int |k(u,(v,\eta))|d\mu((v,\eta)) = \int |k(u,(v,\eta))|du = 1.$$

By Schur's test, we thus obtain $\|A_c\| \leq 1$. Then, note that $(\tau(u),\theta) = (0,\theta)(R_{-\theta}\tau(u),0)$, so that $L_{(\tau,\theta)} = L_{(0,\theta)}L_{\tau_\theta}$, where we write $\tau_\theta(u) = R_{-\theta}\tau(u)$. Additionally, it is easy to see that $A_c L_{(0,\theta)} = A_c$. We have

$$\begin{aligned}\|A_c\Phi_n(L_{(\tau,\theta)}x) - A_c\Phi_n(x)\| &= \|A_c\Phi_n(L_{(0,\theta)}L_{\tau_\theta}x) - A_c\Phi_n(x)\| \\ &= \|A_c L_{(0,\theta)}\Phi_n(L_{\tau_\theta}x) - A_c\Phi_n(x)\| \\ &= \|A_c\Phi_n(L_{\tau_\theta}x) - A_c\Phi_n(x)\| \\ &\leq \|\Phi_n(L_{\tau_\theta}x) - \Phi_n(x)\|,\end{aligned}$$

using the fact that the representation Φ_n is equivariant to roto-translations by construction.

We conclude by using Lemma 9 together with an adapted version of Proposition 4, and by noticing that $\|\nabla\tau_\theta\|_\infty = \|\nabla\tau\|_\infty$ and $\|\tau_\theta\|_\infty = \|\tau\|_\infty$. ■

Appendix D. Proofs Related to the Construction of CNNs in the RKHS

D.1. Proof of Lemma 11

Proof Here, we drop all indices k since there is no ambiguity. We will now characterize the functional space $\mathcal{H}$ by following the same strategy as Zhang et al. (2016, 2017b) for the non-homogeneous Gaussian and inverse polynomial kernels on Euclidean spaces. Using the Maclaurin expansion of κ, we can define the following explicit feature map for the dot-product kernel $K_{\text{dp}}(z,z') := \kappa(\langle z,z'\rangle)$, for any z in the unit-ball of $\mathcal{P}$:

$$\begin{aligned}\psi_{\text{dp}}(z) &= \left(\sqrt{b_0}, \sqrt{b_1}z, \sqrt{b_2}z\otimes z, \sqrt{b_3}z\otimes z\otimes z, \ldots\right) \\ &= \left(\sqrt{b_j}z^{\otimes j}\right)_{j\in\mathbb{N}},\end{aligned} \tag{32}$$

where $z^{\otimes j}$ denotes the tensor product of order j of the vector z. Technically, the explicit mapping lives in the Hilbert space $\oplus_{j=0}^n \otimes^j \mathcal{P}$, where $\oplus$ denotes the direct sum of Hilbert spaces, and with the abuse of notation that $\otimes^0\mathcal{P}$ is simply $\mathbb{R}$. Then, we have that $K_{\text{dp}}(z,z') = \langle\psi(z),\psi(z')\rangle$ for all z,z' in the unit ball of $\mathcal{P}$. Similarly, we can construct an explicit feature map for the homogeneous dot-product kernels (2):

$$\begin{aligned}\psi_{\text{hdp}}(z) &= \left(\sqrt{b_0}\|z\|, \sqrt{b_1}z, \sqrt{b_2}\|z\|^{-1}z\otimes z, \sqrt{b_3}\|z\|^{-2}z\otimes z\otimes z, \ldots\right) \\ &= \left(\sqrt{b_j}\|z\|^{1-j}z^{\otimes j}\right)_{j\in\mathbb{N}}.\end{aligned} \tag{33}$$

From these mappings, we may now conclude the proof by following the same strategy as Zhang et al. (2016, 2017b). By first considering the restriction of K to unit-norm vectors z,

$$\sigma(\langle w,z\rangle) = \sum_{j=0}^{+\infty} a_j\langle w,z\rangle^j = \sum_{j=0}^{+\infty} a_j\langle w^{\otimes j}, z^{\otimes j}\rangle = \langle\bar{w},\psi(z)\rangle,$$

where

$$\bar{w} = \left(\frac{a_j}{\sqrt{b_j}}w^{\otimes j}\right)_{j\in\mathbb{N}}.$$

Then, the norm of $\bar{w}$ is

$$\|\bar{w}\|^2 = \sum_{j=0}^{+\infty}\frac{a_j^2}{b_j}\|w^{\otimes j}\|^2 = \sum_{j=0}^{+\infty}\frac{a_j^2}{b_j}\|w\|^{2j} = C_\sigma^2(\|w\|^2) < +\infty.$$

Using Theorem A.1, we conclude that f is in the RKHS of K, with norm $\|f\| \leq C_\sigma(\|w\|^2)$. Finally, we extend the result to non unit-norm vectors z with similar calculations and we obtain the desired result. ■

D.2. CNN construction and RKHS norm

In this section, we describe the space of functions (RKHS) $\mathcal{H}_{\mathcal{K}_n}$ associated to the kernel $\mathcal{K}_n(x_0,x_0') = \langle x_n, x_n'\rangle$ defined in (6), where x_n, x_n' are the final representations given by Eq. (5), in particular showing it contains the set of CNNs with activations described in Section 4.1.

D.2.1. Construction of a CNN in the RKHS.

Let us consider the definition of the CNN presented in Section 4. We will show that it can be seen as a point in the RKHS of $\mathcal{K}_n$. According to Lemma 11, we consider $\mathcal{H}_k$ that contains all functions of the form $z\in\mathcal{P}_k \mapsto \|z\|\sigma(\langle w,z\rangle/\|z\|)$, with $w\in\mathcal{P}_k$.

We recall the intermediate quantities introduced in Section 4. That is, we define the initial quantities $f_1^i \in \mathcal{H}_1, g_1^i \in \mathcal{P}_1$ for $i = 1,\ldots,p_1$ such that

$$\begin{aligned}g_1^i &= w_1^i \in L^2(S_1,\mathbb{R}^{p_0}) = L^2(S_1,\mathcal{H}_0) = \mathcal{P}_1 \\ f_1^i(z) &= \|z\|\sigma(\langle g_i^0, z\rangle/\|z\|) \quad \text{for } z\in\mathcal{P}_1,\end{aligned}$$

and we recursively define, from layer k–1, the quantities $f_k^i \in \mathcal{H}_k, g_k^i \in \mathcal{P}_k$ for $i = 1,\ldots,p_k$:

$$\begin{aligned}g_k^i(v) &= \sum_{j=1}^{p_{k-1}} w_k^{ij}(v)f_{k-1}^j \quad \text{where} \quad w_k^i(v) = (w_k^{ij}(v))_{j=1,\ldots,p_{k-1}} \\ f_k^i(z) &= \|z\|\sigma(\langle g_k^i, z\rangle/\|z\|) \quad \text{for } z\in\mathcal{P}_k.\end{aligned}$$

Then, we will show that $\tilde{z}_k^i(u) = f_k^i(P_k x_{k-1}(u)) = \langle f_k^i, M_k P_k x_{k-1}(u)\rangle$, which correspond to feature maps at layer k and index i in a CNN. Indeed, this is easy to see for $k=1$ by

construction with filters $w_1^i(v)$, and for $k \geq 2$, we have

$$\begin{aligned}
\tilde{z}_k^i(u) &= n_k(u)\sigma\big(\langle w_k^i, P_k z_{k-1}(u)\rangle / n_k(u)\big) \\
&= n_k(u)\sigma\big(\langle w_k^i, P_k A_{k-1}\tilde{z}_{k-1}(u)\rangle / n_k(u)\big) \\
&= n_k(u)\sigma\left(\frac{1}{n_k(u)}\sum_{j=1}^{p_{k-1}}\int_{S_k} w_k^{ij}(v) A_{k-1}\tilde{z}_{k-1}^j(u+v)d\nu_k(v)\right) \\
&= n_k(u)\sigma\left(\frac{1}{n_k(u)}\sum_{j=1}^{p_{k-1}}\int_{S_k} w_k^{ij}(v)\langle f_{k-1}^j, A_{k-1}M_{k-1}P_{k-1}x_{k-2}(u+v)\rangle d\nu_k(v)\right) \\
&= n_k(u)\sigma\left(\frac{1}{n_k(u)}\int_{S_k}\langle g_k^i(v), A_{k-1}M_{k-1}P_{k-1}x_{k-2}(u+v)\rangle d\nu_k(v)\right) \\
&= n_k(u)\sigma\left(\frac{1}{n_k(u)}\int_{S_k}\langle g_k^i(v), x_{k-1}(u+v)\rangle d\nu_k(v)\right) \\
&= n_k(u)\sigma\left(\frac{1}{n_k(u)}\langle g_k^i(v), P_k x_{k-1}(u)\rangle\right) \\
&= f_k^i(P_k x_{k-1}(u)),
\end{aligned}$$

where $n_k(u) := \|P_k x_{k-1}(u)\|$. Note that we have used many times the fact that A_k operates on each channel independently when applied to a finite-dimensional map.

The final prediction function is of the form $f_\sigma(x_0) = \langle w_{n+1}, z_n\rangle$ with w_{n+1} in $L^2(\mathbb{R}^d, \mathbb{R}^{p_n})$. Then, we can define the following function g_σ in $L^2(\mathbb{R}^d, \mathcal{H}_n)$ such that

$$g_\sigma(u) = \sum_{j=1}^{p_n} w_{n+1}^j(u) f_n^j,$$

which yields

$$\begin{aligned}
\langle g_\sigma, x_n\rangle &= \sum_{j=1}^{p_n}\int_{\mathbb{R}^d} w_{n+1}^j(u)\langle f_n^j, x_n(u)\rangle du \\
&= \sum_{j=1}^{p_n}\int_{\mathbb{R}^d} w_{n+1}^j(u)\langle f_n^j, A_n M_n P_n x_{n-1}(u)\rangle du \\
&= \sum_{j=1}^{p_n}\int_{\mathbb{R}^d} w_{n+1}^j(u) A_n \tilde{z}_n^j(u) du \\
&= \sum_{j=1}^{p_n}\int_{\mathbb{R}^d} w_{n+1}^j(u) z_n^j(u) du \\
&= \sum_{j=1}^{p_n}\langle w_{n+1}^j, z_n^j\rangle = f_\sigma(x_0),
\end{aligned}$$

which corresponds to a linear layer after pooling. Since the RKHS of $\mathcal{K}_n$ in the linear case (6) contains all functions of the form $f(x_0) = \langle g, x_n\rangle$, for g in $L^2(\mathbb{R}^d, \mathcal{H}_n)$, we have that f_σ is in the RKHS.

D.2.2. Proof of Proposition 13

Proof As shown in Lemma 11, the RKHS norm of a function $f : z \in \mathcal{P}_k \mapsto \|z\|\sigma(\langle w, z\rangle/\|z\|)$ in $\mathcal{H}_k$ is bounded by $C_\sigma(\|w\|^2)$, where C_σ depends on the activation σ. We then have

$$\begin{aligned}
&\|f_1^i\|^2 \leq C_\sigma^2(\|w_1^i\|_2^2) \quad \text{where} \quad \|w_1^i\|_2^2 = \int_{S_1}\|w_1^i(v)\|^2 d\nu_1(v) \\
&\|f_k^i\|^2 \leq C_\sigma^2(\|g_k^i\|^2) \\
&\|g_k^i\|^2 = \int_{S_k}\|\sum_{j=1}^{p_{k-1}} w_k^{ij}(v) f_{k-1}^j\|^2 d\nu_k(v) \\
&\qquad \leq p_{k-1}\sum_{j=1}^{p_{k-1}}\left(\int_{S_k}|w_k^{ij}(v)|^2 d\nu_k(v)\right)\|f_{k-1}^j\|^2 \\
&\qquad = p_{k-1}\sum_{j=1}^{p_{k-1}}\|w_k^{ij}\|_2^2\|f_{k-1}^j\|^2,
\end{aligned}$$

where in the last inequality we use $\|a_1 + \ldots + a_n\|^2 \leq n(\|a_1\|^2 + \ldots + \|a_n\|^2)$. Since C_σ^2 is monotonically increasing (typically exponentially in its argument), we have for $k = 1, \ldots, n-1$ the recursive relation

$$\|f_k^i\|^2 \leq C_\sigma^2\left(p_{k-1}\sum_{j=1}^{p_{k-1}}\|w_k^{ij}\|_2^2\|f_{k-1}^j\|^2\right).$$

The norm of the final prediction function $f \in L^2(\mathbb{R}^d, \mathcal{H}_n)$ is bounded as follows, using similar arguments as well as Theorem A.1:

$$\|f_\sigma\|^2 \leq \|g_\sigma\|^2 \leq p_n\sum_{j=1}^{p_n}\left(\int_{\mathbb{R}^d}|w_{n+1}^j(u)|^2 du\right)\|f_n^j\|^2.$$

This yields the desired result. ∎

D.2.3. Proof of Proposition 14

Proof Define

$$\begin{aligned}
F_k &= (f_k^1, \ldots, f_k^{p_k}) \in \mathcal{H}_k^{p_k} \\
G_k &= (g_k^1, \ldots, g_k^{p_k}) \in \mathcal{P}_k^{p_k} \\
W_k(u) &= (w_k^{ij}(u))_{ij} \in \mathbb{R}^{p_k \times p_{k-1}} \quad \text{for } u \in S_k.
\end{aligned}$$

We will write, by abuse of notation, $G_k(u) = (g_k^1(u), \ldots, g_k^{p_k}(u))$ for $u \in S_k$, so that we can write $G_k(u) = W_k(u)F_{k-1}$. In particular, we have $\|G_k(u)\| \leq \|W_k(u)\|_2\|F_{k-1}\|$. This can be seen by considering an orthonormal basis B of $\mathcal{H}_k$, and defining real-valued vectors $F_k^w = (\langle w, f_k^1\rangle, \ldots, \langle w, f_k^{p_k}\rangle)$, $G_k^w(u) = (\langle w, g_k^1(u)\rangle, \ldots, \langle w, g_k^{p_k}(u)\rangle)$ for $w \in B$. Indeed, we

have $G_k^w(u) = W_k(u)F_{k-1}^w$ and hence $\|G_k^w(u)\| \leq \|W_k(u)\|_2 \|F_{k-1}^w\|$ for all $w \in B$, and we conclude using

$$\|G_k(u)\|^2 = \sum_{w \in B} \|G_k^w(u)\|^2 \leq \|W_k(u)\|_2^2 \sum_{w \in B} \|F_{k-1}^w\|^2 = \|W_k(u)\|_2^2 \, \|F_{k-1}\|^2.$$

Then, we have

$$\begin{aligned}\|G_k\|^2 &= \sum_i \|g_k^i\|^2 = \sum_i \int_{S_k} \|g_k^i(u)\|^2 d\nu_k(u) = \int_{S_k} \|G_k(u)\|^2 d\nu_k(u) \\ &\leq \int_{S_k} \|W_k(u)\|_2^2 \, \|F_{k-1}\|^2 \nu_k(u) = \|W_k\|_2^2 \, \|F_{k-1}\|^2.\end{aligned}$$

Separately, we notice that C_σ^2 is super-additive, *i.e.*,

$$C_\sigma^2(\lambda_1^2 + \ldots + \lambda_n^2) \geq C_\sigma^2(\lambda_1^2) + \ldots + C_\sigma^2(\lambda_n^2).$$

Indeed, this follows from the definition of C_σ^2, noting that polynomials with non-negative coefficients are super-additive on non-negative numbers. Thus, we have

$$\begin{aligned}\|F_1\|^2 &= \sum_{i=1}^{p_1} \|f_1^i\|^2 \leq \sum_{i=1}^{p_1} C_\sigma^2(\|w_1^i\|^2) \leq C_\sigma^2(\|W_1\|_F^2) \\ \|F_k\|^2 &\leq \sum_{i=1}^{p_k} C_\sigma^2(\|g_k^i\|^2) \leq C_\sigma^2(\|G_k\|^2), \qquad \text{for } k = 2, \ldots, n.\end{aligned}$$

Finally, note that

$$\|g_\sigma(u)\|^2 \leq \left(\sum_{j=1}^{p_n} |w_{n+1}^j(u)| \|f_n^j\| \right)^2 \leq \|w_{n+1}(u)\|^2 \|F_n\|^2,$$

by using Cauchy-Schwarz, so that $\|g_\sigma\|^2 \leq \|w_{n+1}\|^2 \|F_n\|^2$. Thus, combining the previous relations yields

$$\|f_\sigma\|^2 \leq \|g_\sigma\|^2 \leq \|w_{n+1}\|^2 \, C_\sigma^2(\|W_n\|_2^2 \, C_\sigma^2(\|W_{n-1}\|_2^2 \ldots C_\sigma^2(\|W_1\|_F^2) \ldots)),$$

which is the desired result. ■

Abstract

Tensors are higher-order extensions of matrices. While matrix methods form the cornerstone of traditional machine learning and data analysis, tensor methods have been gaining increasing traction. However, software support for tensor operations is not on the same footing. In order to bridge this gap, we have developed *TensorLy*, a Python library that provides a high-level API for tensor methods and deep tensorized neural networks. TensorLy aims to follow the same standards adopted by the main projects of the Python scientific community, and to seamlessly integrate with them. Its BSD license makes it suitable for both academic and commercial applications. TensorLy's backend system allows users to perform computations with several libraries such as NumPy or PyTorch to name but a few. They can be scaled on multiple CPU or GPU machines. In addition, using the deep-learning frameworks as backend allows to easily design and train deep tensorized neural networks. TensorLy is available at `https://github.com/tensorly/tensorly`

1. Introduction

Tensors are higher-order extensions of matrices. While matrices are indexed by two indices (and hence, second order tensors), tensors can be indexed by an arbitrary number of indices. Tensors have a rich history, stretching almost a century, and have been used in diverse fields such as psychometrics, quantum systems, signal processing etc. Only recently have tensors been employed in machine learning and data analytics. This can be attributed to the availability of large-scale multi-dimensional and multi-modal datasets. Tensors form the natural framework to encode and operate on such data structures.

For multi-dimensional datasets, there are natural extensions of traditional dimensionality-reduction methods, such as principal component analysis (PCA), to higher dimensions. These involve tensor decompositions and have been applied in a number of areas, including the theoretical analysis of deep neural nets (Cohen et al., 2015). Another line of work aims to operate on higher-order moments of the data distribution, i.e., beyond pairwise correlations. This is shown to be fruitful for learning a wide range of probabilistic latent-variable models such as Gaussian mixtures, Independent Component Analysis, topic models etc (Anandkumar et al., 2014). More recently, deep tensorized neural networks have been explored for a variety of applications. They extend linear-algebraic operations in various layers to tensor algebraic operations, such as tensor contraction and tensor regression, in convolutional architectures (Novikov et al., 2015; Kossaifi et al., 2017), generative adversarial networks (Cao and Zhao, 2017) and sequence models (Yu et al., 2017).

Interested readers are referred to several surveys on this topic. Some works focus on the basics of multi-linear (tensor) algebra and different types of tensor decompositions, (Kolda and Bader, 2009; Sidiropoulos et al., 2016). Others focus on algorithmic advances, (Cichocki et al., 2009; Lu et al., 2011; Grasedyck et al., 2013; Cichocki et al., 2015; Papalexakis et al., 2016). Recent surveys focus on their applications (Acar and Yener, 2009) and uses in learning probabilistic models (Janzamin et al., 2019).

Thus, tensor methods can have a profound impact on data analytics and machine learning with clear theoretical, algorithmic, and practical advantages over their matrix counterparts. However, as opposed to matrix methods, tensor methods have not yet been widely adopted by data scientists. This can be mainly attributed to the lack of available software libraries for tensor operations and decompositions, in programming languages that data scientists and practitioners are familiar with (e.g., Python, Java, Scala, etc).

Even though some tensor libraries exist, they are implemented in non-free platforms (e.g., MATLAB's TensorToolbox, (Bader and Kolda, 2015) and TensorLab, (Vervliet et al., 2016)) or in low-level languages like C++ (e.g., TH++). Python is emerging as a language of choice for machine learning, as witnessed with the success of scikit-learn (Pedregosa et al., 2011), and is increasingly used in both academic and industrial research projects. However, there is not yet a Python library implementing tensor operations, decomposition, and learning. The existing ones (e.g., scikit-tensor) offer only limited functionalities and/or have restrictive licenses. Moreover, widely-adopted deep-learning libraries such as Tensorflow and Torch lack advanced tensor operations. For applications to data analytics, machine learning, and deep learning, there is an urgent need for well-developed and documented open-source libraries that include methods for tensor decompositions.

In this paper, to address the aforementioned need, the *TensorLy* [1] library is introduced, allowing several contributions over the existing libraries for tensor methods. In particular, TensorLy a) provides state-of-the-art tensor learning, including core tensor operations and algebra, tensor decomposition and tensor regression methods; b) has a flexible *backend* system that allows switching between NumPy, MXNet, PyTorch, TensorFlow, and CuPy to perform the computation, and to easily combine tensor methods with deep learning; c) is open source and BSD licensed; d) depends by default exclusively on NumPy and SciPy; and e) is accompanied by extensive tests and documentation.

2. *TensorLy*: functionalities and implementation

TensorLy has been developed with the goal of making tensor learning more accessible and to allow for seamless integration with the Python scientific environment. It depends by default only on Numpy (van der Walt et al., 2011) and Scipy, with a soft dependency on Matplotlib (Hunter, 2007) for plotting.

To enable algorithms to be easily run at scale, on various hardware, and to combine tensor methods with deep learning, TensorLy has a flexible backend system. This allows tensor operations to be ran using NumPy, MXNet (Chen et al., 2015), PyTorch (Paszke

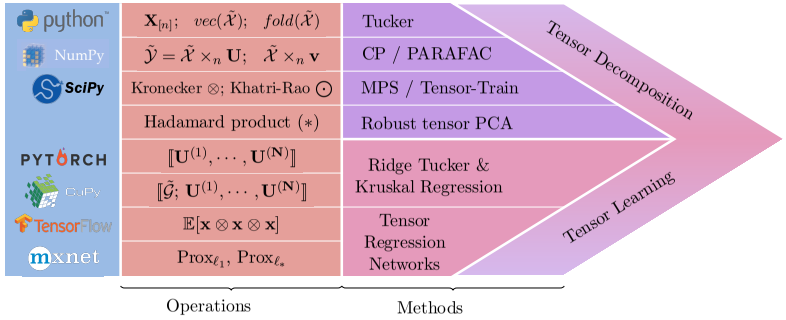

Figure 1: TensorLy builds on top of the Python ecosystem and implements Tensor Algebra *Operations*. These tensor operators are then used for higher level *Methods* such as tensor regression and decomposition, or combined with deep learning.

et al., 2017), Chainer's CuPy (Tokui et al., 2015) or TensorFlow with eager execution (Abadi et al., 2015). **NumPy** is the standard library for numerical computation in Python. It offers high performance structures for manipulating multi-dimensional arrays. **CuPy** works as a drop-in replacement for NumPy with GPU support. **MXNet** is a flexible deep learning library with an NDArray structure that allows to efficiently run code on CPU, GPU and multi-machines. Similarly, **PyTorch** provides a NumPy-like API with GPU acceleration and auto-grad using dynamical graphs. **TensorFlow** is an established machine-learning framework that provides an imperative approach using eager execution.

We aim at making the *API* simple and efficient, following that of scikit-learn (Buitinck et al., 2013), where possible. However, while scikit-learn works with observations (samples) represented as vectors, this library focuses on higher order arrays. *TensorLy*'s main functionalities in term of tensor operations are summarized in Fig. 2, where in the operations column the mathematical notation of Kolda and Bader (2009) is adopted. In the methods column, we summarize the implemented well-known tensor decomposition and regression methods. These include CP and Tucker decompositions, their non-negative versions, matrix-product-state (also known as tensor-train decomposition), Robust tensor PCA, (Goldfarb and Qin, 2014) and low-rank tensor (Kruskal and Tucker) Regression. Additionally, using the deep learning backends, it is easy to combine tensor methods and Deep Learning.

We emphasize code quality and ease of utilization for the end user. To that extent, both testing and documentation are an essential part of the package: all functions come with documentation and unit-tests (at the time of writing, the coverage is of 99%).

3. Performance

TensorLy has been tailored for the Python ecosystem: tensors are multi-dimensional arrays which are effectively manipulated directly by the various methods, decomposition or regression. This allows for competitive performance even though the library is implemented in a high-level, interactive language. The operations are also optimized for speed: tensor operations have been redefined when possible to allow for better performance. In particular,

we propose an efficient unfolding of tensors which differs from the traditional one (Kolda and Bader, 2009) by the ordering of the fibers.

Given a tensor, $\tilde{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$, the mode-$n$ unfolding of $\tilde{\mathcal{X}}$ is a matrix $\mathbf{X}_{[n]} \in \mathbb{R}^{I_n, I_M}$, and is defined by the mapping from element $(i_1, i_2, \cdots, i_N)$ to (i_n, j),

$$\text{with } j = \sum_{\substack{k=1,\\ k \neq n}}^{N} i_k \times \prod_{\substack{m=k+1,\\ k \neq n}}^{N} I_m, \quad \text{and } M = \prod_{\substack{k=1,\\ k \neq n}}^{N} I_k$$

This formulation both achieves better performance when using C-ordering of the elements (Numpy and most Python libraries' default), and translates into more natural properties.

3.1. Numerical test

We generated random third order tensors of size $500 \times 500 \times 500$ (125 million elements). We then compared the decomposition speed for a rank–50 CANDECOMP-PARAFAC (CP) and rank $(50, 50, 50)$–Tucker decomposition with TensorLy on CPU (NumPy backend) and TensorLy on GPU (MXNet, PyTorch, TensorFlow and CuPy backends), and Scikit-Tensor (*Sktensor*), Fig. 2. In all cases we fixed the number of iterations to 100 to allow for a fair comparison. The experiment was repeated 10 times, with the main bar representing the average CPU time and the tip on the bar the standard deviation of the runs. As can be observed, our library offers competitive speed, thanks to optimized formulation and implementation. Experiments were done on an Amazon Web Services p3 instance, with a NVIDIA VOLTA V100 GPU and 8 Intel Xeon E5 (Broadwell) processors.

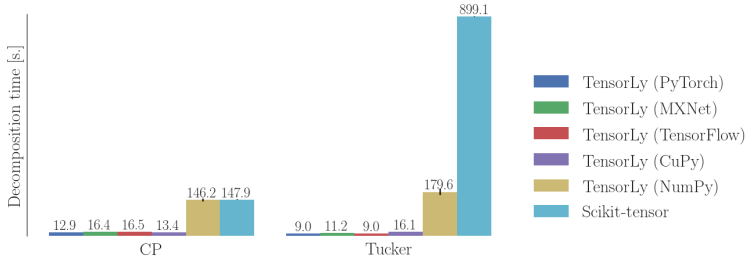

Figure 2: Speed comparison for Tucker and CANDECOMP-PARAFAC decomposition.

4. Conclusion

TensorLy makes tensor learning accessible and straightforward by offering state-of-the-art tensor methods and operations through simple and consistent interfaces, under a permissive license. It is optimized to be fast and robust, with systematic unit-tests and documentation. The library's speed and ease of use allow for an efficient comparison of existing methods and easy implementation of new ones. Its flexible backend system allows to transparently switch between libraries and platforms and help combine tensor methods with deep learning. Going forward, we will further extend the available methods with other state-of-the-art methods and target further improvements in performance, as exemplified by Shi et al. (2016).

Abstract

We introduce a new neural network model, together with a tractable and monotone online learning algorithm. Our model describes feed-forward networks for classification, with one output node for each class. The only nonlinear operation is rectification using a ReLU function with a bias. However, there is a rectifier on every edge rather than at the nodes of the network. There are also weights, but these are positive, static, and associated with the nodes. Our *rectified wire networks* are able to represent arbitrary Boolean functions. Only the bias parameters, on the edges of the network, are learned. Another departure in our approach, from standard neural networks, is that the loss function is replaced by a constraint. This constraint is simply that the value of the output node associated with the correct class should be zero. Our model has the property that the exact norm-minimizing parameter update, required to correctly classify a training item, is the solution to a quadratic program that can be computed with a few passes through the network. We demonstrate a training algorithm using this update, called sequential deactivation (SDA), on MNIST and some synthetic datasets. Upon adopting a natural choice for the nodal weights, SDA has no hyperparameters other than those describing the network structure. Our experiments explore behavior with respect to network size and depth in a family of sparse expander networks.

Keywords: Neural Networks, Online Training Algorithms, Rectified Linear Unit

Some of the simplest modes of machine learning are monotone in character, where the representation of knowledge changes unidirectionally. In the k-nearest-neighbor classification algorithm (Cover and Hart, 1967), for example, exemplars of the classes are amassed, monotonically, over the course of training. It is also possible to have monotone learning where memory does not grow, but decreases over time. Suppose we try to classify Boolean feature vectors using conjunctive normal form formulas, one for each class. Starting with large and randomly initialized formulas, during training we simply discard, from the formula of the feature vector's class, all the inconsistent clauses (Mooney, 1995). Clearly an attractive feature of both of these monotone algorithms is the computational ease of reaching the desired outcome, i.e. additional exemplars for improved discrimination, or discarded clauses to better accommodate a class.

We report on a new kind of monotone learning where during training only the values of a fixed number of parameters are changed, and in a monotone fashion. Like the two examples above, there is a simple and computationally tractable objective when learning each new item. But perhaps the most interesting feature of our scheme is that it operates on deep networks of rectifiers, a setting where training is not normally seen as computationally tractable.

Monotone learning with deep rectifier networks is made possible by two changes to the standard paradigm: (i) *conservative* updates that minimize the norm of the parameter changes, and (ii) eliminating all but the bias variables as learned parameters.

Although the feedforward computations in standard neural network models are inspired by biological neuronal computations, the training protocols in widespread use seem far from natural. Humans are able to generalize the shape of the digit 5 without suffering through many training "epochs" through a data set, and are capable of building a rudimentary representation of digits or other classes of objects from relatively few examples. The conservative learning principle, introduced to the best of our knowledge by Widrow et al. (1988) as the "minimal disturbance principle," comes closer to our experience of natural learning. In this mode of learning the parameters of the network are minimally changed to accommodate each example as it is received, with the rationale that the attention to minimality preserves the representation created by earlier examples.

The minimal disturbance principle was reprised by Crammer et al. (2006) as the "passive-aggressive algorithm", in the context of support-vector machines. There are relatively few models where "aggressive" parameter updates — minimal, yet achieving immediate results — are easily computed. To emphasize the norm-minimizing characteristic of this learning mode we use the term "conservative learning." An approximate implementation of conservative learning was successfully used to discover the Strassen rules of matrix multiplication (Elser, 2016).

In the present work we make changes to the "standard neural network model" to enable conservative learning. In broad outline, the changes guarantee monotonicity, making the computation of the conservative updates tractable. A key step was elevating the role of the additive parameter, or bias. The metaphor that replaces Hebbian synapse (weight) learning is that of a silting river delta, with myriad channels whose levels (bias) rise differentially, but monotonically, over time.

Below is an overview of our contributions.

- Inspired by analog implementations of logic, we propose replacing the conventional rectified sum computed by a standard neuron using a ReLU function

$$y \leftarrow \max\left(0,\ \sum_i w_i x_i - b\right),$$

by a sum of rectifications:

$$y \leftarrow w \sum_i \max(0,\ x_i - b_i). \tag{1}$$

Only the bias parameters are learned; the weights are static.

- Even with just positive weights w in (1), we show that networks of *rectified wires* can represent arbitrary Boolean functions. This construction makes use of doubled inputs, where TRUE is encoded as $(1, 0)$, FALSE as $(0, 1)$, and generalizes, for symbolic data, to one-hot encoding.

- The node values of our networks are non-negative. We propose defining class membership of data by the corresponding output node having value zero.

- Because the biases on all the wires are non-negative and can only increase during training, we choose to initialize them at zero.

- We show that the 2-norm minimizing change of the bias parameters, that sets the class output node for a given input to zero, is the solution to a quadratic program.

- An iterative algorithm similar to stochastic gradient descent, including both backward propagation and a new kind of forward propagation, is proposed to approximately find the 2-norm minimizing bias changes. Executing the minimum number of iterations required to make the class output node the smallest in value defines the *sequential deactivation* algorithm (SDA).

- We show that a particular limit of SDA, on networks with a single hidden layer, learns arbitrary Boolean functions.

- Networks with better scaling have multiple layers, and their training is sensitive to the settings of the static weights. We propose *balanced weights* based just on the in-degrees and out-degrees in this general setting.

- A two-parameter family of random sparse expander networks is introduced to explore the size and depth behavior of learning in our model.

- Conservative learning on rectified wire networks with the SDA algorithm is demonstrated for MNIST and synthetic datasets.

- Despite our model's capacity for depth in its representations, we find that the best experimental results with the SDA algorithm are obtained in a limit where deactivation occurs only in the final layer, where the model is equivalent to a network with just a single hidden layer of rectifier gates. The pursuit of conditions that fully utilize activation/decativation in all layers is identified as the goal of future research.

1. Rectified wire networks

One motivation for our network model is the implementation of logic by analog computations without multiplications. The analog counterparts of TRUE and FALSE are, respectively, the numbers 1 and 0. Before presenting our "rectified wire" network model, we consider networks constructed from biased rectifier gates. A biased rectifier gate with K inputs,

$$R[b](x_1, \ldots, x_K) = \max(0, x_1 + \cdots + x_K - b),$$

generalizes AND and OR gates. AND gates are realized with bias $b = K - 1$. We would get the OR gate with $b = 0$ if we could saturate the output at the value 1. We show below how this detail can be fixed with additional rectifiers and a suitable network design.

Negations are completely absent from our rectifier implementations of general logic circuits. This is made possible by the process of *demorganization*, where NOT gates are pushed through the circuit from output to input, exchanging AND and OR gates as dictated by De Morgan's laws. After all the NOT gates have been pushed through, the only remaining NOT gates act directly on the inputs. We accommodate this by allowing each input to the logic circuit to be replaced by an analog pair with values $(1, 0)$ for TRUE and $(0, 1)$ for FALSE. We refer to this encoding scheme as *input doubling*.

It is relatively straightforward to show, as we do in theorem 1.1, that networks comprising only rectifier gates, with bias variables as the only parameters, can mimic any logic circuit. From the machine learning perspective, our network model has at least the capacity to represent the classes defined by the truth value of arbitrary Boolean functions. However, the parameter settings that realize these Boolean classes are very special points in the continuous parameter space of the model, and are not claimed to be directly relevant for the intended use of these networks.

Theorem 1.1 *Any Boolean function on N inputs and computed with M binary* AND/OR *gates and any number of* NOT *gates can be implemented by an analog network comprising at most $5M$ biased rectifier gates taking the corresponding $2N$ doubled analog inputs.*

Proof As a circuit, the function takes N Boolean inputs and produces one Boolean output. We associate negations in the circuit with gate outputs as shown for the case of the AND gate in the left panel of Figure 1. Upon output, both the gate output y_1 and its negation y_2 by a NOT gate (rendered as an open circle), are made available to gates receiving inputs. One of the output forks might not be used, as for the final gate of the circuit whose single output is the value of the Boolean function. The diagram also shows how each of the gate inputs is derived from one fork of the output of another gate, or an input to the circuit.

The body of the proof consists of confirming that the Boolean gate relationship between the inputs (x_1, x_2), and the output y_1 and its negation y_2, is exactly reproduced by a corresponding rectifier gate network. The replacement for the AND gate is shown in the right panel of Figure 1. All bias parameters are either 0 or 1, and the only values that arise on the nodes are also 0 and 1. The replacement rule for the OR gate is shown in Figure 2. For both of the circuit replacement rules just described there are three others, where one or both of the inputs are negated. These are trivially generated from the ones shown by inserting a negation right after the inputs (x_1 or x_2 or both), which is equivalent to swapping the branches of the input-forks.

For completeness we include the cases where a gate receives both inputs from the same output fork. The case of the AND gate is shown in Figure 3. The replacement rule shown on the left applies when both inputs come from the same branch of the input fork, while the rule on the right applies when the inputs come from both branches. As before, the rule for the other choice of input branch is obtained by swapping branches in the replacement. For the OR gate the rule on the left of Figure 3 is unchanged, while the one on the right has the two bias values swapped.

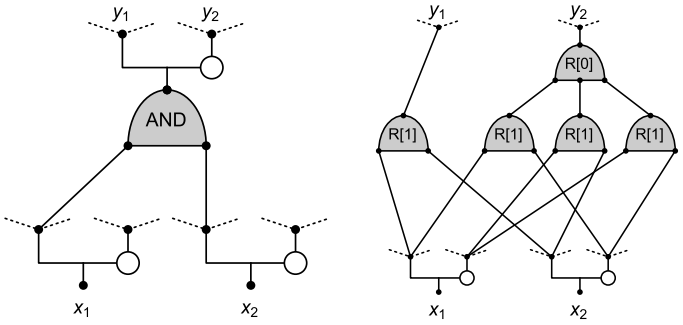

Figure 1: AND gate and its replacement with rectifier gates in the analog network.

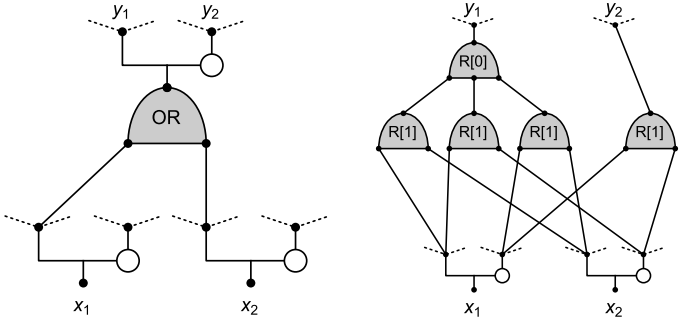

Figure 2: OR gate and its replacement with rectifier gates in the analog network.

The only negations remaining after all AND and OR gates have been replaced are those in the N input forks to the circuit. These are taken care of by defining the input to the analog network as the $2N$ values on the branches of those forks. The resulting network will have only rectifier gates. From the gate replacement rules (Figs. 1-3) we see that the number of rectifier gates is at most $5M$.

■

We now generalize our rectifier gate model in two ways. The first follows from the observation that a rectifier on K inputs with bias b is equivalent to summing those inputs and placing a (single-input) rectifier with bias b on each of the wires leaving the rectifier.

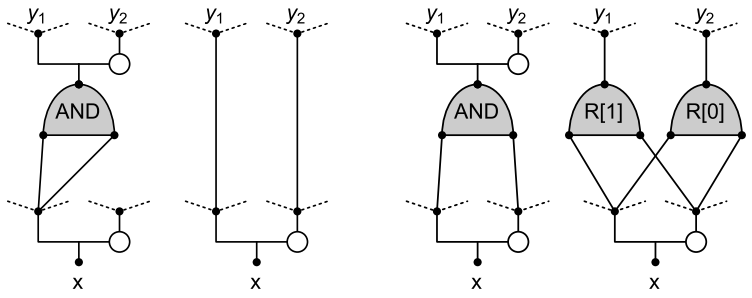

Figure 3: AND gate replacement rules when both inputs come from the same output fork, either the same branch (left) or both branches (right). The rule for the OR gate is the same for the case on the left, and has $R[0]$ and $R[1]$ exchanged for the case on the right.

We give these biases the freedom to take different values, increasing the expressivity of the network and boosting the parameter count commensurate with "standard model" networks, which have a weight on each edge. By setting the biases on selected edges in a completely connected network to large values, thereby disabling them, our model has the capacity to select its architecture.

The second way we generalize the model is to introduce weights at all the summations. These are static — not intended to be learned — and positive. We show in section 6 that in layered networks one can apply a rescaling to the biases that has the effect of restoring all the weights to 1 without changing the classification behavior of the network. The weights therefore only play a role during training, through the gain/decay they impart to the analog signal as it propagates from input to output, and the response this elicits from the bias parameters.

We now formally define our model.

Definition 1.2 *A rectified wire network is a model of computation on a directed acyclic graph. Associated with each wire or edge $i \to j$ joining node i to j is the node value x_i and edge output $y_{i\to j}$ related by*

$$y_{i\to j} = \max(0, x_i - b_{i\to j}),$$

where $b_{i\to j}$ is the bias parameter for the edge. The edge outputs $y_{i\to j}$, from all edges $i \to j$ incident on node j, are summed to give the value x_j of node j:

$$x_j = w_j \sum_{i\to j} y_{i\to j}.$$

The positive constant w_j is the weight of the node. The node values x, edge outputs y, and bias parameters b of a rectified wire network are general real numbers.

The number of edge outputs y summed by a node j is its in-degree $|{\to}j|$, and the number of edges receiving x_j as input is its out-degree $|j{\to}|$. Nodes with in-degree zero are input nodes and have their x values assigned. The outputs of the network are the x values of the nodes with out-degree zero, the output nodes. Nodes which are neither input nor output nodes are the hidden nodes of the network. The connectivity of rectified wire networks is such that there always exists a path between any input node and any output node.

The content of theorem 1.1, re-expressed in terms of rectified wires, takes the following form:

Corollary 1.3 *The truth value of a Boolean function on N variables that can be computed with M binary* AND/OR *gates and any number of* NOT *gates can be represented by a two-output rectified wire network taking $2N$ doubled inputs and having at most $7M$ hidden nodes. Like the doubled inputs, the two output nodes encode the truth of the function with values $(1, 0)$ or $(0, 1)$.*

Proof A logic circuit with M binary AND/OR gates has M nodes, one at each gate output. When re-expressed as a rectified wire network, each gate output is replaced by two nodes and, in the worst case (Figs. 1-2), the gate itself results in five additional nodes. The number of hidden nodes in the resulting rectified wire network is therefore bounded by $7M$. The wiring of the nodes, including the input and output nodes, can be the complete acyclic graph because large bias settings, by deselection, realize any network on the given number of nodes. ■

While possible in principle, we should not expect it to be easy for a rectified wire network to learn bias values on the modest networks promised by corollary 1.3 when presented with data generated by a Boolean function. On the other hand, as we show in section 3, this particular network model has a significant advantage over the "standard model" in having tractable conservative learning. A different, equally valid representation might be learned instead, most likely on a much larger network.

We render rectified wire networks as simple directed graphs, with input nodes at the bottom, output nodes at the top, and all edges directed in the upward direction. The rendering of the bias values — the only learned parameters — is through the edge thickness. Edges with low bias are thick, those with high bias are thin. When the bias on an edge is so great that the rectified value is zero for any input to the network, the edge is effectively absent (zero thickness). Figure 4 shows this style of rendering of a network with four input, four hidden, and two output nodes.

We can generalize both the inputs and the outputs of rectified wire networks to expand their scope beyond Boolean function-value classifiers. In many applications the feature vectors are strings of symbols from a finite alphabet: {TRUE, FALSE}, {A,C,G,T}, etc. As in the Boolean case, for an alphabet of size K we use the one-hot encoding scheme where the k^{th} symbol is expanded into K numerical values all zero except for a 1 in the k^{th} position. Numerical (non-symbolic) data may be encoded in the same style. Suppose the data vectors have length L: $v = (v_1, \ldots, v_L)$. We first obtain the cumulative probability function θ_i for

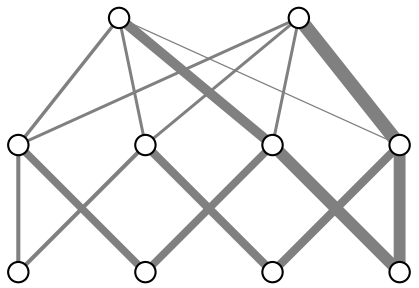

Figure 4: Rectified wire network with four input nodes (bottom row), four hidden nodes, and two output nodes (top row). Thinnest edges have the highest bias.

each component $i = 1, \ldots, L$ over the dataset. The data vector for input to the network, corresponding to v, is then

$$d(v) = [\, \theta_1(v_1)\,, 1 - \theta_1(v_1)\,,\ \ldots\ ,\ \theta_L(v_L)\,, 1 - \theta_L(v_L)\,]\,. \tag{2}$$

With this convention, the input to the network is always a vector of numbers between 0 and 1 whose sum equals the number of components or string length of the data. The mapping by the cumulative probability functions, in the case of analog data, ensures that the distribution in each channel is uniform.

The number of output nodes equals the number of data classes. A Boolean function classifier would have two output nodes to classify the truth value of the input. To classify MNIST data (LeCun et al., 1998), the network would have 10 output nodes. Before we describe how these outputs are interpreted we make a trivial observation:

Lemma 1.4 *In a rectified wire network with input vector $d \geq 0$, there exist settings of the bias parameters where, for any of the output nodes $c \in C$, we have $x_c = 0$ and $x_j > 0$ for $j \in C \setminus \{c\}$.*

Proof All the output nodes will have positive values for zero bias, because the weights are positive and each output is connected by a path to one of the inputs with positive value (see definition 1.2). To exclusively arrange for $x_c = 0$, we set $b_{i\to c} = x_i$ on all the edges $i \to c$ incident on c (keeping all other biases at zero). ■

We will explain in section 3 why zero is the appropriate indicator function value for defining classes on a conservatively trained rectified wire network.

2. Notation

Now that most of the elements of our network model have been introduced, we summarize our notational conventions. Lower case symbols represent variables or parameters on the

network. These bear a latin index when defined on a node of the network. Examples are the node values, x_i, or the weights w_i. The index is written as a directed edge between nodes when defined on an edge of the network. Examples are the bias parameters, $b_{i\to j}$, and edge-outputs $y_{i\to j}$. The same lower case symbols, both for nodes and edges, when written without subscripts denote the vector of all the indexed values. For example, b is the vector of all biases in the network and d the vector of data values on the input nodes. When such symbols appear in an equality/inequality, the relation applies componentwise. Round brackets attached to a variable identify its functional dependence, when relevant. The value of node k, for example, might be written $x_k(b,d)$ to emphasize its dependence on the biases and input data.

Upper case symbols are used for sets. The symbols D, H, C are reserved for the data (input), hidden, and class (output) nodes respectively, while E is the set of directed edges. Upper case symbols are also used for continuous sets with the same convention for functional dependence as variables. For example, $B(d)$ might be the set of bias values b such that for $b \in B(d)$ the node value $x_i(b,d)$ is zero for input d. Cardinality is denoted with vertical bars, e.g. $|E|$ for the number of edges in the network. Node i in a network has in-degree $|{\to}i|$ and out-degree $|i{\to}|$.

3. Counterfactual classification and conservative learning

Monotone learning on rectified wire networks is made possible by the fact that, for a fixed input $d \geq 0$ to the network, the value $x_k(b,d)$ at any node k is a non-negative and non-increasing function of the bias parameters b. This, combined with the fact (lemma 1.4) that zero is always a feasible value on any of the output nodes, motivates the following definition of a classifier.

Definition 3.1 *The output nodes C of a rectified wire network serve as a classifier of $|C|$ classes of inputs when there are biases b such that for inputs d in class $c \in C$, $x_c(b,d) = 0$ and $x_i(b,d) > 0$ for $i \in C \setminus \{c\}$.*

To see why this definition makes sense in the context of conservative learning, suppose that at some stage of training all the output nodes are positive for some input d in class c. By increasing the biases b, the output value $x_c(b,d)$ can always be driven to zero for input d, and by increasing them as little as possible, i.e. conservatively, there is a good chance the other output nodes can be kept positive. If some of the other outputs are also set to zero in the process of increasing biases, the classification is ambiguous. In any case, and after any amount of subsequent training where biases are increased, monotonicity of $x_c(b,d)$ with respect to b ensures $x_c(b,d) = 0$ continues to be a valid indicator for class c.

The outputs of the proposed classifier are counterfactual in the sense that a large positive value x_c on the node for class c represents strong evidence that c is not the correct class. In the case of a class defined by the truth value of a Boolean function, we would use the function that returns FALSE for members of the class, so the value of the corresponding analog circuit output node is zero.

We shall see that we do not need to separately insist that, during training, biases are never decreased, as it will follow automatically from the conservative learning principle which assigns the following cost when biases are changed:

Definition 3.2 *The cost, in a rectified wire network, for changing the biases from b to b', is the p-norm $\|b' - b\|_p$.*

The uniqueness of the cost-minimizing bias change, for fixing a misclassification, depends on the norm exponent p. We mostly use $p = 2$ in this study, where uniqueness can be proved. Our definition of the conservative learning rule, which sidesteps uniqueness, is the following:

Definition 3.3 *Suppose output node $c \in C$ for class c has value $x_c(b,d) > 0$ for an input d, in a network with biases set at b. A conservative bias update is any b' that minimizes $\|b' - b\|_p$ and produces output value $x_c(b',d) = 0$.*

Lemma 3.4 *If b' is any conservative update of b, then $b' \geq b$.*

Proof Biases b' have just learned an input d in some class $c \in C$, so $x_c(b',d) = 0$. Now suppose $b'_{i\to j} < b_{i\to j}$ for some edge $i \to j \in E$. The update b'', where $b''_{i\to j} = b_{i\to j}$ and all others are unchanged, has lower cost than b' and yet, by monotonicity of node values with respect to b, all output nodes with value zero will still be zero, including $x_c(b'',d)$. ■

The outputs of a rectified wire network are compositions of rectifier functions. Composition of convex functions are in general not convex, but for the rectifier function this is true. We give an inductive proof based on the following.

Lemma 3.5 *If $x(b) : \mathbb{R}^K \to \mathbb{R}$ is convex, then $y(a,b) : (\mathbb{R}, \mathbb{R}^K) \to \mathbb{R}$, defined by*

$$y(a,b) = \max(0, x(b) - a),$$

is also convex.

Proof Because x is convex, for arbitrary $b_1, b_2 \in \mathbb{R}^K$ we have

$$x(\lambda b_1 + (1-\lambda)b_2) \leq \lambda\, x(b_1) + (1-\lambda)\, x(b_2) \tag{3}$$

for $0 \leq \lambda \leq 1$. For arbitrary $a_1, a_2 \in \mathbb{R}$,

$$\begin{aligned} y\left(\lambda a_1 + (1-\lambda)a_2,\ \lambda b_1 + (1-\lambda)b_2\right) &= \max(0, x(\lambda b_1 + (1-\lambda)b_2) - \lambda a_1 - (1-\lambda)a_2) \\ &\leq \max(0, \lambda\, x(b_1) + (1-\lambda)\, x(b_2) - \lambda a_1 - (1-\lambda)a_2) \\ &= \max(0, \lambda\, z_1 + (1-\lambda)\, z_2), \end{aligned}$$

where we have used (3) and defined

$$\begin{aligned} z_1 &= x(b_1) - a_1 \\ z_2 &= x(b_2) - a_2. \end{aligned}$$

Since for arbitrary $s, t \in \mathbb{R}$

$$\max(0, s+t) \leq \max(0, s) + \max(0, t),$$

we obtain

$$\begin{aligned}\max(0, \lambda z_1 + (1-\lambda) z_2) &\leq \max(0, \lambda z_1) + \max(0, (1-\lambda) z_2) \\ &= \lambda \max(0, z_1) + (1-\lambda) \max(0, z_2) \\ &= \lambda\, y(a_1, b_1) + (1-\lambda)\, y(a_2, b_2)\end{aligned}$$

as claimed. ■

Theorem 3.6 *The node values $x(b,d)$ of a rectified wire network, given an input d, are convex functions of the bias parameters b.*

Proof The values of the input nodes D, set to the constant values $x_i = d_i, i \in D$, are trivially convex. Since our network is an acyclic graph, the nodes can be indexed by consecutive integers so that all edge outputs $y_{i\to j}$ incident on a node $j \in H \cup C$ are from input nodes $i \in D$ or from hidden nodes $i \in H$ that have $i < j$. For any $j \in H \cup C$, we use induction and suppose all x_i, $i \in H$ with $i < j$ are convex functions of the bias parameters. Consider any of the edge outputs $y_{i\to j}(b)$ incident on j:

$$y_{i\to j}(b) = \max(0, x_i(b) - b_{i\to j}).$$

Seen as a function of bias parameters, where $x_i(b)$ is a convex function of biases not including $b_{i\to j}$, $y_{i\to j}(b)$ fits the hypothesis of lemma 3.5 and is therefore convex. This conclusion also applies to the base case, the hidden node numbered $j = 1$, where all the x_i are inputs $i \in D$ and constant. Since the node value

$$x_j(b) = w_j \sum_{i\to j} y_{i\to j}(b)$$

is a positive multiple of a sum of convex functions, it too is convex and completes the induction. ■

For the case $p = 2$, we can prove uniqueness of the conservative bias update.

Corollary 3.7 *The set $B(d)$, of biases b of a rectified wire network with fixed input d for which $x_c(b,d) = 0$ for a given output node c, is non-empty and convex. Consequently, the conservative bias update $b' \in B(d)$ that minimizes the cost $\|b' - b\|_2$ with respect to the biases b is unique.*

Proof The set $B(d)$ may be defined as the feasible set of $x_c(b,d) \leq 0$ (since this function is non-negative). By lemma 1.4 $B(d)$ is non-empty, and by theorem (3.6) $B(d)$ is closed and convex because $x_c(b,d)$ is a convex function of b. Now suppose $b'_1 \in B(d)$ and $b'_2 \in B(d)$ are distinct minimizers of $\|b' - b\|_2$ for some bias b. Because $B(d)$ is convex we have a contradiction because $b'_3 = (b'_1 + b'_2)/2 \in B(d)$ and $\|b'_3 - b\|_2 < \|b'_1 - b\|_2 = \|b'_2 - b\|_2$ implies b'_1 and b'_2 were not minimizers. ■

To design algorithms for computing the conservative bias update and to establish the complexity of this task we cast the problem as a mathematical program. Consider a rectified wire network with edges E on which we are given bias parameters b, say from previous training. Suppose we now wish to learn the pair (c,d), a vector of input data d in the class associated with output node c. Unless $x_c(b,d) = 0$, the biases must be conservatively updated to b' so this is true. Before we do this we partition E into the set of *active* edges A and its complement, $\bar{A}$.

Definition 3.8 *The set A of active edges of a rectified wire network, given input data d and bias parameters b, are those edges $i \to j$ where $x_i(b,d) > b_{i\to j}$, or equivalently, where $y_{i\to j}(b,d) > 0$.*

The biases $b_{i\to j}$ on the inactive edges $i \to j \in \bar{A}$, when increased, have no effect on any node values, in particular the output nodes, because the corresponding edge-outputs $y_{i\to j}$ are zero by monotonicity of $x(b)$ (non-increasing). To find b' we may therefore work with the network induced by the active edges A, called the "active network."

Our mathematical program makes use of a set of *reduced bias* variables.

Definition 3.9 *Let A be the active edges of a rectified wire network for input data d and bias parameters b. For each edge $i \to j$ of the network, define the reduced bias by*

$$b^-_{i\to j} = \begin{cases} b_{i\to j}, & i \to j \in A \\ x_i(b,d), & i \to j \in \bar{A}. \end{cases}$$

Now consider a conservative update b' of b, and the reduced biases b^- for b'. We always have $b^- \leq b'$, and the reduced values have the property that $x(b^-, d) = x(b', d)$. In particular, for the class output node c we have $x_c(b^-, d) = x_c(b', d) = 0$. The only reason that a conservative update b' of b would not already be reduced ($b' = b^-$) is that the freedom $b^- \leq b'$ may allow a reduction in cost, that is, give a more conservative update.

We now define the mathematical program. For given data d, biases b and weights w on a rectified wire network, we are given the corresponding active edges A and node c of the correct class. The unknowns are the updated biases b', reduced biases b^-, and edge-outputs y on A, and the values of x on c and the input and hidden nodes:

$$\begin{aligned}
&\text{minimize:} && \|b' - b\|_p^p && && \text{(4a)}\\
&\text{such that:} && b^- \leq b', && && \text{(4b)}\\
& && 0 \leq b^-, && && \text{(4c)}\\
& && x_i = d_i, && i \in D && \text{(4d)}\\
& && y_{i\to j} = x_i - b^-_{i\to j}, && i \to j \in A && \text{(4e)}\\
& && 0 \leq y_{i\to j}, && i \to j \in A && \text{(4f)}\\
& && x_j = w_j \sum_{i\to j \in A} y_{i\to j}, && j \in H \cup \{c\} && \text{(4g)}\\
& && x_c = 0. && && \text{(4h)}
\end{aligned}$$

Theorem 3.10 *The mathematical program* (4)*, defined for the network A that is active for given biases b and data d, as part of its solution b' gives a conservative bias update for the class associated with output node c.*

Proof First observe that any valid ($x_c = 0$) assignment of node values x and edge-outputs y, in the corresponding rectified wire network, is realized by a feasible point of the linear system (4c) – (4h) involving just the reduced biases (not b'). For the variables b' to be rectified wire biases consistent with the reduced biases b^-, it is sufficient for them to satisfy (4b), as monotonicity ensures $x_c(b') = 0$. Optimizing (4a) subject to (4b) and the constraints that define the feasible set of reduced biases, gives the most conservative update. ■

For $p = 2$, (4) is a positive semi-definite quadratic program and can be solved in time that grows polynomially (Kozlov et al., 1980) in the size of the active network, $|A|$. The same conclusion applies for $p = 1$, a linear program, because the objective can be replaced by the sum of all the updated biases b' provided we impose the result of lemma (3.4), $b \leq b'$, as a constraint. While these results allow us to add rectified wire networks to the list of models for which there is a tractable conservative learning rule, in most applications it is also important that training scales nearly linearly with the size of the network. The *sequential deactivation algorithm* (SDA) described in the next section is designed to meet that goal.

We close this section by reviewing the features of our model that make training tractable. The insistence on exactly learning individual items should not be counted as a tractability-enabling feature. Indeed, it is easy to see how the mathematical program (4), to compute the conservative update for one data item, would be generalized to find the norm-minimizing update that classifies an entire mini-batch. All the variables and data, with the exception of the biases b and b', now carry a data index $m \in M$, where M is a mini-batch. For example, (4b) would be replaced by

$$b^-{}_{i\to j,m} \leq b'_{i\to j} \qquad i \to j \in A,\ m \in M$$

and imposes consistency of the bias updates for all instantiations of the reduced biases over the mini-batch. While the size of the mathematical program has grown to $O(|A||M|)$ equations and inequalities, it is still tractable.

Convexity of the variables x and y with respect to the bias parameters is clearly important for tractable learning, and the proofs of lemma 3.5 and theorem 3.6 show that this relies on the non-negativity of the static weights and the form of the activation function. Less obvious in facilitating tractability is the proposal to replace the loss function of neural networks by a constraint, and in particular, the simple constraint (4h). For example, one might consider replacing this single constraint with the following set of inequalities,

$$x_i > x_c + \Delta, \quad i \in C \setminus c, \tag{5}$$

where the fixed positive parameter Δ specifies a margin for avoiding ambiguous classification. After all, we still have a tractable mathematical program after this substitution. Unfortunately, this proposal creates a conflict in the relationship between the reduced biases b^- and the actual bias updates b'. While the b^- variables provide an exhaustive parameterization of the node variables x, even under the constraint (5), we cannot count on the

inequality $b^- \leq b'$ to preserve this constraint when b^- biases are replaced by b' biases in the rectified wire model (the monotonic decrease of a non-class output may exceed that of the class output).

4. Sequential deactivation algorithm

This section describes in detail the SDA algorithm for computing bias updates in the rectified wire model. While these updates are not guaranteed to be the most conservative possible, their computation is significantly faster than solving a general quadratic program. The SDA algorithm resembles the gradient methods used for optimizing standard model networks, the most widely used being stochastic gradient descent (SGD) (Rumelhart et al., 1986).

The program (4) would be greatly simplified if inequality (4f) was somehow automatically satisfied. All active edges would remain active in the update and the updated biases b' on them would be equal to the reduced biases b^-. The node variables x, in particular x_c, would be linear functions of the b':

$$x_c(b') = x_c(b) + \nabla x_c \cdot (b' - b).$$

For the $p = 2$ norm on bias updates, the optimal update that achieves $x_c = 0$ is then

$$b' = b - \frac{x_c(b)}{\|\nabla x_c\|^2} \nabla x_c.$$

The conservative update, in this simplification, is the same as gradient descent.

In the general case, where edges may become inactive, from the monotonicity of x_c we know at least that the gradient ∇x_c never has positive components. If we had the stronger property, that ∇x_c is also never zero while $x_c > 0$, then gradient descent will always find an update b^* that satisfies $x_c(b^*) = 0$. But the latter property follows immediately from the fact that $x_c > 0$ is only possible when there are active edges incident to output node c, so that x_c has non-zero derivatives at least with respect to the biases on them.

While gradient descent cannot guarantee the norm minimizing update promised by the solution of program (4), it has some attractive features. First, the computation of the (piecewise constant) gradient is fast, as is the computation of the step size to the next gradient discontinuity (deactivation event). Second, there is an opportunity to make the gradient descent update b^* more conservative on the inactive edges. Using the condition $y_{i\to j}(b^*) = 0$ as the indicator of an inactive edge, the improved update is, for all $i \to j \in A$,

$$b'_{i\to j} = \begin{cases} \max\left(b_{i\to j}, x_i(b^*)\right), & y_{i\to j}(b^*) = 0 \\ b^*_{i\to j}, & y_{i\to j}(b^*) > 0. \end{cases} \tag{6}$$

The SDA algorithm is the efficient implementation of gradient descent on the rectified wire model followed by (6). Its name draws attention to the fact that the steps in the descent are defined by deactivation events.

We now turn to the implementation of the SDA algorithm. The elementary operations are defined in Algorithm 1. Procedure EVAL is simply a forward-pass through the network, from data supplied at the input nodes, to the output nodes whose values directly encode

Algorithm 1 Elementary network procedures

procedure EVAL(E, b, d) $\to (A, x, y)$
$x_i \leftarrow d_i, \quad i \in D$
$x_j \leftarrow w_j \sum_{i\to j\in E}\ y_{i\to j}, \quad j \in H \cup C$
$y_{i\to j} \leftarrow \max(0, x_i - b_{i\to j}), \quad i \to j \in E$

$A \leftarrow \{i \to j \in E : y_{i\to j} = 0\}$
end procedure

procedure GRAD(A, c) $\to \nabla x_c$
$(-\nabla x_c)_j \leftarrow w_c \delta_{jc}, \quad j \in C$
$(-\nabla x_c)_i \leftarrow w_i \sum_{i\to j\in A}(-\nabla x_c)_j, \quad i \in H$
end procedure

procedure VELOCITY(A, ∇x_c) $\to \dot{y}$
$(-\dot{y})_{i\to j} \leftarrow (-\nabla x_c)_j + w_i \sum_{k\to i\in A}(-\dot{y})_{k\to i}, \quad i \to j \in A$
end procedure

the class. In addition to the output node values $\{x_i : i \in C\}$, EVAL also provides the edge outputs y and the set of active edges A (on which the edge outputs are non-zero).

Suppose the current bias parameters are $b(0)$. Denote by $(-\nabla x_c)_{i\to j}$ the negative gradient component for the bias on edge $i \to j \in A$. Because the derivatives with respect to all the $b_{i\to j}$ on active edges into the same node j are equal, the node-indexed variables

$$(-\nabla x_c)_j \coloneqq (-\nabla x_c)_{i\to j}, \quad i \to j \in A$$

are well defined. In particular, if j is an output node, then $(-\nabla x_c)_j = w_c\,\delta_{jc}$. As long as the gradient is constant, the biases evolve as

$$b_{i\to j}(t) = b_{i\to j}(0) + t(-\nabla x_c)_j, \tag{7}$$

where t is a continuous "time".

The gradient $(-\nabla x_c)_i$ is positive only if node i is connected by active edges to node c, with value given by the sum over all paths on active edges, each contributing by the product of weights along the path. The effect on x_c of a bias change on an active edge into i is the same as if the same bias change was instead applied to all the active edges leaving node i, but multiplied by w_i. This implies the recursion,

$$(-\nabla x_c)_i = w_i \sum_{i\to j\in A}(-\nabla x_c)_j, \quad i \in H \tag{8}$$

in the procedure GRAD of Algorithm 1 and corresponds to back propagation in the network.

The third procedure, VELOCITY, is derived from the recursion for the edge-outputs y:

$$y_{i\to j} = w_i \sum_{k\to i\in A} y_{k\to i} - b_{i\to j}.$$

Taking the time derivative and using (7),

$$(-\dot{y})_{i\to j} = w_i \sum_{k\to i\in A}(-\dot{y})_{k\to i} + (-\nabla x_c)_j \tag{9}$$

we obtain the velocities of the edge-outputs by forward propagation. The initialization occurs at edges $i \to j$ from all the input nodes i, for which the sum in (9) is absent and $(-\nabla x_c)_j$ is set by GRAD.

By construction, both $y_{i\to j}(0)$ and the (constant) velocities $(-\dot{y})_{i\to j}$ on the active edges $i \to j \in A$ are positive and the first deactivation event occurs at time

$$t^* = \min_{i\to j\in A} \frac{y_{i\to j}(0)}{(-\dot{y})_{i\to j}}. \tag{10}$$

This is the time step in one iteration of the SDA algorithm. After the biases are incremented by (7) and the newly deactivated edges are removed from A, another round is begun. Iterations are terminated when EVAL returns $x_c = 0$. The final biases are obtained by applying (6) to the gradient descent biases.

We now revisit the classification rule of definition 3.1, where data is declared learned when $x_c = 0$. Recall that this has the desired property of not having the "supremacy" (smallest value among all classes) of node c spoiled by subsequent training. The only way that the latter can have a negative effect, through the general decrease in output values with increasing biases, is when output nodes other than c are in a tie at value zero. To mitigate this effect, and also make the bias changes even more conservative, we introduce the *ultra-conservative learning* rule:

Definition 4.1 *In the ultra-conservative mode of learning with the* SDA *algorithm, iterations are terminated when x_c, the value of the output node c of the correct class, is either zero or smaller than the values of all the other output nodes.*

This termination criterion is conservative from the point of view of testing. Consider the early stages of training, when we might want to test the algorithm on which class is being favored. The natural candidate for the latter is the output node with the smallest value. By terminating SDA as soon as this criterion is met, the test (when performed right after training) will succeed with a smaller change to the biases than is required by the $x_c = 0$ criterion.

Because the property of data d producing the smallest output value on node c can be spoiled by training with data $d' \neq d$, it may be necessary for the network to retrain on d, or data similar to d, in order to properly learn the combination (d, c). The implied heuristic is that the net bias change for this mode of learning class c may be more conservative than always insisting on output $x_c = 0$ for every d in this class.

The SDA algorithm with the ultra-conservative termination criterion is summarized in Algorithm 2. As soon as x_c becomes the smallest output or is zero, the algorithm returns the most conservatively updated biases b' consistent with the activity of the network edges, (6). Estimating the work required to correct a misclassification is complicated by two factors. While the work in one iteration scales linearly with the size of the active network, we do not know how many iterations are needed on average to satisfy the ultra-conservative

Algorithm 2 Sequential Deactivation (SDA)

input $(E, b^0), (d, c)$ (network edges, initial biases), (data vector, class)

$b \leftarrow b^0$ initialize biases
$(A, x, y) \leftarrow \text{EVAL}(E, b, d)$ active edges, node and edge output values

while $x_c > 0$ and $\arg\min_{i \in C} x_i \neq \{c\}$ **do** iterate until node c is smallest
  $\nabla x_c \leftarrow \text{GRAD}(A, c)$ gradient with respect to active biases
  $\dot{y} \leftarrow \text{VELOCITY}(A, \nabla x_c)$ edge output velocity
  $t^* \leftarrow \min_{i \to j \in A} \; y_{i \to j} / (-\dot{y}_{i \to j})$ step size

  for $i \to j \in A$ **do**
    $b_{i \to j} \leftarrow b_{i \to j} + t^* \, (-\nabla x_c)_j$ increase biases
  end for

  $(A, x, y) \leftarrow \text{EVAL}(A, b, d)$ new active edges, node and edge output values
  $\mathsf{iter} \leftarrow \mathsf{iter} + 1$ increment iteration counter
end while

for $i \to j \in E$ **do**
  if $i \to j \in A$ **then**
    $b'_{i \to j} = b_{i \to j}$ keep biases on active edges
  else
    $b'_{i \to j} = \max(b^0_{i \to j}, x_i)$ conservative update for inactive edges
  end if
end for

output b', iter updated biases, iteration count

termination rule. Empirically (section 9) we find the number of iterations is often quite small and depends only weakly on network size. A second effect, serving to lessen the work, is the sparsification of the active network with time. In any event, the total computation in learning each data item would be at most $O(|A|^2)$, since in each iteration at least one of the active edges is deactivated (and eliminated from subsequent rounds).

A possible direction for future research is the design of an algorithm that solves the program (4), for the most conservative update, with only a modest amount of extra work than used by SDA. In this connection we present the simplest instance we know of where the update found by SDA is non-optimal. Figure 5 shows a fragment of a network where the bias updates on four edges can be analyzed in isolation. We consider the original optimization problem (4), where the bias updates must give zero on node c. There may be additional edges incident on the nodes shown, but these are inactive for the data item being learned. Input node 1 has been zero for all previous data and explains why biases $b_{1\to2}$, $b_{2\to3}$ and $b_{2\to c}$ are still zero. The inactive edge incident on node 3 was active on previous data and

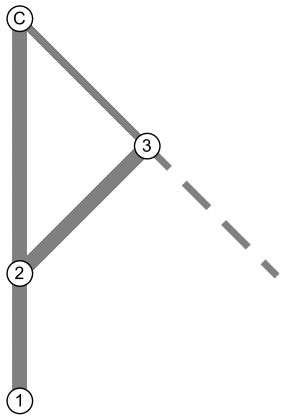

Figure 5: A network fragment on which the SDA update is not optimal. The initial bias on the thick edges is zero, while $b_{3\to c} = b$. Another parameter is the weight w of node 2; all other nodes have unit weight. The dashed edge is inactive initially and irrelevant, but was responsible for $b > 0$ from prior training.

accounts for the positive bias $b_{3\to c} = b$. The nodes all have unit weight except node 2, whose weight is w. Data vector component $d_1 = 1$ (on node 1) is the only one relevant for the fragment shown.

It is easy to see that for the case $w < b$ the SDA solution is optimal, that is, it coincides with the solution of (4). However, with a bit of work one can show that the SDA updates are suboptimal when $w > b$, even when taking advantage of (6). This example only shows there is room for improvement. We do not know how pervasive this type of instance is in practice, let alone how seriously it impacts learning.

We close this section with the observation that SDA is not that different from SGD applied to the loss function x_c. The main differences are that the step size (learning rate) is not a free parameter but set by deactivation events and that multiple steps may be executed when learning each data item. The benefit imparted by the rectified wire model, in this context, is just that the gradient computations and step sizes are very easy to compute. If we set aside monotonicity and solution guarantees, these attributes carry over to loss functions that are much stronger than x_c.

To get a sense of how small a change moves the model into difficult territory, consider the problem of learning the truth value of a Boolean function $f(z)$ on N variables generated by M binary AND/OR gates, as discussed in section 1. The rectified wire network would receive $2N$ doubled inputs and have output nodes f and $\bar{f}$, trained so that $(x_f, x_{\bar{f}}) = (f(z), \bar{f}(z))$. From corollary (1.3) we know such a rectified wire network exists, with unit weights and

having at most $7M$ hidden nodes. The outstanding question, of course, is whether a gradient based algorithm can find the appropriate bias settings.

Instead of the monotone loss function $x_{f(z)}$, fraught with the problem that training cannot prevent $(x_f, x_{\bar{f}}) = (0, 0)$ — an ambiguity — we might try the hinge-loss function

$$\max\left(0,\ x_{f(z)} - x_{\bar{f}(z)} + \Delta\right).$$

By corollary (1.3) we know that it is possible to achieve zero loss over all z with margin $\Delta = 1$, and that the data will be correctly and unambiguously classified. Like $x_{f(z)}$, this loss function is piecewise linear on the rectified wire model and can likewise benefit from fast gradient and step size calculations. Because this loss is no longer monotone decreasing in the bias parameters, there is now no reason to initialize biases at zero. The loss of monotonicity, of course, brings with it the zero gradient problem. We suspect this may be more serious for rectified wires than it is in standard network models.

5. Clause learning

Although the SDA algorithm provides a tractable computation for learning individual data in the rectified wire model, we do not yet have any reason to believe this algorithm can learn any interesting functions. To address that concern, in this section we show that at least in a particular limit, the SDA algorithm is able to learn classes defined by any Boolean function. We already saw in section 1 that rectified wire networks can represent such classes, even with favorable size scaling. To also demonstrate learning we have to rely on an admittedly impractical family of networks, with size growing exponentially with the number of Boolean variables.

Definition 5.1 *The complete Boolean network, for learning a Boolean function $f(z_1, \ldots, z_N)$, has N pairs of input nodes, 2^N hidden nodes, and two output nodes. The input nodes correspond to the literals $z_1, \bar{z}_1, \ldots, z_N, \bar{z}_N$, the hidden nodes to all possible N-clauses $\{z_1, \bar{z}_1\} \times \cdots \times \{z_N, \bar{z}_N\}$ formed from N literals, and the output nodes correspond to the truth value of f. Each hidden node has N edges to each of its constituent literals, and edges to both of the output nodes.*

Figure 6 shows the complete Boolean network for functions of two variables (rendered for zero bias on all edges). In general, the hidden nodes all lie in the same layer. With the weights at the output nodes fixed at 1, the limit of the SDA algorithm we will analyze is where the weight w shared by all the hidden nodes approaches zero. We refer to this limit on complete Boolean networks as *clause learning*

The SDA bias changes in clause learning are very simple. While $(-\nabla x_c)_i \in \{0, 1\}$ when i is an output node, by (8) we have $(-\nabla x_c)_i \in \{0, w\}$ at all the hidden nodes. From (8) it also follows that the bias changes on edges into the hidden nodes are smaller by a factor w relative to edges leaving the hidden nodes. Recall that an SDA iteration is defined by the deactivation of some edge as biases are increased. In clause learning this always occurs in the second layer, in the edges to the outputs. As the hidden node values are $O(w)$, the biases to the output edges will also be $O(w)$ as that suffices for deactivation. While there are corresponding bias changes on edges into the hidden nodes, these are smaller by a factor

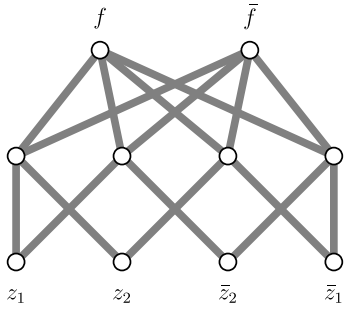

Figure 6: Complete Boolean network for 2-variable Boolean functions $f(z_1, z_2)$. The function value is classified by the smaller of the two output node values, with the convention that node f is smaller when $f(z_1, z_2) = 0$.

of w, or $O(w^2)$, and far from making these edges inactive (since $x_i \in \{0, 1\}$ on the input nodes).

Lemma 5.2 *In clause learning, the hidden nodes and the biases on edges leaving them, always have values of the form $wK + O(w^2)$, $K \in \mathbb{Z}_{\geq 0}$.*

Proof We use induction, with the base case being the start of training where all the biases are zero. For any (doubled) input $d \in \{0, 1\}^{2N}$, the value of a hidden node h is $x_h = wK(d, h)$, where $K(d, h) \in \{0, \ldots, N\}$ counts the number of literals associated with node h that are 1 for input d. Next suppose that a slightly modified statement continues to hold after T iterations of SDA, that is, for any hidden node h and any edge $h \to i$, $x_h, b_{h\to i} \in \{wK + O(w^2) \colon K \in \mathbb{Z}_{\geq 0}\}$. Consider what happens in iteration $T + 1$, invoked when the network makes the wrong prediction and some edge is deactivated by an increase in bias. The deactivated edge will always be an edge leaving a hidden node, and the change of its bias will therefore be the difference of two numbers in the set $\{wK + O(w^2) \colon K \in \mathbb{Z}_{\geq 0}\}$, thus keeping the changed bias in this set. Since the corresponding bias changes on edges into the hidden nodes are $O(w^2)$, the statement about the values of the hidden nodes also continues to hold. ■

Theorem 5.3 *Clause learning succeeds for any Boolean function.*

Proof Consider the values of the two output nodes when clause learning encounters the doubled input $d \in \{0, 1\}^{2N}$ associated with the function argument $z \in \{0, 1\}^N$. By lemma 5.2, $x_f = wK_f + O(w^2)$, $x_{\bar{f}} = wK_{\bar{f}} + O(w^2)$, where $K_f, K_{\bar{f}} \in \mathbb{Z}_{\geq 0}$. As long as the integer for the "wrong" output is greater than zero, SDA will make bias changes, if necessary, to

identify the correct class. For example, suppose $f(z) = 0$ and $K_{\bar{f}} > 0$. Through bias increases SDA can bring about $x_f < x_{\bar{f}}$ because all inactivations will be on edges $h \to f$, that is, from hidden nodes to the "correct" output node. The only effect these changes can have on $x_{\bar{f}}$ is a decrease of order $O(w^2)$, due to $O(w^2)$ bias increases on edges into the hidden nodes. Since each edge $h \to f$ can become inactive just once, the number of SDA iterations required to produce the desired outcome is bounded by the number of hidden nodes.

The above argument does not apply in the case $K_{\bar{f}} = 0$. However, we can argue that this never arises when $f(z) = 0$. If it did, consider the input $d \in \{0,1\}^{2N}$ corresponding to z and the unique hidden node h whose combination of input-literals is such that $x_h = wN + O(w^2)$ (complete Boolean networks sample all N-literal combinations). Since $x_{\bar{f}}$ is a sum of non-negative contributions from all the hidden nodes, $K_{\bar{f}} = 0$ is only possible if $b_{h\to\bar{f}} = wN + O(w^2)$. To finish the proof, we show that this value is inconsistent with conservative learning.

Fixing the hidden node h from above, consider all the arguments z for which $f(z) = 1$ and the bias $b_{h\to\bar{f}}$ required to correctly assign them to the correct class by the smallness of $x_{\bar{f}}$. The corresponding inputs d for such z would produce $x_h = wK + O(w^2)$, with $K < N$, because the clause associated with h is unique in producing $x_h = wN + O(w^2)$ only for an input for which $f(z) = 0$. But to achieve the smallest contribution, $O(w^2)$, to $x_{\bar{f}}$ from edge $h \to \bar{f}$, we only need bias $b_{h\to\bar{f}} = wK + O(w^2)$, $K < N$. This is smaller (more conservative) than the hypothesized value from above.

The same argument, with interchanged output nodes, applies to learning data for which $f(z) = 1$. ■

6. Balanced weights

We say a network is *layered* when the nodes can be partitioned into a sequence of layers $\ell = 0, 1, \ldots, L$, such that all edges in the network are between nodes in adjacent layers. When a rectified wire network has the property that the weights are only layer-dependent, a suitable rescaling applied to the biases will eliminate all the weights — replacing them by 1 — without changing the classification behavior of the network. Denoting the layer of node i as $\ell(i)$, we see from definition 1.2 that the rescalings

$$\begin{aligned} \tilde{x}_i &= x_i / W_{\ell(i)} \\ \tilde{y}_{i\to j} &= y_{i\to j} / W_{\ell(i)} \\ \tilde{b}_{i\to j} &= b_{i\to j} / W_{\ell(i)}, \end{aligned} \tag{11}$$

where

$$W_{\ell(i)} = \prod_{\ell=0}^{\ell(i)} w_\ell,$$

leave the equations unchanged while replacing all the weights by 1. Here $\ell = 0$ and $\ell = L$ correspond to the input nodes and output (class) nodes, respectively. Classification is unchanged because all the output node values are rescaled by the same (positive) factor.

The weights do have an effect on the way the network is trained by the conservative learning rule. In the following we motivate a particular setting of the weights called *balanced*, derived for each node i from its in-degree, $|{\to}i|$, and out-degree, $|i{\to}|$.

From definition 1.2 we see that the choice

$$w_i = \frac{1}{|{\to}i|} \tag{12}$$

will have the effect that there is no net gain or decay in the typical node values x when moving from one layer to the next. The appearance of the in-degree is associated with the forward propagation of x.

A very different choice is suggested by recursion (8), which relates the bias changes $\dot{b} = (-\nabla x_c)$ throughout the network in conservative learning. If we wish the biases to have equal influence on the class output node, so that again there is no net gain/decay moving between layers, then the correct choice is

$$w_i = \frac{1}{|i{\to}|}. \tag{13}$$

Here we have the out-degree because the bias changes are derived from backward propagation.

As edges become inactive over the course of training, the in-degree in (12) and out-degree in (13) should count only the active edges. However, both (12) and (13) are problematic when they are unequal, even at the onset of edges becoming inactive. When (12) and (13) are unequal, the node values x and accumulated bias changes b will grow at different rates from layer to layer. Since edge deactivation is determined by $x - b$, it will not be uniform in the network, but will be concentrated either at the input layer or the output layer.

To promote a more uniform distribution of edge activations in the network we use *balanced weights*:

$$w_i = \frac{1}{\sqrt{|{\to}i|\ |i{\to}|}}, \quad i \in H. \tag{14}$$

With this choice, the propagation of x in the limit of small bias takes the form

$$x_i = \frac{|{\to}i|}{\sqrt{|{\to}i|\ |i{\to}|}}\, x_{{\to}i},$$

where $x_{{\to}i}$ denotes an average over nodes on the in-edges to i. From (8) we have

$$(\nabla x_c)_i = \frac{|i{\to}|}{\sqrt{|{\to}i|\ |i{\to}|}}\, (\nabla x_c)_{i{\to}},$$

where $(\nabla x_c)_{i\to}$ denotes an average over nodes on out-edges of i. The two growth rates, adjusted for the same direction through the network, are now equal:

$$\frac{x_i}{x_{{\to}i}} = \sqrt{\frac{|{\to}i|}{|i{\to}|}} = \frac{(\nabla x_c)_{i\to}}{(\nabla x_c)_i}.$$

Whereas neither x nor $\dot{b} = (-\nabla x_c)$ will have zero layer-to-layer growth when there is a systematic imbalance in the in-degrees and out-degrees, by having equal growth there is a

better chance that deactivations will occur uniformly across layers. Non-zero layer-to-layer growth/decay of variables in a rectified wire network does not present a problem because the equations have no intrinsic scale. Suitable rescalings of the type given at the start of this section, applied after training, can neutralize the layer-to-layer growth without changing the classification behavior of the network.

So far we have only considered the weights of the hidden nodes. The only other nodes with weights are the output nodes. These might be weighted differently based on prior information about the classes, such as their frequency in the data. However, when there is no distinguishing prior information about the classes, the weights on the output nodes should be given equal values. By scale invariance we are free to impose

$$w_i = 1, \quad i \in C.$$

As a tool for the study of rectified wire networks, we introduce a global weight-multiplier hyperparameter q where formula (14) is replaced by

$$w_i = \frac{q}{\sqrt{|{\to}i|\ |i{\to}|}}, \quad i \in H, \tag{15}$$

and $q = 1$ corresponds to balanced weights. The limit $q \to 0$ is interesting because it collapses the rectified wire model to a much simpler one. As explained in section 5, and easily generalized to arbitrary numbers of layers, two things happen in the $q \to 0$ limit: (i) only edges in the final layer ever become inactive, and (ii) all biases except those in the final layer can be neglected. Because of (i), all the layers below the final hidden layer of nodes combine into a single linear layer, resulting in a model with just a single hidden layer. After scaling away the weights, the expression for the value of an output node $k \in C$ takes the form

$$x_k = \sum_{j \in H} \max\left(0, \sum_{i \in D} a_{ji}\, x_i - b_{j \to k}\right), \tag{16}$$

where the integers a_{ji} count the number of paths in the network from an input node i to a hidden layer node j. This model, comprising a single layer of rectifier gates, is of course much easier to analyze than a general, multi-layered rectified wire model. By decreasing q in experiments one can assess the value of depth in the network. In particular, if $q \to 0$ does not compromise performance, then depth is not being utilized in an essential way.

7. Small networks

Because both our network model (rectified wires) and training method (conservative learning) are unconventional, we use this section to demonstrate the model and method on very small networks before turning to more standard demonstrations in section 9. We first describe how the SDA algorithm trains the complete Boolean network on functions of two variables. This is followed by the study of a two-hidden-layer network, for functions on three Boolean variables.

We already proved (section 5) that the 16-edge network shown in Figure 6 learns all 2^{2^2} two-variable Boolean functions with SDA in the limit of vanishing weights in the hidden layer. Here we check that this continues to be true for balanced weights. Thanks to the

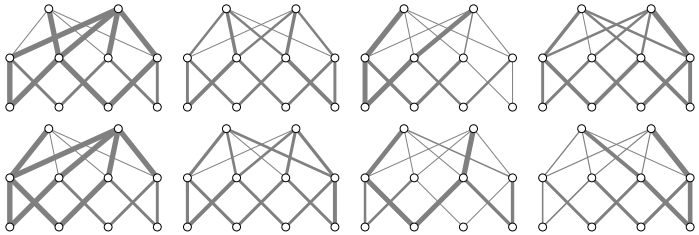

Figure 7: Two examples of final bias settings, in columns, for networks trained on the functions (left to right) f_0, f_1, f_+, $f_\times$ with different data orderings.

symmetry of this network, we only need to check four equivalence classes of functions. Here equivalence is with respect to negating inputs or the output, or swapping the two variables. In all cases, these operations on the function correspond to relabelings of the input and output nodes of the network. Using the algebra of GF(2) for Boolean operations, representatives of the four equivalence classes are

$$\begin{aligned} f_0(z_1, z_2) &= 0 \\ f_1(z_1, z_2) &= z_1 \\ f_+(z_1, z_2) &= z_1 + z_2 \\ f_\times(z_1, z_2) &= z_1 z_2. \end{aligned}$$

We have verified that the four functions above are learned on the 16-edge network with SDA and balanced weights ($q = 1$). The biases were always initialized at zero, as rendered by equal-thickness wires in Figure 6. Recall how the network is trained on a function f with the SDA algorithm. After a data vector $d = (z_1, z_2, \bar{z}_2, \bar{z}_1)$ is forward-propagated, the two output nodes will have equal or unequal values. If unequal, and the correct node — corresponding to class $f(z_1, z_2)$ — is smallest, no biases are changed and the next item is processed. If the smallest output is positive but wrong, or equal to the other output, then the SDA algorithm executes iterations until the correct output is smallest or zero. The network will then have learned d, except for the case where the iterations drive both outputs to zero. This irreversible mode of classification ambiguity does not arise with the 16-edge network and any of the four functions.

In ultra-conservative learning there is no guarantee that successfully learned data is not unlearned in subsequent training. However, by testing on all four data each time biases are changed by SDA, one can establish whether the function is learned. The order in which data are processed matters, as manifested in the final bias values. Figure 7 shows two examples of final bias settings for each of the four functions.

Define a *trial* as a single training experiment where, starting with zero bias, the data are processed in some prescribed order. All trials, for any of the four functions above, are successful on the 16-edge network. That is, there always is a point where the biases stop

changing and the data are correctly and unambiguously classified. Two numbers of interest in a successful trial are (i) $\#_{\text{err}}$, the total number of wrong or ambiguously classified data (invocations of SDA) over the course of training, and (ii) $\#_{\text{iter}}$, the total number of SDA iterations performed. These numbers are equal on the 16-edge network trained on any of the 2-variable functions, as one SDA iteration is sufficient to fix any incorrect classification in this case. Not surprisingly, the constant function f_0 is the easiest to learn, with $\#_{\text{err}} = 1$. All trials with f_1 have $\#_{\text{err}}$ equal to 4 or 5. The XOR function, f_+, always has $\#_{\text{err}} = 3$, while the AND function, $f_\times$, has the greatest variation with $\#_{\text{err}} = 2, 3$ or 4.

The more aggressive variant of SDA, where iterations continue until the class output node is zero, also succeeds for all four functions on the 16-edge network with balanced weights. In this mode of training one pass through the data always suffices. We find, for all four functions, that the network must see all the data ($\#_{\text{err}} = 4$) and $6 \leq \#_{\text{iter}} \leq 9$.

Complete Boolean networks, such as the 16-edge network, quickly become too large for functions of many Boolean variables, and alternative network designs must be considered. For example, the nodes in the single hidden layer could be clauses formed from all small subsets of the variables, or even an incomplete sampling of such clauses. The success of clause learning ($w \to 0$) with such networks would of course depend on the nature of the function.

The opposite limit applied to the hidden-layer weights, $w \to \infty$, suggests a different design for single-hidden-layer networks. Because biases on edges to the outputs never change in this limit, we connect each hidden-layer node to a single output. The hidden-layer nodes are now interpreted as proto-clauses, because their composition in literals is modified during training by changes to the input biases. For example, a proto-clause could sample both a variable and its negation, and rely on training (bias change) to select one or the other. Moving bias changes to the input side of the network alleviates the exponential explosion of static clauses one faces in the $w \to 0$ limit.

The departure from complete Boolean networks we feel is most interesting is increasing the number of hidden node layers. Indeed, keeping training tractable in this setting was the primary motivation for the rectified wire model. To explore this feature we trained a network on three-variable Boolean functions where the hidden layer nodes only have in-degree two. To potentially express relationships among three variables, the hidden nodes are arranged in two layers.

The three-variable network, shown in Figure 8, is complete in the following sense. The nodes in the first hidden layer exhaust the 3×4 ways of collecting inputs from distinct Boolean pairs, with and without negation. One attribute of these nodes is the identity of the Boolean variable — 1, 2 or 3 — that was *not* sampled. The second layer of hidden nodes exhausts all $3 \times 4 \times 4$ combinations of input pairs for which this first hidden layer attribute is different. As in the 16-edge network, the wiring between the final hidden layer and the output nodes is complete in the conventional sense. The resulting network has 216 edges.

Bias renderings, after training, of networks with over 200 edges are not very comprehensible. However, the statistics of the numbers $\#_{\text{err}}$ and $\#_{\text{iter}}$ appear to correlate well with the naive complexity of the Boolean function. We considered three functions that evaluate

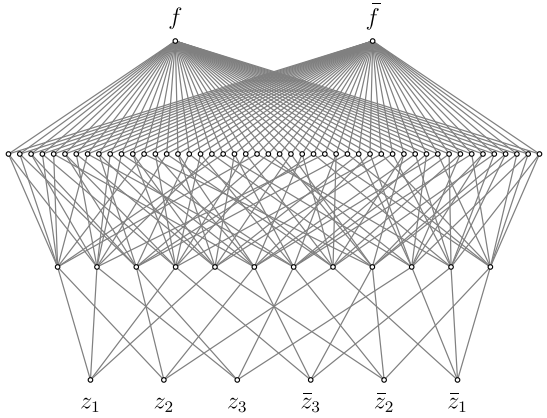

Figure 8: A rectified wire network with two hidden layers that, we conjecture, learns all Boolean functions $f(z_1, z_2, z_3)$ on three variables. All hidden nodes in this network have two inputs.

to 0 and 1 with equal frequency:

$$f_1(z_1, z_2, z_3) = z_1$$
$$f_>(z_1, z_2, z_3) = z_1 z_2 + z_2 z_3 + z_3 z_1$$
$$f_+(z_1, z_2, z_3) = z_1 + z_2 + z_3.$$

Learning f_1, or learning to ignore z_2 and z_3, should be easiest. Function $f_>$, the logical majority function, we expect to be harder because its value, in some but not all cases, is sensitive to all three variables. By the same argument, the parity function f_+ should be the hardest of the three.

All trials we performed on f_1, $f_>$ and f_+, using SDA on the 216-edge network with balanced weights, were successful. Figure 9 shows the distribution of $\#_{\text{err}}$ and $\#_{\text{iter}}$ in 50 trials for each, differing only in the order in which the data are processed. By either metric — the total number of false classifications or the total work in training — the difficulty ranking of the functions is $f_1 < f_> < f_+$. Less extensive trials on the full set of 2^{2^3} Boolean functions all proved successful and leads us to conjecture that the 216-edge network of Figure 8 learns all 3-variable Boolean functions regardless of data order.

We note that the complete Boolean network, with only $2^3(3+2) = 40$ edges, would have been much smaller in this instance and by theorem 5.3 can learn all the Boolean functions in the $w \to 0$ limit. Still, it is reassuring to see that SDA also works in deep networks.

The three-variable Boolean functions also highlight the advantage of the ultra-conservative termination rule for SDA iterations. When we repeat the 50 trials with the stricter zero-

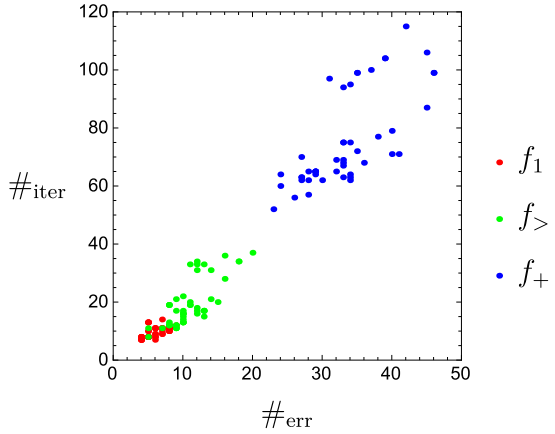

Figure 9: Distribution of $\#_{\text{err}}$ and $\#_{\text{iter}}$ in 50 trials when learning the three-variable Boolean functions f_1, $f_>$ and f_+ on the network shown in Figure 8.

output-value rule ($x_c = 0$), we find that training is not always successful. While training on f_1 was always successful, the success rate on $f_>$ was 76% and on f_+ only 22%. The success rate improves for smaller q and appears to be at 100% for all three functions when $q = 0.5$. Another point in favor of ultra-conservative termination is the greatly reduced number of iterations. For example, by forcing zero outputs, the total number of iterations needed to learn f_1, averaged over data ordering, is about 140, or about 15 times the number needed by the ultra-conservative rule.

8. Sparse expander networks

A nice simplification provided by rectified wire networks is that the training algorithm has very few hyperparameters. Learning succeeds or fails mostly on the basis of the network we choose. However, it is possible that the tractability of rectified wire training comes at the cost of a greater sensitivity to network design. We therefore anticipate that network characteristics — size, depth, sparsity — will take over the role of hyperparameters.

As a general rule, learning improves with larger networks. Since the edge-biases are the only learned parameters of a rectified wire network, the appropriate measure of network size is the number of edges. In this section we introduce a family of networks that adds depth — the number of hidden layers — as a second design parameter.

Layered networks that are completely connected in the conventional sense suffer from a symmetry breaking problem. Since we start with all biases set at zero, a completely connected network has perfect permutation symmetry of its hidden nodes. This symmetry

extends, during training, to the bias updates on all edges between the hidden nodes. To allow for independent settings of the biases, the initial biases must break the symmetry in some data-neutral fashion. Incompletely connected or even sparse networks are an extreme form of symmetry breaking, and correspond to infinite bias settings.

Our network design, called *sparse expander networks*, generalizes the networks of section 7. Sparsity in our case is the property that all the hidden nodes have in-degree of only two. At the same time, the representation of the data is expanded, layer to layer, by a constant growth factor g in the size of layers. The expander structure cannot be applied to the final two layers because of the fixed (and small) number of output nodes. Here the layers are completely connected, thereby making all the information in the last (largest) hidden layer available to each output node. Letting h denote the number of hidden layers, the number of edges in a sparse expander network for $|D|$ inputs and $|C|$ classes, with parameters (g, h), is

$$|E| = |D|(2g + \cdots + 2g^{h-1} + (2 + |C|)g^h). \tag{17}$$

To introduce a degree of uniformity, our networks have a constant out-degree of $2g$ on all input and hidden nodes. This requires that g is an integer. The in-edges to the nodes in a hidden layer are generated by the simplest random algorithm. In a first pass through the hidden layer we create one edge per node to the layer below by drawing uniformly from the nodes that currently have the smaller of two possible out-degrees. A second edge is added in a second pass, at the completion of which all the nodes on the layer below will have out-degree $2g$. Edges from the first hidden layer to the input layer are constructed no differently. This construction is implemented by the publicly available[1] C program `expander` and was used for all the experiments reported in the next section.

We can use the hyperparameter q to assess the role of depth. If performance does not degrade in the limit $q \to 0$, then the network could have been replaced by the much simpler single-hidden-layer model (16). When this limit is applied to a sparse expander network, the number of hidden nodes is $|H| = |D|g^h$. The sampling of the fixed weights a_{ji} in the rectifier gates is also controlled by g and h.

9. Experiments

To describe experiments with conservatively trained rectified wire networks it suffices to specify the network. The SDA algorithm has no other hyperparameters, since there even is a balancing principle that sets the weights. The two-parameter sparse expander networks offer a convenient way to study behavior both with respect to network size and depth. These characteristics were our main focus and guided the choice of experiments going into this study. Follow-up experiments, that featured the weight-multiplier hyperparameter q, later provided critical insights for network design that have yet to be explored.

All our experiments were carried out with a publicly available[1] C implementation of the SDA algorithm called `rainman`. This program requires that the user-supplied network is layered and the number of inputs and outputs are compatible with the data. Our networks were all created by the program `expander`.

1. `github.com/veitelser/rectified-wires`

Although `rainman` reports results at regular intervals, after a specified number of data have been processed, this "batch size" has no bearing on the actual training because bias parameters are only updated in response to wrong classifications. The batch size merely sets the frequency with which the network is tested against a body of test-data. The main result of this test is the classification accuracy: the test-data average of the indicator variable that is 1 for correct, unambiguous classifications, and $1/m$ when the correct class node is in an m-fold tie.

In addition to the classification accuracy, `rainman` also reports a number of other quantities of interest. Two we have already seen in section 7: the running total of misclassifications, $\#_{\text{err}}$, and the work (iterations) performed so far by SDA, $\#_{\text{iter}}$. These should increase while the classification accuracy is below 100%. However, in an "overfitting" situation $\#_{\text{err}}$ and $\#_{\text{iter}}$ stop increasing before the accuracy has reached 100%. Evidence of this phenomenon is more directly discerned through another statistic reported by `rainman`: the average number of SDA iterations required to fix each of the incorrect classifications encountered in the batch, $\langle \#_{\text{iter}} \rangle$. As defined, $\langle \#_{\text{iter}} \rangle$ is never less than 1. However, when there are no misclassifications in the batch at all (keeping $\#_{\text{err}}$ and $\#_{\text{iter}}$ static), the value $\langle \#_{\text{iter}} \rangle = 0$ is reported.

Information more revealing of the internal workings of the network is provided by the layer-averages of the edge activations, $\langle \alpha_1 \rangle, \ldots, \langle \alpha_h \rangle$. Here $\langle \alpha_h \rangle$ is the fraction of edges, in the layer leading to the output nodes, that are active in an average test-data item. These numbers decrease during training, a result of biases being increased.

Lastly, a statistic relevant to the termination of training is the frequency, in the test-data, of irreversible misclassifications, $\langle 0_{\text{err}} \rangle$. The latter arise whenever an output node, not of the correct class, has value zero. The onset of $\langle 0_{\text{err}} \rangle > 0$ signals that training should terminate because activation levels are so low that SDA is forced to make multiple outputs zero even while targeting just the class output. A simple remedy for preventing $\langle 0_{\text{err}} \rangle > 0$ is to increase the size of the network. The case of m-fold classification ambiguities, mentioned above, occurs in practice only when m output nodes are tied at zero. Ambiguous classification is therefore not a problem as long as $\langle 0_{\text{err}} \rangle > 0$.

On a single Intel Xeon 2.00GHz core `rainman` runs at a rate of 50ns per iteration per network edge. Multiplying this number by the product of $\#_{\text{iter}}$ and $|E|$ (17) gives a good estimate of the wall-clock time in all our experiments.

9.1. Nested majority functions

We first describe experiments with a synthetic data set. Synthetic data has some advantages over natural data. Our *nested majority functions* (NMF) data has two nice features. First, through the level of nesting we can systematically control the complexity of the data. Second, because these Boolean functions are defined for all possible Boolean arguments, it is easy to generate large training sets for supervised learning.

NMFs are a parameterized family of Boolean functions that evaluate to 0 and 1 with equal frequency. The first parameter, a prime p, sets the number of arguments at $p-1$. Instances are defined by three integers $a, b, c \in \{1, \ldots, p-1\}$ and a nesting level $n = 0, 1, 2, \ldots$. Starting with

$$f_a^0(z_1, \ldots, z_{p-1}) = z_a,$$

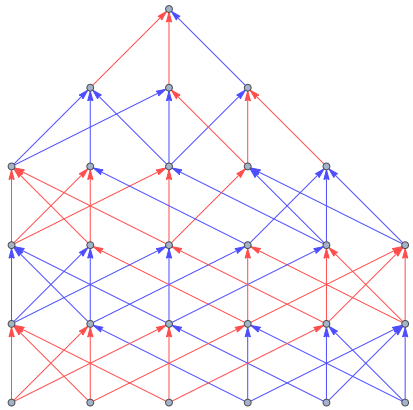

Figure 10: An instance of a depth 5 nested majority function on 6 variables. The nodes are majority gates and the two edge colors indicate the presence/absence of negation. The depth $4, \ldots, 1$ functions correspond to removing $1, \ldots, 4$ layers from the bottom of the circuit.

the other functions (taking values in GF(2)) are defined via the recurrence

$$f_a^n = f_> \left(f^{n-1}_{(ab \bmod p)} + z(ac) \, , \; f^{n-1}_{(2ab \bmod p)} + z(2ac) \, , \; f^{n-1}_{(3ab \bmod p)} + z(3ac) \right) ,$$

where $f_>$ is the 3-argument majority function and

$$z(x) = (x \bmod p) \mod 2$$

should be interpreted as an element of GF(2). The functions f^n at level n correspond to depth-n Boolean circuits taking $p-1$ inputs and constructed from NOT and MAJORITY gates. Figure 10 shows an instance of the function f^5 for $p = 7$.

From the identity

$$f_>(z_1 + 1, z_2 + 1, z_3 + 1) = f_>(z_1, z_2, z_3) + 1$$

it follows that negating all the arguments of a NMF negates its value. The two classes, defined by the NMF value, are therefore equal in size.

Our experiments used data generated by the functions f_1^n for $p = 31$ and $b = 2$, $c = 3$. The easiest of these, with $n = 0$, only depends on a single argument. To learn this function the rectified wire network (taking 2×30 inputs) must identify the correct one and ignore all the others. In the case of f_1^1 it must select three of the arguments and also whether to apply negations. The functions f_1^2, f_1^3, etc. become progressively harder as they depend on

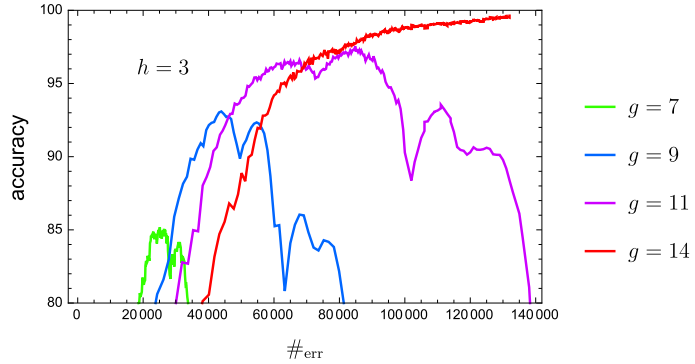

Figure 11: Improvement of the classification accuracy with network size, for the function f_1^3, on rectified wire networks with three hidden layers.

more arguments and with more complicated rules. The possibility of generalizing the value of f^n, from many fewer than 2^{p-1} data, is clearly only possible for small n. Our results go as far as $n = 4$.

We generated training and test data samples (of the 30 Boolean variables) with a pseudo-random number generator. In the longest experiment, with 10^7 training samples, less than 1% of the data was seen more than once by the training algorithm.

We first present results for the function f_1^3. Fixing the number of hidden layers at $h = 3$, Figure 11 shows the effect of increasing the network size via the growth factor g. The accuracy is plotted as a function of $\#_{\text{err}}$, rather than the number of training data, because learning (change of bias) occurs only when there has been a misclassification. In all except the $g = 14$ network (683760 edges), the accuracy reaches a maximum after which there is a sharp decline that coincides with the onset of $\langle 0_{\text{err}} \rangle > 0$. The smaller networks could still serve as imperfect classifiers by terminating their training at the empirical maximum test accuracy, or, in the absence of test data, when $\langle 0_{\text{err}} \rangle$ exceeds a threshold. We have no explanation of the intriguing similarity of the unsuccessful accuracy plots. We also find that many of the seemingly random features in the accuracy plots are nearly reproduced in different random instances of expander networks with the same (h, g).

We emphasize that it is not really surprising that generalization performance can drastically deteriorate with more training examples for small networks. Conservative learning is using a fundamentally different principle than the standard approach that tries to minimize an overall loss function across training examples. Conservative learning is merely trying to myopically account for the most recently seen example, which can have negative consequences for other training examples, to say nothing of unseen test examples.

The effect of changing network depth is shown in Figures 12 and 13. Although the three featured networks have about the same number of edges, only the two deeper networks are

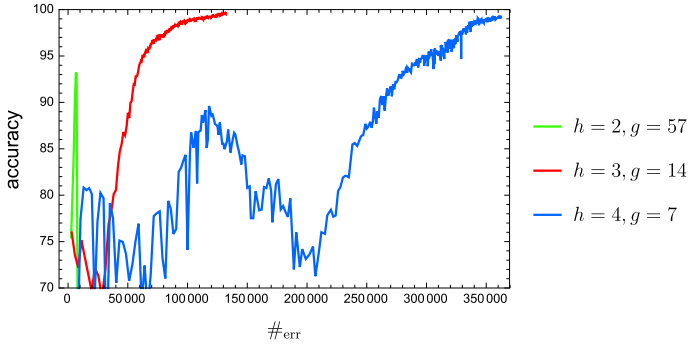

Figure 12: Of three networks with comparable size trained on the function f_1^3, the deeper networks are more successful and require more data.

successful. Figure 12, with accuracy plotted against $\#_{\text{err}}$, shows that learning is faster on shallower networks. On the other hand, when plotted against $\#_{\text{iter}}$ in Figure 13, we see that less work is required to train the deeper networks. Work, as measured in SDA iterations, is not evenly distributed over the course of training. Figure 14 shows $\langle \#_{\text{iter}} \rangle$ plotted against $\#_{\text{err}}$. More iterations are needed early in training, especially so in shallow networks.

The balanced weight heuristic is far from successful in keeping the layer-averaged activation levels uniform. After training the $(h, g) = (3, 14)$ network, we find $\langle \alpha_3 \rangle = 1.1\%$, $\langle \alpha_2 \rangle = 47\%$ with the rest at 100%. For the deeper and also successful $(h, g) = (4, 7)$ network, the diminished activations are $\langle \alpha_4 \rangle = 4.1\%$, $\langle \alpha_3 \rangle = 57\%$, $\langle \alpha_2 \rangle = 76\%$.

The lower complexity of the functions f_1^n for $n < 3$ is reflected in the smaller networks required to learn them. On networks with two hidden layers ($h = 2$), f_1^2 is successfully learned with $g = 21$ (108360 edges) after only 5000 misclassifications. For f_1^1 the corresponding numbers are $g = 6$ (9360 edges) and $\#_{\text{err}} = 900$. On the other hand, if we train f_1^4 on the same network ($h = 4$, $g = 7$) that learned f_1^3 with $\#_{\text{err}} \approx 4 \times 10^5$, the best accuracy, achieved for roughly the same $\#_{\text{err}}$, is only 91.9%.

The prediction accuracy on NMF data, for all of our networks, is improved by decreasing the weight-multiplier hyperparameter q. In fact, it appears that $q \to 0$ is optimal, or that the best performance can be achieved with the model (16) comprising a single layer of rectifier gates with fixed weights a_{ji}. A striking case is the function f_1^3 trained on the sparse expander graph with $h = 2, g = 57$, already encountered in Figure 12. Figure 15 shows the effect of decreasing q from the balanced setting, $q = 1$. We see that the 94% accuracy of the $q = 1$ network reaches 100% already for $q = 0.7$. It seems the only downside in decreasing q is an increase in the number of training data (greater $\#_{\text{err}}$). The $q \to 0$ weight "codewords" a_{ji} associated with the sparse expander network are very simple. Because the network has in-degree two and depth $h = 2$, almost all the rectifiers see four random inputs that are

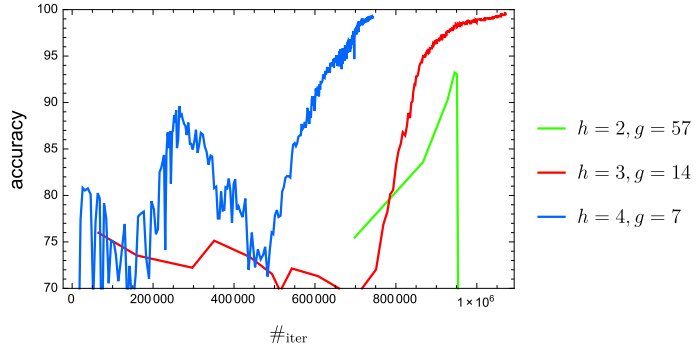

Figure 13: Same as Figure 12, except plotted against the total work (SDA iterations).

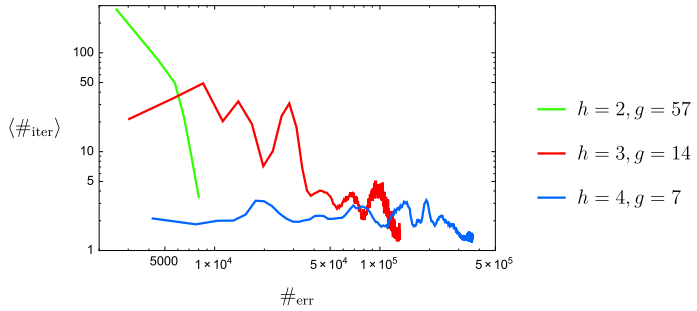

Figure 14: Average number of iterations used by the SDA algorithm to fix a wrong classification over the course of training for the three networks featured in Figs. 12 and 13.

given equal weight. It is likely that the performance of model (16) can be further improved with weight codewords that go beyond those generated by sparse expander networks.

In light of the $q \to 0$ findings, it is not surprising that conventional neural networks, even with just a single hidden layer, easily outperform the rectified wire model on the NMF data. A fully-connected ReLU network with one layer of only 50 hidden nodes was sufficient to learn f_1^3 completely after seeing 5×10^5 samples. This can be compared with the 2×10^4 samples ($\#_{\text{err}}$) that informed bias changes in the rectified wire model when learning the same data (Figure 15). The vast reduction in the number of hidden nodes, from 2×10^5 (penultimate layer of the $h = 2, g = 57$ network) to 50, no doubt is attributable to the

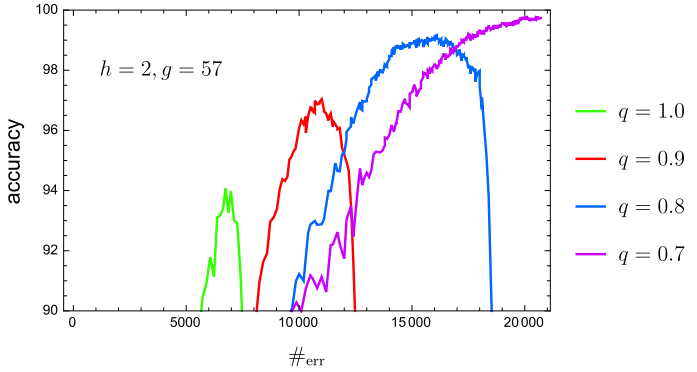

Figure 15: Evolution of the prediction accuracy with the weight-multiplier hyperparameter q on the $h = 2, g = 57$ network for the function f_1^3.

standard model's capacity for "designing" the weight-codewords that in model (16) are static.

9.2. MNIST

Seen as images, the MNIST handwritten digits (LeCun et al., 1998) are analog data. Because the contrast in these images is well approximated as two-valued, it makes sense to map pixels to a two-symbol alphabet and train a rectified wire network on data of that type. We report results with this approach at the end of this section. However, we first try processing MNIST non-symbolically, using the analog data vectors described in equation (2).

One motivation for the analog approach is that MNIST images are highly compressible. Playing to a possible strength of rectified wire networks, it might be advantageous to first map MNIST images, and images in general, to data vectors the components of which are more nearly statistically independent. We use a method based on principal component analysis.

Using singular value decomposition, we approximate the 60000×28^2 matrix X of flattened MNIST training images as the product $X \approx UV$, where the rows of the $r \times 28^2$ matrix V are the orthonormal "eigen-images" associated with the r largest singular values of X. A flattened image x (training or testing) is mapped to r analog channels by $v = Vx$. Applying the component-wise cumulative probability distribution functions to this v then gives us the $2r$-component data vector as in equation (2). We compute the cumulative probability function from the training data and use the same function when processing the test data (with test samples below the minimum or above the maximum training samples mapped to 0 and 1 respectively).

Figure 16 shows the test accuracy when training a sparse expander network on analog MNIST data with $r = 50$ channels. This network has 205400 edges, the same number a conventional network would have with a single fully-connected layer of 259 hidden nodes. After making about $\#_{\text{err}} = 25000$ misclassifications, there are no further misclassifications on the training data and training ceases. The test accuracy attains a maximum of 94.54% at this point. Figure 17 shows the evolution of $\langle \#_{\text{iter}} \rangle$ over the course of training. Generalization (test accuracy) improves when we decrease the q hyperparameter from the value $q = 1$ for balanced weights. However, the improvement, reaching 94.99% at $q = 0.2$, is much more modest than we found for the NMF data. The time used by `rainman` in any of these training runs was about 65 minutes. Although about one million data (16 epochs) are processed, only for about 25000 of these does SDA do anything.

We also used the analog MNIST data to compare SDA training with stochastic gradient descent (SGD) training on the same model and network architecture. Because the sparse networks we use for SDA are a poor fit for GPU-based software, we wrote a C++ SGD optimizer that, like SDA, runs on a single core without calls to a GPU. In the strictest comparison SGD used the same monotone loss function, x_c, used by SDA. For SGD we also tried multi-class hinge loss, with margin parameter 0.1. As discussed in section 3, this loss spoils tractability (monotone bias changes) and is therefore not applicable for SDA. The mini-batch size for SGD was fixed at 100 and we employed standard stochastic gradient descent without momentum.

SGD does poorly when forced to use SDA's monotone loss. With the learning rate set at 0.002, training accuracy reaches a maximum of 91.5% in 6 minutes; this is also the test accuracy for this mode of operation. Since SDA uses adaptive gradient steps (set by deactivations), we also tried SGD with a ten-fold reduction in learning rate. While training now goes through 97 epochs of data and takes about as long as SDA, there is no improvement in either the training or test accuracy. We interpret this as supporting the conservative learning principle: there are gains when parameters are optimally adjusted in response to individual data.

The performance of SGD improves significantly when the rectified wire model is trained with multi-class hinge loss. However, due to the structure of expander networks, this loss is problematic when applied exclusively. When evaluated on the initial expander network (all edges active), the partial derivatives of the loss with respect to all biases, except those on edges to the outputs, are identically zero. This occurs because the effect of all bias changes (except in the final layer) passes through the penultimate layer of nodes that is completely connected to the outputs, and equal changes on these leaves the hinge loss unchanged. To avoid the zero derivative problem we used a hybrid approach, where hinge loss was used only after some number of data had first been processed with the monotone x_c loss to create deactivations that break the symmetry in the final layer. Switching to hinge loss after 5 epochs had no effect on accuracy, but switching after 10 epochs improved training and test accuracies to 94.4% and 94.1%, respectively. This trend in improvement continues and reaches 96.8% (training) and 95.6% (test) when the switch is made after 20 epochs (121 minutes). We attribute the modest improvement in generalization (0.6%), over the SDA trained model, to the margins that hinge loss is able to insert in the class boundaries.

We do not believe the overfitting we saw with SDA was caused by limiting the analog data vectors to only 50 channels, because essentially the same classification accuracy is

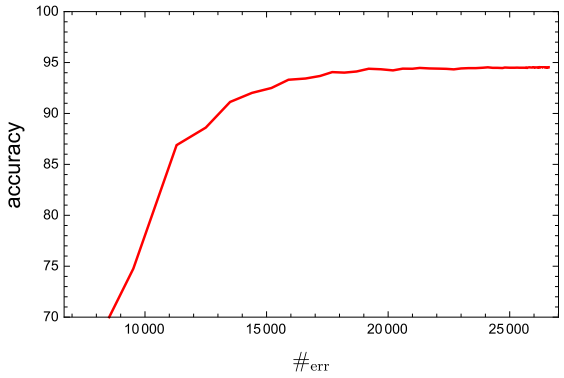

Figure 16: Classification accuracy of MNIST images from 50-principal-component data vectors with the SDA algorithm on a sparse expander network with parameters $h = 2$, $g = 13$.

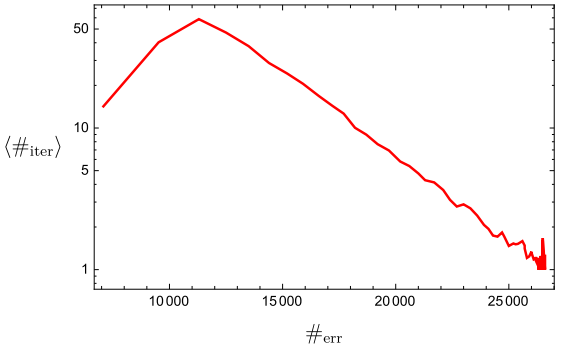

Figure 17: SDA iterations per misclassification for the same data and network as in Figure 16

.

obtained with the uncompressed symbolic data. The latter was generated from the raw MNIST images by thresholding pixel values at 40% of the maximum (the minimum point of the pixel histogram) to define the two symbols. Figure 18 shows the evolution of the accuracy at fixed depth $h = 4$ as the network size increases. In the smallest network ($g = 1$),

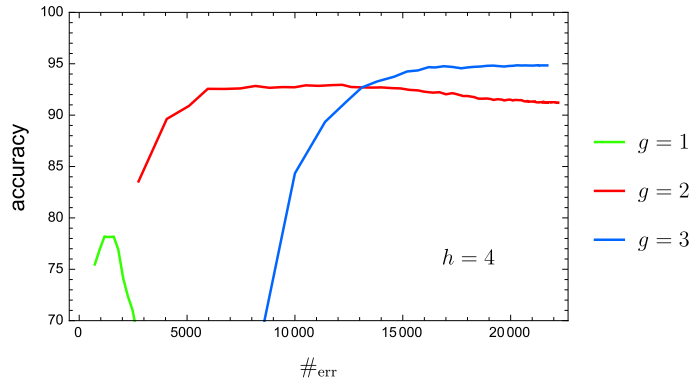

Figure 18: Classification accuracy of binarized MNIST images on rectified wire networks with four hidden layers.

as expected, the accuracy drops precipitously at the onset of $\langle 0_{\rm err}\rangle > 0$. However, already in the next network ($g = 2$) we have the situation where training terminates because most (training) data are correctly classified and the remaining ambiguous cases are ties at zero (in output) and untrainable. At termination we find $\langle 0_{\rm err}\rangle = 2.7\%$, contributing to the reduction in accuracy. Increasing the network size further ($g = 3$) gives accuracy 94.8% at termination, where now $\langle 0_{\rm err}\rangle = 0$. This accuracy is close to that obtained with the analog data.

Although our results for MNIST are an improvement over the simple linear classifier with accuracy 88%, and even a pairwise-boosted linear classifier (92.4%), the appropriate comparison should be with other tractable methods. Of these, we note that support vector machines with a Gaussian kernel already achieve 98.6% accuracy on MNIST. These and other techniques for MNIST are reviewed in LeCun et al. (1998).

9.3. Markov sequences

As our final application we study a synthetic symbolic dataset where, unlike the nested majority function data, samples are generated probabilistically. The data are strings in the alphabet {A,B,C,D} generated by Markov chains. Examples of 12-symbol strings from the two classes are shown in Table 1. Those in class 1 are extracts from the Markov chain defined by the transition matrix

$$T = \frac{1}{10}\begin{bmatrix} 1 & 2 & 1 & 6 \\ 3 & 1 & 4 & 2 \\ 4 & 1 & 4 & 1 \\ 2 & 6 & 1 & 1 \end{bmatrix}. \qquad (18)$$

ABDDBADCABBD	CCCBDABCADBD

Table 1: Examples of 12-symbol strings extracted from the Markov chain with transition matrix (18), in class 1, and its transpose, in class 2.

Since T is doubly stochastic, its transpose defines another Markov chain and is the source of the strings in class 2. The doubly stochastic property also ensures that the four symbols occur with equal frequency. Finally, the absence of zeros means that all bigrams have finite probability.

Even a machine that managed to reconstruct T from the data could never have perfect classification accuracy, because every 12-symbol string occurs with finite probability in either chain. The optimal classifier selects the chain (class) that gives each string the highest probability. With this criterion applied to our T, the true-positive rate for 12-symbol strings is 95.1%. We also trained networks on 25-symbol strings, for which the true-positive rate is 99.1%. These numbers set the maximum achievable classification accuracy.

In Figures 20 and 21 we compare classification accuracies for 12- and 25-symbol strings as learned on networks having approximately 2×10^5 edges. We see that here the depth of the network has very little effect on the maximum accuracy. By the probabilistic nature of

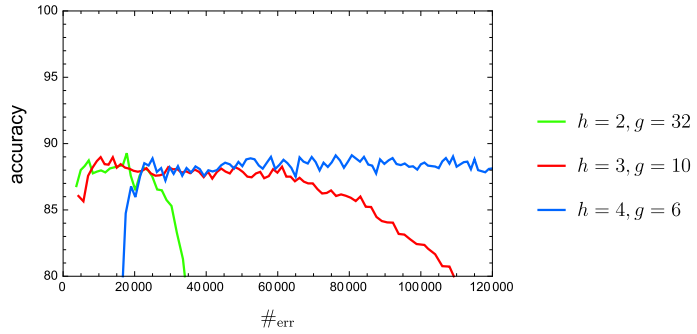

Figure 20: Classification accuracy of 12-symbol strings generated by the Markov chain (18) or its transpose.

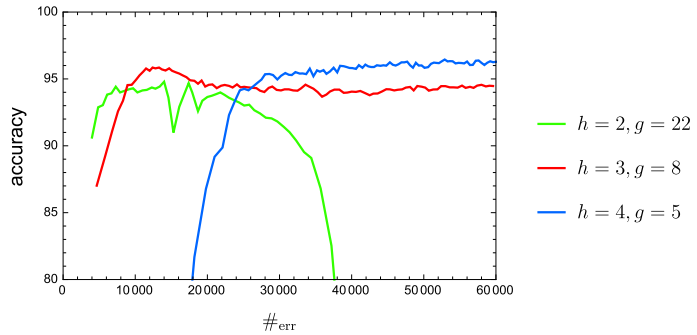

Figure 21: Classification accuracy of 25-symbol strings generated by the Markov chain (18) or its transpose.

the data, these accuracies must eventually decline as strings having higher probability, in the class with the other label, are encountered. Deeper networks are less vulnerable to this phenomenon. The highest accuracy achieved for 12-symbol strings is 6% below that of the optimal classifier; for 25-symbol strings the shortfall is 3%.

We did not explore the effect of decreasing the q hyperparameter for this data set.

10. Discussion

The rectified wire model is a significant departure from the "standard model" of neural networks. Even so, the training algorithm we derived for this model, SDA, deserves comparison with the leading algorithm for the standard model: stochastic gradient descent (SGD) (Rumelhart et al., 1986). In both algorithms the network parameters are updated after only a small amount of data has been seen: a single item in the case of SDA, a mini-batch for SGD. The computation of updates involves propagating data vectors in a forward pass, and the class of the data — or the associated loss — in a backward pass. SDA makes an extra forward pass that determines the size of each update, signaled by a deactivation event. In SGD the size of the update is set by the learning rate, a hyperparameter, and the update itself is an average over the mini-batch, whose size is another hyperparameter.

The characteristic of SDA that most differentiates itself from SGD is the monotone evolution of the network parameters. Ostensibly this is problematic: there is no "going back" on any updates, including those made early when very little of the data had been seen. This tacitly assumes the learned state of the network is unique, or nearly so. But an alternative hypothesis is also worth considering: a high multiplicity of learned states, all equally viable. Our experiments with SDA support this hypothesis. Very different final bias settings, all giving perfect classification, were obtained even for simple classes just by changing the order of the data. Our experiments with Markov-chain generated strings showed that SDA is also not tripped up by outlier data. Although the final network in this probabilistic setting must have 100% classification ambiguity, the accuracy in practice is near that of the optimal classifier long before this asymptotic state is reached.

Not all our experiments with SDA were successful. On the MNIST dataset the algorithm suffered from overfitting: whereas the network had learned to perfectly classify the training data, the classification accuracy on the test data was only 95%. Does this reflect a fundamental deficiency in the rectified wire model, and the conservative learning principle more generally, or is it a result of poor execution?

An even more serious problem with the rectified wire model was exposed, in experiments, upon decreasing the weight-multiplier hyperparameter q. Recall that the primary motivation for the model was tractable training in the presence of network depth. Significant simplifications of the standard neural network model, such as fixing the weights and replacing loss by a constraint, were key in facilitating tractable training. Even so, the expressivity provided by the remaining bias parameters remains high (arbitrary Boolean functions), and the training algorithm (SDA) fully utilizes activations (ReLU nonlinearities) in every layer of the network. The q parameter was introduced to explore behavior with respect to depth: small/large q favors bias changes near the output/input nodes. Though we studied a very limited class of networks — sparse expander nets — the experimental results pointed uniformly in favor of $q \to 0$. In this limit the rectified wire model reduces to a much simpler model (16), comprising a single layer of rectifier gates. While this limiting model is still non-trivial and interesting, it definitely lacks depth.

Our experience with the rectified wire model highlights the difference between the capacity for depth and the learnability of depth. Although there exist bias settings in the model that efficiently represent complex Boolean functions and utilize activations on all levels, experiments show that these are not the kinds of bias settings that are learned by

the tractable, conservative route. At least that is the conclusion we should draw from the experiments performed so far.

There are still some directions to explore before we can conclude that conservatively trained rectified wire networks lack the capacity to learn "in depth". The most obvious is to try architectures very different from the sparse expander networks considered so far. These need not even be layered, although they must break symmetry if we continue to initialize all the bias parameters at zero. Specialized architectures may be inherently better at exploiting depth, as in the case of standard model networks with convolutional layers. Next, we recall that the bias updates given by the SDA algorithm can fall short of the most conservative possible. While we do not know whether the quadratic program (4) can be solved by something as efficient as the SDA algorithm, experiments with general-purpose solvers could study the effect of update quality on training. By the same route one could study the effect of learning, in aggregate, entire mini-batches (section 3, conclusions). Another avenue is to define "conservative" by the 1-norm on the bias updates. Our choice of the 2-norm was motivated by the uniqueness of the optimal updates. However, it seems likely that in the mini-batch setting even the 1-norm will have unique optima. Finally, it might be interesting to allow the weights in the network to vary slowly over the course of training. This could be as simple as favoring different depths over time using the q parameter, or a more sophisticated scheme based on running averages.

Acknowledgments

We thank Alex Alemi, Sergei Burkov, Pat Coady, Cris Moore and Mehul Tikekar for discussions over the course of this project. We also thank the three reviewers whose comments brought significant improvements to the paper.

Abstract

Pyro is a probabilistic programming language built on Python as a platform for developing advanced probabilistic models in AI research. To scale to large data sets and high-dimensional models, Pyro uses stochastic variational inference algorithms and probability distributions built on top of PyTorch, a modern GPU-accelerated deep learning framework. To accommodate complex or model-specific algorithmic behavior, Pyro leverages Poutine, a library of composable building blocks for modifying the behavior of probabilistic programs.

Keywords: Probabilistic programming, graphical models, approximate Bayesian inference, generative models, deep learning

```python
def model():
  loc, scale = torch.zeros(20), torch.ones(20)
  z = pyro.sample("z", Normal(loc, scale))
  w, b = pyro.param("weight"), pyro.param("bias")
  ps = torch.sigmoid(torch.mm(z, w) + b)
  return pyro.sample("x", Bernoulli(ps))

def guide(x):
  pyro.module("encoder", nn_encoder)
  loc, scale = nn_encoder(x)
  return pyro.sample("z", Normal(loc, scale))
```

```python
def conditioned_model(x):
  return pyro.condition(model, data={"x": x})()

optimizer = pyro.optim.Adam({"lr": 0.001})
loss = pyro.infer.Trace_ELBO()

svi = pyro.infer.SVI(model=conditioned_model,
                     guide=guide,
                     optim=optimizer,
                     loss=loss)

losses = []
for batch in batches:
    losses.append(svi.step(batch))
```

Figure 1: A complete Pyro example: the generative model (`model`), approximate posterior (`guide`), constraint specification (`conditioned_model`), and stochastic variational inference (`svi`, `loss`) in a variational autoencoder. `encoder` is a `torch.nn.Module` object. `pyro.module` calls `pyro.param` on every parameter of a `torch.nn.Module`.

1. Introduction

In recent years, richly structured probabilistic models have demonstrated promising results on a number of fundamental problems in AI (Ghahramani (2015)). However, most such models are still implemented from scratch as one-off systems, slowing their development and limiting their scope and extensibility. Probabilistic programming languages (PPLs) promise to reduce this burden, but in practice more advanced models often require high-performance inference engines tailored to a specific application. We identify design principles that enable a PPL to scale to advanced research applications while retaining flexibility, and we argue that these principles are fully realized together in the Pyro PPL.

2. Design Principles

First, a PPL suitable for developing state-of-the-art AI research models should be **expressive**: it should be able to concisely describe models with have data-dependent internal control flow or latent variables whose existence depends on the values of other latent variables, or models which only be defined in closed form as unnormalized joint distributions.

For a PPL to be practical, it must be **scalable**: its approximate inference algorithms must be able to seamlessly handle the large data sets and non-conjugate, high-dimensional models common in AI research, and should exploit compiler and hardware acceleration to approach the performance of optimized bespoke implementations of these models.

A PPL targeting research models should be **flexible**: in addition to scalability, many advanced models require inference algorithms with complex, model-specific behavior. A PPL should enable researchers to quickly and easily implement such behavior and should enforce a separation of concerns between between model, inference, and runtime implementations.

Finally, a PPL targeting researchers as users should strive to be **minimal**: in order to minimize cognitive overhead, it should share most of its syntax and semantics with existing languages and and systems and work well with other tools such as libraries for visualization.

As is clear from Table 2, these four principles are often in conflict, with one being achieved at the expense of others. For example, an overly flexible design may be very difficult to implement efficiently and scalably, especially while simultaneously integrating a new language with existing tools. Similarly, enabling development of custom inference algorithms may be difficult without limiting model expressivity. In this section, we describe the design choices we made in Pyro to balance between all four objectives.

Pyro is embedded in Python, and Pyro programs are written as Python functions, or callables, with just two extra language primitives (whose behavior is overridden by inference algorithms): `pyro.sample` for annotating calls to functions with internal randomness, and `pyro.param` for registering learnable parameters with inference algorithms that can change them. Pyro models may contain arbitrary Python code and interact with it in arbitrary ways, including expressing unnormalized models through the `obs` keyword argument to `pyro.sample`. Pyro's language primitives may be used with all of Python's control flow constructs, including recursion, loops, and conditionals. The existence of random variables in a particular execution may thus depend on any Python control flow construct.[1]

Pyro implements several generic probabilistic inference algorithms, including the No U-turn Sampler (Hoffman and Gelman (2014)), a variant of Hamiltonian Monte Carlo. However, the primary inference algorithm is gradient-based stochastic variational inference (SVI) (Kingma and Welling (2014)), which uses stochastic gradient descent to optimize Monte Carlo estimates of a divergence measure between approximate and true posterior distributions. Pyro scales to complex, high-dimensional models thanks to GPU-accelerated tensor math and reverse-mode automatic differentiation via PyTorch, and it scales to large data sets thanks to stochastic gradient estimates computed over mini-batches of data in SVI.

Some inference algorithms in Pyro, such as SVI and importance sampling, can use arbitrary Pyro programs (called *guides*, following webPPL) as approximate posteriors or proposal distributions. A guide for a given model must take the same input arguments as the model and contain a corresponding sample statement for every unconstrained sample statement in the model but is otherwise unrestricted. Users are then free to express complex hypotheses about the posterior distribution, e.g. its conditional independence structure. Unlike webPPL and Anglican, in Pyro guides may not depend on values inside the model.

Finally, to achieve flexibility and separation of concerns, Pyro is built on Poutine, a library of effect handlers (Kammar et al. (2013)) that implement individual control and book-keeping operations used for inspecting and modifying the behavior of Pyro programs, separating inference algorithm implementations from language details.

3. Project Openness and Development

Pyro's source code is freely available under an MIT license and developed by the authors and a community of open-source contributors at `https://github.com/uber/pyro` and documentation, examples, and a discussion forum are hosted online at `https://pyro.ai`. A comprehensive test suite is run automatically by a continuous integration service before code is merged into the main codebase to maintain a high level of project quality and usability.

We also found that while PyTorch was an invaluable substrate for tensor operations and automatic differentiation, it was lacking a high-performance library of probability

1. See the `geometric` example in `http://pyro.ai/examples/intro_part_i.html`

distributions. As a result, several of the authors made substantial open-source contributions upstream to PyTorch Distributions,[2] a new PyTorch core library inspired by TensorFlow Distributions (Dillon et al. (2017)).

4. Existing Systems

System	Expressivity: Dynamic control	Scalability: Subsampling, AD	Flexibility: Flexible inference	Minimality: Host language
Stan	Static control flow	Some, CPU	Automated	None
Church	Yes	No, None	Automated	Scheme
Venture	Yes	No, None	Yes	None
webPPL	Yes	No, CPU	Some	JavaScript
Edward	Static control flow	Yes, CPU/GPU	Yes	TensorFlow
Pyro	Yes	Yes, CPU/GPU	Yes	Python, PyTorch

Figure 2: Simplified summary of design principles of Pyro and some other PPLs.

Probabilistic programming and approximate inference are areas of active research, so there are many existing probabilistic programming languages and systems. We briefly mention several that were especially influential in Pyro's development, regretfully omitting (due to space limitations) many systems for which simple direct comparisons are more difficult. We also emphasize that, as in conventional programming language development, our design decisions are not universally applicable or desirable for probabilistic programming, and that other systems purposefully make different tradeoffs to achieve different goals.

Stan (Carpenter et al. (2017)) is a domain-specific language designed for describing a restricted class of probabilistic programs and performing high-quality automated inference in those models. Church (Goodman et al. (2008)), a probabilistic dialect of Scheme, was an early universal probabilistic programming language, capable of representing any computable probability distribution. Venture (Mansinghka et al. (2018)) is a universal language with a focus on expressiveness and flexibility and a custom syntax and virtual machine. Anglican (Tolpin et al. (2016)) and webPPL (Goodman and Stuhlmüller (2014)) are lightweight successors to Church, embedded as syntactic subsets (Wingate et al. (2011)) in the general-purpose programming languages Clojure and JavaScript. Edward (Tran et al. (2017)) is a PPL built on static TensorFlow graphs that features composable representations for models and inference. ProbTorch (Siddharth et al. (2017)) is a PPL built on PyTorch with a focus on deep generative models and developing new objectives for variational inference. Turing (Ge et al. (2018)) is a PPL embedded in Julia featuring composable MCMC algorithms.

5. Experiments

To demonstrate that Pyro meets our design goals, we implemented several state-of-the-art models.[3] Here we focus on the variational autoencoder (VAE; Kingma and Welling (2014))

Figure 4: Test ELBOs for DMM and extension with IAF guide

and the Deep Markov Model (DMM; Krishnan et al. (2017)), a non-linear state space model that has been used for several applications including audio generation and causal inference. The VAE is a standard example in deep probabilistic modeling, while the DMM has several characteristics that make it ideal as a point of comparison: it is a high-dimensional, non-conjugate model designed to be fit to large data sets; the number of latent variables in a sequence depends on the input data; and it uses a hand-designed approximate posterior.

The models and inference procedures derived by Pyro replicate the original papers almost exactly, except that we use Monte Carlo estimates rather than exact analytic expressions for KL divergence terms. We use the MNIST data set and 2-hidden-layer MLP encoder and decoder networks with varying hidden layer size $\#h$ and latent code size $\#z$ for the VAE and the same data set of digitized music[4] to train the DMM.

To demonstrate that Pyro's abstractions do not reduce its scalability by introducing too much overhead, we compared our VAE implementation with an idiomatic PyTorch implementation.[5] After verifying that they converge to the same test ELBO, we compared the wall-clock time taken to compute one gradient update, averaged over 10 epochs of GPU-accelerated mini-batch stochastic gradient variational inference (batch size 128) on a single NVIDIA GTX 1080Ti. Figure 3 shows that the relative performance gap between the Pyro and PyTorch versions is moderate, and, more importantly, that it shrinks as the total time spent performing tensor operations increases.

We used the DMM to evaluate Pyro's flexibility and expressiveness. As Figure 4 shows, we found that we were able to quickly and concisely replicate the exact DMM model and inference configuration and quantitative results reported in the paper after 5000 training epochs. Furthermore, thanks to Pyro's modular design, we were also able to build DMM variants with more expressive approximate posteriors via autoregressive flows (IAFs) (Kingma et al. (2016)), improving the results with a few lines of code at negligible computational cost.

Editor: Mehryar Mohri

Abstract

A classic finding by (Kalish et al., 2007) shows that no language can be learned iteratively by rational agents in a self-sustained manner. In other words, if A teaches a foreign language to B, who then teaches what she learned to C, and so on, the language will quickly get lost and agents will wind up teaching their own common native language. If so, how can linguistic novelty ever be sustained? We address this apparent paradox by considering the case of iterated learning in a social network: we show that by varying the lengths of the learning sessions over time or by keeping the networks dynamic, it is possible for iterated learning to endure forever with arbitrarily small loss.

1. Introduction

People typically form opinions by updating their current beliefs and reasons in response to new signals from other sources (friends, colleagues, social media, newspapers, etc.) (Tahbaz-Salehi et al., 2009; Acemoglu and Ozdaglar, 2011; Golub and Jackson, 2010). Suppose there were an information source that made a noisy version of the "truth" available to agents connected through a social network. Under which conditions would the agents reach consensus about their beliefs? What would ensure truthful consensus (meaning that the consensus coincided with the truth)? How long would it take for the process to converge? Addressing these questions requires agreeing on a formal model of distributed learning. Fully rational agents update their beliefs by assuming a prior and using Bayes' rule to integrate all past information available to them (Acemoglu et al., 2011; Mueller-Frank, 2013; Lobel and Sadler, 2015; Mossel et al., 2011; Banerjee, 1992; Bala and Goyal, 1998). Full rationality is intractable in practice (Molavi et al., 2015; Rahimian and Jadbabaie, 2016a), so much effort has been devoted to developing computationally effective mechanisms, including non- (or partially) Bayesian methods (Jadbabaie et al., 2012; Molavi et al., 2015; Golub and Jackson, 2010, 2012; Jadbabaie et al., 2013). Much of this line of work can be traced back to the seminal work of (DeGroot, 1974) on linear opinion pooling.

As the simplest example of iterated learning in a social network, consider a system consisting of one teacher and one learner. The teacher samples data from a distribution and sends it to the learner; the learner updates her belief via Bayes rule repeatedly in order to learn that distribution. This system is equivalent to the usual Bayesian inference scenario. Under mild assumptions, the learner will eventually learn the ground truth asymptotically (Gelman et al., 2013).

When the network structure comes into play, the dynamics of the learning process becomes more complicated. If the social network forms a chain $X, Y, Z, \ldots$ such that agents teach each other in sequence: X teaches Y, who then teaches Z, and so on, by a classic result of Griffiths and Kalish (Griffiths and Kalish, 2005), the information from the source will vanish after a finite number of iterations. At that point, the agents, assumed to be rational, will be "teaching" each other nothing they don't already know: iterated learning is not self-sustaining (Beppu and Griffiths, 2009; Griffiths and Kalish, 2007, 2005; Rafferty et al., 2009; Kirby et al., 2014; Griffiths et al., 2008; Perfors and Navarro, 2011; Rafferty et al., 2014; Smith, 2009; Kalish et al., 2007). Such findings are hard to validate empirically but variants of it are within the reach of experimental psychology (Kalish et al., 2007). Similar laboratory experiments with human subjects have confirmed the unstainability of iterated learning (Kalish et al., 2007; Beppu and Griffiths, 2009; Tamariz and Kirby, 2015; Bartlett; Griffiths et al., 2008). Similar results of unstainability are found in computational linguistics where, instead of agents sending information, the scenario is about language evolution through generations (Rafferty et al., 2009).

If agents interact in a more complicated and dynamic network, more possibilities of the learning dynamics will emerge. Dynamic networks are common occurrences in opinion dynamics (Hegselmann and Krause, 2002; Mohajer and Touri, 2013; Chazelle and Wang, 2016; Chazelle, 2015), but, to our knowledge, somewhat new in the context of social learning. Following the *Bayesian-Without-Recall* (BWR) model proposed by Rahimian and Jadbabaie in (Rahimian and Jadbabaie, 2016a), we assume the agents to be memoryless and rational: this means that they use Bayesian updates based on current beliefs and signals with no other information from the past, see also (Rahimian et al., 2015a,b; Rahimian and Jadbabaie, 2016b). The BWR model seeks to capture the benefits of rational behavior while keeping both the computation and the information stored to a minimum (Rahimian and Jadbabaie, 2016b).

We focus in this paper on sustainable learning: the conditions to ensure arbitrarily small information loss in truthful consensus (formal definition in the following sections). For chained learning, we show how keeping the length of the training sessions (number of samples transferred) growing slightly allows iterated learning to be sustained in perpetuity. This resolves the paradox raised from language evolution models (Kalish et al., 2007). We further analyze the case when the learner has the ability to reach back to her early ancestors for "fresher" data instead of listening to her direct ancestor, and show how this "hopped" learning mechanism further helps prevent information decay. For the case when the learning network changes over time, we show that under the assumption that each agent hears a noisy signal from the truth at a frequency bounded away from zero, the system reaches truthful consensus almost surely with a convergence rate polynomial in expectation. The relation between the convergence rate and the graph structure is also revealed with a seemingly counter-intuitive finding that agents in a better connected network learn more slowly.

We first introduce the iterated learning model framework with the notation, definitions, and basic properties in Section 2. Then we exam the scenarios of chained learning, hopped learning, and networked learning in Section 3, Section 4, and Section 5, respectively. We show our main results in each section, followed by details of the proofs and discussions.

2. Models, Preliminaries, and Notation

In this section, we formally define the problem mathematically. Assume there are n agents denoted by their indices $1, 2, \ldots, n$. At time $t = 0, 1, \ldots$, the belief of agent i is a probability distribution

over a state space Θ, which is denoted by $\mu_{t,i}$. The interactions between agents are modeled by an infinite sequence $(G_t)_{t\geq 0}$, where each G_t is a directed graph over the node set $\{1,\ldots,n\}$. An edge pointing from i to j in G_t indicates that i receives data from j at time t. Intuitively, the direction of the edge has the same meaning as the "listen-to" activity. Typically, the sequence of graphs is specified ahead of time or is chosen randomly: the only condition that matters is that it should be independent of the randomness used in the data generating and learning process; specifically, taking expectations and variances of the random variables that govern the dynamics will assume a fixed graph sequence (possibly random). The adjacency matrix of G_t is denoted by A_t: it is an $n \times n$ $0/1$ matrix.

2.1. The existence of an information source

When an information source exists whose belief is fixed, we label it agent 0 and refer to it as the *truth*. In such a case, the graph G_t is over the node set $\{0,1,\ldots,n\}$. Because agent 0 (if it exists) holds the truth, no edge out of it points to another node. The adjacency matrix then becomes an $(n+1)\times(n+1)$ matrix whose first row is $(1,0,\ldots,0)$, with a self-loop at agent 0 for simplicity.

2.2. Data generation

At time $t \geq 0$, each agent $i > 0$ samples a state $\theta_{t,i} \in \mathbb{R}$ consistent with her own belief: $\theta_{t,i} \sim \mu_{t,i}$. A noisy measurement $a_{t,i} = \theta_{t,i} + \varepsilon_{t,i}$ is then sent to each agent j such that $(A_t)_{ji} = 1$. All the noise terms $\varepsilon_{t,i}$ are sampled *iid* from $\mathcal{N}(0,\sigma^2)$. An equivalent formulation is to say that the likelihood function $l(a|\theta)$ is drawn from $\mathcal{N}(\theta,\sigma^2)$. In our setting, agent i sends the same data to all of her neighbors; this is done for notational convenience and the same results would still hold if we were to resample independently for each neighbor. Except for the omission of explicit utilities and actions, our setting is easily identified as a variant of the BWR model of (Rahimian and Jadbabaie, 2016a).

2.3. Beliefs update

A single-step update for agent $i > 0$ consists of setting $\mu_{t+1,i}$ as the posterior $\mathbb{P}[\mu_{t+1,i}|d] \propto \mathbb{P}[d|\mu_{t,i}]\mathbb{P}[\mu_{t,i}]$, where d is the data from the neighbors of i received at time t. For the case when the beliefs are Gaussian, we get the classical update rules from Bayesian inference by plugging in the corresponding normal distribution (Box and Tiao, 2011). Updated beliefs remain Gaussian so we can use the notation $\mu_{t,i} \sim \mathcal{N}(x_{t,i}, \tau_{t,i}^{-1})$, where $\tau_{t,i}$ denotes the precision (inverse variance) $\sigma_{t,i}^{-2}$. Writing $\tau = \sigma^{-2}$ and letting $d_{t,i}$ denote the outdegree of i in G_t, for any $i > 0$ and $t \geq 0$, we have

$$\begin{cases} x_{t+1,i} = (\tau_{t,i}x_{t,i} + \tau a_{t,1} + \cdots + \tau a_{t,d_{t,i}})/(\tau_{t,i} + d_{t,i}\tau); \\ \tau_{t+1,i} = \tau_{t,i} + d_{t,i}\tau, \end{cases} \tag{1}$$

where $a_{t,1},\ldots,a_{t,d_{t,i}}$ are the signals received by agent i from its neighbors at time t.

2.4. The influence of the graph sequence

The graph sequence G_t plays a crucial role in the dynamics of the system. A simple starting example is the constant graph of two agents with one directed edge. Such a graph sequence defines the case where one learner repeatedly gets samples from the information source. If the information source is regarded as the ground truth, this system is equivalent to the usual Bayesian inference

scenario. Instead of exhausting all possible graph sequences, in this paper, we focus on three representative types, namely the *chained learning*, *hopped learning*, and *networked learning* models. The fundamental problem we would like to solve is whether the system is able to converge to the *truth*; in other words, whether the truthful information is able to propagate uncorruptedly across the entire system.

3. Chained Learning

Following (Beppu and Griffiths, 2009; Griffiths and Kalish, 2007, 2005; Rafferty et al., 2009; Kirby et al., 2014; Griffiths et al., 2008; Perfors and Navarro, 2011; Rafferty et al., 2014; Smith, 2009; Kalish et al., 2007), we begin with *chained iterated learning*: a learner's state of belief is modeled by a distribution over a hypothesis space $\mathcal{H}$, which is itself equipped with a likelihood function: $\mathbb{P}[d|h]$ indicates the probability of generating data $d \in \mathcal{D}$ given the hypothesis $h \in \mathcal{H}$. A learner's state of belief may change after a learning process, and we naturally call her belief before and after the learning prior and posterior. Notice that the hypothesis space $\mathcal{H}$ is the same as the state space Θ, but we will use $\mathcal{H}$ to emphasize the application background and avoid confusion. The initial hypothesis $\boldsymbol{h}_{\texttt{init}}$ generates m_1 items *iid* for the first learner. These items provide the training data $\mathbf{d}_1 = (d_{1,1},\ldots,d_{1,m_1})$ with which the first learner Bayes-updates its prior. Its posterior is given by setting $t = 1$ in this formula:

$$\mathbb{P}[h|\mathbf{d}_t] = \mathbb{P}[\mathbf{d}_t|h]\,\mathbb{P}[h]/\mathbb{P}[\mathbf{d}_t], \quad \text{with } \mathbb{P}[\mathbf{d}_t] = \sum_{h\in\mathcal{H}} \mathbb{P}[\mathbf{d}_t|h]\,\mathbb{P}[h]. \tag{2}$$

From that point on, each successive learner updates its prior from their predecessor. For any $t > 1$, learner t receives m_t items sampled by the posterior of agent $t-1$ to form the training set $\mathbf{d}_t$. To do that, she picks a random hypothesis h from $\mathcal{H}$ with probability $\mathbb{P}[h|\mathbf{d}_{t-1}]$ (the posterior of learner $t-1$) and then samples m_t items *iid* from h to form $\mathbf{d}_t \in \mathcal{D}^{m_t}$. The posterior $\mathbb{P}[h|\mathbf{d}_t]$ is derived according to (2). Note that learner t has no direct access to the posterior of learner $t-1$ but only to data drawn from a hypothesis sampled from the posterior. Our formulation assumes a discrete space $\mathcal{H}$ but extends to continuous settings, as we show in §3.5.

In the case of linguistic transmission, each hypothesis $h \in \mathcal{H}$ is a "knob" whose setting is given by a number between 0 and 1, specifically the prior probability $\mathbb{P}[h]$. All learners share the same prior. Picking some h from that prior specifies a *language* (also denoted h for convenience). In this case, a language is defined as a probability distribution over $\mathcal{D}$, interpreted here as a set of *sentences*. In this way, the prior can be viewed as a mixture over $\mathcal{H}$: by abuse of terminology, we call it a *mixed* hypothesis, which we distinguish from a *pure* hypothesis of the form $h \in \mathcal{H}$ (corresponding to a single-point distribution). Access to language h is achieved by random sampling: the sentence $d \in \mathcal{D}$ is picked with probability $\mathbb{P}[d|h]$.

Iterated learning proceeds as follows. After selecting language h with probability $\mathbb{P}[h|\mathbf{d}_{t-1}]$, learner t collects m_t independent samples from h. Thus, given a tuple $\mathbf{d}_t = (d_1,\ldots,d_{m_t})$ of sentences from $\mathcal{D}$, the likelihood $\mathbb{P}[\mathbf{d}_t|h]$ is equal to $\prod_{1\leq k\leq m_t} \mathbb{P}[d_k|h]$. The learner is now ready to Bayes-update its prior. Of course, the first one ($t = 1$) samples directly from the language $\boldsymbol{h}_{\texttt{init}}$ chosen for iterated learning. The notation is boldfaced to indicate that $\boldsymbol{h}_{\texttt{init}}$ may be a mixed hypothesis or, in other words, a distribution over hypotheses.

Suppose that $\mathcal{D} = \{d_1, \ldots, d_s\}$ and $\mathcal{H} = \{h_1, \ldots, h_n\}$ are both finite. After observing the data generated by the posterior of learner $t-1$, if learner t winds up choosing h_i then, by Bayesian updating, the probability $P_{ij}^{|t}$ that its posterior picks h_j is given by:

$$P_{ij}^{|t} = \sum_{\mathbf{d} \in \mathcal{D}^{m_t}} \mathbb{P}[h_j|\mathbf{d}]\, \mathbb{P}[\mathbf{d}|h_i] = \sum_{\mathbf{d} \in \mathcal{D}^{m_t}} \frac{\mathbb{P}[\mathbf{d}|h_i]\, \mathbb{P}[\mathbf{d}|h_j]\, \mathbb{P}[h_j]}{\sum_{k=1}^{n} \mathbb{P}[\mathbf{d}|h_k]\, \mathbb{P}[h_k]}\,. \tag{3}$$

To our knowledge, the entire literature on the topic assumes a common, fixed sample size for all the learners: $m_t = m$. Equation (3) can be then interpreted as marginalizing a Gibbs sampler over the data space, which creates a Markov chain over the hypothesis space $\mathcal{H}$: if $\boldsymbol{h}^t$ denotes the row vector formed by the n probabilities $\mathbb{P}[h_k \,|\, \mathbf{d}_t]$, then $\boldsymbol{h}^t = \boldsymbol{h}^{t-1} P^t$, where $\boldsymbol{h}^0 = \boldsymbol{h}_{\mathtt{init}}$. Assuming ergodicity (in this case, a fairly inconsequential technical assumption), the chain can be shown to converge to a unique stationary distribution $\boldsymbol{h}$. It can be easily checked that it coincides with the prior: $\boldsymbol{h} = (\mathbb{P}[h_1], \ldots, \mathbb{P}[h_n])$ (Griffiths and Kalish, 2005; Norris, 1998); see (Rafferty et al., 2009, 2014) for an analysis of the mixing time in specific linguistic scenarios. This convergence reveals the long-term unsustainability of iterated learning. We show how diversifying the sample sizes m_t, hence making the Markov chain time-inhomogeneous, can overcome this weakness. In particular, we prove that it is sufficient for m_t to increase logarithmically with respect to t in order to achieve sustainability.

3.1. Self-Sustainability

We show how to make iterated learning self-sustaining in the presence of a finite hypothesis space $\mathcal{H} = \{h_1, \ldots, h_n\}$. This involves specifying a sequence of training session lengths $m_1, m_2, \ldots$ so that the posterior of any learner ends up differing from $\boldsymbol{h}_{\mathtt{init}}$ by an arbitrarily small amount. Formally, given any $\delta, \varepsilon \geq 0$, we say that iterated learning is (δ, ε)-*self-sustaining* if, with probability at least $1-\varepsilon$, a random $h \in \mathcal{H}$ picked from any learner's posterior distribution differs from $\boldsymbol{h}_{\mathtt{init}}$ in total variation by at most δ. We recall a few facts: the hypothesis h denotes a language modeled as a probability distribution over $\mathcal{D}$; the total variation distance is half the ℓ_1-norm; and the posterior of learner t after the t-th iteration is defined by marginalizing $\mathbb{P}[h|\mathbf{d}_t]$ over all samples $\mathbf{d}_t$ drawn from a random h picked from the posterior of learner $t-1$ (or $\boldsymbol{h}_{\mathtt{init}}$ if $t = 1$). As a shorthand, we speak of ε-self-sustainability to refer to the case $\delta = 0$.

The parameters δ and ε allow us to distinguish between two metrics: the distance between two languages over $\mathcal{D}$ and the distance between two mixtures over $\mathcal{H}$. The two notions could differ widely. For example, if all of $\mathcal{H}$ corresponds to languages very close to $\boldsymbol{h}_{\mathtt{init}}$, to achieve (δ, ε)-self-sustainability might be easy for a tiny $\delta > 0$ but hopelessly difficult for $\delta = 0$. The complexity of iterated learning depends on the geometry of the languages formed by the pure hypotheses. This is best captured by introducing a metric that, though more specialized than the total variation (it works only on the simplex of probability vectors), brings all sorts of technical benefits: the *root-sine distance* between two probability distributions $\boldsymbol{u} = (u_1, \ldots, u_s)$ and $\boldsymbol{v} = (v_1, \ldots, v_s)$ over $\mathcal{D}$ is defined as

$$d_{RS}(\boldsymbol{u}, \boldsymbol{v}) = \sqrt{\frac{1}{2} \sum_{i,j=1}^{s} \left(\sqrt{u_i v_j} - \sqrt{u_j v_i}\right)^2} = \sqrt{1 - \left(\sum_{i=1}^{s} \sqrt{u_i v_i}\right)^2}\,. \tag{4}$$

Note that the *root-sine distance* will be used to measure similarities between two likelihoods, and we will continue the analysis of sustainability defined based on the total variation distance.

It would be surprising if this distance had not been used before, but we could not find a reference. We prove that it is indeed a metric in the Appendix and also explain its name. We show that it is related to the Hellinger, Bhattacharyya and total variation distances, d_H, d_B, d_{TV} by the following relations:

$$\begin{cases} d_H = \sqrt{1 - \sqrt{1 - d_{RS}^2}}\,; \\ d_B = -\frac{1}{2} \ln(1 - d_{RS}^2)\,; \\ d_{TV} \leq \sqrt{2s}\, d_{RS}. \end{cases} \tag{5}$$

3.2. The results

We focus on the "pure" case $\boldsymbol{h}_{\mathtt{init}} \in \mathcal{H}$, and later briefly discuss how to generalize the method to mixed hypotheses. Using the shorthand $\mathtt{d}_{ij}$ for $d_{RS}(\mathbb{P}[\cdot|h_i], \mathbb{P}[\cdot|h_j])$, we define $\mathtt{d}_i := \min_{j:j \neq i} \mathtt{d}_{ij}$. Let $\boldsymbol{p} = (p_1, p_2, \ldots, p_n)$ be the prior distribution over $\mathcal{H}$, where $p_i := \mathbb{P}[h_i]$. We can obviously assume that each p_i is positive and that all the pure hypotheses are distinct, hence $\mathtt{d}_i > 0$. The two theorems below assume that $\boldsymbol{h}_{\mathtt{init}} = h_1$.

Theorem 1. *For any positive $\varepsilon < 1$, the following sample size sequence makes iterated learning ε-self-sustaining:*

$$m_t = \frac{4}{\mathtt{d}_1^2} \ln \frac{nt}{\varepsilon\, p_1} = \frac{4}{\mathtt{d}_1^2} \Big(\log \frac{t}{\varepsilon} + C\Big),$$

for some $C > 0$ independent of $t, \varepsilon, \mathtt{d}_1$.

The factor 4 can be reduced to $2^{1+o(1)}$ if we adjust the constant C. It is to be expected that the lengths of the training sessions should grow to infinity as p_1 tends to zero, as the vanishing prior makes it increasingly difficult for the posteriors to "attach" to h_1. The session lengths are sensitive to the minimum distance between the languages specified by $\mathcal{H}$ and the target language h_1. Settling for (δ, ε)-self-sustainability allows us to remove this dependency.

Theorem 2. *For any positive $\delta, \varepsilon < 1$, the following sample size sequence makes iterated learning (δ, ε)-self-sustaining:*

$$m_t = \frac{8sn^2}{\delta^2} \Big(\ln \frac{t}{\varepsilon} + C\Big).$$

for some $C > 0$ independent of t, δ, ε.

3.3. The proofs

To establish Theorem 1, we estimate the probability P^* that each leaner ends up picking h_1. Recall that $\boldsymbol{h}^t$ is the posterior distribution of learner t, by the Markovian property of the system,

$$P^* = \mathbb{P}[\boldsymbol{h}^0 = h_1] \prod_{t\geq 0} \mathbb{P}[\boldsymbol{h}^{t+1} = h_1 | \boldsymbol{h}^t = h_1] = \prod_{t\geq 1} P_{11}^{|t}. \tag{6}$$

Since the matrix $P^{|t}$ is the transition matrix of a Markov chain, we proceed by bounding its off-diagonal elements $P_{ij}^{|t}$ for $i \neq j$. We have

$$\begin{aligned} P_{ij}^{|t} &\leq \sum_{\mathbf{d}\in\mathcal{D}^{m_t}} \frac{\mathbb{P}[\mathbf{d}|h_i]\,\mathbb{P}[\mathbf{d}|h_j]p_j}{\mathbb{P}[\mathbf{d}|h_i]p_i + \mathbb{P}[\mathbf{d}|h_j]p_j} = \frac{p_j}{p_i} \sum_{\mathbf{d}\in\mathcal{D}^{m_t}} \frac{\left(\frac{p_i}{p_j}\right)\mathbb{P}[\mathbf{d}|h_i]\,\mathbb{P}[\mathbf{d}|h_j]}{\left(\frac{p_i}{p_j}\right)\mathbb{P}[\mathbf{d}|h_i] + \mathbb{P}[\mathbf{d}|h_j]} \\ &\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \sum_{\mathbf{d}\in\mathcal{D}^{m_t}} \sqrt{\mathbb{P}[\mathbf{d}|h_i]\,\mathbb{P}[\mathbf{d}|h_j]} = \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \Big(\sum_{d\in\mathcal{D}} \sqrt{\mathbb{P}[d|h_i]\,\mathbb{P}[d|h_j]}\Big)^{m_t} \\ &\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \exp\left\{\frac{m_t}{2}\Big(\Big(\sum_{d\in\mathcal{D}} \sqrt{\mathbb{P}[d|h_i]\,\mathbb{P}[d|h_j]}\Big)^2 - 1\Big)\right\}, \end{aligned}$$

where the two equalities are simple deformations, the first inequality is achieved by dropping some non-negative terms from the definition of $P_{ij}^{|t}$ in (3), the second inequality is obtained via Young's inequality, and the last inequality is from Taylor expansion of the natural logarithm function at 1. By definition of the root-sine distance, we have

$$P_{ij}^{|t} \leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} e^{-\frac{1}{2}\mathtt{d}_{ij}^2 m_t} \quad (i \neq j). \tag{7}$$

Setting $i = 1$ in (7) and summing over $2 \leq j \leq n$, it follows by Cauchy-Schwarz that

$$\sum_{j=2}^{n} P_{1j}^{|t} \leq \frac{1}{2}\sqrt{\frac{n(1-p_1)}{p_1}}\, e^{-\frac{1}{2}\mathtt{d}_1^2 m_t}. \tag{8}$$

Combining (6) and (8) yields

$$P^* \geq \prod_{t\geq 1}\left(1 - \frac{1}{2}\sqrt{\frac{n(1-p_1)}{p_1}}\, e^{-\frac{1}{2}\mathtt{d}_1^2 m_t}\right) \geq 1 - \frac{1}{2}\sqrt{\frac{n(1-p_1)}{p_1}} \sum_{t\geq 1} e^{-\frac{1}{2}\mathtt{d}_1^2 m_t}. \tag{9}$$

Given $0 < \varepsilon < 1$, we constrain the sequence (m_t) to satisfy:

$$\sum_{t\geq 1} e^{-\frac{1}{2}\mathtt{d}_1^2 m_t} < \varepsilon\sqrt{\frac{4p_1}{n(1-p_1)}}. \tag{10}$$

For example, we can pick the sequence

$$m_t = \frac{1}{\mathtt{d}_1^2} \ln \frac{n(1-p_1)t^4}{\varepsilon^2 p_1},$$

which completes the proof. A closer look at the calculation shows that the factor t^4 can be reduced to $C_\alpha t^{2+\alpha}$ for any small $\alpha > 0$ and a suitable constant $C_\alpha > 0$, which makes the dependency on t arbitrarily close to $(2/\mathtt{d}_1^2)\ln t$.

To prove Theorem 2, we set a target distance $\rho := \delta/(n\sqrt{2s})$ and find a subset $A \subseteq \mathcal{H}$ such that (i) $\mathtt{d}_{1j} \leq \rho n$ for $j \in A$ and (ii) $\mathtt{d}_{ij} \geq \rho$ for $i \in A$ and $j \notin A$. To see why such a subset must exist, consider spheres centered at $\boldsymbol{h}_{\mathtt{init}} = h_1$ of radius $k\rho$, for $k = 1, \ldots, n+1$ (with respect to d_{RS}). These define $n+1$ disjoint (open) regions and, by the pigeonhole principle, at least one of them must be empty. We set A to include all the points in the regions preceding the empty one; note that $h_1 \in A$. The claim follows from the triangular inequality. We begin with a straightforward generalization of (8): for any $i \in A$,

$$\sum_{j\notin A} P_{ij}^{|t} \leq \frac{1}{2}\sqrt{\frac{n(1-p_A)}{p_A}}\, e^{-\frac{1}{2}\rho^2 m_t}, \tag{11}$$

where $p_A := \min_{i\in A} p_i$. Now let P^* be the probability that $\boldsymbol{h}^t \in A$ for each t, then (6) and (9) are generalized to

$$P^* \geq \prod_{t\geq 1}\left(1 - \max_{i\in A}\sum_{j\notin A} P_{ij}^{|t}\right) \geq 1 - \frac{1}{2}\sqrt{\frac{n(1-p_A)}{p_A}} \sum_{t\geq 1} e^{-\frac{1}{2}\rho^2 m_t}. \tag{12}$$

Setting

$$m_t = \frac{1}{\rho^2}\ln\frac{n(1-p_A)t^4}{\varepsilon^2 p_A} \tag{13}$$

ensures that $P^* > 1 - \varepsilon$. The root-sine distance between the languages denoted by h_1 and any $h \in A$ is at most ρn, so that, by (5), the total variation distance is bounded by $\sqrt{2s}\rho n = \delta$, which concludes the proof of Theorem 2.

So far, we have analyzed only the "pure" case $\boldsymbol{h}_{\mathtt{init}} \in \mathcal{H}$. The idea of the training is to prevent the prior to "drag" the posterior mixture all across $\mathcal{H}$. It should be clear that a similar result obtains if $\boldsymbol{h}_{\mathtt{init}} \in \Delta\mathcal{H}$ is concentrated on a subset A of $\mathcal{H}$. The proof follows the path charted in Theorem 2 and need not be repeated here. It is crucial to note, however, that this result is to be understood in a coarse-graining sense: iterated learning cannot ensure that the original weights in the mixture $\boldsymbol{h}_{\mathtt{init}}$ are retained but only that A contributes most of the mass in the posteriors. To retain the weights would require changing the stationary distribution to conform with $\boldsymbol{h}_{\mathtt{init}}$, as the process unfolds, something that straightforward Bayesian learning seems unable to do. Learning pure hypotheses bypasses that difficulty.

3.4. Applications

We briefly discuss a direct application of our results to a well-known model of language acquisition via iterated learning and we mention some natural extensions of the techniques.

Language evolution. Rafferty et al. show how iterated learning fails rapidly in a simple model of language evolution (Rafferty et al., 2009). Given n hypotheses, iterated learning with fixed-length training sessions ceases to learn anything new after only $O(\log n \log\log n)$ rounds. Our previous theorems show how to turn this around and achieve self-sustainality. In our notational system, their model is defined on a hypothesis space $\mathcal{H} = \{h_1, \ldots, h_n\}$, where $n = 2^k$ and h_i denotes the

language whose sentences are words in $\{0,1,?\}^k$ with exactly m question marks and $0,1$ matching the binary decomposition of $i-1$ outside the question marks. For example, if $k=4$ and $m=2$, then h_3 denotes the language

$$\{\,00??, 0?1?, ?01?, 0??0, ?0?0, ??10\,\}.$$

We can assume that m is much smaller than k. Each language has the same length $\binom{k}{m}$ and the total number of sentences is $s=\binom{k}{m}2^{k-m}$. The prior is given by $\mathbb{P}[h_i]=p_i=1/n$. Given a hypothesis h_i, $\mathbb{P}[d|h_i]=1/\binom{k}{m}$ if d has m question marks and match the bits of $i-1$ elsewhere; else it is 0 (and d,h are called incompatible). Given $h\in\mathcal{H}$,

$$\begin{cases}\mathbb{P}[d]=\sum_{h\in\mathcal{H}}\mathbb{P}[d|h]\mathbb{P}[h]=2^{m-k}/\binom{k}{m};\\ \mathbb{P}[h|d]=\mathbb{P}[d|h]\mathbb{P}[h]/\mathbb{P}[d]=2^{-m}\quad\text{(or 0 if } d,h \text{ are incompatible).}\end{cases}$$

We easily check that $\mathtt{d}_1^2=1-\left(\sum_{i=1}^s\sqrt{a_ib_i}\right)^2\geq 1-\left(\frac{m}{k}\right)^2>\frac{1}{2}$; hence, by Theorem 1, session lengths m_t no larger than $O(\log\frac{t}{\varepsilon})$ are sufficient to maintain ε-self-sustainability.

Meanings and utterances. In the use of iterated learning for studying language evolution (Griffiths and Kalish, 2005; Perfors and Navarro, 2011), it is common to model the data $\mathbf{d}$ as a joint distribution $(\boldsymbol{x},\boldsymbol{y})$ over a product space $\mathcal{X}^{m_t}\times\mathcal{Y}^{m_t}$. The idea is to distinguish between "meanings" $\boldsymbol{x}$ and "utterances" $\boldsymbol{y}$. In this setting, $\mathbb{P}[\mathbf{d}|h]=\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h]\mu(\boldsymbol{x})$, where $\mu(\boldsymbol{x})$ is the probability of generating $\boldsymbol{x}$. The transition matrix of the Markov chain thus becomes

$$\begin{aligned}P_{ij}^{|t}&=\sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}}\sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}}\mathbb{P}[h_j|\boldsymbol{x},\boldsymbol{y}]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\mu(\boldsymbol{x})\\&=\sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}}\sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}}\frac{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]\,\mathbb{P}[h_j]}{\sum_{k=1}^m\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_k]\,\mathbb{P}[h_k]}\mu(\boldsymbol{x})\,.\end{aligned}\tag{14}$$

Since the output $\boldsymbol{y}$ now depends on both the hypothesis and the input data, we redefine $\mathtt{d}_{ij}$ as the root-sine distance between the two distributions $\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\mu(\boldsymbol{x})$ and $\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]\mu(\boldsymbol{x})$:

$$\left(\mathtt{d}'_{ij}\right)^2:=1-\left(\sum_{\boldsymbol{x}\in\mathcal{X}}\sum_{\boldsymbol{y}\in\mathcal{Y}}\sqrt{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]}\,\mu(\boldsymbol{x})\right)^2\tag{15}$$

and we define $\mathtt{d}'_i:=\min_{j:j\neq i}\mathtt{d}'_{ij}$. Given any $i\neq j$,

$$\begin{aligned}P_{ij}^{|t}&\leq\sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}}\sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}}\frac{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]\,p_j}{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\,p_i+\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]\,p_j}\mu(\boldsymbol{x})\\&\leq\frac{1}{2}\sqrt{\frac{p_j}{p_i}}\sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}}\sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}}\sqrt{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]}\,\mu(\boldsymbol{x})\\&\leq\frac{1}{2}\sqrt{\frac{p_j}{p_i}}\Big(\sum_{\boldsymbol{x}\in\mathcal{X}}\sum_{\boldsymbol{y}\in\mathcal{Y}}\sqrt{\mathbb{P}[\boldsymbol{y}|h_i]\,\mathbb{P}[\boldsymbol{y}|h_j]}\,\mu(\boldsymbol{x})\Big)^{m_t}\\&\leq\frac{1}{2}\sqrt{\frac{p_j}{p_i}}\exp\left\{\frac{m_t}{2}\Big(\Big(\sum_{\boldsymbol{x}\in\mathcal{X}}\sum_{\boldsymbol{y}\in\mathcal{Y}}\sqrt{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_i]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x},h_j]}\,\mu(\boldsymbol{x})\Big)^2-1\Big)\right\}.\end{aligned}$$

This gives us this new version of inequality (7), which we can use as the basis for a repeat of the argument of the previous section:

$$P_{ij}^{|t}\leq\frac{1}{2}\sqrt{\frac{p_j}{p_i}}e^{-\frac{1}{2}\mathtt{d}'^2_{ij}m_t}\quad(i\neq j).\tag{16}$$

3.5. Gaussian chained learning

When iterated learning operates over a hypothesis space $\mathcal{H}$ parametrized continuously, say, in $\mathbb{R}$, the minimum root-sine distance usually vanishes and the previous arguments run into singularities and collapse. A new approach is needed. To make our discussion concrete, we assume that the prior distribution of each learner is a Gaussian $\mathbb{P}[h]\sim N(\bar\mu,\bar\sigma^2)$ and that the likelihood of producing data d given hypothesis h is also normal: $\mathbb{P}[d|h]=N(h,\sigma^2)$. The likelihood can also be understood as a noisy measurement of h: $d=h+\phi$, where the noise $\phi\sim N(0,\sigma^2)$. We assume that the data received by the first learner comes from $N(\mu_0,\sigma_0^2)$. This is the simplest instance of a continuous setting in which the root-sine distance argument fails. We discuss it in some detail, considering both chained learning and its generalizations; and then we use the results to treat the case of iterated Bayesian linear regression.

During its training session, the t-th learner receives data $\mathbf{d}_t=(d_{t,1},\ldots,d_{t,m_t})$ from its predecessor: it is obtained by first picking a random hypothesis h from the posterior of learner $t-1$ and then collecting m_t independent random samples from $N(h,\sigma^2)$. For the case $t=1$, we can treat the original teacher as learner 0 with its posterior equal to $N(\mu_0,\sigma_0^2)$. Learner t Bayes-updates its posterior as follows:

$$\mathbb{P}[h|\mathbf{d}_t]\propto\mathbb{P}[\mathbf{d}_t|h]\mathbb{P}[h]\propto\exp\Big(-\frac{1}{2\sigma^2}\sum_{i=1}^{m_t}(d_{t,i}-h)^2\Big)\exp\Big(-\frac{1}{2\bar\sigma^2}(h-\bar\mu)^2\Big),$$

which is still Gaussian, with mean and variance denoted by μ_t and σ_t^2, respectively. Carrying out the usual square completion gives up these update rules: for $t>0$,

$$\begin{cases}\mu_t=\frac{1}{\bar\tau+m_t\tau}\left(\bar\tau\bar\mu+\tau(d_{t,1}+d_{t,2}+\cdots+d_{t,m_t})\right)\\ \tau_t=\bar\tau+m_t\tau,\end{cases}\tag{17}$$

where we define the precisions $\tau=1/\sigma^2$, $\bar\tau=1/\bar\sigma^2$, and $\tau_t=1/\sigma_t^2$. We say that iterated learning is *ε-self-sustaining* if $|\mathbb{E}\,\mu_t-\mu_0|\leq\varepsilon$ and $\sigma_t^2+\operatorname{var}\mu_t$ remains bounded for all t. If $\sigma_t^2+\operatorname{var}\mu_t\to 0$ as $t\to\infty$, we say that iterated learning is *strongly ε-self-sustaining*. We consider successively the case of chained iterated learning and the more challenging "hopping" scenario in which a new learner picks a random teacher from the past (instead of the previous one).

In chained iterated learning, the data $d_{t,i}$ is a noisy message drawn from the posterior of the $(t-1)$-th learner; hence $d_{t,i}\sim N(\mu_{t-1},\sigma_{t-1}^2+\sigma^2)$. In view of (17), μ_t is itself Gaussian. By taking the expectation and variance of equation (17), we find the following recursive relations for $\mathbb{E}\,\mu_t$ and $\operatorname{var}\mu_t$: for $t>0$,

$$\begin{cases}\mathbb{E}\,\mu_t=\frac{1}{\bar\tau+m_t\tau}\left(\bar\tau\bar\mu+m_t\tau\,\mathbb{E}\,\mu_{t-1}\right);\\ \operatorname{var}\mu_t=\frac{m_t\tau^2}{(\bar\tau+m_t\tau)^2}\left(\operatorname{var}\,\mu_{t-1}+\sigma_{t-1}^2+\sigma^2\right).\end{cases}\tag{18}$$

If we define $\beta_t := m_t\tau/(\bar{\tau} + m_t\tau)$, then (18) becomes $\mathbb{E}\,\mu_t = \beta_t\,\mathbb{E}\,\mu_{t-1} + (1-\beta_t)\bar{\mu}$. If $m_t = m$ is a constant, then so is β_t, and the recursive relation (18) becomes

$$\mathbb{E}\,\mu_t - \bar{\mu} = \beta_1^t(\mu_0 - \bar{\mu}),$$

which shows that $\mathbb{E}\,\mu_t$ converges to $\bar{\mu}$ exponentially fast. As in the discrete case, iterated learning is not self-sustainable with constant-length training sessions. By letting m_t increase as $t^{1+o(1)}$ order, however, we can achieve self-sustainability:

Theorem 3 *For any $0 < \varepsilon < 1$, the following sample size sequence makes chained iterated learning strongly ε-self-sustaining:*

$$m_t = \frac{|\mu_0 - \bar{\mu}|}{\varepsilon}\Big(1 + \frac{1}{c}\Big)\Big(\frac{\sigma}{\bar{\sigma}}\Big)^2 t^{1+c},$$

for an arbitrarily small constant $c > 0$.

Proof We observe that $\mathbb{E}\,\mu_t$ is a convex combination of $\bar{\mu}$ and $\mathbb{E}\,\mu_s$ $(s < t)$; specifically,

$$\mathbb{E}\,\mu_t = \prod_{s=1}^{t}\beta_s\mu_0 + \Big(1 - \prod_{s=1}^{t}\beta_s\Big)\bar{\mu}. \tag{19}$$

Because $\sum_{s>0}(1/s)^{1+c} < 1 + \int_1^\infty x^{-1-c}\,dx = 1 + 1/c$, we have

$$\begin{aligned} 1 \;&\geq\; \prod_{s=1}^{t}\beta_s = \prod_{s=1}^{t}\Big(1 - \frac{\bar{\tau}}{m_s\tau + \bar{\tau}}\Big) \geq 1 - \sum_{s=1}^{t}\frac{\bar{\tau}}{m_s\tau + \bar{\tau}} \\ &\geq\; 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|}\Big(\frac{c}{c+1}\Big)\sum_{s=1}^{\infty}\frac{1}{s^{1+c}} > 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|}\,. \end{aligned}$$

This shows that

$$|\mathbb{E}\,\mu_t - \mu_0| = \Big(1 - \prod_{s=1}^{t}\beta_s\Big)|\bar{\mu} - \mu_0| \leq \varepsilon.$$

By (17), $\sigma_t^2 = 1/\tau_t < 1/m_t\tau \to 0$. Since $\sigma_{t-1}^2 \leq \bar{\sigma}^2$ for $t > 1$, it follows from (18) that $\operatorname{var}\mu_t \leq (\operatorname{var}\mu_{t-1} + \sigma^2 + \bar{\sigma}^2)/m_t$ for $t > 1$, and $\operatorname{var}\mu_1 \leq (\sigma_0^2 + \sigma^2)/m_1$. Writing $M_t := m_t m_{t-1}\ldots m_1$, we have

$$\begin{aligned} M_t\operatorname{var}\mu_t &\leq M_{t-1}\operatorname{var}\mu_{t-1} + M_{t-1}(\sigma^2 + \bar{\sigma}^2) \\ &\leq tM_{t-1}(\sigma_0^2 + \sigma^2 + \bar{\sigma}^2), \end{aligned}$$

and thus $\operatorname{var}\mu_t \leq (\sigma_0^2 + \sigma^2 + \bar{\sigma}^2)t/m_t \to 0$ since $m_t = \Omega(t^{1+c})$. ■

3.6. Iterated Bayesian Linear Regression

The iterated version of Bayesian linear regression has been the subject of extensive study in the field of psychology (Kalish et al., 2007; Beppu and Griffiths, 2009; Tamariz and Kirby, 2015; Bartlett; Griffiths et al., 2008). The work has involved experimentation with human subjects but little in

the way of theoretical analysis. This section is a first step toward filling this gap. The task at hand is to estimate a hypothesis $h \in \mathcal{H} := \mathbb{R}^d$ given a noisy measurements on the hyperplane $y = h^T x$, where $x \in \mathbb{R}^d$. In the Bayesian setting, we assume a Gaussian prior on the hypothesis space: $\mathbb{P}[h] \sim N(\bar{\mu}, \bar{\sigma}^2 I_d)$. The data is given by (x, y), where $x \sim N(0, I_d)$ and $y = h^T x + \phi$, for $\phi \sim N(0, \sigma^2)$ (with x, ϕ independent). Since we typically make several measurements, we write this (likelihood) relation in matrix form: $y = Xh + \phi$, where $y \in \mathbb{R}^m$ (with m the number of measurements); $\phi \sim N(0, \sigma^2 I_m)$; and X is an m-by-d matrix each of whose rows denotes a random vector $x \sim N(0, I_d)$. This means that the matrix X is random (a fact of key importance in our discussion below). We have:

$$\begin{cases} \mathbb{P}[\phi] \sim \exp\{-\frac{1}{2\sigma^2}\|\phi\|_2^2\} & \texttt{(noise)} \\ \mathbb{P}[h] \sim \exp\{-\frac{1}{2\bar{\sigma}^2}\|h - \bar{\mu}\|_2^2\} & \texttt{(prior)} \\ \mathbb{P}[y|X,h] \sim \exp\{-\frac{1}{2\sigma^2}\|y - Xh\|_2^2\} & \texttt{(likelihood)} \end{cases}$$

In iterated Bayesian linear regression, the t-th learner receives her data from learner $t-1$. Here, learner 0 is treated just like any other agent, except that his prior $\mathbb{P}[h] \sim N(\mu_0, \bar{\sigma}^2 I_d)$ is the distribution to be learned iteratively. Since sampling from the prior is independent of X, Bayesian updating gives the posterior $N(\mu_t, \Sigma_t)$, where

$$\mathbb{P}[h|X,y] = \mathbb{P}[h]\,\mathbb{P}[y|X,h]/\mathbb{P}[y|X] \sim \exp\Big\{-\frac{1}{2\bar{\sigma}^2}\|h - \bar{\mu}\|_2^2 - \frac{1}{2\sigma^2}\|y - Xh\|_2^2\Big\}.$$

Completing the square in the usual fashion shows that the posterior of learner t is given by:

$$\begin{cases} \Sigma_t = \big(\bar{\sigma}^{-2}I_d + \sigma^{-2}X_t^T X_t\big)^{-1}; \\ \mu_t = \Sigma_t\left(\bar{\sigma}^{-2}\bar{\mu} + \sigma^{-2}X_t^T y_t\right), \end{cases} \tag{20}$$

where (X_t, y_t) is the data gathered by learner t from her predecessor: specifically, $y_t = X_t h + \phi_t$, where h is collected from the $(t-1)$-th learner by sampling his posterior distribution $N(\mu_{t-1}, \Sigma_{t-1})$.

Theorem 4 *Given any small enough $\delta, \varepsilon > 0$, the following sample size sequence for iterated Bayesian linear regression ensures that $\|\mathbb{E}\mu_t - \mu_0\|_2 \leq \delta$ with probability greater than $1 - \varepsilon$:*

$$m_t = D_c\frac{\|\mu_0 - \bar{\mu}\|_2}{\delta}\Big(\frac{\sigma}{\bar{\sigma}}\Big)^2 t^{1+c} + D_c\,d\log\frac{t+1}{\varepsilon},$$

for an arbitrarily small $c > 0$ and a constant D_c that depends only on c.

Proof We proceed in two steps: first, we show that to keep $\mathbb{E}\mu_t$ arbitrarily close to μ_0 for all t hinges on spectral properties of certain random matrices; second, we call on known facts about the singular values of random Gaussian matrices to translate the spectral condition into a high-probability event. The proof unfolds as a series of simple relations, which we state first and then demonstrate. The first one follows directly from (20):

$$\mathbb{E}\mu_t = (I_d + M_t)^{-1}\left(\bar{\mu} + M_t\,\mathbb{E}\mu_{t-1}\right), \quad \text{where} \quad M_t := \Big(\frac{\bar{\sigma}}{\sigma}\Big)^2 X_t^T X_t. \tag{21}$$

Note that (21) is a randomized recursive relation since the data points $X_1, X_2, \ldots$ are themselves random. We note that all the matrices whose inverses are taken are positive definite, hence nonsingular. To move on to our second relation, we define the matrix

$$Q_t := (I_d + M_t)^{-1} M_t (I_d + M_{t-1})^{-1} M_{t-1} \cdots (I_d + M_1)^{-1} M_1,$$

for $t > 0$, with $Q_0 = I_d$, and prove by induction that

$$\mathbb{E}\,\mu_t = Q_t \mu_0 + (I_d - Q_t)\bar{\mu}. \tag{22}$$

The base case is obvious so we assume that $t > 0$: by (21),

$$\begin{aligned}
\mathbb{E}\,\mu_t &= (I_d + M_t)^{-1}(\bar{\mu} + M_t\,\mathbb{E}\,\mu_{t-1}) \\
&= (I_d + M_t)^{-1}(\bar{\mu} + M_t Q_{t-1}\mu_0 + M_t(I_d - Q_{t-1})\bar{\mu}) \\
&= (I_d + M_t)^{-1} M_t Q_{t-1}\mu_0 + (I_d + M_t)^{-1}(I_d + M_t(I_d - Q_{t-1}))\bar{\mu} \\
&= Q_t\,\mu_0 + (I_d - (I_d + M_t)^{-1} M_t Q_{t-1})\bar{\mu},
\end{aligned}$$

which proves (22). Our next goal is to bound the information decay $\|\mathbb{E}\,\mu_t - \mu_0\|_2$. To do that, we investigate the spectral norm of the matrix $I_d - Q_t$, which leads to our third relation. We prove by induction that, for $t > 0$,

$$\|I_d - Q_t\|_2 \le \sum_{s=1}^{t} \|A_s\|_2, \tag{23}$$

where $A_s := (I_d + M_s)^{-1}$. For $t = 1$, $Q_1 = (I_d + M_1)^{-1} M_1 = I_d - (I_d + M_1)^{-1}$ and the claim follows. If $t > 1$, then

$$\begin{aligned}
\|I_d - Q_t\|_2 &= \|(I_d - Q_{t-1}) + (Q_{t-1} - Q_t)\|_2 \\
&\le \|I_d - Q_{t-1}\|_2 + \|Q_t - Q_{t-1}\|_2 \le \sum_{s=1}^{t-1} \|A_s\|_2 + \|\Psi\|_2,
\end{aligned}$$

where $\Psi := (A_t M_t - I_d) Q_{t-1}$. Since $A_t(I_d + M_t) = I_d$, we have $\Psi = -A_t Q_{t-1}$. Each matrix M_s is positive semidefinite, so the eigenvalues of $(I_d + M_s)^{-1} M_s$ are of the form $\lambda/(1+\lambda)$, where $\lambda \ge 0$. This shows that all the eigenvalues of Q_s are between 0 and 1; therefore $\|Q_s\|_2 \le 1$. The eigenvalues of $I_d - A_t M_t$ are the same as those of A_t; hence, by submultiplicativity, $\|\Psi\|_2 \le \|A_t\|_2 \|Q_{t-1}\|_2 \le \|A_t\|_2$, which establishes (23).

We are now ready to express the information decay in spectral terms. Pick an arbitrarily small constant $c > 0$ and assume that

$$\|A_s\|_2 \le \frac{\delta}{\|\bar{\mu} - \mu_0\|_2} \Big(\frac{c}{1+c}\Big)\Big(\frac{1}{s}\Big)^{1+c}. \tag{24}$$

By (22), $\mathbb{E}\,\mu_t - \mu_0 = (I_d - Q_t)(\bar{\mu} - \mu_0)$; therefore, by (23),

$$\begin{aligned}
\|\mathbb{E}\,\mu_t - \mu_0\|_2 &\le \|\bar{\mu} - \mu_0\|_2 \sum_{s=1}^{t} \|A_s\|_2 \le \frac{\delta c}{1+c} \sum_{s=1}^{t} s^{-1-c} \\
&\le \frac{\delta c}{1+c}\Big(1 + \int_1^{\infty} x^{-1-c}\,dx\Big) = \delta,
\end{aligned} \tag{25}$$

The relation says that, on average, the means of any of the agents' posteriors can be brought as close to the original mean to be learned as we want. We can turn this into a high-probability event by using some basic random matrix theory. Recall that $\mathbb{E}\,\mu_t$ is itself a random variable whose stochasticity comes from the matrices X_s, which are all drawn from Gaussians. Because M_s is positive semidefinite,

$$\|A_s\|_2 \le \|M_s^{-1}\|_2 \le \frac{(\sigma/\bar{\sigma})^2}{\lambda_{\min}(X_t^T X_t)} \le \Big(\frac{\sigma/\bar{\sigma}}{\sigma_1(X_t)}\Big)^2, \tag{26}$$

which gives us a relation between the spectral norm of $(I_s + M_s)^{-1}$ and the smallest singular value $\sigma_1(X_t)$ of an m_t-by-d matrix X_t whose elements are drawn *iid* from $N(0,1)$. The asymptotic behavior of $\sigma_1(X_t)$ for large values of m_t has been extensively studied within the field of random matrix theory (Davidson and Szarek, 2001; Edelman, 1988; Rudelson and Vershynin, 2009). Following Theorem II.13 in (Davidson & Szarek (Davidson and Szarek, 2001)), for any $\gamma_t > 0$,

$$\mathbb{P}[\sigma_1(X_t) < \sqrt{m_t} - \sqrt{d} - \gamma_t] \le e^{-\gamma_t^2/2}.$$

We use C below as a generic constant large enough to satisfy the inequalities where it appears. Setting $\gamma_t = C\sqrt{\log((t+1)/\varepsilon)}$ ensures that $\sum_{t>0} e^{-\gamma_t^2/2} < \varepsilon$, hence that $\sigma_1(X_t) < \sqrt{m_t} - \sqrt{d} - \gamma_t$ holds for all t with probability less than ε. With our setting of m_t, this means that, for all $t > 0$,

$$\mathbb{P}\Big[\,\sigma_1(X_t) \ge \frac{\sqrt{m_t}}{2}\,\Big] > 1 - \varepsilon. \tag{27}$$

Assuming the event in (27), it follows from (26) and our setting of m_t that

$$\|A_t\|_2 \le \frac{4}{m_t}\Big(\frac{\sigma}{\bar{\sigma}}\Big)^2 \le \frac{\delta}{\|\bar{\mu} - \mu_0\|_2}\Big(\frac{4}{D_c}\Big)\Big(\frac{1}{t}\Big)^{1+c};$$

hence (24) holds for D_c large enough. By (25, 27), this proves that, with probability greater than $1 - \varepsilon$, $\|\mathbb{E}\,\mu_t - \mu_0\|_2 \le \delta$ for all $t > 0$, which completes the proof. ■

4. Hopped Learning

In this section, we consider the "hopped learning" scenario in which learner t hops back to pick a teacher from $\{0, 1, \ldots, t-1\}$ at random, and then takes m_t samples from her posterior. To model the data generating process, we continue to adopt the Gaussian setting from Sections 3.5 and 3.6. Note that the graph sequence G_t becomes random under the constraint that a learner can only get data from the learners before her. Since multiple samples can be sent from a teacher to a learner, we use $d_{t,s,i}$ to denote the i-th sample generated by agent s at time t. Note that though a learner only receives data from one teacher, without loss of generality, we assume all her predecessors generate samples but she only listens to one of them. The recursive relation for μ_t becomes

$$\mu_t = \frac{\beta_t}{m_t} \sum_{s=0}^{t-1} \chi_{t,s} \sum_{i=1}^{m_t} d_{t,s,i} + (1 - \beta_t)\bar{\mu}, \tag{28}$$

where, given t, the random variable $\chi_{t,s}$ is 1 for a value of s picked at random between 0 and $s-1$, and is zero elsewhere; recall that $\beta_t := m_t\tau/(\bar{\tau} + m_t\tau)$. Hopped iterated learning provides access

to earlier data, so one would expect the lengths of the training sessions to grow more slowly than in chained learning. The change is indeed quite dramatic:

Theorem 5 *For any positive $\varepsilon < |\mu_0 - \bar{\mu}|$, the following sample size sequence makes hopped iterating learning ε-self-sustaining:*

$$m_t = B_c \frac{|\mu_0 - \bar{\mu}|}{\varepsilon} \Big(\frac{\sigma}{\bar{\sigma}}\Big)^2 (1 + \log t)^{1+c},$$

for an arbitrarily small $c > 0$ and a constant B_c that depends only on c.

Proof By taking expectation on both sides of (28), for any $t > 0$,

$$\mathbb{E}\,\mu_t = \frac{\beta_t}{t} \sum_{s=0}^{t-1} \mathbb{E}\,\mu_s + (1 - \beta_t)\bar{\mu},$$

We define $\gamma_1 = \beta_1$ and, for $t > 1$,

$$\gamma_t := (1 + \beta_1)\left(1 + \frac{\beta_2}{2}\right) \cdots \left(1 + \frac{\beta_{t-1}}{t-1}\right) \frac{\beta_t}{t}.$$

We verify easily that $\mathbb{E}\,\mu_t = \gamma_t \mu_0 + (1 - \gamma_t)\bar{\mu}$, for $t > 0$; therefore, the first part in establishing ε-self-sustainability consists of proving that

$$1 \geq \gamma_t \geq 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|}\,, \tag{29}$$

which will show that $|\mathbb{E}\,\mu_t - \mu_0| \leq \varepsilon$. Note that

$$\gamma_t \leq \frac{1}{t} \prod_{s=1}^{t-1} \Big(1 + \frac{1}{s}\Big) = 1.$$

Now define

$$\alpha_s = \frac{\varepsilon}{B_c |\mu_0 - \bar{\mu}| s (1 + \log s)^{1+c}}.$$

for $s > 0$. We pick a constant B_c large enough so that α_s is small enough to carry out first-order Taylor approximations around $1 + \alpha_s$. We find that

$$\begin{aligned} 1 + \frac{\beta_s}{s} &= 1 + \frac{1}{s}\Big(1 - \frac{1}{1 + m_s \tau/\bar{\tau}}\Big) \geq \Big(1 + \frac{1}{s}\Big)\Big(1 - \frac{1}{(s+1) m_s \tau/\bar{\tau}}\Big) \\ &\geq \Big(1 + \frac{1}{s}\Big)\Big(1 - \frac{s\alpha_s}{s+1}\Big) \geq \Big(1 + \frac{1}{s}\Big)(1 - \alpha_s) \geq \Big(1 + \frac{1}{s}\Big) e^{-2\alpha_s}. \end{aligned}$$

Thus,

$$\gamma_t \geq \frac{\beta_t}{t} \prod_{s=1}^{t-1} \Big(1 + \frac{1}{s}\Big) e^{-2\sum_{s=1}^{t-1} \alpha_s} = \beta_t e^{-2\sum_{s=1}^{t-1} \alpha_s} \geq 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|},$$

which establishes (29). Our derivation relies on the fact that

$$\beta_t \geq 1 - \frac{\varepsilon}{B_c |\mu_0 - \bar{\mu}| (1 + \log t)^{1+c}} \geq 1 - \frac{\varepsilon}{2|\mu_0 - \bar{\mu}|}$$

and

$$\sum_{s=1}^{t-1} \frac{1}{s(1 + \log s)^{1+c}} \leq 1 + \frac{1}{(\log e)^{1+c}} \int_2^{t-1} \frac{1}{x(\ln x)^{1+c}}\, dx = O\Big(\frac{1}{c}\Big)\,;$$

hence,

$$e^{-2\sum_{s=1}^{t-1} \alpha_s} \geq e^{-O(\varepsilon/(cB_c|\mu_0 - \bar{\mu}|))} \geq 1 - \frac{\varepsilon}{2|\mu_0 - \bar{\mu}|}.$$

Having shown that $|\mathbb{E}\,\mu_t - \mu_0| \leq \varepsilon$ for all t, it now suffices to prove that $\sigma_t^2 + \operatorname{var} \mu_t$ remains bounded. We note that $\tau_t > m_t \tau \to \infty$, hence $\sigma_t^2 = 1/\tau_t \to 0$, so the remainder of the proof needs to establish that the variance of μ_t stays bounded. Writing $D_{t,s} := d_{t,s,1} + \cdots + d_{t,s,m_t}$, we have $\operatorname{var} D_{t,s} = m_t \operatorname{var} d_{t,s,1} = m_t(\sigma_s^2 + \sigma^2 + \operatorname{var} \mu_s)$; hence

$$\mathbb{E}\, D_{t,s}^2 = \operatorname{var} D_{t,s} + (\mathbb{E}\, D_{t,s})^2 = m_t(\sigma_s^2 + \sigma^2 + \operatorname{var} \mu_s) + m_t^2 (\mathbb{E}\,\mu_s)^2.$$

In (28), the variables $\chi_{t,s}$ and $D_{t,s}$ are independent, for $0 \leq s \leq t-1$; furthermore, $\mathbb{E}\,\chi_{t,s} = \mathbb{E}\,\chi_{t,s}^2 = 1/t$, and $\mathbb{E}\,\chi_{t,s_1}\chi_{t,s_2} = 0$ if $s_1 \neq s_2$; therefore,

$$\begin{aligned} \operatorname{var}[\chi_{t,s} D_{t,s}] &= \mathbb{E}\,\chi_{t,s}^2\, \mathbb{E}\, D_{t,s}^2 - (\mathbb{E}\,\chi_{t,s})^2 (\mathbb{E}\, D_{t,s})^2 = \frac{\mathbb{E}\, D_{t,s}^2}{t} - \frac{(\mathbb{E}\, D_{t,s})^2}{t^2} \\ &= \Big(\frac{m_t}{t}\Big)(\sigma_s^2 + \sigma^2 + \operatorname{var} \mu_s + m_t (\mathbb{E}\,\mu_s)^2) - \Big(\frac{m_t}{t}\Big)^2 (\mathbb{E}\,\mu_s)^2 \end{aligned} \tag{30}$$

and, for $s_1 \neq s_2$,

$$\begin{aligned} \operatorname{cov}[\chi_{t,s_1} D_{t,s_1}, \chi_{t,s_2} D_{t,s_2}] &= \mathbb{E}\,[\chi_{t,s_1}\chi_{t,s_2} D_{t,s_1}, D_{t,s_2}] - \mathbb{E}\,[\chi_{t,s_1} D_{t,s_1}]\mathbb{E}\,[\chi_{t,s_2} D_{t,s_2}] \\ &= \mathbb{E}\,[\chi_{t,s_1}\chi_{t,s_2}]\mathbb{E}\,[D_{t,s_1} D_{t,s_2}] - \mathbb{E}\,\chi_{t,s_1}\mathbb{E}\, D_{t,s_1}\mathbb{E}\,\chi_{t,s_2}\mathbb{E}\, D_{t,s_2} \\ &= -\frac{1}{t^2}\,\mathbb{E}\, D_{t,s_1}\mathbb{E}\, D_{t,s_2} = -\Big(\frac{m_t}{t}\Big)^2 \mathbb{E}\,\mu_{s_1}\mathbb{E}\,\mu_{s_2}. \end{aligned} \tag{31}$$

Then, by taking the variance on both sides of (28), we have

$$\begin{aligned} \operatorname{var} \mu_t &= \Big(\frac{\beta_t}{m_t}\Big)^2 \operatorname{var} \sum_{s=0}^{t-1} \chi_{t,s} D_{t,s} \\ &= \Big(\frac{\beta_t}{m_t}\Big)^2 \Big(\sum_{s=0}^{t-1} \operatorname{var}[\chi_{t,s} D_{t,s}] + \sum_{0 \leq s_1 \neq s_2 \leq t-1} \operatorname{cov}[\chi_{t,s_1} D_{t,s_1}, \chi_{t,s_2} D_{t,s_2}]\Big) \\ &= \Big(\frac{\beta_t}{m_t}\Big)^2 \Big(\sum_{s=0}^{t-1} \Big(\frac{m_t}{t}\Big)(\sigma_s^2 + \sigma^2 + \operatorname{var} \mu_s + m_t (\mathbb{E}\,\mu_s)^2) - \Big(\frac{m_t}{t}\Big)^2 \Big(\sum_{s=0}^{t-1} \mathbb{E}\,\mu_s\Big)^2\Big) \\ &\leq \frac{1}{t m_t} \sum_{s=0}^{t-1} (\sigma_s^2 + \sigma^2 + \operatorname{var} \mu_s + m_t (\mathbb{E}\,\mu_s)^2). \end{aligned}$$

Notice that $\sigma_s^2 \to 0$ and $(\mathbb{E}\,\mu_s)^2$ is bounded since $|\mathbb{E}\,\mu_t - \mu_0| \leq \varepsilon$. We conclude that $\sigma_t^2 + \operatorname{var} \mu_t$ remains bounded for all t. ■

5. Networked Learning

In this section, we study the information transfer and iterated learning with general graph sequence G_t. We assume that the initial belief $\mu_{0,i}$ of agent i is Gaussian: $\mu_{0,i} \sim \mathcal{N}(x_{0,i}, \sigma_{0,i}^2)$. Without loss of generality, the truth is assumed to be a constant (single-point distribution: $\mu_{t,0} = 0$; $\sigma_{t,0} = 0$ for all t) and the standard deviation is the same for all other agents, i.e., $\sigma_{0,i} = \sigma_0 > 0$ for $i > 0$. Because agent 0 holds the truth, no edge points out of it. The adjacency matrix of G_t is denoted by A_t: it is an $(n+1) \times (n+1)$ matrix whose first row is $(1, 0, \ldots, 0)$. Note that n is the number of learners and should not be confused with the number of hypotheses in Section 3.

5.1. The dynamics in matrix form

Let D_t and P_t denote the $(n+1)$-by-$(n+1)$ diagonal matrices $\mathrm{diag}(\eta_{t,i})$ and $(\tau_0/\tau)I + \sum_{k=0}^{t-1} D_k$, respectively, where $\eta_{t,i}$ is the out-degree of agent i at time t, I is the identity matrix and the sum is 0 for $t = 0$. It follows from (1) that $\mu_{t,i} \sim \mathcal{N}(x_{t,i}, (\tau P_t)_{ii}^{-1})$ for $i > 0$. Regrouping the means in vector form, $\boldsymbol{x}_t := (x_{t,0}, \ldots, x_{t,n})^T$, where $x_{t,0} = 0$ and $x_{0,1}, \ldots, x_{0,n}$ are given as inputs, we have

$$\boldsymbol{x}_{t+1} = (P_t + D_t)^{-1} \left(P_t \boldsymbol{x}_t + A_t \left(\boldsymbol{x}_t + \boldsymbol{u}_t + \boldsymbol{\varepsilon}_t\right)\right), \tag{32}$$

where $\boldsymbol{u}_t$ is such that $u_{t,0} \sim \mathcal{N}(0,0)$ and, for $i > 0$, $u_{t,i} \sim \mathcal{N}(\mathbf{0}, (\tau(P_t)_{ii})^{-1})$; and $\boldsymbol{\varepsilon}_t$ is such that $\varepsilon_{t,0} \sim \mathcal{N}(0,0)$ and, for $i > 0$, $\varepsilon_{t,i} \sim \mathcal{N}(\mathbf{0}, 1/\tau)$. We refer to the vectors $\boldsymbol{x}_t$ and $\boldsymbol{y}_t := \mathbb{E}\,\boldsymbol{x}_t$ as the *mean process* and the *expected mean process*, respectively. Taking expectations on both sides of (32) with respect to the random vectors $\boldsymbol{u}_t$ and $\boldsymbol{\varepsilon}_t$ yields the update rule for the expected mean process: $\boldsymbol{y}_0 = \boldsymbol{x}_0$ and, for $t > 0$,

$$\boldsymbol{y}_{t+1} = (P_t + D_t)^{-1} (P_t + A_t)\, \boldsymbol{y}_t. \tag{33}$$

A key observation is that $(P_t + D_t)^{-1}(P_t + A_t)$ is a stochastic matrix, so the expected mean process $\boldsymbol{y}_t$ forms a diffusive influence system (Chazelle, 2015): the vector evolves by taking convex combinations of its own coordinates. What makes the analysis different from standard multiagent agreement systems is that the weights vary over time. In fact, some weights typically tend to 0, which violates one of the cardinal assumptions used in the analysis of averaging systems (Chazelle, 2015; Moreau, 2005). This leads us to the use of arguments, such as fourth-order moment bounds, that are not commonly encountered in this area.

5.2. The results

The belief vector $\boldsymbol{\mu}_t$ is Gaussian with mean $\boldsymbol{x}_t$ and covariance matrix Σ_t formed by zeroing out the top-left element of $(\tau P_t)^{-1}$. We say that the system reaches *truthful consensus* if both the mean process $\boldsymbol{x}_t$ and the covariance matrix tend to zero as t goes to infinity. This indicates that all the agents' beliefs share a common mean equal to the truth and the "error bars" vanish over time. In view of (1), the covariance matrix indeed tends to 0 as long as the degrees are nonzero infinitely often, a trivial condition. To establish truthful consensus, therefore, boils down to studying the mean process $\boldsymbol{x}_t$. We do this in two parts: first, we show that the expected mean process converges to the truth; then we prove that fluctuations around it eventually vanish almost surely.[1]

1. The Kullback-Leibler divergence (Jadbabaie et al., 2012) is not suitable here because the estimator is Gaussian, hence continuous, whereas the truth is a single-point distribution.

Truth-hearing assumption: Given any interval of length $\kappa := \lfloor 1/\gamma \rfloor$, every agent $i > 0$ has an edge $(i, 0)$ in G_t for at least one value of t in that interval.

Theorem 6 *Under the truth-hearing assumption, the system reaches truthful consensus with a convergence rate bounded by $O(t^{-\gamma/2\eta})$, where η is the maximum outdegree over all the networks.*

We prove the theorem in the next two sections. It will follow directly from Lemmas 7 and 8 below. The convergence rate can be improved to the order of $t^{-(1-\varepsilon)\gamma/\eta}$, for arbitrarily small $\varepsilon > 0$. The inverse dependency on γ is not surprising: the more access to the truth the stronger the attraction to it. On the other hand, it might seem counterintuitive that a larger outdegree should slow down convergence. This illustrates the risk of groupthink. It pays to follow the crowds when the crowds are right. When they are not, however, this distracts from the lonely voice that happens to be right.

How essential is the truth-hearing assumption? We show that it is necessary. Simply having access to the truth infinitely often is not enough to achieve truthful consensus.

5.3. The proofs

In this subsection, we demonstrate technical details for the proof of the results. We begin with some repeated used inequalities.

5.3.1. USEFUL MATRIX INEQUALITIES

We highlight certain matrix inequalities to be used throughout. We use the standard element-wise notation $R \le S$ to indicate that $R_{ij} \le S_{ij}$ for all i, j. The infinity norm $\|R\|_\infty = \max_i \sum_j |r_{ij}|$ is submultiplicative: $\|RS\|_\infty \le \|R\|_\infty \|S\|_\infty$, for any matching rectangular matrices. On the other hand, the max-norm $\|R\|_{\max} := \max_{i,j} |r_{ij}|$ is not, but it is transpose-invariant and also satisfies: $\|RS\|_{\max} \le \|R\|_\infty \|S\|_{\max}$. It follows that

$$\begin{aligned} \|RSR^T\|_{\max} &\le \|R\|_\infty \|SR^T\|_{\max} = \|R\|_\infty \|RS^T\|_{\max} \\ &\le \|R\|_\infty^2 \|S^T\|_{\max} = \|R\|_\infty^2 \|S\|_{\max}. \end{aligned} \tag{34}$$

5.3.2. THE EXPECTED MEAN PROCESS DYNAMICS

We analyze the convergence of the mean process in expectation. The expected mean $\boldsymbol{y}_t = \mathbb{E}\,\boldsymbol{x}_t$ evolves through an averaging process entirely determined by the initial value $\boldsymbol{y}_0 = (0, x_{0,1}, \ldots, x_{0,n})^T$ and the graph sequence G_t. Intuitively, if an agent communicates repeatedly with a holder of the truth, the weight of the latter should accumulate and increasingy influence the belief of the agent in question. Our goal in this section is to prove the following result:

Lemma 7 *Under the truth-hearing assumption, the expected mean process $\boldsymbol{y}_t$ converges to the truth asymptotically. If, at each step, no agent receives information from more than η agents, then the convergence rate is bounded by $Ct^{-\gamma/2\eta}$, where C is a constant that depends on $\boldsymbol{x}_0, \gamma, \eta, \sigma_0/\sigma$.*

Proof We define B_t as the matrix formed by removing the first row and the first column from the stochastic $P_{t+1}^{-1}(P_t + A_t)$. If we write $\boldsymbol{y}_t$ as $(0, \boldsymbol{z}_t)$ then, by (33),

$$\begin{pmatrix} 0 \\ \boldsymbol{z}_{t+1} \end{pmatrix} = \begin{pmatrix} 1 & \mathbf{0} \\ \boldsymbol{\alpha}_t & B_t \end{pmatrix} \begin{pmatrix} 0 \\ \boldsymbol{z}_t \end{pmatrix}, \tag{35}$$

where $\boldsymbol{\alpha}_{t,i} = (P_{t+1}^{-1})_{ii}$ if there is an edge $(i, 0)$ at time t and $\boldsymbol{\alpha}_{t,i} = 0$ otherwise. This further simplifies to

$$\boldsymbol{z}_{t+1} = B_t \boldsymbol{z}_t. \tag{36}$$

Let $\mathbf{1}$ be the all-one column vector of length n. Since $P_{t+1}^{-1}(P_t + A_t)$ is stochastic,

$$\boldsymbol{\alpha}_t + B_t \mathbf{1} = \mathbf{1} \tag{37}$$

In matrix terms, the truth-hearing assumption means that, for any $t \geq 0$,

$$\boldsymbol{\alpha}_t + \boldsymbol{\alpha}_{t+1} + \cdots + \boldsymbol{\alpha}_{t+\kappa-1} \geq Q_{t+\kappa}^{-1} \mathbf{1}, \tag{38}$$

where Q_t is the matrix derived from P_t by removing the first row and the last column; the inequality relies on the fact that P_t is monotonically nondecreasing. For any $t > s \geq 0$, we define the product matrix $B_{t:s}$ defined as

$$B_{t:s} := B_{t-1} B_{t-2} \ldots B_s, \tag{39}$$

with $B_{t:t} = I$. By (36), for any $t > s \geq 0$,

$$\boldsymbol{z}_t = B_{t:s}\, \boldsymbol{z}_s. \tag{40}$$

To bound the infinity norm of $B_{t:0}$, we observe that, for any $0 \leq l < \kappa - 1$, the i-th diagonal element of $B_{s+\kappa:s+l+1}$ is lower-bounded by

$$\begin{aligned} \prod_{j=l+1}^{\kappa-1} (B_{s+j})_{ii} &= \prod_{j=l+1}^{\kappa-1} \frac{(P_{s+j} + A_{s+j})_{ii}}{(P_{s+j+1})_{ii}} \\ \geq \prod_{j=l+1}^{\kappa-1} \frac{(P_{s+j})_{ii}}{(P_{s+j+1})_{ii}} &= \frac{(P_{s+l+1})_{ii}}{(P_{s+\kappa})_{ii}} \geq \frac{(P_s)_{ii}}{(P_{s+\kappa})_{ii}}. \end{aligned} \tag{41}$$

The inequalities follow from the nonnegativity of the entries and the monotonicity of $(P_t)_{ii}$. Note that (41) also holds for $l = \kappa - 1$ since $(B_{s+\kappa:s+\kappa})_{ii} = 1$.

Since $P_{t+1}^{-1}(P_t + A_t)$ is stochastic, the row-sum of B_t does not exceed 1; therefore, by pre-multiplying $B_{s+1}, B_{s+2}, \ldots$ on both sides of (37), we obtain:

$$B_{s+\kappa:s} \mathbf{1} \leq \mathbf{1} - \sum_{l=0}^{\kappa-1} B_{s+\kappa:s+l+1} \boldsymbol{\alpha}_{s+l}. \tag{42}$$

Noting that $\|B_t\|_\infty = \|B_t \mathbf{1}\|_\infty$ for any t, as B_t is non-negative, we combine (38), (41), and (42) together to derive:

$$\|B_{s+\kappa:s}\|_\infty \leq 1 - \min_{i>0} \frac{(P_s)_{ii}}{(P_{s+\kappa})_{ii}^2}. \tag{43}$$

Let $\eta := \max_{t \geq 0} \max_{1 \leq i \leq n} \eta_{t,i}$ denote the maximum outdegree in all the networks, and define $\delta = \min\{\tau_0/\tau, 1\}$. For any $i > 0$ and $s \geq \kappa$,

$$\frac{s\delta}{\kappa} \leq (P_s)_{ii} \leq \eta s + \frac{\tau_0}{\tau}; \tag{44}$$

hence,

$$\max_i (P_{s+\kappa})_{ii} \leq \eta(s + \kappa) + \frac{\tau_0}{\tau}. \tag{45}$$

It follows that

$$\frac{(P_{s+\kappa})_{ii} - (P_s)_{ii}}{(P_{s+\kappa})_{ii}} = \frac{\sum_{l=0}^{\kappa-1} \eta_{s+l,i}}{(P_{s+\kappa})_{ii}} \leq \frac{\eta \kappa^2 \delta^{-1}}{s + \kappa}. \tag{46}$$

Thus, we have

$$\begin{aligned} \min_{i>0} \frac{(P_s)_{ii}}{(P_{s+\kappa})_{ii}} &= 1 - \max_{i>0} \frac{(P_{s+\kappa})_{ii} - (P_s)_{ii}}{(P_{s+\kappa})ii} \\ &\geq 1 - \frac{\eta \kappa^2 \delta^{-1}}{s + \kappa}. \end{aligned} \tag{47}$$

We can replace the upper bound of (43) by

$$1 - \frac{1}{\max_{i>0} (P_{s+\kappa})_{ii}} \min_{i>0} \frac{(P_s)_{ii}}{(P_{s+\kappa})_{ii}^2},$$

which, together with (45) and (47) gives us

$$\begin{aligned} \|B_{s+\kappa:s}\|_\infty &\leq 1 - \frac{1}{\eta(s+\kappa) + \tau_0/\tau} \left(1 - \frac{\eta \kappa^2 \delta^{-1}}{s + \kappa}\right) \\ &\leq 1 - \frac{1}{2\eta\kappa(m+2)}. \end{aligned} \tag{48}$$

The latter inequality holds as long as $s = m\kappa > 0$ and

$$m \geq m^* := \frac{2\eta\kappa}{\delta} + \frac{\tau_0}{\eta\kappa\tau}.$$

It follows that, for $m_0 \geq m^*$,

$$\begin{aligned} \|B_{(m_0+m)\kappa:m_0\kappa}\|_\infty &\leq \prod_{j=2}^{m+1} \left(1 - \frac{1}{2\eta\kappa(m_0 + j)}\right) \\ &\leq \exp\left\{-\frac{1}{2\eta\kappa} \sum_{j=2}^{m+1} \frac{1}{m_0 + j}\right\}. \end{aligned} \tag{49}$$

The matrices B_t are sub-stochastic so that

$$\|B_t\, \boldsymbol{z}\|_\infty \leq \|B_t\|_\infty \|\boldsymbol{z}\|_\infty \leq \|\boldsymbol{z}\|_\infty.$$

By (40), for any $t \geq (m_0 + m)\kappa$,

$$\boldsymbol{z}_t = B_{t:(m_0+m)\kappa} B_{(m_0+m)\kappa:m_0\kappa}\, \boldsymbol{z}_{m_0},$$

so that, by using standard bounds for the harmonic series, $\ln(k+1) < 1 + \frac{1}{2} + \cdots + \frac{1}{k} \leq 1 + \ln k$, we find that

$$\begin{aligned}\|\boldsymbol{z}_t\|_\infty &\leq \|B_{(m_0+m)\kappa:m_0\kappa}\, \boldsymbol{z}_{m_0}\|_\infty \\ &\leq \|B_{(m_0+m)\kappa:m_0\kappa}\|_\infty \|\boldsymbol{z}_0\|_\infty \\ &\leq C t^{-1/(2\eta\kappa)},\end{aligned}$$

where $C > 0$ depends on $\boldsymbol{z}_0, \kappa, \eta, \tau_0/\tau$. We note that the convergence rate can be improved to the order of $t^{-(1-\varepsilon)\gamma/\eta}$, for arbitrarily small $\varepsilon > 0$, by working a little harder with (48). ■

5.3.3. THE MEAN PROCESS DYNAMICS

Recall that $\mu_{t,i} \sim \mathcal{N}(x_{t,i}, \tau_{t,i}^{-1})$, where $\tau_{t,i}$ denotes the precision $\sigma_{t,i}^{-2}$. A key observation about the updating rule in (1) is that the precision $\tau_{t,i}$ is entirely determined by the graph sequence G_t and is independent of the actual dynamics. Adding to this the connectivity property implied by the truth-hearing assumption, we find immediately that $\tau_{t,i} \to \infty$ for any agent i. This ensures that the covariance matrix Σ_t tends to 0 as t goes to infinity, which satisfies the second criterion for truthful consensus. The first criterion requires that the mean process $\boldsymbol{x}_t$ should converge to the truth $\mathbf{0}$. Take the vector $\boldsymbol{x}_t - \boldsymbol{y}_t$ and remove the first coordinate $(\boldsymbol{x}_t - \boldsymbol{y}_t)_0$ to form the vector $\boldsymbol{\Delta}_t \in \mathbb{R}^n$. Under the truth-hearing assumption, we have seen that $\boldsymbol{y}_t \to \mathbf{0}$ (Lemma 7), so it suffices to prove the following:

Lemma 8 *Under the truth-hearing assumption, the deviation $\boldsymbol{\Delta}_t$ vanishes almost surely.*

Proof We use a fourth-moment argument. The justification for the high order is technical: it is necessary to make a certain "deviation power" series converge. By (32), $\boldsymbol{x}_t$ is a linear combination of independent Gaussian random vectors $\boldsymbol{u}_s$ and $\boldsymbol{\varepsilon}_s$ for $0 \leq s \leq t-1$, and thus $\boldsymbol{x}_t$ itself is a Gaussian random vector. Therefore $\boldsymbol{\Delta}_t$ is also Gaussian and its mean is zero. From Markov's inequality, for any $c > 0$,

$$\sum_{t\geq 0} \mathbb{P}[|\Delta_{t,i}| \geq c] \leq \sum_{t\geq 0} \frac{\mathbb{E}\,\Delta_{t,i}^4}{c^4}. \tag{50}$$

If we are able to show the right hand side of (50) is finite for any $c > 0$, then, by the Borel-Cantelli lemma, with probability one, the event $|\Delta_{t,i}| \geq c$ occurs only a finite number of times, and so $\Delta_{t,i}$ goes to zero almost surely. Therefore, we only need to analyze the order of the fourth moment $\mathbb{E}\,\Delta_{t,i}^4$. By subtracting (33) from (32), we have:

$$\boldsymbol{\Delta}_{t+1} = B_t \boldsymbol{\Delta}_t + M_t \boldsymbol{v}_t, \tag{51}$$

where $\boldsymbol{v}_t := \boldsymbol{u}_t + \boldsymbol{\varepsilon}_t$ and $M_t := P_{t+1}^{-1} A_t$; actually, for dimensions to match, we remove the top coordinate of $\boldsymbol{v}_t$ and the first row and first column of M_t (see previous section for definition of B_t). Transforming the previous identity into a telescoping sum, it follows from $\boldsymbol{\Delta}_0 = \boldsymbol{x}_0 - \boldsymbol{y}_0 = \mathbf{0}$ and the definition $B_{t:s} = B_{t-1} B_{t-2} \ldots B_s$ that

$$\boldsymbol{\Delta}_t = \sum_{s=0}^{t-1} B_{t:s+1} M_s \boldsymbol{v}_s = \sum_{s=0}^{t-1} R_{t,s} \boldsymbol{v}_s, \tag{52}$$

where $R_{t,s} := B_{t:s+1} M_s$. We denote by $C_1, C_2, \ldots$ suitably large constants (possibly depending on $\kappa, \eta, n, \tau, \tau_0$). By (44), $\|M_s\|_\infty \leq C_1/(s+1)$ and, by (49), for sufficiently large s,

$$\|B_{t:s+1}\|_\infty \leq C_2 (s+1)^\beta (t+1)^{-\beta},$$

where $\beta = 1/2\eta\kappa < 1$. Combining the above inequalities, we obtain the following estimate of $R_{t,s}$ as

$$\|R_{t,s}\|_\infty \leq C_3 (s+1)^{-1+\beta} (t+1)^{-\beta}. \tag{53}$$

In the remainder of the proof, the power of a vector is understood element-wise. We use the fact that $\boldsymbol{v}_s$ and $\boldsymbol{v}_{s'}$ are independent if $s \neq s'$ and that the expectation of an odd power of an unbiased Gaussian is always zero. By Cauchy-Schwarz and Jensen's inequalities,

$$\begin{aligned}\mathbb{E}\,\boldsymbol{\Delta}_t^4 &= \left(\sum_{s=0}^{t-1} R_{t,s} \boldsymbol{v}_s\right)^4 \\ &= \sum_{s=0}^{t-1} \mathbb{E}(R_{t,s}\boldsymbol{v}_s)^4 + \sum_{0\leq s\neq s'<t} 3\,\mathbb{E}(R_{t,s}\boldsymbol{v}_s)^2 \mathbb{E}(R_{t,s'}\boldsymbol{v}_{s'})^2 \\ &\leq \sum_{s=0}^{t-1} \mathbb{E}(R_{t,s}\boldsymbol{v}_s)^4 + 3\left(\sum_{s=0}^{t-1} \mathbb{E}(R_{t,s}\boldsymbol{v}_s)^2\right)^2 \\ &\leq \sum_{s=0}^{t-1} \mathbb{E}(R_{t,s}\boldsymbol{v}_s)^4 + 3t \sum_{s=0}^{t-1} \mathbb{E}^2(R_{t,s}\boldsymbol{v}_s)^2 \\ &\leq (3t+1) \sum_{s=0}^{t-1} \mathbb{E}(R_{t,s}\boldsymbol{v}_s)^4. \end{aligned} \tag{54}$$

Notice that since the variance of $\boldsymbol{v}_t = (v_{t,1}, \ldots, v_{t,n})^T$ is nonincreasing, there exists a constant C_4 such that $\mathbb{E}\, v_{t,i}^4 \leq C_4$. By Jensen's inequality and the fact that the variables $v_{t,i}$ are independent for different values of i, we have, for any i, j, k, l,

$$|\mathbb{E}\, v_{t,i} v_{t,j} v_{t,k} v_{t,l}| \leq \max_k \mathbb{E}\, v_{t,k}^4.$$

By direct calculation, it then follows that

$$\begin{aligned}\max_i \mathbb{E}(R_{t,s}\boldsymbol{v}_s)_i^4 &= \max_i \mathbb{E}\Big(\sum_{j=1}^n (R_{t,s})_{ij} v_{s,j}\Big)^4 \\ &\leq \max_i \Big(\sum_{j=1}^n (R_{t,s})_{i,j}\Big)^4 \max_k \mathbb{E}\, v_{s,k}^4 \\ &= \|R_{t,s}\|_\infty^4 \max_k \mathbb{E}\, v_{s,k}^4 \\ &\leq C_5 (s+1)^{-4+4\beta} (t+1)^{-4\beta}. \end{aligned} \tag{55}$$

Summing (55) over $0 \leq s \leq t-1$, we conclude from (54) that $\mathbb{E}\,\boldsymbol{\Delta}_t^4 \leq C_6 t^{-2}$, and thus

$$\sum_{t\geq 0} \mathbb{E}\,\boldsymbol{\Delta}_t^4 \leq C_6 \sum_{t\geq 1} t^{-2} \leq C_7. \tag{56}$$

By the Borel-Cantelli lemma, it follows that $\boldsymbol{\Delta}_t$ vanishes almost surely. ■

Theorem 6 follows directly from Lemmas 7 and 8.

Why the truth-hearing assumption is necessary. We describe a sequence of graphs G_t that allows every agent infinite access to the truth and yet does not lead to truthful consensus. For this, it suffices to ensure that the expected mean process $\boldsymbol{y}_t$ does not converge. Consider a system with two learning agents with priors $\mu_{0,1}$ and $\mu_{0,2}$ from the same distribution $\mathcal{N}(2,1)$. We have $x_{0,1} = x_{0,2} = y_{0,1} = y_{0,2} = 2$ and, as usual, the truth is assumed to be 0; the noise variance is $\sigma^2 = 1$. The graph sequence is defined as follows: set $t_1 = 0$; for $k = 1, 2, \ldots$, agent 1 links to the truth agent at time t_k and to agent 2 at times $t_k + 1, \ldots, s_k - 1$; then at time s_k, agent 2 links to the truth agent, and then to agent 1 at times $s_k + 1, \ldots, t_{k+1} - 1$. Other than the links mentioned, we assume no additional link exists. The time points s_k and t_k are defined recursively to ensure that

$$y_{s_k,1} \geq 1 + 2^{-2k+1} \quad \text{and} \quad y_{t_k,2} \geq 1 + 2^{-2k}. \tag{57}$$

In this way, the expected mean processes of the two agents alternate while possibly sliding down toward 1 but never lower. The existence of these time points can be proved by induction. Since $y_{0,2} = 2$, the inequality $y_{t_k,2} \geq 1 + 2^{-2k}$ holds for $k = 1$, so let's assume it holds up to $k > 0$. The key to the proof is that, by (33), as agent 1 repeatedly links to agent 2, she is pulled arbitrarily close to it. Indeed, the transition rule gives us

$$y_{t+1,1} = \frac{(P_t)_{11}}{(P_{t+1})_{11}}\, y_{t,1} + \frac{1}{(P_{t+1})_{11}}\, y_{t,2},$$

where $(P_{t+1})_{11} = (P_t)_{11} + 1$, which implies that $y_{t,1}$ can be brought arbitrarily close to $y_{t,2}$ while the latter does not move: this follows from the fact that any product of the form $\prod_{t>t_a}^{t_b} \frac{t}{t+1}$ tends to 0 as t_b grows.[2] Thus a suitably increasing sequence of s_k, t_k ensures the two conditions (57). The beliefs of the two agents do not converge to the truth even though they link to the truth agent infinitely often.

2. We note that the construction shares a family resemblance with one used by Moreau (Moreau, 2005) to show the non-consensual dynamics of certain multiagent averaging systems. The difference here is that the weights of the averaging change at each step by increasing the agent's self-confidence.

Appendix A. Analysis of the Root-Sine-Distance

In this appendix, we provide detailed discussion of the root-sine-distance. We will first show that it is a metric, followed by the proof of its equivalency to Euclidean distance and the discussion of its relation to other similar metrics. The notation in the appendix is local and should not be confused with the one used in the main body of this paper.

The root-sine-distance is a metric. The two forms of the function d_{RS} in (4) make it clear that $0 \le d_{RS}(\boldsymbol{a},\boldsymbol{b}) \le 1$ and $d_{RS}(\boldsymbol{a},\boldsymbol{b}) = 0$ if and only if $\boldsymbol{a}$ and $\boldsymbol{b}$ are identical. We easily check that d_{RS} makes the simplex $\mathcal{S}$ of distributions over $\mathcal{D}$ into a metric space. Indeed, $d_{RS}(\cdot,\cdot)$ is obviously symmetric, and $d_{RS}(\boldsymbol{a},\boldsymbol{b}) = 0$ implies that $\boldsymbol{a} = \boldsymbol{b}$. To check the triangular inequality, notice that

$$d_{RS}(\boldsymbol{a},\boldsymbol{b}) = \sqrt{1 - \Big(\sum_{i=1}^{s} \sqrt{a_i b_i}\Big)^2} = \sin\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\,\rangle, \tag{58}$$

where $\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle$ is the angle between the unit vectors $\sqrt{\boldsymbol{a}}$ and $\sqrt{\boldsymbol{b}}$, using the notation $\sqrt{\boldsymbol{v}} = (\sqrt{v_1}, \ldots, \sqrt{v_s})$. To prove that $d_{RS}(\boldsymbol{a},\boldsymbol{b}) + d_{RS}(\boldsymbol{b},\boldsymbol{c}) \ge d_{RS}(\boldsymbol{a},\boldsymbol{c})$ for any $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c} \in \mathcal{S}$, we denote by α,β,γ the corresponding angles in that order, ie, $\alpha = \langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle$, etc. The coordinates in $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c}$ are nonnegative; therefore $0 \le \alpha,\beta,\gamma \le \pi/2$. These form the three angles at the origin of a tetrahedron with a vertex at the origin; therefore, by the triangular inequality in spherical geometry, $\alpha+\beta \ge \gamma$. If $\alpha+\beta \le \frac{\pi}{2}$, then $\sin\alpha + \sin\beta \ge \sin\alpha\cos\beta + \cos\alpha\sin\beta = \sin(\alpha+\beta) \ge \sin\gamma$. On the other hand, if $\alpha+\beta > \pi/2$, then $\sin\alpha+\sin\beta = 2\sin\frac{\alpha+\beta}{2}\cos\frac{\alpha-\beta}{2} \ge 2\sin\frac{\pi}{4}\cos\frac{\pi}{4} = 1 \ge \sin\gamma$, which establishes the triangular inequality.

Relation to the Euclidean distance. Shrinking the simplex $\mathcal{S}$ by a tiny amount, we define $\mathcal{S}_\varepsilon := \{\boldsymbol{a} \in \mathcal{S} : \varepsilon \le a_i \le 1-\varepsilon\}$ and note that

$$d_E(\boldsymbol{a},\boldsymbol{b}) := \|\boldsymbol{a}-\boldsymbol{b}\|_2 = \sqrt{\sum_{i=1}^{s} (\sqrt{a_i} - \sqrt{b_i})^2 (\sqrt{a_i} + \sqrt{b_i})^2}.$$

It follows that, for $\boldsymbol{a},\boldsymbol{b} \in \mathcal{S}_\varepsilon$,

$$\frac{1}{2} d_E(\boldsymbol{a},\boldsymbol{b}) \le d_E(\sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\,) \le \frac{1}{2\sqrt{\varepsilon}}\, d_E(\boldsymbol{a},\boldsymbol{b}). \tag{59}$$

On the other hand, $\|\sqrt{\boldsymbol{a}}\|_2 = \|\sqrt{\boldsymbol{b}}\|_2 = 1$, so the vectors $\sqrt{\boldsymbol{a}}$ and $\sqrt{\boldsymbol{b}}$ form an isosceles triangle; hence

$$d_E(\sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\,) = 2\sin\frac{1}{2}\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle = \frac{\sin\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle}{\cos\frac{1}{2}\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle} = \frac{d_{RS}(\boldsymbol{a},\boldsymbol{b})}{\cos\frac{1}{2}\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle}\,.$$

Since $0 \le \langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\rangle \le \frac{\pi}{2}$,

$$d_{RS}(\boldsymbol{a},\boldsymbol{b}) \le d_E(\sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}}\,) \le \sqrt{2}\, d_{RS}(\boldsymbol{a},\boldsymbol{b}).$$

Together with (59) this shows that, for any $\boldsymbol{a},\boldsymbol{b} \in \mathcal{S}_\varepsilon$,

$$\frac{1}{2\sqrt{2}}\, d_E(\boldsymbol{a},\boldsymbol{b}) \le d_{RS}(\boldsymbol{a},\boldsymbol{b}) \le \frac{1}{2\sqrt{\varepsilon}}\, d_E(\boldsymbol{a},\boldsymbol{b}), \tag{60}$$

which shows that the Euclidean distance and the metric d_{RS} are equivalent in $\mathcal{S}_\varepsilon$.

Relation to other distances. The metric d_{RS} is related to the Hellinger and Bhattacharyya distances. Writing $C(\boldsymbol{a},\boldsymbol{b}) = \sum_{i=1}^{s} \sqrt{a_i b_i}$ (Comaniciu et al., 2000), then $d_{RS}(\boldsymbol{a},\boldsymbol{b}) = \sqrt{1 - C(\boldsymbol{a},\boldsymbol{b})^2}$. The Hellinger distance is defined as $d_H(\boldsymbol{a},\boldsymbol{b}) = \sqrt{1 - C(\boldsymbol{a},\boldsymbol{b})}$ (Hazewinkel, 2013), while the Bhattacharyya distance is defined as $d_B(\boldsymbol{a},\boldsymbol{b}) = -\ln C(\boldsymbol{a},\boldsymbol{b})$ (Bhattachayya, 1943). The total variation distance d_{TV} is half the ℓ_1-norm; therefore $d_{TV}(\boldsymbol{a},\boldsymbol{b}) \le \frac{1}{2}\sqrt{s}\, d_E(\boldsymbol{a},\boldsymbol{b})$. Combining these observations with (60) establishes (5):

$$\begin{cases} d_H = \sqrt{1 - \sqrt{1 - d_{RS}^2}}\,; \\ d_B = -\frac{1}{2}\ln(1 - d_{RS}^2)\,; \\ d_{TV} \le \sqrt{2s}\, d_{RS}. \end{cases}$$

Abstract

As a model problem for clustering, we consider the densest k-disjoint-clique problem of partitioning a weighted complete graph into k disjoint subgraphs such that the sum of the densities of these subgraphs is maximized. We establish that such subgraphs can be recovered from the solution of a particular semidefinite relaxation with high probability if the input graph is sampled from a distribution of clusterable graphs. Specifically, the semidefinite relaxation is exact if the graph consists of k large disjoint subgraphs, corresponding to clusters, with weight concentrated within these subgraphs, plus a moderate number of nodes not belonging to any cluster. Further, we establish that if noise is weakly obscuring these clusters, i.e, the between-cluster edges are assigned very small weights, then we can recover significantly smaller clusters. For example, we show that in approximately sparse graphs, where the between-cluster weights tend to zero as the size n of the graph tends to infinity, we can recover clusters of size polylogarithmic in n under certain conditions on the distribution of edge weights. Empirical evidence from numerical simulations is also provided to support these theoretical phase transitions to perfect recovery of the cluster structure.

1. Introduction

Clustering is a fundamental problem in machine learning and statistics, focusing on the identification and classification of groups, called *clusters*, of similar items in a given data set. Clustering is ubiquitous, playing a prominent role in varied fields such as computational biology, information retrieval, pattern recognition, image processing and computer vision, and network analysis. This problem is inherently ill-posed, as the partition or clustering of any given data set will depend heavily on how we quantify similarity between items in the data set and how we characterize clusters; it is not outside the realm of possibility to have two drastically different clusterings of the same data if two different similarity metrics are used in the clustering process. Regardless of the similarity metric used, clustering is a combinatorial optimization problem at its core: given data, identify a partition or labeling of the data (approximately) maximizing some measure of quality of the clustering. Due to the difficulties inherent with optimization over discrete sets, many popular approaches for clustering involve the approximate solution of an NP-hard combinatorial optimization problem; for example, the spectral clustering heuristic for the normalized cut problem (Dhillon et al., 2004; Ng et al., 2002), the convex relaxation approaches for the correlation clustering problem (Mathieu and Schudy, 2010), robust principal component analysis (Chen et al., 2014a; Oymak and Hassibi, 2011), and the densest k-disjoint-clique problem (Ames and Vavasis, 2014; Ames, 2014), among many others.

In spite of the inherent intractability of clustering, many recent analyses have established that if data is sampled from some distribution of clusterable data, then one can efficiently recover the underlying cluster structure using a variety of clustering algorithms. In particular, the recent results of Abbe et al. (2016); Ailon et al. (2013); Ames and Vavasis (2014); Ames (2014); Amini and Levina (2018); Cai and Li (2015); Chen et al. (2014a,b); Chen and Xu (2014); Guédon and Vershynin (2015); Hajek et al. (2015); Lei and Rinaldo (2015); Mathieu and Schudy (2010); Nellore and Ward (2015); Oymak and Hassibi (2011); Rohe et al. (2011); Qin and Rohe (2013); Vinayak et al. (2014) all establish sufficient conditions under which we can expect to identify the latent cluster structure efficiently. Most of these results assume that the similarity structure of the data can be modeled as a graph sampled from some generalization of the *stochastic block model* proposed by Holland et al. (1983). In this model, the nodes of the graph, called the *similarity graph* of the data, are associated with the items in the data set. An edge is drawn between two items with fixed probability p if the corresponding items belong to the same cluster, and with fixed probability $q < p$ if the corresponding items belong to different clusters. Under this block model, the analyses cited above establish that the block structure of the data can be recovered in polynomial-time with high probability provided that the smallest cluster in the data is sufficiently large,

typically larger than $\tilde{c}\sqrt{n}$, where n denotes the number of items in the data (and nodes in the similarity graph) and $\tilde{c}$ is a polylogarithmic factor in n depending on $p-q$.

Although valuable in establishing sufficient conditions for data to be clusterable, these results are not immediately applicable to data sets seen in many applications, particularly those arising from the analysis of social networks. For example, statistical analysis of social networks suggests that communities, playing the role of clusters, tend to be limited in size to several hundred users, while the networks themselves can contain thousands, if not millions or even billions, of users (Leskovec et al., 2008, 2009). However, the recent analyses of Chen et al. (2014a); Chen and Xu (2014); Guédon and Vershynin (2015); Jalali et al. (2015); Rohe et al. (2014), among others, suggest that these clusterability results are overly conservative with respect to the size of clusters we can expect to recover in polynomial-time. Specifically, these analyses allow the edge probabilities p and q to vary with n, and investigate how the size of the smallest cluster that can be recovered depends on the relative scaling of p, q and n. In this case, the data is often assumed to be sampled from a *sparse* generalized stochastic block model where the parameters p and q governing edge formation are functions depending on the number of items n and one or both tends to 0 as $n \to \infty$. In the case where p tends to 0 much more slowly than q, the noise obscuring the block structure is significantly weaker than in the dense graph case (where p and q are assumed fixed). Here, sparsity refers to the fact that graphs generated according to the block model contain very few edges between clusters with high probability when n is large, and not that the graph itself is sparse in the sense that the nodes have small average degree. In this case, it has been shown that clusters significantly smaller than $\sqrt{n}$ can be recovered efficiently; specifically, several methods have been shown to recover clusters with size polylogarithmic in n under certain assumptions on the probability functions p and q (see Chen et al., 2014a; Chen and Xu, 2014; Guédon and Vershynin, 2015; Rohe et al., 2014). We should note that these results provide evidence of a computational limit for cluster recovery; that is, these results establish that clusters can be recovered in a computationally efficient way if the underlying data satisfies certain sufficient conditions. We should note further that the lower bounds on cluster size given by these sufficient conditions typically do not match information-theoretic limits; it is well-known that it is possible to identify clusters of size on the order of $\log n$ in certain settings, however, no polynomial-time algorithms are known to do so (Chen and Xu 2014; Hajek et al. 2015 provide further details).

The primary contribution of this paper is an analysis establishing similar clusterability results for a particular convex relaxation of the clustering problem. That is, we present an analysis establishing the following theorem, which provides conditions for perfect recovery of the underlying cluster structure from the solution of a particular semidefinite program. As an immediate corollary, the theorem establishes that one may identify clusters as small

as $\Omega(\log n)$, i.e., there exists constant c such that the size of the smallest cluster recoverable cluster is bounded below by $c \log n$ for sufficiently large n, with high probability if the data is sampled from the sparse block model described above for particular choices of p and q. Here, we say that an event occurs *with high probability (w.h.p.)* if the event occurs with probability tending polynomially to 1 as $n \to \infty$.

Theorem 1 *Suppose that the n-node graph $G = (V, E)$ is sampled from the generalized stochastic block model, with k disjoint blocks, in-cluster edge probability p, and between-cluster edge probability q. Let $\boldsymbol{A} \in \mathbf{R}^{n \times n}$ denote the adjacency matrix of G and let $\hat{r}$ and $\tilde{r}$ denote the cardinality of the smallest and largest clusters, respectively, in the block model for G. Then there exists constants $c_1, c_2, c_3 > 0$ such that the columns of the optimal solution $\boldsymbol{X}^*$ of the semidefinite program*

$$\max_{\boldsymbol{X} \in \Sigma_+^n} \{\mathrm{Tr}(\boldsymbol{A}\boldsymbol{X}) : \boldsymbol{X}\boldsymbol{e} \leq \boldsymbol{e}, \mathrm{Tr}(\boldsymbol{X}) = k, \boldsymbol{X} \geq \boldsymbol{0}\}$$

are scalar multiples of the characteristic vectors of the clusters in our underlying block model with high probability if

$$p - q \geq c_3 \max\left\{ \sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}} \right\},$$

where $\tilde{\sigma}^2 = \max\{p(1-p), q(1-q)\}$, and

$$(p-q)\hat{r} \geq c_1 \max\left\{ \sqrt{q(1-q)n}, \sqrt{\log n} \right\} + c_2 \max\left\{ \sqrt{p(1-p)\tilde{r}}, \sqrt{\log n} \right\}.$$

Moreover, in this case, every characteristic vector of a cluster in the block model is a scalar multiple of at least one column of $\boldsymbol{X}^*$.

Here, the characteristic vector of a set $S \subseteq \{1, 2, \ldots, n\}$ is the vector $\boldsymbol{x} \in \{0,1\}^n$ with ith element

$$x_i = \begin{cases} 1, & \text{if } i \in S \\ 0, & \text{otherwise.} \end{cases}$$

In Theorem 1, $\mathrm{Tr}(\boldsymbol{X})$ denotes the trace of the matrix $\boldsymbol{X}$, $\boldsymbol{e}$ denotes the all-ones vector of appropriate dimension, the notation $\boldsymbol{X} \geq \boldsymbol{0}$ indicates that the entries of $\boldsymbol{X}$ are nonnegative, and Σ_+^n denotes the cone of $n \times n$ symmetric positive semidefinite matrices.

Note that if G is sampled from the *dense* block model, i.e., p, q are independent of n, then Theorem 1 suggests that we have exact recovery if $\hat{r} \geq c\sqrt{n}$ with high probability, where c is a constant depending on p, q; this bound matches that established by Ames (2014) (among many others) up to constant terms. On the other hand, when G is sampled from the *sparse* block model, we see that Theorem 1 suggests that we may have perfect

recovery of significantly smaller clusters. For example, suppose that $p = 1$ is fixed and $q = \log n/n$. Then we have exact recovery with high probability if the smallest cluster has size $\hat{r} = \Omega(\log n)$; see the discussion following Theorem 3.

We will show that analogous phenomena occur in what we will call *approximately* sparse graphs. In many practical applications, the expectation that we have a binary labeling indicating whether any pair of items in a given data set are similar or dissimilar is unrealistic. However, it is often possible to describe the *level* of similarity between any two items using some affinity function based on distance between the items in question. For example, we could consider the discrepancy in pixel intensity and geographic location in image segmentation applications or Euclidean distance between two items represented as vectors in a Euclidean space (or some other vector space with corresponding norm). In this case, we can summarize the pairwise similarity relationships within our data using a weighted graph, called a *weighted similarity graph*. Specifically, given a data set with affinity function f, the weighted similarity graph is the weighted complete graph with nodes corresponding to the items in the data set, and edge weight w_{ij} between nodes i and j given by the value of $f(i, j)$. Clearly, this contains the similarity graphs discussed earlier as a special case where $w_{ij} = 1$ if items i and j are known to be similar and $w_{ij} = 0$ otherwise; note that we assume that we have an undirected graph with symmetric adjacency matrix.

We can generalize the stochastic block model in an identical fashion. We assume that items in the same cluster are significantly more similar than pairs of items in different clusters. This corresponds to edge weights within clusters being larger, on average, than edge weights between clusters. This motivates the following random graph model, which we will call the *planted cluster model*. Let $G = (V, \boldsymbol{W})$ be the weighted complete graph whose node set represents the items in some data set containing k clusters and (potentially) some nodes that will not be assigned to a cluster. For each pair of nodes u, v in the same cluster C_ℓ, $\ell \in \{1, 2, \ldots, k\}$, we randomly sample edge weight $w_{uv} \geq 0$, and w_{vu} by symmetry, from some probability distribution Ω_ℓ with mean $\alpha_\ell \geq \alpha > 0$. If $u \in C_i$, $v \in C_j$, where $i \neq j$, i.e., u, v do not belong to the same cluster, we sample $w_{uv} = w_{vu} \geq 0$ from a different probability distribution Ω_{ij} with mean $\beta_{ij} \leq \beta \in [0, \alpha)$. Note that this model contains the generalized stochastic block model discussed earlier as a special case when Ω_ℓ and Ω_{ij} are Bernoulli distributions with probabilities of success $p_\ell = p$ and $q_{ij} = q$, respectively.

It was shown by Ames (2014) that if $G = (V, \boldsymbol{W})$ is sampled from the planted cluster model with minimum cluster size at least $c\sqrt{n}$ in the homogeneous case where all within-cluster edges are i.i.d. with mean α and all between-cluster edges are i.i.d. with mean β, where c is a constant depending on α and β, then we can recover the clusters from the

optimal solution of the semidefinite program

$$\max_{\boldsymbol{X} \in \Sigma_+^n} \left\{ \operatorname{Tr}(\boldsymbol{W}\boldsymbol{X}) : \boldsymbol{X}\boldsymbol{e} \leq \boldsymbol{e}, \operatorname{Tr}(\boldsymbol{X}) = k, \boldsymbol{X} \geq \boldsymbol{0} \right\} \tag{1}$$

with high probability, where k is the number of clusters in the graph. We will show that these results can be strengthened to establish that much smaller clusters can be recovered in the presence of *approximately* sparse noise. That is, we will see that if the between-cluster edge weights have expectation β and variance σ_2^2 approaching zero sufficiently quickly as $n \to \infty$, then we may recover clusters containing as few as $\Omega(\log n)$ nodes with high probability. We will derive the semidefinite program (1) as a relaxation of a particular model problem for clustering in Section 2.1 and formally state our recovery guarantees in Section 2.2; we will see that these results immediately specialize to those stated in Theorem 1 for the semidefinite program (1).

2. Semidefinite Relaxations of the Densest k-Disjoint Clique Problem

In this section, we derive a semidefinite relaxation for the densest k-disjoint clique problem and present an analysis illustrating a sufficient condition ensuring that this relaxation is exact. This problem will act as a model problem for clustering and we will see that we should expect to accurately recover the underlying cluster structure if the given data satisfies this sufficient condition.

2.1. The Densest k-disjoint Clique Problem

We begin by deriving a heuristic for the clustering problem based on semidefinite relaxation of the densest disjoint clique problem. A similar discussion motivating the relaxation was originally presented by Ames (2014); we repeat it here for completeness. Let $K_n = (V, \boldsymbol{W})$ be a weighted complete graph with vertex set $V = \{1, 2, \ldots, n\}$ and nonnegative edge weights $w_{ij} \in [0, 1]$ for all $i, j \in V$. Given a subgraph H of K_n, the *density* d_H of H is the average edge weight incident at a vertex in H:

$$d_H = \sum_{ij \in E(H)} \frac{w_{ij}}{|V(H)|}.$$

If we assume that K_n is the similarity graph of some data set consisting of k disjoint clusters and that weight is concentrated more heavily on within-cluster edges than between-cluster edges, then we may cluster this data set by finding the set of k disjoint subgraphs, corresponding to these clusters, with maximum density; we call this problem the *densest k-partition problem*. Peng and Wei (2007) established that the densest k-partition problem is

NP-hard. Moreover, this partition model excludes the case where some items in the data set do not naturally associate with any of the clusters in the data. To simultaneously motivate a convex relaxation of the densest k-partition problem and address the inclusion of nodes that do not naturally belong to clusters, we consider the *densest k-disjoint clique problem*.

Given a graph $G = (V, E)$, a *clique* of G is a pairwise adjacent subset of V. That is, $C \subseteq V$ is a clique of G if $ij \in E$ for every pair of nodes $i, j \in C$ or, equivalently, the subgraph $G(C)$ induced by C is complete. We say that H is a *k-disjoint-clique* subgraph of K_n if $V(H)$ consists of k disjoint cliques, i.e., H is the union of k disjoint complete subgraphs of K_n. The *densest k-disjoint-clique problem* seeks a k-disjoint-clique subgraph H^* maximizing the sum of the densities of the disjoint complete subgraphs comprising H^*. Note that if we add the additional constraint that each node in K_n belongs to exactly one k-disjoint-clique subgraph in K_n, then the densest k-disjoint-clique problem becomes the densest k-partition problem. However, in general, the densest k-disjoint-clique problem allows an assignment of nodes to clusters, represented by the disjoint cliques, which excludes some nodes. For example, if such nodes are present in the data, they would not be assigned to a cluster by the optimal k-disjoint-clique subgraph.

The complexity of the densest k-disjoint-clique problem is unknown; in particular, no polynomial-time algorithm for its solution is known. To address this potential intractability, we will attempt to approximately solve the k-disjoint-clique problem by convex relaxation. Suppose that $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k$ are the characteristic vectors of a set of disjoint cliques $C_1, C_2, \ldots, C_k$ forming a k-disjoint-clique subgraph of K_n. Using this notation, the density of the complete subgraph induced by C_i is equal to

$$d_{G(C_i)} = \sum_{u,v \in C_i} \frac{w_{uv}}{|C_i|} = \frac{\boldsymbol{v}_i^T \boldsymbol{W} \boldsymbol{v}_i}{\boldsymbol{v}_i^T \boldsymbol{v}_i}.$$

If we let $\boldsymbol{P}$ be the $n \times k$ matrix with ith column equal to $\boldsymbol{v}_i / \|\boldsymbol{v}_i\|$, where $\|\cdot\| = \|\cdot\|_2$ denotes the standard Euclidean norm, then it is easy to see that

$$\sum_{i=1}^{k} d_{G(C_i)} = \operatorname{Tr}(\boldsymbol{P}^T \boldsymbol{W} \boldsymbol{P}).$$

We call such a matrix $\boldsymbol{P}$ a *normalized k-cluster matrix* and denote the set of normalized k-cluster matrices of the vertex set V by $ncm(V, k)$. It follows that the densest k-disjoint-clique problem may be formulated as

$$\max \left\{ \operatorname{Tr}(\boldsymbol{P}^T \boldsymbol{W} \boldsymbol{P}) : \boldsymbol{P} \in ncm(V, k) \right\}. \tag{2}$$

Again, the complexity of (2) is unknown, however, the maximization of quadratic functions subject to combinatorial constraints is known to be NP-hard.

A process for relaxation of (2) using matrix lifting is described by Ames (2014); a similar relaxation technique was applied by Ames and Vavasis (2011, 2014) and Ames (2015). In particular, each proposed cluster C_i, with characteristic vector $\boldsymbol{v}_i$, corresponds to the rank-one symmetric matrix

$$\boldsymbol{X}^{(i)} = \frac{\boldsymbol{v}_i \boldsymbol{v}_i^T}{\boldsymbol{v}_i^T \boldsymbol{v}_i}.$$

It is easy to see that the density of $G(C_i)$ is equal to

$$d_{G(C_i)} = \frac{\boldsymbol{v}_i^T \boldsymbol{W} \boldsymbol{v}_i}{\boldsymbol{v}_i^T \boldsymbol{v}_i} = \operatorname{Tr}(\boldsymbol{W} \boldsymbol{X}^{(i)}).$$

Moreover, each of the matrices $\boldsymbol{X}^{(i)}$ has row and column sums equal to either 0 or 1, and trace equal to 1. Finally, for each proposed clustering $C_1, \ldots, C_k$, the corresponding rank-one matrices are orthogonal in the trace inner product, due to the orthogonality of the characteristic vectors of the corresponding disjoint clusters. Thus, the matrix

$$\boldsymbol{X} = \sum_{i=1}^{k} \boldsymbol{X}^{(i)} = \sum_{i=1}^{k} \frac{\boldsymbol{v}_i \boldsymbol{v}_i^T}{\boldsymbol{v}_i^T \boldsymbol{v}_i} \tag{3}$$

has rank equal to k. This suggests that we may relax (2) as the rank-constrained semidefinite program

$$\max_{\boldsymbol{X} \in \Sigma_+^n} \left\{ \operatorname{Tr}(\boldsymbol{W} \boldsymbol{X}) : \boldsymbol{X} \boldsymbol{e} \leq \boldsymbol{e}, \operatorname{rank} \boldsymbol{X} = k, \operatorname{Tr} \boldsymbol{X} = k, \boldsymbol{X} \geq \boldsymbol{0} \right\}. \tag{4}$$

The relaxation (4) can be relaxed further to a semidefinite program by omitting the nonconvex rank constraint:

$$\max_{\boldsymbol{X} \in \Sigma_+^n} \left\{ \operatorname{Tr}(\boldsymbol{W} \boldsymbol{X}) : \boldsymbol{X} \boldsymbol{e} \leq \boldsymbol{e}, \operatorname{Tr} \boldsymbol{X} = k, \boldsymbol{X} \geq \boldsymbol{0} \right\}. \tag{5}$$

We should note that the semidefinite program (5) is remarkably similar to the semidefinite relaxation of the minimum sum of squared distance partition of Peng and Wei (2007) and the semidefinite relaxation of the maximum likelihood estimate of the stochastic block model considered by Amini and Levina (2018), among others, although our relaxation approach differs slightly from that used in these two papers.

2.2. Block Models and Recovery Guarantees

Given a set of clusterable data or, more accurately, a clusterable graph representation of data, Ames (2014) established that one can recover the underlying cluster structure from the optimal solution of the semidefinite program (5). Specifically, it is assumed that data with strong cluster structure should correspond to similarity graphs with heavy weight assigned to edges within clusters, relative to that between cluster edges. This corresponds to pairs of

items within clusters being significantly more similar than pairs of items in different clusters. This motivates the following block model.

Let H^* be a k-disjoint-clique subgraph of $K_n = (V, \boldsymbol{W})$ with vertex set composed of the disjoint cliques $C_1, \ldots, C_k$ and let Σ^n denote the set of all $n \times n$ symmetric matrices. We consider weight matrices $\boldsymbol{W} = [w_{ij}] \in \Sigma^n$ with entries sampled independently from one of two probability distributions Ω_1, Ω_2 as follows.

- For each $i = 1, \ldots, k$ and each $u, v \in C_i$, we sample $w_{uv} = w_{vu}$ from a distribution Ω_1 such that
$$\mathbf{E}[w_{uv}] = \mathbf{E}[w_{vu}] = \alpha, \qquad 0 \leq w_{uv} \leq 1,$$
for fixed $\alpha \in (0, 1]$.
- For each remaining edge uv, $u \in C_i, v \in C_j$, we sample the edge weight $w_{uv} = w_{vu}$ from a second distribution Ω_2 such that
$$\mathbf{E}[w_{uv}] = \mathbf{E}[w_{vu}] = \beta, \qquad 0 \leq w_{uv} \leq 1,$$
for fixed $\beta \in [0, \alpha)$ if $1 \leq i, j \leq k$ or $i = j = k + 1$, and $\mathbf{E}[w_{uv}] = \beta/2$ otherwise.

We should note that the assumption that the entries of $\boldsymbol{W}$ are bounded between 0 and 1 is made for simplicity in the statement and proof of our main result; analogous recovery guarantees hold if we assume that random variables sampled according to Ω_1 and Ω_2 are bounded and nonnegative with high probability. We say that such random matrices $\boldsymbol{W}$ are sampled from the *planted cluster model*. Note that if $\boldsymbol{W}$ is sampled from the planted cluster model, then weight is concentrated on within-cluster edges (in expectation). This provides a natural generalization of the stochastic block model. Indeed, the stochastic block model corresponds to the planted cluster model in the special case that Ω_1 and Ω_2 are Bernoulli distributions with probabilities of success p and q, respectively. Ames (2014) established the following theorem, ensuring recovery of the planted cliques $C_1, \ldots, C_k$ from the optimal solution of (5) under the planted cluster model (see Ames, 2014, Theorem 2.1).

Theorem 2 *Suppose that the vertex sets $C_1, \ldots, C_k$ define a k-disjoint-clique subgraph H^* of the n-node weighted complete graph $K_n(V, \boldsymbol{W})$ and let $C_{k+1} := V \setminus \left(\cup_{i=1}^k C_i\right)$. Let $r_i := |C_i|$ for all $i = 1, \ldots, k+1$ and let $\hat{r} = \min_{i=1,\ldots,k} r_i$. Let $\boldsymbol{W} \in \Sigma^n$ be a random symmetric matrix sampled from the planted cluster model according to distributions Ω_1 and Ω_2 with means α and β, respectively, satisfying*

$$\gamma = \gamma(\alpha, \beta, r) := \alpha - \beta > 0.$$

Let $\boldsymbol{X}^*$ be the feasible solution of (5) corresponding to $C_1, \ldots, C_k$ defined by (3). Then there exist scalars $c_1, c_2, c_3 > 0$ such that if

$$c_1\sqrt{n} + c_2\sqrt{kr_{k+1}} + c_3 r_{k+1} \leq \gamma \hat{r},$$

then $\boldsymbol{X}^*$ is the unique optimal solution of (5), and H^* is the unique maximum density k-disjoint-clique subgraph of K_n with probability tending exponentially to 1 as $\hat{r} \to \infty$.

In contrast to Theorem 1, the result of Theorem 2 implies that we can have perfect recovery if the graph contains a small number of nodes that shouldn't be assigned to any of the planted clusters. Each potential edge from each of these nodes to any other node is added independently to the graph with probability q, so that each node in C_{k+1} has roughly the same number of neighbours in each cluster block. This implies that such a node is not assigned to any of the planted clusters because it is weakly associated with all of the planted clusters. It is important to note that this edge assignment is performed randomly and not deterministically by an adversary attempting to obscure the cluster structure present in the graph. We present a new analysis that improves upon the recovery guarantee of Theorem 2 in two ways. First, the hypothesis of Theorem 2 assumes that between-cluster and within-cluster edge weights are i.i.d. We consider the more general heterogeneous case constructed as follows:

- For each $u \in C_i$, $v \in C_j$, we sample the edge weight $w_{uv} = w_{vu}$ from distribution Ω_{ij} with
$$\mathbf{E}[w_{uv}] = \mathbf{E}[w_{vu}] = \mu_{ij}, \qquad \mathrm{Var}[w_{uv}] = \mathrm{Var}[w_{vu}] = \sigma_{ij}^2, \qquad 0 \leq w_{uv} \leq 1.$$

This forces weights within the same block to be i.i.d., but weight may not be identically distributed in different blocks.

Second, the analysis leading to Theorem 2 assumes that the expectations of Ω_1, Ω_2 in the planted cluster model are fixed and that the variances are bounded by 1. We improve upon the recovery guarantee of Theorem 2 by considering the case where the parameters α and β depend on the number of nodes n in the graph. In particular, our recovery guarantees explicitly depend on the variances of the distributions Ω_{ij}, and their scaling with n, which will expand the set of graphs known to be clusterable by (5). We have the following theorem.

Theorem 3 *Suppose that the vertex sets $C_1, \ldots, C_k$ define a k-disjoint-clique subgraph K^* of the weighted complete graph $K_n = (V, \boldsymbol{W})$ on n vertices and let $C_{k+1} = V \setminus \left(\cup_{i=1}^k C_i\right)$. Let $r_i = |C_i|$ for all $i = 1, \ldots, k+1$ and let $\hat{r} = \min_{i=1,\ldots,k} r_i$. Let $\boldsymbol{W} \in \Sigma^n$ be a random symmetric matrix sampled from the heterogeneous planted cluster model according to distributions $\{\Omega_{ij}\}$*

with expected values $\mu_{ij} = \mu_{ij}(n)$ *and variances* $\sigma_{ij}^2 = \sigma_{ij}^2(n)$. *Let* $\tilde{\sigma} := \max_{q,s} \sigma_{qs}$ *and* $\hat{\sigma} := \max_q \sigma_{qq}$. *Let* $\boldsymbol{X}^*$ *be the feasible solution to* (5) *corresponding to* $C_1, \ldots, C_k$ *defined by* (3). *Let*

$$\gamma := \min_{\substack{q,s=1,2,\ldots,k \\ q \neq s}} \{\mu_{qq} - \mu_{qs}\}.$$

Then there exists scalar $c > 0$ *such that if*

$$\gamma \hat{r} \geq c \max\left\{\sqrt{\tilde{\sigma}^2 n},\ \sqrt{\tilde{\sigma}^2 \hat{r} \log n},\ \sqrt{\hat{\sigma}^2 k r_{k+1}},\ \sqrt{k r_{k+1} \log n / \hat{r}},\ \mu_{k+1,k+1} r_{k+1},\ \log n\right\}, \quad (6)$$

then $\boldsymbol{X}^*$ *is the unique optimal solution for* (5), *and* K^* *is the unique maximum density* k*-disjoint-clique subgraph of* K_n *with high probability.*

The *weak assortativity* condition (6) implies that we have perfect recovery provided that the gap between the cluster block expectation μ_{qq} and the largest between-cluster block expectation μ_{qs} is sufficiently large for all clusters C_q, $q = 1, \ldots, k$, relative to the minimum cluster size, number of unassigned nodes r_{k+1}, number of clusters, and edge weight variances. In the Bernoulli case, i.e., within-cluster and between-cluster edges are added independently with probabilities p and q, respectively, Theorem 3 and, in particular, (6) establish that we can recover the planted clusters provided that

$$\frac{(p-q)^2}{\tilde{\sigma}^2} = \frac{(p-q)^2}{\max\{p(1-p), q(1-q)\}} = \Omega\left(\frac{n}{\hat{r}^2}\right).$$

This result agrees with the Easy Regime for cluster recovery proposed by Chen and Xu (2014), where a polynomial-time algorithm exists for exact recovery of the planted clusters, in this case, the solution of the semidefinite relaxation (5). One distinct advantage of this result over similar recovery guarantees is that our model and phase transition are largely parameter free. For example, Amini and Levina (2018) present an analysis of three semidefinite relaxations that obtain nearly identical conditions on $\{\Omega_{ij}\}$ guaranteeing recovery but restrict their analysis to the case where the clusters are identical in size or otherwise known and when $\{\Omega_{ij}\}$ are Bernoulli distributions; we should note that Amini and Levina (2018) consider heterogeneous Bernoulli distributions where the within-cluster and between-cluster probabilities of adding an edge vary across clusters. Similarly, Chen and Xu (2014) and Jalali et al. (2015) give identical conditions for recovery (up to constants and logarithmic terms) in the Bernoulli case to those in Theorem 3 for semidefinite relaxations that require the sizes of the clusters to be used as input parameters (or all clusters to have identical size), neither of which are realistic assumptions in practice. In contrast, our approach achieves this recovery guarantee using *only the desired number of clusters as a parameter*. Further, our guarantee extends to the general weighted case where the vast

majority of existing recovery guarantees for stochastic block models are restricted to the Bernoulli case.

It is important to note that tighter recovery guarantees than those provided by Theorem 3 are known for specific problem settings. This is a natural consequence of the more general framework of our analysis. For example, Yan et al. (2017) studies a convex relaxation for cluster recovery in the Bernoulli (unweighted) case. The main theorem of this article establishes conditions for perfect recovery that allow larger clusters to have higher variance, although specialized for the unweighted case. Moreover, Yan et al. (2017) consider the use of a tuning parameter to allow recovery without knowledge of the number of clusters k. On the other hand, the results of Amini and Levina (2018); Jalali et al. (2015) also provide tighter recovery guarantees but require knowledge of cluster sizes. The key contribution of this work is the presentation of a recovery guarantee that extends to the weighted case without strict assumptions regarding input parameters, as well as the first-order method for solution of (1) discussed in detail in Section 4.

To further illustrate the consequences of Theorem 3, we consider several examples. In each, we assume that the graph is generated in the homogeneous setting where within-cluster weights are i.i.d. according to Ω_1 with mean α and variance σ_1^2, and between-cluster weights are i.i.d. according to Ω_2 with mean $\beta < \alpha$ and variance σ_2^2.

2.2.1. The Dense Case

When α, β are fixed, we obtain the same recovery guarantee as before, up to constants and logarithmic terms: we have exact recovery w.h.p. if $\hat{r} \geq \tilde{c}_1 \sqrt{n}$ and $\hat{r} \geq \tilde{c}_2 r_{k+1}$ for some constants $\tilde{c}_1$ and $\tilde{c}_2$ depending on Ω_1 and Ω_2. Indeed, each of the pointwise maximums in the first three terms of (6) is bounded above by $O(\sqrt{n})$ since $\tilde{r} \leq n$, and $k r_{k+1} = O(n)$ if $r_{k+1} = O(\hat{r})$.

2.2.2. The Sparse Case

On the other hand, if noise in the form of between-cluster edge-weight is small, then we should expect to be able recover much smaller clusters. For example, suppose that Ω_2 is the Bernoulli distribution with probability of adding an edge q and that Ω_1 is the Bernoulli distribution with probability of adding an edge $p = 1$ (the assumption that $p = 1$ is for the sake of simplicity in this example and we can expect analogous recovery guarantees for any p tending slowly enough to 0). Assume further that $q(1-q) \leq \log n / n$. Finally, again for simplicity, assume that we have k equally sized clusters of size $\hat{r} = n/k$ and $(r_{k+1} = 0)$. In

this case, (6) holds if

$$\gamma\hat{r} \geq c\log n = c\max\left\{\sqrt{\log n},\ \sqrt{\frac{\hat{r}\log^2 n}{n}},\ \log n\right\} \geq c\max\left\{\sqrt{\tilde{\sigma}^2 n},\ \sqrt{\tilde{\sigma}^2 r\log n},\ \log n\right\},$$

since $\tilde{\sigma}^2 = \max\{p(1-p), q(1-q)\} = q(1-q) \leq \log n/n$ and the terms involving r_{k+1} and $1-p$ are equal to zero. This implies that we have exact recovery of the planted clusters w.h.p. provided $\hat{r} = \Omega(\log n)$. This exceeds the state of the art recovery bound of $\hat{r} = \Omega(\sqrt{\log n})$ established in Jalali et al. (2015) by a factor of $\sqrt{\log n}$. However, the convex relaxation proposed by Jalali et al. (2015) requires knowledge of $\sum_{i=1}^{k} r_i^2$, which is often an unrealistic expectation in practice; in contrast, our approach only requires knowledge of the number of clusters k present in the data. Further, the requirement $\hat{r} = \Omega(\log n)$ is enforced by the gap inequality (6), which itself is a consequence of the use of the Bernstein inequality to establish certain dual variables are nonnegative in the proof of Theorem 3 (see Section 3.1 for more details). It may be possible to improve this bound to $\hat{r} = \Omega(\sqrt{\log n})$ with improved concentration inequalities but it is unclear what form these improvements may take.

2.2.3. The Planted Clique and Sparsest Subgraph

In the special case when $k = 1$ and Ω_1 and Ω_2 are Bernoulli distributions, the planted cluster model specializes to the planted clique model considered in Ames and Vavasis (2011) and Ames (2015). In this case, (6) suggests that we can recover a planted clique (in the dense case) of size $r_1 = \Omega\left(\max\left\{\sqrt{n}, r_2\right\}\right) = \Omega\left(\max\left\{\sqrt{n}, n - r_1\right\}\right)$. This recovery guarantee is far more conservative than those provided by Ames and Vavasis (2011) and Ames (2015), among others, which establish that a planted clique of size $\Omega(\sqrt{n})$ can be recovered from the optimal solution of a particular nuclear norm relaxation of the maximum clique problem.

Unfortunately, it appears that this lower bound restricting the size of a recoverable planted clique to a constant multiple of the number of nonclique vertices is tight. For example, let p and q be the probabilities of adding an edge given by Ω_1 and Ω_2. Then the expected value of the proposed solution $\boldsymbol{X}^*$ in (5) is equal to

$$\mathbf{E}[\mathrm{Tr}(\boldsymbol{W}\boldsymbol{X}^*)] = \frac{1}{\hat{r}}\sum_{i\in C_1}\sum_{j\in C_1}\mathbf{E}[w_{ij}] = p\hat{r}.$$

On the other hand, the solution $\frac{1}{n}\boldsymbol{e}\boldsymbol{e}^T$ is also feasible for (5) with expected objective value

$$\mathbf{E}\left[\frac{1}{n}\mathrm{Tr}(\boldsymbol{W}\boldsymbol{e}\boldsymbol{e}^T)\right] \geq \hat{c}qn,$$

for some constant $\hat{c}$. This implies that the proposed solution is suboptimal if $p\hat{r} < \hat{c}qn$, which holds unless $\hat{r} \geq \hat{c}(q/p)n$. We will see that the realized values of these sums are concentrated

near their expectations and thus we cannot reasonably expect to recover planted clusters with unassigned nodes significantly outnumbering the smallest cluster. This implies that we cannot recover planted cliques of size $\omega(n)$ by maximizing density of a complete subgraph because the planted clique is not the index set of the densest such graph; in this case, the entire graph is a denser complete subgraph, as measured by average vertex degree, in expectation.

3. Derivation of the Recovery Guarantee

In this section, we show that if the hypothesis of Theorem 3 is satisfied then the solution $\boldsymbol{X}^*$ constructed according to (3) is optimal for (5) and the corresponding k-disjoint-clique subgraph has maximum density. In particular, we will show that $\boldsymbol{X}^*$ satisfies the following sufficient condition for optimality of a feasible solution of (5) (see Ames, 2014, Theorem 4.1).

Theorem 4 *Let $\boldsymbol{X}$ be feasible for (5) and suppose that there exist some $\tau \in \mathbf{R}$, $\boldsymbol{\lambda} \in \mathbf{R}^n_+$, $\boldsymbol{\Xi} \in \mathbf{R}^{n\times n}_+$ and $\boldsymbol{S} \in \Sigma^n_+$ such that*

$$-\boldsymbol{W} + \boldsymbol{\lambda}\boldsymbol{e}^T + \boldsymbol{e}\boldsymbol{\lambda}^T - \boldsymbol{\Xi} + \tau\boldsymbol{I} = \boldsymbol{S} \tag{7}$$

$$\boldsymbol{\lambda}^T(\boldsymbol{X}\boldsymbol{e} - \boldsymbol{e}) = 0 \tag{8}$$

$$\mathrm{Tr}(\boldsymbol{X}\boldsymbol{\Xi}) = 0 \tag{9}$$

$$\mathrm{Tr}(\boldsymbol{X}\boldsymbol{S}) = 0. \tag{10}$$

Then $\boldsymbol{X}$ is optimal for (5).

Theorem 4 is a restriction of the Karush-Kuhn-Tucker optimality conditions to the semidefinite program (5) (see, for example, Boyd and Vandenberghe, 2004, Section 5.5.3). The goal of this section is to establish that we can construct dual variables $\tau \in \mathbf{R}$, $\boldsymbol{\lambda} \in \mathbf{R}^n_+$, $\boldsymbol{\Xi} \in \mathbf{R}^{n\times n}_+$ and $\boldsymbol{S} \in \Sigma^n_+$ which satisfy the hypothesis of Theorem 4 with high probability if the weight matrix $\boldsymbol{W}$ is sampled from a distribution of clusterable block models. To motivate our proposed choice of dual variables, we note that the complementary slackness condition $\mathrm{Tr}(\boldsymbol{X}\boldsymbol{S}) = 0$ holds if and only if $\boldsymbol{X}\boldsymbol{S} = \boldsymbol{0}$ under the assumption that both $\boldsymbol{X}$ and $\boldsymbol{S}$ are positive semidefinite. Therefore, the block structure of $\boldsymbol{X}$ implies that each block of $\boldsymbol{S}$ corresponding to a cluster block in $\boldsymbol{W}$ must sum to zero.

Before we continue with the construction of our dual variables, let us first remind ourselves of the notation of Theorem 3. Let K^* be a k-disjoint-clique subgraph of K_n with vertex set composed of the disjoint cliques $C_1, \ldots, C_k$ of sizes $r_1, \ldots, r_k$ and let $\boldsymbol{X}^*$ be the corresponding

feasible solution of (5) defined by (3). Let $C_{k+1} := V \setminus (\cup_{i=1}^{k} C_i)$ and $r_{k+1} := n - \sum_{i=1}^{k} r_i$ be the size of C_{k+1}. Moreover, let $\hat{r} := \min_{i=1,\ldots,k} r_i$ and $\tilde{r} := \max_{i=1,\ldots,k} r_i$ be the size of the smallest and largest clusters, respectively. Let $\boldsymbol{W} \in \Sigma^n$ be a random symmetric matrix sampled from the planted cluster model with planted clusters $C_1, \ldots, C_k$ and remaining nodes C_{k+1} according to the distributions $\{\Omega_{ij}\}$ with means $\{\mu_{ij}\}$ and variances $\{\sigma_{ij}^2\}$.

We now propose a choice of dual variables satisfying the complementary slackness condition $\boldsymbol{X}\boldsymbol{S} = \boldsymbol{0}$. Restricting this condition to the blocks $\boldsymbol{X}_{C_q,C_q}$ and $\boldsymbol{S}_{C_q,C_q}$ of $\boldsymbol{X}$ and $\boldsymbol{S}$ with rows and columns indexed by C_q, $q \in \{1, 2, \ldots, k\}$, we see that $\boldsymbol{X}^*\boldsymbol{S} = \boldsymbol{0}$ holds if and only if

$$\boldsymbol{0} = \boldsymbol{S}_{C_q,C_q}\boldsymbol{e} = \tau\boldsymbol{e} + r_q\boldsymbol{\lambda}_{C_q} + (\boldsymbol{\lambda}_{C_q}^T\boldsymbol{e})\boldsymbol{e} - \boldsymbol{W}_{C_q,C_q}\boldsymbol{e},$$

by the block structure of $\boldsymbol{X}^*$; note that $\boldsymbol{\Xi}_{C_q,C_q} = \boldsymbol{0}$ is chosen to satisfy the complementary slackness condition (9). Solving this linear system for $\boldsymbol{\lambda}_{C_q}$ using the Sherman-Morrison-Woodbury Formula (Golub and Van Loan, 2013, Equation (2.1.4)) gives

$$\boldsymbol{\lambda}_{C_q} = \frac{1}{r_q}\left(\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \frac{1}{2}\left(\tau + \frac{\boldsymbol{e}^T\boldsymbol{W}_{C_q,C_q}\boldsymbol{e}}{r_q}\right)\boldsymbol{e}\right). \tag{11}$$

On the other hand, we choose $\boldsymbol{\lambda}_{C_{k+1}} = \boldsymbol{0}$ to satisfy the complementary slackness condition (8). Next, we use this choice of $\boldsymbol{\lambda}$ to construct the remaining dual variables.

Fix $q, s \in \{1, 2, \ldots, k+1\}$ such that $q \neq s$. We will choose $\boldsymbol{\Xi}_{C_q,C_s}$ so that $\boldsymbol{S}_{C_q,C_s}\boldsymbol{e} = \boldsymbol{0}$ and $\boldsymbol{S}_{C_s,C_q}\boldsymbol{e} = \boldsymbol{0}$. In particular, we choose

$$\boldsymbol{\Xi}_{C_q,C_s} = \left(\tfrac{1-\delta_{q,k+1}}{2}\left(\mu_{qq} - \tfrac{\tau}{r_q}\right) + \tfrac{1-\delta_{s,k+1}}{2}\left(\mu_{ss} - \tfrac{\tau}{r_s}\right) - \mu_{qs}\right)\boldsymbol{e}\boldsymbol{e}^T + \boldsymbol{y}^{q,s}\boldsymbol{e}^T + \boldsymbol{e}(\boldsymbol{z}^{q,s})^T, \tag{12}$$

where the vectors $\boldsymbol{y}^{q,s}$ and $\boldsymbol{z}^{q,s}$ are unknown vectors parametrizing the entries of $\boldsymbol{\Xi}_{C_q,C_s}$; here $\delta_{i,j}$ is the Kronecker delta function defined by $\delta_{i,j} = 1$ if $i = j$ and 0 otherwise. That is, we choose $\boldsymbol{\Xi}_{C_q,C_s}$ to be the expected value of $\boldsymbol{\lambda}_{C_q}\boldsymbol{e}^T + \boldsymbol{e}\boldsymbol{\lambda}_{C_s}^T - \boldsymbol{W}_{C_q,C_s}$ plus the parametrizing term $\boldsymbol{y}^{q,s}\boldsymbol{e}^T + \boldsymbol{e}(\boldsymbol{z}^{q,s})^T$; the vectors $\boldsymbol{y}^{q,s}$ and $\boldsymbol{z}^{q,s}$ are chosen to be solutions of the systems of linear equations given by the complementary slackness conditions $\boldsymbol{S}_{C_q,C_s}\boldsymbol{e} = \boldsymbol{0}$ and $\boldsymbol{S}_{C_s,C_q}\boldsymbol{e} = \boldsymbol{0}$. It is reasonably straight-forward to show that we may choose

$$\boldsymbol{y}^{q,s} = \frac{1}{r_s}\left(\boldsymbol{b}_{q,s} - \frac{\boldsymbol{b}_{q,s}^T\boldsymbol{e}}{r_q + r_s}\boldsymbol{e}\right) \qquad \boldsymbol{z}^{q,s} = \frac{1}{r_q}\left(\boldsymbol{b}_{s,q} - \frac{\boldsymbol{b}_{s,q}^T\boldsymbol{e}}{r_q + r_s}\boldsymbol{e}\right), \tag{13}$$

where

$$\boldsymbol{b}_{q,s} = \left(\boldsymbol{\lambda}_{C_q}\boldsymbol{e}^T + \boldsymbol{e}\boldsymbol{\lambda}_{C_s}^T - \boldsymbol{W}_{C_q,C_s} - \mathbf{E}\left[\boldsymbol{\lambda}_{C_q}\boldsymbol{e}^T + \boldsymbol{e}\boldsymbol{\lambda}_{C_s}^T - \boldsymbol{W}_{C_q,C_s}\right]\right)\boldsymbol{e}. \tag{14}$$

Indeed, we must choose $\boldsymbol{y} = \boldsymbol{y}^{q,s}$ and $\boldsymbol{z} = \boldsymbol{z}^{q,s}$ to be solutions of the system

$$\begin{pmatrix} r_s\boldsymbol{I} + \boldsymbol{e}\boldsymbol{e}^T & \boldsymbol{0} \\ \boldsymbol{0} & r_q\boldsymbol{I} + \boldsymbol{e}\boldsymbol{e}^T \end{pmatrix}\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{z} \end{pmatrix} = \begin{pmatrix} \boldsymbol{b}^{q,s} \\ \boldsymbol{b}_{s,q} \end{pmatrix}, \tag{15}$$

to ensure that the complementary slackness conditions are satisfied. Note that taking the inner product of each side of (15) with the vector $(\boldsymbol{e}; -\boldsymbol{e})$ yields

$$(r_q + r_s)(\boldsymbol{e}^T\boldsymbol{y} - \boldsymbol{e}^T\boldsymbol{z}) = \boldsymbol{e}^T\boldsymbol{b}^{q,s} - \boldsymbol{e}^T\boldsymbol{b}^{s,q} = 0,$$

by the symmetry of $\boldsymbol{W}$. This establishes that the solution $(\boldsymbol{y}; \boldsymbol{z})$ of (15) is also a solution of the (singular) system of equations,

$$\begin{pmatrix} r_s\boldsymbol{I} & \boldsymbol{e}\boldsymbol{e}^T \\ \boldsymbol{e}\boldsymbol{e}^T & r_q\boldsymbol{I} \end{pmatrix}\begin{pmatrix} \boldsymbol{y} \\ \boldsymbol{z} \end{pmatrix} = \begin{pmatrix} \boldsymbol{b}^{q,s} \\ \boldsymbol{b}_{s,q} \end{pmatrix},$$

imposed by the complementary slackness conditions $\boldsymbol{S}_{C_q,C_s}\boldsymbol{e} = \boldsymbol{0}$ and $\boldsymbol{S}_{C_s,C_q} = \boldsymbol{0}$. Solving (15) for $\boldsymbol{y}$ and $\boldsymbol{z}$ using the Sherman-Morrison-Woodbury Formula yields the formula for $\boldsymbol{y}$ and $\boldsymbol{z}$ given by (13). We set the remaining block $\boldsymbol{\Xi}_{C_{k+1},C_{k+1}} = \boldsymbol{0}$. Ames (2014, Section 4.2) provides further details.

Finally, we choose

$$\tau = \min_{\substack{q,s=1,\ldots,k \\ q\neq s}} \{\mu_{qq} - \mu_{qs}\}\, \epsilon\hat{r} =: \gamma\epsilon\hat{r}, \tag{16}$$

where $\epsilon > 0$ is a parameter to be chosen later. In particular, the analysis provided in Sections 3.1, 3.2, and 3.3 establishes that a suitable choice of ϵ exists if the hypothesis of Theorem 3 is satisfied.

The entries of $\boldsymbol{S}$ are chosen according to the stationarity condition (7), but we will also define an auxiliary variable $\tilde{\boldsymbol{S}} \in \Sigma^n$ as the following $(k+1) \times (k+1)$ block matrix:

$$\tilde{\boldsymbol{S}}_{C_q,C_s} = \begin{cases} \mu_{q,s}\boldsymbol{e}\boldsymbol{e}^T - \boldsymbol{W}_{C_q,C_s}, & \text{if } q, s \in \{1, \ldots, k\}, \\ \mu_{q,k+1}\boldsymbol{e}\boldsymbol{e}^T - \boldsymbol{W}_{C_q,C_{k+1}} + (\boldsymbol{\lambda}_{C_q} - \mathbf{E}[\boldsymbol{\lambda}_{C_q}])\boldsymbol{e}^T, & \text{if } s = k+1, \\ \mu_{k+1,s}\boldsymbol{e}\boldsymbol{e}^T - \boldsymbol{W}_{C_{k+1},C_s} + \boldsymbol{e}(\boldsymbol{\lambda}_{C_s} - \mathbf{E}[\boldsymbol{\lambda}_{C_s}])^T, & \text{if } q = k+1. \end{cases} \tag{17}$$

We next provide the following theorem, first stated by Ames (2014, Theorem 4.2), which characterizes when the proposed dual variables satisfy the hypothesis of Theorem 4.

Theorem 5 *Suppose that the vertex sets $C_1, \ldots, C_k$ define a k-disjoint-clique subgraph K^* of the weighted complete graph $K_n = (V, \boldsymbol{W})$, where $\boldsymbol{W} \in \Sigma^n$ is a random symmetric matrix sampled from the planted cluster model according to the distributions $\{\Omega_{ij}\}$ with means $\{\mu_{ij}\}$ and variances $\{\sigma_{ij}^2\}$. Let $r_1, \ldots, r_{k+1}$, and $\hat{r}$ be defined as in Theorem 3. Let $\boldsymbol{X}^*$ be the feasible solution for (5) corresponding to $C_1, \ldots, C_k$ defined by (3). Let $\tau \in \mathbf{R}$, $\boldsymbol{\lambda} \in \mathbf{R}^n$, and $\boldsymbol{\Xi} \in \mathbf{R}^{n\times n}$ be chosen according to (16), (11), and (12), respectively, and let $\tilde{\boldsymbol{S}}$ be chosen according to (17). Suppose that the entries of $\boldsymbol{\lambda}$ and $\boldsymbol{\Xi}$ are nonnegative. Then $\boldsymbol{X}^*$ is optimal for (5), and K^* is the maximum density k-disjoint-clique subgraph of K_n corresponding to $\boldsymbol{W}$, if*

$$\|\tilde{\boldsymbol{S}}\| \leq \epsilon\gamma\hat{r}. \tag{18}$$

Moreover, if (18) *is satisfied and*

$$r_s \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_q} \boldsymbol{e} > r_q \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_s} \boldsymbol{e}, \tag{19}$$

for all $q, s \in \{1, \ldots, k\}$ *such that* $q \neq s$*, then* $\boldsymbol{X}^*$ *is the unique optimal solution of* (5) *and* K^* *is the unique maximum density* k*-disjoint-clique subgraph of* K_n*.*

The proof of Theorem 5 is nearly identical to that by Ames (2014, Theorem 4.2), and is omitted. Theorem 5 provides a clear roadmap for the remainder of the proof; if we can show that if $\boldsymbol{W}$ is sampled from the planted cluster model satisfying (6) then $\boldsymbol{\lambda}$ and $\boldsymbol{\Xi}$ are nonnegative and $\|\tilde{\boldsymbol{S}}\| \leq \epsilon\gamma\hat{r}$ with high probability, then we will have established that we can recover the underlying block structure with high probability in this case. We establish the necessary bounds on $\boldsymbol{\lambda}$, $\boldsymbol{\Xi}$, and $\|\tilde{\boldsymbol{S}}\|$ in the following sections.

3.1. Nonnegativity of $\boldsymbol{\lambda}$ and $\boldsymbol{\Xi}$

We first establish that the entries of $\boldsymbol{\Xi}$, as constructed according to (12), are nonnegative with high probability. To do so, we will make repeated use of the following specialization of the Bernstein inequality which provides a bound on the tail of a sum of bounded independent random variables; see Boucheron et al. (2013, Section 2.8), for more details regarding the Bernstein inequality.

Theorem 6 *Let* $x_1, \ldots, x_m$ *be independent identically distributed (i.i.d.) variables with mean* μ *and variance* σ^2*. Let* $S = x_1 + \cdots + x_m$*. Then*

$$Pr\left(|S - \mu m| > 6\max\left\{\sqrt{\sigma^2 m \log T}, \log T\right\}\right) \leq 2T^{-6}, \tag{20}$$

for all $T > 1$*.*

The following bound on the parametrizing vectors $\boldsymbol{y}^{q,s}$ and $\boldsymbol{z}^{q,s}$ in the choice of the (C_q, C_s) block of $\boldsymbol{\Xi}$ defined by (12) is an immediate consequence of Theorem 6.

Lemma 7 *There exists constant* $c > 0$ *such that*

$$\|\boldsymbol{y}^{q,s}\|_\infty + \|\boldsymbol{z}^{q,s}\|_\infty \leq c\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\},$$

w.h.p., where $\tilde{\sigma} := \max\{\sigma_{ij} : i, j = 1, 2, \ldots, k+1\}$*, for all* $q, s \in \{1, \ldots, k+1\}$ *such that* $q \neq s$*.*

For $q, s \in \{1, \ldots, k+1\}$ such that $q \neq s$, we define $\boldsymbol{y}^{q,s}$ and $\boldsymbol{z}^{q,s}$ as in (13). To bound the absolute values of the entries of $\boldsymbol{y}^{q,s}$ and $\boldsymbol{z}^{q,s}$, we must estimate the sums $\boldsymbol{e}^T \boldsymbol{W}_{C_q,C_q} \boldsymbol{e}$, $\boldsymbol{e}^T \boldsymbol{W}_{C_s,C_s} \boldsymbol{e}$ and $\boldsymbol{e}^T \boldsymbol{W}_{C_q,C_s} \boldsymbol{e}$; applying Theorem 6 to bound the tails of these sums yields Lemma 7. See Appendix A for the full argument.

We have the following bound on the entries of $\boldsymbol{\Xi}$ as an immediate consequence of Lemma 7.

Proposition 8 *Suppose that* $\{\mu_{ij}\}$ *satisfy* (6)*. Then there exists constant* $c > 0$ *such that each entry of* $\boldsymbol{\Xi}$ *is nonnegative w.h.p. if* ϵ *satisfies*

$$0 < \epsilon \leq 1 - \frac{c}{\gamma}\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}. \tag{21}$$

Proof Fix $q, s \in \{1, \ldots, k\}$ such that $q \neq s$. By construction, we have

$$\begin{aligned}\boldsymbol{\Xi}_{C_q,C_s} &= \mathbf{E}\left[\boldsymbol{\lambda}_{C_q}\boldsymbol{e}^T + \boldsymbol{e}\boldsymbol{\lambda}_{C_s}^T - \boldsymbol{W}_{C_q,C_s}\right] + \boldsymbol{y}^{q,s}\boldsymbol{e}^T + \boldsymbol{e}\left(\boldsymbol{z}^{q,s}\right)^T \\ &= \left(\frac{1}{2}\left(\mu_{qq} - \frac{\tau}{r_q}\right) + \frac{1}{2}\left(\mu_{ss} - \frac{\tau}{r_s}\right) - \mu_{qs}\right)\boldsymbol{e}\boldsymbol{e}^T + \boldsymbol{y}^{q,s}\boldsymbol{e}^T + \boldsymbol{e}\left(\boldsymbol{z}^{q,s}\right)^T.\end{aligned}$$

Using (16) and Lemma 7, we see that

$$\begin{aligned}\Xi_{ij} &\geq \frac{1}{2}\left(\mu_{qq} - \gamma\epsilon\right) + \frac{1}{2}\left(\mu_{ss} - \gamma\epsilon\right) - \mu_{sq} - \|\boldsymbol{y}^{q,s}\|_\infty - \|\boldsymbol{z}^{q,s}\|_\infty \\ &\geq (1-\epsilon)\gamma - c\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\},\end{aligned}$$

for all $i \in C_q$, $j \in C_s$ w.h.p., where c is the constant appearing in Lemma 7. Note that the right-hand side of this inequality is nonnegative if and only if

$$\epsilon \leq 1 - \frac{c}{\gamma}\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}.$$

The argument for the case when one of q or s is equal to $k+1$ follows analogously. Applying the union bound over all blocks of $\boldsymbol{\Xi}$ shows that each entry of $\boldsymbol{\Xi}$ is nonnegative w.h.p. if ϵ satisfies (21). ■

We have an analogous result ensuring that the entries of $\boldsymbol{\lambda}$ are nonnegative with high probability; we present the proof of this result in Appendix B.

Proposition 9 *Suppose $\{\mu_{ij}\}$ satisfy (6). Then there exists constant $c' > 0$ such that each entry of $\boldsymbol{\lambda}$ is nonnegative w.h.p. if ϵ satisfies*

$$0 < \epsilon \leq \frac{1}{2\gamma}\left(\mu_{qq} - c' \max\left\{\sqrt{\frac{\sigma_{qq}^2 \log n}{r_q}}, \frac{\log n}{r_q}\right\}\right), \tag{22}$$

for all $q \in \{1, \ldots, k\}$.

We conclude this section with a result ensuring that the uniqueness condition (19) of Theorem 5 is satisfied for all $q, s \in \{1, \ldots, k\}$ such that $q \neq s$; we provide a proof in Appendix C.

Proposition 10 *Suppose that*

$$\gamma \geq 12 \max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}^2}}, \frac{\log n}{\hat{r}^2}\right\}. \tag{23}$$

Then $r_s \boldsymbol{e}^T \boldsymbol{W}_{C_q, C_q} \boldsymbol{e} > r_q \boldsymbol{e}^T \boldsymbol{W}_{C_q, C_s} \boldsymbol{e}$ for all $q, s \in \{1, \ldots, k\}$ such that $q \neq s$ with high probability.

3.2. A Bound on $\tilde{\boldsymbol{S}}$

It remains to establish the following bound on the spectral norm of the matrix $\tilde{\boldsymbol{S}}$.

Proposition 11 *There exists scalars $C, C' > 0$ such that*

$$\|\tilde{\boldsymbol{S}}\| \leq C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + C'\left(\max\left\{\hat{\sigma}^2, \frac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + \mu_{k+1,k+1} r_{k+1}, \tag{24}$$

where $\hat{\sigma}^2 = \max_{q=1,\ldots,k}\left\{\sigma_{qq}^2\right\}$, with high probability.

The proof of Proposition 11 follows the same structure as that of Ames (2014, Lemma 4.5). In particular, we decompose $\tilde{\boldsymbol{S}}$ as $\tilde{\boldsymbol{S}} = \tilde{\boldsymbol{S}}_1 + \tilde{\boldsymbol{S}}_2 + \tilde{\boldsymbol{S}}_3$, where

$$\tilde{\boldsymbol{S}}_1 = \mathbf{E}[\boldsymbol{W}] - \boldsymbol{W}, \tag{25}$$

$$[\tilde{\boldsymbol{S}}_2]_{C_q, C_s} = \begin{cases} \left(\boldsymbol{\lambda}_{C_q} - \mathbf{E}\left[\boldsymbol{\lambda}_{C_q}\right]\right)\boldsymbol{e}^T, & \text{if } s = k+1, \\ \boldsymbol{e}\left(\boldsymbol{\lambda}_{C_s} - \mathbf{E}\left[\boldsymbol{\lambda}_{C_s}\right]\right)^T, & \text{if } q = k+1, \\ \mathbf{0}, & \text{otherwise,} \end{cases} \tag{26}$$

$$[\tilde{\boldsymbol{S}}_3]_{C_q, C_s} = \begin{cases} -\mu_{k+1,k+1}\boldsymbol{e}\boldsymbol{e}^T, & \text{if } q = s = k+1, \\ \mathbf{0}, & \text{otherwise.} \end{cases} \tag{27}$$

Note that $\|\tilde{\boldsymbol{S}}_3\| = \mu_{k+1,k+1}\|\boldsymbol{e}\boldsymbol{e}^T\| = \mu_{k+1,k+1} r_{k+1}$. The following lemmas provide the necessary bounds on $\|\tilde{\boldsymbol{S}}_1\|$ and $\|\tilde{\boldsymbol{S}}_2\|$.

Lemma 12 *Suppose that $\tilde{\boldsymbol{S}}_1$ is constructed according to (25) for some $\boldsymbol{W} \in \Sigma^n$ sampled from the heterogeneous planted cluster model. Then there exists constant $C > 0$ such that*

$$\|\tilde{\boldsymbol{S}}_1\| \leq C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\}, \tag{28}$$

with high probability.

Lemma 13 *Suppose that $\tilde{\boldsymbol{S}}_2$ is constructed according to (26) for some $\boldsymbol{W} \in \Sigma^n$ sampled from the heterogeneous planted cluster model. Then there exists constant $C' > 0$ such that*

$$\|\tilde{\boldsymbol{S}}_2\| \leq C'\left(\max\left\{\hat{\sigma}^2, \frac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2},$$

with high probability, where $\hat{\sigma} := \max_{q=1,\ldots,k} \sigma_{qq}$.

We delay the proof of Lemmas 12 and 13 until Appendix D and Appendix E, respectively. Combining the three bounds on $\|\tilde{\boldsymbol{S}}_1\|$, $\|\tilde{\boldsymbol{S}}_2\|$, and $\|\tilde{\boldsymbol{S}}_3\|$ and applying the triangle inequality one last time shows that (24) holds with high probability.

3.3. The Conclusion of the Proof

According to Theorem 5, it suffices to prove that $\|\tilde{\boldsymbol{S}}\| \leq \epsilon\gamma\hat{r}$ is satisfied with high probability in order to prove Theorem 3. According to Proposition 11, if

$$\gamma\epsilon\hat{r} \geq C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + C'\left(\max\left\{\hat{\sigma}^2, \tfrac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + \mu_{k+1,k+1} r_{k+1}, \tag{29}$$

then $\|\tilde{\boldsymbol{S}}\| \leq \epsilon\gamma\hat{r}$ holds with high probability. Hence, we have three conditions, (21), (22) and (29), on $\epsilon > 0$ that need to be satisfied simultaneously; choosing any $\epsilon > 0$ satisfying all three establishes the desired recovery guarantee. We see that (21) and (29) can be simultaneously fulfilled if

$$1 - \tfrac{c}{\gamma}\max\left\{\sqrt{\tfrac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \tfrac{\log n}{\hat{r}}\right\} \geq \tfrac{1}{\gamma\hat{r}}\left(C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + C'\left(\max\left\{\hat{\sigma}^2, \tfrac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + \mu_{k+1,k+1} r_{k+1}\right),$$

which holds if and only if

$$\hat{r}\left(\gamma - c \max\left\{\sqrt{\tfrac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \tfrac{\log n}{\hat{r}}\right\}\right) \geq C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + C'\left(\max\left\{\hat{\sigma}^2, \tfrac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + \mu_{k+1,k+1} r_{k+1}. \tag{30}$$

Next, we see that (29) and (22) are simultaneously fulfilled if

$$\tfrac{1}{2\gamma}\left(\mu_{qq} - c' \max\left\{\sqrt{\tfrac{\sigma_{qq}^2 \log n}{\hat{r}}}, \tfrac{\log n}{\hat{r}}\right\}\right) \geq \tfrac{1}{\gamma\hat{r}}\left(C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + C'\left(\max\left\{\hat{\sigma}^2, \tfrac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + \mu_{k+1,k+1} r_{k+1}\right),$$

which holds if and only if

$$\hat{r}\left(\mu_{qq} - c' \max\left\{\sqrt{\tfrac{\sigma_{qq}^2 \log n}{r_{qq}}}, \tfrac{\log n}{r_{qq}}\right\}\right) \geq 2\left(C \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + C'\left(\max\left\{\hat{\sigma}^2, \tfrac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + \mu_{k+1,k+1} r_{k+1}\right). \tag{31}$$

Finally, suppose that we choose the parameter $c_4 > \max\{c, c', 12\}$ so that gap condition (23) is satisfied and

$$\gamma > \max\{c, c', 12\} \max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}.$$

Then there exist constants c_1, c_2, c_3, depending on c_4, such that (30) and (31) are satisfied, i.e., there exists ϵ satisfying (21), (22) and (29) simultaneously, if

$$\gamma\hat{r} \geq c_1 \max\left\{\tilde{\sigma}\sqrt{n}, \sqrt{\log n}\right\} + c_2 \left(\max\left\{\sigma_1^2, \frac{\log n}{\hat{r}}\right\} k r_{k+1}\right)^{1/2} + c_3 \mu_{k+1,k+1} r_{k+1}.$$

This concludes the proof of Theorem 3.

4. Numerical Methods and Simulations

We conclude with a discussion of an algorithm for solution of (5) based on the alternating direction method of multipliers (ADMM), and provide the results of a series of experiments that empirically verify the phase transitions predicted in Section 2.2. In particular, we randomly sample graphs $G = (V, \boldsymbol{W})$ from the planted cluster model and compare the optimal solution of (5) with the planted partition.

4.1. Alternating Direction Method of Multipliers for the Densest k-Disjoint Clique Problem

We solve (5) iteratively using the algorithm proposed by Ames (2014). Specifically, we split the decision variable $\boldsymbol{X}$ to obtain the equivalent formulation

$$\max\left\{\operatorname{Tr}(\boldsymbol{W}\boldsymbol{Y}) : \boldsymbol{X} - \boldsymbol{Y} = \boldsymbol{0}, \boldsymbol{X}\boldsymbol{e} \leq \boldsymbol{e}, \boldsymbol{X} \geq \boldsymbol{0},\ \operatorname{Tr}\boldsymbol{Y} = k, \boldsymbol{Y} \in \Sigma_+^V\right\}.$$

We then apply an approximate dual ascent scheme to maximize the augmented Lagrangian

$$L_\rho(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}) = \operatorname{Tr}(\boldsymbol{W}\boldsymbol{Y}) - \operatorname{Tr}(\boldsymbol{Z}(\boldsymbol{X} - \boldsymbol{Y})) + \frac{\rho}{2}\|\boldsymbol{X} - \boldsymbol{Y}\|_F^2,$$

where $\rho > 0$ is a penalty parameter for violation of the linear equality constraint $\boldsymbol{X} - \boldsymbol{Y} = \boldsymbol{0}$. In particular, we minimize L_ρ with respect to $\boldsymbol{Y}$ and $\boldsymbol{X}$ successively, and then update $\boldsymbol{Z} = \boldsymbol{Z} - \rho(\boldsymbol{X} - \boldsymbol{Y})$ using approximate gradient ascent.

We update $\boldsymbol{Y}$ as the minimizer of the subproblem

$$\boldsymbol{Y}^{t+1} = \operatorname*{arg\,min}_{\boldsymbol{Y} \in \Sigma_+^n} \left\{\left\|\boldsymbol{Y} - \left(\boldsymbol{X}^t - \frac{\boldsymbol{W} + \boldsymbol{Z}^t}{\rho}\right)\right\|_F^2 : \operatorname{Tr}\boldsymbol{Y} = k\right\},$$

where $(\boldsymbol{X}^t, \boldsymbol{Y}^t, \boldsymbol{Z}^t)$ is the current iterate after t iterations. That is, $\boldsymbol{Y}^{t+1}$ is the projection of the matrix $\boldsymbol{U}^t := \boldsymbol{X}^t - (\boldsymbol{W} + \boldsymbol{Z}^t)/\rho$ onto the intersection of the positive semidefinite

cone and the set of matrices with trace equal to zero. Such a projection can be computed explicitly by projecting the vector of eigenvalues $\boldsymbol{\lambda}^t$ of $\boldsymbol{U}^t$ onto the nonnegative simplex $\{\boldsymbol{y} \in \mathbf{R}^n : \boldsymbol{e}^T\boldsymbol{y} = k,\ \boldsymbol{y} \geq \boldsymbol{0}\}$. Zhang and Lu (2011, Proposition 2.6) and Van Den Berg and Friedlander (2008) can be consulted for further details.

We update $\boldsymbol{X}^{t+1}$ as the optimal solution of

$$\boldsymbol{X}^{t+1} = \operatorname*{arg\,min}_{\boldsymbol{X} \in \mathbf{R}^{n\times n}} \left\{\left\|\boldsymbol{X} - \left(\boldsymbol{Y}^t + \boldsymbol{Z}^t/\rho\right)\right\|_F^2 : \boldsymbol{X} \geq \boldsymbol{0},\ \boldsymbol{X}\boldsymbol{e} \leq \boldsymbol{e}\right\}. \tag{32}$$

Applying strong duality, we know that the optimal solution of (32) is given by

$$\boldsymbol{X}^{t+1} = \left[\left(\boldsymbol{Y}^{t+1} + \boldsymbol{Z}^t/\rho\right) - \frac{\boldsymbol{z}^*\boldsymbol{e} + \boldsymbol{e}(\boldsymbol{z}^*)^T}{2}\right]_+,$$

where the operator $[\cdot]_+$ is the projection onto the symmetric nonnegative cone $\Sigma^V \cap \mathbf{R}_+^{V\times V}$ given by $[[\boldsymbol{Z}]_+]_{ij} = \max\{0, Z_{ij}\}$ for all $\boldsymbol{Z} \in \Sigma^V$, and $\boldsymbol{z}^*$ is the optimal solution of the dual problem of (32) given by

$$\min_{\boldsymbol{z} \geq \boldsymbol{0}} \frac{1}{2}\left\|\left[\left(\boldsymbol{Y}^{t+1} + \boldsymbol{Z}^t/\rho\right) - \frac{\boldsymbol{z}\boldsymbol{e} + \boldsymbol{e}\boldsymbol{z}^T}{2}\right]_+\right\|_F^2 + \boldsymbol{z}^T\boldsymbol{e} - \frac{1}{2}\|\boldsymbol{Y}^{t+1} + \boldsymbol{Z}^t/\rho\|_F^2. \tag{33}$$

The objective function of the dual problem (33) is differentiable and coercive in $\boldsymbol{z}$, so it can be solved efficiently by applying the spectral projected gradient method of Birgin et al. (2000). We complete each iteration by performing an approximate dual ascent step to update the dual variable $\boldsymbol{Z}^{t+1}$. We stop the projected gradient method when the relative duality gap, given by $|v_p^{(t)} - v_d^{(t)}|/\max\{v_p^{(t)}, 1\}$, and primal constraint violation are both smaller than a desired error tolerance. We summarize the algorithm as Algorithm 1. Please see the work of Ames (2014, Section 6) for further implementation details.

4.2. Empirical Verification of Exact Recovery

We perform two sets of experiments, one to illustrate the recovery guarantee for dense graphs sampled from the heterogeneous planted cluster model and another to illustrate the guarantee when the noise is sparse. For the dense graph experiments, we fix $n = 1000$, and sample 10 graphs from the heterogeneous planted cluster model corresponding to the Bernoulli distributions $\Omega_{ij} = Bern(p_{ij})$ with probabilities of success p_{ij} given by

$$p_{ij} := \begin{cases} \left(1 - \left(\frac{0.35}{k+1}\right) i\right) p, & \text{if } i = j, \\ \left(1 - \left(\frac{0.35}{k+1}\right) \min\{i, j\}\right) q, & \text{if } i \neq j, \end{cases}$$

for $q = 0.25$ and each $p = \{0.25, 0.275, 0.3, \ldots, 0.975, 1\}$ and $\hat{r} \in \{20, 40, \ldots, 500\}$. We choose the number of clusters $k = \lfloor n/\hat{r} \rfloor$ and distribute the remaining $n - k\hat{r}$ nodes evenly

Algorithm 1 ADMM for (1)

Input: Initial iterates $\boldsymbol{X}^0 = \boldsymbol{Y}^0 = \boldsymbol{Z}^0 = \boldsymbol{0}$, augmented Lagrangian parameter $\rho > 0$, and stopping tolerance $\epsilon > 0$.

Output: Approximate solution $(\boldsymbol{X}^*, \boldsymbol{Y}^*, \boldsymbol{Z}^*)$ of (1).

For $t = 0, 1, 2 \ldots$ until converged

Compute spectral decomposition $\boldsymbol{V}^t \text{Diag}\boldsymbol{\lambda}^t (\boldsymbol{V}^t)^T = \boldsymbol{U}^t = \boldsymbol{X}^t - (\boldsymbol{W} + \boldsymbol{Z}^t)/\rho$.

Project $\boldsymbol{\lambda}^t$ onto the nonnegative simplex $\{\boldsymbol{y} \in \mathbf{R}^n : \boldsymbol{e}^T \boldsymbol{y} = k,\ \boldsymbol{y} \geq \boldsymbol{0}\}$ to obtain $\bar{\boldsymbol{\lambda}}^t$.

Update $\boldsymbol{Y}^{t+1} = \boldsymbol{V}^t \text{Diag}\bar{\boldsymbol{\lambda}}^t (\boldsymbol{V}^t)^T$.

Compute approximate optimal solution $\boldsymbol{z}^*$ of the dual subproblem (33) using spectral projected gradient method of Birgin et al. (2000).

Update $\boldsymbol{X}^{t+1} = \left[\left(\boldsymbol{Y}^{ts+1} + \boldsymbol{Z}^t/\rho \right) - \frac{\boldsymbol{z}^* \boldsymbol{e} + \boldsymbol{e}(\boldsymbol{z}^*)^T}{2} \right]_+$.

Update $\boldsymbol{Z}^{t+1}$ using approximate dual ascent

$$\boldsymbol{Z}^{t+1} = \boldsymbol{Z}^t - \rho(\boldsymbol{X}^{t+1} - \boldsymbol{Y}^{t+1}).$$

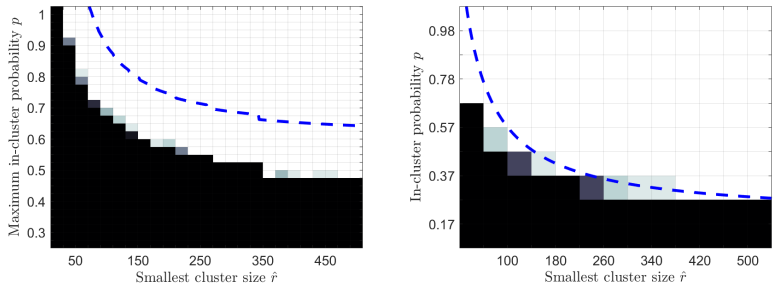
Compute primal feasibilty gap

$$pfeas = \min \left\{ \min_{ij} Y_{ij}^t, \min \left(\boldsymbol{e} - \boldsymbol{Y}^t \boldsymbol{e} \right) \right\}.$$

Compute estimates of primal and dual objective values (note that $v_d^{(t+1)}$ is not necessarily a lower bound on the optimal dual value, but is asymptotically converging to the optimal dual value):

$$v_p^{(t+1)} = \text{Tr}(\boldsymbol{W}\boldsymbol{Y}^t) \qquad v_d^{(t+1)} = k\lambda_{min}(\boldsymbol{W} + \boldsymbol{Z}^{t+1}) - \text{Tr}(\boldsymbol{X}^{t+1}\boldsymbol{Z}^{t+1}).$$

Calculate relative duality gap



$$relgap = \frac{|v_p^{(t+1)} - v_d^{(t+1)}|}{\max \left\{ |v_p^{(t+1)}|, 1 \right\}}.$$

Declare sequence of iterates to have converged if $relgap < \epsilon$ and $pfeas > -\epsilon$.

End For

among $k-1$ clusters to ensure that at least one cluster has minimum size. Under this choice of p_{ij} the smallest gap between the in-cluster and between-cluster means occurs when $i = 1$ and $j = k$; this implies that

$$\gamma = \left(1 - \frac{0.35k}{k+1} \right) p - q.$$

(a) Dense Noise (b) Sparse Noise

Figure 1: Empirical recovery rate for n-node graph with k planted cliques of size at least $\hat{r}$ and $\boldsymbol{W}$ generated according to the planted heterogeneous cluster model with distributions $\Omega_{ij} = Bern(p_{ij})$. Brighter colors indicate higher rates of recovery, with black corresponding to 0 recoveries and white corresponding to 10 recoveries (out of 10 trials). The dashed curves indicate the phase transition to perfect recovery predicted by Theorem 3.

For each graph G, we call the ADMM algorithm sketched above to solve (5); in the algorithm, we use penalty parameter $\rho = \min\{\max\{5n/k, 80\}, 500\}/2$, stopping tolerance $\epsilon = 10^{-4}$, and maximum number of iterations 100. We declare the block structure of G to be recovered if $\|\boldsymbol{X}^* - \boldsymbol{X}_0\|_F^2 / \|\boldsymbol{X}_0\|_F^2 < 10^{-3}$, where $\boldsymbol{X}^*$ is the solution returned by the ADMM algorithm and $\boldsymbol{X}_0$ is the proposed solution given by (3). Note that Theorem 3 implies that we should expect exact recovery (w.h.p.) provided that $\gamma\hat{r} = \Omega\left(\sqrt{\tilde{\sigma}^2 n}\right)$. Figure 1(a) illustrates the empirical success rate for each choice of $\hat{r}$ and p, as well as the curve $p = \left((k+1)/(0.65k+1)\right)(q + \frac{1}{2}\sqrt{n})$, where we use the upper bound $\tilde{\sigma}^2 \leq 1/4$ to estimate the constant term in (6).

We perform identical experiments for graphs sampled from the homogeneous planted cluster model with sparse noise. In particular, we fix $n = 1000$ and set $q = 1/\sqrt{n}$. We then sample 10 graphs from the planted cluster model corresponding to the Bernoulli distributions $\Omega_{ij} = Bern(p)$ if $i = j$ and $\Omega_{ij} = Bern(q)$ if $i \neq j$ for each $\hat{r} \in \{20, 60, \ldots, 440, 500\}$ and $p = tq$ for 10 equally spaced scaling factors t between 2 and $\lfloor\sqrt{n}\rfloor$. As before, we set $k = \lfloor n/\hat{r} \rfloor$ and distribute the remaining nodes equally amongst the clusters so that the smallest has size $\hat{r}$ and $r_{k+1} = 0$. For each graph G, we call the ADMM algorithm to solve (5) (with the same parameters as before) and declare the block structure of G recovered if $\|\boldsymbol{X}^* - \boldsymbol{X}_0\|_F^2 / \|\boldsymbol{X}_0\|_F^2 < 10^{-3}$. Theorem 3 suggests that we should expect recovery of the

cluster structure in the case that

$$p > \Omega\left(\frac{1}{\sqrt{n}} + \frac{n^{1/4}}{\hat{r}}\right),$$

for this particular choice of p and q. Note that this implies that we have perfect recovery (w.h.p.) for $\hat{r} = \Omega(n^{1/4})$, rather than $\Omega(\sqrt{n})$ (as observed in the dense case). Figure 1(b) provides the empirical success rate for each choice of $\hat{r}$ and p, as well as the curve $p = 1/\sqrt{n} + n^{1/4}/\hat{r}$. It is clear that we are able to recover significantly smaller clusters under sparse noise than under dense noise, in accordance with (6).

5. Conclusions

We have established theoretical guarantees for graph clustering via a semidefinite relaxation of the densest k-disjoint problem. These results add to the growing corpus of evidence that clustering, while intractable in general, is possible if we seek to cluster clusterable data, i.e., data consisting of well-defined and well-separated groups of similar items. Moreover, our results provide further evidence that the $\omega(\sqrt{n})$ barrier can be broken for perfect cluster recovery in approximately sparse graphs and, specifically, that the size of recoverable clusters scales logarithmically with n at worst in the special case that all clusters are roughly the same size. Finally, our semidefinite relaxation requires only an estimate of the number of clusters present in the data as input.

Our results suggest several areas of further research. The numerical simulations suggest that our theoretical guarantees may be overly conservative, especially in the dense noise case; further investigation is needed to determine if tighter estimates on the minimum size of clusters efficiently recoverable exist. Moreover, our model assumes clusters are disjoint. This is clearly not met in many practical applications; for example, returning to the social networking realm, users may belong to several overlapping communities. It would be worthwhile to see how our model and recovery guarantees can be modified to address overlapping clusters. Finally, our algorithm for graph clustering requires the solution of a semidefinite program, which may be impractical for even moderately large graphs. For example, the proposed algorithm, based on the ADMM, has per-iteration cost of $O(n^3)$ flops per iteration, primarily to compute the spectral decomposition needed to update $\boldsymbol{Y}$. Classical methods based on interior-point methods will scale even more poorly. Efficient, scalable methods for solving this semidefinite relaxation, and semidefinite programming in general, are needed.

Appendix A. Proof of Lemma 7

We give the full proof of Lemma 7 in this appendix.

Proof We fix $q, s \in \{1, \ldots, k\}$ such that $q \neq s$ and assume without loss of generality that $r_q \leq r_s$. By the definition (13) of $\boldsymbol{y} := \boldsymbol{y}^{q,s}$ and the triangle inequality, we have

$$\|\boldsymbol{y}\|_\infty \leq \frac{1}{r_s}\left(\|\boldsymbol{b}_{q,s}\|_\infty + \frac{|\boldsymbol{b}_{q,s}^T \boldsymbol{e}|}{r_q + r_s}\right).$$

For simplicity, let $\boldsymbol{b}_1 := \boldsymbol{b}_{q,s}$ and $\boldsymbol{b}_2 := \boldsymbol{b}_{s,q}$. It follows from (14) and our choice of $\boldsymbol{\lambda}$ that the ith element of $\boldsymbol{b}_1$, denoted b_i^1, is given by

$$b_i^1 = r_s\left(\lambda_i - \frac{1}{2r_q}(\mu_{qq} r_q - \tau)\right) + \left(\boldsymbol{\lambda}_{C_s}^T \boldsymbol{e} - \frac{1}{2}(\mu_{ss} r_s - \tau)\right) - \left(\sum_{j \in C_s} w_{ij} - \mu_{qs} r_s\right).$$

It follows from the definition (11) of $\boldsymbol{\lambda}_{C_s}$ that

$$\boldsymbol{\lambda}_{C_s}^T \boldsymbol{e} = \frac{1}{2r_s}\left(\boldsymbol{e}^T \boldsymbol{W}_{C_s, C_s} \boldsymbol{e} - r_s \tau\right),$$

which implies that

$$\left|\boldsymbol{\lambda}_{C_s}^T \boldsymbol{e} - \frac{1}{2}(\mu_{ss} r_s - \tau)\right| = \frac{1}{2r_s}\left|\boldsymbol{e}^T \boldsymbol{W}_{C_s, C_s} \boldsymbol{e} - \mu_{ss} r_s^2\right|.$$

Applying (20) with $T = n$ to the right-hand side in the equation above shows that

$$|\boldsymbol{e}^T \boldsymbol{W}_{C_s, C_s} \boldsymbol{e} - \mu_{ss} r_s^2| \leq 6 \max\{\sqrt{\sigma_{ss}^2 r_s^2 \log n}, \log n\}, \tag{34}$$

with high probability, which in turn implies that

$$\left|\boldsymbol{\lambda}_{C_s}^T \boldsymbol{e} - \frac{1}{2}(\mu_{ss} r_s - \tau)\right| \leq 3 \max\left\{\sqrt{\sigma_{ss}^2 \log n}, \frac{\log n}{r_s}\right\},$$

with high probability. Similarly, applying (20) with $T = n$ to the sum $\sum_{j \in C_s} w_{ij}$ shows that

$$\left|\sum_{j \in C_s} w_{ij} - \mu_{qs} r_s\right| \leq 6 \max\left\{\sqrt{\sigma_{qs}^2 r_s \log n}, \log n\right\},$$

for all $i \in C_q$, with high probability. Finally, we note that

$$\left|\lambda_i - \frac{1}{2r_q}(\mu_{qq}r_q - \tau)\right| \leq \frac{1}{r_q}\left|\sum_{j\in C_q} w_{ij} - \mu_{qq}r_q\right| + \frac{1}{2r_q^2}\left|\boldsymbol{e}^T\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \mu_{qq}r_q^2\right|.$$

We bound the first term in the sum using (20) with $T = n$, which establishes that

$$\left|\sum_{j\in C_q} w_{ij} - \mu_{qq}r_q\right| \leq 6\max\left\{\sqrt{\sigma_{qq}^2 r_q \log n}, \log n\right\},$$

w.h.p., and note that the second term has upper bound

$$\left|\boldsymbol{e}^T\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \mu_{qq}r_q^2\right| \leq 6\max\left\{\sqrt{\sigma_{qq}^2 r_q^2 \log n}, \log n\right\},$$

w.h.p., by a calculation identical to that used to obtain (34). Applying these bounds using the triangle inequality and the union bound over all $i \in C_q$, we conclude that

$$\begin{aligned}
\|\boldsymbol{b}_1\|_\infty &\leq r_s\left|\lambda_i - \frac{1}{2r_q}(\mu_{qq}r_q - \tau)\right| + \left|\boldsymbol{\lambda}_{C_s}^T\boldsymbol{e} - \frac{1}{2}(\mu_{ss}r_s - \tau)\right| + \left|\sum_{j\in C_s} w_{ij} - \mu_{qs}r_s\right| \\
&\leq r_s\left(\frac{6}{r_q}\max\left\{\sqrt{\sigma_{qq}^2 r_q \log n}, \log n\right\} + 3\max\left\{\sqrt{\sigma_{qq}^2 \log n}, \frac{\log n}{r_q}\right\}\right) \\
&\qquad + 3\max\left\{\sqrt{\sigma_{ss}^2 \log n}, \frac{\log n}{r_s}\right\} + 6\max\left\{\sqrt{\sigma_{qs}^2 r_s \log n}, \log n\right\} \\
&= O\left(r_s\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}\right), \qquad (35)
\end{aligned}$$

with high probability.

We next bound $\left|\boldsymbol{b}_1^T\boldsymbol{e}\right|$. We have

$$\boldsymbol{b}_1^T\boldsymbol{e} = r_s\left(\boldsymbol{\lambda}_{C_q}^T\boldsymbol{e} - \frac{1}{2}(\mu_{qq}r_q - \tau)\right) + r_q\left(\boldsymbol{\lambda}_{C_s}^T\boldsymbol{e} - \frac{1}{2}(\mu_{ss}r_s - \tau)\right) + \left(\mu_{qs}r_s r_q - \boldsymbol{e}^T\boldsymbol{W}_{C_q,C_s}\boldsymbol{e}\right).$$

Applying (20) to bound the sum of the entries of $\boldsymbol{W}_{C_q,C_s}$ and the above concentration inequalities for $\boldsymbol{\lambda}_{C_q}^T\boldsymbol{e}$ and $\boldsymbol{\lambda}_{C_s}^T\boldsymbol{e}$ we have

$$\begin{aligned}
\left|\boldsymbol{b}_1^T\boldsymbol{e}\right| &\leq r_s\left|\boldsymbol{\lambda}_{C_q}^T\boldsymbol{e} - \frac{1}{2}(\mu_{qq}r_q - \tau)\right| + r_q\left|\boldsymbol{\lambda}_{C_s}^T\boldsymbol{e} - \frac{1}{2}(\mu_{ss}r_s - \tau)\right| + \left|\mu_{qs}r_s r_q - \boldsymbol{e}^T\boldsymbol{W}_{C_q,C_s}\boldsymbol{e}\right| \\
&\leq 3r_s\max\left\{\sqrt{\sigma_{qq}^2 \log n}, \frac{\log n}{r_q}\right\} + 3r_q\max\left\{\sqrt{\sigma_{ss}^2 \log n}, \frac{\log n}{r_s}\right\} \\
&\qquad + 6\max\left\{\sqrt{\sigma_{qs}^2 r_q r_s \log n}, \log n\right\} \\
&= O\left(r_s\max\left\{\sqrt{\tilde{\sigma}^2 \log n}, \frac{\log n}{\hat{r}}\right\}\right), \qquad (36)
\end{aligned}$$

w.h.p. Finally, we bound $\|\boldsymbol{y}\|_\infty$ using (35) and (36):

$$\|\boldsymbol{y}^{q,s}\|_\infty \leq \frac{1}{r_s}\left(\|\boldsymbol{b}_1\|_\infty + \frac{|\boldsymbol{b}_1^T\boldsymbol{e}|}{r_q + r_s}\right) = O\left(\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}\right),$$

w.h.p. Since this holds for any $q, s \in \{1, \ldots, k\}$ such that $q \neq s$, we conclude that

$$\|\boldsymbol{y}\|_\infty = O\left(\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}\right),$$

w.h.p. An identical argument shows that

$$\|\boldsymbol{z}^{q,s}\|_\infty = O\left(\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}\right),$$

w.h.p. We conclude that

$$\|\boldsymbol{y}^{q,s}\|_\infty + \|\boldsymbol{z}^{q,s}\|_\infty = O\left(\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}}}, \frac{\log n}{\hat{r}}\right\}\right),$$

w.h.p. ■

Appendix B. Proof of Proposition 9

We next prove Proposition 9.

Proof We follow the proof of Lemma 4.3 given by Ames (2014). Fix $q \in \{1, \ldots, k\}$ and $i \in C_q$. It follows from (11) that

$$\lambda_i = \sum_{j\in C_q} w_{ij} - \frac{1}{2r_q}\boldsymbol{e}^T\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \frac{\tau}{2},$$

for each $i \in C_q$. Applying (20) with $S = \sum_{j\in C_q} w_{ij}$ and $T = n$ yields

$$\sum_{j\in C_q} w_{ij} \geq \mu_{qq}r_q - 6\max\left\{\sqrt{\sigma_{qq}^2 r_q \log n}, \log n\right\},$$

w.h.p. Moreover, by a similar argument, we have

$$\frac{1}{2r_q}\boldsymbol{e}^T\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} \leq \frac{1}{2}\left(\mu_{qq}r_q + 6\max\left\{\sqrt{\sigma_{qq}^2 \log n}, \frac{\log n}{r_q}\right\}\right),$$

w.h.p. Combining the above inequalities shows that

$$\lambda_i \geq r_q\left(\frac{\mu_{qq}}{2} - \epsilon\gamma - O\left(\max\left\{\sqrt{\frac{\sigma_{qq}^2 \log n}{r_q}}, \frac{\log n}{r_q}\right\}\right)\right),$$

w.h.p. Since $\gamma > 0$ by (6), this implies that there exists constant $c > 0$ such that if

$$\epsilon \leq \frac{1}{2\gamma}\left(\mu_{qq} - c\max\left\{\sqrt{\frac{\sigma_{qq}^2 \log n}{r_q}}, \frac{\log n}{r_q}\right\}\right), \tag{37}$$

then $\lambda_i \geq 0$ w.h.p. Applying the union bound over all $q = 1, 2, \ldots, k$ and $i \in C_q$ shows that each entry of $\boldsymbol{\lambda}_{C_q}$ is nonnegative w.h.p. if ϵ is chosen to satisfy (37) for all q. ■

Appendix C. Proof of Proposition 10

Our proof of Proposition 10 follows a similar structure to that of Ames (2014, Lemma 4.4).

Proof Fix $q \neq s$ with $q \in 1, \ldots, k$. Applying (34) and (20) with $S = \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_s}\boldsymbol{e}$ and $T = n$, we have

$$\begin{aligned}
&r_s \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - r_q \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_s}\boldsymbol{e} \\
&\quad \geq (\mu_{qq} - \mu_{qs}) r_s r_q^2 - 6 r_s \max\left\{\sqrt{\sigma_{qq}^2 r_q^2 \log n}, \log n\right\} - 6 r_q \max\left\{\sqrt{\sigma_{qs}^2 r_s r_q \log n}, \log n\right\} \\
&\quad \geq r_q^2 r_s \left(\gamma - 12\max\left\{\sqrt{\frac{\tilde{\sigma}^2 \log n}{\hat{r}^2}}, \frac{\log n}{\hat{r}^2}\right\}\right),
\end{aligned}$$

w.h.p. This implies that $r_s \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_q}\boldsymbol{e} \geq r_q \boldsymbol{e}^T \boldsymbol{W}_{C_q,C_s}\boldsymbol{e}$ w.h.p. if (23) is satisfied. ■

Appendix D. Proof of Lemma 12

We next prove Lemma 12.

Proof We will make repeated use of the following lemma, which specializes the concentration inequality on the spectral norm of a random symmetric matrix with i.i.d. mean zero entries given by Bandeira and van Handel (2016, Corollary 3.12).

Lemma 14 *Let $\boldsymbol{A} = [a_{ij}] \in \Sigma^n$ be a random symmetric matrix with i.i.d. mean zero entries a_{ij} having variance at most σ^2 and satisfying $|a_{ij}| \leq 1$. Then there exists constant $C > 0$ such that*

$$\Pr\left\{\|\boldsymbol{A}\| > C\max\left\{\sqrt{\sigma^2 n}, \sqrt{T}\right\}\right\} \leq nT^{-7} \tag{38}$$

for all $T > 0$.

Proof (of Lemma 14) Corollary 3.12 of Bandeira and van Handel (2016) establishes that for each $t > 0$ there exists $\tilde{c} = \tilde{c}(t) > 0$ such that

$$\Pr\left\{\|\boldsymbol{A}\| \geq 3\sqrt{\sigma^2 n} + t\right\} \leq ne^{-\tilde{c}t^2}. \tag{39}$$

Here we have substituted the upper bound $\sigma^2 n \geq \tilde{\sigma}^2$, in place of $\tilde{\sigma} := \max_i \sum_j \mathbf{E}[X_{ij}^2]$ in the original statement of Corollary 3.12. Let $t = (C-3)\max\{\sqrt{\sigma^2 n}, \sqrt{\log T}\}$ where C is chosen large enough that $\tilde{c}(C-3)^2 > 7$. In this case, (39) specializes to

$$\Pr\left\{\|\boldsymbol{A}\| \geq C\max\{\sqrt{\sigma^2 n}, \sqrt{\log n}\}\right\} \leq ne^{-7\max\{\sigma^2 n, \log n\}} \leq ne^{-7\log n} = nT^{-7}.$$

This completes the proof. ■

Before we continue with the derivation of the desired bound on $\|\tilde{\boldsymbol{S}}_1\|$, we note that the entries $[\tilde{\boldsymbol{S}}_1]_{ij}$ of $\tilde{\boldsymbol{S}}_1$ all satisfy $|[\tilde{\boldsymbol{S}}_1]_{ij}| \leq 1$ if we assume that $w_{ij} \in [0,1]$ for all i, j; note that an identical argument establishes the result if we make the weaker assumption that the entries of $\boldsymbol{W}$ are bounded with high probability. On the other hand, note that the entries of $\tilde{\boldsymbol{S}}_1$ are not identically distributed (but are independent) since each w_{ij} is sampled according to Ω_{qs}, where $i \in C_q$, $j \in C_s$. However, we know that $\sigma_{qs}^2 \leq \tilde{\sigma}^2$ by our definition of $\tilde{\sigma}^2$. Moreover, $\mathbf{E}[[\tilde{\boldsymbol{S}}_1]_{ij}] = \mathbf{E}[\mu_{qs} - w_{ij}] = 0$. Thus, we can apply Lemma 14 to place a bound on $\|\tilde{\boldsymbol{S}}_1\|$. Doing so establishes that (28) holds w.h.p. ■

Appendix E. Proof of Lemma 13

We conclude with the following proof of Lemma 13.

Proof Note that $\|\tilde{\boldsymbol{S}}_2\| \leq \|\boldsymbol{\lambda} - \mathbf{E}[\boldsymbol{\lambda}]\|\sqrt{r_{k+1}}$. Thus, it remains to bound $\|\boldsymbol{\lambda} - \mathbf{E}[\boldsymbol{\lambda}]\|$. To do so, fix $q \in \{1, 2, \ldots, k\}$. Recall that

$$\boldsymbol{\lambda}_{C_q} - \mathbf{E}[\boldsymbol{\lambda}_{C_q}] = \frac{1}{r_q}(\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \mu_{qq} r_q \boldsymbol{e}) - \frac{1}{r_q^2}(\boldsymbol{e}^T \boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \mu_{qq} r_q^2)\boldsymbol{e}.$$

Applying (38) with $T = n$ establishes that

$$\begin{aligned}
\|\boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \mu_{qq} r_q \boldsymbol{e}\| &\leq \|\boldsymbol{W}_{C_q,C_q} - \mu_{qq}\boldsymbol{e}\boldsymbol{e}^T\|\|\boldsymbol{e}\| \\
&\leq C\sqrt{r_q}\max\{\sigma_{qq}\sqrt{r_q}, \sqrt{\log n}\},
\end{aligned}$$

w.h.p. On the other hand, Bernstein's inequality establishes that

$$|\boldsymbol{e}^T \boldsymbol{W}_{C_q,C_q}\boldsymbol{e} - \mu_{qq} r_q^2| \leq 6\max\left\{\sqrt{\sigma_{qq}^2 r_q \log n}, \log n\right\},$$

w.h.p. Combining these two inequalities using the triangle inequality establishes that

$$\begin{aligned}\|\boldsymbol{\lambda}_{C_q} - \mathbf{E}[\boldsymbol{\lambda}_{C_q}]\| \leq & C \max\left\{\sigma_{qq}, \sqrt{\frac{\log n}{r_q}}\right\} + 6\max\left\{\sqrt{\frac{\sigma_{qq}^2 \log n}{r_q^2}}, \frac{\log n}{r_q^{3/2}}\right\} \\ = & O\left(\max\left\{\sigma_{qq}, \sqrt{\frac{\log n}{\hat{r}}}\right\}\right),\end{aligned}$$

w.h.p. Finally, applying the union bound over all choices of q shows that

$$\|\boldsymbol{\lambda} - \mathbf{E}[\boldsymbol{\lambda}]\|^2 = \sum_{q=1}^{k} \|\boldsymbol{\lambda}_{C_q} - \mathbf{E}[\boldsymbol{\lambda}_{C_q}]\|^2 = O\left(k \max\left\{\sigma_{qq}^2, \frac{\log n}{\hat{r}}\right\}\right),$$

w.h.p. This establishes that

$$\|\tilde{\boldsymbol{S}}_2\|^2 = O\left(k r_{k+1} \max\left\{\sigma_{qq}^2, \frac{\log n}{\hat{r}}\right\}\right),$$

w.h.p., as required. ■

Abstract

We present a novel framework for learning with sequential data of any kind, such as multivariate time series, strings, or sequences of graphs. The main result is a "sequentialization" that transforms any kernel on a given domain into a kernel for sequences in that domain. This procedure preserves properties such as positive definiteness, the associated kernel feature map is an ordered variant of sample (cross-)moments, and this sequentialized kernel is consistent in the sense that it converges to a kernel for paths if sequences converge to paths (by discretization). Further, classical kernels for sequences arise as special cases of this method. We use dynamic programming and low-rank techniques for tensors to provide efficient algorithms to compute this sequentialized kernel.

Keywords: Sequential data, kernels, signature, ordered moments, signature kernels

1. Introduction

Sequentially ordered data are ubiquitous in modern science, occurring as time series, location series, or, more generally, sequentially observed samples of structured objects. Two stylised facts make learning with sequential data an ongoing challenge:

(A) Sequential data is very diverse, e.g. it includes sequences of different length of scalars, letters, images, graphs (in time series, text, video, network evolution) or even heterogeneous combinations of these. This diversity is usually addressed by *ad-hoc approaches, extensive pre-processing and manual extraction of features*, thus specific to the data at hand.

(B) Sequential data is often large, with sequences easily obtaining the length of hundreds, thousands, millions. Hence, the data sets quickly become *very huge*, and with them computational cost.

In this paper, we present a novel approach to learning with sequential data based on joining ideas from *stochastic analysis* and *kernel learning*, addressing the points above:

(a) The (discretized) *signature* is a *canonical feature map* for sequences. It can intuitively be described as an ordered version of sample moments. It completely describes a sequence and makes sequences of different size and length comparable.

(b) The *kernel trick* applied to signature features avoids the combinatorial explosion of coordinates inherent to the signature feature map (in analogy to the classic polynomial kernel in $\mathbb{R}^d$).

The main results of this article can be described as follows: if $\mathcal{X}$ is a topological space ("structured objects") and we denote with $\mathcal{X}^+ = \bigcup_{\ell \geq 1} \mathcal{X}^\ell$ the set of arbitrary length sequences in $\mathcal{X}$ ("sequences of structured objects") then we construct a map that takes

$$\text{a kernel } \mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R} \text{ to a kernel } \mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}.$$

We call k^+ the *discretized signature kernel* (or *sequentialization*) over k and provide efficient algorithms to evaluate k^+. This transformation is canonical in the sense that it preserves important properties of k, such as positive definiteness and it is consistent in the sense that $\mathrm{k}(x, y)$ for $x, y \in \mathcal{X}^+$ converges to an inner product of a "feature map" for paths that is classic in stochastic analysis (the path signature) if the sequences x, y converge to paths (from discrete to continuous time).

Classical kernels for sequences such as string, global alignment or relation-convolution kernels can be identified as special cases of the discretized signature kernel k^+; for example string kernels arise by taking $\mathcal{X}$ to be a finite set of "letters". More interestingly, even for $\mathcal{X} = \mathbb{R}$ this yields new kernels for time series by the sequentialization of classic non-linear kernels such as Gaussian, Laplace, etc. From a methodological point of view, this gives a canonical way to transform static features (resp. kernels k) for structured objects into features (resp. kernels k^+) for evolving structured objects.

1.1. Kernels for paths

We first discuss the situation for path-valued observations (continuous time) rather than sequence-valued observations (discrete time) — the latter then follows by discretizing time. That is, if we denote with $\mathcal{P}_\mathcal{X} \subset \mathcal{X}^{[0,1]}$ a sufficiently regular subset of the space of paths that evolve in $\mathcal{X}$ (without loss of generality the paths are parameterized by $[0, 1]$), our aim is to transform

$$\text{a kernel } \mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R} \text{ into a kernel } \mathrm{k}^{\oplus} : \mathcal{P}_\mathcal{X} \times \mathcal{P}_\mathcal{X} \to \mathbb{R}.$$

Therefore, first recall that $\mathcal{X} \ni u \mapsto \mathrm{k}_u := \mathrm{k}(u, \cdot) \in \mathcal{H} \subset \mathbb{R}^\mathcal{X}$ can be thought of as the "(canonical) feature map" induced by k. It is then natural to proceed as follows:

1. **Lift a path evolving in data space $\mathcal{X}$ to a path evolving in feature space $\mathcal{H}$.** We lift the path x that evolves in data space $\mathcal{X}$ to a path[1] k_x that evolves in the feature space $\mathcal{H}$ via the kernel k. That is, we map

$$x = (x(t))_{t\in[0,1]} \in \mathcal{P}_\mathcal{X} \text{ to } \mathrm{k}_x = \big(\mathrm{k}_{x(t)}\big)_{t\in[0,1]} \in \mathcal{P}_\mathcal{H}$$

where $\mathcal{P}_\mathcal{H}$ denotes a sufficiently regular subset of $\mathcal{H}^{[0,1]}$.

1. Note the slight abuse of notation that $\mathrm{k}_u \in \mathcal{H}$ if $u \in \mathcal{X}$ and $\mathrm{k}_x \in \mathcal{P}_\mathcal{H}$ if $x \in \mathcal{P}_\mathcal{X}$.

2. **Signature features for paths in $\mathcal{H}$.** We use a feature map that is well-known in stochastic analysis for paths that evolve in *linear* spaces such as $\mathcal{H}$. This map is called the signature map S. It maps a path $h \in \mathcal{P}_\mathcal{H}$ into a series of tensors,

$$h \mapsto \mathrm{S}(h) \in \prod_{m\geq 0} \mathcal{H}^{\otimes m}.$$

   By applying this map to the lifted path $\mathrm{k}_x \in \mathcal{P}_\mathcal{H}$, we get the feature map $\mathcal{P}_\mathcal{X} \to \prod_{m\geq 0}\mathcal{H}^{\otimes m}$, defined as $x \mapsto \mathrm{S}(\mathrm{k}_x)$.

3. **Signature kernels**. Taking inner products yields the kernel

$$\mathrm{k}^\oplus : \mathcal{P}_\mathcal{X} \times \mathcal{P}_\mathcal{X} \to \mathbb{R} \text{ defined as inner product } \mathrm{k}^\oplus(x,y) = \langle \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y)\rangle.$$

   It turns out, that $\mathrm{k}^\oplus$ has a recursive structure that allows for an efficient and robust calculation even though $\mathrm{k}_x, \mathrm{k}_y$ are paths evolving in the (in general infinite-dimensional) state space $\mathcal{H}$.

Below we give more details about the last two points of this construction.

1.2. The signature map

The signature S maps a (sufficiently regular) path $h \in \mathcal{P}_\mathcal{H} \subset \mathcal{H}^{[0,1]}$ into a series of tensors,

$$h \mapsto \mathrm{S}(h) = (\mathrm{S}_m(h))_{m\geq 0} \in \prod_{m\geq 0} \mathcal{H}^{\otimes m}$$

where by convention $\mathcal{H}^{\otimes 0} := \mathbb{R}$ and $\mathrm{S}_0(h) := 1$. The remaining terms $\mathrm{S}_m(h)$ are defined as follows: the first degree, $\mathrm{S}_1(h)$, of the signature is simply the average change,

$$\mathrm{S}_1(h) := \mathbb{E}_t[\dot{h}(t)] \in \mathcal{H},$$

where $\dot{h}$ denotes the derivative of h and the expectation is taken over t sampled uniformly from $[0,1]$. The second degree of the signature, $\mathrm{S}_2(h)$, is the (non-centred) covariance of changes at two subsequent time points, that is

$$\mathrm{S}_2(h) := \frac{1}{2}\mathbb{E}_{t_1<t_2}[\dot{h}(t_1)\otimes\dot{h}(t_2)] \in \mathcal{H}^{\otimes 2},$$

where the expectation is over the time points t_1, t_2 sampled from the uniform distribution on $[0,1]$ and put in chronological order. In general, the m-th degree of the signature, $\mathrm{S}_m(h)$, is defined as the m-th moment tensor of the infinitesimal changes, where the expectation is taken over m time points, $t_1, \dots, t_m$, that are sampled from the order statistic[2] of the uniform distribution on $[0,1]$, that is

$$\mathrm{S}_m(h) := \frac{1}{m!}\mathbb{E}_{t_1<\dots<t_m}[\dot{h}(t_1)\otimes\cdots\dot{h}(t_m)] \in \mathcal{H}^{\otimes m}.$$

2. The order statistic for the uniform distribution $[0,1]$ of m points has a density $p(t_1,\dots,t_m) = m!1_{t_1<\cdots t_m<1}$

Hence, the signature $\mathrm{S}(h)$ of a path h characterises the sequential structure in h by quantifying dependencies in their change, similar to classic sample moments in $\mathbb{R}^d$. In fact, signatures are in close mathematical analogy to polynomials: the feature map $x \mapsto \mathrm{S}(h)$ is injective and if $h \mapsto f(h)$ is a *non-linear function on pathspace*, then it can be well approximated as a *linear function* of the signature features $\mathrm{S}(h)$, that is $f(h) \approx \langle \ell, \mathrm{S}(h)\rangle$. However, signature features have the following drawbacks

- Even if $\mathcal{H} = \mathbb{R}^d$ is finite dimensional, we have $\mathrm{S}_m(h) \in \left(\mathbb{R}^d\right)^{\otimes m}$, thus the number of (scalar) coordinates needed to store $\mathrm{S}_m(h)$ grows as $O(d^m)$ as m increases. This combinatorial explosion makes the use of signature features costly for paths that evolve in high-dimensional state spaces $\mathcal{H}$ and infeasible for paths evolving in infinite dimensional state spaces $\mathcal{H}$.
- Signatures are only defined for paths evolving in linear spaces; $\mathrm{S}(h)$ does not make sense when h evolves in a general topological space $\mathcal{X}$ since $\dot{h}(t)dt = dh(t)$ is not well-defined.

However, as we will show, both of these shortcomings can be addressed by kernelization.

1.3. Inner products of signature features

The space $\prod_{m\geq 0}\mathcal{H}^{\otimes m}$ is a linear space and by restricting to a subspace, we can work with an inner product space (in fact, again a Hilbert space after completion); that is we define for $(s_m), (t_m) \in \prod_{m\geq 0}\mathcal{H}^{\otimes m}$

$$\begin{aligned}(s_0, s_1, \dots) + (t_0, t_1, \dots) &:= (s_0 + t_0, s_1 + t_1, \dots),\\ \langle (s_0, s_1, \dots), (t_0, t_1, \dots)\rangle &:= \sum_{m\geq 0}\langle s_m, t_m\rangle_{\mathcal{H}^{\otimes m}}\end{aligned}$$

where $\langle\cdot,\cdot\rangle_{\mathcal{H}^{\otimes m}}$ is given as $\langle u_1\otimes\cdots\otimes u_m, v_1\otimes\cdots\otimes v_m\rangle_{\mathcal{H}^{\otimes m}} := \prod_{i=1}^m\langle u_i, v_i\rangle_\mathcal{H}$. The inner product $\langle \mathrm{S}(g), \mathrm{S}(h)\rangle$ of the signature features of (sufficiently regular) paths $g, h \in \mathcal{P}_\mathcal{H}$ is finite and using conditional expectations we get that $\langle \mathrm{S}(g), \mathrm{S}(h)\rangle$ equals

$$\begin{aligned}&\sum_{m\geq 0}\frac{1}{m!^2}\mathbb{E}_{\substack{s_1<\dots<s_m\\ t_1<\dots<t_m}}[\langle \dot{g}(s_1)\otimes\cdots\otimes\dot{g}(s_m), \dot{h}(t_1)\otimes\cdots\otimes\dot{h}(t_m)\rangle_{\mathcal{H}^{\otimes m}}]\\ =&\sum_{m\geq 0}\frac{1}{m!^2}\mathbb{E}_{\substack{s_1<\dots<s_m\\ t_1<\dots<t_m}}[\langle \dot{g}(s_1), \dot{h}(t_1)\rangle_\mathcal{H}\cdots\langle \dot{g}(s_m), \dot{h}(t_m)\rangle_\mathcal{H}]\\ =&\left(1 + \mathbb{E}_{s_1,t_1}\left[\langle \dot{g}(s_1), \dot{h}(t_1)\rangle\cdot\left(1 + \frac{1}{2^2}\mathbb{E}_{\substack{s_2|s_1\\ t_2|t_1}}\left[\langle \dot{g}(s_2), \dot{h}(t_2)\rangle\cdot\left(1 + \frac{1}{3^2}\mathbb{E}_{\substack{s_3|s_2\\ t_3|t_2}}[\dots]\right)\right]\right)\right]\right).\end{aligned}$$

Now applied to $g = \mathrm{k}_x \in \mathcal{P}_\mathcal{H}$, $h = \mathrm{k}_y \in \mathcal{P}_\mathcal{H}$, using the reproducing property of k we get

$$\langle \dot{\mathrm{k}}_{x(s)}, \dot{\mathrm{k}}_{y(t)}\rangle_\mathcal{H}\,\mathrm{d}s\,\mathrm{d}t = \langle \mathrm{d}g(s), \mathrm{d}h(s)\rangle_\mathcal{H} = \mathrm{d}_s\,\mathrm{d}_t\,\mathrm{k}(x(s), y(t)) = \kappa(\mathrm{d}s, \mathrm{d}t)$$

where κ denotes the measure on $[0,1]^2$ defined as

$$\kappa([s,t]\times[u,v]) = \mathrm{k}(x(t), y(v)) - \mathrm{k}(x(s), y(v)) - \mathrm{k}(x(t), y(u)) + \mathrm{k}(x(s), y(u)).$$

(Note that this measure does not use differentiability of x, y). Replacing above expectations over the order statistic by explicit integration over $[0,1]$, we arrive at

$$\mathrm{k}^{\oplus}(x,y) = 1 + \int_{s_1,t_1} \left[\kappa(\mathrm{d}s_1, \mathrm{d}t_1) \cdot \left(1 + \int_{\substack{s_2>s_1 \\ t_2>t_1}} \left[\kappa(\mathrm{d}s_2, \mathrm{d}t_2) \cdot \left(1 + \int_{\substack{s_3>s_2 \\ t_3>t_2}} [\dots] \right) \right] \right) \right] . \quad (1)$$

Finally, the data we have access is to is only a sequence $(x(t_1), \dots, x(t_n)) \in \mathcal{X}^+$ rather than the whole path $x = (x(t))_{t\in[0,1]} \in \mathcal{P}_\mathcal{X}$, but replacing the integrals by sums immediately gives an explicit recursive formula for a kernel $\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}$ that is determined by a Horner-type[3] recursive evaluation; especially, one never computes the signature map of a path that evolves in the high/infinite-dimensional Hilber space $\mathcal{H}$ directly. This yields a robust and computationally effective formula for a kernel k^+ for sequences, that has well-defined behaviour in the scaling limit when sequences approximate paths. We make the above informal derivation rigorous in the following sections, study its properties and extended it to non-smooth paths in Appendix B.

1.4. Prior art and literature review

Learning with sequential data is a vast field. Prior art that inspired our present approach can be found in

(i) dynamic programming algorithms for sequence comparison in the engineering community,

(ii) kernel and Gaussian processes for sequences in the machine learning community,

(iii) Rough paths in the stochastic process community.

Beyond the above, we are not aware of literature in statistics that deals with sequence-valued data points in a way other than first identifying one-dimensional sequences with real vectors of same size, or even forgetting the sequence structure entirely and replacing the sequences with (order-agnostic) aggregates such as cumulants, quantiles or principal component scores. Below we discuss above three points in more detail:

(i) Dynamic programming algorithms for sequence comparison.

The earliest use of order information in sequences for learning can probably be found in Sakoe and Chiba (1970) and Sakoe (1979) by using editing or distortion distances. These distances are then employed for classification by maximum similarity/minimum distance principles. Through theoretical appeal and efficient computability, sequence comparison methods, later synonymously called dynamic time warping methods, have become one of the standard methods in comparing sequential data Kruskal (1983); Giorgino (2009). Sequence comparison methods in their original formulation can only be directly applied to relatively simple distance-based learning algorithms. This has been addressed by combining such methods with kernel learning (discussed below).

3. Horner's scheme to evaluate a uni-variate polynomial $p(x) = \sum_{i=0}^m a_i x^i$ is to write $p(x) = a_0 + x\,(a_1 + x\,(a_2 + \cdots + x\,(a_{m-1} + x a_m)))$ and compute the brackets from the inside to the outside. This needs only n additions and n multiplications which is optimal and in contrast to the n additions and $\frac{n^2+n}{2}$ multiplications needed for the naive evaluation of $p(x)$; further, it is numerically more stable since one never adds floats that live on different scales (such as $a_1 x$ and $a_m x^m$). This structural similarity with formula (1) will be the key to our algorithms.

(ii) Kernels and Gaussian processes for sequences.

Kernel learning is one of the most popular approaches to make non-linear data of arbitrary kind amenable to classic and scalable linear algorithms and it provides learning theoretical guarantees, see Schölkopf and Smola (2002); Shawe-Taylor and Cristianini (2004); Cucker and Smale (2002). Kernels for strings, that is, sequences of symbols, were among the first to be considered by Haussler (1999) and fast algorithms were obtained a few years later Lohdi et al. (2002); Leslie and Kuang (2004). Kernels based on the above-mentioned dynamic programming (time warping) approach were developed, for sequences of arbitrary objects leading to so-called alignment kernel, see Bahlmann et al. (2002); Noma (2002); Cuturi et al. (2007); Cuturi (2011). All of the mentioned kernels can be viewed from Haussler's original, visionary relation-convolution kernel framework, Haussler (1999), the existing literature provides no unifying approach to kernels for sequences: for example the relation between string kernels and dynamic time warping/global alignment kernels, or to the classical theory of time series has remained unclear. Further, the only known kernels for sequences of arbitrary objects, the dynamic time warping/global alignment kernels, are in general not positive definite.

(iii) Rough paths and stochastic processes.

Series of iterated integrals appear in diverse areas such as control theory, combinatorics, homotopy theory, physics (Feynman–Dyson–Schwinger theory) and more recently probability theory; see (Lyons, 2004, Section "Historic papers", p97). This series is treated under various names in the literature like "Magnus expansion", "time ordered" or "non-commutative exponential", or the one we follow, namely "the signature of a path". Signatures have found many applications in stochastic analysis (rough path theory, regularity structures), but their use in statistics and machine learning is very recent: Papavasiliou et al. (2011) applies it to SDE parameter estimation; Levin et al. (2013); Lyons et al. (2014) applies it to forecasting and classification; Yang et al. (2015) uses signature features as input to deep neural nets. So far, all applications are restricted to paths evolving in low-dimensional linear spaces due to the computational bottleneck given by the combinatorial explosion of signature coordinates.

1.5. Outline

Section 2 introduces the signature as a canonical feature map for path-valued data. Section 3 shows that this signature can be kernelized to get a kernel $\mathrm{k}^{\oplus}$ for paths and studies its properties. Section 4 studies the discretization to turn $\mathrm{k}^{\oplus}$ into a kernel k^+ for sequences. Section 5 shows that classic kernels for sequences arise as special cases of our construction. Section 6 presents effective algorithms for computing k^+ using above recursion with low-rank techniques. Section 7 presents a Numpy implementation and basic benchmarks.

1.6. Notation

Spaces, sequences and paths	
$\mathcal{X}$	an arbitrary set
$\mathcal{X}^+$	$\mathcal{X}^+ := \bigcup_{\ell \geq 1} \mathcal{X}^\ell$ sequences of arbitrary length in $\mathcal{X}$
$\mathcal{P}_\mathcal{X}$	a set of continuous paths from $[0,1]$ to $\mathcal{X}$
$\mathcal{H}$	the reproducing kernel Hilbert space, $\mathcal{H} \subset \mathbb{R}^\mathcal{X}$, of the kernel k
$\mathcal{H}^+$	$\mathcal{H}^+ := \bigcup_{\ell \geq 1} \mathcal{H}^\ell$ sequences of arbitrary length in $\mathcal{H}^+$
$\mathcal{P}_\mathcal{H}$	a set of continuous bounded variation paths from $[0,1]$ to $\mathcal{H}$
Signature features for paths and sequences in $\mathcal{H}$	
$\prod_{m\geq 0} \mathcal{H}^{\otimes m}$	the linear space of series of tensors in $\mathcal{H}$
S	the signature map $\mathrm{S} : \mathcal{P}_\mathcal{H} \to \prod_{m\geq 0} \mathcal{H}^{\otimes m}$
S^+	the discretized signature map $\mathrm{S}^+ : \mathcal{H}^+ \to \prod_{m\geq 0} \mathcal{H}^{\otimes m}$
$\langle \cdot, \cdot \rangle$	inner product on the subset of square-summable elements of $\prod_{m\geq 0} \mathcal{H}^{\otimes m}$
$\| \cdot \|$	norm given by $\langle \cdot, \cdot \rangle$ for square summable elements of $\prod_{m\geq 0} \mathcal{H}^{\otimes m}$
Kernels	
k	a kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$
k_x with $x \in \mathcal{X}$	the element $\mathrm{k}_x := \mathrm{k}(x, \cdot) \in \mathcal{H} \subset \mathbb{R}^\mathcal{X}$
k_x with $x \in \mathcal{X}^+$	the sequence $\mathrm{k}_x := (\mathrm{k}_{x_i})_{i=1,\dots,\ell} \in \mathcal{H}^+$ with $x = (x_i)_{i=1,\dots,l}$
k_x with $x \in \mathcal{P}_\mathcal{X}$	the path $\mathrm{k}_x := (\mathrm{k}_{x(t)})_{t\in[0,1]} \in \mathcal{P}_\mathcal{H}$ with $x = (x(t))_{t\in[0,1]}$
k^+	a kernel $\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}$, $\mathrm{k}^+(x,y) := \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y) \rangle$
$\mathrm{k}^\oplus$	a kernel $\mathrm{k}^\oplus : \mathcal{P}_\mathcal{X} \times \mathcal{P}_\mathcal{X} \to \mathbb{R}$, $\mathrm{k}^\oplus(x,y) := \langle \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y) \rangle$
Partitions of $[0,1]$	
π	a partition of $[0,1]$, i.e. a collection of points $0 = t_1 < \cdots < t_l = 1$
$\mathrm{mesh}(\pi)$	$\mathrm{mesh}(\pi) := \max_{i=1,\dots,l-1} \lvert t_{i+1} - t_i \rvert$
x^π for $x \in \mathcal{P}_\mathcal{X}$	$x^\pi := (x(t_i))_{i=1,\dots,l} \in \mathcal{X}^+$, the path x sampled along π

1.7. Author's contribution

Both authors contributed equally, HO is the corresponding author.

2. The signature feature map

Mapping paths to series of tensors is well-known technique in stochastic analysis. In this section we give a short introduction and highlight aspects of the signature map that make it a good feature map for paths.

2.1. Bounded variation paths

Definition 2.1 *Let $\mathcal{H}$ a Hilbert space. We denote the set of $\mathcal{H}$-valued paths of bounded variation on $[0,1]$ starting at the origin by*

$$C^1([0,1],\mathcal{H}) := \{h \in C([0,1],\mathcal{H}) \,:\, h(0) = 0, \quad \|h\|_1 < \infty\}$$

where $\|h\|_1 = \sup_\pi \sum_{i=1}^{l-1} \|h(t_{i+1}) - h(t_i)\|_\mathcal{H}$ and the supremum is taken over all finite partitions $\pi = \{(t_i)_{i=1,\dots,l} : 0 = t_1 < \cdots < t_l = 1\}$ of $[0,1]$.

As in the finite-dimensional case, the integral $\int_0^1 y(t)\,\mathrm{d}h(t) \in \mathcal{H}$ is defined as the limit of Riemann–Stieltjes sums, see Appendix A for details. The integral itself is in general not a scalar, but an element of the Hilbert space, $\int y\,\mathrm{d}h \in \mathcal{H}$.

Definition 2.2 *We define the sequence $\left(\int \mathrm{d}h^{\otimes m}\right)_{m\geq 0} \in \prod_{m\geq 0} \mathcal{H}^{\otimes m}$ as*[4]

$$\int \mathrm{d}h^{\otimes 0} := 1 \text{ and } \int \mathrm{d}h^{\otimes m} := \int_0^1 \left(\int_0^t \mathrm{d}h^{\otimes (m-1)} \right) \otimes \mathrm{d}h(t).$$

We define

$$\mathrm{S} : C^1([0,1],\mathcal{H}) \to \prod_{m\geq 0} \mathcal{H}^{\otimes m}, \; h \mapsto \left(\int \mathrm{d}h^{\otimes m} \right)_{m\geq 0}$$

and call $\mathrm{S}(h)$ the signature of the path h and denote $\mathrm{S}_m(h) = \int \mathrm{d}h^{\otimes m}$.

Example 2.3 *Let $\mathcal{H} = \mathbb{R}^2$ and $h(t) = (a(t), b(t))^\top$. The first levels of the signature of h are*

$$\mathrm{S}_0(h) = 1, \quad \mathrm{S}_1(h) = \begin{pmatrix} \int_0^1 \mathrm{d}a(t) \\ \int_0^1 \mathrm{d}b(t) \end{pmatrix}, \quad \mathrm{S}_2(h) = \begin{pmatrix} \int_0^1 \int_0^{t_2} \mathrm{d}a(t_1)\,\mathrm{d}a(t_2) & \int_0^1 \int_0^{t_2} \mathrm{d}a(t_1)\,\mathrm{d}b(t_2) \\ \int_0^1 \int_0^{t_2} \mathrm{d}b(t_1)\,\mathrm{d}a(t_2) & \int_0^1 \int_0^{t_2} \mathrm{d}b(t_1)\,\mathrm{d}b(t_2) \end{pmatrix}.$$

The degree $m = 3$, $\mathrm{S}_3(h) \in \left(\mathbb{R}^2\right)^{\otimes 3}$, has 2^3-scalar valued coordinates, etc. In general, for a path in $\mathbb{R}^d$ we need d^m scalars to describe $\int \mathrm{d}h^{\otimes m}$ and it is exactly this combinatorial explosion that makes the use of signatures prohibitively expensive already for moderately high-dimensional $\mathcal{H}$ and impossible to use for infinite-dimensional $\mathcal{H}$ (such as the RKHS associated with most kernels relevant in machine learning).

Example 2.4 *For the special case of a linear path in $\mathcal{H} = \mathbb{R}^d$, i.e. $h(t) = t \cdot v$ for a fixed vector $v \in \mathbb{R}^d$, a direct calculation shows that*

$$\mathrm{S}_m(h) = \frac{v^{\otimes m}}{m!} = \frac{h(1)^{\otimes m}}{m!} \text{ for } m \geq 0$$

or in more concise notation[5]*, $\mathrm{S}(h) = \exp(v) = \exp(h(1) - h(0))$. This explains why the signature $\mathrm{S}(h)$ is also known as time-ordered exponential. This analogy with the exponential function will be key motivation for the estimates in Section 4.*

4. Recall that by convention $\mathcal{H}^{\otimes 0} := \mathbb{R}$.

5. where one denotes $\boldsymbol{t} = (t_m)_m \in \prod_{m\geq 0} \mathcal{H}^{\otimes m}$ as $\boldsymbol{t} = t_0 + t_1 + t_2 + \cdots$, set $\exp(\boldsymbol{t}) = \sum_{m\geq 0} \frac{\boldsymbol{t}^{\otimes m}}{m!}$ and identify $v \in \mathbb{R}^d$ as $\boldsymbol{t} = 0 + v + 0 + 0 + \cdots$.

2.2. The signature as a canonical feature map

The signature $\mathrm{S}(h)$ describes a path h by an element in the linear space $\prod_{m\geq 0}\mathcal{H}^{\otimes m}$ and the following properties make it a good feature map

Theorem 1

1. *The map $h \mapsto \mathrm{S}(h)$ is continuous,*
2. *The map $h \mapsto \mathrm{S}(h)$ is injective up to tree-like equivalence*[6]*,*
3. *For any $f \in C(K,\mathbb{R})$, $K \subset C^1([0,1],\mathcal{H})$ compact, and $\epsilon > 0$ there exists a $\ell \in \bigoplus_{m\geq 0}\mathcal{H}^{\otimes m}$ such that*

$$\sup_{h\in K} |f(h) - \langle \ell, \mathrm{S}(h)\rangle| < \epsilon.$$

The proof is classic in stochastic analysis and given in Appendix A; the key insight is that the space of linear combinations of iterated integrals forms an algebra. To sum up

1. the signature features are a *mathematically faithful representation of the underlying path-valued data h.*
2. *linear combinations* of signature coordinates *approximate continuous functions of paths* arbitrarily well. In the kernel learning context this is known as "universality".
3. the signature features are *sequentially ordered analogues to moments.* Similar to polynomials, the feature space has the natural grading by m designating the "polynomial degree".

3. Signature kernels

We come back to our original motivation: we are given a RKHS $(\mathcal{H},\mathrm{k})$ on $\mathcal{X}$ and we want to transform this into a RKHS for paths in $\mathcal{X}$. Therefore recall that the reproducing property implies that

$$\mathrm{k}:\mathcal{X}\times\mathcal{X}\to\mathbb{R} \text{ equals } \mathrm{k}(u,v) = \langle \mathrm{k}_u, \mathrm{k}_v\rangle_{\mathcal{H}}$$

and that one may think of $\mathcal{X}\ni u \mapsto \mathrm{k}_u(\cdot) := \mathrm{k}(u,\cdot)\in\mathcal{H}$ as the (canonical) feature map induced by the kernel k. Now given a path $x\in\mathcal{P}_{\mathcal{X}}$ we lift it to a path[7] $\mathrm{k}_x\in\mathcal{P}_{\mathcal{H}}$ given as

6. We call h, h' tree-like equivalent if the concatenation $h\sqcup h'^{-1}$ is tree-like. A path $z\in C^1([a,b],\mathcal{H})$ is called tree-like if there exists a continuous map $f:[a,b]\to[0,\infty)$ with $f(0)=f(T)=0$ and $|z(t)-z(s)|\leq f(s)+f(t)-2\inf_{u\in[s,t]} f(u)$ for all $s\leq t\in[a,b]$. The key remark is that being tree-like equivalent is a very strong assumption, typically not seen in real data. Even if presented with a tree-like path, adding time as extra coordinate transforms the path to a non-treelike path (that is, working with $t\mapsto(t,h(t))$ instead of $t\mapsto h(t)$).
7. Recall the slight clash of notation $\mathrm{k}_u\in\mathcal{H}$ for $u\in\mathcal{X}$ and $\mathrm{k}_x\in\mathcal{P}_{\mathcal{H}}$ if $x\in\mathcal{P}_{\mathcal{X}}$, but the meaning will always be clear from the context. In fact, later we are also going to use $\mathrm{k}_x\in\mathcal{H}^+$ if $x\in\mathcal{X}^+$.

$t\mapsto \mathrm{k}_x(t) := \mathrm{k}_{x(t)}(\cdot) := \mathrm{k}(x(t),\cdot)$. The results of Section 2 suggest $\mathrm{S}(\mathrm{k}_x)$ as features for k_x, that is the feature map

$$\mathcal{P}_{\mathcal{X}}\ni x\mapsto \mathrm{S}(\mathrm{k}_x)\in\prod_{m\geq 0}\mathcal{H}^{\otimes m}. \tag{2}$$

Theorem 1 guarantees that $\mathrm{S}(\mathrm{k}_x)$ captures all the information about $x\in\mathcal{P}_{\mathcal{X}}$ that can be obtained by looking at the path x through the kernel k.

Most RKHS $\mathcal{H}$ in machine learning are infinite dimensional which makes this approach infeasible; even for finite dimensional $\mathcal{H}$ we suffer from the combinatorial explosion of the number of signature coordinates, Example 2.3. The main result of this section is that the feature map (2) can be complety kernelized, that is by defining

$$(x,y)\mapsto \mathrm{k}^{\oplus}(x,y) = \langle \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y)\rangle$$

we get a kernel for paths in $\mathcal{X}$ that can be very efficiently evaluated using only $\mathrm{k}(x(s),y(t))$ for $s,t\in[0,1]$. That is, only evaluations of the "static" kernel $\mathrm{k}:\mathcal{X}\times\mathcal{X}\to\mathbb{R}$.

We henceforth restrict attention to positive definite kernels on $\mathcal{X}$ and a set of paths $\mathcal{P}_{\mathcal{X}}$ that lift to bounded variation paths. All our arguments extend to unbounded variation such as semi-martingales, diffusion processes, Markov processes or Gaussian processes and we give the needed modifications in Appendix B.

Assumption 3.1 *Throughout the remainder of this article we assume that $\mathrm{k}:\mathcal{X}\times\mathcal{X}\to\mathbb{R}$ is continuous and positive definite. We denote with $\mathcal{H}$ the associated RKHS. Further, we denote with $\mathcal{P}_{\mathcal{X}}\subset\mathcal{X}^{[0,1]}$ a set of paths in a topological space $\mathcal{X}$ and $(\mathcal{H},\mathrm{k})$ a RKHS on $\mathcal{X}$ such that*

$$\{t\mapsto \mathrm{k}_{x(t)} : x\in\mathcal{P}_{\mathcal{X}}\}\subset C^1([0,1],\mathcal{H}).$$

This yields the following kernel,

Definition 3.2 *We call*

$$\mathrm{k}^{\oplus}:\mathcal{P}_{\mathcal{X}}\times\mathcal{P}_{\mathcal{X}}\to\mathbb{R}\,,\quad (x,y)\mapsto\langle \mathrm{S}(\mathrm{k}_x),\mathrm{S}(\mathrm{k}_y)\rangle,$$

the signature kernel *over* k.

Theorem 2 *The signature kernel over* k

$$\mathrm{k}^{\oplus}:\mathcal{P}_{\mathcal{X}}\times\mathcal{P}_{\mathcal{X}}\to\mathbb{R},\quad \mathrm{k}^{\oplus}(x,y)=\langle \mathrm{S}(\mathrm{k}_x),\mathrm{S}(\mathrm{k}_x)\rangle$$

1. *is a positive definite kernel,*
2. *$\mathrm{k}^{\oplus}(x,y)=\sum_{m\geq 0}\int_{\substack{s_1<\cdots<s_m\\ t_1<\cdots<t_m}}\prod_{i=1}^m \mathrm{d}\kappa(s_i,t_i)$ with κ defined as*

$$\kappa([s,t]\times[u,v]) := \mathrm{k}(x(t),y(v)) - \mathrm{k}(x(s),y(v)) - \mathrm{k}(x(t),y(u)) + \mathrm{k}(x(s),y(u))$$

and κ is a signed Borel measure on $[0,1]^2$ for every $x,y\in\mathcal{P}_{\mathcal{X}}$.

Proof Point (1) follows since $\mathrm{k}^{\oplus}$ is given as an inner product, see Schölkopf and Smola (2002). Using the definition of $\mathrm{k}^{\oplus}$ we calculate

$$\begin{aligned}
\mathrm{k}^{\oplus}(x,y) &= \langle \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y)\rangle = \sum_{m\geq 0} \langle \int \mathrm{dk}_x^{\otimes m}, \int \mathrm{dk}_y^{\otimes m}\rangle_{\mathcal{H}^{\otimes m}} \\
&= \sum_{m\geq 0} \langle \int_0^1 \left(\int_0^{s_{m-1}} \mathrm{dk}_x^{\otimes (m-1)}\right) \otimes \mathrm{dk}_{x(s_m)}, \int_0^1 \left(\int_0^{t_{m-1}} \mathrm{dk}_y^{\otimes (m-1)}\right) \otimes \mathrm{dk}_{y(t_m)}\rangle \\
&= 1 + \sum_{m\geq 1} \int_{\substack{s_m\in[0,1]\\ t_m\in[0,1]}} \langle \int_0^{s_m} \mathrm{dk}_x^{\otimes (m)}, \int_0^{t_{m-1}} \mathrm{dk}_y^{\otimes (m-1)}\rangle \langle \mathrm{dk}_{x(s_m)}, \mathrm{dk}_{y(t_m)}\rangle \\
&= \vdots \\
&= 1 + \sum_{m\geq 1} \int_{\substack{s_m\in[0,1]\\ t_m\in[0,1]}} \int_{\substack{s_{m-1}\in[0,s_m]\\ t_{m-1}\in[0,t_m]}} \cdots \int_{\substack{s_1\in[0,s_2]\\ t_1\in[0,t_2]}} \langle \mathrm{dk}_{x(s_1)}, \mathrm{dk}_{y(t_1)}\rangle \cdots \langle \mathrm{dk}_{x(s_m)}, \mathrm{dk}_{y(t_m)}\rangle.
\end{aligned} \tag{3}$$

Now consider two paths x, y that are piecewise linear, that is there are time points $s_1 \leq \cdots \leq s_k$ such that $\dot{x}$ is constant on intervals (s_i, s_{i+1}) and analogous for y there exists $t_1 \leq \cdots \leq t_l$ such that $\dot{y}$ is constant on all intervals (t_i, t_{i+1}). Then

$$\begin{aligned}
&\int_{(s_1,s_k)\times(t_1,t_l)} \langle \mathrm{dk}_{x(s)}, \mathrm{dk}_{y(t)}\rangle_{\mathcal{H}} \\
&= \sum_{\substack{1\leq i\leq k-1\\ 1\leq j\leq l-1}} \int_{(s_i,s_{i+1})\times(t_j,t_{j+1})} \langle \mathrm{dk}_{x(s)}, \mathrm{dk}_{y(t)}\rangle_{\mathcal{H}} \\
&= \sum_{\substack{1\leq i\leq k-1\\ 1\leq j\leq l-1}} \langle \mathrm{k}_{x(s_{i+1})} - \mathrm{k}_{x(s_i)}, \mathrm{k}_{y(t_{j+1})} - \mathrm{k}_{y(t_j)}\rangle_{\mathcal{H}} \\
&= \sum_{\substack{1\leq i\leq k-1\\ 1\leq j\leq l-1}} \mathrm{k}(x(s_{i+1}), y(t_{j+1})) - \mathrm{k}(x(s_i), y(t_{j+1})) - \mathrm{k}(x(s_{i+1}), y(t_j)) + \mathrm{k}(x(s_i), y(t_j))
\end{aligned}$$

where we used the reproducing property $\langle \mathrm{k}_{x(s)}, \mathrm{k}_{y(t)}\rangle = \mathrm{k}(x(s), y(t))$ for the last equality. Note that

$$\kappa([r,s]\times[u,v]) := \mathrm{k}(x(s_{i+1}), y(t_{j+1})) - \mathrm{k}(x(s_i), y(t_{j+1})) - \mathrm{k}(x(s_{i+1}), y(t_j)) + \mathrm{k}(x(s_i), y(t_j))$$

defines a signed measure on $[0,1]^2$, hence above reads

$$\int_{(s_1,s_k)\times(t_1,t_l)} \langle \mathrm{dk}_{x(s)}, \mathrm{dk}_{y(t)}\rangle_{\mathcal{H}} = \sum_{\substack{1\leq i\leq k\\ 1\leq j\leq l}} \kappa([s_1,s_k]\times[t_1,t_l]) = \int_{(s_1,s_k)\times(t_1,t_l)} \mathrm{d}\kappa_{x,y}(s,t).$$

Combined with the identity (3) this shows (2) for piecewise constant paths. For general x, y fix a sequence $\{(s_i^n) : 0 = s_1 < \cdots < s_{l+1}^n = 1\} \subset [0,1]^n$ such that $\max_i |s_{i+1}^n - s_i^n| \to 0$

as $n \to \infty$ and denote with x^n, resp. y^n, the piecewise linear path given by interpolating between points $(x(s_i^n))_i$, resp. $(y(s_j^n))_j$. Then

$$\kappa_{x^n,y^n}([r,s]\times[u,v]) \to \kappa_{x,y}([r,s]\times[u,v])$$

for all $r < s, u < v$ directly by the definition of κ. Thus κ_{x^n,y^n} converges weakly to $\kappa_{x,y}$ On the other hand, $\langle \mathrm{S}(x^n), \mathrm{S}(y^n)\rangle$ converges to $\langle \mathrm{S}(x), \mathrm{S}(y)\rangle$ which finishes the proof by sending $n \to \infty$ ■

The equality in Point (2) in Theorem 2 suggests the expansion

$$\mathrm{k}^{\oplus}(x,y) = 1 + \int_{(s_1,t_1)\in(0,1)\times(0,1)} \left(1 + \int_{(s_2,t_2)\in(0,s_1)\times(0,t_1)} (1+\cdots)\,\mathrm{d}\kappa_{x,y}(s_2,t_2)\right) \mathrm{d}\kappa_{x,y}(s_1,t_1). \tag{4}$$

This recursive structure will be the key for an efficient computation.

4. Discretization and recursion: from paths to sequences

To make the kernel $\mathrm{k}^{\oplus} : \mathcal{P}_{\mathcal{X}} \times \mathcal{P}_{\mathcal{X}} \to \mathbb{R}$ useful for real-world applications, we need to address the following two points:

1. (Sequences). We do not observe the full path $(x(t))_{t\in[0,1]} \in \mathcal{P}_{\mathcal{X}}$ but only a sequence $x^{\pi} = (x(t_i))_{i=1}^{l} \in \mathcal{X}^+$ for a partition $\pi = \{0 = t_1 < \cdots < t_\ell = 1\}$. The partition π might even vary from path to path.
2. (Computational cost). Computing the kernel $\mathrm{k}^{\oplus} : \mathcal{P}_{\mathcal{X}} \times \mathcal{P}_{\mathcal{X}} \to \mathbb{R}$ by evaluating it as an inner product is computationally prohibitive even with $\mathcal{X} = \mathbb{R}^d = \mathcal{H}$ and the linear kernel $\mathrm{k}(\cdot,\cdot) = \langle \cdot, \cdot\rangle_{\mathbb{R}^d}$ is used if d is large (Example 2.3). It is infeasible for standard kernels such as the Gaussian kernel that have an infinite-dimensional RKHS.

To address point (1), we approximate the signature map

$$x \mapsto \mathrm{S}(\mathrm{k}_x) = \left(\int \mathrm{dk}_x^{\otimes m}\right)_{m\geq 0}$$

by discretization of the integrals. This gives a feature map S^+ for sequences

$$x^{\pi} \mapsto \mathrm{S}^+(\mathrm{k}_{x^{\pi}}) = \left(\sum_{1\leq i_1<\cdots<i_m\leq \ell-1} \nabla_{i_1}\mathrm{k}_x \otimes \cdots \otimes \nabla_{i_m}\mathrm{k}_x\right)_{m\geq 0}$$

where we use the notation $\nabla_i \mathrm{k}_x := \mathrm{k}_{x(t_{i+1})} - \mathrm{k}_{x(t_i)}$ and $\mathrm{k}_{x^{\pi}} = (\mathrm{k}_{x(t_i)})_{i=1}^{l} \in \mathcal{H}^+$. A simple calculation shows that this is equivalent to

$$x^{\pi} \mapsto \mathrm{S}^+(\mathrm{k}_{x^{\pi}}) = \prod_{i=1}^{\ell} (1 + \nabla_i \mathrm{k}_{x_i^{\pi}})$$

if $\prod$ denotes the linear extension[8] of the tensor product to the linear space $\prod_{m\geq 0}\mathcal{H}^{\otimes m}$ and this is the definition we are going to use. The kernel k^+ is defined as the inner product of this feature map

$$\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}, \quad (x,y) \mapsto \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y)\rangle$$

To address Point (2), we make heavy use of the recursive expansion (4) for $\mathrm{k}^{\oplus}$ and truncate after a given degree m (that is usually determined by cross-validation to avoid overfitting in analogy to the classic polynomial kernel).

4.1. Discretized signatures

Definition 4.1 *We call the map*

$$\mathrm{S}^+ : \mathcal{H}^+ \to \prod_{m\geq 0}\mathcal{H}^{\otimes m}, \quad (h_i)_{i=1}^l \mapsto \prod_{i=1}^{l}(1+\nabla_i h)$$

the discretized signature map (of order 1*).*

To prove quantitative results about the quality of this discretization, we need to understand how fast $\mathrm{S}^+(\mathrm{k}_{x^\pi})$ approximates $\mathrm{S}(\mathrm{k}_x)$ as $\mathrm{mesh}(\pi) := \max_i |t_{i+1}-t_i| \to 0$. We first study this approximation of paths by sequences for general paths $h \in \mathcal{P}_{\mathcal{H}}$.

Definition 4.2 *Define for* $d \geq 1$

$$\exp_d : \mathbb{R}^d \to \mathbb{R}, \quad v = (v_i)_{i=1}^d \mapsto \prod_{i=1}^{d}(1+v_i)$$

Define for a partition $\pi = (t_i)_{i=1}^{\ell}$ *with* $0 = t_1 < \cdots < t_\ell = 1$

$$\|h\|_{(\pi)} : C^1([0,1],\mathcal{H}) \to \mathbb{R}, \quad h \mapsto \left(\|h_{[t_1,t_2]}\|_1, \ldots, \|h_{[t_{\ell-1},t_\ell]}\|_1\right) \in \mathbb{R}^{\ell-1}$$

where $h_{[a,b]}$ *denotes the restriction of* $h \in C^1([0,1],\mathcal{H})$ *to* $C^1([a,b],\mathcal{H})$*.*

Using this notation, the main result of this section reads

Theorem 3 *For* $h \in C^1([0,1],\mathcal{H})$ *and a partition* $\pi = (t_i)_{i=1}^{\ell}$, $0 = t_1 < \cdots < t_\ell = 1$,

$$\left\|\mathrm{S}^+(h^\pi) - \mathrm{S}(h)\right\| \leq \exp\left(\|h\|_1\right) - \exp_1\left(\|h\|_{(\pi)}\right),$$

where $h^\pi = (h(t_i))_{i=1,\ldots,\ell} \in \mathcal{H}^+$*.*

As a consequence, we get explicit convergence rates.

8. For $\boldsymbol{s},\boldsymbol{t} \in \prod_{m\geq 0}\mathcal{H}^{\otimes m}$ with $s_0 = t_0 = 1$ define $\boldsymbol{s}\cdot\boldsymbol{t} \in \prod_{m\geq 0}\mathcal{H}^{\otimes m}$ as having the m-element equal to $\sum_{i=0}^m s_i t_{m-i}$. If we denote $\boldsymbol{s} = (s_0, s_1, \ldots)$ as $\boldsymbol{s} = s_0 + s_1 + \cdots$, then this reads $\boldsymbol{s}\cdot\boldsymbol{t} = 1 + s_1 + t_1 + s_2 + s_1 t_1 + t_2 + \cdots$ and $\prod(1+\nabla_i h)$ refers to this product. Informally speaking, we multiply series of tensors in the same way we multiply polynomials.

Corollary 4.3 *With the same notation as in Theorem 3 above, it holds that*

$$\left\|\mathrm{S}^+(h^\pi) - \mathrm{S}(h)\right\| \leq \|h\|_1 e^{\|h\|_1} \cdot \max_{i=1,\ldots,\ell-1}\|h_{[t_i,t_{i+1}]}\|_1.$$

Hence, the convergence $\lim_{\|h\|_{(\pi)}\to\|h\|_1}\mathrm{S}^+(h^\pi) = \mathrm{S}(h)$*, is of order* $O\left(\max_i\|h_{[t_i,t_{i+1}]}\|_1\right)$*.*

Corollary 4.4 *With the same notation as in Theorem 3 above, it holds that if* π *is chosen such that* $\|h_{[t_i,t_{i+1}]}\|_1 = \frac{\|h\|_1}{\ell-1}$ *for all* $i = 1,\ldots,\ell-1$*, then one has the asymptotically tight bound*

$$\left\|\mathrm{S}^+(h^\pi) - \mathrm{S}(h)\right\| \leq \frac{e^{\|h\|_1}}{\ell-1}\left(1 + \frac{\|h\|_1^{\ell-1}}{(\ell-3)!}\right).$$

The proofs of Theorem 3 and Corollaries 4.3 and 4.4 are given in Appendix A.

Remark 4.5 (About geometric approximations) *The reader familiar with path signatures will note that the approximations* $\mathrm{S}^+(h^\pi)$ *to* $\mathrm{S}(h)$ *are not group-like elements of the tensor (Hopf) algebra* $\prod_{m\geq 0}\mathcal{H}^{\otimes m}$*, thus "non-geometric" in the sense that there can not exist a path* $\hat{h}$ *such that* $\mathrm{S}^+(h^\pi) = \mathrm{S}(\hat{h})$*. However, as we will see in the following sections, from a computational perspective non-geometric approximations have many benefits. In fact, the "non-geometric" approximations of this section recover classic machine learning constructions, see Section 5. Nevertheless, one can modify the discussion of this section to produce geometric approximations and we carry this out in Appendix B; see also Remark B.6.*

4.2. Discretized signature kernels

Definition 4.6 *Given* $x = (x_i)_{i=1}^l \in \mathcal{X}^+$ *denote* $\mathrm{k}_x = (\mathrm{k}_{x_i})_{i=1}^l \in \mathcal{H}^+$*. We refer to*

$$\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}, \quad \mathrm{k}^+(x,y) = \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y)\rangle$$

as the discretized signature kernel (or sequentialization) over k *of order* 1*.*

Theorem 4 *The discretized signature kernel over* k*,*

$$\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}, \quad \mathrm{k}^+(x,y) = \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_x)\rangle$$

1. *is a positive definite kernel,*
2. $\mathrm{k}^+(x,y) = \sum_{m\geq 0}\sum_{\substack{1\leq i_1<\cdots<i_m<|x|\\ 1\leq j_1<\cdots<j_m<|y|}}\prod_{r=1}^m \nabla_{i_r,j_r}\mathrm{k}(x,y)$*,*
3. $\mathrm{k}^+(x,y) = 1 + \sum_{\substack{i_1\geq 1\\ j_1\geq 1}}\nabla_{i_1,j_1}\mathrm{k}(x,y)\cdot\left(1 + \sum_{\substack{i_2>i_1\\ j_2>j_1}}\nabla_{i_2,j_2}\mathrm{k}(x,y)\cdot\left(1+\sum_{\substack{i_3>j_2\\ j_3>j_2}}\cdots\right)\right)$*,*

where we use the notation $x = (x_i)_{i=1}^{|x|}, y = (y_i)_{i=1}^{|y|} \in \mathcal{X}^+$ *and*

$$\nabla_{i,j}\mathrm{k}(x,y) := \mathrm{k}(x_{i+1},y_{j+1}) + \mathrm{k}(x_i,y_j) - \mathrm{k}(x_i,y_{j+1}) - \mathrm{k}(x_{i+1},y_j).$$

Proof The first point follows, since k^+ is an inner product. For the second point note that $\nabla_i \mathrm{k}_x \equiv \mathrm{k}_{x_{i+1}} - \mathrm{k}_{x_i}$, $\nabla_i \mathrm{k}_y \equiv \mathrm{k}_{y_{j+1}} - \mathrm{k}_{y_j}$ and that by the reproducing property $\langle \nabla_i \mathrm{k}_x, \nabla_j \mathrm{k}_y \rangle = \nabla_{i,j} \mathrm{k}(x,y)$. The identity then follows from multiplying out

$$\langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y) \rangle = \langle \prod_i (1 + \nabla_i \mathrm{k}_x), \prod_j (1 + \nabla_j \mathrm{k}_y) \rangle$$

and using the definition of the inner product on $\mathcal{H}^{\otimes m}$. The last point follows by rearranging the summation. ∎

We can now combine this with Theorem 3 to quantify how fast the kernel k^+ for sequences approximates the kernel $\mathrm{k}^\oplus$ for paths as the mesh of partitions gets finer.

Corollary 4.7 *Let $x, y \in \mathcal{P}_\mathcal{X}$, and $\pi = (s_i)_{i=1}^k$ with $0 = s_1 < \cdots < s_k = 1$ and $\rho = (t_j)_{j=1}^l$ with $0 = t_1 < \cdots < t_l = 1$. Then,*

$$\left| \mathrm{k}^+(x^\pi, y^\rho) - \mathrm{k}^\oplus(x,y) \right| \leq 4e^{\|x\|_1 + \|y\|_1} - 2e^{\|x\|_{(\pi)} + \|y\|_1} - 2e^{\|x\|_1 + \|y\|_{(\rho)}}.$$

In particular,

$$\lim_{\substack{\|x\|_{(\pi)} \to \|x\|_1 \\ \|y\|_{(\rho)} \to \|y\|_1}} \mathrm{k}^+(x^\pi, y^\rho) = \mathrm{k}^\oplus(x,y)$$

where convergence is uniform of order $O\left(\max_i \|x_{[s_i, s_{i+1}]}\|_1 + \max_j \|y_{[t_j, t_{j+1}]}\|_1\right)$.

Proof It holds that

$$\begin{aligned} \mathrm{k}^+(x^\pi, y^\rho) - \mathrm{k}^\oplus(x,y) =& \langle \mathrm{S}^+(\mathrm{k}_x^\pi), \mathrm{S}^+(\mathrm{k}_y^\rho) \rangle - \langle \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y) \rangle \\ =& \langle \mathrm{S}^+(\mathrm{k}_x^\pi), \mathrm{S}^+(\mathrm{k}_y^\rho)) - \mathrm{S}(\mathrm{k}_y) \rangle + \langle \mathrm{S}^+(\mathrm{k}_x^\pi) - \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y) \rangle. \end{aligned}$$

The Cauchy–Schwarz inequality implies that

$$|\langle \mathrm{S}^+(\mathrm{k}_x^\pi), \mathrm{S}^+(\mathrm{k}_y^\rho)) - \mathrm{S}(\mathrm{k}_y) \rangle| \leq \| \mathrm{S}^+(\mathrm{k}_x^\pi) \| \cdot \| \mathrm{S}^+(\mathrm{k}_y^\rho) - \mathrm{S}(\mathrm{k}_y) \|.$$

Theorem 3 implies

$$\| \mathrm{S}^+(\mathrm{k}_x^\pi) \| \cdot \| \mathrm{S}^+(\mathrm{k}_y^\rho)) - \mathrm{S}(\mathrm{k}_y) \| \leq 2 \exp(\|x\|_1) \cdot \left(\exp(\|y\|_1 - \exp(\|y\|_\rho) \right)$$

and similarly, one obtains

$$\| \langle \mathrm{S}^+(\mathrm{k}_y^\rho), \mathrm{S}^+(\mathrm{k}_x^\pi) - \mathrm{S}(\mathrm{k}_x) \rangle \| \leq 2 \exp(\|y\|_1) \cdot (\exp(\|x\|_1) - \exp(\|x\|_\pi).$$

Putting all (in-)equalities together yields the main claim, the convergence statement follows from Theorem 3 (ii). ∎

4.3. Truncation and variations on a theme

The final step to get a practically useful kernel for sequences is to truncate the discrete signature features $\mathrm{S}^+(\mathrm{k}_x) \in \prod_{m \geq 0} \mathcal{H}^{\otimes m}$ at a given degree $m \geq 1$. In analogy with the classic polynomial features (resp. kernel), this not only serves a computational purpose but is also necessary to avoid overfitting; in applications the truncation degree m will be typically determined by cross-validation.

Definition 4.8 *Given an integer $m \geq 1$, we call*

$$\mathrm{k}_m^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}, \quad \mathrm{k}_m^+(x,y) = \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y) \rangle_m$$

the discretized signature kernel (or sequentialization) over k truncated at degree m. Here we use the notation $\mathrm{k}_x = (\mathrm{k}_{x_i})_i \in \mathcal{H}^+$ for $x = (x_i)_i \in \mathcal{X}^+$ and $\langle \cdot, \cdot \rangle_m$ for the inner product truncated[9] at m.

Corollary 4.9 *The discretized signature kernel k_m^+ over k truncated at degree m,*

$$\mathrm{k}_m^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}, \quad \mathrm{k}_m^+(x,y) = \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y) \rangle_m,$$

1. *is a positive definite kernel,*
2. $\mathrm{k}_m^+(x,y) = \sum_{d=1}^m \sum_{\substack{1 \leq i_1 < \cdots < i_d < |x| \\ 1 \leq j_1 < \cdots < j_d < |y|}} \prod_{r=1}^d \nabla_{i_r, j_r} \mathrm{k}(x,y)$
3. $\mathrm{k}_m^+(x,y) = 1 + \sum_{\substack{|x| > i_1 \geq 1 \\ |y| > j_1 \geq 1}} \nabla_{i_1, j_1} \mathrm{k}(x,y) \cdot \left(1 + \cdots (1 + \sum_{\substack{|x| > i_m > j_{m-1} \\ |y| > j_m > j_{m-1}}} \nabla_{i_m, j_m} \mathrm{k}(x,y)) \right)$

where we denote $x = (x_i)_{i=1}^{|x|}, y = (y_i)_{i=1}^{|y|} \in \mathcal{X}^+$ and

$$\nabla_{i,j} \mathrm{k}(x,y) := \mathrm{k}(x_{i+1}, y_{j+1}) + \mathrm{k}(x_i, y_j) - \mathrm{k}(x_i, y_{j+1}) - \mathrm{k}(x_{i+1}, y_j).$$

While above follows as simple corollary from the discussion so far, the identity Point (3) will be the key to an efficient algorithm; it is clearly more efficient than computing first $\mathrm{S}^+(x)$ and $\mathrm{S}^+(y)$ and then their inner product; but it is also much more efficient than the identity in Point (2) since it only uses $\nabla_{i,j} \mathrm{k}(x,y)$ for each i, j once.

Remark 4.10 (Variations on a theme) *Modifications of the above are possible. For example,*

(i) One can omit the first differences, that is consider the sequentialization

$$\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}; \quad (x,y) \mapsto 1 + \sum_{\substack{m \geq 1 \\ 1 \leq i_1 < \cdots < i_m \leq |x| \\ 1 \leq j_1 < \cdots < j_m \leq |y|}} \prod_{k=1}^m \mathrm{k}(x_{i_k}, y_{j_k}).$$

In feature space, this amounts to replacing the path $(\mathrm{k}_t)_{t \in [0,1]}$ by the path $(\int_0^t \mathrm{k}_s \, \mathrm{d}s)_{t \in [0,1]}$ and calculating the signature of the latter.

9. $\langle (s_0, s_1, \ldots), (t_0, t_1, \ldots) \rangle_m := \langle (s_0, s_1, \ldots, s_m, 0, \ldots), (t_0, t_1, \ldots, t_m, 0, \ldots) \rangle$

(ii) More generally, one may replace for each m, the inner product $\prod_{k=1}^{m} \mathrm{k}(x_{i_k}, y_{j_k})$ by a kernel $\mathrm{k}^m : \mathcal{X}^m \times \mathcal{X}^m \to \mathbb{R}$. This leads to a sequentialization of the family of kernels $(\mathrm{k}^m)_m$ given as

$$\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}; \quad (x, y) \mapsto \sum_{\substack{m \geq 1 \\ 1 \leq i_1 < \cdots < i_m \leq |x| \\ 1 \leq j_1 < \cdots < j_m \leq |y|}} \mathrm{k}^m((x_{i_1}, \ldots, x_{i_m}), (y_{j_1}, \ldots, y_{j_m})).$$

This corresponds to choosing different kernels on different levels of the tensor algebra, e.g., re-normalization.

(iii) One may (additionally) opt to remember the position of elements in the sequence. This can be done by mapping sequences in $\mathcal{X}^+$ to a position-remembering sequence in $(\mathcal{X} \times \mathbb{N})^+$ first, and then carrying out the sequentialization in (ii) for the family of kernels $(\mathrm{k}^m)_m$ where $\mathrm{k}^m : (\mathcal{X} \times \mathbb{N})^+ \times (\mathcal{X} \times \mathbb{N})^+ \to \mathbb{R}$ is defined as

$$\kappa\left((i_1, \ldots, i_m), (j_1, \ldots, j_m)\right) \cdot \mathrm{k}^m\left((x_{i_1}, \ldots, x_{i_m}), (y_{j_1}, \ldots, y_{j_m})\right).$$

and $\kappa : \mathbb{N}^+ \times \mathbb{N}^+ \to \mathbb{R}$ denotes an arbitrary positive definite kernel. Further, one can replace the strict inequalities $<$ in the summation over $1 \leq i_1 < \cdots < i_m \leq |x|$ and $1 \leq j_1 < \cdots < j_m \leq |y|$ by $\leq$.

Further, Assumption 3.1, especially the continuity of k *can be dropped and any of above sequentializations gives a kernel for sequences (but convergence to a kernel on paths is no longer guaranteed). There are many other modifications and above choices, while minor, seem somewhat arbitrary. The above have their justification in explaining prior art, see Section 5 below.*

5. Revisiting classic kernels for sequences: string, alignment and convolution kernels

In this section we show that the discretized signature kernel is closely related to the existing kernels for sequential data, in the sense that classic kernels for sequences arise as special cases of our approach, namely:

(a) String kernels Lohdi et al. (2002); Leslie and Kuang (2004) can be seen as a case of discretized signature kernels.

(b) The global alignment kernel Cuturi et al. (2007); Cuturi (2011) can be obtained from a special case of the discretized signature kernel, by deleting some smaller terms, in the process destroying positive definiteness.

(c) The discretized signature kernel can be related to the framework of the relation-convolution kernel Haussler (1999) with the relation "being a subsequence".

The results of this section are not important for using our method as presented in the previous and following section, but it might be of interest to researchers who are familiar with above kernels.

5.1. The string kernel

The string kernel is a kernel for sequences in a finite set $\mathcal{X}$; in this context, the elements of $\mathcal{X}$ are usually called letters and $\mathcal{X}$ is called the alphabet. Two important examples are the Latin alphabet $\mathcal{X} = \{A, B, \ldots, Z, a, b, \ldots, z\}$ for classic text mining, or $\mathcal{X}$ being DNA nucleotides, proteins, etc., in bioinformatics.

Definition 5.1 (Definition 1, page 423 of Lohdi et al. (2002)) *Fix a finite set $\mathcal{X}$ and a parameter $\lambda \in [0, 1]$. The string kernel on $\mathcal{X}$ with parameter λ is defined as*

$$\mathrm{k}_{\mathrm{string}} : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R} \quad (x, y) \mapsto \sum_{w \in \mathcal{X}^+} \Phi_w(x)\Phi_w(y)$$

where

$$\Phi_w(x) = \sum_{1 \leq i_1 < \cdots < i_m \leq r} \lambda^{|i_m - i_1 + 1|} 1_{(x_{i_1}, \ldots, x_{i_k}) = w} \text{ for } w \in \mathcal{X}^+.$$

Proposition 5.2 *Fix a finite set $\mathcal{X}$ and a parameter $\lambda \in [0, 1]$. Define a kernel*

$$\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}, \quad \mathrm{k}(a, b) = 1_{a=b}.$$

Then the sequentialization of k *given in Remark 4.10 (i), equals the string kernel with parameter $\lambda = 1$ up to an additive constant 1, that is $\mathrm{k}^+(x, y) = 1 + \mathrm{k}_{\mathrm{string}}(x, y)$ for all $x, y \in \mathcal{X}^+$.*

Proof We apply Theorem 4 in the variation given in Remark 4.10 (i) to the kernel k to get

$$\begin{aligned}
\mathrm{k}^+(x, y) &= 1 + \sum_{m \geq 1} \sum_{\substack{1 \leq i_1 < \cdots < i_m \leq |x| \\ 1 \leq j_1 < \cdots < j_m \leq |y|}} \prod_{r=1}^{m} \mathrm{k}(x_{i_r}, y_{j_r}) = 1 + \sum_{m \geq 1} \sum_{\substack{1 \leq i_1 < \cdots < i_m \leq |x| \\ 1 \leq j_1 < \cdots < j_m \leq |y|}} 1_{x_{i_1} = y_{j_1}} \cdots 1_{x_{i_m} = y_{j_m}} \\
&= 1 + \sum_{m \geq 1} \sum_{\substack{1 \leq i_1 < \cdots < i_m \leq |x| \\ 1 \leq j_1 < \cdots < j_m \leq |y|}} 1_{(x_{i_1}, \ldots, x_{i_m}) = (y_{j_1}, \ldots, y_{j_m})} \\
&= 1 + \sum_{m \geq 1} \sum_{w \in \mathcal{X}^+, |w| = m} \Phi_w(x)\Phi_w(y) = 1 + \sum_{w \in \mathcal{X}^+} \Phi_w(x)\Phi_w(y) = 1 + \mathrm{k}_{\mathrm{string}}(x, y)
\end{aligned}$$

■

More generally, for any $\lambda \in [0, 1]$ one can apply the κ-sequentialization given in Remark 4.10 (iii), to the kernel $\mathrm{k}(a, b) = 1_{a=b}$ and

$$\kappa((i_1, \ldots, i_m), (j_1, \ldots, j_m)) = \lambda^{i_m - i_1 + 1} \lambda^{j_m - j_1 + 1}$$

to recover the string kernel $\mathrm{k}_{\mathrm{string}}$ for the parameter λ; this follows as above. Similarly, various variants of the vanilla string kernel such as gappy kernels, Leslie and Kuang (2004) can be recovered[10]. Note that the $+1$ in $\mathrm{k}_{\mathrm{string}} + 1 = \mathrm{k}^+$ arises since in string kernels one usually does not count the empty word (if we count the empty word then $\mathrm{k}^+ = \mathrm{k}_{\mathrm{string}}$). However, this is merely convention and of non-importance for the Gram matrix.

10. As one of the reviewers pointed out, a very general framework for sequences that encompasses string kernels are so-called rational kernels.

Remark 5.3 *Implicit in above discussion is the identification of a string formed from an alphabet $\mathcal{X}$ as a lattice path in $\mathcal{H} = \mathbb{R}^{|\mathcal{X}|}$, that is the string $x = (a_{i_1}, \dots, a_{i_l})$ is identified as the lattice path in the vector space $\mathbb{R}^{|\mathcal{X}|}$ for which we identify $\mathcal{X}$ as an orthnomal basis (the free vector space over $\mathcal{X}$),*

$$x \in C^1([0,l], \mathcal{H}) \quad x(t) = \{t\} \cdot a_{i_{\lfloor t \rfloor}} + \sum_{r=1}^{\lfloor t \rfloor} a_{i_r},$$

where $\lfloor t \rfloor$ is the floor function of t, and $\{t\}$ is the fractional part of t. We deal with "non-geometric rough paths'', see Remark 4.5.

5.2. The global alignment kernel

The global alignment kernel is one of the most used kernels for sequences. We give its definition in modern terminology (Section 2.2 of Cuturi (2011)).

Definition 5.4 *Define*

$$\mathcal{A}(m,n) = \Big\{ \pi = (\pi_i)_{i=1}^k \in \left(\mathbb{N}^2\right)^+ : k \le m+n-1, \pi_1 = (1,1), \pi_k = (m,n), \\ (\pi_{i+1} - \pi_i) \in \{(0,1),(1,0),(1,1)\} \Big\}$$

We call an element of $\mathcal{A}(m,n)$ an alignment of (m,n).

Definition 5.5 *For a set $\mathcal{X}$ and a kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, the global alignment kernel is defined as*

$$\mathrm{k}_{\mathrm{GA}} : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R} \quad (x,y) \mapsto \sum_{\pi \in \mathcal{A}(|x|,|y|)} e^{-D_{x,y}(\pi)}$$

where $D_{x,y}(\pi) = \sum_{i=1}^{|\pi|} \mathrm{k}(x_{\pi_i^1}, y_{\pi_i^2})$, and we denote with $|x|, |y|$ the length of the sequences x, y and we denote the entries of an alignment $\pi = (\pi_1, \dots, \pi_k)$ as $\pi_i = (\pi_i^1, \pi_i^2) \in \mathbb{N}^2$.

In its native form, the global alignment kernel cannot be written as a discretized signature kernel since these preserve positive definiteness, while the global alignment kernel does not (see the discussion in Cuturi (2011)). However, a simple modification turns the global alignment kernel into a positive definite kernel that can be obtained by sequentialization.

Definition 5.6 *Define*

$$\mathcal{A}_{\frac{1}{2}}(l) = \{\pi = (\pi_1, \dots, \pi_k) \in \left(\mathbb{N}^1\right)^+ : \pi_k \le l,\ \pi_{i+1} - \pi_i \in \{0,1\}\}$$

and call an element of $\mathcal{A}_{\frac{1}{2}} := \bigcup_{l \ge 1} \mathcal{A}_{\frac{1}{2}}(l)$ a half-alignment.

Definition 5.7 *Fix a set $\mathcal{X}$ and a kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. The global half-alignment kernel is defined as*

$$\mathrm{k}_{\mathrm{GHA}} : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R} \quad (x,y) \mapsto \sum_{\substack{\pi \in \mathcal{A}_{\frac{1}{2}}(|x|) \\ \rho \in \mathcal{A}_{\frac{1}{2}}(|y|) \\ |\pi| = |\rho|}} e^{-D_{x,y}(\pi,\rho)}$$

where $D_{x,y}(\pi,\rho) = \sum_{i=1}^{|\pi|} \mathrm{k}(x_{\pi_i}, y_{\rho_i})$.

Proposition 5.8 *Fix a set $\mathcal{X}$ and a positive definite kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. Then the global half-alignment kernel $\mathrm{k}_{\mathrm{GHA}}$ equals the κ-sequentialization of the kernel $(x,y) \mapsto e^{-\mathrm{k}(x,y)}$ given in Remark 4.10(iii), that is $\mathrm{k}_{\mathrm{GHA}}(x,y) = \mathrm{k}^+(x,y)$ with $\kappa(\pi,\rho) = 1_{\pi \in \mathcal{A}_{\frac{1}{2}}} 1_{\rho \in \mathcal{A}_{\frac{1}{2}}}$.*

Proof The κ-sequentializtion yields

$$\begin{aligned}
\mathrm{k}^+(x,y) &= \sum_{\substack{m \ge 1 \\ 1 \le \pi_1 \le \dots \le \pi_m \le |x| \\ 1 \le \rho_1 \le \dots \le \rho_m \le |y|}} \kappa((\pi_1,\dots,\pi_m),(\rho_1,\dots,\rho_m)) \prod_{r=1}^m \mathrm{k}(x_{\pi_r}, y_{\rho_r}) \\
&= \sum_{m \ge 1} \sum_{\substack{1 \le \pi_1 \le \dots \le \pi_m \le |x| \\ 1 \le \rho_1 \le \dots \le \rho_m \le |y|}} 1_{(\pi_1,\dots,\pi_m) \in \mathcal{A}_{\frac{1}{2}}} 1_{(\rho_1,\dots,\rho_m) \in \mathcal{A}_{\frac{1}{2}}} \prod_{r=1}^m e^{-\mathrm{k}(x_{\pi_r}, y_{\rho_r})} \\
&= \sum_{m \ge 1} \sum_{\substack{\pi \in \mathcal{A}_{\frac{1}{2}}(|x|) \\ \rho \in \mathcal{A}_{\frac{1}{2}}(|y|) \\ |\pi| = |\rho| = m}} e^{-\sum_{i=1}^m \mathrm{k}(x_{\pi_i}, y_{\rho_i})} = \mathrm{k}_{\mathrm{GHA}}(x,y).
\end{aligned}$$

■

Remark 5.9 *The terms missing in k_{GA}, when compared to $\mathrm{k}_{\mathrm{GHA}}$ are those arising from sequence pairs $\pi \in \left(\mathbb{N}^2\right)^+$ in which there is an increment $(0,0)$. In view of the discussion in Section 3.2 of Cuturi (2011), these missing terms are exactly the locus of non-transitivity in the sense of Shin and Kuboyama (2008). Concerning the possible non positive definiteness of k_{GA}, one can follow Cuturi (2011) and study sufficient conditions under which the original global alignment kernel is positive definite.*

5.3. The relation-convolution kernel

Finally, we would like to point out that the discretized signature kernels are closely related to the relation-convolution kernels, see Haussler (1999), Section 2.2.

Definition 5.10 *Fix kernels $\mathrm{k}_i : \mathcal{X}_i \times \mathcal{X}_i \to \mathbb{R}$ for $i = 1, \dots, m$. Fix a relation R between the sets $\mathcal{X}_1 \times \cdots \times \mathcal{X}_m$ and $\mathcal{X}$, that is a subset $R \subset \mathcal{X}_1 \times \cdots \times \mathcal{X}_m \times \mathcal{X}$ and say that $(x_1, \dots, x_m) \in \mathcal{X}_1 \times \cdots \times \mathcal{X}_m$ decomposes $x \in \mathcal{X}$ if $(x_1, \dots, x_m, x) \in R$. The relation-convolution kernel of $(\mathrm{k}_1, \dots, \mathrm{k}_m)$ is defined as*

$$\mathrm{k}_{\mathrm{RC}} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}, \quad (x,y) \mapsto \sum_{\substack{(x_1,\dots,x_m):((x_1,\dots,x_m),x) \in R \\ (y_1,\dots,y_m):((y_1,\dots,y_m),y) \in R}} \prod_{i=1}^m \mathrm{k}_i(x_i, y_i).$$

The intuition for above definition is that we can measure similarity of two objects $x, y \in \mathcal{X}$ by decomposing them into substructures and comparing these substructures.

Proposition 5.11 *Let $\mathcal{X}$ be any set and $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. Then the sequentialization $\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}$ given in Remark 4.10 (i) is a relation-convolutional kernel for the relation*

"being an ordered subsequence''. More precisely, define $\mathcal{X}_1 = \mathbb{N}$, $\mathcal{X}_i = \mathcal{X}$ *for* $i = 2, \dots, m+1$ *and*

$$\mathrm{k}_1(i,j) = 1_{i=j} \text{ and } \mathrm{k}_i(x,y) = \mathrm{k}(x,y) \text{ for } i = 2, \dots, m+1.$$

Then for

$$R = \{(l, x_1, \dots, x_{m+1}, x') \in \mathcal{X}_1 \times \cdots \times \mathcal{X}_{m+1} \times \mathcal{X}^+ : l \le m \text{ and } \exists i_1 < \cdots < i_l \text{ such that } (x'_1, \dots, x'_l) = (x_{i_1}, \dots, x_{i_l})\}$$

the relation-convolutional kernel k_{RC} *equals* k^+.

The proof follows by spelling out the definitions of k_{RC} and k^+. It is interesting to note the native discretized signature kernel of Theorem 4 does not, at least naturally, fall into Haussler's convolutional kernel framework since it heavily relies on the additional differences $\nabla \mathrm{k}$. (Above variation is only obtained after the summation step described in Remark 4.10).

6. Efficient algorithms

In this section, we design effective algorithms to evaluate or approximate the $(n \times n)$-Gram matrix $\left(\mathrm{k}^+_m(x_i, x_j)\right)_{i,j\in\{1,\dots,n\}}$ of n sequences $x_1, \dots, x_n \in \mathcal{X}^+$. The results are summarized in Table 2. The key are the recursive Horner-type formula given in Corollary 4.9 together with ideas from dynamic programming and low-rank approximations.

method	algorithm	time	storage
naive evaluation	Definition 4.8	$O(n^2 \cdot \ell \cdot \dim(\mathcal{H})^m)$	$O(n^2 \dim(\mathcal{H})^m)$
dynamic programming	Algorithm 3	$O(n^2 \cdot \ell^2 \cdot m)$	$O(\ell^2)$
DP & LR, per-element	Algorithm 4	$O(n^2 \cdot \ell \cdot \rho \cdot m)$	$O(\ell \cdot \rho)$
DP & LR, per-sequence	Section 6.3.1	$O((n+\rho) \cdot \ell^2 \cdot \rho \cdot m)$	$O(n \cdot \ell^2)$
DP & LR, simultaneous	Algorithm 5	$O(n \cdot \ell \cdot \rho \cdot m)$	$O(n \cdot \ell \cdot \rho)$

Table 2: Computational time (in elementary arithmetic operations) and storage cost for computing (an approximation) to the $(n \times n)$-Gram matrix $\left(\mathrm{k}^+_m(x_i, x_j)\right)_{i,j\in\{1,\dots,n\}}$ between sequences $x_1, \dots, x_n \in \mathcal{X}^+$ of length at most ℓ, that is $|x_i| \le \ell$ for $i = 1, \dots, n$. Methods: DP = dynamic programming, LR = low-rank. In the low-rank methods, ρ is a meta-parameter which controls accuracy of approximation.

Remark 6.1 *Naive evaluation of* $\mathrm{k}^+_m(x,y)$ *by directly calculating it as an inner product of signature features incurs an exponential storage cost* $O(\dim(\mathcal{H})^m)$. *Even for* $\mathcal{H} = \mathbb{R}^d$ *this becomes quickly very expensive and infeasible when* $\dim(\mathcal{H}) = \infty$ *which is the case for most practically relevant kernels.*

Remark 6.2 *Above algorithms are already powerful for* $\mathcal{H} = \mathbb{R}^d$ *with the inner product in* $\mathbb{R}^d$ *as kernel* k. *In this case,* $\mathrm{k}^+_x \approx \mathrm{S}(\mathrm{k}_x) = \mathrm{S}(\langle \mathrm{k}_x, \cdot \rangle) \simeq \mathrm{S}(x) \in \prod_{m\ge 0} \left(\mathbb{R}^d\right)^{\otimes m}$, *that is the feature map for a path* x *is the usual signature* $\mathrm{S}(x) \in \prod_{m\ge 0} \left(\mathbb{R}^d\right)^{\otimes m}$. *Compared to naive computation of* $\mathrm{S}(x)$, *Algorithm 5 gives a massive reduction in complexity (from exponential to linear!).*

Remark 6.3 *For readability we have absorbed in Table 2 the computational time* c *that is needed to evaluate* $\mathrm{k}(x,y)$ *for* $x, y \in \mathcal{X}$ *into the big O bound since this is just a multiplicative factor. E.g. the computational time for Algorithm 3 would read* $O(c \cdot n^2 \cdot \ell^2 \cdot m)$ *if we include* c.

6.1. Notation and subroutines for computations with arrays (tensors)

We introduce notation (inspired by Python/Numpy) and fast algorithms for dynamic programming subroutines. This allows us to express our algorithms as operations on arrays alone and makes it easy to implement them in high-level languages that are optimized for operating on arrays (such as Numpy, etc).

Notation 6.4 (Arrays/tensors) *We will denote the* $(i_1, \dots, i_k)$*-th element of a* k*-fold array (= degree* k *tensor)* A *by* $A[i_1, \dots, i_k]$. *Occasionally, for ease of reading, we will use "|" instead of "," as a separator, for example* $A[i_1, i_2|i_3, \dots, i_k]$ *if the indices on the left side of "|" are semantically distinct from those on the right side. The arrays all contain elements in* $\mathbb{R}$, *and the indices will always be positive integers, excluding zero.*

Notation 6.5 (functions applied elementwise) *For a function* $f : \mathbb{R} \to \mathbb{R}$, *and an array* A, *we will denote by* $f(A)$ *the array where* f *is applied element-wise. I.e.,* $f(A)[i_1, \dots, i_k] = f(A[i_1, \dots, i_k])$. *Similarly, for* $f : \mathbb{R}^m \to \mathbb{R}$ *and arrays* $A_1, \dots, A_m$, *we denote*

$$f(A_1, \dots, A_m)[i_1, \dots, i_k] = f(A_1[i_1, \dots, i_k], \dots, A_m[i_1, \dots, i_k]).$$

For example, $\frac{1}{2} \cdot A^2$ *is the array* A *having all elements squared, then divided by two. The array* $A + B$ *contains, element-wise, sums of elements of* A *and* B.

Notation 6.6 (slice, shift, cumulative sum) *Let* A *be a* k*-fold array of size* $(n_1 \times \cdots \times n_k)$.

(i) For an index i_j *(at* j*-th position), we will write* $A[:, \dots, :, i_j, :, \dots, :]$ *for* $(k-1)$*-fold array of size* $(n_1 \times \cdots \times n_{j-1} \times n_{j+1} \times \dots n_k)$ *such that*

$$A[:, \dots, :, i_j, :, \dots, :][i_1, \dots, i_{j-1}, i_{j+1}, \dots, i_k] = A[i_1, \dots, i_k].$$

We define in analogy, iteratively, $A[:, \dots, :, i_j, :, \dots, :, i_{j'}, :, \dots, :]$, *and so on. Arrays of this type are called slices (of* A*).*

(ii) For an integer m, *we will write* $A[:, \dots, :, +m, :, \dots, :]$ *for the* k*-fold array of size* $(n_1 \times \cdots \times n_{j-1} \times (n_j + m) \times n_{j+1} \times \cdots \times n_k)$ *such that*

$$A[:, \dots, :, i_j, :, \dots, :][i_1, \dots, i_{j-1}, i_j + m, i_{j+1}, \dots, i_k] = A[i_1, \dots, i_k],$$

and where non-existing indices of A *are treated as zero. Arrays of this type are called shifted (versions of* A*). For negative* m, *the shifts will be denoted with a "minus"-sign instead of a "plus"-sign.*

(iii) We will write $A[:,\dots,:,\boxplus,:,\dots,:]$, where $\boxplus$ is at the j-th position, for the k-fold array of size $(n_1 \times \cdots \times n_k)$ such that

$$A[:,\dots,:,\boxplus,:,\dots,:][i_1,\dots,i_k] = \sum_{\kappa=i_j}^{n_j} A[i_1,\dots,i_{j-1},\kappa,i_{j+1},\dots,i_k].$$

Arrays of this type are called slice-wise cumulative sums (of A).

(iv) We will write $A[:,\dots,:,\Sigma,:,\dots,:]$, where Σ is at the j-th position, for the $(k-1)$-fold array of size $(n_1 \times \cdots \times n_{j-1} \times n_{j+1} \times \cdots \times n_k)$ such that $A[:,\dots,:,\Sigma,:,\dots,:][i_1,\dots,i_{k-1}] = \sum_{\kappa=1}^{n_j} A[i_1,\dots,i_{j-1},\kappa,i_j,\dots,i_{k-1}]$. Arrays of this type are called slice-wise sums (of A).

We will further use iterations and mixtures of the above notation, noting that the index-wise sub-setting, shifting, and accumulation commute with each other. Therefore expressions such as $A[+1,:|\Sigma,+2]$ or $A[j|:,+3,\boxplus]$ are well-defined, for example. We will also use the notation $A[\boxplus+m,\dots]$ to indicate the shifted variant of the cumulative sum array.

Cumulative sums can be computed efficiently, in the order of the size of an array, as opposed to squared complexity of more naive approaches. The algorithm is classical, we present it for the convenience of the reader in Algorithms 1 and 2.

Algorithm 1 Computing the cumulative sum of a vector.
Input: A 1-fold array A of size (n)
Output: The cumulative sum array $A[\boxplus]$

1: Let $Q \leftarrow A$.
2: **for** $\kappa = 2$ to n **do**
3: $\quad Q[\kappa] \leftarrow Q[\kappa-1] + A[\kappa]$
4: **end for**
5: Return Q

Algorithm 2 Computing the cumulative sum of an array.
Input: A k-fold array A of size $(n_1 \times \cdots \times n_k)$
Output: The cumulative sum array $A[\boxplus,\dots,\boxplus,:,\dots,:]$ (up to the m-th index)

1: Let $Q \leftarrow A$
2: **for** $\kappa = 2$ to m **do**
3: $\quad$ Let $Q \leftarrow Q[:,\dots,:,\boxplus,:,\dots,:]$ (at the κ-th index), where the right side is computed via applying algorithm 1 slice-wise.
4: **end for**
5: Return Q

6.2. Computing the discretized signature kernel

Algorithm 3 Evaluation of k_m^+.
Input: Sequences $x, y \in \mathcal{X}^+$. A kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. A truncation degree m.
Output: $\mathrm{k}_m^+(x,y)$

1: Set $\ell_x = |x| - 1, \ell_y = |y| - 1$
2: Compute the $(\ell_x \times \ell_y)$-array K with entries $K[i,j] = \nabla_{i,j}\,\mathrm{k}(x,y)$
3: Initialize an $(m \times \ell_x \times \ell_y)$-array A
4: Set $A[1|:,:] \leftarrow K$
5: **for** $d = 2$ to m **do**
6: $\quad$ Compute $Q \leftarrow A[d-1|\boxplus,\boxplus]$
7: $\quad$ Set $A[d|:,:] \leftarrow K \cdot (1 + Q[+1,+1])$
8: **end for**
9: Compute $R \leftarrow 1 + A[m|\Sigma,\Sigma]$
10: Return R

The correctness of above Algorithm follows directly from the recursive formula (3) in Corollary 4.9: we start by evaluating the innermost parenthesis and then use the summation to build the content of the next parenthesis. In symbols, define for $d = 1,\dots,m-1$,

$$A^1_{i,j} := \nabla_{i,j}\,\mathrm{k}(x,y) \text{ and } A^{d+1}_{i,j} := \nabla_{i,j}\,\mathrm{k}(x,y)\left(1 + \sum_{\substack{i'>i\\ j'>j}} A^d_{i',j'}\right),$$

then $\mathrm{k}_m^+(x,y) = 1 + \sum_{\substack{i\geq 1\\ j\geq 1}} A^m_{i',j'}$. In above Algorithm 3 we denote $A[d|i,j] = A^d_{i,j}$.

Remark 6.7

- *Disregarding the cost of computing the $(\ell_x \times \ell_y)$-matrix $(\nabla_{i,j}\,\mathrm{k}(x,y))_{i,j}$, the computational cost of Algorithm 3 is $O(m|x||y|)$ elementary arithmetic operations (= the number of loop elements) and $O(m|x||y|)$ units of elementary storage. The storage requirement can be reduced to $O(|x||y|)$ by discarding $A[d-1|:,:]$ from memory after step 7 each time.*

- *In each run of the loop, a matrix Q is pre-computed to avoid a five-fold loop that would be necessary with the more naive version of line 7,*

$$A[m|i,j] \leftarrow A[m|i,j] \cdot \left(1 + \sum_{i'>i}\sum_{j'>j} A[m-1|i',j']\right),$$

that leads to a blown up computational cost of $O(m\ell_x^2\ell_y^2)$ at the asymptotically insignificant gain of storing one $(\ell_x \times \ell_y)$-matrix less (the matrix Q).

6.3. Large scale strategies

By using Algorithm 3 one can compute the Gram matrix $\left(\mathrm{k}^+_m(x_i, x_j)\right)_{i,j=1,\dots,n}$ of n sequences $x_1, \dots, x_n \in \mathcal{X}^+$ in $O(n^2 \cdot \ell^2 \cdot m)$ elementary arithmetic operations. While this is for moderate sizes of n,m and ℓ achievable on contemporary desktop computers, it becomes quickly prohibitive for large n, ℓ due to the quadratic growth — especially when combined with parameter tuning or cross-validation schemes (as later in our experiments). We present two low-rank techniques to address this: the first is classic and reduces the quadratic cost in n to linear, the second reduces the quadratic cost in ℓ to linear. Finally, we combine these two techniques to get $O(n \cdot \ell \cdot m \cdot \rho)$ computation time with ρ denoting an approximation parameter.

6.3.1. Low-rank methods for the sequence-vs-sequence kernel matrix

Since $\left(\mathrm{k}^+_m(x_i, x_j)\right)_{i,j=1,\dots,n}$ is a Gram-matrix, it is directly amenable to large-scale variants of low-rank type. Strategies of this kind include the incomplete Cholesky decomposition, Nyström approximation, or the inducing point formalism in a Gaussian process framework. For n sequences, all strategies mentioned above require evaluation of at most an $(n \times r)$ and an $(r \times r)$ matrix (where r is a meta-parameter), which costs $O((r+n) \cdot r \cdot \ell^2 \cdot m)$ elementary operations and $O((r+n) \cdot r \cdot \ell^2)$ storage[11]. Any of these low-rank strategies reduces the complexity of the Gram matrix to be linear in n, but not in ℓ since the strategy is completely independent of how the discretized signature kernel was evaluated at a given pair $(x_i, x_j) \in \mathcal{X}^+ \times \mathcal{X}^+$. For the same reason, any improvements on the cost of evaluating $\mathrm{k}^+_m(x_i, x_j)$ will combine with this strategy.

6.3.2. Low-rank methods for the element-vs-element kernel matrix

The evaluation $\mathrm{k}^+_m(x_i, x_j)$ for a pair $(x_i, x_j) \in \mathcal{X}^+$ is given by nested partial summations and multiplications applied to the $(\ell_j \times \ell_j)$-matrix $(\mathrm{k}(x_{i,r}, x_{j,s}))_{r,s}$ where $r = 1, \dots, \ell_i$, $s = 1, \dots, \ell_j$ and we denote $x_i = (x_{i,1}, \dots, x_{i,\ell_i}), x_j = (x_{j,1}, \dots, x_{j,\ell_j}) \in \mathcal{X}^+$. The low-rank methods of the previous paragraph cannot be applied naively to this $(\ell_i \times \ell_j)$- matrix: firstly, this matrix is in general non-symmetric; secondly, the summation- and multiplication-type operations require in naive form at each recursion step access to the full $(\ell_i \times \ell_j)$-matrix. The first issue is easily addressed by replacing the respective symmetric decomposition with the analogous non-symmetric one. The second issue is much harder to deal with, but below we show that by working exclusively on low-rank factorizations in each recursion step this issue can also be dealt with.

Definition 6.8 *Let A be an $(a \times b)$-matrix. For U an $(a \times r)$-matrix, and V a $(b \times r)$-matrix, we say that (U, V) is a low-rank presentation of A, of rank r, if*

$$A_{i,j} = \sum_{r'=1}^{r} U_{i,r'} V_{j,r'}$$

With $\bullet$ denoting the usual matrix multiplication this is equivalent to $A = U \bullet V^\top$.

11. followed by a slightly modified variant of the learning algorithm itself which usually costs $O((r+n) \cdot r^2)$ elementary operations and storage (at most) instead of the unmodified variant which usually costs $O(n^3)$ (at most).

The fact that A has a low-rank presentation of rank r does imply that A is of rank r or less (by equivalence of matrix rank with decomposition rank), but it does not imply that A is of rank exactly r.

We state a number of straightforward but computationally useful Lemmas that show how low-rank matrices behave under shifting, summation and cumulative summation, componentwise addition and multiplication. This allows us to replace these operations on matrices in Algorithm 4 by the operations on low-rank matrices.

Lemma 6.9 (Low-rank under cumulative summations and shifts) *Let (U, V) be a low-rank representation of rank r for an $(a \times b)$-matrix A. Then*

(i) Define A' and A'' as $A'_{i,j} = \sum_{i' \geq i} A_{i',j}$ and $A''_{i,j} = \sum_{j' \geq j} A_{i,j'}$. Define U' as $U'_{i,r} = \sum_{i' \geq i} U_{i',r}$ and V' as $V'_{j,r} = \sum_{j' \geq j} V_{j',r}$. Then (U', V) is a low-rank representation or rank r of A' of rank and (U, V') is a low-rank representation of rank r of A'.

(ii) Define A' and A'' as $A'_{i,j} = A_{i+s,j}$ and $A''_{i,j} = A_{i,j+s}$ for $s \geq 1$. Define U' and V' as $U'_{i,r} = U_{i+s,r} 1_{i+s \leq a}$ and $V'_{j,r} = V_{j+s,r} 1_{j+s \leq b}$. Then (U', V) is a low-rank representation of A' of rank r and (U, V') is a low rank representation of rank r of A''.

Proof This follows by spelling out the definition: for (i)

$$A'_{i,j} = \sum_{i' \geq i} A_{i',j} = \sum_{i' \geq i} \sum_{r'=1}^{r} U_{i',r'} V_{j,r'} = \sum_{r'=1}^{r} U'_{i,r'} V_{j,r'};$$

for (ii)

$$A'_{i,j} = A_{i+s,j} = \sum_{r'=1}^{r} U_{i+s,r'} V_{j,r'} = \sum_{r'=1}^{r} U'_{i,r'} V_{j,r'}.$$

The statements for A'' follow similarly. ■

Lemma 6.10 (Low rank under addition and multiplication) *Let A_1, A_2 be $(a \times b)$-matrices such that (U, V) is a low-rank representation of A_1 of rank r_1, and (R, S) is a low-rank representation of A_2 of rank r_2. Then*

(i) (U', V') is a low rank representation of $A_1 + A_2$ of rank $r_1 + r_2$ where

$$U'_{i,r} = \begin{cases} U_{i,r} & \text{, if } 1 \leq r \leq r_1 \\ R_{i,r-r_1} & \text{, if } 1 + r_1 \leq r \leq r_1 + r_2 \end{cases}, \; V'_{j,r} = \begin{cases} V_{j,r} & \text{, if } 1 \leq r \leq r_1 \\ S_{j,r-r_1} & \text{, if } 1 + r_1 \leq r \leq r_1 + r_2 \end{cases}$$

(ii) $(\bar{U}, \bar{V})$ is a low rank representation of[12] $A_1 \circ A_2$ of rank $r_1 r_2$ where

$$\bar{U}_{i,r} = U_{i,a} R_{i,b} \text{ and } \bar{V}_{j,r} = V_{j,a} S_{j,b}$$

and a, b are such that $r = (a-1) \cdot r_2 + b - 1$ with $a \in \{1, \dots, r_1\}$ and $b \in \{1, \dots, r_2\}$

12. We denote the elementwise product of matrices with $A \circ B$, that is $(A \circ B)_{i,j} = A_{i,j} B_{i,j}$.

Proof Since the (i,j)-entry of the matrix A_1+A_2 equals $\sum_{r=1}^{r_1} U_{i,r}V_{j,r}+\sum_{r'=1}^{r_2} R_{i,r'}S_{j,r'}$ and the (i,j)-entry of $A_1 \circ A_2$ equals $\sum_{r=1}^{r_1} U_{i,r}V_{j,r}\sum_{r'=1}^{r_2} R_{i,r'}S_{j,r'}$, the result follows by substituting the two sums over $r \in \{1,\dots,r_1\}$ and $r' \in \{1,\dots,r_2\}$ by one sum over $\{1,\dots,r_1+r_2\}$ resp. over $\{1,\dots,r_1 r_2\}$. ■

In view of Point (ii) of above Lemma we introduce new array notation:

Notation 6.11 *Let A_1 be a k-fold array of size $(n_1 \times \cdots \times n_k)$ and A_2 be a k-fold array of size $(n_1 \times \cdots \times n_{k-1} \times n'_k)$. Write $A_1 \star A_2$ for the $(n_1 \times \cdots \times n_{k-1} \times (n_k \cdot n'_k))$ array with entries*

$$A_1 \star A_2[i_1,\dots,i_k] = A_1[i_1,\dots,i_{k-1},a]A_2[i_1,\dots,i_{k-1},b]$$

where a,b are such that $i_k = (a-1)\cdot n_2 + b - 1$ with $a \in \{1,\dots,n_1\}$ and $b \in \{1,\dots,n_2\}$.

Algorithm 4 Evaluation of k_m^+, with low-rank speed-up.
Input: Sequences $x, y \in \mathcal{X}^+$. A kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. A truncation degree $m \geq 1$. An integer $1 \leq r \leq \min(\ell_x, \ell_y)$.
Output: An approximation to $\mathrm{k}_m^+(x,y)$

1: Set $\ell_x \leftarrow |x| - 1$ and $\ell_y \leftarrow |y| - 1$
2: Compute a low-rank representation (U,V) of rank r, approximating the element-vs-element matrix/array with entries $K[i,j] = \nabla_{i,j}\,\mathrm{k}(x,y)$, $i \in \{1,\dots,\ell_x\}$, $j \in \{1,\dots,\ell_y\}$
3: Initialize an $(m \times \ell_x \times *)$-array B and an $(m \times \ell_y \times *)$-array C (* means that the size may change dynamically)
4: Set $B[1|\,:,:] \leftarrow U$ and $C[1|\,:,:] \leftarrow V$
5: **for** $d = 2$ to m **do**
6: $\quad P \leftarrow B[d-1|\boxplus+1,:]$ and $Q \leftarrow C[d-1|\boxplus+1,:]$
7: $\quad$ Append an $(\ell_x \times 1)$-array of 1's to P and append an $(\ell_y \times 1)$-array of 1's to Q
8: $\quad$ Set $B[d|\,:,:] \leftarrow (U \star P)[:,:]$ and $C[d|\,:,:] \leftarrow (V \star Q)[:,:]$
9: $\quad$ optional: "simplify" the low-rank presentation (B,C), reducing its rank
10: **end for**
11: Set $R \leftarrow B[m|\Sigma,:]$ and $S \leftarrow C[m|\Sigma,:]$
12: Return $1 + (R \cdot S)[\Sigma]$

Algorithm 4 first approximates the element-vs-element $(\ell_x \times \ell_y)$-matrix $K = (\nabla_{i,j}\,\mathrm{k}(x,y))_{i,j}$ by a low rank approximation (U,V). It then uses the formula for k_m^+ given in Corollary 4.9 and updates the low-rank representation in each recursion step (starting from the innermost parenthesis):

- The first time line 6 is called it uses Lemma 6.9 to calculate a low-rank representation (P,Q) of the $(\ell_x \times \ell_y)$-matrix $\left(\sum_{i'>i,j'>j} \nabla_{i',j'}\,\mathrm{k}(x,y)\right)_{i,j}$ from the low-rank approximation (U,V) for $K = (\nabla_{i,j}\,\mathrm{k}(x,y))_{i,j}$; later calls of line 6 do the same but with K replaced by another matrix with low-rank factorization stored in $B[d|\,:,:]$ and $C[d|\,:,:]$.

- The first time line 7 is called, it calculates a low-rank representation $(\bar{P},\bar{Q})$ of the $(\ell_x \times \ell_y)$-matrix $(1 + (P \bullet Q^\top)_{i,j})_{i,j}$ by using (P,Q) and the trivial identity

$$1 + \sum_{k=1}^{r} P_{i,k}Q_{j,k} = \sum_{k=1}^{r+1} \bar{P}_{i,k}\bar{Q}_{j,k}$$

  where $\bar{P}$ and $\bar{Q}$ are given by adding a $(r+1)$-th column consisting of 1's. Note that the rank increases by one by going from (P,Q) to $(\bar{P},\bar{Q})$. Later calls do the same but with (P,Q) replaced by another matrix with low-rank factorization stored in $B[d|\,:,:]$ and $C[d|\,:,:]$.

- Line 8 calculates a low-rank representation $(\bar{U},\bar{V})$ for the elementwise product between the $(\ell_x \times \ell_y)$-matrices $K = U \bullet V^\top$ and $\bar{P} \bullet \bar{Q}^\top$. By Lemma 6.10 it is given as $\bar{U}_{i,\bar{r}} = U_{i,a}\bar{P}_{i,b}$ and $\bar{V}_{\bar{r},j} = V_{a,j}\bar{Q}_{b,j}$.

- Line 9 is optional, aiming at keeping the low-rank presentation small[13].

- Line 11 uses that

$$\sum_{i\geq 1, j\geq 1} (R \bullet S^\top)_{i,j} = \sum_{i\geq 1, j\geq 1}\sum_{k} R_{i,k}S_{j,k} = \sum_{k}(\sum_{i\geq 1} R_{i,k})(\sum_{j\geq 1} S_{j,k}).$$

  (Recall that $R \cdot S$ denotes elementwise multiplication of arrays R,S and $R \bullet S$ denotes the usual matrix multiplication if R,S are interpreted as matrices).

- The computational cost of Algorithm 4 is of the same order as the maximum size of B and C. That is, if ρ is the smallest integer such that at any time B requires $\ell_x \cdot m \cdot \rho$ space, and C requires $\ell_y \cdot m \cdot \rho$ space, then the computational complexity of Algorithm 4 is[14] $O((\ell_x + \ell_y)\cdot \rho \cdot m)$.

6.3.3. Simultaneous low-rank methods

Algorithm 4 yields an efficient low-rank speed-up for computing a single entry $\mathrm{k}_m^+(x_i,x_j)$. Thus total computational cost for the Gram matrix $(\mathrm{k}_m^+(x_i,x_j))_{i,j\in\{1,\dots,n\}}$ is $O(n^2 \cdot \ell \cdot \rho \cdot m)$ and cost quadratic in the number of data points n may be prohibitive on large scale data. We address this by combining both low-rank strategies mentioned before to achieve a further reduction of computational cost from $O(n^2 \cdot \ell \cdot \rho \cdot m)$ to $O(n \cdot \ell \cdot \rho \cdot m)$.

13. This can be achieved for example via singular value decomposition, sub-sampling, or random projection type techniques.
14. Since one can always choose a low-rank representation of $B[m|\,:,:]$ and $C[m|\,:,:]$ of rank $\min(\ell_x,\ell_y)$ or less, the computational complexity is bounded by $O(\ell_x \cdot \ell_y \cdot m)$ (which is the complexity of Algorithm 3).

Algorithm 5 Computation of the Gram matrix of k_m^+, with (double) low-rank speed-up.
Input: Sequences $x_1, \dots, x_n \in \mathcal{X}^+$. A kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. A truncation degree m. An integer $r \geq 1$.
Output: A low-rank approximation (U, U) of the Gram matrix $K = \left(\mathrm{k}_m^+(x_i, x_j)\right)_{i,j=1,\dots,n}$.

1: Compute arrays $U^{(i)}$ such that each pair $(U^{(i)}, U^{(j)})$ $i, j \in \{1, \dots, n\}$ is a low-rank presentation of rank r for the $((|x_i| - 1) \times (|x_j| - 1))$-matrix $K^{(ij)}$ with entries $K^{(ij)}_{a,b} = \nabla_{a,b} \mathrm{k}(x_i, x_j)$
2: Initialize an $(n \times m \times * \times *)$-array B (where * means that the sizes may change dynamically)
3: $B[i|1| :, :] \leftarrow U^{(i)}$ for all $i \in \{1, \dots, n\}$
4: **for** $d = 2$ to m **do**
5: Compute $P \leftarrow B[: |d-1| \boxplus +1, :]$
6: Set κ, ρ such that $(n \times \kappa \times \rho)$ is the size of P
7: Append an $(n \times \kappa \times 1)$-array of ones to P
8: $B[: |d| :, :] \leftarrow B[: |1| :, :] \star P[:, :, :]$
9: optional: "simplify" the low-rank presentation encoded in B, reducing its rank
10: **end for**
11: Compute $U \leftarrow B[: |m|\Sigma, :]$
12: Return U

Algorithm 5 is obtained as follows:

- The previous Algorithm 4 transforms for any pair $x_i, x_j \in \mathcal{X}^+$ a low rank representation $(U^{(ij)}, V^{(ij)})$ of the $(\ell_i \times \ell_j)$-matrix $K^{(ij)} = (\nabla_{a,b} \mathrm{k}(x_{i,a}, x_{j,b}))_{a,b}$ into a low-rank representation $(R^{(ij)}, S^{(ij)})$ such that

$$\mathrm{k}^+(x_i, x_j) = 1 + \sum_{a \geq 1, b \geq 1} \left(R^{(ij)} \bullet (S^{(ij)})^\top \right)_{a,b}.$$

  But if $U^{(ij)}$ is independent of j and if $V^{(ij)}$ is independent i, then $R^{(ij)}$ will depend by Algorithm 4 only on i and $S^{(ij)}$ will depend only on j; hence $R^{(ij)} = S^{(ji)}$. If we denote $R^{(i)} := R^{(ij)} := S^{(ji)}$, then in above Algorithm 5, $B[i, m, a, r]$ equals $R^{(i)}_{a,r}$ when the end of the for loop is reached, line 10.

- Write

$$\mathrm{k}_m^+(x_i, x_j) = 1 + \sum_{\substack{a \geq 1 \\ b \geq 1}} \left(R^{(i)} \bullet (R^{(j)})^\top \right)_{a,b} = 1 + \sum_{k=1}^{r'} \left(\sum_{a \geq 1} R^{(i)}_{a,k} \sum_{b \geq 1} R^{(j)}_{b,k} \right)$$
$$= \sum_{k=1}^{r'+1} \bar{R}_{i,k} \bar{R}_{j,k}$$

  where we denote with r' the rank of $(R^{(i)}, R^{(j)})$ and set $\bar{R}_{i,k} := \sum_{a \geq 1} R^{(i)}_{a,k}$ and $\bar{R}_{a,k} := 1$ if $k = r' + 1$. Hence, $(\bar{R}, \bar{R})$ is a low-rank representation of the $(n \times n)$-Gram matrix $K = (\mathrm{k}_m^+(x_i, x_j))_{i,j}$. In Algorithm 5, the array entry $U[i, r']$ equals $\bar{R}_{i,r'}$, line 11.

Remark 6.12 *Line 1 requires that for each pair of sequences $x_i = (x_{i,a})_{a=1,\dots,\ell_i}, x_j = (x_{j,b})_{b=1,\dots,\ell_j} \in \mathcal{X}^+$ we compute the $(\ell_i \times \ell_j)$-matrix $K^{(ij)}$ with entries $K^{(ij)}_{a,b} = \mathrm{k}(x_{i,a}, x_{j,b})$. That is, the matrices $U^{(i)}$, when row-concatenated, should have low rank*[15]*. Jointly low-rank $U^{(i)}$ can be obtained by running a suitable joint diagonalization or singular value decomposition scheme on the matrices $K^{(ij)}$.*

Remark 6.13 (Fast sequential kernel methods) *By Section 5, fast string kernel methods such as the gappy, substitution, or mismatch kernels presented in Leslie and Kuang (2004) may be transferred to general sequential kernels. In general, this amounts to small modification of Algorithm 3; for example, to obtain a gappy variant of the sequential kernel, summation in line 6 of Algorithm 3 over the whole matrix, of quadratic size, is replaced by summation over a linear part of it.*

7. Experimental validation

We perform two experiments to validate the practical usefulness of the signature kernels:

(1) On a real world data set of hand movement classification (eponymous UCI data set Sapsanis et al. (2013)), we show the discretized signature kernel outperforms the best previously reported predictive performance Sapsanis et al. (2013), as well as non-sequential kernel and aggregate baselines.

(2) On a real world data set on hand written digit recognition (pendigits), we show that the discretized signature kernel over the Euclidean kernel (= linear use of signature features) achieves only sub-baseline performance. Using the discretized signature kernel over a Gaussian kernel improves prediction accuracy to the baseline region.

We emphasize that our experiments do not constitute a systematic benchmark comparison to prior work, only validation that the signature kernel is a practically meaningful concept: experiment (1), shows that the sequentialization of standard kernels can achieve state-of-the-art performance on time series data; experiment (2) shows that even for paths in low dimensions, $\mathcal{X} = \mathbb{R}^2$, using a non-linear static kernel for the sequentialization outperforms the linear kernel (the latter corresponds to learning with signature features of a 2-dimensional path; the former, corresponds to learning with signature features of the path lifted to the RKHS $\mathcal{H}$ of the non-linear kernel).

A systematic benchmark comparison is likely to require a larger amount of work, since it would have to include a number of previous methods (multiple variants of the string and general alignment kernels, dynamic time warping, naive use of signatures), for most of which there is no freely available code with interface to a machine learning toolbox, and benchmark methods (order-agnostic baselines such as summary aggregation and chunking; distributional regression; naive baselines).

15. For example, if k is the Euclidean scalar product, $U^{(i)}$ can be taken as the raw data matrix, where rows are different time points and columns are features.

7.1. Validation and prediction set-up

7.1.1. Prediction tasks

In all data sets, samples are multi-variate (time) series. All learning tasks are supervised classification tasks of predicting class labels attached to series of equal length.

7.1.2. Prediction methods

For prediction, we use eps-support vector classification (as available in the python/scikit-learn package) on the kernel matrices obtained from the following kernels:

(1.a) the Euclidean kernel $\mathrm{k}(x, y) = \langle x, y \rangle$. This kernel has no parameters.

(1.b) the Gaussian kernel $\mathrm{k}(x, y) = \exp\left(\frac{1}{2}\gamma^2 \|x - y\|^2\right)$. This kernel has one parameter, a scaling constant γ.

(2.a) the (truncated) discretized signature kernel k_m^+ over the linear/Euclidean kernel $\mathrm{k}(x, y) = \gamma\langle x, y \rangle$. This kernel has two parameters, a scaling constant γ, and the truncation degree m.

(2.b) the (truncated) discretized signature k_m^+ over the Gaussian kernel $\mathrm{k}(x, y) = \theta \exp\left(\frac{1}{2}\gamma^2 \|x - y\|^2\right)$. This kernel has three parameters: scaling constants γ and θ, and truncation degree m.

(1.a) and (1.b) are considered standard kernels, (2.a) and (2.b) are discretized signature kernels. Note that the kernels (1.a) and (1.b) can only be applied to sequential data samples of equal length which is the case for the data sets considered. Even though (1.a), (1.b) may be applied to sequences of same length, they do not use any information about their ordering: both the Euclidean and the Gaussian kernel are invariant under (joint) permutation of the order of the indexing in the arguments. Another subtlety is that the discretized signature kernels (2.a), (2.b) do use information about the ordering of the sequences, but only for a truncation $m \geq 2$. For $m = 1$, the kernel corresponds to choosing the increment/mean aggregate feature (Euclidean) or a type of distributional classification (Gaussian). We will therefore explicitly compare truncation degrees 1 versus 2 and higher, to enable us to make a statement about whether using the order information was beneficial (or not).

7.1.3. Tuning and error estimation

In all experiments, we use nested (double) cross-validation for parameter tuning (inner loop) and estimation of error metrics (outer loop). In both instances of cross-validation, we perform uniform 5-fold cross-validation.

Unless stated otherwise, parameters are tuned on the tuning grid given in Table 3 (when applicable). Kernel parameters are the same as in the above section "prediction mehods". The best parameter is selected by 5-fold cross-validation, as the parameter yielding the minimum test-f1-score, averaged over the five folds.

parameter	range
kernel param. γ	0.01, 0.1, 1
kernel param. θ	0.01, 0.1, 1
truncation degree m	1,2,3
SVC regularizer	0.1, 1, 10, 100, 1000

Table 3: Tuning grid

7.1.4. Error metrics

The out-of-sample classification error is reported as precision, recall, and f1-score of out-of-sample prediction on the test fold. Errors measures are aggregated with equal weights on classes and folds. These aggregates are reported in the result tables.

7.2. Experiment: Classifying hand movements

We performed classification with the eps-support vector machine (SVC) on the hand movements data set from UCI Sapsanis et al. (2013). The first database in the data set which we considered for this experiment contains, for each of five subjects (two male, three female) 180 samples of hand movement sEMG recordings. Each sample is a time series in two variables (channels) at 3.000 time points. The time series fall into six classes of distinct types of hand movement (spherical, tip, palmar, lateral, cylindrical, hook). For each subject, 30 samples of each class were recorded. Hence, for each subject, there is a total of 180 sequences in $\mathcal{X}^{3000}$ with $\mathcal{X} = \mathbb{R}^2$.

For each of the five subjects, we conducted the classification experiment as described in Section 7.1, comparing prediction via SVC using one of the following kernels: (1.a) the Euclidean kernel, (1.b) the Gaussian kernel, (2.a) the sequentialized Euclidean kernel. For the non-sequential kernels (1.a), (1.b), prediction was performed with and without prior standardization of the data. For the sequential kernel, the tuning grid was considered in two parts: a truncation degree of $m = 1$, corresponding to mean aggregation, and truncation degrees of $m = 2, 3$, corresponding to the case where genuine sequence information is used. Further, we use the low-rank speed, Algorithm 5, to compute the Gram matrix.

The results are reported in Tables 4 to 8. Jackknife standard errors (pooling the five folds) are all 0.04 or smaller. Baseline performance of an uninformed estimator is $1/6 \approx 0.17$.

One can observe that for all five subjects, SVC with sequential kernel of degree 2 or higher

method	precision	recall	f1-score
(1.a) linear	0.37	0.38	0.36

outperforms SVC using any of the other kernels not using any sequence information. The sequence kernel outperforms the reported methods from the original paper Sapsanis et al. (2013) as well (Figures 11 and 12).

(2.a) sequential, degree ≥ 2	0.93	0.93	0.93

Table 8: male2.mat

7.3. Experiment: Pendigits

We performed classification on the pendgits data set from the UCI repository[16]. It contains 10992 samples of digits between 0 and 9 written by 44 different writers with a digital pen on a tablet. One sample consists of a pair of horizontal and vertical coordinates of sampled at 8 different time points, hence we deal with a sequence in $\mathcal{X}^8$ with $\mathcal{X} = \mathbb{R}^2$. The data set comes with a pre-specified training fold of 7494 samples, and a test fold of 3498 samples. Estimation of the prediction error is performed in this validation split, while tuning is done as described via nested 5-fold cross-validation, inside the pre-specified training fold.

We compared prediction via SVC using one of the following three kernels: (2.a) the sequentialized Euclidean kernel, and (2.b) the sequentialized Gaussian kernel. For both, the truncation degree was set to $m = 4$. The results are reported in Table 9. Jackknife standard errors (pooling the five folds) are all 0.01 or smaller. Baseline performance of an uninformed estimator is $1/10 \approx 0.10$.

16. `https://archive.ics.uci.edu/ml/datasets/Pen-Based+Recognition+of+Handwritten+Digits`

method\method	precision	recall	f1-score
sequential, linear	0.91	0.90	0.89
sequential, Gaussian	0.97	0.97	0.97

Table 9: Pendigits

The quality of the SVC prediction with the sequentialzed linear kernel is comparable to results reported in Diehl (2013). It is outperformed by SVC prediction with the sequentialized Gaussian kernel. The latter performance is similar to the baseline performance of k-nearest neighbors reported in the documentation of the pendigits data set.

Appendix A. Signatures, and proofs of Theorem 1 and Theorem 3

A.1. Signatures

Definition A.1 *Let E be a normed space and denote with $L(\mathcal{H}, E)$ the set of continuous linear maps from $\mathcal{H}$ to E. Given $x \in C^1([0,1], \mathcal{H})$ and $y \in C^1([0,1], L(\mathcal{H}, E))$, the Riemann–Stieltjes integral of y over $[a,b] \subseteq [0,1]$ is defined as the element in E given as*

$$\int_a^b y \, \mathrm{d}x := \lim_{\mathrm{mesh}(\pi) \to 0} \sum_{i=1}^{l} y(t_i) \left(x(t_{i+1}) - x(t_i) \right)$$

where the limit is taken over all partitions $\pi = \{a \leq t_1 < \cdots < t_l \leq b\}$ and $\mathrm{mesh}(\pi) := \max_{i=1,\ldots,l-1} |t_{i+1} - t_i|$. We also use the shorter notation $\int y \, \mathrm{d}x$ if the integration domain is clear from the context.

See (Lyons, 2004, Theorem 1.16) for a proof of a more general result. Applying the above with E being the subspace of $\prod_{m \geq 0} \mathcal{H}^{\otimes m}$ of square summable tensors and the linear map being tensor multiplication, gives the series

$$\mathrm{S}(x) := (\mathrm{S}_m(x))_{m \geq 0} := \left(\int \mathrm{d}x^{\otimes m} \right)_{m \geq 0} \in \prod_{m \geq 0} \mathcal{H}^{\otimes m}$$

with $\int \mathrm{d}x^{\otimes 0} := 1$ and $\int \mathrm{d}x^{\otimes (m+1)} := \int \mathrm{d}x^{\otimes m}$.

A.2. Proof of Theorem 1

This is more or less a folk theorem in rough path theory, but we recall it for readers not familiar with the subject. Point (1) of Theorem 1 follows since $\mathrm{S}(h)$ is itself a solution of a linear ODE driven by h and this solution map is continuous, see Lyons (2004). Point (2) is

more involved and we refer to Hambly and Lyons (2010). For the last point, Point (3), the key insight is that the series $\mathrm{S}(h)$ behaves like monomials.

Theorem 5 (Shuffle product) *Let $h \in C^1([0,1],\mathcal{H})$, then*

$$\int \mathrm{d}h^{\otimes m} \otimes \int \mathrm{d}h^{\otimes m'} = \sum_{\sigma} \sigma\left(\int \mathrm{d}h^{\otimes (m+m')}\right).$$

Here the sum is taken over all ordered shuffles $\mathrm{OS}_{m,m'}$ which are defined as

$$\left\{\sigma : \sigma \text{ permutation of } \left\{1,\dots,m+m'\right\}, \sigma(1) < \cdots < \sigma(m), \sigma(m+1) < \cdots < \sigma\left(m+m'\right)\right\}.$$

and $\sigma \in \mathrm{OS}_{m,m'}$ acts on $\mathcal{H}^{\otimes(m+m')}$ as $\sigma\left(e_{i_1}\otimes\cdots\otimes e_{i_{m+m'}}\right) = e_{\sigma(i_1)}\otimes\cdots\otimes e_{\sigma(i_{m+m'})}$.

The proof of above is given in (Lyons, 2004, Theorem 2.29 (ii)). A direct consequence by applying Stone–Weierstrass (in analogy to classic monomials) is that *linear* functionals of signatures approximate *nonlinear* functions of paths aribtrary well, thus showing Point (3) of Theorem 1.

A.3. Proof of Theorem 3 and Corollaries 4.3 and 4.4

Definition A.2 *Denote with $\Delta^{\ell}_{[a,b]}$ the n-simplex over the interval $[a,b]$, that is*

$$\Delta^{\ell}_{[a,b]} = \{(t_i)_{i=1}^{\ell} : a = t_1 < \cdots < t_\ell = 1\},$$

and with $\Delta_{[a,b]} = \bigcup_{\ell\geq 2} \Delta^{\ell}_{[a,b]}$. If the interval $[a,b]$ is clear from the context is clear, then we just write Δ^{ℓ} and Δ.

The following notation for sequences becomes useful.

Notation A.3 *For $n \geq 1$ denote*

1. *$[n] := \{1,\dots,n\}$,*
2. *sequences in $[n]$ as $\boldsymbol{i} = (i_1,\dots,i_l) \in [n]^l$ and call $|\boldsymbol{i}| = l$ the length of the sequence $\boldsymbol{i}$,*
3. *$d(\boldsymbol{i}) := \max\{r : i_1 = i_2 = \cdots = i_r\}$ the number of repetitions of the first element in the sequence $\boldsymbol{i}$ where by convention $d(\boldsymbol{i}) = 0$ if $i_1 \neq i_2$,*
4. *$\boldsymbol{i}! := n_1!\cdots n_k!$ if $\boldsymbol{i}$ consists of $k = |\{i_1,\dots,i_l\}|$ different elements in $[n]$ and $n_1,\dots,n_k$ denote the number of times they occur in $\boldsymbol{i}$,*
5. *$\boldsymbol{i} \sqsubset [n]$ if $\boldsymbol{i} = (i_1,\dots,i_l) \in [n]^l$ and $i_1 < \cdots < i_l$,*
6. *$\boldsymbol{i} \sqsubseteq [n]$ if $\boldsymbol{i} = (i_1,\dots,i_l) \in [n]^l$ and $i_1 \leq \cdots \leq i_l$,*
7. *$\boldsymbol{i} \sqsubseteq_d [n]$ if $\boldsymbol{i} \sqsubseteq [n]$ and no element in the sequence $\boldsymbol{i}$ appears more than than d times.*

Lemma A.4 *Let $h \in C^1([a,b],\mathcal{H})$, $\pi \in \Delta^{\ell}_{[a,b]}$ and define $h^{\pi} = (h(t_i))_{i=1,\dots,\ell} \in \mathcal{H}^+$. For any sequence $\boldsymbol{i} = (i_k)_{k=1,\dots,m} \in [\ell]^m$ with $1 \leq i_1 \leq \cdots \leq i_m \leq \ell$ denote $\Delta_{\boldsymbol{i}} := \Delta \cap \bigtimes_{k=1}^{m-1}[t_{i_k}, t_{i_k+1}]$. Then*

$$\mathrm{S}_m(h) - \mathrm{S}^+_m(h^{\pi}) = \sum_{\boldsymbol{i}} \int_{\Delta_{\boldsymbol{i}}} \mathrm{d}h^{\otimes m},$$

where the sum is taken over all $\boldsymbol{i} = (i_k)_{k=1}^m$ with $1 \leq i_1 \leq \cdots \leq i_m \leq \ell$ that have at least one repeating index, that is $i_k = i_{k+1}$ for at least one $1 \leq k \leq m-1$. Moreover, each term in above sum can be bounded as follows

$$\left\|\int_{\Delta_{\boldsymbol{i}}} \mathrm{d}h^{\otimes m}\right\|_{\mathcal{H}} \leq \frac{1}{\boldsymbol{i}!} \prod_{i\in\boldsymbol{i}} \|h|_{[t_i,t_{i+1}]}\|_1.$$

where we use $\boldsymbol{i}!$ as introduced in Notation A.3.

Proof We can decompose Δ into a disjoint union of $\Delta_{\boldsymbol{i}}$ over all sequences $\boldsymbol{i}$, with $1 \leq i_1 \leq \cdots \leq i_m \leq \ell$, hence

$$\mathrm{S}_m(h) = \int \mathrm{d}h^{\otimes m} = \sum_{\boldsymbol{i}} \int_{\Delta_{\boldsymbol{i}}} \mathrm{d}h^{\otimes m}.$$

Split the sum $\sum_{\boldsymbol{i}}$ into a sum over $\boldsymbol{i}$ that have an repeating element, i.e. $i_k = i_{k+1}$ for at least one k, and a sum $\sum_{\boldsymbol{i}}$ over indices that do not have repeating elements. For the latter, the integration can be done explicitly and this sum equals

$$\sum_{\boldsymbol{i}} \nabla_{i_1} h \otimes \cdots \otimes \nabla_{i_m} h$$

with our usual notation $\nabla_i h = h(t_{i+1}) - h(t_i)$. However, this is exactly $\mathrm{S}^+_m(h)$, hence the first statement follows.

For the first sum over sequences $\boldsymbol{i}$ with repeating elements, denote with $\bar{i}_1,\dots,\bar{i}_k$ the distinct indices in $\boldsymbol{i}$, and $n_1,\dots,n_k$ the total counts of their respective occurrences. Then $\Delta_{\boldsymbol{i}} = \bigtimes_{j=1}^k \bar{\Delta}_j$ with $\bar{\Delta}_j := \Delta^{n_j} \cap [t_{\bar{i}_j}, t_{\bar{i}_j+1}]^{n_j}$ and it follows that

$$\int_{\Delta_{\boldsymbol{i}}} \mathrm{d}h^{\otimes m} = \bigotimes_{j=1}^k \int_{\bar{\Delta}_j} \mathrm{d}h^{\otimes n_j}.$$

Therefore, we obtain

$$\left\|\bigotimes_{j=1}^k \int_{\bar{\Delta}_j} \mathrm{d}h^{\otimes n_j}\right\|_{\mathcal{H}} = \prod_{j=1}^k \left\|\int_{\bar{\Delta}_j} \mathrm{d}h^{\otimes n_j}\right\|_{\mathcal{H}} \leq \frac{1}{\boldsymbol{i}!} \prod_{i\in\boldsymbol{i}} \|h|_{[t_i,t_{i+1}]}\|_1.$$

■

This is enough to prove our main approximation result:

Theorem 6 *Let $h \in C^1([0,1],\mathcal{H})$ let $\pi \in \Delta^{\ell}$. Then for every $m \geq 0$*

$$\|\mathrm{S}_m(h) - \mathrm{S}^+_m(h^{\pi})\|_{\mathcal{H}^{\otimes m}} \leq g_m$$

where (g_m) are the coefficients in the Taylor expansion around 0 of the function

$$g(z) := \sum_{m=1}^{\infty} g_m \cdot z^m := \exp(z \cdot \|h\|_1) - \prod_{i=1}^{\ell-1} \left(1 + z \cdot \|h|_{[t_i,t_{i+1}]}\|_1\right).$$

Moreover,

$$\|\operatorname{S}(h) - \operatorname{S}^+(h^\pi)\| \leq \exp(\|h\|_1) - \prod_{i=1}^{\ell-1} \left(1 + \|h|_{[t_i,t_{i+1}]}\|_1\right)$$

If π is chosen such that $\|h|_{[t_i,t_{i+1}]}\|_1 = \frac{1}{\ell-1}\|h\|_1$ for all $i = 1, \dots, \ell-1$, then

$$\|\operatorname{S}(h) - \operatorname{S}^+(h)\| \leq \frac{\exp(\|h\|_1)}{\ell - 1} \left(1 + \frac{\|h\|_1^{\ell-1}}{(\ell-3)!}\right).$$

Proof The bound for $\|\operatorname{S}_m(h) - \operatorname{S}_m^+(h^\pi)\|_{\mathcal{H}^{\otimes m}}$ follows from Lemma A.4 by explicitly writing out the coefficient g_m. Applying the triangle inequality and using this bound and one obtains

$$\|\operatorname{S}(h) - \operatorname{S}^+(h^\pi)\| \leq \sum_{m=1}^{\infty} \|\operatorname{S}_m(h) - \operatorname{S}_m^+(h^\pi)\|_{\mathcal{H}^{\otimes m}} \leq \sum_{m=1}^{\infty} g_m = g(1)$$

Finally, for the special choice of a uniform partition π

$$g(1) = \exp\|h\|_1 - \left(1 + \frac{\|h\|_1}{\ell-1}\right)^{\ell-1},$$

to which we apply Euler's approximation theorem, Theorem 7, below using that $\|h|_{[a,b]}\|_1 + \|h|_{[b,c]}\|_1 = \|h|_{a,c}\|_1$. ■

The first part of Theorem 6 implies Theorem 3, the second part implies Corollary 4.4. For readers' convenience we recall Euler's well-known approximation to the exponential function.

Theorem 7 *Let $x \in \mathbb{R}, n \in \mathbb{N}$. Then,*

$$\left(1 + \frac{x}{n}\right)^n - \exp(x) = g(x,n), \quad \text{with } |g(x,n)| \leq \frac{\exp(x)}{n}\left(1 + \frac{x^n}{(n-2)!}\right).$$

In particular, it holds that

$$\lim_{n\to\infty} \left(1 + \frac{x}{n}\right)^n = \exp(x),$$

where convergence is uniform of order $O(n^{-1})$ on any compact subset of $\mathbb{R}$.

Proof All statements follow from the first, which we proceed to prove. By the binomial theorem, it holds that

$$\left(1 + \frac{x}{n}\right)^n = \sum_{k=0}^{n} \binom{n}{k} \cdot \frac{x^k}{n^k}.$$

From the definition of the binomial coefficient and an elementary computation, one obtains

$$\binom{n}{k} \cdot \frac{x^k}{n^k} = \frac{x^k}{k!} + g(x,n,k), \text{ where } \|g(x,n,k)\| \leq \frac{x^k}{k!n},$$

for $k \leq n$. For $k \geq n$, one has

$$\frac{x^k}{k!} \leq \frac{x^n}{n!} \cdot \frac{x^{k-n}}{(k-n)!}.$$

Putting together all inequalities and using the Taylor expansion of exp yields the claim. ■

To prove Corollary 4.3 we need to generalize Euler's approximation of $\exp x$ to the case when x is not divided into uniform parts, but potentially very unbalanced parts. This is done in the proposition below

Proposition A.5 *Let $x \in \mathbb{R}, n \in \mathbb{N}$, $x \geq 0$. Let $x_1, \dots, x_\ell \in \mathbb{R}$, $x_i \geq 0$ for $i = 1, \dots, \ell$ such that $\sum_{i=1}^{\ell} x_i = x$. Then,*

$$\exp(x) = \prod_{i=1}^{\ell} (1 + x_i) + g(x, x_1, \dots, x_\ell), \quad \text{where } 0 \leq g(x, x_1, \dots, x_\ell) \leq x \exp(x) \cdot \max_{i=1,\dots,\ell} x_i.$$

In particular, it holds that

$$\lim_{\max_i x_i \to 0} \prod_i (1 + x_i) = \exp(x),$$

where convergence is uniform of order $O(\max_i x_i)$ on any compact subset of $[0, \infty)$.

Proof All statements follow from the first, which we proceed to prove. We use Notation A.3 Writing out the product, we obtain

$$\prod_{i=1}^{\ell} (1 + x_i) = \sum_{\boldsymbol{i} \sqsubset [\ell]} x^{\boldsymbol{i}},$$

where abbreviatingly we have written $x^{\boldsymbol{i}} := \prod_{i \in \boldsymbol{i}} x_i$. The Taylor expansion of the exponential on the other hand yields

$$\exp(x) = \exp\left(\sum_{i=1}^{\ell} x_i\right) = \sum_{\boldsymbol{i} \sqsubset [\ell]} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}}.$$

Note the major different between both sums above being the repeating indices which may occur in the expansions of $\exp(x)$. More precisely, we obtain

$$\exp(x) - \prod_{i=1}^{m} (1 + x_i) = \sum_{\substack{\boldsymbol{i} \sqsubset [\ell] \\ \boldsymbol{i}! > 1}} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}}.$$

We further split up the sum by length of $\boldsymbol{i}$:

$$\exp(x) - \prod_{i=1}^{\ell}(1+x_i) = \sum_{m=2}^{\infty} \sum_{\substack{\boldsymbol{i}\sqsubseteq[\ell] \\ |\boldsymbol{i}|=m \\ \boldsymbol{i}!>1}} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}}.$$

Positivity of g follows from this equation and positivity of x. Now consider the map ϕ which removes the first duplicated index in an ordered index sequence $\boldsymbol{i}$ yielding a sequence of length $|\boldsymbol{i}| - 1$. On sequences of length m, the map ϕ is at most m-to-one, and surjective onto sequences of length $m-1$. Therefore,

$$\sum_{\substack{\boldsymbol{i}\sqsubseteq[\ell] \\ |\boldsymbol{i}|=m \\ \boldsymbol{i}!>1}} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}} \leq X \cdot \sum_{m=2}^{\infty} \frac{m}{2} \sum_{\substack{\boldsymbol{i}\sqsubseteq[\ell] \\ |\boldsymbol{i}|=m-1}} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}},$$

where $X = \max_i x_i$. Thus,

$$\sum_{m=2}^{\infty} \sum_{\substack{\boldsymbol{i}\sqsubseteq[\ell] \\ |\boldsymbol{i}|=m \\ \boldsymbol{i}!>1}} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}} \leq X \cdot \sum_{m=1}^{\infty} m \cdot \sum_{\substack{\boldsymbol{i}\sqsubseteq[\ell] \\ |\boldsymbol{i}|=m}} \frac{1}{\boldsymbol{i}!} x^{\boldsymbol{i}}.$$

Comparing to the expansion of $\exp(x)$ above, one observes that the right hand side is equal to

$$X \cdot \sum_{m=1}^{\infty} m \cdot \frac{x^m}{m!} = X \cdot x \sum_{m=0}^{\infty} \frac{x^m}{m!} = X \cdot x \cdot \exp(x).$$

■

The bounds in Proposition A.5 are worse than those from Euler's classic approximation result to the exponential in the case of equal x_i, by a factor of x. This is due to the fact that the bound also needs to be valid for heavily imbalanced partitions of x into x_i.

Appendix B. Higher order signature kernels and noisy observations

The discretized signature kernel was defined as inner product

$$\mathrm{k}^+ : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R} \quad \mathrm{k}^+(x,y) = \langle \mathrm{S}^+(\mathrm{k}_x), \mathrm{S}^+(\mathrm{k}_y) \rangle$$

of features S^+ that approximate the signature S, thus k^+ will approximate the signature kernel

$$\mathrm{k}^{\oplus} : \mathcal{P}_{\mathcal{X}} \times \mathcal{P}_{\mathcal{X}} \to \mathbb{R} \quad \mathrm{k}^{\oplus}(x,y) = \langle \mathrm{S}(\mathrm{k}_x), \mathrm{S}(\mathrm{k}_y) \rangle$$

when the sequences are discretizations of paths: in Section 4 we showed under Assumption 3.1 that

$$\mathrm{k}^+(x^\pi, y^{\pi'}) \to \mathrm{k}^{\oplus}(x,y) \text{ as } \max(\mathrm{mesh}(\pi), \mathrm{mesh}(\pi')) \to 0.$$

For essentially all practically relevant kernels $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ Assumption 3.1 holds whever the underlying paths x, y are of bounded variation. However, a common situation is that observations are perturbed by noise which are generically of unbounded variation.

Example B.1 *Let $\mathcal{X} = \mathbb{R}$ and $\mathrm{k}(x,y) = \langle x, y \rangle_{\mathbb{R}}$ (that is $\mathcal{H} = \mathbb{R}$). If $x \in C^1([0,1], \mathcal{X})$ and $B = (B_t)_{t\in[0,1]}$ is a Brownian motion in $\mathcal{X}$ then $\mathrm{S}(\mathrm{k}_{x+B}) \simeq \mathrm{S}(x+B) = \left(\int \mathrm{d}(x+B)^{\otimes m}\right)$ is not well-defined as a Riemann–Stieltjes integral.*

A general strategy is to replace the signature map $x \mapsto \mathrm{S}(x)$ by a a map from paths to $\prod_{m\geq 0} \mathcal{H}^{\otimes m}$ as follows: construct a sequence of bounded variation paths (x_n) that approximation x and such that $t \mapsto \left(\int_0^t \mathrm{d}x_n^{\otimes m}\right)$ converges to a $\prod_{m\geq 0}\mathcal{H}^{\otimes m}$-valued path which is called the "*(geometric) rough path lift*" of x.

Example B.2 *Constructions for mapping a path to an element of $\prod_{m\geq 0}\mathcal{H}^{\otimes m}$ are known for a wide range of stochastic processes; below we mention a few*

- Brownian motion *(leading to p-rough paths for any $p > 2$)*
- *more generally, continuous* Semimartingale *(leading to p-rough paths for any $p > 2$),*
- fractional Brownian motion *of Hurst parameter $H > \frac{1}{4}$,*
- *more generally,* Gaussian processes *(leading to p-rough paths where p depends on the regulary of the covariation process),*
- Markov processes *in continuous time (leading to p-rough paths with p depending on the generator of the Markov process).*

For details and more examples see Lyons (2004).

The notion of a geometric rough path allows to study classes of much "rougher" paths by the same approach we developed for the bounded variation case: below we provide the needed modifications for obtaining a sequentialized kernel such that $\mathrm{k}^+(x^\pi, y^{\pi'})$ is still well-defined as the mesh vanishes when x, y are paths of unbounded variation but a "rough path lift" exists (e.g. all the stochastic processes in Example B.2)

Remark B.3 *A more radical approach is to assume that the we are not only given paths as data but also the first levels of their "rough path lift", see for example Crisan et al. (2013). The same recursion applies to give a kernel, however, we do not spell out details since all benchmark data sets we are aware of, only provide path increments.*

Definition B.4 *Let $d \in \mathbb{N}$. We call the map*

$$\mathrm{S}^+_{(d)} : \mathcal{H}^+ \to \prod_{m\geq 0} \mathcal{H}^{\otimes m}, \quad (h_i)_{i=1}^{\ell} \mapsto \prod_{i=1}^{\ell} \sum_{j=0}^{d} \frac{(\nabla_i h)^{\otimes j}}{j!}$$

the discretized signature map of degree d. We denote with $\mathrm{S}^+_{(d,m)}$ the projection of $\mathrm{S}^+_{(d)}$ to $\bigoplus_{n=0}^{m} \mathcal{H}^{\otimes n}$.

Definition B.5 *Let* $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ *and* $d, m \geq 1$, $d \geq m$. *The discretized signature kernel over* k *of order* d *and at degree* m *is defined as*

$$\mathrm{k}^+_{(d,m)}(x,y) : \mathcal{X}^+ \times \mathcal{X}^+ \to \mathbb{R}, \quad \mathrm{k}^+_{(d,m)}(x,y) = \langle \mathrm{S}^+_{(d,m)}(\mathrm{k}_x), \mathrm{S}^+_{(d,m)}(\mathrm{k}_y) \rangle.$$

Remark B.6

- *The sequentialization* k^+_m *from Section 4 arises as special case of above, more general, definition:* $\mathrm{k}^+_m = \mathrm{k}^+_{(d,m)}$ *for* $d = 1$, $m \in \mathbb{N}$.
- *Readers familiar with rough paths will notice that the choice* $m = d = \lfloor p \rfloor$ *recovers the notion of* $(\mathrm{k}_{x(t)})_{t\in[0,1]}$ *lifted to a geometric* p*-rough path. However, for machine learning applications it is often beneficial to take* $d = \lfloor p \rfloor$ *to ensure convergence but to consider* $m > d$ *and find the optimal degree* m *from the data (e.g. by cross-validation).*

In analogy to the order $d = 1$ approximations discussed in Section 4, the central mathematical identity is now

$$\prod_{i=1}^{\ell-1} \sum_{m=0}^{d} \frac{(x(t_{i+1}) - x(t_i))^{\otimes m}}{m!} = \sum_{\boldsymbol{i} \sqsubseteq_d [\ell-1]} \frac{1}{\boldsymbol{i}!} \prod_{r=1}^{|\boldsymbol{i}|} (x(t_{i_r+1}) - x(t_i)) \approx \left(\int \mathrm{d}x^{\otimes m} \right)_{m \geq 0}$$

where we use Notation A.3.

Proposition B.7 *For* $x, y \in \mathcal{X}^+$, $d, m \geq 1$, $m \geq d$,

(a) $\mathrm{S}^+_{(d,m)}(\mathrm{k}_x) = 1 + \sum_{n=1}^{m} \sum_{\substack{\boldsymbol{i} \sqsubseteq_d [|x|-1] \\ |\boldsymbol{i}|=n}} \frac{1}{\boldsymbol{i}!} \prod_{r=1}^{|\boldsymbol{i}|} \nabla_{i} \mathrm{k}_x$,

(b) $\mathrm{k}^+_{(d,m)}(x,y) = 1 + \sum_{n=1}^{m} \sum_{\substack{\boldsymbol{i} \sqsubseteq_d [|x|-1] \\ \boldsymbol{j} \sqsubseteq_d [|y|-1] \\ |\boldsymbol{i}|=|\boldsymbol{j}|=n}} \frac{1}{\boldsymbol{i}!\boldsymbol{j}!} \prod_{r=1}^{|\boldsymbol{i}|} \nabla_{i_r, j_r} \mathrm{k}(x,y)$.

where $\nabla_i \mathrm{k}_x := \mathrm{k}_{x_{i+1}} - \mathrm{k}_{x_i} \in \mathcal{H}$.

Proof By definition

$$\mathrm{S}^+_{(d)}(\mathrm{k}_x) = \prod_{r=1}^{|x|-1} \sum_{n=0}^{d} \frac{1}{n!} (\nabla_r \mathrm{k}_x)^{\otimes n}.$$

Application of the (non-commutative) associative law yields

$$\prod_{r=1}^{|x|-1} \sum_{n=0}^{d} \frac{1}{n!} (\nabla_r \mathrm{k}_x)^{\otimes n} = \sum_{\boldsymbol{i} \sqsubseteq_d [|x|-1]} \frac{1}{\boldsymbol{i}!} \prod_{r=1}^{|\boldsymbol{i}|} \nabla_{i_r} \mathrm{k}_x \,.$$

Using the analogous expression for $\mathrm{S}^+_{(d)}(y)$, taking the scalar product while noting

$$\langle \prod_{r=1}^{|\boldsymbol{i}|} \nabla_{i_r} \mathrm{k}_x, \prod_{r'=1}^{|\boldsymbol{j}|} \nabla \mathrm{k}_{j_{r'}} \rangle = \delta_{|\boldsymbol{i}|,|\boldsymbol{j}|} \cdot \prod_{r=1}^{|\boldsymbol{i}|} \langle \nabla \mathrm{k}_{i_r}, \nabla_{j_r} \mathrm{k}_y \rangle.$$

and truncating at tensor degree m and restricting to $\boldsymbol{i} \sqsubseteq_d [|x|-1]$ and $\boldsymbol{j} \sqsubseteq_d [|y|-1]$ yields the claim. ∎

Remark B.8 *The appearance of the* $\boldsymbol{i}!$ *term together with* $\boldsymbol{i} \sqsubseteq_d [|x|-1]$ *makes a recursion formula more complex since one needs to keep track how many elements in* $\boldsymbol{i}$ *are equal in every recursion step. We give an effective algorithm in Section B.1 that relies on multi-way recursion.*

B.1. Computing the higher order discretized signature kernel

Algorithm 6 Evaluation of $\mathrm{k}^+_{(d,m)}$.
Input: Sequences $x, y \in \mathcal{X}^+$. A kernel $\mathrm{k} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. A truncation degree m. An approximation order d with $1 \leq d \leq m$.
Output: $\mathrm{k}^+_{(d,m)}(x,y)$

Let $\ell_x \leftarrow |x| - 1$ and $\ell_y \leftarrow |y| - 1$
Compute an $(\ell_x \times \ell_y)$ array K such that $K[i,j] = \nabla_{i,j} \mathrm{k}(x,y)$
Initialize an $(m \times d \times d \times \ell_x \times \ell_y)$-array A, all entries zero
for $n = 2$ to m **do**
  $d' \leftarrow \min(d, n-1)$

    end for
  end for
end for
Compute $R \leftarrow 1 + A[m|\Sigma,\Sigma|\Sigma,\Sigma]$
Return R

Recall that multiplications of arrays in Algorithm 6 are entry-wise (not matrix multiplications). At the end of Algorithm 6, the array A contains as elements $A[m|r,s|i,j]$ the contributions from sub-sequences $\boldsymbol{i} \sqsubseteq [\ell_x], \boldsymbol{j} \sqsubseteq [\ell_y]$, beginning at i and j, with start-sequences $iii\ldots$ of length r and $jjj\ldots$ of length s, and of total length at most m.

Proposition B.9 *Let* $x, y \in \mathcal{X}^+$, $m \geq 1$ *and* d *with* $1 \leq d \leq m$. *Define* $\ell_x = |x| - 1$, $\ell_y = |y| - 1$ *and*

$$A^{n,r,s}_{i,j} := \sum_{\substack{\boldsymbol{i} \sqsubseteq_d [\ell_x] \\ \boldsymbol{j} \sqsubseteq_d [\ell_y] \\ |\boldsymbol{i}|=|\boldsymbol{j}|=n}} \frac{1}{\boldsymbol{i}!\boldsymbol{j}!} \prod_{\kappa=1}^{n} \nabla_{i_\kappa, j_\kappa} \mathrm{k}(x_{i_\kappa}, y_{j_\kappa})$$

for every $r, s \geq 1$ *and* $i \in [\ell_x]$, $j \in [\ell_y]$ *where the sum over* $\boldsymbol{i} = (i_1, \ldots, i_n), \boldsymbol{j} = (j_1, \ldots, j_n)$ *is additionally restricted in the following way:*

$$i = i_1 = i_2 = \cdots = i_r \neq i_{r+1} \quad \textit{and} \quad j = j_1 = j_2 = \cdots = j_s \neq j_{s+1}.$$

By convention, set $A_{i,j}^{n,r,s} = 0$ *if* $r < n$ *or* $s < n$*. Then,*

$$\mathrm{k}^{+}_{(d,m)}(x,y) = 1 + \sum_{n=1}^{m}\sum_{i=1}^{\ell_x}\sum_{j=1}^{\ell_y}\sum_{r=1}^{d}\sum_{s=1}^{d} A_{i,j}^{n,r,s} \tag{5}$$

and the following equalities hold

$$A_{i,j}^{n,r,s} = \frac{1}{rs}\cdot\nabla_{i,j}\,\mathrm{k}(x,y)\cdot A_{i,j}^{n-1,r-1,s-1}, \tag{6}$$

$$A_{i,j}^{n,1,1} = \nabla_{i,j}\,\mathrm{k}(x,y)\cdot\left(1+\sum_{i'>i}\sum_{j'>j}\sum_{r=1}^{d}\sum_{s=1}^{d} A_{i',j'}^{n-1,r,s}\right), \tag{7}$$

$$A_{i,j}^{n,r,1} = \frac{1}{r}\cdot\nabla_{i,j}\,\mathrm{k}(x,y)\cdot\sum_{j'>j}\sum_{s=1}^{d} A_{i,j'}^{n-1,r-1,s}, \tag{8}$$

$$A_{i,j}^{n,1,s} = \frac{1}{s}\cdot\nabla_{i,j}\,\mathrm{k}(x,y)\cdot\sum_{i'>i}\sum_{r=1}^{d} A_{i',j}^{n-1,r,s-1}, \tag{9}$$

for $r,s \geq 2$*,* $i \in [\ell_x]$*,* $j \in [\ell_y]$*.*

Proof By Proposition B.7

$$\begin{aligned}\mathrm{k}^{+}_{(d,m)}(x,y) &= 1 + \sum_{n=1}^{m}\sum_{\substack{\boldsymbol{i}\sqsubseteq_d[\ell_x]\\ \boldsymbol{j}\sqsubseteq_d[\ell_y]\\ |\boldsymbol{i}|=|\boldsymbol{j}|=n}}\frac{1}{\boldsymbol{i}!\boldsymbol{j}!}\prod_{r=1}^{n}\nabla_{i_r,j_r}\,\mathrm{k}(x,y)\\ &= 1 + \sum_{\substack{\boldsymbol{i}\sqsubseteq_d[\ell_x]\\ \boldsymbol{j}\sqsubseteq_d[\ell_y]}}\frac{1}{\boldsymbol{i}!\boldsymbol{j}!}\nabla_{i_1,j_1}\,\mathrm{k}(x,y)\,(1+\nabla_{i_2,j_2}\,\mathrm{k}(x,y)\,(1+\cdots(1+\nabla_{i_m,j_m}\,\mathrm{k}(x,y)))\cdots)\end{aligned}$$

and the first equality shows the identity (5) by explicitly summing over that starting point of sequences and the number of repeated elements. Equality (6) follows directly by definition of $A_{i,j}^{n,r,s}$ and that for $\boldsymbol{i} = (i_1, i_2, \ldots, i_n)$ with $d(\boldsymbol{i}) = r$ and $\boldsymbol{i}' = (i_2, \ldots, i_n)$ we have $\boldsymbol{i}! = \frac{1}{r}(\boldsymbol{i}'!)$. Equality (7) follows since

$$\begin{aligned}\{\boldsymbol{i} = (i_1,\ldots,i_n) : d(\boldsymbol{i}) = 0,\, i_1 = i\} &= \{(i,\boldsymbol{i}') : \boldsymbol{i}' = (i_1',\ldots,i_{n-1}'),\, i_1' > i\}\\ &= \bigcup_{r=0}^{d}\{(i,\boldsymbol{i}') : \boldsymbol{i}' = (i_1',\ldots,i_{n-1}'),\, i_1' > i,\, d(\boldsymbol{i}') = r\}\end{aligned}$$

where in above equalities we implicitly additionally assume that all indices $\boldsymbol{i}$, $\boldsymbol{i}'$ are increasing (that is, $i_1 \leq \cdots \leq i_n$, $i_1' \leq \cdots \leq i_{n-1}'$). Equalities (8),(9) follow similarly. ■

Remark B.10 *The computational cost of Algorithm 6 is* $O(d^2 m|x||y|)$ *elementary arithmetic operations (= the number of loop elements) and* $O(d^2|x||y|)$ *units of elementary storage (when freeing up space for array entries directly after the last time they are read out).*

Remark B.11 *The higher order Algorithm 6 can be combined with the low-rank techniques analogous to the treatment of the order* $d = 1$ *algorithm in Section 6 by applying the low-rank representation to the matrices/2D-arrays* $A[m|i,j|\,:,:]$*. Since all assignments and manipulations can be re-phrased in those matrices, the same strategy applies.*

Abstract

Semantic data mining (SDM) is a form of relational data mining that uses annotated data together with complex semantic background knowledge to learn rules that can be easily interpreted. The drawback of SDM is a high computational complexity of existing SDM algorithms, resulting in long run times even when applied to relatively small data sets. This paper proposes an effective SDM approach, named NetSDM, which first transforms the available semantic background knowledge into a network format, followed by network analysis based node ranking and pruning to significantly reduce the size of the original background knowledge. The experimental evaluation of the NetSDM methodology on acute lymphoblastic leukemia and breast cancer data demonstrates that NetSDM achieves radical time efficiency improvements and that learned rules are comparable or better than the rules obtained by the original SDM algorithms.

Keywords: data mining, semantic data mining, ontologies, subgroup discovery, network analysis

1. Introduction

In data mining applications, relevant information can be scattered across disparate resources in heterogeneous data formats. Extraction of knowledge from large heterogeneous data is technically challenging and time consuming, and presents a significant obstacle to wider adoption of data mining in real-life applications. While most of the data mining algorithms (Witten and Frank, 2005) work only with tabular data, *relational data mining* (RDM) (Džeroski and Lavrač, 2001) and *relational learning* (De Raedt, 2008) algorithms can use additional relational information about the analyzed data to build richer and more accurate predictive models. One such form of additional information is domain knowledge (relational background knowledge) about instances of a data set. As shown by Page et al. (2012) and Peissig et al. (2014), relational data mining can significantly outperform classical machine learning approaches.

Previous work on RDM has shown that the use of *background knowledge* is vital for data analysis in many domains. However, the issue with using more complex data (i.e., data along with relations and background knowledge) is that it can no longer be easily represented in a tabular format (also referred to as a design matrix (Rendle, 2013)). Better data representations are needed when instances under examination are interconnected to a various (non-fixed) number of instances. Representing each connection from an instance as a separate column would result in a different number of columns for each row. Alternatively, if we encoded connections of an instance with a single column, columns would have to contain composite data structures such as lists. In RDM, this problem is addressed by representing data sets with *multi-relational databases* and by applying specialized relational data mining algorithms for data analysis (Džeroski and Lavrač, 2001). Examples of such instances are genes that are connected through mutual activation, or research papers connected through citations.

An alternative way to describe a data set containing inter-connected instances is to represent it as a *network* (Burt and Minor, 1983), a data structure containing nodes, information about the nodes, and connections between the nodes. In mathematical terms, such a structure is described as a *graph*, where the nodes are referred to as vertices, and the connections as edges. The field of *network analysis* deals with several types of networks. In social networks, nodes represent people and connections represent their social links. Biological networks include gene regulatory networks, protein interaction networks, drug interaction networks, etc. In information networks, directed connections encode information flow between the network nodes. While most researchers deal with *homogeneous information networks*, where all nodes and edges are of the same node/edge type, Sun and Han (2012) addressed the problem of *heterogeneous information network* analysis, where nodes and edges belong to different node or edge types. For example, we may have a network containing both the genes and the proteins they encode, which necessitates the use of two node types to represent the data. Sun and Han (2012) introduced the concept of *authority ranking* for heterogeneous information networks, where the impact of a node is transferred along the edges to simultaneously rank nodes of different types, while class labels can also be propagated through the network (Vanunu et al., 2010).

Network analysis can be considered as a form of relational learning, where instances are linked by relations and connected in a complex graph. Special form of relational data are *ontologies* (Guarino et al., 2009). The challenge of incorporating domain ontologies in the data mining process has been addressed in the work on *semantic data mining* (SDM) (Lavrač and Vavpetič, 2015). Semantic data mining can discover complex rules describing subgroups of data instances that are connected to terms (annotations) of an ontology, where the ontology is referred to as background knowledge used in the learning process. An example SDM problem is to find subgroups of enriched genes in a biological experiment, where background knowledge is the Gene Ontology (Ashburner et al., 2000).

Given that SDM algorithms are relatively slow, the size of the background knowledge used by SDM approaches is usually several orders of magnitude lower than the problems typically handled by network analysis approaches. Take for example SDM algorithm Hedwig (Vavpetič et al., 2013), which is one of the semantic data mining algorithm used in this work. Hedwig performs beam search to explore the space of all possible explanations to find the best rules explaining the data. The search space it explores is very large and even using an adequate heuristic to guide the search, the algorithm takes a long time to find relevant patterns in real-life data annotated by ontological background knowledge. As illustration,

take a SDM application where Hedwig was applied to a data set of 337 examples and a background knowledge of 21,062 interconnected ontology terms (Vavpetič et al., 2013), which is small compared to typical network analysis applications that deal with much larger data sets, possibly composed of e.g., hundred millions network nodes.

Despite large differences in the current sizes of data sets analyzed by SDM and network analysis approaches, the two research fields are aligned in terms of the research question of interest, which can be posed as follows: *Which part of the network structure is the most important for the analyst's current query?* The challenge addressed in this work is the reduction of the search space of SDM algorithms, which can be achieved by using network analysis approaches. To this end, we have developed an approach that is capable of utilizing network analysis algorithms Personalized PageRank (Page et al., 1999) and node2vec (Grover and Leskovec, 2016) to improve the efficiency of SDM. We show that the proposed approach, named NetSDM, can efficiently generate high quality rules by investigating only a fraction of the entire search space imposed by the background knowledge considered.

The rest of the paper is structured as follows. Section 2 presents the related work, as well as the technologies used; we first introduce the semantic data mining algorithms used, Hedwig and Aleph (Srinivasan, 1999), and then present the two network analysis algorithms, Personalized PageRank and node2vec. Section 3 presents the proposed NetSDM approach that exploits network analysis to reduce the size of the background knowledge used by SDM algorithms. Section 4 presents the experimental setup, and Section 5 presents the experimental results. Section 6 concludes the paper and presents plans for further work.

2. Related work and background technologies

This section presents the related work in the fields of semantic data mining and network analysis. It starts with the related work in the field of semantic data mining in Section 2.1, which presents also the two algorithms used in our experiments: Hedwig and Aleph. It continues with the related work in the field of network analysis in Section 2.2, and includes the two algorithms used in our experiments: Personalized PageRank and node2vec.

2.1. Semantic data mining

To find patterns in data annotated with ontologies, we rely on semantic data mining (SDM) (Dou et al., 2015; Lavrač and Vavpetič, 2015). In SDM, the input is composed of a set of class labeled instances and the background knowledge encoded in the form of ontologies, and the goal is to find descriptions of target class instances as a set of rules of the form `TargetClass` ← `Explanation`, where the explanation is a logical conjunction of terms from the ontology. Semantic data mining has its roots in symbolic rule learning, subgroup discovery and enrichment analysis research, briefly explained below.

2.1.1. Rule learning and subgroup discovery

One of the established techniques for data mining (Piatetsky-Shapiro, 1991) is symbolic rule learning (Fürnkranz et al., 2012). While rule learning was initially focused on learning predictive models in the form of classification rules, there is also a substantial research in descriptive rule learning, including association rule learning (Agrawal and Srikant, 1994), that aims at finding interesting descriptive patterns in the unsupervised as well as in supervised learning settings (Liu et al., 1998).

Building on classification and association rule learning, subgroup discovery techniques aim at finding interesting patterns as sets of rules that best describe the target class (Klösgen, 1996; Wrobel, 1997). Typical output of subgroup discovery algorithms are rules where the rule condition (`Explanation`) is a conjunction of features (attribute values) that characterize the target class instances covered by the rule, and each rule describes a particular interesting subgroup of target class instances.

2.1.2. Using ontologies in enrichment analysis

Enrichment analysis (EA) techniques are statistical methods used to identify putative explanations for a set of entities based on over- or under-representation of their attribute values, which can be referred to as *differential expression*. In life sciences, EA is widely used with the Gene Ontology (GO) (Ashburner et al., 2000) to profile the biological role of genes, such as differentially expressed cancer genes in microarray experiments (Tipney and Hunter, 2010).

While standard EA provides explanations in terms of concepts from a single ontology, researchers are increasingly combining several ontologies and data sets to uncover novel associations. The ability to detect patterns in data sets that do not use only the GO can yield valuable insights into diseases and their treatment. For instance, it was shown that Werner's syndrome, Cockayne syndrome, Burkitt's lymphoma, and Rothmund-Thomson syndrome are all associated with aging related genes (Puzianowska-Kuznicka and Kuznicki, 2005; Cox and Faragher, 2007). On the clinical side, EA can be used to learn adverse events from Electronic Health Record (EHR) data such as increased comorbidities in rheumatoid arthritis patients (LePendu et al., 2013), or to identify phenotypic signatures of neuropsychiatric disorders (Lyalina et al., 2013). An ontology-based EA approach was used to identify genes linked to aging in worms (Callahan et al., 2015), aberrant pathways—the network drivers in HIV infection identifying HIV inhibitors strongly associated with mood disorders (Hoehndorf et al., 2012), or to learn a combination of molecular functions and chromosome positions from lymphoma gene expression (Jiline et al., 2011).

2.1.3. Using ontologies in rule learning

An abundance of taxonomies and ontologies that are readily available can provide higher-level descriptors and explanations of discovered subgroups. In the domain of systems biology the Gene Ontology (Ashburner et al., 2000), KEGG orthology (Ogata et al., 1999) and Entrez gene–gene interaction data (Maglott et al., 2005) are examples of structured domain knowledge. In rule learning, the terms in the nodes of these ontologies can take the role of additional high-level descriptors (generalizations of data instances) used in the induced rules, while the hierarchical relations among the terms can be used to guide the search for conjuncts of the induced rules.

The SEGS algorithm (Trajkovski et al., 2008a) was the first to combine enrichment analysis and machine learning research in the construction of rules explaining gene expression data. SEGS constructs rules where the explanation is a logical conjunction of terms from several ontologies, explaining sets of differentially expressed (target class) genes as

combinations of Gene Ontology (GO) terms, KEGG orthology terms, and terms describing gene–gene interactions obtained from the Entrez database.

The challenge of incorporating domain ontologies in data mining was addressed in SDM research by several other authors. Žáková et al. (2006) used an engineering ontology of Computer-Aided Design (CAD) elements and structures as a background knowledge to extract frequent product design patterns in CAD repositories and to discover predictive rules from CAD data. Using ontologies, the algorithm Fr–ONT for mining frequent concepts was introduced by Lawrynowicz and Potoniec (2011).

Vavpetič and Lavrač (2013) developed a SDM toolkit that includes two semantic data mining systems: SDM-SEGS and SDM-Aleph. SDM-SEGS is an extension of the earlier domain-specific algorithm SEGS (Trajkovski et al., 2008a), which supports semantic subgroup discovery in gene expression data. SDM-SEGS extends and generalizes this approach by allowing the user to input a set of ontologies in the OWL ontology specification language and an empirical data set annotated with domain ontology terms. SDM-SEGS employs a predefined selection of ontologies to constrain and guide a top-down search of the hierarchically structured hypothesis space. SDM-Aleph is an extension of the Inductive Logic Programming system Aleph (Srinivasan, 1999), which does not have the limitations of SDM-SEGS imposed by domain-specific properties of algorithm SEGS, and can accept any number of ontologies as domain background knowledge, including different relations.

In summary, semantic subgroup discovery algorithms SDM-SEGS and SDM-Aleph are either specialized for a specific domain (Trajkovski et al., 2008b) or adapted from systems that do not take into account the hierarchical structure of background knowledge (Vavpetič and Lavrač, 2013), respectively. Therefore in this work, we rather use the Hedwig algorithm (Vavpetič et al., 2013) and the original Aleph algorithm (Srinivasan, 1999), which can both accept any number of input ontologies, where Aleph can also use different types of relations.

2.1.4. Hedwig

To illustrate the rules induced by the Hedwig subgroup discovery algorithm (Vavpetič et al., 2013), take as an example a task of analyzing differential expression of genes in breast cancer patients, originally addressed by Sotiriou et al. (2006). In this task, the `TargetClass` of the generated rules is the class of genes that are differentially expressed in breast cancer patients as compared to the general population.

Rule rank	Explanation
1	chromosome ∧ cell cycle
2	cellular macromolecule metabolic process ∧ intracellular non-membrane-bounded organelle ∧ cell cycle
3	cell division ∧ nucleus ∧ cell cycle
4	regulation of mitotic cell cycle ∧ cytoskeletal part
5	regulation of mitotic cell cycle ∧ microtubule cytoskeleton
6	regulation of G2/M transition of mitotic cell cycle
7	regulation of cell cycle process ∧ chromosomal part
8	regulation of cell cycle process ∧ spindle
9	enzyme binding ∧ regulation of cell cycle process ∧ intracellular non-membrane-bounded organelle
10	ATP binding ∧ mitotic cell cycle ∧ nucleus

Figure 1: An example output of the Hedwig semantic subgroup discovery algorithm, where `Explanations` represent subgroups of genes, differentially expressed in patients with breast cancer.

The Hedwig algorithm generated ten rules (subgroup descriptions), each describing a subgroup of differentially expressed genes. In the rules, the `TargetClass` is the set of differentially expressed genes and the `Explanation` is a conjunction of Gene Ontology terms and covers the set of genes annotated by the terms in the conjunction. The resulting set of `Explanations` (rule conditions) is shown in Figure 1.

Take the first ranked rule, where the `Explanation` is a conjunction of biological concepts `chromosome` ∧ `cell cycle`, which covers all the genes that are covered by both ontology terms. Take as another example the fourth best ranked rule, which explains that the regulation of the mitotic cell cycle and cytoskeletal formation explain the breast cancer based on gene expression.

The semantic subgroup discovery task addressed by Hedwig takes three types of inputs: the training examples, the domain knowledge, and a mapping between the two.

- Data set, composed of training examples expressed as RDF (Resource Description Framework) triples in the form subject-predicate-object, e.g., geneX–suppresses–geneY. Data set S is split into a set of positive examples S_+, i.e. 'interesting' target class instances (for example, genes enriched in a particular biological experiment), and a set of negative examples S_- of non-target class instances (e.g., non-enriched genes).
- Domain knowledge, composed of domain ontologies in RDF form.
- Object-to-ontology mapping, which associates each RDF triple with an appropriate ontological concept. We refer to these object-to-ontology mappings as *annotations*, meaning that object x is *annotated by* ontology term o if the pair (x, o) appears in the mapping.

For given inputs, the output of Hedwig is a set of descriptive patterns in the form of rules, where rule conditions are conjunctions of domain ontology terms that explain a group of target class instances. Ideally, Hedwig discovers explanations that best describe and cover as many target class instances and as few non-target instances as possible.

The Hedwig algorithm uses beam search, where the beam contains the best N rules. It starts with the default rule that covers all the training examples. In every search iteration, each rule from the beam is specialized via one of the four operations: (i) replace the predicate of a rule with a predicate that is a sub-class of the previous one, (ii) negate a predicate of a rule, (iii) append a new unary predicate to the rule, or (iv) append a new binary predicate, introducing a new existentially quantified variable, where the new variable has to be 'consumed' by a literal that has to be added as a conjunction to this clause in the next step of rule refinement.

Hedwig learns rules through a sequence of specialization steps. Each step either maintains or reduces the current number of covered examples. A rule will not be specialized once its coverage is zero or falls below some predetermined threshold. When adding a new conjunct, the algorithm checks if the specialized rule improves the probability of rule consequent—to this end the redundancy coefficient is used (Hämäläinen, 2010); if not, the specialized rule is not added to the list of specializations. After the specialization step is applied to each rule in the beam, a new set of best scoring N rules is selected. If no improvement is made to the rule collection, the search terminates. In principle, the procedure supports any rule scoring function. Numerous rule scoring functions for discrete targets are available: χ^2, Precision, WRAcc (Lavrač et al., 2004), Leverage, and Lift. Note that Lift is the default measure in Hedwig (see Section 2.1.6) that was used in our experiments.

In addition to an illustrative financial use case (Vavpetič et al., 2013), Hedwig was shown to perform well in breast cancer data analysis (Vavpetič et al., 2014), as well as in a biological setting when analyzing DNA aberration data for various cancer types (Adhikari

et al., 2016), where it was a part of three-step methodology, together with mixture models and banded matrices using several ontologies obtained from various sources: hierarchical structure of multiresolution data, chromosomal location of fragile sites, virus integration sites, cancer genes, and amplification hotspots.

2.1.5. Aleph

Aleph (A Learning Engine for Proposing Hypotheses) (Srinivasan, 1999) is a general purpose system for Inductive Logic Programming (ILP) that was conceived as a workbench for implementing and testing concepts and procedures from a variety of different ILP and relational learning systems and papers. The system can construct rules, trees, constraints and features; invent abnormality predicates; perform classification, regression, clustering, and association rule learning; allows for choosing between different search strategies (general-to-specific or specific-to-general, i.e. top-down or bottom-up, bidirectional, etc.), search algorithms (hill-climbing, exhaustive search, stochastic search, etc.) and evaluation functions. It allows users to specify their own search procedure, proof strategy, and visualization of hypotheses.

Similarly to Hedwig, Aleph accepts as input a set of positively and negatively labeled training examples and a file describing the background knowledge, including a mapping between the examples and the background knowledge. The training examples are expressed as Prolog facts, and the background knowledge is in the form of Prolog facts and clauses. In contrast to Hedwig that was used in our experiments for semantic subgroup discovery, we used Aleph in its default operation mode to learn a classifier (a Theory) composed of as a set of classification rules, which also explain the target class examples.

Aleph constructs rules in several steps. It first selects a positive example and builds the most specific rule explaining the example following the steps described by Muggleton (1995). Next, the algorithm searches for a more general rule, performed with a branch-and-bound search strategy, searching first through generalizations of the rule containing the fewest terms. Finally, the rule with the best score is added to the current theory, and all the examples covered by this rule are removed (this step is sometimes called the "cover removal" step). This procedure is repeated until all the positive examples are covered.

Aleph was incorporated into the SDM-toolkit (Vavpetič and Lavrač, 2013), which allows Aleph (named SDM-Aleph) to use the same input data as Hedwig. However, a drawback of using SDM-Aleph is that it can reason only over one type of background knowledge relations, while the original Aleph algorithm can reason over any type of relations. In the case of Gene Ontology, which was used as the background knowledge in our experiments, this generality allows Aleph to encode both the *is_a* and *is_part_of* relations, which are the most frequent relations in ontologies, as well as the relationships composed of these two relations.

2.1.6. Rule quality measures

We use several measures to evaluate the quality of rules discovered by Hedwig and Aleph. Take for example rule R with a condition that is true for 80 positive instances (*True Positives*, TP) and 20 negative instances (*False Positives*, FP) from the set S of 100 positive instances (*Positives*) and 100 negative instances (*Negatives*). Coverage$(R) = TP + FP =$ 100 is the total number of instances covered by the rule. Support of the rule is calculated as follows: Support$(R) = \frac{TP+FP}{|S|} = \frac{\text{Coverage(R)}}{|S|} = 0.5$. Precision$(R) = 0.8$ is calculated as $\frac{TP}{TP+FP}$, and Accuracy$(R) = 0.8$ is calculated as $\frac{TP+TN}{|S|}$, where TN denotes the number of *True Negatives*.

In our experiments we use the Lift metric to evaluate the performance of SDM algorithms Hedwig and Aleph. Lift(R) is defined as the ratio between the precision of a rule and the proportion of positive examples in the data set (i.e. the precision of the empty default rule that classifies all examples as positive). In our example Lift$(R) = \frac{0.8}{0.5} = 1.6$, which is calculated using the following formula:

$$\text{Lift(R)} = \frac{\text{Precision}(R)}{PR} \tag{1}$$

where $PR = \frac{|Positives|}{|S|}$ is the ratio of positive instances in the data set. The range of values Lift can take is from 0 to ∞ and larger values indicate better rules.

2.2. Network analysis

Network analysis uses concepts from graph theory to investigate characteristics of networked structures in terms of nodes (such as individual actors, people, or any other objects in the network) and edges or links that connect them (relationships, interactions or ties between the objects). This section focuses on the algorithms which we used or adapted to rank nodes in information networks.

2.2.1. Node ranking: Using Personalized PageRank algorithm

The objective of node ranking in information networks is to assess the relevance of a given node either globally (with regard to the whole graph) or locally (relative to some other node or group of nodes in the graph). A network node ranking algorithm assigns a *score* (or a *rank*) to each node in the network, with the goal of ranking the nodes in terms of their relevance.

A well known node ranking method is PageRank (Page et al., 1999), which was used in the Google search engine. Other methods for node ranking include Weighted PageRank method (Xing and Ghorbani, 2004), SimRank (Jeh and Widom, 2002), diffusion kernels (Kondor and Lafferty, 2002), hubs and authorities (Kleinberg, 1999), and spreading activation (Crestani, 1997). More recent network node ranking methods include PL-ranking (Zhang et al., 2016) and NCDawareRank (Nikolakopoulos and Garofalakis, 2013). Another way to rank nodes in a network is to use network centrality measures, such as Freeman's network centrality (Freeman, 1979), betweenness centrality (Freeman, 1977), closeness centrality (Bavelas, 1950), and Katz centrality (Katz, 1953).

In this paper, we are interested in network node ranking methods that can be 'localized', i.e. which do not compute the global importance/score of a node, but rather the score of a node in the context of a given subset of other nodes. An example of this type of network node ranking approaches is the Personalized PageRank (P-PR) algorithm (Page et al., 1999), sometimes referred to as random walk with restart (Tong et al., 2006). P-PR calculates the node score locally to a given network node—it is hence especially interesting for our work because it calculates the importance of network nodes relative to a given set of

starting nodes, in our case, those representing the positive examples. In the context of data set annotation with ontologies, this allows us to estimate the importance of background knowledge terms in relation to the positive examples in the data set.

Personalized PageRank uses a random walk approach to calculate the significance of nodes in an information network. Given a set of 'starting' nodes A, the Personalized PageRank calculated for A (denoted P-PR$_A$) is defined as the stationary distribution of random walker positions, where the walk starts in a randomly chosen member of A and then at each step either selects one of the outgoing connections or teleports back to a randomly selected member of A. Probability p of continuing the walk is a parameter of the Personalized PageRank algorithm and is usually set to 0.85. In our context, the P-PR algorithm is used to calculate the importance of network nodes *with respect to* a given set of starting nodes.

Remark 1 *P-PR$_A$ is a vector, and each value of the vector corresponds to some network node u. If u is the i-th node of the network, notation P-PR$_A(u)$ is used (rather than P-PR$_{A_i}$) to denote the i-th value of P-PR$_A$.*

2.2.2. Network embedding: Using node2vec algorithm

Network embedding is a mechanism for converting networks into a tabular/matrix representation format, where each network node is represented as a vector of some predefined fixed length k, and a set of nodes is represented as a table with k columns. The goal of such a conversion is to preserve structural properties of a network, which is achieved by preserving node similarity in both representations, i.e. node similarity is converted into vector similarity.

Network nodes vectorization can be effectively performed by the node2vec algorithm (Grover and Leskovec, 2016), which uses a random walk approach to calculate features that express the similarities between node pairs. The node2vec algorithm takes as input a network of n nodes, represented as a graph $G = (V, E)$, where V is the set of nodes and E is the set of edges in the network. For a user-defined number of columns k, the algorithm returns a matrix $f^* \in \mathbb{R}^{|V|\times k}$, defined as follows:

$$f^* = \text{node2vec}(G) = \underset{f\in\mathbb{R}^{|V|\times k}}{\text{argmax}} \sum_{u\in V} \left(-\log(Z_u) + \sum_{n\in N(u)} f(n)\cdot f(u) \right) \tag{2}$$

where $N(u)$ denotes the network neighborhood of node u (to be defined below).

Remark 2 *Each matrix f is a collection of k-dimensional feature vectors, with the i-th row of the matrix corresponding to the feature vector of the i-th node in the network. We write $f(u)$ to denote the row of matrix f corresponding to node u.*

The goal of the node2vec algorithm is to construct feature vectors $f(u)$ in such a way that feature vectors of nodes that share a certain neighborhood will be similar. The inner sum of the value, maximized in Equation 2, calculates the similarities between node u and all nodes in its neighborhood: it is large if the feature vectors of nodes in the same neighborhood are collinear, however it also increases if feature vectors of nodes have a large

norm. Next, value Z_u calculates the similarities between node u and all the nodes in the network as follows:

$$Z_u = \sum_{v\in V} e^{f(u)\cdot f(v)}$$

Note that value of $-\log(Z_u)$ decreases when the norms of feature vectors $f(v)$ increase, thereby penalizing collections of feature vectors with large norms.

Equation 2 has a probabilistic interpretation that models a process of randomly selecting nodes from the network (Grover and Leskovec, 2016). In this process, probability $P(n|u)$ of node n following node u in the selection process is proportional to $e^{f(n)\cdot f(u)}$. Assuming that selecting a node is independent from selecting any other node, we can calculate the probability of selecting all nodes from a given set N as $P(N|u) = \prod_{n\in N} P(n|u)$, and Equation 2 can then be rewritten as follows:

$$f^* = \text{node2vec}(G) = \underset{f\in\mathbb{R}^{|V|\times k}}{\text{argmax}} \sum_{u\in V} \log\left(P(N(u)|f(u))\right) \tag{3}$$

Finally, let us explain neighborhood $N(u)$ in Equations 2 and 3, calculated by simulating a random walker traversing the network starting at node u. Unlike the PageRank random walker, the transition probabilities for traversing from node n_1 to node n_2 depend on node n_0 that the walker visited before node n_1, making the process of traversing the network a second order random walk. The non-normalized transition probabilities are set using two parameters, p and q, and are equal to:

$$P(n_2|\text{moved from node } n_0 \text{ to } n_1 \text{ in previous step}) = \begin{cases} \frac{1}{p} & \text{if } n_2 = n_0 \\ 1 & \text{if } n_2 \text{ can be reached from } n_1 \\ \frac{1}{q} & \text{otherwise} \end{cases}$$

The parameters of the expression are referred to as the *return* parameter p and the *in-out* parameter q. A low value of the return parameter p means that the random walker is more likely to backtrack its steps and the random walk will be closer to a breadth first search. On the other hand, a low value of parameter q encourages the walker to move away from the starting node and the random walk resembles a depth first search of the network. To calculate the maximizing matrix f^*, a set of random walks of limited size is simulated starting from each node in the network to generate several samples of sets $N(u)$.

The function maximizing Equation 2 is calculated using the stochastic gradient descent. The matrix of feature vectors node2vec(G) in Equation 2 is estimated at each generated sampling of neighborhoods $N(u)$ for all nodes in the network to discover matrix f^* that maximizes the expression for the simulated neighborhood set.

3. NetSDM methodology: Combining SDM with network analysis

SDM algorithms perform well on relatively small real world data sets, but even for small data sets the algorithms search through a very large space of possible patterns to find the 'best' pattern. The more conjuncts we allow in rule conditions and the larger the background knowledge, the larger the search space. This section presents the proposed

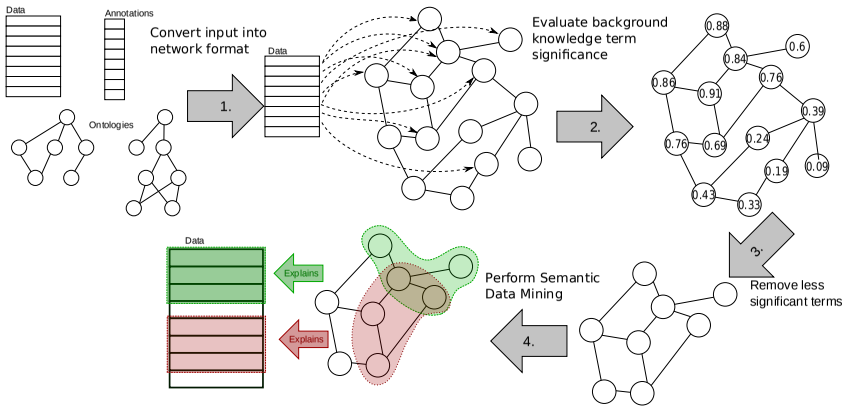

Figure 2: Illustrative outline of the proposed NetSDM methodology.

NetSDM methodology that combines semantic data mining with network analysis to reduce the search space of SDM algorithms. This section starts with an overview of the proposed methodology in Section 3.1, illustrated by an example in Section 3.2. Section 3.3 provides a detailed step-by-step description of the NetSDM methodology.

3.1. Methodology outline

SDM algorithms use heuristic search when mining for patterns in the data to limit the search to only the most promising parts of the search space. Constraining the search is necessary, as traversing the entire search space—consisting of conjuncts of logical expressions containing ontological expressions—is computationally unfeasible. However, heuristic search can produce poor results in some cases. For example, when searching for patterns with Hedwig using beam search, the beam may be too narrow, and consequently a branch that would lead to a high quality solution could be discarded early on; in large search spaces even wide beams can be quickly filled with terms that do not lead to good final solutions. Similarly, the search algorithm in Aleph can miss important patterns if all their sub-patterns exhibit low quality. In this paper we propose a new methodology, which aims to solve this problem. The proposed NetSDM methodology, which is illustrated in Figure 2, consists of the following four steps:

1. Convert a background knowledge ontology into a network format.
2. Estimate the importance of background knowledge terms using a scoring function.
3. Shrink the background knowledge, keeping only a proportion c of the top ranking terms.
4. Apply a semantic data mining algorithm on the original data set and the reduced background knowledge.

Input: SDM algorithm, network conversion method, scoring function, term removal method, background knowledge ontology O, set of examples S annotated with terms from O
Output: set of rules discovered by SDM algorithm
Parameters: shrinkage coefficient $c \in [0, 1]$

```
Convert ontology O into network format G_e (see Section 3.3.1)
Calculate significance scores score(t), for all terms t ∈ T(O) (see Section 3.3.2)
for term t ∈ T(O) do
    if RelativeRank(t) > c then
        mark term t for removal.
    end
end
form G_e' by removing marked terms from G_e (see Section 3.3.3)
convert G_e' to O'
Run SDM algorithm on S using reduced background knowledge O'
return Rules discovered by SDM algorithm
```

Algorithm 1: The NetSDM algorithm, implementing the proposed approach to semantic data mining with network node ranking and ontology shrinking.

The NetSDM methodology improves the efficiency of SDM algorithms by using a shrinking step in which we filter out background knowledge terms that are not likely to appear in significant rules. The methodology is implemented in Algorithm 1. A scoring function used in ontology shrinkage should (i) be able to evaluate the significance of terms based on the data, and (ii) be efficiently computed.
The input for the scoring function is the data used in SDM algorithms, consisting of:

- Set of instances S consisting of target (S_+) and non-target (S_-) instances,
- Ontology O represented as a set of RDF triples (*subject, predicate, object*) (to simplify the notation, for each term t appearing as either a subject or object in a triple, we will write $t \in O$ to denote that t is a term of the ontology O),
- Set of annotations $\mathcal{A}$ connecting instances in $S = S_+ \cup S_-$ with terms in O (annotations are presented as triples $(s, \textit{annotated-with}, t)$, where $s \in S$ and $t \in O$ denoting that data instance s is annotated by an ontology term t.

The output of the scoring function is a vector which, for each term in the background knowledge, contains a score estimating its significance. In other words, using $\mathcal{T}(O)$ to denote the set of all terms appearing (either as subjects or objects) in ontology O, the scoring function is defined as:

$$\text{score}_{S,O,\mathcal{A}} : \mathcal{T}(O) \to [0, \infty)$$

After defining a suitable scoring function *score* (in the subsequent subsections, we examine two possibilities), we use the computed scores to shrink the background knowledge ontology

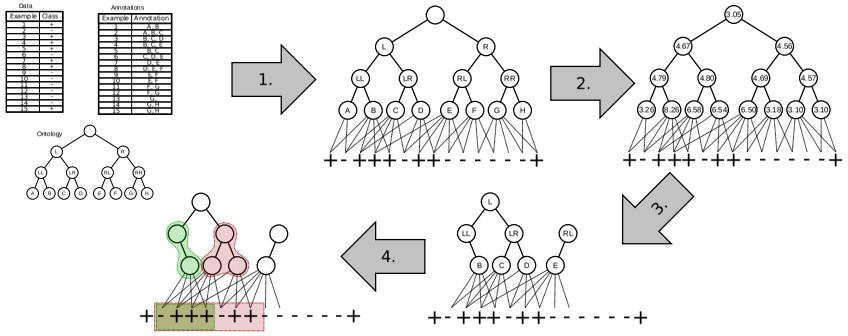

Figure 3: Illustration of using Algorithm 1 on example from Table 1.

O. Using a scoring function, a higher score of term $t \in O$ means that term t is more likely to be used in rules describing the positive examples. For every term $t \in \mathcal{T}(O)$, we use the results of the scoring function to assign *relative ranks* to ontology terms defined as

$$\text{RelativeRank}(t) = \frac{\text{Rank}(t)}{|\mathcal{T}(O)|} = \frac{|\{t' \in \mathcal{T}(O) : \text{score}(t') \geq \text{score}(t)\}|}{|\mathcal{T}(O)|}$$

which calculates the ratio of terms in the ontology that score higher than t, divided by the number of all terms. For example, a value $\text{RelativeRank}(t) = 0.05$ means that only 5% of all terms in the ontology score higher than t using a given scoring function.

3.2. Illustrative example

As an illustrative example consider the data set described in Table 1. The data set consists of 15 instances, 7 of which belong to the target class (positive examples, marked with + in Table 1). The instances are annotated by one or more terms in a hierarchy (i.e., simple ontology) consisting of 8 base nodes and 7 higher-level terms, shown on the left-hand side of Figure 3. Using the Personalized PageRank scoring function (described in Section 3.3.2), high scores are assigned to the background knowledge terms that are strongly related to the positive examples. The resulting scores are shown in the middle of Figure 3. We can see that the left-hand side terms have higher scores compared to the right-hand side terms as they annotate mostly the positive (target) examples.

Table 1: An illustrative data set consisting of 15 examples annotated by 8 possible annotations.

Example	Class	Annotated by
1	+	A,B
2	-	A,B,C
3	+	B,C,D
4	+	B,C,E
5	+	B,C
6	-	C,D,E
7	+	D,E
8	+	D,E,F
9	-	E,F
10	-	E,F
11	-	F,G
12	-	F,G
13	-	G
14	+	G,H
15	+	G,H

In the next step, the algorithm prunes the lower-ranked terms, leaving only the best 8 background terms in the reduced hierarchy of ontology terms. As most of the top scoring terms were in the left part of the hierarchy, the reduced hierarchy mostly contains these terms. In the final step, we use a SDM algorithm—in this case we use Hedwig—to find rules based on the instances from Table 1 and the reduced ontology. The best two rules discovered by Hedwig, which cover most of the positive examples, are:

`Positive` ← `LL` (shown in green in Figure 3), covering 3 positive and 1 negative instance (Coverage = 4, Precision = $\frac{3}{4}$).

`Positive` ← `LR` (shown in red in Figure 3), covering 5 positive and 2 negative instances (Coverage = 7, Precision = $\frac{5}{7}$).

If we run Hedwig using the original ontology for this data set, we get the same rules as on the reduced background knowledge. However, as demonstrated by the experiments on large real-life data sets in Section 5, removing unimportant parts of large ontologies benefits both the execution time and the quality of discovered rules.

3.3. Detailed description of NetSDM

In this section, we describe four steps of the NetSDM methodology outlined in Algorithm 1. We first describe the conversion of a background knowledge ontology into an information network, which we can then analyze using network analysis methods. Next, we describe two methods for term importance estimation in information networks. The section concludes with a discussion on the term deletion step of the algorithm in which low-scoring terms are removed from the network.

3.3.1. Conversion of background knowledge ontology into network format

The first step of the NetSDM methodology is conversion of the background knowledge ontologies into a network. We present two methods, a *direct* method and a *hypergraph* method of conversion.

Direct conversion. Input ontologies for the NetSDM methodology are collections of triples that represent relations between background knowledge terms. As any information network is also composed of a set of nodes and the connections between them, a natural conversion from the background knowledge into an information network is to convert each relation between two ontology terms into an edge between two corresponding nodes in an information network. This gives rise to the first function converting the input ontology into the information network, in which we view the ontology and the data instances as parts of one network. In the conversion, we merge the data set and the background knowledge into one network $G_e = (V_e, E_e)$ where

- $V_e = \mathcal{T}(O) \cup S_+$ are vertices of the new network consisting of all background knowledge terms $\mathcal{T}(O)$ and all target class instances (positive examples) S_+;
- $E_e = \{(t_1, t_2) | \exists r : (t_1, r, t_2) \in O\} \cup \{(s, t) | (s, \textit{annotated-with}, t) \in \mathcal{A}\}$ are edges of the new network consisting of edges that represent background knowledge relations, as well as all edges that represent the *annotated-with* relations between

data instances and background knowledge terms (the meaning of O, S, S_+, S_- and $\mathcal{A}$ is explained in Section 3.1).

Hypergraph conversion. Liu et al. (2013) proposed an alternative approach to converting an ontology into an information network format. They treat every relation in a semantic representation of data as a triple, consisting of a subject, predicate and object. They construct a network (which they call a *hypergraph*) in which every triple of the original background knowledge (along with the background knowledge terms) forms an additional node in the network with three connections: one connection with the subject of the relation, one with the object of the relation, and one with the predicate of the relation. In this conversion, each predicate that appears in the background knowledge is an additional node in the resulting network. This conversion results in a network $G_e = (V_e, E_e)$ where:

- $V_e = \mathcal{T}(O) \cup S_+ \cup \{n_r | r \in O \cup \mathcal{A}\} \cup \{p | \exists s, o : (s, p, o) \in O\} \cup \{\textit{annotated-with}\}$ are vertices of the new network consisting of (i) all background knowledge terms, (ii) all target class instances, (iii) one new node n_r for each relation r either between background knowledge terms or linking background knowledge terms to data instances and (iv) one node for each predicate appearing in the ontology O, as well as (v) one node representing the *annotated-with* predicate;
- $E_e = \bigcup_{r=(s,p,o) \in O \cup \mathcal{A}} \{(s, n_r), (p, n_r), (o, n_r)\}$ are edges of the new network, each relation r inducing three connections to node n_r that it induces (terms V, S, S_+, S_- and $\mathcal{A}$ are defined in Section 3.1).

While hypergraph conversion results in a slightly larger information network, less information is lost in the conversion process than in the direct conversion process presented above.

An important aspect of both conversion methods, presented above, is that they are defined simply on a set of triples that represent relations between background knowledge terms. This means that both methods can be used to transform an arbitrarily complex ontology with any number of predicates.

3.3.2. Term significance score calculation

After converting the background knowledge and the input data into a joined network, we use either Personalized PageRank or node2vec based scoring function to evaluate the significance of background knowledge terms. Term importance scoring function $\text{score}_{S,O,\mathcal{A}}$ is constructed by taking into account the data set S and background knowledge terms $\mathcal{T}(O)$.

P-PR based score computation. The first scoring function is computed using the Personalized PageRank algorithm (Page et al., 1999). While the basic PageRank algorithm evaluates the global importance of each node in a network (i.e. with respect to all other nodes), the Personalized PageRank (described in Section 2.2.1) evaluates the significance of nodes with respect to a given node (or a set of nodes). This fits well with our demand that a scoring function must evaluate the significance of a term

based on the actual data - in our case the importance of the nodes is not global but calculated in the context of the given positive examples. We can therefore reasonably expect that the highest scoring terms will not simply be the most prominent terms of the background knowledge ontology but rather those terms which are the most relevant to the input data set that a researcher is interested in. As each term $t \in \mathcal{T}(O)$ is a vertex in network G_e, we calculate the P-PR score of each term $t \in \mathcal{T}(O)$ as follows:

$$\text{score}_{\text{P-PR}}(t) = \text{P-PR}_{S_+}(t) \tag{4}$$

where the P-PR vector is calculated on the network G_e. A simple algebraic calculation (Grčar et al., 2013) shows that this value is equal to the average of all Personalized PageRank scores of v where the starting set for the random walker is a node from S_+:

$$\text{P-PR}_{S_+}(t) = \frac{1}{|S_+|} \sum_{w \in S_+} \text{P-PR}_{\{w\}}(t) \tag{5}$$

Following the definition of the Personalized PageRank score, the value of $\text{score}_{\text{P-PR}}$ is the stationary distribution of a random walker that starts its walk in one of the target data instances (elements of the set S_+) and follows the connections (either the is-annotated-by relation or a relation in the background knowledge). Another interpretation of $\text{score}_{\text{P-PR}}(t)$ is that it tells us how often we will reach node t in random walks, starting with positive (target class labeled) data instances. Note that the Personalized PageRank algorithm is defined on directed networks, allowing us to calculate the Personalized PageRank vectors of nodes by taking the direction of connections into account. In our experiments, we also tested the performance of the scoring function if network G_e is viewed as an undirected network. To calculate the PageRank vector on an undirected network, each edge between two nodes u and v is interpreted as a pair of directed edges, one going from u to v and another from v to u, allowing the random walker to traverse the original undirected edge in both directions.

node2vec based score computation. The second estimator of background knowledge terms significance is the node2vec algorithm (Grover and Leskovec, 2016). In our experiments, we used the default settings of $p = q = 1$ for the parameters of node2vec, meaning that the generated random walks are balanced between the depth-first and breadth-first search of the network. The maximum length of random walks was set to 15. The function node2vec (described in Section 2.2.2) calculates the feature matrix $f^* = \text{node2vec}(G_e)$, and each row of f^* represents a feature vector $f^*(u)$ for node u in G_e. The resulting feature vectors of nodes can be used to compute the similarity between any two nodes in the network. The approach uses the cosine similarity of the two feature vectors u and v, computed as follows:

$$\text{similarity}_{\text{node2vec}}(u, v) = \frac{f^*(u) \cdot f^*(v)}{|f^*(u)||f^*(v)|}$$

In our approach, we form feature vectors for nodes representing both background knowledge terms and data instances. We use these feature vectors to compute the

similarity between the background knowledge terms and the positive data instances (target class examples) using a formula inspired by Equation 5. With the Personalized PageRank, we evaluate the score of each node as P-PR$_{S_+}(v)$ where S_+ is the set of all target class instances. As the value P-PR$_{\{w\}}(t)$ measures the similarity between w and t, Equation 5 can also be used to construct a node2vec scoring function. We replace the individual P-PR similarities in Equation 5 with the individual node2vec similarities:

$$\text{score}_{\text{node2vec}}(t) = \frac{1}{|S_+|} \sum_{w \in S_+} \frac{f^*(w) \cdot f^*(t)}{|f^*(w)||f^*(t)|} \tag{6}$$

3.3.3. Network node removal

In the third step of Algorithm 1, low-scored nodes are removed from the network. We present and test two options for network node removal.

Naïve node removal. The first (naïve) option is to take every node that is marked for removal and delete both the node and any connection leading to or from it. This method is robust and can be applied to any background knowledge. However, when background knowledge is heavily pruned, this method may cause the resulting network to get decomposed into several disjoint connected components. If we convert the background knowledge into a hypergraph, the hypergraph has to contain relation nodes with *exactly* three neighbors (the subject, predicate and object of the relation) if we are to convert it back into a standard representation of background knowledge. Thus, naïvely removing nodes from the hypergraph may result in a network that we can no longer convert back to the standard background knowledge representation.

Advanced node removal. We tested an alternative approach that takes into account that the relations, encoded by the network edges, are often transitive. For example, in our work we use the *is-a* and *is-part-of* relations that are both transitive. Using transitivity, we design an algorithm for advanced removal of low scoring nodes from information networks, obtained by direct conversion of the background knowledge (Algorithm 2). This advanced node removal step can be used for ontologies with any number of relations. Just like the is-a relation in Algorithm 2, other transitive relation are added back to the network in row three of the algorithm. As the background knowledge is in direct correspondence with the information network obtained from it, removing the node from the information network corresponds to removing a matching term from the background knowledge. In this sense, Algorithm 2 can be used as the term-removal step of Algorithm 1. Algorithm 2 can also be used to remove low scoring nodes from hypergraphs constructed from the background knowledge if we first convert hypergraphs into a simple network form resulting from the direct conversion of background knowledge ontologies.

3.3.4. Applying SDM algorithms

SDM algorithms Hedwig and Aleph (described in Sections 2.1.4 and 2.1.5, respectively) were used in the last step of the NetSDM methodology to discover rules explaining the target class instances.

Input: Information network G_e (obtained by direct conversion of background knowledge into information network format with directed edges) and node $n \in G_e$ (a term of the original background knowledge) we wish to remove
Output: New background knowledge that does not contain node n

```
for b ∈ G_e : (b, n) is an edge in G_e do
    for a ∈ G_e : (n, a) is an edge in G_e do
        Add edge (b, a) into G_e
        Remove edge (n, a) from G_e
    end
    Remove edge (b, n) from G_e
end
Remove node n from G_e
Return G_e
```

Algorithm 2: The algorithm for removing a node from a network, obtained through direct conversion of the background knowledge into the information network format.

Applying Hedwig. Hedwig—which was previously successfully used in a real-life application for explaining biological data (Vavpetič et al., 2014)—can use only one relation type in the background knowledge, i.e. the *is-a* relation in the case of the Gene Ontology. Hedwig uses this relation and its transitivity property (if A *is-a* B and B *is-a* C, then A *is-a* C) to construct rules.

Applying Aleph. In contrast to Hedwig, the input to Aleph can contain several relations as well as interactions between them. Therefore applying Aleph enabled us to use both the *is-a* and *is-part-of* relations in the Gene Ontology. Aleph is capable of using not only these two relations and their transitivity, but also the interaction between the two relations in the form of two facts: (i) if A *is-a* B and B *is-part-of* C, then A *is-part-of* C and (ii) if A *is-part-of* B and B *is-a* C, then A *is-part-of* C.

Since Aleph can use several relations for constructing rules, the background knowledge network used in Aleph experiments contained the edges representing *is-a* relations as well as the edges representing *is-part-of* relations.

4. Experimental settings

This section presents the settings of the experiments with two semantic data mining algorithms (Hedwig and Aleph) and two search space reduction mechanisms (based on Personalized PageRank and node2vec). We first describe the data sets, followed by the outline of the three experimental setups.

4.1. Data sets

In the main experiments, presented in this paper, we used two data sets: the acute lymphoblastic leukemia (ALL) and the breast cancer data set.

ALL (acute lymphoblastic leukemia) data. The ALL data set, introduced by Chiaretti et al. (2004), is a typical dataset for medical research. In data preprocessing we followed the steps used by Podpečan et al. (2011) to obtain a set of 1,000 enriched genes (forming the target set of instances) from a set of 10,000 genes, annotated by concepts from the Gene Ontology (Ashburner et al., 2000), which was used as the background knowledge in our experiments. In total, the data set contained 167,339 annotations (connections between genes and Gene Ontology terms). In previous work on analyzing the ALL data set, the performance of the SegMine methodology (Podpečan et al., 2011) was compared to the performance of the DAVID algorithm (Huang et al., 2008). In this work, we use the same data set to assess if network node ranking and reduction can decrease the run time and improve the performance of the tested SDM algorithms.

Breast cancer data. The breast cancer data set, introduced by Sotiriou et al. (2006), contains gene expression data on patients suffering from breast cancer. In previous work, Vavpetič et al. (2014) first clustered the genes into several subsets and then used a semantic subgroup discovery algorithm to interpret the most important subset (as determined by domain experts). In this work, we constructed rules for the same subset of genes as by Vavpetič et al. (2014) and did not use the input of domain experts. The set contains 990 genes out of a total of 12,019 genes. In our experiments, we used SDM algorithms to describe the 990 interesting genes. The data instances are connected to the Gene Ontology terms by 195,124 annotations.

To test whether the results of NetSDM on the Gene-Ontology-annotated data sets described above can be generalized to other data sets, we ran the NetSDM algorithm also on a set of smaller data sets, annotated by hierarchical background knowledge, which were used in conjunction with the Hedwig algorithm in our previous work (Adhikari et al., 2016). The results of these experiments are shown in Appendix A of this paper.

4.2. Experimental setups

We constructed three experimental setups to test the NetSDM methodology. In all setups, both Hedwig and Aleph are used in their standard modes (subgroup discovery and classification rule learning, respectively) to return the set of rules explaining the target class examples. Hedwig returns a rule set containing all the rules in the search beam at the end of search (meaning that the size of the returned rule set matches the size of the beam). Aleph returns a rule set consisting of rules with a sufficient coverage and low enough noise (i.e. rules covering at least 10 positive examples and at most 100 negative examples). In the first setup, the entire set of rules was analyzed. In the second setup, we used the NetSDM methodology with the direct method of ontology conversion and the naïve version of node removal. Given their different operation modes (Hedwig was used for learning individual patterns and Aleph was used for predictive theory construction), we always analyzed only the top rule discovered by Hedwig, and the top 3 rules of the theory discovered by Aleph. We also list the metrics for the entire theory discovered by Aleph. This allows clearer comparison and is sufficient to demonstrate how shrinking the background knowledge affects the quality of discovered rules. In the third setup, we use the advanced (transitivity based)

node removal approach (described in Section 3.3.3). We compare the quality of the resulting rules by measuring the Lift values of each rule (defined in Equation 1 in Section 2.1.4). Details of each experimental setup are given below.

First experimental setup. We ran the two SDM algorithms on the entire data set to determine the baseline performance and examine the returned rules. Using Hedwig, we ran the algorithm with all combinations of depth (1 or 10), beam width (1 or 10) and support (0.1 or 0.01). For Aleph, we ran the algorithm using the settings recommended by the algorithm author—minimum number of positive examples covered by a rule was set to 10, and maximum number of negative examples covered by a rule was set to 100. These settings resulted in rules comparable to those discovered by Hedwig.

In both cases, our goal was to determine whether the terms used by the SDM algorithms are correlated with the scores of the terms returned by the network analysis algorithms, i.e., calculated by P-PR (Equation 4) or node2vec (Equation 6). We evaluated this relation by observing the ranks of terms used by both algorithms to construct the rules. For each term t appearing in the constructed rules, we computed the relative rank of the term t (as defined in Section 3.1). If the correlation between SDM algorithm's use of terms and returned scores is strong, the relative rank calculated for a term t and used by the algorithm will be low. Low percentages ensure that we can retain only a small percentage of the highest ranked scores.

Second experimental setup. In the second set of experiments, we exploited the correlations discovered in the first experimental setup. We used the scores of background knowledge terms to prune the background knowledge. Specifically, we ran the NetSDM algorithm by setting the shrinkage coefficient values of c to values between 0.005 and 1, thereby running the SDM algorithms on the gene ontology (GO) background knowledge containing only a subset of as little as 0.5% of the terms with the highest scores. We calculated the P-PR values of GO terms in two ways: (i) we viewed *is-a* relations as directed edges pointing from a more specific GO term to a more general term, and (ii) we viewed the relations as undirected edges. When running the experiments with Hedwig, we set the beam size, depth and minimum coverage parameters to the values that returned the best rules on each data set in the first set of experiments. For example, the results of the first experimental setup showed that the rules obtained by setting the beam size or rule depth to one are too general to be of any biological interest; we therefore decided to set both values to 10. In the case of rule depth, this value allows Hedwig to construct arbitrarily long rules (given that in our data sets Hedwig returned no rules of length greater than five). Setting the beam size to 10 allows Hedwig to discover important rules (as shown in the first set of experiments) in a reasonable amount of time; note that the run time of Hedwig increases drastically with increased beam size, and at size 10 the algorithm takes several hours to complete. Running the experiments with the Aleph algorithm, we again used the setting recommended by the algorithm author.

Third experimental setup. In the first two sets of experiments, we used the direct method for converting background knowledge into an information network and the naïve method for deleting low scoring nodes. In the third set of experiments, we

Table 2: The best rules discovered by the Hedwig algorithm on the ALL data set. The conjuncts (Gene Ontology terms) of each top ranking rule are separated by a horizontal line in the table with the 4 right-most columns denoting the settings used to discover the rule, and the Lift value of the entire rule. The second (third) column can be understood as the percentage of GO terms with the Personalized PageRank (node2vec) score higher than the corresponding term.

Term	RelativeRank (P-PR)[%]	RelativeRank (Node2vec)[%]	Beam	Depth	Support	Lift

GO:0003674	0.0046	46.38	1	10	0.01	1

tested the advanced versions of both steps: hypergraph conversion and advanced node deletion, respectively. As the node2vec function proved inferior to the Personalized PageRank scoring function in the second set of experiments, we ran the third round of experiments only using the P-PR scoring function. The results of this third set of experiments can then be compared to the results of the second set.

5. Experimental results

We present the results of algorithms Hedwig and Aleph using two scoring functions, two network conversion methods and two node deletion methods on the two data sets. We analyze the results obtained from the three experimental setups.

5.1. First setup: Scores of terms used in SDM algorithms

We begin by presenting the results of the first experimental setup where we analyze the scores and the ranks of terms appearing in rules constructed by Hedwig and Aleph, respectively.

5.1.1. Using Hedwig

Tables 2 and 3 present the best ranked rules discovered by Hedwig using different parameter settings in the first experimental setup using Personalized PageRank and node2vec node relevance scores for the ALL and breast cancer data sets, respectively. The results show for all the terms used by Hedwig that the relative ranks calculated by the P-PR scoring function are remarkably high. In all the cases, the terms used to construct rules are in top

Table 3: The best rules discovered by the Hedwig algorithm on the breast cancer data set. The meaning of columns is the same as explained in the caption of Table 2.

Term	RelativeRank (P-PR)[%]	RelativeRank (Node2vec)[%]	Beam	Depth	Support	Lift
GO:0043230	11.350	31.000	1	1	0.01	1.400

GO:0071840	29.454	58.599	10	10	0.1	1.556
GO:0044428	0.051	13.580				
GO:0003674	0.202	36.568				

percentiles of all term scores, giving credence to our hypothesis that high scoring terms are usually used in rules. On the other hand, use of the node2vec based scoring function was much less successful in this experiment.

This phenomenon is clearly shown in the top two charts of Figure 4 showing all the terms used by Hedwig and their ranks. Even taking into account all (not only the best) rules, we see that predominantly the used terms come from the top 5 percent of all the terms as scored by the Personalized PageRank scoring function. On the other hand, this phenomenon does not occur with the node2vec scoring function, as the results in Table 2 and Table 3 show for the ALL and breast cancer data sets. The rules used by Hedwig score quite low according to the node2vec function, however as seen in the bottom two charts of Figure 4, the node2vec score of the used terms is still above average, and it is possible that the node2vec scores are useful. We consider the node2vec scores to contain sufficient information to warrant testing both scores in the second experimental setup.

The rules discovered in the first experimental setup are biologically relevant, except when the search beam for the Hedwig algorithm was set to 1. In this case the only significant rule discovered contained in its condition a single gene ontology term GO:0003674 that denotes molecular function. This is a very general term that offers little insight and shows that a larger search beam is necessary in order for Hedwig to make significant discoveries. The most interesting results are uncovered when the beam size is set to 10 and the support is set to 0.01. When the depth is set to 1, the most important term GO:0050851 (antigen receptor-mediated signaling pathway) relates to the immune system related cell type. When searching with a depth of 10, we discovered a conjunct of four terms: immune system process (GO:0002376), immune response-activating cell surface receptor signaling pathway, (GO:0002429), plasma membrane (GO:0005886) and binding (GO:0005488). This conjunct provides additional insights about the action (binding), effect (immune response signaling pathway), and location (plasma membrane).

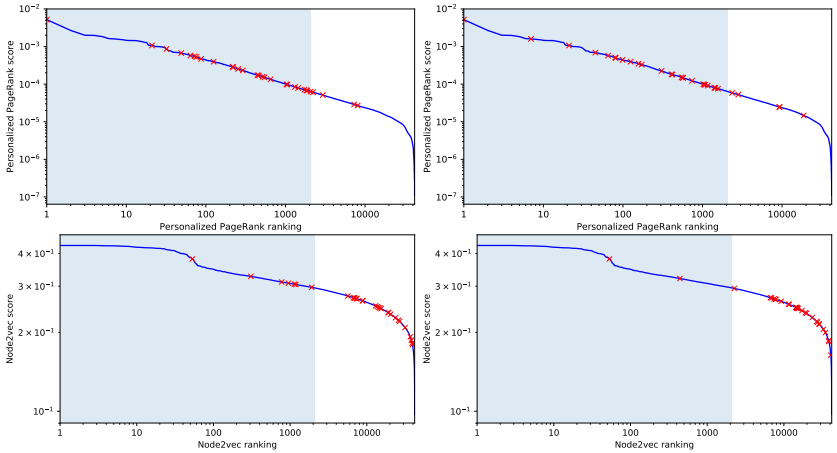

Figure 4: The ranks of the terms used by Hedwig to construct rules on the ALL (left) and breast cancer (right) data sets. The blue line shows the score for each of the terms in the background knowledge—the scores on the top two charts were calculated with Personalized PageRank and the scores on the bottom two charts were produced with node2vec. The terms in each chart are sorted by descending score. Each red cross highlights one of the terms used by Hedwig. The blue area on the left denotes the top 5 percent of all nodes (i.e. nodes with a relative rank of 0.05 or lower). Note the logarithmic scale of both axes.

5.1.2. Using Aleph

Tables 4 and 5 show the terms, used in the 10 best rules discovered by the Aleph algorithm that describe the ALL and breast cancer data sets, respectively, and the P-PR and node2vec scores of the terms in the rules. The scores were calculated taking both *is-a* and *is-part-of* relations into account.

The results again show that the Personalized PageRank scoring function ranks all the terms used by Aleph remarkably high. Moreover, similar to the experiments with Hedwig, the node2vec scoring function is much less successful in this experiment. The high Personalized PageRank ranking of terms appearing in rules discovered by the Aleph algorithm is also seen in Figure 5.

Similar to the results using the Hedwig algorithm, the discovered rules contain terms predominantly from the top 5 percent of all terms as scored by the Personalized PageRank scoring function. A high value of the node2vec scoring function is again a weaker predictor of whether a rule will be useful or not. Nevertheless, as seen in the bottom two charts of Figures 4 and 5, the node2vec score of the used terms is still above average, and it is

possible that the node2vec scores are useful. We consider the node2vec scores to contain sufficient information to warrant testing both scores in the second experimental setup.

5.2. Second setup: Shrinking the background knowledge ontology

This section presents the result of the second set of experiments with the NetSDM methodology. We present the results of shrinking the background knowledge for Hedwig and Aleph.

5.2.1. Ontology shrinking for Hedwig

The results of the first experimental setup show that the scores, calculated using the network analysis techniques, are relevant to determine whether background knowledge nodes will be used by SDM algorithms in the construction of rules describing the target instances. Here we present the results of using the computed scores to shrink the background knowledge used by Hedwig. We first present the results of both scoring functions on the ALL data set and then on the breast cancer data set. We set the beam and depth parameters of Hedwig to 10, and the minimum coverage parameter to 0.01; these are the settings that produced the best results for both data sets in the first experimental setup with Hedwig with no shrinking of the background knowledge (see Tables 2 and 3).

For Personalized PageRank-based network shrinkage we also test if taking into account edge directions makes a difference. Table 6 (undirected edges) and Table 7 (directed edges) show the results of semantic rule discovery using the P-PR function on the ALL data set. Both tables show a similar phenomenon: by decreasing the size of the background knowledge

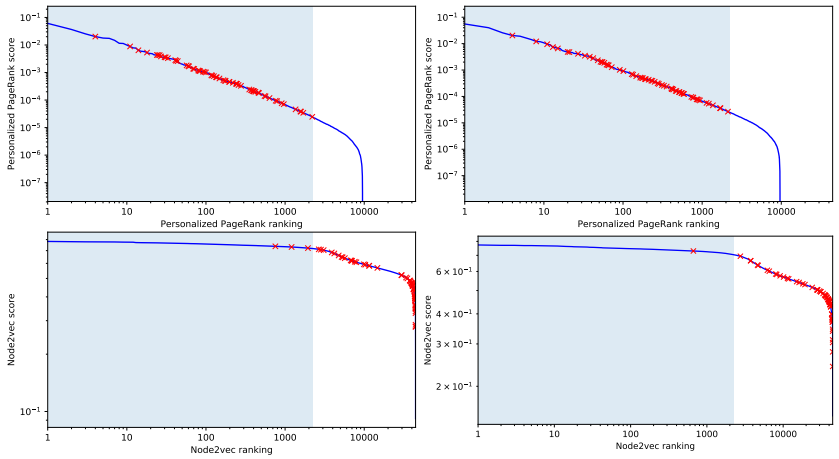

Figure 5: The ranks of the terms used by Aleph to construct rules on the ALL (left) and breast cancer (right) data sets. The chart interpretation is the same as explained in the caption of Figure 4. Note again the logarithmic scale of both axes.

Table 4: The 10 best rules discovered by the Aleph algorithm on the ALL data set. The meaning of the second and third column is the same as in Table 2. The scores were calculated by taking the *is-a* and *is-part-of* relations into account.

100	GO:0002376	immune system process	3.420	105	40
	GO:0002429	immune response-activating cell surface receptor signaling pathway			
	GO:0005886	plasma membrane			
	GO:0005488	binding			

50% still allows us to discover the same high quality conjunct of the terms GO:0002376, GO:0002429, GO:0005886 and GO:0005488 as before.

Comparing Table 6 and Table 7 we see that there is a slight difference in the resulting rules if we take the direction of the relations in the background knowledge into account. Better Lift values and more consistent results are obtained when we choose to ignore the direction of the relations. Taking edge directions into account, for example, leads to a discovery of a very low quality rule with Lift value of only 2.219 when the background knowledge is at 20% of its original size. When we do not ignore the direction of the relations, the score of each node is only allowed to propagate to the 'parent' nodes in the background knowledge, i.e. high scores will be given to those GO terms whose child terms (specializations) have a high score. On the other hand, when ignoring the direction, we allow nodes to pass their high scores also to sibling nodes, allowing Hedwig in the final step of our NetSDM methodology (outlined in Algorithm 1) to choose the correct specialization of the parent node. More experiments are needed to analyze this phenomenon.

Table 8 and Table 9 show the results of the experiments using the node2vec function on the ALL data set. The results show that node2vec based ontology shrinkage did not achieve the same performance as the shrinkage using the Personalized PageRank function. The results in both tables show that lower shrinkage coefficients consistently decrease the quality of the rules discovered by Hedwig, meaning that shrinking of the background knowledge with the node2vec scoring function removes several informative terms and connections. Without these terms Hedwig could not extract the relevant information from the data, causing decreased performance.

Another interesting phenomenon in the node2vec results is that as the background knowledge decreases in size, the resulting rules become shorter, with the lowest values

returning a single GO term as the only important node. This may be a consequence of so many terms pruned that the remaining terms describe non-intersecting sets of enriched genes (or sets with a very small intersection). In this case, term GO:0044281 covers the largest number of instances and is therefore selected as the best term. Upon selecting this term, Hedwig is not able to improve the rule by adding further conjuncts, as adding any other term to the conjunction drastically decreases the coverage of the resulting rule.

Tables 11 and 10 show the results of the Personalized PageRank scoring function used in reducing the background knowledge for the breast cancer data set. As in the ALL data set, we see that decreasing the background knowledge size does not drastically decrease the

quality of rules discovered by Hedwig. In fact, the rules discovered from only 20% of the original background knowledge achieve almost the same Lift score as the rules produced from the entire data set. Further shrinking the data set allows Hedwig to discover an even better rule. Comparing the two tables we see—even more clearly than in the ALL data set—that ignoring the direction of edges resulted in better overall performance of the algorithm. Especially for small background knowledge sizes, NetSDM finds rules with substantially lower Lift values using scores calculated on directed edges compared to those calculated by ignoring the edge direction.

The results of NetSDM using the node2vec scoring funciton on the breast cancer data set, shown in Tables 12 and 13 are comparable to those on the ALL data set. The Hedwig algorithm does not discover important rules to explain the positive examples with the pruned background knowledge. As on the ALL data set, too many important nodes were pruned. Again we observe the phenomenon that as the background knowledge is shrunk, the length of the rules decreases to 1.

While the increased rule quality shows that using the Personalized PageRank as a filter before applying the Hedwig algorithm can improve the performance of the algorithm, the results are also significant considering the fact that with small background knowledge sizes

the search space of Hedwig (and thus the computational complexity of the algorithm) is much smaller.

Figure 6 shows the relationship between the time taken by the Hedwig semantic rule learning algorithm (together with network preprocessing) to discover the relevant rules and the network shrinkage coefficient c, i.e. the relative size of the background knowledge left for Hedwig to analyze. As the network preprocessing steps were completed in seconds, the times reported in Figure 6 correspond almost entirely to the work of the Hedwig algorithm. The fact that shrinking takes orders of magnitude less time than rule discovery is a prerequisite for the SDM algorithms to be useful in real-life applications. We timed the algorithm on the ALL data set using different settings for the beam, depth and support on 8 core 2.60 GHz Intel Xeon(R)E5-2697 v3 machine with 64GB of RAM. The graph clearly shows that smaller background knowledge ontologies result in much shorter run times (note the logarithmic scale). This confirms our hypothesis that shrinking the background knowledge decreases the time it takes Hedwig to search the space of possible hypotheses. We can conclude that using the NetSDM background knowledge shrinking approach is beneficial both for increasing the quality of the rules and for speeding up the Hedwig algorithm.

5.2.2. Ontology shrinking for Aleph

This section examines the results of the second set of experiments with the Aleph algorithm used in the final step of the NetSDM methodology. Due to low quality of results achieved using node2vec in the first set of experiments with Aleph and Hedwig (presented in Section 5.1) as well as in the second set of experiments with Hedwig, we only tested Personalized PageRank based background knowledge shrinkage with the Aleph algorithm. Furthermore, due to low effect of taking directions of edges into account in the experiments with Hedwig, we only used the undirected network to calculate the scores for the terms in the background knowledge.

Table 14 shows the results of the Aleph algorithm on the ALL data set in the second set of experiments. The results of the algorithm on the breast cancer data set are shown in Table 24 of Appendix B. The results show that unlike with the Hedwig algorithm, using the Aleph algorithm on very heavily pruned data set does not result in the discovery of high quality rules. When the background knowledge is very small, the quality of the discovered rules, as

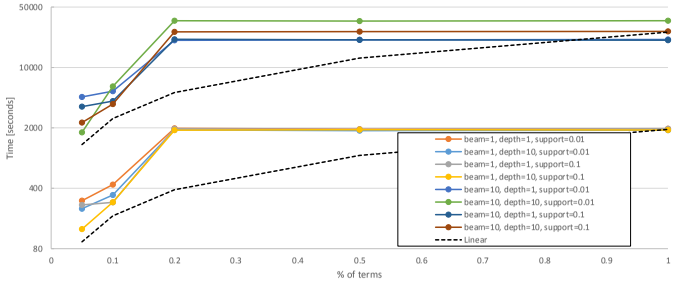

Figure 6: The times (in seconds) on logarithmic scale taken by Hedwig to discover rules on the ALL data set with different settings for beam, depth and support at varying sizes of the background knowledge set (different percentages of terms remaining in the background knowledge) in the second experimental setup. The times are plotted using a logarithmic scale on the y axis, and two linear trendlines (dashed) are drawn for comparison.

well as of the set of all rules, drops significantly. The benefits of network shrinkage for Aleph are visible when the background knowledge is pruned to 20% of its original size. At this background knowledge size, while the time taken to discover the rules was comparable to the time taken on the original background knowledge, the quality of the top two discovered rules is actually higher. Similar results were obtained using the Aleph algorithm on the breast cancer data set, shown in table 24 in Appendix B.

5.3. Third setup: Advanced network conversion and node deletion

This section presents the results of the final set of experiments using the advanced network conversion and node removal on both data sets using both learning algorithms.

5.3.1. Advanced network conversion for Hedwig

The results of the third set of experiments show somewhat different results from those achieved in the second experimental setup. Table 15 shows the results of both network conversion methods on the ALL data set, while Table 16 shows the results of the methods on the breast cancer data set. Unlike in the second set of experiments, the results of this setup show that the quality of rules, and also the discovered rules, remain the same when we reduce the size of background knowledge to one tenth of its original size. When further reducing the network size we see that the direct method of network conversion outperforms the advanced hypergraph based construction; while the hypergraph version of background knowledge conversion returns significantly worse results at 1% of its original size (in the breast cancer data set), the direct version still finds the same rule we find using the original background knowledge. When shrinking the network even further, the quality of the best

Table 15: Results of NetSDM on the ALL data set using the P-PR scoring function with advanced node removal, using Hedwig. We only list the smallest background knowledge size at which a network conversion method (direct or hypergraph) discovers the same rules as with no pruning, and one size below that.

Conversion method	Shrinkage coefficient [%]	GO-term		Lift	Coverage	TP
None	1	GO:0002376 GO:0002429 GO:0005886 GO:0005488	immune system process immune response-activating cell surface receptor signaling pathway plasma membrane binding	3.420	105	40

discovered rule decreases, but the decrease in quality occurs at a smaller size for the direct network conversion.

Figure 7 shows the run times of Hedwig on the pruned networks in the third set of experiments. The graph shows that unlike with the naïve network reduction methods in the second set of experiments, the time required to discover rules decreases linearly as we lower the shrinkage coefficient. When reducing the background knowledge network to 1% of its original size, the algorithm was able to discover the rules in two minutes, compared to over 11 hours on the unpruned network.

The result of this set of experiments can be compared with the results of the second set of experiments to draw two conclusions. First, the naïve version of network node removal causes Hedwig to discover rules of a slightly higher quality, but the results of shrinking the background knowledge are unpredictable both in terms of the quality of the rules discovered (which for some background knowledge sizes falls below the base value obtained on the unpruned network). Second, the times taken to discover the rules do not decrease significantly until we decrease the size of the background knowledge to 20% of its original size. On the other hand, the advanced version of node removal allows the algorithm to discover the same results as on the unpruned network even for very heavily pruned background knowledge sets. The results remain consistent, and the times taken to discover the rules decrease much more predictably with this node deletion method.

Table 16: Results of NetSDM on the breast cancer data set using the P-PR scoring function with advanced node removal, using Hedwig.

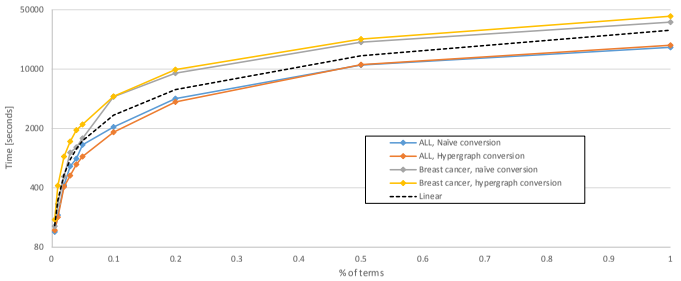

Figure 7: The times (in seconds) on logarithmic scale taken by Hedwig in the third experimental setup to discover rules with different conversion methods at varying sizes of the background knowledge (different percentages of terms remaining in the background knowledge). The times are plotted using a logarithmic scale on the y axis, and a linear trendline (dashed) is drawn for comparison.

5.3.2. Advanced network conversion for Aleph

Table 17 shows the results of the Aleph algorithm on the background knowledge pruned using advanced node reduction and direct network conversion, while Table 18 shows the results of background knowledge reduction using hypergraph network conversion. The results for all possible shrinkage coefficients are shown in Tables 22 and 23 in Appendix B. The results are comparable to the results obtained using the Hedwig algorithm: when the background knowledge is pruned to 10% (for the direct conversion) and 50% (for the hypergraph con-

version) of its original size, Aleph discovers the same best three rules. Furthermore, while shrinking the background knowledge further to only 3% of its original size, the quality of the discovered rules (measured by their Accuracy and Lift value) remains very close to the quality of the rules discovered on the entire background knowledge. The drop in quality is slightly smaller when using the hypergraph network conversion. Interestingly, for both network conversion methods, on a heavily pruned background knowledge (1% and 2% of its original size for the direct network conversion and for the hypergraph network conversion, respectively), the algorithms are able to discover rules of a higher quality than those on the original background knowledge. Similar results were obtained on the breast cancer data set and are shown in Appendix B in Tables 25 and 26.

Table 17: Results of NetSDM on the ALL data set using the P-PR scoring function, direct network conversion and advanced node removal. For each percentage of terms remaining in the reduced ontology, we show only the top 3 rules discovered by Aleph, and the properties of the entire set of rules (Theory).

	GO:0010008, GO:0032991	97	28	0.881	2.526

The run times of Aleph are shown in Figure 8. Compared to Hedwig, shrinking the background knowledge to a relatively small set does not have the same drastic effect on the run time. For example, shrinking the background knowledge to 10% of its original size for the direct network construction, which allows us to discover the same rules as with no ontology shrinkage, only decreases the run time by 14%, compared to the 90% time decrease for the Hedwig algorithm. Using the hypergraph network construction, a slightly larger speed-up was achieved in our experiments, however this is counter-balanced by the fact that for hypergraph network construction, the shrinkage coefficient must be set to a higher value in order to obtain the same rules.

The most promising finding of this series of experiments is that for very heavily pruned background knowledge (1% and 2% of the original size), Aleph (using the hypergraph conversion method) is capable of discovering high quality rules explaining the data. The times taken to discover the rules at this background knowledge size are halved when compared to times on the original background knowledge, and the resulting rules are of a higher quality

Table 18: Results of NetSDM on the ALL data set using the P-PR scoring function, hypergraph network conversion and advanced node removal. For each percentage of terms remaining in the reduced ontology, we show only the top 3 rules discovered by Aleph, and the properties of the entire set of rules (Theory).

than even the best rule discovered without ontology shrinking. The main drawback of this result at this point is the fact that the ideal background knowledge size at which this occurs is different for different shrinkage methods, meaning that for a new data set we have to tune the background knowledge size.

6. Conclusions and further work

This paper presents an efficient approach to semantic data mining that uses network analysis for shrinking of background knowledge to significantly reduce the search space and make semantic data mining practically applicable. We tested several variants of combining network analysis with semantic data mining. The result is a four-step NetSDM framework for data analysis: background knowledge conversion, network node importance calculation, network shrinkage, and semantic data mining. We tested NetSDM using two rule learning algorithms: Hedwig and Aleph. In all the setups Hedwig and Aleph were used in their standard modes of operation: Hedwig was used for subgroup discovery and Aleph was used for classification rule learning. Nevertheless, as output, both algorithms return a set of rules explaining the target class examples.

The results of using Hedwig as the semantic data mining algorithm for rule learning in the final step of the NetSDM methodology show that using a direct network conversion, the Personalized PageRank function to estimate term importance, and an advanced version of network shrinkage (using transitivity of underlying relations) provides the most consistent results. Using this setup, the entire algorithm was able to discover the same rules as the original Hedwig algorithm, being faster by a factor of almost 100. If we replace the advanced node removal function with the naïve version, the time savings are less predictable, but the algorithm discovers different rules than if run on the unpruned data set. Consequently, when applying Hedwig the advanced node removal strategy is recommended. The results of comparing NetSDM by taking/not taking network edge directions into account were less conclusive and require further experiments for detailed analyisis.

Using Aleph as the SDM algorithm also yielded interesting results. Using any of the three shrinking methods, our results show that on largely reduced background knowledge, Aleph is capable of discovering high quality rules explaining the data set. Rule discovery in this case is faster by a factor of 2 which is a significant improvement. Using larger background knowledge, NetSDM is still capable of shrinking the background knowledge and (with direct network conversion and the Personalized PageRank scoring function) achieve a noticeable (15%) speed-up in the run time of the Aleph algorithm.

In summary, the purpose of this work is to examine the effect of using network analysis inspired network shrinkage on semantic data mining algorithms in the context of the proposed NetSDM methodology. Due to the different modes of operation of algorithms Hedwig and Aleph (performing subgroup discovery and classification rule learning, respectively), comparing their results does not provide additional insights regarding their operation. Nevertheless, comparing Aleph and Hedwig, our results show that the Hedwig algorithm is very consistent in that Hedwig can discover the same rules, but in a much shorter time, when applying NetSDM to reduce the background knowledge. In contrast, the speed-up—while still noticeable—was much less pronounced when using NetSDM with Aleph. The quality of the discovered rules also decreased more quickly with Aleph used as the final algorithm of NetSDM.

In future work, we plan a more comprehensive examination of how the performance of NetSDM compares to enrichment analysis based methods like SEGS (Trajkovski et al., 2008b) and SegMine (Podpečan et al., 2011). We plan further experiments with different methods for network reduction. For example, other network ranking methods or even other

network analysis methods, such as community detection, could be used to identify the most relevant parts of the background knowledge. The existing two methods, PageRank and node2vec, contain parameters (especially parameters p and q of node2vec) which may affect the resulting scoring function.

Additionally, a non-deterministic approach to background knowledge shrinking could be used instead of the hard shrinkage coefficient used in the current experiments. With a non-deterministic approach, the scores of background knowledge terms may represent (non-scaled) probabilities of sampling a given node. Such an approach has the benefit of not eliminating any background knowledge term outright. However, the probabilistic nature of the sampling would require multiple runs of the entire algorithm, including the SDM rule learner, causing additional computations that would negate the improvements in performance achieved by network shrinking. Alternatively, we could more tightly integrate network analysis scores and the SDM algorithms. Instead of using the relevance scores to prune the ontology and feed the pruned ontology to SDM algorithms, we could use the scores, calculated by the network analysis algorithms, to guide the search in SDM algorithms. The main drawback of this approach would be the lack of modularity: while it is now relatively simple to replace one SDM algorithm in NetSDM with another (for example, replacing Hedwig with Aleph), this would no longer be possible if the scores were an integral part of a SDM algorithm.

We plan applications of the NetSDM methodology to larger data sets. Our experiments so far have been limited to hierarchies (experiments described in Appendix A) and the Gene Ontology, which is a big ontology but relatively simple in structure and logic relationships (in the experiments, we used only two relationships out of five relationships available in GO). Without our shrinking approach, Hedwig required several hours to discover interesting rules using this ontology, and therefore using larger ontologies was not feasible without dramatically reducing the parameters guiding the search. However, using the NetSDM, the algorithm can now be applied to a much wider range of background knowledge sets, including more complex ontologies and large knowledge graphs, such as the BioMine graph (Eronen and Toivonen, 2012) of biological entities and connections between them, as well as the Bio2RDF knowledge graph (Callahan et al., 2013), two knowledge graphs we intend to examine in our further work.

Acknowledgments

We express our thanks to Michel Dumontier for joint work in defining this challenging research problem. We are grateful to Anže Vavpetič for useful discussions and support in using the Hedwig algorithm, to Ashwin Srinivasan for the support and advice in running the experiments with the Aleph algorithm, and to anonymous reviewers whose constructive feedback helped us to improve this manuscript. We acknowledge the financial support from the Slovenian Research Agency through core research programmes P2-0103 and P6-0411 and project *HinLife: Analysis of Heterogeneous Information Networks for Knowledge Discovery in Life Sciences* (J7-7303) and *Semantic Data Mining for Linked Open Data* (financed under the ERC Complementary Scheme, N2-0078).

Appendix A

The Hedwig algorithm was previously used on several publicly available data sets (Adhikari et al., 2016). To show generality of the proposed NetSDM approach, we tested the performance of the NetSDM algorithm on the same data sets. The results, shown in Tables 19, 21, and 20, show similar trends as for the biological data sets which comprise the main part of this paper. The use of NetSDM can drastically decrease the running time of the algorithm with little to no decrease in the quality of the discovered rules. The speed-ups, achieved on the reported data sets, are around the factor of 5, which is less than for the Gene Ontology background knowledge. This lower, though still very promising speed-up can be explained by the fact that (1) the background knowledge in this case is smaller, meaning that less pruning can take place, (2) because of smaller background knowledge, a larger portion of Hedwig's running time consists of pre-processing and post-processing of the data, the tasks that are not affected by background knowledge pruning.

Table 19: Results of NetSDM on the Cities data set using the P-PR scoring function, regular network conversion, and advanced node removal.

Shrinkage coefficient [%]	Time taken [s]	Rule	Coverage	TP	Precision	Lift

Abstract

A selective classifier (f, g) comprises a classification function f and a binary selection function g, which determines if the classifier abstains from prediction, or uses f to predict. The classifier is called pointwise-competitive if it classifies each point identically to the best classifier in hindsight (from the same class), whenever it does not abstain. The quality of such a classifier is quantified by its rejection mass, defined to be the probability mass of the points it rejects. A "fast" rejection rate is achieved if the rejection mass is bounded from above by $\tilde{O}(1/m)$ where m is the number of labeled examples used to train the classifier (and $\tilde{O}$ hides logarithmic factors). Pointwise-competitive selective (PCS) classifiers are intimately related to disagreement-based active learning and it is known that in the realizable case, a fast rejection rate of a known PCS algorithm (called Consistent Selective Strategy) is equivalent to an exponential speedup of the well-known CAL active algorithm.

We focus on the agnostic setting, for which there is a known algorithm called LESS that learns a PCS classifier and achieves a fast rejection rate (depending on Hanneke's disagreement coefficient) under strong assumptions. We present an improved PCS learning algorithm called ILESS for which we show a fast rate (depending on Hanneke's disagreement coefficient) without any assumptions. Our rejection bound smoothly interpolates the realizable and agnostic settings. The main result of this paper is an equivalence between the following three entities: (i) the existence of a fast rejection rate for any PCS learning algorithm (such as ILESS); (ii) a poly-logarithmic bound for Hanneke's disagreement coefficient; and (iii) an exponential speedup for a new disagreement-based active learner called Active-ILESS.

Keywords: active learning, selective prediction, disagreement coefficient, selective sampling, selective classification, reject option, pointwise-competitive, selective classification, statistical learning theory, PAC learning, sample complexity, agnostic case

1. Introduction

Selective classification is a unique and extreme instance of the broader concept of confidence-rated prediction (Chow, 1970; Vovk et al., 2005; Bartlett and Wegkamp, 2008; Yuan and Wegkamp, 2010; Cortes et al., 2016a; Wiener and El-Yaniv, 2012; Kocak et al., 2016; Zhang and Chaudhuri, 2014). Given a training sample consisting of m labeled instances, the learning algorithm is required to output a *selective classifier* (El-Yaniv and Wiener, 2010), defined to be a pair (f, g), where f is a prediction function, chosen from some hypothesis class $\mathcal{F}$, and $g : \mathcal{X} \to \{0, 1\}$ is a *selection function*, serving as a qualifier for f as follows: for any x, if $g(x) = 1$, the classifier predicts $f(x)$, and otherwise it abstains. The general performance of a selective classifier is quantified in terms of its *coverage* and *risk*, where coverage is the probabilistic mass of non-rejected instances, and risk is the normalized average loss of f restricted to non-rejected instances. Let f^* be any (unknown) true risk minimizer[1] in $\mathcal{F}$ for the given problem. The selective classifier (f, g) is said to be *pointwise-competitive* if, for each x with $g(x) = 1$, it must hold that $f(x) = f^*(x)$ for all $f^* \in \mathcal{F}$ (Wiener and El-Yaniv, 2015). Thus, pointwise-competitiveness w.h.p. over choices of the training sample, is a highly desirable property: it guarantees, for each non-rejected test point, the best possible classification obtainable using the best in-hindsight classifier from $\mathcal{F}$. We do not restrict g to be from any specific hypothesis class, however, because we use disagreement-based selective prediction, the selection of $\mathcal{F}$ will limit the possibilities of g. The scenario of a predefined decision functions hypothesis class is investigated in Cortes et al. (2016b).

Pointwise-competitive selective classification (PCS) was first considered in the realizable case (El-Yaniv and Wiener, 2010), for which a simple consistent selective strategy (CSS) was shown to achieve a bounded and monotonically increasing (with m) coverage in various non-trivial settings. Note that in the realizable case, any PCS strategy attains zero risk (over the sub-domain it covers). These results were recently extended to the agnostic setting (Wiener and El-Yaniv, 2015; El-Yaniv and Wiener, 2011) with a related but different algorithm called *low-error selective strategy (LESS)*, for which a number of coverage bounds were shown. These bounds relied on the fact that the underlying probability distribution and the hypothesis class $\mathcal{F}$ will satisfy the so-called "(β_1, β_2)-Bernstein property" (Bartlett et al., 2004). The coverage bounds used by Wiener and El-Yaniv (2015); El-Yaniv and Wiener (2011) are dependent on the parameters β_1, β_2. This Bernstein property assumption (as presented in Bartlett et al., 2004), which allows for better concentration, nevertheless, can be problematic. First, it is defined with respect to a unique true risk minimizer f^*, a property that is unlikely to hold in noisy agnostic settings. Moreover, for arbitrary $\mathcal{F}$, even for the 0/1 loss function,there is little knowledge about cases for which the property holds with a non-trivial β_2.[2] We removed the Bernstein assumption from our analysis.

Assuming that a selective classifier is w.h.p. pointwise-competitive, our key goal is a small rejection rate. We will say that a learner has a **fast R^* rejection rate**, if w.h.p. the rejection rate is bounded by

$$\text{polylog}\left(\frac{1}{R(f^*) + 1/m}\right) \cdot R(f^*) + \frac{d \cdot \text{polylog}(m, 1/\delta)}{m},$$

1. We assume that there exists an f^* in $\mathcal{F}$. Otherwise, we can artificially define f^* to be any function whose risk is sufficiently close to $\inf_{f \in \mathcal{F}}(R(f))$, for instance, not greater than a small additive factor from this infimum.
2. It was mentioned by Wiener and El-Yaniv (2015) that, under the Tsybakov noise condition (Tsybakov, 2004), the desired property holds, but this is guaranteed only for cases in which the Bayes classifier is within $\mathcal{F}$, which is a fairly strong assumption in itself.

where $R(f^*)$, d and δ are defined in Section 2. Selective classification is very closely related to the field of **active learning (AL)**. In active learning, the learner can actively influence the learning process by selecting the points to be labeled. The incentive for introducing this extra flexibility is to reduce labeling efforts. A key question in theoretical studies of AL is how many label requests are sufficient to learn a given (unknown) target concept to a specified accuracy, a quantity called *label complexity*. For an AL algorithm satisfying the "passive example complexity" property (consuming the same number of unlabeled (and labeled) examples, as a passive algorithm consumes labeled examples for achieving the same error; see Definition 6.2), we will say it has R^* **exponential speedup**, if w.h.p. the number of labels it requests is bounded by

$$\text{polylog}\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*)m + d\cdot\text{polylog}(m,1/\delta).$$

The connection between active learning and confidence-rated prediction is quite intuitive. A pointwise-competitive selective classifier P can be straightforwardly used as the querying component of an active learning algorithm. This reduction is most naturally demonstrated in the stream-based AL model: at each iteration, the active algorithm trains a selective classifier on the currently available labeled samples, and then decides to query a newly introduced (unlabeled) point x if P abstains on x.

Hanneke's **disagreement coefficient** (Hanneke, 2007), see Definition 2.1, is a well-known parameter of the hypothesis class and the marginal distribution; it is used in most of the known label complexity bounds (Hsu, 2010; Hanneke, 2007; Ailon et al., 2012). The disagreement coefficient is the supremum of the relation between the disagreement mass of functions that are r-distanced from f^* to r, over r. PCS classification is based on using generalization bounds to estimate the empirical error of f^*, and more specifically, its distance from the empirical error of the ERM. Whenever all the functions that reside within a ball around the ERM unanimously agree, the classifier chooses to classify. Thus, the abstain rate is dependent on the disagreement mass of the functions within the ball. The radius of the ball depends on the generalization bounds. The generalization bounds we use are of the form $\tilde{O}(R(f^*)+d/m)$ for the agnostic case. After observing m examples, we can bound the disagreement mass of a ball around the ERM, by multiplying the radius of the ball, which is $\tilde{O}(R(f^*)+d/m)$, with the disagreement coefficient. Thus, if for example, the disagreement coefficient is bounded by a constant, the abstain rate of some PCS algorithms can be bounded by $\tilde{O}(R(f^*)+d/m)$. This gives a basic idea of the disagreement coefficient, which will be formally presented later on.

Note that, in principle, the disagreement coefficient can be replaced by another important quantity, namely, the **version space compression set size**, recently shown to be equivalent to it (Wiener et al., 2015; El-Yaniv and Wiener, 2015). Specifically, an $O(\text{polylog}(m)log(1/\delta))$ version space compression set size minimal bound was shown by Wiener et al. (2015, Corollary 11), to be equivalent to an $O(\text{polylog}(1/r))$ disagreement coefficient.

Zhang and Chaudhuri (2014) present a new algorithm that uses LP in order to achieve better label complexity analysis than was previously known. This paper proposes a quantity, denoted φ_c, to replace the disagreement coefficient (see a streamlined definition of φ_c at the top of page 24 in Hanneke, 2016), which is smaller than the disagreement coefficient. They

show that for the case of linear classification under log-concave distributions, their analysis can improve (reduce) the argument inside the logarithm of the label complexity bound, and the dependency on the VC-dimension is also reduced by a square root. However, in our paper we focus mainly on the more basic question: *when* can we achieve an exponential speedup in terms of $1/\epsilon$. Thus, due to the simplicity of the disagreement coefficient, and its widespread use in the literature, we chose to focus on it. See a detailed discussion on the φ_c quantity in Section 9.

The first contribution of this paper is a novel selective classifier, called ILESS, which uses a tighter generalization error bound than LESS and depends on $R(f^*)$ (and interpolates the agnostic and realizable cases). Most importantly, the new strategy can be analyzed completely without the Bernstein condition.

We derive an active learning algorithm, called Active-ILESS, corresponding to our selective classifier, ILESS. Active-ILESS is constructed to work in a stream-based AL model and its querying function is extremely conservative: for each unlabeled example, the algorithm requests its label if and only if the labeling of the optimal classifier (from the same class) on this point cannot be inferred from information already acquired. This querying strategy, which is often termed "disagreement-based," has been used in a number of stream-based AL algorithms such as Agnostic CAL and Oracular CAL (Hsu, 2010), A^2 (*Agnostic Active*), developed by Balcan et al. (2006), RobustCAL, studied in Hanneke (2012, 2014b) and Hanneke and Yang (2012), or the general agnostic AL algorithm of Dasgupta et al. (2007). Paper Huang et al. (2015) presented a computationally efficient algorithm for disagreement-based AL.

We prove that Active-ILESS, despite being very similar to Oracular CAL Hsu (2010), exhibits an improved label complexity, in comparison to that proved for Oracular CAL. Specifically, Active-ILESS achieves the same label complexity as Agnostic CAL, while being simpler in the sense that its consumption of ERM computations is smaller.

The first formal relationship between PCS classification and AL was proposed by El-Yaniv and Wiener (2012); Wiener (2013), where the aforementioned CSS algorithm was shown to be equivalent to the well-known CAL AL algorithm of Cohn et al. (1994), in the sense that a fast coverage rate for CSS was proven to be equivalent to an exponential label complexity speedup for CAL. This result applies to the realizable setting only. Our first contribution is a similar equivalence relation between pointwise-competitive selective classification and AL, which applies to the more challenging agnostic case and smoothly interpolates the realizable and agnostic settings.

Our second and main contribution is to show a complete equivalence between (i) selective classification with a fast R^* rejection rate, (ii) an AL algorithm, Active-ILESS, with an R^* exponential speedup, and (iii) the existence of an f^* with a disagreement coefficient bounded by $\text{polylog}(1/r)$. This is illustrated in Figure 1, where the blue errors indicate the equivalence relationships we prove in this paper, and the red arrow indicates a previously known result (Hsu, 2010; Hanneke, 2007), and can also be deduced from the other arrows.

2. Definitions

Consider a domain $\mathcal{X}$, and a binary label set $\mathcal{Y}=\{\pm 1\}$. A learning problem is specified via a hypothesis class $\mathcal{F}$ and an unknown probability distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$. Given a sequence

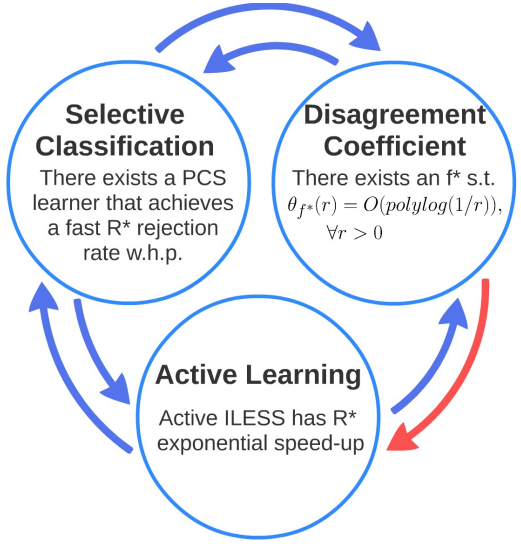

Figure 1: Main results

of labeled training examples $S_m = ((x_1, y_1), (x_2, y_2), ..., (x_m, y_m))$, such that $\forall i, (x_i, y_i) \in \mathcal{X} \times \mathcal{Y}$, the empirical error of a hypothesis f over S_m is $\hat{R}(f, S_m) \triangleq \frac{1}{m}\sum_{i=1}^{m} \ell(f(x_i), y_i)$, where $\ell : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^+$ is a loss function. In this paper, we focus mainly on the zero-one loss function, $\ell_{01}(y, y') \triangleq \mathbb{1}\{y \neq y'\}$. The true (zero-one) error of f is $R(f) \triangleq \mathbb{E}_{\mathcal{P}}\left[\ell_{01}(f(x), y)\right]$. An empirical risk minimizer hypothesis (henceforth, an ERM) is

$$\hat{f}(S_m) \triangleq \operatorname*{argmin}_{f \in \mathcal{F}} \hat{R}(f, S_m), \tag{1}$$

and a true risk minimizer is $f^* \triangleq \operatorname{argmin}_{f \in \mathcal{F}} R(f)$.[3]

We acquire the following definitions from Wiener and El-Yaniv (2015). For any hypothesis class $\mathcal{F}$, hypothesis $f \in \mathcal{F}$, distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$, sample S_m, and real number $r > 0$, define the true and empirical *low-error sets*,

$$\mathcal{V}(f, r) \triangleq \left\{f' \in \mathcal{F} : R(f') \leq R(f) + r\right\} \tag{2}$$

and

$$\hat{\mathcal{V}}(f, r) \triangleq \left\{f' \in \mathcal{F} : \hat{R}(f', S_m) \leq \hat{R}(f, S_m) + r\right\}. \tag{3}$$

Let $G \subseteq \mathcal{F}$. The *disagreement set* (Hanneke, 2007) and *agreement set* (El-Yaniv and Wiener, 2010) w.r.t. G are defined, respectively, as

$$DIS(G) \triangleq \{x \in \mathcal{X} : \exists f_1, f_2 \in G \quad , \quad f_1(x) \neq f_2(x)\} \tag{4}$$

3. We assume that f^* exists, and that it need not be unique, in which case f^* refers to any one of the minimizers.

$$\text{and} \quad AGR(G) \triangleq \{x \in \mathcal{X} : \forall f_1, f_2 \in G \quad , \quad f_1(x) = f_2(x)\}. \tag{5}$$

In *selective classification* (El-Yaniv and Wiener, 2010), the learning algorithm receives S_m and is required to output a *selective classifier*, defined to be a pair (f, g), where $f \in \mathcal{F}$ is a classifier, and $g : \mathcal{X} \to \{0, 1\}$ is a *selection function*, serving as a qualifier for f as follows. For any $x \in \mathcal{X}$, $(f, g)(x) = f(x)$ iff $g(x) = 1$. Otherwise, the classifier outputs "I don't know". For any selective classifier (f, g), we define its coverage to be

$$\Phi(f, g) \triangleq \Pr_{X \sim \mathcal{P}_{\mathcal{X}}}(g(X) = 1),$$

and its complement, $1 - \Phi$, is called the **abstain rate**. For any $f \in \mathcal{F}$ and $r > 0$, define the set $B(f, r)$ of all hypotheses that reside within a ball of radius r around f,

$$B(f, r) \triangleq \left\{f' \in \mathcal{F} : \Pr_{X \sim \mathcal{P}_{\mathcal{X}}}\left\{f'(X) \neq f(X)\right\} \leq r\right\}.$$

For any $G \subseteq \mathcal{F}$, and distribution $\mathcal{P}_{\mathcal{X}}$, we denote by ΔG the volume of the disagreement set of G (see (4)), $\Delta G \triangleq \Pr\{DIS(G)\}$.

Definition 2.1 (Disagreement Coefficient) *Let $r_0 \geq 0$. Hanneke's* disagreement coefficient *(Hanneke, 2007) of a classifier $f \in \mathcal{F}$ with respect to the target distribution $\mathcal{P}_{\mathcal{X}}$ is*

$$\theta_f(r_0) \triangleq \sup_{r > r_0} \frac{\Delta B(f, r)}{r}, \tag{6}$$

and the general disagreement coefficient *of the entire hypothesis class $\mathcal{F}$ is*

$$\theta(r_0) \triangleq \sup_{f \in \mathcal{F}} \theta_f(r_0). \tag{7}$$

Notice that this definition of the disagreement coefficient is independent of $\mathcal{P}_{\mathcal{Y}|\mathcal{X}}$. Another commonly used definition of the disagreement coefficient does depend on a true risk minimizer f^*, as follows:

$$\theta'(r_0) = \sup_{r > r_0} \frac{\Delta B(f^*, r)}{r}. \tag{8}$$

Clearly, it always holds that $\theta' \leq \theta$. The independence of θ of unknown quantities such as the underlying distribution (and f^*), however, is a convenient property that sometimes allows for a direct estimation of θ, which only depends on the marginal distribution, $\mathcal{P}_{\mathcal{X}}$. This is, for example, the case in AL, where labels are expensive but information about the marginal distribution (provided by unlabeled examples) is cheap. Note also that the above definition of θ' implicitly assumes a unique f^*. Nevertheless, the definition can be extended to cases where f^* is not unique, in which case the infimum over all f^* can be considered (the analysis can be extended accordingly using limits). For more on the disagreement coefficient, and examples of probabilities distributions and hypothesis classes for which it is bounded, see Hanneke (2014b).

3. Convergence Bounds and LESS

We use a uniform convergence bound from Vapnik and Chervonenkis (1974); Dasgupta et al. (2007); Bousquet et al. (2003). Define convergence slacks $\sigma_{R-\hat{R}}(m,\delta,d,R,\hat{R})$ and $\sigma_{\hat{R}-R}(m,\delta,d,R,\hat{R})$, given in terms of the training sample, S_m, its size, m, the confidence parameter, δ, and the VC-dimension d of the class $\mathcal{F}$. For any $f \in \mathcal{F}$,

$$\sigma_{R-\hat{R}}(m,\delta,d,R,\hat{R}) \triangleq \min\left\{\underbrace{\frac{4d\ln(\frac{16me}{d\delta})}{m}+\sqrt{\frac{4d\ln(\frac{16me}{d\delta})}{m}\cdot\hat{R}}}_{\hat{\sigma}_{R-\hat{R}}(m,\delta,d,\hat{R})},\underbrace{\sqrt{\frac{4d\ln(\frac{16me}{d\delta})}{m}\cdot R}}_{\bar{\sigma}_{R-\hat{R}}(m,\delta,d,R)}\right\} \tag{9}$$

and

$$\sigma_{\hat{R}-R}(m,\delta,d,R,\hat{R}) \triangleq \min\left\{\underbrace{\frac{4d\ln(\frac{16me}{d\delta})}{m}+\sqrt{\frac{4d\ln(\frac{16me}{d\delta})}{m}\cdot R}}_{\bar{\sigma}_{\hat{R}-R}(m,\delta,d,R)},\underbrace{\sqrt{\frac{4d\ln(\frac{16me}{d\delta})}{m}\cdot\hat{R}}}_{\hat{\sigma}_{\hat{R}-R}(m,\delta,d,\hat{R})}\right\}. \tag{10}$$

To simplify the analysis, we further decompose the above slack terms into their empirical and non-empirical components. For (9), we thus have, respectively,

$$\hat{\sigma}_{R-\hat{R}}(m,\delta,d,\hat{R}) \triangleq \frac{4d\ln(\frac{16me}{d\delta})}{m}+\sqrt{\frac{4d\ln(\frac{16me}{d\delta})}{m}\cdot\hat{R}} \tag{11}$$

and

$$\hat{\sigma}_{\hat{R}-R}(m,\delta,d,\hat{R}) \triangleq \sqrt{\frac{4d\ln(\frac{16me}{d\delta})}{m}\cdot\hat{R}}. \tag{12}$$

Similarly, the non-empirical part in these minimums are denoted by $\bar{\sigma}_{R-\hat{R}}$ and $\bar{\sigma}_{\hat{R}-R}$. With this notation, we can write, for example, $\sigma_{R-\hat{R}} = \min\{\hat{\sigma}_{R-\hat{R}}, \bar{\sigma}_{R-\hat{R}}\}$. Our Lemma 1 is taken from the work of Dasgupta et al. (2007, Lemma 1), which is based on Bousquet et al. (2003, Theorem 7) [4].

Lemma 1 *Let $\mathcal{F}$ be a hypothesis class with VC-dimension d. For any $0 < \delta < 1$, with probability of at least $1-\delta$ over the choice of S_m from $\mathcal{P}^m$, any hypothesis $f \in \mathcal{F}$ satisfies*

$$R(f) \le \hat{R}(f) + \sigma_{R-\hat{R}}\left(m,\delta,d,R(f),\hat{R}(f)\right) \tag{13}$$

$$\hat{R}(f) \le R(f) + \sigma_{\hat{R}-R}\left(m,\delta,d,R(f),\hat{R}(f)\right). \tag{14}$$

4. In the original lemma from Dasgupta et al. (2007), $S(\mathcal{H},n)$, the growth function, is given. We insert Sauer's Lemma, $S(\mathcal{H},n) \le (\frac{em}{d})^d$, into Lemma 1 from Dasgupta et al. (2007) to get our lemma.

Strategy 1 is the LESS algorithm of Wiener and El-Yaniv (2015). LESS learns w.h.p. a pointwise-competitive selective classifier, (f,g), where $f \in \mathcal{F}$ and $g : \mathcal{X} \to \{0,1\}$ is its selection function that determines whether to abstain or to classify. A *pointwise-competitive selective classifier* must satisfy the following condition: For each x with $g(x)=1$, it must hold that $f(x) = f^*(x)$ for all $f^* \in \mathcal{F}$. A PCS learning algorithm must output a PCS classifier w.h.p. **for all** $\mathcal{P}_{\mathcal{Y}|\mathcal{X}}$; otherwise, one can consider a tailor-made trivial algorithm for each distribution, which simply returns f^*.

Remark 2 *The original definition of pointwise-competitiveness from Wiener and El-Yaniv (2015) requires a single f^*. We widen the definition to cases for which there are more than one f^*, and require that a pointwise-competitive selective classifier be equal to* all *f^*, wherever $g=1$. This extrapolation seems a bit strict. Nevertheless, even if the requirement would have been relaxed to "any f^*", any pointwise-competitive selective classifier would still have been forced to identify with all f^*, as it is impossible to determine whether a set of functions are all f^*, or one is better than the rest.*

The main idea behind LESS is that, w.h.p., all f^* lie within a ball around an ERM hypothesis with an error radius of $2\sigma(m,\delta/4,d)$, where

$$\sigma(m,\delta,d) \triangleq 2\sqrt{\frac{2d\left(\ln\frac{2me}{d}\right)+\ln\frac{2}{\delta}}{m}} \tag{15}$$

is the slack term of a certain uniform convergence bound. Therefore, if all the functions in that ball agree over the labeling of any instance x, we know with high probability that all f^* label x the same way as the ERM. This property ensures that LESS is pointwise-competitive w.h.p.

Strategy 1 Agnostic Low-Error Selective Strategy (LESS)

Input: Sample set of size m, S_m,
Confidence level δ
Hypothesis class $\mathcal{F}$ with VC dimension d
Output: A selective classifier (h,g)
1: Set $\hat{f} = ERM(\mathcal{F},S_m)$, i.e., $\hat{f}$ is any empirical risk minimizer from $\mathcal{F}$
2: Set $G = \hat{\mathcal{V}}\left(\hat{f}, 2\sigma(m,\delta/4,d)\right)$
3: Construct g such that $g(x)=1 \iff x \in \{\mathcal{X} \setminus DIS(G)\}$
4: $f = \hat{f}$

4. ILESS

We now introduce an improved version of LESS, called ILESS, which uses a radius of the form $d\cdot\text{polylog}(m,1/\delta)\cdot\left(\frac{1}{m}+\sqrt{\frac{R(f^*)}{m}}\right)$. Noting that the radius, $2\sigma(m,\delta/4,d)$, used by LESS to define $G=\hat{\mathcal{V}}$, is of the form $d\cdot\text{polylog}(m,1/\delta)/\sqrt{m}$, we observe that in cases where $R(f^*)\approx\frac{C}{m}$, this new radius behaves as $\frac{d\cdot\text{polylog}(m,1/\delta)}{m}$. We later show that this radius allows ILESS to achieve a faster rejection decay rate than the one achieved by LESS.

Consider the pseudo-code of ILESS given in Strategy 2. We now analyze ILESS, and begin by showing in Lemma 3 that ILESS is pointwise-competitive w.h.p., i.e., for any x

Strategy 2 Improved Low-Error Selective Strategy (ILESS)

Input: Sample set of size m, S_m,
Confidence level δ
Hypothesis class $\mathcal{F}$ with VC dimension d
Output: A selective classifier (h, g)
1: Set $\hat{f} = ERM(\mathcal{F}, S_m)$, i.e., $\hat{f}$ is any empirical risk minimizer from $\mathcal{F}$
2: Set $\sigma_{\text{ILESS}} = \hat{\sigma}_{R-\hat{R}}\left(m, \delta, d, \hat{R}(\hat{f}, S_m)\right) + \bar{\sigma}_{\hat{R}-R}\left(m, \delta, d, \hat{R}(\hat{f}, S_m) + \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}(\hat{f}, S_m))\right)$
3: Set $G = \hat{\mathcal{V}}\left(\hat{f}, \sigma_{\text{ILESS}}\right)$
4: Construct g such that $g(x) = 1 \Longleftrightarrow x \in \{\mathcal{X} \setminus DIS(G)\}$
5: $h = \hat{f}$

for which $g(x) = 1$, $f(x) = f^*(x)$ for all f^*. The calculation of g appears to be very problematic, as for a specific x, a unanimous decision over an infinite number of functions must be ensured. This problem was shown to be reducible to finding an ERM under one constraint (Lemma 6.1 in El-Yaniv and Wiener, 2011, a.k.a. the disbelief principle). This is a difficult problem, nonetheless, albeit one that could be estimated with heuristics.

Definition 4.1 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown probability distribution. Given a sample set S_m, drawn from $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$, we denote by $\mathcal{E}$ the event where both inequalities (13) and (14) of Lemma 1 simultaneously hold. We know from the lemma that $\mathcal{E}$ occurs with probability of at least $1 - \delta$.*

Lemma 3 (ILESS **is pointwise-competitive)** *Given that event $\mathcal{E}$ occurred (see Definition 4.1), for all $f^* \in \mathcal{F}$, f^* resides within G (from Strategy 2), and therefore,* ILESS *is pointwise-competitive w.h.p.*

Proof From (14), it follows that

$$\begin{aligned}\hat{R}(f^*, S_m) &\leq R(f^*) + \sigma_{\hat{R}-R}(m, \delta, d, R(f^*), \hat{R}(f^*, S_m)) \\ &\leq R(f^*) + \bar{\sigma}_{\hat{R}-R}\left(m, \delta, d, R(f^*)\right). \end{aligned} \tag{16}$$

Additionally, by the definition of f^*, we know that it has the lowest true error, and using Inequality (13) from Lemma 1 we obtain,

$$\begin{aligned}R(f^*) &\leq R(\hat{f}) \\ &\leq \hat{R}(\hat{f}, S_m) + \sigma_{R-\hat{R}}(m, \delta, d, R(\hat{f}), \hat{R}(\hat{f}, S_m)) \\ &\leq \hat{R}(\hat{f}, S_m) + \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}(\hat{f}, S_m)). \end{aligned} \tag{17}$$

Finally, by applying (17) in (16), we have,

$$\begin{aligned}\hat{R}(f^*, S_m) \leq \hat{R}(\hat{f}, S_m) &+ \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}(\hat{f}, S_m)) \\ &+ \bar{\sigma}_{\hat{R}-R}\left(m, \delta, d, \hat{R}(\hat{f}, S_m) + \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}(\hat{f}, S_m))\right),\end{aligned}$$

which means that $f^* \in G$. ■

Lemma 4 below bounds the radius σ_{ILESS} of ILESS. The lemma uses the notation

$$A \triangleq 4d \ln(\frac{16me}{d\delta}),$$

with which, by the definition of σ_{ILESS} (see Strategy 2), we have,

$$\begin{aligned}\sigma_{\text{ILESS}} &= \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}(\hat{f}, S_m)) + \bar{\sigma}_{\hat{R}-R}\left(m, \delta, d, \hat{R}(\hat{f}, S_m) + \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}(\hat{f}, S_m))\right) \\ &= \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \hat{R}(\hat{f}, S_m)} + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \left[\hat{R}(\hat{f}, S_m) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \hat{R}(\hat{f}, S_m)}\right]}. \end{aligned} \tag{18}$$

Lemma 4 *Given that event $\mathcal{E}$ (see Definition 4.1) occurred, the radius of* ILESS *satisfies*

$$\sigma_{\text{ILESS}} \leq 6\frac{A}{m} + 3\sqrt{\frac{A}{m} \cdot R(f^*)} = O\left(\frac{A}{m} + \sqrt{\frac{A}{m} \cdot R(f^*)}\right), \tag{19}$$

where $A \triangleq 4d \ln(\frac{16me}{d\delta})$.

Proof Under our assumption, inequalities (13) and (14) hold for every $f \in \mathcal{F}$. We thus have

$$\hat{R}(\hat{f}, S_m) \leq \hat{R}(f^*, S_m) \leq R(f^*) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot R(f^*)}. \tag{20}$$

Replacing the three occurrences of $\hat{R}(f^*, S_m)$ in (18) with the R.H.S. of (20), and using the basic inequalities $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$ and $\sqrt{ab} \leq a/2 + b/2$, we get,

$$\begin{aligned}
\sigma_{\text{ILESS}} &\leq \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \left(R(f^*) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot R(f^*)} \right)} + \frac{A}{m} + \\
&\quad + \sqrt{\frac{A}{m} \cdot \left[R(f^*) + \frac{2A}{m} + \sqrt{\frac{A}{m} \cdot R(f^*)} + \sqrt{\frac{A}{m} \cdot \left(R(f^*) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot R(f^*)} \right)} \right]} \\
&\leq \frac{2A}{m} + \sqrt{\frac{A}{m} \cdot \left(R(f^*) + \frac{A}{m} + \frac{A}{2m} + \frac{1}{2} R(f^*) \right)} + \\
&\quad + \sqrt{\frac{A}{m} \cdot \left[R(f^*) + \frac{3A}{2m} + \frac{1}{2} R(f^*) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \left(R(f^*) + \frac{3A}{2m} + \frac{1}{2} R(f^*) \right)} \right]} \\
&\leq \frac{2A}{m} + \frac{3A}{2m} + \frac{3}{2}\sqrt{\frac{A}{m} R(f^*)} + \sqrt{\frac{A}{m} \cdot \left[\frac{5A}{2m} + \frac{3}{2} R(f^*) + \sqrt{\frac{A}{m} \cdot \left(\frac{3A}{2m} + \frac{3}{2} R(f^*) \right)} \right]} \\
&\leq \frac{7A}{2m} + \frac{3}{2}\sqrt{\frac{A}{m} \cdot R(f^*)} + \sqrt{\frac{A}{m} \cdot \left[\frac{5A}{2m} + \frac{3}{2} R(f^*) + \frac{3A}{2m} + \sqrt{\frac{3A}{2m} \cdot R(f^*)} \right]} \\
&\leq \frac{7A}{2m} + \frac{3}{2}\sqrt{\frac{A}{m} \cdot R(f^*)} + \sqrt{\frac{A}{m} \cdot \left[\frac{5A}{2m} + \frac{3}{2} R(f^*) + \frac{3A}{2m} + \frac{3A}{4m} + \frac{3}{4} R(f^*) \right]} \\
&\leq \frac{7A}{2m} + \frac{3}{2}\sqrt{\frac{A}{m} \cdot R(f^*)} + \sqrt{\frac{19}{4}} \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \frac{9}{4} R(f^*)} \\
&\leq 6\frac{A}{m} + 3\sqrt{\frac{A}{m} \cdot R(f^*)}. \qquad (21)
\end{aligned}$$

■

In comparison, the radius of LESS is of order $O(\sqrt{\frac{A}{m}})$, which can be significantly larger when $R(f^*)$ is small. This potential radius advantage translates into a potential coverage advantage of ILESS, as stated in the following theorem.

Theorem 5 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and let $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown probability distribution. Given that event $\mathcal{E}$ (see Definition 4.1) occurred, G defined in Strategy 2, holds that*

$$G \subseteq B(f^*, R_0),$$

where

$$R_0 \triangleq 2 \cdot R(f^*) + 11 \cdot \frac{A}{m} + 6 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)},$$

and thus, for all f^*, the abstain rate is bounded by

$$1 - \Phi(\text{ILESS}) \leq \theta_{f^*}(R_0) \cdot R_0.$$

This immediately implies (by definition) that

$$1 - \Phi(\text{ILESS}) \leq \theta(R_0) \cdot R_0.$$

Remark 6 *Note that $R_0 = O\left(R(f^*) + \frac{A}{m}\right)$ due to $\sqrt{\frac{A}{m} \cdot R(f^*)} \leq \frac{1}{2}(\frac{A}{m} + R(f^*))$.*

Proof We start by showing that G, defined in Strategy 2, resides within a ball around any specific f^*. To do so, we need to bound the true error of all functions in G.

$$\begin{aligned}
f \in G \quad &\Rightarrow \quad \hat{R}(f, S_m) \leq \hat{R}(\hat{f}, S_m) + \sigma_{\text{ILESS}} \qquad (22) \\
&\Rightarrow \quad \hat{R}(f, S_m) \leq R(f^*) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot R(f^*)} + 6\frac{A}{m} + 3\sqrt{\frac{A}{m} \cdot R(f^*)} \qquad (23) \\
&\Rightarrow \quad \hat{R}(f, S_m) \leq R(f^*) + 7 \cdot \frac{A}{m} + 4 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)}, \qquad (24)
\end{aligned}$$

where Inequality (22) is explained by the definition of G, and inequality (23) follows from (20) and (21) (under event $\mathcal{E}$). We then have,

$$\begin{aligned}
R(f) &\leq \hat{R}(f, S_m) + \hat{\sigma}_{R-\hat{R}}(m, \delta, d, \hat{R}) \qquad (25) \\
&\leq \hat{R}(f, S_m) + \frac{A}{m} + \sqrt{\frac{A}{m} \cdot \hat{R}(f, S_m)} \qquad (26) \\
&\leq R(f^*) + 8 \cdot \frac{A}{m} + 4 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)} + \\
&\quad + \sqrt{\frac{A}{m} \cdot \left[R(f^*) + 7 \cdot \frac{A}{m} + 4 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)} \right]} \qquad (27) \\
&\leq R(f^*) + 8 \cdot \frac{A}{m} + 4 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)} + \sqrt{\frac{A}{m} \cdot \left[3R(f^*) + 9 \cdot \frac{A}{m} \right]} \qquad (28) \\
&\leq R(f^*) + 11 \cdot \frac{A}{m} + 6 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)}, \qquad (29)
\end{aligned}$$

where inequality (25) is (13) (which holds given $\mathcal{E}$), inequality (26) follows directly from the definition of $\hat{\sigma}_{R-\hat{R}}$, inequality (27) is obtained using (24), Inequality (28) follows from $\sqrt{ab} \leq a/2 + b/2$, and (29) from $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$.

Using (29), for all $f \in G$, and any f^*, we have,

$$\begin{aligned}
\Pr_{X \sim \mathcal{P}_{\mathcal{X}}} \{f(X) \neq f^*(X)\} &= \Pr_{X,Y \sim \mathcal{P}_{\mathcal{X},\mathcal{Y}}} \{f(X) \neq f^*(X) \wedge f^*(X) = Y\} + \\
&\quad \Pr_{X,Y \sim \mathcal{P}_{\mathcal{X},\mathcal{Y}}} \{f(X) \neq f^*(X) \wedge f^*(X) \neq Y\} \\
&\leq \Pr_{X,Y \sim \mathcal{P}_{\mathcal{X},\mathcal{Y}}} \{f(X) \neq f^*(X) \wedge f^*(X) = Y\} + R(f^*) \\
&\leq \Pr_{X,Y \sim \mathcal{P}_{\mathcal{X},\mathcal{Y}}} \{f(X) \neq Y\} + R(f^*) \\
&= R(f) + R(f^*) \\
&\leq 2 \cdot R(f^*) + 11 \cdot \frac{A}{m} + 6 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)}. \qquad (30)
\end{aligned}$$

It follows that

$$f \in B\left(f^*, 2 \cdot R(f^*) + 11 \cdot \frac{A}{m} + 6 \cdot \sqrt{\frac{A}{m} \cdot R(f^*)}\right) = B(f^*, R_0),$$

and, in particular,

$$G \subseteq B(f^*, R_0),$$

so,

$$\Delta G \leq \Delta B(f^*, R_0).$$

The abstain rate of ILESS equals ΔG. We can now use the disagreement coefficient to bound the abstain rate from above,

$$\Delta G \leq \Delta B(f^*, R_0) = \frac{\Delta B(f^*, R_0)}{R_0} \cdot R_0 \leq \theta(R_0) \cdot R_0, \tag{31}$$

which concludes the proof. ■

According to Theorem 5, assuming the disagreement coefficient is $\theta(r) = O(\text{polylog}(1/r))$ for $r \geq R(f^*)$, the rejection mass of ILESS, defined as the probability that the classifier trained by ILESS will output "I don't know" is bounded w.h.p. by

$$\text{polylog}_1\left(\frac{1}{R(f^*) + 1/m}\right) \cdot R(f^*) + \frac{d \cdot \text{polylog}_2(m, 1/\delta)}{m}. \tag{32}$$

In many cases, the disagreement coefficient, $\theta(r)$, is bounded by a constant, or by $O(\text{polylog}(1/r))$ for all $r > 0$ (see Hanneke, 2014b). For example, it was shown in Wiener et al. (2015), that for linear separators under mixture of Gaussians, and for axis-aligned rectangles with probability mass bounded away from zero under product densities over $\mathbb{R}^k$, $\theta(r)$ is bounded by $O(\text{polylog}(1/r))$ for all $r > 0$. For such cases, we know that (32) always holds, regardless of the size of $R(f^*)$. The disagreement coefficient is only dependent on the marginal $\mathcal{P}_\mathcal{X}$, the hypothesis class $\mathcal{F}$, and the identity of the true risk minimizers, f^* (which is not necessarily unique). This fact motivates the following definition of a rejection rate of a selective learning algorithm, which is only dependent on $\mathcal{P}_\mathcal{X}$,$\mathcal{F}$ and f^*.

Definition 4.2 (Fast R^* Rejection Rate) *Given $\mathcal{P}_\mathcal{X}$,$\mathcal{F}$ and f^*, if for all $\delta > 0$, and all $\mathcal{P}_{\mathcal{Y}|\mathcal{X}}$ for which f^* is a true risk minimizer, the rejection mass of a selective classifier learning algorithm is bounded by (32) with probability of at least $1 - \delta$, we say that the algorithm achieves a **fast** R^* **rejection rate**, with* polylog_1 *and* polylog_2 *as its parameters.*

Corollary 7 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d. Given $\mathcal{P}_\mathcal{X}$ and f^*, if $\theta_{f^*}(r)$ is bounded by $O(\text{polylog}(1/r))$ for all $r > 0$, then there exists a* PCS *learning algorithm (*ILESS*) which achieves a fast R^* rejection rate.*

Proof The proof is immediate from Theorem 5. ■

In the next section, we will show the other direction; that is, if there is a PCS learning algorithm that has a fast R^* rejection rate, then $\theta(r) = O(\text{polylog}(1/r))$ for all $r > 0$.

As long as the number of training examples that ILESS receives is not "too large" relative to $1/R(f^*)$, i.e., $m \ll \frac{1}{R(f^*)}$, the rejection mass of ILESS is

$$O\left(\frac{d \cdot \text{polylog}(m, 1/\delta)}{m}\right).$$

When m is large, and $R(f^*)$ becomes more dominant than $\frac{1}{m}$, our coverage bound is dominated by $R(f^*)$. This should not surprise us, as ILESS achieves *pointwise-competitiveness* w.h.p., and any strategy that achieves pointwise-competitiveness cannot ensure a better rejection mass than $R(f^*)$ without making more assumptions about the error or the distribution. This can be seen in the following example, in which $\theta(r) \leq 1$ for all $r > 0$, but the rejection mass of any pointwise-competitive strategy is always at least $R(f^*)$.

Example 1 *Given any $0 < \epsilon < 0.5$, let $\mathcal{X} = [0, 1]$, and $\mathcal{F} = \{f_1, f_2\}$ where*

$$f_1(x) = \begin{cases} 1, & x < \epsilon \\ 0, & \textit{otherwise} \end{cases}, f_2(x) = \begin{cases} 1, & x > 1 - \epsilon \\ 0, & \textit{otherwise.} \end{cases}$$

Let $\mathcal{P}_\mathcal{X}$ be the uniform distribution over $[0, 1]$. Assume that Y will always be zero. f_1 and f_2 are both f^*. Every pointwise-competitive classifier will have to output $g(x) = 0$ for every x in the disagreement set of f_1 and f_2. $R(f^*) = \epsilon$, and the rejection mass is $2\epsilon (= 2R(f^*))$.

5. From Selective Classification to the Disagreement Coefficient

We now turn to show a reduction from selective classification, to the disagreement coefficient.

Theorem 8 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution. Let* PCS *be an algorithm that returns a pointwise-competitive selective classifier w.h.p. for all distributions whose marginal is $\mathcal{P}_\mathcal{X}$. If for every $m \leq 1/R(f^*)$, $0 < \delta$, with probability of at least $1-\delta$, the abstain rate $1-\Phi$ of* $\text{PCS}(S_m, \delta, \mathcal{F}, d)$ *is bounded by a monotonic*[5] *polylog as follows:*

$$1 - \Phi(\text{PCS}) \leq \frac{\text{polylog}_0(\text{m}, 1/\delta)}{\text{m}}. \tag{33}$$

Then for every f^* (every true risk minimizer), for every $r \geq R(f^*)$,

$$\theta_{f^*}(r) \leq 20\left(\text{polylog}_0(1/r, 1/r) + 3\right).$$

Proof For any $m \in \{4, 5, ..., \lfloor 1/R(f^*) \rfloor\}$, denote by $\mathcal{S}_m$ a random training sample drawn from $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$. Let Z be a random variable representing a single random unlabeled example sampled from $\mathcal{P}_\mathcal{X}$, and let f^* to be a specific true risk minimizer.

For $Z \in DIS\left(B(f^*, \frac{1}{m})\right)$, we use the following argument from Hanneke (2012, Lemma 47). We know that there exists a function $h_Z \in \mathcal{F}$ s.t. $h_Z(Z) \neq f^*(Z)$ and $Pr(h_Z(X) \neq f^*(X)) \leq \frac{1}{m}$. We denote by $\mathcal{P}_{\mathcal{X},\mathcal{Y}_z}$ a new probability distribution, where the marginal, $\mathcal{P}_\mathcal{X}$,

5. If the polylog is not monotonic, the following holds: $\theta_{f^*}(r) \leq 16(\text{polylog}(\lfloor 1/r \rfloor, \lfloor 1/r \rfloor) + 3) \cdot \frac{5}{4}$; see Eq. (44).

remains the same, but Y becomes $Y \triangleq h_Z(x)$. Clearly, h_Z is a true risk minimizer (f^*) for such a distribution.

Denote by e_1 the probability event where (33) holds (for a specific $m \leq 1/R(f^*)$). Denote by e_2 the event where PCS has succeeded in returning a pointwise-competitive selective classifier (f_{s_m}, g_{s_m}) under S_m.

Define S'_m to be a modified S_m where, for every $(x,y) \in S_m$ s.t. $h_Z(x) \neq y$, y is modified to become $y = h_Z(x)$. S'_m is a random training sample drawn from $\mathcal{P}_{\mathcal{X},\mathcal{Y}_z}$. Denote by e_{3z} the event where PCS has succeeded in returning a pointwise-competitive selective classifier $(f_{s'_m}, g_{s'_m})$ under S'_m. h_Z is only defined for cases in which $Z \in DIS\left(B(f^*, \frac{1}{m})\right)$, and thus we define that e_{3z} will vacuously hold when $Z \notin DIS\left(B(f^*, \frac{1}{m})\right)$.

Under our assumptions, $\Pr(e_1), \Pr(e_2) \geq 1-\delta$. For every $Z \in DIS(B(f^*, \frac{1}{m}))$, $\Pr(e_{3z}|Z) \geq 1-\delta$, and for every $Z \notin DIS(B(f^*, \frac{1}{m}))$, $\Pr(e_{3z}|Z) = 1$, which implies that $\Pr(e_{3z}) \geq 1-\delta$. We denote by $h_Z(X_m) = Y_m$ the event where $h_Z(x) = y$ for all $(x_i, y_i) \in S_m$. The explanations for the following (in)equalities follow.

$$
\begin{aligned}
& \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right) \wedge h_Z(X_m) = Y_m\right\} && (34)\\
= \;& \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right) \wedge h_Z(X_m) = Y_m \wedge e_1 \wedge e_2 \wedge e_{3z}\right\} && (35)\\
& + \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right) \wedge h_Z(X_m) = Y_m \mid \neg(e_1 \wedge e_2 \wedge e_{3z})\right\} \cdot \Pr(\neg(e_1 \wedge e_2 \wedge e_{3z}))\\
\leq \;& \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right) \wedge h_Z(X_m) = Y_m \wedge e_1 \wedge e_2 \wedge e_{3z}\right\} + 3\delta && (36)\\
\leq \;& \Pr\{g_{s_m}(Z) = 0 \wedge e_1 \wedge e_2 \wedge e_{3z}\} + 3\delta && (37)\\
\leq \;& \Pr\{g_{s_m}(Z) = 0 \wedge e_1\} + 3\delta\\
\leq \;& \Pr\{g_{s_m}(Z) = 0 \mid e_1\} + 3\delta\\
\leq \;& \frac{\text{polylog}_0(m, 1/\delta)}{m} + 3\delta. && (38)
\end{aligned}
$$

In (34), it is convenient to view the random experiment as if we draw z first, and then S_m. If $Z \in DIS\left(B(f^*, \frac{1}{m})\right)$, then consider h_Z to be any function that holds $h_Z(Z) \neq f^*(Z)$ and $Pr(h_Z(X) \neq f^*(X) \leq \frac{1}{m})$. If $Z \notin DIS\left(B(f^*, \frac{1}{m})\right)$, then the event described in (34) does not occur, and h_Z is undefined. In (35), we use conditional probability, and in (36) we apply the union bound. Inequality (37) is justified as follows. If $h_Z(X_m) = Y_m$, then the algorithm received the same input under $\mathcal{P}_{\mathcal{X},\mathcal{Y}_z}$ and $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$. Given that e_2 and e_{3z} occurred, we know that the algorithm has successfully output a pointwise-competitive selective classifier for both probabilities, which means that whenever f^* and h_Z disagree, g_{s_m} has to output zero; otherwise, it will not be pointwise-competitive for one of the distributions. By the definition of h_Z, $h_Z(Z) \neq f^*(Z)$, which explains the inequality. Inequality (38) follows from the definition of e_1. Taking $\delta = \frac{1}{m}$, we get,

$$
\Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right) \wedge h_Z(X_m) = Y_m\right\} \;\leq\; \frac{\text{polylog}_0(m,m) + 3}{m}. \qquad (39)
$$

The following inequalities are derived using elementary conditional probability. In Equation (41) we use an argument taken from the proof of Hanneke (2012, Lemma 47). $h_Z \in$

$B(f^*, \frac{1}{m})$, and thus the probability that f^* and h_Z will have a different label for a specific example is bounded by $1/m$. The probability that f^* will mispredict is by definition $R(f^*)$, and thus, using the union bound, we get (41).

$$
\begin{aligned}
& \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right) \wedge h_Z(X_m) = Y_m\right\}\\
= \;& \Pr\left\{h_Z(X_m) = Y_m \mid Z \in DIS\left(B(f^*, \frac{1}{m})\right)\right\} \cdot \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right)\right\}\\
\geq \;& \Pr\left\{f^*(X_m) = Y_m \wedge h_Z(X_m) = f^*(X_m) \mid Z \in DIS\left(B(f^*, \frac{1}{m})\right)\right\} \cdot && (40)\\
& \cdot \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right)\right\}\\
\geq \;& \left(1 - R(f^*) - \frac{1}{m}\right)^m \cdot \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right)\right\} && (41)\\
\geq \;& \left(1 - \frac{1}{m} - \frac{1}{m}\right)^m \cdot \Pr\left\{Z \in DIS\left(B(f^*, \frac{1}{m})\right)\right\}\\
\geq \;& \frac{1}{16} \cdot \Delta B\left(f^*, \frac{1}{m}\right). && (42)
\end{aligned}
$$

Combining (39) and (42), we get that for every $m \in \{4, 5, ..., \lfloor 1/R(f^*) \rfloor\}$,

$$
\frac{\Delta B(f^*, 1/m)}{1/m} \;\leq\; 16\left(\text{polylog}_0(m,m) + 3\right). \qquad (43)
$$

The following inequalities follow from (43), and from the fact that $\Delta B(f^*, x)$ and $\text{polylog}_0(\cdot)$ are non-decreasing. For any r in $[R(f^*), \frac{1}{5}]$, and noting that $\frac{1}{\lfloor 1/r \rfloor} \geq r$,

$$
\begin{aligned}
\frac{\Delta B(f^*, r)}{r} &\leq \frac{\Delta B\left(f^*, \frac{1}{\lfloor 1/r \rfloor}\right)}{\frac{1}{\lfloor 1/r \rfloor}} \cdot \frac{1}{r \cdot \lfloor 1/r \rfloor}\\
&\leq 16(\text{polylog}_0(\lfloor 1/r \rfloor, \lfloor 1/r \rfloor) + 3) \cdot \frac{1}{r \cdot (1/r - 1)}\\
&\leq 16\left(\text{polylog}_0(\lfloor 1/r \rfloor, \lfloor 1/r \rfloor) + 3\right) \cdot \frac{1}{1-r}\\
&\leq 16(\text{polylog}_0(\lfloor 1/r \rfloor, \lfloor 1/r \rfloor) + 3) \cdot \frac{5}{4} && (44)\\
&\leq 20(\text{polylog}_0(1/r, 1/r) + 3)
\end{aligned}
$$

and for r in $[\frac{1}{5}, 1]$,

$$
\frac{\Delta B(f^*, r)}{r} \;\leq\; \frac{1}{1/5} = 5, \qquad (45)
$$

which concludes the proof. ■

Corollary 9 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and let $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution. If for every $m \leq 1/R(f^*)$, $0 < \delta$, with probability of at least $1-\delta$, the abstain rate $1-\Phi$ of* ILESS$(S_m, \delta, \mathcal{F})$ *is bounded by a monotonic* polylog *as follows:*

$$1 - \Phi(\text{ILESS}) \leq \frac{\text{polylog}_0(m, 1/\delta)}{m}.$$

Then for every f^* (every true risk minimizer), for every $r \geq R(f^*)$,

$$\theta_{f^*}(r) \leq 20(\text{polylog}_0(1/r, 1/r) + 3).$$

Proof This is a direct result from Theorem 8, and from the fact that ILESS is PCS. ■

Given $\mathcal{P}_{\mathcal{X}}$,$\mathcal{F}$ and f^*, if any PCS learning algorithm has a fast R^* rejection rate, we can apply Theorem 8 with a deterministic $\mathcal{P}_{\mathcal{Y}|\mathcal{X}}$ distribution for which $Y = f^*(X)$, and get that $R(f^*) = 0$. Thus, by definition,

$$1 - \Phi(\text{PCS}) \leq \text{polylog}_1\left(\frac{1}{\text{R(f*)} + 1/\text{m}}\right) \cdot 0 + \frac{\text{d} \cdot \text{polylog}_2(\text{m}, 1/\delta)}{\text{m}}.$$

We can now apply Theorem 8 with $R(f^*) = 0$, and get that the disagreement coefficient is bounded by polylog$(1/r)$ for all $r > 0$. Thus, together with Corollary 7, we complete a two sided equivalence from PCS with a fast R^* rejection rate to a disagreement coefficient bounded by polylog$(1/r)$ for all $r > 0$.

6. Active-ILESS

In this section in Strategy 3 we introduce an agnostic active learning algorithm called Active-ILESS. Active-ILESS is very similar to Agnostic CAL and to Oracular CAL (Dasgupta et al., 2007), which were inspired by A^2 (Balcan et al., 2006). Both Agnostic CAL and Oracular CAL use a $LEARN_{\mathcal{H}}(S,T)$ subroutine, which returns an ERM over a certain set T with the constraint that a zero training error must be achieved over a set S (see details in Hsu, 2010). Oracular CAL has an advantage over Agnostic CAL in that it only uses one such constraint while using the $LEARN_{\mathcal{H}}$ subroutine. Nevertheless, as Hsu mentions, this weakens the label complexity analysis of Oracular CAL, and makes it dependent on the square of the disagreement coefficient. Similar to Oracular CAL, Active-ILESS can be implemented with an ERM computation under only one constraint (as seen from the disbelief principle in El-Yaniv and Wiener, 2011, already discussed in Section 4), but its proven label complexity is only dependent linearly on the disagreement coefficient. In this sense, Active-ILESS enjoys the best of both worlds. The label complexity analysis of Active-ILESS appears in Section 8.

As Agnostic CAL and Oracular CAL, Active-ILESS creates artificial labels (step 1), but unlike these other algorithms, Active-ILESS works in batches (inside each batch, the decision whether to query an example is made instantly and not at the end of the batch). This allows Active-ILESS to be a bit more conservative with its deltas. This also allows us to achieve a tighter label complexity.

In Section 7 we use Active-ILESS to show an equivalence between active learning (represented by Active-ILESS) and selective classification (represented by a variant of ILESS,

Strategy 3 Agnostic Low-Error Active Learning Strategy (Active-ILESS)

Input: ϵ and/or m depending on the desired termination condition (error or labeling budget, respectively)
Confidence level δ
Hypothesis class $\mathcal{F}$ with VC dimension d
An unlabeled input sequence sampled i.i.d from $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$: $x_1, x_2, x_3, \ldots$
Output: A classifier $\hat{f}$
Initialize:
Set $\hat{S} = \emptyset$, $G_0 = \mathcal{F}$, $t = 1$
Perform for each example x_t received:
1: if $x_t \in AGR(G_{t-1})$: don't request label for x_t and set $y_t = f(x_t)$ using any $f \in G_{t-1}$
otherwise: request label y_t
2: Set $\hat{S} = \hat{S} \cup \{(x_t, y_t)\}$
3: Set $\hat{f} = \hat{f}(\hat{S})$
4: if $\log_2(t) \in \mathbb{N}$:

- Set $\sigma_{Active} = \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2}, \frac{\delta}{2t}, d, \hat{R}(\hat{f}, \hat{S})\right) + \bar{\sigma}_{\hat{R}-R}\left(\frac{t}{2}, \frac{\delta}{2t}, d, \hat{R}(\hat{f}, \hat{S}) + \hat{\sigma}_{R-\hat{R}}(\frac{t}{2}, \frac{\delta}{2t}, d, \hat{R}(\hat{f}, \hat{S}))\right)$
- If ϵ was given as input and $\sigma_{Active} < \epsilon$, terminate and return $\hat{f}$
- If m was given as input and $t > m/2$, terminate and return $\hat{f}$
- Set $G_t = \hat{\mathcal{V}}\left(\hat{f}, \sigma_{Active}\right)$
- Set $\hat{S} = \emptyset$

otherwise:

- $G_t = G_{t-1}$

5: Set t = t +1

"Batch-ILESS"). The introduction of these new variants facilitates a straightforward proof of the equivalence relationship. This equivalence implies a novel relationship between selective and active classification in the agnostic setting.

We begin by analyzing Active-ILESS and showing that much like ILESS, $f^* \in G_t$ in each iteration t. The low-error set G, maintained by ILESS, contains all the hypotheses that have an empirical error smaller than $\hat{R}(\hat{f}) + \sigma_{\text{ILESS}}$. In Lemma 1 we showed that this condition implies that f^* resides within the low-error set G of ILESS. A proof that $f^* \in G_t$, after each iteration of Active-ILESS, cannot follow the same argument due to the fact that Active-ILESS, shown in Strategy 3, labels by itself each example whose label is not requested from the teacher. Further, since we consider an agnostic setting, these self-labels can differ from the true labels.

Active-ILESS, as seen in Strategy 3, receives as a termination condition either $\epsilon > 0$ and/or m, and terminates when the radius of its low-error set, G_t, is smaller than ϵ, or when it has processed m examples.

Active-ILESS changes its low-error set, G_t, only for t that are natural powers of 2. For each change, Active-ILESS begins to create fake labels for $x_t \in AGR(G_{t-1})$ that may or may not be equal to the real label of x_t (under the original distribution). In fact, this G_t defines a new distribution, $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)$, and this distribution changes for every t that is a natural power of 2. With respect to a run of Active-ILESS, and $t = 2^i, i \in \mathbb{N}$, we denote by $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)$, the new probability distribution implied by G_t, and the fake labels created by the algorithm. $R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f)$ will be the true risk under the new distribution, while $R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f)$ is the true risk of f under the original distribution.

Definition 6.1 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and let $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution. Given a run of Active-ILESS, we denote by $\mathcal{K}$ the event where both inequalities (46) and (47) hold simultaneously for every $f \in \mathcal{F}$, for all iterations of Active-ILESS where $t = 2^i, i \in \mathbb{N}$. $\hat{R}(f) \triangleq \hat{R}(f, \hat{S})$ for $\hat{S}$ before it was initialized:*

$$R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f) \leq \hat{R}(f) + \sigma_{R-\hat{R}}\left(\frac{t}{2}, \frac{\delta}{2t}, d, R(f), \hat{R}(f)\right) \tag{46}$$

$$\hat{R}(f) \leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f) + \sigma_{\hat{R}-R}\left(\frac{t}{2}, \frac{\delta}{2t}, d, R(f), \hat{R}(f)\right) \tag{47}$$

Lemma 10 *$\mathcal{K}$ occurs with probability of at least $1 - \delta$.*

Proof G_t changes only for iterations of the type $2^i, i \in \mathbb{N}$. We know by Lemma 1 that the probability that inequalities (46) and (47) do not hold is smaller than $\delta/(2t)$. By the union bound, the probability that one of these inequalities does not hold after any iteration is smaller than

$$\sum_{t=2^i, i\in\mathbb{N}} \frac{\delta}{2t} \leq \delta.$$

■

Lemma 11 *If f^*, a true risk minimizer under probability distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$, resides within G_t, then it is also a true risk minimizer under probability distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)$.*

Proof

$$\operatorname*{argmin}_{f\in\mathcal{F}} R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f) = \operatorname*{argmin}_{f\in\mathcal{F}} \left(\underbrace{R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f)}_{A} + \underbrace{R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f) - R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f)}_{B} \right).$$

We know that f^* minimizes A, and we note that every function that resides within G_t minimizes B, because every difference in the labeling between $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ and $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)$ was done according to the label given by the unanimous decision of functions in G_t. In other words, whenever $x \in AGR(G_t)$, the labelling of x is done according to any function in G_t, for instance, f^*. Thus,

$$\begin{aligned} R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f) - R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f) &= \mathbb{E}\left[\mathbb{1}[X \in AGR(G_t)](\mathbb{1}[f(X) \neq f^*(X)] - \mathbb{1}[f(X) \neq Y])\right] \\ &= \mathbb{E}\left[\mathbb{1}[X \in AGR(G_t) \wedge f^*(X) \neq Y] \cdot (-1)^{\mathbb{1}(f(X)=f^*(X))}\right] \end{aligned}$$

and we see that f^* minimizes the last term. Hence, f^* minimizes $A + B$. ■

The proofs of the following four lemmas appear in Appendix A. They all show basic good qualities of Active-ILESS.

Lemma 12 *Given that event $\mathcal{K}$ (see Definition 6.1) occurred, each f^* of the **original** distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ resides within G_t for all t. This implies that $R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_t)}(f^*) \leq R(f^*)$, for all t, as every change in the labeling is done according to f^*.*

Lemma 13 *Given that event $\mathcal{K}$ (see Definition 6.1) occurred, and under the assumption that Active-ILESS terminated with the ϵ condition, the hypothesis returned by Active-ILESS, $\hat{f}$, holds:*

$$R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(\hat{f}) \leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f^*) + \epsilon.$$

Lemma 14 *Given that event $\mathcal{K}$ (see Definition 6.1) occurred, the final radius of Active-ILESS satisfies*

$$\sigma_{Active} = O\left(\frac{B}{m} + \sqrt{\frac{B}{m} \cdot R(f^*)}\right), \tag{48}$$

where $B \triangleq 16d\ln(\frac{16m^2 e}{d\delta})$.

Lemma 15 *Given that event $\mathcal{K}$ (see Definition 6.1) occurred, the total number of examples that Active-ILESS(ϵ) processed (without necessarily requesting labels) is*

$$O\left(\frac{1}{\epsilon}\ln(\frac{1}{\epsilon}) + \frac{R(f^*)}{\epsilon^2}\ln(\frac{R(f^*)}{\epsilon^2})\right),$$

where we hide factors of $d, \ln(1/\delta)$ under the O.

Definition 6.2 *An active learner that generates a hypothesis whose true error is smaller than ϵ w.h.p., has **passive example complexity**, if it observes up to*

$$O\left(\frac{1}{\epsilon}\ln(\frac{1}{\epsilon}) + \frac{R(f^*)}{\epsilon^2}\ln(\frac{R(f^*)}{\epsilon^2})\right)$$

examples (not necessarily labeled).

By Lemmas 13 and 15 we know that Active-ILESS has passive example complexity.

The definition of a fast R^* rejection rate for selective classification induces the following related definition for the exponential speedup of active learning algorithms.

Definition 6.3 (R^* Exponential Speedup) *Given $\mathcal{P}_{\mathcal{X}}$,$\mathcal{F}$ and f^*, we say that an active learner has an R^* **exponential speedup**, with polylog_1 and polylog_2 as its parameters, if for every $\mathcal{P}_{\mathcal{Y}|\mathcal{X}}$ for which f^* is a true risk minimizer, and for every $m > 0$, with probability of at least $1 - \delta$, the number of labels requested by the active learner after observing m examples is not greater than*

$$\text{polylog}_1\left(\frac{1}{R(f^*) + 1/m}\right) \cdot R(f^*)m + d \cdot \text{polylog}_2(m, 1/\delta).$$

Hsu (2010) introduced the agnostic CAL algorithm and showed (Theorem 4.3, page 41) that if the disagreement coefficient is bounded, then Agnostic CAL has an R^* exponential speedup (under our new definition). Any active algorithm that has passive example complexity and achieves an R^* exponential speedup requires w.h.p. no more than $O\left(\text{polylog}(\frac{R(f^*)}{\epsilon^2})\frac{R(f^*)^2}{\epsilon^2} + \text{polylog}(\frac{1}{\epsilon})\right)$ labels to reach a true error smaller than ϵ. The proof is immediate by considering the cases $\frac{R(f^*)}{\epsilon} \geq 1$ and $\frac{R(f^*)}{\epsilon} < 1$. The leading term of this bound is $\frac{R(f^*)^2}{\epsilon^2}$, which is also the case for A^2 (Balcan et al., 2006).

7. A Reduction from Active-iLess to Batch-ILESS

In Strategy 4 we define a selective classifier, called Batch-ILESS, which uses Active-ILESS as its engine. Given a labeled sample S_m, Batch-ILESS simulates the active algorithm, by applying it over S_m in a straightforward manner (i.e., it sequentially introduces to the active algorithm an unlabeled example and reveals the label only if the active algorithm requests it). Upon termination, after the active algorithm has consumed all examples, our batch algorithm receives $\hat{f}$ from the active algorithm and uses its last low-error set G_t to define its selection function.

Lemma 12 implies that Batch-ILESS is pointwise-competitive. We note that Lemma 4, Theorem 5 and Theorem 9, which were proven for ILESS, can also be proven for Batch-ILESS. We chose to prove it for ILESS, as it is simpler than Batch-ILESS, and does not require an active algorithm as its engine. We state these ideas formally, and give sketches of their proofs, in Lemma 23 and Theorem 24 which appear in Appendix C.

Strategy 4 Batch Improved Low-Error Selective Strategy (Batch-ILESS)

Input: Sample set of size m, S_m,
Confidence level δ
Hypothesis class $\mathcal{F}$ with VC dimension d
Output: A selective classifier (h, g)
1: Simulate Active-ILESS with S_m as its input stream; let G_t be the low-error set obtained by Active-ILESS in its last round, and let $\hat{f}$ be its resulting classifier.
2: Construct g such that $g(x) = 1 \iff x \in \{\mathcal{X} \setminus DIS(G_t)\}$
3: $h = \hat{f}$

Theorem 16 shows a deep connection between the speedup of Active-ILESS and the rejection mass of Batch-ILESS for specific $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$. An immediate corollary of this theorem is that if Active-ILESS has R^* exponential speedup (see Definition an 6.3), then Batch-ILESS has a fast R^* rejection rate (see Definition 4.2).

Theorem 16 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and let $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution. If for every $m \leq m_{max}$, after observing m examples, with probability of at least $1-\delta$, the number of labels requested by Active-ILESS is not greater than*

$$\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*)m + d\cdot\text{polylog}_2(m,1/\delta),$$

then the rejection mass of Batch-ILESS for every $m \leq \frac{m_{max}}{2}$ is bounded w.h.p. by

$$8\cdot\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*) + \frac{2\left(\sqrt{\ln(2/\delta)}+\sqrt{\ln(2/\delta)+2d\cdot\text{polylog}_2(2m,2/\delta)}\right)^2}{m}.$$

Proof Consider an application of Active-ILESS with $\delta = \delta_0$ over $m_0 \triangleq 2^{\lceil\log(m+1)\rceil}$ examples. Denote by X_i an indicator random variable for the labeling of its ith example, $1 \leq i \leq m_0$. With probability of at least $1-\delta_0$ over the choice of samples from $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$,

$$\sum_{i=1}^{m_0} X_i \leq \text{polylog}_1\left(\frac{1}{R(f^*)+1/m_0}\right)\cdot R(f^*)m_0 + d\cdot\text{polylog}_2\left(m_0,1/\delta_0\right). \tag{49}$$

We know by the definition of Active-ILESS (Strategy 3), that the last $m_0/2$ examples had the exact same probability, $\Delta G_{m_0/2}$, of requiring a label, and that this is exactly the probability that Batch-ILESS will decide to abstain after receiving m examples, according to Strategy 4.

We now estimate $\Delta G_{m_0/2}$ using the version of the Chernoff bound given by Canny (2012). For the sake of self-containment, Canny's statement and proof of the bound are provided in Lemma 21 in Appendix B.

The statement of the lemma is as follows. Let $Z_1, Z_2, \ldots, Z_n$ be independent Bernoulli trials with $Pr[Z_i = 1] = p$, let $Z \triangleq \sum_{i=1}^{n} Z_i$, and $\mu = \mathbb{E}Z$. Then, for every $\alpha > 0$:

$$\Pr\left(Z < (1-\alpha)\mu\right) \leq \exp(-\mu\alpha^2/2).$$

Applying the Chernoff bound with the indicator variables of the last $m_0/2$ examples, we have $X = \sum_{m_0/2}^{m_0} X_i$, $\mu = p\frac{m_0}{2}$, and set $p \triangleq \Delta G_{m_0/2}$. Select α such that

$$\exp\left(-p\frac{m_0}{2}\alpha^2/2\right) = \delta_2.$$

Solving for α,

$$\alpha = \sqrt{\frac{4\ln(1/\delta_1)}{m_0 p}}.$$

We conclude that with probability of at least $1-\delta_1$,

$$\begin{aligned} & X \geq \left(1-\sqrt{\frac{4\ln(1/\delta_1)}{m_0 p}}\right)\cdot p\frac{m_0}{2} \\ \Leftrightarrow\quad & 0 \geq \frac{pm_0}{2} - \sqrt{pm_0\cdot\ln(1/\delta_1)} - X. \end{aligned} \tag{50}$$

Solving the quadratic equation (50) for $\sqrt{pm_0}$, we get that

$$\begin{aligned} & \sqrt{pm_0} \leq \sqrt{\ln(1/\delta_1)} + \sqrt{\ln(1/\delta_1)+2X} \\ \Rightarrow\quad & p \leq \frac{(\sqrt{\ln(1/\delta_1)}+\sqrt{\ln(1/\delta_1)+2X})^2}{m_0}. \end{aligned} \tag{51}$$

Combining (49) and (51), from the union bound we get that with probability of at least $1-\delta_0-\delta_1$,

$$\begin{aligned} &\Delta G_{m_0/2} \leq \\ &\leq \frac{\left(\sqrt{\ln(\frac{1}{\delta_1})}+\sqrt{\ln(\frac{1}{\delta_1})+2\text{polylog}_1\left(\frac{1}{R(f^*)+1/m_0}\right)R(f^*)m_0 + 2d\cdot\text{polylog}_2(m_0,\frac{1}{\delta_0})}\right)^2}{m_0}. \end{aligned}$$

If we take $\delta_0 = \delta_1 = \delta/2$, then, since $m \leq m_0 \leq 2m$, we can use $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$ and $(a+b)^2 \leq 2a^2 + 2b^2$, to obtain

$$\begin{aligned}
&\Delta G_{m_0/2} \leq \\
\leq\ & \frac{\left(\sqrt{\ln(\frac{2}{\delta})} + \sqrt{\ln(\frac{2}{\delta}) + 4\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*)m + 2d\cdot\text{polylog}_2(2m,\frac{2}{\delta})}\right)^2}{m} \\
\leq\ & \frac{\left(\sqrt{\ln(\frac{2}{\delta})} + \sqrt{\ln(\frac{2}{\delta}) + 2d\cdot\text{polylog}_2(2m,\frac{2}{\delta})} + \sqrt{4\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)R(f^*)m}\right)^2}{m} \\
\leq\ & \frac{2\left(\sqrt{\ln(\frac{2}{\delta})} + \sqrt{\ln(\frac{2}{\delta}) + 2d\cdot\text{polylog}_2(2m,\frac{2}{\delta})}\right)^2}{m} + \\
& + \frac{2\left(\sqrt{4\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*)m}\right)^2}{m} \\
=\ & \frac{2\left(\sqrt{\ln(\frac{2}{\delta})} + \sqrt{\ln(\frac{2}{\delta}) + 2d\cdot\text{polylog}_2(2m,\frac{2}{\delta})}\right)^2}{m} + \\
& + 8\cdot R(f^*)\cdot\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)
\end{aligned}$$

■

Corollary 17 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and let $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution. If for every $m \leq 2/R(f^*)$, $0 < \delta$ after observing m examples, with probability of at least $1-\delta$, the number of labels requested by Active-ILESS is not greater than*

$$\text{polylog}_1\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*)m + d\cdot\text{polylog}_2(m, 1/\delta),$$

then for every $r \geq R(f^*)$,

$$\begin{aligned}
\theta_{f^*}(r) &\leq 20\left(2\left(\sqrt{\ln(2/r)} + \sqrt{\ln(2/r) + 2d\cdot\text{polylog}_2(2/r, 2/r)}\right)^2 + 8\cdot\text{polylog}_1(1/r) + 3\right) \\
&= O\left(d\cdot\text{polylog}(1/r)\right).
\end{aligned}$$

Proof The proof follows from Theorems 16 and 8. Applying Theorem 16, we know that for $m \leq 1/R(f^*)$, the rejection mass of Batch-ILESS is bounded w.h.p. by,

$$\frac{2\left(\sqrt{\ln(2/\delta)} + \sqrt{\ln(2/\delta) + 2d\cdot\text{polylog}_2(2m, 2/\delta)}\right)^2 + 8\cdot\text{polylog}_1(\frac{1}{R(f^*)+1/m})}{m}.$$

We know by Lemma 12 that $f^* \in G_t$, and thus Batch-ILESS is PCS. We apply Theorem 8, and get that for every $r \geq R(f^*)$,

$$\begin{aligned}
\theta_{f^*}(r) &\leq 20\left(2\left(\sqrt{\ln(\frac{2}{r})} + \sqrt{\ln(\frac{2}{r}) + 2d\cdot\text{polylog}_2(\frac{2}{r},\frac{2}{r})}\right)^2 + 8\cdot\text{polylog}_1\left(\frac{1}{R(f^*)+r}\right) + 3\right) \\
&\leq 20\left(2\left(\sqrt{\ln(\frac{2}{r})} + \sqrt{\ln(\frac{2}{r}) + 2d\cdot\text{polylog}_2(\frac{2}{r},\frac{2}{r})}\right)^2 + 8\cdot\text{polylog}_1(1/r) + 3\right).
\end{aligned}$$

■

8. From the Disagreement Coefficient to Active Learning

In this section we show that when $\theta'(r)$ is bounded by $\text{polylog}_1(1/r)$ for all $r > R(f^*)$ for some specific $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$, then the label complexity of Active-ILESS under the same $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ is bounded by

$$\text{polylog}_2\left(\frac{1}{R(f^*)+1/m}\right)\cdot R(f^*)m + d\cdot\text{polylog}_3(m, 1/\delta), \tag{52}$$

where the parameters of polylog_2 and polylog_3 are only dependent on $\text{polylog}_1(1/r)$. Thus, if $\theta'(r) \leq \text{polylog}_1(1/r)$ for all $r > 0$, we get that Active-ILESS has an R^* exponential speedup. This direction has been shown before in Hsu (2010); Hanneke (2007) for Oracular CAL, Agnostic CAL and A^2. For the sake of self-containment, we show it here for Active-ILESS. Due to the fact that Active-ILESS relies on ILESS, for which we already have bounds, the proof is straightforward.

As a preparation for Theorem 19, we present Lemma 18 (shown before in Hanneke, 2014b, Theorem 7.1), which introduces a small feature of the disagreement coefficient that will serve us later.

Lemma 18 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, and let $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution. For every $f \in \mathcal{F}$ and $0 < r \leq 1$, $\theta_f(r)\cdot r$ is a non-decreasing function.*

Theorem 19 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution, and f^*, a true risk minimizer of $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$. The label complexity of Active-ILESS$(m, \delta/2)$ is bounded w.h.p. by*

$$\theta'\left(5R(f^*) + 14\frac{A}{m}\right)\cdot 2e\cdot mR(f^*) + \log_2(2/\delta) + 56e\cdot\log_2 m\cdot A\cdot\theta'\left(5R(f^*) + 14\frac{A}{m}\right).$$

Proof Each run of Active-ILESS$(m, \delta/2)$ simulates $\lceil\log_2 m\rceil$ runs of ILESS. Denote by T indices of iterations where $\log_2(t) \in \mathbb{N}$. We know by Lemma 10 that with probability of at least $1 - \delta/2$, inequalities (46) and (47) hold for each run. Recall that we denoted by $\mathcal{K}$ the event where both inequalities hold throughout all runs of ILESS, which is exactly the definition of event $\mathcal{E}$ per run (see Definition 4.1). Under event $\mathcal{K}$, Lemma 12 implies that

all f^* of the original distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ reside within G_T for all T. This also implies that all f^* of the original distribution remain the true risk minimizers under $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_T)$, for all T, as they always benefit from the creation of the artificial labels.

Because the marginal of the distribution does not change during the run of Active-ILESS, and because event $\mathcal{E}$ holds for each iteration of ILESS, we can apply Theorem 5 for all the runs of ILESS. We thus get that for every run of ILESS, which we denote by ILESS_T,

$$G_T \subseteq B(f^*, R_T),$$

and thus, the rejection mass is bounded as follows

$$1 - \Phi(\text{ILESS}_T) \leq \Delta B(f^*, R_T) \leq \theta(R_T) \cdot R_T,$$

where

$$R_T \triangleq 2 \cdot R(f^*) + 11 \cdot \frac{A}{T} + 6 \cdot \sqrt{\frac{A}{T} \cdot R(f^*)}.$$

We denoted by $R(f^*)$ the true error according to the original distribution, which might be larger than the true error implied by the fake label distributions that the algorithm induces. According to Lemma 18, enlarging R_T can only weaken the bound, and thus, there is no problem doing so. We additionally bound R_T using $\sqrt{ab} \leq a/2 + b/2$ to get

$$R_T \leq 5 \cdot R(f^*) + 14 \cdot \frac{A}{T}.$$

and thus,

$$\Delta B(f^*, R_T) \leq \theta' \left(5 \cdot R(f^*) + 14 \cdot \frac{A}{T}\right) \cdot \left(5 \cdot R(f^*) + 14 \cdot \frac{A}{T}\right).$$

In this proof we bound the sum $\sum_{t=1}^{m} X_t$, where $X_t \triangleq \mathbb{1}[x_t \in \Delta G_t]$, as ΔG_t is by definition the probability that Active-ILESS requests a label. To do so, we will bound the sum $\sum_{t=1}^{m} P_t$ where $P_t \triangleq \mathbb{1}[x_t \in \Delta B(f^*, R_t)]$, as we know that when $\mathcal{K}$ holds, $\Delta G_t \subseteq \Delta B(f^*, R_t)$.

According to the definition of G_t in Strategy 3, the probability distribution of the artificial labeling done by Active-ILESS changes only when t is a natural power of 2. Thus, R_t only changes when $\log_2(t) \in \mathbb{N}$, and we get that

$$P_t \leq \theta' \left(5 \cdot R(f^*) + 14 \cdot \frac{A}{T}\right) \cdot 5R(f^*) + \frac{14A \cdot \theta' \left(5 \cdot R(f^*) + 14 \cdot \frac{A}{T}\right)}{T}, \tag{53}$$

where $T = 2^{\lfloor \log_2(t-1) \rfloor - 1}$.

We now have a series of Poisson trials, $P_1, P_2, \ldots, P_m$. We use a version of the Chernoff bound (as shown by Canny, 2012) to bound the label complexity.[6] The statement and a sketch of the proof of this bound are provided in Lemma 22 in Appendix B.

For independent Poisson variables $P_1, P_2, \ldots, P_m$, where $Pr[P_i = 1] = p_i$, $P \triangleq \sum_{i=1}^{n} P_i$, and $\mu = \mathbb{E}P$, for every $\alpha > 2e - 1$:

$$\Pr(P > (1+\alpha)\mu) \leq 2^{-\mu\alpha}.$$

6. This useful bound was used by Hanneke (2014a, Theorem 5.4).

To bound $\mu = \mathbb{E}P$ from above, we use Inequality (53) and plug it into the definition of μ.

$$\begin{aligned}
\mu &= P_1 + P_2 + \sum_{i=3}^{m} P_t \\
&\leq 2 + \sum_{k=1}^{\lceil \log_2 m \rceil - 1} 2^k P_{2^{k+1}} \\
&\leq 2 + m \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right) \cdot R(f^*) + \sum_{k=1}^{\lceil \log_2 m \rceil - 1} 2^k \frac{14A \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right)}{2^{k-1}} \\
&\leq 2 + m \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right) \cdot R(f^*) + 28 \log_2 m \cdot A \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right).
\end{aligned} \tag{54}$$

We need to choose an α that satisfies both $2^{-\mu\alpha} \leq \delta/2$, and $\alpha > 2e - 1$. Clearly, $\alpha = \frac{\log_2(2/\delta)}{\mu} + 2e - 1$ suffices. Hence, we get that with probability of at least $1 - \delta/2$,

$$\begin{aligned}
P &\leq \left(1 + \frac{\log_2(\frac{2}{\delta})}{\mu} + 2e - 1\right)\mu \\
&= \log_2(\frac{2}{\delta}) + 2e\mu.
\end{aligned}$$

Inequality (54) holds with probability of at least $1 - \delta/2$, and using the union bound, we get that with probability of at least $1 - \delta$,

$$\begin{aligned}
P &\leq \log_2(\frac{2}{\delta}) + \\
&\quad +2e\left(2 + m \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right) \cdot R(f^*) + 28 \log_2 m \cdot A \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right)\right) \\
&= \theta' \left(5R(f^*) + 14\frac{A}{m}\right) 2e \cdot mR(f^*) + \log_2(\frac{2}{\delta}) + 56e \cdot \log_2 m \cdot A \cdot \theta' \left(5R(f^*) + 14\frac{A}{m}\right)
\end{aligned} \tag{55}$$

■

Corollary 20 *Let $\mathcal{F}$ be a hypothesis class with a finite VC dimension d, $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown distribution, and f^* a true risk minimizer of $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$. If for all $r > R(f^*)$,*

$$\theta'(r) \leq \text{polylog}_1(1/r),$$

then the label complexity of Active-ILESS$(m, \delta/2)$ is bounded w.h.p. by

$$\text{polylog}_1 \left(\frac{1}{5R(f^*) + 14\frac{A}{m}}\right) 2e \cdot mR(f^*) + \log_2(2/\delta) + 56e \cdot \log_2 m \cdot A \cdot \text{polylog}_1 \left(\frac{1}{5R(f^*) + 14\frac{A}{m}}\right),$$

which has the same form as Equation (52).

Hsu (2010) calculated the label complexity of Agnostic CAL and Oracular CAL under the assumption that the disagreement coefficient is bounded by a constant, θ for all $r > 0$. If we adopt this assumption and use it in our analysis, we get that the label complexity is bounded by

$$O\left(\theta m R(f^*) + \ln(1/\delta) + \theta d \ln m \ln\left(\frac{m}{d\delta}\right)\right).$$

This result is nearly identical (up to some logarithmic factors) to the result shown by Hsu (2010, Theorem 4.3) for Agnostic CAL. Agnostic CAL, however, as mentioned before, requires calculation of ERM under several constraints. Oracular CAL only requires one constrained ERM calculation, and its label complexity depends on $\theta^2 \ln^3 m$ (Hsu, 2010, Theorem 5.2). Our algorithm thus enjoys the good properties of both algorithms.

The dominant factor of Equation (55), if we ignore the logarithmic factors, is $mR(f^*)$. Active-ILESS has passive example complexity (see Definition 6.2), which means that the total sample complexity is bounded by $\tilde{O}(\frac{1}{\epsilon} + \frac{R(f^*)}{\epsilon^2})$, where $\tilde{O}(\cdot)$ hides logarithmic factors. Plugging the sample complexity into m in (55), we get that the total label complexity is bounded by $\tilde{O}(\frac{R(f^*)^2}{\epsilon^2})$, in cases for which ILESS has a fast R^* rejection rate. Kääriäinen (2006, Theorem 3) showed that for every AL algorithm, under a specific (non-trivial) hypothesis class $\mathcal{F}$, there exists a deterministic target function g, and a marginal distribution $\mathcal{P}_\mathcal{X}$, s.t. the label complexity is $\tilde{\Omega}(\frac{R(f^*)^2}{\epsilon^2})$ (where $\tilde{\Omega}(\cdot)$ hides logarithmic factors).

9. Concluding Remarks

In this paper we focused on disagreement-based methods. Namely, we always required that f^* remains inside a low-error subset of hypotheses w.h.p., and made decisions based on disagreement considerations. We have always chosen to abstain (in selective classification) or require a label (in AL) whenever there was no consensus in the low error set for a given example. However, this approach is not necessary when you have an epsilon budget for error. Zhang and Chaudhuri (2014) presented an AL algorithm that uses a confidence-rated predictor to decide which labels to query. This predictor (see top of page 6 in their paper) uses LP to minimize the query probability under a constraint on the total error. They also provided a new complexity measure, which is nicely presented in Hanneke (2016), and termed φ_c. Up to certain constants, φ_c replaces the disagreement coefficient in the error bounds of Equation (16) and Theorem 16 in that paper. φ_c is a potential improvement because it is shown that $\varphi_c(r) \leq \theta_f(r)$. Zhang and Chaudhuri show an example where this improvement can be as large as $\sqrt{d}$ for linear classification under the log-concave distribution.

In our paper we focused only on consensus based decisions. This approach did not affect our results significantly as our main concern was the dependency on $1/\epsilon$ (logarithmic or linear). Consensus was an important element in the proof of Theorem 8. Pointwise-competitive selective classifiers are based on consensus decisions, and thus the LP idea is not an appropriate AL equivalent for PCS. Nevertheless, our reduction from PCS to $\theta_{f^*}(r)$ (Theorem 8), is immediately translated to $\varphi_c(r)$, as $\varphi_c(r) \leq \theta_{f^*}(r)$. It is interesting, however, to define a selective classifier that is not PCS, has an error budget, and apply the LP technique. We leave this for future work.

We introduced a new selective classification algorithm, called ILESS, whose rejection "engine" uses sharp generalization bounds (which depend on $R(f^*)$). Our analysis proves

that ILESS has sometimes significantly better rejection guarantees relative to the best known pointwise-competitive selective strategy of Wiener and El-Yaniv (2015). Moreover, the guarantees we provide for ILESS do not depend at all on the Bernstein assumption. For the general agnostic setting, we showed an equivalence relation between pointwise-competitive selective classification, active learning with Active-ILESS, and the disagreement coefficient (see Figure 1). This equivalence is formulated in terms of a fast R^* rejection rate and an R^* exponential speedup (Definitions 4.2 and 6.3).

Theorems 8 and 5 show that selective classification with a fast R^* rejection rate is completely equivalent to having a disagreement coefficient bounded by polylog$(1/r)$ for $r > 0$. In Section 6, in Strategy 3, we define Active-ILESS using ILESS implicitly as its engine (see Statement 4 in Strategy 3). We can replace ILESS with another pointwise-competitive selective algorithm, and thus construct a new active learner, that queries a label whenever the selective classifier abstains, and create a fake label according to the decision of the classifier whenever it decides to predict. Because the selective predictor is pointwise-competitive, we know that the underlying distribution induced by its fake labels is equivalent to a distribution defined by a deterministic labeling according to f^* and the same $\mathcal{P}_\mathcal{X}$. The algorithm will terminate using the exact same termination condition as Active-ILESS (when $\sigma_{Active} < \epsilon$), and thus the total sample complexity (labeled and unlabeled examples) will remain the same. The change will only be in the labeling criterion. Lemmas 11, 12, 13, 14, and 15 can all be generalized to such an algorithm.

Going in the other direction to create a selective classifier from a general active learner is more challenging. If the active learner, however, follows the Active-ILESS paradigm, and in particular, uses a pointwise-competitive selective classifier to decide on label requests, then a new pointwise-competitive selective classifier can be created in the same way that Batch-ILESS was created. We can then restate Theorem 16, providing a reduction from an R^* exponential speedup of the active algorithm to a fast R^* rejection rate of the selective classifier.

Disagreement-based decision making in active and selective learning leads to "defensive" algorithms. For example, in the active learning case, this means that a defensive algorithm will ask for more labels than a more aggressive algorithm. In selective classification, this defensiveness provides the power to be pointwise-competitive, but at a cost of an increased rejection rate. It would be interesting to consider more aggressive algorithms that could, for example, take into consideration an estimation of $\mathcal{P}_\mathcal{X}$ in order to ignore examples that cause disagreement only between functions that are very similar to each other (in terms of the probability mass of their difference). Such algorithms can be seen in Dasgupta (2005); Freund et al. (1997); Gonen et al. (2013); Zhang and Chaudhuri (2014), for the realizable and the low-error scenarios. We believe that there is still work to be done for the agnostic scenario.

Many aggressive algorithms could be devised under assumptions about knowledge of $\mathcal{P}_\mathcal{X}$ (that could be acquired during the algorithm run, and is given in the transductive case), or in a Bayesian setting where a prior distribution on $\mathcal{F}$ exists. When researching this direction, one might also want to define a cost over unlabeled examples, and discuss the trade-off between labeled and unlabeled examples. The main open question inspired by our results would be to identify similar correspondence between aggressive selective classification algorithms and aggressive active learners.

Another aspect of selective classification and active learning, which was not addressed in this paper, is differentiating between more and less noisy areas of the distribution. If we define the noise to be the error of the Bayes classifier, and we assume that the noise behaves similarly in close areas (for instance, we assume that the derivative of the noise is bounded), we can derive an active learner that will estimate the noise, and take it into consideration. A noisy area could be defined as an area for which even the best classifier in the class could not achieve a low-error. This motivates a new type of labeling for selective prediction, where one can abstain for two reasons: (i) lack of knowledge in a specific region of $\mathcal{X}$, i.e., not enough examples were observed in that region, and the generalization bounds are not sufficiently tight. (ii) The region was well explored, but even the best classifier performs poorly, and thus the answer is unknown (the region is noisy). In our paper, an active learner will query for both scenarios; however, a more clever active learner might only query examples of the first type, as examples of the second type cannot reduce its error.

Consider the following experiment in Active Learning; Suppose we are trying to learn a hyperspace hypothesis over R^2, where we have a Gaussian distribution of positive points located at $(-1,0)$, and another Gaussian distribution of negative points located at $(1,0)$. A simple active learner that is based on distance from the margin, will quickly converge to querying points that have $x \sim 0$, but will have no preferation over the value of y. Now consider another Gaussian distribution of noisy points, located at $(0,1)$, where each point is -1 or 1 with equal probability. Querying in areas where $y \sim 1$ is almost completely unbeneficial, however, this is still very close to the margin. We devised a simple active learner that creates a noise hit map over R^2, and consider the noise as part of its heuristics. Thus, achieving faster convergence over the usual margin based algorithm. Of course, this is only a toy example, and when running this experiment over some few real world data sets, we got no improvement. We believe that some more experimental work in this area, might prove to be beneficial.

There has been a lot of progress on the theoretical level, in the field of active learning with noise estimation (Locatelli et al., 2017; Hanneke, 2017; Minsker, 2012; Hanneke and Yang, 2015) However most of the work requires either the Tsybakov noise condition (Tsybakov, 2004), a finite VC dimension, or some other strong smoothing assumptions. It would be interesting to see some experimental work on real data sets, accompanied with some theoretical work with a simplistic noise locality assumption.

Acknowledgments

We are indebted to an anonymous referee for extremely useful comments and for fixing an error in an earlier version of this manuscript. This research was supported by The Israel Science Foundation (grant No. 1890/14).

Appendix A. Proofs for Lemmas in Section 6

Proof of Lemma 12 We prove the claim by induction over t for which G_t is different from G_{t-1}. The base case of the induction is clear. We now show that functions that are true risk minimizers of $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})$ reside within G_t. According to Lemma 11, f^* is a true risk minimizer under $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})$ (given the induction hypothesis), and hence will also be within

G_t. We refer by f^* to a true risk minimizer according to $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})$. Using Inequality (47) and the definition of $\bar{\sigma}_{\hat{R}-R}$,

$$\begin{aligned}\hat{R}(f^*,\hat{S}) &\leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) + \sigma_{\hat{R}-R}\left(\frac{t}{2},\frac{\delta}{2t},d,R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*),\hat{R}(f^*,\hat{S})\right)\\ &\leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) + \bar{\sigma}_{\hat{R}-R}\left(\frac{t}{2},\frac{\delta}{2t},d,R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*)\right),\end{aligned} \tag{56}$$

and by Inequality (46) and the definition of $\hat{f}$ we get,

$$\begin{aligned}R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) &\leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(\hat{f})\\ &\leq \hat{R}(\hat{f},\hat{S}) + \sigma_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(\hat{f}),\hat{R}(\hat{f},\hat{S})\right)\\ &\leq \hat{R}(\hat{f},\hat{S}) + \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right).\end{aligned} \tag{57}$$

Plugging (57) into (56) we get,

$$\begin{aligned}\hat{R}(f^*,\hat{S}) \leq\ & \hat{R}(\hat{f},\hat{S}) + \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\\ &+\bar{\sigma}_{\hat{R}-R}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S}) + \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\right)\\ &\Rightarrow f^* \in G_t.\end{aligned}$$

■

Proof of Lemma 13 Let G_{t-1} be the final low-error set of Active-ILESS, and $\hat{S}$ be the final set of examples. The following inequalities are derived from Lemma 10 and inequalities

(56) and (57).

$$\begin{aligned}
R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(\hat{f}) &\leq \hat{R}(\hat{f},\hat{S}) + \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\\
&\leq \hat{R}(f^*,\hat{S}) + \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\\
&\leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) + \bar{\sigma}_{\hat{R}-R}\left(\frac{t}{2},\frac{\delta}{2t},d,R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*)\right)\\
&\quad +\hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\\
&\leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) + \bar{\sigma}_{\hat{R}-R}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S}) + \hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\right)\\
&\quad +\hat{\sigma}_{R-\hat{R}}\left(\frac{t}{2},\frac{\delta}{2t},d,\hat{R}(\hat{f},\hat{S})\right)\\
&\leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) + \epsilon.
\end{aligned}$$

By Lemma 12 we know that f^* resides within G_{t-1}, which implies that any change in $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})$ in comparison to $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ reduces the true error of f^*. This also means that for every $f \in \mathcal{F}$,

$$R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f) - R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f) \leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f^*) - R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*),$$

which results in

$$R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(\hat{f}) \leq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}}(f^*) + \epsilon.$$

■

Proof of Lemma 14 The proof is similar to the proof of Lemma 4. We consider the last modification of G_t as a run of ILESS, under $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})$, with $m_0 \triangleq 2^{\lfloor log_2 m \rfloor - 1}$ examples and delta equal to $\frac{\delta}{4m_0}$.

Under event $\mathcal{K}$, the conditions of Lemma 4 hold, and by Lemma 12, $R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*) \leq R(f^*)$. We simply apply Lemma 4 with these parameters to get A' (A in Lemma 4).

$$A' = 4d\ln\left(\frac{16m_0 e}{d\delta/4m_0}\right) = 4d\ln\left(\frac{64m_0^2 e}{d\delta}\right).$$

The fact that $m/4 \leq m_0 \leq m/2$ completes the proof. ■

Proof of Lemma 15 We know by Lemma 14 that there exist constants C_1,C_2 that depend only on $\ln(\frac{1}{\delta})$ and d, and are independent of m, s.t.

$$\sigma_{Active} \leq C_1\frac{\ln m}{m} + C_2\sqrt{\frac{\ln m}{m}\cdot R(f^*)}.$$

We also know by the definition of Active-ILESS (Strategy 3), that it terminates when σ_{Active} is smaller than the given ϵ. We will find m large enough s.t.

$$C_1\frac{\ln m}{m} \leq \epsilon/2, \tag{58}$$

$$C_2\sqrt{\frac{\ln m}{m}\cdot R(f^*)} \leq \epsilon/2. \tag{59}$$

We assume that $\epsilon \leq 1/e$, as it is easy to find a proper m for $\epsilon > 1/e$. Starting with Equation (58), we want to show that $m = O(\frac{1}{\epsilon}\ln(\frac{1}{\epsilon}))$ satisfies it. Thus, we find k_1 s.t.

$$\begin{aligned}
& C_1\frac{\ln(k_1\frac{1}{\epsilon}\ln\left(\frac{1}{\epsilon}\right))}{k_1\frac{1}{\epsilon}\ln\left(\frac{1}{\epsilon}\right)} \leq \frac{\epsilon}{2}\\
\Leftrightarrow\quad & \frac{\ln\left(k_1\frac{1}{\epsilon}\cdot\ln(\frac{1}{\epsilon})\right)}{\ln\left(\frac{1}{\epsilon}\right)} \leq \frac{k_1}{2C_1}.
\end{aligned} \tag{60}$$

Bounding the left-hand side of Inequality (60) for $\epsilon \leq 1/e$ gives us,

$$\begin{aligned}
\frac{\ln\left(k_1\frac{1}{\epsilon}\cdot\ln(\frac{1}{\epsilon})\right)}{\ln(\frac{1}{\epsilon})} &\leq \frac{\ln\left(k_1\frac{1}{\epsilon}\cdot\frac{1}{\epsilon}\right)}{\ln\left(\frac{1}{\epsilon}\right)}\\
&\leq 2+\ln k_1.
\end{aligned}$$

We need to find k_1 that will satisfy

$$2+\ln k_1 \leq \frac{k_1}{2C_1}.$$

$k_1 = 16C_1^2$ will work for $C_1 \geq 1$; otherwise, we take $k_1 = 10$.

We use the same procedure to show that $m = O\left(\frac{R(f^*)}{\epsilon^2}\ln\left(\frac{R(f^*)}{\epsilon^2}\right)\right)$ satisfies Equation (59). We rewrite the equation in the following way:

$$\frac{\ln m}{m} \leq \frac{\epsilon^2}{4C_2^2 R(f^*)} \triangleq \epsilon_0.$$

We assume that $\epsilon_0 \leq 1/e$ ($m = 4$ holds otherwise) and find k_2 s.t.

$$\frac{\ln\left(k_2\frac{1}{\epsilon_0}\ln\left(\frac{1}{\epsilon_0}\right)\right)}{k_2\frac{1}{\epsilon_0}\ln\left(\frac{1}{\epsilon_0}\right)} \leq \epsilon_0.$$

As before, we reduce the problem to finding k_2 that satisfies

$$2+\ln(k_2) \leq k_2.$$

$k_2 = 4$ suffices. We thus get that $m = O\left(\frac{1}{\epsilon_0^2}\ln\left(\frac{1}{\epsilon_0^2}\right)\right) = O\left(\frac{R(f^*)}{\epsilon^2}\ln\left(\frac{R(f^*)}{\epsilon^2}\right)\right)$ satisfies Equation (59). This implies that there exists a function

$$m(1/\epsilon, R(f^*)) = O\left(\frac{1}{\epsilon}\ln\left(\frac{1}{\epsilon}\right) + \frac{R(f^*)}{\epsilon^2}\ln\left(\frac{R(f^*)}{\epsilon^2}\right)\right)$$

that bounds the total number of labels processed by Active-ILESS. ■

Appendix B. Proofs of Chernoff Bounds

Lemma 21 *Let $X_1, X_2, ..., X_n$ be independent Bernoulli trials with $Pr[X_i = 1] = p$, $X \triangleq \sum_{i=1}^{n} X_i$, and $\mu = \mathbb{E}X$. Then, for every $\alpha \geq 0$:*

$$\Pr(X < (1-\alpha)\mu) \leq \exp(-\mu\alpha^2/2).$$

Proof This proof is taken from the work of John Canny Canny (2012).

For $t > 0$, we have

$$\Pr\left(X < (1-\alpha)\mu\right) = \Pr\left(\exp(-tX) > \exp(-t(1-\alpha)\mu)\right). \tag{61}$$

We use Markov's inequality. For a nonnegative random variable X, and $a > 0$,

$$\Pr(X \geq a) \leq \frac{\mathbb{E}(X)}{a}.$$

We apply the inequality for the right-hand side of Equation (61), to get

$$\Pr(X < (1-\alpha)\mu) \leq \frac{\mathbb{E}(\exp(-tX))}{\exp(-t(1-\alpha)\mu)}. \tag{62}$$

$X_1, X_2, ..., X_n$ are independent and thus

$$\mathbb{E}(\exp(-tX)) = \prod_{i=1}^{n} \mathbb{E}(\exp(-tX_i)).$$

For each X_i

$$\mathbb{E}(\exp(-tX_i)) = pe^{-t} + (1-p) = 1 - p(1-e^{-t}).$$

We use the fact that $1 - x < \exp(-x)$ for all x, with $x = p(1-e^{-t})$, to get

$$\mathbb{E}(\exp(-tX_i)) \leq \exp(-p(1-e^{-t})),$$

and conclude that

$$\begin{aligned}\mathbb{E}(\exp(-tX)) &= \prod_{i=1}^{n} \mathbb{E}\left(\exp(-tX_i)\right) \leq \prod_{i=1}^{n} \exp\left(-p(1-e^{-t})\right) \\ &= \exp\left(\sum_{i=1}^{n} p(e^{-t}-1)\right) = \exp\left(\mu(e^{-t}-1)\right).\end{aligned} \tag{63}$$

Going back to Equation (62), we have,

$$\Pr(X < (1-\alpha)\mu) \leq \frac{\exp\left(\mu(e^{-t}-1)\right)}{\exp\left(-t(1-\alpha)\mu\right)} = \exp\left(\mu(e^{-t}-1+t-t\alpha)\right). \tag{64}$$

We choose $t > 0$ to make the right-hand side of the equation as small as possible. After derivation, we get that the best t is $t = \ln\left(\frac{1}{1-\alpha}\right)$, and plugging it into Equation (64) gives

us,

$$\begin{aligned}\Pr(X < (1-\alpha)\mu) &\leq \exp\left(\mu(1-\alpha-1+\ln\left(\frac{1}{1-\alpha}\right) - \ln\left(\frac{1}{1-\alpha}\right)\alpha)\right) \\ &= \exp\left(\mu(-\alpha+\ln\left(\frac{1}{1-\alpha}\right)(1-\alpha))\right) \\ &= \left(\frac{e^{-\alpha}}{(1-\alpha)^{1-\alpha}}\right)^{\mu}.\end{aligned} \tag{65}$$

We now simplify this bound to get the desired result. We know that $(1-\alpha)^{1-\alpha} = e^{(1-\alpha)ln(1-\alpha)}$, and by Taylor expansion

$$ln(1-\alpha) = -\alpha - \frac{\alpha^2}{2} - \frac{\alpha^3}{3}...,$$

which multiplied by $(1-\alpha)$, gives us

$$(1-\alpha)ln(1-\alpha) = -\alpha + \frac{\alpha^2}{2} + \text{positive terms} > -\alpha + \frac{\alpha^2}{2}. \tag{66}$$

Plugging (66) into Equation (65), we finally get,

$$\begin{aligned}\Pr(X < (1-\alpha)\mu) &\leq \left(\frac{e^{-\alpha}}{(1-\alpha)^{1-\alpha}}\right)^{\mu} \\ &= \left(\frac{e^{-\alpha}}{e^{(1-\alpha)ln(1-\alpha)}}\right)^{\mu} \\ &\leq \left(\frac{e^{-\alpha}}{e^{-\alpha+\frac{\alpha^2}{2}}}\right)^{\mu} \\ &= e^{-\mu\alpha^2/2}\end{aligned}$$

■

Lemma 22 *Let $X_1, X_2, ..., X_n$ be independent Poisson trials with $Pr[X_i = 1] = p_i$, $X \triangleq \sum_{i=1}^{n} X_i$, and $\mu = \mathbb{E}X$. Then, for every $\alpha \geq 2e - 1$:*

$$\Pr(X > (1+\alpha)\mu) \leq 2^{-\mu\alpha}.$$

Proof Sketch This sketch is taken from the work of John Canny Canny (2012). It is almost identical to the proof of Lemma 21.

We start by showing that

$$\Pr(X > (1+\alpha)\mu) \leq \left(\frac{e^{\alpha}}{(1+\alpha)^{1+\alpha}}\right)^{\mu}.$$

For every $t > 0$,

$$\Pr(X > (1+\alpha)\mu) \quad = \quad \Pr[\exp(tX) > \exp\left(t(1+\alpha)\mu\right)].$$

As we did in Lemma 21, we compute the Markov bound,

$$\Pr(X > (1+\alpha)\mu) \quad \leq \quad \frac{\mathbb{E}(\exp(tX))}{\exp(t(1+\alpha)\mu)},$$

and use the fact that X_i are independent, just like in (63), to get that

$$\mathbb{E}(\exp(tX)) \leq \exp\left(\mu(e^t - 1)\right).$$

Thus we get that

$$\Pr(X > (1+\alpha)\mu) \quad \leq \quad \frac{\exp(\mu(e^t-1))}{\exp(t(1+\alpha)\mu)} = \exp\left(\mu(e^t - 1 - t - \alpha t)\right).$$

From deviation, we choose $t = \ln(1+\alpha)$ to get

$$\Pr(X > (1+\alpha)\mu) \quad \leq \quad \left(\frac{e^\alpha}{(1+\alpha)^{1+\alpha}}\right)^\mu.$$

For $\alpha \geq 2e - 1$:

$$\Pr(X > (1+\alpha)\mu) \quad \leq \quad \left(\frac{e^\alpha}{(1+\alpha)^{1+\alpha}}\right)^\mu \leq \left(\frac{e^\alpha}{(2e)^{1+\alpha}}\right)^\mu \leq \left(\frac{e^\alpha}{(2e)^\alpha}\right)^\mu = 2^{-\mu\alpha}.$$

■

Appendix C. The Rejection Rate of Batch-ILESS

Lemma 23 *Given that event $\mathcal{K}$ (see Definition 6.1) occurred, the radius of Batch-ILESS, as defined in Strategy 3, Stage 4, satisfies*

$$\sigma_{Active} = O\left(\frac{B}{m} + \sqrt{\frac{B}{m} \cdot R(f^*)}\right),$$

where $B \triangleq 4d\ln\left(\frac{8m^2e}{d\delta}\right)$.

Proof The proof is very similar to the proof of Lemma 14. ■

Theorem 24 *Let $\mathcal{F}$ be a hypothesis class with VC-dimension d, and $\mathcal{P}_{\mathcal{X},\mathcal{Y}}$ be an unknown probability distribution. Assume that event $\mathcal{K}$ (see Definition 6.1) occurred. Then, for all f^*, the abstain rate is bounded by*

$$1 - \Phi(\textit{Batch-ILESS}) \leq \theta_{f^*}(R_0) \cdot R_0,$$

where

$$R_0 \triangleq 2 \cdot R(f^*) + 44 \cdot \frac{B}{m} + 12 \cdot \sqrt{\frac{B}{m} \cdot R(f^*)}.$$

where $B \triangleq 4d\ln\left(\frac{8m^2e}{d\delta}\right)$. This immediately implies (by definition) that

$$1 - \Phi(\textit{Batch-ILESS}) \leq \theta(R_0) \cdot R_0.$$

Proof Sketch The proof is very similar to the proof of Lemma 23. We observe the last modification of G_T, and notice that the change was made according to a run of ILESS, on the implied probability distribution $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{T-1})$. Then we simply activate Theorem 5 with the relevant parameters plugged into it.

Note that by Lemma 12, all f^* of the original distribution reside within G_t for all t, and thus, by Lemma 11, they are all true risk minimizers of $\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{T-1})$. This also implies that $R(f^*) \geq R_{\mathcal{P}_{\mathcal{X},\mathcal{Y}}(G_{t-1})}(f^*)$ and thus can be used to bound Equation (30) of the original theorem that was proven for ILESS. θ_f is independent of $\mathcal{P}_{\mathcal{Y}|\mathcal{X}}$ for all f, and thus the change of the labels does not affect it.

Abstract

Community detection or clustering is a fundamental task in the analysis of network data. Many real networks have a bipartite structure which makes community detection challenging. In this paper, we consider a model which allows for matched communities in the bipartite setting, in addition to node covariates with information about the matching. We derive a simple fast algorithm for fitting the model based on variational inference ideas and show its effectiveness on both simulated and real data. A variation of the model to allow for degree-correction is also considered, in addition to a novel approach to fitting such degree-corrected models.

Keywords: bipartite networks, community detection, stochastic block model, bipartite matching, node attributes

1. Introduction

Network analysis has been a very active area of research with applications to social sciences, biology and marketing, to name a few. A fundamental problem in network data analysis is community detection, or clustering: Given a collection of nodes and a similarity matrix among them, interpreted as the adjacency matrix of a (weighted) network, one wants to partition the nodes into clusters, or communities, of high similarity. For undirected networks, a popular model for community-structured networks is the stochastic block model (SBM) (Holland et al., 1983) and its variants (Karrer and Newman, 2011; Gopalan and Blei, 2013), which have been extensively investigated in recent years both in terms of theoretical properties and efficient fitting algorithms. See for instance Bickel and Chen (2009); Decelle et al. (2011); Rohe et al. (2011); Mossel et al. (2015); Zhao et al. (2012); Amini et al. (2013); Qin and Rohe (2013); Mossel et al. (2013); Massoulié (2014); Amini and Levina (2018); Gao et al. (2017); Abbe (2017); Jing and Rinaldo (2015); Hajek et al. (2016); Abbe et al. (2016); Gao et al. (2016) for a sample of the work. On the other hand, a natural structure is often present in many real networks, that of being bipartite, where nodes are divided into two sets, or *sides*, and only connections between nodes of different sides are allowed. Examples include networks of actors and movies, scientific papers and their authors, shoppers and products, and proteins and the genes they regulate. Block-modeling with the explicit aim of taking into account the bipartite nature of a network has received comparatively less attention. Interesting new modeling possibilities emerge in the bipartite case, chief among them being the issue of matching between the communities of the two sides.

Finding matched node communities in a bipartite network is a necessary task for network analysis in many applications, especially in biomedical sciences. For example, in molecular biology, a key question is to understand how thousands of proteins regulate their downstream genes in a collaborative manner (Davidson and Levin, 2005; Hecker et al., 2009). Provided with a protein-gene interaction network, constructed from high-throughput biological data, a much needed task is to find clusters of proteins that co-regulate a cluster of genes (Barabasi and Oltvai, 2004). Understanding this complicated protein-gene relationship will shed new light on understanding molecular mechanisms underlying diseases, such as cancers (Madhamshettiwar et al., 2012) and neurodegenerative diseases (Parikshak et al., 2015). For another example, in evolutionary biology, certain genes in two different species share common ancestors in the evolutionary history (Harvey et al., 1991). The pairwise gene conservation relationship is described by an ortholog bipartite network, where an edge connects two conserved genes, one from each species, and such two genes are referred to as *orthologs* (Liao and Zhang, 2005). How to identify two clusters of genes, one cluster in each species, that are jointly evolutionarily conserved, is a matched community detection question. For a third example, in cancer biology, researchers are often interested in linking DNA profiles with gene expression (RNA) profiles of cancer patients (Hedenfalk et al., 2001; Iwakawa et al., 2015; Robinson et al., 2015). In other words, researchers would like to learn what DNA mutations would cause what gene expression changes, so that they can design treatment strategies at the RNA or protein levels given a patient's DNA profile. It is well known that multiple mutations often have a joint effect on the expression levels of multiple genes (Vogelstein and Kinzler, 2004). Thus how to detect such a joint effect given a mutation-gene bipartite network is a matched community detection problem. Another key question in cancer biology is to discover new and rare subtypes for a given type of cancer (Sørlie et al., 2001, 2003; Banerji et al., 2012; Wang et al., 2011). To address this question, one can consider the bipartite gene-patient network where the edges are mutation status (or the expression value) of a gene in a patient. This is clearly a matched community detection problem where the co-cluster of the genes and patients determine the cancer subtypes.

In addition to biomedical sciences, finding matched clusters in a bipartite network also has broad applications in social sciences. For example, consider the author–paper bipartite networks where an edge signifies the authorship. There is a matching between the authors and the papers in these networks since most authors follow a theme in their publications. The matched communities in this case correspond to high-level fields of study. As an another example, consider the Wikipedia page–user networks where an edge captures the act of editing a page. In these networks, the users also congregate in groups based on their interests and the subject matter of the pages or, say, their language. The common subject or the language constitutes a matched community pair in this case. We refer to Section 5 for a detailed analysis of some of these networks.

The problem of community detection in bipartite networks is closely related to that of co-clustering, also known as bi-clustering, which goes back at least to (Hartingan, 1972). Co-clustering refers to simultaneous clustering of the rows and columns of a matrix, the *bi-adjacency matrix* of a bipartite graph. It has been extensively used in biological applications (Cheng and Church, 2000; Madeira et al., 2010) and text mining (Dhillon, 2001, 2003; Bisson and Hussain, 2008). Recently, (Choi and Wolfe, 2014; Flynn and Perry, 2012) studied

likelihood-based co-clustering. Rohe et al. (2016) proposed a spectral co-clustering algorithm for directed networks and discussed how it can be applied to bipartite setting. Often, the co-clustering formulation ignores the issue of matching of the clusters, in the sense that in general any row cluster can be in relation to any column cluster.

Another common approach is to reduce community detection in the bipartite setting to two separate instances of usual clustering of (undirected) unipartite networks, by forming *one-mode projections* of the network onto the two sides (Zhou et al., 2007). Despite a moderate reduction in the dimension (having to deal with two smaller networks), the projection approach suffers from information loss and identifiability issues (Zhou et al., 2007). Projection can also turn a structured bipartite network into unstructured unipartite ones or vice versa (Larremore et al., 2014). Another major difficulty is establishing a link between the communities on the two sides. One can come up with ad-hoc association measures between communities of the two sides, e.g., by counting links between each pair. This, however, leads to another bipartite graph on the communities, leading to the difficulty of interpretation. In effect, the problem transfers from community detection on the individual nodes, to that on the newly-discovered communities, or supernodes.

Block-modeling in the bipartite setting has recently gained more attention. Wyse et al. (2014) proposed a method to infer both community memberships as well as the number of communities in a bipartite network using a block model and an algorithm similar to the iterated conditional modes (Besag, 1986). Larremore et al. (2014) has proposed a bipartite stochastic block model (BiSBM) that built on the work of Karrer and Newman (2011) to infer bipartite community structure in both degree-corrected and uncorrected regimes by maximizing a profile likelihood over all partitions. In both cases, the issue of matching of the communities on the two sides is not the main concern.

Motivated by the matching problem, in this paper, we consider the problem of *matched community detection* in a bipartite network. In many practical examples, one either expects a one-to-one correspondence between the communities of the two sides, or it is reasonable to postulate such structure, due to ease of interpretation (Section 2). The problem of "finding communities in a bipartite network that are in one-to-one correspondence between the two sides" is what we refer to as matched community detection. In its simplest form, the model assumes that nodes belonging to matched communities have a higher probability of connection (cf. Equation (3)) and may also have correlated values for their nodal covariates. In other words, we will propose a generative model for such networks where there is a hidden matched community structure that affects the distribution of the observed network and the nodal covariates. This avoids the need for post-hoc matching of the communities: the matching is built into the model and inferred simultaneously along with the communities in the process of fitting the model. Our model is a natural extension of the well-known stochastic block model (SBM) and is discussed in detail in Section 2. We also discuss an extension of our model to allow for degree-correction (Section A.3), providing a matched version of the degree-corrected block model (DC-SBM).

In another direction, many networks come with metadata, often in the form of node attributes, or covariates. In our four motivating examples from biomedical sciences, node covariates are often available and provide useful information for detecting matched communities. In the protein-gene example, expression levels of the proteins and genes are natural node covariates (Segal et al., 2003; Bansal et al., 2006). Incorporating the covariate information will allow us to more accurately identify a group of proteins that co-regulate a cluster of genes,

because it is expected that the proteins in a group should share similar expression patterns, and likewise for the genes. In the ortholog example, the expression levels of genes in each species are useful node covariates, which will help researchers better identify clusters of genes that are not only conserved between the two species but also share similar functional characteristics within each species (Li et al., 2014; Gerstein et al., 2014). In the mutation-gene network, gene expression levels are the covariates of the gene nodes. Using this covariate information will be useful for identifying the active genes as a result of mutations (Hedenfalk et al., 2001; Iwakawa et al., 2015; Robinson et al., 2015). For cancer sub-type detection example, using the patient's data such as age, gender, race, progression-free and overall survival time, the primary site of the tumor as well as its stage and grade, etc. as node covariates will help in identifying rare and often more aggressive subtypes (Cheang et al., 2009; Arvold et al., 2011; Von Minckwitz et al., 2012). For the author–paper example, the frequencies of the words in each paper can be considered as node covariates for the paper side. In the Wikipedia user–page networks, the location of the users can be informative covariates.

The potential for improving quality of the clusters by incorporating node covariates has been explored in recent work, in the context of unipartite networks (Binkiewicz et al., 2017; Zhang et al., 2016; Yan and Sarkar, 2016; Newman and Clauset, 2016). The bipartite setting adds another challenge to modeling node covariates, in particular, how to jointly model the covariates on the two sides, considering that one often has covariates of different dimensions on each side. (The extreme case is when only one side has node covariates.) We extend our proposed model to allow for the presence of node covariates that are aware of the matching between communities of the two sides. In other words, covariates corresponding to nodes in matched communities are statistically linked. The linkage can be tuned using a general cross-covariance matrix, allowing for varying degrees of covariate influence on the community detection problem (Section 2). It is worth noting that we specifically model the problems where the network and node covariates are driven by a single latent community structure. This is often a plausible assumption in many applications. In these cases, one expects to obtain more accurate community estimates by properly combining the two sources of information; our model allows for a natural incorporation of these two sources by maximizing the joint likelihood. Modeling cases where the node covariates and the network provide conflicting information about a potential clustering remains a challenging task and is outside the scope of the present paper.

To fit our models, we derive an algorithm based on the variational inference, also known as the variational Bayes (Jordan et al., 1999; Blei et al., 2017) ideas (Section 3). We derive both the degree-corrected and uncorrected versions of algorithm within the same unified framework, namely, sequential block-coordinate ascent on the variational likelihood. This in particular leads to a novel approach to fitting degree-corrected likelihoods using methods of continuous optimization (as opposed to profiling out the degree-correction parameters and optimizing over the space of discrete labels.). As part of the initialization of the algorithm, we revisit a bipartite spectral clustering algorithm, `biSC` first proposed in Dhillon (2001), and identify it as an effective algorithm for matched bipartite clustering. We show the effectiveness of our approach on simulated (Section 4) and real data, namely, page-user networks collected from Wikipedia and two sets of author-paper networks, one extracted from Arnetminer collection by Tang et al. (2012) and the other scraped from DBLP(Section 5).

To summarize, our contributions in this paper are the following:

(i) Identify the matching problem in bipartite community detection more clearly and give it the prominent role, by showing that it is possible to consider matched communities from the start in the modeling process. Bringing attention to matched bipartite clustering (or community detection) as a well-defined problem also allows us to identify an earlier spectral algorithm, namely that of Dhillon (2001), originally proposed in the context of topic modeling, as effectively solving the matched version of bipartite clustering. At present, we are unaware of any other algorithm that attempts to solve this problem directly.

(ii) Propose a natural bipartite extension of the SBM and DC-SBM: *matched bipartite stochastic block model* (`mbiSBM`), which has a latent structure of matched communities and allows for node covariates that are potentially informative about the matching (see Section 2). Some of the challenges involved in joint modeling of the node covariates of the two sides are resolved by appealing to hierarchical Bayesian modeling ideas (Gelman et al., 2003).

(iii) Show the effectiveness of the variational Bayes approach in fitting the overall `mbiSBM` model, when combined with good initialization, especially a variant of the `biSC` algorithm of Dhillon (2001). The algorithm is a block-coordinate ascent with a closed-form, fairly cheap iterations, and can be scaled to large networks.

Notation. We write $[K] := \{1, \dots, K\}$ and $\mathcal{P}_K := \{p \in \mathbb{R}_+^K : \mathbf{1}^T p = 1\}$, for the set of probability vectors on $[K]$. Here, $\mathbf{1}$ is the all-ones vector of dimension K. We identify $[K]$ with $\{0,1\}^K \cap \mathcal{P}_K$, the set of binary vectors of length K having exactly a single entry equal to one. The identification is via the so-called *one-hot* encoding: $z = k$ as an element of $[K]$ iff $z_k = 1$, treating z as element of $\{0,1\}^K \cap \mathcal{P}_K$. We will use I_d to denoted the $d \times d$ identity matrix.

The probability density function (PDF) of a multivariate Gaussian distribution with mean μ and covariance Σ is denoted as $x \mapsto N(x; \mu, \Sigma)$. The constant terms in an expression are denoted as "const.". We write $\doteq$ for equality up to additive constants. We use $[Z_1; Z_2]$ to denote the vertical concatenation of two matrices Z_1 and Z_2, having the same number of columns.

2. Matched Bipartite SBM

The stochastic block model (SBM) is a generative model for networks with communities (or blocks). In the most basic SBM, sometimes called the *planted partition model*, each node is assigned to one of the K communities and the edges are placed independently between two nodes i and j, with probability p if i and j belong to the same community, and with probability q otherwise. When $p = q$, one recovers the famous Erdős–Rényi model, where there is no genuine community structure. The interesting cases are the *assortative* model where $p > q$ and the *dissortative* model where $p < q$. Our focus in this paper is mainly on the assortative case, though the results can be easily adapted to the other case.

We start with the ingredients needed to define the matched bipartite SBM (`mbiSBM`). Assume that we have two groups of nodes $[N_1] = \{1, \dots, N_1\}$ and $[N_2] = \{1, \dots, N_2\}$, representing nodes on the two sides of a bipartite network. We assume that there is a partition $\{C_{rk}\}_{k=1}^K$ of $[N_r]$, for each $r = 1, 2$. This is our latent community structure. In referring to C_{rk}, we will use the terms *community* and *cluster* interchangeably. We assume the following implicit (true) *one-to-one matching* between these communities:

$$C_{1k} \leftrightarrow C_{2k}, \quad k = 1, \dots, K. \tag{1}$$

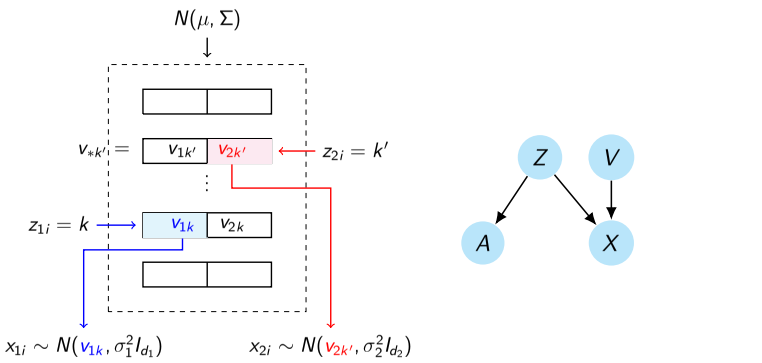

Figure 1: Schematic diagram for the hierarchical generation of node covariates (left) and the overall graphical representation of the model (right). The label z_{ri} selects which of $v_{k*} = (v_{1k}, v_{2k})$ for $k = 1, \dots, K$ we select and the index "$r \in \{1, 2\}$" determines which component of v_{k*} is used to generate x_{ri}. For example, if $z_{1i} = k$ then the v_{1k} component of v_{k*} is used as the mean of x_{1i}, and similarly if you replace 1 with 2. Here, k and k' distinguish two different clusters. For example, if $z_{2i} = k'$ then $v_{2k'}$ will be the mean of x_{2i}, and so on.

To each node i in group r, we assign a community membership variable z_{ri} showing which community it belongs to:

$$z_{ri} = k \iff i \in C_{rk}, \quad \forall i \in [N_r],\ r = 1, 2.$$

Recalling the identification $[K] \cong \{0,1\}^K \cap \mathcal{P}^K$, we treat z_{ri} as both an element of $[K]$ and a binary vector of length K, hence, with some abuse of notation, $z_{ri} = k$ and $z_{rik} = 1$ are equivalent. We collect these labels in *membership matrices* $Z_r := (z_{ri} : i \in [N_r]) \in \{0,1\}^{N_r \times K}$, $r = 1, 2$, where each z_{ri}, treated as a binary vector, appears as a row in Z_r. We also let $Z = [Z_1; Z_2] \in \{0,1\}^{(N_1+N_2)\times K}$ be the *matched membership matrix* obtained by vertical concatenation of Z_1 and Z_2.

For each node i in group r, we observe a covariate vector $x_{ri} \in \mathbb{R}^{d_r}$. If we want to specify the components of this vector we write $x_{rij}, j = 1, \dots, d_r$. Let $X := (x_{ri}, i \in [N_r], r = 1, 2)$. We often think of X as a matrix in $\mathbb{R}^{(N_1+N_2)\times(d_1+d_2)}$, by padding covariate vectors with zeros on the left or right: x_{1i} form rows $(x_{1i}, 0_{d_2})$ for $i \in [N_1]$ and x_{2j} form rows $(0_{d_1}, x_{2j})$ for $j \in [N_2]$.

In addition to the covariate matrix X, we also observe a bipartite network on $[N_1] \times [N_2]$ represented as a *bi-adjacency matrix* $A \in \{0,1\}^{N_1 \times N_2}$. Thus, the observed data is (X, A). We assume that given the latent community labels Z, X is independent of A. Below, we outline how each of these components are generated given Z.

2.1. Generating Covariates

To generate x_{ri}, we use a hierarchical mixture model: First we generate the mean vector $v_{rk} \in \mathbb{R}^{d_r}$ associated with each cluster C_{rk}, and then we draw x_{ri} from a normal distribution with mean v_{rk} when $z_{ri} = k$; see Figure 1. In order to model the correlation (i.e., a statistical link) between covariates of matched clusters, we draw the entire vector $v_{*k} := (v_{rk}, r = 1, 2) =$

(v_{1k}, v_{2k}) from a multivariate normal distribution with possibly nonzero covariance matrix between the two components v_{1k}, v_{2k}. We have the following model:

$$\begin{aligned} z_{ri} &\sim \text{Mult}(1, \pi_r), \\ (v_{rk}, r = 1, 2) &\overset{\text{iid}}{\sim} N(\mu, \Sigma), \quad k = 1, \ldots, K. \\ (x_{ri} \mid z_{ri} = k,\, v_{rk}) &\sim N(v_{rk}, \sigma_r^2 I_{d_r}), \quad i \in [N_r],\ r = 1, 2 \end{aligned} \tag{2}$$

where the draws are independent over r and $i \in [N_r]$, on each line. Here, $\pi_r = (\pi_{r1}, \ldots, \pi_{rK})$ is the prior on cluster proportions for group r ($\pi_r \in [0,1]^K$ with $\sum_{k=1}^K \pi_{rk} = 1$). $(\sigma_r^2, r = 1, 2)$ models the variance of measurement noise in the two groups.

The idea behind the covariate generation is as follows: Each covariate x_{ri} is going to to be determined by v_{rk}, that is x_{1i} will have mean v_{1k} and x_{2j} will have mean v_{2k}, assuming nodes i and j belong to the same cluster k (a single cluster encompasses both sides of the network, based on the matching). That is, we break each $v_{*k} = (v_{1k}, v_{2k})$ into two pieces v_{1k} and v_{2k} and these two pieces determine the covariates of the two sides, x_{1i} and x_{2j}, assuming nodes i and j belong to the same cluster k.

Note that the covariates for two nodes that are in the same cluster on the same side have the same mean: If $z_{1i} = z_{1j} = k$ then both x_{1i} and x_{1j} have mean v_{1k}. On the other hand the covariates for two nodes that are in the same cluster but on different sides will have different means: If $z_{1i} = z_{2j} = k$, then x_{1i} has mean v_{1k} while x_{2j} as mean v_{2k}. These two mean vectors however are still related since they are the components of the single vector $v_{k*} = (v_{1k}, v_{2k})$ which is derived from a multivariate Gaussian distribution. That is, v_{1k} and v_{2k} are jointly Gaussian with a potential nonzero cross-covariance matrix.

To make the correlation structure in $(v_{rk}, r = 1, 2)$ more explicit, we can partition $\mu = (\mu_r, r = 1, 2)$ and Σ, so that

$$\begin{pmatrix} v_{1k} \\ v_{2k} \end{pmatrix} \overset{\text{ind}}{\sim} N\left[\begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{12}^T & \Sigma_{22} \end{pmatrix} \right], \quad k = 1, \ldots, K.$$

Note that $\mu_r \in \mathbb{R}^{d_r}$. In subsection 2.5, we discuss how this model provides a statistical link between covariates of the two groups. For future reference, $v_{*k} := (v_{rk}, r = 1, 2)$ collects the matched hidden covariate means of the clusters C_{1k} and C_{2k}. On the other hand, we write $v_{r*} = (v_{rk}, k \in [K])$ which collects all the hidden covariate means for side $r = 1, 2$ of the network.

2.2. Generating the Network

Given Z, the bipartite graph is generated as follows: For each node i in $[N_1]$ and each node j in $[N_2]$, we put an edge between them with probability p if they belong to matched clusters, and with probability $q \neq p$ otherwise. With $A = (A_{ij}) \in \{0,1\}^{N_1 \times N_2}$ denoting the resulting bi-adjacency matrix, we have

$$A_{ij} \mid Z \overset{\text{ind}}{\sim} \begin{cases} \text{Ber}(p) & z_{1i} = z_{2j} \\ \text{Ber}(q) & z_{1i} \neq z_{2j} \end{cases}, \quad i \in [N_1],\ j \in [N_2]. \tag{3}$$

Combined, (2) and (3) describe our full matched bipartite SBM model. The objective is to find the posterior probability of Z given A and $X = \{x_{ri} : i \in [N_r], r = 1, 2\}$.

Although we will focus on the simple model (3) in deriving the algorithms, it is possible to allow for a more general edge probability structure as in the usual SBM, by assuming

$$A_{ij} \mid Z \overset{\text{ind}}{\sim} \text{Ber}(\Psi_{z_{1i}, z_{2j}}) \quad i \in [N_1],\ j \in [N_2]. \tag{4}$$

where $\Psi \in [0,1]^{K \times K}$ is a connectivity (or edge probability) matrix. Model (3) corresponds to the case where $\Psi_{kk} = p$ and $\Psi_{k\ell} = q$ for $k \neq \ell$. We will refer to this model as `mbiSBM` for matched bipartite SBM.

Remark 1. Parameter Σ in (2) is key in tuning the effect of the node covariates on community detection. Assume for simplicity that $\sigma_r^2 = 0$, $r = 1, 2$. Then, when $\Sigma = 0$, $v_{*k} = \mu$ a.s. for all k, hence $x_{*i} = \mu$ for all i, and the covariates carry no information about communities. When, $\Sigma \neq 0$ there is variability in v_{*k} across k, hence community detection benefits from the covariate information. On the other hand, it is well-known that the information in the adjacency matrix A about community structure is roughly controlled by the expected degree of the network, i.e., the scaling of $Q = (p, q)$, in addition to the separation of p and q. By scaling of (p, q) we mean the following: One can take $p = a/n$ and $q = b/n$; then, how fast a and b increase as a function of n determines the difficulty of the network community detection problem. For the case $a, b = O(1)$, the so-called sparse regime, only partial recovery of the labels is possible (given only the network information), whereas when $a, b \to \infty$ one can recover with asymptotically vanishing misclassification error; at higher densities, namely $a, b \gtrsim \log n$, it is possible to exactly recover the labels for sufficiently large n. See Abbe (2017) for more details. Thus, by rescaling Σ and $Q = (p, q)$, we can control the balance of the two sources of information (i.e., the network versus node covariate information). This is explored in Section 4 through simulation studies.

2.3. Connection with the Usual SBM

Ignoring the covariate part of the model, one might wonder whether `mbiSBM`, introduced in (4), can be thought of as a sub-model of a usual SBM with perhaps increased number of communities. First, it should be clear that the model is not a usual SBM with K communities. However, it can be thought of as a SBM with $2K$ communities with *restrictions* imposed on both its membership and connectivity matrix. To see this, let us recall the matrix representation of the usual SBM with K blocks, where one has the connectivity matrix $\Psi \in [0,1]^{K \times K}$ and binary membership matrix $Z \in \{0,1\}^{N \times K}$. Such model can be compactly represented as $\mathbb{E}[A|Z] = Z\Psi Z^T$.

Now, consider model (4), and let $Z_r = (z_{ri}) \in \{0,1\}^{N_r \times K}$ for $r = 1, 2$. We express the model compactly as

$$\mathbb{E} \underbrace{\begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}}_{\widetilde{A}} = \underbrace{\begin{pmatrix} Z_1 & 0 \\ 0 & Z_2 \end{pmatrix}}_{\widetilde{Z}} \underbrace{\begin{pmatrix} 0 & \Psi \\ \Psi^T & 0 \end{pmatrix}}_{\widetilde{\Psi}} \begin{pmatrix} Z_1^T & 0 \\ 0 & Z_2^T \end{pmatrix}. \tag{5}$$

given Z_1, Z_2. Letting $N := N_1 + N_2$ and defining the matrices $\widetilde{A} \in \{0,1\}^{N \times N}$, $\widetilde{Z} \in \{0,1\}^{N \times 2K}$ and $\widetilde{\Psi} \in [0,1]^{2K \times 2K}$ as in (5), it is clear that model (4) is equivalent to $\mathbb{E}[\widetilde{A}|\widetilde{Z}] = \widetilde{Z}\widetilde{\Psi}\widetilde{Z}^T$. This is a SBM with restrictions on both $\widetilde{Z}$ and $\widetilde{\Psi}$: Nodes $1, \ldots, N_1$ can only belong to communities $1, \ldots, K$ and nodes $N_1 + 1, \ldots, N_1 + N_2$ can only belong to communities $K + 1, \ldots, 2K$. As for $\widetilde{\Psi}$, the restriction imposes zero connectivity among communities $1, \ldots, K$ and among those of

$K+1, \ldots, 2K$. With these restrictions in place, we have a natural bipartite matching between communities: $\ell \leftrightarrow K+\ell$ for $\ell \in [K]$.

2.4. Degree-corrected Version

A limitation of the SBM is that nodes in the same community have the same expected degree. To allow for degree heterogeneity within communities, bringing the model closer to real networks, a common approach is to use the DC-SBM (Dasgupta et al., 2004; Karrer and Newman, 2011). It is fairly straightforward to introduce degree-correction in our setup. Consider the form of the matched SBM introduced in (4). To each node i in group r, we associate a propensity parameter $\theta_{ri} > 0$. Thus, we have additional parameters $\theta_r := (\theta_{ri},\ i \in [N_r])$ for $r = 1, 2$. The degree-corrected (DC) version of the model replaces (4) with

$$A_{ij} \mid Z \overset{\text{ind}}{\sim} \text{Poi}(\theta_{1i}\theta_{2j}\Psi_{z_{1i},\, z_{2j}}) \quad i \in [N_1],\ j \in [N_2]. \tag{6}$$

Replacing the Bernoulli with Poisson is for convenience in later derivations, and is common in dealing with DC-SBM (Karrer and Newman, 2011). In order for the parameters $(\theta_1, \theta_2, \Psi)$ to be identifiable, we need to agree on a normalization of θ_{ri} per each community. Here, we adopt the following:

$$\frac{1}{|C_{rk}|}\sum_{i \in C_{rk}} \theta_{ri} = 1 \iff \sum_{i=1}^{N_r}(\theta_{ri} - 1)z_{rik} = 0, \quad k \in [K],\ r = 1, 2. \tag{7}$$

With this normalization, we recover the original model when $\theta_{ri} = 1$ for all i and r. Our normalization is similar to the one considered in Gao et al. (2016).

Remark 2. A normalization of the form (7) is often assumed when one considers both $\theta = (\theta_1, \theta_2)$ and Z to be deterministic unknown parameters, or alternatively when working conditioned on θ and Z. Throughout, we assume θ to be an unknown parameter. However, to be pedantic, (7) is inconsistent with i.i.d. random generation of z_{ri} from a $\text{Mult}(1, \pi_r)$ as in (2). One way to get around this is to assume that the labels are generated a priori from the product multinomial distribution described in (2) *conditioned* on the set of labels satisfying (7). We will ignore the change in the label prior this conditioning makes in deriving the algorithms. In the end, we enforce (7) in an "averaged" sense, replacing z_{rik} with the corresponding (approximate) posterior τ_{rik}, as detailed in subsection A.3. Viewed as a set of constraints on the collection of soft-labels (τ_{rik}), (7) is not that restrictive.

2.5. Covariate Correlation on Matched Clusters

One desirable feature in modeling covariates, in the context of a matched bipartite network, is the ability to gain some information about whether a pair $(i, j) \in [N_1] \times [N_2]$ belongs to a matched cluster, by just looking at their respective covariates x_{1i} and x_{2j}. Assume for the moment that there is no measurement noise, i.e., $\sigma_r^2 = 0$, $r = 1, 2$. Then, the question boils down to whether we can tell $(v_{1k}, v_{2k'})$ for $k \neq k'$ apart from (v_{1k}, v_{2k}). According to the model, (v_{1k}, v_{2k}) and $(v_{1k'}, v_{2k'})$ are independent Gaussian vectors, hence $(v_{1k}, v_{2k}, v_{1k'}, v_{2k'})$ is Gaussian with mean $(\mu, \mu) = (\mu_1, \mu_2, \mu_1, \mu_2)$ and covariance $\left(\begin{smallmatrix}\Sigma & 0\\ 0 & \Sigma\end{smallmatrix}\right)$. Recalling the decomposition of Σ, it follows that $(v_{1k}, v_{2k'}) \sim N(\mu, \left(\begin{smallmatrix}\Sigma_{11} & 0\\ 0 & \Sigma_{22}\end{smallmatrix}\right))$ for $k \neq k'$ whereas $(v_{1k}, v_{2k}) \sim N(\mu, \left(\begin{smallmatrix}\Sigma_{11} & \Sigma_{12}\\ \Sigma_{21} & \Sigma_{22}\end{smallmatrix}\right))$. As long as $\Sigma_{12} \neq 0$, these two distributions are different, hence the model is able to distinguish

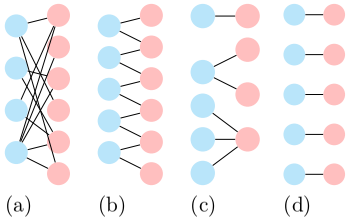

Figure 2: Possible relations between communities of the two sides, in a bipartite network. (a) and (b) are hard to interpret. Structures like (c), i.e., collections of disjoint stars, are interpretable and (d) is the simplest within this class.

between the two cases. In other words, there is information in the covariates about the matching of the clusters in the two groups. However, this information (in itself) is quite weak since it amounts to distinguishing between two multivariate Gaussian distributions, based only on a single draw from each. Fortunately, the model also carries information about the matching in the adjacency matrix A.

2.6. Interpretability and Identifiability

We alluded earlier to the merits of having a 1-1 matching between the communities of the two sides built into the model. Our main argument for the advantage of a 1-1 matching is interpretability. Figure 2 shows some possible relations that could exist between communities of the two side (each circle represents a community). The closer this relation is to a complete bipartite graph, the harder it is to interpret; Figure 2(a) is perhaps the least informative relation among the four. In Figure (b), the relation is much sparser. However, it is still hard to interpret: all communities seem to be related, albeit indirectly. We would like to argue that structures like (c) where the graph is a collection of disjoint *stars* is interpretable. One would like to fit such models, though in full generality, this seems to be a difficult task. One has to somehow control the branching numbers of the stars, which indirectly control the number of communities on either side. Thus, the problem is at least as hard as deciding the number of communities in the usual SBM. Our 1-1 matching relation, Figure 2(d), is the simplest structure of the type depicted in (c). It is in a sense a first-order approximation of the models in this class. It is easiest to fit and is the most interpretable.

3. Model Fitting

In order to fit the model, we derive algorithms based on variational inference ideas. The algorithm starts from some initial guess of the labels and parameters and proceeds to improve the likelihood via simple iterative updates to the parameters and an approximate posterior on the labels. We first discuss the case with no degree correction. The extension to the degree-corrected model is discussed in subsection A.3.

3.1. The Likelihood

Let us introduce some notation. We write $v_{*k} = (v_{rk}, r = 1, 2) \in \mathbb{R}^{d_1+d_2}$ and $v_{r*} = (v_{rk}, k \in [K]) \in \mathbb{R}^{Kd_r}$, and $V = (v_{rk},\, r = 1, 2,\, k \in [K]) \in \mathbb{R}^{K(d_1+d_2)}$. Similarly, $Z = (z_{ri},\, i \in [N_r],\, r = 1, 2)$ and $X = (x_{ri},\, i \in [N_r],\, r = 1, 2)$. (In this section, the particular matrix form of Z and X are not of interest. Z and X are simply placeholders for the collections of labels and covariates.) Let

$$y_{ij} := \mathbb{1}\{z_{1i} = z_{2j}\}, \quad z_{rik} := \mathbb{1}\{z_{ri} = k\}.$$

The joint distribution of all the variables in the model factorizes as follows:

$$\begin{aligned} p(A, X, Z, V) &= p(A|Z)\, p(X|Z, V)\, p(Z)\, p(V) \\ &= \prod_{i=1}^{N_1}\prod_{j=1}^{N_2} p(A_{ij}|z_{1i}, z_{2j}) \prod_{r=1}^{2}\prod_{i=1}^{N_r} \Big\{ p(x_{ri}|z_{ri}, v_{r*}) p(z_{ri}) \Big\} \prod_{k=1}^{K} p(v_{*k}). \end{aligned}$$

We have $p(x_{ri}|z_{ri}, v_{r*}) = \prod_{k=1}^{K} [f_r(x_{ri}; v_{rk})]^{z_{rik}}$ where $f_r(x_{ri}; v_{rk}) := N(x_{ri}; v_{rk}, \sigma_r^2 I_{d_r})$. In addition, $p(z_{ri}) = \prod_{k=1}^{K} \pi_{rk}{}^{z_{rik}}$. For the network part, we in general have

$$\ell_1(\Psi) =: \log p(A|Z) = \sum_{ij}\sum_{k\ell} z_{1ik} z_{2j\ell}\; g(\Psi_{k\ell}, A_{ij}) \tag{8}$$

where g is either the log-likelihood of the Bernoulli, $g_{\text{ber}}(p, \alpha) = \alpha \log \frac{p}{1-p} + \log(1 - p)$, or Poisson, $g_{\text{poi}}(p, \alpha) = \alpha \log p - p$.

In the special planted partition case, $\log p(A|Z)$ greatly simplifies: By breaking up over $k = \ell$ and $k \neq \ell$, we obtain

$$\begin{aligned} \ell_1(\Psi) = \log p(A|Z) &= \sum_{ij} \Big[\sum_{k} z_{1ik} z_{2jk}\; g(p, A_{ij}) + \sum_{k\neq\ell} z_{1ik} z_{2j\ell}\; g(q, A_{ij}) \Big] \\ &= \sum_{ij} y_{ij} g(p, A_{ij}) + (1 - y_{ij}) g(q, A_{ij}). \end{aligned} \tag{9}$$

where we have used $\sum_{k\ell} z_{1ik} z_{2j\ell} = 1$. The complete log-likehood of the model, i.e., assuming we observe the latent variables (Z, V), is then

$$\ell(\mu, \Sigma, \sigma, \pi, \Psi) = \ell_1(\Psi) + \ell_2(\mu, \Sigma, \sigma, \pi)$$

where $\ell_1(\Psi)$ is as defined in (8) and

$$\ell_2(\mu, \Sigma, \sigma, \pi) = \sum_{r=1}^{2}\sum_{i=1}^{N_r}\sum_{k} z_{rik} \log \big[\pi_{rk}\, f_r(x_{ri}; v_{rk})\big] + \sum_{k} \log p(v_{*k}|\mu, \Sigma).$$

3.2. Mean-Field Approximation

Variational inference is often regarded as the approximation of a posterior distribution by solving an optimization problem (Wainwright and Jordan, 2008; Blei et al., 2017). The idea is to pick an approximation q from some tractable family of distributions over the latent variables (Z, V) and try to make this approximation as close as possible in KL divergence to the true

posterior. We prefer to think of the approach as a generalization of the EM algorithm, i.e., a general approach to maximize the incomplete likelihood by maximizing a lower bound on it. This lower bound, which we call variational likelihood, also known as the evidence lower bound (ELBO) (Jordan et al., 1999), involves both the likelihood parameters and a distribution q, namely,

$$J := \mathbb{E}_q[\ell(\mu, \Sigma, \sigma, \pi, \Psi) - \log q(Z, V)]. \tag{10}$$

Here the expectation is taken, assuming $(Z, V) \sim q$. One maximizes J by alternating between maximizing over likelihood parameters $(\mu, \Sigma, \sigma, \pi, \Psi)$ and the variational posterior q. Without additional constraints, the optimization over q leads to the posterior distribution of (Z, V) given (X, A), resulting in the EM algorithm. A genuine variational inference procedure, however, imposes some simplifying constraints on q. In particular, we impose the following factorized form, often referred to as the *mean-field approximation*:

$$q(Z, V) = q_V(V) q_Z(Z), \quad q_Z(Z) = \textstyle\prod_{r,i} q_{ri}(z_{ri}), \quad q_V(V) = \prod_{k=1}^{K} N(v_{*k}; \tilde{\mu}_k, \tilde{\Sigma}_k) \tag{11}$$

where $q_{ri}(z_{ri}) = \prod_{k=1}^{K} \tau_{rik}^{z_{rik}}$ is a multinomial distribution. In keeping up with our notation we write $\tau_{ri} = (\tau_{rik},\ k \in [K])$. Note that $\tau = (\tau_{ri})$ collects the approximate posteriors on node labels. They are the key parameters in our inference.

The particular form assumed for q_V in (11) is motivated by looking at the (true) posterior of V given Z. We could have assumed a factorized form $q(Z, V) = q_Z(Z) p(V|Z)$ where $p(V|Z)$ is the the true posterior of V given Z. However, the parameters of $p(V|Z)$ have a complicated dependence on Z. We have kept the form of $p(V|Z)$ while freeing the parameters, letting them be optimized by the algorithm.

To simplify notation, let us define $\widetilde{\Gamma} := ((\widetilde{\Sigma}_k, \widetilde{\mu}_k), k = 1, \ldots, K)$, collecting the parameters for the variational posterior q_V. Plugging in the variational distribution (11) into the variational likelihood (10) using expression (9) for $\ell_1(\Psi)$, after some algebra detailed in Appendix B.2, we get

$$\begin{aligned} J = &\sum_{i,j} \Big[\gamma_{ij}(\tau) g(p; A_{ij}) + (1 - \gamma_{ij}(\tau)) g(q; A_{ij}) \Big] + \sum_{r,i,k} \tau_{rik} \big[\beta_{rik}(\widetilde{\Gamma}, \sigma^2) + \log \frac{\pi_{rk}}{\tau_{rik}} \big] \\ &- \frac{1}{2} \sum_{r} d_r N_r \log \sigma_r^2 - \frac{K}{2} \big\{ \log |\Sigma| + \operatorname{tr}[\Sigma^{-1} S(\widetilde{\Gamma}, \mu)] \big\} + \frac{1}{2} \sum_{k} \log |\widetilde{\Sigma}_k| + \text{const.} \end{aligned} \tag{12}$$

where

$$\gamma_{ij}(\tau) := \mathbb{E}_{q_Z}(y_{ij}) = \sum_{k=1}^{K} \tau_{1ik} \tau_{2jk}, \quad \beta_{rik}(\widetilde{\Gamma}, \sigma^2) := -\frac{1}{2\sigma_r^2} \Big[\operatorname{tr}\big((\widetilde{\Sigma}_k)_{rr}\big) + \|x_{ri} - \widetilde{\mu}_{rk}\|^2 \Big], \tag{13}$$

$(\widetilde{\Sigma}_k)_{rr}, r = 1, 2$ refers to the two diagonal blocks of $\widetilde{\Sigma}_k$ of sizes $d_r \times d_r$, and

$$S(\widetilde{\Gamma}, \mu) := \frac{1}{K} \sum_{k=1}^{K} \big[\widetilde{\Sigma}_k + (\widetilde{\mu}_k - \mu)(\widetilde{\mu}_k - \mu)^T \big]. \tag{14}$$

3.3. Optimizing the Variational Likelihood

We proceed to maximize J by alternating between the likelihood parameters $(\mu, \Sigma, \sigma, \pi, \Psi)$ and variational parameters $(\tau, \widetilde{\Gamma})$. Each of these two sets of parameters is also optimized by alternating maximization. In other words, the overall optimization algorithm is a block coordinate ascent. The key update is that of label distributions τ, which we describe in details below. The other updates are more or less standard and detailed in Appendix B.4.

Updating node labels (τ). To optimize τ, we use block coordinate ascent, by fixing $\tau_2 := (\tau_{2j}, j \in [N_2])$ and optimizing over $\tau_1 := (\tau_{1j}, j \in [N_1])$ and vice versa. Here we only consider optimization over τ_1 given τ_2. To simplify notation, let $h(p, q; \alpha) := g(p; \alpha) - g(q; \alpha)$. Considering only the terms in J that depend on τ, we have

$$J = \sum_{ij} \gamma_{ij}(\tau)\, h(p, q; A_{ij}) + \sum_{r,i,k} \tau_{rik} \big[\beta_{rik}(\widetilde{\Gamma}, \sigma^2) + \log \frac{\pi_{rk}}{\tau_{rik}}\big] + \text{const.}$$

where const. collects terms that do not depend on τ. Let $\xi_{rik} := \beta_{rik}(\widetilde{\Gamma}, \sigma^2) + \log \pi_{rk}$. Using the definition of $\gamma_{ij}(\tau) = \sum_{k=1}^{K} \tau_{1ik}\tau_{2jk}$,

$$J = \sum_{ij} \Big(\sum_{k} \tau_{1ik}\tau_{2jk} \Big)\, h(p, q; A_{ij}) + \sum_{r,i,k} \tau_{rik} \big[\xi_{rik} - \log \tau_{rik}\big] + \text{const.}$$

Now, assume further that τ_2 is constant. Then,

$$\begin{aligned} J &= \sum_{i} \sum_{k} \tau_{1ik} \Big(\sum_{j} \tau_{2jk}\, h(p, q; A_{ij}) \Big) + \sum_{i,k} \tau_{1ik} \big[\xi_{1ik} - \log \tau_{1ik}\big] + \text{const.} \\ &= \sum_{i} \sum_{k} \tau_{1ik} \Big(\sum_{j} \tau_{2jk}\, h(p, q; A_{ij}) + \xi_{1ik} - \log \tau_{1ik} \Big) + \text{const.} \end{aligned} \tag{15}$$

where const. includes terms also dependent on τ_2, but not on τ_1. The cost function above is separable over i, and for each i we have an instance of the problem given in the following lemma. Recall that $\mathcal{P}_K$ is the set of probability vectors in $\mathbb{R}^K$.

Lemma 1. *For any nonnegative vector $(a_1, \ldots, a_K)$, let $f_a : \mathcal{P}_K \to \mathbb{R}$ be defined by $f_a(p) := \sum_{k=1}^{K} p_k(a_k - \log p_k)$. Then the maximizer of f_a over $\mathcal{P}_K$ is given by the softmax operation:*

$$\operatorname*{argmax}_{p \in \mathcal{P}_k} f_a(p) = \text{softmax}(a) := \frac{e^{a_k}}{\sum_{\ell} e^{a_\ell}}. \tag{16}$$

We write the solution of Lemma 1 simply as $p_k \propto_k e^{a_k}$ where $\propto_k$ means proportional as a function of k. Then, τ_1 update is $\tau_{1ik} \propto_k \exp\big[\sum_j \tau_{2jk}\, h(p, q; A_{ij}) + \xi_{1ik}\big]$, or after unpacking ξ_{1ik},

$$\tau_{1ik} \;\propto_k\; \pi_{1k} \exp\Big[\sum_{j} \tau_{2jk}\, h(p, q; A_{ij}) + \beta_{1ik}(\widetilde{\Gamma}, \sigma^2)\Big] \quad i = 1, \ldots, N_1. \tag{17}$$

The update for τ_2 is similar.

Updating $\widetilde{\Sigma}$ and $\widetilde{\mu}$. Let us define $\bar{\tau}_{rk} := \sum_{i=1}^{N_r} \tau_{rik}$ and $D_k^{-1} := \text{diag}\,(\frac{\bar{\tau}_{1k}}{\sigma_1^2} I_{d_1}, \frac{\bar{\tau}_{2k}}{\sigma_2^2} I_{d_2})$ Then, as a function of $\widetilde{\Sigma}$, J can be written as (see Appendix B.3)

$$J(\widetilde{\Sigma}) \doteq -\frac{1}{2} \sum_{k} \text{tr}\,\big[(D_k^{-1} + \Sigma^{-1})\widetilde{\Sigma}_k\big] - \log|\widetilde{\Sigma}_k|. \tag{18}$$

This is separable over k, with each term being the likelihood of a multivariate Gaussian with covariance parameter. The maximizers are then simply $\widetilde{\Sigma}_k = (D_k^{-1} + \Sigma^{-1})^{-1}$ for $k \in [K]$.

To derive the updates for $\widetilde{\mu}$, let $\bar{x}_{rk} := \sum_{i=1}^{N_r} \tau_{rik} x_{ri}$ and $\bar{\mu}_{rk} := \bar{x}_{rk}/\bar{\tau}_{rk}$. Then, as a function of $\widetilde{\mu}$, J can be written as (see Appendix B.3):

$$J(\widetilde{\mu}) \doteq -\frac{1}{2} \sum_{k} (\widetilde{\mu}_k - m_k)^T (D_k^{-1} + \Sigma^{-1})(\widetilde{\mu}_k - m_k) \tag{19}$$

where $m_k = (D_k^{-1} + \Sigma^{-1})^{-1}(D_k^{-1}\bar{\mu}_k + \Sigma^{-1}\mu)$. It is clear that the optimal value of $\widetilde{\mu}_k$ is equal to m_k, which using the optimal value of $\widetilde{\Sigma}_k$, can be written as $\widetilde{\mu}_k = \widetilde{\Sigma}_k(D_k^{-1}\bar{\mu}_k + \Sigma^{-1}\mu)$.

Updating Σ, μ and σ^2. As a function of Σ, we have $J(\Sigma) \doteq -\frac{K}{2}\big[\log|\Sigma| + \text{tr}(\Sigma^{-1}S(\widetilde{\Gamma}))\big]$ which is the standard Gaussian likelihood, giving the optimal value $\Sigma = S(\widetilde{\Gamma}, \mu)$. Similarly, as a function of μ, $J(\mu) \doteq -\frac{K}{2}\big[\text{tr}(\Sigma^{-1}S(\widetilde{\Gamma}))\big] \doteq -\frac{1}{2}\sum_k \big[(\widetilde{\mu}_k - \mu)^T\Sigma^{-1}(\widetilde{\mu}_k - \mu)\big]$ giving the optimal solution $\mu = \frac{1}{K}\sum_k \widetilde{\mu}_k$. The update for $\sigma^2 = (\sigma_1^2, \sigma_2^2)$ can be easily obtained too (see Appendix B.4)

$$\sigma_r^2 = \frac{1}{N_r d_r}\Big[\sum_k \bar{\tau}_{rk}\,\text{tr}\,\big((\widetilde{\Sigma}_k)_{rr}\big) + \sum_{i,k} \tau_{rik}\|x_{ri} - \widetilde{\mu}_{rk}\|^2\Big], \quad r = 1, 2. \tag{20}$$

Updating π and $\Psi \equiv (p, q)$. Updating these parameters is standard (See Appendix B.4):

$$\pi_r = \frac{(\bar{\tau}_{r1}, \ldots, \bar{\tau}_{rK})}{\sum_k \bar{\tau}_{rk}},\ r = 1, 2, \quad p = \frac{\sum_{ij}\gamma_{ij}(\tau)A_{ij}}{\sum_{ij}\gamma_{ij}(\tau)}, \quad q = \frac{\sum_{ij}\big(1 - \gamma_{ij}(\tau)\big)A_{ij}}{\sum_{ij}\big(1 - \gamma_{ij}(\tau)\big)}. \tag{21}$$

3.4. Extensions

Various extensions and improvements of the basic algorithm discussed in Section 3.3 are presented in Appendix A. A detailed derivation of an algorithm for fitting the degree-corrected model is given in Appendix A.3. The algorithm employs a novel application of the Douglas–Rachford splitting algorithm for optimization over the degree inhomogeneity parameter θ. We also provide in Appendix A.2 an extension of the algorithm to the general matched SBM model (4). Improvement to the speed for the basic algorithm of Section 3.3 is discussed in Appendix A.1.1 as well as the possibility of adding a diagonal restriction on covariate covariance matrices (Appendix A.1.2).

Overall the algorithm has 16 variations based on four options: (1) Poisson versus binomial likelihood, (2) planted partition versus general edge probability matrix, (3) full versus diagonal covariances, (4) with or without degree correction. In the following we will focus on the following defaults for the first three options: A Poisson likelihood with planted partition connectivity and full covariances.

Algorithm 1 Variational block coordinate ascent for fitting `mbiSBM`

1: Initialize τ_r using `biSC`, and $\theta_r = \mathbf{1}_{N_r}$ for $r = 1, 2$. Pick tolerance $\varepsilon \in (0, 1]$.
2: Initialize $\Sigma, \widetilde{\Sigma}_k$ with $I_{d_1+d_2}$ and $\mu, \widetilde{\mu}_k$ with 0, for $k \in [K]$, and $\sigma_r^2 = 1$ for $r = 1, 2$.
3: **while** not `CONVERGED`, nor maximum iterations reached **do**
4: Update (p, q) using (26) and $\pi_r, r = 1, 2$ using (21).
5: Update $(\phi_0, \phi_1) \leftarrow (q - p, \log(p/q))$.
6: **if** DC-version **then**
7: Update θ_r by repeating (36) till convergence.
8: **end if**
9: Update $\beta_r, r = 1, 2$ using (13).
10: $\tau_r^{\text{old}} \leftarrow \tau_r$, $r = 1, 2$.
11: Update τ_1 by repeating (34) till convergence.
12: Update τ_2 by repeating (34), with subscripts 1 and 2 switched and A replaced with A^T, till convergence.
13: Update the following for for $r = 1, 2$ and $k \in [K]$: ▷ Update parameters
14: $\bar{\tau}_{rk} \leftarrow \sum_{i=1}^{N_r} \tau_{rik}$, and $D_k^{-1} \leftarrow \operatorname{diag}\left(\bar{\tau}_{1k} I_{d_1}/\sigma_1^2, \bar{\tau}_{2k} I_{d_2}/\sigma_2^2\right)$,
15: $\bar{x}_{rk} \leftarrow \sum_{i=1}^{N_r} \tau_{rik} x_{ri}$, and $\bar{\mu}_{rk} \leftarrow \bar{x}_{rk}/\bar{\tau}_{rk}$.
16: Update $\widetilde{\Sigma}_k \leftarrow (D_k^{-1} + \Sigma^{-1})^{-1}$ and $\widetilde{\mu}_k \leftarrow \widetilde{\Sigma}_k(D_k^{-1}\bar{\mu}_k + \Sigma^{-1}\mu)$.
17: Update $\mu \leftarrow \frac{1}{K}\sum_k \widetilde{\mu}_k$ and $\Sigma \leftarrow \frac{1}{K}\sum_{k=1}^K \left[\widetilde{\Sigma}_k + (\widetilde{\mu}_k - \mu)(\widetilde{\mu}_k - \mu)^T\right]$.
18: Update $\sigma_r^2, r = 1, 2$ using (27).
19: `CONVERGED` $\leftarrow \left[\max\{\delta_1, \delta_2\} < \varepsilon/K\right]$, where $\delta_r := \|\tau_r - \tau_r^{\text{old}}\|_\infty, r = 1, 2$
20: **end while**

3.5. Summary of the Algorithms

Algorithm 1 summarizes the updates for fitting the proposed matched bipartite SBM model, to which we refer as `mbiSBM`. We have stated the general form of the algorithm with degree correction (DC) and covariates. Note for example that if no degree-correction is desired, θ_r remains equal to $\mathbf{1}_{N_r}$ and the iterations (34) in steps 11 and 12, for updating the label distributions (τ_r), automatically reduce to the simple update (25) (that is, the iterations converge in one step.). There are other variations available. For example, if desired, step 5 can be replaced with $(\phi_0, \phi_1) \leftarrow (\log\frac{1-p}{1-q}, \log\frac{p(1-q)}{q(1-p)})$ to use values based on a Bernoulli likelihood instead of a Poisson. Empirically, we have not found much difference between the two. With minor modifications, the algorithm can be used when only one side has covariates or without covariates for either side. The code is available on `Github` (Razaee et al.).

3.5.1. Initialization of the Algorithms

It is known that variational inference is sensitive to initialization (Blei et al., 2017). The main component of the algorithm that needs careful initialization is the matrix of (approximate) posterior node labels $\tau = [\tau_1; \tau_2]$. We propose to initialize τ using a bipartite spectral clustering algorithm, `biSC` for short, which is a variant of the approach of Dhillon (2001). The difference

Algorithm 2 Bipartite Spectral Clustering (`biSC`)

1: Input: bi-adjacency matrix $A \in \{0, 1\}^{N_1 \times N_2}$.
2: Let $D_1 = \operatorname{diag}(\sum_j A_{ij}, i = 1, \ldots, N_1)$ and $D_2 = \operatorname{diag}(\sum_i A_{ij}, j = 1, \ldots, N_2)$.
3: Form $L = D_1^{-1/2} A D_2^{-1/2}$.
4: Let $L = USV^T$ be the SVD of L truncated to K largest singular values ($U \in \mathbb{R}^{N_1 \times K}$ and $V \in \mathbb{R}^{N_2 \times K}$).
5: Normalize each row of U and V to unit ℓ_2 norm to get $\widetilde{U}$ and $\widetilde{V}$, resp., then form

$$Z = \begin{bmatrix} D_1^{-1/2}\widetilde{U} \\ D_2^{-1/2}\widetilde{V} \end{bmatrix}.$$

6: Run k-means with K clusters on the rows of Z.

between our version and that of Dhillon (2001) is that Dhillon (2001) does not normalize the rows of the singular vectors and keeps top $\lceil \log_2 K \rceil$ singular vectors, as opposed to K. We have found that row normalization greatly improves the performance, and it is fairly standard in usual (non-bipartite) Laplacian-based spectral clustering. Algorithm 2 summarizes our version.

In simulation studies, we also consider a couple of competing initializations. One interesting choice is to use the usual Laplacian-based spectral clustering, which is oblivious to the bipartite nature of the problem. For this choice, we use the regularized version described in Amini et al. (2013) as `SCP`. Note that `SCP` will be applied to the (symmetric) adjacency matrix $\widetilde{A}$; see (5). It is also possible to regularize `biSC` using similar ideas, though surprisingly, we found the simple unregularized version of `biSC` is quite robust, and we have used this simple version when reporting results.

When working with simulated data, since we have access to the true labels, we will also consider a perturbed version of truth as an initialization. Specifically, we generate from a mixture of the true label distribution and Dirichlet noise, i.e. $\tau_{ri} = \omega z_{ri} + (1 - \omega)\varepsilon_{ri}$ where $\varepsilon_{ri} \sim \text{Dir}(.5\mathbf{1}_K)$. Here, we treat z_{ri}, the true label of node i in group r, as a distribution on the K labels. Parameter $\omega \in [0, 1]$ measures the degree of initial perturbation towards noise. For example, with $\omega = 0.1$, about 10% of the initial labels are correct. We will refer to this initialization as $\sim$`rnd`, for approximately random. This initialization will act as a proxy for a "good enough" initialization and allows us to study the behavior of our variational inference procedure decoupled from specific initializations produced by spectral clustering (or other methods).

Let us say a few words about the initialization of other parameters. The algorithm is moderately sensitive to the initialization of p, q and $\pi_r, r = 1, 2$. When the quality of the initial labels (τ_1 and τ_2) is good, one can initialize these parameters, based on (τ_r), by running the corresponding updates first, as is done in Algorithm 1, lines 4–5. This is the form we suggest in practice when using the `biSC` initialization, and is used in the real data application (Section 5). However, when the quality of the initial labels is not good, for example, when using `SCP` in the simulations, p and q obtained based on initial (τ_r) can become quite close leading to numerical instability. We have found in those cases that initializing these parameters with fixed values, say $(p, q) = (0.1, 0.01)$ and π_r set to uniform distribution of $[K]$, greatly improves the stability of the algorithm. (This is since even one iteration of the algorithm could significantly

improve upon initial labels.) This fixed initialization of (p, q, π_r), independent of τ_r is what we have used in Monte Carlo simulations on synthetic data, when comparing different label initializations (Section 4).

4. Simulations

In this section, we show that effectiveness of our proposed algorithm in recovering the true labels in synthetic bipartite networks. For the most part, we generate data from our proposed model (2)–(3). In the plots investigating the degree-corrected version of the algorithm, we generate from the degree-corrected version of the network described in subsection 2.4.

4.1. Data generation

Key parameters regarding covariate generation in (2) are (μ, Σ) for generating v_{*k}. We take $\mu = 0$ and $\Sigma = \nu I_{d_1+d_2}$ throughout. Varying ν (or dimensions d_r) changes the information provided by the covariates (Appendix E). Larger ν causes v_{*k} to be further apart, hence covariates are more informative. $\nu = 0$ corresponds to zero covariate information. We also fix covariate noise levels at $\sigma_r = 0.5$ for $r = 1, 2$, and the network size at $N = (N_1, N_2) = (200, 800)$.

Key parameters regarding network generation in (3) are p and q. We reparametrize our planted partition model in terms of expected average degree

$$\lambda = \frac{2N_1N_2}{N_1 + N_2}\big[q + (p - q)\sum_k \pi_{1k}\pi_{2k}\big] \tag{22}$$

(see Appendix D) and the out-in-ratio $\alpha = q/p \in [0, 1)$. Estimation becomes harder when λ decreases (few edges) or when α increases (communities are not well separated). We fix $\alpha = 1/7$ and vary λ in the subsequent simulations.

When generating from the degree-corrected version, we draw $(\theta_i, i \in C_{rk})$ from a Pareto (i.e., power-law) distribution, for each $k \in [K]$ and $r = 1, 2$. Real networks are frequently reported to have power-law degree distributions Barabási and Albert (1999). The Pareto(a, R) in general has density $\theta \mapsto (aR^a)\theta^{-a-1}1\{\theta > a\}$, with mean $aR/(a-1)$ for $a > 1$ and variance $R^2a/[(a-1)^2(a-2)]$ for $a > 2$. Since $|C_{rk}|^{-1}\sum_{i\in C_{rk}}\theta_i$ will be approximately equal to the mean of the Pareto, and we want this average to be 1, we have to choose $R = (a-1)/a$, that is, we generate $\theta_i \overset{\text{iid}}{\sim} \text{Pareto}(a, (a-1)/a)$ for $i \in C_{rk}$. (To comply with our model specification, we further normalize θ_i for their within-community averages to be exactly one; this will have little effect since the average is already close to 1.) The variance in this case is $[a(a-2)]^{-1}$ which is decreasing in a over $(2, \infty)$. In order to get maximum degree heterogeneity (i.e., the worse case in terms of the difficulty of fitting), we take $a = 2$, corresponding to infinite variance. We note that expression (22) remains valid for the degree-corrected case without modification, assuming normalization (7); see Appendix D.

4.2. Matched NMI for evaluation

In general, we measure the accuracy of the algorithms by the normalized mutual information (NMI) between the inferred and correct communities which is defined as the mutual information of the (empirical) joint distribution of the two label assignments divided by the joint entropy (Malvestuto, 1986). NMI has a maximum value of 1 for perfect agreement and a minimum of 0 for no agreement. One could measure NMI individually between $Z_r \in \{0, 1\}^{N_r\times K}$

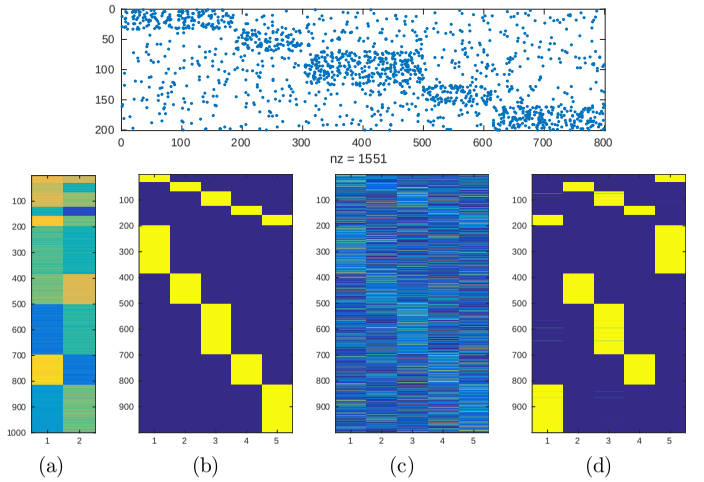

Figure 3: Typical output of the algorithm. Top row: bi-adjacency matrix. Bottom row: (a) Concatenated covariate matrix $[X_1; X_2]$. (b) Concatenated true labels $[Z_1; Z_2]$. (c) Initial labels for the algorithm, Dirichlet-perturbed truth $0.1[Z_1; Z_2] + 0.9\,\text{Dir}(0.5\mathbf{1}_K)$. (d) Concatenated output of the algorithm $[\tau_1; \tau_2]$.

(the true label matrix) and $\tau_r \in [0, 1]^{N_r\times K}$ (the estimated soft-label matrix) for each $r = 1, 2$. However, one can also measure a *matched NMI* by concatenating the labels of two sides vertically, i.e., forming $[Z_1; Z_2]$ and $[\tau_1; \tau_2]$ and measuring a single NMI between the resulting $(N_1 + N_2) \times K$ matrices. Some thought should convince the reader that this the natural way to also measure the effectiveness of the matching between the communities of the two sides: We have a matched NMI of 1, if the true and estimated clusters on each side are in perfect agreement, and the matching between them is perfectly recovered.

4.3. Typical output

Figure 3 shows the typical output of the algorithm on the data generated from the model without degree correction (DC), i.e., $a = \infty$. Here the empirical average degree is $\hat{\lambda} = 3.1$, $K = 5$, $\nu = 10$ and $d = (2, 2)$, the dimensions of the covariates. Concatenated matrices of the true labels and the initial and final labels are shown. Vertical concatenation is used as discussed earlier, giving matrices of dimension $(N_1 + N_2) \times K$. Initial labels are the Dirichlet-perturbed truth with $\rho = 0.1$, i.e. 90% noise, as discussed in Section 3.5.1. It is interesting to note that the output of the algorithm has recovered the communities with a nontrivial permutation of the community labels.

In other words, the perturbation of the initial labels is high enough that the convergence of the algorithm cannot simply be explained by a local perturbation analysis: the algorithm has not converged to the original labels, but to a perfectly valid permuted version of the original labels. That is, $\tau_r \approx Z_rQ_r$ for $r = 1, 2$ where Q_1 and Q_2 are $K \times K$ permutation matrices. The matched NMI and misclassification rate for the algorithm are 0.98 and 0.30% in this case. If

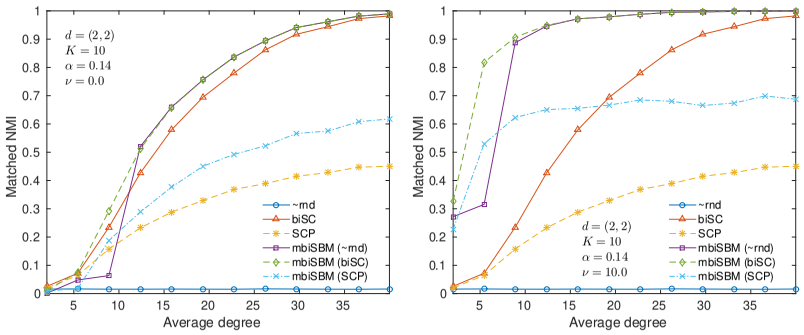

Figure 4: Effect of different initialization methods on mbiSBM with (left) $\nu = 0$ and (right) $\nu = 10$. The case $\nu = 0$ corresponds to no covariate information whereas $\nu > 0$ gives some covariates information.

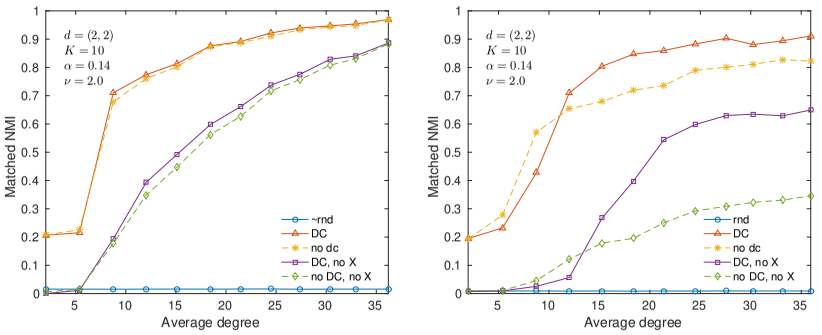
one runs k-means on the concatenated matrix of covariates $[X_1; X_2]$, disregarding the network information, one gets matched NMI and misclassification rate, 0.44 and 38.50%. That is, the covariates themselves are not as informative alone as in combination with the network.



4.4. Average behavior

Figure 4 shows the mathched NMI versus average expected degree λ for various methods. The results are averaged over 50 Monte Carlo replications. Naive (regularized) spectral clustering, denoted as `SCP`, is shown in addition to `biSC` as discussed in Section 3.5.1. Moreover, the plots show our algorithm `mbiSBM`, initialized with both spectral methods and with Dirichlet-perturbed truth ($\rho = 0.1$) denoted as $\sim$`rnd`. The two plots correspond to the case with no covariate information, $\nu = 0$, and the case with covariate information $\nu = 10$. In both cases, covariate dimensions are $d = (2, 2)$, number of communities $K = 10$ and out-in-ratio is $\alpha = 1/7$. There is no degree-correction in the model or `mbiSBM` algorithm.

As can be seen, `biSC` outperforms SCP significantly. Without covariates, `mbiSBM` started with `biSC` slightly improves upon `biSC`; initializing with $\approx 10\%$ truth (`mbiSBM` ($\sim$`rnd`)) has similar performance for sufficiently large λ, showing that `mbiSBM` behaves well with any sufficiently good initialization. Note also that `mbiSBM` initialized with SCP, improves upon SCP for large λ. With covariate information ($\nu = 10$), `mbiSBM` significantly outperforms `biSC` which does not incorporate the covariates.

4.5. Effect of degree correction

Figure 5 investigates the effect of employing degree-correction in the algorithm. In both plots of the figure, we are generating from the same DC-version of the model using within-community Pareto degree distribution with parameter $a = 2$ as described earlier, $d = (2, 2)$, $K = 10$, $\alpha = 1/7$, and $\nu = 2$. The difference between the two plots is how we initialize `mbiSBM` algorithm. The left panel corresponds to "Dirichlet-perturbed truth" initialization ($\rho = 0.1$) denoted as $\sim$`rnd`, whereas the right panel corresponds to completely random initialization, denoted as `rnd`. Four versions of the algorithm are considered, with or without covariate (X) incorporation, and with or without degree-correction (DC).

(a) (b)

Figure 5: Effect of the degree correction steps 6–8 in the algorithm, for a power-law network. Data is generated from DC version of the model (subsection 2.4) with Pareto distribution $p(\theta) \propto \theta^{-3}$, $\theta > 2$ for degree parameters within each community. (Left) shows the results for a good initialization, the Dirichlet perturbed truth, denoted as $\sim$`rnd` (with $\approx 10\%$ true labels) and the (right) shows the results for a completely random initialization, denoted as `rnd`.

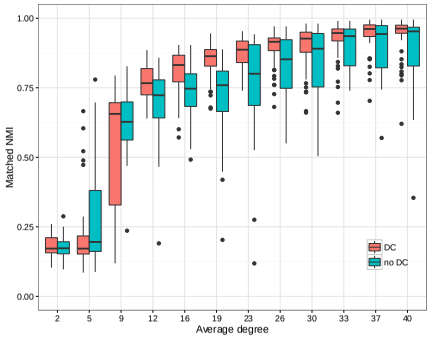


Figure 6: Effect of degree correction steps on variability, for a power-law network.

Surprisingly, as the left panel shows, with sufficiently good initialization ($\sim$`rnd`), degree-correction step of the algorithm provides only a slight improvement. However, the improvement of degree-correction is quite significant when starting from a poor initialization (`rnd`). In general, it is advisable to use the DC version since its solution has less variance. Figure 6, illustrates the algorithm with DC correction and without, in the same setup of the left panel of Figure 5, that is, both cases initialized with $\sim$`rnd` (and both incorporating covariates). Though Figure 5(a) shows that mean behaviors are close, Figure 6 shows that the distributions of the outputs are quite different, with the solution of DC version having less variability. This is expected as the DC version is solving an optimization problem with much restricted feasible region.

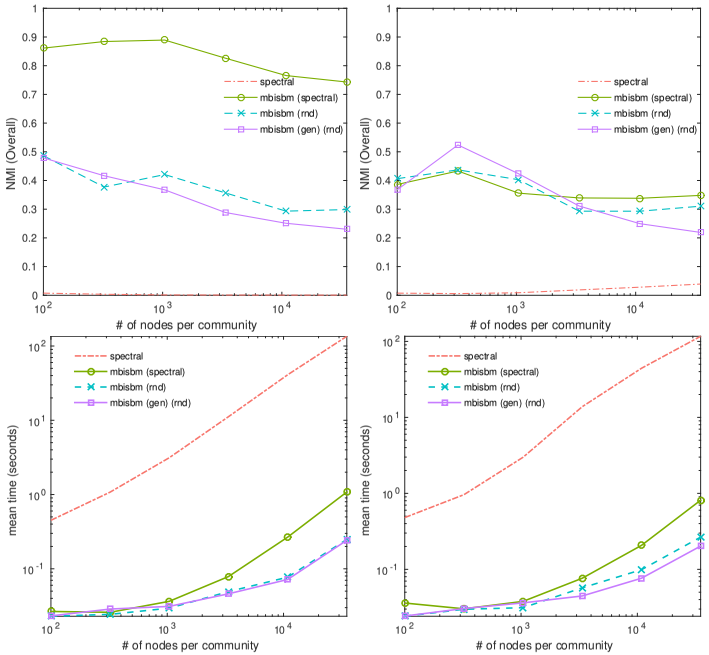

Figure 7: Scaling behavior. Both the average NMI (top) and the mean execution time (time) are shown as a function of the number of clusters per community for three-community ($K = 3$) networks. The two columns show two block models generated according to model (23): (Left) $B_0^{(1)}$ and (Right) $B_0^{(2)}$ as defined in (24).

4.6. Scaling behavior

Figure 7 illustrates how the algorithm scales to large networks compared to the spectral approach. The simulation setup for this figure is as follows: We consider a base connectivity matrix $B_0 \in \mathbb{R}_+^{K\times K}$ and let the edge probability matrix be

$$B = \frac{\log(N_1 N_2)}{\sqrt{N_1 N_2}} B_0, \quad N_1 = n_0 K,\ N_2 = [0.75 n_0 K] \tag{23}$$

where n_0 is the number of nodes per community; that is, we assume that communities of both sides are balanced and each contains n_0 nodes. We then let n_0 vary from 100 to 35000, while $K = 3$ is fixed, to study the large-scale behavior of the network. This simulation setup has recently been considered in Zhou and Amini (2018) and is suitable for studying the semi-sparse asymptotic regime. Note that the average degree of the network will be $\sim \log(n_0)$ as $n_0 \to \infty$ resulting in fairly sparse large networks. We consider two versions of B_0, corresponding to the

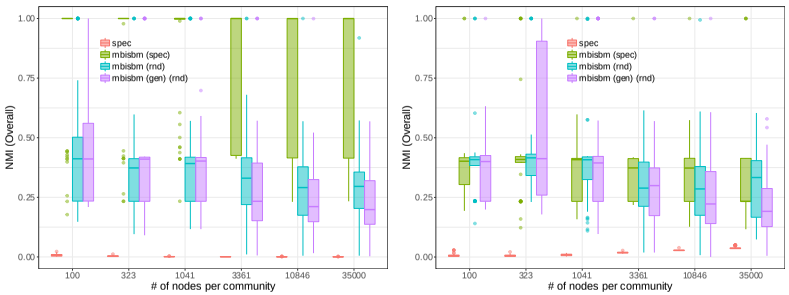

Figure 8: Boxplot of the NMI corresponding to Figure 7.

two columns in Figure 7:

$$B_0^{(1)} = \frac{1}{2}\begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{bmatrix}, \quad B_0^{(2)} = \frac{1}{3}\begin{bmatrix} 1 & 2 & 3 \\ 3 & 2 & 1 \\ 2 & 1 & 3 \end{bmatrix}. \tag{24}$$

Note that $B_0^{(1)}$ gives a planted partition model whereas $B_0^{(2)}$ corresponds to the more general class of SBM given by (4), i.e., it contains both assortative and dissortative relations. We also note that for $B_0^{(2)}$, the within-community connectivities are variable (i.e., $B_0^{(2)}$ has unequal diagonal elements). Both models are quite hard as the so-called out-in-ratio is quite high; in the planted partition case $B_0^{(1)}$, for which the ratio directly characterizes hardness, we have $q/p = 0.5$. The covariates are generated similar to Section 4.4 with $\nu = 10$ and $d = (5, 5)$. The results are averaged over 50 replications.

The hardness of the two problems are reflected in the NMI plots of Figure 7 where the spectral method (`spectral`) is barely above the random assignment. In addition to the spectral method, three versions of `mbiSBM` have been shown: (1) Algorithm 1 with spectral initialization, `mbiSBM (spectral)`, (2) Algorithm 1 with random initialization, `mbiSBM (rnd)`, (3) modification of Algorithm 1 to allow for a general connectivity matrix (Section A.2), with random initialization, `mbiSBM (gen)(rnd)`.

All the three versions perform reasonably and comparably except for the `mbiSBM` with `spectral` initialization which significantly outperforms other versions on the planted partition model $B_0^{(1)}$. It is also worth nothing that the performance of `mbiSBM` with general connectivity matrix is not much better than the planted partition version (i.e., the default Algorithm 1), even on $B_0^{(2)}$ which is far from satisfying the simplifying planted partition assumption. We note that the spectral approach alone performs very poorly in both cases. (We also experimented with moderate perturbations for the spectral approach which did not result in noticeable improvement.) Figure 8 shows the box plots corresponding to the NMI plots in Figure 7, illustrating the variability of the results. It is worth noting that for planted partition model, `mbiSBM (spectral)` achieves a NMI of 1 for most replications.

The bottom row in Figure 7 illustrates the average run time of the algorithms. For `mbiSBM (spectral)` only the overhead relative the spectral initialization is considered. It is clear the family of `mbiSBM` algorithms are about an order of magnitude faster than the

`spectral` approach. We conclude that when the signal is high, `mbiSBM` with random initialization is outperforms in both speed and accuracy. When the signal is low, we can initialize with the spectral approach and then boost the performance by computationally cheap `mbiSBM` iterations.

5. Application to Real Data

5.1. Wikipedia networks

We have applied the algorithm to two wikipedia page–user networks, which we will call TopArticles and Cities. Each is a bipartite network between a collection of Wikipedia pages and the users who edited them: An edge is placed between a user and a page if the user has edited that page (at least once). In the TopArticles, the pages are selected from the top articles (based on monthly contributions) from Chinese (CN), Korean (KR) and Japanese (JP) language Wikipedia, corresponding to the period from January to October 2016. In the Cities network, the pages correspond to city names in English language Wikipedia; the cities were chosen from five countries: Unites States (US), United Kingdom (GB), Australia (AU), India (IN), Japan (JP). In both cases, on the user side, only those with IP addresses were retained. Although, not perfect, IP addresses were the only means by which we could obtain additional information about each user, esp. geo-location data. Wikipedia usage statistics were scraped from Wikimedia Statistics using code inspired by Keegan (2014). For geo-data we used both the `ggmap` R package by Kahle and Wickham (2013) and the API provided by ipapi.

In TopArticles, the true labels are the language assigned to each page and each user, that is, matched communities are specified by common language. The user language was assigned based on the dominant language of the country from which the IP address originates. In Cities network, the true labels are the country names assigned to each user based on user's IP address and assigned to each city page based on its geo-location tag. The IPs were also used to obtain latitude and longitude coordinates on each user, providing us with user covariate matrix $X_2 \in \mathbb{R}^{N_2 \times 2}$,

For TopArticles, we do not have any page covariate. For Cities, we use the geo-location data of the city (latitude and longitude) to give us the page covariate matrix $X_1 \in \mathbb{R}^{N_1 \times 2}$.

Figure 9 shows the two networks along with the true communities. Note that Cities is specially hard to cluster based only on network data due to the presence of nodes of different communities among each community (as positioned by the layout algorithm). Tables 1 and 2 show the break-down of pages/users based on community for the two networks. Also shown are the average degrees of each side of the network, as well as the overall average degree. For each of the two networks, we first obtained a 2-core, restricted to the giant component, then removed users from countries not under consideration. (If the last step created disjoint components we restricted again to the giant component. This only happened for Cities and only removed 5 nodes.)

Results on Wikipedia networks. Table 3 illustrates the result of the application of `biSC`, and the `mbiSBM` (`biSC`) algorithm with various combination of covariates. In all cases the degree-corrected (DC) version of `mbiSBM` is used. For TopArticles, without using covariates, there is no improvement on `biSC` while using X_2 gives significant boost to `mbiSBM`. For Cities, `biSC` outperforms `mbiSBM` with no covariates. One the other hand, adding X_2 or both X_1 and X_2 significantly improves the result of `mbiSBM`.

	CN	JP	KR	Total	Avg. deg.	Covariates

Users	579	695	828	2102	3.1	X_2 = user (lat.,lon.)
Total	718	838	999	2555	5	

Table 1: TopArticles page–user network

	US	IN	AU	JP	GB	Total	Avg. deg.	Covariates
Pages	267	235	182	113	59	856	10.2	X_1 = city (lat.,lon.)
Users	1054	1029	705	101	201	3090	2.8	X_2 = user (lat.,lon.)
Total	1321	1264	887	214	260	3946	4.4	

Table 2: Cities page–user network

To get a more refined understanding of the relative standing of `biSC` and `mbiSBM` (`biSC`), we have run two Monte Carlo analyses based on these real networks, one using *subsampling* and the other by adding Erdös–Rényi noise. Figure 10 shows the results when we subsample the network to retain a fraction of the nodes on each side (from 95% down to 10%). The x-axis shows the resulting overall average degree of the network at each subsampling level. The results are averaged over 50 replications and the interquartile range (IQR) is also shown as a measure of variability. The figures in Table 3 correspond to the rightmost point of these plots. (Average degrees of Cities vary in these ranges: overall $\in [0.4, 4.2]$, page $\in [1, 9.7]$ and user $\in [0.3, 2.7]$, whereas for TopArticles the ranges are: overall $\in [0.6, 4.9]$, page $\in [1.6, 13.8]$ and user $\in [0.3, 3]$.)

The plots show that `mbiSBM` (`biSC`) with covariates outperforms `biSC`, and the improvement is quite significant the sparser the network becomes. Note for example that in Cities adding X_1 does not have much effect in the original network, however, there is a considerable improvement when average degree starts to drop under subsampling. In the Cities case, the two covariates X_1 and X_2 together are quite strong leading to an NMI ≈ 1 and masking the effect of the network to some extent.

However, by looking at cases where only one of X_1 and X_2 is present, we observe that `mbiSBM` (`biSC`) manges to pass the covariate information via the network to the side without covariates, thus improving matched NMI significantly. To see this, consider for example the TopArticles, where only X_2 is present. In this case, even if a method could cluster X_2 perfectly and, in the absence of network information randomly guessed the labels of the other side, the NMI would be 0.42. That in Figure 10(b), the NMI starts at 0.98 and remains much

Network	`biSC`	`mbiSBM` (`biSC`), DC			
		X_1 & X_2	X_1	X_2	no X
TopArticles	0.86	-	-	0.98	0.86
Cities	0.6	1.0	0.59	0.85	0.47

Table 3: Matched NMI for `biSC` and `mbiSBM` on the two Wikipedia networks.

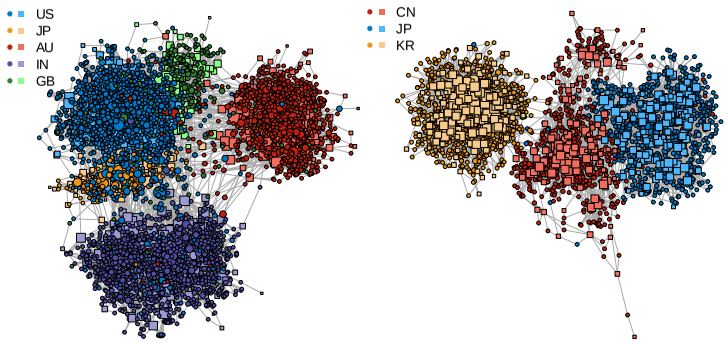

Figure 9: The two Wikipedia networks: (left) Cities (right) TopArticles. Nodes are colored according to true communities. Pages are denoted with squares and users with circles. Node sizes are proportional to log-degrees.

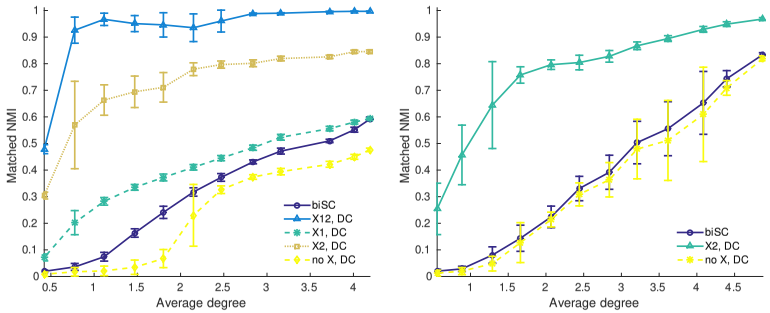

Figure 10: Effect of subsampling on Wikipedia networks: (left) Cities (right) TopArticles.

above 0.42 for most of the range of subsampling illustrates the ability of `mbiSBM` to effectively utilize both covariate and network information to correctly infer the labels of the other side. The same can be observed in the case of Cities. Finally, we note that without covariates, `biSC` usually performs better. We expect this since it is hard for local methods starting from `biSC` to improve upon it. The strength comes when we use the covariate information.

Figure 11 shows another experiment where we added Erdös–Rényi noise of average degree from 0 to 10. Again, the advantage gained by `mbiSBM` from using covariates can be quite clearly observed when one increases the noise. The covariates mitigate the effect of noise and lead to a much graceful degradation of performance for `mbiSBM` relative to `biSC`.

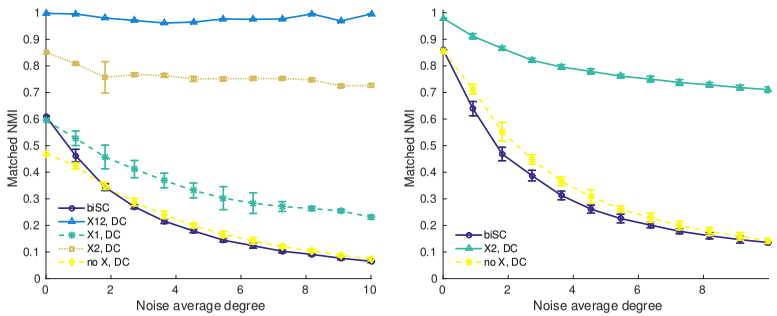

Figure 11: Effect of adding Erdös–Rényi noise on Wikipedia networks: (left) Cities (right) TopArticles.

5.2. Author-Paper networks

In this subsection, we use real data examples to showcase the performance of our algorithm when the the network is large, has high dimensional covariates and under model misspecification, that is, when the covariates are discrete.

We have applied the algorithm to two sets of author-paper networks. The first set represents papers and their authors in different sub-domains of computer science (CS): (1) data mining, (2) medical informatics, (3) visualization , (4) database, and (5) theory. The data for the first set was extracted from the Arnetminer collection, based on papers published from 1990 to 2005 in certain CS venues by Tang et al. (2012). The second set of data was scraped from DBLP, using the papers published in bioinformatics (BI), biomedical/medical informatics (BM) and computational neuroscience (CN) venues from 1995 to 2018. Each set contains various subnetworks of the two basic bipartite network described above.

In both sets, we first consider the paper-author bipartite networks with covariates being high-dimensional vectors of word frequencies appearing in the title of the papers. To deal with the binary nature of the covariates, we take their z-scores. Although the Gaussian assumption about these transformed covariates does not hold, we have found that such transformation allows us to apply our model to discrete covariates with minimal modification and with good empirical performance as discussed below. A more principled approach to dealing with discrete covariates would be to model them using a multinomial likelihood (cf. Section 6). The process of building the network and extracting the covariates is done by restricting to the giant component of the author-paper network such that each paper is associated with at least one word after removing sparse words. For the second set, we also removed some non-informative words to slightly boost the covariate signals.

These datasets have an interesting feature: They can be viewed as tri-partite author-paper-word networks. Thus, although not intuitive, we can also view the paper-word frequency matrix as a bipartite network and use the (binary) author vectors as covariates for the papers. Taking z-scores again bring these binary covariates within our framework.

For these datasets, the ground truth labels are only available for the papers: we treat their venues (i.e., their main topic) as the true community of the paper. As a result, we can only find the NMI for the paper labels. Note that assuming a matching between authors and

	Dimensions			Avg. deg.	
	authors	papers	words	authors	papers
CS12345	5126	8500	1089	4.75	2.87
BM-BI-CN	10561	8482	1649	3.4	4.23

Table 4: Statistics on the author–paper networks with words as covariates

Table 5: NMI for `biSC` and `mbiSBM` on the Author-Paper networks.

papers is reasonable as most authors have a theme; similarly a matching between words and papers is plausible, as previously has been considered in the text mining applications by Dhillon (2001). Table 4 shows the break-down of authors/papers/words for CS12345 and BM-BI-CN networks. Also shown are the average degrees of each side of the networks.

CS12345 refers to the the dataset including all the five topics. CS2345 refers to the dataset excluding the first topic (data mining), and so on. Note that CS2345, for instance, is not necessarily an induced subnetwork of CS12345 as we take the giant component each time to make the networks for each set of topics.

Results on paper-author-word networks. Tables 5 and 6 illustrate the results for various algorithms. The first column from the left is the NMI obtained by applying k-means on the truncated SVD of the covariates (X_2 column); this approach captures the covariate-only information. The next three columns show the result for the application of `biSC` with various levels of perturbation α. Here, we are adding the constant perturbation $\alpha(N_1N_2)^{-1/2}$ to every entry of the adjacency matrix before forming the Laplacian. This is similar to the approach of Amini et al. (2013) for unipartite setups and is known to have a regularization effect on the spectral clustering, especially for sparse networks. Note that the case $\alpha = 0$ corresponds to the unregularized version as shown in Algorithm 2.

The remaining columns show the performance of `mbiSBM` initialized with each of `biSC` results, collected under `mbiSBM (biSC)` columns, as well as `mbiSBM` initialized at random, where both the mean and the maximum achieved on 25 random initializations is recorded, under `mbiSBM (rnd)` columns.

The results show that `mbiSBM` outperforms covariate-only clustering in all cases and outperforms `biSC` in 12 out of 14 datasets, indicating that utilizing covariates as well as network structure can boost the signals compared to using each source of the information alone. It is

Network	X_2	`biSC`			`mbiSBM (biSC)`			`mbiSBM (rnd)`	
		$\alpha=0$	$\alpha=1$	$\alpha=10$	$\alpha=0$	$\alpha=1$	$\alpha=10$	mean	max
CS12345	0.00	0.26	0.26	0.24	0.43	**0.45**	0.45	0.03	0.11
CS2345	0.00	0.27	0.28	0.28	0.52	0.52	**0.54**	0.02	0.20
CS345	0.00	0.24	0.39	0.37	0.74	0.74	**0.76**	0.02	0.29

Table 6: NMI for `biSC` and `mbiSBM` on the Word-Paper networks.

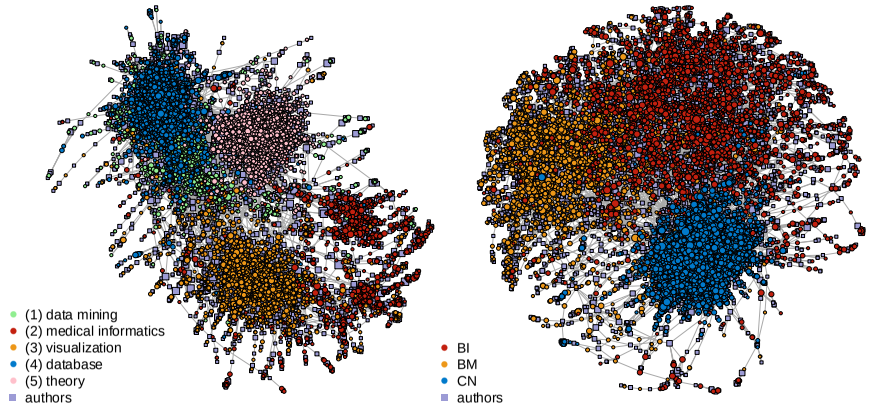

Figure 12: The two paper-author networks: (left) CS12345 (right) BM-BI-CN. Nodes corresponding to the papers are colored according to their true communities. The authors are denoted with squares and the papers with circles. Node sizes are proportional to log-degrees.

also worth noting that perturbation often boosts the performance of `biSC`, but not always. In cases where a version of `biSC` works well, `mbiSBM` often boosts the results; this is especially pronounced for the word-paper networks. Overall random initialization of `mbiSBM` performs respectably and surprisingly in some outperforms `biSC` and `biSC`-initialized `mbiSBM`.

6. Discussion

In this paper, we considered the problem of matched community detection in the bipartite setting, where one assumes a latent one-to-one correspondence between communities of the two sides. This matching is built into the model and inferred simultaneously with the communities in the process of fitting the model. Our model is an extension of the stochastic block model (SBM) and its degree-corrected version (DC-SBM). We extended our proposed model

to allow for the presence of node covariates that are aware of the matching between communities: Covariates corresponding to nodes in matched communities are statistically linked using hierarchical Bayesian modeling ideas.

Although we only considered Gaussian distributions in generating covariates, our hierarchical mixture approach has the potential for extension to more general settings. For example, one can easily model discrete covariates, such as word counts in documents, as mixtures of multinomial distributions. Some care however is needed when deciding the distribution of the top layer if one wants to allow for information sharing among the lower level variables (i.e., v_{rk}) from the two sides. In addition, as mentioned (cf. Section 2.5), our current statistical linkage carries weak information about the matching and it would be interesting to design models in which the degree of covariate information about the matching can be tuned more effectively.

Our model has natural extensions to r-partite ($r > 2$) networks where some of the modes may or may not have node covariates. We note that the general r-partite case is related to the so-called multilayer or multiplex community detection problem (Kivela et al., 2014). Finally, one would like to allow for edge covariates to accommodate many cases in real data, where edges are annotated in some way, say by the ratings as in recommender systems, by time-stamps as in our Wikipedia user-page examples, and so on. Poisson model of edge generation can, to some extent, take simple edge weights into account. Whether one can go beyond that in modeling more complex edge information is an interesting avenue for future work.

Acknowledgment

We would like to thank the referees and Associate Editor for their helpful comments that improved this paper and Nan Deng for helpful discussions. This work used computational and storage services associated with the Hoffman2 Shared Cluster provided by UCLA Institute for Digital Research and Education's Research Technology Group.

Appendix A. Extensions and improvements

A.1. Speed improvement and diagonal restriction

A.1.1. Improving the Speed

For $r = 1, 2$, we treat each $(\tau_{rik})_{ik}$ as a matrix $\tau_r \in [0,1]^{N_r \times K}$. The τ-update in (17) can be simplified to improve computational complexity for sparse networks A. We can write $h(p, q; \alpha) = \alpha\phi_1 + \phi_0$, where for the binary likelihood, $\phi_1 = \log \frac{p(1-q)}{q(1-p)}$ and $\phi_0 = \log \frac{1-p}{1-q}$, and for the Poisson likelihood considered in Section A.3 below, $\phi_0 = q - p$ and $\phi_1 = \log(p/q)$. Then, in matrix notation

$$\tau_{1ik} \ \propto_k \ \pi_{1k} \exp\Big(\phi_1 [A\tau_2]_{ik} + \phi_0 \bar{\tau}_{2k} + \beta_{1ik}(\widetilde{\Gamma}, \sigma^2)\Big) \quad i = 1, \dots, N_1$$

where $[A\tau_2]_{ik} = \sum_j \tau_{2jk} A_{ij}$ and we recall $\bar{\tau}_{2k} := \sum_{i=1}^{N_2} \tau_{2ik}$. When A is sparse, the matrix-vector product $A\tau_2$ can be computed quite fast. Letting $\beta_r = (\beta_{rik})_{ik} \in \mathbb{R}^{N_r \times K}$, we have the τ-update in vector form:

$$\tau_1 = \texttt{row-softmax}\big[\phi_1 A\tau_2 + \phi_0 \mathbf{1}_{N_1} (\bar{\tau}_2 + \log \pi_1)^T + \beta_1\big] \tag{25}$$

and similarly for τ_2. Here, `row-softmax` is the row-wise softmax operator, applying (16) to each row of a matrix.

Further improvements are possible in estimating p and q. Note that we can write $\bar{\tau}_{rk} := [\tau_r^T \mathbf{1}_{N_r}]_k$. Let us treat $\bar{\tau}_r$ as a K-vector, with elements $\bar{\tau}_{rk}$. Then, we have $\sum_{ij} \gamma_{ij}(\tau) A_{ij} = \mathrm{tr}(\tau_1^T A \tau_2)$ and $\sum_{ij} \gamma_{ij}(\tau) = \langle \bar{\tau}_1, \bar{\tau}_2 \rangle$, and

$$p = \frac{\mathrm{tr}(\tau_1^T A \tau_2)}{\langle \bar{\tau}_1, \bar{\tau}_2 \rangle}, \quad q = \frac{\delta\rho - p}{\delta - 1}, \quad \text{where } \frac{1}{\delta} = \langle \frac{\bar{\tau}_1}{N_1}, \frac{\bar{\tau}_2}{N_2} \rangle \text{ and } \rho = \frac{1}{N_1 N_2} \sum_{ij} A_{ij}. \tag{26}$$

Note that ρ is the density of the graph (or A) and that $\langle \bar{\tau}_1, \bar{\tau}_2 \rangle = \mathrm{tr}(\tau_1^T E \tau_2)$ where E is the all-ones matrix of appropriate dimension. Finally, let us define $\beta'_{rik} = \mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right) + \|x_{ri} - \widetilde{\mu}_{rk}\|^2$ noting that $\beta_{rik} = \frac{1}{2\sigma_r^2} \beta'_{rik}$ from definition (13). Letting $\beta'_r = (\beta'_{rik})_{ik}$ be its matrix form, we can write the update for σ_r^2 compactly as

$$\sigma_r^2 = \frac{1}{N_r d_r} \sum_{ik} \tau_{rik} \beta'_{rik} = \frac{1}{N_r d_r} \mathrm{tr}(\tau_r^T \beta'_r). \tag{27}$$

A.1.2. Diagonal covariance restriction

For ultra high-dimensional covariates, one can restrict the covariance matrix Σ to be diagonal, which greatly improves the speed of the algorithm. This choice is also reasonable from a statistical perspective since in high-dimensions, without additional restrictions (such as sparsity), estimates of a full-dimensional covariance matrix are unreliable. Under the diagonal restriction, one only needs to make a minor modification to the algorithm: Recalling the variational likelihood $J(\Sigma) \doteq -\frac{K}{2}\big[\log|\Sigma| + \mathrm{tr}(\Sigma^{-1} S(\widetilde{\Gamma}))\big]$, the maximizer over Σ under the diagonal constraint is $\Sigma_{ii} = [S(\widetilde{\Gamma}))]_{ii}$ and $\Sigma_{ij} = 0$ for $i \neq j$, or compactly

$$\Sigma = \mathrm{ddiag}(S(\widetilde{\Gamma})),$$

where $A \mapsto \mathrm{ddiag}(A)$ is an operator that take a square matrix A and outputs a diagonal matrix with the same diagonal as A. We note that the update for $\widetilde{\Sigma}_k$ goes as before: $\widetilde{\Sigma}_k = (D_k^{-1} + \Sigma^{-1})^{-1}$ for $k \in [K]$. Since both D and Σ are diagonal, $\widetilde{\Sigma}_k$ will be diagonal as well. Thus, all the covariance matrices throughout the algorithm will remain diagonal which improves the speed and scalability.

A.2. Extension to general SBM

Let us now briefly discuss the changes needed for fitting the general SBM model (4). We only consider the case with no degree correction. Let us derive the label updates first. Using the general form of the network likelihood (8), the variational likelihood in (15) is replaced with

$$J = \sum_i \sum_k \tau_{1ik} \Big(\sum_j \sum_\ell \tau_{2j\ell}\, g(\Psi_{k\ell}, A_{ij}) + \xi_{1ik} - \log \tau_{1ik} \Big) + \text{const.} \tag{28}$$

which by the same argument used for (17), gives the following τ_{1ik} update

$$\tau_{1ik} \ \propto_k \ \pi_{1k} \exp\Big[\sum_j \sum_\ell \tau_{2j\ell}\, g(\Psi_{k\ell}, A_{ij}) + \beta_{1ik}(\widetilde{\Gamma}, \sigma^2) \Big] \quad i = 1, \dots, N_1. \tag{29}$$

The update for τ_2 follows similarly. The only other modification to the algorithm is the update for the edge probabilities Ψ, replacing the (p, q) updates. For Ψ updates, we need to maximize

$$\mathbb{E}_q[\ell_1(\Psi)] = \sum_{ij}\sum_{k\ell} \tau_{1ik}\tau_{2j\ell}\; g(\Psi_{k\ell}, A_{ij})$$

over Ψ. Assume that $g(p, \alpha) = \alpha\phi_1(p) + \phi_0(p)$. For any fixed (k, ℓ), we need to maximize

$$\Big(\sum_{ij} \tau_{1ik}\tau_{2j\ell}A_{ij}\Big)\phi_1(\Psi_{k\ell}) + \bar\tau_{1k}\bar\tau_{2\ell}\,\phi_0(\Psi_{k\ell})$$

where we have used $\bar\tau_{rk} := \sum_i \tau_{rik}$. The problem reduces to maximizing $p \mapsto a\phi_1(p) + b\phi_0(p)$ for some positive $a, b \in \mathbb{R}$. It is not hard to see that the maximizer is the same for both the Bernoulli likelihood ($\phi_1(p) = \log[p/(1-p)]$, $\phi_0 p) = \log(1-p)$) and the Poisson ($\phi_1(p) = \log p$, $\phi_0(p) = -p$), and is equal to $p^* = a/b$. This give the following Ψ-update

$$\Psi_{k\ell} = \frac{1}{\bar\tau_{1k}\bar\tau_{2\ell}}\sum_{ij} \tau_{1ik}\tau_{2j\ell}A_{ij}. \tag{30}$$

Speeding up the updates. Using the notation introduced for g, we have

$$\sum_j\sum_\ell \tau_{2j\ell}\, g(\Psi_{k\ell}, A_{ij}) = \sum_\ell \Big(\sum_j \tau_{2j\ell}A_{ij}\Big)\phi_1(\Psi_{k\ell}) + \sum_\ell \bar\tau_{2\ell}\,\phi_0(\Psi_{k\ell}).$$

Let $\Phi_1, \Phi_0 \in \mathbb{R}^{K\times K}$ be matrices with entries $[\Phi_s]_{k\ell} = \phi_s(\Psi_{k\ell})$ for $s = 0, 1$. Then, τ_1 update is

$$\tau_{1ik} \;\propto_k\; \pi_{1k}\exp\Big([A\tau_2\Phi_1^T]_{ik} + [\Phi_0\bar\tau_2]_k + \beta_{1ik}(\widetilde\Gamma, \sigma^2)\Big) \quad i = 1, \dots, N_1$$

or in matrix form (similar to (25))

$$\tau_1 = \texttt{row-softmax}\big(A\tau_2\Phi_1^T + \mathbf{1}_{N_1}[\Phi_0\bar\tau_2 + \log\pi_1]^T + \beta_1\big). \tag{31}$$

Here $\bar\tau_2 = (\bar\tau_{2\ell}) \in \mathbb{R}^K$ is viewed as a column vector.

A.3. Extension to the Degree-Corrected Case

In this case the network-dependent part of the likelihood is replaced with

$$\ell_1(\Psi, \theta) = \sum_{ij}\sum_{k\ell} z_{1ik}z_{2j\ell}\; g(\theta_{1i}\theta_{2j}\Psi_{k\ell}, A_{ij}).$$

Again, we focus on the case where $\Psi_{kk} = p$ and $\Psi_{k\ell} = q$ for $k \neq \ell$. Recalling the notation $h(p, q, \alpha) = g(p, \alpha) - g(q, \alpha)$, we have

$$\ell_1(\Psi, \theta) = \sum_{ij}\big[y_{ij}\, h\big(p\theta_{1i}\theta_{2j},\, q\theta_{1i}\theta_{2j},\, A_{ij}\big) + g\big(\theta_{1i}\theta_{2j}q, A_{ij}\big)\big]. \tag{32}$$

We assume a Poisson log-likelihood with $g(p, \alpha) = \alpha\log p - p$ for which $h(p, q, \alpha) = \alpha\log(p/q) + q - p$. We also recall the normalization assumption (7), $\sum_i \theta_{ri}z_{rik} = \sum_i z_{rik}$, which implies

$\sum_{ij} y_{ij}\theta_{1i}\theta_{2j} = \sum_{ij} y_{ij}$ and $\sum_{ij}\theta_{1i}\theta_{2j} = N_1N_2$. Using these two implications, the first term in (32) simplifies to

$$\sum_{ij} y_{ij}\big[(q-p)\theta_{1i}\theta_{2j} + A_{ij}\log(p/q)\big] + \sum_{ij}\big[-\theta_{1i}\theta_{2j}q + A_{ij}\log(\theta_{1i}\theta_{2j}q)\big]$$
$$= \sum_{ij} y_{ij}\big[(q-p) + A_{ij}\log(p/q)\big] - qN_1N_2 + \sum_{ij} A_{ij}\log(\theta_{1i}\theta_{2j}q)$$

Let $\phi_0 = q - p$ and $\phi_1 = \log(p/q)$.

τ-update. Let us fix θ and obtain updates for the label posteriors τ. Taking expectations of the objective and the constraints, the τ-portion of the update is equivalent to maximizing

$$\sum_{ij}\gamma_{ij}(\tau)\big[\phi_0 + A_{ij}\phi_1\big] + \sum_{rik}\tau_{rik}\big[\beta_{rik}(\widetilde\Gamma, \sigma^2) + \log\frac{\pi_{rk}}{\tau_{rik}}\big]$$

subject to constraints $\sum_i \tau_{rik}(\theta_{ri} - 1) = 0$ for all k. Note that these constraints follow by taking expectations of the normalization constraints (7) under $Z \sim q$. Focusing on updating τ_{1k}, we have the following optimization problem:

$$\begin{array}{ll} \max\limits_{\tau_1} & \sum_{i,k}\tau_{1ik}\big(\sum_j \tau_{2jk}\big[\phi_0 + A_{ij}\phi_1\big] + \xi_{1ik} - \log\tau_{1ik}\big) \\ \text{subject to} & \sum_i \tau_{1ik}(\theta_{1i} - 1) = 0, \quad \sum_k \tau_{1ik} = 1, \quad \tau_{1ik} \geq 0 \end{array} \tag{33}$$

where $\xi_{1ik} = \beta_{1ik} + \log\pi_{1k}$ as before. In Appendix C.1, we derive a dual ascent algorithm for solving this problem with the following updates:

$$\begin{aligned} \tau_1(\lambda) &= \texttt{row-softmax}\big[\phi_1 A\tau_2 + \phi_0\mathbf{1}_{N_1}(\bar\tau_2 + \log\pi_1)^T + \beta_1 + (\theta_1 - \mathbf{1})\lambda^T\big], \\ \lambda^+ &= \lambda - \mu[\tau_1(\lambda)]^T(\theta_1 - \mathbf{1}). \end{aligned} \tag{34}$$

Here, $\lambda \in \mathbb{R}^K$ is the dual variable, λ^+ is its update, $\theta_1 = (\theta_{1i}) \in \mathbb{R}^n$, and μ is a proper step-size. These two iterations are repeated till convergence, before updating other parameters. Note that when $\theta_1 = \mathbf{1}$, the dual ascent algorithm reduces to the single step of (25) obtained for the case without degree correction.

θ-update. Let us now fix τ and the rest of the parameters and optimize over θ. The relevant portion of the objective function is

$$\sum_{ij}\gamma_{ij}(\tau)\big[q - p + A_{ij}\log(p/q)\big] - qN_1N_2 + \sum_{ij} A_{ij}\log(\theta_{1i}\theta_{2j}q).$$

Consider optimizing over (θ_{1i}), which is equivalent to maximizing $\sum_i d_{1i}\log\theta_{1i}$, subject to $\sum_i \tau_{1ik}(\theta_{1i} - 1) = 0$ for all k, and $\theta_{1i} \geq 0$ for all i. This problem is suitable for an application of the Douglas–Rachford (DR) splitting algorithm (Douglas and Rachford, 1956; O'Connor and Vandenberghe, 2014). Let $f_t(\cdot; d) : \mathbb{R}^n_+ \to \mathbb{R}^n_+$ with $d \in \mathbb{R}^n_+$ and $t > 0$, be defined by

$$[f_t(x; d)]_i := \frac{1}{2}\big[x_i + \sqrt{x_i^2 + 4td_i}\big]. \tag{35}$$

Also, let $H_1 := \tau_1(\tau_1^T\tau_1)^{-1}\tau_1^T$ be the projection operator onto the span of $\tau_1 \in \mathbb{R}^{N_1\times K}$. The algorithm performs the following iterations for updating (ξ_1, θ_1) to (ξ_1^+, θ_1^+):

$$\begin{aligned}\theta_1^+ &= f_t(\xi_1; d_1)\\ \xi_1^+ &= \theta_1^+ - H_1(2\theta_1^+ - \xi_1 - \mathbf{1})\end{aligned} \tag{36}$$

where $\xi_1 \in \mathbb{R}^{N_1}$ is an auxiliary variable, $d_1 = (d_{1i}) \in \mathbb{R}^{N_1}$ collects the degrees of side 1, and $t > 0$ is the fixed parameter of DR algorithm (often set to 1). The details for the derivation of this algorithm can be found in Appendix C.2. The same updates apply to θ_2, replacing subscript 1 with 2.

Remark 3. Note that if $\tau_1 = (\tau_{1ik})$ was a hard label assignment, then the optimization for (θ_{1i}) would have a simple solution. To see this, let $C_k(\tau_1)$ be the kth cluster of hard label τ_1. Then, the optimal value of θ_1 is given by

$$\theta_{1i} = \frac{d_{1i}}{\sum_{i'\in C_k(\tau_1)} d_{1i'}}, \quad \text{for } i \in C_{1k}(\tau_1).$$

This is in fact, the choice in profile-likelihood approaches to fitting DC-SBM, where one replaced θ_1 with this optimal value, in addition to optimal values of edge probabilities and class priors, all in terms of $\{C_{1k}(\tau_1)\}$, and then optimize the resulting profile likelihood over $\{C_{1k}(\tau_1)\}$. See for example (Karrer and Newman, 2011). Our approach here, allows us to keep a soft-label assignment τ_1 throughout the algorithm, viewing optimization over θ_1 as another phase of block-coordinate ascent for the overall constrained optimization problem.

(p, q)-update. To optimize over p and q we note that because of the Poisson model, p and q are not tied together and the only constraint we have is $p, q \geq 0$. Optimizing over p is equivalent to maximizing $-p\sum_{ij}\gamma_{ij} + \log p\sum_{ij}\gamma_{ij}A_{ij}$ and optimizing over q, is equivalent to maximizing over $-q\sum_{ij}(1-\gamma_{ij}) + \log q\sum_{ij}(1-\gamma_{ij})A_{ij}$, both giving the same updates as those in (21).

Appendix B. Details of Section 3

B.1. Proof of Lemma 1

We have $f_a(p) = -\sum_k p_k \log(p_k/e^{a_k})$. If $\sum_k e^{a_k} = 1$, then $-f_a(p)$ is the KL-divergence between (p_k) and (e^{a_k}) and the result follows. Otherwise, normalizing only adds a constant to f_a, that is, with $C = 1/\sum_k e^{a_k}$ and $q_k = Ce^{a_k}$, we have $f_a(p) = -\sum_k p_k \log(p_k/q_k) - \log C$ and the result follows.

B.2. Derivation of (12)

We write $\mathbb{E}_q$ for expectation w.r.t. the above joint distribution on (Z, V). Similarly, we write $\mathbb{E}_{q_Z}$ and $\mathbb{E}_{q_V}$ for the expectation (or integration) w.r.t. to each of q_Z and q_V. Note that $\mathbb{E}_q[\cdot] = \mathbb{E}_{q_V}\mathbb{E}_{q_Z}[\cdot]$. Plugging in the variational distribution (11) into the variational likelihood (10). we have

$$J = \mathbb{E}_q\Big[\ell(\mu, \Sigma, \sigma, Q)] - \log q(Z, V)\Big] = T_1 + T_2 + T_3 - T_4 - T_5$$

where

$$T_1 = \mathbb{E}_{q_Z}\Big[\sum_{i,j}\psi(A_{ij}, y_{ij})\Big], \quad T_2 = \mathbb{E}_{q_V}\mathbb{E}_{q_Z}\Big[\sum_{r,i,k} z_{rik}\big[\log f_r(x_{ri}; v_{rk}) + \log\pi_{rk}\big]\Big]$$
$$T_3 = \mathbb{E}_{q_V}\Big[\sum_k \log p(v_{*k}|\mu, \Sigma)\Big], \quad T_4 = \mathbb{E}_{q_Z}\log q(Z), \quad T_5 = \mathbb{E}_{q_V}\log q(V)$$

Let $\gamma_{ij}(\tau) := \mathbb{E}_{q_Z}(y_{ij}) = \sum_{k=1}^K \tau_{1ik}\tau_{2jk}$, so that

$$T_1 = \sum_{i,j}\Big[\gamma_{ij}(\tau)\log(p^{A_{ij}}(1-p)^{1-A_{ij}}) + (1-\gamma_{ij}(\tau))\log(q^{A_{ij}}(1-q)^{1-A_{ij}})\Big] \tag{37}$$

We frequently use the following elementary result in the sequel. Let $x \mapsto N(x; \mu, \Sigma)$ be the PDF of the multivariate normal distribution with mean μ and covariance Σ.

Lemma 2. *Let ε be a random vector with mean $\widetilde{\mu}$ and covariance $\widetilde{\Sigma}$, and x a nonrandom vector. Then,*

$$\mathbb{E}[\varepsilon^T\Lambda\varepsilon] = \mathrm{tr}[\Lambda\widetilde{\Sigma}] + \widetilde{\mu}^T\Lambda\widetilde{\mu}, \tag{38}$$
$$\begin{aligned}\mathbb{E}[\log N(x; \varepsilon, \Sigma)] = \mathbb{E}[\log N(\varepsilon; x, \Sigma)] &= -\frac{1}{2}\Big\{\log|\Sigma| + (x-\widetilde{\mu})^T\Sigma^{-1}(x-\widetilde{\mu}) + \mathrm{tr}(\Sigma^{-1}\widetilde{\Sigma})\Big\}\\ &= -\frac{1}{2}\Big\{\log|\Sigma| + \mathrm{tr}(\Sigma^{-1}\Psi)\Big\},\end{aligned} \tag{39}$$

where $\Psi = \widetilde{\Sigma} + (x-\widetilde{\mu})(x-\widetilde{\mu})^T$.

Proof Let us prove (39). We have $\log N(x; \varepsilon, \Sigma) = -\frac{1}{2}\log|\Sigma| - \frac{1}{2}(x-\varepsilon)^T\Sigma^{-1}(x-\varepsilon)$. Noting that $x - \varepsilon$ has mean $x - \widetilde{\mu}$ and covariance $\widetilde{\Sigma}$ and applying (38) gives the desired result. ■

Recall that $f_r(x_{ri}; v_{rk}) = N(x_{ri}; v_{rk}, \sigma_r^2 I_{d_r})$, and note that under q_V, v_{rk} has mean $\widetilde{\mu}_{rk}$ and covariance $(\widetilde{\Sigma}_k)_{rr}$. Note that we are partitioning $\widetilde{\Sigma}_k$ into four blocks of sizes $\{d_1, d_2\}\times\{d_1, d_2\}$ and $(\widetilde{\Sigma}_k)_{rr}, r = 1, 2$ correspond to the two diagonal blocks in this partition. Using Lemma 2, we have

$$\begin{aligned}T_2 &= \mathbb{E}_{q_V}\Big\{\sum_{r,i,k}\tau_{rik}\big[\log N(x_{ri}; v_{rk}, \sigma_r^2 I_{d_r}) + \log\pi_{rk}\big]\Big\}\\ &= \sum_{r,i,k}\tau_{rik}\big[-\frac{d_r}{2}\log\sigma_r^2 - \frac{\mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right) + \|x_{ri} - \widetilde{\mu}_{rk}\|^2}{2\sigma_r^2} + \log\pi_{rk}\big].\end{aligned}$$

Recall that $\widetilde{\Gamma} := ((\widetilde{\Sigma}_k, \widetilde{\mu}_k), k = 1, \ldots, K)$ and $S(\widetilde{\Gamma}) := \frac{1}{K}\sum_{k=1}^K\big[\widetilde{\Sigma}_k + (\widetilde{\mu}_k - \mu)(\widetilde{\mu}_k - \mu)^T\big]$. Another application of Lemma 2 gives

$$\begin{aligned}T_3 = \mathbb{E}_{q_V}\Big[\sum_k \log N(v_{*k}; \mu, \Sigma)\Big] &= -\frac{1}{2}\sum_k\big[\log|\Sigma| + \mathrm{tr}(\Sigma^{-1}\tilde{\Sigma}_k) + (\tilde{\mu}_k - \mu)^T\Sigma^{-1}(\mu_k - \mu)\big]\\ &= -\frac{1}{2}\sum_k\big[\log|\Sigma| + \mathrm{tr}(\Sigma^{-1}\Psi_k(\widetilde{\Gamma}))\big]\\ &= -\frac{K}{2}\big[\log|\Sigma| + \mathrm{tr}(\Sigma^{-1}S(\widetilde{\Gamma}))\big].\end{aligned}$$

Using Lemma 2 once more, we have

$$T_5 = \mathbb{E}_{q_V} \log q(V) = \sum_k \mathbb{E}_{q_V} \log N(v_{*k}; \widetilde{\mu}_k, \widetilde{\Sigma}_k)$$
$$= \sum_k -\frac{1}{2}\big[\log|\widetilde{\Sigma}_k| + \mathrm{tr}(I_{d_1+d_2})\big] = -\frac{1}{2}K(d_1+d_2) - \frac{1}{2}\sum_k \log|\widetilde{\Sigma}_k|$$

Finally, we have

$$T_4 = \mathbb{E}_{q_Z} \log q(Z) = \mathbb{E}_{q_Z} \sum_{r,i,k} z_{rik} \log \tau_{rik} = \sum_{r,i,k} \tau_{rik} \log \tau_{rik}. \tag{40}$$

Putting the pieces together we get expression (12).

B.3. Updates of $\widetilde{\Sigma}$ and $\widetilde{\mu}$

From (12), the relevant portion of J which is a function of $\widetilde{\Gamma} = (\widetilde{\mu}, \widetilde{\Sigma})$ is given by

$$J(\widetilde{\mu}, \widetilde{\Sigma}) \doteq \sum_{r,i,k} \tau_{rik}\beta_{rik}(\widetilde{\Gamma}, \sigma^2) - \frac{K}{2}\,\mathrm{tr}[\Sigma^{-1}S(\widetilde{\Gamma}, \mu)] + \frac{1}{2}\sum_k \log|\widetilde{\Sigma}_k|$$

Substituting $\beta_{rik}(\widetilde{\Gamma}, \sigma^2) := -\frac{1}{2\sigma_r^2}[\mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right) + \|x_{ri} - \widetilde{\mu}_{rk}\|^2]$, and $S(\widetilde{\Gamma}, \mu) := \frac{1}{K}\sum_{k=1}^K \big[\widetilde{\Sigma}_k + (\widetilde{\mu}_k - \mu)(\widetilde{\mu}_k - \mu)^T\big]$ from their definitions, and looking at the result only as a function of $\widetilde{\Sigma}$, we obtain

$$J(\widetilde{\Sigma}) \doteq -\frac{1}{2}\sum_k \Big[\sum_{r,i} \tau_{rik}\frac{\mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right)}{\sigma_r^2} + \mathrm{tr}[\Sigma^{-1}\widetilde{\Sigma}_k] - \log|\widetilde{\Sigma}_k|\Big] \tag{41}$$

Recalling $\bar{\tau}_{rk} := \sum_{i=1}^{N_r} \tau_{rik}$ and $D_k^{-1} := \mathrm{diag}\left(\frac{\bar{\tau}_{1k}}{\sigma_1^2} I_{d_1}, \frac{\bar{\tau}_{2k}}{\sigma_2^2} I_{d_2}\right)$, we have

$$\sum_{r,i} \tau_{rik}\frac{\mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right)}{\sigma_r^2} = \sum_r \bar{\tau}_{rk}\frac{\mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right)}{\sigma_r^2} = \mathrm{tr}\Big[\sum_r \frac{\bar{\tau}_{rk}}{\sigma_r^2}(\widetilde{\Sigma}_k)_{rr}\Big] = \mathrm{tr}(D_k^{-1}\widetilde{\Sigma}_k).$$

Hence, we obtain $J(\widetilde{\Sigma}) \doteq -\frac{1}{2}\sum_k \mathrm{tr}[(\Sigma^{-1} + D_k^{-1})\widetilde{\Sigma}_k] - \log|\widetilde{\Sigma}_k|$ which is the desired result.

Similarly, by substituting $\beta_{rik}(\widetilde{\Gamma}, \sigma^2)$ and $S(\widetilde{\Gamma}, \mu)$ and looking at the result as a function only of $\widetilde{\mu}$, we obtain

$$J(\widetilde{\mu}) = -\frac{1}{2}\sum_k \Big[\sum_{r,i} \tau_{rik}\frac{\|x_{ri} - \widetilde{\mu}_{rk}\|^2}{\sigma_r^2} + (\widetilde{\mu}_k - \mu)^T\Sigma^{-1}(\widetilde{\mu}_k - \mu)\Big].$$

Let us simplify the sum over r and i. Up to constants as function of $\widetilde{\mu}$, we have

$$\sum_i \tau_{rik}\|x_{ri} - \widetilde{\mu}_{rk}\|^2 \doteq \sum_i \tau_{rik}\big(\|\widetilde{\mu}_{rk}\|^2 - 2\langle x_{ri}, \widetilde{\mu}_{rk}\rangle\big)$$
$$= \bar{\tau}_{rk}\|\widetilde{\mu}_{rk}\|^2 - 2\langle \bar{x}_{rk}, \widetilde{\mu}_{rk}\rangle$$
$$= \bar{\tau}_{rk}\big(\|\widetilde{\mu}_{rk}\|^2 - 2\langle \bar{\mu}_{rk}, \widetilde{\mu}_{rk}\rangle\big)$$
$$\doteq \bar{\tau}_{rk}\|\widetilde{\mu}_{rk} - \bar{\mu}_{rk}\|^2$$

where the second to last equality is by definition of $\bar{\mu}_{rk} := \bar{x}_{rk}/\bar{\tau}_{rk}$. Recalling the definitions of $\bar{\tau}_{rk}$ and $\bar{x}_{rk} := \sum_{i=1}^{N_r} \tau_{rik}x_{ri}$. Hence,

$$\sum_{r,i} \tau_{rik}\frac{\|x_{ri} - \widetilde{\mu}_{rk}\|^2}{\sigma_r^2} \doteq \sum_r \frac{\bar{\tau}_{rk}}{\sigma_r^2}\|\widetilde{\mu}_{rk} - \bar{\mu}_{rk}\|^2 = (\widetilde{\mu}_k - \bar{\mu}_k)^T D_k^{-1}(\widetilde{\mu}_k - \bar{\mu}_k)$$

Thus, we obtain

$$J(\widetilde{\mu}) \doteq -\frac{1}{2}\sum_k \big[(\widetilde{\mu}_k - \bar{\mu}_k)^T D_k^{-1}(\widetilde{\mu}_k - \bar{\mu}_k) + (\widetilde{\mu}_k - \mu)^T\Sigma^{-1}(\widetilde{\mu}_k - \mu)\big].$$

Desired expression (19) follows by applying the following lemma.

Lemma 3 (Sum of quadratic forms). *For symmetric matrices $Q_1, Q_2, \ldots,$*

$$\sum_r (x - m_r)^T Q_r^{-1}(x - m_r) = (x - m)^T Q^{-1}(x - m) + const., \quad \forall x$$

where $Q = (\sum_r Q_r^{-1})^{-1}$ and $m = \sum_r QQ_r^{-1}m_r$.

Proof *Since the two sides are quadratic functions, they are equal up to constants if their derivatives up to second-order match. Equating the Hessians gives $\sum_r Q_r^{-1} = Q^{-1}$. Then, equating the gradients gives $\sum_r Q_r^{-1}(x - m_r) = Q^{-1}(x - m)$, which simplifies to $\sum_r Q_r^{-1}m_r = Q^{-1}m$ in light of the Hessian equality.* ■

B.4. Updates of σ^2, π, p and q

The relevant portion of J as a function (σ_r^2) is

$$J((\sigma_r^2)) = -\frac{1}{2}\sum_r \Big[\frac{1}{\sigma_r^2}\sum_{i,k} \tau_{rik}\big[\mathrm{tr}\left((\widetilde{\Sigma}_k)_{rr}\right) + \|x_{ri} - \widetilde{\mu}_{rk}\|^2\big] + d_r N_r \log\sigma_r^2\Big]. \tag{42}$$

The maximizer of the function $x \mapsto Ax^{-1} + B\log x$ is A/B (assuming $A, B > 0$), from which (20) follows.

As a function π, J has the form $J(\pi) \doteq \sum_{r,i,k} \tau_{rik}\log\pi_{rk} = \sum_{r,k} \bar{\tau}_{rk}\log\pi_{rk}$ using the definition of $\bar{\tau}_{rk}$. The following lemma is standard. (Recall that $\mathcal{P}_K$ is the set of probability K-vectors.)

Lemma 4. *For any nonnegative vector $(a_1, \ldots, a_K)$,*

$$\underset{p\,\in\,\mathcal{P}_K}{\mathrm{argmax}} \sum_k a_k \log p_k = \frac{1}{\sum_k a_k}(a_1, \ldots, a_K).$$

Based on the lemma, π_1-update is $\pi_1 = (\bar{\tau}_{11}, \ldots, \bar{\tau}_{1K})/(\sum_k \bar{\tau}_{1k})$. The update for π_2 is similar.

To update p we note that $J(p) \doteq \sum_{i,j} \gamma_{ij}(\tau)(A_{ij}\log p + (1 - A_{ij})\log(1 - p))$. The update is obtained by setting the derivative to zero. The q-update is similar.

Appendix C. Details for degree-corrected algorithm

C.1. τ-update with degree restriction

In this section, we derive a dual ascent algorithm for the optimization problem (33) which has to be solved for updating τ under the degree corrected model. Letting $a_{ik} := \phi_1[A\tau_2]_{ik} + \phi_0\bar{\tau}_{2k} + \xi_{1ik}$, and with some notational simplifications, problem (33) can be stated as

$$\min_{X=(x_{ik})} -\sum_{ik} x_{ik}(a_{ik} - \log x_{ik}), \quad \text{s.t. } X \in \mathcal{P}_{n,K}, \ \sum_i x_{ik}(\theta_i - 1) = 0, \forall k \tag{43}$$

where $\mathcal{P}_{n,K} := \{(x_{ik}) \in \mathbb{R}_+^{n\times K} : \sum_k x_{ik} = 1, \forall i\}$. Let $f(X)$ be the objective function in (43), and let us write the constraint in vector form $\sum_i x_{ik}(\theta_i - 1) = X^T(\theta - \mathbf{1}) = 0$. With the Lagrangian $L(X, \lambda) = f(X) - \lambda^T[X^T(\theta - \mathbf{1})]$, the dual function is

$$\Phi(\lambda) := \min_{X\in\mathcal{P}_{n,K}} L(X, \lambda),$$

and the dual problem is $\max_\lambda \Phi(\lambda)$. A dual-descent algorithm maximizes Φ by performing a gradient ascent on Φ: $\lambda^+ = \lambda + \mu\nabla\Phi(\lambda)$. We know that the gradient of Φ is given by $\partial_\lambda L(X, \lambda)$ evaluated at $X^*(\lambda)$, the optimizer of the Lagrangian. More precisely,

$$\nabla\Phi(\lambda) = [X^*(\lambda)]^T(\theta - \mathbf{1}), \quad \text{where } X^*(\lambda) = \operatorname*{argmax}_{X\in\mathcal{P}_{n,K}} -L(X, \lambda)$$

Solving for $X^*(\lambda)$ is an instance of the problem in Lemma 1. The problem is separable over i and for fixed i, we are maximizing $\sum_k x_{ik}(a_{ik} - \log x_{ik}) + \sum_k \lambda_k x_{ik}(\theta_i - 1) = \sum_k x_{ik}\{[a_{ik} + \lambda_k(\theta_i - 1)] - \log x_{ik}\}$ over $x_{i*} \in \mathcal{P}_{1,K}$, the solution of which is given by the softmax operation

$$x^*_{ik}(\lambda) \propto_k \exp(a_{ik} + \lambda_k(\theta_i - 1)). \tag{44}$$

Thus, the update for the dual descent can be written

$$\lambda_k^+ = \lambda_k - \mu\sum_i x^*_{ik}(\lambda)(\theta_i - 1), \quad \forall k. \tag{45}$$

C.2. θ-update

Simplyfying the notation, let $h(\theta) = -\sum_i d_i \log\theta_i$ and $V := \{\theta : \sum_i \tau_{ik}(\theta_i - 1) = 0\}$. The problem is equivalent to minimizing $h(\theta) + \delta_V(\theta)$ over θ where δ_V is the indicator of V in the sense of convex analysis. Douglas-Rachford algorithm, also known as Spingarn's method of partial inverses in this special case, is given by

$$\begin{aligned}\theta^+ &= \operatorname{prox}_{th}(\xi)\\ \xi^+ &= \xi + P_V(2\theta^+ - \xi) - \theta^+\end{aligned} \tag{46}$$

where prox_{th} is the proximal operator of $th(\cdot)$ and P_V is the projection onto V. Due to separability, it is not hard to see that $[\operatorname{prox}_{th}(\theta)]_i = \operatorname{prox}_{td_i\log(\cdot)}(\theta_i)$. This univariate proximal operator can be easily shown to coincide with $[f_t(\theta, d)]_i$ as given in (35).

As for the projection, in general with $C = \{x : Ax = b\}$, we have $P_C(x) = x + A^T(AA^T)^{-1}(b - Ax)$. Note that $V = \{\theta : \tau^T(\theta - \mathbf{1}) = 0\}$. Applying the general result with $A = \tau^T$ and $b = \tau^T\mathbf{1}$, we get $P_V(\theta) = \theta + \tau(\tau^T\tau)^{-1}\tau^T(\mathbf{1} - \theta) = \theta - H(\theta - \mathbf{1})$, with the obvious choice for H. Thus (46) simplifies to

$$\xi^+ = \xi + (2\theta^+ - \xi) - H(2\theta^+ - \xi - \mathbf{1}) - \theta^+$$

which gives the claimed update.

Appendix D. Expected average degree

Let $\hat{\lambda}_i = \sum_j A_{ij}$ and $\hat{\lambda}_j = \sum_i A_{ij}$ be the degree of node i from group 1, and node j from group 2, respectively. Then, the average degree of the network is

$$\hat{\lambda} = \frac{\sum_i \hat{\lambda}_i + \sum_j \hat{\lambda}_j}{N_1 + N_2} = \frac{2\sum_{i,j} A_{ij}}{N_1 + N_2}.$$

Recall the definition of clusters C_{rk} from (1). The expected average degree can be derived as follows: Assume that $i \in C_{1k}$, then $\mathbb{E}[A_{ij}] = \theta_{1i}\theta_{2j}(p1\{j \in C_{2k}\} + q1\{j \notin C_{2k}\})$. Then

$$\mathbb{E}(\hat{\lambda}_i) = \theta_{1i}\Big(p\sum_{j\in C_{2k}}\theta_{2j} + q\sum_{j\notin C_{2k}}\theta_{2j}\Big) = \theta_i r_k, \quad \text{where} \quad r_k := |C_{2k}|p + (N_2 - |C_{2k}|)q$$

Here, we have used the normalization (7): $\sum_{j\in C_{2\ell}}\theta_{2j} = |C_{2\ell}|$ for all $\ell \in [K]$. Now,

$$\sum_{i=1}^{N_1}\mathbb{E}(\hat{\lambda}_i) = \sum_{i=1}^{N_1}\sum_k 1\{i \in C_{1k}\}\mathbb{E}(\hat{\lambda}_i) = \sum_k r_k\sum_{i=1}^{N_1}\theta_{1i}1\{i \in C_{1k}\} = \sum_k r_k|C_{1k}|$$

using the normalization of θ_{1i}. Dividing by N_1N_2 and using $|C_{rk}|/N_r = \pi_{rk}$ for $r = 1, 2$,

$$\sum_{i=1}^{N_1}\mathbb{E}(\hat{\lambda}_i) = N_1N_2\sum_k\big[\pi_{1k}q + \pi_{1k}\pi_{2k}(p - q)\big] = N_1N_2(q + \Pi(p - q)),$$

where $\Pi := \sum_k \pi_{1k}\pi_{2k}$. By symmetry, $\sum_{j=1}^{N_2}\mathbb{E}(\hat{\lambda}_j) = N_1N_2(q + \Pi(p - q))$. Hence,

$$\lambda = \mathbb{E}[\hat{\lambda}] = \frac{2N_1N_2}{N_1 + N_2}\big(q + \Pi(p - q)\big), \quad \text{where } \Pi := \sum_k \pi_{1k}\pi_{2k}.$$

Note that $\frac{2N_1N_2}{N_1+N_2} = 2/(N_1^{-1} + N_2^{-1})$ is the harmonic mean of N_1 and N_2.

Appendix E. More simulations

Figure 13 shows the effect of varying the dimension of the covariates $d = (d_1, d_2)$ and the scale of the covariance matrix ν. The setup is as in Section 4, and in particular $\Sigma = \nu I$ controls how far apart the centers of the covariate clusters $v_{*k} \in \mathbb{R}^{d_1+d_2}$ are. Only the `mbiSBM` algorithm is shown (with no degree correction and) initialized with Dirichlet-perturbed truth ($\sim$`rnd`). As one expects, increasing the dimensions of the covariates increases the performance (seemingly without bound). Increasing ν improves the performance up to a point, but there is a saturation effect beyond that point, where the performance remains more or less the same.

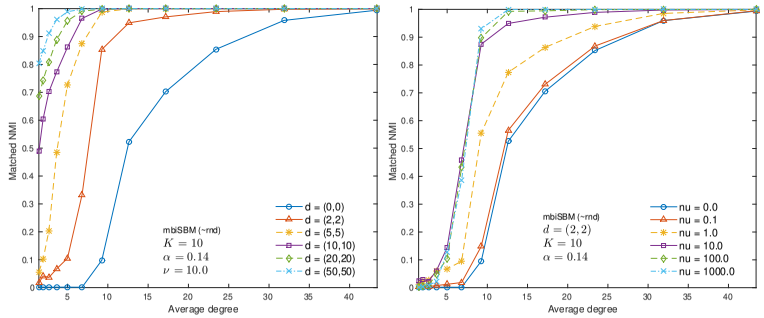

Figure 13: (Left) Effect of changing the dimension of covariates $d = (d_1, d_2)$ and (right) the parameter ν where $\Sigma = \nu I_{d_1+d_2}$.

Abstract

The trade-off between the cost of acquiring and processing data, and uncertainty due to a lack of data is fundamental in machine learning. A basic instance of this trade-off is the problem of deciding when to make noisy and costly observations of a discrete-time Gaussian random walk, so as to minimise the posterior variance plus observation costs. We present the first proof that a simple policy, which observes when the posterior variance exceeds a threshold, is optimal for this problem. The proof generalises to a wide range of cost functions other than the posterior variance. It is based on a new verification theorem by Niño-Mora that guarantees threshold structure for Markov decision processes, and on the relation between binary sequences known as *Christoffel words* and the dynamics of discontinuous nonlinear maps, which frequently arise in physics, control and biology.

This result implies that optimal policies for *linear-quadratic-Gaussian control with costly observations* have a threshold structure. It also implies that the restless bandit problem of observing multiple such time series, has a well-defined *Whittle index policy*. We discuss computation of that index, give closed-form formulae for it, and compare the performance of the associated index policy with heuristic policies.

Keywords: restless bandits, Whittle index, Christoffel words, Sturmian words, Kalman filter, linear-quadratic-Gaussian control

1. Introduction

This paper answers three closely-related questions about discrete-time filtering of scalar time series with costly observations, where the nature of the observations is controlled through a query action. The first two questions concern the structure of optimal policies for observing a single time series so as to minimise either a function of the posterior variance (Theorem 1, Excerpt) or a quadratic function of the system state and control input (Corollary 2). The third question concerns the observation of several such time series with a constraint on the number of time series that can be observed simultaneously. This is an instance of a *restless bandit problem* and it is interesting to know that the problem has a well-defined *Whittle index policy* (Theorem 1).

This introduction begins with the time-series model (Section 1.1) that the three questions have in common. It then motivates, formulates and states the key results for each question in turn (Sections 1.2 to 1.4). It concludes with an intuitive guide to the main concepts involved in the proof (Section 1.5) and a description of the structure of the rest of the paper (Section 1.6).

Notation. In this paper, $\mathbb{Z}_+ = \{0, 1, 2, \dots\}$, $\mathbb{Z}_{++} = \{1, 2, 3, \dots\}$, $\mathbb{R}_+ = [0, \infty)$, $\mathbb{R}_{++} = (0, \infty)$ and $\overline{\mathbb{R}} = [-\infty, \infty] = \mathbb{R} \cup \{-\infty, \infty\}$ denotes the extended real numbers. Left limits are denoted by $f(y^-) = \lim_{x \uparrow y} f(x)$ and right limits by $f(y^+) = \lim_{x \downarrow y} f(y)$. The terms *increasing* and *decreasing* are used in the strict sense, with non-decreasing and non-increasing used otherwise.

1.1. Time-Series Model

We consider the classic discrete-time scalar normally-distributed state-space model. In this model, the state is partially observed through measurements as fully described by the conditional dependencies

$$\left.\begin{aligned} Z_0 &\sim \mathcal{N}(z_0, v_0) \\ Z_{t+1}|Z_t, u_t &\sim \mathcal{N}(\bar{A}Z_t + \bar{B}u_t, \Sigma_Z) \\ Y_{t+1}|Z_{t+1}, a_t &\sim \mathcal{N}(Z_{t+1}, \Sigma_Y(a_t)) \end{aligned}\right\} \quad \text{for } t \in \mathbb{Z}_+. \tag{1}$$

The state Z_t is a real-valued random variable with initial mean z_0 and variance v_0. The sequence of states depends on the control or exogenous input $u_t \in \mathbb{R}$. The measurement Y_{t+1} is a real-valued random variable which depends on a query action $a_t \in \{0, 1\}$. The variances $\Sigma_Z, \Sigma_Y(0), \Sigma_Y(1) > 0$ and real-valued parameters $\bar{A}, \bar{B}$ are known. Query action $a_t = 1$ is assumed to correspond to a higher-quality observation than query action $a_t = 0$, so that $\Sigma_Y(1) < \Sigma_Y(0)$ and it is possible that $\Sigma_Y(0) = \infty$ which represents a totally uninformative observation or no observation at all.

The observed history H_t at time t is $z_0, v_0, a_0, a_1, \dots, a_{t-1}, u_0, u_1, \dots, u_{t-1}, Y_1, Y_2, \dots, Y_t$. Under the Bayesian filter, the information state is given by the posterior mean $z_t := \mathbb{E}[Z_t|H_t]$ and variance $v_t := \mathbb{E}[(Z_t - z_t)^2|H_t]$. In this case, the Bayesian filter is the Kalman filter (Thiele, 1880; Kalman, 1960) and it follows that the information state undergoes the following Markovian transitions:

$$\left.\begin{aligned} z_{t+1}|z_t, v_t, a_t, u_t &\sim \mathcal{N}(\bar{A}z_t + \bar{B}u_t, \bar{A}^2 v_t + \Sigma_Z - \Phi_{a_t}(v_t)) \\ v_{t+1}|z_t, v_t, a_t, u_t &= \Phi_{a_t}(v_t) \end{aligned}\right\} \quad \text{for } t \in \mathbb{Z}_+ \tag{2}$$

where $\Phi_a : \mathbb{R}_+ \to \mathbb{R}_+$ for $a \in \{0, 1\}$ is the Möbius transformation

$$\Phi_a(v) := \frac{(\bar{A}^2 v + \Sigma_Z) \times \Sigma_Y(a)}{(\bar{A}^2 v + \Sigma_Z) + \Sigma_Y(a)}. \tag{3}$$

The above model excludes the relatively-simple case of learning a *stationary* parameter Z_t, since we assume that $\Sigma_Z > 0$. Under this assumption, to facilitate analysis, we shall scale the units of variance such that $\Sigma_Z = 1$. Specifically, we consider the (relative) variance state at time t given by $x_t := v_t/\Sigma_Z$ and the (relative) precision of the observations given by $\theta_a := \Sigma_Z/\Sigma_Y(a)$ for $a \in \{0, 1\}$. We also define the parameter $r := |\bar{A}|$, noting that $\bar{A}$ can be negative. After this change of coordinates, the variance transitions are now given by the Möbius transformation

$$\phi_a(x) := \frac{\Phi_a(\Sigma_Z x)}{\Sigma_Z} = \frac{(r^2\Sigma_Z x + \Sigma_Z)\Sigma_Y(a)}{\Sigma_Z(r^2\Sigma_Z x + \Sigma_Z + \Sigma_Y(a))} = \frac{r^2 x + 1}{\theta_a(r^2 x + 1) + 1}. \tag{4}$$

The above model also excludes *totally informative* observations, since we assume that $\Sigma_Y(1) > 0$. Such models are nevertheless partly-addressed in the limit as the precision $\theta_1 \to \infty$ in Proposition 31, where it is possible to find closed-form formulae relating to optimal policies for the three problems discussed in the rest of this introduction. The rationale for excluding such cases from our analysis is that our characterisation of the behaviour of maps-with-gaps (Theorem 12) no longer applies.

1.2. Optimal Policies for Observing a Single Time Series

The simplest problem addressed here involves an uncertainty cost $C(x)$, where x is the (relative variance) state introduced just above, and a price $\lambda \in \mathbb{R}$ to be paid every time query action $a = 1$ is taken. Price λ might reflect costs of energy, labour, communication, computational processing, hardware or risks associated with each measurement. Recall that a policy is *non-anticipative* if it selects actions at time t based only on information available up-to and including time t. The objective is to find a non-anticipative policy π that selects query actions so as to minimise the β-discounted performance functional, for discount factor $\beta \in [0, 1)$, for all initial states x,

$$\mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t (\lambda A_t + C(X_t)) \right] \tag{5}$$

where $\mathbb{E}_x^\pi$ denotes the expectation over sequences $(X_t, A_t)_{t=0}^\infty$ of states X_t and actions A_t with initial state $X_0 = x$, where actions A_t are taken according to policy π and transitions are according to (2). Note that this performance functional depends neither on the control or exogenous input u_t nor on the posterior mean z_0 since these appear neither in the costs nor in the transitions of the posterior variance, which are given by the deterministic mapping (4). So, while in some settings, such as that considered in Section 1.3, it is natural to require policies π to also select the control u_t, in the setting considered here it does not matter which value for u_t is chosen and we only require the policy to select the query action a_t. Thus, this problem corresponds to the following deterministic dynamic program for value function $V : \mathbb{R}_{++} \to \mathbb{R}$,

$$V(x) = \min_{a \in \{0,1\}} \Big\{ \lambda a + C(x) + \beta V(\phi_a(x)) \Big\}. \tag{6}$$

The first question addressed in this paper is: *for what cost functions is a threshold policy optimal for this problem?* For instance, one may intuitively guess that optimal policies for variance minimisation with $C(x_t) = x_t$, for entropy minimisation with $C(x_t) = \log(x_t)$, or for precision maximisation with $C(x_t) = -1/x_t$, might involve making expensive observations at time t when the variance state x_t exceeds a threshold. The following assumption on the model covers these examples.

Assumption A1

(i) The state space $\mathcal{I}$ is either $[0, \infty)$ or $(0, \infty)$.

(ii) The discount factor β is in $[0, 1)$.

(iii) The transition functions $\phi_a : \mathbb{R}_+ \to \mathbb{R}_+$ for $a \in \{0, 1\}$ are of the form

$$\phi_a(x) = \frac{r^2 x + 1}{\theta_a(r^2 x + 1) + 1}$$

for some $0 \le \theta_0 < \theta_1 < \infty$ and some $r \in (0, 1]$.

(iv) The uncertainty cost function $C : \mathcal{I} \to \mathbb{R}$ is of the form $C(x) = \sum_{i=1}^{n_C} C_i(x)$ for some $n_C \in \mathbb{Z}_{++}$, where each of the functions $C_i : \mathcal{I} \to \mathbb{R}$ satisfies one of the following conditions:

C1. For $x \in \mathcal{I}$, the derivatives $C_i'(x) := \frac{d}{dx} C_i(x)$ and $C_i''(x) := \frac{d^2}{dx^2} C_i(x)$ exist and

- *the function $C_i(x)$ is concave,*
- *the function $\frac{1}{x^3} C_i''\left(\frac{1}{x}\right)$ is non-decreasing,*
- *and the function $\frac{1}{x^2} C_i'\left(\frac{1}{x}\right)$ is non-increasing and convex.*

C2. For $x \in \mathcal{I}$, the function $C_i(x)$ is non-decreasing, convex and differentiable.

(v) There exists a measurable function $w : \mathcal{I} \to [1, \infty)$ and constants $M > 0$ and $\gamma \in [\beta, 1)$ such that for every state $x \in \mathcal{I}$:

(a) $|C(x)| \le M w(x)$; and

(b) $\beta \max_{a \in \{0,1\}} w(\phi_a(x)) \le \gamma w(x)$.

Regarding part (i) of the above assumption, note that we may work with the interval $\mathcal{I} = (0, \infty)$ in cases where the cost function $C(x)$ is not a real number for $x = 0$, in order to include cases like $\log(x)$ and $-1/x$, but the results of the paper continue to hold in cases where $C(0)$ is defined. In fact, the main results of the paper also apply to smaller intervals $\mathcal{I}$, as long as the initial state is contained in the interval $\mathcal{I}$ and the open interval (y_1, y_0) is in $\mathcal{I}$, where y_a is the unique solution to $\phi_a(y_a) = y_a$ (see Section 2 for further discussion of such fixed points.)

In part (iii) of the above assumption, the inequality $\theta_0 < \theta_1$ is taken to be strict as otherwise the problem is trivial. Specifically, if $\theta_0 = \theta_1$ then the state sequence does not depend on the policy, so the policy that always takes action 0 is optimal if $\lambda > 0$, whereas the policy that always takes action 1 is optimal if $\lambda < 0$.

Part (iv) of the above assumption is at the heart of our answer to our first question: it represents the most general class of cost functions $C(\cdot)$ that our approach to proving optimality of threshold policies naturally allows for. Delving into the proof, the specific form of part (iv) results from a requirement that certain *majorisation* inequalities (Marshall et al., 2010) hold in Lemma 25.

Uncertainty cost functions $C(\cdot)$ satisfying part (iv) may be neither convex nor concave. For instance in the case $C(x) = (x^3 - 1)/x$, we can write $C(x) = \sum_{i=1}^{n_C} C_i(x)$ for $n_C = 2$ with $C_1(x) = x^2$, a convex function satisfying part C1, and with $C_2(x) = -1/x$, a concave function satisfying part C2. In this instance, the cost $C(x) = (x^3 - 1)/x$ is *unbounded* from both below and above (that is, $\lim_{x \downarrow 0} C(x) = -\infty$ and $\lim_{x \uparrow \infty} C(x) = \infty$). However,

it is possible that the cost is *bounded* both below and above, for instance in the case $C(x) = x/(x+1)$.

In general part (iv) of the above assumption can always be satisfied with $n_C = 2$ terms. This is because finite sums of functions satisfying part C1 also satisfy part C1, since finite sums of functions satisfying part C2 also satisfy part C2, and since the zero-function ($C(x) = 0$ for all x) satisfies both cases.

Also part (iv) of the above assumption requires that functions C_i satisfying C2 have a derivative C_i'. This is simply for convenience in the proofs of Section 3.3. As such functions are real-valued convex functions, one can instead set C_i' equal to any subderivative at points where the derivative is not defined.

Part (v) is key to the *weighted supremum norm* approach to infinite-horizon discounted Markov decision problems, as is explained in detail by Wessels (1977) and Hernández-Lerma and Lasserre (1999, Chapter 8). It ensures that the infinite series in the objective function is well-defined for all policies π and initial states $x \in \mathcal{I}$, even though the cost function $C(\cdot)$ may be unbounded. Furthermore, although Bellman's equation may have multiple unbounded solutions $V(\cdot)$, part (v) guarantees that the optimal value function is the unique solution with $\sup_{x\in\mathcal{I}} |V(x)/w(x)| < \infty$. For $|C(x)| = x^q$ with $q \geq -1$, it is not hard to see that part (v) is satisfied for $w(x) := \max\{y_1/x, \alpha^{x-y_1}\}$ where y_1 is the unique positive solution of $\phi_1(x) = x$ and α is any number in the interval $(1, 1/\beta)$. Further, for this choice of $w(x)$, if $M(q)$ satisfies $x^q \leq M(q)w(x)$ and $C(x) = \sum_{k=1}^m a_k x^{q_k}$ for some $a_k \in \mathbb{R}$ and $q_k \geq -1$, then the triangle inequality gives $|\sum_{k=1}^m a_k x^{q_k}| \leq (\sum_{k=1}^m |a_k| M(q_k))\, w(x)$. Thus part (v) is satisfied for all the examples of the function $C(\cdot)$ considered above. Given the above assumption, we may now answer our first question. The full theorem (see page 14), of which the following is only an excerpt, also characterises the optimal choice of threshold and the associated Whittle index.

Theorem 1 (Excerpt) *Suppose A1 holds. Then for some threshold $s \in \bar{\mathbb{R}}$, the threshold policies $A_t = \mathbf{1}_{X_t > s}$ and $A_t = \mathbf{1}_{X_t \geq s}$ both minimise performance functional (5) for every initial state $x \in \mathcal{I}$.*

Theorem 1 only holds for cost functions that are functions of the posterior variance $v_t = \mathbb{E}[(Z_t - z_t)^2 | H_t]$ alone, although this includes non-quadratic expressions like $\mathbb{E}[|Z_t - z_t|^p | H_t]$ for $p > -1$, which is of the form $k(p)v_t^p$ for an appropriate function $k(\cdot)$. For cost functions that explicitly depend on the posterior mean, we have a Markov decision problem in a 2-dimensional real-valued state space and there are several possible extensions of the notion of a "threshold policy" that might be considered. Also, as transitions of the posterior mean depend on the values of the observations, the problem would no-longer be deterministic if dependence on the posterior mean were introduced.

From one perspective, this answer is a rare example of an explicit solution to a real-state partially-observed Markov decision process (POMDP). From another perspective, this answer is a rare example of an explicit solution to the problem of observation selection in sensor management (Hero and Cochran, 2011). Indeed, given a collection of variables which can (in principle) be observed and a single variable to predict, which are jointly Gaussian with known covariance, even the problem of deciding whether there exists a subset of k observations that reduces the prediction variance below a given threshold is NP-hard (Davis et al., 1997). Work has therefore focused on finding covariance structures for which the

problem is tractable, for instance Das and Kempe (2008) show that selection of Gaussian observations with an exponential covariance can be solved by a simple discrete dynamic program, and on finding appropriate choices of cost functions for which there are guaranteed approximation algorithms (Krause et al., 2008, 2011; Badanidiyuru et al., 2014; Chen et al., 2014).

1.3. The Linear Quadratic Gaussian Problem with Costly Observations

The second question addressed by this paper is: *when are threshold policies optimal for making observations in a generalisation of the linear-quadratic-Gaussian control problem in which observations are costly but controlled through a query action?* Specifically, suppose the states and observations are as in (1) but the objective is to find a non-anticipative policy π that selects a feedback-control action $u_t \in \mathbb{R}$ and a sensor-query action $a_t \in \{0, 1\}$ so as to minimise the β-discounted performance functional

$$\mathbb{E}^{\pi}_{z_0,v_0}\left[\sum_{t=0}^{\infty} \beta^t (DZ_t^2 + Fu_t^2 + \lambda A_t)\right],$$

where $D, F \in \mathbb{R}_+$ and the expectation $\mathbb{E}^{\pi}_{z_0,v_0}$ is over the Markovian transitions (2) under policy π when the initial state Z_0 is normally distributed with mean z_0 and variance v_0. In this expression $\lambda \in \mathbb{R}$ denotes a cost to be paid each time action $A_t = 1$ is taken, just as in (5), and if $\lambda = 0$ then the problem reduces to the classical linear-quadratic-Gaussian control problem.

The problem with price $\lambda \neq 0$ is an old but unsolved problem, although it has been known for a long time that in finite-horizon versions of the problem the optimal timing of observations can in principle be determined *a priori*, and does not depend on the values of the observations (Kushner, 1964; Meier et al., 1967). Thus, the subproblems of state-estimation, observation scheduling and control can be decoupled, and this is often known as the *separation principle*. Meier et al. (1967) addressed the observation scheduling sub-problem using a tree search for forward dynamic programming. Other numerical attacks on the problem have included formulating it as a two-point boundary value problem, whether in continuous time (Athans, 1972) or discrete time (Kerr, 1981). Wu and Arapostathis (2008) study the long-term average and infinite-horizon discounted version of the problem and prove that a separation principle still holds over the infinite horizon, while Molin and Hirche (2009) extended these results to a setting where measurements are subject to random packet losses. Zhao et al. (2014) studied the infinite-horizon average-cost version of the problem, showing that optimal policies can be approximated arbitrarily closely by periodic schedules, but without giving any insight into the structure of such periodic schedules, or results about the discounted case.

Studies of linear quadratic control with costly observations were initially motivated by aerospace applications in which telemetry data from space vehicles was transmitted over band-limited links to ground stations (Kushner, 1964; Meier et al., 1967). More recently, continued research has been motivated by applications to networked control systems for unmanned aerial vehicles (Seiler, 2001), vehicle control (Daoud et al., 2006) and teleoperation (Hirche et al., 2007).

An immediate corollary of Theorem 1 is the following answer to the above question.

Corollary 2 *Suppose $\bar{A} \in [-1, 1]$, $\bar{B} \in \mathbb{R}\backslash\{0\}$, $D \in \mathbb{R}_{++}$, $F \in \mathbb{R}_{+}$, $\beta \in (0, 1)$, $\Sigma_Y(a) \in [0, \infty]$ for $a \in \{0, 1\}$ with $\Sigma_Y(0) \geq \Sigma_Y(1)$, and that $\lambda \in \mathbb{R}$. Then, there exists a threshold $s \in \overline{\mathbb{R}}$ such that an optimal policy for the problem of linear-quadratic-Gaussian control with costly observations is to set*

$$a_t = \begin{cases} 1 & \text{if } v_t \geq s \\ 0 & \text{if } v_t < s \end{cases} \qquad \text{and} \qquad u_t = -\left(\frac{\bar{A}}{\bar{B} + \frac{F}{\beta \bar{B} R}}\right) z_t$$

whatever the initial state, where R is the unique positive root of the quadratic equation

$$-\beta \bar{B}^2 R^2 + (\beta \bar{B}^2 D + \beta \bar{A}^2 F - F)R + DF = 0.$$

A proof of Corollary 2 is presented in Section 3.6.

1.4. Multi-Target Tracking and Restless Bandits

This paper also addresses the problem of monitoring *multiple* time series so as to maintain a precise belief while imposing a *constraint* on the number of time series that may be sensed at each time. This problem is often called the *multi-target tracking* problem. Multiple heuristics have been proposed for this problem. The simplest heuristics include round-robin schedules, and greedy or myopic schedules (Oshman, 1994). More sophisticated heuristics exploit probabilistic sensor allocations based on "steady-state" covariance matrices in continuous time (Mourikis and Roumeliotis, 2006; Le Ny et al., 2011) or in discrete time (Gupta et al., 2006). Also, Whittle (1988) proposed a *restless bandit* heuristic, and one of the applications of that heuristic is to the multi-target tracking problem. As that heuristic is a major focus of the current paper, we review the literature on the restless bandit approaches to multi-target tracking straight after explaining what restless bandits are below.

One example of a real-world application of the discrete-time problem, which was our original motivation for studying the problems in this paper, is the measurement of on-street parking occupancy (Dey, 2014), in a setting where cheap-but-low-quality observations are available through payment data (at parking meters or through mobile phones), expensive-but-high-quality observations are available through portable cameras, which are moved daily or weekly (and thus in discrete time), and there are a limited number of portable cameras with which to observe many streets.

To formulate the problem, suppose there are $n \in \mathbb{Z}_{++}$ independent time series of the form (1), indexed by $i \in \{1, 2, \ldots, n\}$, and time series i has state $Z_{t,i}$ at time $t \in \mathbb{Z}_{+}$. Each time series may have its own parameters $z_{i,0}, v_{i,0}, \bar{A}_i, \bar{B}_i, \Sigma_{Z_i}$, and its own input $u_{i,t}$. As in Section 1.1, we scale the posterior variance of each time series to get a variance state $x_{i,t}$ on a state space $\mathcal{I}_i$. As in Section 1.2, each time series has its own uncertainty cost $C_i : \mathcal{I}_i \to \mathbb{R}$. Corresponding to these time series there are n query actions $a_{i,t} \in \{0, 1\}$ at each time t which specify the nature of the observation $Y_{i,t}$ of time series i. These observations have their own parameters $\Sigma_{Y_i} : \{0, 1\} \to (0, \infty]$. However, these actions are subject to the constraint that only $m \in \mathbb{Z}_{++}$ with $m < n$ expensive observations can be made at each time. As in Section 1.1, the transitions of the posterior variance are given by the Möbius transformation (4), which does not involve the exogenous inputs $u_{i,t}$, and which is deterministic.

The problem is then to find a history-dependent randomised policy π that minimises the total β-discounted uncertainty cost

$$\mathbb{E}_x^{\pi}\left[\sum_{i=1}^{n}\sum_{t=0}^{\infty}\beta^t C_i(X_{t,i})\right]$$

for any initial state $x \in \mathcal{I}_1 \times \cdots \times \mathcal{I}_n$, subject to the constraint that policy π makes m observations at each time, so that

$$\sum_{i=1}^{n} A_{t,i} = m \qquad \text{for } t \in \mathbb{Z}_{+},$$

where $\mathbb{E}_x^{\pi}$ denotes the expectation over sequences $(X_t, A_t)_{t=0}^{\infty}$ with initial state $X_{0,1} = x_1, \ldots, X_{0,n} = x_n$, where actions are taken according to the potentially non-deterministic policy π and transitions are according to (4). It is equally possible to work with the constraint $\sum_{i=1}^{n} A_{t,i} \leq m$ as discussed below.

Restless Bandits. The multi-target tracking problem is an instance of a *restless bandit problem* (Whittle, 1988). Typically, such problems are defined in terms of a set of $n \in \mathbb{Z}_{++}$ two-action Markov decision processes (MDPs), although generalisations to a time-varying number of MDPs (Verloop, 2016) and to more than two actions per MDP (Glazebrook et al., 2011) have been explored. The two actions are usually referred to as *active* or *play* versus *inactive* or *passive* and each of the MDPs is referred to as an *project* or *arm*.

In a restless bandit problem, these n MDPs are coupled into a single MDP as follows. The state space is the Cartesian product of the state spaces of the projects, and the state of each project transitions independently of the other projects given the actions taken on that project. Thus the transitions of a project depend only on the actions taken on that project and on that project's current state. The objective is to find a non-anticipative policy that minimises the sum of the projects' individual performance functionals if those functionals all represent costs (or that maximises the sum of the projects' individual performance functionals if those functionals all represent rewards), for all initial states. The precise notion of the performance functional for an individual project depends on the setting: infinite horizon average cost and infinite horizon discounted cost settings are both commonly considered.

However, the action space is only a subset of the Cartesian product of the action spaces of the projects, as there is a constraint on the number m of projects that are simultaneously active at each time, where $m \in \mathbb{Z}_{++}$ with $m < n$. Typically, the constraint is that *exactly* m projects are active at each time, but this is readily relaxed to a constraint that *at most* m projects are active by including "dummy projects", whose cost is always zero, in the population of n projects. More general constraints have been explored (Niño-Mora, 2015), in which each project consumes resources as a function of both its state and the action taken, and the total cost of the resources consumed at each time is constrained. In the absence of any such action constraint, the problem would be solved by applying an optimal policy for each project independently. Moreover, it turns out that if the constraint were only on the (discounted) time-average number of projects that are simultaneously active, rather than a constraint at each time, the problem could again be separated into n smaller problems

after introducing a Lagrange multiplier. Indeed, this observation was one motivation for the Whittle-index approach first proposed in Whittle (1988), as discussed below.

Let us relate the above definition to the typical usage of the term *bandit* in the machine-learning literature. In that context, multi-armed bandits are reinforcement-learning problems involving a set of projects whose reward distributions are unknown. At each time, the learner must select which project to play. Such bandits involve a trade-off between exploring projects to acquire information about their expected payoffs and exploiting projects with the highest expected payoffs. In the simplest versions of such problems, where the prior on the reward distributions is independent over projects, each project can be viewed as an MDP whose state corresponds to the belief about that project's payoff distribution. Each time the project is played, its reward is observed and this belief is updated. Such updates correspond to state transitions. Each time the project is inactive, its state does not change.

If we allow projects to make general Markovian state transitions, not just transitions corresponding to belief updates, while preserving the requirement that a project only changes state when it is played, then we arrive at a more general class of problems known as *ordinary* or *classical bandits* (Gittins et al., 2011). In turn, restless bandits generalise ordinary bandits in two ways. Firstly, restless bandits allow more than one project to be simultaneously active (if $m > 1$). Secondly, restless bandits allow the state of a project to change even when the project is not active, which is why they are called *restless*.

While this additional generality is important in modelling real-world problems, it comes at a price. On the one hand, the *Gittins index policy* is optimal for ordinary bandit problems and can be computed in polynomial time for problems with finite state spaces (Niño-Mora, 2007). On the other hand, it is in general PSPACE-hard (Papadimitriou and Tsitsiklis, 1999; Guha et al., 2010) to find policies that approximate optimal policies for restless bandit problems with finite state spaces to any non-trivial factor. At first glance, this might suggest that the multi-target tracking problem addressed here, with uncountable state-space $\mathbb{R}_+$ or $\mathbb{R}_{++}$, is impossibly difficult. At second glance, this poses an interesting question: for which restless bandit problems can we find approximately-optimal policies efficiently?

Whittle Index Policy. Whittle (1988) proposed a policy which generalises the Gittins index policy to restless bandit problems. This policy associates a real (or in some definitions an extended-real) number $\lambda_i^*(x_i)$ called the *Whittle index* with the state x_i of each project i. The policy then plays the m projects with the largest Whittle indices at each time, or for restless bandits with more general constraints, it selects a subset of projects with the largest Whittle indices such that the constraint is met. Ties are usually broken uniformly at random or according to a predefined priority ordering.

Whittle's index policy has been the subject of great interest for computational, empirical and theoretical reasons. The policy is potentially attractive in terms of computational cost as it reduces the original restless bandit problem, whose state space is the Cartesian product of the state spaces of the projects, to the computation of n Whittle indexes for individual projects. The policy is also attractive from a systems-architecture point-of-view, as it allows one to mix-and-match different types of projects, and it naturally accommodates the arrival or departure of projects in the sense that the Whittle index does not depend on the number of projects n. Additionally, extensive numerical tests of Whittle's policy in different applications repeatedly demonstrate that it performs remarkably well when the projects are

all indexable. Indeed, 12 references to such empirical work are cited in Section 8 of Verloop (2016).

The literature contains several definitions of the Whittle index $\lambda_i^*(x_i)$ of project i, which are not equivalent in general, although they turn out to be equivalent for the problem addressed in this paper. The definition in Whittle (1988) is slightly informal and does not clearly distinguish between these definitions. All the definitions involve a modified version of project i's MDP, called the *λ-price problem*. For restless bandits with a constraint on the number m of projects that can be simultaneously active, the λ-price problem involves replacing the reward $r_i(x_i, a_i)$ for taking action a_i in state x_i by $r_i(x_i, a_i) - \lambda a_i$ where $\lambda \in \mathbb{R}$ represents a price for taking the active action $a_i = 1$. Verloop (2016) then defines $\lambda_i^*(x_i)$ as the least price λ for which action $a_i = 0$ is optimal for the λ-price problem in state x_i. Meanwhile, Guha et al. (2010) define $\lambda_i^*(x_i)$ as the largest price λ for which the actions $a_i = 0$ and $a_i = 1$ are both optimal for the λ-price problem in state x_i.

In this paper, we use the following definition (Niño-Mora, 2014, 2015) which applies to restless bandits with general resource-consumption constraints. Let us drop the subscript i and consider a single project $\mathcal{P} = \langle \mathcal{X}, c, r, \mathscr{Q}, \beta \rangle$ with state space $\mathcal{X}$, resource function $c : \mathcal{X} \times \{0, 1\} \to \mathbb{R}$, reward function $r : \mathcal{X} \times \{0, 1\} \to \mathbb{R}$, transition law $\mathscr{Q}$ and discount factor $\beta \in [0, 1)$, with the following interpretation. At the start of period $t \in \mathbb{Z}_+$ the state $X_t \in \mathcal{X}$ is observed and an action $A_t \in \{0, 1\}$ is chosen. If $X_t = x$ and $A_t = a$ then $c(x, a)$ units of resource are consumed (the projects of the previous paragraph would have $c(x, a) = a$), the project yields a reward $r(x, a)$ and the state transitions to X_{t+1} which has distribution $\mathscr{Q}(\cdot|x, a)$. Let Π denote the class of all history-dependent randomised policies for project $\mathcal{P}$ and let $\mathbb{E}_x^\pi$ denote the expectation over sequences $(X_t, A_t)_{t=0}^\infty$ with initial state $X_0 = x$, where actions are taken according to policy π and transitions are according to $\mathscr{Q}$. Then, the *λ-price problem* for project $\mathcal{P}$ and price $\lambda \in \mathbb{R}$ is to find a policy $\pi_\lambda^* \in \Pi$ that maximises the performance functional

$$\mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t \left(r(X_t, A_t) - \lambda c(X_t, A_t) \right) \right]$$

for all initial states $x \in \mathcal{X}$.

Definition 3 ***(Niño-Mora, 2014, 2015)***

The ***Whittle index*** *of project $\mathcal{P}$ in state x is a price $\lambda^*(x)$ for which*

1. *Action $a = 1$ is optimal in state x of the λ-price problem if and only if $\lambda \leq \lambda^*(x)$,*
2. *Action $a = 0$ is optimal in state x of the λ-price problem if and only if $\lambda \geq \lambda^*(x)$.*

Project $\mathcal{P}$ is ***indexable*** *if it has a Whittle index $\lambda^*(x)$ for all states x in its state space.*

For all of the above definitions, it is immediate that the Whittle index is unique if it exists. Verloop's definition has the advantage that the Whittle index, and hence the Whittle index policy, exist for a wider range of projects. On the other hand, if we know project i is indexable, the definition used in this paper has the advantage that we know we have found the Whittle index when we find a price $\lambda \in \mathbb{R}$ for which actions $a_i = 0$ and $a_i = 1$ are both optimal in state x_i of the λ-price problem.

Although Whittle's policy is not an optimal policy for general restless bandits, under certain sufficient conditions and for a certain limit, it is an *asymptotically* optimal policy. Specifically, in the limit as the number of projects n tends to infinity, while the number of projects that can be simultaneously active m varies in such a way that m/n is as constant as possible, the ratio of the cost-rate of Whittle's policy to the cost-rate of an optimal policy for the given n, m tends to one. Assuming an average-cost setting, for collections of identical projects whose size n does not vary with time, where each project has a finite state space, Whittle (1988) originally conjectured that it was sufficient that the identical project was indexable for such an asymptotic optimality result to hold. However, Weber and Weiss (1990) found counterexamples to this conjecture. Nevertheless, Weber and Weiss also found sufficient conditions for asymptotic optimality to hold, and those sufficient conditions imply that the projects are indexable (Lemma 2 of that paper). Under similar sufficient conditions, this asymptotic optimality result has recently been generalised by Verloop (2016) to restless bandits with dynamic populations of non-identical projects. Both the results of Weber and Weiss and the results of Verloop assume an average-cost setting and projects with finite state spaces. So new theoretical work may be required to understand asymptotic optimality for projects with uncountable state spaces, as studied here.

The Whittle index for a project is often written as the ratio of a *marginal reward* metric to a *marginal resource* metric, where:

- The *marginal reward* is the (discounted) reward-to-go by taking the active action ($a = 1$) then following an optimal policy minus the (discounted) reward-to-go by taking the passive action ($a = 0$) then following an optimal policy;
- and the *marginal resource* is the (discounted) resource-to-go by taking the active action ($a = 1$) then following an optimal policy minus the (discounted) resource-to-go by taking the passive action ($a = 0$) then following an optimal policy;
- with the additional complexity that *optimal policy* here means optimal for the λ-price problem where λ equals the Whittle index in state x.

For examples of such expressions, see for instance: Niño-Mora (2002, equation (4.14), Theorem 4.7 and Section 6), Niño-Mora (2006, equation 19), Niño-Mora (2007, equation 6), Gittins et al. (2011, Theorem 6.4) and Larrañaga et al. (2016, Proposition 2). In particular, Niño-Mora (2002) appears to have been the first ever paper to use such marginal metrics to study questions of indexability, it also introduced resource metrics that are more general than those considered by Whittle (1988) and it established indexability of a general birth-death model. The intuition behind this expression is as follows. By definition, the Whittle index for state x corresponds to a price λ that makes both action 0 and action 1 optimal when in state x in the λ-price problem. Now, if both of these actions are optimal, then they are *equally good*. Let the reward-to-go by following policy π for a project $\mathcal{P} = \langle \mathcal{X}, c, r, \mathscr{Q}, \beta \rangle$ be denoted by

$$F(x, \pi) := \mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t r(X_t, A_t) \right], \tag{7}$$

let the resource-to-go be denoted by

$$G(x, \pi) := \mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t c(X_t, A_t) \right],$$

let $\langle a, \pi \rangle$ be the policy that first takes action a then follows policy π at subsequent times and let π_λ^* denote an optimal policy for the λ-price problem for project $\mathcal{P}$. Then the condition that the price λ makes actions 0 and 1 *equally good* in state x reads

$$F(x, \langle 0, \pi_\lambda^* \rangle) - \lambda G(x, \langle 0, \pi_\lambda^* \rangle) = F(x, \langle 1, \pi_\lambda^* \rangle) - \lambda G(x, \langle 1, \pi_\lambda^* \rangle).$$

This rearranges to give

$$\lambda = \frac{F(x, \langle 1, \pi_\lambda^* \rangle) - F(x, \langle 0, \pi_\lambda^* \rangle)}{G(x, \langle 1, \pi_\lambda^* \rangle) - G(x, \langle 0, \pi_\lambda^* \rangle)} \tag{8}$$

which is the ratio of a marginal reward to a marginal resource, as claimed. Unfortunately, this expression is usually only an *implicit* expression for λ, since the right-hand side involves π_λ^*. However, for projects of the multi-target tracking problem, this turns out to be an explicit expression, as we shall see below.

Literature on Restless Bandit Approach to Multi-Target Tracking. Whittle (1988) mentioned the problem of m aircraft tracking $n > m$ submarines as an example of a restless bandit problem. That problem seems rather an interesting challenge as it seems to couple multi-target tracking with a pursuit-evasion game. Nevertheless, the idea of taking a restless-bandit approach to multi-target tracking was discussed many times before anyone even experimented with such an approach, at least in the public literature. For instance, La Scala and Moran (2006) pointed out the potential interest of a restless multi-armed bandit approach to the multi-target tracking problem, but they did not pursue the Whittle index approach, rather focussing on trying to find conditions under which a one-step greedy policy is optimal when tracking a pair of targets with a single sensor. Also, Washburn (2008) reviewed applications of multi-armed bandit approaches to partially-observed sensor-management problems, expressing doubts as to whether Whittle's indexability conditions typically hold for such problems.

In contrast to such doubts, Le Ny et al. (2011) claimed to have found conditions under which the continuous-time version of the problem is indexable, at least for a scalar state, in the average-cost case, and with posterior variance as the cost function. A closer reading of that paper reveals that those authors present an incomplete argument leading to hypothetical values for optimal thresholds under the assumption that threshold policies are optimal. In particular, a key step of that argument is those authors' Theorem 1, which is Proposition 8 of Whittle (1988). This result gives an expression for the Whittle index, which the authors then invert to find a cubic equation for an optimal threshold. Now, as remarked by Whittle (1988, p. 295), *"that argument is formal, and conditions are certainly required for the calculations to make sense"*. However, Le Ny et al. (2011) do not try to find a suitable set of such conditions. Further, those authors *assume* the form of the optimal policy hoping that it can be verified a posteriori by substituting their expressions for an optimal threshold into the dynamic programming equation. However, they make no attempt to

perform such a substitution and in fact such a verification may prove challenging since the thresholds are given by a cubic equation, and because the dynamic programming equation involves the trajectory of the posterior variance which is the solution of a Ricatti differential equation. In summary, the arguments presented in Le Ny et al. (2011) are incomplete and do not convincingly demonstrate the optimality of threshold policies and the indexability for continuous-time systems.

Meanwhile, discrete-time versions of the problem have proved to be far more challenging. Niño-Mora and Villar (2009) made the first empirical evaluation of Whittle's index policy applied to the multi-target tracking problem with a scalar state in discrete time. That paper claims that the problem is indexable and suggests an approach to studying its indexability based on partial conservation laws, which is the approach that we take in Section 3 of this paper. However, it provides no proof or argument to substantiate this claim. The dissertation of Villar (2012) began a theoretical investigation of the problem, without establishing indexability of the model of concern. More recently, Dance and Silander (2015) proved that the index function is a monotone function of the variance state, but they did so under the assumption that threshold policies are optimal.

A number of closely-related problems have also been explored. For instance, Le Ny et al. (2008) and Liu and Zhao (2010) both establish indexability results about the tracking of n targets with *binary* state-spaces given $m < n$ sensors. Meanwhile, Niño-Mora (2016) empirically explored a Whittle's index approach to a generalisation of the multi-target tracking problem in which measurements are randomly jammed.

Whittle Index for the Multi-Target Tracking Problem. The above discussion prompts the third question addressed in this paper: *is each project of the multi-target tracking problem indexable, and if so, what is a computationally-convenient expression for the Whittle index of a project?* To state the first part of this question explicitly, consider a single project of the multi-target tracking problem, corresponding to one of n time series to be tracked with $m < n$ sensors. For each $\lambda \in \mathbb{R}$ and initial state $x \in \mathcal{I}$, the corresponding λ-price problem then to minimise the performance functional

$$\mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t \left(\lambda A_t + C(X_t) \right) \right] \tag{9}$$

with respect to the policy π for taking actions A_t where the state-sequence is given in terms of the variance updates of (4) as

$$X_0 = x, \qquad\qquad X_{t+1} = \phi_{A_t}(X_t),$$

for $t = 0, 1, \ldots$. The question is then whether there exists a simple-to-compute function $\lambda^* : \mathcal{I} \to \mathbb{R}$, for which action $A_t = 1$ is optimal if and only if $\lambda \leq \lambda^*(X_t)$, while action $A_t = 0$ is optimal if and only if $\lambda \geq \lambda^*(X_t)$, for all $t \in \mathbb{Z}_+$.

As suggested by Theorem 1 (Excerpt), to state a convenient expression for the Whittle index, some definitions concerning threshold policies should be useful. So, for any threshold $s \in \overline{\mathbb{R}}$, let the *s-threshold policy* be the policy that takes the action 1 if the state exceeds the threshold s and takes action 0 otherwise. Also, let $X_t(x, a; s)$ denote the state at time $t = 0, 1, \ldots$ if the system starts in state $x \in \mathcal{I}$ at time $t = 0$, then action $a \in \{0, 1\}$ is taken

and the s-threshold policy is followed thereafter, so that $A_t(x, a; s) := \mathbf{1}_{X_t(x,a;s)>s}$ for $t > 0$. The answer to our third question is then given by the following theorem, whose proof is given in Section 3.

Theorem 1 *Suppose A1 holds. Then the family of λ-price problems, given by equation (9), is indexable and for each $x \in \mathcal{I}$ the Whittle index is*

$$\lambda^*(x) := \frac{\sum_{t=0}^{\infty} \beta^t (C(X_t(x, 0; x)) - C(X_t(x, 1; x)))}{\sum_{t=0}^{\infty} \beta^t (A_t(x, 1; x) - A_t(x, 0; x))}.$$

Furthermore,

1. *If $\lambda^*(s) = \lambda$ for some $s \in \mathcal{I}$ then both of the following threshold policies are optimal:*

$$A_t = \mathbf{1}_{X_t > s}, \qquad\qquad A_t = \mathbf{1}_{X_t \geq s};$$

2. *If $\lambda^*(s) > \lambda$ for all $s \in \mathcal{I}$ then the always-active policy is the unique optimal policy;*
3. *If $\lambda^*(s) < \lambda$ for all $s \in \mathcal{I}$ then the always-passive policy is the unique optimal policy.*

This paper thus generalises the work of Dance and Silander (2015) by demonstrating that threshold policies are in fact optimal for the single project problem, which was Assumption A1 of (Dance and Silander, 2015). It also generalises by considering the case of multipliers $\bar{A} < 1$ rather than only considering $\bar{A} = 1$, where $\bar{A}$ is as in equation (1), and by considering cost functions $C(x) \neq x$ other than the (scaled) posterior variance.

1.5. Intuitive Guide to the Paper

As with other work on Markov decision processes, we work with the cost-to-go $Q(x, a)$ when starting in initial state x and taking initial action a, but then following an optimal policy. A common way to prove that threshold policies are optimal when the state x is real-valued, is to show that the difference $Q(x, 1) - Q(x, 0)$ is a non-increasing function of x. Such approaches have been studied by Serfozo (1976), Altman and Stidham Jr. (1995) and Altman et al. (2000). Unfortunately, as shown in Figure 1, such an approach fails for the process considered in this paper, even when the cost equals the variance.

Instead, this paper proves the optimality of threshold policies using a new verification theorem by Niño-Mora (Niño-Mora, 2015, 2019). This theorem applies to Markov decision processes that satisfy the so-called *partial conservation law indexability* (PCLI) conditions (Section 3). The central concept underlying the verification theorem is the *marginal productivity index* which turns out to be equal to the ratio $\lambda^*(\cdot)$ given in Theorem 1.

One of the PCLI conditions requires that the marginal productivity index is a non-decreasing and continuous function of the state x and that it is bounded from below. This is the most challenging of the conditions to verify. As a quick check, we plot $\lambda^*(x)$ in Figure 2. Although $\lambda^*(x)$ is increasing, the numerator and denominator have a fractal structure, so it is surprising that the index is continuous. Furthermore, if we subtract a cubic fit to $\lambda^*(x)$, the residual has a complicated sequence of cusps. Therefore the paper then focusses on characterising the sequence of actions $A_t(x, a; x)$ resulting from applying

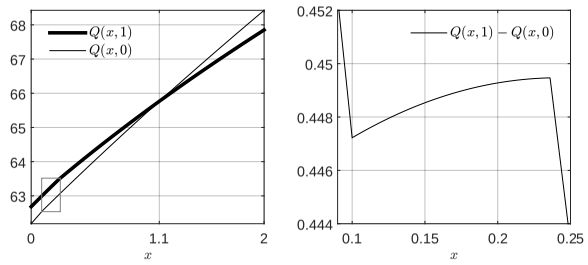

Figure 1: Counterexample to monotonicity of the difference in Q-functions. The functions $Q(x,0)$ and $Q(x,1)$ cross only a single time at $x = 1.1$ (*left plot*). However, the difference $Q(x,1) - Q(x,0)$ is increasing for some x (*right plot*, for x in the left plot's grey box). The model has $\beta = 0.95$, $C(x) = x$, $\phi_0(x) = x + 1$, $\phi_1(x) = 1/(\theta_1 + 1/(x+1))$ with $\theta_1 = 0.1$ and $\nu = 0.7647$.

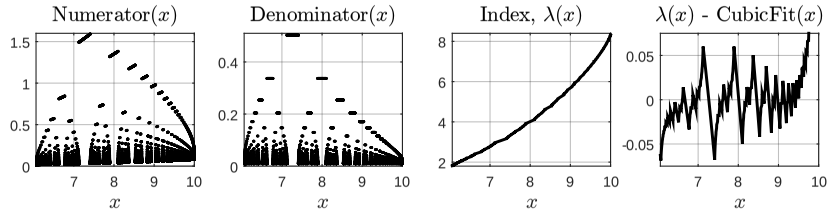

Figure 2: The numerator (*left*) and denominator (*mid-left*) of the index (*mid-right*), and the error in a cubic fit to the index (*right*). The model has cost $C(x) = x$, discount factor $\beta = 0.99$, map-with-a-gap $\phi_0(x) = r^2 x + 1$ and $\phi_1(x) = 1/(\theta_1 + 1/(r^2 x + 1))$ with $r^2 = 0.9$ and $\theta_1 = 0.01$.

an x-threshold policy, that give rise to this fractal pattern. We describe these sequences in terms of special binary strings that we call $\mathcal{M}$-*words* (Corollary 13 of Section 2). Such words include the set of all *Christoffel words* (Berstel et al., 2008) as well as a subset of the family of *Sturmian words* (Lothaire, 2002).

To understand what an $\mathcal{M}$-word is, consider the Cartesian coordinates $(x, y(x))$ of the points on a straight line $y(x) = \alpha x$ through the origin with slope $\alpha \in [0,1]$. To draw this line on a screen with pixel coordinates that are integer pairs, for each integer $\tilde{x}$ one might fill the pixel $(\tilde{x}, \tilde{y}(\tilde{x}))$ where $\tilde{y}(\tilde{x}) = \lfloor \alpha \tilde{x} \rfloor$. Now consider the differences $\Delta_{\tilde{x}} := \tilde{y}(\tilde{x}) - \tilde{y}(\tilde{x} - 1)$ for positive integers $\tilde{x}$. As α is in the range $[0,1]$ it follows that each such difference $\Delta_{\tilde{x}}$ is in the set $\{0,1\}$. Also, the sequence $\Delta := (\Delta_1, \Delta_2, \Delta_3, \dots)$ is periodic when α is rational and aperiodic when α is irrational. Correspondingly, the $\mathcal{M}$-*word of rate* α is the finite sequence $(\Delta_1, \Delta_2, \dots, \Delta_n)$ if Δ is periodic with (shortest) period n, and otherwise it is the infinite sequence Δ itself.

The characterisation of the action sequences $(A_t(x, a; x))_{t=0}^{\infty}$ viewed as a function of $x \in \mathcal{I}$ (noting that x represents both the initial state and the threshold) shows that the interval $\mathcal{I}$ can be partitioned into intervals corresponding to finite $\mathcal{M}$-words and points corresponding to infinite aperiodic $\mathcal{M}$-words. In the most important case for our analysis, x lies in such an interval and the denominator of the index involves periodic sequences of the form

$$\left.\begin{aligned}(A_t(x,1;x))_{t=0}^{\infty} &= (1, 0, p_1, \dots, p_n, 1, 0, p_1, \dots, p_n, \dots)\\ (A_t(x,0;x))_{t=0}^{\infty} &= (0, 1, p_1, \dots, p_n, 0, 1, p_1, \dots, p_n, \dots)\end{aligned}\right\} \tag{10}$$

for some binary sequence $(p_1, \dots, p_n)$. Thus the denominator equals

$$\sum_{t=0}^{\infty} \beta^t (A_t(x,1;x) - A_t(x,0;x)) = 1 - \beta + \beta^{n+2} - \beta^{n+3} + \dots = \frac{1-\beta}{1-\beta^{n+2}}.$$

Hence, the behaviour of the denominator in Figure 2 is given entirely by changes in the period $(n+2)$ of this binary sequence and does not depend on the values of $p_1, \dots, p_n$.

As this denominator equals a positive constant on such intervals, to show that the index is non-decreasing on such an interval, we show that the derivative of the numerator is non-negative. One key to proving this is the fact that the mappings $\phi_0(x)$ and $\phi_1(x)$ are Möbius transformations of the form

$$\mu_B(x) := \frac{B_{11}x + B_{12}}{B_{21}x + B_{22}}$$

for some $B \in \mathbb{R}^{2\times 2}$. Now the composition of Möbius transformations is homomorphic to matrix multiplication, so that

$$\mu_B(\mu_D(x)) = \mu_{BD}(x)$$

for any $B, D \in \mathbb{R}^{2\times 2}$. Further, if $\det(B) = 1$ then the derivative of the corresponding Möbius transformation is

$$\frac{d}{dx}\mu_B(x) = \frac{1}{(B_{21}x + B_{22})^2}$$

which is a convex function for $x \in \mathbb{R}_+$ and $B_{21}, B_{22} \in \mathbb{R}_{++}$. So the derivative of the numerator of the index, in the case $C(x) = x$, is of the form

$$\sum_{t=0}^{\infty} \frac{\beta^t}{(B_{21}^{(0,t)} x + B_{22}^{(0,t)})^2} - \sum_{t=0}^{\infty} \frac{\beta^t}{(B_{21}^{(1,t)} x + B_{22}^{(1,t)})^2}$$

where $(B^{(a,t)})_{t=0}^{\infty}$, for $a \in \{0, 1\}$, are sequences of 2×2 matrices that are determined by the action sequences $(A_t(x, a; x))_{t=0}^{\infty}$, but which otherwise do not depend on the value of x. This derivative is the difference of two sums, and each of these sums involves a sequence of convex functions $(z \mapsto \beta^t / z^2)_{t=0}^{\infty}$ applied to a sequence of linear functions of x. Inequalities involving such sums can be addressed by the theory of *majorisation* (Marshall et al., 2010), provided the sequences $(B_{21}^{(a,t)} x + B_{22}^{(a,t)})_{t=0}^{\infty}$ of linear functions of x satisfy certain *majorisation conditions* involving partial sums of those sequences. In the case where x lies in an interval such that the action sequences are given by (10), it turns out that those majorisation conditions are satisfied because the sequence $p_1, \ldots, p_n$ is a *palindrome*. That is, the sequence reads the same forwards as backwards, so that $p_k = p_{n-k}$ for $k = 1, \ldots, n-1$: see (11) for a proof of this well-known palindromic property of Christoffel words.

1.6. Structure of the Paper

First we relate the sequence of actions under threshold policies to $\mathcal{M}$*-words* (Section 2) before presenting proofs of our main results, Theorem 1 and Corollary 2 (Section 3). The proofs are based on Niño-Mora's theorem about the optimality of threshold policies (Section 3.1), which uses three *partial conservation law indexability (PCLI)* conditions. We use the properties of $\mathcal{M}$-words to demonstrate that each PCLI condition holds. These conditions concern the positivity of a *marginal resource* metric (Section 3.2), the continuity and non-decreasing nature of a *marginal productivity index* (Section 3.3), and a condition that characterises that index as a Radon-Nikodym derivative (Section 3.4). These results are then coupled into a proof of Theorem 1 (Section 3.5) and a proof of Corollary 2 is presented immediately thereafter (Section 3.6).

Having completed the proofs, we then turn to closed-form expressions for the index and numerical methods for evaluating it when such closed forms are not available (Section 4). We demonstrate the accuracy of such numerical methods and show how the index varies as its parameters change. Also, we compare the performance of Whittle's index policy with other well-known heuristics. Finally, we discuss interesting avenues for further work (Section 5). The appendices contain detailed proofs about the relation of itineraries to $\mathcal{M}$-words (Appendix A), of a key majorisation inequality (Appendix B) and about the linear systems orbits to which this majorisation result is applied (Appendix C).

2. Itineraries and Words

The transitions from state-to-state under threshold policies are given by a discontinuous mapping known as a *map-with-a-gap*, and the corresponding action sequence is known as the *itinerary* of that map. A detailed understanding of the properties of such itineraries is central to our proof of the optimality of threshold policies for the problems posed in the Introduction. So the main purpose of this section is to characterise these itineraries in terms

of special binary strings that we call $\mathcal{M}$*-words* and to discuss relevant properties of such words.

This section is structured as follows. We begin by introducing definitions and notations for itineraries (Section 2.1). As itineraries can be viewed as infinite strings, we then remind the reader of notations commonly used in the study of combinatorics on strings (Section 2.2). This notation enables us to define $\mathcal{M}$-words and an important subset of such words called the *Christoffel words* (Section 2.3). It also enables us to discuss properties of such words that are important for our proof of the optimality of threshold policies, notably a palindromic property (11), a description of the lexicographic ordering of the cyclic rotations of such words which are called *conjugates* (Lemma 8), and a description of the prefixes of $\mathcal{M}$-words (Lemma 10). Finally, we introduce three results (Theorem 12, Corollary 13 and Theorem 14) which describe itineraries in terms of $\mathcal{M}$-words, for a variety of relations between the threshold and initial state, and for versions of the threshold policy that are either active or passive at the threshold (Section 2.4).

2.1. Maps-with-Gaps

Many phenomena involve the iterated application of discontinuous maps or *maps-with-gaps* in the terminology of Hogan et al. (2007). Such phenomena are important in control problems (Haddad et al., 2014), in physics, electronics and mechanics (Bernardo et al., 2008; Makarenkov and Lamb, 2012), economics (Tramontana et al., 2010), biology and medicine (Aihara and Suzuki, 2010). Such maps either arise directly from a discrete-time model or they may arise as the Poincaré maps of continuous-time systems. The *orbit* and *itinerary* of the following definition, which is illustrated in Figure 3, are the standard way to describe the behaviour of such maps in the study of dynamical systems (Devaney, 2008).

Definition 5 *Consider an interval $\mathcal{I}$ of $\mathbb{R}$, functions $\phi_0 : \mathcal{I} \to \mathcal{I}$ and $\phi_1 : \mathcal{I} \to \mathcal{I}$, an initial state $x \in \mathcal{I}$ and a threshold $s \in \overline{\mathbb{R}}$. The* ***s*-threshold orbit** *from x for ϕ_0 and ϕ_1, denoted by* $\mathrm{orbit}(x|s, \phi_0, \phi_1)$*, is the sequence $(x_k)_{k=1}^{\infty}$ with*

$$x_1 = x \quad \textit{and} \quad x_{k+1} = \begin{cases} \phi_0(x_k) & \textit{if } x_k \leq s \\ \phi_1(x_k) & \textit{if } x_k > s. \end{cases}$$

In terms of that sequence, the ***s*-threshold itinerary** *from x for ϕ_0 and ϕ_1 is the infinite binary string $\sigma(x|s, \phi_0, \phi_1)$ with letters $\sigma(x|s, \phi_0, \phi_1)_k := \mathbf{1}_{x_k > s}$ for $k \in \mathbb{Z}_{++}$.*

Looking ahead, when we use the results of this section to prove Theorem 1, the mappings in the above definition will represent the transitions of a (relative) variance state. Thus ϕ_0, ϕ_1 and the interval $\mathcal{I}$ will satisfy Assumption A1 after a change of coordinates (as discussed straight after Theorem 12). However, the analysis of this section and Appendix A applies to *any* real interval $\mathcal{I}$ if not otherwise stated, and in most cases the analysis will make Assumption A2.

In most cases, the maps ϕ_0 and ϕ_1 are clear from the context, so we talk of the s-threshold orbit from x, denoted by $\mathrm{orbit}(x|s)$, and the s-threshold itinerary from x, denoted by $\sigma(x|s)$. Also, we use of the s^-*-threshold orbit* from x, which is the left limit $\mathrm{orbit}(x|s^-) =$

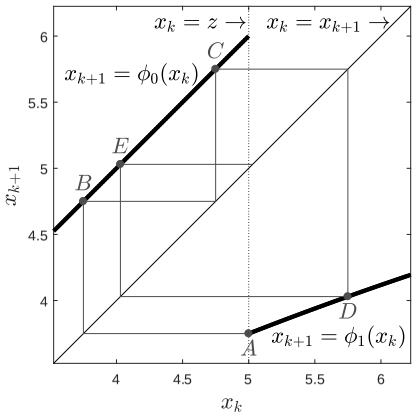

Figure 3: Map-with-a-gap. The s^--threshold orbit from $x = 5$ traces the path $ABCDE\ldots$ corresponding to the itinerary $10010\ldots$. The map has $\phi_0(x) = x + 1$, $\phi_1(x) = 1/(\theta_1 + 1/(x + 1))$ with $\theta_1 = 0.1$ and threshold $s = 5$.

$\lim_{s' \uparrow s} \text{orbit}(x|s') = (x_k)_{k=1}^{\infty}$ with

$$x_1 = x \quad \text{and} \qquad x_{k+1} = \begin{cases} \phi_0(x_k) & \text{if } x_k < s \\ \phi_1(x_k) & \text{if } x_k \geq s \end{cases}$$

and the corresponding *s^--threshold itinerary* from x, with letters $\sigma(x|s^-)_k := \mathbf{1}_{x_k \geq s}$ for $k \in \mathbb{Z}_{++}$. These left limits exist provided the maps ϕ_0, ϕ_1 are continuous, which is true when Assumption A2 holds (Lemma 32).

It is helpful to view such itineraries as *words* as we now explain.

2.2. Standard Definitions about Words

We remind the reader of standard definitions used in the study of the combinatorics of strings: see for instance Lothaire (2002) and Berstel et al. (2008).

In this paper, a *word* w is a string on the alphabet $\{0, 1\}$ and the empty word is denoted by ϵ. The *length* of a word w is the number of letters in the string, which is finite or countably infinite, and is denoted by $|w|$. The k^{th} letter of word w is w_k for $k \in \mathbb{Z}_{++}$ with $k \leq |w|$. Letters i-through-j of word w are denoted by $w_{i:j} := w_i w_{i+1} \ldots w_j$ for $i, j \in \mathbb{Z}_{++}$ with $i \leq j \leq |w|$. For $j < i$, we treat $w_{i:j}$ as the empty word. The *reverse* word of a finite word w is denoted by $w^R := w_{|w|} \ldots w_2 w_1$. A finite word satisfying $w^R = w$ is called a *palindrome*.

The *concatenation* of a finite word u and a word v is denoted by uv. For $n \in \mathbb{Z}_+$, the n-fold concatenation of a finite word w is denoted by w^n, with the convention that $w^0 = \epsilon$, and the word resulting from infinitely concatenating the word w is denoted by w^∞. For an infinite word w and $n \in \mathbb{Z}_{++}$ we define $w^n = w^\infty = w$.

A finite word f is a *factor* of a word w if $w = ufv$ for some finite word u and some word v. The number of times that word f appears in w, overlapping appearances included, is denoted by $|w|_f$. A finite word p is a *prefix* of word w if $w = ps$ for some word s and a word s is a *suffix* of word w if $w = ps$ for some finite word p.

We say that a word u is *lexicographically less than* a word v, written $u \prec v$, if either u is a finite word and $v = ua$ for some non-empty word a, or if $u = a0b$ and $v = a1c$ for some finite word a and some words b and c. We use $\succ$, $\preceq$ and $\succeq$ for the other lexicographic ordering relations.

We say an infinite word w is the *limit* of a sequence of words $(w^{(n)})_{n=1}^{\infty}$ and write $w = \lim_{n\to\infty} w^{(n)}$ if for each $i \in \mathbb{Z}_{++}$ there is an $n \in \mathbb{Z}_{++}$ such that $w_i = w_i^{(m)}$ for all $m \in \mathbb{Z}_{++}$ with $m \geq n$.

The *rate* of any finite non-empty word w is the ratio $\text{rate}(w) := |w|_1/|w|$ whereas for an infinite word w, when the limit exists, we define $\text{rate}(w) := \lim_{n\to\infty} |w_{1:n}|_1/n$. While some authors refer to such ratios as the "slope" of a word, we use the term "rate" as the "slope" of a word w is sometimes defined as the ratio $|w|_1/|w|_0$ and this seems justified from a geometrical point of view in terms of *digital straight lines* (Berstel et al., 2008).

Examples. For $w = 010111$ we have $|w| = 6$, $w_3 = 0$, $w_{2:4} = 101$, $|w|_{01} = |w|_{11} = 2$ and $w^2 = ww = 010111010111$. Also for $a = 01, b = 11$ we have $w = aab$ and $a \prec w \prec b$.

2.3. $\mathcal{M}$-Words

We characterise itineraries of maps-with-gaps in terms of the following type of words.

Definition 6 *The **$\mathcal{M}$-word** of rate $\alpha \in [0, 1]$ is the shortest word w such that*

$$(w^\infty)_n = \lfloor \alpha n \rfloor - \lfloor \alpha(n-1) \rfloor \quad \textit{for } n \in \mathbb{Z}_{++}.$$

*If α is rational then w is called a **Christoffel word**. If α is irrational then w is called a **Sturmian $\mathcal{M}$-word.***

Example. The shortest $\mathcal{M}$-words are the words $0, 1$ and 01 with rates $0, 1$ and $\frac{1}{2}$.

The notion of a Christoffel word is a standard one (Berstel et al., 2008). Also, *Sturmian words* have been studied intensively, for instance Lothaire (2002, Chapter 2) says an infinite word w is Sturmian if it has $n+1$ distinct factors of length n for any integer $n \geq 0$. Lothaire (2002) then goes on to explore many other definitions of Sturmian words that turn out to be equivalent. Our intention in defining $\mathcal{M}$-words is to group together the Christoffel words with a specific subset of Sturmian words, so that together they characterise the possible itineraries of a large class of maps-with-gaps, as described in Theorem 16.

We call such words $\mathcal{M}$-words as our definition is closely related to the set of *mechanical words*. For a given *slope* $\alpha \in [0, 1]$ and *intercept* $\rho \in \mathbb{R}$, Morse and Hedlund (1940) defined the *upper* and *lower mechanical words* to be the infinite sequences, for $n \in \mathbb{Z}_+$,

$$u_n = \lceil \alpha(n+1) + \rho \rceil - \lceil \alpha n + \rho \rceil$$

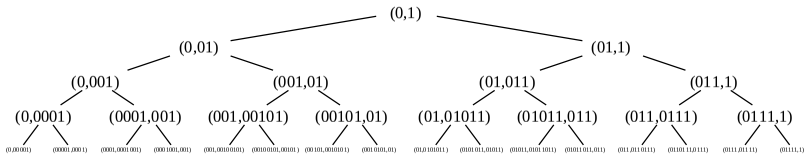

Figure 4: Part of the Christoffel tree.

$$l_n = \lfloor \alpha(n+1) + \rho \rfloor - \lfloor \alpha n + \rho \rfloor$$

Lothaire (2002) and Berstel et al. (2008) offer rich introductions to the mathematics of mechanical words, while Bousch and Mairesse (2002) and Altman et al. (2000) explore other optimisation problems that give rise to such words. Our $\mathcal{M}$-words are prefixes of lower-mechanical-words-of-zero-intercept up to a change of indexing from $n \in \mathbb{Z}_+$ to $n \in \mathbb{Z}_{++}$.

It is not hard to see that the Christoffel word of rate a/b, where a, b are relatively-prime integers, has length b. In contrast, Sturmian $\mathcal{M}$-words are infinite and aperiodic.

In general the $\mathcal{M}$-word w of rate α does have $\text{rate}(w) = \alpha$. Indeed if w is the $\mathcal{M}$-word of rate a/b for some $a, b \in \mathbb{Z}_{++}$, then

$$\text{rate}(w) = |w|_1/|w| = \lfloor (a/b)|w| \rfloor / |w| = a/b,$$

whereas, if w is an $\mathcal{M}$-word of irrational rate α, then

$$\text{rate}(w) = \lim_{n\to\infty} |w_{1:n}|_1/n = \lim_{n\to\infty} \lfloor \alpha n \rfloor / n = \alpha.$$

Furthermore, as remarked by Christoffel (1875), all Christoffel words other than the words 0 and 1 are of the form $0p1$ where the word p is a *palindrome*. Indeed for relatively-prime positive integers $m < n$, the letters of the Christoffel word w of rate m/n satisfy

$$w_{n-k} = \left\lfloor \frac{m}{n}(n-k) \right\rfloor - \left\lfloor \frac{m}{n}(n-k-1) \right\rfloor = \left\lfloor -\frac{m}{n}k \right\rfloor - \left\lfloor -\frac{m}{n}(k+1) \right\rfloor = w_{k+1} \tag{11}$$

for $k = 1, 2, \ldots, n-2$.

The Christoffel words can be defined in other ways. In this paper the most important alternative-but-equivalent definition is in terms of the *Christoffel tree* (Figure 4), which is an infinite complete binary tree (Berstel et al., 2008) in which each node is labelled with a pair (u, v) of words, called a *Christoffel pair*. The root of the tree is labelled with the pair $(0, 1)$ and the left and right children of node (u, v) are the nodes (u, uv) and (uv, v) respectively. In fact the Christoffel words are the words $0, 1$ and the set of concatenations uv for all (u, v) in the Christoffel tree.

Another definition of Christoffel words is in terms of modular arithmetic, as in the following lemma, where we use a bar to denote the remainder modulo the length $n = |w|$ of a Christoffel word w, so that $\overline{x} := x \bmod n$ for $x \in \mathbb{Z}$, and for any positive integer n, the set of integers modulo n is denoted by $\mathbb{Z}_n := \{0, 1, \ldots, n-1\}$. The following lemma does not explicitly appear in Berstel et al. (2008) but is easily related to multiple discussions of modular arithmetic in that book.

Lemma 7 *Suppose w is a Christoffel word of length n. Let $m := |w|_1$ and $p := |w|_0$. Then*

$$w_{i+1} = \mathbf{1}_{\overline{mi} \geq p} \qquad (i \in \mathbb{Z}_n).$$

Proof As $n\lfloor mi/n \rfloor = mi - \overline{mi}$, the definition of Christoffel words gives

$$\begin{aligned} w_{i+1} &= -\lfloor mi/n \rfloor + \lfloor m(i+1)/n \rfloor \\ &= (-mi + \overline{mi} + m(i+1) - \overline{m(i+1)})/n \\ &= (-mi + \overline{mi} + m(i+1) - (\overline{mi} + m - n\mathbf{1}_{\overline{mi} \geq n-m}))/n, \end{aligned}$$

which simplifies to $\mathbf{1}_{\overline{mi} \geq p}$, as claimed. ■

Finally, we give two results about $\mathcal{M}$-words that play a key role elsewhere in the paper. The first result is about *conjugacy* and lexicographic order. In particular, we say two finite words a and b are conjugate if $a = uv$ and $b = vu$ for some words u and v. For instance, the words $a = 00011$ and $b = 01100$ are conjugate. Words that are conjugate can be viewed as cyclic shifts of each other, like the X86 assembler instruction ROL. The notion of conjugate words is also standard in the study of the combinatorics of strings (Lothaire, 2002; Berstel et al., 2008). The following lemma is rather similar to Berstel et al. (2008, Exercise 6.3, p. 49), where an outline of its proof is suggested, although the result that we state is more specific about the lexicographic ordering of the conjugates.

Lemma 8 *Suppose w is a Christoffel word of length n and that l satisfies $\overline{lm} = 1$ where $m = |w|_1$. Then the conjugates $u(i) := w_{\overline{(i+1)}:n} w_{1:\overline{i}}$ satisfy*

$$w = u(0) \prec u(l) \prec u(2l) \prec \cdots \prec u((n-1)l) = w^R.$$

Furthermore, if the words c and d satisfy $w = 0dc1$, then $c01d$ and $c10d$ are lexicographically-consecutive conjugates of w.

Proof Let $x_i := \overline{mi - 1}$, $y_i := \overline{mi}$ and $p := n - m$. Then $x_0 = n - 1$ and $x_{n-1} = p - 1$. As $\gcd(m, n) = 1$, the sequence $x_0, \ldots, x_{n-1}$ is a permutation of $\mathbb{Z}_n$. So, $x_i \notin \{p-1, n-1\}$ for $i \in \{1, \ldots, n-2\}$. As $y_i = \overline{x_i + 1}$ these results give

$$\begin{aligned} \mathbf{1}_{x_i \geq p} &> \mathbf{1}_{y_i \geq p} && \text{for } i = 0 \\ \mathbf{1}_{x_i \geq p} &= \mathbf{1}_{y_i \geq p} && \text{for } i = 1, \ldots, n-2 \\ \mathbf{1}_{x_i \geq p} &< \mathbf{1}_{y_i \geq p} && \text{for } i = n-1. \end{aligned}$$

But Lemma 7 gives $u(0)_{j+1} = \mathbf{1}_{y_j \geq p}$ and $u((n-1)l)_{j+1} = \mathbf{1}_{x_j \geq p}$ for $j \in \mathbb{Z}_n$. Thus $u(0) = 0a1$ and $u((n-1)l) = 1a0$ for some word a. But $u(0) = w$ and w is a Christoffel word, so a is a palindrome. Therefore $u((n-1)l) = w^R$.

Now for $i = 0, \ldots, n-2$, the conjugates $u(il)$ and $u((i+1)l)$ are related to $u((n-1)l)$ and $u(0)$ respectively by the same non-zero cyclic rotation. Thus $u(il) = c01d$ and $u((i+1)l) = c10d$ for some words c and d with $dc = a$. Therefore $u(il) \prec u((i+1)l)$. ■

To illustrate this lemma, consider the Christoffel word $w = 00101$. As $n = |w| = 5$ and $m = |w|_1 = 2$, we set $l = 3$ so that $\overline{lm} = 1$. The sequence $(u(kl))_{k=0}^{n-1}$ of conjugates of w as defined in the lemma is then

$$\begin{aligned} u(0) &= 00101 \\ u(3) &= 01001 \\ u(6) &= 01010 \\ u(9) &= 10010 \\ u(12) &= 10100 \end{aligned}$$

which is indeed the same as the conjugates arranged in increasing lexicographic order. This lemma plays a key role in showing that the index function in Theorem 1 is non-decreasing in the case that the cost function $C(\cdot)$ is convex, by enabling the application of a rearrangement inequality at Steps (29) and (30) of the corresponding proof.

The second result shows how the prefixes of $\mathcal{M}$-words vary as a function of their rates. It requires one more definition, which is well known: see for instance Graham et al. (1994).

Definition 9 *For each positive integer n, the **Farey sequence** F_n is the sequence of rational numbers on $[0, 1]$ whose denominator is at most n, sorted in increasing order.*

Clearly, it is implicit in this definition that the numerator and denominator of each such rational number are relatively prime. For example, the Farey sequence F_5 is

$$0, \frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{2}{5}, \frac{1}{2}, \frac{3}{5}, \frac{2}{3}, \frac{3}{4}, \frac{4}{5}, 1.$$

Lemma 10 *Suppose $n \in \mathbb{Z}_{++}$ and $q \in [0, 1]$. Let $q_1 < q_2 < \cdots < q_m$ be the Farey sequence F_n. Let $p(s)$ be the first n letters of the word w^∞ where w is the $\mathcal{M}$-word of rate $s \in [0, 1]$. Then $p(q) = p(q_i)$ if and only if either $q = q_i = 1$ or $q \in [q_i, q_{i+1})$ for some $1 \le i < m$.*

Proof Let $b(q) := (\lfloor q \rfloor, \lfloor 2q \rfloor, \ldots, \lfloor nq \rfloor)$ and consider the intervals $\mathcal{Q}_i := [q_i, q_{i+1})$ for $i < m$ and $\mathcal{Q}_m := \{1\}$. As the line $y = qx$ hits an integer point $(x, y) \in \mathbb{Z}^2$ with $1 \le x \le n$ and $0 \le y \le x$ if and only if q is an element of F_n, it follows that $b(q) = b(q_i)$ if and only if $q \in \mathcal{Q}_i$. Let $g(x_1, x_2, \ldots, x_n) := (x_1, x_2 - x_1, \ldots, x_n - x_{n-1})$. By definition of $\mathcal{M}$-words, $p(q) = g(b(q))$. As g is invertible it follows that $p(q) = p(q_i)$ if and only if $q \in \mathcal{Q}_i$. ■

2.4. Characterising Itineraries with $\mathcal{M}$-Words

Our aim here is to characterise the itineraries of maps-with-gaps. We first set up some notation and then demonstrate a simple result about the lexicographical ordering of itineraries. Then we state an assumption under which Theorem 12 guarantees that itineraries correspond to specific $\mathcal{M}$-words.

Let $\mathcal{I}$ be an interval of $\mathbb{R}$ and consider two mappings $\phi_0 : \mathcal{I} \to \mathcal{I}$ and $\phi_1 : \mathcal{I} \to \mathcal{I}$. For any finite word w, the *composition* $\phi_w : \mathcal{I} \to \mathcal{I}$ is the mapping

$$\phi_w(x) := \phi_{w_{|w|}} \circ \cdots \circ \phi_{w_2} \circ \phi_{w_1}(x) \quad \text{and} \quad \phi_\epsilon(x) := x.$$

A simple application of compositions gives the following result about lexicographic ordering of the itineraries $\sigma(\cdot|s)$ of a map-with-a-gap given by mappings $\phi_0 : \mathcal{I} \to \mathcal{I}$ and $\phi_1 : \mathcal{I} \to \mathcal{I}$ and threshold s. We remind the reader that this paper uses *increasing* and *decreasing* in the strict sense.

Lemma 11 *Suppose ϕ_0, ϕ_1 are increasing mappings and that $x, y \in \mathcal{I}$ with either $\sigma(x|s^-) \prec \sigma(y|s^-)$ or $\sigma(x|s) \prec \sigma(y|s)$. Then $x < y$.*

Proof If $\sigma(x|s^-) \prec \sigma(y|s^-)$ then $\sigma(x|s^-) = a0b$ and $\sigma(y|s^-) = a1c$ for some finite word a and some infinite words b, c, by the definition of lexicographic order. So, the definition of $\sigma(\cdot|s^-)$ gives $\phi_a(x) < s \le \phi_a(y)$. But $\phi_a(\cdot)$ increasing as it is a finite composition of increasing functions. It follows that $x < y$. The proof for $\sigma(\cdot|s)$ is similar. ■

However, without additional assumptions about the mappings ϕ_0, ϕ_1, it is not possible to precisely characterise the itineraries of the associated maps-with-gaps. In order to state such an assumption, we shall say that a map $f : \mathcal{I} \to \mathcal{I}$, where $\mathcal{I}$ is an interval of $\mathbb{R}$ is *contractive* if for all $x, y \in \mathcal{I}$ with $x \ne y$, we have

$$|f(y) - f(x)| < |y - x|.$$

Also, a *fixed point* of such a map f is any $x \in \mathcal{I}$ for which the equation $x = f(x)$ is satisfied.

Assumption A2
Functions $\phi_0 : \mathcal{I} \to \mathcal{I}$ and $\phi_1 : \mathcal{I} \to \mathcal{I}$, where $\mathcal{I}$ is an interval of $\mathbb{R}$, are increasing, contractive and have unique fixed points y_0 and y_1 on $\mathcal{I}$ which satisfy $y_1 < y_0$.

Not all the maps-with-gaps considered in this paper satisfy Assumption A2 directly. For instance, the function $\phi_0(x) = x + 1$, which corresponds to Kalman-filter update of equation (3) in the case of an uninformative observation (for $A = 1, \Sigma_X = 1$ and $\Sigma_Y(0) \to \infty$), is not contractive. This can be addressed by a change of coordinates, and is discussed in the remark following Theorem 12.

Before using Assumption A2 to characterise the itineraries of maps-with-gaps, we must first clarify the notion of fixed points. A *fixed point* for a finite word w, is a solution to the equation $x = \phi_w(x)$. If Assumption A2 holds, then Lemma 32 in Appendix A.1 shows that there is a unique such fixed point on $\mathcal{I}$ for any finite non-empty word w and we shall denote it by y_w.

In general, it is not clear what a "fixed point" corresponding to an *infinite* word w might mean. One approach might be to consider a sequence $(w^{(n)})_{n=1}^\infty$ of words with $w = \lim_{n\to\infty} w^{(n)}$ and to define "y_w" as $\lim_{n\to\infty} y_{w^{(n)}}$ if that limit exists. However, for any word b, the sequence with elements $w^{(n)}b$ also converges to w and it is not hard to find examples where

$$\lim_{n\to\infty} y_{w^{(n)}} \ne \lim_{n\to\infty} y_{w^{(n)}b}.$$

Therefore we shall only define fixed points for a particular class of infinite words, as follows. Let $0s$ be the Sturmian $\mathcal{M}$-word of rate α. Consider the sequence of Christoffel words $0w^{(n)}1$ that lie on the following path through the Christoffel tree. We start from the root,

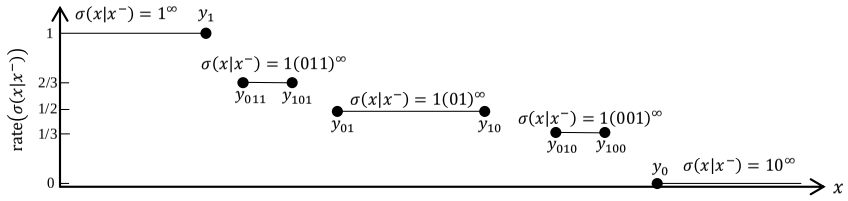

Figure 5: The itinerary $\sigma(x|x^-)$ of Theorem 12. The filled circles in this plot emphasise that the corresponding intervals are closed.

so that $w^{(1)} = \epsilon$. Then for $n \in \mathbb{Z}_{++}$, we set $0w^{(n+1)}1$ equal to the left child of $0w^{(n)}1$ if the rate of $0w^{(n)}1$ exceeds α and equal to the right child otherwise. We call

$$y_s := \lim_{n\to\infty} y_{01w^{(n)}} = \lim_{n\to\infty} y_{10w^{(n)}}$$

the *fixed point* of the Sturmian $\mathcal{M}$-word $0s$. The fact that these limits exist and are equal is proved as Lemma 55 in Appendix A.3.

We are now ready to fully characterise the itineraries of maps-with-gaps, or equivalently to describe the action sequences resulting from applying threshold policies, under Assumption A2. We do so in three cases. Theorem 12 considers the itinerary $\sigma(x|x^-)$ of an active-at-threshold map with initial state equal to the threshold. Corollary 13 considers the pair of itineraries for a passive-at-threshold map with initial states $\phi_0(x)$ or $\phi_1(x)$ for threshold x. Finally, Theorem 14 characterises the itinerary $\sigma(x|s)$ in the general case where the initial state x is unrelated to the threshold s.

Let us begin with an intuitive description of our characterisation of the itineraries $\sigma(x|x^-)$ of active-at-threshold maps with initial state x equal to the threshold. This description is illustrated by Figure 5. Firstly, all such itineraries begin with the letter or action 1, since the initial state equals the threshold. For low values of x, at or below the fixed point y_1 of the map $\phi_1(\cdot)$, taking action 1 leaves the state at or above the threshold, so the itinerary repeats 1 for ever. Similarly, for large values of x, at or above the fixed point y_0 of the map $\phi_0(\cdot)$, after taking action 1, the orbit never goes as high as its initial state again, so the itinerary repeats 0 for ever. Meanwhile, at intermediate values of x, there is an interval $[y_{01}, y_{10}]$ for which the itinerary repeats the Christoffel word 01 for ever. Given that $y_{10} > y_{01}$, such a ping-pong behaviour is very intuitive for x in the set $\{y_{01}, y_{10}\}$, since $\phi_0(y_{01}) = y_{10}$ and $\phi_1(y_{10}) = y_{01}$ by definition of the fixed points.

For other values of x, the itinerary is more complex. In fact, for any Christoffel word, there is an interval of positive length for which the itinerary simply repeats that word over and over again. See for instance the interval $[y_{011}, y_{101}]$ in Figure 5 on which the itinerary repeats the Christoffel word 011, or the interval $[y_{010}, y_{100}]$ on which it repeats the word 001. Now, between these intervals of positive length, there are individual *points* at which the itinerary equals any given Sturmian $\mathcal{M}$-word. Such points are not shown in Figure 5 but lie somewhere in the gaps between the intervals that are shown. Furthermore, as x

increases through the interval $\mathcal{I}$, the itinerary goes through all the $\mathcal{M}$-words in order of decreasing rate, and it never takes a value that is not given by an $\mathcal{M}$-word.

In the following theorem, let $\{0,1\}^\infty$ denote the set of all infinite binary strings and let $\{0,1\}^+$ denote the set of all finite non-empty binary strings. Also, the *image* of a function is the subset of the function's range consisting of those values that the function takes for some point in the function's domain. Although in general an itinerary $\sigma(x|x^-)$ is in $\{0,1\}^\infty$, the following theorem shows that, under Assumption A2, the itinerary comes from a very specific subset of such binary strings that is generated by the set of $\mathcal{M}$-words.

Theorem 12 *Suppose A2 holds, $0p1$ is a Christoffel word and $0s$ is a Sturmian $\mathcal{M}$-word. Then the fixed points y_{01p}, y_{10p}, y_s exist in $\mathcal{I}$. Also, the itinerary $\sigma(x|x^-)$ is a lexicographically non-increasing function of $x \in \mathcal{I}$ and is of the form $\sigma(x|x^-) = 1\ell(x)^\infty$ for some mapping $\ell : \mathcal{I} \to \{0,1\}^\infty \cup \{0,1\}^+$ whose image is the set of $\mathcal{M}$-words. Specifically,*

$$\sigma(x|x^-) = \begin{cases} 1^\infty & \text{if and only if } x \le y_1 \\ (10p)^\infty & \text{if and only if } x \in [y_{01p}, y_{10p}] \\ 10s & \text{if and only if } x = y_s \\ 10^\infty & \text{if and only if } x \ge y_0. \end{cases}$$

See Appendix A.4 for a proof. This result is previously known for *linear* maps-with-gaps (Rajpathak et al., 2012), although those authors do not draw any relation to mechanical words. Dance and Silander (2015) previously extended those authors' proof to the nonlinear case under Assumption A2. The proof presented in Appendix A of this paper can be seen as a simplification of that extension. On the other hand, it is known that itineraries of a broader class of nonlinear maps-with-gaps that do not necessarily satisfy Assumption A2 also correspond to mechanical words (Kozyakin, 2003). However such generality comes at a cost, as it is not clear in that work which range of thresholds gives rise to which words.

Remark. Not all the maps-with-gaps considered in this paper satisfy Assumption A2. However, this does not always prevent the application of Theorem 12. Notably for $\mathcal{I} := [0, \infty)$ and $\theta \in (0, \infty)$, the pair

$$\phi_0(x) = x + 1, \qquad \phi_1(x) = 1/(\theta + 1/(x + 1))$$

involves the non-contractive map ϕ_0. Nevertheless, after the change of coordinates

$$g : x \mapsto x/(x + 1),$$

the transformed functions

$$\tilde{\phi}_0(x) := g(\phi_0(g^{(-1)}(x))) = 1/(2 - x), \qquad \tilde{\phi}_1(x) := g(\phi_1(g^{(-1)}(x))) = 1/(2 + \theta - x)$$

and the interval $\tilde{\mathcal{I}} := [0, 1]$ do satisfy Assumption A2. Indeed

$$\frac{d\tilde{\phi}_1(x)}{dx} = 1/(2 + \theta - x)^2 \in (0, 1]$$

for $x \in \tilde{\mathcal{I}}$ and $\theta \in [0, \infty)$, and this derivative only equals 1 for the endpoint $x = 1$. Thus $\tilde{\phi}_1$ is increasing and contractive on $\tilde{\mathcal{I}}$. Noting that $\tilde{\phi}_0(x) = \lim_{\theta \to 0} \tilde{\phi}_1(x)$, the same holds for $\tilde{\phi}_0$. Also $\tilde{\phi}_1$ has a fixed point at $y(\theta) = (2 + \theta - \sqrt{\theta^2 + 4\theta})/2$ which lies in $\tilde{\mathcal{I}}$ for $\theta \in [0, \infty)$, and $\tilde{\phi}_0$ has a fixed point at $y(0) = 1 > y(\theta)$. As g is an increasing function, all conclusions of Theorem 12 still hold for the original functions ϕ_0, ϕ_1.

Pairs of Itineraries. As we are particularly interested in expressions like the Whittle index in Theorem 1, it is important to have a result characterising itineraries starting from $\phi_0(x)$ and $\phi_1(x)$, as in the following Corollary of Theorem 12, whose proof is given as Appendix A.5.

Corollary 13 *Suppose A2 holds,* $0p1$ *is a Christoffel word and* $0s$ *is a Sturmian* $\mathcal{M}$*-word. Then the pair of itineraries* $(\sigma(\phi_0(x)|x), \sigma(\phi_1(x)|x))$ *is given by*

$$\begin{cases} (1^\infty, 1^\infty) & \text{if } x < y_1 \\ (1^\infty, 01^\infty) & \text{if } x = y_1 \\ ((1p0)^\infty, (0p1)^\infty) & \text{if } x \in [y_{01p}, y_{10p}) \\ ((1p0)^\infty, 0p(01p)^\infty) & \text{if } x = y_{10p} \\ (1s, 0s) & \text{if } x = y_s \\ (0^\infty, 0^\infty) & \text{if } x \geq y_0. \end{cases}$$

Looking ahead, applying this corollary to the problem addressed in Theorem 1 shows that the interval $\mathcal{I}$ can be partitioned into intervals corresponding to Christoffel words on which the marginal resource $g(x, x)$ of Section 3 is a constant function of x and points corresponding to Sturmian $\mathcal{M}$-words. In particular, this partition of the interval $\mathcal{I}$ is central to our analysis of the the marginal productivity index $m^*(x)$ in Section 3.3.

Discontinuities of the Itinerary. We conclude this section by considering the number of discontinuities of the mapping from the threshold to the length-n prefix of the itinerary, for any given positive integer n. We show that this number of discontinuities can be upper-bounded by a polynomial function of n. Now for any finite word w and state $x \in \mathcal{I}$, the map $s \mapsto \mathbf{1}_{s < \phi_w(x)}$ is right continuous. Also, if Assumption A2 holds, then the map ϕ_w is continuous (Lemma 32), and it then follows from Definition 5 that the itinerary satisfies $\sigma(x|s)_{1:n} = \sigma(x|s^+)_{1:n}$ for any $n \in \mathbb{Z}_+$, and that the limit $\sigma(x|s^-)_{1:n}$ exists. Thus, in the following theorem, a *discontinuity* of the mapping $s \mapsto \sigma(x|s)_{1:n}$ is a point $d \in \mathcal{I}$ at which its left and right limits disagree, so that $\sigma(x|d^-)_{1:n} \neq \sigma(x|d^+)_{1:n}$. Also, in the following theorem, we say that a finite word w is a *factor of a lower mechanical word* if there exists a slope $\alpha \in [0, 1]$ and an intercept $\rho \in \mathbb{R}$ such that $w_n = \lfloor \alpha(n+1) + \rho \rfloor - \lfloor \alpha n + \rho \rfloor$ for $n = 1, 2, \ldots, |w|$.

Theorem 14 *Suppose* ϕ_0, ϕ_1 *satisfy A2, that* $n \in \mathbb{Z}_{++}$ *and* $x \in \mathcal{I}$*. Then* $\sigma(x|s)$ *is a lexicographically non-increasing function of* $s \in \mathcal{I}$*. Also, for any fixed* $x, s \in \mathcal{I}$*, we have*

$$\sigma(x|s)_{1:n} = l^m w$$

for some $l \in \{0, 1\}$*, some* $m \in \{0, 1, \ldots, n\}$*, and some factor* w *of a lower mechanical word. Furthermore, for any* $x \in \mathcal{I}$*, the mapping* $s \mapsto \sigma(x|s)_{1:n}$ *for* $s \in \mathcal{I}$ *has at most a polynomial number* $p(n)$ *of discontinuities.*

This result is an immediate consequence of work by Kozyakin (2003) and Mignosi (1991). Its proof is given as Appendix A.6. Looking ahead, this result is important for changing the order of certain summations in the proof of Proposition 30, which shows that the Radon-Nikodym condition (PCLI3) of Section 3 holds.

3. Proof of Main Result

First we present a theorem due to Niño-Mora (Niño-Mora, 2015, 2019) which guarantees the indexability and optimality of threshold policies for projects satisfying three so-called partial conservation law indexability (PCLI) conditions (Section 3.1). The following three subsections show that these three conditions in turn are satisfied for projects satisfying Assumption A1, by making intensive use of our characterisation of the itineraries of maps-with-a-gap from Section 2. Then we couple the results together to prove our main result, Theorem 1, concerning threshold policies for observing time-series and the associated Whittle indices (Section 3.5). Finally, we prove Corollary 2 concerning the structure of optimal policies for the linear-quadratic Gaussian problem with costly observations (Section 3.6).

3.1. Verification Theorem

We present a theorem which guarantees the optimality of threshold policies for two-action Markov decision problems called *projects* under certain hypotheses. Under the same hypotheses, the theorem also guarantees the indexability of such projects. This theorem is due to Niño-Mora (2015) and extends previous work on countable state spaces (Niño-Mora, 2001, 2002, 2006) to problems where the state space is an interval of the real line. Niño-Mora calls the theorem's hypotheses the *partial conservation law indexability (PCLI)* conditions. This terminology was chosen to contrast with the *strong* conservation law conditions of Shanthikumar and Yao (1992) and the *generalised* conservation law conditions of Bertsimas and Niño-Mora (1996), which have their roots in *conservation laws* for queueing systems under which waiting times are invariant to the queueing discipline (Kleinrock, 1965). Although, at the time of writing, Niño-Mora (2015) is not published in a peer-reviewed publication, we have developed our own proofs of a version of the verification theorem and associated results for the special case addressed in this paper in Dance and Silander (2017).

Projects and λ-Price Problems. A *project* $\mathcal{P} = \langle \mathcal{X}, c, r, \mathscr{Q}, \beta \rangle$ describes a stochastic process with state space $\mathcal{X}$, resource function $c : \mathcal{X} \times \{0, 1\} \to \mathbb{R}$, reward function $r : \mathcal{X} \times \{0, 1\} \to \mathbb{R}$, transition law $\mathscr{Q}$ and discount factor $\beta \in [0, 1)$, with the same interpretation as on page 10. Let Π denote the class of all history-dependent randomized policies. Let $\mathbb{E}_x^\pi$ denote the expectation over sequences $(X_t, A_t)_{t=0}^\infty$ with initial state $X_0 = x$, where actions are taken according to policy π and transitions are according to transition law $\mathscr{Q}$. Then the *λ-price problem* for project $\mathcal{P}$ and price $\lambda \in \mathbb{R}$ is to is to find a policy $\pi \in \Pi$ that minimises

$$V_\lambda(x, \pi) := \mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t \left(r(X_t, A_t) - \lambda c(X_t, A_t) \right) \right]$$

for all initial states $x \in \mathcal{X}$. Such a policy is said to be *optimal* for the λ-price problem. We say action $a \in \{0,1\}$ is *optimal in state* x if there is a policy $\pi^* \in \Pi$ such that $V(x, \langle a, \pi^* \rangle) = \sup_{\pi \in \Pi} V(x, \pi)$, where $\langle a, \pi \rangle$ denotes the policy which first takes action a then follows policy π. Niño-Mora (2015) makes the following assumption about projects.

Assumption A3

(i) The state space is $\mathcal{X} = \{x \in \mathbb{R} : l \leq x \leq u\}$ *for some endpoints* $-\infty \leq l < u \leq \infty$.

(ii) For each action $a \in \{0,1\}$, *the reward function* $r(\cdot, a)$ *and resource function* $c(\cdot, a)$ *are continuous on* $\mathcal{X}$, *and* $c(\cdot, a)$ *satisfies* $0 \leq c(x,0) < c(x,1)$ *for all* $x \in \mathcal{X}$.

(iii) There exists a measurable weight function $w : \mathcal{X} \to [1, \infty)$ *and constants* $M > 0$ *and* $\gamma \in [\beta, 1)$, *such that for every state* $x \in \mathcal{X}$ *and action* $a \in \{0,1\}$,

(a) $\max\{|C(x,a)|, |c(x,a)|\} \leq M w(x)$; *and*

(b) $\beta \int_{\mathcal{X}} w(y) \mathcal{Q}(dy|x,a) \leq \gamma w(x)$.

In part (i) of this assumption, the state space $\mathcal{X}$ is of one of the forms $(-\infty, \infty)$, $(-\infty, u']$, $[l', \infty)$ or $[l', u']$ for some $l', u' \in \mathbb{R}$. Although this does not include the state space $\mathcal{I} = (0, \infty)$ in Assumption A1, we show that the result still holds for $\mathcal{X} = (0, \infty)$ in the proof of Theorem 1. The assumption allows c and r to be unbounded functions of the state, however part (iii) ensures that the weighted supremum approach to discounted problems (Wessels, 1977; Hernández-Lerma and Lasserre, 1999) can be applied. This assumption guarantees that discounted sums involving c or r are well-defined for all policies. Furthermore, although Bellman's equations may have multiple unbounded solutions, this assumption identifies the solution corresponding to the optimal value function $V^*(\cdot)$ as the unique solution for which the ratio $|V^*(x)/w(x)|$ is bounded on $\mathcal{X}$.

Optimality of Threshold Policies. For a threshold $s \in \bar{\mathbb{R}}$ and assuming a state-space consisting of real numbers, let π_s denote the *s-threshold policy* that takes actions $A_t = \mathbf{1}_{X_t > s}$ and let π_{s^-} denote the *s^--threshold policy* that takes actions $A_t = \mathbf{1}_{X_t \geq s}$. As on page 11, given a policy π for a project $\mathcal{P}$ in initial state x, we define the reward-to-go or *reward metric* $F(\cdot,\cdot)$ and the resource-to-go or *resource metric* $G(\cdot,\cdot)$ by

$$F(x,\pi) := \mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t r(X_t, A_t) \right], \qquad G(x,\pi) := \mathbb{E}_x^\pi \left[\sum_{t=0}^{\infty} \beta^t c(X_t, A_t) \right].$$

Motivated by expression (8) for the Whittle index, we define the *marginal reward* $f : \mathcal{X} \times \bar{\mathbb{R}} \to \mathbb{R}$ and the *marginal resource* $g : \mathcal{X} \times \bar{\mathbb{R}} \to \mathbb{R}$ by

$$f(x,s) := F(x, \langle 1, \pi_s \rangle) - F(x, \langle 0, \pi_s \rangle), \qquad g(x,s) := G(x, \langle 1, \pi_s \rangle) - G(x, \langle 0, \pi_s \rangle).$$

Finally, we define the *marginal productivity index* $m^*(\cdot)$ to be the ratio of marginal reward to marginal resource when the threshold equals the state, so that

$$m^*(x) := \frac{f(x,x)}{g(x,x)}.$$

Note that the marginal productivity index has the same form as the right-hand side of (8) under the assumption that the x-threshold policy is optimal in the λ-price problem. Niño-Mora (2015) makes the following assumption about the behaviour of the above metrics.

Assumption A4 (Partial Conservation Law Indexability Conditions)

PCLI1. *The marginal resource* $g(x,s)$ *is positive for every state* $x \in \mathcal{X}$ *and threshold* $s \in \bar{\mathbb{R}}$.

PCLI2. *The marginal productivity index* $m^*(\cdot)$ *is non-decreasing, continuous and bounded from below on* $\mathcal{X}$.

PCLI3. *The marginal productivity index* $m^*(\cdot)$ *and metrics* $F(x,\cdot)$ *and* $G(x,\cdot)$ *satisfy*

$$F(x, \pi_{s_2}) - F(x, \pi_{s_1}) = \int_{(s_1, s_2]} m^*(s) G(x, \pi_{ds})$$

for each pair of thresholds $-\infty < s_1 < s_2 < \infty$ *and for each state* $x \in \mathcal{X}$.

In this assumption, PCLI1 ensures that the marginal productivity index is well defined in the sense that its denominator does not vanish. To clarify the notation in PCLI3, for fixed $x \in \mathcal{X}$, let $\tilde{F}(s) := F(x, \pi_s)$ and $\tilde{G}(s) := G(x, \pi_s)$ for $s \in \bar{\mathbb{R}}$. Then PCLI3 requires that $\tilde{F}(s_2) - \tilde{F}(s_1) = \int_{(s_1, s_2]} m^*(s) \tilde{G}(ds)$ where the right-hand side is a Lebesgue-Stieltjes integral (Carter and van Brunt, 2000). Thus, PCLI3 requires that marginal productivity index is a Radon-Nikodym derivative of the reward metric for an s-threshold policy with respect to the resource metric for an s-threshold policy, so that $m^* = \frac{d\tilde{F}}{d\tilde{G}}$. In analyses of discrete-state projects (Niño-Mora, 2001, 2002, 2006), PCLI3 is not required as it is implied by PCLI1 and PCLI2. Niño-Mora (2015, Appendix B) gives sufficient conditions for PCLI3 to hold, but it is not clear that those are satisfied for the problem addressed in this paper.

We now state the verification theorem, which is central to our proof of Theorem 1.

Theorem 15 (Niño-Mora, 2015, Theorem 2.1, p. 13) *Suppose project* $\mathcal{P}$ *satisfies A3 and A4. Then project* $\mathcal{P}$ *is indexable with Whittle index equal to its marginal productivity index* $m^*(\cdot)$. *Furthermore, for every* $\lambda \in \mathbb{R}$, *there exists an* $s \in \bar{\mathbb{R}}$ *such that both the s-threshold and* s^-*-threshold policies are optimal for the* λ*-price problem for project* $\mathcal{P}$.

Remark. For the project in Theorem 1 we have $c(x,a) = a$ and $r(x,a) = -C(x)$. Let us give some expressions for the metrics F, G, f and g for that project that we shall use in the rest of this section. Firstly, let $(X_t(x,a;s))_{t=0}^{\infty}$ be the sequence of states starting from $X_0(x,a;s) = x$ then taking action $a \in \{0,1\}$ to give $X_1(x,a;s) = \phi_a(x)$ then acting according to the s-threshold policy, so that the action sequence is $A_0(x,a;s) = a$ and $A_t(x,a;s) = \mathbf{1}_{X_t(x,a;s) > s}$ for $t > 0$. Let $X_t(x,a;s^-)$ and $A_t(x,a;s^-)$ be the state and actions from initial state x and initial action a when the s^--threshold policy is followed thereafter, so that $A_t(x,a;s) = \mathbf{1}_{X_t(x,a;s) \geq s}$ for $t > 0$. Also, let $X_t(x;s) := X_t(x, \mathbf{1}_{x>s}; s)$, $A_t(x;s) = A_t(x, \mathbf{1}_{x>s}; s)$, $A_t(x,a;s^-) = A_t(x, \mathbf{1}_{x \geq s}; s^-)$ for $t \in \mathbb{Z}_+$. Then

$$f(x,s) = \sum_{t=0}^{\infty} \beta^t \left(C(X_t(x,0;s)) - C(X_t(x,1;s)) \right), \; g(x,s) = \sum_{t=0}^{\infty} \beta^t \left(A_t(x,1;s) - A_t(x,0;s) \right).$$

Given the notation for itineraries (Definition 5) and for compositions of maps ϕ_0, ϕ_1 we can write more-explicit expressions for the reward and cost metric for that project under a threshold policy, for instance

$$F(x, \langle a, \pi_s \rangle) = \sum_{n=1}^{\infty} \beta^{n-1} C(\phi_{(a\sigma(\phi_0(x)|s))_{1:n}}(x)).$$

Furthermore, in the light of Corollary 13, we can find expressions for the marginal reward and marginal resource in terms of $\mathcal{M}$-words. For instance if $0p1$ is a Christoffel word of length N and $x \in [y_{01p}, y_{10p})$ then

$$g(x,x) = \sum_{n=1}^{\infty} \beta^{n-1} \left[((10p)^\infty)_n - ((01p)^\infty)_n \right] = \sum_{k=0}^{\infty} \beta^{kN}(1-\beta) = \frac{1-\beta}{1-\beta^N} \tag{12}$$

since $((10p)^\infty)_n$ and $((01p)^\infty)_n$ only differ when n is 1 or 2 modulo N, whereas for $x = y_{10p}$ we have

$$g(x,x) = \sum_{n=1}^{\infty} \beta^{n-1} \left[(10p(01p)^\infty)_n - ((01p)^\infty)_n \right] = 1 - \beta.$$

In spite of this discontinuity in $g(x,x)$, Lemma 19 shows that the marginal productivity index does not have a discontinuity at points such as y_{10p}. Similarly, if $0s$ is a Sturmian $\mathcal{M}$-word and $x = y_s$, then the same argument gives $g(x,x) = 1 - \beta$.

3.2. Positivity of Marginal Resource Metric (PCLI1)

We prove that condition PCLI1 holds. The argument is based on the following notion of *swapping*, which is partly inspired by results about the Burrows-Wheeler transform of Christoffel words (Berstel et al., 2008, Chapter 6).

Definition 16 *A finite word a **swaps to** a finite word b if either $a = b$ or there exist words $p_1, q_1, p_2, q_2, \ldots, p_n, q_n$ for some $n \in \mathbb{Z}_{++}$ with*

$$a = p_1 10 q_1, \qquad p_1 01 q_1 = p_2 10 q_2, \qquad \ldots, \qquad p_n 01 q_n = b.$$

*We call a transformation $p_k 10 q_k \to p_k 01 q_k$ an **exchange**.*

Example. The word 1100 swaps to the word 0101 via the exchanges

$$1100 \to 1010 \to 0110 \to 0101$$

for which $p_1 = 1$, $q_1 = 0$, $p_2 = \epsilon$, $q_2 = 10$, $p_3 = 01$ and $q_3 = \epsilon$.

The idea of our proof is as follows. First we find conditions on the number of 1's in prefixes of two words that make it possible to swap one word for another (Lemma 17). Proposition 18 shows that those conditions are satisfied by the dynamical system (statement 1), and they imply positivity of the marginal resource metric (statement 2).

Lemma 17 *Suppose a, b are words of common length $|a| = |b| = n \in \mathbb{Z}_+$ with*

$$|a|_1 = |b|_1 \quad \textit{and} \quad |a_{1:k}|_1 \geq |b_{1:k}|_1 \quad \textit{for } k < n.$$

Then a swaps to b.

Proof Given any words u, v of length n, consider the distance

$$d(u,v) := \sum_{i=1}^{n} \left| |u_{1:i}|_1 - |v_{1:i}|_1 \right|.$$

If $a = b$ then a swaps to b after $d(a,b) = 0$ exchanges. Otherwise $a \neq b$ and we shall show that there exists a word a' such that

$$a \text{ and } a' \text{ differ by a single exchange,} \tag{13}$$
$$d(a', b) = d(a, b) - 1, \tag{14}$$
$$\text{and } a' \text{ and } b \text{ satisfy the hypotheses of this Lemma.} \tag{15}$$

Repeating this argument shows that a swaps to b after $d(a,b)$ exchanges.

We now define an appropriate word a'. As $a \neq b$ and $|a_{1:i}|_1 \geq |b_{1:i}|_1$ for $i = 1, 2, \ldots, n-1$, there must exist a first index i such that $|a_{1:i}|_1 > |b_{1:i}|_1$. Also, as $|a|_1 = |b|_1$, there must exist a first index $j > i$ such that $a_j = 0$. As i, j are the first such indices, it follows that $a_k = 1$ for $i \leq k < j$. Thus

$$a = a_{1:(j-2)} 10 a_{(j+1):n}$$

with the convention that $a_{1:0} = a_{(n+1):n} = \epsilon$. Now consider the word

$$a' := a_{1:(j-2)} 01 a_{(j+1):n}.$$

It is immediate that (13) holds. Furthermore, as $a_k = 1$ for $i \leq k < j$, we have

$$\left|a_{1:(j-1)}\right|_1 - \left|b_{1:(j-1)}\right|_1 \geq |a_{1:i}|_1 - |b_{1:i}|_1 > 0$$

where the second inequality follows from the definition of i. Thus the definition of a' gives

$$\left|a'_{1:l}\right|_1 = |a_{1:l}|_1 - \mathbf{1}_{l=j-1} \geq |b_{1:l}|_1 \quad \text{for } l = 1, 2, \ldots, n, \tag{16}$$

so that

$$d(a', b) = \sum_{i=1}^{n} \left(\left|a'_{1:i}\right|_1 - |b_{1:i}|_1 \right) = d(a,b) - 1.$$

Therefore (14) holds.

Finally, combining (16) with the fact that $|a'|_1 = |a|_1 = |b|_1$, we conclude that (15) holds. This completes the proof. ■

The next proposition shows that PCLI1 holds if $\langle \mathcal{I}, C, \phi_0, \phi_1, \beta \rangle$ satisfy Assumption A1. To see that the hypotheses of this proposition follow from A1, note that A1 gives

$$\frac{d\phi_a(x)}{dx} = \frac{r^2}{(\theta_a(r^2x+1)+1)^2} > 0$$

for $a \in \{0,1\}$. Also, putting $u \coloneqq r^2x+1$, the inequality

$$\phi_{10}(x) = \frac{u\theta_1 \quad + \quad (r^2u+1)}{(r^2u+1)\theta_0 + u\theta_1 + (u\theta_0\theta_1+1)} > \frac{u\theta_0 \quad + \quad (r^2u+1)}{(r^2u+1)\theta_1 + u\theta_0 + (u\theta_0\theta_1+1)} = \phi_{01}(x)$$

follows directly from the mediant inequality, as $\theta_1 > \theta_0$.

Proposition 18 *Suppose $\mathcal{I}$ is an interval of $\mathbb{R}$ and that $\phi_0 : \mathcal{I} \to \mathcal{I}, \phi_1 : \mathcal{I} \to \mathcal{I}$ satisfy*

(i) $\phi_0(\cdot), \phi_1(\cdot)$ are increasing functions

(ii) $\phi_{01}(z) < \phi_{10}(z)$ for all $z \in \mathcal{I}$.

Also suppose that $x \in \mathcal{I}$, $s \in \overline{\mathbb{R}}$ and consider the itineraries

$$a := 1\sigma(\phi_1(x)|s) \quad \textit{and} \quad b := 0\sigma(\phi_0(x)|s).$$

Then the following statements hold:

1. *For any $n \in \mathbb{Z}_{++}$, we have $|a_{1:n}|_1 \geq |b_{1:n}|_1$.*
2. *For any $\beta \in (0,1)$, the marginal resource metric $g(x,s)$ is positive.*

Proof We prove statement 1 by induction. In the base case $|a_1|_1 = 1 \geq 0 = |b_1|_1$. For the inductive step, suppose $|a_{1:k}|_1 \geq |b_{1:k}|_1$ for all $k \leq m$ for some $m \in \mathbb{Z}_{++}$. This induction hypothesis shows that either $|a_{1:m}|_1 > |b_{1:m}|_1$ or $|a_{1:m}|_1 = |b_{1:m}|_1$. In the first case, $\left|a_{1:(m+1)}\right|_1 \geq \left|b_{1:(m+1)}\right|_1$ as we are only adding one letter to $a_{1:m}$ and $b_{1:m}$. In the second case, the induction hypothesis shows that the words $a_{1:m}$ and $b_{1:m}$ satisfy the assumptions of Lemma 17, so there is a sequence of swaps that transforms $a_{1:m}$ into $b_{1:m}$. Consider any swap $p10q$ to $p01q$ in this sequence. Then hypothesis (ii) gives $\phi_{10}(\phi_p(x)) > \phi_{01}(\phi_p(x))$ and hypothesis (i) implies that $\phi_q(\cdot)$ is increasing, so

$$\phi_{p10q}(x) > \phi_{p01q}(x).$$

Repeating this argument over the sequence of swaps gives

$$\phi_{a_{1:m}}(x) > \phi_{b_{1:m}}(x).$$

Thus, it follows from the definition of itineraries that the last letters of $a_{1:(m+1)}, b_{1:(m+1)}$ have $a_{m+1}b_{m+1} \in \{00, 10, 11\}$. Hence $\left|a_{1:(m+1)}\right|_1 \geq \left|b_{1:(m+1)}\right|_1$. This proves statement 1.

To prove statement 2, note that the definition of $g(x,s)$ gives

$$g(x,s) = \sum_{k=1}^{\infty} \beta^{k-1}(a_k - b_k)$$

$$\begin{aligned}
&= \sum_{k=1}^{\infty} \beta^{k-1}(|a_{1:k}|_1 - \left|a_{1:(k-1)}\right|_1 - |b_{1:k}|_1 + \left|b_{1:(k-1)}\right|_1) \\
&= (1-\beta)\sum_{k=1}^{\infty} \beta^{k-1}(|a_{1:k}|_1 - |b_{1:k}|_1) \\
&\geq 1-\beta
\end{aligned}$$

where the second line follows as $a_k = |a_{1:k}|_1 - \left|a_{1:(k-1)}\right|_1$ and similarly for b_k, the third line holds because $|a_{1:0}|_1 = |b_{1:0}|_1 = 0$, and the last line follows from statement 1 and the fact that $a_1 = 1, b_1 = 0$. As $\beta < 1$, this completes the proof. ■

3.3. Behaviour of the Marginal Productivity Index (PCLI2)

Condition PCLI2 requires that the marginal productivity index $m^*(x) = f(x,x)/g(x,x)$ is continuous, non-decreasing and bounded from below for $x \in \mathcal{I}$. We begin by showing that this index is *Lipschitz* continuous on any finite interval of $\mathcal{I}$ in Proposition 21. To show the index is non-decreasing, we couple Lipschitz continuity with a piecewise analysis of the index, driven by Theorem 12, which shows that the interval $\mathcal{I}$ can be divided up into intervals corresponding to Christoffel words and points corresponding to Sturmian $\mathcal{M}$-words. The central result of this analysis is Lemma 25, which shows that the marginal reward with threshold equal to initial state $x \mapsto f(x,x)$ is non-decreasing for x in the interval corresponding to any given Christoffel word of the form $0p1$. Since the marginal resource metric $g(x,x)$ equals a positive constant on such intervals, given by (12), this implies that $m^*(x)$ is non-decreasing on such intervals. Since $m^*(\cdot)$ is also Lipschitz continuous on any finite interval, Proposition 27 concludes that $m^*(\cdot)$ is non-decreasing on $\mathcal{I}$. We note that Proposition 27 would not follow if we were only to have shown that $m^*(\cdot)$ is continuous (rather than Lipschitz continuous). Indeed, there are functions that are continuous and have a positive derivative almost everywhere, but are not non-decreasing. One example is the function $x \mapsto x - \text{Cantor}(x)$ where $\text{Cantor}(\cdot)$ is the Cantor-Lebesgue function (Royden and Fitzpatrick, 2010, page 50). Finally, Proposition 28 shows that the index is bounded below, so PCLI2 is satisfied.

A related proof was given by Dance and Silander (2015). However, that proof only covers systems for which the multiplier r in Assumption A1 is $r = 1$, rather than multipliers $r \in (0,1]$ as addressed here. For $r = 0$, we have $\phi_0(x) = \phi_1(x) = 1$ for all $x \in \mathcal{I}$, so the sum in Lemma 25 vanishes, and the analysis presented here is unnecessary. Also, the proof of Dance and Silander (2015) only addressed the cost function $C(x) = x$, whereas here we generalise to any cost function satisfying Assumption A1, which includes any cost function of the form x^q/q for $q \in [-1, \infty)$. A counterexample in Figure 7, shows that the marginal reward is not necessarily increasing on intervals corresponding to Christoffel words for $C(x) = x^q/q$ with $q < -1$.

3.3.1. The Marginal Productivity Index is Continuous

We demonstrate Proposition 21 which shows that the marginal productivity index m^* for systems satisfying Assumption A1 is Lipschitz continuous on any finite interval. We begin by showing that m^* is continuous.

Lemma 19 *If A1 holds then the marginal productivity index $m^*(\cdot)$ is continuous on $\mathcal{I}$.*

Proof Consider the itineraries $h_a(x) := a\sigma(\phi_a(x)|x)$ for $a \in \{0,1\}$ and $x \in \mathcal{I}$. In terms of these itineraries the marginal productivity index is

$$m^*(x) = \frac{\sum_{n=1}^{\infty} \beta^{n-1} \left(C(\phi_{[h_0(x)]_{1:n}}(x)) - C(\phi_{[h_1(x)]_{1:n}}(x))\right)}{\sum_{n=1}^{\infty} \beta^{n-1} \left([h_1(x)]_n - [h_0(x)]_n\right)}.$$

Since A1 holds, this is a continuous function of x at any point where $h_a(x^-) = h_a(x) = h_a(x^+)$. By following paths in the Christoffel tree to find the limiting word just lexicographically higher or lower than a given Christoffel word, and using Corollary 13, we obtain the following limits:

- $h_0(x^-) = 01p(10p)^\infty$ if $0p1$ is a Christoffel word and $x = y_{01p}$; $h_0(x^-) = 010^\infty$ if $x = y_0$; and $h_0(x^-) = h_0(x)$ otherwise.
- $h_1(x^-) = 1^\infty$ if $x = y_1$; $h_1(x^-) = (10p)^\infty$ if $0p1$ is a Christoffel word and $x = y_{10p}$; and $h_1(x^-) = h_1(x)$ otherwise.
- $h_a(x^+) = h_a(x)$ for all $x \in \mathcal{I}$ and all $a \in \{0,1\}$.

In view of these limits, it remains to show that $m^*(x^-) = m^*(x)$ when: (i) $x = y_{01p}$ for some Christoffel word $0p1$; (ii) $x = y_{10p}$ for some Christoffel word $0p1$; (iii) $x = y_0$; and (iv) $x = y_1$. We only consider (i) as the proofs for (ii)-(iv) are similar.

Say $x = y_{01p}$ for a Christoffel word $0p1$. The itineraries above and Corollary 13 give

$$h_0(y_{01p}^-) = 01p(10p)^\infty, \quad h_0(y_{01p}) = (01p)^\infty, \quad h_1(y_{01p}^-) = (10p)^\infty, \quad h_1(y_{01p}) = (10p)^\infty.$$

So the marginal resource satisfies

$$\lim_{x \uparrow y_{01p}} g(x,x) = \sum_{n=1}^{\infty} \beta^{n-1} \left([(10p)^\infty]_n - [01p(10p)^\infty]_n\right) = 1-\beta, \tag{17}$$

$$g(y_{01p}, y_{01p}) = \sum_{n=1}^{\infty} \beta^{n-1} \left([(10p)^\infty]_n - [(01p)^\infty]_n\right) = \frac{1-\beta}{1-\beta^{|0p1|}}. \tag{18}$$

Consider the sum $S(w,x) := \sum_{n=1}^{|w|} \beta^{n-1} C(\phi_{w_{1:n}}(x))$ for any (possibly infinite) word w. Then the marginal reward $f(\cdot,\cdot)$ satisfies

$$\begin{aligned}
\lim_{x \uparrow y_{01p}} f(x,x) &= S(01p(10p)^\infty, y_{01p}) - S((10p)^\infty, y_{01p}) && (19)\\
&= S(01p, y_{01p}) + \beta^{|01p|} S((10p)^\infty, \phi_{01p}(y_{01p})) - S((10p)^\infty, y_{01p})\\
&= S(01p, y_{01p}) - (1-\beta^{|0p1|}) S((10p)^\infty, y_{01p}) && (20)
\end{aligned}$$

$$\begin{aligned}
&= (1-\beta^{|0p1|}) S((01p)^\infty, y_{01p}) - (1-\beta^{|0p1|}) S((10p)^\infty, y_{01p}) && (21)\\
&= (1-\beta^{|0p1|}) f(y_{01p}, y_{01p}). && (22)
\end{aligned}$$

In more detail, (19) follows from the fact that for any word w, we have $S(w,x^-) = S(w,x)$ for any $x \in \mathcal{I}$ as A1 holds; (20) holds as $\phi_{01p}(y_{01p}) = y_{01p}$; (21) follows from the expression for the sum of a geometric progression.

Combining (17), (18) and (22), shows the marginal productivity index $m^*(\cdot)$ satisfies

$$m^*(y_{01p}^-) = \lim_{x \uparrow y_{01p}} \frac{f(x,x)}{g(x,x)} = \frac{(1-\beta^{|0p1|}) f(y_{01p}, y_{01p})}{1-\beta} = \frac{f(y_{01p}, y_{01p})}{g(y_{01p}, y_{01p})} = m^*(y_{01p}).$$

This completes the proof. ■

In order to show that the marginal productivity index $m(\cdot)$ is in fact Lipschitz continuous, Proposition 21 must consider how much $m(\cdot)$ changes over any finite interval $[a,b]$. The analysis proceeds by cutting up any such interval into pieces on each of which the length-k prefixes of the itineraries $[\sigma(\phi_a(u)|u)]_{1:k}$ for $a \in \{0,1\}$ are constant. The following lemma bounds how much $m(\cdot)$ can change over any one such interval.

Lemma 20 *Suppose A1 holds, that $k \in \mathbb{Z}_{++}$ and $0 \le x < y$ with $\sigma(\phi_a(x)|x)_{1:k} = \sigma(\phi_a(y)|y)_{1:k}$ for $a \in \{0,1\}$. Let $K := \sup_{z \in [\phi_1(x), \phi_0(y)]} C'(z)$ where $C'(\cdot)$ is the derivative of $C(\cdot)$. Then*

$$|m^*(x) - m^*(y)| \le \frac{K(3\beta^k(y+1) + 2(y-x))}{(1-\beta)^2}.$$

Proof Let $1p := [\sigma(\phi_0(x)|x)]_{1:k}$ and let s, s' be the shortest words such that $0\sigma_0(\phi_0(x)|x) = (01ps)^\infty$ and $0\sigma_0(\phi_0(y)|y) = (10ps')^\infty$. Also let

$$\begin{aligned}
a_n &:= C(\phi_{((01ps)^\infty)_{1:n}}(x)) - C(\phi_{((10ps)^\infty)_{1:k}}(x)), && e := (1-\beta^{|01ps|})/(1-\beta),\\
b_n &:= C(\phi_{((01ps')^\infty)_{1:n}}(y)) - C(\phi_{((10ps')^\infty)_{1:k}}(y)), && f := (1-\beta^{|01ps'|})/(1-\beta).
\end{aligned}$$

Then the simple bounds

$$\sup_{m \ge 1} |a_m| \le K(y+1), \qquad \sup_{m \ge 1} |a_m - b_m| \le 2K(y+1), \qquad \sup_{m \le k} |a_m - b_m| \le 2K(y-x)$$

follow from the facts that: (i) the lowest and highest points on the z-threshold orbit are $\phi_1(z)$ and $\phi_0(z)$ (by Lemma 39); (ii) $y \ge x$; (iii) function $C(\cdot)$ is non-decreasing and differentiable; (iv) function $\phi_w(\cdot)$ is non-expansive for any word w; (v) for any $z \in \mathbb{R}_+$, $\phi_0(z) \le z+1$ and $\phi_1(z) > 0$.

Also, as $|0p| = k$ it follows that $|e-f| \le \beta^k/(1-\beta)$. Therefore

$$\begin{aligned}
&\beta|m^*(x) - m^*(y)|\\
&\quad = \left| (e-f) \sum_{n=1}^{\infty} \beta^n a_n + f \sum_{n=1}^{k} \beta^n (a_n - b_n) + f \sum_{n=k+1}^{\infty} \beta^n (a_n - b_n) \right|
\end{aligned}$$

$$\leq |e-f| \sum_{n=1}^{\infty} \beta^n \sup_{m \geq 1} |a_m| + f \sum_{n=1}^{k} \beta^n \sup_{m \leq k} |a_m - b_m| + f \sum_{n=k+1}^{\infty} \beta^n \sup_{m > k} |a_m - b_m|$$
$$\leq \frac{\beta^k}{1-\beta} \frac{\beta}{1-\beta} K(y+1) + \frac{1}{1-\beta} \frac{\beta}{1-\beta} 2K(y-x) + \frac{1}{1-\beta} \frac{\beta^{k+1}}{1-\beta} 2K(y+1)$$

which rearranges to the inequality claimed. ■

Proposition 21 *Suppose A1 holds. Then the marginal productivity index m^* is Lipschitz continuous on any finite interval $[x, y]$ of $\mathcal{I}$.*

Proof Let $k \in \mathbb{Z}_{++}$. Now, the length-k prefixes of the itineraries $[\sigma(\phi_a(u)|u)]_{1:k}$ for $a \in \{0, 1\}$ are piecewise constant functions of $u \in \mathcal{I}$. Say there are n_k pieces as u increases from x to y and let $[a, b] \subseteq [x, y]$. Then Lemmas 19 and 20 together show that

$$|m^*(b) - m^*(a)| \leq \frac{3K(y+1)}{(1-\beta)^2} n_k \beta^k + \frac{2K}{(1-\beta)^2}(b-a)$$

where

$$K := \sup_{z \in [\phi_1(x), \phi_0(y)]} C'(z) < \infty.$$

However, the total number of pieces of f_k is at most a polynomial function $p(k)$ of k, by Theorem 14. As k was an arbitrary positive integer, it follows that

$$|m^*(b) - m^*(a)| \leq \frac{3K(y+1)}{(1-\beta)^2} \underbrace{\lim_{k \to \infty} \left(p(k) \beta^k \right)}_{=0} + \frac{2K}{(1-\beta)^2}(y-x).$$

As $[a, b] \subseteq [x, y]$ was arbitrary, we conclude that m^* is Lipschitz continuous on $[x, y]$. ■

3.3.2. The Marginal Productivity Index is Non-Decreasing

We use the following well-known result about *majorisation* (Marshall et al., 2010). A proof is given in Appendix B.

Lemma 22 *Suppose that:*

1. *The sequences $a_{1:n}$ and $b_{1:n}$ are non-decreasing sequences on $\mathbb{R}_{++}$*
2. *The inequality $\sum_{i=1}^{k} a_i \leq \sum_{i=1}^{k} b_i$ holds for $k = 1, 2, \ldots, n$*
3. *For $i = 1, 2, \ldots, n$, the function $f_i : \mathbb{R}_{++} \to \mathbb{R}$ is non-increasing and convex*
4. *For $i = 2, 3, \ldots, n$, the difference $f_{i-1}(x) - f_i(x)$ is non-increasing for $x \in \mathbb{R}_{++}$.*

Then

$$\sum_{i=1}^{n} f_i(a_i) \geq \sum_{i=1}^{n} f_i(b_i).$$

We apply this majorisation result to the sequences appearing in Lemma 24 below. To state that Lemma, we first define some matrices that are motivated by the form of the Kalman Filter variance updates.

Definition 23 *Let I be the 2-by-2 identity matrix. For $r \in (0, 1]$ and $0 \leq a \leq b$, let*

$$F := \begin{pmatrix} r & 1/r \\ ar & (a+1)/r \end{pmatrix}, \qquad G := \begin{pmatrix} r & 1/r \\ br & (b+1)/r \end{pmatrix}.$$

Let $M(\epsilon) = I, M(0) = F, M(1) = G$ and for any finite non-empty word w let

$$M(w) = M(w_{|w|}) \cdots M(w_2) M(w_1).$$

Thus, if $a = \theta_0, b = \theta_1$ and ϕ_0, ϕ_1 are as in Assumption A1, we have

$$\phi_0(x) = \frac{F_{11}x + F_{12}}{F_{21}x + F_{22}}, \qquad \phi_1(x) = \frac{G_{11}x + G_{12}}{G_{21}x + G_{22}}.$$

As remarked in Section 3, the central portion of Christoffel words are palindromes. The following result holds for any palindromes, not just palindromes generated by Christoffel words.

Lemma 24 *Suppose p is a palindrome, $r \in (0, 1]$, $n \in \mathbb{Z}_+$ and x satisfies*

$$\phi_p(0) \leq x \leq \phi_p\left(\frac{1}{1-r^2}\right).$$

Let $m := |01p|$ and for $k = 1, 2, \ldots, m$ let

$$\begin{pmatrix} a_k(x) \\ c_k(x) \end{pmatrix} := M\Big((01p)^n (01p)_{1:k}\Big) \begin{pmatrix} x \\ 1 \end{pmatrix}, \qquad \begin{pmatrix} b_k(x) \\ d_k(x) \end{pmatrix} := M\Big((10p)^n (10p)_{1:k}\Big) \begin{pmatrix} x \\ 1 \end{pmatrix}.$$

Then

1. *The sequences $a_{1:m}(x), b_{1:m}(x), c_{1:m}(x)$ and $d_{1:m}(x)$ are non-decreasing and positive*
2. *The inequality $a_k(x) \leq b_k(x)$ holds for $k = 1, 2, \ldots, m$*
3. *The inequality $\sum_{i=1}^{k} c_i(x) \leq \sum_{i=1}^{k} d_i(x)$ holds for $k = 1, 2, \ldots, m$*
4. *The inequalities $c_1(x) \leq d_1(x)$ and $c_k(x) \geq d_k(x)$ hold for $k = 2, 3, \ldots, m$.*
5. *The fixed points y_{01p} and y_{10p} satisfy*

$$\phi_p(0) \leq y_{01p} < y_{10p} \leq \phi_p\left(\frac{1}{1-r^2}\right)$$

so Claims 1-4 hold if $x \in [y_{01p}, y_{10p}]$.

The proof of the above lemma is given in Appendix C.

Now we are ready to demonstrate that marginal reward is non-decreasing for a wide range of cost functions on the intervals $[y_{01p}, y_{10p}]$ corresponding to a Christoffel word $0p1$ appearing in Theorem 12.

Lemma 25 *Suppose that A1 holds, that* $0p1$ *is a Christoffel word and that* $N \in \mathbb{Z}_+$. *Then*

$$\sum_{k=1}^{n} \beta^k (C(\phi_{(01p)^N(01p)_{1:k}}(x)) - C(\phi_{(10p)^N(10p)_{1:k}}(x)))$$

is a non-decreasing function of x *for* $y_{01p} \leq x \leq y_{10p}$, *where* $n = |0p1|$.

We prove the result for functions satisfying parts C1 and C2 of Assumption A1 separately, as sums of non-decreasing functions are non-decreasing, the result holds for any function satisfying Assumption A1.

Proof [Proof when $C(\cdot)$ satisfies part C1 of Assumption A1 (iv).] Let $a_k(x), b_k(x), c_k(x), d_k(x)$ be as defined in Lemma 24. Then the proposition is proved by the following inequalities (as justified immediately below):

$$\begin{aligned}
&\frac{d}{dx}\sum_{k=1}^{n} \beta^k (C(\phi_{(01p)^N(01p)_{1:k}}(x)) - C(\phi_{(10p)^N(10p)_{1:k}}(x))) \\
&\quad = \sum_{k=1}^{n} \left(\frac{\beta^k}{c_k(x)^2} C'\left(\frac{a_k(x)}{c_k(x)}\right) - \frac{\beta^k}{d_k(x)^2} C'\left(\frac{b_k(x)}{d_k(x)}\right)\right) && (23)\\
&\quad \geq \sum_{k=1}^{n} \left(\frac{\beta^k}{c_k(x)^2} C'\left(\frac{b_k(x)}{c_k(x)}\right) - \frac{\beta^k}{d_k(x)^2} C'\left(\frac{b_k(x)}{d_k(x)}\right)\right) && (24)\\
&\quad = \sum_{k=1}^{n} (f_k(c_k(x)) - f_k(d_k(x))) \quad \text{where } f_k(u) := \beta^k C'(b_k(x)/u)/u^2 \\
&\quad \geq 0. && (25)
\end{aligned}$$

Step (23) follows from the chain rule as the homomorphism of matrix multiplication and composition of Möbius transformations gives

$$\phi_{(01p)^n(01p)_{1:k}}(x) = \frac{\left[M((01p)^N(01p)_{1:k})\begin{pmatrix} x \\ 1 \end{pmatrix}\right]_1}{\left[M((01p)^N(01p)_{1:k})\begin{pmatrix} x \\ 1 \end{pmatrix}\right]_2} = \frac{a_k(x)}{c_k(x)}$$

while the fact that matrices F and G have unit determinant implies that the matrix $M((01p)^N(01p)_{1:k})$ also has unit determinant so that

$$\frac{d}{dx}\phi_{(01p)^N(01p)_{1:k}}(x) = \frac{1}{c_k(x)^2}.$$

Step (24) follows as $\beta^k, c_k(x) > 0$, as $C(\cdot)$ is concave and as $a_k(x) \leq b_k(x)$ by Lemma 24.

Step (25) follows from Lemma 22. In particular, Lemma 24 shows that the sequences $c_{1:n}(x)$ and $d_{1:n}(x)$ satisfy the hypotheses of Lemma 22. Also, the fact that $C(\cdot)$ satisfies part C1 shows that the functions $f_i(\cdot)$ for $i = 1, \ldots, n$ satisfy hypotheses 1 and 2 of Lemma 22. Indeed, $f_i(\cdot)$ is non-increasing and convex as $\frac{1}{u^2}C'\left(\frac{1}{u}\right)$ is non-increasing and convex and $\beta^i, b_i(x) > 0$. Also, as $\frac{1}{u^3}C''\left(\frac{b}{u}\right)$ is non-decreasing in u for $b > 0$ and $0 < b_{i-1}(x) \leq b_i(x)$ for $i = 2, \ldots, n$, by Claim 1 of Lemma 24, the following integral is also non-decreasing in u:

$$\int_{b_{i-1}(x)}^{b_i(x)} \frac{1}{u^3} C''\left(\frac{b}{u}\right) db = \frac{1}{u^2} C'\left(\frac{b_i(x)}{u}\right) - \frac{1}{u^2} C'\left(\frac{b_{i-1}(x)}{u}\right) = \frac{1}{\beta^i}\left(f_i(u) - \beta f_{i-1}(u)\right)$$

So $f_{i-1}(u) - f_i(u)$ is the sum of the non-increasing functions $\beta f_{i-1}(u) - f_i(u)$ and $(1-\beta)f_{i-1}(u)$.

This completes the proof. ■

Proof [Proof when $C(\cdot)$ satisfies part C2 of Assumption A1 (iv).] For $k \in \mathbb{Z}_n$ let

$$\begin{aligned}
a'_k &:= \beta^{k+1}\frac{d}{dx}\phi_{(01p)^N(01p)_{1:(k+1)}}(x), & b'_k &:= \beta^{k+1}\frac{d}{dx}\phi_{(10p)^N(10p)_{1:(k+1)}}(x),\\
a_k &:= C'(y_{(1p0)_{(k+1):n}(1p0)_{1:k}}), & b_k &:= C'(y_{(0p1)_{(k+1):n}(0p1)_{1:k}}).
\end{aligned}$$

Let $r_{[0]} \geq \cdots \geq r_{[n-1]}$ denote real numbers $r_0, \ldots, r_{n-1}$ in non-increasing numerical order. Let $\overline{x}$ denote x modulo n and let l satisfy $\overline{l|0p1|}_1 = 1$. Then the proposition is proved by the following inequalities (as justified immediately below):

$$\begin{aligned}
&\frac{d}{dx}\sum_{k=1}^{n} \beta^k \left(C\left(\phi_{(01p)^N(01p)_{1:k}}(x)\right) - C\left(\phi_{(10p)^N(10p)_{1:k}}(x)\right)\right)\\
&\quad = \sum_{k=1}^{n} \left(C'\left(\phi_{(01p)^N(01p)_{1:k}}(x)\right) a'_{k-1} - C'\left(\phi_{(10p)^N(10p)_{1:k}}(x)\right) b'_{k-1}\right) && (26)\\
&\quad \geq \sum_{k=1}^{n} \left(C'\left(y_{(1p0)_{k:n}(1p0)_{1:(k-1)}}\right) a'_{k-1} - C'\left(y_{(0p1)_{k:n}(0p1)_{1:(k-1)}}\right) b'_{k-1}\right) && (27)\\
&\quad = \sum_{k=0}^{n-1} \left(a_k a'_k - b_k b'_k\right) && (28)\\
&\quad = \sum_{k=0}^{n-1} a_{[k]}\left(a'_{\overline{l(n-k)}} - b'_{\overline{l(n-k-1)}}\right) && (29)\\
&\quad \geq \sum_{k=0}^{n-1} a_{[k]}\left(a'_{\overline{l(n-k)}} - b'_{\overline{l(n-k)}}\right) && (30)\\
&\quad \geq \sum_{k=0}^{n-1} a_{[0]}\left(a'_{\overline{l(n-k)}} - b'_{\overline{l(n-k)}}\right) && (31)\\
&\quad \geq 0 && (32)
\end{aligned}$$

Step (26) follows from the chain rule and definition of a'_k, b'_k.

Step (27) follows as $C(\cdot)$ is convex, as $a'_k, b'_k \geq 0$, and as, for $k = 1, 2, \ldots, n$, we have

$$\begin{aligned}\phi_{(01p)^N(01p)_{1:k}}(x) &= \phi_{(01p)_{1:k}}(\phi_{(01p)^N}(x)) \\ &\geq \phi_{(01p)_{1:k}}(y_{01p}) \\ &= y_{(01p)_{(k+1):n}(01p)_{1:k}} \\ &= y_{(1p0)_{k:n}(1p0)_{1:(k-1)}}\end{aligned}$$

where the inequality holds as $x \geq y_{01p}$ so that $\phi_{(01p)^N}(x) \geq y_{01p}$, and as $\phi_{(01p)_{1:k}}(\cdot)$ is increasing. The same argument using $x \leq y_{10p}$ gives an upper bound on $C'(\phi_{(10p)^N(10p)_{1:k}}(x))$.

Step (28) follows by shifting the summation indices and from the definition of a_k, b_k.

Step (29) follows from Lemmas 8 and 11 and the convexity of $C(\cdot)$. Let $w_{[0]} \succeq \cdots \succeq w_{[n-1]}$ denote words $w(0), \ldots, w(n-1)$ in non-increasing lexicographic order and let $c_k := (1p0)_{(k+1):n}(1p0)_{1:k}, d_k := (0p1)_{(k+1):n}(0p1)_{1:k}$ for $k \in \mathbb{Z}_n$. Then Lemma 8 shows that $c_{[i]} = d_{[i]} = c_{\overline{l(n-i)}} = d_{\overline{l(n-i-1)}}$. Thus Lemma 11 gives $y_{c_{[i]}} = y_{d_{[i]}} = y_{c_{\overline{l(n-i)}}} = y_{d_{\overline{l(n-i-1)}}}$. Therefore the convexity of $C(\cdot)$ gives

$$a_{[i]} = b_{[i]} = a_{\overline{l(n-i)}} = b_{\overline{l(n-i-1)}}.$$

Step (30) follows as $C(\cdot)$ is non-decreasing, so that $a_{[i]} \geq 0$, and as $\phi_0(\cdot), \phi_1(\cdot)$ are non-decreasing and non-expansive, so that b'_i is a product of derivatives where each derivative is in $[0, 1]$. Thus $a_{[0]}, \ldots, a_{[n-1]}$ and $b'_0, \ldots, b'_{n-1}$ are non-negative non-increasing sequences. Therefore the rearrangement inequality $a_{[i]}b'_j + a_{[i+1]}b'_0 \leq a_{[i]}b'_0 + a_{[i+1]}b'_j$ holds for all $i \in \mathbb{Z}_{n-1}$ and all $j \in \mathbb{Z}_n$. But $b'_{\overline{l(n-(n-1)-1)}} = b'_0$ so repeated application of the rearrangement inequality gives

$$\sum_{k=0}^{n-1} a_{[k]} b'_{\overline{l(n-k-1)}} \leq \sum_{k=0}^{n-1} a_{[k]} b'_{\overline{l(n-k)}}.$$

Step (31) follows as $a_{[0]} = a_{\overline{ln}} = a_0$, as a_0 is non-negative, and from Claim 4 of Lemma 24, as for the $c_i(x), d_i(x)$ defined in that lemma, we have

$$a'_{i-1} - b'_{i-1} = \frac{\beta^i}{c_i(x)^2} - \frac{\beta^i}{d_i(x)^2} \begin{cases} \geq 0 & \text{for } i = 1 \\ \leq 0 & \text{for } i = 2, 3, \ldots, n. \end{cases}$$

Step (32) follows from this lemma using the function $\tilde{C}(x) = x$ which satisfies part C1 and which was already proved above.

This completes the proof. ■

It is much simpler to show that the marginal reward is non-decreasing when the itinerary is 0^∞ (that is, $x \geq y_0$) or when the itinerary is 01^∞ (that is, $x \leq y_1$). Now the sums in the following lemma correspond to the numerator of the marginal productivity index m^* in these cases, up to a multiple of β. Also, the denominator of m^* in these cases is

$$\sum_{k=1}^{\infty} \beta^{k-1} \left((10^\infty)_k - (0^\infty)_k\right) = 1 - \beta = \sum_{k=1}^{\infty} \beta^{k-1} \left((1^\infty)_k - (01^\infty)_k\right)$$

which is positive. So, it follows from this lemma that m^* is non-decreasing on such intervals.

Lemma 26 *Suppose A1 holds. Then*

$$\sum_{k=1}^{\infty} \beta^k \left(C(\phi_{0^k}(x)) - C(\phi_{10^{k-1}}(x))\right) \qquad \text{and} \qquad \sum_{k=1}^{\infty} \beta^k \left(C(\phi_{01^{k-1}}(x)) - C(\phi_{1^k}(x))\right)$$

are non-decreasing functions of $x \in \mathcal{I}$.

Proof Consider the first sum. As in Lemma 24, for $k \in \mathbb{Z}_{++}$, we define

$$\begin{pmatrix} a_k(x) & b_k(x) \\ c_k(x) & d_k(x) \end{pmatrix} := \left(M(0^k) \begin{pmatrix} x \\ 1 \end{pmatrix} \quad M(10^{k-1}) \begin{pmatrix} x \\ 1 \end{pmatrix} \right).$$

As $G \geq F$, the entries of F are non-negative and $x \geq 0$, it follows that

$$\begin{pmatrix} b_k(x) - a_k(x) \\ d_k(x) - c_k(x) \end{pmatrix} = F^{k-1}(G - F) \begin{pmatrix} x \\ 1 \end{pmatrix} \geq 0. \tag{33}$$

If C satisfies part C1 of Assumption A1, then for any $k \in \mathbb{Z}_{++}$,

$$\begin{aligned}\frac{d}{dx}\left(C(\phi_{0^k}(x)) - C(\phi_{10^{k-1}}(x))\right) &= \frac{1}{c_k(x)^2} C'\left(\frac{a_k(x)}{c_k(x)}\right) - \frac{1}{d_k(x)^2} C'\left(\frac{b_k(x)}{d_k(x)}\right) \\ &\geq \frac{1}{c_k(x)^2} C'\left(\frac{b_k(x)}{c_k(x)}\right) - \frac{1}{d_k(x)^2} C'\left(\frac{b_k(x)}{d_k(x)}\right) \geq 0.\end{aligned}$$

The first inequality holds as C' is concave and $a_k(x) \leq b_k(x)$ by (33). The second inequality holds as $C'(1/x)/x^2$ is non-increasing and $c_k(x) \leq d_k(x)$ by (33).

If C satisfies part C2 of Assumption A1, then for any $k \in \mathbb{Z}_{++}$,

$$\frac{d}{dx}\left(C(\phi_{0^k}(x)) - C(\phi_{10^{k-1}}(x))\right) = \frac{1}{c_k(x)^2} C'(\phi_{0^k}(x)) - \frac{1}{d_k(x)^2} C'(\phi_{10^{k-1}}(x)) \geq 0.$$

The inequality is justified as follows. As $a \leq b$ in the definition of F, G, we have $\phi_0(x) \geq \phi_1(x)$. As $\phi_{0^{k-1}}(\cdot)$ is an increasing function, it follows that $\phi_{0^k}(x) \geq \phi_{10^{k-1}}(x)$. As C is convex, it follows that $C'(\phi_{0^k}(x)) \geq C'(\phi_{10^{k-1}}(x))$. Furthermore, $c_k(x) \leq d_k(x)$, by (33).

Thus, if C satisfies Assumption A1, the sum

$$\sum_{k=1}^{\infty} \beta^k \left(C(\phi_{0^k}(x)) - C(\phi_{10^{k-1}}(x))\right)$$

is the sum of non-decreasing functions. Therefore this sum is non-decreasing.

The proof for the second sum is similar. This completes the proof. ■

Proposition 27 *Suppose Assumption A1 holds. Then the marginal productivity index m^* is non-decreasing.*

Proof Consider any $a, b \in \mathcal{I}$ with $a < b$. By Proposition 21, the index m^* is Lipschitz continuous on any finite interval of $\mathcal{I}$, such as the interval $[a, b]$. Now, if a function is Lipschitz continuous on a closed interval then it is absolutely continuous on that interval (Royden and Fitzpatrick, 2010, Proposition 7, p. 120). Also, an absolutely continuous function m^* has a derivative $m^{*\prime}$ almost everywhere, which is Lebesgue integrable, and which satisfies (Pugh, 2002, Theorem 38, p. 399)

$$m^*(b) = m^*(a) + \int_a^b m^{*\prime}(t)\, dt. \tag{34}$$

Now, for any Christoffel word $0p1$ and for t in the interval $[y_{01p}, y_{10p}]$, the derivative $m^{*\prime}(t)$ is non-negative, since $m^*(t) = f(t,t)/g(t,t)$, in which $f'(t) \geq 0$ by Lemma 25, and in which $g(t,t)$ is a positive constant depending on $0p1$. Similarly, Lemma 26 shows that the marginal productivity index is non-decreasing on $\mathcal{I}\backslash(y_1, y_0)$. Therefore, $m^*(a) \leq m^*(b)$. This completes the proof. ■

Remark. Having proved that the marginal productivity index is non-decreasing, one might wonder if it is actually always strictly increasing. It is not. In particular, Assumption A1 allows the cost function $C(\cdot)$ to be a constant, in which case the marginal productivity index is a constant. In other cases, the marginal productivity index is not a constant, yet it is constant over a finite interval of the state space $\mathcal{I}$. For instance, this is the case for sufficiently large precision parameter θ_1 that $y_1 < 1$, and for the cost function

$$C(x) = \begin{cases} 0 & x < 1 \\ (x-1)^2 & x \geq 1, \end{cases}$$

which satisfies A1.

3.3.3. The Marginal Productivity Index is Bounded Below

Proposition 28 *Suppose Assumption A1 holds. Then the marginal productivity index m^* is bounded from below.*

Proof Let $[l, u] := \mathcal{I}$. By Proposition 27, m^* is non-decreasing, so

$$\inf_{x \in [l,u]} m^*(x) = f(l,l)/g(l,l).$$

Now $l \leq y_1$ so $\sigma(l|l) = 01^\infty$ and $\sigma(l|l^-) = 1^\infty$. Thus $g(l,l) = 1 - \beta$ and

$$f(l,l) = \sum_{t=0}^{\infty} \beta^t \left(C(\phi_{(01^\infty)_{1:t}}(l)) - C(\phi_{1^\infty_{1:t}}(l)) \right) \geq \frac{C(l) - C(y_1)}{1-\beta}$$

where the inequality follows as $\phi_{(01^\infty)_{1:t}}(l) \geq l$ and $\phi_{(1^\infty)_{1:t}}(l) \leq y_1$ for all t, and as C is increasing. As $C(l) > -\infty$, $C(y_1) < \infty$ and $\beta < 1$, it follows that $m^*(x) > -\infty$ for $x \in \mathcal{I}$. ■

3.4. Radon-Nikodym Condition (PCLI3)

We demonstrate that PCLI3 holds. The argument is based on the fact that the reward metric $F(x, \pi_s)$ and resource metric $G(x, \pi_s)$ for threshold policies are *jump functions* when viewed as a function of the threshold s, because the number of discontinuities of the itinerary map $s \mapsto \sigma(x|s)_{1:n}$ is bounded by a polynomial function of n by Theorem 14. First we recall what a jump function is.

Definition 29 (Kolmogorov and Fomin, 1975, p. 341) *A function $h : \mathbb{R} \to \mathbb{R}$ is a **jump function** if $h(x) = h_0 + \sum_{n=1}^{\infty} h_n \mathbf{1}_{x_n < x} + \sum_{n=1}^{\infty} h'_n \mathbf{1}_{x'_n \leq x}$ for some real-valued sequences $(h_i)_{i=0}^{\infty}$, $(h'_i)_{i=1}^{\infty}$, $(x_i)_{i=1}^{\infty}$ and $(x'_i)_{i=1}^{\infty}$ satisfying $\sum_{i=1}^{\infty} |h_i| < \infty$ and $\sum_{i=1}^{\infty} |h'_i| < \infty$.*

Proposition 30 *Suppose $\langle \mathcal{I}, C, \phi_0, \phi_1, \beta \rangle$ satisfy Assumption A1. Then PCLI3 holds.*

Proof Throughout the proof, let us consider a fixed initial state $x \in \mathcal{I}$. Recall the notation for the state $X_t(x; s)$ and action $A_t(x; s)$ from initial state x under the s-threshold policy discussed in the remark on page 30. Also recall also that a function $h : \mathbb{R} \to \mathbb{R}$ is *càdlàg* if both limits $h(s^-)$ and $h(s^+)$ exist and $h(s) = h(s^+)$ for all $s \in \mathbb{R}$.

First we use induction to show that $A_t(x; s)$ is a càdlàg function of s for any $t \in \mathbb{Z}_+$. In the base case, we have $X_0(x; s) = x$ and $A_0(x; s) = \mathbf{1}_{x>s}$, which are càdlàg in s. Now say $t \geq 0$ and $X_t(x; s)$ and $A_t(x; s)$ are càdlàg in s. Then, $\phi_a(X_t(x; s))$ is càdlàg in s for $a \in \{0, 1\}$ as it is the composition of a continuous function and a càdlàg function. Thus

$$X_{t+1}(x; s) = A_t(x; s)\phi_1(X_t(x; s)) + (1 - A_t(x; s))\phi_0(X_t(x; s))$$

is càdlàg in s, since sums and products of càdlàg functions are càdlàg. Hence $s - X_{t+1}(x; s)$ is càdlàg in s. Noting that $z \mapsto \mathbf{1}_{z<0}$ is càdlàg, it follows that the composition

$$A_{t+1}(x; s) = \mathbf{1}_{s - X_{t+1}(x;s) < 0}$$

is càdlàg in s, completing the induction.

Also, note that $\lim_{s \to -\infty} A_t(x; s) = 1$, since under Assumption A1, the state is never less than zero, so for any $s < 0$, the s-threshold policy always takes action 1.

For $t \in \mathbb{Z}_+$, let $\mathcal{D}_t(x)$ be a sequence consisting of all the values of the threshold s at which $A_t(x; s)$ is discontinuous. As $A_t(x; s)$ is a càdlàg function of s, taking values in $\{0, 1\}$, with $\lim_{s \to -\infty} A_t(x; s) = 1$, it follows from the definition of $\mathcal{D}_t(x)$ that

$$A_t(x; s) = 1 + \sum_{d \in \mathcal{D}_t(x)} (A_t(x; d) - A_t(x; d^-)) \mathbf{1}_{d \leq s},$$

noting that this sum is finite as $\mathrm{card}(\mathcal{D}_t(x)) \leq p(t)$ for some polynomial $p(t)$ by Theorem 14. Now let $d_1, d_2, \ldots$ be the sequence generated by first concatenating $\mathcal{D}_0(x)$ then $\mathcal{D}_1(x)$ then $\mathcal{D}_2(x)$ and so forth, then deduplicating that sequence by including only the first occurrence of each distinct element. Since the sequence $d_1, d_2, \ldots, d_k$ contains all of $\mathcal{D}_t(x)$ for some finite k, and because $A_t(x; d_i) - A_t(x; d_i^-) = 0$ for any d_i in the sequence which is not an element of $\mathcal{D}_t(x)$, it follows that

$$A_t(x; s) = 1 + \sum_{i=1}^{\infty} (A_t(x; d_i) - A_t(x; d_i^-)) \mathbf{1}_{d_i \leq s}.$$

Thus the resource metric is

$$G(x,\pi_s) = (1-\beta)^{-1} + \sum_{t=0}^{\infty}\sum_{i=1}^{\infty} \beta^t (A_t(x;d_i) - A_t(x;d_i^-))\mathbf{1}_{d_i \le s}.$$

As $\text{card}(\mathcal{D}_t(x)) \le p(t)$ for some polynomial $p(t)$ by Theorem 14 and $A_t(x;s) \in \{0,1\}$, we have

$$\sum_{t=0}^{\infty}\sum_{i=1}^{\infty} \left|\beta^t (A_t(x;d_i) - A_t(x;d_i^-))\mathbf{1}_{d_i \le s}\right| \le \sum_{t=0}^{\infty} \beta^t p(t) < \infty.$$

So Fubini's theorem gives

$$G(x,\pi_s) = (1-\beta)^{-1} + \sum_{i=1}^{\infty}\left(\sum_{t=0}^{\infty} \beta^t (A_t(x;d_i) - A_t(x;d_i^-))\right)\mathbf{1}_{d_i \le s}.$$

Thus the mapping $s \mapsto G(x,\pi_s)$ is a càdlàg jump function.

Let $\tau := \inf\{t > 0 : X_t(s;s^-) = s\}$ with $\tau = \infty$ if $X_t(s;s^-) \neq s$ for all $t > 0$. Then

$$\begin{aligned}
G(s,\pi_{s^-}) &= \sum_{t=0}^{\infty} \beta^t A_t(s;s^-) \\
&= \sum_{t=0}^{\infty} \beta^t A_t(s,1;s) + \sum_{t=\tau}^{\infty} \beta^t (A_t(s;s^-) - A_t(s,0;s)) \\
&= G(s,\langle 1,\pi_s\rangle) + \beta^\tau (G(s,\pi_{s^-}) - G(s,\langle 0,\pi_s\rangle)) \\
&= \frac{G(s,\langle 1,\pi_s\rangle) - \beta^\tau G(s,\langle 0,\pi_s\rangle)}{1-\beta^\tau}.
\end{aligned}$$

Let $\tau_1 := \inf\{t \ge 0 : X_t(x;s) = s\}$ with $\tau_1 = \infty$ if $X_t(x;s) \neq s$ for all $t \ge 0$. Then the expression for $G(x,\pi_{s^-})$ just derived gives

$$\begin{aligned}
G(x,\pi_s) - G(x,\pi_{s^-}) &= \beta^{\tau_1}(G(s,\pi_s) - G(s,\pi_{s^-})) \\
&= \beta^{\tau_1}\left(G(s,\langle 0,\pi_s\rangle) - \frac{G(s,\langle 1,\pi_s\rangle) - \beta^\tau G(s,\langle 0,\pi_s\rangle)}{1-\beta^\tau}\right) \\
&= -\frac{\beta^{\tau_1}}{1-\beta^\tau} g(s,s)
\end{aligned}$$

using definition of the marginal resource metric $g(\cdot,\cdot)$.

A similar argument shows that the mapping $s \mapsto F(x,\pi_s)$ for the reward metric is also a càdlàg jump function which can be described in terms of the same sequence of discontinuities $d_1, d_2, \ldots$ as $G(x,\pi_s)$. Furthermore, it is related to the marginal reward $f(s,s)$ through

$$F(x,\pi_s) - F(x,\pi_{s^-}) = -\frac{\beta^{\tau_1}}{1-\beta^\tau} f(s,s).$$

Recalling that $m^*(s) = f(s,s)/g(s,s)$ gives

$$F(x,\pi_s) - F(x,\pi_{s^-}) = m^*(s)(G(x,\pi_s) - G(x,\pi_{s^-})).$$

As $F(x,\pi_s), G(x,\pi_s)$ are càdlàg jump functions of s, the Lebesgue-Stieltjes integral of this expression over any interval $(s_1,s_2]$ of $\mathbb{R}$ is

$$F(x,\pi_{s_2}) - F(x,\pi_{s_1}) = \int_{(s_1,s_2]} m^*(s)\; dG(x,\pi_{ds}).$$

Therefore PCLI3 holds. ■

In the above proof, the expressions for the jumps $G(x,\pi_s) - G(x,\pi_{s^-})$ and $F(x,\pi_s) - F(x,\pi_{s^-})$ fit with a general pattern for such jumps given in Lemma 7.5 of Niño-Mora (2015). Also, Section 7.1 of that paper shows that the metrics $F(x,\pi_s)$ and $G(x,\pi_s)$ are càdlàg functions of the threshold s. However, while Appendix B of that paper also presents sufficient conditions for PCLI3 to hold, we were unable to apply those conditions to the model at hand.

3.5. Proof of Theorem 1

Proof First we show that the system considered in Theorem 1 can be seen as a project in the sense of Theorem 15, except that the former system may have a state space of the form $(0,\infty)$ which is not explicitly addressed by the verification theorem (Step 1). So, we then demonstrate that this choice of interval is in fact implicitly addressed by the verification theorem (Step 2). Finally, we recall that the PCLI conditions and A3 hold (Step 3) and explain the characterisation of the optimal thresholds (Step 4).

Step 1. The system given by $\mathcal{I}, C(\cdot), \phi_0(\cdot), \phi_1(\cdot)$ and factor β that is addressed in Theorem 1 is a project $\mathcal{P} = \langle \mathcal{X}, r, c, \mathscr{Q}, \beta\rangle$ with the same discount factor β, with $\mathcal{X} = \mathcal{I}$, $r(x,a) = -C(x)$, $c(x,a) = a$ and a transition law corresponding to deterministic transitions $\mathscr{Q}(\mathcal{B}|x,a) = \mathbf{1}_{\phi_a(x)\in\mathcal{B}}$ for each Borel subset $\mathcal{B}$ of $\mathcal{X}$, for all $x \in \mathcal{X}$ and $a \in \{0,1\}$.

Step 2. Assumption A1 allows the interval $\mathcal{I} = [0,\infty)$, which explicitly matches the assumptions of Theorem 15. The interval $\mathcal{I} = (0,\infty)$ is also allowed by A1. If Assumption A3 and the PCLI conditions are satisfied for a project $\mathcal{P} = \langle \mathcal{X}, r, c, \mathscr{Q}, \beta\rangle$ with state space $\mathcal{X} = (0,\infty)$ then they are also satisfied by the equivalent project $\tilde{\mathcal{P}} = \langle \tilde{\mathcal{X}}, \tilde{r}, \tilde{c}, \tilde{\mathscr{Q}}, \beta\rangle$ after the change of coordinates $\tilde{x} := \log(x)$. Now project $\tilde{\mathcal{P}}$ has state space $\tilde{\mathcal{X}} := (-\infty,\infty)$, so the conclusions of Theorem 15 apply to project $\tilde{\mathcal{P}}$ and therefore to project $\mathcal{P}$.

(To see this, note that continuity of $\tilde{r}(\tilde{x},a) = r(\exp(\tilde{x}),a)$, $\tilde{c}(\tilde{x},a) = c(\exp(\tilde{x}),a)$ follows from continuity of $\exp(\cdot), r(\cdot,a)$ and $c(\cdot,a)$. Also, for any Borel set $\tilde{\mathcal{B}}$ we have $\tilde{\mathscr{Q}}(\tilde{\mathcal{B}}|\tilde{x},a) = \mathscr{Q}(\{\exp(\tilde{y}) : \tilde{y} \in \tilde{\mathcal{B}}\}|\exp(\tilde{x}),a)$ and this is a valid transition law since the mapping $x \mapsto \log(x)$ is one-to-one. Further, if the weight function $w(\cdot)$ satisfies A3 for $\mathcal{P}$ then $\tilde{w}(\tilde{x}) := w(\exp(\tilde{x}))$ satisfies A3 for $\tilde{\mathcal{P}}$. Finally, for a threshold policy $\pi_s(x) = 1_{x>s}$ consider the threshold policy $\tilde{\pi}_{\tilde{s}}(\tilde{x}) := 1_{\tilde{x}>\tilde{s}}$ where $\tilde{s} := \log(s)$. Then the metrics $\tilde{F}(\cdot,\cdot), \tilde{G}(\cdot,\cdot), \tilde{f}(\cdot,\cdot), \tilde{g}(\cdot,\cdot)$ for $\tilde{\mathcal{P}}$ and $F(\cdot,\cdot), G(\cdot,\cdot), f(\cdot,\cdot), g(\cdot,\cdot)$ for $\mathcal{P}$ satisfy

$$\begin{aligned}
\tilde{F}(\tilde{x},\langle a,\tilde{\pi}_{\tilde{s}}\rangle) &= F(\exp(\tilde{x}),\langle a,\pi_s\rangle), & \tilde{G}(\tilde{x},\langle a,\tilde{\pi}_{\tilde{s}}\rangle) &= G(\exp(\tilde{x}),\langle a,\pi_s\rangle), \\
\tilde{f}(\tilde{x},\tilde{s}) &= f(\exp(\tilde{x}),\exp(\tilde{s})), & \tilde{g}(\tilde{x},\tilde{s}) &= g(\exp(\tilde{x}),\exp(\tilde{s})).
\end{aligned}$$

As $\exp(\cdot)$ is increasing and continuous, and as the PCLI conditions hold for $\mathcal{P}$, it follows that the PCLI conditions hold for $\tilde{\mathcal{P}}$.)

Step 3. Clearly the assumptions about C and w in A1 imply that A3 holds. Furthermore, the PCLI conditions hold by Propositions 18, 21, 27, 28 and 30. Thus it follows from Theorem 15 that the family of λ-price problems in equation (9) is indexable, that the Whittle index has the form claimed and that a threshold policy is optimal.

Step 4. Say $\lambda^*(s) = \lambda$. If $x < s$ then $\lambda^*(x) \leq \lambda$, as $\lambda^*(\cdot)$ is non-decreasing by PCLI2. Yet if $\lambda^*(x) \leq \lambda$ then action 0 is optimal, by the definition of indexability (Definition 3). A similar argument shows that action 1 is optimal for $x > s$. Also, indexability shows that both actions 0 and 1 are optimal at s. Therefore policies $\mathbf{1}_{X_t>s}$ and $\mathbf{1}_{X_t\geq s}$ are both optimal.

If $\lambda^*(s) > \lambda$ for all $s \in \mathcal{I}$ then action 0 is never optimal, by definition of indexability. Therefore the always-active policy is the unique optimal policy. The argument when $\lambda^*(s) < \lambda$ for all $s \in \mathcal{I}$ is similar.

This completes the proof. ■

3.6. Proof of Corollary 2

Proof As $\mathbb{E}[Z_t^2|H_t] = z_t^2 + v_t$, it is not hard to see that the problem corresponds to the dynamic program

$$V(z_t, v_t) = \min_{u_t\in\mathbb{R}, a_t\in\{0,1\}} \left\{ Dz_t^2 + Dv_t + Fu_t^2 + \lambda a_t + \beta\mathbb{E}[V(z_{t+1}, v_{t+1})|z_t, v_t, a_t, u_t] \right\} \quad (35)$$

where the expectation is over the following Markovian transitions of the information state:

$$\begin{aligned} z_{t+1}|z_t, v_t, a_t, u_t &\sim \mathcal{N}(\bar{A}z_t + \bar{B}u_t, \bar{A}^2 v_t + \Sigma_Z - \Phi_{a_t}(v_t)) \\ v_{t+1}|z_t, v_t, a_t, u_t &= \Phi_{a_t}(v_t). \end{aligned}$$

For trial solutions of the form $V(z, v) = Rz^2 + Rv + g(v)$, where $R \in \mathbb{R}$ and $g : \mathbb{R}_+ \to \mathbb{R}$ are to be determined, the expectation in (35) is

$$\begin{aligned} &\mathbb{E}[V(z_{t+1}, v_{t+1})|z_t, v_t, a_t, u_t] \\ &\qquad = R((\bar{A}z_{t+1} + \bar{B}u_t)^2 + \bar{A}^2 v_t + \Sigma_Z - \Phi_{a_t}(v_t) + \Phi_{a_t}(v_t)) + g(\Phi_{a_t}(v_t)). \end{aligned}$$

Thus (35) is solved if

$$\begin{aligned} Rz_t^2 + Rv_t + g(v_t) = \min_{u_t\in\mathbb{R}} &\left\{ Dz_t^2 + Fu_t^2 + \beta R(\bar{A}z_{t+1} + \bar{B}u_t)^2 \right\} \\ &+ \min_{a_t\in\{0,1\}} \left\{ \lambda a_t + \beta R\Sigma_Z + (D + \beta R\bar{A}^2)v_t + \beta g(\Phi_{a_t}(v_t)) \right\}. \end{aligned} \quad (36)$$

Now the minimum with respect to u_t is achieved if the coefficient $(F + \beta\bar{B}^2 R)$ of u_t^2 is positive, in which case the minimiser is

$$u_t = -\frac{\beta\bar{A}\bar{B}R}{F + \beta\bar{B}^2 R} z_t.$$

So (36) is solved if R satisfies

$$R = D + F\left(\frac{\beta\bar{A}\bar{B}R}{F + \beta\bar{B}^2 R}\right)^2 + \beta R\left(\bar{A} - \bar{B}\frac{\beta\bar{A}\bar{B}R}{F + \beta\bar{B}^2 R}\right)^2$$

and if $g(\cdot)$ satisfies the dynamic program

$$g(v) = \min_{a\in\{0,1\}} \left\{ \lambda a + \beta R\Sigma_Z + \alpha v + \beta g(\Phi_a(v)) \right\} \quad (37)$$

where $\alpha := D - (1 - \beta\bar{A}^2)R$.

After simple algebra, the condition on R is equivalent to the quadratic equation

$$-\beta\bar{B}^2 R^2 + (\beta\bar{B}^2 D + \beta\bar{A}^2 F - F)R + DF = 0.$$

Using Descartes' rule of signs and considering the cases $F = 0$ and $F > 0$ separately, we see that this equation has a unique positive root for $\beta\bar{B}^2 > 0$ and $D > 0$.

To apply Theorem 1 to the dynamic program for $g(\cdot)$ we must ensure that Assumption A1 holds, which is not hard to see provided that $\alpha \geq 0$. Noting that $m := 1-\beta\bar{A}^2 > 0$ by the hypotheses about $\bar{A}, \beta$, we see that $\alpha \geq 0$ if $R \leq D/m$. But, substituting $R = y+(D/m)$ in the equation for R gives

$$\begin{aligned} 0 &= [-\beta\bar{B}^2 R^2 + (\beta\bar{B}^2 D + \beta\bar{A}^2 F - F)R + DF]_{R=y+(D/m)} \\ &= -\beta\bar{B}^2 y^2 - ((\beta^2\bar{A}^2 + \beta)\bar{B}^2(D/m) + mF)y - \beta^2\bar{A}^2\bar{B}^2(D/m)^2 \end{aligned}$$

in which the coefficients of y^0, y^1, y^2 are all negative by the hypotheses about $\bar{A}, \bar{B}, D, F$ and β. So this quadratic equation for y has no positive roots and it follows that $\alpha \geq 0$. Therefore Theorem 1 shows that there is an optimal policy for (37) that sets $a_t = 1$ if and only if $v_t \geq s$ for some $s \in \overline{\mathbb{R}}$. This completes the proof. ■

4. Numerical Experiments

We discuss algorithms for computing the Whittle index given in Theorem 1, we present closed-form expressions for that index and compare the performance of the Whittle index policy with two previously-proposed heuristics.

4.1. Approximating the Index for Discount Factor $\beta \leq 0.999$

Truncating the sums in the Whittle index $\lambda^*(x)$ after a suitably large number of terms T suggests the approximation

$$\hat{\lambda}(x) = \frac{\sum_{t=0}^{T} \beta^t \big(C(X_t(x, 0; x)) - C(X_t(x, 1; x))\big)}{\sum_{t=0}^{T} \beta^t \big(A_t(x, 1; x) - A_t(x, 0; x)\big)}. \quad (38)$$

Assuming accurate calculation of the terms in the numerator and denominator, as well as continuity of the cost function C, this approximation requires $O(T)$ basic arithmetical and

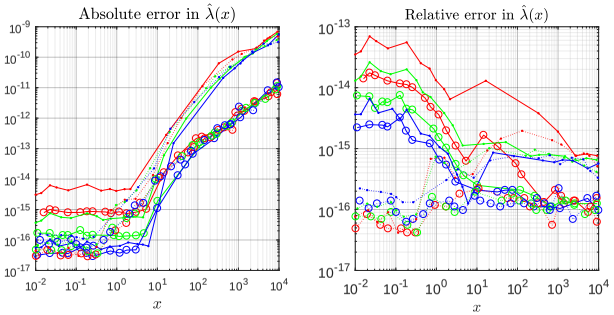

Figure 6: Errors in approximating the index. The cost $C(x)$ corresponds to variance ($C(x) = x$, red), to entropy ($C(x) = \log(x)$, green) or to negative precision ($C(x) = -1/x$, blue). The discount factor β is either 0.9 (open circles) or 0.999 (filled circles). The map-with-a-gap has $\phi_0(x) = x + 1$ and $\phi_1(x) = 1/(\theta_1 + 1/(x + 1))$ with θ_1 equal to 0.001 (solid lines) or 1 (dotted lines), where $\phi_a(\cdot)$ and θ_a for $a \in \{0, 1\}$ are as in Assumption A1.

comparison operations, and setting T to $\Omega(\log(\epsilon)/\log(\beta))$ guarantees absolute errors in the numerator and denominator of $O(\epsilon)$. Of course, the constants hidden by the $O(\cdot)$ or $\Omega(\cdot)$ depend on the detailed properties of C and choice of x.

However, this approximation faces a potential complication. Indeed, some of the iterates $X_t(x, a; x)$ may be so close to the threshold x that an arbitrarily small tolerance is required to correctly decide whether $X_t(x, a; x) \geq x$. This might be problematic as errors in such decisions can result in large changes to the numerator and denominator of this approximation.

Dance and Silander (2015) overcame this problem by constraining the sequence of decisions to correspond to $\mathcal{M}$-words. This resulted in a polynomial-time algorithm for approximating the index $\lambda^*(x)$ using variable-precision arithmetic. Specifically, suppose that basic arithmetic operations to tolerance 2^{-m} on positive numbers less than 2^n require at most $M(n + m)$ operations, and that $C(x) = x$. Then, the approximate index $\hat{\lambda}(x)$ output by their algorithm satisfies $\left|\hat{\lambda}(x) - \lambda^*(x)\right| < \epsilon$ when $x < 2^n$ and $\epsilon > 2^{-m}$ and is computed in $O((n + m)^3 M(n + m))$ operations. Nevertheless, that algorithm requires the tabulation of the fixed points of all Christoffel words of at most a given length.

Here we suggest that such tabulation is an unnecessary expense, and conjecture that standard floating-point approximations of the decision sequences $A_t(x, a; x)$ correspond to $\mathcal{M}$-words (at least for the vast majority of floating point values of x). Perhaps such a conjecture might be proven by extending results by Kozyakin (2003). His results concern mappings ϕ_0, ϕ_1 which are strictly increasing but potentially discontinuous. In the floating-point case

one would only require those mappings to be non-decreasing and piecewise constant, but might perhaps impose additional conditions.

Rather than attempting to prove such a conjecture here, we simply evaluate the accuracy of approximation (38). Figure 6 shows the accuracy based on comparing double-precision and quadruple-precision implementations, with $T = \lceil \log 10^{-17}/\log \beta \rceil$ and $T = \lceil \log 10^{-34}/\log \beta \rceil$ respectively. As the difference between these approximations is a highly variable function of x, we only show points that are local maxima of the error. Specifically, we used a logarithmically-spaced grid with $10^{-2} = x_1, x_2, \ldots, x_{1000} = 10^4$ and plot the error $e(x_i)$ only for points with $e(x_i) = \max_{i-20 \leq j \leq i+20} e(x_j)$. The plot shows no line for x less than the first such point or greater than the last such point.

The worst absolute and relative errors are below 10^{-6} and 10^{-11} respectively. In any practical application, such errors would be swamped by imprecision in the time-series models. The absolute error remains small as x increases to the fixed point y_1 of the mapping ϕ_1, and then it increases due to round-off in computing iterates of the map-with-a-gap for large x. Overall, the worst results are for large discount factors and for variance as the cost function.

Finally, it is possible to substantially accelerate the convergence of the numerator, for instance with Aitken acceleration (Brezinski, 2000), particularly if one has high accuracy requirements. For instance, if the itinerary $\sigma(x|x)$ is periodic with small enough period n, one may accumulate n terms of the sum at a time and apply acceleration methods to such partial sums. Having experimented with such approaches, we find that further work is required in selecting appropriate termination conditions if one is interested in accuracy guarantees for a wide range of problem instances. The difficulty we encountered is that *two* types of linear convergence are going on simultaneously, namely the convergence due to ϕ_0 (when $\theta_0 > 0$ or $r < 1$) and ϕ_1, and the convergence due to β. In such situations, what looks like a healthy stopping time to existing termination criteria can actually be a misleading and unhealthy prematurity.

4.2. Approximating the Index for Discount Factor $\beta \to 1$

For discount factors $\beta > 0.999$ the number of terms T required for accuracy in approximation (38) becomes prohibitively large. In such cases, it makes sense to Taylor expand the numerator of λ as a function of β. For brevity, we only do so here for the case $\beta \to 1$.

Suppose the actions $A_t(x, a; x)$ in the expression in Theorem 1 for the index $\lambda^*(x)$ correspond to a Christoffel word of length n. By (12) the denominator of the index is

$$\lim_{\beta \to 1} \frac{1 - \beta}{1 - \beta^n} = \frac{1}{n}.$$

Let $X_t^{a,\infty} := \lim_{k \to \infty} X_{kn+t}(x, a; x)$. Now, as $C(\cdot)$ is continuous by Assumption A1, we have

$$\lim_{k \to \infty} C(X_{kn+t}(x, a; x)) = C(\lim_{k \to \infty} C(X_{kn+t}(x, a; x)) = C(X_t^{a,\infty}). \tag{39}$$

Thus, putting $\Delta_t := C(X_t^{1,\infty}) - C(X_t^{0,\infty})$, the numerator of index has the limit

$$\lim_{\beta \to 1} \sum_{t=0}^{\infty} \beta^t \left(C(X_t(x, 0; x)) - C(X_t(x, 1; x)) \right)$$

$$= \underbrace{\sum_{t=0}^{\infty} \left(C(X_t(x,0;x)) - C(X_t(x,1;x)) + \Delta_t\right)}_{=:T_1} - \lim_{\beta\to 1} \sum_{k=0}^{\infty} \beta^{kn} \sum_{t=0}^{n-1} \beta^t \Delta_t$$
$$= T_1 - \lim_{\beta\to 1} \frac{\sum_{t=0}^{n-1} \beta^t \Delta_t}{1-\beta^n}$$
$$= T_1 + \frac{1}{n} \sum_{t=0}^{n-1} t\Delta_t$$

having applied L'Hôpital's rule. Now (39) shows that the sequences $C(X_t(x,a;x)) - C(X_t^{a,\infty})$ appearing in sum T_1 converge to zero. This suggests the approximation

$$X_{kn+t}^{a,\infty} \approx X_{Tn-n+t}(x,a;x) \qquad (a \in \{0,1\}, k \in \mathbb{Z}_+, t = 0,1,\ldots,n-1)$$

for a suitably large positive integer T. This also suggests approximating the first sum by truncating it after Tn terms. While the itinerary for x might have a very large and possibly infinite period n, we did not encounter such situations when tabulating the index. If this were an issue, it is possible to find a good rational approximation to the rate of the x-threshold itinerary from initial state x, for instance as in Dance and Silander (2015). To summarise, given an appropriate choice of n and T, the discussion above suggests approximating the index by

$$\hat{\lambda}(x) := n \sum_{k=0}^{T-1} \sum_{t=0}^{n-1} \left(\tilde{C}_{kn+t}^0 - \tilde{C}_{Tn-n+t}^0 - \tilde{C}_{kn+t}^1 + \tilde{C}_{Tn-n+t}^1\right) + \sum_{t=0}^{n-1} t \left(\tilde{C}_{Tn-n+t}^1 - \tilde{C}_{Tn-n+t}^0\right)$$

where $\tilde{C}_k^a := C(X_t(x,a;x))$ for $k \in \mathbb{Z}_+$ and $a \in \{0,1\}$.

4.3. Closed Form Expressions and Graphs

We analyse the behaviour of the index as the cost function $C(\cdot)$ and parameters $\beta, r, \theta_0, \theta_1$ vary.

Given noise free observations for action $a = 1$ and totally uninformative observations for action $a = 0$, it is easy to find a closed form for the index.

Proposition 31 *Suppose the cost function is $C(x) = x$ and the precision $\theta_0 = 0$. Then*

$$\lim_{\theta_1\to\infty} \lambda^*(x) = \frac{1-\beta^{n+1}}{1-\beta}\left(rx + 1 - \frac{\beta}{1-\beta^{n+1}}\left(\frac{1-(\beta r)^n}{1-\beta r} - \beta^n \frac{1-r^n}{1-r}\right)\right),$$

for all $\beta \in [0,1)$, $r \in [0,1)$ and $x \in [0, 1/(1-r))$, where $n := \left\lceil \frac{\log(1-(1-r)x)}{\log r} \right\rceil$. Thus

$$\lim_{\beta\to 1} \lim_{r\to 1} \lim_{\theta_1\to\infty} \lambda^*(x) = \lceil x+1 \rceil \left(x + 1 - \frac{\lceil x \rceil}{2}\right) = \int_0^{x+1} \lceil u \rceil \, du, \qquad \text{for all } x \in \mathbb{R}_+.$$

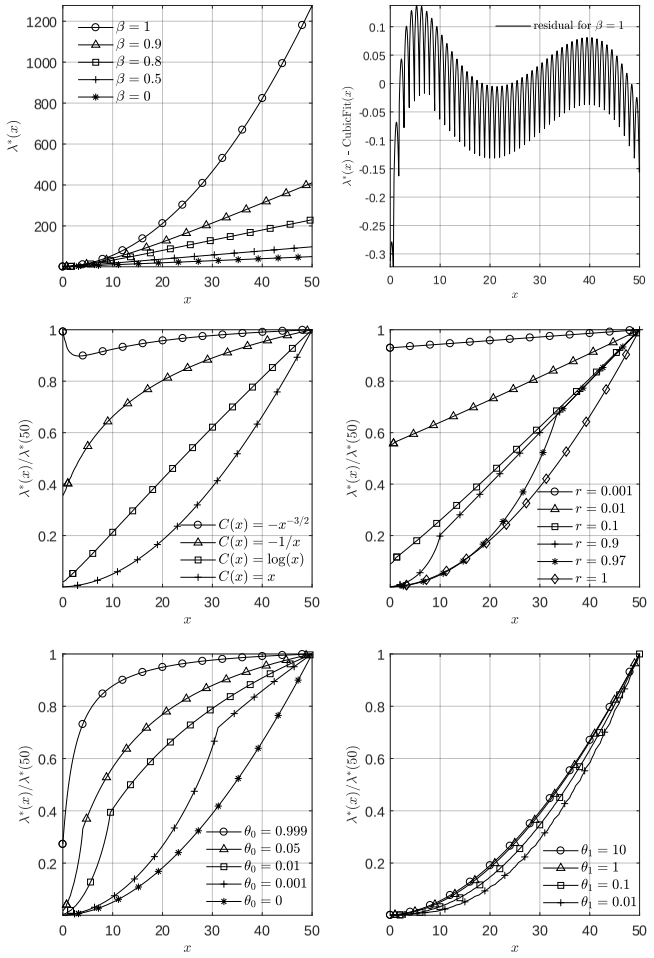

Figure 7: Behaviour of the index. The index as a function of the discount factor β (*top-left*) and the residual after fitting a cubic to this curve in the case $\beta = 1$ (*top-right*). The index, normalised by $\lambda^*(50)$, as the cost function $C(x)$, the multiplier r and the observation precisions θ_0 and θ_1 are varied (*other plots*). In all plots, all parameters (or function) other than that varied are set to $\beta = 0.99$, $C(x) = x$, $\phi_0(x) = 1/(\theta_0 + 1/(rx+1))$ and $\phi_1(x) = 1/(\theta_1 + 1/(rx+1))$, with $\theta_0 = 0$, $\theta_1 = 1$ and $r = 1$.

Proof As $\lim_{\theta_1 \to \infty} \phi_1(x) = 0$, the orbits involve the sequence $0, 1, r+1, r^2+r+1, \ldots, r^{n-1}+\cdots+r+1$, where n is the least integer for which $r^{n-1}+\cdots+r+1 \geq x$. The result then follows from the definition of the index, using well-known summation formulae. ■

Other closed forms exist, for instance in the limit $\beta \to 0$, or whenever the cost is a polynomial function of x or whenever the process tends to the continuous-time process analysed in Le Ny et al. (2011). However, the usefulness of the above proposition to provide practical approximations in circumstances where observations are not perfectly precise, so that $\theta_1 < \infty$, is limited. For instance, if $C(x) = x, \beta \to 1, r = 1, \theta_0 = 0$ and $\theta_1 = 4$, then we have

$$\lambda^*(0.2) = 1.01\cdots, \quad \int_0^{1.2} \lceil u \rceil \, du = 1.4$$

which corresponds to a relative error of over 38%.

Therefore, Figure 7 graphs the index using the algorithms of the previous subsection. Looking at these graphs, one notices that the index is increasing in all-but-one of the cases shown: indeed $C(x) = -x^{-3/2}$ is *not* covered by Assumption A1. Also, the index has cusps at the fixed point $x = \phi_0(x)$ which are clearly visible as θ_0 and r vary. Finally, the index becomes increasingly serrated as $\beta \to 1$ and $\theta_1 \to 0$. One would anticipate such serrations on the basis of the above proposition as

$$\int_0^{x+1} \lceil u \rceil \, du \; - \; \frac{1}{2}(x+1)(x+2) = \frac{1}{2}(\lceil x \rceil - x)(x - \lfloor x \rfloor)$$

and they are visible in the plot of the residual after subtracting a cubic fit, for $\theta_1 = 1$ and $\beta \to 1$. However, in general, the serrations have a complex non-periodic pattern and give a slightly ragged appearance to the plot with $\theta_1 = 0.01$.

4.4. Performance Relative to Heuristic Policies

Two heuristic policies have been commonly used for the problem of multi-sensor scheduling. The *myopic* policy observes the m time series with the highest current cost $C_i(x_{i,t})$ and has been used in radar systems (Moran et al., 2008). Meanwhile, the *round robin* policy chooses an ordering of the n projects and observes the next m projects, according to this ordering, at each time.

Figure 8 compares the costs incurred by these heuristics in a simple scenario in which uncertainty about one of the projects is more expensive than for the other projects. In detail, there are $n = 10$ projects, the number of observations per round is $m = 1$, the cost at time t is $40x_{1,t} + \sum_{i=2}^{n} x_{i,t}$, and the initial variance is $x_{i,0} = 4$ for all projects. The discount factor is $\beta = 0.99$ and the "total cost" for a given method is computed as $\sum_{t=0}^{199} \beta^t (40x_{1,t} + \sum_{i=2}^{n} x_{i,t})$. The projects have the same map-with-a-gap given by $\phi_0(x) = x+1$ and $\phi_1(x) = 1/(0.1 + 1/(x+1))$. The colours in this plot represent the variance state $x_{i,t}$.

Clearly, the myopic policy is overeager to observe project $i = 1$ and does so at the expense of projects $i = 2, \ldots, 10$. In contrast, the round robin policy makes no special effort to observe project $i = 1$ and incurs substantial expense for that project. Meanwhile,

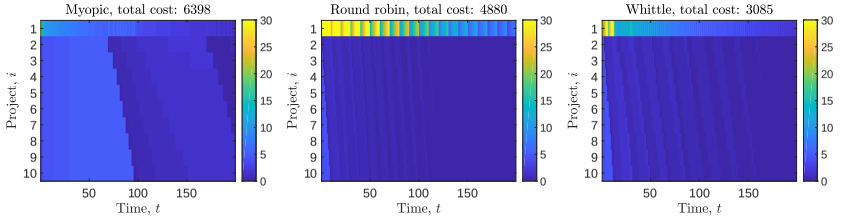

Figure 8: Comparison of heuristic policies. Colour represents the variance state $x_{i,t}$.

the Whittle index policy's behaviour lies between these extremes and it is by far the least costly policy. Indeed the ratio of the total cost of the round robin policy to the total cost of the Whittle index policy is just over 1.5, whereas the ratio of the total cost for the myopic policy to the total cost for the Whittle index policy is just over 2.

5. Further Work

This paper presented conditions under which threshold policies are optimal for observing a single time series with costly observations. It also explored the implications of this result by showing that it leads to optimal policies for the linear-quadratic Gaussian problem with costly observations and that it demonstrates the indexability of related restless bandit problems, which were both long-standing open questions.

It would be natural to extend this work to situations where more than two observation actions are available, perhaps using known generalisations of Sturmian words (Glen and Justin, 2009). Additionally, it would be interesting to complete the work by Le Ny et al. (2011) analysing optimal policies and indexability for scalar-valued time series in continuous time. In particular, there are a number of gaps in their argument to close, as discussed on page 12, and there is as yet no analysis of the discounted case nor of the class of cost function for which threshold policies are optimal. There are also truly-stochastic versions of the one-dimensional problem considered here. These include situations where the costs depend on the posterior mean rather than just the posterior variance (Kuhn et al., 2014), situations where the quality of the observation is a random variable, as well as situations involving non-Gaussian time series. It is also important to understand the structure of optimal policies for making costly observations with discrete-time Kalman filters in *multiple* dimensions. One attack on this problem would begin by extending the verification theorem of Niño-Mora (2015) to multi-dimensional state spaces for a variety of extensions of the notion of a "threshold policy". Finally, we cannot claim the asymptotic optimality of Whittle's index policy for the problem studied here as the results of Verloop (2016) only apply to *countable* state spaces. Furthermore, little is known about the performance of policies for restless bandits in *non-asymptotic* situations involving finite numbers of projects and finite time horizons.

Acknowledgments

We thank José Niño-Mora for pointing out his work on the verification theorem, Sofia Michel for her careful reading of an initial draft of the manuscript, and the reviewers for their tenacity and numerous helpful suggestions. Much of the work described in this paper was done while the authors were with Xerox Research Centre Europe.

Appendix A. Itineraries as Words

We begin with some elementary properties of compositions of functions satisfying Assumption A2 and their fixed points (Section A.1). This enables us to present a proof of Theorem 12 which is based on the Christoffel tree. First we consider the case where itineraries correspond to Christoffel words (Section A.2), then the case where itineraries correspond to Sturmian $\mathcal{M}$-words (Section A.3) and finally we couple these results together to prove the theorem (Subsection A.4). We also present proofs of Corollary 13 concerning x-threshold itineraries from initial state $\phi_0(x)$ and $\phi_1(x)$ (Section A.5) and of Theorem 14 about itineraries from general initial points not equal to the threshold (Section A.6) .

A.1. Compositions and Fixed Points

The following fundamental result about compositions is well known.

Lemma 32 *Suppose A2 holds and that w is a finite non-empty word. Then ϕ_w is increasing, contractive, continuous and has a unique fixed point y_w on $\mathcal{I}$.*

Proof First we show that $\phi_w(x)$ is increasing, by induction on the length of word w. In the base case, as w is non-empty, we suppose that $|w| = 1$. The claim then follows immediately from A2. For the inductive step, assume $\phi_u(x)$ is increasing, where $w = au$ for some letter $a \in \{0, 1\}$ and some finite non-empty word u. Then for any $x, y \in \mathcal{I}$ such that $x < y$,

$$\begin{aligned} \phi_w(y) &= \phi_u(\phi_a(y)) \\ &> \phi_u(\phi_a(x)) && \text{as } \phi_a(y) > \phi_a(x) \text{ and } \phi_u \text{ is increasing} \\ &= \phi_w(x). \end{aligned}$$

Therefore ϕ_w is increasing.

Now we show that $\phi_w(x)$ is contractive, again by induction on $|w|$. If $|w| = 1$ then this follows immediately from A2. Else, say $\phi_u(x)$ is contractive where $w = ua$ and $a \in \{0, 1\}$. Then for any $x, y \in \mathcal{I}$ such that $x < y$,

$$\begin{aligned} \phi_w(y) - \phi_w(x) &= \phi_a(\phi_u(y)) - \phi_a(\phi_u(x)) \\ &< \phi_u(y) - \phi_u(x) && \text{as } \phi_u(y) > \phi_u(x) \text{ and } \phi_a \text{ is contractive} \\ &< y - x && \text{as } \phi_u \text{ is contractive.} \end{aligned}$$

Therefore ϕ_w is contractive.

As ϕ_w is contractive, for any $\epsilon > 0$ and $c \in \mathcal{I}$, it follows that

$$|\phi_w(x) - \phi_w(c)| < |x - c| < \epsilon \quad \text{for any } x \in \mathcal{I} \text{ with } |x - c| < \epsilon.$$

Therefore ϕ_w is continuous.

Now we show that the fixed point y_w exists, using the intermediate value theorem applied to the function $g(x) := x - \phi_w(x)$. First we show that $g(y_0) \geq 0$. Indeed, as ϕ_1 is contractive, the definition of y_1 gives

$$y_0 - y_1 > \phi_1(y_0) - \phi_1(y_1) = \phi_1(y_0) - y_1, \quad \text{so that} \quad \phi_1(y_0) < y_0.$$

So, it follows from the definition of y_0 that the upper bound $\psi(x) := \max\{\phi_0(x), \phi_1(x)\}$ satisfies $\psi(y_0) = \phi_0(y_0) = y_0$. As $\phi_u(x)$ is increasing for any finite word u, it follows that

$$\phi_w(y_0) = \phi_{w_{2:|w|}} \circ \phi_{w_1}(y_0) \leq \phi_{w_{2:|w|}} \circ \psi(y_0) = \phi_{w_{2:|w|}}(y_0) \leq \cdots \leq y_0,$$

so that

$$g(y_0) = y_0 - \phi_w(y_0) \geq y_0 - y_0 = 0.$$

A similar argument, using the lower bound $\min\{\phi_0(x), \phi_1(x)\}$, gives $g(y_1) \leq 0$. In summary, $g(y_1) \leq 0 \leq g(y_0)$, where $y_1 < y_0$ by A2, and $g(x)$ is continuous as $\phi_w(x)$ is continuous. So the intermediate value theorem shows that $g(y) = 0$ for some $y \in [y_1, y_0]$. Therefore a fixed point y_w exists on $\mathcal{I}$.

Now we show that the fixed point y_w is unique. Suppose both y and z are fixed points of ϕ_w with $y > z$. This leads to the following contradiction: as ϕ_w is contractive we have

$$\frac{\phi_w(y) - \phi_w(z)}{y - z} < 1,$$

yet as $\phi_w(y) = y$ and $\phi_w(z) = z$ we have

$$\frac{\phi_w(y) - \phi_w(z)}{y - z} = 1.$$

Therefore the fixed point is unique. This completes the proof. ■

We make widespread use of the following simple lemma. Given a word w, this lemma gives necessary and sufficient conditions for $\phi_w(x)$ to be greater than or less than x.

Lemma 33 *Suppose A2 holds, that $x \in \mathcal{I}$ and w is a finite non-empty word. Then*

$$x < \phi_w(x) \;\Leftrightarrow\; \phi_w(x) < y_w \;\Leftrightarrow\; x < y_w \quad \textit{and} \quad x > \phi_w(x) \;\Leftrightarrow\; \phi_w(x) > y_w \;\Leftrightarrow\; x > y_w.$$

Proof We use Lemma 32 and the definition of y_w throughout without further mention.

As ϕ_w is increasing, if $x < y_w$ then $\phi_w(x) < \phi_w(y_w) = y_w$. Similarly, if $x > y_w$ then $\phi_w(x) > y_w$. Thus if $\phi_w(x) \leq y_w$ then $x \leq y_w$, by the contrapositive. But if $\phi_w(x) \neq y_w$ then $x \neq y_w$, as ϕ_w is increasing and therefore injective. So if $\phi_w(x) < y_w$ then $x < y_w$. Therefore

$$x < y_w \quad \Leftrightarrow \quad \phi_w(x) < y_w.$$

As ϕ_w is contractive, if $x < y_w$ then $\phi_w(y_w) - \phi_w(x) < y_w - x$. As $\phi_w(y_w) = y_w$, this rearranges to give $x < \phi_w(x)$. Similarly, if $x > y_w$ then $x > \phi_w(x)$. Thus if $x \leq \phi_w(x)$ then $x \leq y_w$, by the contrapositive. But if $x \neq \phi_w(x)$ then x is not a fixed point, so $x \neq y_w$. So if $x < \phi_w(x)$ then $x < y_w$. Therefore

$$x < y_w \quad \Leftrightarrow \quad x < \phi_w(x).$$

A similar argument shows that $x > y_w \Leftrightarrow \phi_w(x) > y_w$ and $x > y_w \Leftrightarrow x > \phi_w(x)$. ■

Lemma 34 *Suppose A2 holds and w is a finite word with $|w|_0|w|_1 > 0$. Then*

$$y_1 < y_w < y_0.$$

Proof As $|w|_0 > 0$ we have $w =: s01^q$ for some finite word s and some $q \in \mathbb{Z}_+$. As $y_0 > y_1$ by A2, Lemma 33 gives $\phi_0(y_1) > y_1$. Thus the definition of y_1 and the fact that ϕ_s is increasing give

$$\phi_w(y_1) = \phi_{s01^q}(y_1) = \phi_{s0}(y_1) = \phi_s(\phi_0(y_1)) > \phi_s(y_1) \geq y_1$$

where the last step follows by repeating the same argument. But if $\phi_w(y_1) > y_1$ then Lemma 33 shows that $y_w > y_1$.

A similar argument leads to the conclusion that $y_w < y_0$. ■

Lemma 35 *Suppose A2 holds, $x \in \mathcal{I}$ and w is a finite non-empty word. Then*

$$\lim_{n\to\infty} \phi_{w^n}(x) = y_w.$$

Proof The sequence with elements $x_n := \phi_{w^n}(x)$ for $n \in \mathbb{Z}_{++}$ is monotone and bounded, by Lemma 33. So the monotone convergence theorem for sequences of real numbers shows that $l := \lim_{n\to\infty} x_n$ exists. But as ϕ_w is continuous, by Lemma 32, the limit l satisfies

$$\phi_w\big(l\big) = \phi_w\big(\lim_{n\to\infty} x_n\big) = \lim_{n\to\infty} \phi_w\big(x_n\big) = \lim_{n\to\infty} x_{n+1} = l.$$

So l is a fixed point of ϕ_w. By Lemma 32, y_w is the unique such fixed point. ■

As a contractive function is not necessarily a contraction mapping, some additional work is required to prove the following result which is essential in the Sturmian case addressed in Subsection A.3.

Lemma 36 *Suppose A2 holds, w is an infinite word and $y_0 \geq a > b \geq y_1$. Then*

$$\lim_{n\to\infty} (\phi_{w_{1:n}}(a) - \phi_{w_{1:n}}(b)) = 0.$$

Proof Let $a_n := \phi_{w_{1:n}}(a)$ and $b_n := \phi_{w_{1:n}}(b)$ for $n \in \mathbb{Z}_{++}$. By Assumption A2, ϕ_{w_n} is a contractive function, so $(a_n - b_n)_{n=1}^{\infty}$ is a decreasing sequence and as $a, b \in [y_1, y_0]$ Lemma 33 shows that this is also a bounded sequence. Therefore the monotone convergence theorem for real-valued sequences shows that

$$\lim_{n\to\infty} (a_n - b_n) \text{ exists.}$$

Now we argue that the limit is zero, by contradiction. Assume that $a_n - b_n \geq \epsilon$ for all $n \in \mathbb{Z}_{++}$, where ϵ is a positive real number. Let the domain $\mathcal{D} \subset \mathbb{R}^2$ be

$$\mathcal{D} := \{(h, l) \ : \ h, l \in [y_1, y_0], \ h \geq l + \epsilon\},$$

let the functions $f_c : \mathcal{D} \to \mathbb{R}$ for letters $c \in \{0, 1\}$ be

$$f_c(h, l) := \frac{\phi_c(h) - \phi_c(l)}{h - l}$$

where $(h, l) \in \mathcal{D}$ and define the number $q \in \mathbb{R}$ by

$$q := \sup_{(h,l)\in\mathcal{D}} \left\{ \max_{c\in\{0,1\}} f_c(h, l) \right\}.$$

Now the functions f_0, f_1 are continuous on their domain $\mathcal{D}$ by Lemma 32. Also, the domain $\mathcal{D}$ is a non-empty, bounded and closed set. So the extreme value theorem for functions of several variables shows that the maximum equals the supremum. Thus

$$q = \max_{(h,l)\in\mathcal{D}} \left\{ \max_{a\in\{0,1\}} f_a(h, l) \right\}.$$

As ϕ_c is contractive for $c \in \{0, 1\}$ it follows that

$$q < 1$$

and as ϕ_c is increasing we have $q > 0$. So the definition of q and hypothesis that $a > b$ give

$$a_n - b_n \leq q^n(a - b) < \epsilon \quad \text{for } n > \log((a - b)/\epsilon)/\log(1/q).$$

Thus there is an $n \in \mathbb{Z}_{++}$ with $a_n - b_n < \epsilon$. This contradicts the assumption that $a_n - b_n \geq \epsilon$ for all $n \in \mathbb{Z}_{++}$. Since $\epsilon > 0$ was arbitrary, we conclude that

$$\lim_{n\to\infty} (a_n - b_n) = 0.$$

This completes the proof. ■

A.2. x-Threshold Words as Christoffel Words

We begin with some definitions that go beyond the main text.

In Definition 5 and the text immediately following it, we introduced the s^--threshold itinerary $\sigma(x|s^-, \phi_0, \phi_1)$ from initial state x for a pair of maps ϕ_0 and ϕ_1. Let us focus on the case where the threshold equals the initial state as in Theorem 12. Now, the first letter of this itinerary is always 1 and as that theorem suggests, the remainder of the itinerary is frequently periodic, motivating the following definition.

Definition 37 *Consider an interval $\mathcal{I} \subseteq \mathbb{R}$, maps $\phi_0 : \mathcal{I} \to \mathcal{I}$ and $\phi_1 : \mathcal{I} \to \mathcal{I}$, and a state $x \in \mathcal{I}$. The **x-threshold word** for ϕ_0 and ϕ_1 is the shortest word $\ell(x, \phi_0, \phi_1)$ such that $\sigma(x|x^-, \phi_0, \phi_1) = 1\ell(x, \phi_0, \phi_1)^\infty$.*

If the maps are evident from the context, we talk of the x-threshold word $\ell(x)$ and if we are also focusing on a particular x, we talk of the x-threshold word ℓ.

The set $\{0,1\}^*$ consists of all finite words on the alphabet $\{0,1\}$, including the empty string ϵ. The *morphism* $\mathscr{M} : \{0,1\}^* \to \{0,1\}^*$ generated by a mapping $s : \{0,1\} \to \{0,1\}^*$, substitutes $s(w_k)$ for each letter w_k of a word w, so that

$$\mathscr{M}(\epsilon) = \epsilon \text{ and } \mathscr{M}(w) = s(w_1)s(w_2)\cdots s(w_{|w|}).$$

We work with the morphisms $\mathscr{L} : \{0,1\}^* \to \{0,1\}^*$ and $\mathscr{R} : \{0,1\}^* \to \{0,1\}^*$ given by

$$\mathscr{L} : \begin{cases} 0 \mapsto 0 \\ 1 \mapsto 01 \end{cases} \qquad \mathscr{R} : \begin{cases} 0 \mapsto 01 \\ 1 \mapsto 1 \end{cases}.$$

Let $\circ$ denote composition of morphisms, for example $\mathscr{R} \circ \mathscr{L}(1) = \mathscr{R}(01) = 011$.

Remark 38 *These morphisms generate the Christoffel tree through pre-composition. Say (u, v) is a Christoffel pair and consider the morphism*

$$\mathscr{M} : \begin{cases} 0 \mapsto u \\ 1 \mapsto v \end{cases}.$$

Then pre-composition maps the node (u, v) of the Christoffel tree to its children:

$$\begin{aligned} (\mathscr{M} \circ \mathscr{L}(0),\ \mathscr{M} \circ \mathscr{L}(1)) &= (\mathscr{M}(0),\ \mathscr{M}(01)) = (u, uv) \\ (\mathscr{M} \circ \mathscr{R}(0),\ \mathscr{M} \circ \mathscr{R}(1)) &= (\mathscr{M}(01),\ \mathscr{M}(1)) = (uv, v). \end{aligned} \tag{40}$$

Now let us give a simple upper and lower bound on the elements of x^--threshold orbits.

Lemma 39 *Suppose A2 holds and $(x_k)_{k=1}^\infty = \text{orbit}(\phi_1(x)|x^-)$. Then*

$$x \in [y_1, y_0] \ \Rightarrow\ \phi_1(x) \le x_k < \phi_0(x) \quad \text{for } k \in \mathbb{Z}_{++}.$$

Proof Say $z \in [y_1, y_0)$. Then Lemma 33 gives

$$y_1 \le \phi_1(z) \le z < \phi_0(z) < y_0.$$

An induction using this fact, immediately shows that for $k \in \mathbb{Z}_{++}$,

$$y_1 \le x_k < y_0.$$

Now we prove the claim by induction with hypothesis

$$H_k : \quad \phi_1(x) \le x_k < \phi_0(x)$$

for $k \in \mathbb{Z}_{++}$. The base case H_1 is true as $x_1 = \phi_1(x)$ by definition of orbit$(\phi_1(x)|x^-)$. For the inductive step, say H_k is true for some $k \in \mathbb{Z}_{++}$. Then there are two cases to consider: $x_k \in [\phi_1(x), x)$ and $x_k \in [x, \phi_0(x))$. If $x_k \in [\phi_1(x), x)$ then $x_{k+1} = \phi_0(x_k)$ and

$$\begin{aligned} \phi_1(x) &\le x_k \\ &< \phi_0(x_k) && \text{by Lemma 33 as } x_k < y_0 \\ &< \phi_0(x) && \text{as } x_k < x \text{ and } \phi_0(\cdot) \text{ is increasing,} \end{aligned}$$

so H_{k+1} is true. If $x_k \in [x, \phi_0(x))$ then $x_{k+1} = \phi_1(x_k)$ and

$$\begin{aligned} \phi_1(x) &\le \phi_1(x_k) && \text{as } x \le x_k \text{ and } \phi_1(\cdot) \text{ is increasing} \\ &\le x_k && \text{by Lemma 33 as } y_1 \le x_k \\ &< \phi_0(x), \end{aligned}$$

so H_{k+1} is true. This completes the proof. ■

Now we show that x-threshold words are Christoffel words in three important special cases and then we find the general conditions on x for which x-threshold words are Christoffel words (Lemma 44).

Lemma 40 *Suppose ℓ is the x-threshold word for ϕ_0, ϕ_1 satisfying A2. Then*

$$\begin{aligned} \ell = 1 &\ \Leftrightarrow\ x \le y_1 \\ \ell = 01 &\ \Leftrightarrow\ x \in [y_{01}, y_{10}] \\ \ell = 0 &\ \Leftrightarrow\ x \ge y_0. \end{aligned}$$

Proof If $\ell = 1$ then the definition of the x-threshold word shows that $\phi_1(x) \ge x$. Therefore Lemma 33 shows that $x \le y_1$.

If $x \le y_1$ then Lemma 33 shows that $x \le \phi_{1^n}(x) \le y_1$ for all $n \in \mathbb{Z}_{++}$. Therefore $\ell = 1$.

If $\ell = 01$ then the next letter of ℓ^∞ after $(01)^n$ is 0 for any $n \in \mathbb{Z}_+$. So $x > \phi_{(01)^n}(\phi_1(x))$. Therefore Lemma 35 gives

$$x \ge \lim_{n\to\infty} \phi_{(01)^n}(\phi_1(x)) = y_{01}.$$

If $\ell = 01$ then $\ell_2 = 1$. So $x \le \phi_{10}(x)$. Therefore Lemma 33 gives

$$x \le y_{10}.$$

If $x \ge y_{01}$ then $x > y_1$ by Lemma 34. So $\phi_1(x) < x$ by Lemma 33. As ϕ_{01} is increasing by Lemma 32, it follows that for any $n \in \mathbb{Z}_+$,

$$\phi_{(01)^n}(\phi_1(x)) < \phi_{(01)^n}(x) \le x$$

where the second inequality follows from Lemma 33 as $x \ge y_{01}$. Therefore, if ℓ^∞ begins with $(01)^n$ then the next letter is 0.

If $x \le y_{10}$ then Lemma 33 shows that $\phi_{(10)^n}(x) \ge x$ for all $n \in \mathbb{Z}_+$. Therefore, if ℓ^∞ begins with $(01)^n 0$ then the next letter is 1.

The proof for the case $\ell = 0$ is symmetric to that for $\ell = 1$. This completes the proof. ■

Lemma 41 *Suppose ϕ_0, ϕ_1 satisfy A2, $x \in \mathcal{I}$ and ℓ is the x-threshold word. Then*

$$\begin{cases} |\ell|_{11} > 0 & \Rightarrow \quad x < y_{01} \\ |\ell|_{00} > 0 & \Rightarrow \quad x > y_{10}. \end{cases}$$

Proof If $|\ell|_{11} > 0$ then $x < y_0$ by Lemma 40. So, either $x \le y_1$, in which case Lemma 34 shows that $x < y_{01}$, or $x \in (y_1, y_0)$. In the latter case, let $(x_k)_{k=1}^\infty = \text{orbit}(\phi_1(x)|x^-)$. As $|\ell|_{11} > 0$ there exists a $k \in \mathbb{Z}_{++}$ with $\phi_1(x_k) \ge x$ by definition of the x-threshold word. Now $x_k < \phi_0(x)$ by Lemma 39, so that $\phi_1(\phi_0(x)) > \phi_1(x_k) \ge x$ as ϕ_1 is increasing. But $\phi_{01}(x) > x$ implies that $x < y_{01}$ by Lemma 33.

The proof for $|\ell|_{00} > 0$ is symmetric. This completes the proof. ■

Lemma 42 *Suppose ϕ_0, ϕ_1 satisfy A2. Then for $x \in [y_{10}, y_0]$, there is a unique $z \in \mathcal{I}$ with*

$$\phi_0(z) = x.$$

Furthermore

$$\ell(x, \phi_0, \phi_1) = \begin{cases} \mathscr{L}(\ell(\phi_0^{(-1)}(x), \phi_0, \phi_{01})) & \text{if } x \in [y_{10}, y_0] \\ \mathscr{R}(\ell(x, \phi_{01}, \phi_1)) & \text{if } x \in [y_1, y_{01}]. \end{cases}$$

Proof In the first claim, existence of z follows from the intermediate value theorem, as ϕ_0 is continuous by Lemma 32, as $y_{01} \in [y_0, y_1] \subseteq \mathcal{I}$ by Lemma 34, as $\phi_0(y_{01}) = y_{10} \le x$ by definition of y_{01}, and as $\phi_0(y_0) = y_0 \ge x$ by definition of y_0. Uniqueness follows as ϕ_0 is increasing.

Now say $x \in [y_{10}, y_0]$ consider the claim involving the morphism $\mathscr{L}$. Let

$$V := \ell(\phi_0^{(-1)}(x), \phi_0, \phi_{01})^\infty \quad \text{and} \quad W := \ell(x, \phi_0, \phi_1)^\infty.$$

We show by induction that the hypothesis

$$H_i \ : \ \mathscr{L}(V_{1:i}) \text{ is a prefix of } W$$

is true for all $i \in \mathbb{Z}_+$, noting that this proves the claim.

In the base case, $\mathscr{L}(\epsilon) = \epsilon$ is a prefix of W, so H_0 is true. For the inductive step, say H_{i-1} is true for some $i \in \mathbb{Z}_{++}$. Let

$$(x_n)_{n=1}^\infty := \text{orbit}(\phi_1(x)|x^-, \phi_0, \phi_1),$$
$$(\tilde{x}_n)_{n=1}^\infty := \text{orbit}(\psi_1(\phi_0^{(-1)}(x))|\phi_0^{(-1)}(x)^-, \psi_0, \psi_1)$$

where $\psi_0 := \phi_0, \psi_1 := \phi_{01}$ and let $k := \left|\mathscr{L}(V_{1:(i-1)})\right| + 1$. Then

$$\tilde{x}_1 = \psi_1(\phi_0^{(-1)}(x)) = \phi_1(x) = x_1$$

and, letting ψ_w denote the composition of ψ_0, ψ_1 corresponding to a word w,

$$\begin{aligned} \tilde{x}_i &= \psi_{V_{1:(i-1)}}(\tilde{x}_1) && \text{by definition of } V \\ &= \phi_{\mathscr{L}(V_{1:(i-1)})}(\tilde{x}_1) && \text{by definition of } \psi_0, \psi_1 \\ &= \phi_{W_{1:(k-1)}}(\tilde{x}_1) && \text{as } H_{i-1} \text{ is true} \\ &= \phi_{W_{1:(k-1)}}(x_1) && \text{as } \tilde{x}_1 = x_1 \\ &= x_k && \text{by definition of } W. \end{aligned}$$

As $x \in [y_{10}, y_0]$, we have $\tilde{x} := \phi_0^{(-1)}(x) \in [y_{01}, y_0]$. Letting $\tilde{y}_0, \tilde{y}_1$ be the fixed points of ψ_0, ψ_1, this reads $\tilde{x} \in [\tilde{y}_1, \tilde{y}_0]$. But ψ_0, ψ_1 satisfy A2, as Lemma 32 shows that these functions are increasing and contractive, and Lemma 34 shows that $\tilde{y}_1 < \tilde{y}_0$. Thus Lemma 39 shows that

$$\tilde{x}_i < \psi_0(\tilde{x}) = \phi_0(\phi_0^{(-1)}(x)) = x.$$

But we already showed that $x_k = \tilde{x}_i$ so this gives $x_k < x$. Therefore $W_k = 0$, by definition of the x-threshold word. If $V_i = 0$ then we can conclude that H_i is true. Otherwise $V_i = 1$ so that $\tilde{x}_i \ge \phi_0^{(-1)}(x)$. But we already showed that $W_k = 0$ and $x_k = \tilde{x}_i$, so $x_{k+1} = \phi_0(x_k) = \phi_0(\tilde{x}_i) \ge x$. Therefore $W_{k+1} = 1$ and we conclude that H_i is true.

The proof for the claim involving $\mathscr{R}$ is similar. This completes the proof. ■

Lemma 43 *Suppose ϕ_0, ϕ_1 satisfy A2, $x \in \mathcal{I}$ and $0v1$ is a finite word. Then*

$$\begin{cases} \ell(\phi_0(x), \phi_0, \phi_1) = \mathscr{L}(0v1) & \Leftrightarrow \quad \ell(x, \phi_0, \phi_{01}) = 0v1 \\ \ell(x, \phi_0, \phi_1) = \mathscr{R}(0v1) & \Leftrightarrow \quad \ell(x, \phi_{01}, \phi_1) = 0v1. \end{cases}$$

Proof Consider the claim involving the morphism $\mathscr{L}$.

If $\ell(\phi_0(x), \phi_0, \phi_1) = \mathscr{L}(0v1)$ then $|\ell(\phi_0(x), \phi_0, \phi_1)|_{00} > 0$, as $|0v1|_{01} > 0$ for any finite word v and $\mathscr{L}(01) = 001$. So Lemma 41 shows that $\phi_0(x) > y_{10}$. Thus $x > y_{01}$. Also,

$|\ell(\phi_0(x),\phi_0,\phi_1)|_1 = |\mathscr{L}(0v1)|_1 > 0$, so Lemma 40 shows that $\phi_0(x) < y_0$. Thus $x < y_0$. Hence Lemma 42 gives

$$\mathscr{L}(0v1) = \mathscr{L}(\ell(x,\phi_0,\phi_{01})).$$

As $\mathscr{L}$ is injective, it follows that

$$0v1 = \ell(x,\phi_0,\phi_{01}).$$

If $\ell(x,\phi_0,\phi_{01}) = 0v1$ then $|\ell(x,\phi_0,\phi_{01})|_0 > 0$ and $|\ell(x,\phi_0,\phi_{01})|_1 > 0$. So Lemma 40 shows that $x \in (y_{01}, y_0)$. Hence Lemma 42 gives

$$\ell(\phi_0(x),\phi_0,\phi_1) = \mathscr{L}(0v1).$$

The argument for the claim involving $\mathscr{R}$ is symmetric. This completes the proof. ■

Lemma 44 *Suppose ϕ_0, ϕ_1 satisfy A2 and $0w1$ is a Christoffel word. Then*

$$x \in [y_{01w}, y_{10w}] \;\Leftrightarrow\; \ell(x,\phi_0,\phi_1) = 0w1.$$

Proof We use induction on the depth of $0w1$ in the Christoffel tree, with hypothesis

$$H_n : \begin{cases} \text{If } 0w1 \text{ is at depth } n \text{ of the tree and } \phi_0,\phi_1 \text{ satisfy A2, then} \\ x \in [y_{01w}, y_{10w}] \;\Leftrightarrow\; \ell(x,\phi_0,\phi_1) = 0w1. \end{cases}$$

Lemma 40 shows that the base case (H_1) with $0w1 = 01$ is true. For the inductive step, let $0w1$ be a word at depth $n+1$ of the tree and assume H_n is true. Then either $0w1 = \mathscr{L}(0v1)$ or $0w1 = \mathscr{R}(0v1)$ for some word $0v1$ which is at depth n of the tree. If $0w1 = \mathscr{L}(0v1)$ then Lemma 43 gives

$$\ell(x,\phi_0,\phi_1) = 0w1 \quad\Leftrightarrow\quad \ell(\phi_0^{(-1)}(x),\phi_0,\phi_{01}) = 0v1.$$

Now ϕ_{01} is increasing and contractive by Lemma 32 and $y_{01} < y_0$ by Lemma 34. Thus ϕ_0, ϕ_{01} satisfy A2. So the assumption that H_n is true shows that

$$\ell(\phi_0^{(-1)}(x),\phi_0,\phi_{01}) = 0v1 \quad\Leftrightarrow\quad \phi_0^{(-1)}(x) \in [y_{\mathscr{L}(01v)}, y_{\mathscr{L}(10v)}].$$

But as $0w1 = \mathscr{L}(0v1) = 0\mathscr{L}(v)01$, we have

$$\begin{aligned} \phi_0(y_{\mathscr{L}(01v)}) &= \phi_0(y_{001\mathscr{L}(v)}) = y_{01\mathscr{L}(v)0} = y_{01w} \\ \phi_0(y_{\mathscr{L}(10v)}) &= \phi_0(y_{010\mathscr{L}(v)}) = y_{10\mathscr{L}(v)0} = y_{10w}. \end{aligned}$$

As ϕ_0 is increasing and continuous, it follows that

$$\phi_0^{(-1)}(x) \in [y_{\mathscr{L}(01v)}, y_{\mathscr{L}(10v)}] \quad\Leftrightarrow\quad x \in [y_{01w}, y_{10w}].$$

Therefore H_{n+1} is true.

If $0w1 = \mathscr{R}(0v1)$ then the proof is similar. This completes the proof. ■

A.3. x-Threshold Words as Sturmian $\mathcal{M}$-Words

It turns out that Lemma 44 characterises x-threshold words for nearly all $x \in (y_1, y_0)$. However, its proof cannot be extended to all values of x as it is based on induction on the depth $n \in \mathbb{Z}_{++}$ in the Christoffel tree, and we need to take the limit as $n \to \infty$ to address the remaining values of x. Those remaining values correspond to Sturmian $\mathcal{M}$-words, as we show in this subsection.

First we show how Sturmian $\mathcal{M}$-words can be written as the limit of a sequence of words.

Lemma 45 *A word w is a Sturmian $\mathcal{M}$-word if and only if it is of the form*

$$w = \lim_{n\to\infty} \mathscr{M}_1 \circ \mathscr{M}_2 \circ \cdots \circ \mathscr{M}_n(01)$$

for some sequence of morphisms $(\mathscr{M}_n)_{n=1}^{\infty}$ with $\mathscr{M}_n \in \{\mathscr{L},\mathscr{R}\}$ which is not eventually constant (i.e. there is no $m \in \mathbb{Z}_{++}$ such that $\mathscr{M}_n = \mathscr{M}_m$ for all $n \in \mathbb{Z}_{++}$ with $n > m$).

The above result is well known, for instance, noting the isomorphism of the Christoffel tree and the Stern-Brocot tree, see Chapter 4 of Graham et al. (1994).

Remark 46 *The requirement that the sequence of morphisms generating Sturmian $\mathcal{M}$-words is not eventually constant rules out words such as*

$$\lim_{n\to\infty} \mathscr{L}^n(01) = 0^{\infty}.$$

Indeed, this corresponds to the Christoffel word 0. It also rules out words such as

$$\lim_{n\to\infty} \mathscr{R}^n(01) = 01^{\infty}.$$

Indeed, this is not an $\mathcal{M}$-word because there is no $\alpha \in [0,1]$ with

$$0 = \lfloor \alpha n \rfloor - \lfloor \alpha(n-1) \rfloor \text{ for } n = 1 \text{ and } 1 = \lfloor \alpha n \rfloor - \lfloor \alpha(n-1) \rfloor \text{ for } n = 2, 3, \ldots.$$

Now we show that every x-threshold word corresponds to an $\mathcal{M}$-word.

Lemma 47 *Suppose ϕ_0, ϕ_1 satisfy A2 and $x \in \mathcal{I}$. Then $\ell(x,\phi_0,\phi_1)$ is an $\mathcal{M}$-word.*

Proof Lemma 40 shows that $\ell(x,\phi_0,\phi_1)$ is an $\mathcal{M}$-word for $x \in \mathcal{I}\backslash(y_1, y_0)$. So, for the rest of this proof we assume that $x \in (y_1, y_0)$. We shall now define procedure which generates a sequence of morphisms $\mathscr{M}_k$, thresholds $x_k \in \mathcal{I}$, mappings $\phi_{k,a} : \mathcal{I} \to \mathcal{I}$ for $a \in \{0,1\}$ and we denote the compositions of those mappings by

$$\phi_{k,w} = \phi_{k,w_{|w|}} \circ \cdots \phi_{k,w_2} \circ \phi_{k,w_1}$$

for any finite word w. The procedure is as follows:

1. **let** $k \leftarrow 1$
2. **let** $(x_k, \phi_{k,0}, \phi_{k,1}) \leftarrow (x,\phi_0,\phi_1)$
3. **let** $y_{k,01}, y_{k,10}$ be the fixed points of $\phi_{k,01}, \phi_{k,10}$

4. **while** $x_k \notin [y_{k,01}, y_{k,10}]$
5. **if** $x_k < y_{k,01}$
6. **set** $(x_{k+1}, \phi_{k+1,0}, \phi_{k+1,1}, \mathscr{M}_k) \leftarrow (x_k, \phi_{k,01}, \phi_{k,1}, \mathscr{R})$
7. **else**
8. **set** $(x_{k+1}, \phi_{k+1,0}, \phi_{k+1,1}, \mathscr{M}_k) \leftarrow (\phi_{k,0}^{(-1)}(x), \phi_{k,0}, \phi_{k,01}, \mathscr{L})$
9. **end**
10. **let** $k \leftarrow k+1$
11. **let** $y_{k,01}, y_{k,10}$ be the fixed points of $\phi_{k,01}, \phi_{k,10}$
12. **end**

The sequence of morphisms $\mathscr{M}_1, \mathscr{M}_2, \ldots$ generated by this procedure is either empty, of finite length $n \in \mathbb{Z}_{++}$ or of infinite length. We consider each of these cases in turn.

If the sequence is empty, then $x \in [y_{1,01}, y_{1,10}] = [y_{01}, y_{10}]$. So Lemma 40 shows that $\ell(x, \phi_0, \phi_1) = 01$, which is an $\mathcal{M}$-word.

If the sequence has finite length, let n be that length. As the morphisms $\mathscr{L}$ and $\mathscr{R}$ generate the Christoffel tree by pre-composition, as remarked at (40), the word

$$w := \mathscr{M}_1 \circ \cdots \circ \mathscr{M}_n(01)$$

is a Christoffel word. Also, when the procedure sets $\mathscr{M}_k = \mathscr{R}$ for some $k \in \mathbb{Z}_{++}$, we have $x_k < y_{k,01} < y_{k,10}$ so Lemma 42 shows that

$$\ell(x_k, \phi_{k,0}, \phi_{k,1}) = \mathscr{R}(\ell(x_{k+1}, \phi_{k+1,0}, \phi_{k+1,1})).$$

Similarly, when the procedure sets $\mathscr{M}_k = \mathscr{L}$ we have

$$\ell(x_k, \phi_{k,0}, \phi_{k,1}) = \mathscr{L}(\ell(x_{k+1}, \phi_{k+1,0}, \phi_{k+1,1})).$$

Therefore the x-threshold word is $\ell(x, \phi_0, \phi_1) = w$ which is an $\mathcal{M}$-word.

Finally, if the sequence does not terminate, then Lemma 45 shows that the word

$$w := \lim_{n\to\infty} \mathscr{M}_1 \circ \cdots \circ \mathscr{M}_n(01)$$

is a Sturmian $\mathcal{M}$-word *provided* there is no $m \in \mathbb{Z}_{++}$ such that $\mathscr{M}_n = \mathscr{M}_m$ for all $n \in \mathbb{Z}_{++}$ with $n \geq m$. Also, the argument given for finite sequences above shows that $w = \ell(x, \phi_0, \phi_1)$. If there were such an m and $\mathscr{M}_m = \mathscr{R}$, then

$$\begin{aligned} w &= \mathscr{M}_1 \circ \cdots \circ \mathscr{M}_{m-1} \circ \lim_{k\to\infty} \mathscr{R}^k(01) \\ &= \mathscr{M}_1 \circ \cdots \circ \mathscr{M}_{m-1}(01^\infty). \end{aligned}$$

Thus the word at stage m is $\ell(x_m, \phi_{m,0}, \phi_{m,1}) = 01^\infty$. But this is impossible, as the fact that the first letter is 0 requires $\phi_{m,1}(x_m) < x_m$, so that $x_m > y_{m,1}$, whereas the fact that remaining letters are 1 requires $\phi_{m,101^n}(x_m) \geq x_m$ for all $n \in \mathbb{Z}_+$, so that $y_{m,1} \geq x_m$, which is a contradiction. If there were such an m and $\mathscr{M}_m = \mathscr{L}$, then

$$w = \mathscr{M}_1 \circ \cdots \circ \mathscr{M}_{m-1} \circ \lim_{k\to\infty} \mathscr{L}^k(01)$$

$$= \mathscr{M}_1 \circ \cdots \circ \mathscr{M}_{m-1}(0^\infty)$$

Therefore at stage m the word $\ell(x_m, \phi_{m,0}, \phi_{m,1}) = 0$, but this is impossible as $x_m < y_{m,0}$. In conclusion, $\ell(x, \phi_0, \phi_1)$ is an $\mathcal{M}$-word.

This completes the proof. ■

Lemma 48 *Suppose $0 \leq \alpha < \beta \leq 1$ and let a, b be the $\mathcal{M}$-words of rate α, β respectively. Then $a^\infty \prec b^\infty$.*

Proof Consider the first $n \in \mathbb{Z}_{++}$ with $(a^\infty)_n \neq (b^\infty)_n$. Then

$$\lfloor \alpha(n-1) \rfloor = \left|(a^\infty)_{1:(n-1)}\right|_1 = \left|(b^\infty)_{1:(n-1)}\right|_1 = \lfloor \beta(n-1) \rfloor,$$

by definition of $\mathcal{M}$-words, so that

$$(a^\infty)_n = \lfloor \alpha n \rfloor - \lfloor \alpha(n-1) \rfloor = \lfloor \alpha n \rfloor - \lfloor \beta(n-1) \rfloor < \lfloor \beta n \rfloor - \lfloor \beta(n-1) \rfloor = (b^\infty)_n$$

where the inequality holds as $(a^\infty)_n \neq (b^\infty)_n$, as $\alpha < \beta$ and as the floor function is non-decreasing. Therefore $a^\infty \prec b^\infty$. ■

Consider a tree and a node x of the tree. Recall that the *subtree rooted at* x is the tree of all descendants of x that has node x as a root. If the tree is a binary tree, the *left subtree of* x is the subtree rooted at the left child of x, and the *right subtree of* x is the subtree rooted at the right child of x. Thus the subtree rooted at x contains node x, but the left and right subtrees of x do not contain node x.

Lemma 49 *Suppose (u, v) is a Christoffel pair. Considering uv as a node of the Christoffel tree, let l and r be Christoffel words in the left and right subtrees of uv. Then*

$$\text{rate}(u) < \text{rate}(l) < \text{rate}(uv) < \text{rate}(r) < \text{rate}(v).$$

Proof First we use induction to show that for any Christoffel pair (u, v), we have

$$\text{rate}(u) < \text{rate}(v). \tag{41}$$

In the base case $(u, v) = (0, 1)$ and (41) is true. For the inductive step, say (u, v) is the left child of a Christoffel pair (a, b) with $\text{rate}(a) < \text{rate}(b)$. Then $(u, v) = (a, ab)$ so that

$$\text{rate}(u) = \frac{|a|_1}{|a|} < \frac{|a|_1 + |b|_1}{|a| + |b|} = \text{rate}(v)$$

by the mediant inequality. The proof for right children is similar. Therefore (41) is true.

As l is in the left subtree of uv, it follows from the construction of the Christoffel tree that l consists of m copies of u and n copies of uv concatenated in some order, for some $m, n \in \mathbb{Z}_{++}$. Thus the mediant inequality and (41) give

$$\text{rate}(l) = \text{rate}(u^m (uv)^n) = \frac{m|u|_1 + n|uv|_1}{m|u| + n|uv|} \in \left(\frac{|u|_1}{|u|}, \frac{|uv|_1}{|uv|} \right)$$

Therefore $\text{rate}(u) < \text{rate}(l) < \text{rate}(uv)$, as claimed.

The proof for a node r in the right subtree of uv is similar. This completes the proof. ■

Lemma 50 *Suppose* $(0a1, 0b1)$ *is a Christoffel pair. Then* $a10b = b01a$.

Proof As $a, b, a10b$ are palindromes, we have $a10b = (a10b)^R = b^R01a^R = b01a$. ■

Lemma 51 *Suppose the word* $0c1$ *is in the subtree of the Christoffel tree rooted at* $0p1$. *Then* p *is both a prefix and suffix of* c.

Proof There are four cases to consider:

1. The word $0c1$ has no parent, in which case $c = p = \epsilon$ and the claim holds.
2. The word c is of one of the forms 0^m or 0^m10^m for some $m \in \mathbb{Z}_{++}$. In that case either $p = c$ or $p = 0^l$ for some $l \in \mathbb{Z}_+$ with $l < m$ and the claim holds.
3. The word c is of one of the forms 1^m or 1^m01^m for some $m \in \mathbb{Z}_{++}$. This is similar to the previous case.
4. The Christoffel pair of the parent of $0c1$ is of the form $(0a1, 0b1)$.

In the last case, we use induction on the length of the path $n \in \mathbb{Z}_+$ through the Christoffel tree from $0p1$ to $0c1$. In the base case, $n = 0$, we have $c = p$ and the claim is true. For the inductive step, say $0c1$ is a child of the node with Christoffel pair $(0a1, 0b1)$, that $0a10b1$ is n steps along the path from $0p1$, and that p is both a prefix and suffix of $a10b$, so that $a10b = pq = rp$ for some words q, r. If $0c1$ is a left-child, then $c = a10a10b = a10rp$ and Lemma 50 gives

$$c = a10a10b = a10b01a = pq01a$$

so p is a prefix and suffix of c. Similarly, if $0c1$ is a right child, then $c = a10b10b$ and

$$pq10b = a10b10b = b01a10b = b01rp.$$

This completes the proof. ■

Lemma 52 *Suppose* ϕ_0, ϕ_1 *satisfy A2. Then*

$$\ell(x, \phi_0, \phi_1)^\infty \text{ is a lexicographically non-increasing function of } x \in \mathcal{I}.$$

Proof If $a, b \in \mathcal{I}$ and $\ell(a, \phi_0, \phi_1)^\infty \succ \ell(b, \phi_0, \phi_1)^\infty$, then there is a finite word u such that

$$\ell(a, \phi_0, \phi_1)^\infty = u1v, \qquad \ell(b, \phi_0, \phi_1)^\infty = u0w,$$

for some words v, w. So the definition of threshold orbits and Lemma 33 give

$$y_{1u} \geq \phi_{1u}(a) \geq a, \qquad y_{1u} < \phi_{1u}(b) < b.$$

Therefore $a < b$. This completes the proof. ■

In the main text, we defined the fixed point y_s of a Sturmian $\mathcal{M}$-word as the limit of a sequence of fixed points $y_{01w^{(n)}}$ or $y_{10w^{(n)}}$ where the words $(0w^{(n)}1)_{n=1}^\infty$ correspond to a particular path in the Christoffel tree. We now define a subsequence associated with each of these sequences of words and fixed points. Consider a Sturmian $\mathcal{M}$-word

$$0s = \lim_{n\to\infty} \mathscr{L}^{a_1} \circ \mathscr{R}^{b_1} \circ \cdots \circ \mathscr{L}^{a_n} \circ \mathscr{R}^{b_n}(01)$$

where $a_1 \in \mathbb{Z}_+$ and $a_{n+1}, b_n \in \mathbb{Z}_{++}$ for $n \in \mathbb{Z}_{++}$. We define the sequences $(u^{(n)})_{n=1}^\infty$ and $(l^{(n)})_{n=1}^\infty$ of the central portions of the Christoffel words as

$$0u^{(n)}1 := \mathscr{L}^{a_1} \circ \mathscr{R}^{b_1} \circ \cdots \circ \mathscr{L}^{a_n}(01), \quad 0l^{(n)}1 := \mathscr{L}^{a_1} \circ \mathscr{R}^{b_1} \circ \cdots \circ \mathscr{L}^{a_n} \circ \mathscr{R}^{b_n}(01). \quad (42)$$

These words form a subsequence of $(0w^{(n)}1)_{n=1}^\infty$, so if $\lim_{n\to\infty} y_{01w^{(n)}}$ exists, then so does $\lim_{n\to\infty} y_{01l^{(n)}}$ and these limits are equal.

Lemma 53 *Suppose A2 holds,* $n \in \mathbb{Z}_{++}$ *and that* $0u^{(n)}1$ *and* $0l^{(n)}1$ *are as in (42). Then*

$$y_{01l^{(n)}} < y_{01l^{(n+1)}} < y_{10u^{(n+1)}} < y_{10u^{(n)}}.$$

Proof By definition, $0l^{(n+1)}1$ is in the left subtree of $0l^{(n)}1$, so Lemma 49 gives

$$\text{rate}(0l^{(n+1)}1) < \text{rate}(0l^{(n)}1).$$

Hence Lemma 44 and Lemma 48 give

$$\ell(y_{01l^{(n+1)}})^\infty = (0l^{(n+1)}1)^\infty \prec (0l^{(n)}1)^\infty = \ell(y_{10l^{(n)}})^\infty.$$

Therefore Lemma 52 shows that

$$y_{01l^{(n)}} < y_{01l^{(n+1)}}.$$

But $0l^{(n+1)}1$ is in the right subtree of $0u^{(n+1)}1$. So the same argument gives

$$y_{01l^{(n+1)}} < y_{10u^{(n+1)}}.$$

Similarly, $0u^{(n+1)}1$ is in the right subtree of $0u^{(n)}1$, so

$$y_{10u^{(n+1)}} < y_{10u^{(n)}}.$$

This completes the proof. ■

Note that the argument in the above proof also shows that any word $0w^{(m)}1$ lying strictly between $0u^{(n)}1$ and $0l^{(n)}1$ on the path through the Christoffel tree from $0u^{(n)}1$ to $0l^{(n)}1$ has

$$y_{10l^{(n)}} < y_{01w^{(m)}} < y_{10w^{(m)}} < y_{01u^{(n)}}.$$

Similarly, any word $0w^{(m)}1$ lying strictly between $0l^{(n)}1$ and $0u^{(n+1)}1$ on the path from $0l^{(n)}1$ to $0u^{(n+1)}1$ has

$$y_{10l^{(n)}} < y_{01w^{(m)}} < y_{10w^{(m)}} < y_{01u^{(n+1)}}.$$

Thus if the subsequences $(y_{01l^{(n)}})_{n=1}^{\infty}$ and $(y_{10u^{(n)}})_{n=1}^{\infty}$ have limits, then so do the full sequences $(y_{01w^{(m)}})_{n=1}^{\infty}$ and $(y_{10w^{(m)}})_{n=1}^{\infty}$.

Lemma 54 *Suppose $(0w^{(n)}1)_{n=1}^{\infty}$ is the sequence of words traversed along an infinite path down the Christoffel tree. Let $(n_i)_{i=1}^{\infty}$ be an increasing sequence on $\mathbb{Z}_{++}$. Then there exists an infinite word s and an increasing sequence $(k_i)_{i=1}^{\infty}$ on $\mathbb{Z}_{++}$ such that $s_{1:k_i}$ is a suffix of both $w^{(n_i)}$ and $w^{(n_{i+1})}$, for all $i \in \mathbb{Z}_{++}$.*

Proof We show that $s_{1:k_i} := w^{(n_i)}$ for $i \in \mathbb{Z}_{++}$, is well-defined and satisfies this claim. As $w^{(n_i)}$ is a prefix of all of its descendants by Lemma 51, it follows that $s_{1:k_i}$ is a prefix of $s_{1:k_{i+1}}$. Also, as $w^{(n_i)}$ is a suffix of all of its descendants, it follows that $s_{1:k_i}$ is a suffix of both $w^{(n_i)}$ and $w^{(n_{i+1})}$. ■

Lemma 55 *Suppose ϕ_0, ϕ_1 satisfy A2 and $0s$ is a Sturmian $\mathcal{M}$-word. Consider the sequence of Christoffel words $(0w^{(n)}1 : n \in \mathbb{Z}_{++})$ traversed on the infinite path through the Christoffel tree towards $0s$ (as defined in the main text just before Theorem 12). Then the fixed points*

$$y_{01s} := \lim_{n\to\infty} y_{01w^{(n)}} \qquad \text{and} \qquad y_{10s} := \lim_{n\to\infty} y_{10w^{(n)}}$$

exist and are equal.

Proof Let $a_n, b_n, 0u^{(n)}1, 0l^{(n)}1$ for $n \in \mathbb{Z}_{++}$ be as in (42).

Existence of the fixed points follows from the monotone convergence theorem for real-valued sequences. Indeed, Lemma 53 shows that $(y_{01l^{(n)}})_{n=1}^{\infty}$ is an increasing sequence, that $(y_{10u^{(n)}})_{n=1}^{\infty}$ is a decreasing sequence, and that these sequences are bounded.

By Lemma 54 we have $u^{(n)} = c^{(n)}w_{1:k_n}$ and $l^{(n)} = d^{(n)}w_{1:k_n}$ for all $n \in \mathbb{Z}_{++}$ for some sequences of finite words $(c^{(n)})_{n=1}^{\infty}$ and $(d^{(n)})_{n=1}^{\infty}$, for some infinite word w and for some increasing sequence $(k_n)_{n=1}^{\infty}$ on $\mathbb{Z}_{++}$.

As $\phi_a(x)$ is an increasing function of $x \in \mathcal{I}$ for any finite word a, by Lemma 32,

$$\begin{aligned} y_{10u^{(n)}} &= \phi_{10u^{(n)}}(y_{10u^{(n)}}) \\ &< \phi_{10u^{(n)}}(y_0) \\ &= \phi_{10c^{(n)}w_{1:k_n}}(y_0) \\ &= \phi_{w_{1:k_n}}(\phi_{10c^{(n)}}(y_0)) \end{aligned}$$

$$< \phi_{w_{1:k_n}}(y_0).$$

Similarly, we have

$$y_{01l^{(n)}} > \phi_{w_{1:k_n}}(y_1).$$

Thus

$$\lim_{n\to\infty}(y_{10u^{(n)}} - y_{01l^{(n)}}) \le \lim_{n\to\infty}(\phi_{w_{1:k_n}}(y_0) - \phi_{w_{1:k_n}}(y_1)) = 0$$

where the last step is Lemma 36. But $y_{10u^{(n)}} > y_{01l^{(n)}}$ for $n \in \mathbb{Z}_{++}$ by Lemma 53. Therefore

$$y_{10s} = \lim_{n\to\infty} y_{10u^{(n)}} = \lim_{n\to\infty} y_{01l^{(n)}} = y_{01s}.$$

This completes the proof. ■

In view of the above Lemma, from now on we shall write $y_s = y_{10s} = y_{01s}$.

Lemma 56 *Suppose ϕ_0, ϕ_1 satisfy A2 and $0s$ is a Sturmian $\mathcal{M}$-word. Then*

$$\ell(x, \phi_0, \phi_1) = 0s \;\Leftrightarrow\; x = y_s.$$

Proof Let $(u^{(n)})_{n=1}^{\infty}$ and $(l^{(n)})_{n=1}^{\infty}$ be the sequences (42) appearing in the definition of the fixed point of $0s$. For fixed ϕ_0, ϕ_1 let us write $\ell(x)$ in place of $\ell(x, \phi_0, \phi_1)$.

Say $x = y_s$. Recall that $x = y_{10s} = y_{01s}$ by Lemma 55. As $y_{10u^{(n)}} > y_{10s}$ for all $n \in \mathbb{Z}_{++}$ by Lemma 53, and $\ell(z)^{\infty}$ is a lexicographically non-increasing function of z, by Lemma 52, it follows that

$$\ell(x)^{\infty} \succ \ell(y_{10u^{(n)}})^{\infty} = (0u^{(n)}1)^{\infty}$$

where the equality follows from Lemma 44. A similar argument gives $\ell(x)^{\infty} \prec (0l^{(n)}1)^{\infty}$ for $n \in \mathbb{Z}_{++}$. Therefore

$$0s = \lim_{n\to\infty}(0u^{(n)}1)^{\infty} \preceq \ell(x)^{\infty} \preceq \lim_{n\to\infty}(0l^{(n)}1)^{\infty} = 0s.$$

Now say $\ell(x) = 0s$ for some $x \in \mathcal{I}$. Then $y_{01l^{(n)}} < x < y_{10u^{(n)}}$ as $\ell(z)^{\infty}$ is a lexicographically non-increasing function of z and $(0u^{(n)}1)^{\infty} \prec 0s \prec (0l^{(n)}1)^{\infty}$ for all $n \in \mathbb{Z}_{++}$. Therefore

$$y_s = \lim_{n\to\infty} y_{01l^{(n)}} \le x \le \lim_{n\to\infty} y_{10u^{(n)}} = y_s.$$

This completes the proof. ■

A.4. Proof of Theorem 12

Proof The existence of fixed points y_{01p}, y_{10p} follows from Lemma 32 and the existence of y_s follows from Lemma 55.

The fact that $\sigma(z|z^-) = 1\ell(z, \phi_0, \phi_1)^\infty$ is a lexicographically non-decreasing function of $z \in \mathcal{I}$ follows from Lemma 52.

Lemma 40 addresses the value of $\sigma(z|z^-)$ for $z \le y_1$ and $z \ge y_0$, Lemma 44 addresses the case $z \in [y_{01p}, y_{10p}]$ and Lemma 56 address the case $z = y_s$. Thus the image of $\ell(z, \phi_0, \phi_1)$ as z ranges over $\mathcal{I}$ contains all $\mathcal{M}$-words. Using Lemma 47, it follows that this image is exactly the set of $\mathcal{M}$-words.

This completes the proof. ■

A.5. Proof of Corollary 13

Proof First we give a simple result about the relation between $\mathcal{M}$-words of rates r and $1-r$. Then we demonstrate the result for itineraries of the form $\sigma(\phi_0(x)|x)$ and finally the result for itineraries of the form $\sigma(\phi_1(x)|x)$.

Relation between $\mathcal{M}$-words. Let bitflip$(\cdot)$ denote the bitwise NOT operation, that maps any finite or infinite word w to the word of the same length whose n^{th} letter is $1 - w_n$. We now show that

$$\text{if } 0s \text{ is a Sturmian } \mathcal{M}\text{-word then } 0\,\text{bitflip}(s) \text{ is also a Sturmian } \mathcal{M}\text{-word.}$$

Let $r := \text{rate}(0s)$. By definition, the word w of rate $1-r$ has

$$w_n = \lfloor (1-r)n \rfloor - \lfloor (1-r)(n-1) \rfloor = 1 - \lceil rn \rceil + \lceil r(n-1) \rceil$$

for any positive integer n. As $0s$ is Sturmian, its rate r is irrational, so rm is not an integer for any positive integer m and it follows that $\lceil rm \rceil = \lfloor rm \rfloor$. Thus

$$w_n = 1 - (\lfloor rn \rfloor - \lfloor r(n-1) \rfloor) = \text{bitflip}(0s)_n$$

as claimed. A similar argument shows that

$$\text{if } 0p1 \text{ is a Christoffel word then } 0\,\text{bitflip}(p)1 \text{ is also a Christoffel word.}$$

Result for $\sigma(\phi_0(x)|x)$. Let $\tilde{\phi}_0(x) := -\phi_1(-x)$, $\tilde{\phi}_1(x) := -\phi_0(-x)$ and $\tilde{\mathcal{I}} := \{-x : x \in \mathcal{I}\}$. For a word w, let $\tilde{y}_w$ be the fixed point $y_w = \tilde{\phi}_w(y_w)$ of the composition $\tilde{\phi}_w$ of $\tilde{\phi}_0, \tilde{\phi}_1$ corresponding to w. Since A2 holds for $\mathcal{I}, \phi_0$ and ϕ_1, it is easy to see that it also holds for $\tilde{\mathcal{I}}, \tilde{\phi}_0$ and $\tilde{\phi}_1$. Let $\tilde{\sigma}(x|s^-)$ denote the s^--threshold itinerary from $x \in \tilde{\mathcal{I}}$ for the maps $\tilde{\phi}_0, \tilde{\phi}_1$. From these definitions, for any $x \in \mathcal{I}$ we have

$$\sigma(\phi_0(x)|x) = \text{bitflip}(\tilde{\sigma}(\tilde{\phi}_1(-x)|(-x)^-)).$$

But if $x \le y_1$ then $-x \ge \tilde{y}_0$, so Theorem 12 gives $\tilde{\sigma}(-x|(-x)^-) = 10^\infty$ and thus $\sigma(\phi_0(x)|x) = 1^\infty$. The argument that $\sigma(\phi_0(x)|x) = 0^\infty$ for $x \ge y_0$ is similar. Also if $x \in [y_{01p}, y_{10p}]$ then $-x \in [\tilde{y}_{01\,\text{bitflip}(p)}, \tilde{y}_{10\,\text{bitflip}(p)}]$, and the relation between $\mathcal{M}$-words above shows that

$0\,\text{bitflip}(p)1$ is a Christoffel word, so Theorem 12 gives $\tilde{\sigma}(-x|(-x)^-) = (10\,\text{bitflip}(p))^\infty$ and thus $\sigma(\phi_0(x)|x) = (1p0)^\infty$. Finally if $x = y_s$ then $-x = \tilde{y}_{\text{bitflip}(s)}$, and the relation between $\mathcal{M}$-words above shows that $0\,\text{bitflip}(s)$ is a Sturmian $\mathcal{M}$-word, so Theorem 12 gives $\tilde{\sigma}(-x|(-x)^-) = 10\,\text{bitflip}(s)$ and thus $\sigma(\phi_0(x)|x) = 1s$.

Result for $\sigma(\phi_1(x)|x)$. Let $\text{orbit}(x|s^-)$ denote the sequence of states in the s^--threshold orbit from initial state x under maps ϕ_0 and ϕ_1. The core of our argument is that if $\text{orbit}(x|s^-)$ does not contain s then $\sigma(x|s) = \sigma(x|s^-)$. Indeed if s is not in $\text{orbit}(x|s^-) =: (x_1, x_2, \dots)$, the decisions $\mathbf{1}_{x_k > s}$ and $\mathbf{1}_{x_k \ge s}$ are the same for each $k = 1, 2, \dots$.

Say $x \in [y_{01p}, y_{10p})$. First we show that assuming that x is is in $\text{orbit}(\phi_1(x)|x^-)$ leads to a contradiction. If indeed x were in that orbit, then either $x = \phi_{(10p)^N}(x)$ for some $N \in \mathbb{Z}_{++}$ or $x = \phi_{(10p)^N(10p)_{1:m}}(x)$ for some $N \in \mathbb{Z}_+$ and $1 \le m < |10p|$. The first case gives $x = y_{10p}$ which contradicts $x < y_{10p}$. The second case gives $\sigma(x|x^-) = (10p)^N(10p)_{1:m}\sigma(x|x^-) = ((10p)^N(10p)_{1:m})^\infty$ and as m is not a multiple of $|10p|$, this contradicts Theorem 12 which shows that $\sigma(x|x^-) = (10p)^\infty$. It follows that

$$\sigma(\phi_1(x)|x) = \sigma(\phi_1(x)|x^-).$$

Since $\sigma(x|x^-) = (10p)^\infty$ by Theorem 12, we conclude that $\sigma(\phi_1(x)|x) = (0p1)^\infty$.

If $x = y_{10p}$ then $\sigma(x|x^-) = (10p)^\infty$ by Theorem 12 and the first time $\text{orbit}(x|x^-)$ returns to x is after the letters $10p$. Thus $\sigma(\phi_1(x)|x)$ and $\sigma(\phi_1(x)|x^-)$ agree up to that point, so $\sigma(\phi_1(x)|x) = 0p0\sigma(\phi_0(x)|x) = 0p(0p1)^\infty$ using the result about $\sigma(\phi_0(x)|x)$ proved earlier.

Say $x = y_s$. Theorem 12 gives $\sigma(x|x^-) = 10s$. Say $\phi_{(10s)_{1:k}}(x) = x$ for some $k \in \mathbb{Z}_{++}$. Then $\sigma(x|x^-) = (10s)_{1:k}\sigma(x|x^-) = ((10s)_{1:k})^\infty$ which contradicts the fact that Sturmian $\mathcal{M}$-words are not periodic. Therefore $\text{orbit}(x|x^-)$ does not return to x and it follows that $\sigma(\phi_1(x)|x) = \sigma(\phi_1(x)|x^-) = 0s$.

This completes the proof. ■

A.6. Proof of Theorem 14

Based on the work of Kozyakin (2003), we begin by showing that maps-with-gaps formed from functions satisfying Assumption A2 are *locally-growing relaxation functions* (Lemmas 58 and 59) and that the itineraries of such functions are 1-*balanced words* (Lemmas 61 and 62). As 1-balanced words correspond to factors of lower mechanical words (Lemma 63), this enables us to describe the itineraries of maps-with-gaps, for arbitrary initial states and thresholds (Lemma 64). We couple this description with an easy result about lexicographic ordering (Lemma 65) and with a result about the number of factors of mechanical words (Lemma 66) to bound the number of discontinuities of the itinerary of a map-with-a-gap as a function of its threshold (Lemma 67). Finally, we prove Theorem 14.

Definition 57 *Let $\mathcal{I}$ be an interval of $\mathbb{R}$. A function $f : \mathcal{I} \to \mathcal{I}$ is a* ***locally-growing relaxation function*** *with threshold $z \in \mathcal{I}$ if*

1. $f(z) < z < f(z^-) < \infty$
2. $f(f(z^-)) \le f(f(z))$

3. $f(x)$ is increasing for $x \in [f(z), z)$

4. $f(x)$ is increasing for $x \in [z, f(z^-))$.

In Kozyakin (2003), this terminology was used for a smaller class of functions f. In particular, the domain and range were restricted to the interval $[0, 1)$ and there was a requirement that f is continuous on each of the intervals $[f(z), z)$ and $[f(z^-), f(z))$.

The following two Lemmas show that maps-with-gaps whose parts satisfy Assumption A2 lead to locally-growing relaxation functions.

Lemma 58 *Suppose ϕ_0, ϕ_1 satisfy A2 and $x \in [y_1, y_0]$. Then $\phi_{01}(x) < \phi_{10}(x)$.*

Proof Suppose that $x \in [y_1, y_0)$. Then using Lemma 33 gives

$$\begin{aligned} \phi_1(\phi_0(x)) - \phi_1(x) &< \phi_0(x) - x && \text{as } \phi_1 \text{ is contractive and } x < y_0 \\ \phi_0(x) - \phi_0(\phi_1(x)) &\le x - \phi_1(x) && \text{as } \phi_0 \text{ is contractive and } x \ge y_1 \\ \phi_{01}(x) &< \phi_{10}(x) && \text{by adding these inequalities.} \end{aligned}$$

A symmetric argument holds if $x \in (y_1, y_0]$. This completes the proof. ■

Lemma 59 *Suppose ϕ_0, ϕ_1 satisfy A2, that $z \in (y_1, y_0)$ and let $f(x) := \phi_{\mathbf{1}_{x \ge z}}(x)$ for $x \in \mathcal{I}$. Then f is a locally-growing relaxation function with threshold z.*

Proof By definition $f(z^-) = \phi_0(z^-) = \phi_0(z)$, as ϕ_0 is continuous by Lemma 32. Also $f(z) = \phi_1(z)$, $f(f(z^-)) = \phi_{01}(z)$ and $f(f(z)) = \phi_{10}(z)$. So the conditions defining a locally-growing relaxation function read as follows:

1. $\phi_1(z) < z < \phi_0(z) < \infty$, which is true for $z \in (y_1, y_0)$ by Lemma 33
2. $\phi_{01}(z) < \phi_{10}(z)$, which is the result of Lemma 58
3. $\phi_0(x)$ is increasing for $x \in [\phi_1(z), z)$, which holds by A2
4. $\phi_1(x)$ is increasing for $x \in [z, \phi_0(z))$, which holds by A2.

This completes the proof. ■

The following definition is due to Morse and Hedlund (1940).

Definition 60 *An word w is 1-**balanced** if*

$$\big|\, |u|_1 - |v|_1 \big| \le 1$$

for all factors u, v of w with $|u| = |v|$.

The next two Lemmas use an argument from Kozyakin (2003) to show that the itineraries of a locally-growing relaxation function are 1-balanced. We denote the fractional part of a real number x by $\{x\} := x - \lfloor x \rfloor$.

Lemma 61 *Suppose f is a locally-growing relaxation function with threshold z. Let*

$$F(x) := \frac{f(t\{x\} - t\mathbf{1}_{\{x\} \in [\alpha, 1)} + z) - z}{t} + \lfloor x \rfloor + 1 \qquad \text{for } x \in \mathbb{R}$$

where $t := f(z^-) - f(z)$ and $\alpha := (f(z^-) - z)/t$. Then

F1. $F(0) \in [0, 1)$

F2. $F(x + 1) = F(x) + 1$ for all $x \in \mathbb{R}$

F3. F is increasing

F4. The itineraries of f and F agree in the sense that

$$f^{(n-1)}(x) \ge z \;\Leftrightarrow\; \left\{ F^{(n-1)}\left(\frac{x - z}{t}\right) \right\} \in [0, F(0))$$

for all $n \in \mathbb{Z}_{++}$ and all $x \in [f(z), f(z^-))$.

Proof First, note that the function F is well-defined as $f(z) \in \mathbb{R}$ and $f(z) < z < f(z^-) < \infty$ so that $t \in \mathbb{R}_{++}$ and

$$\alpha = \frac{f(z^-) - z}{f(z^-) - f(z)} \in (0, 1). \tag{43}$$

It is easy to see that F1 and F2 hold. Indeed

$$F(0) = \frac{f(z) - z}{t} + 1 = \frac{f(z) - z + f(z^-) - f(z)}{f(z^-) - f(z)} = \alpha \in (0, 1)$$

and as the ratio in the definition of $F(x)$ only depends on $\{x\}$, we have

$$F(x + 1) - F(x) = \lfloor x + 1 \rfloor - \lfloor x \rfloor = 1 \qquad \text{for } x \in \mathbb{R}. \tag{44}$$

Now we show that F3 holds.

- If $x \in [0, \alpha)$ then $tx + z \in [z, f(z))$. But $f(\cdot)$ is increasing on $[z, f(z))$ and $t \in \mathbb{R}_{++}$. It follows that $F(x) = (f(tx + z) - z)/t$ is increasing for $x \in [0, \alpha)$.
- As $f(f(z^-)) \le f(f(z))$ and f is increasing on $[z, f(z^-))$, it follows that

$$F(\alpha^-) = \frac{\lim_{x \uparrow f(z^-)} f(u) - z}{t} + 1 \le \frac{f(f(z^-)) - z}{t} + 1 \le \frac{f(f(z)) - z}{t} + 1 = F(\alpha).$$

- If $x \in [\alpha, 1)$ then $tx - t + z \in [f(z^-), z)$. But $f(\cdot)$ is increasing on $[f(z^-), z)$ and $t \in \mathbb{R}_{++}$. It follows that $F(x) = (f(tx - t + z) - z)/t$ is increasing for $x \in [\alpha, 1)$.
- The definition of F gives

$$F(1^-) = \frac{f(z^-) - z}{t} + 1 = \alpha + 1 = F(1).$$

In summary, $F(x)$ is increasing for $x \in [0,1]$. But as $F(x+1) = F(x)+1$ for $x \in \mathbb{R}$ we conclude that F is increasing for $x \in \mathbb{R}$. Therefore F3 holds.

Now, we note that for any $m \in \mathbb{Z}_+$ and any $x \in [\alpha-1, \alpha)$ we have

$$\frac{f^{(m)}(tx+z)-z}{t} \in [\alpha-1, \alpha). \tag{45}$$

Indeed, for $m=0$ we have $(f^{(m)}(tx+z)-z)/t = x \in [\alpha-1,\alpha)$. Also if $y \in [f(z), f(z^-))$ then the assumptions about f show that $f(y) \in [f(z), f(z^-))$, while if $x \in [\alpha-1,\alpha)$ then the definitions of t and α show that $tx+z \in [f(z), f(z^-))$. Thus $(f^{(m)}(tx+z)-z)/t \in [\alpha-1,\alpha)$.

Now, we show by induction that for any for any $x \in [\alpha-1,\alpha)$ and $n \in \mathbb{Z}_+$ we have

$$F^{(n)}(\{x\}) - \frac{f^{(n)}(tx+z)-z}{t} \in \mathbb{Z}. \tag{46}$$

In the base case $n=0$ we have $F^{(0)}(\{x\}) - (f^{(0)}(tx+z)-z)/t = \{x\} - ((tx+z)-z)/t \in \mathbb{Z}$. For the inductive step, let $p := F^{(n)}(\{x\})$ and $q := (f^{(n)}(tx+z)-z)/t$ and suppose that $p-q \in \mathbb{Z}$. Then we have

$$F^{(n+1)}(\{x\}) = F(p) = F(q)+p-q$$

as F satisfies F2 and by the assumption that $p-q \in \mathbb{Z}$. Furthermore, $q \in [\alpha-1,\alpha)$, by (45) so that for some $k \in \mathbb{Z}$,

$$\begin{aligned}
F^{(n+1)}(\{x\}) &= p-q+\begin{cases} \dfrac{f(tq+z)-z}{t}+1 & \text{if } q \in [0,\alpha) \\ \dfrac{f(t(q+1)-t+z)-z}{t} & \text{if } q \in [\alpha-1,0) \end{cases} \\
&= \frac{f(tq+z)-z}{t}+k \\
&= \frac{f(t\frac{f^{(n)}(tx+z)-z}{t}-z)}{t}+k \\
&= \frac{f^{(n+1)}(tx+z)-z}{t}+k.
\end{aligned}$$

Therefore (46) is true.

From (45) and (46) it follows that for any $x \in [\alpha-1,\alpha)$ and $n \in \mathbb{Z}_+$ we have

$$\begin{aligned}
\{F^{(n-1)}(\{x\})\} \in [0,\alpha) &\Leftrightarrow \left\{\frac{f^{(n-1)}(tx+z)-z}{t}\right\} \in [0,\alpha) \\
&\Leftrightarrow \frac{f^{(n-1)}(tx+z)-z}{t} \in [0,\alpha) \\
&\Leftrightarrow f^{(n-1)}(tx+z) \geq z.
\end{aligned} \tag{47}$$

Therefore F4 holds. This completes the proof. ■

Lemma 62 *Suppose $F : \mathbb{R} \to \mathbb{R}$ satisfies Claims F1-F3 of Lemma 61. Let $\alpha := F(0)$ and for $x \in \mathbb{R}$ let $s(x)$ denote the infinite word with letters*

$$s_n(x) := \begin{cases} 1 & \text{if } \{F^{(n-1)}(x)\} \in [0,\alpha) \\ 0 & \text{if } \{F^{(n-1)}(x)\} \in [\alpha,1) \end{cases}$$

for $n \in \mathbb{Z}_{++}$. Then $s(x)$ is 1-balanced.

Proof For any $n \in \mathbb{Z}_{++}$ and any $x \in [0,1)$ we have

$$\begin{aligned}
&\lfloor F^{(n)}(x)-\alpha\rfloor - \lfloor F^{(n-1)}(x)-\alpha\rfloor \\
&\quad= \lfloor F(r+z)-\alpha\rfloor - \lfloor r+z-\alpha\rfloor && \text{for } r := \{F^{(n-1)}(x)\}, z := \lfloor F^{(n-1)}(x)\rfloor \\
&\quad= \lfloor F(r)+z-\alpha\rfloor - \lfloor r+z-\alpha\rfloor && \text{as } F(u)+1 = F(u) \text{ for } u \in \mathbb{R} \\
&\quad= \lfloor F(r)-\alpha\rfloor - \lfloor r-\alpha\rfloor && \text{as } \lfloor r+z\rfloor = \lfloor r\rfloor + z \text{ since } z \in \mathbb{Z} \\
&\quad= -\lfloor r-\alpha\rfloor && \text{as } \alpha = F(0) \leq F(r) < F(1) = \alpha+1 \\
&&& \text{since } F(\cdot) \text{ is increasing and } r \in [0,1) \\
&\quad= \lceil \alpha - r\rceil \\
&\quad= \begin{cases} 1 & \text{if } r \in [0,\alpha) \\ 0 & \text{if } r \in [\alpha,1) \end{cases} \\
&\quad= s_n(x).
\end{aligned}$$

Therefore, for any $m \in \mathbb{Z}_+$,

$$\sum_{k=1}^{m} s_k(x) = \sum_{k=1}^{m}\Big(\lfloor F^{(k)}(x)-\alpha\rfloor - \lfloor F^{(k-1)}(x)-\alpha\rfloor\Big) = \lfloor F^{(m)}(x)-\alpha\rfloor - \lfloor x-\alpha\rfloor. \tag{48}$$

Now we show by induction that for any $m \in \mathbb{Z}_+$,

$$F^{(m)}(z) - F^{(m)}(y) \in [0,1) \qquad \text{for any } y,z \in \mathbb{R} \text{ with } z-y \in [0,1). \tag{49}$$

The base case with $m=0$ reads $z-y \in [0,1)$ which is true. For the inductive step, let $z' := F^{(m-1)}(z)$ and $y' := F^{(m-1)}(y)$ for $m-1 \in \mathbb{Z}_+$ and assume that $z'-y' \in [0,1)$. Then $F(y') \leq F(z')$ as $y' \leq z'$ and F is increasing. Also $F(z') < F(y'+1) = F(y')+1$ as $z'-y' < 1$, as F is increasing and as $F(u+1) = F(u)+1$ for any $u \in \mathbb{R}$. Therefore $F^{(m)}(z) - F^{(m)}(y) = F(z') - F(y') \in [0,1)$.

For any choice of $m \in \mathbb{Z}_+$ and $x,y \in [0,1)$, we wish to prove that $|\Delta| \leq 1$ for

$$\begin{aligned}
\Delta &:= |s_1(x)s_2(x)\dots s_m(x)|_1 - |s_1(y)s_2(y)\dots s_m(y)|_1 \\
&= \sum_{k=1}^{m}(s_k(x)-s_k(y)) = \underbrace{\Big(\lfloor F^{(m)}(x)-\alpha\rfloor - \lfloor F^{(m)}(y)-\alpha\rfloor\Big)}_{=:A} - \underbrace{(\lfloor x-\alpha\rfloor - \lfloor y-\alpha\rfloor)}_{=:B}
\end{aligned}$$

using equation (48). But if $x \geq y$ then $x-y \in [0,1)$ so (49) shows that A and B are both of the form $\lfloor a\rfloor - \lfloor b\rfloor$ for some $a-b \in [0,1)$ and it follows that both A and B are in $\{0,1\}$.

Whereas if $x \leq y$ then $y - x \in [0, 1)$ so both A and B are in $\{-1, 0\}$. We conclude that $|\Delta| = |A - B| \leq |1 - 0| = 1$. ■

The following is Theorem 3.1 of Dulucq and Gouyou-Beauchamps (1990) and provides the missing link between 1-balanced words and mechanical words.

Lemma 63 *Suppose w is a word of length $n \in \mathbb{Z}_{++}$ with $|w|_0|w|_1 > 0$. Then w is 1-balanced if and only if $w_k = \left\lfloor \frac{pk+r}{q} \right\rfloor - \left\lfloor \frac{p(k-1)+r}{q} \right\rfloor$ for $k = 1, 2, \ldots, n$, where $p, q, r \in \mathbb{Z}$ satisfy $0 < p < q \leq n$, $0 \leq r < q \leq n$ and $\gcd(p, q) = 1$.*

Now we are ready to describe the itineraries of maps-with-gaps, for arbitrary initial states and thresholds.

Lemma 64 *Suppose ϕ_0, ϕ_1 satisfy A2 and that $n \in \mathbb{Z}_{++}$, $x \in \mathcal{I}$, $s \in \overline{\mathbb{R}}$ and $a \in \{0, 1\}$. Then*

$$\sigma(x|s^-)_{1:n} = l^m w$$

for some $l \in \{0, 1\}$, some $m \in \{0, 1, \ldots, n\}$, and some factor w of a lower mechanical word.

Proof First, note that if $a, b \in \mathcal{I}$, then Lemma 35 shows that

$$b > y_1 \Rightarrow \phi_{1^m}(a) < b \text{ for some } m \in \mathbb{Z}_{++} \tag{50}$$
$$b \leq y_0 \Rightarrow \phi_{0^m}(a) \geq b \text{ for some } m \in \mathbb{Z}_{++}. \tag{51}$$

We consider seven cases.

1. Say $s \leq y_1$ and $x \geq s$. Then $\sigma(x|s^-) = 1\sigma(\phi_1(x)|s^-)$. But if $x > y_1$ then Lemma 33 gives $\phi_1(x) > y_1 \geq s$, whereas if $x \leq y_1$ then $\phi_1(x) \geq x \geq s$. In both cases, $\sigma(\phi_1(x)|s^-) = 1\sigma(\phi_{11}(x)|s^-)$. Repeating this argument gives $\sigma(x|s^-) = 1^\infty$, so the claim is true.

2. Say $s \leq y_1$ and $x < s$. Then $\sigma(x|s^-)$ begins with 0, and as $s < y_0$ it follows from (51) that there is a least $m \in \mathbb{Z}_{++}$ with $\phi_{0^m}(x) \geq s$. Thus $\sigma(x|s^-) = 0^m\sigma(\phi_{0^m}(x)|s^-) = 0^m1^\infty$ by Case 1, so the claim is true.

3. Say $s \in (y_0, y_1)$ and $x \in [\phi_1(s), \phi_0(x))$. As ϕ_0, ϕ_1 satisfy A2, Lemmas 59, 61 and 62 together show that $\sigma(x|s^-)$ is a 1-balanced word. Thus Lemma 63 shows that $\sigma(x|s^-)_{1:n} = w$ for some factor w of a lower mechanical word, so the claim is true.

4. Say $s \in (y_0, y_1)$ and $x < \phi_1(s)$. Then Lemma 33 shows that $\phi_1(s) < s$. Thus $x < s$, so $\sigma(x|s^-)$ begins with 0, and $\phi_1(s) < y_0$, so (51) shows that there is a least $m \in \mathbb{Z}_{++}$ with $\phi_{0^m}(x) \geq \phi_1(s)$. Thus $\sigma(x|s^-) = 0^m\sigma(\phi_{0^m}(x)|s^-)$ where $\sigma(\phi_{0^m}(x)|s^-)_{1:n} = w$ for some factor w of a lower mechanical word, by Case 3, so the claim is true.

5. Say $s \in (y_0, y_1)$ and $x \geq \phi_0(s)$. Then arguing as in Case 4, but using (50), shows that $\sigma(x|s^-)_{1:n} = 1^m w$ for some $m \in \mathbb{Z}_{++}$ and some factor w of a lower mechanical word.

6. Say $s \geq y_0$ and $x < s$. Then arguing as in Case 1 shows that $\sigma(x|s^-) = 0^\infty$.

7. Say $s \geq y_0$ and $x \geq s$. Then arguing as in Case 2 shows that $\sigma(x|s^-) = 1^m0^\infty$ for some $m \in \mathbb{Z}_{++}$.

This completes the proof. ■

The following is an analogue of Lemma 52 in which only the threshold varies.

Lemma 65 *Suppose ϕ_0, ϕ_1 satisfy A2 and $x \in \mathcal{I}$. Then $\sigma(x|s^-)$ is a lexicographically non-increasing function of $s \in \overline{\mathbb{R}}$.*

Proof If $s, t \in \overline{\mathbb{R}}$ and $\sigma(x|s^-) \succ \sigma(x|t^-)$, then for some finite word u and words v, w,

$$\sigma(x|s^-) = u1v, \qquad \sigma(x|t^-) = u0w.$$

So the definition of the itinerary gives $t > \phi_u(x) \geq s$. This completes the proof. ■

The following is Theorem 17 and part of Corollary 18 of Mignosi (1991).

Lemma 66 *Let $\mathcal{A}_n$ be the set of factors of length $n \in \mathbb{Z}_{++}$ of lower mechanical words. Then*

$$\operatorname{card}(\mathcal{A}_n) = 1 + \sum_{i=1}^{n} (n - i + 1)\,\text{EulerTotient}(i) = \frac{2n^3}{\ell^2} + O(n^2 \log n).$$

Now we are ready to bound the number of discontinuities of the itinerary of a map-with-a-gap as a function of its threshold.

Lemma 67 *Suppose ϕ_0, ϕ_1 satisfy A2, that $t \in \mathbb{Z}_+$, $x \in \mathcal{I}$ and $a \in \{0, 1\}$. Then the mapping $s \mapsto A_{1:t}(x, a; s)$ for $s \in \overline{\mathbb{R}}$ has at most a polynomial number $p(t)$ of discontinuities.*

Proof Let $\mathcal{A}_n$ be the set of all factors of length n of lower mechanical words. Let $\mathcal{F}_t$ be the set of all words of the form $l^m w$ for some $l \in \{0, 1\}$, some $m \in \{0, 1, \ldots, n\}$ and some factor w of a lower mechanical word. By Lemma 64, the word $A_{1:t}(x, a; s)$ is in $\mathcal{F}_t$. Also, Lemma 65, shows that the mapping $s \mapsto A_{1:t}(x, a; s)$ is lexicographically non-increasing. Thus, the number of discontinuities of this mapping is at most

$$\operatorname{card}(\mathcal{F}_t) = \operatorname{card}\left(\{l^m w : l \in \{0, 1\}, m \in \mathbb{Z}_+, m \leq t, w \in \mathcal{A}_{t-m}\}\right) = 2\sum_{m=0}^{t} \operatorname{card}(\mathcal{A}_{t-m}).$$

Finally, Lemma 66 shows the right-hand side is $O(t^4)$. This completes the proof. ■

Proof [Proof of Theorem 14.] The theorem simply couples together Lemmas 64, 65 and 67. ■

Appendix B. Proof of Lemma 22

Demonstrating Lemma 22 by combining results in Marshall et al. (2010) requires as much text as a direct proof.

Proof Let $\mathcal{X}$ be the set of sequences X with components $X_k = \sum_{i=1}^{k} x_i$ for $k = 1, 2, \ldots, n$ where $x_1, x_2, \ldots, x_n$ is a non-decreasing sequence on $\mathbb{R}_{++}$. Let $g : \mathcal{X} \to \mathbb{R}$ be the function

$$g(X) := f_1(X_1) + \sum_{i=2}^{n} f_i(X_i - X_{i-1}).$$

Let $f_i'(\cdot)$ denote the (sub)gradient of $f_i(\cdot)$. For $i = 1, 2, \ldots, n-1$, the (sub)gradients of $g(\cdot)$ are

$$\frac{\partial g(X)}{\partial X_i} = f_i'(x_i) - f_{i+1}'(x_{i+1}) \leq f_{i+1}'(x_i) - f_{i+1}'(x_{i+1}) \leq 0$$

where the first inequality holds as $f_i'(x) \leq f_{i+1}'(x)$ for $x \in \mathbb{R}_{++}$ (by Hypothesis 4) and the second holds as $x_i \leq x_{i+1}$ and $f_{i+1}(\cdot)$ is convex (by Hypothesis 3). Also,

$$\frac{\partial g(X)}{\partial X_n} = f_n'(x_n) \leq 0$$

as $f_n(\cdot)$ is non-increasing (by Hypothesis 3). Therefore $g(\cdot)$ is non-increasing in all of its arguments. As the sequences A, B with components $A_k := \sum_{i=1}^{k} a_i, B_k := \sum_{i=1}^{k} b_k$ are in $\mathcal{X}$ (by Hypothesis 1) and $A_k \leq B_k$ for $k = 1, 2, \ldots, n$ (by Hypothesis 2), it follows that $g(A) \geq g(B)$. So the definition of $g(\cdot)$ gives

$$\sum_{i=1}^{n} f(a_i) = g(A) \geq g(B) = \sum_{i=1}^{n} f(b_i)$$

as claimed. ■

Appendix C. Proof of Lemma 24

We start by recalling the definition of the matrix $M(w)$ corresponding to a given finite word w, which corresponds to the composition of Kalman-Filter variance updates, and introducing some related matrices $K, S(w)$ and X. We then prove Claims 1 to 5 of Lemma 24 in turn.

Definition 68 *Let I be the 2-by-2 identity matrix. For $r \in (0, 1]$ and $0 \leq a \leq b$, let*

$$F := \begin{pmatrix} r & 1/r \\ ar & (a+1)/r \end{pmatrix}, \qquad G := \begin{pmatrix} r & 1/r \\ br & (b+1)/r \end{pmatrix}, \qquad K := \begin{pmatrix} r & 1/r \\ r - r^3 & -r \end{pmatrix}.$$

Let $M(\epsilon) = I, M(0) = F, M(1) = G$ and for any finite word w let

$$M(w) = M(w_{|w|}) \cdots M(w_2) M(w_1), \qquad S(w) = \sum_{i=0}^{|w|} M(w_{1:i}).$$

Let

$$X := \begin{pmatrix} -r/(1-r^2) & 0 \\ 0 & 1/r \end{pmatrix}.$$

Remark 69 *We use the the following facts repeatedly without mention. Clearly* $\det(F) = \det(G) = 1$, *so that* $\det(M(w)) = 1$ *for any word* w. *Also,* $KF = F^{-1}K, KG = G^{-1}K$ *and* $K^2 = I$. *Thus for* $A \in \{KF, KG, K\}$ *we have* $A^2 = I$, *so* A *is an involutory matrix. Thus* $KM(w)^{-1}K = M(w^R)$, *where* w^R *denotes the reverse* $w_n \ldots w_2 w_1$ *of a word* $w = w_1 w_2 \ldots w_n$.

Notation. For a vector $v \in \mathbb{R}^m$ where $m \in \mathbb{Z}_{++}$, we write $v > 0$ if $v_i > 0$ for $i = 1, 2, \ldots, m$ and $v \geq 0$ if $v_i \geq 0$ for $i = 1, 2, \ldots, m$. Similarly, for a matrix $P \in \mathbb{R}^{m \times n}$ where $m, n \in \mathbb{Z}_{++}$, we write $P > 0$ ($P \geq 0$) if $P_{ij} > 0$ ($P_{ij} \geq 0$) for $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$.

C.1. Claim 1

We require one simple Lemma.

Lemma 70 *Suppose* $a \in \mathbb{R}_+$ *and* $r \in (0, 1]$. *Then the fixed point* y_0 *satisfies*

$$y_0 \leq \frac{1}{1 - r^2}.$$

Proof As the positive root of

$$y_0 = \frac{r^2 y_0 + 1}{a r^2 y_0 + 1 + a}$$

is a decreasing function of a for $a \in \mathbb{R}_+$, setting $a = 0$ gives an upper bound. This upper bound u satisfies $u = r^2 u + 1$, so that $u = 1/(1 - r^2)$. ■

Proof [Proof of Claim 1 of Lemma 24.] We prove the claim for x satisfying

$$\phi_p(0) \leq x \leq \frac{1}{r - r^2},$$

noting that

$$\phi_p\left(\frac{1}{1-r^2}\right) \leq \frac{1}{1-r^2} \leq \frac{1}{r-r^2}$$

where the first inequality follows from Lemma 33 (in Appendix A) as Lemma 70 gives $1/(1-r^2) \geq y_0 \geq y_p$, and the second inequality holds as $r \in (0, 1]$.

For any word w and for $k = 1, 2, \ldots, |w|$, let

$$\begin{pmatrix} u_k \\ v_k \end{pmatrix} := M(w_{1:k}) \begin{pmatrix} x \\ 1 \end{pmatrix}.$$

Clearly u_k, v_k are positive as $x \geq \phi_p(0) \geq 0$ and

$$M(w_{1:k}) \begin{pmatrix} x \\ 1 \end{pmatrix} \geq \begin{pmatrix} r & \frac{1}{r} \\ 0 & \frac{1}{r} \end{pmatrix}^k \begin{pmatrix} 0 \\ 1 \end{pmatrix} > 0.$$

Now, for any $0 \leq z \leq 1/(r-r^2)$ and $H = M(w_k)$, noting that $a, b, r \geq 0$ and $r \leq 1$ gives

$$\frac{H_{11}z + H_{12}}{H_{21}z + H_{22}} \leq r^2 z + 1 \leq \frac{r^2}{r-r^2} + 1 \leq \frac{1}{r-r^2}.$$

For $k = 1, 2, \ldots, |w|$, induction using this inequality proves that

$$\frac{u_k}{v_k} \leq \frac{1}{r-r^2}.$$

(For $k = 1$, put $z = x \leq 1/(r-r^2)$. For $k > 1$, assume that $z = u_{k-1}/v_{k-1} \leq 1/(r-r^2)$.) Thus

$$\begin{pmatrix} u_{k+1} - u_k \\ v_{k+1} - v_k \end{pmatrix} = (M(w_{k+1}) - I) \begin{pmatrix} \frac{u_k}{v_k} \\ 1 \end{pmatrix} v_k \geq \begin{pmatrix} r-1 & \frac{1}{r} \\ 0 & \frac{1}{r} - 1 \end{pmatrix} \begin{pmatrix} \frac{1}{r-r^2} \\ 1 \end{pmatrix} v_k \geq 0.$$

But both $a_k(x), b_k(x)$ are of the form u_k and $c_k(x), d_k(x)$ are of the form v_k for appropriate w. Thus $a_{1:m}(x), b_{1:m}(x), c_{1:m}(x)$ and $d_{1:m}(x)$ are non-decreasing and positive. ■

C.2. Claim 2

To prove Claim 2 we need two simple Lemmas.

Lemma 71 *If w is a word, then $M(w) - M(w^R) = tr(KM(w))K$.*

Proof For any $C \in \mathbb{R}^{2\times 2}$, direct calculation gives $C - K\text{adj}(C)K = \text{tr}(KC)K$. But $\det(M(w)) = 1$, so $M(w) - M(w^R) = M(w) - KM(w)^{-1}K = M(w) - K\text{adj}(M(w))K = \text{tr}(KM(w))K$. ■

Lemma 72 *Suppose p is a palindrome, $r \in (0,1]$ and $n \in \mathbb{Z}_+$. Then for some $x \geq 0$,*

$$M((10p)^n 10) - M((01p)^n 01) = xK.$$

Proof For any matrices $P, Q \in \mathbb{R}^{2\times 2}$ with $\det(P) = 1$ and $Q \geq 0$, direct calculation gives

$$\begin{aligned}&[QGFP]_{22}[QFGP]_{21} - [QFGP]_{22}[QGFP]_{21} \\ &\quad = (b-a)\det(P)((1-r^2+a+b+ab)Q_{22}^2 + (2+a+b)Q_{22}Q_{21} + Q_{21}^2) \geq 0\end{aligned}$$

as $1 \geq r^2, b \geq a \geq 0$. Therefore, for any words w, w',

$$\frac{M(w01w')_{22}}{M(w01w')_{21}} \geq \frac{M(w10w')_{22}}{M(w10w')_{21}}. \tag{52}$$

Let $A = M((10p)^n 10), B = M((01p)^n 01)$. Repeated application of (52) gives

$$\frac{B_{22}}{B_{21}} = \frac{M(01p01p\cdots 01)_{22}}{M(01p01p\cdots 01)_{21}} \geq \frac{M(10p01p\cdots 01)_{22}}{M(10p01p\cdots 01)_{21}} \geq \frac{M(10p10p\cdots 10)_{22}}{M(10p10p\cdots 10)_{21}} = \frac{A_{22}}{A_{21}}.$$

As $A, B \geq 0$ and Lemma 71 gives $A = B + xK$ for some $x \in \mathbb{R}$, it follows that

$$(B+xK)_{21}B_{22} \geq (B+xK)_{22}B_{21} \quad \Rightarrow \quad K_{21}B_{22}x \geq K_{22}B_{21}x.$$

Finally, the fact that $K_{22} \leq 0 < K_{21}$ and $B \geq 0$ gives $x \geq 0$. ■

Proof [Proof of Claim 2 of Lemma 24.] For some $t \geq 0$, Lemma 72 gives

$$\begin{aligned}(d/dx)(b_1(x) - a_1(x)) &= [M((10p)^n 1) - M((01p)^n 0)]_{11} \\ &= [(F^{-1} - G^{-1})M((01p)^n 01) + tF^{-1}K]_{11} \\ &= [(0,0)M((01p)^n 01)]_1 + t[KF]_{11} \\ &= t\,(rF_{11} + (1/r)F_{21}) \\ &\geq 0\end{aligned}$$

and

$$\begin{aligned}b_1(\phi_p(0)) - a_1(\phi_p(0)) &= [M(p(10p)^n 1) - M(p(01p)^n 0)]_{12} \\ &= [(F^{-1} - G^{-1})M(p(01p)^n 01) + tF^{-1}KM(p)]_{12} \\ &= t[KFM(p)]_{12} \\ &= t(rM(p0)_{12} + (1/r)M(p0)_{22}) \\ &\geq 0.\end{aligned}$$

Also, if $k > 1$ and $w = p_{1:(k-2)}$, then

$$\begin{aligned}(d/dx)(b_k(x) - a_k(x)) &= [M((10p)^n 10w) - M((01p)^n 01w)]_{11} \\ &= t[M(w)K]_{11} \\ &= t(M(w)_{11}r + M(w)_{12}r(1-r^2)) \\ &\geq 0\end{aligned}$$

and as p is a palindrome, $p = sw^R$ for some word s, so

$$\begin{aligned}b_k(\phi_p(0)) - a_k(\phi_p(0)) &= [M(p(10p)^n 10w) - M(p(01p)^n 01w)]_{12} \\ &= t[M(w)KM(p)]_{12} \\ &= t[KM(w^R)^{-1}M(w^R)M(s)]_{12} \\ &= t[KM(s)]_{12} \\ &= t(rM(s)_{12} + (1/r)M(s)_{22}) \\ &\geq 0.\end{aligned}$$

This completes the proof. ■

C.3. Claim 3

Claim 3 of Lemma 24 is more challenging than Claims 1 and 2. We begin with six Lemmas.

Lemma 73 *Suppose p is any palindrome and $r \in (0,1]$. Then for any $k \in \mathbb{Z}_+$,*

$$\Delta_k := [M(((10p)^\infty)_{1:k}) - M(((01p)^\infty)_{1:k})]_{21} \geq 0.$$

Proof If $k = 1$ then

$$\begin{aligned}\Delta_k &= [M(1) - M(0)]_{21} \\ &= [G - F]_{21} \\ &= (b-a)r \\ &\geq 0.\end{aligned}$$

If $k = (n+1)|01p| + 1$ for some $n \in \mathbb{Z}_+$ then Lemma 72 shows there is an $x \geq 0$ such that

$$\begin{aligned}\Delta_k &= [M((10p)^n 10p1) - M((01p)^n 01p0)]_{21} \\ &= [M(p1)(xK + M((01p)^n 01)) - M(p0)M((01p)^n 01)]_{21} \\ &= [xM(p1)K + (G-F)M((01p)^{n+1})]_{21} \\ &= x(M(p1)_{21}r + M(p1)_{22}(r - r^3)) \\ &\qquad + (b-a)(rM((01p)^{n+1})_{12} + (1/r)M((01p)^{n+1})_{22}) \\ &\geq 0.\end{aligned}$$

Otherwise, there is a prefix w of p and an $n \in \mathbb{Z}_+$ such that

$$\begin{aligned}\Delta_k &= [M((10p)^n 10w) - M((01p)^n 01w)]_{21} \\ &= [M(w)(M((10p)^n 10) - M((01p)^n 01))]_{21} \\ &= [xM(w)K]_{21} \qquad \text{for some } x \geq 0 \text{ by Lemma 72} \\ &= x(M(w)_{21}r + M(w)_{22}(r - r^3)) \\ &\geq 0.\end{aligned}$$

This completes the proof. ∎

Lemma 74 *Suppose $p = ws$ is a palindrome, $n \in \mathbb{Z}_+$ and $r \in (0,1]$. Then*

$$[M(p(10p)^n 10w) - M(p(01p)^n 01w)]_{22} \leq 0.$$

Proof First note that for any finite word u,

$$M(u)_{22} \geq M(u)_{21}. \tag{53}$$

Indeed, if $u = \epsilon$ then $M(\epsilon) = I$ so the inequality holds. Otherwise, for some $c \in \{a, b\}$

$$M(u)_{22} - M(u)_{21} = \left[M(u_{2:|u|})M(u_1)\begin{pmatrix}-1\\1\end{pmatrix}\right]_2 = \left[M(u_{2:|u|})\frac{1}{r}\begin{pmatrix}1-r^2\\1+(1-r^2)c\end{pmatrix}\right]_2 \geq 0$$

as the definition of $M(\cdot)$ assumes that $0 \leq a < b$ so that $c \geq 0$, and as $r \in (0,1]$ and $M(u_{2:|u|}) \geq 0$.

Also, by Lemma 72, for some $x \geq 0$

$$\begin{aligned}[M(p(10p)^n 10w) - M(p(01p)^n 01w)]_{22} &= [M(s)^{-1}(M((10p)^{n+1}) - M((01p)^{n+1}))M(p)]_{22} \\ &= x[M(s)^{-1}KM(p)]_{22} \\ &= x[KM(ps^R)]_{22} \\ &= xr\left((1-r^2)M(ps^R)_{21} - M(ps^R)_{22}\right) \\ &\leq xr\left((1-r^2)M(ps^R)_{22} - M(ps^R)_{22}\right) \\ &\leq 0\end{aligned}$$

where the penultimate line is (53). ∎

Lemma 75 *Suppose p is a palindrome, $n \in \mathbb{Z}_+$ and $r \in (0,1]$. Then*

$$\left[\Big(M((10p)^n 10)X - M((01p)^n 01)X + M((10p)^n 1) - M((01p)^n 0)\Big)M(p)\right]_{22} = 0.$$

Proof Let $P = M(p)$. Solving $KP = P^{-1}K$ shows that there exist $f, h \in \mathbb{R}$ such that

$$P = \begin{pmatrix} \dfrac{1 - f^2r^2 + fhr^2 + f^2r^4}{fr^2 + h} & f \\ \dfrac{-1 - fh + h^2 + fhr^2}{fr^2 + h}r^2 & h \end{pmatrix}.$$

Directly substituting this expression into

$$Q_n := \left[\Big(FG(PFG)^n X - GF(PGF)^n X + G(PFG)^n - F(PGF)^n\Big)P\right]_{22}$$

shows that $Q_0 = Q_1 = 0$. (Showing that $Q_1 = 0$ directly is algebraically tedious and we had to check this with computer algebra. The authors would be interested in a short demonstration that $Q_1 = 0$ as this may give insight into related problems.)

Lemma 71, then the fact that $\mathrm{tr}(K) = 0$, then the cyclic property of the trace give

$$\mathrm{tr}(PFG) = \mathrm{tr}(GFP + \mathrm{tr}(KPFG)K) = \mathrm{tr}(GFP) = \mathrm{tr}(PGF).$$

So PFG and PGF are 2-by-2 matrices with unit determinant whose traces are equal. For some matrices of eigenvectors U, V and some eigenvalue $\lambda \geq 1$, such matrices may be written in the form

$$PFG = U\Lambda U^{-1}, \qquad PGF = V\Lambda V^{-1}, \qquad \Lambda := \begin{pmatrix}\lambda & 0\\ 0 & 1/\lambda\end{pmatrix}.$$

Thus, for some $\alpha, \beta \in \mathbb{R}$,

$$Q_n = \alpha\lambda^n + \beta\lambda^{-n}$$

But $Q_0 = 0$ implies that $\beta = -\alpha$. Thus $Q_1 = \alpha(\lambda - 1/\lambda) = 0$ implies that either $\alpha = 0$ or $\lambda = 1$. In either case, $Q_n = \alpha(\lambda^n - \lambda^{-n}) = 0$ for all $n \geq 0$. ∎

Lemma 76 *Suppose p is a palindrome. Then $S(p)KM(p) = KS(p)$.*

Proof We proceed by induction on the length of p. In the base case, $S(\epsilon)KM(\epsilon) = IKI = KS(\epsilon)$ and if a is a letter then $S(a)KM(a) = (I + M(a))KM(a) = K(I + M(a)^{-1})M(a) = KS(a)$. Otherwise, say $p = aqa$ where a is a letter and $S(q)KM(q) = KS(q)$. Then

$$\begin{aligned}
S(p)KM(p) &= (I + M(a) + S(q)M(a) + M(aqa))KM(aqa) \\
&= (I + M(a) + M(aqa))KM(aqa) + S(q)KM(a)^{-1}M(a)M(q)M(a) \\
&= K(I + M(a)^{-1} + M(aqa)^{-1})M(aqa) + S(q)KM(q)M(a) \\
&= K(M(aqa) + M(aq) + I) + KS(q)M(a) \\
&= KS(p).
\end{aligned}$$

■

Lemma 77 *Suppose w is a finite word and $r \in (0, 1]$. Then $[K(S(w) - XM(w))]_{22} \geq 0$.*

Proof We proceed by induction on the length of w. In the base case,

$$[K(S(\epsilon) - XM(\epsilon))]_{22} = [K(I - X)]_{22} = 1 - r \geq 0.$$

Otherwise, say $w = ul$ where $|l| = 1$, $|u| < \infty$ and $[K(S(u) - XM(u))]_{22} \geq 0$. Then

$$\begin{aligned}
[K(S(w) - XM(w))]_{22} &= [K(S(u) + M(w) - X(M(w) - M(u)) - XM(u))]_{22} \\
&= [K(S(u) - XM(u))]_{22} + [K(I - X(I - M(l)^{-1}))M(w)]_{22} \\
&\geq [K(I - X(I - M(l)^{-1}))M(w)]_{22} \\
&= (1 - r)(r^2 M(w)_{12} + M(w)_{22}) \\
&\geq 0
\end{aligned}$$

where in the penultimate line we substituted the definitions of K and X, noting that $M(l) \in \{F, G\}$, and where the final inequality follows as $r \leq 1$ and $M(w) \geq 0$. ■

Lemma 78 *Suppose p is a palindrome and $r \in (0, 1]$. Then for any $n \in \mathbb{Z}_+$*

$$[(S(10p) - I)M(p(10p)^n) - (S(01p) - I)M(p(01p)^n)]_{22} \geq 0.$$

Proof Let $P := M(p)$. Then

$$\begin{aligned}
&[(S(10p) - I)M(p(10p)^n) - (S(01p) - I)M(p(01p)^n)]_{22} \\
&= [S(p)(FG(PFG)^n - GF(PGF)^n)P + (G(PFG)^n - F(PGF)^n)P]_{22} \\
&= [S(p)(FG(PFG)^n - GF(PGF)^n)P - (FG(PFG)^n - GF(PGF)^n)XP]_{22} \\
&= [S(p)xKP - xKXP]_{22} \\
&= [xK(S(p) - X)P]_{22}
\end{aligned}$$

$$\geq 0$$

where the second equality uses Lemma 75, the third holds for some $x \geq 0$ by Lemma 72, the fourth follows from Lemma 76 and the final inequality is Lemma 77. ■

Proof [Proof of Claim 3 of Lemma 24.] Say $1 \leq k \leq m$. Using Lemmas 73, 74 and 78 successively gives

$$\begin{aligned}
\sum_{i=1}^{k}(d_i(x) - c_i(x)) &= \sum_{i=1}^{k}[M((10p)^n(10p)_{1:i}) - M((01p)^n(01p)_{1:i})]_{21}x \\
&\quad + \sum_{i=1}^{k}[M((10p)^n(10p)_{1:i}) - M((01p)^n(01p)_{1:i})]_{22} \\
&\geq \sum_{i=1}^{k}[M((10p)^n(10p)_{1:i}) - M((01p)^n(01p)_{1:i})]_{21}\frac{M(p)_{12}}{M(p)_{22}} \\
&\quad + \sum_{i=1}^{k}[M((10p)^n(10p)_{1:i}) - M((01p)^n(01p)_{1:i})]_{22} \\
&= \frac{1}{M(p)_{22}}\sum_{i=1}^{k}[M(p(10p)^n(10p)_{1:i}) - M(p(01p)^n(01p)_{1:i})]_{22} \\
&\geq \frac{1}{M(p)_{22}}\sum_{i=1}^{m}[M(p(10p)^n(10p)_{1:i}) - M(p(01p)^n(01p)_{1:i})]_{22} \\
&= \frac{1}{M(p)_{22}}[(S(10p) - I)M(p(10p)^n) - (S(01p) - I)M(p(01p)^n)]_{22} \\
&\geq 0.
\end{aligned}$$

This completes the proof. ■

C.4. Claim 4

The proof of Claim 4 requires only one preparatory Lemma.

Lemma 79 *Suppose w is any finite word. Then*

$$[M(w)^{-1}]_{21} \leq 0 \leq [M(w)^{-1}]_{22}.$$

Proof We use induction on the length of w. In the base case, $M(\epsilon) = I$, for which

$$[I^{-1}]_{21} = 0 \leq 1 = [I^{-1}]_{22}.$$

Otherwise, suppose $w = 0u$ (the case $w = 1u$ is similar), let $U := M(u)^{-1}$ and assume that

$$U_{21} \leq 0 \leq U_{22}.$$

Then the induction assumption and and fact that $a, r \geq 0$ give

$$[M(w)^{-1}]_{21} = [UF^{-1}]_{21} = \frac{1}{r}((1+a)U_{21} - ar^2 U_{22}) \leq 0$$
$$[M(w)^{-1}]_{22} = [UF^{-1}]_{22} = \frac{1}{r}(U_{22}r^2 - U_{21}) \geq 0.$$

This completes the proof. ■

Proof [Proof of Claim 4 of Lemma 24.] Claim 3 of Lemma 24 applied for $k = 1$ shows that

$$c_1(x) \leq d_1(x).$$

For $k = 2, 3, \ldots, m$, as Lemma 73 shows that $c_k(x) - d_k(x)$ is a decreasing function of x, it suffices to prove that

$$\left[M((01p)^n(01p)_{1:k}) \begin{pmatrix} \phi_p\left(\frac{1}{1-r^2}\right) \\ 1 \end{pmatrix}\right]_2 \geq \left[M((10p)^n(10p)_{1:k}) \begin{pmatrix} \phi_p\left(\frac{1}{1-r^2}\right) \\ 1 \end{pmatrix}\right]_2.$$

The left-hand side minus the right-hand side, up to a positive factor, is

$$\begin{aligned}
&\left[\left(M((01p)^n(01p)_{1:k}) - M((10p)^n(10p)_{1:k})\right) M(p) \begin{pmatrix} 1 \\ 1-r^2 \end{pmatrix}\right]_2 \\
&\quad = -z\left[M(p_{1:(k-2)})KM(p)\begin{pmatrix} 1 \\ 1-r^2 \end{pmatrix}\right]_2 \quad \text{for some } z \geq 0 \text{ by Lemma 72} \\
&\quad = -z\left[M(p_{1:(|p|-k+2)})^{-1}K\begin{pmatrix} 1 \\ 1-r^2 \end{pmatrix}\right]_2 \\
&\quad = -z\left[M(p_{1:(|p|-k+2)})^{-1}\begin{pmatrix} \frac{1}{r} \\ 0 \end{pmatrix}\right]_2 \\
&\quad = -\frac{z}{r}[M(p_{1:(|p|-k+2)})^{-1}]_{21} \\
&\quad \geq 0
\end{aligned}$$

where the last line is Lemma 79. Therefore

$$c_k(x) \geq d_k(x) \quad \text{for } k = 2, 3, \ldots, m \text{ and } x \leq \phi_p\left(\frac{1}{1-r^2}\right).$$

This completes the proof. ■

C.5. Claim 5

Proof [Proof of Claim 5 of Lemma 24.] We show that

$$\phi_w(0) \leq y_{01w} < y_{10w} \leq \phi_w\left(\frac{1}{1-r^2}\right)$$

for any finite word w (not just for palindromes p).

The first inequality follows as

$$\phi_w(0) \leq \phi_w(\phi_{01}(0)) = \phi_{01w}(0) \leq y_{01w}$$

as $0 \leq \phi_{01}(0)$, as ϕ_w is increasing, as $0 \leq y_{01w}$ and by Lemma 33 (in Appendix A).

The second inequality holds as $\phi_{01}(x) < \phi_{10}(x)$ for $x \in \mathbb{R}_+$. Thus

$$y_{01w} = \phi_w(\phi_{01}(y_{01w})) < \phi_w(\phi_{10}(y_{01w})) = \phi_{10w}(y_{01w})$$

so applying Lemma 33 gives

$$y_{01w} < y_{10w}.$$

The third inequality holds as

$$y_{10w} = \phi_w(y_{w10}) < \phi_w(y_0) \leq \phi_w\left(\frac{1}{1-r^2}\right)$$

by definition of y_{10w}, as $y_{w10} < y_0$, as ϕ_w is increasing and by Lemma 70.

This completes the proof. ■

Abstract

This paper investigates the behavior of the Min-Sum message passing scheme to solve systems of linear equations in the Laplacian matrices of graphs and to compute electric flows. Voltage and flow problems involve the minimization of quadratic functions and are fundamental primitives that arise in several domains. Algorithms that have been proposed are typically centralized and involve multiple graph-theoretic constructions or sampling mechanisms that make them difficult to implement and analyze. On the other hand, message passing routines are distributed, simple, and easy to implement. In this paper we establish a framework to analyze Min-Sum to solve voltage and flow problems. We characterize the error committed by the algorithm on general weighted graphs in terms of hitting times of random walks defined on the computation trees that support the operations of the algorithms with time. For d-regular graphs with equal weights, we show that the convergence of the algorithms is controlled by the total variation distance between the distributions of non-backtracking random walks defined on the original graph that start from neighboring nodes. The framework that we introduce extends the analysis of Min-Sum to settings where the contraction arguments previously considered in the literature (based on the assumption of walk summability or scaled diagonal dominance) can not be used, possibly in the presence of constraints.

Keywords: Min-Sum, message passing, decentralized algorithms, Laplacian solver, network flows.

1. Introduction

Voltage and flow problems. Laplacian matrices of graphs are fundamental. Solving linear systems of equations in these matrices constitutes the back-bone of many algorithms with applications to a wide variety of fields. See Spielman (2011); Vishnoi (2013). When a weighted graph is viewed as an electric circuit, where weighted edges represent resistors and vertices represent nodes to which some external current is applied, solving linear systems of equations in the Laplacian matrix of the graph corresponds to computing the voltages induced to each node by the external currents. For this reason, we refer to the Laplacian problem as the "voltage problem." Along with the problem of computing the voltages is the problem of computing the current induced across each resistor, which we refer to as the "flow problem." The two problems are related by Ohm's law—which says that electric flows are induced by voltage differences across the nodes—and they both can be cast in the form of quadratic optimization problems. The voltage problem is an unconstrained problem to find the voltage assignment that maximizes the quadratic Laplacian form. The flow problem is a constrained problem to find the flow assignment that minimizes the circuit energy and satisfies Kirchhoff's law. The voltage problem is the dual of the flow problem.

Previous literature on Laplacian solvers. The extensive literature on approximately solving the voltage and flow problems typically involves algorithms that rely on multiple graph-theoretic constructions or sampling mechanisms which make them difficult to implement and analyze. The first quasi-linear time solver was given in Spielman and Teng (2004, 2014), and it achieves a running time of $\tilde{O}(m \log^c n \log 1/\varepsilon)$ in the Laplacian-modified ℓ_2 norm. Here, n and m are, respectively, the number of vertices and edges in the graph, c is a constant close to 100, and the $\tilde{O}$ notation hides $\log \log n$ factors. Since this result, many algorithms have been proposed and showed to yield smaller values of c. The work in Koutis et al. (2011) has reduced the constant c to 1. Currently, the best running time is in Cohen et al. (2014) where $c = 1/2$. These algorithms all rely on the same general architecture, which combines the Chebyshev method or the conjugate gradient algorithm with the use of recursive preconditioning, spectral sparsifiers, low-stretch spanning trees, and expander graphs. Despite their theoretical guarantees, these algorithms present noticeable difficulties to practitioners due to the involved machinery they rely upon. Lately, new algorithms have been proposed that depart from this framework and use fewer graph-theoretic constructions. The method in Kelner et al. (2013), for instance, which operates in the flow domain and yields a fast solver with $c = 2$, using very little of the previous machinery—although it still requires low-stretch spanning trees. More recently, the work in Kyng and Sachdeva (2016), which relies on sparse Gaussian elimination for Laplacian matrices to yield a fast solver with $c = 3$, without the use of any graph-theoretic construction. While more appealing, these new algorithms still rely on random sampling so the convergence analysis is only performed in expectation, or with high probability. Moreover, all these algorithms are centralized. There has also been some work in parallelizing these solvers, with the first parallel solver with near linear work and poly-logarithmic depth presented in Peng and Spielman (2014). These solvers work in the shared memory model and are not completely distributed.

Min-Sum algorithm. The aforementioned limitations prompted us to investigate the behavior of the Min-Sum algorithm to solve both the voltage and the flow problem. Min-Sum is a distributed, deterministic (i.e., not randomized), general-purpose message passing algorithm that is used to optimize objective functions that are sums of component functions supported on a given graph. Min-Sum has emerged as a canonical procedure to address large scale problems in a variety of domains. Its success comes from the fact that the algorithm is simple and easy to implement, require minimal data structures and low communication per iteration, and in many applications it has been shown to converge to the problem solution. Interest in Min-Sum has been triggered by its success in solving certain classes of challenging combinatorial optimization problems, such as decoding low-density parity-check codes, see Berrou et al. (1993); Richardson and Urbanke (2001) for instance, and solving certain type of satisfiability problems, see Mezard et al. (2002); Braunstein et al. (2005), for instance.

Despite its successes, the convergence analysis of the Min-Sum algorithm remains limited. For quadratic optimization problems and, more generally, convex optimization prob-

lems, the Min-Sum algorithm has been shown to converge to the problem solution for *any* graph topology under the assumption that the objective function is walk-summable (Malioutov et al., 2006), or, equivalently, scaled diagonal dominant (Moallemi and Van Roy, 2010). These conditions allow the use of contraction arguments to establish exponential convergence rates. These conditions do not apply to quadratic objective functions in Laplacian matrices, hence to the voltage problem, and they do not apply to constrained optimization problems, hence to the flow problem. At the same time, on the one hand quadratic approximations of the Min-Sum algorithm leading to the Approximate Message Passing (AMP) algorithm are becoming increasingly popular in high-dimensional statistics and machine learning (Donoho et al., 2009; Montanari, 2012; Barbier et al., 2018). The AMP algorithm is typically analysed from an asymptotical point of view and this analysis is *not* based on contraction arguments. The recent success of the AMP algorithm prompts for improving the understanding of the convergence and correctness of the Min-Sum algorithm directly applied to quadratic models, where previously-considered contraction-based assumptions do not hold. On the other hand, while some work has been done to study the behavior of Min-Sum in constrained settings, this work seems to have focused on linear objective functions and a general theory is missing. See Gamarnik et al. (2012) and references therein.

Results. This paper investigates the convergence behavior of the Min-Sum algorithm applied to the voltage and flow problems and establishes a general framework for the analysis of message-passing algorithms that can accommodate for non contraction-based assumptions and for constrained-based optimization problems. The algorithms that we analyze—Algorithm 3 for the voltage problem and Algorithm 5 for the flow problem—are easy to implement, with a pseudo-code that fits two lines. We investigate the behavior of these algorithms on general weighted graphs, and we show that the error they incur can be characterized in terms of hitting times of ordinary diffusion random walks defined on the computation trees that are obtained by unraveling the operations of the algorithms with time (Weiss and Freeman, 2001). We specialize the analysis to the case of d-regular graphs. When $d = 2$, we show that the flow algorithm converges to the true solution in the ℓ_∞ norm with rate $O(1/t)$, where t is the iteration time, independently of the graph dimensions n and m, yielding a ε-approximate solution with a running time $O(m/\varepsilon)$, linear in m (Corollary 16). On the other hand, when $d = 2$, we show that the voltage algorithm does *not* converge, as it keeps oscillating (Corollary 10). For graphs with equal weights, when $d \geq 3$, we show that the error both algorithms commit is characterized by quantities involving the difference of non-backtracking random walks on the original graph that originate from neighbor nodes (Lemma 9). We show that the convergence rate of the algorithms (with respect to various norms) can be controlled by uniform bounds on the total variation distance between the distributions of these walks. For graphs where these bounds decay exponentially $O(e^{-t})$ (such as complete graphs, as we show numerically) or polynomially $O(1/t^\beta)$ with $\beta > 0$ (such as cycles and tori, where $\beta = 1/2$ as we show numerically), possibly under additional assumptions on the problem instance (depending on the norm chosen for the analysis), the Min-Sum algorithm yield ε-approximate solutions for both voltage and flow problem with time $O(m \log 1/\varepsilon)$ or $O(m/\varepsilon^{1/\beta})$, respectively, linear in m (Theorem 15 for voltages, and Theorem 18 for flows).

Novelty in the analysis of message passing. Our analysis of the Min-Sum algorithm presents two key contributions that go beyond the specifics of the problems here addressed.

1. Beyond contraction arguments. Typically, the convergence analysis of the Min-Sum scheme exploits a decay of correlation property in the computation tree established upon imposing *local* assumptions on the original problem, such as the assumption of scaled diagonal dominance. These conditions essentially yield a bound on the local interactions in the computation tree by a quantity strictly less than one. In this case, a contraction argument can be performed at each level of the tree to establish an *exponential* decay of correlation from root to leaves, which translates into an exponential convergence for the algorithm. On the other hand, the analysis of message passing that we present in this paper is based on a *global* analysis of the problem supported on the computation tree, via the analogy with electric circuits and the characterization with hitting times of random walks, which is not captured by contraction arguments based on worst-case bounds for local interactions. In fact, as mentioned above, for some graphs this analysis yields a convergence *polynomial* in time, not exponential.
2. Beyond unconstrained optimization. Typically, the convergence analysis of the Min-Sum algorithm relies on finding the fix point(s) of the message updates. For unconstrained optimization problems, the key insight to find fix point(s) is that the first order optimality conditions for the original problem are respected by the problem supported on the computation tree, for every node that is not a leaf (Weiss and Freeman, 2001; Moallemi and Van Roy, 2010). The convergence analysis that we present for the flow problem—a constrained problem—is based on the observation that the Karush-Kuhn-Tucker (KKT) optimality conditions for constrained problems are respected on the computation tree, for every non-leaf node. This insight allows to extend the analysis of the Min-Sum algorithm to more general constrained optimization problems.

Structure of the paper. The structure of the paper is as follows. In Section 2 we define the voltage and flow problems as optimization routines. In Section 3 we introduce the general-purpose Min-Sum algorithm, and we specialize it to the voltage and flow problem, respectively. In Section 4 we present the error characterization for the Min-Sum algorithms for d-regular graphs, and we present the main results on their convergence. In Section 5 we develop the general framework to investigate the Min-Sum algorithm, yielding the characterization of the error in terms of hitting times of random walks on the computation trees, and we present the proofs of the results given in the previous section. In Appendix A we establish a general connection between the inverse of restricted Laplacian matrices and hitting times of ordinary diffusion random walks on graphs—which is the main computational tool used in our analysis. Technical results are in Appendix B.

Remark 1 (Notation) *Given a matrix M, we denote by M^T its transpose, by M^{-1} its inverse, and by M^+ its Moore-Penrose pseudoinverse. Given a set $\mathcal{I}$ and $i \in \mathcal{I}$, we denote by i both the element $i \in \mathcal{I}$ and the subset $\{i\} \subseteq \mathcal{I}$ (e.g., we write $\mathcal{I}\backslash i$ to mean $\mathcal{I}\backslash\{i\}$). Given a function $f : \mathbb{R}^{\mathcal{I}} \to \mathbb{R}$, $i \in \mathcal{I}$, we write $f(x_{\mathcal{I}\backslash i}\,\cdot)$ to mean the function $z \in \mathbb{R} \to f(x_{\mathcal{I}\backslash i} z)$. We adopt the following taxonomy of notation:*

- *the arrow notation $\vec{}$ is used to either refer to quantities related to directed graphs or to refer to probability distributions related to non-backtracking random walks;*
- *the hat notation $\hat{}$ is used to refer to the output of algorithms;*
- *the bar notation $\bar{}$ is for quantities related to graphs where a node has been removed;*
- *the double-struck notation is for quantities related to computation trees, cf. Section 5.*

2. Voltage and Flow Problems

Throughout, let us consider a simple (i.e., no self-loops, and no multiple edges), undirected, weighted graph G given by the triple (V, E, W), where V is a set of n vertices, E is a set of m edges, and $W \in \mathbb{R}^{V\times V}$ is a symmetric matrix that assigns a positive weight to every edge, namely, $W_{vw} > 0$ if $\{v, w\} \in E$, and $W_{vw} = 0$ if $\{v, w\} \notin E$. The matrix W is called the weighted *adjacency matrix* of the weighed graph G. Define the weighted degree of a vertex v by $d_v := \sum_{w\in V} W_{vw}$, and let $D \in \mathbb{R}^{V\times V}$ be the diagonal matrix defined by $D_{vv} := d_v$. The Laplacian L of the graph G is the matrix defined as $L := D - W$. Without loss of generality, in what follows we assume that the graph G is connected, otherwise we can treat each connected component on its own. It can be verified that in this case the null space of the Laplacian matrix L is spanned by the all-ones vector $1 \in \mathbb{R}^V$, so that the range of L is spanned by the vectors orthogonal to 1.

Voltage problem. We are interested in solving linear equations in the Laplacian matrix L. That is, given b in the range of L, i.e., $1^T b = 0$, our goal is to find ν that satisfies

$$L\nu = b. \tag{1}$$

As it can immediately be checked from first order optimality conditions, the set of solutions to (1) coincides with the set of solutions to the "voltage problem," namely:

$$\text{maximize} \quad -\frac{1}{2}\nu^T L\nu + b^T\nu. \tag{2}$$

We are interested in the unique solution that is orthogonal to the all one vector, namely, $\nu^\star = L^+ b$, where L^+ is the Moore-Penrose pseudoinverse of L. Given an accuracy parameter $\varepsilon > 0$, the fast solvers mentioned in the introduction achieve a quasi-linear running time $\tilde{O}(m \log^c n \log 1/\varepsilon)$ to return an estimate $\hat{\nu}$ that satisfies $\|\nu^\star - \hat{\nu}\|_L \le \varepsilon\|\nu^\star\|_L$, where $\|\nu\|_L := \sqrt{\nu^T L\nu}$ is the Laplacian-modified ℓ_2 norm, also known as L-norm. It can be seen that $\|\cdot\|_L$ is a pseudo-norm, as $\|\nu\|_L = 0$ for any vector ν orthogonal to the all one vector. In many applications where Laplacian solvers are needed, the L-norm is the natural norm to run the analysis. See Vishnoi (2013), for instance. The L-norm is related to the Euclidean norm as follow: $\|\nu\|_L \le \kappa\|\nu\|_2$ and $\|\nu\|_2 \le \kappa\|\nu\|_L$, where κ is the ratio between the the maximum and minimum non-zero eigenvalues of L.

Flow problem. To introduce the flow problem, let us fix an arbitrary orientation of the edges in E. Denote this set of directed edges by $\vec{E}$, and let $\vec{G} = (V, \vec{E})$ be the corresponding directed graph. Let $A \in \mathbb{R}^{V\times\vec{E}}$ be the *signed vertex-edge incidence* matrix of the graph $\vec{G}$, defined as $A_{ve} := 1$ if edge e leaves node v, $A_{ve} := -1$ if edge e enters node v, $A_{ve} := 0$ otherwise. To each directed edge $e = (v, w)$ let $R \in \mathbb{R}^{\vec{E}\times\vec{E}}$ be the diagonal matrix defined by $R_{ee} := 1/W_{vw}$. It is easy to verify that the Laplacian L of the undirected graph G can be expressed as $L = AR^{-1}A^T$. Note that while A depends on the choice of the direction of the edges in $\vec{E}$, L does not. The "flow problem" is defined as follows:

$$\begin{aligned} \text{minimize} \quad & \frac{1}{2}x^T Rx \\ \text{subject to} \quad & Ax = b. \end{aligned} \tag{3}$$

This problem can be interpreted as a minimal-energy electrical network problem. To each directed edge $e \in \vec{E}$ is associated a resistor of value R_{ee} (analogously, a conductor of value $1/R_{ee}$) through which a current x_e flows, with the convention that $x_e > 0$ if the current is in the direction of the edge, $x_e < 0$ if the current is in the direction opposite the edge. The energy of having current x_e on edge e is given by the $\frac{1}{2}R_{ee}x_e^2$. For each node $v \in V$, b_v represents a given external current: $b_v > 0$ represents a source where the current enters node v, whereas $b_v < 0$ represents a sink where the current exits node v. The constraint equations $Ax = b$ embody Kirchhoff's conservation law, by which at each vertex the net sum of the incoming and outgoing internal flows equals the external flow.

Connection between voltage and flow problems. From the KKT optimality conditions it can be shown (see Proposition 31 in Appendix B) that the unique solution of problem (3) reads $x^\star = R^{-1}A^T L^+ b = R^{-1}A^T\nu^\star$. That is, if $e = (v, w) \in \vec{E}$, we have $x_e^\star = W_{vw}(\nu_v^\star - \nu_w^\star)$ which represents Ohm's law. Finally, notice that problem (2) is the dual of (3). Recall that the Lagrangian of (3) is the function $\mathcal{L}$ from $\mathbb{R}^{\vec{E}} \times \mathbb{R}^V$ to $\mathbb{R}$ defined as

$$\mathcal{L}(x, \nu) := \frac{1}{2}x^T Rx + \nu^T(b - Ax). \tag{4}$$

The dual function is $q(\nu) = \min_{x\in\mathbb{R}^{\vec{E}}} \mathcal{L}(x, \nu) = -\frac{1}{2}\nu^T L\nu + b^T\nu$, and the dual problem reads $\max_{\nu\in\mathbb{R}^V} q(\nu)$, which is problem (2).

3. Min-Sum Algorithm

The Min-Sum algorithm is a distributed routine to optimize a cost function that has a graph structure. Let $\mathcal{V}$ and $\mathcal{F}$ be two finite sets, whose elements are respectively referred to as *variables* and *factors*, to be interpreted as two groups of vertices in a certain undirected bipartite graph with edge set $\mathcal{E}$, where each edge in $\mathcal{E}$ connects an element of $\mathcal{V}$ with an element of $\mathcal{F}$. For any variable node $i \in \mathcal{V}$, we use the notation ∂i to denote the set of neighbors of vertex i in the factor graph. Analogously, for any factor node $a \in \mathcal{F}$, we use the notation ∂a to denote the set of neighbors of vertex a in the factor graph. Consider the following optimization problem over $x \in \mathbb{R}^{\mathcal{V}}$:

$$\text{minimize} \quad g(x) := \sum_{i\in\mathcal{V}} g_i(x_i) + \sum_{a\in\mathcal{F}} g_a(x_{\partial a}), \tag{5}$$

for a given set of functions $g_i : \mathbb{R} \to \mathbb{R} \cup \{\infty\}$, for each $i \in \mathcal{V}$, and $g_a : \mathbb{R}^{\partial a} \to \mathbb{R} \cup \{\infty\}$, for each $a \in \mathcal{F}$. The Min-Sum algorithm is an iterative algorithm that proceeds by updating a set of *messages* associated to each edge in the underlying factor graph. Messages are functions of the optimization variables x_i, for $i \in \mathcal{V}$, and each edge in the factor graph is associated with two messages at any given iteration of the algorithm. For any time $s \ge 0$, and $i \in \mathcal{V}, a \in \mathcal{F}$ so that $\{i, a\} \in \mathcal{E}$, $\mu_{i\to a}^s : \mathbb{R} \to \mathbb{R} \cup \{\infty\}$ represents a message from variable to factor, and $\mu_{a\to i}^s : \mathbb{R} \to \mathbb{R} \cup \{\infty\}$ represents a message from factor to variable.

In this work we consider the *synchronous* implementation of the Min-Sum algorithm, where at each iteration all messages are updated. For a given iteration step $t \ge 1$, the algorithm reads as in Algorithm 1.

The iterations of the Min-Sum algorithm correspond to the dynamic programming iterations to solve (5) when the underlying graph is a tree. In general, the Min-Sum algorithm

Algorithm 1: Min-Sum

Input: Initial messages $\{\mu^0_{a\to i}\}$, for each $\{i,a\}\in\mathcal{E}$;
for $s\in\{1,\dots,t\}$ **do**
  Compute, for each $\{i,a\}\in\mathcal{E}$,
  $\mu^s_{i\to a}=g_i+\sum_{b\in\partial i\setminus a}\mu^{s-1}_{b\to i}$, $\quad\mu^s_{a\to i}=\min_{x\in\mathbb{R}^\nu}\{g_a(x_{\partial a\setminus i}\,\cdot)+\sum_{j\in\partial a\setminus i}\mu^s_{j\to a}(x_j)\}$;
Compute $\mu^t_i=g_i+\sum_{a\in\partial i}\mu^t_{a\to i}$, for each $i\in\mathcal{V}$;
Output: $\hat{x}^t_i:=\arg\min_{z\in\mathbb{R}}\mu^t_i(z)$, for each $i\in\mathcal{V}$.

is not guaranteed to converge, and even when it converges it is not guaranteed that it converges to an optimal point of problem (5). The Min-Sum algorithm is suited for cooperative distributed multi-agents optimization. In this framework, to each variable $i\in\mathcal{V}$ is associated an agent who has access only to the local objective functions g_i and g_a, for each $a\in\partial i$. At each time step, each agent can only exchange information with his near-neighbors in the factor graph, i.e., the agents who share at least one factor with him. Agents' goal is to cooperate over time to solve problem (5). The Min-Sum algorithm is a mean to achieve this goal: iteratively, each agent i updates a set of messages $\{\mu^s_{i\to a}\}, a\in\partial i$, using the messages that he has received from his neighbors at the previous time step, i.e., $\{\mu^{s-1}_{j\to a}\}, a\in\partial j$, for each neighbor j of i, and using the locally known functions g_i and g_a, for each $a\in\partial i$.

Remark 2 (Belief Propagation) *The Min-Sum algorithm alternates minimizations and summations to compute the minimum of a sum of functions of the form in* (5)*. The main property that is used to derive the local updates of this algorithm (on a tree, where the algorithm computes the correct solution) is the fact that the minimum distributes over the summation. Closely related to the Min-Sum algorithm is the Sum-Product algorithm, where the goal is to compute the sum (or integral) of a product of functions of the following form:*

$$\prod_{i\in\mathcal{V}} g_i(x_i)\prod_{a\in\mathcal{F}} g_a(x_{\partial a}). \tag{6}$$

As the sum (or integral) distributes over the product, the Sum-Product algorithm takes the exact same form as Algorithm 1 with minima replaced by sums and sums replaced by products. In the machine learning community, the Sum-Product algorithm is usually referred to as Belief Propagation, and a classical application involves the computation of the normalization function of graphical models, where random variables $\{X_v\}_{v\in V}$ have a joint density that factorizes as in (6)*. While Min-Sum and Sum-Product are formally related, they are known to produce results that are qualitatively different. In particular, while there are sufficient conditions that guarantee the convergence and correctness of Min-Sum in graphs of arbitrary topology, the Sum-Product algorithm is known to yield correct results only on locally tree-like graphs (Weiss and Freeman, 2001).*

We now specialize the Min-Sum algorithm to the voltage and flow problem, respectively.

3.1. Min-Sum for the Voltage Problem

In order to apply the Min-Sum algorithm to solve the voltage problem (2), throughout the rest of this paper we consider the equivalent minimization form: minimize $\frac{1}{2}\nu^TL\nu-b^T\nu$. We

rewrite this problem in the form (5).[1] To this end, let us identify $\mathcal{V}\leftrightarrow V$ and $\mathcal{F}\leftrightarrow E$. In this context, the notation ∂v indicates the set of edges in E are connected to $v\in V$; analogously, the notation ∂e indicates the pair of vertices that are connected by edge e. For each $v\in V$, define the function $g_v(\nu_v)=-b_v\nu_v$, and for each $e\in E$ define the function $g_e(\nu_{\partial e}):=\frac{1}{2}W_{vw}(\nu_v-\nu_w)^2$, where $\partial e=\{v,w\}$. Recalling that $\nu^TL\nu=\sum_{\{v,w\}\in E}W_{vw}(\nu_v-\nu_w)^2$, the problem above is equivalent to the problem of minimizing the function $\sum_{v\in V}g_v(\nu_v)+\sum_{e\in E}g_e(\nu_{\partial e})$, which is of the form (5). As in the factor graph interpretation each factor node (i.e., edge in E) is adjacent to exactly two variable nodes (i.e., vertices in V), it is convenient to rewrite the Min-Sum algorithm in terms of updates of messages from factors to variables only. At each time step $t\geq 1$, to each edge $e=\{v,w\}\in E$ are associated two messages: $\mu^t_{e\to v}$ and $\mu^t_{e\to w}$. It is easy to verify that in the present setting Algorithm 1 becomes Algorithm 2.

Algorithm 2: Min-Sum, voltage problem

Input: Initial messages $\{\mu^0_{e\to v}\}$, for $e\in E, v\in\partial e$;
for $s\in\{1,\dots,t\}$ **do**
  Compute, for each $e\in E$, $v\in\partial e$, with $w=\partial e\setminus v$
  $\mu^s_{e\to v}=\min_{\nu_w\in\mathbb{R}}\{g_w(\nu_w)+g_e(\nu_w\,\cdot)+\sum_{f\in\partial w\setminus e}\mu^{s-1}_{f\to w}(\nu_w)\}$;
Compute $\mu^t_v=g_v+\sum_{e\in\partial v}\mu^t_{e\to v}$, for each $v\in V$;
Output: $\hat{\nu}^t_v:=\arg\min_{z\in\mathbb{R}}\mu^t_v(z)$, for each $v\in V$.

Algorithm 2 applies for any choice of the initial messages $\{\mu^0_{e\to v}\}$, for $e\in E, v\in\partial e$. If we choose initial messages that are quadratic functions, then the messages computed by the algorithm remain quadratic. The following Proposition presents the quadratic updates, without stating formulas for the constant terms as these terms do not influence the output of the Min-Sum algorithm, as we will show next.

Proposition 3 *For a given $s\geq 1$, for each $e\in E$, $v\in\partial e$ let $\mu^{s-1}_{e\to v}(z)=\frac{1}{2}W^{s-1}_{e\to v}z^2+w^{s-1}_{e\to v}z+c^{s-1}_{e\to v}$. Then, for each $e\in E$, $v\in\partial e$, we have $\mu^s_{e\to v}(z)=\frac{1}{2}W^s_{e\to v}z^2+w^s_{e\to v}z+c^s_{e\to v}$, where $\{c^s_{e\to v}\}$ is a certain set of constants, and (here $w=\partial e\setminus v$)*

$$W^s_{e\to v}=W_{vw}\frac{\sum_{f\in\partial w\setminus e}W^{s-1}_{f\to w}}{W_{vw}+\sum_{f\in\partial w\setminus e}W^{s-1}_{f\to w}},\qquad w^s_{e\to v}=W_{vw}\frac{\sum_{f\in\partial w\setminus e}w^{s-1}_{f\to w}-b_w}{W_{vw}+\sum_{f\in\partial w\setminus e}W^{s-1}_{f\to w}}.$$

Proof Fix $s\geq 1$, $e\in E$, $v\in\partial e$, and let $w=\partial e\setminus v$. The Min-Sum update rule reads $\mu^s_{e\to v}(\nu_v)=\min_{z\in\mathbb{R}}\{-b_wz+\frac{1}{2}W_{vw}(\nu_v-z)^2+\frac{1}{2}z^2\sum_{f\in\partial w\setminus e}W^{s-1}_{f\to w}+z\sum_{f\in\partial w\setminus e}w^{s-1}_{f\to w}+\sum_{f\in\partial w\setminus e}c^{s-1}_{f\to w}\}$. The solution is $z^\star=(W_{vw}\nu_v+b_w-\sum_{f\in\partial w\setminus e}w^{s-1}_{f\to w})/(W_{vw}+\sum_{f\in\partial w\setminus e}W^{s-1}_{f\to w})$, and the proof is immediately concluded by substitution. ■

From Proposition 3 it follows that if we initialize Algorithm 2 with quadratic messages of the form $\mu^0_{e\to v}(z)=\frac{1}{2}W^0_{e\to v}z^2+w^0_{e\to v}z$, then, modulo the constant terms, we can track the evolution of the quadratic messages computed by the algorithm by evaluating recursively

1. It is well known that different ways of mapping the original optimization problem to the form (5) yield different convergence results. See Moallemi and Roy (2009), for instance.

the set of parameters $\{W^s_{e\to v}\}, \{w^s_{e\to v}\}$ as prescribed by Proposition 3. The belief function associated to vertex v at time t then reads $\mu^t_v(z) = -b_v z + \sum_{e\in\partial v}(\frac{1}{2}W^t_{e\to v}z^2 + w^t_{e\to v}z + c^t_{e\to v})$, so that $\hat{\nu}^t_v = \arg\min_{z\in\mathbb{R}} \mu^t_v(z) = (b_v - \sum_{e\in\partial v} w^t_{e\to v})/(\sum_{e\in\partial v} W^t_{e\to v})$, independent of $\{c^t_{e\to v}\}$. The final procedure, in the case of quadratic initial messages, yields Algorithm 3.

Algorithm 3: Min-Sum, voltage problem, quadratic messages

Input: Initial messages $\{W^0_{e\to v}\}, \{w^0_{e\to v}\}$, $e \in E, v \in \partial e$;
for $s \in \{1, \dots, t\}$ **do**
  Compute, for each $e \in E$, $v \in \partial e$, with $w = \partial e \setminus v$
  $W^s_{e\to v} = W_{vw}\frac{\sum_{f\in\partial w\setminus e} W^{s-1}_{f\to w}}{W_{vw}+\sum_{f\in\partial w\setminus e} W^{s-1}_{f\to w}}$, $\quad w^s_{e\to v} = -W_{vw}\frac{b_w - \sum_{f\in\partial w\setminus e} w^{s-1}_{f\to w}}{W_{vw}+\sum_{f\in\partial w\setminus e} W^{s-1}_{f\to w}}$;
Output: $\hat{\nu}^t_v = \frac{b_v - \sum_{e\in\partial v} w^t_{e\to v}}{\sum_{e\in\partial v} W^t_{e\to v}}$, for each $v \in V$.

Algorithm 3, with the choice of initial conditions $W^0_{e\to v} = W_{vw}$ and $w^0_{e\to v} = 0$, for each $e = \{v, w\} \in E, v \in \partial e$, will be the focus of our investigation for the voltage problem. The convergence analysis will rely on the general formulation of Algorithm 2.

Remark 4 (Gaussian Belief Propagation) *When applied to quadratic objective functions, the Min-Sum algorithm (e.g., Algorithm 3) corresponds to the computation of the mean performed by the Belief Propagation algorithm applied to Gaussian graphical models (Weiss and Freeman, 2001). This connection is due to the fact that in the Gaussian case the mode of a distribution coincides with its mean. Min-Sum can be seen as computing the maximum a posteriori (MAP) estimate of the graphical model (i.e., the mode), which corresponds to the mean computed by Belief Propagation. Typically, the convergence and correctness of the mean of Gaussian Belief Propagation is investigated within the framework of walk-summability (Malioutov et al., 2006), or, equivalently, scaled diagonal dominance (Moallemi and Van Roy, 2010). As the Laplacian L is not positive definite, the existing framework can not be applied to investigate the convergence behavior of Algorithm 3. In this paper, we overcome this limitation by using a different approach based on the global analysis of the computation tree that supports the operations of the algorithm with time.*

3.2. Min-Sum for the Flow Problem

To apply the Min-Sum algorithm to solve the flow problem (3), we first rewrite this problem in the unconstrained form (5). To this end, let us identify $\mathcal{V} \leftrightarrow \vec{E}$ and $\mathcal{F} \leftrightarrow V$. In this context, the notation ∂v indicates the set of edges in $\vec{E}$ that either enter or leave node $v \in V$; analogously, the notation ∂e indicates the pair of vertices that are connected by edge e. For each $e \in \vec{E}$, define the function $g_e(x_e) = \frac{1}{2}R_{ee}x_e^2$, and for each $v \in V$ define the function $g_v(x_{\partial v}) := 0$ if $\sum_{e\in\vec{E}} A_{ve}x_e = b_v$, and $g_v(x_{\partial v}) := \infty$ otherwise. Clearly, problem (3) is equivalent to the problem of minimizing the function $\sum_{e\in\vec{E}} g_e(x_e) + \sum_{v\in V} g_v(x_{\partial v})$, which is of the form (5). As in the factor graph interpretation each variable node (i.e., edge in $\vec{E}$) is adjacent to exactly two factor nodes (i.e., vertices in V), it is convenient to rewrite the Min-Sum algorithm in terms of updates of messages from variables to factors only. At each time step $t \geq 1$, to each edge $e \in \vec{E}$ such that $\partial e = \{v, w\}$ (that is, either $e = (v, w)$ or $e = (w, v)$) are associated two messages: $\mu^t_{e\to v}$ and $\mu^t_{e\to w}$. It can be verified that in the present setting Algorithm 1 becomes Algorithm 4.[2]

Algorithm 4: Min-Sum, flow problem

Input: Initial messages $\{\mu^0_{e\to v}\}$, for $e \in \vec{E}, v \in \partial e$;
for $s \in \{1, \dots, t\}$ **do**
  Compute, for each $e \in \vec{E}$, $v \in \partial e$, with $w = \partial e \setminus v$
  $\mu^s_{e\to v} = g_e + \min_{x\in\mathbb{R}^{\vec{E}}} \left\{ g_w(x_{\partial w\setminus e}\,\cdot) + \sum_{f\in\partial w\setminus e} \mu^{s-1}_{f\to w}(x_f) \right\}$;
Compute $\mu^t_e = \mu^t_{e\to v} + \mu^t_{e\to w} - g_e$, for $e = (v, w) \in \vec{E}$;
Output: $\hat{x}^t_e := \arg\min_{z\in\mathbb{R}} \mu^t_e(z)$, for each $e \in \vec{E}$.

Note that if $\partial w \setminus e = \varnothing$, then the message $\mu^s_{e\to v}$ in Algorithm 4 reads $\mu^s_{e\to v}(z) = \frac{1}{2}R_{ee}b_w^2$ if $z = A_{we}b_w$, and $\mu^s_{e\to v}(z) = \infty$ otherwise, for any $s \geq 1$, irrespective of the choice of the initial messages. This is a consequence of the fact that if node $w \in V$ is a *leaf* of G (i.e., w has degree 1), then by Kirchhoff's law the value x_e of the flow on the unique edge e that is associated to w is $x_e = A_{we}b_w$. Without loss of generality, in what follows we assume that the graph G has no leaves. Otherwise, by removing one leaf at a time as described above, we can reduce the original problem to a new problem supported on a graph with no leaves (if G is a tree we can exactly compute all the components of the solution $x^\star$ in this way).

Algorithm 4 applies for any choice of the initial messages $\{\mu^0_{e\to v}\}$, for $e \in \vec{E}, v \in \partial e$. If we choose initial messages that are quadratic functions, then also the following messages computed by the algorithm remain quadratic. The next Lemma presents the quadratic updates, without stating formulas for the constant terms as these terms do not influence the output of the Min-Sum algorithm, as we will show next.

Proposition 5 *For a given $s \geq 1$, for each $e \in \vec{E}$, $v \in \partial e$ let $\mu^{s-1}_{e\to v}(z) = \frac{1}{2}R^{s-1}_{e\to v}z^2 + r^{s-1}_{e\to v}z + c^{s-1}_{e\to v}$. Then, if the graph G has no leaves, for each $e \in \vec{E}$, $v \in \partial e$, we have $\mu^s_{e\to v}(z) = \frac{1}{2}R^s_{e\to v}z^2 + r^s_{e\to v}z + c^s_{e\to v}$, where $\{c^s_{e\to v}\}$ is a set of constants, and (here $w = \partial e \setminus v$)*

$$R^s_{e\to v} = R_{ee} + \frac{1}{\sum_{f\in\partial w\setminus e} 1/R^{s-1}_{f\to w}}, \qquad r^s_{e\to v} = -A_{we}\frac{\sum_{f\in\partial w\setminus e} A_{wf}r^{s-1}_{f\to w}/R^{s-1}_{f\to w} + b_w}{\sum_{f\in\partial w\setminus e} 1/R^{s-1}_{f\to w}}.$$

Proof Fix $s \geq 1$, $e \in \vec{E}$, $v \in \partial e$, and let $w \in \partial e \setminus v$. As we assume that the graph G has no leaves, then $\partial w \setminus e \neq \varnothing$ and the Min-Sum update rule reads $\mu^s_{e\to v}(z) = g_e(z) + \min_{x\in\mathbb{R}^{\partial w\setminus e}: \tilde{A}x = b_w - A_{we}z} \sum_{f\in\partial w\setminus e} \mu^{s-1}_{f\to w}(x_f)$, where $\tilde{A} := A_{w,\partial w\setminus e}$ is the submatrix of A given by the w-th row and the columns indexed by the elements in $\partial w \setminus e$. The minimization in the definition of $\mu^s_{e\to v}$ can be written as

$$\begin{aligned} \text{minimize} \quad & \frac{1}{2}x^T\tilde{R}x + \tilde{r}^T x + 1^T\tilde{c} \\ \text{subject to} \quad & \tilde{A}x = b_w - A_{we}z \end{aligned} \tag{7}$$

2. For convenience of notation, we present Algorithm 4 with initial messages indexed by time 0. Messages are indexed by a time parameter that is shifted by one unit compared to Algorithm 1.

over $x \in \mathbb{R}^{\partial w \setminus e}$, with $\tilde{R} \in \mathbb{R}^{(\partial w \setminus e) \times (\partial w \setminus e)}$ diagonal with $\tilde{R}_{ff} := R^{s-1}_{f \to w}$, $\tilde{r} \in \mathbb{R}^{\partial w \setminus e}$ with $\tilde{r}_f := r^{s-1}_{f \to w}$, and $\tilde{c} \in \mathbb{R}^{\partial w \setminus e}$ with $\tilde{c}_f := c^{s-1}_{f \to w}$. By Proposition 31 in Appendix B the solution of (7) reads $x^\star = h - A_{we} z y$, with $h := b_w y - (I - y\tilde{A})\tilde{R}^{-1}\tilde{r}$, $y := \tilde{R}^{-1}\tilde{A}^T \tilde{L}^{-1}$, and $\tilde{L} := \tilde{A}\tilde{R}^{-1}\tilde{A}^T \in \mathbb{R}$. Substituting $x^\star$ in (7) we get $\mu^s_{e \to v}(z) = \frac{1}{2} R^s_{e \to v} z^2 + r^s_{e \to v} z + c^s_{e \to v}$, with $R^s_{e \to v} := R_{ee} + y^T \tilde{R} y$, and $r^s_{e \to v} := -A_{we}(y^T \tilde{R} h + \tilde{r}^T y)$. The proof follows as $\tilde{L} = \sum_{f \in \partial w \setminus e} 1/R^{s-1}_{f \to w}$, $y^T \tilde{R} y = \tilde{L}^{-1}$, $y^T \tilde{R} h = \tilde{L}^{-1} b_w$, $\tilde{r}^T y = \tilde{L}^{-1} \sum_{f \in \partial w \setminus e} A_{wf} r^{s-1}_{f \to w} / R^{s-1}_{f \to w}$. ■

From Proposition 5 it follows that if we initialize Algorithm 4 with quadratic messages $\mu^0_{e \to v}(z) = \frac{1}{2} R^0_{e \to v} z^2 + r^0_{e \to v} z$, then, modulo the constant terms, we can track the evolution of the quadratic messages computed by the algorithm by evaluating recursively the set of parameters $\{R^s_{e \to v}\}, \{r^s_{e \to v}\}$ as prescribed by Proposition 5. The belief function associated to edge e at time t then reads $\mu^t_e(z) = \frac{1}{2}(R^t_{e \to v} + R^t_{e \to w} - R_{ee}) z^2 + (r^t_{e \to v} + r^t_{e \to w}) z + c^t_e$, for a certain constant c^t_e, so that $\hat{x}^t_e = \arg\min_{z \in \mathbb{R}} \mu^t_e(z) = -(r^t_{e \to v} + r^t_{e \to w})/(R^t_{e \to v} + R^t_{e \to w} - R_{ee})$, independent of c^t_e. The final procedure so obtained, in the case of quadratic initial messages, for a graph G with no leaves, is given in Algorithm 5.

Algorithm 5: Min-Sum, flow problem, quadratic messages, no leaves

Input: Initial messages $\{R^0_{e \to v}\}, \{r^0_{e \to v}\}$, $e \in \vec{E}, v \in \partial e$;
for $s \in \{1, \dots, t\}$ **do**
  Compute, for each $e \in \vec{E}$, $v \in \partial e$, with $w = \partial e \setminus v$
  $R^s_{e \to v} = R_{ee} + \frac{1}{\sum_{f \in \partial w \setminus e} 1/R^{s-1}_{f \to w}}$, $\quad r^s_{e \to v} = -A_{we} \frac{\sum_{f \in \partial w \setminus e} A_{wf} r^{s-1}_{f \to w}/R^{s-1}_{f \to w} + b_w}{\sum_{f \in \partial w \setminus e} 1/R^{s-1}_{f \to w}}$;
Output: $\hat{x}^t_e = -\frac{r^t_{e \to v} + r^t_{e \to w}}{R^t_{e \to v} + R^t_{e \to w} - R_{ee}}$, for $e = (v, w) \in \vec{E}$.

Algorithm 5, with the choice of initial conditions $R^0_{e \to v} = R_{ee}$, $r^0_{e \to v} = 0$, for each $e \in \vec{E}, v \in \partial e$, will be the focus of our investigation for the flow problem. The convergence analysis will rely on the general formulation of Algorithm 4.

4. Results for d-Regular Graphs

A d-regular graph is a graph where each node has d neighbors. In this section, we first characterize the error committed by the Min-Sum algorithm to solve the voltage and flow problems on connected d-regular graphs in terms of the solution $\nu^\star = L^+ b$ of the voltage problem. Then, we develop convergence results with respect to various norms.

The proofs of the main results here presented—Lemma 6 and Lemma 9—are given in Section 5, where we develop the general machinery to analyze the behavior of the Min-Sum scheme to solve constrained optimization problems, and we present the characterization of the error committed by the voltage and flow algorithms on general weighted graphs in terms of hitting times of random walks on the computation tree (for the sake of simplicity, we postpone the results on general graphs to Section 5, as these results require the notion of computation tree). The proofs of the technical results used here are given in Appendix B.

Henceforth, let $\hat{\nu}^t$ be the outcome of Algorithm 3 at time t with the choice of initial conditions $W^0_{e \to v} = W_{vw}$ and $w^0_{e \to v} = 0$, for each $e = \{v, w\} \in E, v \in \partial e$. Analogously, let $\hat{x}^t$

be the outcome of Algorithm 5 at time t with the choice of initial conditions $R^0_{e \to v} = R_{ee}$, $r^0_{e \to v} = 0$, for each $e \in \vec{E}, v \in \partial e$. Throughout, given a weighted directed graph $\vec{G} = (V, \vec{E}, W)$ with no bi-directed edges (i.e., either $(v, w) \in \vec{E}$ or $(w, v) \in \vec{E}$), let $G = (V, E, W)$ be the weighted undirected graph naturally associated to $\vec{G}$, i.e., edges in E are obtained by removing the orientation of the edges in $\vec{E}$. Let $n := |V|$ and $m := |E|$ be the number of nodes and edges, respectively.

4.1. Error Characterization

We characterize the error committed by the Min-Sum algorithm as a function of time and as a function of the voltage solution $\nu^\star = L^+ b$.

The case $d = 2$, i.e., a cycle graph, allows a characterization for general weighted graphs.

Lemma 6 (Regular graphs, $d = 2$) *Let $\vec{G} = (V = \{0, \dots, n-1\}, \vec{E}, W)$ be a weighted directed cycle, and let $G = (V, E, W)$ be the corresponding undirected graph. Define the function $i \in \mathbb{N} \to \rho(i) := i \mod n$. For $v \in V$, $e = \{\rho(v), \rho(v+1)\} \in E$, $t \geq 2$, we have*

$$\nu^\star_v - \hat{\nu}^t_v = \alpha_{v,t} \, \nu^\star_{\rho(v-t-1)} + (1 - \alpha_{v,t}) \, \nu^\star_{\rho(v+t+1)}, \qquad \alpha_{v,t} := \frac{\sum_{k=v}^{v+t} 1/W_{\rho(k)\rho(k+1)}}{\sum_{k=v-t-1}^{v+t} 1/W_{\rho(k)\rho(k+1)}},$$

$$x^\star_e - \hat{x}^t_e = A_{ve} \, \beta_{e,t} \, (\nu^\star_{\rho(v-t)} - \nu^\star_{\rho(v+t+1)}), \qquad \beta_{e,t} := \frac{1}{\sum_{k=v-t}^{v+t} 1/W_{\rho(k)\rho(k+1)}}.$$

If each edge has the same weight ω, then $\alpha_{v,t} = 1/2$ and $\beta_{e,t} = \omega/(2t+1)$.

In the case of constant weights, this result shows that Min-Sum displays a non-convergent (oscillatory) behavior in the voltage setting (as $\alpha_{v,t}$ does not decay with time), while Min-Sum displays a convergent behavior in the flow setting (as $\beta_{v,t}$ decays with time). We will discuss this behavior more extensively in the following sections.

Remark 7 *The fact that the Min-Sum algorithm does not converge is not surprising. Gaussian BP, see Remark 4, is known to suffer from divergent behaviors even in the absence of degeneracy, i.e., even when the quadratic form of interest is defined by a positive definite matrix, as observed numerically in Rusmevichientong and Roy (2001).*

For $d \geq 3$ we can provide a characterization of the error in the case of graphs with equal weights. We begin by defining and bounding some quantities of interest that we will need to state our results. The proof of the following proposition is given in Appendix B.

Proposition 8 *Fix $d \geq 3$. For $s \geq 1$ let $h_s := \frac{1}{(d-1)^s - 1}$, and let $\delta_0 := \frac{1}{d}$, $\delta_1 := \frac{1}{d-1} + d - 1$, and $\delta_s := \frac{1}{d-1}(2 + \frac{(d-2)^2}{d-1}(1 + h_{s+2}))\delta_{s-1} - \frac{1}{(d-1)^2}\delta_{s-2}$ for $s \geq 2$. For any $t \geq 3$ define*

$$b_{d,t} := \frac{1}{(d-1)^2}\left(1 + (d-2)(1 + h_{t+1})\right)\delta_{t-2} - \frac{(d-2)(1+h_{t+1})}{(d-1)^3}\delta_{t-3},$$

$$c_{d,t} := \frac{1}{d-1}\left(1 + \frac{1}{(d-2)(1+h_t)}\right)\delta_{t-2} - \frac{1}{(d-1)^2}\delta_{t-3}.$$

Then we have $\frac{1}{2} \leq \frac{d-2}{d-1} \leq b_{d,t} \leq c_{d,t} \leq 1 + \varepsilon_d < 4$ and $c_{d,t} \geq 1$, where ε_d is a positive decreasing function of $d \geq 3$ so that $\varepsilon_d \to 0$ as $d \to \infty$ and $\varepsilon_3 < 3$.

For each $v \in V$, let $\vec{\mathbf{P}}_v$ be the law of a time-homogeneous *non-backtracking* random walk $Y_0, Y_1, Y_2, \ldots$ on the nodes of G with initial state $Y_0 = v$, which is defined by $\vec{\mathbf{P}}_v(Y_0 = w) := 1$ if $w = v$ and equal to 0 otherwise, by $\vec{\mathbf{P}}_v(Y_1 = w) := 1/d$ if $\{w, v\} \in E$ and equal to 0, and, for any $\{z, z'\} \in E$, by $\vec{\mathbf{P}}_v(Y_{t+1} = w | Y_t = z, Y_{t-1} = z') := \frac{1}{d-1}$ if $\{w, z\} \in E, w \neq z'$ and equal to 0 otherwise. For ease of notation, for $t \geq 0$, $w \in V$, define the row-stochastic matrices $P^{(t)}$ and $P^{(t,w)}$ as

$$P^{(t)}_{vz} := \vec{\mathbf{P}}_v(Y_t = z), \qquad P^{(t,w)}_{vz} := \vec{\mathbf{P}}_v(Y_t = z | Y_1 \neq w), \qquad v, z \in V. \tag{8}$$

We can now state the main result for d-regular graphs with $d \geq 3$ and equal weights, namely, $W_{vw} = \omega$ for any $\{v, w\} \in E$, for some $\omega > 0$.

Lemma 9 (Regular graphs, $d \geq 3$, equal weights) *Let $\vec{G} = (V, \vec{E}, W)$ be a connected directed d-regular graph, with $d \geq 3$, where each edge has the same weight $\omega > 0$, and let $G = (V, E, W)$ be the corresponding undirected graph. For $v \in V$, $e = (v, w) \in \vec{E}$, $t \geq 3$,*

$$\nu^\star_v - \hat{\nu}^t_v = \frac{1}{b_{d,t}} (P^{(t+1)} \nu^\star)_v, \qquad x^\star_e - \hat{x}^t_e = \frac{\omega}{c_{d,t}} \frac{d-1}{d} ((P^{(t,w)} \nu^\star)_v - (P^{(t,v)} \nu^\star)_w),$$

where $b_{d,t}$ and $c_{d,t}$ are defined and bounded as in Proposition 8.

This result characterizes the error committed by the Min-Sum algorithm in terms of the distribution of properly-defined non-backtracking random walks. Several papers have previously related the convergence properties of message-passing algorithms to non-backtracking random walks. For instance, we refer to Moallemi and Roy (2006) for an application to consensus optimization (this paper also analyzes d-regular graphs), and to Abbe (2018) for a more recent application to the Stochastic Block Model.

Given the error characterizations provided by Lemma 6 and Lemma 9, we now investigate and discuss the convergence properties of the Min-Sum algorithm.

4.2. Convergence Results for the Voltage Problem

We first analyze the convergence behavior of the Min-Sum algorithm when applied to the voltage problem: Algorithm 3. Following the literature on Laplacian solvers, as already noticed in Section 2, we perform the analysis in the L-norm, which is defined as $\|\nu\|_L := \sqrt{\nu^T L \nu}$ for any $\nu \in \mathbb{R}^V$, where $\nu^T L \nu = \sum_{\{v,w\} \in E} W_{vw} (\nu_v - \nu_w)^2$.

In the case $d = 2$, as previously discussed, the results of Lemma 6 attest that the output $\hat{\nu}^t$ of Algorithm 3 does *not* converge, as it keeps oscillating as a function of t. This is particularly evident in the case of equal weights, as the following corollary attests.

Corollary 10 (Regular graphs, $d = 2$) *Consider the setting of Lemma 6 with equal weights $W_{vw} = \omega$. For $t \geq 2$, $\|\nu^\star - \hat{\nu}^t\|^2_L = \frac{1}{2}\|\nu^\star\|^2_L + \frac{\omega}{2} \sum_{v=0}^{n-1} \nu^\star_v (2\nu^\star_{\rho(v+2t+2)} - \nu^\star_{\rho(v+2t+3)} - \nu^\star_{\rho(v+2t+1)})$.*

Proof The proof follows immediately from Lemma 6 noticing that $\|\nu^\star - \hat{\nu}^t\|^2_L$ equals $\omega \sum_{v=0}^{n-1} (\nu^\star_{v+1} - \hat{\nu}^t_{v+1} - (\nu^\star_v - \hat{\nu}^t_v))^2 = \frac{\omega}{4} \sum_{v=0}^{n-1} (\nu^\star_{\rho(v-t)} - \nu^\star_{\rho(v-t-1)} + \nu^\star_{\rho(v+t+2)} - \nu^\star_{\rho(v+t+1)})^2$, which reads $\frac{1}{2}\|\nu^\star\|^2_L + \frac{\omega}{2} \sum_{v=0}^{n-1} (\nu^\star_{\rho(v-t)} - \nu^\star_{\rho(v-t-1)})(\nu^\star_{\rho(v+t+2)} - \nu^\star_{\rho(v+t+1)})$. The result follows by grouping and relabeling the terms in the sum. ■

The oscillatory behavior of the Min-Sum algorithm on cycle graphs in the voltage problem marks a clear difference with what happens in the flow problem where, as we will see in Corollary 16 below, the algorithm *does* converge to the problem solution on cycle graphs.

Let us now consider the case $d \geq 3$. In this case, as Corollary 13 below attests, the convergence of the Min-Sum algorithm in the L-norm can be controlled by the total variation (TV) distance between the probability distributions of non-backtracking random walks that originate from neighbor nodes. In this framework, it is natural to also consider a modification of the L-norm normalized by the probability mass that is left out by the overlap of the above-mentioned random walks, which coincides with the TV distance between the walks. We give a general definition of this norm, and then present some of its properties.

Definition 11 (TV-normalized L-norm) *Given a row-stochastic matrix $M \in \mathbb{R}^{V \times V}$, define the pseudo-norm $\| \cdot \|_{L,M}$ as $\|\nu\|^2_{L,M} := \sum_{\{v,w\} \in E} W_{vw} \left(\frac{(M\nu)_v - (M\nu)_w}{\|M_v - M_w\|_{TV}} \right)^2$, for any $\nu \in \mathbb{R}^V$, where $\|M_v - M_w\|_{TV} := \frac{1}{2} \sum_{z \in V} |M_{vz} - M_{wz}|$ is the TV distance between the probability mass functions defined by the v-th and w-th rows of the matrix M, respectively.*

The fact that $\| \cdot \|_{L,M}$ is a pseudo-norm follows from the fact that $\| \cdot \|_L$ itself is a pseudo-norm. Indeed, note that $\|\nu\|_{L,M} = \|M\nu\|_{L'}$, where L' is the Laplacian of the weighted graph (V, E, W'), with $W'_{vw} := W_{vw} / \|M_v - M_w\|^2_{TV}$. By a well-known result (see Proposition 4.3 in Levin et al. (2009), for instance), we have $\|M_v - M_w\|_{TV} = \sum_{z \in V : M_{vz} > M_{wz}} (M_{vz} - M_{wz}) = \sum_{z \in V : M_{vz} < M_{wz}} (M_{vz} - M_{wz})$, which shows how the TV-normalized L-norm takes into account the overlap of the distributions defined by the rows of the matrix M.

Proposition 12 *For any row-stochastic matrix $M \in \mathbb{R}^{V \times V}$ and $\nu \in \mathbb{R}^V$ we have:*

(i) $\|\nu\|_{L,I} = \|\nu\|_L$, *where I is the identity matrix;*

(ii) $\|M\nu\|_L \leq \max_{\{v,w\} \in E} \|M_v - M_w\|_{TV} \, \|\nu\|_{L,M}$;

(iii) $\|\nu\|_L \leq (\sum_{\{v,w\} \in E} W_{vw})^{1/2} \max_{\{v,w\} \in E} |\nu_v - \nu_w| \leq (\sum_{\{v,w\} \in E} W_{vw})^{1/2} \operatorname{osc}(\nu)$;

(iv) $\|\nu\|_{L,M} \leq (\sum_{\{v,w\} \in E} W_{vw})^{1/2} \operatorname{osc}(\nu)$;

where the oscillation of ν is defined as $\operatorname{osc}(\nu) := \max_{v,w \in V} |\nu_v - \nu_w|$.

Proof Properties $(i), (ii)$ and (iii) are straightforward to verify. Property (iv) follows from $|(M\nu)_v - (M\nu)_w| \leq \|M_v - M_w\|_{TV} \operatorname{osc}(\nu)$. See Georgii (2011), Chapter 8, for instance. ■

We now state a convergence result for the Min-Sum algorithm $\hat{\nu}^t$ for the voltage problem, in the case of d-regular graphs, $d \geq 3$, with the same edge weights. As the L-norm involves a sum over neighbour nodes, and as Lemma 9 shows that the error of Min-Sum is characterized by the distribution of a (non-overlapping) random walk, we immediately see that Min-Sum for the voltage problem does not converge on bipartite graphs as in this case random walks that start at two neighbor locations never overlap. For this reason, we also consider an averaged version of the Min-Sum algorithm where the output of two consecutive iterations

is properly averaged: $\hat{\nu}^t_{ave} := \frac{b_{d,t-1}}{b_{d,t-1}+b_{d,t}}\hat{\nu}^{t-1} + \frac{b_{d,t}}{b_{d,t-1}+b_{d,t}}\hat{\nu}^t$. Let $Q^{(t)} := (P^{(t-1)} + P^{(t)})/2$ and define

$$\gamma(t) := \max_{\{v,w\}\in E} \|P_v^{(t)} - P_w^{(t)}\|_{TV}, \qquad \gamma_{\rm ave}(t) := \max_{\{v,w\}\in E} \|Q_v^{(t)} - Q_w^{(t)}\|_{TV}.$$

Corollary 13 (Regular graphs, $d \geq 3$, equal weights) *Setting of Lemma 9. For $t \geq 4$,*

$$\|\nu^\star - \hat{\nu}^t\|_L \leq 2\,\gamma(t+1)\,\|\nu^\star\|_{L,P^{(t+1)}} \leq 2\,\gamma(t+1)\,\sqrt{m}\,\mathrm{osc}(\nu^\star),$$
$$\|\nu^\star - \hat{\nu}^t_{\rm ave}\|_L \leq 2\,\gamma_{\rm ave}(t+1)\,\|\nu^\star\|_{L,Q^{(t+1)}} \leq 2\,\gamma_{\rm ave}(t+1)\,\sqrt{m}\,\mathrm{osc}(\nu^\star).$$

Proof From Lemma 9, $\nu^\star - \hat{\nu}^t = P^{(t+1)}\nu^\star/b_{d,t}$. Using property (ii) in Proposition 12 with $M = P^{(t+1)}$ we get $\|\nu^\star - \hat{\nu}^t\|_L^2 = \|P^{(t+1)}\nu^\star\|_L^2/b_{d,t}^2 \leq 4\,\gamma(t+1)^2\,\|\nu^\star\|^2_{L,P^{(t+1)}}$, as $b_{d,t} \geq 1/2$ by Proposition 8. As for $t \geq 4$ Lemma 9 yields $(b_{d,t-1}+b_{d,t})(\nu^\star - \hat{\nu}^t_{\rm ave}) = b_{d,t-1}(\nu^\star - \hat{\nu}^{t-1}) + b_{d,t}(\nu^\star - \hat{\nu}^t) = 2Q^{(t+1)}\nu^\star$, we get $\|\nu^\star - \hat{\nu}^t_{\rm ave}\|_L^2 = 4\|Q^{(t+1)}\nu^\star\|_L^2/(b_{d,t-1}+b_{d,t})^2 \leq 4\,\gamma_{\rm ave}(t+1)^2\,\|\nu^\star\|^2_{L,Q^{(t+1)}}$. The proof is concluded using Property (iv) in Proposition 12. ■

Corollary 13 shows that the convergence in the L-norm of the Min-Sum estimate $\hat{\nu}^t$ and its averaged version $\hat{\nu}^t_{\rm ave}$ is controlled by the behavior with time of the quantities $\gamma(t+1)$ and $\gamma_{\rm ave}(t+1)$, respectively, which represent uniform bounds on the TV distance between probability distributions of non-backtracking random walks that make $t+1$ steps originating from neighbor nodes. Proposition 32 in Appendix B yields a recursive formula to compute the matrices $P^{(t)}$'s in terms of the adjacency matrix of the undirected unweighted graph (V, E). This formula can then be used to compute the quantities $\gamma(t)$ and $\gamma_{\rm ave}(t)$. Here we present numerical results for a few classes of d-regular graphs (for convenience of presentation, we include also the numerical results related to the quantities $\widetilde{\gamma}(t)$ and $\widetilde{\gamma}_{\rm ave}(t)$ that control the convergence behavior of the Min-Sum algorithm in the flow problem and that will be defined later on in Section 4.3).

Example 1 (Complete graphs) *A n-complete graph is a graph with n nodes where every pair of nodes is connected by an edge. A n-complete graph is d-regular with degree $d = n-1$. Figure 1 (left). The quantity $\gamma(t)$ is seen to decay (albeit not monotonically) like an exponential function $\alpha(d)\exp(-\beta(d)t)$, where $\alpha(d) > 0$ is a decreasing function of d and $\beta(d) > 0$ is an increasing function of d. Figure 1 (center).*

Example 2 (Connected cycles) *A $d/2$-connected cycle, for $d \geq 4$ even, is a cycle graph where each node is connected to its d nearest nodes. Figure 2 (left). The quantity $\gamma(t)$ is seen to decay like a polynomial function $\alpha(d)/\sqrt{t}$, where $\alpha(d) > 0$ is an increasing function of d. The decay of $\gamma(t)$ is independent[3] of n and m. Figure 2 (center).*

Example 3 (Tori) *A $d/2$-dimensional torus, for $d \geq 4$ even, is a $d/2$-dimensional grid with periodic boundary conditions. Figure 3 (left). The quantity $\gamma_{\rm ave}(t)$ is seen to decay like a polynomial function $\alpha(d)/\sqrt{t}$, where $\alpha(d) > 0$ is an increasing function of d. The decay of $\gamma_{\rm ave}(t)$ is independent of n and m (the same considerations as in Example 2 hold). Figure 3 (center).*

3. It is implied that the decay with time is independent of n and m as long as time t satisfies $t \lesssim D/d$, where D is the diameter of the graph. Once the random walks reach the periodic boundary conditions the decay is faster (exponential instead of polynomial) due to the extra overlaps of the walks.

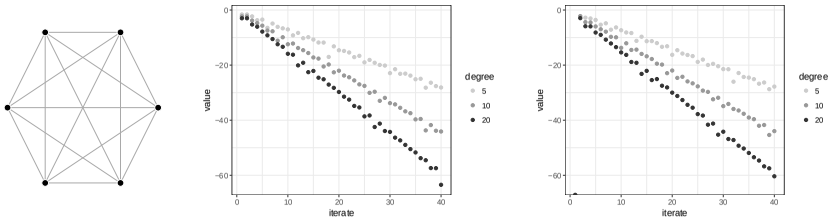

Figure 1: A 6-complete graph (left). Plot of $\log(\gamma(t))$ (center) and of $\log(\widetilde{\gamma}(t))$ (right) versus time t for various $(d+1)$-complete graphs.

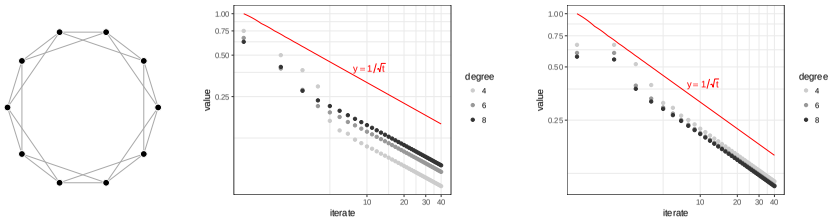

Figure 2: A 2-connected cycle (left). Plot in logarithmic scale of $\gamma(t)$ (center) and of $\widetilde{\gamma}(t)$ (right) versus time t for various $d/2$-connected cycles.

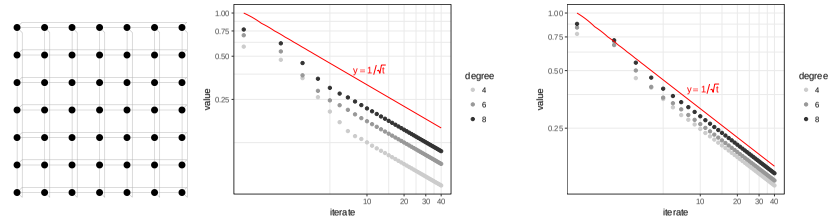

Figure 3: A 2-dimensional torus (left). Plot in logarithmic scale of $\gamma_{\rm ave}(t)$ (center) and of $\widetilde{\gamma}_{\rm ave}(t)$ (right) versus time t for various $d/2$-dimensional tori.

Remark 14 (Dobrushin's ergodicity coefficient) *For Markov chains with transition kernel P, there is a large literature investigating the contraction coefficient $\max_{v,w\in V}\|P_v^t - P_w^t\|_{TV}$ (a.k.a. Dobrushin's ergodicity coefficient), where t here represents the minimal time so that the coefficient is strictly less than 1. The Dobrushin's coefficient is fundamentally different from $\gamma(t)$. The former involves a worst-case bound over all nodes in the graph, while the latter involves a worst-case bound only over nearest-neighbors nodes. As a result,*

the Dobrushin's ergodicity coefficient typically depends on n and m, even when $\gamma(t)$ does not, such as in the examples above.

The fast solvers analyzed in the literature (see Introduction, Section 1, and Section 2) achieve a quasi-linear running time $\tilde{O}(m \log^c n \log 1/\varepsilon)$ to return an estimate $\hat{\nu}$ that satisfies $\|\nu^\star - \hat{\nu}\|_L \leq \varepsilon \|\nu^\star\|_L$. As per the results in Corollary 13, to compare the performance of the Min-Sum algorithm to these solvers we need to relate the TV-normalized L-norm to the ordinary L-norm. It is easy to construct examples where $\|\nu^\star\|_L < \|\nu^\star\|_{L,M}$ or where $\|\nu^\star\|_L > \|\nu^\star\|_{L,M}$, for a certain row-stochastic matrix M, while both norms satisfy $\|\nu^\star\|_L \leq \sqrt{m}\,\mathrm{osc}(\nu)$ (property (iii) in Proposition 12) and $\|\nu^\star\|_{L,M} \leq \sqrt{m}\,\mathrm{osc}(\nu)$ (property (iv) in Proposition 12). The following theorem summarizes the algorithmic complexity of the Min-Sum algorithm ν^t in the L-norm, under the assumption that the two norms of interest can be compared, and under the assumption that $\gamma(t)$ decays exponentially or polynomially, as attested numerically in the examples above (an analogous statement holds for the averaged Min-Sum algorithm ν^t_{ave}, replacing $P^{(t)}$ with $Q^{(t)}$, and $\gamma(t)$ with $\gamma_{\mathrm{ave}}(t)$).

Theorem 15 (Min-Sum voltage, running time, L-norm) *Setting of Lemma 9. Let $\alpha > 0, \beta > 0, \delta > 1$ independent of n, m. Assume that $\|\nu^\star\|_{L,P^{(t)}} \leq \delta \|\nu^\star\|_L$ for $t \geq 0$.*

1. *If $\gamma(t) \leq \alpha \exp(-\beta t)$ for $t \geq 0$, then the Min-Sum algorithm yields an estimate $\hat{\nu}$ such that $\|\nu^\star - \hat{\nu}\|_L \leq \varepsilon \|\nu^\star\|_L$ with running time $O(m \log 1/\varepsilon)$.*
2. *If $\gamma(t) \leq \alpha/t^\beta$ for $t \geq 0$, then the Min-Sum algorithm yields an estimate $\hat{\nu}$ such that $\|\nu^\star - \hat{\nu}\|_L \leq \varepsilon \|\nu^\star\|_L$ with running time $O(m/\varepsilon^{1/\beta})$.*

Proof The proof follows immediately from Corollary 13, recalling that each iteration of the Min-Sum algorithm requires a complexity that is linear in the number of edges, i.e., $O(m)$. If *1.* holds, then $\|\nu^\star - \hat{\nu}^t\|_L \leq \varepsilon \|\nu^\star\|_L$ is guaranteed by choosing t such that $2\alpha\delta \exp(-\beta(t+1)) \leq \varepsilon$; we can choose the smallest value $t = \lceil \log(2\alpha\delta/\varepsilon)/\beta - 1 \rceil \sim O(\log 1/\varepsilon)$. If *2.* holds, then $\|\nu^\star - \hat{\nu}^t\|_L \leq \varepsilon \|\nu^\star\|_L$ is guaranteed by choosing t such that $2\alpha\delta/(t+1)^\beta \leq \varepsilon$; we can choose the smallest value $t = \lceil (2\alpha\delta/\varepsilon)^{1/\beta} - 1 \rceil \sim O(1/\varepsilon^{1/\beta})$. ■

Theorem 15 shows that for certain classes of d-regular graphs, as characterized by the decaying properties of $\gamma(t)$, under the assumption that the TV-normalized L-norm of $\nu^\star$ is bounded by the L-norm of $\nu^\star$, the Min-Sum algorithm yields linear time solvers for the voltage problem, with respect to the L-norm.

4.3. Convergence Results for the Flow Problem

We now analyze the convergence behavior of the Min-Sum algorithm when applied to the flow problem: Algorithm 5. We present the results for the ℓ_∞ norm, defined as $\|x\|_\infty := \max_{e \in \vec{E}} x_e$ for any $x \in \mathbb{R}^{\vec{E}}$. The results for the ℓ_2 norm, defined as $\|x\|_2 := \sqrt{x^T x}$, are analogous to the results in the L-norm for the voltage case, as we describe in Remark 19.

For the case $d = 2$, Lemma 6 immediately yields the following result.

Corollary 16 (Regular graphs, $d = 2$) *Consider the setting of Lemma 6. Let $\omega_M := \max_{\{v,w\} \in E} W_{vw}$. Then, $\|x^\star - \hat{x}^t\|_\infty \leq \frac{2\omega_M}{2t+1} \|\nu^\star\|_\infty$. If ω_M is independent of n and m, then the Min-Sum algorithm yields $\hat{x}$ such that $\|x^\star - \hat{x}\|_\infty \leq \varepsilon \|\nu^\star\|_\infty$ with running time $O(m/\varepsilon)$.*

Proof From Lemma 6, by the triangle inequality, we have $|x^\star_e - \hat{x}^t_e| \leq \frac{\omega_M}{2t+1}(|\nu^\star_{\rho(v-t)}| + |\nu^\star_{\rho(v+t+1)}|)$, and the first bound follows by the triangle inequality for norms. The running time is immediate, as each iteration of the algorithm requires a complexity $O(m)$. ■

Corollary 16 shows that the flow Min-Sum algorithm on cycles converges in linear time to the problem solution, as opposed to the divergent behavior observed in the voltage case.

Let us now consider the case $d \geq 3$. As in the voltage problem, also in this case the convergence of the Min-Sum algorithm can be controlled by the TV distance between the probability distributions of properly-defined non-backtracking random walks that originate from neighbor nodes. As before, we also consider an averaged version of the Min-Sum algorithm where the output of two consecutive iterations is properly averaged: $\hat{x}^t_{\mathrm{ave}} := \frac{c_{d,t-1}}{c_{d,t-1}+c_{d,t}} \hat{x}^{t-1} + \frac{c_{d,t}}{c_{d,t-1}+c_{d,t}} \hat{x}^t$. Analogously to the voltage case, let $Q^{(t,w)} := (P^{(t-1,w)} + P^{(t,w)})/2$ and

$$\widetilde{\gamma}(t) := \max_{\{v,w\} \in E} \|P^{(t,w)}_v - P^{(t,v)}_w\|_{TV}, \qquad \widetilde{\gamma}_{\mathrm{ave}}(t) := \max_{\{v,w\} \in E} \|Q^{(t,w)}_v - Q^{(t,v)}_w\|_{TV}.$$

Corollary 17 (Regular graphs, $d \geq 3$, equal weights) *Setting of Lemma 9. For $t \geq 4$,*

$$\|x^\star - \hat{x}^t\|_\infty \leq 2\,\omega\,\frac{d-1}{d}\,\widetilde{\gamma}(t)\,\|\nu^\star\|_\infty, \qquad \|x^\star - \hat{x}^t_{\mathrm{ave}}\|_\infty \leq 2\,\omega\,\frac{d-1}{d}\,\widetilde{\gamma}_{\mathrm{ave}}(t)\,\|\nu^\star\|_\infty.$$

Proof For any $t \geq 1$, define the matrix $\widetilde{\Delta}^{(t)} \in \mathbb{R}^{\vec{E} \times V}$ as $\widetilde{\Delta}^{(t)}_{ez} := P^{(t,w)}_{vz} - P^{(t,v)}_{wz}, e = (v,w) \in \vec{E}$, $z \in V$. From Lemma 9 we have $x^\star - \hat{x}^t = \frac{\omega}{c_{d,t}} \frac{d-1}{d} \widetilde{\Delta}^{(t)} \nu^\star$, and the first bound follows from the sub-multiplicative property of the induced ℓ_∞ matrix norm, noticing that $\widetilde{\gamma}(t) = \|\widetilde{\Delta}^{(t)}\|_\infty/2$, and using that $c_{d,t} \geq 1$ from Proposition 8. The second bound follows analogously, as for any $t \geq 4$ we have $(c_{d,t-1} + c_{d,t})(x^\star - \hat{x}^t_{\mathrm{ave}}) = c_{d,t-1}(x^\star - \hat{x}^{t-1}) + c_{d,t}(x^\star - \hat{x}^t) = \omega \frac{d-1}{d}(\widetilde{\Delta}^{(t-1)} + \widetilde{\Delta}^{(t)})\nu^\star$, and $\widetilde{\gamma}_{\mathrm{ave}}(t) = \|(\widetilde{\Delta}^{(t-1)} + \widetilde{\Delta}^{(t)})/2\|_\infty/2$. ■

Corollary 17 shows that the convergence in the ℓ_∞ norm of the Min-Sum estimate $\hat{x}^t$ and its averaged version $\hat{x}^t_{\mathrm{ave}}$ is controlled by the behavior with time of the quantities $\widetilde{\gamma}(t)$ and $\widetilde{\gamma}_{\mathrm{ave}}(t)$, respectively, which represent uniform bounds on the TV distance between probability distributions of non-backtracking random walks that make t steps originating from neighbor nodes, conditioned on the event that the two walks avoid each others at the first step. Proposition 32 in Appendix B yields a recursive formula to compute the matrices $P^{(t,w)}$'s in terms of the adjacency matrix of the undirected unweighted graph (V, E). This formula can then be used to compute the quantities $\widetilde{\gamma}(t)$ and $\widetilde{\gamma}_{\mathrm{ave}}(t)$. Numerical results for a few classes of d-regular graphs have been presented in the previous section. See Figure 1 (right)[4], Figure 2 (right), and Figure 3 (right). The following theorem summarizes the algorithmic complexity of the Min-Sum algorithm x^t in the ℓ_∞ norm, under the assumption that $\widetilde{\gamma}(t)$ decays exponentially or polynomially, as attested numerically in the examples above (an analogous statement holds for the output x^t_{ave}, replacing $\widetilde{\gamma}(t)$ with $\widetilde{\gamma}_{\mathrm{ave}}(t)$).

Theorem 18 (Min-Sum flow, running time, ℓ_∞ norm) *Setting of Lemma 9. Let $\alpha > 0, \beta > 0$, and ω be independent of n and m.*

4. It is easy to see that $\widetilde{\gamma}(1) = 0$ for complete graphs, which explains the points at $t = 1$ in Figure 1 (right).

1. *If $\widetilde{\gamma}(t) \le \alpha \exp(-\beta t)$ for $t \ge 0$, then the Min-Sum algorithm yields an estimate $\hat{x}$ such that $\|x^\star - \hat{x}\|_\infty \le \varepsilon \|\nu^\star\|_\infty$ with running time $O(m \log 1/\varepsilon)$.*

2. *If $\widetilde{\gamma}(t) \le \alpha / t^\beta$ for $t \ge 0$, then the Min-Sum algorithm yields an estimate $\hat{x}$ such that $\|x^\star - \hat{x}\|_\infty \le \varepsilon \|\nu^\star\|_\infty$ with running time $O(m/\varepsilon^{1/\beta})$.*

Proof It follows from Corollary 17, analogously to the proof of Theorem 15. ■

Theorem 18 shows that for certain classes of d-regular graphs, as characterized by the decaying properties of $\widetilde{\gamma}(t)$, the Min-Sum algorithm yields linear time solvers for the flow problem, with respect to the ℓ_∞ norm. The following remark shows that an analogous result to Theorem 18 can be derived with respect to the ℓ_2 norm, with an additional assumption in the spirit of the one used in Theorem 15 for the voltage case.

Remark 19 (Analysis in ℓ_2 norm) *For d-regular graphs with $d \ge 3$, the analysis in the ℓ_2 norm for the flow problem follows the same steps as the analysis in the L-norm for the voltage problem. In fact, if one defines the matrices $\Delta^{(t)}$ and $\widetilde{\Delta}^{(t)} \in \mathbb{R}^{\vec{E} \times V}$ respectively as $\Delta^{(t)}_{ez} := P^{(t)}_{vz} - P^{(t)}_{wz}$ and $\widetilde{\Delta}^{(t)}_{ez} := P^{(t,w)}_{vz} - P^{(t,v)}_{wz}$, for any $e = (v,w) \in \vec{E}, z \in V$, then $\|x^\star - \hat{x}^t\|_2 = \frac{\omega}{c_{d,t}} \frac{d-1}{d} \|\widetilde{\Delta}^{(t)} \nu^\star\|_2$, while $\|\nu^\star - \hat{\nu}^t\|_L = \frac{1}{b_{d,t}} \|\Delta^{(t)} \nu^\star\|_2$. In analogy with Theorem 15, the results of Theorem 18 hold when replacing $\|x^\star - \hat{x}\|_\infty \le \varepsilon \|\nu^\star\|_\infty$ with $\|x^\star - \hat{x}\|_2 \le \varepsilon \|\nu^\star\|_L$, upon assuming that there exists $\delta > 1$ independent of n and m such that $\sum_{\{v,w\} \in E} W_{vw} \big(\frac{(P^{(t,w)}\nu)_v - (P^{(t,v)}\nu)_w}{\|P^{(t,w)}_v - P^{(t,v)}_w\|_{TV}} \big)^2 \le \delta^2 \|\nu^\star\|^2_L$, for $t \ge 0$, which corresponds to the assumption $\|\nu^\star\|_{L, P^{(t)}} \le \delta \|\nu^\star\|_L$ in Theorem 15.*

5. Results for General Weighted Graphs

This section develops the characterization of the error committed by the voltage and flow algorithms on general weighted graphs in terms of hitting times of ordinary diffusion random walks defined on the computation trees that are obtained by unraveling the operations of the algorithms with time (Theorem 23 and Lemma 24 for the flow case, and Theorem 28 for the voltage case). As applications, we specialize the general results here developed to prove the error characterization lemmas given in Section 4, i.e., Lemma 6 and Lemma 9.

While the main architecture of the results for the voltage problem (Algorithm 3) and the flow problem (Algorithm 5) is similar, there are some key differences that need to be taken into account. First, as the voltage algorithm updates functions (i.e., messages) on the vertices while the flow algorithm updates functions on the edges, the two algorithms give rise to different topologies for the computation tree. Second, as the voltage problem is an unconstrained optimization problem while the flow problem is an optimization problem with constraints, a different mechanism to find the fix point(s) of the algorithm is needed. As in the literature, to the best of our knowledge, previous analyses of the Min-Sum algorithm for quadratic and, more generally, convex problems only focused on the unconstrained case, we first present the full details of the results for the flow problem. Then, we give an overview of the results for the voltage problem, outlining in details only the parts where the analysis differs significantly from the one done for the flow problem.

5.1. Flow Problem, Algorithm 3

Our framework builds on the general scheme presented in Moallemi and Van Roy (2010) for unconstrained optimization problems, as we investigate the evolution of the Min-Sum algorithm under a set of linear perturbations. Henceforth, we consider Algorithm 5 when the initial messages are parametrized by $\{R^0_{e \to v} = R_{ee}\}, \{r^0_{e \to v} = p_{e \to v}\}$, for a certain set of real numbers $p = \{p_{e \to v}\}$. As far as the analysis is concerned, it is convenient (and more amenable to generalizations) to consider the form of Algorithm 4. For a given choice of perturbation parameters $p = \{p_{e \to v}\}$, define the initial messages as $\mu^0_{e \to v}(\,\cdot\,, p) : z \in \mathbb{R} \longrightarrow \mu^0_{e \to v}(z, p) = \frac{1}{2} R_{ee} z^2 + p_{e \to v} z$, and denote by $\{\mu^s_{e \to v}(\,\cdot\,, p)\}$, $s \ge 1$, the corresponding sequence of messages generated by the Min-Sum algorithm. Denote the estimates at time t as $\hat{x}^t(p)_e := \arg\min_{z \in \mathbb{R}} \mu^t_e(z, p)$, where $\mu^t_e(\,\cdot\,, p)$ is the corresponding belief function. We use the notation $\mathcal{N}(v) := \{w \in V : \{v, w\} \in E\}$ to denote the neighborhood of vertex v in G.

5.1.1. Computation Tree (Flow Problem)

To investigate the convergence behavior of the Min-Sum algorithm, we recall the concept of the computation tree, which is the graph obtained by unraveling the operations of the algorithm with time (Gallager, 1963; Weiss and Freeman, 2001; Tatikonda and Jordan, 2002). Given an edge $\tilde{e} = (\tilde{v}, \tilde{w}) \in \vec{E}$, the computation tree rooted at $\tilde{e}$ of depth t supports the optimization problem that is obtained by unfolding the computations involved in the Min-Sum estimate $\hat{x}^t(p)_{\tilde{e}}$. Formally, the computation tree is a directed tree $\vec{\mathbb{T}} = (\mathbb{V}, \vec{\mathbb{E}})$ (throughout, we use the double-struck notation to refer to quantities related to the computation tree) where each vertex in $\mathbb{V}$ is mapped to a vertex in V through a map $\sigma : \mathbb{V} \to V$ that preserves the edge structure, namely, if $\mathbb{e} = (\mathbb{v}, \mathbb{w}) \in \vec{\mathbb{E}}$ then $(\sigma(\mathbb{v}), \sigma(\mathbb{w})) \in \vec{E}$. Henceforth, we use the notation $\sigma(\mathbb{e}) := (\sigma(\mathbb{v}), \sigma(\mathbb{w}))$. The tree $\vec{\mathbb{T}}$ is defined iteratively. Initially, at level 0, the tree corresponds to a single root edge $\tilde{\mathbb{e}} = (\tilde{\mathbb{v}}, \tilde{\mathbb{w}}) \in \vec{\mathbb{E}}$ corresponding to $\tilde{e}$, i.e., $\sigma(\tilde{\mathbb{e}}) = \tilde{e}$. At this stage, $\tilde{\mathbb{v}}$ and $\tilde{\mathbb{w}}$ are the leaves of the tree. For the remaining t levels, the following procedure is repeated. The leaves in the tree are examined. Given a leaf $\mathbb{v}$ with $\sigma(\mathbb{v}) = v$ that is connected to a vertex $\mathbb{w}$ with $\sigma(\mathbb{w}) = w$, for any $z \in \mathcal{N}(v) \setminus w$, a vertex $\mathbb{z}$ with $\sigma(\mathbb{z}) = z$ and a directed edge $(\mathbb{v}, \mathbb{z})$ (resp. $(\mathbb{z}, \mathbb{v})$) are added to the next level of the tree if $(v, z) \in \vec{E}$ (resp. $(z, v) \in \vec{E}$). Figure 4 gives an example. We denote the set of vertices and edges in the k-th level of the tree respectively by $\mathbb{V}^k \subset \mathbb{V}$ and $\mathbb{E}^k \subset \mathbb{E}$. In what follows we also extend the usual neighborhood notation to vertices and edges in the graph $\mathbb{T}$, namely, $\partial \mathbb{v}$ is the set of edges in $\mathbb{T}$ that are connected to node $\mathbb{v}$, and $\partial \mathbb{e}$ is the set of vertices in $\mathbb{T}$ that are connected to edge $\mathbb{e}$.

The t-th (last) level of the tree $\vec{\mathbb{T}}$ is of particular relevance, as it supports the initial conditions of the Min-Sum algorithm, as we are now about to describe. Let $\mathbb{R} \in \mathbb{R}^{\vec{\mathbb{E}} \times \vec{\mathbb{E}}}$ be the diagonal matrix defined by $\mathbb{R}_{\mathbb{e}\mathbb{e}} := R_{\sigma(\mathbb{e})\sigma(\mathbb{e})}$. For a given choice of the perturbation parameters $p = \{p_{e \to v}\}$, define $\mathbb{p}(p) \in \mathbb{R}^{\vec{\mathbb{E}}}$ by $\mathbb{p}(p)_{\mathbb{e}} := p_{\sigma(\mathbb{e}) \to \sigma(\mathbb{v})}$ if $\mathbb{e} \in \vec{\mathbb{E}}^t, \mathbb{v} = \partial \mathbb{e} \cap \mathbb{V}^{t-1}$, and equals to 0 otherwise. Let $\bar{\mathbb{V}} := \mathbb{V} \setminus \mathbb{V}^t$ (throughout, we use the bar notation to denote quantities related to a graph in which a node has been removed). Define the matrix $\bar{\mathbb{A}} \in \mathbb{R}^{\bar{\mathbb{V}} \times \vec{\mathbb{E}}}$ as $\bar{\mathbb{A}}_{\mathbb{v}\mathbb{e}} := A_{\sigma(\mathbb{v})\sigma(\mathbb{e})}$ if $\mathbb{e} \in \partial \mathbb{v}$ and $\bar{\mathbb{A}}_{\mathbb{v}\mathbb{e}} := 0$ otherwise. Define the vector $\bar{\mathbb{b}} \in \mathbb{R}^{\bar{\mathbb{V}}}$ as $\bar{\mathbb{b}}_{\mathbb{v}} := b_{\sigma(\mathbb{v})}$.

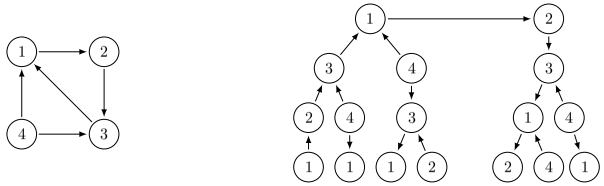

Figure 4: Graph $\vec{G} = (V = \{1, 2, 3, 4\}, \vec{E})$ (left) and computation tree $\vec{\mathbb{T}} = (\mathbb{V}, \vec{\mathbb{E}})$ of depth $t = 3$ with root edge corresponding to $(1, 2) \in \vec{E}$ (right). Vertices in $\vec{\mathbb{T}}$ are labeled by the corresponding vertices in $\vec{G}$.

Consider the following problem supported on the tree $\vec{\mathbb{T}}$, over $\mathbb{x} \in \mathbb{R}^{\vec{\mathbb{E}}}$:

$$\begin{aligned} \text{minimize} \quad & \frac{1}{2}\mathbb{x}^T \mathbb{R}\mathbb{x} + \mathbb{p}(p)^T \mathbb{x} \\ \text{subject to} \quad & \bar{\mathbb{A}}\mathbb{x} = \bar{\mathbb{b}}. \end{aligned} \tag{9}$$

Let $\mathbb{x}^\star(p)$ denote the unique optimal solution of this problem, as a function of the perturbation p. The relationship between the Min-Sum algorithm and the computation tree is made explicit by the following lemma, which can be easily established by inductively examining the operations of Algorithm 4.

Lemma 20 *Given the setting of this section, $\hat{x}^t(p)_{\tilde{e}} = \mathbb{x}^\star(p)_{\tilde{\mathbb{e}}}$.*

We now introduce a few quantities related to the computation tree $\vec{\mathbb{T}}$ and the problem (9) that will play a key role in our analysis. The signed vertex-edge incidence matrix $\mathbb{A} \in \mathbb{R}^{\mathbb{V} \times \vec{\mathbb{E}}}$ associated to the directed graph $\vec{\mathbb{T}}$ is defined for each $\mathbb{v} \in \mathbb{V}$, $\mathbb{e} \in \vec{\mathbb{E}}$ as $\mathbb{A}_{\mathbb{v}\mathbb{e}} := 1$ if edge $\mathbb{e}$ leaves node $\mathbb{v}$, $\mathbb{A}_{\mathbb{v}\mathbb{e}} := -1$ if edge $\mathbb{e}$ enters node $\mathbb{v}$, and $\mathbb{A}_{\mathbb{v}\mathbb{e}} := 0$ otherwise. It is easy to verify that $\bar{\mathbb{A}}$ is the submatrix of $\mathbb{A}$ that corresponds to the rows associated to $\bar{\mathbb{V}}$. Let $\mathbb{W} \in \mathbb{R}^{\mathbb{V} \times \mathbb{V}}$ be a symmetric matrix that assigns a positive weight to every edge in $\vec{\mathbb{E}}$, defined as $\mathbb{W}_{\mathbb{v}\mathbb{w}} := W_{\sigma(\mathbb{v})\sigma(\mathbb{w})}$ if either $(\mathbb{v}, \mathbb{w}) \in \vec{\mathbb{E}}$ or $(\mathbb{w}, \mathbb{v}) \in \vec{\mathbb{E}}$, and $\mathbb{W}_{\mathbb{v}\mathbb{w}} := 0$ otherwise. Henceforth, we think of $\vec{\mathbb{T}} = (\mathbb{V}, \vec{\mathbb{E}}, \mathbb{W})$ as the corresponding weighted graph, and $\mathbb{T} = (\mathbb{V}, \mathbb{E}, \mathbb{W})$ as the undirected graph naturally associated to $\vec{\mathbb{T}}$, where the edge set $\mathbb{E}$ is obtained by removing the orientation from the edges in $\vec{\mathbb{E}}$. As $\mathbb{T}$ is connected by assumption, it is easy to show that the range of $\mathbb{A}$ is spanned by the vectors orthogonal to the all-ones vector. It follows that the matrix $\bar{\mathbb{A}}$ has full row rank. Define the weighted degree of a vertex $\mathbb{v}$ by $\mathbb{d}_{\mathbb{v}} := \sum_{\mathbb{w} \in \mathbb{V}} \mathbb{W}_{\mathbb{v}\mathbb{w}}$, and let $\mathbb{D} \in \mathbb{R}^{\mathbb{V} \times \mathbb{V}}$ be the diagonal matrix defined by $\mathbb{D}_{\mathbb{v}\mathbb{v}} := \mathbb{d}_{\mathbb{v}}$. The Laplacian $\mathbb{L}$ of the graph $\vec{\mathbb{T}}$ is the matrix defined as $\mathbb{L} := \mathbb{D} - \mathbb{W}$. Let $\bar{\mathbb{L}} \in \mathbb{R}^{\bar{\mathbb{V}} \times \bar{\mathbb{V}}}$ denote the submatrix of $\mathbb{L}$ that corresponds to the rows and columns associated to $\bar{\mathbb{V}}$. Note that $\mathbb{R}_{\mathbb{e}\mathbb{e}} := 1/\mathbb{W}_{\mathbb{v}\mathbb{w}}$. It is easy to verify that the following equalities holds: $\mathbb{L} = \mathbb{A}\mathbb{R}^{-1}\mathbb{A}^T$ and $\bar{\mathbb{L}} = \bar{\mathbb{A}}\mathbb{R}^{-1}\bar{\mathbb{A}}^T$. We also define the transition matrix of the ordinary diffusion random walk on $\mathbb{T}$ as the matrix $\mathbb{P} := \mathbb{D}^{-1}\mathbb{W}$.

5.1.2. Fix Point (Flow Problem)

Clearly, the choice $p = 0$ for the linear perturbation parameters yields the original (unperturbed) algorithm. The next theorem below shows that for a particular choice of p the

Min-Sum algorithm yields the optimal solution at any time $t \geq 1$. The optimal choice of p is a function of the optimal Lagrangian multipliers for problem (3). Recall from (4) that the Lagrangian of this optimization problem is given by $\mathcal{L}(x, \nu) := \frac{1}{2}x^T Rx + \nu^T(b - Ax)$, where $\nu = (\nu_v)_{v \in V}$ is the vector formed by the Lagrangian multipliers. Define the function Ψ from $\mathbb{R}^{\vec{E}} \times \mathbb{R}^V$ to $\mathbb{R}^{\vec{E}} \times \mathbb{R}^V$ as $\Psi(x, \nu) := (\nabla_x \mathcal{L}(x, \nu), Ax - b) = (Rx - A^T\nu, Ax - b)$. Recall that $x^\star$ denotes the unique optimal solution of problem (3). As the constraints are linear, by the Lagrange multiplier theorem there exists $\nu^\star \in \mathbb{R}^V$ so that $\Psi(x^\star, \nu^\star) = 0$, i.e.,

$$\begin{cases} R_{ee}x^\star_e - (A^T\nu^\star)_e = 0 \text{ for } e \in \vec{E}, \\ \sum_{e \in \vec{E}} A_{ve}x^\star_e = b_v \text{ for } v \in V. \end{cases} \tag{10}$$

Note that the first line in (10) represents Ohm's law, and the second line represents Kirchhoff's law. Given the pair $(x^\star, \nu^\star)$, we are now ready to define the set of parameters $p^\star = \{p^\star_{e \to v}\}$ so that the Min-Sum algorithm yields the optimal solution at any time step.

Theorem 21 *For each $e \in \vec{E}$, $v \in \partial e$, let $w = \partial e \setminus v$ and define $p^\star_{e \to v} := -A_{we}\nu^\star_w$. Then, for any $\tilde{e} \in \vec{E}$, $t \geq 1$, we have $\hat{x}^t(p^\star)_{\tilde{e}} = x^\star_{\tilde{e}}$.*

Proof Fix $\tilde{e} \in \vec{E}$, $t \geq 1$. Consider the setting in Section 5.1.1, and let $\vec{\mathbb{T}}$ be the computation tree of depth t rooted at $\tilde{e}$. The Lagrangian of the problem (9) corresponding to the choice $p = p^\star$ is the function $\mathbb{L}$ from $\mathbb{R}^{\vec{\mathbb{E}}} \times \mathbb{R}^{\bar{\mathbb{V}}}$ to $\mathbb{R}$ defined by $\mathbb{L}(\mathbb{x}, \mathbb{v}) := \frac{1}{2}\mathbb{x}^T\mathbb{R}\mathbb{x} + \mathbb{p}(p^\star)^T\mathbb{x} + \mathbb{v}^T(\bar{\mathbb{b}} - \bar{\mathbb{A}}\mathbb{x})$, where $\mathbb{v} = (\mathbb{v}_{\mathbb{v}})_{\mathbb{v} \in \bar{\mathbb{V}}}$. Let Ψ from $\mathbb{R}^{\vec{\mathbb{E}}} \times \mathbb{R}^{\bar{\mathbb{V}}}$ to $\mathbb{R}^{\vec{\mathbb{E}}} \times \mathbb{R}^{\bar{\mathbb{V}}}$ be defined as $\Psi(\mathbb{x}, \mathbb{v}) := (\nabla_{\mathbb{x}}\mathbb{L}(\mathbb{x}, \mathbb{v}), \bar{\mathbb{A}}\mathbb{x} - \bar{\mathbb{b}}) = (\mathbb{R}\mathbb{x} + \mathbb{p}(p^\star) - \bar{\mathbb{A}}^T\mathbb{v}, \bar{\mathbb{A}}\mathbb{x} - \bar{\mathbb{b}})$. The Lagrangian multiplier theorem says for the unique minimizer $\mathbb{x}^\star \equiv \mathbb{x}^\star(p^\star) \in \mathbb{R}^{\vec{\mathbb{E}}}$ of (9) there exists $\mathbb{v}^\star \in \mathbb{R}^{\bar{\mathbb{V}}}$ so that $\Psi(\mathbb{x}^\star, \mathbb{v}^\star) = 0$, namely,

$$\begin{cases} \mathbb{R}_{\mathbb{e}\mathbb{e}}\mathbb{x}^\star_{\mathbb{e}} - (\bar{\mathbb{A}}^T\mathbb{v}^\star)_{\mathbb{e}} = 0, \mathbb{e} \in \vec{\mathbb{E}} \setminus \vec{\mathbb{E}}^t, \\ \mathbb{R}_{\mathbb{e}\mathbb{e}}\mathbb{x}^\star_{\mathbb{e}} + p^\star_{\sigma(\mathbb{e}) \to \sigma(\mathbb{v})} - (\bar{\mathbb{A}}^T\mathbb{v}^\star)_{\mathbb{e}} = 0, \mathbb{e} \in \vec{\mathbb{E}}^t, \mathbb{v} = \partial\mathbb{e} \cap \mathbb{V}^{t-1}, \\ \sum_{\mathbb{e} \in \vec{\mathbb{E}}} \bar{\mathbb{A}}_{\mathbb{v}\mathbb{e}}\mathbb{x}^\star_{\mathbb{e}} = \bar{\mathbb{b}}_{\mathbb{v}}, \mathbb{v} \in \bar{\mathbb{V}}. \end{cases}$$

Using (10) it is easy to check that the choice $\mathbb{x}^\star_{\mathbb{e}} = x^\star_{\sigma(\mathbb{e})}$ and $\mathbb{v}^\star_{\mathbb{v}} = \nu^\star_{\sigma(\mathbb{v})}$ satisfies the above system of equations. The proof is concluded by Lemma 20. ■

5.1.3. Error Characterization (Flow Problem)

The next lemma characterizes the sensitivity of the $\tilde{\mathbb{e}}$-th component (root edge of $\vec{\mathbb{T}}$) of the optimal solution of the optimization problem (9) with respect to perturbations of the parameters $p_{e \to v}$'s, which are supported on $\vec{\mathbb{E}}^t$.

Lemma 22 *Consider the setting in Section 5.1.1. Fix $\tilde{e} = (\tilde{v}, \tilde{w}) \in \vec{E}$, $t \geq 1$, and let $\vec{\mathbb{T}}$ be the computation tree of depth t rooted at $\tilde{e}$, with root edge $\tilde{\mathbb{e}} = (\tilde{\mathbb{v}}, \tilde{\mathbb{w}}) \in \vec{\mathbb{E}}$. For any $p = \{p_{e \to v}\}$, $e \in \vec{E}$ and $v \in \partial e$, we have*

$$\frac{\partial}{\partial p_{e \to v}}\mathbb{x}^\star(p)_{\tilde{\mathbb{e}}} = \frac{1}{R_{\tilde{e}\tilde{e}}} \sum_{\mathbb{v} \in \mathbb{V}^{t-1}} (\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}})(\mathbb{y}_{e \to v})_{\mathbb{v}},$$

where $\mathbb{y}_{e \to v} \in \mathbb{R}^{\mathbb{V}^{t-1}}$ is defined, for each $\mathbb{v} \in \mathbb{V}^{t-1}$, as $(\mathbb{y}_{e \to v})_{\mathbb{v}} := \frac{A_{ve}}{R_{ee}}\mathbf{1}_{\sigma(\mathbb{v}) = v}\mathbf{1}_{\sigma(\partial\mathbb{v} \cap \vec{\mathbb{E}}^t) = e}$, where $\mathbf{1}_S$ is the indicator function defined as $\mathbf{1}_S = 1$ if statement S is true, $\mathbf{1}_S = 0$ otherwise.

Proof By Proposition 31 in Appendix B, the solution of problem (9) reads $\mathbb{x}^\star(p) = \mathbb{R}^{-1}\bar{\mathbb{A}}^T\bar{\mathbb{L}}^{-1}\bar{\mathbb{b}} + (\mathbb{R}^{-1}\bar{\mathbb{A}}^T\bar{\mathbb{L}}^{-1}\bar{\mathbb{A}} - I)\mathbb{R}^{-1}\mathbb{p}(p)$, where $I \in \mathbb{R}^{\vec{\mathbb{E}}\times\vec{\mathbb{E}}}$ is the identity matrix. As $\mathbb{p}(p)$ is supported on the edges of $\mathbb{T}$ that are connected to its leaves and $\tilde{\mathbb{e}}$ is the root edge, we have $\frac{\partial}{\partial p_{e\to v}}\mathbb{x}^\star(p)_{\tilde{\mathbb{e}}} = \big(\mathbb{R}^{-1}\bar{\mathbb{A}}^T\bar{\mathbb{L}}^{-1}\bar{\mathbb{A}}\mathbb{R}^{-1}\frac{\partial}{\partial p_{e\to v}}\mathbb{p}(p)\big)_{\tilde{\mathbb{e}}} = \frac{1}{R_{\tilde{e}\tilde{e}}}\sum_{\mathbb{v}\in\mathbb{V}^{t-1}}(\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}})(\mathbb{y}_{e\to v})_{\mathbb{v}}$, where $(\mathbb{y}_{e\to v})_{\mathbb{v}} = (\bar{\mathbb{A}}\mathbb{R}^{-1}\frac{\partial}{\partial p_{e\to v}}\mathbb{p}(p))_{\mathbb{v}} = \frac{A_{ve}}{R_{ee}}\mathbf{1}_{\sigma(\mathbb{v})=v}\mathbf{1}_{\sigma(\partial\mathbb{v}\cap\vec{\mathbb{E}}^t)=e}$ for each $\mathbb{v}\in\mathbb{V}^{t-1}$. ■

As a consequence of Lemma 22, we immediately have the following characterization of the error committed by Algorithm 5 with initial conditions $\{R^0_{e\to v} = R_{ee}\}$, $\{r^0_{e\to v} = 0\}$.

Theorem 23 *Consider the setting in Section 5.1.1. Fix $\tilde{e} = (\tilde{v},\tilde{w}) \in \vec{E}$, $t \geq 1$, and let $\vec{\mathbb{T}}$ be the computation tree of depth t rooted at $\tilde{e}$, with root edge $\tilde{\mathbb{e}} = (\tilde{\mathbb{v}},\tilde{\mathbb{w}}) \in \vec{\mathbb{E}}$. We have*

$$x^\star_{\tilde{e}} - \hat{x}^t_{\tilde{e}} = \mathbb{W}_{\tilde{\mathbb{v}}\tilde{\mathbb{w}}}\sum_{\mathbb{v}\in\mathbb{V}^{t-1}}(\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}})\sum_{\mathbb{w}\in\mathbb{V}^t}\mathbb{W}_{\mathbb{v}\mathbb{w}}\nu^\star_{\sigma(\mathbb{w})}.$$

Proof From Theorem 21 and Lemma 22, by the fundamental theorem of calculus and the chain rule of differentiation, we get $x^\star_{\tilde{e}} - \hat{x}^t_{\tilde{e}} = \hat{x}^t(p^\star)_{\tilde{e}} - \hat{x}^t(0)_{\tilde{e}} = \int_0^1 d\theta\,\frac{d}{d\theta}\mathbb{x}^\star(\theta p^\star)_{\tilde{\mathbb{e}}} = \int_0^1 d\theta\sum_{e\in\vec{E},v\in\partial e}\frac{\partial}{\partial p_{e\to v}}\mathbb{x}^\star(\theta p^\star)_{\tilde{\mathbb{e}}}\,p^\star_{e\to v} = \mathbb{W}_{\tilde{\mathbb{v}}\tilde{\mathbb{w}}}\sum_{\mathbb{v}\in\mathbb{V}^{t-1}}(\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}})\sum_{e\in\vec{E},v\in\partial e}(\mathbb{y}_{e\to v})_{\mathbb{v}}\,p^\star_{e\to v}$. By Theorem 21 $p^\star_{e\to v} = -A_{we}\nu^\star_w$, $w = \partial e\setminus v$, and $\sum_{\substack{e\in\vec{E}\\ v\in\partial e}}(\mathbb{y}_{e\to v})_{\mathbb{v}}\,p^\star_{e\to v} = \sum_{\mathbb{w}\in\mathbb{V}^t}\mathbb{W}_{\mathbb{v}\mathbb{w}}\nu^\star_{\sigma(\mathbb{w})}$. ■

We now use the error characterization provided by Theorem 23 and the general connection between restricted Laplacians and random walks developed in Appendix A to prove the results in Section 4. Henceforth, for each $\mathbb{v}\in\mathbb{V}$, let $\mathbf{P}_{\mathbb{v}}$ be the law of a time homogeneous Markov chain $X_0, X_1, X_2, \ldots$ on $\mathbb{V}$ with transition matrix $\mathbb{P} := \mathbb{D}^{-1}\mathbb{W}$ and initial condition $X_0 = \mathbb{v}$. Analogously, denote by $\mathbf{E}_{\mathbb{v}}$ the expectation with respect to this law. The hitting time to a set $\mathbb{Z}\subseteq\mathbb{V}$ is defined as $T_{\mathbb{Z}} := \inf\{k\geq 0 : X_k\in\mathbb{Z}\}$. We also extend the notation $\mathcal{N}(\mathbb{v}) := \{\mathbb{w}\in\mathbb{V} : \{\mathbb{v},\mathbb{w}\}\in\mathbb{E}\}$ to denote the vertex-neighborhood of vertex $\mathbb{v}$ in $\mathbb{T}$.

The next lemma, which builds on the results developed in Appendix A, gives an expression for the restricted Laplacian in terms of hitting probabilities of random walks. This result represents the computational device that we will use repeatedly in what follows.

Lemma 24 *Consider the setting in Section 5.1.1. Fix $\tilde{e} = (\tilde{v},\tilde{w}) \in \vec{E}$, $t\geq 1$, and let $\vec{\mathbb{T}}$ be the computation tree of depth t rooted at $\tilde{e}$, with root edge $\tilde{\mathbb{e}} = (\tilde{\mathbb{v}},\tilde{\mathbb{w}}) \in \vec{\mathbb{E}}$. For each $\mathbb{v}\in\bar{\mathbb{V}}$, $\mathbb{w}\in\mathbb{V}^{t-1}$, with $\mathbb{z} = \mathcal{N}(\mathbb{w})\setminus\mathbb{V}^t$, we have*

$$\bar{\mathbb{L}}^{-1}_{\mathbb{v}\mathbb{w}} = \frac{\mathbf{P}_{\mathbb{v}}(T_{\mathbb{w}} < T_{\mathbb{V}^t})}{[1-\mathbf{P}_{\mathbb{z}}(T_{\mathbb{w}} < T_{\mathbb{V}^t})\,\mathbf{P}_{\mathbb{w}}(X_1 = \mathbb{z})]\,\mathbb{d}_{\mathbb{w}}}.$$

Proof Fix $\mathbb{v}\in\bar{\mathbb{V}}$, $\mathbb{w}\in\mathbb{V}^{t-1}$, and let $\mathbb{z} = \mathcal{N}(\mathbb{w})\setminus\mathbb{V}^t$. Define the random variable $A := \sum_{k=0}^{T_{\mathbb{V}^t}}\mathbf{1}_{X_k=\mathbb{w}}$. From Proposition 30 we have $\bar{\mathbb{L}}^{-1}_{\mathbb{v}\mathbb{w}} = \frac{1}{\mathbb{d}_{\mathbb{w}}}\mathbf{E}_{\mathbb{w}}[A]\,\mathbf{P}_{\mathbb{v}}(T_{\mathbb{w}} < T_{\mathbb{V}^t})$. By the Markov property, performing a first step analysis for the random walk, we get $\mathbf{E}_{\mathbb{w}}[A] = 1 + \sum_{\tilde{\mathbb{z}}\in\mathcal{N}(\mathbb{w})}\mathbf{E}_{\tilde{\mathbb{z}}}[A]\mathbf{P}_{\mathbb{w}}(X_1 = \tilde{\mathbb{z}}) = 1 + \mathbf{E}_{\mathbb{z}}[A]\mathbf{P}_{\mathbb{w}}(X_1 = \mathbb{z})$, where we used that $\mathbf{E}_{\tilde{\mathbb{z}}}[A] = 0$ for any $\tilde{\mathbb{z}}\in\mathbb{V}^t$. Conditioning on the event $\{T_{\mathbb{w}} < T_{\mathbb{V}^t}\}$ and its complementary, using that $\mathbf{E}_{\mathbb{z}}[A|T_{\mathbb{w}} > T_{\mathbb{V}^t}] = 0$, we also get $\mathbf{E}_{\mathbb{z}}[A] = \mathbf{E}_{\mathbb{z}}[A|T_{\mathbb{w}} < T_{\mathbb{V}^t}]\,\mathbf{P}_{\mathbb{z}}(T_{\mathbb{w}} < T_{\mathbb{V}^t})$. By the strong Markov property $\mathbf{E}_{\mathbb{z}}[A|T_{\mathbb{w}} < T_{\mathbb{V}^t}] = \mathbf{E}_{\mathbb{w}}[A]$, so that $\mathbf{E}_{\mathbb{w}}[A] = 1 + \mathbf{E}_{\mathbb{w}}[A]\,\mathbf{P}_{\mathbb{z}}(T_{\mathbb{w}} < T_{\mathbb{V}^t})\,\mathbf{P}_{\mathbb{w}}(X_1 = \mathbb{z})$ and $\mathbf{E}_{\mathbb{w}}[A] = 1/(1-\mathbf{P}_{\mathbb{z}}(T_{\mathbb{w}} < T_{\mathbb{V}^t})\,\mathbf{P}_{\mathbb{w}}(X_1 = \mathbb{z}))$. ■

5.1.4. Proofs of Results for d-Regular Graphs (Flow Problem)

We can now present the proofs of the results concerning the flow problem contained in Lemma 6 and Lemma 9 on the characterization of the error committed by the Min-Sum algorithm as a function of time and as a function of the voltage solution $\nu^\star = L^+b$.

Proof [Proof of Lemma 6, flow problem] Let $\vec{G} = (V = \{0,\ldots,n-1\},\vec{E},W)$ be a weighted directed cycle. Consider the setting in Section 5.1.1. Fix $v\in V$ and assume that $\tilde{e} = (\tilde{v} = \rho(v),\tilde{w} = \rho(v+1)) \in \vec{E}$ (the case $e = (\tilde{w} = \rho(v+1),\tilde{v} = \rho(v))$ yields to the same result with a minus sign in front). Fix $t\geq 2$, and let $\vec{\mathbb{T}}$ be the computation tree of depth t rooted at $\tilde{e}$, with root edge $\tilde{\mathbb{e}} = (\tilde{\mathbb{v}},\tilde{\mathbb{w}}) \in \vec{\mathbb{E}}$. Label the tree vertices as $\mathbb{V} = \{0,1,\ldots,2t+1\}$, as in Figure 5. Clearly, $\tilde{\mathbb{v}} = t$, $\tilde{\mathbb{w}} = t+1$, $\mathbb{V}^{t-1} = \{1,2t\}$, and $\mathbb{V}^t = \{0,2t+1\}$.

Figure 5: Cycle $G = (V,E)$ (left) and computation tree $\mathbb{T} = (\mathbb{V},\mathbb{E})$ of depth t with root edge $\{\tilde{\mathbb{v}} = t, \tilde{\mathbb{w}} = t+1\} \in \mathbb{E}$ (right).

We will apply Lemma 24 to compute the quantities $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}$, for each $\mathbb{v}\in\mathbb{V}^{t-1}$. We write the computations for $\mathbb{v} = 1$, as the case $\mathbb{v} = 2t$ follows immediately by symmetry. For convenience of notation, we write $\mathbb{W}_s$ to indicate $\mathbb{W}_{s,s+1}$. For each $s\in\mathbb{V}$, define $f_s := \mathbf{P}_s(T_1 < T_{\mathbb{V}^t})$, $p_s := \mathbf{P}_s(X_1 = s+1) = \mathbb{W}_s/\mathbb{d}_s$, $\mathbb{d}_s := \mathbb{W}_{s-1} + \mathbb{W}_s$, and $q_s := \mathbf{P}_s(X_1 = s-1) = 1-p_s$. By a first step analysis of the random walk and the Markov property, we have

$$f_s = f_{s-1}q_s + f_{s+1}p_s, \quad s\in\{2,\ldots,2t\}, \tag{11}$$

with boundary conditions $f_1 = 1$, $f_{2t+1} = 0$. The above system of equations corresponds to the classical Gambler Ruin's problem, with final states 1 and $2t+1$, see Figure 6.

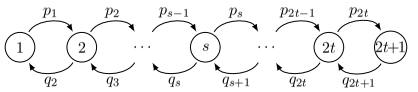

Figure 6: Gambler's Ruin.

To solve these equations, using that $1 = p_s + q_s$, we first rewrite them as $f_{s+1} - f_s = \frac{q_s}{p_s}(f_s - f_{s-1})$, for $s\in\{2,\ldots,2t\}$. Using that $q_s/p_s = \mathbb{W}_{s-1}/\mathbb{W}_s$ we get $f_{s+1} - f_s = \frac{\mathbb{W}_1}{\mathbb{W}_s}(f_2 - f_1)$. Summing these equations side by side, using that $f_1 = 1$, we get $f_s =$

$1+(f_2-1)\mathbb{W}_1(1/\mathbb{W}_1+1/\mathbb{W}_2+\cdots+1/\mathbb{W}_{s-1})$. Using that $f_{2t+1}=0$ we can solve for f_2 and finally obtain $f_s=\frac{1/\mathbb{W}_s+1/\mathbb{W}_{s+1}+\cdots+1/\mathbb{W}_{2t}}{1/\mathbb{W}_1+1/\mathbb{W}_2+\cdots+1/\mathbb{W}_{2t}}$ for any $s\in\{1,\dots,2t\}$. From Lemma 24, noticing that $\mathbb{z}=2$ in this case, we have $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}1}-\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}1}=(f_t-f_{t+1})/((1-f_2p_1)\mathbb{d}_1)$, which equals $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}1}-\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}1}=\frac{1/\mathbb{W}_t}{\mathbb{W}_0(1/\mathbb{W}_0+\cdots+1/\mathbb{W}_{2t})}$. By symmetry, we have $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}},2t}-\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}},2t}=\frac{-1/\mathbb{W}_t}{\mathbb{W}_{2t}(1/\mathbb{W}_0+\cdots+1/\mathbb{W}_{2t})}$. By Theorem 23, as $\mathbb{W}_s=W_{\sigma(s),\sigma(s+1)}$, we finally get $x^\star_{\tilde{e}}-\hat{x}^t_{\tilde{e}}=\frac{\nu^\star_{\sigma(0)}-\nu^\star_{\sigma(2t+1)}}{1/W_{\sigma(0)\sigma(1)}+\cdots+1/W_{\sigma(2t)\sigma(2t+1)}}$. The proof follows as the map $\sigma:\mathbb{V}\to V$ reads $\sigma(s)=\rho(s-t+v)$. ■

Proof [Proof of Lemma 9, flow problem] Let $\vec{G}=(V,\vec{E},W)$ be a connected d-regular graph, with $d\geq 3$, where each edge has the same weight ω. Consider the setting in Section 5.1.1. Fix $\tilde{e}=(\tilde{v},\tilde{w})\in\vec{E}$, $t\geq 3$, and let $\vec{\mathbb{T}}$ be the computation tree of depth t rooted at $\tilde{e}$, with root edge $\tilde{\mathbb{e}}=(\tilde{\mathbb{v}},\tilde{\mathbb{w}})\in\vec{\mathbb{E}}$. Fix $\mathbb{v}\in\mathbb{V}^{t-1}$, and assume that $\mathbb{v}$ is contained in the subtree with root vertex $\tilde{\mathbb{v}}$. For what follows, it is convenient to label some of the vertices in $\mathbb{V}$. Let $\mathbb{v}=0,1=\mathcal{N}(\mathbb{v})\setminus\mathbb{V}^t,2=\mathcal{N}(1)\setminus\mathbb{V}^{t-1},\dots,k+1=\mathcal{N}(k)\setminus\mathbb{V}^{t-k}$, until we reach $\tilde{\mathbb{v}}=t-1$. Label $\tilde{\mathbb{w}}=t$. See Figure 7. We will apply Lemma 24 to compute the quantity $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}}-\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}$. To this

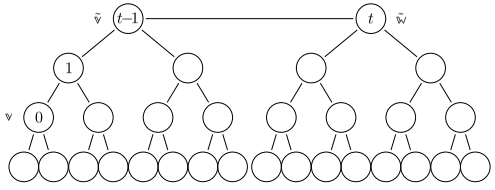

Figure 7: Computation tree $\mathbb{T}=(\mathbb{V},\mathbb{E})$ of depth $t=3$ associated to any 3-regular graph.

end, we need to compute the hitting probabilities $f_{\mathbb{w}}:=\mathbf{P}_{\mathbb{w}}(T_{\mathbb{v}}<T_{\mathbb{V}^t})$ for $\mathbb{w}\in\{1,t-1,t\}$. To do this, it is convenient to first reduce the network topology by invoking the equivalence between random walks and electrical circuits. See Peter G. Doyle (1984). The electrical circuit associated to the random walk X on $\mathbb{T}$ is constructed by assigning to each edge $\mathbb{e}=\{\mathbb{v},\mathbb{w}\}\in\mathbb{T}$ a conductor ω, which corresponds to a resistor $1/\omega$. Then, the quantities $f_{\mathbb{w}}$, $\mathbb{w}\in\mathbb{V}$, correspond to the voltages induced on $\mathbb{V}\setminus\{\mathbb{v}\cup\mathbb{V}^t\}$ when a voltage of intensity 1 is applied to $\mathbb{v}$ ($f_{\mathbb{v}}=1$), and a voltage of intensity 0 is applied to the sites in $\mathbb{V}^t$ ($f_{\mathbb{w}}=0$, $\mathbb{w}\in\mathbb{V}^t$). By repeatedly applying the standard network reduction operations for conductors in parallel and in series, it is easy to verify that, as long as the quantities $f_1,f_2,\dots,f_t$ are concerned, the original network is equivalent to the one represented in Figure 8.

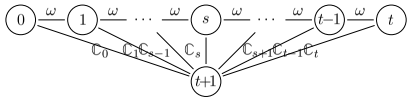

Figure 8: Reduced network.

In the reduced network, the conductance between the pairs of nodes s and $s+1$, for $s\in\{0,\dots,t-1\}$, remain ω as in the unreduced network, i.e., the computation tree. The

effect of all the nodes different from $0,\dots,t$ in the original graph is summarized in the reduced network by node $t+1$. For any $s\in\{0,\dots,t\}$, between node s and node $t+1$ there is a new conductor $\mathbb{C}_s$, which is obtained by reducing the subtree having root vertex s in the original graph. It is easy to verify that

$$\mathbb{C}_0=\omega(d-1),\qquad \mathbb{C}_s=\omega\frac{(d-2)^2}{d-1}(1+h_{s+1}),\ s\in\{1,\dots,t-1\},\qquad \mathbb{C}_t=\omega(d-2)(1+h_t),$$

with $h_s:=\frac{1}{(d-1)^s-1}$. Let $p_0:=\frac{\omega}{\omega+\mathbb{C}_0}, q_0:=1-p_0$, $p_s=q_s:=\frac{\omega}{2\omega+\mathbb{C}_s}$ for $s\in\{1,\dots,t-1\}$, $p_t:=\frac{\mathbb{C}_t}{\omega+\mathbb{C}_t}, q_t:=1-p_t$. By the Markov property we have

$$f_s=f_{s-1}q_s+f_{s+1}p_s,\quad s\in\{1,\dots,t\},\tag{12}$$

with $f_0=1, f_{t+1}=0$. This system of equations corresponds to a modification of the classical Gambler Ruin's problem, where states 0 and $t+1$ are the final states, and each intermediate state s has a probability $r_s:=1-p_s-q_s$ to reach state $t+1$. See Figure 9.

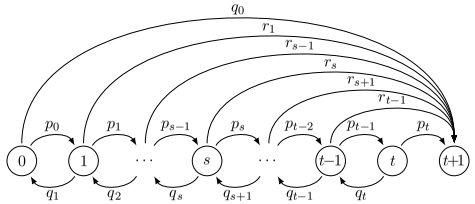

Figure 9: Gambler's Ruin on the reduced network.

Without loss of generality, we set $r_t=0$. We can easily write the solution of this system of equations in a compact form. Define $\alpha_1=\alpha_2:=1,\alpha_s:=\alpha_{s-1}-p_{s-2}q_{s-1}\alpha_{s-2}$ for $s\geq 3$. Define $\beta_1=\beta_2:=1$, $\beta_s:=\beta_{s-1}-p_{s-1}q_s\beta_{s-2}$ for $s\geq 3$. Then, as a function of f_1, we can write the solution of (12) as $f_s=\frac{1}{p_1\cdots p_{s-1}}(\alpha_sf_1-\beta_{s-1}q_1)$, for $s\in\{2,\dots,t+1\}$. In fact, it is easy to verify that this expression satisfies system (12). Using $f_{t+1}=0$ we find $f_1=q_1\beta_t/\alpha_{t+1}$ and $f_s=\frac{p_0q_1}{p_0\cdots p_{s-1}}(\frac{\alpha_s\beta_t}{\alpha_{t+1}}-\beta_{s-1})$ for $s\in\{1,\dots,t+1\}$, with $\beta_0:=0$. Lemma 24 yields the following, using that $\mathbb{d}_{\mathbb{v}}=\omega d$,

$$\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}}=\frac{f_{t-1}}{(1-f_1p_0)\mathbb{d}_{\mathbb{v}}}=\frac{1}{\omega d}\frac{q_1}{p_1\cdots p_{t-2}(\alpha_{t+1}-p_0q_1\beta_t)}(\alpha_{t-1}\beta_t-\alpha_{t+1}\beta_{t-2}),$$
$$\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}=\frac{f_t}{(1-f_1p_0)\mathbb{d}_{\mathbb{v}}}=\frac{1}{\omega d}\frac{q_1}{p_1\cdots p_{t-2}(\alpha_{t+1}-p_0q_1\beta_t)}\frac{1}{p_{t-1}}(\alpha_t\beta_t-\alpha_{t+1}\beta_{t-1}).$$

Using the recursive formulas for α_{t+1} and β_t, and the fact that $p_t+q_t=1$, we get $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}}-\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}=\frac{1}{\omega d}\frac{q_1}{p_1\cdots p_{t-2}(\alpha_{t+1}-p_0q_1\beta_t)}p_t(\alpha_{t-1}\beta_{t-1}-\alpha_t\beta_{t-2})$, which, as $\alpha_s\beta_s-\alpha_{s+1}\beta_{s-1}=p_{s-1}q_s(\alpha_{s-1}\beta_{s-1}-\alpha_s\beta_{s-2})$, becomes

$$\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}}-\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}=\frac{p_t}{q_t}\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}=\frac{1}{\omega d(d-1)^{t-1}}\frac{1}{\xi_{t-1}},\tag{13}$$

where $\xi_{t-1} := \frac{1}{(d-1)^{t-1}} \frac{\alpha_{t+1} - p_0 q_1 \beta_t}{q_1 \cdots q_{t-1} p_t}$ is defined by $\xi_s = \frac{p_s}{q_s p_{s+1}(d-1)} \xi_{s-1} - \frac{p_{s-1} p_s q_{s+1}}{q_{s-1} q_s p_{s+1} (d-1)^2} \xi_{s-2}$ for $s \in \{2, \dots, t-1\}$, with $\xi_0 := \frac{p_0 q_1}{p_1}$ and $\xi_1 = \frac{1}{d-1} \frac{1 - p_0 q_1 - p_1 q_2}{q_1 p_2}$. Plugging in the definitions of the transition probabilities, recalling the quantities defined in Proposition 8, it is immediate to verify that $\delta_s \equiv \xi_s$ for $s \in \{0, \dots, t-2\}$ and $c_{d,t} \equiv \xi_{t-1}$. By symmetry, it is clear that $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\tilde{\mathbb{v}}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\tilde{\mathbb{w}}} = \frac{1}{\omega d (d-1)^{t-1}} \frac{1}{c_{d,t}}$ holds for *any* $\mathbb{v} \in \mathbb{V}^{t-1}$ that is contained in the subtree of $\mathbb{T}$ with root vertex $\tilde{\mathbb{v}}$. On the other hand, again by symmetry, for any $\mathbb{v} \in \mathbb{V}^{t-1}$ contained in the subtree of $\mathbb{T}$ with root vertex $\tilde{\mathbb{w}}$ we have $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}} = -\frac{1}{\omega d (d-1)^{t-1}} \frac{1}{c_{d,t}}$. Theorem 23 yields

$$x^\star_{\tilde{e}} - \hat{x}^t_{\tilde{e}} = \omega^2 \sum_{\mathbb{v} \in \mathbb{V}^{t-1}} (\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} - \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}}) \sum_{\mathbb{w} \in \mathbb{V}^t} \nu^\star_{\sigma(\mathbb{w})} = \frac{\omega}{d(d-1)^{t-1}} \frac{1}{c_{d,t}} \sum_{v \in V} \nu^\star_v (\#^t_{\tilde{v} \to v, \tilde{w}} - \#^t_{\tilde{w} \to v, \tilde{v}}),$$

where $\#^t_{\tilde{v} \to v, \tilde{w}}$ is the number of non-backtracking paths in the original undirected graph $G = (V, E)$ that connect node $\tilde{v}$ to node v in t time steps, where the first step is different from $\tilde{w}$. As the total number of non-backtracking paths after t steps is $d(d-1)^{t-1}$, we have $\vec{\mathbf{P}}_{\tilde{v}}(Y_1 \neq \tilde{w}, Y_t = v) = \#^t_{\tilde{v} \to v, \tilde{w}} / (d(d-1)^{t-1})$. The proof follows as $\vec{\mathbf{P}}_{\tilde{v}}(Y_1 \neq \tilde{w}, Y_t = v) = \vec{\mathbf{P}}_{\tilde{v}}(Y_t = v | Y_1 \neq \tilde{w}) \vec{\mathbf{P}}_{\tilde{v}}(Y_1 \neq \tilde{w})$, and $\vec{\mathbf{P}}_{\tilde{v}}(Y_1 \neq \tilde{w}) = (d-1)/d$. ■

5.2. Voltage Problem, Algorithm 5

We now give an overview of the results in the voltage case. The main framework for these results is the same as the one used in the previous section to investigate the behavior of the Min-Sum algorithm applied to the flow problem. For this reason, as outlined at the beginning of Section 5, here we only discuss in details the parts of the proofs that present major differences compared to the flow problem.

Henceforth we consider Algorithm 3 when the initial messages are parametrized by $\{W^0_{e \to v} = W_{vw}, e = \{v, w\}\}, \{h^0_{e \to v} = p_{e \to v}\}$, for a certain set of real numbers $p = \{p_{e \to v}\}$. Also in this case, as far as the analysis is concerned, it is convenient to consider the form of Algorithm 2. For a given choice of perturbation parameters $p = \{p_{e \to v}\}$, define the initial messages as $\mu^0_{e \to v}(\cdot, p) : z \in \mathbb{R} \longrightarrow \mu^0_{e \to v}(z, p) = \frac{1}{2} W_{vw} z^2 + p_{e \to v} z$, where $e = \{v, w\}$, and denote by $\{\mu^s_{e \to v}(\cdot, p)\}$, $s \geq 1$, the corresponding sequence of messages generated by the Min-Sum algorithm. Denote the estimates at time t as $\hat{\nu}^t_v = \arg\min_{z \in \mathbb{R}} \mu^t_v(z, p)$, where $\mu^t_v(\cdot, p)$ is the corresponding belief function.

5.2.1. Computation Tree (Voltage Problem)

The computation tree for the voltage problem differs from the one in the flow problem due to the fact that the Min-Sum algorithms for the voltage problem propagates messages that are supported on vertices, not on edges. For this reason, the computation tree that we will now define is rooted at a vertex, not at an edge as the one defined in Section 5.1.1.

Given a vertex $\tilde{v} \in V$, the computation tree rooted at $\tilde{v}$ of depth t supports the optimization problem that is obtained by unfolding the computations involved in the Min-Sum estimate $\hat{\nu}^t(p)_{\tilde{v}}$. Formally, the computation tree is an undirected tree $\mathbb{T} = (\mathbb{V}, \mathbb{E})$ where each vertex in $\mathbb{V}$ is mapped to a vertex in V through a map $\sigma : \mathbb{V} \to V$ that preserves the edge structure, namely, if $\mathbb{e} = \{\mathbb{v}, \mathbb{w}\} \in \mathbb{E}$ then $\sigma(\mathbb{e}) := \{\sigma(\mathbb{v}), \sigma(\mathbb{w})\} \in E$. The tree $\mathbb{T}$

is defined iteratively. Initially, at level -1, the tree is made by a single root vertex $\tilde{\mathbb{v}} \in \mathbb{V}$ corresponding to $\tilde{v}$, i.e., $\sigma(\tilde{\mathbb{v}}) = \tilde{v}$. Consecutively, for any $z \in \mathcal{N}(\tilde{v})$, a vertex $\mathbb{z}$ with $\sigma(\mathbb{z}) = z$ and an edge $\{\tilde{\mathbb{v}}, \mathbb{z}\}$ are added to the level 0 of the tree. For the remaining $t-1$ levels, the following procedure is repeated. The leaves in the tree are examined. Given a leaf $\mathbb{v}$ with $\sigma(\mathbb{v}) = v$ that is connected to a vertex $\mathbb{w}$ with $\sigma(\mathbb{w}) = w$, for any $z \in \mathcal{N}(v) \setminus w$, a vertex $\mathbb{z}$ with $\sigma(\mathbb{z}) = z$ and an edge $\{\mathbb{v}, \mathbb{z}\}$ are added to the next level of the tree. Figure 10 gives an example. We denote the set of vertices and edges in the k-th level of the tree respectively by $\mathbb{V}^k \subset \mathbb{V}$ and $\mathbb{E}^k \subset \mathbb{E}$. In what follows we also extend the usual neighborhood notation to vertices and edges in the graph $\mathbb{T}$, namely, $\partial \mathbb{v}$ is the set of edges in $\mathbb{T}$ that are connected to node $\mathbb{v}$, and $\partial \mathbb{e}$ is the set of vertices in $\mathbb{T}$ that are connected to edge $\mathbb{e}$.

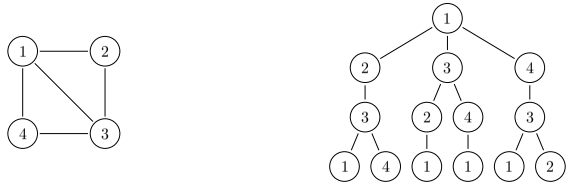

Figure 10: Graph $G = (V = \{1, 2, 3, 4\}, E)$ (left) and computation tree $\mathbb{T} = (\mathbb{V}, \mathbb{E})$ of depth $t = 2$ with root edge corresponding to $1 \in V$ (right). Vertices in $\mathbb{T}$ are labeled by the corresponding vertices in G.

The t-th (last) level of the tree is of particular relevance as it supports the initial conditions of the Min-Sum algorithm, as we are now about to describe. Let $\mathbb{W} \in \mathbb{R}^{\mathbb{V} \times \mathbb{V}}$ be the diagonal matrix defined by $\mathbb{W}_{\mathbb{v}\mathbb{w}} := W_{\sigma(\mathbb{v})\sigma(\mathbb{w})}$ if $\{\mathbb{v}, \mathbb{w}\} \in \mathbb{E}$ and $\mathbb{W}_{\mathbb{v}\mathbb{w}} := 0$ otherwise. Let $\bar{\mathbb{V}} := \mathbb{V} \setminus \mathbb{V}^t$. Define the weighted degree of a vertex $\mathbb{v}$ by $\mathbb{d}_{\mathbb{v}} := \sum_{\mathbb{w} \in \mathbb{V}} \mathbb{W}_{\mathbb{v}\mathbb{w}}$, and let $\mathbb{D} \in \mathbb{R}^{\mathbb{V} \times \mathbb{V}}$ be the diagonal matrix defined by $\mathbb{D}_{\mathbb{v}\mathbb{v}} := \mathbb{d}_{\mathbb{v}}$. The Laplacian $\mathbb{L}$ of the graph $\mathbb{T}$ is the matrix defined as $\mathbb{L} := \mathbb{D} - \mathbb{W}$. Let $\bar{\mathbb{L}} \in \mathbb{R}^{\bar{\mathbb{V}} \times \bar{\mathbb{V}}}$ denote the submatrix of $\mathbb{L}$ that corresponds to the rows and columns associated to $\bar{\mathbb{V}}$. For a given choice of the perturbation parameters $p = \{p_{e \to v}\}$, define $\bar{\mathbb{p}}(p) \in \mathbb{R}^{\bar{\mathbb{V}}}$ by

$$\bar{\mathbb{p}}(p)_{\mathbb{v}} := \begin{cases} \sum_{\mathbb{f} \in \partial \mathbb{v} \setminus \mathbb{e}} p_{\sigma(\mathbb{f}) \to \sigma(\mathbb{v})} & \text{if } \mathbb{v} \in \mathbb{V}^{t-1}, \mathbb{e} = \partial \mathbb{v} \setminus \mathbb{E}^t, \\ 0 & \text{otherwise,} \end{cases} \tag{14}$$

and let $\bar{\mathbb{b}} \in \mathbb{R}^{\bar{\mathbb{V}}}$ defined by $\bar{\mathbb{b}}_{\mathbb{v}} := b_{\sigma(\mathbb{v})}$ for each $\mathbb{v} \in \bar{\mathbb{V}}$.

Consider the following problem supported on the computation tree $\mathbb{T}$, over $\bar{\mathbb{v}} \in \mathbb{R}^{\bar{\mathbb{V}}}$:

$$\text{minimize} \quad \frac{1}{2} \bar{\mathbb{v}}^T \bar{\mathbb{L}} \bar{\mathbb{v}} + (\bar{\mathbb{p}}(p) - \bar{\mathbb{b}})^T \bar{\mathbb{v}}. \tag{15}$$

While the Laplacian $\mathbb{L}$ is positive semi-definite, the restricted Laplacian $\bar{\mathbb{L}}$ is positive definite (Spielman, 2010). Hence, for any choice of the perturbation p the objective function in problem (15) is strictly convex and it admits a unique solution $\bar{\mathbb{v}}^\star(p)$. The relationship between the Min-Sum algorithm and the tree is made explicit by the following lemma, which can be established by inductively examining the operations of Algorithm 2.

Lemma 25 *Given the setting of this section,* $\hat{\nu}^t(p)_{\tilde{v}} = \bar{\mathbb{v}}^\star(p)_{\tilde{\mathbb{v}}}$.

5.2.2. Fix Point (Voltage Problem)

The choice $p = 0$ for the linear perturbation parameters yields the original (unperturbed) algorithm. The next theorem below shows that for a particular choice of p the Min-Sum algorithm yields the optimal solution at any time $t \geq 1$. The optimal choice of p is a function of the optimal solution $\nu^\star$ for problem (2). Recall that, by definition, $\nu^\star$ is the unique vector that satisfy $L\nu^\star = b$ and $1^T\nu^\star = 0$. Hence, component-wise, for each $v \in V$,

$$d_v\nu^\star_v - \sum_{w\in\partial v} W_{vw}\nu^\star_w - b_v = 0, \tag{16}$$

where recall that $d_v := \sum_{w\in\partial v} W_{vw}$. Given $\nu^\star$, we are now ready to define the set of parameters $p^\star = \{p^\star_{e\to v}\}$ so that the Min-Sum algorithm yields the optimal solution at any time step.

Theorem 26 *For each $e \in E$, $v \in \partial e$, let $w = \partial e \setminus v$ and define $p^\star_{e\to v} := -W_{vw}\nu^\star_w$. Then, for any $\tilde v \in V$, $t \geq 1$, we have $\hat\nu^t(p^\star)_{\tilde v} = \nu^\star_{\tilde v}$.*

Proof Fix $\tilde v \in V$, $t \geq 1$. Consider the setting in Section 5.2.1, and let $\mathbb{T}$ be the computation tree of depth t rooted at $\tilde v$. From the first order optimality conditions for problem (15) corresponding to the choice $p = p^\star$, we know that $\bar v^\star \equiv \bar v^\star(p^\star)$ is the unique vector so that

$$\begin{cases} \mathbb{d}_{\mathbb{v}}\bar v^\star_{\mathbb{v}} - \sum_{\mathbb{w}\in\partial\mathbb{v}} \mathbb{W}_{\mathbb{v}\mathbb{w}}\bar v^\star_{\mathbb{w}} - \bar{\mathbb{b}}_{\mathbb{v}} = 0, \mathbb{v} \in \bar{\mathbb{V}} \setminus \mathbb{V}^{t-1}, \\ \mathbb{d}_{\mathbb{v}}\bar v^\star_{\mathbb{v}} - \mathbb{W}_{\mathbb{v}\mathbb{w}}\bar v^\star_{\mathbb{w}} + \bar{\mathbb{p}}(p^\star)_{\mathbb{v}} - \bar{\mathbb{b}}_{\mathbb{v}} = 0, \mathbb{v} \in \mathbb{V}^{t-1}, \{\mathbb{v},\mathbb{w}\} = \partial\mathbb{v} \setminus \mathbb{E}^t. \end{cases}$$

Using (16) it is easy to check that the choice $\bar v^\star_{\mathbb{v}} = \nu^\star_{\sigma(\mathbb{v})}$ satisfies the above system of equations. The proof is concluded by Lemma 25. ∎

5.2.3. Error Characterization (Voltage Problem)

The next lemma characterizes the sensitivity of the $\tilde{\mathbb{v}}$-th component (root vertex of $\mathbb{T}$) of the optimal solution of the optimization problem (15) with respect to perturbations of the parameters $p_{e\to v}$'s, which are supported on $\mathbb{V}^{t-1}$.

Lemma 27 *Consider the setting in Section 5.2.1. Fix $\tilde v \in V$, $t \geq 1$, and let $\mathbb{T}$ be the computation tree of depth t rooted at $\tilde v$, with root edge $\tilde{\mathbb{v}}$. For any $p = \{p_{e\to v}\}$, $e \in E$ and $v \in \partial e$, we have*

$$\frac{\partial}{\partial p_{e\to v}}\bar v^\star(p)_{\tilde{\mathbb{v}}} = -\sum_{\mathbb{v}\in\mathbb{V}^{t-1}} \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}}(\mathbb{y}_{e\to v})_{\mathbb{v}},$$

where $\mathbb{y}_{e\to v} \in \mathbb{R}^{\mathbb{V}^{t-1}}$ is defined, for each $\mathbb{v} \in \mathbb{V}^{t-1}$, as $(\mathbb{y}_{e\to v})_{\mathbb{v}} := \mathbf{1}_{\sigma(\mathbb{v})=v}\mathbf{1}_{\sigma(\partial\mathbb{v}\cap\vec{\mathbb{E}}^t)=e}$.

Proof From the first order optimality conditions, we know that the unique solution of problem (15) reads $\bar v^\star(p) = \bar{\mathbb{L}}^{-1}(\bar{\mathbb{b}} - \bar{\mathbb{p}}(p))$ so that $\frac{\partial}{\partial p_{e\to v}}\bar v^\star(p) = -\bar{\mathbb{L}}^{-1}\frac{\partial}{\partial p_{e\to v}}\bar{\mathbb{p}}(p)$. Using (14) it is easy to check that $(\mathbb{y}_{e\to v})_{\mathbb{v}} = (\frac{\partial}{\partial p_{e\to v}}\bar{\mathbb{p}}(p))_{\mathbb{v}}$. ∎

As a consequence of Lemma 27, we immediately have the following characterization of the error committed by Algorithm 3 with $\{W^0_{e\to v} = W_{vw}, e = \{v,w\}\}, \{h^0_{e\to v} = 0\}$.

Theorem 28 *Consider the setting in Section 5.2.1. Fix $\tilde v \in V$, $t \geq 1$, and let $\mathbb{T}$ be the computation tree of depth t rooted at $\tilde v$, with root vertex $\tilde{\mathbb{v}} \in \mathbb{V}$. We have*

$$\nu^\star_{\tilde v} - \hat\nu^t_{\tilde v} = \sum_{\mathbb{v}\in\mathbb{V}^{t-1}} \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} \sum_{\mathbb{w}\in\mathbb{V}^t} \mathbb{W}_{\mathbb{v}\mathbb{w}}\nu^\star_{\sigma(\mathbb{w})}.$$

Proof From Theorem 26 and Lemma 27, $\nu^\star_{\tilde v} - \hat\nu^t_{\tilde v} = \hat\nu^t(p^\star)_{\tilde v} - \hat\nu^t(0)_{\tilde v} = \int_0^1 d\theta\, \frac{d}{d\theta}\bar v^\star(\theta p^\star)_{\tilde{\mathbb{v}}} = \int_0^1 d\theta \sum_{e\in E, v\in\partial e} \frac{\partial}{\partial p_{e\to v}}\bar v^\star(\theta p^\star)_{\tilde{\mathbb{v}}}\, p^\star_{e\to v} = -\sum_{\mathbb{v}\in\mathbb{V}^{t-1}} \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} \sum_{e\in E, v\in\partial e}(\mathbb{y}_{e\to v})_{\mathbb{v}}\, p^\star_{e\to v}$, by the fundamental theorem of calculus and the chain rule of differentiation. From Theorem 26 we get $p^\star_{e\to v} := -W_{vw}\nu^\star_w$ for $e = \{v,w\}$, and $\sum_{e\in E, v\in\partial e}(\mathbb{y}_{e\to v})_{\mathbb{v}}\, p^\star_{e\to v} = -\sum_{\mathbb{w}\in\mathbb{V}^t} \mathbb{W}_{\mathbb{v}\mathbb{w}}\nu^\star_{\sigma(\mathbb{w})}$. ∎

Lemma 24 for the flow case holds also in the present case, upon referring the notation $\mathbf{P}_{\mathbb{v}}$, $\mathbf{E}_{\mathbb{v}}$, etc. to the Markov chain defined on the computation tree for the voltage case.

5.2.4. Proofs of Results for d-Regular Graphs (Voltage Problem)

We can now present the outline of the proofs for the results concerting the voltage problem in Lemma 6 and Lemma 9 in Section 4. Here we assume that the reader is already familiar with the proofs for the flow case.

Proof [Proof of Lemma 6, voltage problem] Let $G = (V = \{0,\dots,n-1\}, E, W)$ be a weighted cycle. Consider the setting in Section 5.2.1. Fix $v \in V$, $t \geq 2$, and let $\mathbb{T}$ be the computation tree of depth t rooted at $\tilde v$, with root vertex $\tilde{\mathbb{v}}$, i.e., $\sigma(\tilde{\mathbb{v}}) = \tilde v$. Label the vertices of the computation tree as $\mathbb{V} = \{0,1,\dots,2t+2\}$, as in Figure 11. Clearly, $\tilde{\mathbb{v}} = t+1$, $\mathbb{V}^{t-1} = \{1, 2t+1\}$, and $\mathbb{V}^t = \{0, 2t+2\}$.

Figure 11: Ring $G = (V, E)$ (left) and computation tree $\mathbb{T} = (\mathbb{V}, \mathbb{E})$ of depth t with root vertex $\tilde{\mathbb{v}} = t+1 \in \mathbb{V}$ (right).

Given this set up for the computation tree, the remaining of the proof follows exactly the steps of the proof in the flow case. Using the analogue of Lemma 24 for the voltage case, we can compute the quantities $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}}$, for each $\mathbb{v} \in \mathbb{V}^{t-1}$, by solving a system of equations like (11). If we write $\mathbb{W}_s$ to indicate $\mathbb{W}_{s,s+1}$, we find that $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}1} = \frac{1/\mathbb{W}_{t+1}+\cdots+1/\mathbb{W}_{2t+1}}{\mathbb{W}_0(1/\mathbb{W}_0+\cdots+1/\mathbb{W}_{2t+1})}$, and, by symmetry, $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}},2t+1} = \frac{1/\mathbb{W}_0+\cdots+1/\mathbb{W}_t}{\mathbb{W}_{2t+1}(1/\mathbb{W}_0+\cdots+1/\mathbb{W}_{2t+1})}$. By Theorem 28 we get $\nu^\star_{\tilde v} - \hat\nu^t_{\tilde v} = \sum_{\mathbb{v}\in\mathbb{V}^{t-1}} \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{v}}\mathbb{v}} \sum_{\mathbb{w}\in\mathbb{V}^t} \mathbb{W}_{\mathbb{v}\mathbb{w}}\nu^\star_{\sigma(\mathbb{w})} = \frac{1/\mathbb{W}_{t+1}+\cdots+1/\mathbb{W}_{2t+1}}{1/\mathbb{W}_0+\cdots+1/\mathbb{W}_{2t+1}}\nu^\star_{\sigma(0)} + \frac{1/\mathbb{W}_0+\cdots+1/\mathbb{W}_t}{1/\mathbb{W}_0+\cdots+1/\mathbb{W}_{2t+1}}\nu^\star_{\sigma(2t+2)}$, and the proof follows using $\mathbb{W}_s = W_{\sigma(s),\sigma(s+1)}$ and that $\sigma : \mathbb{V} \to V$ reads $\sigma(v) = \rho(s-t-1+\tilde v)$. ∎

Proof [Proof of Lemma 9, voltage problem] Let $G = (V, E, W)$ be a connected d-regular graph, with $d \geq 3$, where each edge has the same weight ω. Consider the setting in Section 5.2.1. Fix $\tilde{w} \in V$, $t \geq 3$, and let $\mathbb{T}$ be the computation tree of depth t rooted at $\tilde{w}$, with root vertex $\tilde{\mathbb{w}} \in \mathbb{V}$. Fix $\mathbb{v} \in \mathbb{V}^{t-1}$. For what follows, it is convenient to label some of the vertices in $\mathbb{V}$. Let $\mathbb{v} = 0, 1 = \mathcal{N}(\mathbb{v}) \setminus \mathbb{V}^t, 2 = \mathcal{N}(1) \setminus \mathbb{V}^{t-1}, \ldots, k+1 = \mathcal{N}(k) \setminus \mathbb{V}^{t-k}$, until we reach $\tilde{\mathbb{w}} = t$. See Figure 12. Given this set up for the computation tree, the remaining

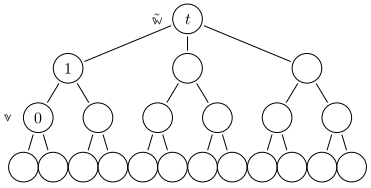

Figure 12: Computation tree $\mathbb{T} = (\mathbb{V}, \mathbb{E})$ of depth $t = 2$ associated to any given d-regular graph, with $d = 3$.

of the proof follows exactly the steps of the proof in the flow case. Using the analogue of Lemma 24 for the voltage case, we can compute $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{w}}$ by solving a system of equations of the form (12) supported on the a reduced network that is exactly like the one in Figure 8. The only difference is that now $\mathbb{C}_t = \omega(d-2)(1+h_{t+1})$, while all other effective conductances $\mathbb{C}_s$, for $s \in \{0, \ldots, t-1\}$, read exactly as for the flow problem. Rearranging (13) we get $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{w}} = \frac{1}{\omega d(d-1)^{t-1}} \frac{q_t}{p_t} \frac{1}{\xi_{t-1}}$, where $\xi_{t-1} := \frac{1}{(d-1)^{t-1}} \frac{\alpha_{t+1} - p_0 q_1 \beta_t}{q_1 \cdots q_{t-1} p_t}$ is defined as in the flow case by $\xi_s = \frac{p_s}{q_s p_{s+1}(d-1)} \xi_{s-1} - \frac{p_{s-1} p_s q_{s+1}}{q_{s-1} q_s p_{s+1}(d-1)^2} \xi_{s-2}$ for $s \in \{2, \ldots, t-1\}$, with $\xi_0 := \frac{p_0 q_1}{p_1}$ and $\xi_1 = \frac{1}{d-1} \frac{1 - p_0 q_1 - p_1 q_2}{q_1 p_2}$. Plugging in the definitions of the transition probabilities, noticing that p_t and q_t differ from the analogous quantities defined in the flow case due to the new definition of $\mathbb{C}_t$, recalling Proposition 8, it is immediate to verify that $\delta_s \equiv \xi_s$ for $s \in \{0, \ldots, t-2\}$ and $\frac{d-1}{(d-2)(1+h_{t+1})} b_{d,t} \equiv \xi_{t-1}$, so that $\bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{w}} = \frac{1}{\omega d(d-1)^t} \frac{1}{b_{d,t}}$. Theorem 28 yields

$$\nu^\star_{\tilde{w}} - \hat{\nu}^t_{\tilde{w}} = \sum_{\mathbb{v} \in \mathbb{V}^{t-1}} \bar{\mathbb{L}}^{-1}_{\tilde{\mathbb{w}}\mathbb{v}} \sum_{\mathbb{w} \in \mathbb{V}^t} \mathbb{W}_{\mathbb{v}\mathbb{w}} \nu^\star_{\sigma(\mathbb{w})} = \frac{1}{d(d-1)^t} \frac{1}{b_{d,t}} \sum_{v \in V} \nu^\star_v \, \#^{t+1}_{\tilde{w} \to v}.$$

where $\#^{t+1}_{\tilde{w} \to v}$ is the number of non-backtracking paths in the original undirected graph $G = (V, E)$ that connect node $\tilde{w}$ to node v in $t+1$ time steps. The proof is easily concluded noticing that the total number of non-backtracking paths after $t+1$ steps is $d(d-1)^t$, so that $\vec{\mathbf{P}}_{\tilde{w}}(Y_{t+1} = v) = \#^{t+1}_{\tilde{w} \to v} / (d(d-1)^t)$. ∎

Appendix A. Inverse of Restricted Laplacians and Hitting Times

In this appendix we establish a standalone general connection between the inverse of restricted Laplacian matrices—which are obtained by removing certain rows and columns from Laplacians matrices—and hitting times of random walks on graphs. This connection (Proposition 30 below) is used repeatedly in Section 5 to prove the error characterization of the min-sum algorithm.

Let $G = (V, E, W)$ be a simple (i.e., no self-loops, and no multiple edges), connected, undirected, weighted graph, where to each edge $\{v, w\} \in E$ is associated a positive weight $W_{vw} = W_{wv} > 0$, and $W_{vw} = 0$ if $\{v, w\} \notin E$. Let D be a diagonal matrix with entries $d_v = D_{vv} = \sum_{w \in V} W_{vw}$ for each $v \in V$. Let $L := D - W$ be the Laplacian matrix for G. Henceforth, for each $v \in V$, let $\mathbf{P}_v$ be the law of a time homogeneous Markov chain $X_0, X_1, X_2, \ldots$ on V with transition matrix $P = D^{-1}W$ and initial condition $X_0 = v$. Analogously, denote by $\mathbf{E}_v$ the expectation with respect to this law. The hitting time to a set $Z \subseteq V$ is defined as $T_Z := \inf\{k \geq 0 : X_k \in Z\}$. Let $Z \subseteq V$ be fixed, and define $\bar{W}$ and $\bar{D}$ as the matrix obtained by removing the rows and columns associated to Z from W and D, respectively. Let $\bar{V} := V \setminus Z$, $\bar{E} := E \setminus \{\{u, v\} \in E : u \in Z \text{ or } v \in Z\}$ and consider the graph $\bar{G} := (\bar{V}, \bar{E})$. The quantity $\bar{L} := \bar{D} - \bar{W}$ represents a restricted Laplacian—sometimes also called grounded Laplacian. Let $\bar{P} := \bar{D}^{-1}\bar{W}$ be the transition matrix of the transient part of the killed random walk that is obtained from X by adding cemeteries at the sites in Z. Creating cemeteries at the sites in Z means modifying the walk X so that each site in Z becomes a recurrent state, i.e., once the walk is in state $\bar{z} \in Z$ it will go back to $\bar{z}$ with probably 1. This is clearly done by replacing the $\bar{z}$-th row of P by a row with zeros everywhere but in the $\bar{z}$-th coordinate, where the entry is equal to 1.

The relation between the transition matrix $\bar{P}$ of the killed random walk and the law of the random walk X itself is made explicit in the next proposition.

Proposition 29 *For any $v, w \in \bar{V}$, $k \geq 0$, we have $\bar{P}^k_{vw} = \mathbf{P}_v(X_k = w, T_Z > k)$.*

Proof Proof is by induction. Clearly, for any $v, w \in \bar{V}$, we have $\mathbf{P}_v(X_0 = w, T_Z > 0) = \mathbf{P}_v(X_0 = w) = \mathbf{1}_{v=w} = \bar{P}^0_{vw}$, which proves the statement for $k = 0$ ($\mathbf{1}_S$ is the indicator function defined as $\mathbf{1}_S = 1$ if statement S is true, $\mathbf{1}_S = 0$ otherwise). Assume that the statement holds for any time $i \geq 0$ up to $k > 0$. By the properties of conditional expectation, as $\{T_Z > k+1\} = \{X_0 \notin Z, \ldots, X_{k+1} \notin Z\}$, we have $\mathbf{P}_v(X_{k+1} = w, T_Z > k+1) = \mathbf{E}_v[\mathbf{P}_v(X_{k+1} = w, T_Z > k+1 | X_0, \ldots, X_k)] = \mathbf{E}_v[\mathbf{1}_{\{X_0 \notin Z, \ldots, X_k \notin Z\}} \mathbf{P}_v(X_{k+1} = w, X_{k+1} \notin Z | X_0, \ldots, X_k)]$ for any $v, w \in \bar{V}$. By the Markov property, on the event $\{X_k \notin Z\}$, we have $\mathbf{P}_v(X_{k+1} = w, X_{k+1} \notin Z | X_0, \ldots, X_k) = \mathbf{P}_{X_k}(X_1 = w, X_1 \notin Z) = \bar{P}_{X_k w}$, so that by the induction hypothesis we have $\mathbf{P}_v(X_{k+1} = w, T_Z > k+1) = \mathbf{E}_v[\mathbf{1}_{\{T_Z > k\}} \bar{P}_{X_k w}] = \sum_{u \in V \setminus Z} \mathbf{P}_v(X_k = u, T_Z > k) \bar{P}_{uw} = \bar{P}^{k+1}_{vw}$, which proves the statement for $k+1$. ∎

We can now relate the inverse of the reduced Laplacian $\bar{L}$ with the hitting times of the original random walk X. The following result represents the main computational tool used in Section 5 to establish decay of correlation in the computation tree that supports the operations of the min-sum algorithm over time.

Proposition 30 *For $v, w \in \bar{V}$, $\bar{L}^{-1}_{vw} = \bar{L}^{-1}_{ww} \mathbf{P}_v(T_w < T_Z)$, and $\bar{L}^{-1}_{ww} = \frac{1}{d_w} \mathbf{E}_w \left[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k = w} \right]$.*

Proof Let us first assume that $\bar{G}$ is connected. The matrix $\bar{P}$ is clearly sub-stochastic. Then $\bar{P}$ is irreducible (in the sense of Markov chains, i.e., for each $v, w \in \bar{V}$ there exists t to that $\bar{P}^k_{vw} \neq 0$) and the spectral radius of $\bar{P}$ is strictly less than 1 (see Corollary 6.2.28 in Horn and Johnson (1986), for instance), so that the Neumann series $\sum_{k=0}^{\infty} \bar{P}^k$ converges. The Neumann series expansion for $\bar{L}^{-1}$ yields $\bar{L}^{-1} = \sum_{k=0}^{\infty}(I - \bar{D}^{-1}\bar{L})^k\bar{D}^{-1} = \sum_{k=0}^{\infty} \bar{P}^k\bar{D}^{-1}$, or, $\bar{L}^{-1}_{vw} = \frac{1}{d_w}\sum_{k=0}^{\infty} \bar{P}^k_{vw}$. As $\bar{P}^k_{vw} = \mathbf{P}_v(X_k = w, T_Z > k)$ by Proposition 29, by the Monotone convergence theorem we can take the summation inside the expectation and get $\sum_{k=0}^{\infty} \bar{P}^k_{vw} = \sum_{k=0}^{\infty} \mathbf{E}_v[\mathbf{1}_{X_k=w}\mathbf{1}_{T_Z>k}] = \mathbf{E}_v[\sum_{k=0}^{T_Z-1} \mathbf{1}_{X_k=w}]$, which equals $\mathbf{E}_v[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}]$ as $X_{T_Z} \in Z$, and $w \notin Z$. Recall that if S is a stopping time for the Markov chain $X := X_0, X_1, X_2, \ldots$, then by the strong Markov property we know that, conditionally on $\{S < \infty\}$ and $\{X_S = w\}$, the chain $X_S, X_{S+1}, X_{S+2}, \ldots$ has the same law as the Markov chain $Y := Y_0, Y_1, Y_2, \ldots$ with transition matrix P and initial condition $Y_0 = w$, and Y is independent of $X_0, \ldots, X_S$. The hitting times T_w and T_Z are two stopping times for X, and so is their minimum $S := T_w \wedge T_Z$. As either $X_S = w$ or $X_S \in Z$, we have $\mathbf{E}_v[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}] = \mathbf{E}_v[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}|X_S = w]\mathbf{P}_v(X_S = w)$, where we used that, conditionally on $\{X_S \in Z\} = \{T_w > k_Z\}$, clearly $\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w} = 0$. Conditionally on $\{X_S = w\} = \{T_w < T_Z\} = \{S = T_w\}$, we have $T_Z = S + \inf\{k \geq 0 : X_{S+k} \in Z\}$, and the strong Markov property yields (note that the event $\{S < \infty\}$ has probability one from any starting point, as the graph G is connected by assumption so that the Markov chain will almost surely eventually hit either w or a site in Z) $\mathbf{E}_v[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}|X_S = w] = \mathbf{E}_v[\sum_{k=0}^{\inf\{k\geq 0:X_{S+k}\in Z\}} \mathbf{1}_{X_{S+k}=w}|X_S = w] = \mathbf{E}_w[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}]$. Putting everything together we have $\bar{L}^{-1}_{vw} = \frac{1}{d_w}\mathbf{E}_w[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}]\mathbf{P}_v(T_w < T_Z)$. As $\mathbf{P}_w(T_w < T_Z) = 1$, clearly $\bar{L}^{-1}_{ww} = \frac{1}{d_w}\mathbf{E}_w[\sum_{k=0}^{T_Z} \mathbf{1}_{X_k=w}]$ so that $\bar{L}^{-1}_{vw} = \bar{L}^{-1}_{ww}\mathbf{P}_v(T_w < T_Z)$. The argument just presented extends easily to the case when $\bar{G}$ is not connected. In this case the matrix $\bar{P}$ has a block structure, where each block corresponds to a connected component and to a sub-stochastic submatrix, so the argument above can be applied to each block. ■

Appendix B. Technical Results

This appendix contains technical results that are used in the paper. The following result on quadratic optimization has been used repeatedly in the main text (see Section 2 and the proofs of Proposition 5 and Lemma 22).

Proposition 31 *Given $R \in \mathbb{R}^{m\times m}$ symmetric positive definite, $r \in \mathbb{R}^m$, $A \in \mathbb{R}^{n\times m}$, $b \in \mathbb{R}^n$ in the range of A, the unique solution of the optimization problem*

$$\begin{aligned} &\textit{minimize} && \frac{1}{2}x^T Rx + r^T x \\ &\textit{subject to} && Ax = b \end{aligned}$$

over $x \in \mathbb{R}^m$ reads $x^\star = R^{-1}A^T L^+ b + (R^{-1}A^T L^+ A - I)R^{-1}r$ with $L := AR^{-1}A^T$.

Proof The KKT optimality equations for this problem read

$$\begin{pmatrix} R & -A^T \\ A & 0 \end{pmatrix}\begin{pmatrix} x \\ \nu \end{pmatrix} = \begin{pmatrix} -r \\ b \end{pmatrix}.$$

Solving the first equation for x we have $x = R^{-1}(A^T\nu - r)$, which, upon substitution into the second equation $Ax = b$ yields a solution $\nu = L^+(AR^{-1}r + b)$, and the proof follows. ■

We now present the proof of Proposition 8 in Section 4.

Proof [Proof of Proposition 8] Fix $d \geq 3$, $t \geq 3$. As $s \to h_s$ monotonically converges to 0 exponentially fast, we expect that the function $s \to \delta_s$, hence the values of both $b_{d,t}$ and $c_{d,t}$, can be controlled by the system that is obtained by replacing h_s with 0 for any $s \geq 0$. Thus, we define $\hat{\delta}_0 := \delta_0$, $\hat{\delta}_1 := \delta_1$, and $\hat{\delta}_s := \frac{1}{d-1}(2 + \frac{(d-2)^2}{d-1})\hat{\delta}_{s-1} - \frac{1}{(d-1)^2}\hat{\delta}_{s-2}, s \geq 2$. The characteristic equation of the dynamical system $\hat{\delta}_s$, $s \geq 0$, reads $(d-1)^2\lambda^2 - (d^2-2d+2)\lambda + 1 = 0$. This equation has two distinct real solutions: $\lambda_+ = 1$ and $\lambda_- = 1/(d-1)^2 < 1$. Imposing the initial conditions for $\hat{\delta}_0$ and $\hat{\delta}_1$, we find $\hat{\delta}_s = c_+ + c_-\lambda_-^s \geq 0$ with $c_+ = \frac{d(d-1)((d-1)^2+1)-1}{d((d-1)^2-1)} > 0$ and $c_- = 1/d - c_+ < 0$.

We begin by analyzing $c_{d,t}$. To this end, define $\hat{c}_{d,t} := \frac{1}{d-1}(1 + \frac{1}{(d-2)(1+h_t)})\hat{\delta}_{t-2} - \frac{1}{(d-1)^2}\hat{\delta}_{t-3}$. First, we prove that $c_{d,t} \geq 1$. By induction it is easy to show that $(d-1)(\delta_s - \hat{\delta}_s) \geq \delta_{s-1} - \hat{\delta}_{s-1} \geq 0$ for any $s \geq 1$, so we have $c_{d,t} \geq \hat{c}_{d,t}$. As $\hat{\delta}_s \geq c_+ + c_-\lambda_-$ for any $s \geq 1$ and $\hat{\delta}_s \leq c_+$ for any $s \geq 0$, we get $\hat{c}_{d,t} \geq \frac{1}{d-1}(1 + \frac{1}{(d-2)(1+h_1)})(c_+ + c_-\lambda_-) - \frac{1}{(d-1)^2}c_+ \geq 1$. Second, we prove that $c_{d,t} \leq 1 + \varepsilon_d$. Given $\alpha := 1 + \frac{1}{(d-1)^2}$, we first show that $(d-1)(\alpha\hat{\delta}_s - \delta_s) \geq \alpha\hat{\delta}_{s-1} - \delta_{s-1} \geq 0$ for any $s \geq 1$, so that $c_{d,t} \leq \alpha\hat{c}_{d,t}$. Define $\xi_s := \alpha\hat{\delta}_s - \delta_s$. We proceed by induction. Note that $(d-1)\xi_1 \geq \xi_0 \geq 0$. For a given $s \geq 3$, assume that $(d-1)\xi_r \geq \xi_{r-1}$ for all $r \leq s-1$. We will prove that $(d-1)\xi_s \geq \xi_{s-1}$. We have $(d-1)\xi_s - \xi_{s-1} = \frac{(d-1)\xi_{s-1} - \xi_{s-2}}{d-1} + \frac{(d-2)^2}{d-1}((1+h_{s+2})\xi_{s-1} - \alpha h_{s+2}\hat{\delta}_{s-1})$. As $\hat{\delta}_{s-1} \leq c_+$ and $(d-1)^{s-1}h_{s+2} \leq h_3$, with $c_+h_3 < 1$, by the induction hypothesis we have $\xi_{s-1} \geq \frac{\xi_1}{(d-1)^{s-2}} = \frac{(\alpha-1)\delta_1}{(d-1)^{s-2}}$ and $(d-1)\xi_s - \xi_{s-1} \geq \frac{(d-2)^2}{(d-1)^s}((d-1)(\alpha-1)\delta_1 - \alpha) = 0$, which proves the induction step. As $\frac{1}{d} = c_+ + c_- \leq \hat{\delta}_s \leq c_+$, we get $c_{d,t} \leq \alpha\hat{c}_{d,t} \leq \bar{\alpha} := \alpha(\frac{c_+}{d-1}(1 + \frac{1}{d-2}) - \frac{1}{d(d-1)^2}))$. The function $d \geq 3 \to \varepsilon_d := \bar{\alpha} - 1$ is decreasing, with $\varepsilon_d \to 0$ as $d \to \infty$, and $\varepsilon_3 < 3$.

By induction it is immediate to show that $(d-1)\delta_s \geq \delta_{s-1} \geq 0$ for any $s \geq 1$, so that a direct comparison yields $b_{d,t} \leq c_{d,t}$. Finally, we prove that $b_{d,t} \geq \frac{d-2}{d-1}$. Define $\hat{b}_{d,t} := \frac{1}{(d-1)^2}(1+(d-2)(1+h_{t+1}))\hat{\delta}_{t-2} - \frac{(d-2)(1+h_{t+1})}{(d-1)^3}\hat{\delta}_{t-3}$. As $(d-1)(\delta_s - \hat{\delta}_s) \geq \delta_{s-1} - \hat{\delta}_{s-1} \geq 0$ for $s \geq 1$, we have $b_{d,t} \geq \hat{b}_{d,t}$. As $\hat{\delta}_s \geq \hat{\delta}_3 = c_+ + c_-\lambda_-^3$ for $s \geq 3$ and $\hat{\delta}_s \leq c_+$ for $s \geq 0$, by the monotonicity of h_s we get $\hat{b}_{d,t} \geq \frac{1}{(d-1)^2}(1+(d-2))(c_+ + c_-\lambda_-^3) - \frac{(d-2)(1+h_1)}{(d-1)^3}c_+ \geq \frac{d-2}{d-1}$. ■

The next proposition yields a recursive formula to compute, in the case of d-regular graphs, the probability distributions $P_v^{(t)}$ and $P_v^{(t,w)}$ (interpreted as row vectors) given by the v-th row of the matrices $P^{(t)}$ and $P^{(t,w)}$ defined in (8), respectively. For any $v \in V$, let $\mathbf{1}_v \in \mathbb{R}^V$ be defined as $(\mathbf{1}_v)_z := 1$ if $v = z$, $(\mathbf{1}_v)_z := 0$ otherwise.

Proposition 32 *Let (V, E) be a connected d-regular graph with $d \geq 2$, and let $B \in \mathbb{R}^{V\times V}$ be its adjacency matrix, that is, the symmetric matrix defined by $B_{vw} := 1$ if $\{v, w\} \in E$,*

$B_{vw} := 0$ *otherwise. For any* $v \in V$ *we have*

$$P_v^{(1)} = \frac{\mathbf{1}_v^T B}{d}, \quad P_v^{(2)} = \frac{P_v^{(1)} B - \mathbf{1}_v^T}{d-1}, \quad P_v^{(t)} = \frac{P_v^{(t-1)} B - P_v^{(t-2)}}{d-1} \; t \geq 3,$$

Given $w \in V$ *such that* $\{v, w\} \in E$*, we have that* $P_v^{(t,w)}$ *satisfies the same recursion as above with initial condition* $P_v^{(1,w)} = (\mathbf{1}_v^T B - \mathbf{1}_w^T)/(d-1)$.

Proof We first prove the recursion for $P_v^{(t,w)}$. Fix $\{v, w\} \in E$, and let $\widetilde{\#}_z^t$ be the number of non-backtracking paths that connect node v to node z in t steps, where the first step is different from w. By definition, B_{vz} equals the number of paths that connect node v to node z in a single step. Clearly, $\widetilde{\#}_z^1 = B_{vz} - (\mathbf{1}_w)_z$, i.e., in row-vector form, $\widetilde{\#}^1 = \mathbf{1}_v^T B - \mathbf{1}_w^T$. It is immediate to verify that $\widetilde{\#}^2 = \widetilde{\#}^1 B - (d-1)\mathbf{1}_v^T$, as there are $d-1$ paths that can backtrack to v at time $t = 2$. For $t \geq 3$ we have $\widetilde{\#}^t = \widetilde{\#}^{t-1} B - (d-1)\widetilde{\#}^{t-2}$. In fact, $(\widetilde{\#}^{t-1} B)_z$ equals the number of paths that go from v to z in t steps such that the first move is different from w and the first $t-1$ steps are non-backtracking. To count only the paths that are non-backtracking for all t steps, we need to subtract from $(\widetilde{\#}^{t-1} B)_z$ the number of paths that backtrack at the t-th step, which are the ones that are at z both at step $t-2$ ant t. There are $(d-1)\widetilde{\#}_z^{t-2}$ of these paths, as vertex z has d neighbors but only $d-1$ moves are allowed at the $(t-1)$-th step due to the non-backtracking nature of the paths up to step $t-1$. The proof follows noticing that the total number of non-backtracking after t steps is $d(d-1)^{t-1}$, so that $\vec{\mathbf{P}}_v(Y_1 \neq w, Y_t = z) = \widetilde{\#}_z^t/(d(d-1)^{t-1})$ and $P_{vz}^{(t,w)} = \vec{\mathbf{P}}_v(Y_t = z | Y_1 \neq w) = \vec{\mathbf{P}}_v(Y_1 \neq w, Y_t = z)/\vec{\mathbf{P}}_v(Y_1 \neq w) = \widetilde{\#}_z^t/(d-1)^t$, $\vec{\mathbf{P}}_v(Y_1 \neq w) = (d-1)/d$. The recursion for $P_v^{(t)}$ is proved analogously. Let $\#_z^t$ be the number of non-backtracking paths that connect node v to node z in t steps. Clearly, $\#^1 = \mathbf{1}_v^T B$, $\#^2 = \#^1 B - d\mathbf{1}_v^T$, and $\#^t = \#^{t-1} B - (d-1)\#^{t-2}$. The proof follows as $P_{vz}^{(t)} = \vec{\mathbf{P}}_v(Y_t = z) = \#_z^t/(d(d-1)^{t-1})$. ■

Abstract

We present a mathematical analysis of a non-convex energy landscape for robust subspace recovery. We prove that an underlying subspace is the only stationary point and local minimizer in a specified neighborhood under a deterministic condition on a dataset. If the deterministic condition is satisfied, we further show that a geodesic gradient descent method over the Grassmannian manifold can exactly recover the underlying subspace when the method is properly initialized. Proper initialization by principal component analysis is guaranteed with a simple deterministic condition. Under slightly stronger assumptions, the gradient descent method with a piecewise constant step-size scheme achieves linear convergence. The practicality of the deterministic condition is demonstrated on some statistical models of data, and the method achieves almost state-of-the-art recovery guarantees on the Haystack Model for different regimes of sample size and ambient dimension. In particular, when the ambient dimension is fixed and the sample size is large enough, we show that our gradient method can exactly recover the underlying subspace for any fixed fraction of outliers (less than 1).

Keywords: robust subspace recovery, non-convex optimization, dimension reduction, optimization on the Grassmannian

1. Introduction

Robust subspace recovery (RSR) involves estimating a low-dimensional linear subspace in a corrupted dataset. It assumes that a portion of the given dataset lies close to or on a subspace, which we will refer to as the "underlying subspace". The other portion of the dataset is assumed to be corrupted and may lie far from the underlying subspace. In this regime, noise and corruption are separate entities: corruption refers to large and potentially arbitrary changes to a data point, while noise is a small perturbation of a data point.

A basic method for modeling data by a low-dimensional subspace is Principal Component Analysis (PCA) (Jolliffe, 2002). PCA is popular for both reducing noise and capturing low-dimensional structure within data. However, PCA is notoriously sensitive to corrupted data and does not perform well in many regimes of the RSR problem.

Many strategies have been proposed for the RSR problem, which are reviewed in Lerman and Maunu (2018b). However, despite nice progress, many of the proposed methods have inherent issues. Perhaps the largest flaw in many existing methods is computational time: many methods require calculation of a full covariance matrix or matrix inversion. If we have a dataset of N points in $\mathbb{R}^D$, these calculations typically have complexity $O(ND^2)$ or $O(D^3)$. On the other hand, the PCA d-dimensional subspace can be calculated with complexity $O(NDd)$. Some recent proposals for RSR have complexity that scales like $O(NDd)$, but they either do not have satisfying theoretical guarantees or have extra user specified parameters. Ideally, we would like algorithms that run in $O(NDd)$ because the set of d-dimensional subspaces has dimension $O(Dd)$.

The key point of our work is the development of a computationally efficient and provably accurate method for RSR. We desire a method that has complexity $O(NDd)$ and that does not sacrifice theoretical guarantees. The method we propose involves minimization of the robust least absolute deviations energy function. Minimizing this function involves solving a non-convex optimization problem that is NP-hard.

Even though the problem is NP-hard in general, we derive conditions that ensure the energy landscape is well-behaved in a substantial neighborhood of an underlying subspace. These conditions also ensure that a geodesic gradient descent method can locally recover an underlying subspace, and the convergence of this method is linear under some slightly stronger assumptions. This linear convergence implies that this $O(NDd)$ algorithm is very efficient. Furthermore, we give the most complete discussion of recovery under various regimes of corruption and relatively broad statistical models. In particular, we show that our method is robust to very high percentages of corruption under special generative models. To our knowledge, we give the strongest guarantees on a non-convex method for RSR to date and even obtain stronger results than some convex methods.

In the rest of this section, we give some necessary background for our method and an overview of this work. First, in Section 1.1, we give some essential background to understand our approach to RSR. Then, Section 1.2 outlines the main contributions of our work. Finally, Section 1.3 summarizes the structure of the paper, and Section 1.4 discusses necessary notation.

1.1. Essential Background

Here, we briefly summarize the necessary background to understand the primary contribution of this work. First, for the rest of this paper, we assume a linear subspace setting, which means that we only consider underlying subspaces that are linear. We leave the case of affine subspaces to future work. For simplicity of discussion, we advocate centering by the geometric median for real data when the center is not known.

The essential problem of RSR is an optimization problem over the Grassmannian, which is the set of linear subspaces of a fixed dimension. The Grassmannian is a non-convex set, which makes optimization over it hard. Frequently, this leads to NP-hard or SSE-hard

formulations (Hardt and Moitra, 2013; Clarkson and Woodruff, 2015). In this paper, we denote by $G(D,d)$ the Grassmannian of linear d-dimensional subspaces in $\mathbb{R}^D$ and refer to such subspaces as d-subspaces.

It is illuminating to first outline the PCA subspace problem, since it has a similar form to our methodology. The basic formulation for the PCA subspace problem can be cast as an optimization over $G(D,d)$. For a dataset $\mathcal{X} = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N\} \subset \mathbb{R}^D$ centered at the origin, the PCA d-subspace is the solution of the least squares problem

$$\min_{L \in G(D,d)} \sum_{i=1}^{N} \|\boldsymbol{x}_i - \boldsymbol{P}_L \boldsymbol{x}_i\|_2^2, \tag{1}$$

where $\boldsymbol{P}_L$ denotes the orthogonal projection matrix onto the subspace L. As has been noted in many past works, the least squares formulation is sensitive to corrupted data.

Some have attempted to make the PCA formulation robust by considering least absolute deviations:

$$\min_{L \in G(D,d)} \sum_{i=1}^{N} \|\boldsymbol{x}_i - \boldsymbol{P}_L \boldsymbol{x}_i\|_2. \tag{2}$$

This optimization can be thought of as estimating a geometric median subspace. Some have tried to directly optimize this problem (Ding et al., 2006; Lerman and Maunu, 2018a), while others have tried to solve convex relaxations of it (McCoy and Tropp, 2011; Xu et al., 2012; Zhang and Lerman, 2014; Lerman et al., 2015).

The goal of this work is to directly analyze the energy landscape of (2) and guarantee that a non-convex gradient descent method for this energy minimization can recover an underlying subspace. This gradient descent method leads to huge gains in speed over previous convex methods but does not sacrifice accuracy in subspace recovery.

In the RSR problem setup, it is common to refer to the uncorrupted portion of the dataset as inliers, which lie on or near the underlying subspace. The case where the inliers lie on the underlying subspace is referred to as the noiseless RSR setting, while the case where the inliers lie near the underlying subspace is referred to as the noisy RSR setting. The corrupted points in the dataset are referred to as outliers, which are assumed to lie somewhere in the ambient space. Exact recovery in the noiseless setting refers to when a method outputs the underlying subspace exactly. Near recovery in the noisy setting refers to when a method outputs a good approximation of the underlying subspace, where the goodness of approximation depends on the noise level.

1.2. Contribution of This Work

As mentioned, the goal of this work is to recover an underlying subspace by directly optimizing the non-convex function in (2). To motivate why such a procedure might work, Figure 1 demonstrates the landscape of the energy function in (2) for two simulated datasets. The novelty of this paper consists of the following observation in these and certain other datasets: despite non-convexity, the energy landscape appears to exhibit basins of attraction around the underlying subspaces. In other words, the energy function decreases over $G(D,d)$ in the direction of L_* within some neighborhood. Indeed, it appears that direct minimization of the energy in a local neighborhood would yield exact recovery of the underlying subspace.

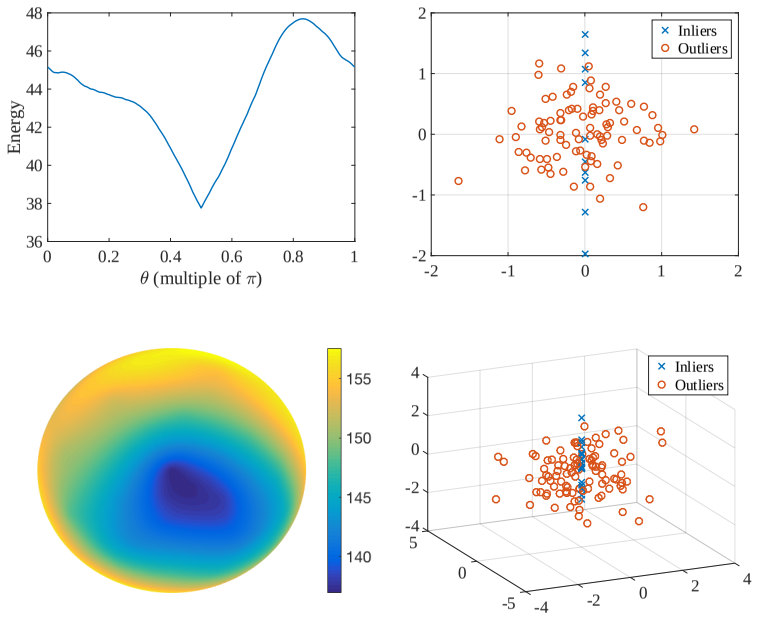

Figure 1: Demonstration of the energy landscape of (2) over $G(2,1)$ and $G(3,1)$ with simulated Gaussian data. The simulated datasets are demonstrated on the right and the corresponding energy landscape is depicted on the left. Top: In $\mathbb{R}^2$, 90 outliers are i.i.d. $\mathcal{N}(\boldsymbol{0}, \boldsymbol{I}/2)$ and 10 inliers are i.i.d. $\mathcal{N}(0,1)$ along the y-axis. $G(2,1)$ is identified with a semicircle and parameterized by angle. The energy is depicted as a function of the parametrizing angle. Its global minimum is at $\pi/2$, which corresponds to the underlying line at the y-axis of $\mathbb{R}^2$. Bottom: In $\mathbb{R}^3$, 100 outliers are i.i.d. $\mathcal{N}(\boldsymbol{0}, 4\boldsymbol{I}_3/3)$ and 20 inliers are i.i.d. $\mathcal{N}(0,1)$ along the z-axis. $G(3,1)$ is identified with the top hemisphere which is flattened to a circle. The energy function is depicted by a heat map on that circle. The global minimum is at the center of the circle, which corresponds to the underlying line at the z-axis of $\mathbb{R}^3$.

It is important to emphasize that this phenomenon is inherently local. Looking at the energy plots in Figure 1, it appears that there may be other local minimizers far from the underlying subspace, and so proper initialization is quite important.

Our key contributions follow:

- We show that, under deterministic conditions, the robust energy landscape of (2) exhibits basins of attraction around an underlying subspace as seen in Figure 1. Theorems 1 and 2 formulate this result for the energy landscape of the noiseless and noisy RSR settings respectively.

- We propose a geodesic gradient descent algorithm in Section 4. Theorems 3 and 4 show that this algorithm exactly recovers the underlying subspace under the conditions of Theorem 1 with proper initialization. Theorem 3 guarantees sublinear convergence of this algorithm to the underlying subspace. With some additional, slightly stronger assumptions, Theorem 4 guarantees linear convergence to the underlying subspace using a piecewise constant step-size scheme. These results can be generalized to near recovery in the noisy RSR setting as well (see Remark 5).

- Lemma 9 guarantees that we can initialize in the correct local neighborhood using PCA under a similar deterministic condition. This yields a complete guarantee for geodesic gradient descent with PCA initialization.

- The deterministic guarantees are shown to hold for a variety of statistical models of data. In particular, we achieve competitive guarantees for recovery under the special Haystack Model. More specifically, we consider three different regimes of sample size. The first regime, $N = O(D)$, describes the scenario of a relatively small sample. The smallest ratio of inliers to outliers where exact recovery is still possible for this model among all algorithms is $d/(D-d)$, although this has only been established for algorithms of complexity $O(ND^2)$ at best (Hardt and Moitra, 2013; Zhang, 2016). We guarantee instead exact recovery for our $O(NDd)$ algorithm in this regime under a larger ratio of inliers to outliers, namely of order $O(d/\sqrt{D})$ (see Corollary 16). In the regime of larger samples, when $N = O(D^2)$, exact recovery with the even smaller ratio $O(d/\sqrt{D(D-d)})$ was previously obtained for a convex algorithm (Zhang and Lerman, 2014). Theorem 17 implies recovery with this same small fraction but in the regime $N = O(d(D-d)^2 \log(D))$. Except for this convex algorithm and our proposed algorithm, we are unaware of any other method that is guaranteed to obtain exact recovery under such a small fraction in the regime $N = O(d(D-d)^2 \log(D))$. Beyond this, in the regime of very large samples, we show that our method can exactly recover an underlying subspace with any fixed fraction of outliers, where N is at least some polynomial order of D and also depends on the ratio of inliers to outliers. This is the only efficient RSR method with such a guarantee.

We will close this section by briefly commenting on how to read the theoretical results of this paper. The first three bullets constitute the primary theoretical interest of this work, since they guarantee the usefulness of our non-convex RSR method under some fairly general conditions. In particular, the stability statistic developed in Section 3.1.1 lies at the core of much of our analysis, and many of the more complicated results are extensions of this statistic's analysis in Theorem 1. The discussion of statistical models as outlined in the fourth bullet above is merely included for interpretability of the general conditions we offer. With such models, we develop a heuristic understanding of these conditions, and, in particular, we gain insight into trade-offs between inliers and outliers. These models also allow for easier comparison of the theoretical guarantees of all RSR methods.

1.3. Paper Organization

First, in Section 2, we review previous work on the RSR problem. In Section 3, we describe deterministic conditions that ensure that the energy landscape of (2) behaves nicely around an underlying subspace. Then, in Section 4, we outline a geodesic gradient descent method on the set of subspaces. We show that this method can locally recover an underlying subspace for datasets satisfying the deterministic conditions and that the convergence rate is linear under some slightly stronger assumptions. We obtain exact recovery in the noiseless RSR setting and near recovery in the noisy RSR setting. Then, Section 5 shows that the conditions hold for certain statistical models of data. In particular, we obtain almost state-of-the-art results on recovery under the Haystack Model and also consider a range of other models. Next, Section 6 gives simulations that agree with the theoretical results of this paper. Finally, Section 7 concludes this work and discusses possible future directions.

1.4. Notation

Before presenting the results of this paper, we explain our commonly used notation. The letter L is used to refer to d-subspaces. We use bold upper case letters for matrices and bold lower case letters for column vectors. For a matrix $\boldsymbol{A}$, $\mathrm{Sp}(\boldsymbol{A})$ is the subspace spanned by the columns of $\boldsymbol{A}$, $\sigma_j(\boldsymbol{A})$ denotes the jth singular value of $\boldsymbol{A}$, and, if $\boldsymbol{A}$ is square, then $\lambda_j(\boldsymbol{A})$ denotes its jth eigenvalue. The spectral norm of $\boldsymbol{A}$ is $\|\boldsymbol{A}\|_2$, and the Euclidean 2-norm for vectors is denoted by $\|\cdot\|$. The notation $\widetilde{\boldsymbol{A}}$ denotes projection of the columns of $\boldsymbol{A}$ to the unit sphere. For $d \leq D$, the set of semi-orthogonal $D \times d$ matrices is denoted by $O(D,d) = \{\boldsymbol{V} \in \mathbb{R}^{D\times d} : \boldsymbol{V}^T\boldsymbol{V} = \boldsymbol{I}_d\}$. For $\boldsymbol{V} \in O(D,d)$, we denote its columns by $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d$. We recall that $G(D,d)$ denotes the Grassmannian, that is, the set of d-dimensional linear subspaces of $\mathbb{R}^D$. The orthogonal projection matrix onto the subspace $L = \mathrm{Sp}(\boldsymbol{V})$ is denoted by $\boldsymbol{P}_L$, and we interchangeably use $\boldsymbol{P}_{\boldsymbol{V}} = \boldsymbol{P}_L$. The projection onto the orthogonal complement of L is $\boldsymbol{Q}_L = \boldsymbol{I} - \boldsymbol{P}_L$. We denote the largest principal angle between two subspaces L_1 and L_2 by $\theta_1(L_1, L_2)$, that is, $\theta_1(L_1, L_2) = \arccos(\sigma_d(\boldsymbol{P}_{L_1}\boldsymbol{P}_{L_2}))$. We say that an event occurs with high probability (w.h.p.) if the probability is bounded below by $1 - O(N^a)$, for some absolute constant $a > 0$. We say that an event occurs with overwhelming probability (w.o.p.) if the probability is bounded below by $1 - O(e^{-aN^b})$, for absolute constants $a, b > 0$. The notation $f(x) \lesssim g(x)$ is used to denote that $f(x) < Cg(x)$ for some absolute constant C (and the notation $\gtrsim$ is used in the same way).

2. Background and Review of Previous Work

In this section, we will review past work on the RSR problem and necessary background concepts for this work. First, Section 2.1 discusses past attempts to solve the RSR problem. Then, Section 2.2 gives the background concepts that are necessary to understand our later results.

2.1. Review of Previous Work

The most ubiquitous subspace modeling framework uses principal component analysis (Jolliffe, 2002). Its optimization problem, which is formulated in (1), is non-convex since $G(D,d)$

is non-convex. However, despite its non-convexity, this problem has a direct solution, which is calculated from the singular value decomposition of the data matrix $\boldsymbol{X} = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N]$. This problem also has a nice energy landscape. Indeed, if the dth singular value of $\boldsymbol{X}$ is larger than the $(d+1)$st singular value, then the global minimum is unique, and there are no other local minima; otherwise, if the dth singular value is equal to the $(d+1)$st, then all local minima are globally optimal. Saddle points are also guaranteed to be sufficiently far from the global minimum, and they have explicit expressions. We discuss the PCA energy landscape further in Appendix A. These nice properties of the PCA subspace optimization are not shared by the algorithms for RSR that we discuss next.

Examples of works on RSR include Maronna (2005); Maronna et al. (2006); Ding et al. (2006); Zhang et al. (2009); Lerman and Zhang (2011); McCoy and Tropp (2011); Xu et al. (2012); Coudron and Lerman (2012); Hardt and Moitra (2013); Zhang and Lerman (2014); Goes et al. (2014); Lerman and Zhang (2014); Lerman et al. (2015); Zhang (2016); Lerman and Maunu (2018a); Cherapanamjeri et al. (2017). A comprehensive overview of this topic is given in Lerman and Maunu (2018b).

We note that this problem is distinct from what is typically called robust PCA (RPCA) (Candès et al., 2011; Zhou et al., 2010), where the corruptions occur element-wise throughout the whole data matrix rather than some samples being wholly corrupted. Algorithms for RPCA typically do not perform well in the RSR setting, and algorithms for RSR do not perform well in the RPCA setting.

RSR is inherently non-convex due to the non-convexity of $G(D, d)$. Robust versions of the PCA energy may have more complicated landscapes in general. One way of making PCA robust is to simply project the data to the unit sphere, S^{D-1}, before running PCA (Locantore et al., 1999; Maronna, 2005; Maronna et al., 2006). This deals with PCA's sensitivity to the scaling of the data and makes it easier to find directions that robustly capture variance. However, it is still not able to deal with correlated outlier directions and does not have good asymptotic guarantees even for simple models (Lerman and Maunu, 2018a).

As mentioned, another way to make PCA robust is to consider least absolute deviations (Ding et al., 2006; McCoy and Tropp, 2011; Xu et al., 2012; Zhang and Lerman, 2014; Lerman and Zhang, 2014; Lerman et al., 2015; Lerman and Maunu, 2018a). The first use of least absolute deviations in subspace modeling was the work on orthogonal regression by Osborne and Watson (1985). This was not extended to general subspace modeling until much later (Watson, 2001; Ding et al., 2006). Previous works have considered convex relaxation of this energy (McCoy and Tropp, 2011; Xu et al., 2012; Zhang and Lerman, 2014; Lerman et al., 2015). However, such convex relaxations are generally slow and may not approximate the underlying problem well. Indeed, most either have complexity $O(ND^2)$ or $O(D^3)$.

The works of Lerman and Zhang (2011, 2014) established under a certain model that an underlying subspace is recoverable by the minimizer of (2). However, they did not provide a guaranteed algorithm for minimizing this energy. The estimates of these works do not hold for small sample sizes: they only hold for large N. Lerman and Maunu (2018a) developed the FMS algorithm, which employs iteratively reweighted least squares to optimize (2). However, the FMS algorithm does not have deterministic guarantees of fast convergence or deterministic results on recovery of the underlying subspace. The FMS algorithm does

have theoretical guarantees of approximate recovery for a very special model of data, with relatively large samples. In contrast, we directly minimize (2) by gradient descent, and we provide deterministic guarantees of fast convergence and subspace recovery.

Another recent work on RSR was given by Cherapanamjeri et al. (2017), where they propose Thresholding based Outlier Robust PCA (TORP). TORP has analysis for arbitrary outliers and noise, as long as the percentage of outliers is known in advance. While the tolerance to very low percentages of arbitrary outliers is not that impressive, the noise analysis is somewhat novel. Under Gaussian noise, the authors are able to show similar sample complexity as that of PCA. One downside of this algorithm is that one must know the percentage of outliers as an input. Further, since the guarantees are only for adversarial models of outliers, there is no discussion of improved estimates when the outliers are not adversarial but instead obey a specific statistical model.

In the existing literature, only a few methods achieve the complexity bound of $O(TNDd)$, where T is iteration count. These include SPCA (Maronna, 2005), RANSAC and RandomizedFind (Hardt and Moitra, 2013; Arias-Castro and Wang, 2017), FMS (Lerman and Maunu, 2018a), and TORP (Cherapanamjeri et al., 2017). Among these, the algorithms either do not have sufficiently satisfying guarantees for recovery, or they do not have a good bound on T, or they require additional parameters. SPCA is the fastest out of these algorithms since it has $T = 1$. Here, we are slightly abusing the complexities and assuming the cost of running PCA is $O(NDd)$, despite the fact that PCA is also an iterative algorithm. We choose this convention due to the fact that many methods use PCA as a sub-routine. While SPCA is somewhat robust to arbitrary outliers, it cannot exactly recover subspaces in the presence of outliers. However, SPCA is nice since it is quite general and lacks the specialized assumptions of many methods. RANSAC requires a user to input specialized parameters, such as the consensus number and a consensus threshold. RANSAC can also only bound T in probability under certain conditions. This also goes for the analysis of RandomizedFind given by Arias-Castro and Wang (2017), along with their updated algorithm that has complexity $O(TDd)$. In many cases, though, this T can be very large. For both the RANSAC and RandomizedFind methods, recovery guarantees exist in the noiseless RSR setting under specialized assumptions, but there are no satisfying extensions of either method to noise. On the other hand, TORP (Cherapanamjeri et al., 2017) requires a user to input the percentage of outliers that is not known in general. TORP has a guarantee of linear convergence under certain conditions, but, as we mentioned earlier, it does not have satisfying guarantees for subspace recovery. FMS (Lerman and Maunu, 2018a) only has guarantees for rate of convergence and recovery for very special models of data.

One way to compare the theoretical guarantees of various methods is to assume a statistical model of data and then determine which algorithm performs best in this model. For example, one common choice of model in past works was the Haystack Model, which can be seen in Lerman et al. (2015). Another model was to assume spherically symmetric outliers, and inliers spherically symmetric on an underlying subspace (Lerman and Zhang, 2014; Lerman and Maunu, 2018a). Others have examined models with arbitrary outliers (Xu et al., 2012; Cherapanamjeri et al., 2017). In this work, after giving our general theoretical guarantees, we will show how they can be applied to a variety of statistical models of data.

This paper also fits in to the surge of recent work that has focused on non-convex optimization for many structured data problems (Dauphin et al., 2014; Hardt, 2014; Jain

et al., 2014; Ge et al., 2015; Lee et al., 2016; Arora et al., 2015; Mei et al., 2018; Ge et al., 2016; Boumal, 2016; Sun et al., 2015b,a; Ma et al., 2018). Some work has focused on non-convex optimization for robust PCA (Netrapalli et al., 2014; Yi et al., 2016; Zhang and Yang, 2017), which is a related but different problem than RSR. Others have attempted to solve non-convex versions of the RSR problem (Lerman and Maunu, 2018a; Cherapanamjeri et al., 2017), but, as we have discussed, these methods each have their own shortcomings.

This work is partially built on optimization on manifolds, and in particular there are important results on optimization over the Grassmannian manifold (Edelman et al., 1999; Absil et al., 2004). Edelman et al. (1999) develop gradient descent on the Grassmannian and give formulations for Newton's method and conjugate gradient for the Grassmannian. We discuss optimization on the Grassmannian in more detail in the next section.

Many other recent works have also focused on using optimization on the Grassmannian to solve various problems (Zhang et al., 2009; Goes et al., 2014; St. Thomas et al., 2014; Zhang and Balzano, 2016; Ye and Lim, 2016; Lim et al., 2016). The work of Zhang and Balzano (2016) examines a rank one geodesic gradient scheme for solving online PCA. Their setting is distinctly different from ours since they attempt to solve the PCA problem rather than RSR. They also only prove recovery of the PCA solution for a specific model of Gaussian noise, and no deterministic condition for global recovery is given. Further, while we assume centered data in this paper, St. Thomas et al. (2014) and Lim et al. (2016) consider estimation on the affine Grassmannian.

2.2. Review of Optimization over $G(D,d)$

The minimization in (2) involves optimization over the Grassmannian manifold. To understand the energy landscape, one must have a basic understanding of the geometry of $G(D,d)$ and how to calculate derivatives over it.

We can write the energy function in (2) in two equivalent ways. First, as a function over $G(D,d)$, we write

$$F(L;\mathcal{X}) = \sum_{\mathcal{X}} \|\boldsymbol{Q}_L \boldsymbol{x}_i\|. \tag{3}$$

On the other hand, we can represent points in $G(D,d)$ by equivalence classes of points in $O(D,d)$. For any $\boldsymbol{V} \in O(D,d)$, the subspace $\mathrm{Sp}(\boldsymbol{V})$ can be represented by the equivalence class $[\boldsymbol{V}] = \{\boldsymbol{V}\boldsymbol{R} : \boldsymbol{R} \in O(d,d)\}$. For $\boldsymbol{V} \in O(D,d)$, the energy (3) is equivalent to

$$F(\boldsymbol{V};\mathcal{X}) = \sum_{i=1}^{N} \|(\boldsymbol{I} - \boldsymbol{V}\boldsymbol{V}^T)\boldsymbol{x}_i\|. \tag{4}$$

While both formulations are equivalent, we use (3) to formulate geodesic derivatives over $G(D,d)$ and the coordinate representation in (4) to calculate gradients. In the following, the geodesic derivative of (3) will be used to characterize the local landscape, and the gradient of (4) will be used to analyze the performance of the gradient descent algorithm we discuss later in Section 4.

One can measure the distance between subspaces in $G(D,d)$ using the principal angles. For a discussion of principal angles between subspaces, see Appendix B. Denoting the largest principal angle between L_0 and L_1 by $\theta_1(L_0,L_1)$, we can define a metric on $G(D,d)$

by $\mathrm{dist}(L_0,L_1) = \theta_1(L_0,L_1)$. We then define a ball on the metric space $G(D,d)$ by

$$B(L,\gamma) = \{L' \in G(D,d) : \ \theta_1(L',L) < \gamma\}.$$

We say that an element of $O(D,d)$ lies in the ball $B(L,\gamma)$ if the subspace spanned by its columns lies in $B(L,\gamma)$.

In the following, we frequently use a construction for geodesics on the Grassmannian. For a review of this construction and necessary terminology, see Appendix B or §3.2.1 of Lerman and Zhang (2014). Suppose that the interaction dimension between L_1 and L_2 is k, that is, $k = d - \dim(L_0 \cap L_1)$. Let $\theta_1,\dots,\theta_k$ be the nonzero principal angles for L_0 and L_1 (in decreasing order), and let the respective principal vectors for L_0 and L_1 be $\boldsymbol{v}_1,\dots,\boldsymbol{v}_k$ and $\boldsymbol{y}_1,\dots,\boldsymbol{y}_k$. Finally, let $\boldsymbol{u}_1,\dots,\boldsymbol{u}_k$ be a complementary orthogonal basis for L_1 with respect to L_0. We can use these to parameterize a geodesic $L(t)$ with $L(0) = L_0$ and $L(1) = L_1$, where the formula is given in (62) of Appendix B. Then, following Lerman and Zhang (2014) and Lerman and Maunu (2018a), we can calculate the directional geodesic subderivative of (3) at L_0 in the direction of L_1:

$$\frac{\mathrm{d}}{\mathrm{d}t} F(L(t);\mathcal{X})\Big|_{t=0} = -\sum_{\|\boldsymbol{Q}_0\boldsymbol{x}_i\|>0} \frac{\sum_{j=1}^{k} \theta_j (\boldsymbol{v}_j^T \boldsymbol{x}_i)(\boldsymbol{u}_j^T \boldsymbol{x}_i)}{\|\boldsymbol{Q}_{L_0}\boldsymbol{x}_i\|}. \tag{5}$$

A subderivative of (4) with respect to $\boldsymbol{V}$ is

$$\frac{\partial}{\partial \boldsymbol{V}} F(\boldsymbol{V};\mathcal{X}) = -\sum_{\|\boldsymbol{Q}_{\boldsymbol{V}}\boldsymbol{x}_i\|>0} \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T \boldsymbol{V}}{\|\boldsymbol{Q}_{\boldsymbol{V}}\boldsymbol{x}_i\|}. \tag{6}$$

The definition of subderivative and subdifferential as we use them are given next. For a more in depth discussion of these concepts, see, for example, Clarke (1990) and Ledyaev and Zhu (2007). In both of the derivatives (5) and (6), the sum is taken over all points that do not lie in $\mathrm{Sp}(\boldsymbol{V})$. This restriction is what makes them both subderivatives. For any general function $f(x)$, a subderivative of f at x_0 is any number in the subdifferential $\partial f(x_0)$. In turn, the subdifferential of f at x_0 is the set of all numbers between the one-sided derivatives of f at x_0. For (5), the subdifferential is defined to be the set of all numbers between

$$a = \lim_{t\to 0^-} \frac{F(L(t);\mathcal{X}) - F(L(0);\mathcal{X})}{t} \text{ and } b = \lim_{t\to 0^+} \frac{F(L(t);\mathcal{X}) - F(L(0);\mathcal{X})}{t}.$$

In other words, the subdifferential is $[\min(a,b), \max(a,b)]$, which is the set of all instantaneous tangent slopes at $L(0)$. For the other case of (6), for any entry of $\boldsymbol{V}$, $\boldsymbol{V}_{ij}$, let $\boldsymbol{\Delta}$ be the matrix of all zeros except $\boldsymbol{\Delta}_{ij} = 1$. Then, the subdifferential of $F(\boldsymbol{V};\mathcal{X})$ for $\boldsymbol{V}_{ij}$ is all numbers between

$$a_{ij} = \lim_{t\to 0^-} \frac{F(\boldsymbol{V}+t\boldsymbol{\Delta};\mathcal{X}) - F(\boldsymbol{V};\mathcal{X})}{t} \text{ and } b_{ij} = \lim_{t\to 0^+} \frac{F(\boldsymbol{V}+t\boldsymbol{\Delta};\mathcal{X}) - F(\boldsymbol{V};\mathcal{X})}{t}.$$

This can be generalized to any direction $\boldsymbol{\Delta}$ with $\|\boldsymbol{\Delta}\|_F = 1$, where the subdifferential is the convex hull of the one sided derivatives. We say that the subdifferential is less than a number if all of its elements are bounded above by that number, that is,

$$\partial F(L(t);\mathcal{X})|_{t=0} < M \iff a < M \ \forall\ a \in \partial F(L(t);\mathcal{X})|_{t=0}. \tag{7}$$

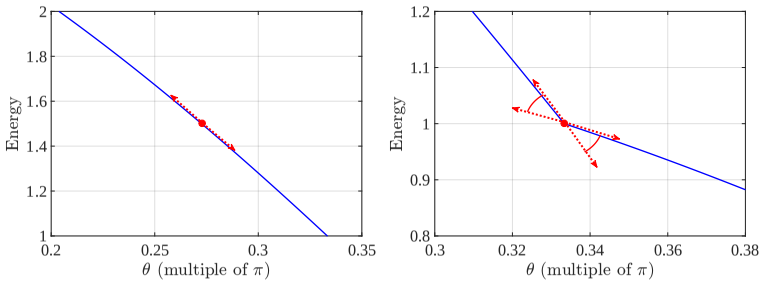

Figure 2: Demonstration of the derivative and subdifferential of the energy in (2). We assume that $d = 1$, $D = 2$ and identify $G(2,1)$ with the unit circle. The energy function in (2) is thus parameterized by angle and its graph is similar to the one in the top left sub-figure of Figure 1. In both images, the slope of the red two-sided arrow represents the magnitude of the directional geodesic derivative or subderivative over $G(2,1)$, which is the same as derivative or subderivative with respect to the representing angle. The first image shows a differentiable energy function on the given domain. In the second image, there is a value where the energy function is not differentiable. In this case, we use the subdifferential, which is the set of slopes of all lines between the acute angles formed by the two red two-sided arrows. Note that this subdifferential is bounded above by a negative number. We later prove that this property generally holds for the energy function of (2) under certain conditions.

To gain an intuition for these concepts, we display a visualization of the derivative and subdifferential for a simulated energy landscape in Figure 2. The derivative follows the standard definition from calculus on manifolds and is just the slope of the tangent line displayed on the left in Figure 2. On the other hand, at points where the function $F(L(t);\mathcal{X})$ is non-smooth at $t = 0$, we use the subdifferential instead. The extreme slopes for the subdifferential are displayed on the right in Figure 2.

In future sections, to save space, we will write the sums in (5) and (6) as $\sum_{\mathcal{X}}$ and leave the condition $\|\boldsymbol{Q}_{\boldsymbol{V}}\boldsymbol{x}_i\| > 0$ as implied. Following Section 2.5.3 of Edelman et al. (1999), to respect the geometry of the Grassmannian, the (sub)gradient of (4) is defined as

$$\nabla F(\boldsymbol{V};\mathcal{X}) = \boldsymbol{Q}_{\boldsymbol{V}}\frac{\partial}{\partial \boldsymbol{V}}F(\boldsymbol{V};\mathcal{X}). \tag{8}$$

3. A Well-Tempered Landscape for Least Absolute Deviations

We assume a dataset $\mathcal{X} = \{\boldsymbol{x}_1,\dots,\boldsymbol{x}_N\} \subset \mathbb{R}^D$ that can be partitioned into corrupted (outlier) and uncorrupted (inlier) parts. We refer to $\mathcal{X}$ as an inlier-outlier dataset, where in the coming sections, we will more rigorously define this notion in the noiseless and noisy RSR settings. We denote the subsets of inliers and outliers in $\mathcal{X}$ as $\mathcal{X}_{\text{in}}$ and $\mathcal{X}_{\text{out}}$,

respectively. The corresponding data matrices for $\mathcal{X}_{\text{in}}$ and $\mathcal{X}_{\text{out}}$ are $\boldsymbol{X}_{\text{in}}$ and $\boldsymbol{X}_{\text{out}}$, where columns represent data points.

As stated previously, the basic problem of RSR is to recover the subspace L_* from an inlier-outlier dataset. In the noiseless setting one can try to exactly recover this subspace, and in the noisy setting one may try to approximately recover it. In the latter case, this means that we wish to estimate it up to a specified approximation error, which may depend on the level of noise in the inliers. In order for this problem to be well-defined, basic assumptions must be made. Indeed, if all inliers lie at the origin, then any subspace would be a solution to the RSR problem. This issue, among others, was extensively discussed in §III-A of Lerman and Maunu (2018b). Our theoretical results for recovery will depend on a condition formulated later in this section that ensures the problem is well-defined.

First, Section 3.1 discusses some statistics that play a fundamental role in our analysis. Next, Section 3.2 uses these statistics to develop the deterministic conditions that ensure the energy landscape of (2) behaves nicely around an underlying subspace in both the noiseless and noisy RSR settings.

3.1. Landscape Statistics

Equipped with the notions laid out in Section 2.2, we are ready to define some important statistics for the landscape of (2). These statistics are inspired by those originally discussed in Lerman et al. (2015), and they are later used for our stability results in Theorems 1 and 2. We first discuss the noiseless RSR setting in Section 3.1.1 and then the noisy RSR setting in Section 3.1.2.

3.1.1. The Noiseless RSR Setting

For the noiseless setting, we assume that the inliers, $\mathcal{X}_{\text{in}} \subset \mathcal{X}$, lie on a low-dimensional linear subspace $L^* \in G(D,d)$, and the rest of the points, $\mathcal{X}_{\text{out}} = \mathcal{X} \setminus \mathcal{X}_{\text{in}}$, are in $\mathbb{R}^D \setminus \{L^*\}$. We call $\mathcal{X}$ defined in this way a noiseless inlier-outlier dataset.

The permeance of the inliers in a noiseless inlier-outlier dataset is defined as

$$\mathcal{P}(\mathcal{X}_{\text{in}}) = \lambda_d\left(\sum_{\boldsymbol{x}\in\mathcal{X}_{\text{in}}}\frac{\boldsymbol{x}_i\boldsymbol{x}_i^T}{\|\boldsymbol{x}_i\|}\right). \tag{9}$$

Here, $\lambda_d(\cdot)$ denotes the dth eigenvalue of a matrix. Notice that large values of $\mathcal{P}$ ensure that the inliers are well-distributed. In other words, they permeate throughout L_*.

We also define an alignment statistic for the noiseless inlier-outlier dataset $\mathcal{X}$. With some abuse of notation, we write $\nabla F(L;\mathcal{X})$ to refer to the gradient with respect to some basis of L, where the choice of basis does not matter. The alignment statistic of a set of outliers with respect to a subspace is

$$\mathcal{A}(\mathcal{X}_{\text{out}}, L) = \|\nabla F(L;\mathcal{X}_{\text{out}})\|_2. \tag{10}$$

It is not hard to show that (10) is invariant with respect to choice of basis for L. In effect, if this term is always small, then the outliers are not concentrated in any low-dimensional space. In other words, they are not aligned. In our later analysis, we use a simple and

illuminating bound for $\mathcal{A}$:

$$\mathcal{A}(\mathcal{X}_{\text{out}}, L) \leq \sqrt{N_{\text{out}}}\|\boldsymbol{X}_{\text{out}}\|_2. \tag{11}$$

The derivation for this bound is left to Appendix C. We note that this bound may be tight, but in most cases it is not.

We will define a stability statistic for a neighborhood of L_*, $B(L_*, \gamma)$. This neighborhood depends on a parameter γ, which fixes the maximum principal angle of subspaces in this neighborhood with L_*. Using the permeance and alignment defined in (9) and (10), the stability statistic of a noiseless inlier-outlier dataset is

$$\mathcal{S}(\mathcal{X}, L_*, \gamma) = \cos(\gamma)\mathcal{P}(\mathcal{X}_{\text{in}}) - \sup_{L \in B(L_*,\gamma)} \mathcal{A}(\mathcal{X}_{\text{out}}, L). \tag{12}$$

The simple condition required in most of our theoretical analysis is $\mathcal{S}(\mathcal{X}, L_*, \gamma) > 0$. This essentially means that the amount that the inliers permeate the underlying subspace must be able to beat the alignment of the outliers with respect to any subspace.

Note that $\mathcal{S}(\mathcal{X}, L_*, 0) = \mathcal{P}(\mathcal{X}_{\text{in}}) - \mathcal{A}(\mathcal{X}_{\text{out}}, L_*)$ is a tighter stability condition than the one in (2.4) of Lerman et al. (2015). Indeed, the stability expression of Lerman et al. (2015), takes the form

$$\mathcal{S}_{\text{REAP}}(\mathcal{X}, L_*) = \frac{1}{4\sqrt{d}}\mathcal{P}_{\text{REAP}}(\mathcal{X}_{\text{in}}) - \mathcal{A}_{\text{REAP}}(\mathcal{X}_{\text{out}}, L_*). \tag{13}$$

Here, $\mathcal{P}_{\text{REAP}}$ and $\mathcal{A}_{\text{REAP}}$ are actually lower and upper bounds on the permeance and alignment defined in (9) and (10), respectively. This, together with the extra factor of $1/(4\sqrt{d})$, means $\mathcal{S}_{\text{REAP}}(\mathcal{X}, L_*)$ is not as tight as $\mathcal{S}(\mathcal{X}, L_*, \gamma)$ for $\gamma = 0$. The upside is that the REAPER alignment only needs to be examined at a single point L_*, whereas $\mathcal{S}(\mathcal{X}, L_*, \gamma)$ becomes hard to estimate as γ increases. It is not clear in general which statistic is tighter when $\gamma > 0$.

3.1.2. The Noisy RSR Setting

The noisy setting occurs when the inliers lie near the low-dimensional subspace rather than exactly on it. In this case, we need to be more careful with the statistics of our inlier points. For each inlier point, we write $\boldsymbol{x}_i = \boldsymbol{P}_{L_*}\boldsymbol{x}_i + \boldsymbol{\epsilon}_i$, where $\boldsymbol{P}_{L_*}\boldsymbol{x}_i \in L_*$ and $\boldsymbol{\epsilon}_i \in L_*^{\perp}$ is added noise. Then, $\mathcal{X}^{\text{dns}} = (\boldsymbol{P}_{L_*}\mathcal{X}_{\text{in}}) \cup \mathcal{X}_{\text{out}}$ is the corresponding noiseless inlier-outlier dataset (here, the $\cdot^{\text{dns}}$ superscript stands for "de-noised"). We assume that the noise in our data is uniformly bounded by ϵ, that is, $\|\boldsymbol{x}_i - \boldsymbol{P}_{L_*}\boldsymbol{x}_i\| < \epsilon$ for all $\boldsymbol{x}_i \in \mathcal{X}_{\text{in}}$.

Some small technical issues come up with noisy RSR datasets that make the conditions harder to interpret. However, the following discussion is just a generalization of the previous section on the noiseless case after dealing with these technicalities.

To write the stability statistic in the noisy RSR setting, we must define the following set-valued functions of $\mathcal{X}_{\text{in}}$. These are defined for a unit vector $\boldsymbol{w} \in L_* \cap S^{D-1}$ and small-projection cutoff δ. They are meant to distinguish between inliers who have a projection onto $\boldsymbol{w}$ with length bigger than δ, and inliers who have a projection onto $\boldsymbol{w}$ with length less than or equal to δ. These functions are defined as

$$\mathcal{F}_0(\mathcal{X}_{\text{in}}, \boldsymbol{w}, \delta) = \{\boldsymbol{x} \in \mathcal{X}_{\text{in}} : |\boldsymbol{w}^T\boldsymbol{x}| \leq \delta\}, \tag{14}$$

$$\mathcal{F}_1(\mathcal{X}_{\text{in}}, \boldsymbol{w}, \delta) = \{\boldsymbol{x} \in \mathcal{X}_{\text{in}} : |\boldsymbol{w}^T\boldsymbol{x}| > \delta\}. \tag{15}$$

Inliers in the first set are coined "small-projection inliers", and inliers in the latter set are coined "large-projection inliers".

With these sets, our noisy inlier-outlier stability statistic is

$$\mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma) = \frac{\cos(\gamma - 2\arctan(\epsilon/\delta))}{2} \min_{\boldsymbol{w} \in L_* \cap S^{D-1}} \left(\sum_{\boldsymbol{x}_i \in \mathcal{F}_1(\mathcal{X}_{\text{in}}, \boldsymbol{w}, \delta)} \frac{\boldsymbol{w}^T\boldsymbol{P}_{L_*}\boldsymbol{x}_i\boldsymbol{x}_i^T\boldsymbol{P}_{L_*}\boldsymbol{w}}{\|\boldsymbol{P}_{L_*}\boldsymbol{x}\| + \sqrt{\epsilon^2 + \delta^2}} \right)$$
$$- \sqrt{\delta^2 + \epsilon^2} \max_{\boldsymbol{w} \in L_* \cap S^{D-1}} \#\left(\mathcal{F}_0(\mathcal{X}_{\text{in}}, \boldsymbol{w}, \delta)\right) - \sup_{B(L_*,\gamma)} \mathcal{A}(\mathcal{X}_{\text{out}}, L). \tag{16}$$

This statistic is somewhat similar to what we had in the noiseless RSR setting, although now we have separated our inlier terms into two parts. The first term behaves like the permeance from the noiseless RSR setting, with the addition that small-projection inliers are trimmed. The last term is again the alignment of the outliers. The middle term is quite technical, and it is meant to capture cases when inliers may have large angle with a fixed direction of L_*. If we take $\delta \to 0$ and $\epsilon/\delta \to 0$, then the stability almost becomes our original stability, with the added factor of $1/2$ on the permeance term. If $\mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma) > 0$, then we will demonstrate later that recovery is possible up to accuracy $\eta = 2\arctan(\epsilon/\delta)$.

An illustration of the small-projection cutoff δ, the noise bound ϵ, and the accuracy η for noisy inliers is given in Figure 3 to help ease understanding of our statistic. For simplicity, we show the case of a one-dimensional subspace in $\mathbb{R}^2$. Here, the vectors $\boldsymbol{w} \in L_* \cap S^{D-1}$ are $(1, 0)^T$ or $(-1, 0)^T$. Since these two vectors are equivalent for the two functions in (14) and (15), the large-projection inliers and small-projection inliers are only determined by the magnitude of δ. Thus, the cutoff defined by a certain choice of δ in (14) and (15) corresponds to separating small and large inliers by their x-value.

We note that the statistic is by no means tight and future work should analyze how accurate these methods can be with noise. As we will discuss in Section 7, one could also study RSR in settings with high noise, such as heavy tailed noise or under the spiked model. The main point of the noisy statistic is to show that our results yield ϵ/δ-approximate recovery when the noise is uniformly bounded by ϵ. Here, δ is constrained in that the stability condition, $\mathcal{S}_n(\mathcal{X}, L_*, \epsilon, \delta, \gamma) > 0$, must hold.

3.2. The Local Landscape under Stability

In this section, we will give results that prove the local stability of the energy landscape of (2). We begin with the theorem for the noiseless RSR setting in Section 3.2.1, and then prove an analogous result for the noisy RSR setting in Section 3.2.2.

3.2.1. Stability in the Noiseless Case
