The Journal of Machine Learning Research
Print-Archive Edition
Volume 20
Issues 1–92

The Journal of Machine Learning Research (JMLR) is an open access journal. All articles published in JMLR are freely available via electronic distribution. This Print-Archive Edition is published annually as a means of archiving the contents of the journal in perpetuity. The contents of this edition are articles published electronically in JMLR in 2019.

JMLR is abstracted in ACM Computing Reviews, INSPEC, and Psychological Abstracts/PsycINFO.

JMLR is a publication of Journal of Machine Learning Research, Inc. For further information regarding JMLR, including open access to articles, visit http://www.jmlr.org/.

JMLR Print-Archive Edition is a publication of Microtome Publishing under agreement with Journal of Machine Learning Research, Inc. For further information regarding the Print-Archive Edition, including subscription and distribution information and background on open-access print archiving, visit Microtome Publishing at http://www.mtome.com/.

Collection copyright © 2019 The Journal of Machine Learning Research, Inc. and Microtome Publishing.
Individual articles copyright © 2019 by their respective authors and distributed under a Creative Commons Attribution 4.0 International License.

ISSN 1532-4435 (print)
ISSN 1533-7928 (online)

JMLR Editorial Board

Editor-in-Chief
Francis Bach, Centre de Recherche INRIA de Paris

Editor-in-Chief
David Blei, Columbia University

Editor-in-Chief
Bernhard Schölkopf, MPI for Intelligent Systems, Germany

Managing Editor
Fabian Pedregosa, Google Reseach

Editorial Assistant
Karin Bierig, MPI for Intelligent Systems

Production Editor
Alp Kucukelbir, Fero Labs and Columbia University

Production Staff
Trevor Campbell, Massachusetts Institute of Technology **Behzad Tabibian**, MPI for Intelligent Systems **Hoon Cho**, Massachusetts Institute of Technology

Web Master
Alp Kucukelbir, Fero Labs and Columbia University **Fabian Pedregosa**, Google Reseach

JMLR Action Editors
Ryan Adams, Princeton University, USA **Shivani Agarwal**, University of Pennsylvania, USA **Edoardo M. Airoldi**, Harvard University, USA **Genevera Allen**, Rice University, USA **Anima Anandkumar**, California Institute of Technology, USA **Peter Auer**, University of Leoben, Austria **Samy Bengio**, Google Research, USA **Yoshua Bengio**, Université de Montréal, Canada **Jeff Bilmes**, University of Washington, USA **Karsten Borgwardt**, ETH Zurich, Switzerland **Miguel A. Carreira-Perpinan**, University of California, Merced, USA **Alexander Clark**, King's College London, UK **Corinna Cortes**, Google Research, USA **Koby Crammer**, Technion, Israel **John P. Cunningham**, Columbia University, USA **Arnak Dalalyan**, ENSAE / CREST, France **Inderjit S. Dhillon**, University of Texas, Austin, USA **Tina Eliassi-Rad**, Northeastern University **Gal Elidan**, Hebrew University, Israel **Charles Elkan**, University of California at San Diego, USA **Barbara Engelhardt**, Princeton University, USA **Rob Fergus**, New York University, USA **Kenji Fukumizu**, The Institute of Statistical Mathematics, Japan **Amir Globerson**, Tel Aviv University, Israel **Moises Goldszmidt**, Microsoft Research, USA **Russ Greiner**, University of Alberta, Canada **Arthur Gretton**, University College London, UK **Maya Gupta**, Google Research, USA **Isabelle Guyon**, ClopiNet, USA **Zaid Harchaoui**, University of Washington **Moritz Hardt**, Google Research, USA **Philipp Hennig**, University of Tübingen **Bert Huang**, Virginia Tech, USA **Aapo Hyvärinen**, University of Helsinki, Finland **Tommi Jaakkola**, Massachusetts Institute of Technology, USA **Prateek Jain**, Microsoft Research, India **Stefanie Jegelka**, Massachusetts Institute of Technology, USA **Samuel Kaski**, Aalto University, Finland **Sathiya Keerthi**, Microsoft Research, USA **Emtiyaz**

Khan, RIKEN Center for Advanced Intelligence, Japan **George Konidaris**, Duke University, USA **Andreas Krause**, ETH Zurich, Switzerland **Sanjiv Kumar**, Google Research, USA **Simon Lacoste-Julien**, Quebec Institute of Artificial Intelligence, Canada **Christoph Lampert**, Institute of Science and Technology, Austria **Honglak Lee**, Google and University of Michigan, Ann Arbor **Daniel Lee**, University of Pennsylvania, USA **Qiang Liu**, Dartmouth College, USA **Gábor Lugosi**, Pompeu Fabra University, Spain **Michael Mahoney**, University of California at Berkeley, USA **Vikash K. Mansinghka**, Massachusetts Institute of Technology, USA **Julien Mairal**, INRIA **Shie Mannor**, Technion, Israel **Jon McAuliffe**, University of California at Berkeley, USA **Robert E. McCulloch**, University of Chicago, USA **Chris Meek**, Microsoft Research, USA **Qiaozhu Mei**, University of Michigan, USA **Vahab Mirrokni**, Google Research, USA **Mehryar Mohri**, New York University, USA **Joris Mooij**, University of Amsterdam, Netherlands **Sayan Mukherjee**, Duke University, USA **Boaz Nadler**, Weizmann Institute of Science, Israel **Long Nguyen**, University of Michigan, USA **Sebastian Nowozin**, Google Research **Una-May O'Reilly**, Massachusetts Institute of Technology, USA **Laurent Orseau**, Google Deepmind, USA **Jie Peng**, University of California, Davis, USA **Jan Peters**, Technische Universitaet Darmstadt, Germany **Avi Pfeffer**, Charles River Analytics, USA **Joelle Pineau**, McGill University, Canada **Massimiliano Pontil**, Istituto Italiano di Tecnologia (Italy), University College London (UK) **Pushmeet Kohli**, DeepMind **Luc de Raedt**, Katholieke Universiteit Leuven, Belgium **Garvesh Raskutti**, University of Wisconsin-Madison, USA **Ben Recht**, University of California, Berkeley, USA **Lorenzo Rosasco**, Massachusetts Institute of Technology, USA **Ruslan Salakhutdinov**, University of Toronto, Canada **Sujay Sanghavi**, University of Texas, Austin, USA **Marc Schoenauer**, INRIA Saclay, France **Ohad Shamir**, Weizmann Institute of Science, Israel **John Shawe-Taylor**, University College London, UK **Xiaotong Shen**, University of Minnesota, USA **David Sontag**, Massachusetts Institute of Technology **Peter Spirtes**, Carnegie Mellon University, USA **Suvrit Sra**, Massachusetts Institute of Technology, USA **Ingo Steinwart**, University of Stuttgart, Germany **Amos Storkey**, University of Edinburgh, UK **Erik Sudderth**, University of California, Irvine, USA **Csaba Szepesvari**, University of Alberta, Canada **Olivier Teytaud**, INRIA Saclay, France **Ambuj Tewari**, University of Michigan **Ivan Titov**, University of Amsterdam, Netherlands **Ryan Tibshirani**, Carnegie Mellon University **Ryota Tomioka**, Microsoft Research Cambridge, UK **Koji Tsuda**, National Institute of Advanced Industrial Science and Technology, Japan **Nicolas Vayatis**, ENS Cachan, France **Jean-Philippe Vert**, Google Research, France **S V N Vishwanathan**, Purdue University, USA **Manfred Warmuth**, University of California at Santa Cruz, USA **Kilian Weinberger**, Cornell University, USA **David Wipf**, Microsoft Research Asia, China **Daniela Witten**, University of Washington **Frank Wood**, University of British Columbia **Tong Zhang**, Baidu Inc, China **Zhihua Zhang**, Peking University, China

JMLR MLOSS Editors

Alexandre Gramfort, INRIA, Université Paris-Saclay, France **Antti Honkela**, University of Helsinki, Finland **Balázs Kégl**, CNRS / Université Paris-Saclay, France **Andreas C. Müller**, Columbia University, USA **Cheng Soon Ong**, Australian National University, Australia

JMLR Editorial Board

Naoki Abe, IBM TJ Watson Research Center, USA **Yasemin Altun**, Google Inc, Switzerland **Jean-Yves Audibert**, CERTIS, France **Jonathan Baxter**, Australia National University, Australia **Richard K. Belew**, University of California at San Diego, USA **Kristin Bennett**, Rensselaer Polytechnic Institute, USA **Christopher M. Bishop**, Microsoft Research, Cambridge, UK **Lashon Booker**, The Mitre Corporation, USA **Henrik Boström**, Stockholm University/KTH, Sweden **Craig Boutilier**,

Google Research, USA **John Patrick Cunningham**, Columbia University, USA **Nello Cristianini**, University of Bristol, UK **Peter Dayan**, University College, London, UK **Dennis DeCoste**, eBay Research, USA **Thomas Dietterich**, Oregon State University, USA **Saso Dzeroski**, Jozef Stefan Institute, Slovenia **Ran El-Yaniv**, Technion, Israel **Peter Flach**, Bristol University, UK **Dan Geiger**, Technion, Israel **Claudio Gentile**, Università degli Studi dell'Insubria, Italy **Sally Goldman**, Google Research, USA **Thore Graepel**, Google DeepMind and University College London, UK **Tom Griffiths**, University of California at Berkeley, USA **Carlos Guestrin**, University of Washington, USA **Stefan Harmeling**, University of Düsseldorf, Germany **David Heckerman**, Microsoft Research, USA **Katherine Heller**, Duke University, USA **Philipp Hennig**, MPI for Intelligent Systems, Germany **Larry Hunter**, University of Colorado, USA **Jens Kober**, Delft University of Technology, Netherlands **Risi Kondor**, University of Chicago, USA **Aryeh Kontorovich**, Ben-Gurion University of the Negev, Israel **Samory Kpotufe**, Princeton University, USA **John Lafferty**, University of Chicago, USA **Erik Learned-Miller**, University of Massachusetts, Amherst, USA **Fei Fei Li**, Stanford University, USA **Yi Lin**, University of Wisconsin, USA **Wei-Yin Loh**, University of Wisconsin, USA **Richard Maclin**, University of Minnesota, USA **Sridhar Mahadevan**, University of Massachusetts, Amherst, USA **Vikash Mansingkha**, Massachusetts Institute of Technology, USA **Yishay Mansour**, Tel-Aviv University, Israel **Jon McAuliffe**, University of California, Berkeley, USA **Andrew McCallum**, University of Massachusetts, Amherst, USA **Raymond J. Mooney**, University of Texas, Austin, USA **Klaus-Robert Muller**, Technical University of Berlin, Germany **Kevin Murphy**, Google, USA **Guillaume Obozinski**, Ecole des Ponts - ParisTech, France **Pascal Poupart**, University of Waterloo, Canada **Konrad Rieck**, University of Göttingen, Germany **Cynthia Rudin**, Massachusetts Institute of Technology, USA **Suchi Saria**, Johns Hopkins University, USA **Robert Schapire**, Princeton University, USA **Fei Sha**, University of Southern California, USA **Shai Shalev-Shwartz**, Hebrew University of Jerusalem, Israel **Padhraic Smyth**, University of California, Irvine, USA **Bharath Sriperumbudur**, Pennsylvania State University, USA **Alexander Statnikov**, New York University, USA **Jean-Philippe Vert**, Mines ParisTech, France **Martin J. Wainwright**, University of California at Berkeley, USA **Chris Watkins**, Royal Holloway, University of London, UK **Max Welling**, University of Amsterdam, Netherlands **Stefan Wrobel**, Fraunhofer IAIS and University of Bonn, Germany **Chris Williams**, University of Edinburgh, UK **Alice Zheng**, GraphLab, USA

Journal of Machine Learning Research

Volume 20

Part A

20(1):1–30 **Adaptation Based on Generalized Discrepancy**
Corinna Cortes, Mehryar Mohri, Andrés Muñoz Medina

20(2):1–52 **Transport Analysis of Infinitely Deep Neural Network**
Sho Sonoda, Noboru Murata

20(3):1–44 **Parsimonious Online Learning with Kernels via Sparse Projections in Function Space**
Alec Koppel, Garrett Warnell, Ethan Stump, Alejandro Ribeiro

20(4):1–45 **Convergence Rate of a Simulated Annealing Algorithm with Noisy Observations**
Clément Bouttier, Ioana Gavra

20(5):1–37 **Non-Convex Projected Gradient Descent for Generalized Low-Rank Tensor Regression**
Han Chen, Garvesh Raskutti, Ming Yuan

20(6):1–22 **scikit-multilearn: A Python library for Multi-Label Classification**
Piotr Szymański, Tomasz Kajdanowicz

20(7):1–45 **Scalable Approximations for Generalized Linear Problems**
Murat Erdogdu, Mohsen Bayati, Lee H. Dicker

20(8):1–39 **Forward-Backward Selection with Early Dropping**
Giorgos Borboudakis, Ioannis Tsamardinos

20(9):1–49 **Dynamic Pricing in High-dimensions**
Adel Javanmard, Hamid Nazerzadeh

20(10):1–44 **Graphical Lasso and Thresholding: Equivalence and Closed-form Solutions**
Salar Fattahi, Somayeh Sojoudi

20(11):1–23 **An Approach to One-Bit Compressed Sensing Based on Probably Approximately Correct Learning Theory**
Mehmet Eren Ahsen, Mathukumalli Vidyasagar

20(12):1–49 **Scalable Kernel K-Means Clustering with Nystrom Approximation: Relative-Error Bounds**
Shusen Wang, Alex Gittens, Michael W. Mahoney

20(13):1–34 **Train and Test Tightness of LP Relaxations in Structured Prediction**
Ofer Meshi, Ben London, Adrian Weller, David Sontag

20(14):1–37 **Approximations of the Restless Bandit Problem**
Steffen Grünewälder, Azadeh Khaleghi

20(15):1–38 **Automated Scalable Bayesian Inference via Hilbert Coresets**
Trevor Campbell, Tamara Broderick

20(16):1–24 **Smooth neighborhood recommender systems**
Ben Dai, Junhui Wang, Xiaotong Shen, Annie Qu

20(17):1–38 **Delay and Cooperation in Nonstochastic Bandits**
Nicolò Cesa-Bianchi, Claudio Gentile, Yishay Mansour

20(18):1–29 **Multiplicative local linear hazard estimation and best one-sided cross-validation**
Maria Luz Gámiz, María Dolores Martínez-Miranda, Jens Perch Nielsen

20(19):1–5 **spark-crowd: A Spark Package for Learning from Crowdsourced Big Data**
Enrique G. Rodrigo, Juan A. Aledo, José A. Gámez

20(20):1–33 **Accelerated Alternating Projections for Robust Principal Component Analysis**
HanQin Cai, Jian-Feng Cai, Ke Wei

20(21):1–55 **Spectrum Estimation from a Few Entries**
Ashish Khetan, Sewoong Oh

20(22):1–36 **Random Feature-based Online Multi-kernel Learning in Environments with Unknown Dynamics**
Yanning Shen, Tianyi Chen, Georgios B. Giannakis

20(23):1–38 **Determining the Number of Latent Factors in Statistical Multi-Relational Learning**
Chengchun Shi, Wenbin Lu, Rui Song

20(24):1–29 **Joint PLDA for Simultaneous Modeling of Two Factors**
Luciana Ferrer, Mitchell McLaren

20(25):1–49 **Group Invariance, Stability to Deformations, and Complexity of Deep Convolutional Representations**
Alberto Bietti, Julien Mairal

20(26):1–6 **TensorLy: Tensor Learning in Python**
Jean Kossaifi, Yannis Panagakis, Anima Anandkumar, Maja Pantic

20(27):1–42 **Monotone Learning with Rectified Wire Networks**
Veit Elser, Dan Schmidt, Jonathan Yedidia

20(28):1–6 **Pyro: Deep Universal Probabilistic Programming**
Eli Bingham, Jonathan P. Chen, Martin Jankowiak, Fritz Obermeyer, Neeraj Pradhan, Theofanis Karaletsos, Rohit Singh, Paul Szerlip, Paul Horsfall, Noah D. Goodman

20(29):1–28 **Iterated Learning in Dynamic Social Networks**
Bernard Chazelle, Chu Wang

20(30):1–34 **Exact Clustering of Weighted Graphs via Semidefinite Programming**
Aleksis Pirinen, Brendan Ames

20(31):1–45 **Kernels for Sequentially Ordered Data**
Franz J. Kiraly, Harald Oberhauser

20(32):1–50 **NetSDM: Semantic Data Mining with Network Analysis**
Jan Kralj, Marko Robnik-Sikonja, Nada Lavrac

20(33):1–38 **The Relationship Between Agnostic Selective Classification, Active Learning and the Disagreement Coefficient**
Roei Gelbhart, Ran El-Yaniv

20(34):1–44 **Matched Bipartite Block Model with Covariates**
Zahra S. Razaee, Arash A. Amini, Jingyi Jessica Li

20(35):1–93 **Optimal Policies for Observing Time Series and Related Restless Bandit Problems**
Christopher R. Dance, Tomi Silander

20(36):1–37 **A New Approach to Laplacian Solvers and Flow Problems**
Patrick Rebeschini, Sekhar Tatikonda

20(37):1–59 **A Well-Tempered Landscape for Non-convex Robust Subspace Recovery**
Tyler Maunu, Teng Zhang, Gilad Lerman

20(38):1–27 **Approximation Hardness for A Class of Sparse Optimization Problems**
Yichen Chen, Yinyu Ye, Mengdi Wang

20(39):1–40 **A Bootstrap Method for Error Estimation in Randomized Matrix Multiplication**
Miles E. Lopes, Shusen Wang, Michael W. Mahoney

20(40):1–47 **Stochastic Modified Equations and Dynamics of Stochastic Gradient Algorithms I: Mathematical Foundations**
Qianxiao Li, Cheng Tai, Weinan E

20(41):1–57 **Decontamination of Mutual Contamination Models**
Julian Katz-Samuels, Gilles Blanchard, Clayton Scott

20(42):1–56 **Utilizing Second Order Information in Minibatch Stochastic Variance Reduced Proximal Iterations**
Jialei Wang, Tong Zhang

20(43):1–58 **DSCOVR: Randomized Primal-Dual Block Coordinate Algorithms for Asynchronous Distributed Optimization**
Lin Xiao, Adams Wei Yu, Qihang Lin, Weizhu Chen

20(44):1–5 **Picasso: A Sparse Learning Library for High Dimensional Data Analysis in R and Python**
Jason Ge, Xingguo Li, Haoming Jiang, Han Liu, Tong Zhang, Mengdi Wang, Tuo Zhao

20(45):1–41 **Robust Frequent Directions with Application in Online Learning**
Luo Luo, Cheng Chen, Zhihua Zhang, Wu-Jun Li, Tong Zhang

20(46):1–36 **Boosted Kernel Ridge Regression: Optimal Learning Rates and Early Stopping**
Shao-Bo Lin, Yunwen Lei, Ding-Xuan Zhou

20(47):1–47 **Analysis of spectral clustering algorithms for community detection: the general bipartite setting**
Zhixin Zhou, Arash A.Amini

20(48):1–23 **Efficient augmentation and relaxation learning for individualized treatment rules using observational data**
Ying-Qi Zhao, Eric B. Laber, Yang Ning, Sumona Saha, Bruce E. Sands

20(49):1–24 **Using Simulation to Improve Sample-Efficiency of Bayesian Optimization for Bipedal Robots**
Akshara Rai, Rika Antonova, Franziska Meier, Christopher G. Atkeson

20(50):1–24 **No-Regret Bayesian Optimization with Unknown Hyperparameters**
Felix Berkenkamp, Angela P. Schoellig, Andreas Krause

20(51):1–18 **Bayesian Combination of Probabilistic Classifiers using Multivariate Normal Mixtures**
Gregor Pirš, Erik Štrumbelj

20(52):1–24 **Thompson Sampling Guided Stochastic Searching on the Line for Deceptive Environments with Applications to Root-Finding Problems**
Sondre Glimsdal, Ole-Christoffer Granmo

20(53):1–32 **Tunability: Importance of Hyperparameters of Machine Learning Algorithms**
Philipp Probst, Anne-Laure Boulesteix, Bernd Bischl

20(54):1–31 **Deep Reinforcement Learning for Swarm Systems**
Maximilian Hüttenrauch, Adrian Šošić, Gerhard Neumann

20(55):1–21 **Neural Architecture Search: A Survey**
Thomas Elsken, Jan Hendrik Metzen, Frank Hutter

20(56):1–23 **Near Optimal Frequent Directions for Sketching Dense and Sparse Matrices**
Zengfeng Huang

20(57):1–31 **Multi-class Heterogeneous Domain Adaptation**
Joey Tianyi Zhou, Ivor W. Tsang, Sinno Jialin Pan, Mingkui Tan

20(58):1–49 **The Common-directions Method for Regularized Empirical Risk Minimization**
Po-Wei Wang, Ching-pei Lee, Chih-Jen Lin

20(59):1–36 **Kernel Approximation Methods for Speech Recognition**
Avner May, Alireza Bagheri Garakani, Zhiyun Lu, Dong Guo, Kuan Liu, Aurélien Bellet, Linxi Fan, Michael Collins, Daniel Hsu, Brian Kingsbury, Michael Picheny, Fei Sha

20(60):1–49 **Robust Estimation of Derivatives Using Locally Weighted Least Absolute Deviation Regression**
WenWu Wang, Ping Yu, Lu Lin, Tiejun Tong

20(61):1–42 **The Sup-norm Perturbation of HOSVD and Low Rank Tensor Denoising**
Dong Xia, Fan Zhou

20(62):1–37 **Multi-scale Online Learning: Theory and Applications to Online Auctions and Pricing**
Sébastien Bubeck, Nikhil R. Devanur, Zhiyi Huang, Rad Niazadeh

20(63):1–17 **Nearly-tight VC-dimension and Pseudodimension Bounds for Piecewise Linear Neural Networks**
Peter L. Bartlett, Nick Harvey, Christopher Liaw, Abbas Mehrabian

20(64):1–32 **A Representer Theorem for Deep Kernel Learning**
Bastian Bohn, Michael Griebel, Christian Rieger

20(65):1–50 **Active Learning for Cost-Sensitive Classification**
Akshay Krishnamurthy, Alekh Agarwal, Tzu-Kuo Huang, Hal Daumé III, John Langford

20(66):1–38 **Proximal Distance Algorithms: Theory and Practice**
Kevin L. Keys, Hua Zhou, Kenneth Lange

20(67):1–28 **Learnability of Solutions to Conjunctive Queries**
Hubie Chen, Matthew Valeriote

20(68):1–55 **Variance-based Regularization with Convex Objectives**
John Duchi, Hongseok Namkoong

20(69):1–39 **On Consistent Vertex Nomination Schemes**
Vince Lyzinski, Keith Levin, Carey E. Priebe

20(70):1–33 **Semi-Analytic Resampling in Lasso**
Tomoyuki Obuchi, Yoshiyuki Kabashima

20(71):1–42 **Lazifying Conditional Gradient Algorithms**
Gábor Braun, Sebastian Pokutta, Daniel Zink

20(72):1–47 **Redundancy Techniques for Straggler Mitigation in Distributed Optimization and Learning**
Can Karakus, Yifan Sun, Suhas Diggavi, Wotao Yin

20(73):1–46 **Analysis of Langevin Monte Carlo via Convex Optimization**
Alain Durmus, Szymon Majewski, Błażej Miasojedow

20(74):1–25 **Deep Optimal Stopping**
Sebastian Becker, Patrick Cheridito, Arnulf Jentzen

20(75):1–42 **Fairness Constraints: A Flexible Approach for Fair Classification**
Muhammad Bilal Zafar, Isabel Valera, Manuel Gomez-Rodriguez, Krishna P. Gummadi

20(76):1–70 **Generalized Score Matching for Non-Negative Data**
Shiqing Yu, Mathias Drton, Ali Shojaie

20(77):1–33 **Nonuniformity of P-values Can Occur Early in Diverging Dimensions**
Yingying Fan, Emre Demirkaya, Jinchi Lv

20(78):1–39 **Prediction Risk for the Horseshoe Regression**
Anindya Bhadra, Jyotishka Datta, Yunfan Li, Nicholas G. Polson, Brandon Willard

20(79):1–33 **Quantification Under Prior Probability Shift: the Ratio Estimator and its Extensions**
Afonso Fernandes Vaz, Rafael Izbicki, Rafael Bassi Stern

20(80):1–37 **Learning to Match via Inverse Optimal Transport**
Ruilin Li, Xiaojing Ye, Haomin Zhou, Hongyuan Zha

20(81):1–8 **Tight Lower Bounds on the VC-dimension of Geometric Set Systems**
Mónika Csikós, Nabil H. Mustafa, Andrey Kupavskii

20(82):1–5 **SMART: An Open Source Data Labeling Platform for Supervised Learning**
Rob Chew, Michael Wenger, Caroline Kery, Jason Nance, Keith Richards, Emily Hadley, Peter Baumgartner

20(83):1–28 **On the optimality of the Hedge algorithm in the stochastic regime**
Jaouad Mourtada, Stéphane Gaïffas

20(84):1–40 **Differentiable Game Mechanics**
Alistair Letcher, David Balduzzi, Sébastien Racanière, James Martens, Jakob Foerster, Karl Tuyls, Thore Graepel

20(85):1–35 **Bayesian Space-Time Partitioning by Sampling and Pruning Spanning Trees**
Leonardo V. Teixeira, Renato M. Assunção, Rosangela H. Loschi

20(86):1–62 **Streaming Principal Component Analysis From Incomplete Data**
Armin Eftekhari, Gregory Ongie, Laura Balzano, Michael B. Wakin

20(87):1–30 **An asymptotic analysis of distributed nonparametric methods**
Botond Szabó, Harry van Zanten

20(88):1–26 **Model Selection via the VC Dimension**
Merlin Mpoudeu, Bertrand Clarke

20(89):1–43 **Dependent relevance determination for smooth and structured sparse regression**
Anqi Wu, Oluwasanmi Koyejo, Jonathan Pillow

20(90):1–56 **A Particle-Based Variational Approach to Bayesian Non-negative Matrix Factorization**
Muhammad A Masood, Finale Doshi-Velez

20(91):1–39 **Best Arm Identification for Contaminated Bandits**
Jason Altschuler, Victor-Emmanuel Brunel, Alan Malek

20(92):1–6 **AffectiveTweets: a Weka Package for Analyzing Affect in Tweets**
Felipe Bravo-Marquez, Eibe Frank, Bernhard Pfahringer, Saif M. Mohammad

Part B

20(93):1–8 **iNNvestigate Neural Networks!**
Maximilian Alber, Sebastian Lapuschkin, Philipp Seegerer, Miriam Hägele, Kristof T. Schütt, Grégoire Montavon, Wojciech Samek, Klaus-Robert Müller, Sven Dähne, Pieter-Jan Kindermans

20(94):1–34 **Simultaneous Private Learning of Multiple Concepts**
Mark Bun, Kobbi Nissim, Uri Stemmer

20(95):1–41 **High-Dimensional Poisson Structural Equation Model Learning via ℓ_1-Regularized Regression**
Gunwoong Park, Sion Park

20(96):1–7 **PyOD: A Python Toolbox for Scalable Outlier Detection**
Yue Zhao, Zain Nasrullah, Zheng Li

20(97):1–22 **Relative Error Bound Analysis for Nuclear Norm Regularized Matrix Completion**
Lijun Zhang, Tianbao Yang, Rong Jin, Zhi-Hua Zhou

20(98):1–63 **Adaptive Geometric Multiscale Approximations for Intrinsically Low-dimensional Data**
Wenjing Liao, Mauro Maggioni

20(99):1–51 **Change Surfaces for Expressive Multidimensional Changepoints and Counterfactual Prediction**
William Herlands, Daniel B. Neill, Hannes Nickisch, Andrew Gordon Wilson

20(100):1–31 **Hamiltonian Monte Carlo with Energy Conserving Subsampling**
Khue-Dung Dang, Matias Quiroz, Robert Kohn, Minh-Ngoc Tran, Mattias Villani

20(101):1–43 **Low Permutation-rank Matrices: Structural Properties and Noisy Completion**
Nihar B. Shah, Sivaraman Balakrishnan, Martin J. Wainwright

20(102):1–56 **Non-Convex Matrix Completion and Related Problems via Strong Duality**
Maria-Florina Balcan, Yingyu Liang, Zhao Song, David P. Woodruff, Hongyang Zhang

20(103):1–68 **Regularization via Mass Transportation**
Soroosh Shafieezadeh-Abadeh, Daniel Kuhn, Peyman Mohajerin Esfahani

20(104):1–34 **Complete Search for Feature Selection in Decision Trees**
Salvatore Ruggieri

20(105):1–23 **Optimal Transport: Fast Probabilistic Approximation with Exact Solvers**
Max Sommerfeld, Jörn Schrieber, Yoav Zemel, Axel Munk

20(106):1–25 **Solving the OSCAR and SLOPE Models Using a Semismooth Newton-Based Augmented Lagrangian Method**
Ziyan Luo, Defeng Sun, Kim-Chuan Toh, Naihua Xiu

20(107):1–34 **Scalable Interpretable Multi-Response Regression via SEED**
Zemin Zheng, M. Taha Bahadori, Yan Liu, Jinchi Lv

20(108):1–30 **Maximum Likelihood for Gaussian Process Classification and Generalized Linear Mixed Models under Case-Control Sampling**
Omer Weissbrod, Shachar Kaufman, David Golan, Saharon Rosset

20(109):1–30 **Learning Unfaithful K-separable Gaussian Graphical Models**
De Wen Soh, Sekhar Tatikonda

20(110):1–30 **A Representer Theorem for Deep Neural Networks**
Michael Unser

20(111):1–40 **An Efficient Two Step Algorithm for High Dimensional Change Point Regression Models Without Grid Search**
Abhishek Kaul, Venkata K. Jandhyala, Stergios B. Fotopoulos

20(112):1–49 **Measuring the Effects of Data Parallelism on Neural Network Training**
Christopher J. Shallue, Jaehoon Lee, Joseph Antognini, Jascha Sohl-Dickstein, Roy Frostig, George E. Dahl

20(113):1–41 **Distributed Inference for Linear Support Vector Machine**
Xiaozhou Wang, Zhuoyi Yang, Xi Chen, Weidong Liu

20(114):1–34 **Sharp Restricted Isometry Bounds for the Inexistence of Spurious Local Minima in Nonconvex Matrix Recovery**
Richard Y. Zhang, Somayeh Sojoudi, Javad Lavaei

20(115):1–58 **Learning Attribute Patterns in High-Dimensional Structured Latent Attribute Models**
Yuqi Gu, Gongjun Xu

20(116):1–42 **Graph Reduction with Spectral and Cut Guarantees**
Andreas Loukas

20(117):1–63 **Generic Inference in Latent Gaussian Process Models**
Edwin V. Bonilla, Karl Krauth, Amir Dezfouli

20(118):1–34 **Binarsity: a penalization for one-hot encoded features in linear supervised learning**
Mokhtar Z. Alaya, Simon Bussy, Stéphane Gaïffas, Agathe Guilloux

20(119):1–38 **Layer-Wise Learning Strategy for Nonparametric Tensor Product Smoothing Spline Regression and Graphical Models**
Kean Ming Tan, Junwei Lu, Tong Zhang, Han Liu

20(120):1–49 **Ivanov-Regularised Least-Squares Estimators over Large RKHSs and Their Interpolation Spaces**
Stephen Page, Steffen Grünewälder

20(121):1–39 **Scaling Up Sparse Support Vector Machines by Simultaneous Feature and Sample Reduction**
Bin Hong, Weizhong Zhang, Wei Liu, Jieping Ye, Deng Cai, Xiaofei He, Jie Wang

20(122):1–55 **Approximate Profile Maximum Likelihood**
Dmitri S. Pavlichin, Jiantao Jiao, Tsachy Weissman

20(123):1–26 **ADMMBO: Bayesian Optimization with Unknown Constraints using ADMM**
Setareh Ariafar, Jaume Coll-Font, Dana Brooks, Jennifer Dy

20(124):1–62 **Deep Exploration via Randomized Value Functions**
Ian Osband, Benjamin Van Roy, Daniel J. Russo, Zheng Wen

20(125):1–5 **ORCA: A Matlab/Octave Toolbox for Ordinal Regression**
Javier Sánchez-Monedero, Pedro A. Gutiérrez, María Pérez-Ortiz

20(126):1–45 **Learning Representations of Persistence Barcodes**
Christoph D. Hofer, Roland Kwitt, Marc Niethammer

20(127):1–32 **Causal Learning via Manifold Regularization**
Steven M. Hill, Chris J. Oates, Duncan A. Blythe, Sach Mukherjee

20(128):1–73 **Unsupervised Basis Function Adaptation for Reinforcement Learning**
Edward Barker, Charl Ras

20(129):1–30 **Time-to-Event Prediction with Neural Networks and Cox Regression**
Håvard Kvamme, Ørnulf Borgan, Ida Scheel

Editor: Multi Task Learning

Abstract

We present a new algorithm for domain adaptation improving upon a discrepancy minimization algorithm, (DM), previously shown to outperform a number of algorithms for this problem. Unlike many previously proposed solutions for domain adaptation, our algorithm does not consist of a fixed reweighting of the losses over the training sample. Instead, the reweighting depends on the hypothesis sought. The algorithm is derived from a less conservative notion of discrepancy than the DM algorithm called *generalized discrepancy*. We present a detailed description of our algorithm and show that it can be formulated as a convex optimization problem. We also give a detailed theoretical analysis of its learning guarantees which helps us select its parameters. Finally, we report the results of experiments demonstrating that it improves upon discrepancy minimization.

Keywords: domain adaptation, learning theory

1. Introduction

A standard assumption in statistical learning theory and PAC learning is that training and test samples are drawn from the same distribution (Vapnik, 1998; Valiant, 1984). In practice, however, this assumption often does not hold: the source and target distributions may somewhat differ. This problem is known as *domain adaptation* and arises in a variety of applications such as natural language processing and computer vision (Dredze et al., 2007; Blitzer et al., 2007; Jiang and Zhai, 2007; Leggetter and Woodland, 1995; Martínez, 2002; Hoffman et al., 2014). The domain adaptation problem may appear when the distributions over the instance space differ, the so-called *covariate shift* problem, or when the labeling functions associated with each domain disagree. In practice, a combination of both issues occurs and, for adaptation to succeed, the divergence between the two domains needs to be relatively small. This is clear for the labeling functions since, if the learner receives source labels that are vastly different from the target ones, no learning algorithm can generalize well to the target domain. The same holds when input distributions largely differ.

This intuition was formalized by Ben-David et al. (2010) and Ben-David and Urner (2012) who showed that even in the favorable scenario where the source and target distribution admit the same support, a sample of size in the order of that of the support is needed in order to solve the domain adaptation problem. As the authors point out, the domain adaptation problem becomes intractable when the labeling function for the training data is vastly different from the labeling function used for testing. On the other hand, when some similarity between domains exist, it has been empirically and theoretically shown that adaptation algorithms can be beneficial and in fact a large number of algorithms for this task have been proposed over the past decade. The large majority of them fall in one of the following paradigms:

1. **Learning a new feature representation**. The core idea behind these algorithms is to map the source and target data into a new feature space where the difference between source and target distributions is reduced. Transfer Component Analysis (TCA) (Pan et al., 2011) and the work on Frustratingly Easy Domain Adaptation (FE) (Daumé III, 2007) belong to this family of algorithms. Whereas some empirical evidence of the effectiveness of these algorithms exists in the literature, to the best of our knowledge, no work has been done to provide learning guarantees for these algorithms.
2. **Reweighting**. Originated in the Statistics literature on sample bias correction, these techniques attempt to correct the difference between distributions by multiplying the loss at each training example by a positive weight. Most of the classical algorithms such as KMM (Huang et al., 2006), KLIEP (Sugiyama et al., 2007) and a two-step algorithm by Bickel et al. (2007) fall in this category.

The main focus of this work will be on the latter. A common trait shared by most algorithms in this category is that their reweighting schemes are based on the minimization of a divergence measure between the empirical source and target distributions. For instance, the KL-divergence in the case of KLIEP and the Maximum Mean Discrepancy (MMD) (Gretton et al., 2012) for KMM. The guarantees of these algorithms are therefore given as a function of the chosen divergence. The main drawback of these measures is that they do not take into account the hypothesis set or the loss function, both crucial components of any learning algorithm. In contrast, the *discrepancy* introduced by Mansour et al. (2009) and further studied by Cortes and Mohri (2011) is a measure of the divergence between distributions tailored to domain adaptation that precisely takes into account both the loss function and the hypothesis set. The $d_{\mathcal{A}}$-distance, introduced by Devroye et al. (1996)[pp. 271-272] under the name of *generalized Kolmogorov-Smirnov distance*, later by Ben-David et al. (2006), coincides with the discrepancy when the binary loss function is used. The discrepancy is a pivotal concept used in the analysis of several adaptation scenarios: the $\mathcal{Y}$-discrepancy or *integral probability metric* (Zhang et al., 2012) was successfully used by Mohri and Muñoz (2012) to provide tight learning guarantees for the related task of learning with drifting distributions, whereas a modified version of the discrepancy was used by Germain et al. (2013) to study the problem of domain adaptation in a PAC-Bayesian setting. The discrepancy-based generalization bounds given by Mansour et al. (2009) motivated a discrepancy minimization (DM) algorithm (Cortes and Mohri, 2013), which attempts to minimize said bounds. Besides its favorable theoretical guarantees, this algorithm was shown to perform well in a number of adaptation tasks and to match or outperform several other algorithms such as KMM, KLIEP and the aforementioned two stage algorithm by Bickel et al. (2007).

One shortcoming of the DM algorithm, however, is that it seeks to reweight the loss on the training samples to minimize a quantity defined as the maximum over *all* pairs of hypotheses, including hypotheses that the learning algorithm might not ever consider as candidates. Thus, the algorithm tends to be too conservative on its choice of weights. We

present an alternative theoretically well founded algorithm for domain adaptation that is based on minimizing a finer quantity, the *generalized discrepancy*, and that seeks to improve upon DM. Unlike the DM algorithm, our algorithm does not consist of a *fixed* reweighting of the losses over the training sample. Instead, the weights assigned to training sample losses vary as a function of the hypothesis h. This helps us ensure that for every hypothesis, h, the empirical loss on the source distribution is as close as possible to the empirical loss on the target distribution for that particular h.

We describe the learning scenario considered (Section 2), then present a detailed description of our algorithm and show that it can be formulated as a convex optimization problem (Section 3). Next, we analyze the theoretical properties of our algorithm, which guide us in choosing the surrogate hypothesis set defining our algorithm (Section 4). In Section 5, we further analyze the optimization problem defining our algorithm and derive an equivalent form that can be handled by a standard convex optimization solver. In Section 6, we report the results of experiments demonstrating that our algorithm improves upon the DM algorithm in several tasks.

2. Learning Scenario

This section defines the learning scenario of domain adaptation we consider, which coincides with that of Ben-David et al. (2006) or Mansour et al. (2009); Cortes and Mohri (2013). We first introduce the definitions and concepts needed for the following sections. For the most part, we follow the definitions and notation of Cortes and Mohri (2013).

Let $\mathcal{X}$ denote the input space and $\mathcal{Y} \subseteq \mathbb{R}$ the output space. We define a *domain* as a pair formed by a distribution over $\mathcal{X}$ and a target labeling function mapping from $\mathcal{X}$ to $\mathcal{Y}$. Throughout the paper, (Q, f_Q) denotes the *source domain* and (P, f_P) the *target domain* with Q the source and P the target distribution over $\mathcal{X}$ and with $f_Q, f_P \colon \mathcal{X} \to \mathcal{Y}$ the source and target labeling functions, respectively.

In the scenario of *domain adaptation* we consider, the learner receives two samples: a labeled sample of m points from the source domain $\mathcal{S} = ((x_1, y_1), \ldots, (x_m, y_m)) \in (\mathcal{X} \times \mathcal{Y})^m$ with $x_1, \ldots, x_m$ drawn i.i.d. according to Q and $y_i = f_Q(x_i)$ for $i \in [1, m]$; and an unlabeled sample $\mathcal{T} = (x'_1, \ldots, x'_n) \in \mathcal{X}^n$ of size n drawn i.i.d. according to the target distribution P. We denote by $\widehat{Q}$ the empirical distribution corresponding to the (unlabeled) sample $\mathcal{S}_{\mathcal{X}} = (x_1, \ldots, x_m)$ and by $\widehat{P}$ the empirical distribution corresponding to $\mathcal{T}$. We will be in fact more interested in the scenario commonly encountered in practice where, in addition to these two samples, the learner receives a small amount of labeled data $\mathcal{T}' = ((x''_1, y''_1), \ldots, (x''_s, y''_s)) \in (\mathcal{X} \times \mathcal{Y})^s$ from the target domain.

We consider a loss function $L \colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}_+$ jointly convex in its two arguments. The L_p losses commonly used in regression and defined by $L_p(y, y') = |y' - y|^p$ for $p \geq 1$ are special instances of this definition. For any two functions $h, h' \colon \mathcal{X} \to \mathcal{Y}$ and any distribution D over $\mathcal{X}$, we denote by $\mathcal{L}_D(h, h')$ the expected loss of $h(x)$ and $h'(x)$: $\mathcal{L}_D(h, h') = \mathrm{E}_{x \sim D}[L(h(x), h'(x))]$. The learning problem consists of selecting a hypothesis h out of a hypothesis set H with a small expected loss $\mathcal{L}_P(h, f_P)$ with respect to the target domain. We further extend this notation to arbitrary functions $\mathsf{q} \colon \mathcal{X} \to \mathbb{R}$ with a finite support as follows: $\mathcal{L}_{\mathsf{q}}(h, h') = \sum_{x \in \mathcal{X}} q(x) L(h(x), h'(x))$.

$\mathcal{X}$	Input space	$\mathcal{Y}$	Output space
P	Target distribution	Q	Source distribution
$\widehat{P}$	Empirical target distribution	$\widehat{Q}$	Empirical source distribution
$\mathcal{T}$	Target unlabeled sample	$\mathcal{S}$	Labeled source sample
$\mathcal{T}'$	Small target labeled sample	$\mathcal{S}_{\mathcal{X}}$	Unlabeled source sample
f_P	Target labeling function	f_Q	Source labeling function
$\mathcal{L}_P(h, f_P)$	Expected target loss	$\mathcal{L}_Q(h, f_Q)$	Expected source loss
$\mathcal{L}_{\widehat{P}}(h, f_P)$	Empirical target loss	$\mathcal{L}_{\widehat{Q}}(h, f_Q)$	Empirical source loss
$\mathrm{disc}(P,Q)$	Discrepancy	$\mathrm{DISC}(\widehat{P},\mathrm{U})$	Generalized discrepancy
$\mathrm{disc}_{H''}(P,Q)$	Local Discrepancy	$\mathrm{disc}_{\mathcal{Y}}(P,Q)$	$\mathcal{Y}$-discrepancy
$\mathsf{q}_{\min}$	DM solution	Q_h	GDM solution

Table 1: Notation table.

3. Algorithm

In this section, we describe our new adaptation algorithm. We first review some related previous work. Next, we present the key idea behind our algorithm and derive its general form, and finally, formulate it as a convex optimization problem.

3.1. Previous Work

It was shown by Mansour et al. (2009) and Cortes and Mohri (2011) (see also the $d_{\mathcal{A}}$-*distance* (Ben-David et al., 2006) in the case of binary loss for classification) that a key measure of the difference of two distributions in the context of adaptation is the *discrepancy*. Given a hypothesis set H, the discrepancy, disc, between two distributions P and Q over $\mathcal{X}$ is defined by:

$$\mathrm{disc}(P, Q) = \max_{h, h' \in H} \left| \mathcal{L}_P(h', h) - \mathcal{L}_Q(h', h) \right|. \tag{1}$$

The discrepancy has several advantages over other common divergence measures such as the L_1 distance. We refer the reader to (Medina, 2015) for a detailed discussion on this subject. Several generalization bounds for adaptation in terms of the discrepancy have been given in the past (Ben-David et al., 2006; Mansour et al., 2009; Cortes and Mohri, 2011, 2013). including pointwise guarantees in the case of kernel-based regularization algorithms, which includes algorithms such as support vector machines (SVM), kernel ridge regression, or support vector regression (SVR). The bounds given in (Mansour et al., 2009) motivated a *discrepancy minimization* algorithm. Given a positive semi-definite (PSD) kernel K, the hypothesis returned by the algorithm is the solution of the following optimization problem

$$\min_{h \in \mathbb{H}} \quad \lambda \|h\|_K^2 + \mathcal{L}_{\mathsf{q}_{\min}}(h, f_Q), \tag{2}$$

where $\|\cdot\|_K$ is the norm in the reproducing Hilbert space $\mathbb{H}$ induced by the kernel K and $\mathsf{q}_{\min}$ is a distribution over the support of $\widehat{Q}$ such that $\mathsf{q}_{\min} = \mathrm{argmin}_{\mathsf{q} \in \mathcal{Q}} \mathrm{disc}(\mathsf{q}, \widehat{P})$, where $\mathcal{Q} = [0, 1]^{\mathcal{S}_{\mathcal{X}}}$ is the set of all distributions defined over the support of $\widehat{Q}$. Besides its theoretical motivation, this algorithm has been shown to outperform several other algorithms in a series of experiments carried out by Cortes and Mohri (2013).

Observe that, by definition, the objective function optimized by $\mathsf{q}_{\min}$ corresponds to a maximum over all pairs of hypotheses. But, the maximizing pair of hypotheses may not be among the candidates ever considered by the learning algorithm. Thus, a learning algorithm based on discrepancy minimization tends to be too conservative.

3.2. Main Idea

From here on we assume the algorithm selected by the learner is an instance of a regularized risk minimization algorithm over the Hilbert space $\mathbb{H}$ induced by a PSD kernel K. With knowledge of the target labels, these algorithms return a hypothesis h^* solution of $\min_{h\in\mathbb{H}} F(h)$ where

$$F(h) = \lambda\|h\|_K^2 + \mathcal{L}_{\widehat{P}}(h, f_P), \tag{3}$$

where $\lambda \geq 0$ is a regularization parameter. Thus, h^* can be viewed as the *ideal hypothesis*.

In view of that, we can formulate our objective, in the *presence* of a domain adaptation problem, as that of finding a hypothesis h whose loss $\mathcal{L}_P(h, f_P)$ with respect to the target domain is as close as possible to $\mathcal{L}_P(h^*, f_P)$. To do so, we will seek in fact a hypothesis h that is as close as possible to h^*, which would imply the closeness of the losses with respect to the target domains. We do not have access to f_P and can only access the labels of the training sample $\mathcal{S}$. Thus, we must resort to using in our objective function, instead of $\mathcal{L}_{\widehat{P}}(h, f_P)$, a reweighted empirical loss over the training sample $\mathcal{S}$. The main idea behind our algorithm is to define, for any $h \in \mathbb{H}$, a reweighting function $\mathsf{Q}_h \colon \mathcal{S}_{\mathcal{X}} = \{x_1, \ldots, x_m\} \to \mathbb{R}$ such that the objective function G defined for all $h \in \mathbb{H}$ by

$$G(h) = \lambda\|h\|_K^2 + \mathcal{L}_{\mathsf{Q}_h}(h, f_Q) \tag{4}$$

is uniformly close to F, thereby resulting in close minimizers. Since the first term of (3) and (4) coincide, the idea consists equivalently of seeking Q_h such that $\mathcal{L}_{\mathsf{Q}_h}(h, f_Q)$ and $\mathcal{L}_{\widehat{P}}(h, f_P)$ be as close as possible. Observe that this departs from the standard reweighting methods: instead of reweighting the training sample with some fixed set of weights, we allow the weights to vary as a function of the hypothesis h. Note that we have further relaxed the condition commonly adopted by reweighting techniques that the weights must be non-negative and sum to one.

Of course, searching for Q_h to directly minimize $|\mathcal{L}_{\mathsf{Q}_h}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, f_P)|$ is in general not possible since we do not have access to f_P, but it is instructive to consider the imaginary case where the average loss $\mathcal{L}_{\widehat{P}}(h, f_P)$ is known to us for any $h \in \mathbb{H}$. Q_h could then be determined via

$$\mathsf{Q}_h = \operatorname*{argmin}_{\mathsf{q}\in\mathcal{F}(\mathcal{S}_{\mathcal{X}},\mathbb{R})} |\mathcal{L}_{\mathsf{q}}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, f_P)|, \tag{5}$$

where $\mathcal{F}(\mathcal{S}_{\mathcal{X}}, \mathbb{R})$ is the set of real-valued functions defined over $\mathcal{S}_{\mathcal{X}}$. For any h, we can in fact select Q_h such that $\mathcal{L}_{\mathsf{Q}_h}(h, f_Q) = \mathcal{L}_{\widehat{P}}(h, f_P)$ since $\mathcal{L}_{\mathsf{q}}(h, f_Q)$ is a linear function of q. Thus, the optimization problem (5) reduces to solving a simple linear equation. With this choice of Q_h, the objective functions F and G coincide and by minimizing G we can recover the ideal solution h^*. Note that, in general, the DM algorithm could not recover that ideal solution. Even a finer discrepancy minimization algorithm exploiting the knowledge of $\mathcal{L}_{\widehat{P}}(h, f_P)$ for all h and seeking a distribution $\mathsf{q}'_{\min}$ minimizing $\max_{h\in H} |\mathcal{L}_{\mathsf{q}}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, f_P)|$ could not,

in general, recover the ideal solution since we could not have $\mathcal{L}_{\mathsf{q}'_{\min}}(h, f_Q) = \mathcal{L}_{\widehat{P}}(h, f_P)$ for all $h \in \mathbb{H}$.

Of course, $\mathcal{L}_{\widehat{P}}(h, f_P)$ is not accessible since the sample $\mathcal{T}$ is unlabeled. Instead, we will consider a non-empty convex set of candidate hypotheses $H'' \subseteq H$ that could contain a good approximation of f_P. Using H'' as a set of surrogate labeling functions leads to the following definition of Q_h instead of (5):

$$\mathsf{Q}_h = \operatorname*{argmin}_{\mathsf{q}\in\mathcal{F}(\mathcal{S}_{\mathcal{X}},\mathbb{R})} \max_{h''\in H''} |\mathcal{L}_{\mathsf{q}}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, h'')|. \tag{6}$$

The choice of the subset H'' is of course key. Our choice will be based on the theoretical analysis of Section 4. Nevertheless, we now present the formulation of the optimization problem for an arbitrary choice of the convex subset H''.

Proposition 1 *For any $h \in \mathbb{H}$, let Q_h be defined by* (6)*. Then, the following identity holds for any $h \in \mathbb{H}$:*

$$\mathcal{L}_{\mathsf{Q}_h}(h, f_Q) = \frac{1}{2}\Big(\max_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'') + \min_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'')\Big).$$

Proof For any $h \in \mathbb{H}$, the equation $\mathcal{L}_{\mathsf{q}}(h, f_Q) = l$ with $l \in \mathbb{R}$ admits a solution $\mathsf{q} \in \mathcal{F}(\mathcal{S}_{\mathcal{X}}, \mathbb{R})$. Thus, $\{\mathcal{L}_{\mathsf{q}}(h, f_Q) : \mathsf{q} \in \mathcal{F}(\mathcal{S}_{\mathcal{X}}, \mathbb{R})\} = \mathbb{R}$ and for any $h \in \mathbb{H}$, we can write

$$\begin{aligned}
\mathcal{L}_{\mathsf{Q}_h}(h, f_Q) &= \operatorname*{argmin}_{l\in\{\mathcal{L}_{\mathsf{q}}(h,f_Q):\, \mathsf{q}\in\mathcal{F}(\mathcal{S}_{\mathcal{X}},\mathbb{R})\}} \max_{h''\in H''} |l - \mathcal{L}_{\widehat{P}}(h, h'')| \\
&= \operatorname*{argmin}_{l\in\mathbb{R}} \max_{h''\in H''} |l - \mathcal{L}_{\widehat{P}}(h, h'')| \\
&= \operatorname*{argmin}_{l\in\mathbb{R}} \max_{h''\in H''} \max\Big\{\mathcal{L}_{\widehat{P}}(h, h'') - l, l - \mathcal{L}_{\widehat{P}}(h, h'')\Big\} \\
&= \operatorname*{argmin}_{l\in\mathbb{R}} \max\Big\{\max_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'') - l, l - \min_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'')\Big\} \\
&= \frac{1}{2}\Big(\max_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'') + \min_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'')\Big),
\end{aligned}$$

since the minimizing l is obtained for $\max_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'') - l = l - \min_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'')$. ■

In view of this proposition, with our choice of Q_h based on (6), the objective function G of our algorithm (4) can be equivalently written for all $h \in \mathbb{H}$ as follows:

$$G(h) = \lambda\|h\|_K^2 + \frac{1}{2}\Big(\max_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'') + \min_{h''\in H''} \mathcal{L}_{\widehat{P}}(h, h'')\Big). \tag{7}$$

Using the fact the $\mathcal{L}_{\widehat{P}}$ is a jointly convex function, it is easy to show (see for instance Boyd and Vandenberghe, 2004) that G is in fact a convex function too.

4. Learning Guarantees

Here, we present two different types of guarantees: a tight learning bound based on the Rademacher complexity and a pointwise bound derived from a stability analysis. We further show that our algorithm is in fact minimizing this pointwise bound. As in previous work, we assume that the loss function L is μ-*admissible*.

Definition 2 *A loss function L is μ-admissible if there exists $\mu > 0$ such that the inequality*

$$|L(h(x), y) - L(h'(x), y)| \leq \mu |h(x) - h'(x)| \tag{8}$$

holds for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$ and $h', h \in H$.

The L_p losses commonly used in regression, $p \geq 1$, verify this condition (see Appendix C).

4.1. Rademacher Complexity Bounds

Definition 3 *Let $\mathcal{Z}$ be any set and G be a family of functions mapping $\mathcal{Z}$ to $\mathbb{R}$. Given a sample $\mathcal{S} = \{z_1, \ldots, z_n\} \subset \mathcal{Z}$, the empirical Rademacher complexity of G is denoted by $\widehat{\mathfrak{R}}_{\mathcal{S}}(G)$ and defined by*

$$\widehat{\mathfrak{R}}_{\mathcal{S}}(G) = \frac{1}{n} \mathop{\mathrm{E}}_{\sigma} \left[\sup_{g \in G} \sum_{i=1}^{n} \sigma_i g(z_i) \right],$$

where σ_is, called Rademacher variables, are independent random variables distributed according to the uniform distribution over $\{-1, 1\}$. The Rademacher complexity of G is defined as

$$\mathfrak{R}_n(G) = \mathop{\mathrm{E}}_{\mathcal{S}} \left[\widehat{\mathfrak{R}}_{\mathcal{S}}(G) \right].$$

Our first generalization bound is given in terms of the $\mathcal{Y}$-*discrepancy*, which is a generalization of the discrepancy distance. The $\mathcal{Y}$-discrepancy was first introduced by Mohri and Muñoz (2012) in the context of learning with drifting distributions.

Definition 4 *The $\mathcal{Y}$-discrepancy between two domains (P, f_P) and (Q, f_Q) is defined by*

$$\mathrm{disc}_{\mathcal{Y}}(P, Q) = \sup_{h \in H} \left| \mathcal{L}_Q(h, f_Q) - \mathcal{L}_P(h, f_P) \right|.$$

Note that the definition depends on the labeling functions f_P and f_Q. We do not explicitly indicate that dependency for the sake of simplicity of the notation.

We follow the analysis of (Mohri and Muñoz, 2012) to derive the following tight generalization bounds based on the notion of $\mathcal{Y}$-discrepancy.

Proposition 5 *Let $\mathcal{H}_Q$ and $\mathcal{H}_P$ be the families of functions defined as follows: $\mathcal{H}_Q := \{x \mapsto L(h(x), f_Q(x)) \colon h \in H\}$ and $\mathcal{H}_P := \{x \mapsto L(h(x), f_P(x)) \colon h \in H\}$. Define M_Q and M_P as $M_Q = \sup_{x \in \mathcal{X}, h \in H} L(h(x), f_Q(x))$ and $M_P = \sup_{x \in \mathcal{X}, h \in H} L(h(x), f_P(x))$. Then, for any $\delta > 0$,*

1. *with probability at least $1 - \delta$ over the choice of a labeled sample $\mathcal{S}$ of size m, the following inequality holds for all $h \in H$:*

$$\mathcal{L}_P(h, f_P) \leq \mathcal{L}_{\widehat{Q}}(h, f_Q) + \mathrm{disc}_{\mathcal{Y}}(P, Q) + 2\mathfrak{R}_m(\mathcal{H}_Q) + M_Q \sqrt{\frac{\log(\frac{1}{\delta})}{2m}}; \tag{9}$$

2. *with probability at least $1 - \delta$ over the choice of a sample $\mathcal{T}$ of size n, the following inequality holds for all $h \in H$ and any distribution q over a sample $\mathcal{S}_{\mathcal{X}}$:*

$$\mathcal{L}_P(h, f_P) \leq \mathcal{L}_{\mathsf{q}}(h, f_Q) + \mathrm{disc}_{\mathcal{Y}}(\widehat{P}, \mathsf{q}) + 2\mathfrak{R}_n(\mathcal{H}_P) + M_P \sqrt{\frac{\log(\frac{1}{\delta})}{2n}}. \tag{10}$$

Proof Let $\Phi(\mathcal{S})$ denote $\sup_{h \in H} \mathcal{L}_{\widehat{Q}}(h, f_Q) - \mathcal{L}_P(h, f_P)$. Changing one point in $\mathcal{S}$ changes $\Phi(\mathcal{S})$ by at most $\frac{M_Q}{m}$. Thus, by McDiarmid's inequality, we have $\mathbb{P}\big(\Phi(\mathcal{S}) - \mathrm{E}[\Phi(\mathcal{S})] > \epsilon\big) \leq e^{-\frac{2m\epsilon^2}{M_Q^2}}$. Therefore, for any $\delta > 0$, with probability at least $1 - \delta$, the following holds for all $h \in H$:

$$\mathcal{L}_P(h, f_P) \leq \mathcal{L}_{\widehat{Q}}(h, f_Q) + \mathrm{E}[\Phi(\mathcal{S})] + M_Q \sqrt{\frac{\log(\frac{1}{\delta})}{2m}}.$$

Next, we can bound $\mathrm{E}[\Phi(\mathcal{S})]$ as follows:

$$\begin{aligned}
\mathrm{E}[\Phi(\mathcal{S})] &= \mathrm{E}\left[\sup_{h \in H} \mathcal{L}_{\widehat{Q}}(h, f_Q) - \mathcal{L}_P(h, f_P) \right] \\
&\leq \mathrm{E}\left[\sup_{h \in H} \mathcal{L}_{\widehat{Q}}(h, f_Q) - \mathcal{L}_Q(h, f_Q) \right] + \sup_{h \in H} \mathcal{L}_Q(h, f_Q) - \mathcal{L}_P(h, f_P) \\
&\leq 2\mathfrak{R}_m(\mathcal{H}_Q) + \mathrm{disc}_{\mathcal{Y}}(P, Q),
\end{aligned}$$

where the last inequality follows from a standard symmetrization inequality in terms of the Rademacher complexity and the definition of $\mathrm{disc}_{\mathcal{Y}}(P, Q)$.

For the second bound we have, starting with a standard Rademacher complexity bound for $\mathcal{H}_P$, for any $\delta > 0$, with probability at least $1 - \delta$, the following holds for all $h \in H$:

$$\begin{aligned}
\mathcal{L}_P(h, f_P) &\leq \mathcal{L}_{\widehat{P}}(h, f_P) + 2\mathfrak{R}_n(\mathcal{H}_P) + M_P \sqrt{\frac{\log(\frac{1}{\delta})}{2n}} \\
&\leq \mathcal{L}_{\mathsf{q}}(h, f_Q) + \mathcal{L}_{\widehat{P}}(h, f_P) - \mathcal{L}_{\mathsf{q}}(h, f_Q) + 2\mathfrak{R}_n(\mathcal{H}_P) + M_P \sqrt{\frac{\log(\frac{1}{\delta})}{2n}}.
\end{aligned} \tag{11}$$

Moreover, by definition $\mathcal{L}_{\widehat{P}}(h, f_P) - \mathcal{L}_{\mathsf{q}}(h, f_Q) \leq \mathrm{disc}_{\mathcal{Y}}(\widehat{P}, \mathsf{q})$ for any q. Replacing this bound in (11) yields the result. ■

Observe that these bounds are tight as a function of the divergence measure (discrepancy) we use: in the absence of adaptation, the following standard Rademacher complexity learning bound holds:

$$\mathcal{L}_{\widehat{P}}(h, f_P) \leq \mathcal{L}_{\widehat{P}}(h, f_P) + 2\mathfrak{R}_n(\mathcal{H}_P) + M_P \sqrt{\frac{\log(\frac{1}{\delta})}{2n}}.$$

Our second adaptation bound differs from this inequality only by the fact that $\mathcal{L}_{\widehat{P}}(h, f_P)$ is replaced with $\mathcal{L}_{\mathsf{q}}(h, f_Q) + \mathrm{disc}_{\mathcal{Y}}(\widehat{P}, \mathsf{q})$. But, by definition of $\mathcal{Y}$-discrepancy, there exists an $h \in H$ such that $|\mathcal{L}_{\widehat{P}}(h, f_P) - \mathcal{L}_{\mathsf{q}}(h, f_Q)| = \mathrm{disc}_{\mathcal{Y}}(\widehat{P}, \mathsf{q})$. A similar analysis shows that our first bound is also tight.

Given a labeled sample $\mathcal{S}$ from the source domain, Proposition 5 suggests choosing a distribution q with support $\mathcal{S}_{\mathcal{X}}$ that minimizes the right-hand side of (10). However, the quantity $\mathrm{disc}_{\mathcal{Y}}(\widehat{P}, \mathsf{q})$ depends, by definition, on the unknown labels from the target domain and therefore cannot be minimized. Thus, we will instead upper bound the $\mathcal{Y}$-discrepancy in terms of quantities that can be estimated.

Let $\mathcal{A}(H)$ denote the set of all functions $\mathsf{U}\colon h \mapsto \mathsf{U}_h$ mapping H to $\mathcal{F}(\mathcal{S}_\mathcal{X}, \mathbb{R})$ such that for all $h \in H$, $h \mapsto \mathcal{L}_{\mathsf{U}_h}(h, f_Q)$ is a convex function. Thus, for any $h \in H$, U_h is a reweighting function defined over $\mathcal{S}_\mathcal{X}$. $\mathcal{A}(H)$ contains all constant functions U such that $\mathsf{U}_h = \mathsf{q}$ for all $h \in H$, where q is a distribution over $\mathcal{S}_\mathcal{X}$. We will abuse the notation and denote this functions also by q. By Proposition 1, $\mathcal{A}(H)$ also includes the function $\mathsf{Q}\colon h \to \mathsf{Q}_h$ used by our algorithm.

Definition 6 (Generalized discrepancy) *For any $\mathsf{U} \in \mathcal{A}(H)$, the* generalized discrepancy between $\widehat{P}$ and U *is denoted by* $\mathrm{DISC}(\widehat{P}, \mathsf{U})$ *and is defined by*

$$\mathrm{DISC}(\widehat{P}, \mathsf{U}) = \sup_{h \in H, h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)|. \tag{12}$$

We also denote by $d_1(f_P, H'')$ the L_1 distance of f_P to H'':

$$d_1(f_P, H'') = \min_{h_0 \in H''} \mathop{\mathrm{E}}_{\widehat{P}} |h_0(x) - f_P(x)|. \tag{13}$$

The following theorem gives an upper bound on the $\mathcal{Y}$-discrepancy in terms of the generalized discrepancy and $d_1(f_P, H'')$.

Proposition 7 *For any distribution q over $\mathcal{S}_\mathcal{X}$ and any set H'', the following inequality holds:*

$$\mathrm{disc}_\mathcal{Y}(\widehat{P}, \mathsf{q}) \leq \mathrm{DISC}(\widehat{P}, \mathsf{q}) + \mu\, d_1(f_P, H'').$$

Proof Let $h_0 \in H''$, by the triangle inequality, we can write

$$\begin{aligned}
\mathrm{disc}_\mathcal{Y}(\widehat{P}, \mathsf{q}) &= \sup_{h \in H} |\mathcal{L}_\mathsf{q}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, f_P)| \\
&\leq \sup_{h \in H} |\mathcal{L}_\mathsf{q}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, h_0)| + \sup_{h \in H} |\mathcal{L}_{\widehat{P}}(h, h_0) - \mathcal{L}_{\widehat{P}}(h, f_P)| \\
&\leq \sup_{h \in H} \max_{h'' \in H''} |\mathcal{L}_\mathsf{q}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, h'')| + \sup_{h \in H} |\mathcal{L}_{\widehat{P}}(h, h_0) - \mathcal{L}_{\widehat{P}}(h, f_P)|.
\end{aligned}$$

The hypothesis h_0 will later be chosen to minimize the distance of f_P to H''. By the μ-admissibility of the loss, the last term can be bounded as follows:

$$\sup_{h \in H} |\mathcal{L}_{\widehat{P}}(h, h_0) - \mathcal{L}_{\widehat{P}}(h, f_P)| \leq \mu \mathop{\mathrm{E}}_{\widehat{P}} |f_P(x) - h_0(x)|.$$

Using this inequality and minimizing over $h_0 \in H''$ yields:

$$\begin{aligned}
\mathrm{disc}_\mathcal{Y}(\widehat{P}, \mathsf{q}) &\leq \sup_{h \in H} \max_{h'' \in H''} |\mathcal{L}_\mathsf{q}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, h'')| + \mu\, d_1(f_P, H'') \\
&= \mathrm{DISC}(\widehat{P}, \mathsf{q}) + \mu\, d_1(f_P, H''),
\end{aligned}$$

which completes the proof. ■

We can also bound the $\mathcal{Y}$-discrepancy in terms of the discrepancy measure and the following measure of the difference of the source and target labeling functions:

$$\eta_H(f_P, f_Q) = \min_{h_0 \in H} \Big(\max_{x \in \mathrm{supp}(\widehat{P})} |f_P(x) - h_0(x)| + \max_{x \in \mathrm{supp}(\widehat{Q})} |f_Q(x) - h_0(x)| \Big).$$

Proposition 8 *The following inequality holds for all distributions q over $\mathcal{S}_\mathcal{X}$:*

$$\mathrm{disc}_\mathcal{Y}(\widehat{P}, \mathsf{q}) \leq \mathrm{disc}(\widehat{P}, \mathsf{q}) + \mu\, \eta_H(f_P, f_Q).$$

Proof By the triangle inequality and the μ-admissibility of the loss, the following inequality holds for all $h_0 \in H$:

$$\begin{aligned}
&\mathrm{disc}_\mathcal{Y}(\widehat{P}, \mathsf{q}) \\
&= \sup_{h \in H} |\mathcal{L}_\mathsf{q}(h, f_Q) - \mathcal{L}_{\widehat{P}}(h, f_P)| \\
&\leq \sup_{h \in H} \Big(|\mathcal{L}_{\widehat{P}}(h, h_0) - \mathcal{L}_{\widehat{P}}(h, f_P)| + |\mathcal{L}_\mathsf{q}(h, f_Q) - \mathcal{L}_\mathsf{q}(h, h_0)| \Big) + \sup_{h \in H} |\mathcal{L}_\mathsf{q}(h, h_0) - \mathcal{L}_{\widehat{P}}(h, h_0)| \\
&\leq \mu \Big(\sup_{x \in \mathrm{supp}(\widehat{P})} |h_0(x) - f_P(x)|] + \sup_{x \in \mathrm{supp}(\widehat{Q})} [|f_Q(x) - h_0(x)|] \Big) + \mathrm{disc}(\widehat{P}, \mathsf{q}).
\end{aligned}$$

Minimizing over all $h_0 \in H$ gives $\mathrm{disc}_\mathcal{Y}(\widehat{P}, \mathsf{q}) \leq \mu\, \eta_H(f_P, f_Q) + \mathrm{disc}(\widehat{P}, \mathsf{q})$ and completes the proof. ■

The following learning guarantees are immediate consequences of Propositions 5, 7 and 8.

Corollary 9 *Let $H'' \subset H$ be a convex set and q a distribution over $\mathcal{S}_\mathcal{X}$. Then, for any $\delta > 0$, each of the following inequalities holds with probability at least $1 - \delta$ for all $h \in H$:*

$$\mathcal{L}_P(h, f_P) \leq \mathcal{L}_\mathsf{q}(h, f_Q) + \mathrm{DISC}(\widehat{P}, \mathsf{q}) + \mu\, d_1(f_P, H'') + 2\mathfrak{R}_n(\mathcal{H}_P) + M_P \sqrt{\frac{\log(\frac{1}{\delta})}{2n}}, \tag{14}$$

$$\mathcal{L}_P(h, f_P) \leq \mathcal{L}_\mathsf{q}(h, f_Q) + \mathrm{disc}(\widehat{P}, \mathsf{q}) + \mu\, \eta_H(f_P, f_Q) + 2\mathfrak{R}_n(\mathcal{H}_P) + M_P \sqrt{\frac{\log(\frac{1}{\delta})}{2n}}. \tag{15}$$

In general, the bounds (14) and (15) are not comparable. However, when L is an L_P loss for some $p \geq 1$, we can show the existence of a set H'' for which (14) is a tighter bound than (15). The result is expressed in terms of the *local discrepancy* defined by:

$$\mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) = \sup_{h \in H, h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_\mathsf{q}(h, h'')|,$$

which is a finer measure than the standard discrepancy for which the supremum is defined over a pair of hypotheses *both* in $H \supseteq H''$.

Theorem 10 *Let L be the L_P loss for some $p \geq 1$. Let $\mathcal{H} := \{B(r)\colon r \geq 0\}$ be a set of all balls $B(r) = \{h'' \in H | \mathcal{L}_\mathsf{q}(h'', f_Q) \leq r^p\}$. Then, for any distribution q over $\mathcal{S}_\mathcal{X}$, there exists $H'' \in \mathcal{H}$ such that the following holds:*

$$\mathrm{DISC}(\widehat{P}, \mathsf{q}) + \mu\, d_1(f_P, H'') \leq \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) + \mu\, \eta_H(f_P, f_Q).$$

Proof Fix a distribution q over $\mathcal{S}_{\mathcal{X}}$. Let h_0^* be an element of $\operatorname{argmin}_{h_0 \in H} \left(\mathcal{L}_{\widehat{P}}(h_0, f_P)^{\frac{1}{p}} + \mathcal{L}_{\mathsf{q}}(h_0, f_Q)^{\frac{1}{p}}\right)$. Choose $H'' \in \mathcal{H}$ as $H'' = \{h'' \in H | \mathcal{L}_{\mathsf{q}}(h'', f_Q) \leq r^p\}$ with $r = \mathcal{L}_{\mathsf{q}}(h_0^*, f_Q)^{\frac{1}{p}}$. Then, by definition, h_0^* is in H''. For the L_p loss, it is not hard to show that for all $h, h'' \in H$, $|\mathcal{L}_{\mathsf{q}}(h, h'') - \mathcal{L}_{\mathsf{q}}(h, f_Q)| \leq \mu[\mathcal{L}_{\mathsf{q}}(h'', f_Q)]^{\frac{1}{p}}$ (see Appendix C). In view of this inequality, we can write:

$$\begin{aligned}
\mathrm{DISC}(\widehat{P}, \mathsf{q}) &= \sup_{h \in H, h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{q}}(h, f_Q)| \\
&\leq \sup_{h \in H, h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{q}}(h, h'')| + \sup_{h \in H, h'' \in H''} |\mathcal{L}_{\mathsf{q}}(h, h'') - \mathcal{L}_{\mathsf{q}}(h, f_Q)| \\
&\leq \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) + \max_{h'' \in H''} \mu[\mathcal{L}_{\mathsf{q}}(h'', f_Q)]^{\frac{1}{p}} \\
&= \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) + \mu r = \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) + \mu \mathcal{L}_{\mathsf{q}}(h_0^*, f_Q)^{\frac{1}{p}}.
\end{aligned}$$

Using this inequality, Jensen's inequality, and the fact that h_0^* is in H'', we can write

$$\begin{aligned}
&\mu\, d_1(f_P, H'') + \mathrm{DISC}(\widehat{P}, \mathsf{q}) \\
&\leq \mu \min_{h_0 \in H''} \mathop{\mathrm{E}}_{x \in \widehat{P}}[|f_P(x) - h_0(x)|] + \mu \mathcal{L}_{\mathsf{q}}(h_0^*, f_Q)^{\frac{1}{p}} + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) \\
&\leq \mu \min_{h_0 \in H''} \mathop{\mathrm{E}}_{x \in \widehat{P}}[|f_P(x) - h_0(x)|^p]^{\frac{1}{p}} + \mu \mathcal{L}_{\mathsf{q}}(h_0^*, f_Q)^{\frac{1}{p}} + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) \\
&\leq \mu\, \mathcal{L}_{\widehat{P}}(h_0^*, f_P)^{\frac{1}{p}} + \mu \mathcal{L}_{\mathsf{q}}(h_0^*, f_Q)^{\frac{1}{p}} + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}).
\end{aligned}$$

Moreover, by definition of h_0^* the last expression is equal to

$$\begin{aligned}
&\mu \min_{h_0 \in H} \left(\mathcal{L}_{\widehat{P}}(h_0, f_P)^{\frac{1}{p}} + \mathcal{L}_{\mathsf{q}}(h_0, f_Q)^{\frac{1}{p}}\right) + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) \\
&\quad \leq \mu \min_{h_0 \in H} \Big(\max_{x \in \mathrm{supp}(\widehat{P})} |f_P(x) - h_0(x)| + \max_{x \in \mathrm{supp}(\widehat{Q})} |f_Q(x) - h_0(x)| \Big) + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) \\
&\quad = \mu\, \eta_H(f_P, f_Q) + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}).
\end{aligned}$$

which concludes the proof. ■

Theorem 10 shows that the generalized discrepancy can provide a finer measure of the difference between two domains for some choices of H''. Therefore, for a good choice of H'', an algorithm minimizing the right-hand side of (14) would benefit from better theoretical guarantees than the DM algorithm. However, the optimization problem defined by (14) is not jointly convex in q and h. Instead, we propose to first minimize the generalized discrepancy and then use this reweighting function as input to our learning algorithm. Further motivation for this two-stage algorithm is given in the following section.

4.2. Pointwise Guarantees

Similar to the guarantee presented by Cortes and Mohri (2013), we will seek to bound the difference between an *ideal solution* h^* and the solution obtained by our algorithm. We begin by stating the following bound motivating the DM algorithm.

Theorem 11 (Cortes and Mohri, 2013) *Let q be an arbitrary distribution over $\mathcal{S}_{\mathcal{X}}$ and let h^* and h_{q} be the hypotheses minimizing $\lambda\|h\|_K^2 + \mathcal{L}_{\widehat{P}}(h, f_P)$ and $\lambda\|h\|_K^2 + \mathcal{L}_{\mathsf{q}}(h, f_Q)$ respectively. Then, the following inequality holds:*

$$\lambda\|h^* - h_{\mathsf{q}}\|_K^2 \leq \mu\, \eta_H(f_P, f_Q) + \mathrm{disc}(\widehat{P}, \mathsf{q}). \tag{16}$$

Notice that the solution of DM minimizes the right-hand side of (16), that is $\mathrm{disc}(\widehat{P}, \mathsf{q})$. The following theorem provides an analogous bound for our algorithm.

Theorem 12 *Let U be an arbitrary element of $\mathcal{A}(H)$ and let h^* and h_{U} be the hypotheses minimizing $\lambda\|h\|_K^2 + \mathcal{L}_{\widehat{P}}(h, f_P)$ and $\lambda\|h\|_K^2 + \mathcal{L}_{\mathsf{U}_h}(h, f_Q)$ respectively. Then, the following inequality holds for any convex set $H'' \subseteq H$:*

$$\lambda\|h^* - h_{\mathsf{U}}\|_K^2 \leq \mu\, d_1(f_P, H'') + \mathrm{DISC}(\widehat{P}, \mathsf{U}). \tag{17}$$

Proof Fix $\mathsf{U} \in \mathcal{A}(H)$ and let $G_{\widehat{P}}$ denote $h \mapsto \mathcal{L}_{\widehat{P}}(h, f_P)$ and G_{U} the function $h \mapsto \mathcal{L}_{\mathsf{U}_h}(h, f_Q)$. Since $h \mapsto \lambda\|h\|_K^2 + G_{\widehat{P}}(h)$ is convex and differentiable and since h^* is its minimizer, the gradient is zero at h^*, that is $2\lambda h^* = -\nabla G_{\widehat{P}}(h^*)$. Similarly, since $h \mapsto \lambda\|h\|_K^2 + G_{\mathsf{U}}(h)$ is convex, it admits a sub-differential at any $h \in \mathbb{H}$. Since h_{U} is a minimizer, its sub-differential at h_{U} must contain 0. Thus, there exists a sub-gradient $g_0 \in \partial G_{\mathsf{U}}(h_{\mathsf{U}})$ such that $2\lambda h_{\mathsf{U}} = -g_0$, where $\partial G_{\mathsf{U}}(h_{\mathsf{U}})$ denotes the sub-differential of G_{U} at h_{U}. Using these two equalities we can write

$$\begin{aligned}
2\lambda\|h^* - h_{\mathsf{U}}\|_K^2 &= \langle h^* - h_{\mathsf{U}}, g_0 - \nabla G_{\widehat{P}}(h^*)\rangle = \langle g_0, h^* - h_{\mathsf{U}}\rangle - \langle \nabla G_{\widehat{P}}(h^*), h^* - h_{\mathsf{U}}\rangle \\
&\leq G_{\mathsf{U}}(h^*) - G_{\mathsf{U}}(h_{\mathsf{U}}) + G_{\widehat{P}}(h_{\mathsf{U}}) - G_{\widehat{P}}(h^*) \\
&= \mathcal{L}_{\widehat{P}}(h_{\mathsf{U}}, f_P) - \mathcal{L}_{\mathsf{U}_h}(h_{\mathsf{U}}, f_Q) + \mathcal{L}_{\mathsf{U}_h}(h^*, f_Q) - \mathcal{L}_{\widehat{P}}(h^*, f_P) \\
&\leq 2 \sup_{h \in H} |\mathcal{L}_{\widehat{P}}(h, f_P) - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)|,
\end{aligned}$$

where we used for the first inequality the convexity of G_{U} combined with the sub-gradient property of $g_0 \in \partial G_{\mathsf{U}}(h_{\mathsf{U}})$, and the convexity of $G_{\widehat{P}}$. For any $h \in H$, using the μ-admissibility of the loss, we can upper bound the operand of the max operator as follows:

$$\begin{aligned}
|\mathcal{L}_{\widehat{P}}(h, f_P) - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)| &\leq |\mathcal{L}_{\widehat{P}}(h, f_P) - \mathcal{L}_{\widehat{P}}(h, h_0)| + |\mathcal{L}_{\widehat{P}}(h, h_0) - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)| \\
&\leq \mu \mathop{\mathrm{E}}_{x \sim \widehat{P}} |f_P(x) - h_0(x)| + \max_{h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)|,
\end{aligned}$$

where h_0 is an arbitrary element of H''. Since this bound holds for all $h_0 \in H''$, it follows immediately that

$$\lambda\|h^* - h_{\mathsf{U}}\|_K^2 \leq \mu \min_{h_0 \in H''} \mathop{\mathrm{E}}_{\widehat{P}} |f_P(x) - h_0(x)| + \sup_{h \in H} \max_{h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)|,$$

which concludes the proof. ■

Note that our choice of $\mathsf{Q}\colon h \mapsto \mathsf{Q}_h$ minimizes the right-hand side of (17) among all functions $\mathsf{U} \in \mathcal{A}(H)$ since, for any U, we can write

$$\begin{aligned}
\mathrm{DISC}(\widehat{P}, \mathsf{U}) &= \sup_{h \in H} \max_{h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{U}_h}(h, f_Q)| \geq \sup_{h \in H} \min_{\mathsf{q} \in \mathcal{F}(\mathcal{S}_{\mathcal{X}})} \max_{h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{q}}(h, f_Q)| \\
&= \sup_{h \in H} \max_{h'' \in H''} |\mathcal{L}_{\widehat{P}}(h, h'') - \mathcal{L}_{\mathsf{Q}_h}(h, f_Q)| = \mathrm{DISC}(\widehat{P}, \mathsf{Q}).
\end{aligned}$$

Thus, in view of Theorem 10, for any constant function $\mathsf{U} \in \mathcal{A}(H)$ with $\mathsf{U}_h = \mathsf{q}$ for some fixed distribution q over $\mathcal{S}_{\mathcal{X}}$, the right-hand side of the bound of Theorem 11 is lower bounded by the right-hand side of the bound of Theorem 12, since the local discrepancy is a finer quantity than the discrepancy: $\mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}) \leq \mathrm{disc}(\widehat{P}, \mathsf{q})$. Thus, as expected from the discussion after Theorem 10, our algorithm benefits from a more favorable guarantee than the DM algorithm for some particular choices of H'', especially since, our choice of Q is based on the minimization over all elements in $\mathcal{A}(H)$ and not just the subset of constant functions mapping to a distribution. The following pointwise guarantee follows directly from Theorem 12.

Corollary 13 *Let h^* be a minimizer of $\lambda\|h\|_K^2 + \mathcal{L}_{\widehat{P}}(h, f_P)$ and h_{Q} a minimizer of $\lambda\|h\|_K^2 + \mathcal{L}_{\mathsf{Q}_h}(h, f_Q)$. Then, the following holds for any convex set $H'' \subseteq H$ and for all $(x, y) \in \mathcal{X} \times \mathcal{Y}$:*

$$|L(h_{\mathsf{Q}}(x), y) - L(h^*(x), y)| \leq \mu R \sqrt{\frac{\mu\, d_1(f_P, H'') + \mathrm{DISC}(\widehat{P}, \mathsf{Q})}{\lambda}}, \tag{18}$$

where $R^2 = \sup_{x \in \mathcal{X}} K(x, x)$.

Proof By the μ-admissibility of the loss, the reproducing property of $\mathbb{H}$, and the Cauchy-Schwarz inequality, the following holds for all $x \in \mathcal{X}$ and $y \in \mathcal{Y}$:

$$\begin{aligned}
|L(h_{\mathsf{Q}}(x), y) - L(h^*(x), y)| &\leq \mu |h_{\mathsf{Q}}(x) - h^*(x)| \\
&= \mu |\langle h_{\mathsf{Q}} - h^*, K(x, \cdot)\rangle_K| \\
&\leq \mu \|h_{\mathsf{Q}} - h^*\|_K \sqrt{K(x, x)} \leq R \|h_{\mathsf{Q}} - h^*\|_K.
\end{aligned}$$

Upper bounding $\|h_{\mathsf{Q}} - h^*\|_K$ using Theorem 12 and using the fact that $\mathsf{Q} \colon h \to \mathsf{Q}_h$ is a minimizer of the bound over all choices of $\mathsf{U} \in \mathcal{A}(H)$ yields the desired result. ■

The pointwise loss guarantee just presented can be directly used to bound the difference of the expected loss of h^* and h_{Q} in terms of the same upper bounds, e.g.,

$$\mathcal{L}_P(h_{\mathsf{Q}}, f_P) \leq \mathcal{L}_P(h^*, f_P) + \mu R \sqrt{\frac{\mu\, d_1(f_P, H'') + \mathrm{DISC}(\widehat{P}, \mathsf{Q})}{\lambda}}. \tag{19}$$

Similarly, Theorem 10 directly implies the following Corollary.

Corollary 14 *Let h^* be a minimizer of $\lambda\|h\|_K^2 + \mathcal{L}_{\widehat{P}}(h, f_P)$ and h_{Q} a minimizer of $\lambda\|h\|_K^2 + \mathcal{L}_{\mathsf{Q}_h}(h, f_Q)$. Let $\sup_{x \in \mathcal{X}} K(x, x) = R^2$. Then, there exists a choice of $H'' \in \mathcal{H}$ for which the following inequality holds uniformly over over $(x, y) \in \mathcal{X} \times \mathcal{Y}$:*

$$|L(h_{\mathsf{Q}}(x), y) - L(h^*(x), y)| \leq \mu R \sqrt{\frac{\mu \eta_H(f_P, f_Q) + \mathrm{disc}_{H''}(\widehat{P}, \mathsf{q}_{min})}{\lambda}},$$

where q_{min} is the solution of the DM algorithm.

The choice of the set H'' defining our algorithm is strongly motivated by the theoretical results of this section. In view of Theorem 10, we restrict our choice of H'' to the family $\mathcal{H}$, parametrized only by the radius r. Since the generalized discrepancy DISC is a function of the set H'' which in turn depends only on r, the radius r is chosen to minimize (19). This can be done by using as a validation set a small amount of labeled data from the target domain which is typically available in practice. In particular, as the size of the unlabeled sample $\mathcal{T}'$ increases, our estimate of the optimal radius r becomes more accurate. We provide a detailed description of our algorithm's implementation in Section 5.

4.3. Comparison against Other Learning Bounds

We now compare the learning bounds just derived for our algorithm with those of some common reweighting techniques. In particular, we compare our bounds with those of Cortes et al. (2008) for the KMM algorithm. A similar comparison however can be derived for other algorithms based on importance weighting such as KLIEP or uLSIF.

Assume P and Q admit densities p and q respectively. For every $x \in \mathcal{X}$ we denote by $\beta(x) = \frac{p(x)}{q(x)}$ the importance ratio and by $\overline{\beta} = \beta|_{\mathcal{S}_{\mathcal{X}}}$ its restriction to $\mathcal{S}_{\mathcal{X}}$. We also let $\widehat{\beta}$ be the solution to the optimization problem solved by the KMM algorithm. Let $h_{\overline{\beta}}$ denote the solution to

$$\min_{h \in \mathbb{H}} \lambda\|h\|^2 + \mathcal{L}_{\overline{\beta}}(h, f_Q), \tag{20}$$

and $h_{\widehat{\beta}}$ be the solution to

$$\min_{h \in \mathbb{H}} \lambda\|h\|^2 + \mathcal{L}_{\widehat{\beta}}(h, f_Q). \tag{21}$$

The following proposition due to Cortes et al. (2008) relates the error of these hypotheses. The proposition requires the kernel K to be a strictly positive definite universal kernel, with Gram matrix $\mathbf{K}$ given by $\mathbf{K}_{ij} = K(x_i, x_j)$.

Proposition 15 *Assume $L(h(x), y) \leq 1$ for all $(x, y) \in \mathcal{X} \times \mathcal{Y}, h \in H$. For any $\delta > 0$, with probability at least $1 - \delta$ we have:*

$$\begin{aligned}
|\mathcal{L}_P(h_{\overline{\beta}}, f_P) - \mathcal{L}_P(h_{\widehat{\beta}}, f_P)| \leq \frac{\mu^2 R^2 \lambda_{\max}^{\frac{1}{2}}(\mathbf{K})}{\lambda} \Big(& \frac{\epsilon B'}{\sqrt{m}} \\
& + \frac{\kappa^{1/2}}{\lambda_{\min}^{1/2}(\mathbf{K})} \sqrt{\frac{B'^2}{m} + \frac{1}{n}} \Big(1 + \sqrt{2 \log \frac{2}{\delta}}\Big) \Big),
\end{aligned} \tag{22}$$

where ϵ and B' are the hyperparameters defining the KMM algorithm and $\lambda_{\max}(\mathbf{K}), \lambda_{\min}(\mathbf{K})$ denote the largest and smallest eigenvalues of $\mathbf{K}$ respectively.

This bound and the one obtained in (19) are of course not comparable since the dependence on μ, R and λ is different. In some cases this dependency can be more favorable in (22) whereas for other values of these parameters (19) provides a better bound. Moreover, (22) depends on the condition number of $\mathbf{K}$ which can become really large in practice. However, the most important difference between these bounds is that (19) is given in terms of the ideal hypothesis h^* while (22) is given in terms of $h_{\overline{\beta}}$, which, in view of the results of Cortes et al. (2010) is not guaranteed to have a good performance on the target distribution. Therefore (22) does not, in general, provide an informative bound.

4.4. Scenario of Additional Labeled Data

Here, we consider a rather common scenario in practice where, in addition to the labeled sample $\mathcal{S}$ drawn from the source domain and the unlabeled sample $\mathcal{T}$ from the target domain, the learner receives a small amount of labeled data from the target domain $\mathcal{T}' = ((x'_1, y'_1), \ldots, (x'_s, y'_s)) \in (\mathcal{X} \times \mathcal{Y})^s$. This sample is typically too small to be used solely to train an algorithm and achieve a good performance. However, it can be useful in at least two ways that we discuss here.

One important benefit of $\mathcal{T}'$ is to serve as a validation set to determine the parameter r that defines the convex set H'' used by our algorithm. The sample $\mathcal{T}'$ can also be used to enhance the discrepancy minimization algorithm as we now show. Let $\widehat{P}'$ denote the empirical distribution associated with $\mathcal{T}'$. To take advantage of $\mathcal{T}'$, the DM algorithm can be trained on the sample of size $(m+s)$ obtained by combining $\mathcal{S}$ and $\mathcal{T}'$, which corresponds to the new empirical distribution $\widehat{Q}' = \frac{m}{m+s}\widehat{Q} + \frac{s}{m+s}\widehat{P}'$. Note that for a fixed value m and large values of s, $\widehat{Q}'$ essentially ignores the points from the source distribution Q, which corresponds to the standard supervised learning scenario in the absence of adaptation. Let $\mathsf{q}'_{\min}$ denote the discrepancy minimization solution when using $\widehat{Q}'$. Since $\mathrm{supp}(\widehat{Q}') \supseteq \mathrm{supp}(\widehat{Q})$, the discrepancy using $\mathsf{q}'_{\min}$ is a lower bound on the discrepancy using $\mathsf{q}_{\min}$:

$$\mathrm{disc}(\mathsf{q}'_{\min}, \widehat{P}) = \min_{\mathrm{supp}(\mathsf{q}) \subseteq \mathrm{supp}(\widehat{Q}')} \mathrm{disc}(\widehat{P}, \mathsf{q}) \leq \min_{\mathrm{supp}(\mathsf{q}) \subseteq \mathrm{supp}(\widehat{Q})} \mathrm{disc}(\widehat{P}, \mathsf{q}) = \mathrm{disc}(\mathsf{q}_{\min}, \widehat{P}).$$

5. Optimization Solution

As shown in Section 3.2, the function G defining our algorithm is convex and the problem of minimizing the expression (7) is a convex optimization problem. Nevertheless, the problem is not straightforward to solve, in particular because evaluating a term like $\max_{h'' \in H''} \mathcal{L}_{\widehat{P}}(h, h'')$ that it contains requires solving a non-convex optimization problem. Here, we present an exact solution in the case of the L_2 loss by solving a semi-definite programming (SDP) problem.

5.1. SDP Formulation

As discussed in Section 4, the choice of H'' is a key component of our algorithm. In view of Corollary 14, we will consider the set $H'' = \{h'' \,|\, \mathcal{L}_{\mathsf{q}_{\min}}(h'', f_Q) \leq r^2\}$. Equivalently, as a result of the reproducing property of $\mathbb{H}$ and the representer theorem, H'' may be defined as $\{\mathbf{a} \in \mathbb{R}^m | \sum_{j=1}^m \mathsf{q}_{\min}(x_j)(\sum_{i=1}^m a_i \mathsf{q}_{\min}(x_i)^{1/2} K(x_i, x_j) - y_j)^2 \leq r^2\}$. Also by the representer theorem, the solution to (7) will be of the form $h = n^{-1/2} \sum_{i=1}^n b_i K(x'_i, \cdot)$. Therefore, given *normalized* kernel matrices $\mathbf{K}_t$, $\mathbf{K}_s$, $\mathbf{K}_{st}$ defined respectively as $\mathbf{K}_t^{ij} = n^{-1} K(x'_i, x'_j)$, $\mathbf{K}_s^{ij} = \mathsf{q}_{\min}(x_i)^{1/2} \mathsf{q}_{\min}(x_j)^{1/2} K(x_i, x_j)$ and $\mathbf{K}_{st}^{ij} = n^{-1/2} \mathsf{q}_{\min}(x_j)^{1/2} K(x'_i, x_j)$, problem (7) is equivalent to

$$\min_{\mathbf{b} \in \mathbb{R}^n} \lambda \mathbf{b}^\top \mathbf{K}_t \mathbf{b} + \frac{1}{2}\left(\max_{\substack{\mathbf{a} \in \mathbb{R}^m \\ \|\mathbf{K}_s \mathbf{a} - \mathbf{y}\|^2 \leq r^2}} \|\mathbf{K}_{st}\mathbf{a} - \mathbf{K}_t \mathbf{b}\|^2 + \min_{\substack{\mathbf{a} \in \mathbb{R}^m \\ \|\mathbf{K}_s \mathbf{a} - \mathbf{y}\|^2 \leq r^2}} \|\mathbf{K}_{st}\mathbf{a} - \mathbf{K}_t \mathbf{b}\|^2 \right), \quad (23)$$

where $\mathbf{y} = (\mathsf{q}_{\min}(x_1)^{1/2} y_1, \ldots, \mathsf{q}_{\min}(x_m)^{1/2} y_m)$ is the vector of normalized labels.

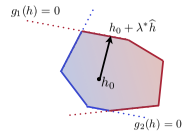

Figure 1: Illustration of the sampling process on the set H''.

Lemma 16 *The Lagrangian dual of the problem*

$$\max_{\substack{\mathbf{a} \in \mathbb{R}^m \\ \|\mathbf{K}_s \mathbf{a} - \mathbf{y}\|^2 \leq r^2}} \frac{1}{2}\|\mathbf{K}_{st}\mathbf{a}\|^2 - \mathbf{b}^\top \mathbf{K}_t \mathbf{K}_{st} \mathbf{a},$$

is given by

$$\min_{\eta \geq 0, \gamma} \gamma$$
$$s.t. \begin{pmatrix} -\frac{1}{2}\mathbf{K}_{st}^\top \mathbf{K}_{st} + \eta \mathbf{K}_s^2 & \frac{1}{2}\mathbf{K}_{st}^\top \mathbf{K}_t \mathbf{b} - \eta \mathbf{K}_s \mathbf{y} \\ \frac{1}{2}\mathbf{b}^\top \mathbf{K}_t \mathbf{K}_{st} - \eta \mathbf{y}^\top \mathbf{K}_s & \eta(\|\mathbf{y}\|^2 - r^2) + \gamma \end{pmatrix} \succeq 0.$$

Furthermore, the duality gap for these problems is zero.

The proof of the lemma is given in Appendix A. The lemma helps us derive the following equivalent SDP formulation for our original optimization problem. Its solution can be found in polynomial time using standard convex optimization solvers.

Proposition 17 *The optimization problem* (23) *is equivalent to the following SDP:*

$$\max_{\alpha, \beta, \nu, \mathbf{Z}, \mathbf{z}} \frac{1}{2}\mathrm{Tr}(\mathbf{K}_{st}^\top \mathbf{K}_{st} \mathbf{Z}) - \beta - \alpha$$
$$s.\ t \begin{pmatrix} \nu \mathbf{K}_s^2 + \frac{1}{2}\mathbf{K}_{st}^\top \mathbf{K}_{st} - \frac{1}{4}\widetilde{\mathbf{K}} & \nu \mathbf{K}_s \mathbf{y} + \frac{1}{4}\widetilde{\mathbf{K}}\mathbf{z} \\ \nu \mathbf{y}^\top \mathbf{K}_s + \frac{1}{4}\mathbf{z}^\top \widetilde{\mathbf{K}} & \alpha + \nu(\|\mathbf{y}\|^2 - r^2) \end{pmatrix} \succeq 0 \quad \begin{pmatrix} \lambda \mathbf{K}_t + \mathbf{K}_t^2 & \frac{1}{2}\mathbf{K}_t \mathbf{K}_{st} \mathbf{z} \\ \frac{1}{2}\mathbf{z}^\top \mathbf{K}_{st}^\top \mathbf{K}_t & \beta \end{pmatrix} \succeq 0$$
$$\begin{pmatrix} \mathbf{Z} & \mathbf{z} \\ \mathbf{z}^\top & 1 \end{pmatrix} \succeq 0 \wedge \nu \geq 0 \wedge \mathrm{Tr}(\mathbf{K}_s^2 \mathbf{Z}) - 2\mathbf{y}^\top \mathbf{K}_s \mathbf{z} + \|\mathbf{y}\|^2 \leq r^2,$$

where $\widetilde{\mathbf{K}} = \mathbf{K}_{st}^\top \mathbf{K}_t (\lambda \mathbf{K}_t + \mathbf{K}_t^2)^\dagger \mathbf{K}_t \mathbf{K}_{st}$, *and* $\mathbf{A}^\dagger$ *denotes the pseudo-inverse of matrix* A.

In the following section we derive a more efficient approximate solution to the optimization problem using sampling, which helps reducing the problem to a simple QP.

5.2. QP Formulation

The SDP formulation described in the previous section is applicable for a specific choice of H''. In this section, we present an analysis that holds for an arbitrary compact, convex set H''. First, notice that the problem of minimizing G (expression (7)) is related to the

minimum enclosing ball (MEB) problem. For a set $D \subseteq \mathbb{R}^d$, the MEB problem is defined as follows:

$$\min_{\mathbf{u}\in\mathbb{R}^d} \max_{\mathbf{v}\in D} \|\mathbf{u}-\mathbf{v}\|^2.$$

Omitting the regularization and the min term from (7) leads to a problem similar to the MEB. Thus, we could benefit from the extensive literature and algorithmic study available for this problem (Kumar et al., 2003; Schőnherr, 2002; Yildirim, 2008). However, to the best of our knowledge, there is currently no solution available to this problem in the case of an infinite set D, as in the case of our problem. Instead, we present a solution for solving an approximation of (7) based on sampling.

Let $\{h_1, \ldots, h_k\}$ be a set of hypotheses on the boundary of H'', $\partial H''$ and let $\mathcal{C} = \mathcal{C}(h_1, \ldots, h_k)$ denote their convex hull. The following is the sampling-based approximation of (7) that we consider:

$$\min_{h\in\mathbb{H}} \lambda\|h\|_K^2 + \frac{1}{2}\max_{i=1,\ldots,k} \mathcal{L}_{\widehat{P}}(h, h_i) + \frac{1}{2}\min_{h'\in\mathcal{C}} \mathcal{L}_{\widehat{P}}(h, h'). \tag{24}$$

Proposition 18 *Let $\mathbf{Y} = (Y_{ij}) \in \mathbb{R}^{n\times k}$ be the matrix defined by $Y_{ij} = n^{-1/2}h_j(x_i')$ and $\mathbf{y}' = (y_1', \ldots, y_k')^\top \in \mathbb{R}^k$ the vector defined by $y_i' = n^{-1}\sum_{j=1}^n h_i(x_j')^2$. Then, the dual problem of (24) is given by*

$$\max_{\boldsymbol{\alpha},\boldsymbol{\gamma},\beta} -\Big(\mathbf{Y}\boldsymbol{\alpha}+\frac{\boldsymbol{\gamma}}{2}\Big)^\top \mathbf{K}_t\Big(\lambda\mathbf{I}+\frac{1}{2}\mathbf{K}_t\Big)^{-1}\Big(\mathbf{Y}\boldsymbol{\alpha}+\frac{\boldsymbol{\gamma}}{2}\Big) - \frac{1}{2}\boldsymbol{\gamma}^\top\mathbf{K}_t\mathbf{K}_t^\dagger\boldsymbol{\gamma} + \boldsymbol{\alpha}^\top\mathbf{y}' - \beta \tag{25}$$
$$s.t.\ \mathbf{1}^\top\boldsymbol{\alpha} = \frac{1}{2}, \qquad \mathbf{1}\beta \geq -\mathbf{Y}^\top\boldsymbol{\gamma}, \qquad \boldsymbol{\alpha} \geq 0,$$

where $\mathbf{1}$ is the vector in $\mathbb{R}^k$ with all components equal to 1. Furthermore, the solution h of (24) can be recovered from a solution $(\boldsymbol{\alpha}, \boldsymbol{\gamma}, \beta)$ of (25) by $\forall x, h(x) = \sum_{i=1}^n a_i K(x_i, x)$, where $\boldsymbol{a} = \big(\lambda\mathbf{I} + \frac{1}{2}\mathbf{K}_t\big)^{-1}\big(\mathbf{Y}\boldsymbol{\alpha} + \frac{1}{2}\boldsymbol{\gamma}\big)$.

The proof of the proposition is given in Appendix B. The result shows that, given a finite sample $h_1, \ldots, h_k$ on the boundary of H'', (24) is in fact equivalent to a standard QP. Hence, a solution can be found efficiently with one of the many off-the-shelf algorithms for quadratic programming.

We now describe the process of sampling from the boundary of the set H'', which is a necessary step for defining problem (24). We consider compact sets of the form $H'' := \{h'' \in \mathbb{H} \mid g_i(h'') \leq 0\}$, where the functions g_i are continuous and convex. For instance, we could consider the set H'' defined in the previous section. More generally, we can consider a family of sets $H_p'' = \{h'' \in H| \mid \sum_{i=1}^m \mathsf{q}_{\min}(x_i)|h(x_i) - y_i|^p \leq r^p\}$.

Assume that there exists h_0 satisfying $g_i(h_0) < 0$. Our sampling process is illustrated by Figure 1 and works as follows: pick a random direction $\widehat{h}$ and define λ_i to be the minimal solution to the system

$$(\lambda \geq 0) \wedge (g_i(h_0 + \lambda\widehat{h}) = 0).$$

Set $\lambda_i = \infty$ if no solution is found and define $\lambda^* = \min_i \lambda_i$. By the convexity and compactness of H'' we can guarantee that $\lambda^* < \infty$. The hypothesis $h = h_0 + \lambda^*\widehat{h}$ satisfies $h \in H''$ and $g_j(h) = 0$ for j such that $\lambda_j = \lambda^*$. The latter is straightforward. To verify the former,

assume that $g_i(h_0 + \lambda^*\widehat{h}) > 0$ for some i. The continuity of g_i would imply the existence of λ_i' with $0 < \lambda_i' < \lambda^* \leq \lambda_i$ such that $g_i(h_0 + \lambda_i'\widehat{h}) = 0$. This would contradict the choice of λ_i, thus, the inequality $g_i(h_0 + \lambda^*\widehat{h}) \leq 0$ must hold for all i.

Since a point h_0 with $g_i(h_0) < 0$ can be obtained by solving a convex program and solving the equations defining λ_i is, in general, simple, the process described provides an efficient way of sampling points from the convex set H''.

5.3. Implementation for the L_2 Loss

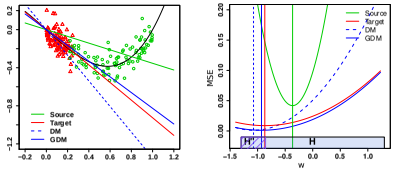
We now describe how to fully implement our sampling-based algorithm for the case where L is equal to the L_2 loss. In view of the results of Section 4, we let $H'' = \{h''|\|h''\|_K \leq \Lambda \ \wedge \ \mathcal{L}_{\mathsf{q}}(h'', f_Q) \leq r^2\}$. We first describe the steps needed to find a point $h_0 \in H''$. Let h_Λ be such that $\|h_\Lambda\|_K = \Lambda$ and $\lambda_r \in \mathbb{R}_+$ be such that the solution h_r to the optimization problem

$$\min_{h\in\mathbb{H}} \lambda_r\|h\|^2 + \mathcal{L}_{\mathsf{q}}(h, f_Q),$$

satisfies $\mathcal{L}_{\mathsf{q}}(h_r, f_Q) = r^2$. It is easy to verify that the existence of λ_r is guaranteed for $\min_{h\in H}\mathcal{L}_{\mathsf{q}}(h, f_Q) \leq r^2 \leq \sum_{i=1}^m \mathsf{q}(x_i)y_i^2$. It is clear that the point $h_0 = \frac{1}{2}(h_r + h_\Lambda)$ is in the interior of H''. Of course, finding λ_r with the desired properties is not straightforward. However, since r is chosen via validation, we do not need to find λ_r as a function of r. Instead, we can simply select λ_r through validation too.

In order to complete the sampling process, we must have an efficient way of selecting a random direction $\widehat{h}$. If $H \subset \mathbb{R}^d$ is a set of linear hypotheses, a direction $\widehat{h}$ can be sampled uniformly by letting $\widehat{h} = \frac{\xi}{\|\xi\|}$, where ξ is a standard Gaussian random variable in $\mathbb{R}^d$. If H is a subset of a RKHS, by the representer theorem, we only need to consider hypotheses of the form $h = \sum_{i=1}^m \alpha_i K(x_i, \cdot)$. Therefore, we can sample a direction $\widehat{h} = \sum_{i=1}^m \alpha_i' K(x_i, \cdot)$, where the vector $\boldsymbol{\alpha'} = (\alpha_1', \ldots, \alpha_m')$ is drawn uniformly from the unit sphere in $\mathbb{R}^m$. A full implementation of our algorithm thus consists of the following steps:

- find the distribution $\mathsf{q}_{\min} = \operatorname{argmin}_{\mathsf{q}\in\mathcal{Q}} \operatorname{disc}(\mathsf{q}, \widehat{P})$. This can be done by using the smooth approximation algorithm of Cortes and Mohri (2013);
- sample points from the set H'' using the sampling process described above;
- solve the QP introduced in Section 5.2.



Notice that our algorithm only requires solving a simple QP and therefore its complexity is the same as other adaptation algorithms such as KMM, KLIEP and DM.

6. Experiments

Here, we report the results of extensive comparisons between GDM and several other adaptation algorithms which demonstrate the benefits of our algorithm. We use the implementation described in the previous section. The source code for our algorithm as well as all other baselines described in this section can be found at `http://cims.nyu.edu/~munoz`.

6.1. Synthetic Data Set

To compare the performances of the GDM and DM algorithms, we considered the following synthetic one-dimensional task, which is similar to the one considered by Huang et al.

(a) (b)

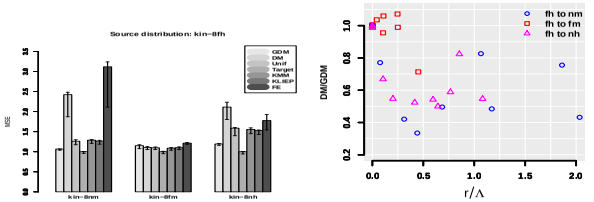


Figure 2: (a) Hypotheses obtained by training on source (green circles), target (red triangles) and using DM (dashed blue) and GDM algorithms (solid blue). (b) Objective functions for source and target distribution as well as GDM and DM algorithms. Sets H and surrogate hypothesis set $H'' \subseteq H$ are shown at the bottom. The vertical lines represent the minimizing hypothesis for each loss.

(2006): the source domain examples were sampled from the uniform distribution over the interval $[.2, 1]$ and target ones sampled uniformly over $[0, .25]$. The labels were given by the map $x \mapsto -x + x^3 + \xi$, where ξ is a Gaussian random variable with mean 0 and standard deviation 0.1. Our hypothesis set was defined by the family of linear functions without an offset. Figure 2(a) shows the regression hypotheses obtained by training the DM and GDM algorithm as well as those obtained by training on the source and target distributions. The ideal hypothesis is shown in red. Notice how the GDM solution gives a closer approximation than DM to the ideal solution. In order to better understand the difference between the solutions of these algorithms, Figure 2(b) depicts the objective function minimized by each algorithm as a function of the slope w of the linear function, the only variable of the hypothesis. The vertical lines show the value of the minimizing hypothesis for each loss. Keeping in mind that the regularization parameter λ used in ridge regression corresponds to a Lagrange multiplier for the constraint $w^2 \leq \Lambda^2$ for some Λ (Cortes and Mohri, 2013) [Lemma 1], the hypothesis set $H = \{w | w^2 \leq \Lambda^2\}$ is depicted at the bottom of this plot. The shaded region represents the set $H'' = H \cap \{h'' | \mathcal{L}_{\mathbf{q}_{\min}}(h'') \leq r\}$. It is clear from this plot that DM helps approximate the target loss function. Nevertheless, only GDM seems to uniformly approach it. This should come as no surprise since our algorithm was precisely designed to achieve that.

6.2. Adaptation Data Sets

We now present the results of evaluating our algorithm against several other adaptation algorithms. GDM is compared against DM and training on the uniform distribution. The following baselines were also used:

1. The KMM algorithm (Huang et al., 2006), which reweights examples from the source distribution in order to match the mean of the source and target data in a feature space induced by a universal kernel. The hyper-parameters of this algorithm were set to the recommended values of $B = 1000$ and $\epsilon = \frac{\sqrt{m}}{\sqrt{m}-1}$.
2. KLIEP (Sugiyama et al., 2007). This algorithm estimates the importance ratio of the source and target distribution by modeling this ratio as a mixture of basis functions and learning the mixture coefficients from the data. Gaussian kernels were used as basis functions for this algorithm and KMM. The bandwidth for the kernel was selected from the set $\{\sigma d \colon \sigma = 2^{-5}, \ldots, 2^5\}$ via validation on the *test* set, where d is the mean distance between points sampled from the source domain.
3. FE (Daumé III, 2007). This algorithm maps source and target data into a common high-dimensional feature space where the difference of the distributions is expected to reduce.

(a) (b)

Figure 3: (a)MSE performance for different adaptation algorithms when adapting from `kin-8fh` to the three other `kin-8xy` domains. (b) Relative error of DM over GDM as a function of the ratio $\frac{r}{\Lambda}$.

Since the two-stage algorithm of Bickel et al. (2007) was already shown to perform similarly to KMM and KLIEP (Cortes and Mohri, 2013), for the sake of readability of our results, we omitted the results of comparison with this algorithm. Finally, we compare our algorithm with the ideal hypothesis h^* returned by training on the target sample $\mathcal{T}$, which we denote by `Tar`. Notice that in practice, this is impossible as $\mathcal{T}$ is unlabeled so we use this result only to show the best attainable performance.

We selected the set of linear functions as our hypothesis set. The learning algorithm used for all tasks was ridge regression and the performance evaluated by the mean squared error. We follow the setup of Cortes and Mohri (2011) and for all adaptation algorithms we selected the parameter λ via 10-fold cross validation over the training data by using a grid search over the set of values $\lambda \in \{2^{-10}, \ldots, 2^{10}\}$. The results of training on the target distribution are presented for a parameter λ tuned via 10-fold cross validation over the target data. We used the QP implementation of our algorithm with the sampling set H'' and the sampling mechanism defined at the end of Section 5.2, where the parameter λ_r was chosen from the same set as λ via validation on a small amount of data from the target distribution. Whereas there are other methods such as transfer cross validation (Zhong et al., 2010) to select the parameters for our algorithm, these methods require the use of importance weighting which as shown in (Cortes et al., 2010) is not theoretically justified.

In order to achieve a fair comparison, all other algorithms were allowed to use the small amount of labeled data too. Since, with the exception of FE, all other baselines do not propose a way of dealing with labeled data from the target distribution, we simply added this data to the training set and ran the algorithms on the extended source data as discussed in Section 4.4.

Table 2: Adaptation from `books` (B), `kitchen` (K), `electronics` (E) and `dvd` (D) to all other domains. Normalized results: MSE of training on the unweighted source data is equal to 1. Results in bold represent the algorithm with the lowest MSE.

The first task we considered is given by the 4 `kin-8xy` Delve data sets (Rasmussen et al., 1996). These data sets are variations of the same model: a realistic simulation of the forward dynamics of an 8 link all-revolute robot arm. The task in all data sets consists of predicting the distance of the end-effector from a target. The data sets differ by the degree of non-linearity (fairly linear, `x=f`, or non-linear, `x=n`) and the amount of noise in the output (moderate, `y=m`, or high, `y=h`). The data set defines 4 different domains, that is 12 pairs of different distributions and labeling functions. A sample of 200 points from each domain was used for training and 10 labeled points from the target distribution were used to select H''. The experiment was carried out 10 times and the results of testing on a sample of 400 points from the target domain are reported in Figure 3(a). The bars represent the median performance of each algorithm. The error bars are the low and high 25% quartiles respectively. All results were normalized in such a way that the median performance of training on the source is equal to 1. Notice that the performance of all algorithms is comparable when adapting to `kin8-fm` since both labeling functions are fairly linear, yet only GDM is able to reasonably adapt to the two data sets with different labeling functions. In order to better understand the advantages of GDM over DM we plot the relative error of DM against GDM as a function of the ratio r/Λ in Figure 3(b), where r is the radius defining H'' and is selected through cross validation. Notice that when the ratio r/Λ is small then both algorithms behave similarly which is most of the times for the adaptation task `fh` to `fm`. On the other hand, a better performance of GDM can be obtained when the ratio is larger. This is due to the fact that r/Λ measures the effective size of the set H''. A small ratio means that the size of H'' is small and therefore the hypothesis returned by GDM will be close to that of DM where as if H'' is large then GDM has the possibility of finding a better hypothesis.

For our next experiment we considered the cross-domain sentiment analysis data set of Blitzer et al. (2007). This data set consists of consumer reviews from 4 different domains: `books, kitchen, electronics` and `dvds`. We used the top 1000 uni-grams and bi-grams

Table 3: Adaptation from `caltech256` (C), `imagenet` (I), `sun` (S) and `bing` (B).

as the features for this task. For each pair of adaptation tasks we sampled 700 points from the source distribution and 700 unlabeled points from the target. Only 50 labeled points from the target distribution were used to tune the parameter r of our algorithm. The final evaluation is done on a test set of 1000 points. The mean results and standard deviations of this task are shown in Table 2 where the MSE values have been normalized in such a way that the performance of training on the source without reweighting is always 1.

Finally, we considered a novel domain adaptation task (Tommasi et al., 2014) of paramount importance in the computer vision community. The domains correspond to 4 well known collections of images: `bing, caltech256, sun` and `imagenet`. These data sets have been standardized so that they all share the same feature representation and labeling function (Tommasi et al., 2014). We sampled 800 labeled points from the source distribution and 800 unlabeled points from the target distribution as well as 50 labeled target points to be used for validation of r. The results of testing on 1000 points from the target domain are presented in Table 3 where, again, the results were normalized in such a way that the performance of training on the source data is always 1.

After analyzing the results of this section we notice that the GDM algorithm consistently outperforms DM and achieves similar or better performance than all other common adaptation algorithms. It is worth noticing that in some cases, other algorithms perform even worse than training on the unweighted sample. This deficiency of the KLIEP algorithm had already been pointed out by Sugiyama et al. (2007) but here we observe that this problem can also affect the KMM algorithm. Finally, let us point out that even though the FE algorithm also achieved performances similar to GDM on the sentiment and image adaptation, its performance was far from optimal adapting on the `kin-8xy` task. Since there is a lack of theoretical understanding for this algorithm, it is hard to characterize the scenarios where FE would perform better than GDM.

7. Conclusion

We presented a new theoretically well-founded domain adaptation algorithm seeking to minimize a less conservative quantity than the DM algorithm. We presented an SDP so-

lution for the particular case of the L_2 loss which can be solved in polynomial time. Our empirical results show that our new algorithm always performs better than or is on par with the otherwise state-of-the-art DM algorithm. We also provided tight generalization bounds for the domain adaptation problem based on the $\mathcal{Y}$-discrepancy. As pointed out in Section 4, an algorithm that minimizes the $\mathcal{Y}$-discrepancy would benefit from the best possible guarantees. However, the lack of labeled data from the target distribution makes this algorithm not viable. This suggests analyzing a richer scenario where the learner is allowed to ask for a limited number of labels from the target distribution. This setup, which is related to active learning, seems to be in fact the closest one to real-life applications and has started to receive attention from the research community (Berlind and Urner, 2015). We believe that the discrepancy disc will play a central role in the analysis of that scenario as well.

Acknowledgments

We would like to thank the reviewers of KDD and JMLR for their suggestions to improve this paper. This work was partly funded by the NSF awards IIS-1117591 and CCF-1535987.

Appendix A. SDP Formulation

Lemma 19 *The Lagrangian dual of the problem*

$$\max_{\substack{\mathbf{a}\in\mathbb{R}^m \\ \|\mathbf{K}_s\mathbf{a}-\mathbf{y}\|^2\leq r^2}} \frac{1}{2}\|\mathbf{K}_{st}\mathbf{a}\|^2 - \mathbf{b}^\top\mathbf{K}_t\mathbf{K}_{st}\mathbf{a}, \tag{26}$$

is given by

$$\begin{array}{ll}\min\limits_{\eta\geq 0,\gamma} & \gamma \\ s.\ t. & \begin{pmatrix} -\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}+\eta\mathbf{K}_s^2 & \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b}-\eta\mathbf{K}_s\mathbf{y} \\ \frac{1}{2}\mathbf{b}^\top\mathbf{K}_t\mathbf{K}_{st}-\eta\mathbf{y}^\top\mathbf{K}_s & \eta(\|\mathbf{y}\|^2-r^2)+\gamma \end{pmatrix} \succeq 0.\end{array}$$

Furthermore, the duality gap for these problems is zero.

Proof For $\eta\geq 0$ the Lagrangian of (26) is given by

$$\begin{aligned} L(\mathbf{a},\eta) &= \frac{1}{2}\|\mathbf{K}_{st}\mathbf{a}\|^2 - \mathbf{b}^\top\mathbf{K}_t\mathbf{K}_{st}\mathbf{a} - \eta(\|\mathbf{K}_s\mathbf{a}-\mathbf{y}\|^2 - r^2) \\ &= \mathbf{a}^\top\Big(\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st} - \eta\mathbf{K}_s^2\Big)\mathbf{a} + (2\eta\mathbf{K}_s\mathbf{y} - \mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b})^\top\mathbf{a} - \eta(\|\mathbf{y}\|^2 - r^2). \end{aligned}$$

Since the Lagrangian is a quadratic function of $\mathbf{a}$ and that the conjugate function of a quadratic can be expressed in terms of the pseudo-inverse, the dual is given by

$$\begin{array}{ll}\min\limits_{\eta\geq 0} & \frac{1}{4}(2\eta\mathbf{K}_s\mathbf{y} - \mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b})^\top\Big(\eta\mathbf{K}_s^2 - \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}\Big)^\dagger(2\eta\mathbf{K}_s\mathbf{y} - \mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b}) - \eta(\|\mathbf{y}\|^2 - r^2) \\ \text{s. t.} & \eta\mathbf{K}_s^2 - \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st} \succeq 0.\end{array}$$

Introducing the variable γ to replace the objective function yields the equivalent problem

$$\begin{array}{ll}\min\limits_{\eta\geq 0,\gamma} & \gamma \\ \text{s. t.} & \eta\mathbf{K}_s^2 - \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st} \succeq 0 \\ & \gamma - \frac{1}{4}(2\eta\mathbf{K}_s\mathbf{y} - \mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b})^\top\Big(\eta\mathbf{K}_s^2 - \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}\Big)^\dagger(2\eta\mathbf{K}_s\mathbf{y} - \mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b}) + \eta(\|\mathbf{y}\|^2 - r^2) \geq 0\end{array}$$

Finally, by the properties of the Schur complement (Boyd and Vandenberghe, 2004), the two constraints above are equivalent to

$$\begin{pmatrix} -\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}+\eta\mathbf{K}_s^2 & \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b}-\eta\mathbf{K}_s\mathbf{y} \\ \Big(\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b}-\eta\mathbf{K}_s\mathbf{y}\Big)^\top & \eta(\|\mathbf{y}\|^2-r)+\gamma \end{pmatrix} \succeq 0.$$

Since duality holds for a general QCQP with only one constraint (Boyd and Vandenberghe, 2004)[Appendix B], the duality gap between these problems is 0. ■

Proposition 20 *The optimization problem* (23) *is equivalent to the following SDP:*

$$\begin{array}{ll}\max\limits_{\alpha,\beta,\nu,\mathbf{Z},\mathbf{z}} & \frac{1}{2}\operatorname{Tr}(\mathbf{K}_{st}^\top\mathbf{K}_{st}\mathbf{Z}) - \beta - \alpha \\ s.\ t. & \begin{pmatrix} \nu\mathbf{K}_s^2+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}} & \nu\mathbf{K}_s\mathbf{y}+\frac{1}{4}\widetilde{\mathbf{K}}\mathbf{z} \\ \nu\mathbf{y}^\top\mathbf{K}_s+\frac{1}{4}\mathbf{z}^\top\widetilde{\mathbf{K}} & \alpha+\nu(\|\mathbf{y}\|^2-r^2) \end{pmatrix} \succeq 0 \quad\wedge\quad \begin{pmatrix} \mathbf{Z} & \mathbf{z} \\ \mathbf{z}^\top & 1 \end{pmatrix} \succeq 0 \\ & \begin{pmatrix} \lambda\mathbf{K}_t+\mathbf{K}_t^2 & \frac{1}{2}\mathbf{K}_t\mathbf{K}_{st}\mathbf{z} \\ \frac{1}{2}\mathbf{z}^\top\mathbf{K}_{st}^\top\mathbf{K}_t & \beta \end{pmatrix} \succeq 0 \ \wedge\ \operatorname{Tr}(\mathbf{K}_s^2\mathbf{Z}) - 2\mathbf{y}^\top\mathbf{K}_s\mathbf{z} + \|\mathbf{y}\|^2 \leq r^2 \ \wedge\ \nu\geq 0,\end{array}$$

where $\widetilde{\mathbf{K}} = \mathbf{K}_{st}^\top\mathbf{K}_t(\lambda\mathbf{K}_t+\mathbf{K}_t^2)^\dagger\mathbf{K}_t\mathbf{K}_{st}$.

Proof

By Lemma 16, we may rewrite (23) as

$$\begin{array}{ll}\min\limits_{\mathbf{a},\gamma,\eta,\mathbf{b}} & \mathbf{b}^\top(\lambda\mathbf{K}_t+\mathbf{K}_t^2)\mathbf{b} + \frac{1}{2}\mathbf{a}^\top\mathbf{K}_{st}^\top\mathbf{K}_{st}\mathbf{a} - \mathbf{a}^\top\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b} + \gamma \\ \text{s. t.} & \begin{pmatrix} -\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}+\eta\mathbf{K}_s^2 & \frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b}-\eta\mathbf{K}_s\mathbf{y} \\ \frac{1}{2}\mathbf{b}^\top\mathbf{K}_t\mathbf{K}_{st}-\eta\mathbf{y}^\top\mathbf{K}_s & \eta(\|\mathbf{y}\|^2-r^2)+\gamma \end{pmatrix} \quad\wedge\quad \eta\geq 0 \\ & \|\mathbf{K}_s\mathbf{a}-\mathbf{y}\|^2 \leq r^2.\end{array} \tag{27}$$

Let us apply the change of variables $\mathbf{b} = \frac{1}{2}(\lambda\mathbf{K}_t+\mathbf{K}_t^2)^\dagger\mathbf{K}_t\mathbf{K}_{st}\mathbf{a}+\mathbf{v}$. The following equalities can be easily verified.

$$\begin{aligned} \mathbf{b}^\top(\lambda\mathbf{K}_t+\mathbf{K}_t^2)\mathbf{b} &= \frac{1}{4}\mathbf{a}^\top\mathbf{K}_{st}^\top\mathbf{K}_t(\lambda\mathbf{K}_t+\mathbf{K}_t^2)^\dagger\mathbf{K}_t\mathbf{K}_{st}\mathbf{a} + \mathbf{v}^\top\mathbf{K}_t\mathbf{K}_{st}\mathbf{a} + \mathbf{v}^\top(\lambda\mathbf{K}_t+\mathbf{K}_t^2)\mathbf{v}. \\ \mathbf{a}^\top\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{b} &= \frac{1}{2}\mathbf{a}^\top\mathbf{K}_{st}^\top\mathbf{K}_t(\lambda\mathbf{K}_t+\mathbf{K}_t^2)^\dagger\mathbf{K}_t\mathbf{K}_{st}\mathbf{a} + \mathbf{v}^\top\mathbf{K}_t\mathbf{K}_{st}\mathbf{a}. \end{aligned}$$

Thus, replacing $\mathbf{b}$ on (27) yields

$$\min_{\mathbf{a},\mathbf{v},\gamma,\eta} \ \mathbf{v}^\top(\lambda\mathbf{K}_t+\mathbf{K}_t^2)\mathbf{v}+\ \mathbf{a}^\top\Big(\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}}\Big)\mathbf{a}+\gamma$$
$$\text{s. t.} \quad \begin{pmatrix} -\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}+\eta\mathbf{K}_s^2 & \frac{1}{4}\widetilde{\mathbf{K}}\mathbf{a}+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{v}-\eta\mathbf{K}_s\mathbf{y} \\ \frac{1}{4}\mathbf{a}^\top\widetilde{\mathbf{K}}+\frac{1}{2}\mathbf{v}^\top\mathbf{K}_t\mathbf{K}_{st}-\eta\mathbf{y}^\top\mathbf{K}_s & \eta(\|\mathbf{y}\|^2-r^2)+\gamma \end{pmatrix}\succeq 0 \quad\wedge\quad \eta\geq 0$$
$$\|\mathbf{K}_s\mathbf{a}-\mathbf{y}\|^2\leq r^2.$$

Introducing the scalar multipliers $\mu,\nu\geq 0$ and the matrix

$$\begin{pmatrix} \mathbf{Z} & \mathbf{z} \\ \mathbf{z}^\top & \widetilde{z}, \end{pmatrix}\succeq 0$$

as a multiplier for the matrix constraint, we can form the Lagrangian:

$$\mathfrak{L}:=\mathbf{v}^\top(\lambda\mathbf{K}_t+\mathbf{K}_t^2)\mathbf{v}+\mathbf{a}^\top\Big(\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}}\Big)\mathbf{a}+\gamma-\mu\eta+\nu(\|\mathbf{K}_s\mathbf{a}-\mathbf{y}\|^2-r^2)$$
$$-\operatorname{Tr}\left(\begin{pmatrix} \mathbf{Z} & \mathbf{z} \\ \mathbf{z} & \widetilde{z} \end{pmatrix}\begin{pmatrix} -\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}+\eta\mathbf{K}_s^2 & \frac{1}{4}\widetilde{\mathbf{K}}\mathbf{a}+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{v}-\eta\mathbf{K}_s\mathbf{y} \\ \frac{1}{4}\mathbf{a}^\top\widetilde{\mathbf{K}}+\frac{1}{2}\mathbf{v}^\top\mathbf{K}_t\mathbf{K}_{st}-\eta\mathbf{y}^\top\mathbf{K}_s & \eta(\|\mathbf{y}\|^2-r^2)+\gamma \end{pmatrix}\right).$$

The KKT conditions $\frac{\partial\mathfrak{L}}{\partial\eta}=\frac{\partial\mathfrak{L}}{\partial\gamma}=0$ trivially imply $\widetilde{z}=1$ and $\operatorname{Tr}(\mathbf{K}_s^2\mathbf{Z})-2\mathbf{y}^\top\mathbf{K}_s\mathbf{z}+\|\mathbf{y}\|^2-r^2+\mu=0$. These constraints on the dual variables guarantee that the primal variables η and γ will vanish from the Lagrangian, thus yielding

$$\mathfrak{L}=\frac{1}{2}\operatorname{Tr}(\mathbf{K}_{st}^\top\mathbf{K}_{st}\mathbf{Z})+\nu(\|\mathbf{y}\|^2-r^2)+\mathbf{v}^\top(\lambda\mathbf{K}_t+\mathbf{K}_t^2)\mathbf{v}^\top-\mathbf{z}^\top\mathbf{K}_{st}^\top\mathbf{K}_t\mathbf{v}$$
$$+\mathbf{a}^\top\Big(\nu\mathbf{K}_s^2+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}}\Big)\mathbf{a}-\Big(2\nu\mathbf{K}_s\mathbf{y}+\frac{1}{2}\widetilde{\mathbf{K}}\mathbf{z}\Big)^\top\mathbf{a}.$$

This is a quadratic function on the primal variables $\mathbf{a}$ and $\mathbf{v}$ with minimizing solutions

$$\mathbf{a}=\frac{1}{2}\Big(\nu\mathbf{K}_s^2+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}}\Big)^\dagger\Big(2\nu\mathbf{K}_s\mathbf{y}+\frac{1}{2}\widetilde{\mathbf{K}}\mathbf{z}\Big)\qquad\text{and}\qquad\mathbf{v}=\frac{1}{2}(\lambda\mathbf{K}_t+\mathbf{K}_t^2)^\dagger\mathbf{K}_t\mathbf{K}_{st}\mathbf{z},$$

and optimal value equal to the objective of the Lagrangian dual:

$$\frac{1}{2}\operatorname{Tr}(\mathbf{K}_{st}^\top\mathbf{K}_{st}\mathbf{Z})+\nu(\|\mathbf{y}\|^2-r^2)-\frac{1}{4}\mathbf{z}^\top\widetilde{\mathbf{K}}\mathbf{z}$$
$$-\frac{1}{4}\Big(2\nu\mathbf{K}_s\mathbf{y}+\frac{1}{2}\widetilde{\mathbf{K}}\mathbf{z}\Big)^\top\Big(\nu\mathbf{K}_s^2+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}}\Big)^\dagger\Big(2\nu\mathbf{K}_s\mathbf{y}+\frac{1}{2}\widetilde{\mathbf{K}}\mathbf{z}\Big).$$

As in Lemma 16, we apply the properties of the Schur complement to show that the dual is given by

$$\max_{\alpha,\beta,\nu,\mathbf{Z},\mathbf{z}} \ \frac{1}{2}\operatorname{Tr}(\mathbf{K}_{st}^\top\mathbf{K}_{st}\mathbf{Z})-\beta-\alpha$$
$$\text{s. t}\ \begin{pmatrix} \nu\mathbf{K}_s^2+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}} & \nu\mathbf{K}_s\mathbf{y}+\frac{1}{4}\widetilde{\mathbf{K}}\mathbf{z} \\ \nu\mathbf{y}^\top\mathbf{K}_s+\frac{1}{4}\mathbf{z}^\top\widetilde{\mathbf{K}} & \alpha+\nu(\|\mathbf{y}\|^2-r^2) \end{pmatrix}\succeq 0 \quad\wedge\quad \begin{pmatrix} \mathbf{Z} & \mathbf{z} \\ \mathbf{z}^\top & 1 \end{pmatrix}\succeq 0$$
$$\operatorname{Tr}(\mathbf{K}_s^2\mathbf{Z})-2\mathbf{y}^\top\mathbf{K}_s\mathbf{z}+\|\mathbf{y}\|^2\leq r^2 \quad\wedge\quad \beta\geq\frac{1}{4}\mathbf{z}^\top\widetilde{\mathbf{K}}\mathbf{z} \quad\wedge\quad \nu\geq 0.$$

Finally, recalling the definition of $\widetilde{\mathbf{K}}$ and using the Schur complement one more time we arrive to the final SDP formulation

$$\max_{\alpha,\beta,\nu,\mathbf{Z},\mathbf{z}} \ \frac{1}{2}\operatorname{Tr}(\mathbf{K}_{st}^\top\mathbf{K}_{st}\mathbf{Z})-\beta-\alpha$$
$$\text{s. t}\ \begin{pmatrix} \nu\mathbf{K}_s^2+\frac{1}{2}\mathbf{K}_{st}^\top\mathbf{K}_{st}-\frac{1}{4}\widetilde{\mathbf{K}} & \nu\mathbf{K}_s\mathbf{y}+\frac{1}{4}\widetilde{\mathbf{K}}\mathbf{z} \\ \nu\mathbf{y}^\top\mathbf{K}_s+\frac{1}{4}\mathbf{z}^\top\widetilde{\mathbf{K}} & \alpha+\nu(\|\mathbf{y}\|^2-r^2) \end{pmatrix}\succeq 0 \quad\wedge\quad \begin{pmatrix} \mathbf{Z} & \mathbf{z} \\ \mathbf{z}^\top & 1 \end{pmatrix}\succeq 0$$
$$\begin{pmatrix} \lambda\mathbf{K}_t+\mathbf{K}_t^2 & \frac{1}{2}\mathbf{K}_t\mathbf{K}_{st}\mathbf{z} \\ \frac{1}{2}\mathbf{z}^\top\mathbf{K}_{st}^\top\mathbf{K}_t & \beta \end{pmatrix}\succeq 0 \ \wedge\ \operatorname{Tr}(\mathbf{K}_s^2\mathbf{Z})-2\mathbf{y}^\top\mathbf{K}_s\mathbf{z}+\|\mathbf{y}\|^2\leq r^2 \ \wedge\ \nu\geq 0.$$

■

Appendix B. QP Formulation

Proposition 21 *Let $\mathbf{Y}=(Y_{ij})\in\mathbb{R}^{n\times k}$ be the matrix defined by $Y_{ij}=n^{-1/2}h_j(x_i')$ and $\mathbf{y}'=(y_1',\ldots,y_k')^\top\in\mathbb{R}^k$ the vector defined by $y_i'=n^{-1}\sum_{j=1}^n h_i(x_j')^2$. Then, the dual problem of (24) is given by*

$$\max_{\boldsymbol{\alpha},\boldsymbol{\gamma},\beta} \ -\Big(\mathbf{Y}\boldsymbol{\alpha}+\frac{\boldsymbol{\gamma}}{2}\Big)^\top\mathbf{K}_t\Big(\lambda\mathbf{I}+\frac{1}{2}\mathbf{K}_t\Big)^{-1}\Big(\mathbf{Y}\boldsymbol{\alpha}+\frac{\boldsymbol{\gamma}}{2}\Big)-\frac{1}{2}\boldsymbol{\gamma}^\top\mathbf{K}_t\mathbf{K}_t^\dagger\boldsymbol{\gamma}+\boldsymbol{\alpha}^\top\mathbf{y}'-\beta \qquad (28)$$
$$s.t.\ \mathbf{1}^\top\boldsymbol{\alpha}=\frac{1}{2},\qquad \mathbf{1}\beta\geq-\mathbf{Y}^\top\boldsymbol{\gamma},\qquad \boldsymbol{\alpha}\geq 0,$$

where $\mathbf{1}$ is the vector in $\mathbb{R}^k$ with all components equal to 1. Furthermore, the solution h of (24) can be recovered from a solution $(\boldsymbol{\alpha},\boldsymbol{\gamma},\beta)$ of (28) by $\forall x, h(x)=\sum_{i=1}^n a_iK(x_i,x)$, where $\boldsymbol{a}=\big(\lambda\mathbf{I}+\frac{1}{2}\mathbf{K}_t\big)^{-1}(\mathbf{Y}\boldsymbol{\alpha}+\frac{1}{2}\boldsymbol{\gamma})$.

We will first prove a simplified version of the proposition for the case of linear hypotheses, i.e. we can represent hypotheses in $\mathbb{H}$ and elements of $\mathcal{X}$ as vectors $\mathbf{w},\mathbf{x}\in\mathbb{R}^d$ respectively. Define $\mathbf{X}'=n^{-1/2}(\mathbf{x}_1',\ldots,\mathbf{x}_n')$ to be the matrix whose columns are the normalized sample points from the target distribution. Let also $\{\mathbf{w}_1,\ldots,\mathbf{w}_k\}$ be a sample taken from $\partial H''$ and define $\boldsymbol{W}:=(\mathbf{w}_1,\ldots,\mathbf{w}_k)\in\mathbb{R}^{d\times k}$. Under this notation, problem (24) may be rewritten as

$$\min_{\mathbf{w}\in\mathbb{R}^d}\lambda\|\mathbf{w}\|^2+\frac{1}{2}\max_{i=1,\ldots,k}\|\mathbf{X}'^\top(\mathbf{w}-\mathbf{w}_i)\|^2+\frac{1}{2}\min_{\mathbf{w}'\in\mathcal{C}}\|\mathbf{X}'^\top(\mathbf{w}-\mathbf{w}')\|^2. \qquad (29)$$

Lemma 22 *The Lagrange dual of problem (29) is given by*

$$\max_{\boldsymbol{\alpha},\boldsymbol{\gamma},\beta}-\Big(\mathbf{Y}\boldsymbol{\alpha}+\frac{\boldsymbol{\gamma}}{2}\Big)^\top\mathbf{X}'^\top\Big(\lambda\mathbf{I}+\frac{\mathbf{X}'\mathbf{X}'^\top}{2}\Big)^{-1}\mathbf{X}'\Big(\boldsymbol{Y}\boldsymbol{\alpha}+\frac{\boldsymbol{\gamma}}{2}\Big)-\frac{1}{2}\boldsymbol{\gamma}^\top\mathbf{X}'^\top(\mathbf{X}'\mathbf{X}'^\top)^\dagger\mathbf{X}'\boldsymbol{\gamma}+\boldsymbol{\alpha}^\top\mathbf{y}'-\beta$$
$$s.\ t.\ \mathbf{1}^\top\boldsymbol{\alpha}=\frac{1}{2}\qquad\mathbf{1}\beta\geq-\mathbf{Y}^\top\boldsymbol{\gamma}\qquad\boldsymbol{\alpha}\geq 0,$$

where $\mathbf{Y}=\mathbf{X}'^\top\boldsymbol{W}$ and $\mathbf{y}_i'=\|\mathbf{X}'^\top\mathbf{w}_i\|^2$.

Proof By applying the change of variable $\mathbf{u} = \mathbf{w}' - \mathbf{w}$, problem (29) is can be made equivalent to

$$\min_{\mathbf{w}\in\mathbb{R}^d \mathbf{u}\in\mathcal{C}-\mathbf{w}} \lambda\|\mathbf{w}\|^2 + \frac{1}{2}\|\mathbf{X}'^\top\mathbf{w}\|^2 + \frac{1}{2}\|\mathbf{X}'^\top\mathbf{u}\|^2 + \frac{1}{2}\max_{i=1,\ldots,k}\|\mathbf{X}'^\top\mathbf{w}_i\|^2 - 2\mathbf{w}_i^\top\mathbf{X}'\mathbf{X}'^\top\mathbf{w}.$$

By making the constraints on $\mathbf{u}$ explicit and replacing the maximization term with the variable r the above problem becomes

$$\begin{aligned}\min_{\mathbf{w},\mathbf{u},r,\boldsymbol{\mu}} \quad & \lambda\|\mathbf{w}\|^2 + \frac{1}{2}\|\mathbf{X}'^\top\mathbf{w}\|^2 + \frac{1}{2}\|\mathbf{X}'^\top\mathbf{u}\|^2 + \frac{1}{2}r\\ \text{s. t.} \quad & \mathbf{1}r \geq \mathbf{y}' - 2\mathbf{Y}^\top\mathbf{X}'^\top\mathbf{w} \quad \wedge \quad \mathbf{1}^\top\boldsymbol{\mu} = 1 \quad \wedge \quad \boldsymbol{\mu} \geq 0 \quad \wedge \quad \boldsymbol{W}\boldsymbol{\mu} - \mathbf{w} = \mathbf{u}.\end{aligned}$$

For $\boldsymbol{\alpha}, \boldsymbol{\delta} \geq 0$, the Lagrangian of this problem is defined as

$$\begin{aligned}\mathfrak{L}(\mathbf{w},\mathbf{u},\boldsymbol{\mu},r,\boldsymbol{\alpha},\beta,\boldsymbol{\delta},\boldsymbol{\gamma}') = {} & \lambda\|\mathbf{w}\|^2 + \frac{1}{2}\|\mathbf{X}'^\top\mathbf{w}\|^2 + \frac{1}{2}\|\mathbf{X}'^\top\mathbf{u}\|^2 + \frac{1}{2}r + \beta(\mathbf{1}^\top\boldsymbol{\mu} - 1)\\ & + \boldsymbol{\alpha}^\top(\mathbf{y}' - 2(\mathbf{X}'\mathbf{Y})^\top\mathbf{w} - \mathbf{1}r) - \boldsymbol{\delta}^\top\boldsymbol{\mu} + \boldsymbol{\gamma}'^\top(\boldsymbol{W}\boldsymbol{\mu} - \mathbf{w} - \mathbf{u}).\end{aligned}$$

Minimizing with respect to the primal variables yields the following KKT conditions:

$$\mathbf{1}^\top\boldsymbol{\alpha} = \frac{1}{2} \qquad \mathbf{1}\beta = \boldsymbol{\delta} - \boldsymbol{W}^\top\boldsymbol{\gamma}'. \tag{30}$$

$$\mathbf{X}'\mathbf{X}'^\top\mathbf{u} = \boldsymbol{\gamma}' \qquad 2\left(\lambda\mathbf{I} + \frac{\mathbf{X}'\mathbf{X}'^\top}{2}\right)\mathbf{w} = 2(\mathbf{X}'\boldsymbol{Y})\boldsymbol{\alpha} + \boldsymbol{\gamma}'. \tag{31}$$

Condition (30) implies that the terms involving r and $\boldsymbol{\mu}$ will vanish from the Lagrangian. Furthermore, the first equation in (31) implies that any feasible $\boldsymbol{\gamma}'$ must satisfy $\boldsymbol{\gamma}' = \mathbf{X}'\boldsymbol{\gamma}$ for some $\gamma \in \mathbb{R}^n$. Finally, it is immediate that $\boldsymbol{\gamma}'^\top\mathbf{u} = \mathbf{u}^\top\mathbf{X}'\mathbf{X}'^\top\mathbf{u}$ and $2\mathbf{w}^\top\left(\lambda\mathbf{I} + \frac{\mathbf{X}'\mathbf{X}'^\top}{2}\right)\mathbf{w} = 2\boldsymbol{\alpha}^\top(\mathbf{X}'\mathbf{Y})^\top\mathbf{w} + \boldsymbol{\gamma}'^\top\mathbf{w}$. Thus, at the optimal point, the Lagrangian becomes

$$\begin{aligned}& -\mathbf{w}^\top\left(\lambda\mathbf{I} + \frac{1}{2}\mathbf{X}'\mathbf{X}'^\top\right)\mathbf{w} - \frac{1}{2}\mathbf{u}^\top\mathbf{X}'\mathbf{X}'^\top\mathbf{u} + \boldsymbol{\alpha}^\top\mathbf{y}' - \beta\\ \text{s. t.} \quad & \mathbf{1}^\top\boldsymbol{\alpha} = \frac{1}{2} \qquad \mathbf{1}\beta = \boldsymbol{\delta} - \boldsymbol{W}^\top\boldsymbol{\gamma}' \qquad \boldsymbol{\alpha} \geq 0 \wedge \boldsymbol{\delta} \geq 0.\end{aligned}$$

The positivity of $\boldsymbol{\delta}$ implies that $\mathbf{1}\beta \geq -\boldsymbol{W}^\top\boldsymbol{\gamma}'$. Solving for $\mathbf{w}$ and $\mathbf{u}$ on (31) and applying the change of variable $\mathbf{X}'\boldsymbol{\gamma} = \boldsymbol{\gamma}'$ we obtain the final expression for the dual problem:

$$\begin{aligned}\max_{\boldsymbol{\alpha},\boldsymbol{\gamma},\beta} \; & -\left(\mathbf{Y}\boldsymbol{\alpha} + \frac{\boldsymbol{\gamma}}{2}\right)^\top\mathbf{X}'^\top\left(\lambda\mathbf{I} + \frac{\mathbf{X}'\mathbf{X}'^\top}{2}\right)^{-1}\mathbf{X}'\left(\mathbf{Y}\boldsymbol{\alpha} + \frac{\boldsymbol{\gamma}}{2}\right) - \frac{1}{2}\boldsymbol{\gamma}^\top\mathbf{X}'^\top(\mathbf{X}'\mathbf{X}'^\top)^\dagger\mathbf{X}'\boldsymbol{\gamma} + \boldsymbol{\alpha}^\top\mathbf{y}' - \beta\\ \text{s. t.} \; & \mathbf{1}^\top\boldsymbol{\alpha} = \frac{1}{2} \qquad \mathbf{1}\beta \geq -\mathbf{Y}^\top\boldsymbol{\gamma} \qquad \boldsymbol{\alpha} \geq 0,\end{aligned}$$

where we have used the fact that $\mathbf{Y}^\top\boldsymbol{\gamma} = \mathbf{W}\mathbf{X}'^\top\boldsymbol{\gamma}$ to simplify the constraints. Notice also that we can recover the solution $\mathbf{w}$ of problem (29) as $\mathbf{w} = (\lambda\mathbf{I} + \frac{1}{2}\mathbf{X}'^\top\mathbf{X}')^{-1}\mathbf{X}'(\mathbf{Y}\boldsymbol{\alpha} + \frac{1}{2}\boldsymbol{\gamma})$ ■

The proof of Proposition 18 follows from a straightforward application of the well known matrix identities $\mathbf{X}'(\lambda\mathbf{I} + \mathbf{X}'^\top\mathbf{X}')^{-1} = (\lambda\mathbf{I} + \mathbf{X}'\mathbf{X}'^\top)^{-1}\mathbf{X}'$ and $\mathbf{X}'^\top\mathbf{X}'(\mathbf{X}'^\top\mathbf{X}')^\dagger = \mathbf{X}'^\top(\mathbf{X}'\mathbf{X}'^\top)^\dagger\mathbf{X}'$, and by the fact that the kernel matrix $\mathbf{K}_t$ is equal to $\mathbf{X}'^\top\mathbf{X}'$.

Appendix C. μ-admissibility

Lemma 23 *Assume that $L_p(h(x), y) \leq M$ for all $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, then L_p is μ-admissible with $\mu = pM^{p-1}$.*

Proof Since $x \mapsto x^p$ is p-Lipschitz over $[0, 1]$ we can write

$$\begin{aligned}|L(h(x), y) - L(h'(x), y)| &= M^p\left|\left(\frac{|h(x) - y|}{M}\right)^p - \left(\frac{|h'(x) - y|}{M}\right)^p\right|\\ &\leq pM^{p-1}|h(x) - y + y - h'(x)| = pM^{p-1}|h(x) - h'(x)|.\end{aligned}$$

■

Lemma 24 *Let L be the L_p loss for some $p \geq 1$ and let h, h', h'' be functions satisfying $L_p(h(x), h'(x)) \leq M$ and $L_p(h''(x), h'(x)) \leq M$ for all $x \in \mathcal{X}$, for some $M \geq 0$. Then, for any distribution $\mathcal{D}$ over $\mathcal{X}$, the following inequality holds:*

$$|\mathcal{L}_\mathcal{D}(h, h') - \mathcal{L}_\mathcal{D}(h'', h')| \leq pM^{p-1}[\mathcal{L}_\mathcal{D}(h, h'')]^{\frac{1}{p}}. \tag{32}$$

Proof Proceeding as in the proof of Lemma 23, we obtain

$$\begin{aligned}|\mathcal{L}_\mathcal{D}(h, h') - \mathcal{L}_\mathcal{D}(h'', h')| &= |\operatorname*{E}_{x\in\mathcal{D}}\left[L_p(h(x), h'(x)) - L_p(h''(x), h'(x)\right]|\\ &\leq pM^{p-1}\operatorname*{E}_{x\in\mathcal{D}}\left[|h(x) - h''(x)|\right].\end{aligned}$$

Since $p \geq 1$, by Jensen's inequality, we can write $\operatorname{E}_{x\in\mathcal{D}}\left[|h(x) - h''(x)|\right] \leq \operatorname{E}_{x\in\mathcal{D}}\left[|h(x) - h''(x)|^p\right]^{1/p} = [\mathcal{L}_\mathcal{D}(h, h'')]^{\frac{1}{p}}$. ■

Abstract

We investigated the feature map inside deep neural networks (DNNs) by tracking the transport map. We are interested in the *role of depth*—why do DNNs perform better than shallow models?—and the *interpretation* of DNNs—what do intermediate layers do? Despite the rapid development in their application, DNNs remain analytically unexplained because the hidden layers are nested and the parameters are not faithful. Inspired by the *integral representation* of shallow NNs, which is the continuum limit of the width, or the hidden unit number, we developed the *flow representation* and *transport analysis* of DNNs. The flow representation is the continuum limit of the depth, or the hidden layer number, and it is specified by an ordinary differential equation (ODE) with a vector field. We interpret an ordinary DNN as a *transport map* or an Euler broken line approximation of the flow. Technically speaking, a dynamical system is a natural model for the nested feature maps. In addition, it opens a new way to the coordinate-free treatment of DNNs by avoiding the redundant parametrization of DNNs. Following *Wasserstein geometry*, we analyze a flow in three aspects: dynamical system, continuity equation, and Wasserstein gradient flow. A key finding is that we specified a series of transport maps of the *denoising autoencoder* (DAE), which is a cornerstone for the development of deep learning. Starting from the shallow DAE, this paper develops three topics: the transport map of the deep DAE, the equivalence between the stacked DAE and the composition of DAEs, and the development of the double continuum limit or the integral representation of the flow representation. As partial answers to the research questions, we found that deeper DAEs converge faster and the extracted features are better; in addition, a deep Gaussian DAE transports mass to decrease the Shannon entropy of the data distribution. We expect that further investigations on these questions lead to the development of an interpretable and principled alternatives to DNNs.

Keywords: representation learning, denoising autoencoder, flow representation, continuum limit, backward heat equation, Wasserstein geometry, ridgelet analysis

1. Introduction

Despite the rapid development in their application, deep neural networks (DNN) remain analytically unexplained. We are interested in the *role of depth—why do DNNs perform better than shallow models?*—and the *interpretation* of DNNs—*what do intermediate layers do?* To the best of our knowledge, thus far, traditional theories, such as the statistical learning theory (Vapnik, 1998), have not succeeded in completely answering the above questions (Zhang et al., 2018). Existing DNNs lack interpretability; hence, a DNN is often called a *blackbox*. In this study, we propose the *flow representation* and *transport analysis* of DNNs, which provide us with insights into why DNNs can perform better and facilitate our understanding of what DNNs do. We expect that these lines of study lead to the development of an interpretable and principled alternatives to DNNs.

Compared to other *shallow models*, such as kernel methods (Shawe-Taylor and Cristianini, 2004) and ensemble methods (Schapire and Freund, 2012), DNNs have at least two specific technical issues: the *function composition* and the *redundant and complicated parametrization*. First, a DNN is formally a composite $\boldsymbol{g}_L \circ \cdots \circ \boldsymbol{g}_0$ of intermediate maps $\boldsymbol{g}_\ell (\ell = 0, \dots, L)$. Here, each $\boldsymbol{g}_\ell$ corresponds to the ℓ-th hidden layer. Currently, our understanding of learning machines is based on *linear algebra*, i.e., the *basis and coefficients* (Vapnik, 1998). Linear algebra is compatible with shallow models because a shallow model is a linear combination of basis functions. However, it has poor compatibility with deep models because the function composition $(\boldsymbol{f}, \boldsymbol{g}) \mapsto \boldsymbol{f} \circ \boldsymbol{g}$ is not assumed in the standard definition of the linear space. Therefore, we should move to spaces where the function composition is defined, such as monoids, semigroups, and *dynamical systems*. Second, the standard parametrization of the NN, such as $\boldsymbol{g}_\ell(\boldsymbol{x}) = \sum_{j=1}^{p} \boldsymbol{c}_j^\ell \sigma(\boldsymbol{a}_j^\ell \cdot \boldsymbol{x} - b_j^\ell)$, is redundant because there exist different sets of parameters that specify the same function, which causes technical problems, such as local minima. Furthermore, it is complicated because the interpretation of parameters is usually impossible, which results in the blackbox nature of DNNs. Therefore, we need a new parametrization that is concise in the sense that different parameters specify different functions and simple in the sense that it is easy to understand.

For shallow NNs, the *integral representation theory* (Murata, 1996; Candès, 1998; Sonoda and Murata, 2017a) provides a concise and simple reparametrization. The integral representation is derived by a continuum limit of the *width* or the number of hidden units. Owing to the *ridgelet transform* or a pseudo-inverse operator of the integral representation operator, it is concise and simple (see Section 1.3.2 for further details on the ridgelet transform). Furthermore, in the integral representation, we can compute the parameters of the shallow NN that attains the *global minimum* of the backpropagation training (Sonoda et al., 2018). In the integral representation, thus far, the shallow NNs is no longer a blackbox, and the training is principled. However, the integral representation is again based on linear algebra, the scope of which does not include DNNs.

Inspired by the integral representation theory, we introduced the *flow representation* and developed the *transport analysis* of DNNs. The flow representation is derived by a continuum limit of the *depth* or the number of hidden layers. In the flow representation, we formulate a DNN as a flow of an ordinary differential equation (ODE) $\dot{\boldsymbol{x}}_t = \boldsymbol{v}_t(\boldsymbol{x}_t)$ with vector field $\boldsymbol{v}_t$. In addition, we introduced the *transport map* by which we call a discretization $\boldsymbol{x} \mapsto \boldsymbol{x} + \boldsymbol{f}_t(\boldsymbol{x})$ of the flow. Specifically, we regard the intermediate map $\boldsymbol{g} : \mathbb{R}^m \to \mathbb{R}^n$ of an ordinary DNN as a transport map that transfers the mass at $\boldsymbol{x} \in \mathbb{R}^m$ toward $\boldsymbol{g}(\boldsymbol{x}) \in \mathbb{R}^n$. Since the flow and transport map are independent of coordinates, they enable us the coordinate-free treatment of DNNs. In the transport analysis, following *Wasserstein geometry* (Villani, 2009), we track a flow by analyzing the three profiles of the

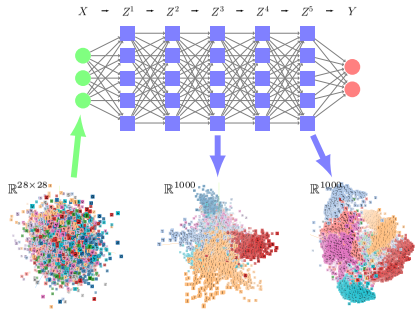

Figure 1: Mass transportation in a deep neural network that classifies images of digits. In the final hidden layer, the feature vectors have to be linearly separable because the output layer is just a linear classifier. Hence, through the network, the same digits gradually accumulate and different digits gradually separate.

flow: *dynamical system*, *pushforward measure*, and *Wasserstein gradient flow* (Ambrosio et al., 2008) (see Section 2 for further details).

We note that when the input and the output differ in dimension, i.e., $m \neq n$, we simply consider that both the input space and the output space are embedded in a common high-dimensional space. As a composite of transport maps leads to another transport map, the transport map has compatibility with deep structures. In this manner, transportation is a universal characteristic of DNNs. For example, let us consider a digit recognition problem with DNNs. We can expect the feature extractor in the DNN to be a transport map that separates the feature vectors of different digits, similar to the separation of *oil and water* (see Figure 1 for example). At the time of the initial submission in 2016, the flow representation seemed to be a novel viewpoint of DNNs. At present, it is the mainstream of development. For example, two important DNNs—residual network (ResNet) (He et al., 2016) and generative adversarial net (GAN) (Goodfellow et al., 2014)—are now considered to be transport maps (see Section 1.2 for a more detailed survey). Instead of directly investigating DNNs in terms of the redundant and complex parametrization, we perform transport analysis associated with the flow representation. We consider that the flow representation is potentially concise and simple because the flow is independent of parametrization, and it is specified by a single vector field $\boldsymbol{v}$.

In this study, we demonstrate transport analysis of the *denoising autoencoder (DAE)*. The DAE was introduced by Vincent et al. (2008) as a heuristic modification to enhance the robustness of the traditional autoencoder. The traditional autoencoder is an NN that is trained as an identity map $\boldsymbol{g}(\boldsymbol{x}) = \boldsymbol{x}$. The hidden layer of the network is used as a feature map, which is often called the "code" because the activation pattern appears to be random, but it surely encodes some information about the input data. On the other hand, the DAE is an NN that is trained as a "denoising" map $\boldsymbol{g}(\widetilde{\boldsymbol{x}}) \approx \boldsymbol{x}$ of deliberately corrupted inputs $\widetilde{\boldsymbol{x}}$. The DAE is a cornerstone for the development of deep learning or representation learning (Bengio et al., 2013a). Although the *corrupt and denoise* principle is simple, it is

successful and has inspired many representation learning algorithms (see Section 1.3.1 for example). Furthermore, we investigate *stacking* (Bengio et al., 2007) of DAEs. Because *stacked DAE* (Vincent et al., 2010) runs DAEs on the codes in the hidden layer, it has been less investigated, so far.

The key finding is that when the corruption process is additive, i.e., $\widetilde{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{\varepsilon}$ with some noise $\boldsymbol{\varepsilon}$, then the DAE $\boldsymbol{g}$ is given by the sum of the traditional autoencoder $\widetilde{\boldsymbol{x}} \mapsto \widetilde{\boldsymbol{x}}$ and a certain denoising term $\widetilde{\boldsymbol{x}} \mapsto \boldsymbol{f}_t(\widetilde{\boldsymbol{x}})$ parametrized by noise variance t:

$$\boldsymbol{g}_t(\widetilde{\boldsymbol{x}}) = \widetilde{\boldsymbol{x}} + \boldsymbol{f}_t(\widetilde{\boldsymbol{x}}). \tag{1}$$

From the statistical viewpoint, this equation is reasonable because the DAE amounts to an estimation problem of the mean parameter. Obviously, (1) is a transport map because the denoising term $\boldsymbol{f}_t$ is a displacement vector from the origin $\widetilde{\boldsymbol{x}}$ and the noise variance t is the transport time. Starting from the shallow DAE, this paper develops three topics: the transport map of the deep DAE, the equivalence between the stacked DAE and the composition of DAEs, and the development of the double continuum limit, or the integral representation of the flow representation.

1.1. Contributions of This Study

In this paper, we introduce the flow representation of DNNs and develop the transport analysis of DAEs. The contributions of this paper are listed below.

- We introduced the flow representation, which can avoid the redundancy and complexity of the ordinary parametrization of DNNs.
- We specified the transport maps of shallow, deep, and infinitely deep DAEs, and provided their statistical interpretations. The shallow DAE is an estimator of the mean, and the deep DAE transports data points to decrease the Shannon entropy of the data distribution. According to analytic and numerical experiments, we showed that deep DAEs can extract much more information than shallow DAEs.
- We proved the equivalence between the stacked DAE and the composition of DAEs. Because of the peculiar construction, it is difficult to formulate and understand stacking. Nevertheless, by tracking the flow, we succeeded in formulating the stacked DAE. Consequently, we can interpret the effect of the *pre-training* as a regularization of hidden layers.
- We provided a new direction for the mathematical modeling of DNNs: the double continuum limit or the integral representation of the flow representation. We presented some examples of the double continuum limit of DAEs. In the integral representation, the shallow NNs is no longer a blackbox, and the training is principled. We consider that further investigations on the double continuum limit lead to the development of an interpretable and principled alternatives to DNNs.

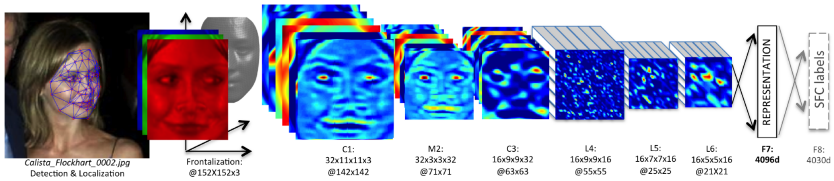

Figure 2: The activation patterns in DeepFace gradually changes (Taigman et al., 2014).

1.2. Related Work

1.2.1. Why Deep?

Before the success of deep learning, traditional theories were skeptical of the depth concept. According to approximation theory, (not only NNs but also) various shallow models can approximate any function (Pinkus, 2005). According to estimation theory, various shallow models can attain the minimax optimal ratio (Tsybakov, 2009). According to optimization theory, the depth does nothing but increase the complexity of loss surfaces unnecessarily (Boyd and Vandenberghe, 2004). In reality, of course, DNNs perform overwhelmingly better than shallow models. Thus far, the learning theory has not succeeded in explaining the gap between theory and reality (Zhang et al., 2017).

In recent years, these theories have changed drastically. For example, many authors claim that the depth increases the expressive power in the exponential order while the width does so in the polynomial order (Telgarsky, 2016; Eldan and Shamir, 2016; Cohen et al., 2016; Yarotsky, 2017), and that DNNs can attain the minimax optimal ratio in wider classes of functions (Schmidt-Hieber, 2017; Imaizumi and Fukumizu, 2019). Radical reviews of the shape of loss surfaces (Dauphin et al., 2014; Choromanska et al., 2015; Kawaguchi, 2016; Soudry and Carmon, 2016), the implicit regularization by stochastic gradient descent (Neyshabur, 2017), and the acceleration effect by over-parametrization (Nguyen and Hein, 2017; Arora et al., 2018) are ongoing. Besides the recent trends toward the rationalization of deep learning, neutral yet interesting studies have been published (Ba and Caruana, 2014; Lin et al., 2017; Poggio et al., 2017). In this study, we found that deep DAEs converge faster and that the extracted features are different from each other.

1.2.2. What Do Deep Layers Do?

Traditionally, DNNs are said to construct the hierarchy of meanings (Hinton, 1989). In convolutional NNs for image recognition, such hierarchies are empirically observed (Lee, 2010; Krizhevsky et al., 2012; Zeiler and Fergus, 2014). The hierarchy hypothesis seems to be acceptable, but it lacks explanations as to how the hierarchy is organized.

Taigman et al. (2014) reported an interesting phenomenon whereby the activation patterns in the hidden layers change by gradation from face-like patterns to codes. Inspired by Figure 2, we came up with the idea of regarding the activation pattern as a coordinate and the depth as the transport time.

1.2.3. Flow Inside Neural Networks

At the time of the initial submission in 2016, the flow representation, especially the continuum limit of the depth and collaboration with Wasserstein geometry, seemed to be a novel viewpoint of DNNs. At present, it is the mainstream of development.

Alain and Bengio (2014) was the first to derive a special case of (1), which motivated our study. Then, Alain et al. (2016) developed the generative model as a probabilistic reformulation of DAE. The generative model was a new frontier at that time; now, it is widely used in variational autoencoders (Kingma and Welling, 2014), generative adversarial nets (GANs) (Goodfellow et al., 2014), minimum probability flows (Sohl-Dickstein et al., 2015), and normalizing flows (Rezende and Mohamed, 2015). Generative models have high compatibility with transport analysis because they are formulated as Markov processes. In particular, the *generator* in GANs is exactly a transport map because it is a change-of-distribution $\boldsymbol{g} : M \to N$ from a normal distribution to a data distribution. From this viewpoint, Arjovsky et al. (2017) succeeded in stabilizing the training process of GANs by introducing Wasserstein geometry.

The *skip connection* in the residual network (ResNet) (He et al., 2016) is considered to be a key structure for training a super-deep network with more than $1,000$ layers. Formally, the skip connection is a transport map because it has an expression $\boldsymbol{g}(\boldsymbol{x}) = \boldsymbol{x} + \boldsymbol{f}(\boldsymbol{x})$. From this viewpoint, Nitanda and Suzuki (2018) reformulated the ResNet as a functional gradient and estimated the generalization error, and Lu et al. (2018) unified various ResNets as ODEs. In addition, Chizat and Bach (2018) proved the global convergence of stochastic gradient descent (SGD) using Wasserstein gradient flow. Novel deep learning methods have been proposed by controlling the flow (Ioffe and Szegedy, 2015; Gomez et al., 2017; Haber and Ruthotto, 2018; Li and Hao, 2018; Chen et al., 2018).

We remark that in shrinkage statistics, the expression of the transport map $\boldsymbol{x} + \boldsymbol{f}(\boldsymbol{x})$ is known as Brown's representation of the posterior mean (George et al., 2006). Liu and Wang (2016) analyzed it and proposed a Bayesian inference algorithm, apart from deep learning.

1.3. Background

1.3.1. Denoising Autoencoders

The *denoising autoencoder (DAE)* is a fundamental model for representation learning, the objective of which is to capture a good representation of the data. Vincent et al. (2008) introduced it as a heuristic modification of traditional autoencoders for enhancing robustness. In the setting of traditional autoencoders, we train an NN as an identity map $\boldsymbol{x} \mapsto \boldsymbol{x}$ and extract the hidden layer to obtain the so-called "code." On the other hand, the DAE is trained as a denoising map $\widetilde{\boldsymbol{x}} \mapsto \boldsymbol{x}$ of deliberately corrupted inputs $\widetilde{\boldsymbol{x}}$. Although the *corrupt and denoise* principle is simple, it has inspired many next-generation models. In this study, we analyze DAE variants such as shallow DAE, deep DAE (or composition of DAEs), infinitely deep DAE (or continuous DAE), and stacked DAE. Stacking (Bengio et al., 2007) was proposed in the early stages of deep learning, and it remains a mysterious treatment because it runs DAEs on codes in the hidden layer.

The theoretical justifications and extensions follow from at least five standpoints: manifold learning (Rifai et al., 2011; Alain and Bengio, 2014), generative modeling (Vincent et al., 2010; Bengio et al., 2013b, 2014), infomax principle (Vincent et al., 2010), learning

dynamics (Erhan et al., 2010), and score matching (Vincent, 2011). The first three standpoints were already mentioned in the original paper (Vincent et al., 2008). According to these standpoints, a DAE extracts one of the following from the data set: a manifold on which the data are arranged (manifold learning); the latent variables, which often behave as nonlinear coordinates in the feature space, that generate the data (generative modeling); a transformation of the data distribution that maximizes the mutual information (infomax); good initial parameters that allow the training to avoid local minima (learning dynamics); or the data distribution (score matching). A turning point appears to be the finding of the score matching aspect (Vincent, 2011), which reveals that score matching with a special form of the energy function coincides with a DAE. Thus, a DAE is a density estimator of the data distribution μ. In other words, it extracts and stores information as a function of μ. Since then, many researchers have avoided stacking deterministic autoencoders and have developed generative density estimators (Bengio et al., 2013b, 2014) instead.

1.3.2. Integral Representation Theory and Ridgelet Analysis

The flow representation is inspired by the integral representation theory (Murata, 1996; Candès, 1998; Sonoda and Murata, 2017a).

The integral representation

$$S[\gamma](\boldsymbol{x}) = \int \gamma(\boldsymbol{a}, b)\sigma(\boldsymbol{a}\cdot\boldsymbol{x} - b)\mathrm{d}\lambda(\boldsymbol{a}, b) \tag{2}$$

is a continuum limit of a shallow NN $g_p(\boldsymbol{x}) = \sum_{j=1}^p c_j\sigma(\boldsymbol{a}_j\cdot\boldsymbol{x}-b_j)$ as the hidden unit number $p\to\infty$. In $S[\gamma]$, every possible nonlinear parameter $(\boldsymbol{a}, b)$ is "integrated out," and only linear parameters c_j remain as a coefficient function $\gamma(\boldsymbol{a}, b)$. Therefore, we do not need to select which $(\boldsymbol{a}, b)$'s to use, which amounts to a non-convex optimization problem. Instead, the coefficient function $\gamma(\boldsymbol{a}, b)$ automatically selects the $(\boldsymbol{a}, b)$'s by weighting them. Similar reparametrization techniques have been proposed for Bayesian NNs (Radford M. Neal, 1996) and convex NNs (Bengio et al., 2006; Bach, 2017a). Once a coefficient function γ is given, we can obtain an ordinary NN g_p that approximates $S[\gamma]$ by numerical integration. We also remark that the integral representation $S[\gamma_p]$ with a singular coefficient $\gamma_p := \sum_{j=1}^p c_j\delta_{(\boldsymbol{a}_j,b_j)}$ leads to an ordinary NN g_p.

The advantage of the integral representation is that the solution operator—the *ridgelet transform*—to the integral equation $S[\gamma] = f$ and the optimization problem of $L[\gamma] := \|S[\gamma]-f\|^2+\beta\|\gamma\|^2$ is known. The ridgelet transform with an admissible function ρ is given by

$$R[f](\boldsymbol{a}, b) := \int_{\mathbb{R}^m} f(\boldsymbol{x})\overline{\rho(\boldsymbol{a}\cdot\boldsymbol{x} - b)}\mathrm{d}\boldsymbol{x}. \tag{3}$$

The integral equation $S[\gamma] = f$ is a traditional form of learning, and the ridgelet transform $\gamma = R[f]$ satisfies $S[\gamma] = S[R[f]] = f$ (Murata, 1996; Candès, 1998; Sonoda and Murata, 2017a). The optimization problem of $L[\gamma]$ is a modern form of learning, and a modified version of the ridgelet transform gives the global optimum (Sonoda et al., 2018). These studies imply that a shallow NN is *no longer a blackbox* but a ridgelet transform of the data set. Traditionally, the integral representation has been developed to estimate the

approximation and estimation error bounds of shallow NNs g_p (Barron, 1993; Kůrková, 2012; Klusowski and Barron, 2017, 2018; Suzuki, 2018). Recently, the numerical integration methods for $R[f]$ and $S[R[f]]$ were developed (Candès, 1998; Sonoda and Murata, 2014; Bach, 2017b) with various f, including the MNIST classifier. Hence, by computing the ridgelet transform of the data set, we can obtain the global minimizer without gradient descent.

Thus far, the integral representation is known as an efficient reparametrization method to facilitate understanding of the hidden layers, to estimate the approximation and estimation error bounds of shallow NNs, and to calculate the hidden parameters. However, it is based on linear algebra, i.e., it starts by regarding c_j and $\sigma(\boldsymbol{a}_j\cdot\boldsymbol{x} - b_j)$ as coefficients and basis functions, respectively. Therefore, the integral representation for DNNs is not trivial at all.

1.3.3. Optimal Transport Theory and Wasserstein Geometry

The optimal transport theory (Villani, 2009) originated from the practical requirement in the 18th century to transport materials at the minimum cost. At the end of the 20th century, it was transformed into *Wasserstein geometry,* or the geometry on the space of probability distributions. Recently, Wasserstein geometry has attracted considerable attention in statistics and machine learning. One of the reasons for its popularity is that the *Wasserstein distance* can capture the difference between two singular measures, whereas the traditional Kullback-Leibler distance cannot (Arjovsky et al., 2017). Another reason is that it gives a unified perspective on a series of function inequalities, including the concentration inequality. Computation methods for the Wasserstein distance and Wasserstein gradient flow have also been developed (Peyré and Cuturi, 2018; Nitanda and Suzuki, 2018; Zhang et al., 2018). In this study, we employ *Wasserstein gradient flow* (Ambrosio et al., 2008) for the characterization of DNNs.

Given a density μ of materials in $\mathbb{R}^m$, a density ν of final destinations in $\mathbb{R}^m$, and a cost function $c : \mathbb{R}^m\times\mathbb{R}^m\to\mathbb{R}$ associated with the transportation, under some regularity conditions, there exist some optimal transport map(s) $\boldsymbol{g} : \mathbb{R}^m\to\mathbb{R}^m$ that attain the minimum transportation cost. Let $W(\mu,\nu)$ denote the minimum cost of the transportation problem from μ to ν. Then, it behaves as the distance between two probability densities μ and ν, and it is called the *Wasserstein distance*, which is the start point of Wasserstein geometry.

When the cost function c is given by the ℓ^p-distance, i.e., $c(\boldsymbol{x},\boldsymbol{y}) = |\boldsymbol{x}-\boldsymbol{y}|_p$, the corresponding Wasserstein distance is called the L^p-Wasserstein distance $W_p(\mu,\nu)$. Let $\mathcal{P}_p(\mathbb{R}^m)$ be the space of probability densities on $\mathbb{R}^m$ that have at least the p-th moment. The distance space $\mathcal{P}_p(\mathbb{R}^m)$ equipped with L^p-Wasserstein distance W_p is called the *L^p-Wasserstein space*. Furthermore, the L^2-Wasserstein space $(\mathcal{P}_2, W_2)$ admits the *Wasserstein metric* $\mathfrak{g}_2$, which is an infinite-dimensional Riemannian metric that induces the L^2-Wasserstein distance as the geodesic distance. Owing to $\mathfrak{g}_2$, the L^2-Wasserstein space is an infinite-dimensional manifold. On $\mathcal{P}_2$, we can introduce the tangent space $T_\mu\mathcal{P}_2$ at $\mu\in\mathcal{P}_2$, and the gradient operator grad, which are fundamentals to define *Wasserstein gradient flow*. See Section 2 for more details.

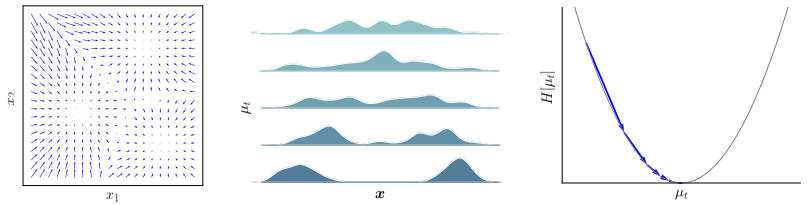

Figure 3: Three profiles of a flow analyzed in the transport analysis: dynamical system in $\mathbb{R}^m$ described by vector field (or transport map) (**left**), pushforward measure described by continuity equation in $\mathbb{R}^m$ (**center**), and Wasserstein gradient flow in $\mathcal{P}_2(\mathbb{R}^m)$ (**right**).

Organization of This Paper

In Section 2, we describe the framework of transport analysis, which combines a quick introduction to dynamical systems theory, optimal transport theory, and Wasserstein gradient flow. In Section 3 and 4, we specify the transport maps of shallow, deep, and infinitely deep DAEs, and we give their statistical interpretations. In Section 5, we present analytic examples and the results of numerical experiments. In Section 6, we prove the equivalence between the stacked DAE and the composition of DAEs. In Section 7, we develop the integral representation of the flow representation.

Remark

After the initial submission of the manuscript in 2016, the present manuscript has been substantially reorganized and updated. The authors presented the digests of some results from Section 3, 4 and 7 in two workshops (Sonoda and Murata, 2017b,c).

2. Transport Analysis of Deep Neural Networks

In the transport analysis, we regard a deep neural network as a transport map, and we track the flow in three scales: microscopic, mesoscopic, and macroscopic. Wasserstein geometry provides a unified framework for bridging these three scales. In each scale, we analyze three profiles of the flow: dynamical system, pushforward measure, and Wasserstein gradient flow.

First, on the microscopic scale, we analyze the transport map $\boldsymbol{g}_t : \mathbb{R}^m \to \mathbb{R}^m$, which simply describes the transportation of every point. In continuum mechanics, this viewpoint corresponds to the Eulerian description. The transport map $\boldsymbol{g}_t$ is often associated with a velocity field $\boldsymbol{v}_t$ that summarizes all the behavior of $\boldsymbol{g}_t$ by an ODE or the continuous dynamical system: $\partial_t \boldsymbol{g}_t(\boldsymbol{g}_t(\boldsymbol{x})) = \boldsymbol{v}_t(\boldsymbol{g}_t(\boldsymbol{x}))$. We note that, as suggested by chaos theory, it is generally difficult to track a continuous dynamics.

Second, on the mesoscopic scale, we analyze the pushforward μ_t or the time evolution of the data distribution. In continuum mechanics, this viewpoint corresponds to the Lagrangian description. When the transport map is associated with a vector field $\boldsymbol{v}_t$, then the corresponding distributions evolve according to a partial differential equation (PDE) or the

continuity equation $\partial_t \mu_t = -\nabla \cdot [\boldsymbol{v}_t \mu_t]$. We note that, as suggested by fluid dynamics, it is generally difficult to track a continuity equation.

Finally, on the macroscopic scale, we analyze the Wasserstein gradient flow or the trajectories of time evolution of μ_t in the space $\mathcal{P}(\mathbb{R}^m)$ of probability distributions on $\mathbb{R}^m$. When the transport map is associated with a vector field $\boldsymbol{v}_t$, then there exists a time-independent potential functional F on $\mathcal{P}(\mathbb{R}^m)$ such that an evolution equation or the Wasserstein gradient flow $\dot{\mu}_t = -\mathsf{grad}\, F[\mu_t]$ coincides with the continuity equation. We remark that tracking a Wasserstein gradient flow may be easier compared to the two above-mentioned cases, because the potential functional is independent of time.

2.1. Transport Map and Flow

In the broadest sense, a *transport map* is simply a measurable map $\boldsymbol{g} : M \to N$ between two probability spaces M and N (see Definition 1.2 in Villani, 2009, for example). In this study, we use the term as an update rule. Depending on the context, we distinguish the term "flow" from "transport map." While a flow is associated with a continuous dynamical system, a transport map is associated with a discrete dynamical system. We understand that a transport map arises as a discretization of a flow. An ordinary DNN coincides with a transport map, and the depth continuum limit coincides with a flow.

Definition 1 *A transport map* $\boldsymbol{g} : \mathbb{R}^m \to \mathbb{R}^m$ *is a measurable map given by*

$$\begin{cases} \boldsymbol{g}_t(\boldsymbol{x}) = \boldsymbol{x} + \boldsymbol{f}_t(\boldsymbol{x}), & \boldsymbol{x} \in \mathbb{R}^m,\ t > 0 \\ \boldsymbol{g}_0(\boldsymbol{x}) = \boldsymbol{x}, & \boldsymbol{x} \in \mathbb{R}^m,\ t = 0, \end{cases} \tag{4}$$

with an update vector $\boldsymbol{f}_t$.

Definition 2 *A flow* $\boldsymbol{\varphi}_t$ *is given by an ordinary differential equation (ODE),*

$$\begin{cases} \dot{\boldsymbol{\varphi}}_t(\boldsymbol{x}) = \boldsymbol{v}_t(\boldsymbol{\varphi}_t(\boldsymbol{x})), & \boldsymbol{x} \in \mathbb{R}^m,\ t > 0 \\ \boldsymbol{\varphi}_0(\boldsymbol{x}) = \boldsymbol{x}, & \boldsymbol{x} \in \mathbb{R}^m,\ t = 0, \end{cases} \tag{5}$$

with a velocity field $\boldsymbol{v}_t$.

In particular, we are interested in the case when the update rule (4) is a tangent line approximation of a flow (5). i.e., $\boldsymbol{g}_t$ satisfies

$$\lim_{t \to 0} \frac{\boldsymbol{g}_t(\boldsymbol{x}) - \boldsymbol{x}}{t} = \boldsymbol{v}_0(\boldsymbol{x}), \quad \boldsymbol{x} \in \mathbb{R}^m \tag{6}$$

for some $\boldsymbol{v}_t$. In this case, the velocity field $\boldsymbol{v}_t$ is the only parameter that determines the transport map.

2.2. Pushforward Measure and Continuity Equation

In association with the mass transportation $\boldsymbol{x} \mapsto \boldsymbol{g}_t(\boldsymbol{x})$, the data distribution μ_0 itself changes its shape to, say, μ_t (see Figure 4, for example). Technically speaking, μ_t is called (the density of) the *pushforward measure* of μ_0 by $\boldsymbol{g}_t$, and it is denoted by $\boldsymbol{g}_{t\sharp}\mu_0$.

Definition 3 *Let μ be a Borel measure on M and $\boldsymbol{g} : M \to N$ be a measurable map. Then, $\boldsymbol{g}_\sharp\mu$ denotes the image measure (or pushforward) of μ by $\boldsymbol{g}$. It is a measure on N, defined by $(\boldsymbol{g}_\sharp\mu)(B) = \mu \circ \boldsymbol{g}^{-1}(B)$ for every Borel set $B \subset N$.*

The pushforward μ_t is calculated by the change-of-variables formula. In particular, the following extended version by Evans and Gariepy (2015, Theorem 3.9) from geometric measure theory is useful.

Fact 1 *Let $\boldsymbol{g} : \mathbb{R}^m \to \mathbb{R}^n$ be Lipschitz continuous, $m \leq n$, and μ be a probability density on $\mathbb{R}^m$. Then, the pushforward $\boldsymbol{g}_\sharp\mu$ satisfies*

$$\boldsymbol{g}_\sharp\mu \circ \boldsymbol{g}(\boldsymbol{x})[\nabla \boldsymbol{g}](\boldsymbol{x}) = \mu(\boldsymbol{x}), \quad \text{a.e. } \boldsymbol{x}. \tag{7}$$

Here, the Jacobian is defined by

$$[\nabla \boldsymbol{g}] = \sqrt{\det |(\nabla \boldsymbol{g})^* \circ (\nabla \boldsymbol{g})|}. \tag{8}$$

The continuity equation describes the one-to-one relation between a flow and the pushforward.

Fact 2 *Let $\boldsymbol{\varphi}_t$ be the flow of an ODE (5) with vector field $\boldsymbol{v}_t$. Then, the pushforward μ_t of the initial distribution μ_0 evolves according to the* continuity equation

$$\partial_t \mu_t(\boldsymbol{x}) = -\nabla \cdot [\mu_t(\boldsymbol{x}) \boldsymbol{v}_t(\boldsymbol{x})], \quad \boldsymbol{x} \in \mathbb{R}^m, t \geq 0. \tag{9}$$

Here, $\nabla\cdot$ denotes the divergence operator in $\mathbb{R}^m$.

The continuity equation is also known as the *conservation of mass formula*, and this relation between the partial differential equation (PDE) (9) and the ODE (5) is a well-known fact in continuum physics (Villani, 2009, pp.19). See Appendix B for a sketch of the proof and Ambrosio et al. (2008, § 8) for more detailed discussions.

2.3. Wasserstein Gradient Flow Associated with Continuity Equation

In addition to the ODE and PDE in $\mathbb{R}^m$, we introduce the third profile: the *Wasserstein gradient flow* or the evolution equation in the space of the probability densities on $\mathbb{R}^m$. The Wasserstein gradient flow has a distinct advantage that the potential functional F of the gradient flow is independent of time t; on the other hand, the vector field $\boldsymbol{v}_t$ is usually time-dependent. Furthermore, it often facilitates the understanding of transport maps because we will see that both the Boltzmann entropy and the Renyi entropy are examples of F.

Let $\mathcal{P}_2(\mathbb{R}^m)$ be the L^2-Wasserstein space defined in Section 1.3.3, and let $\mu_t \in \mathcal{P}_2(\mathbb{R}^m)$ be the solution of the continuity equation (9) with initial distribution $\mu_0 \in \mathcal{P}_2(\mathbb{R}^m)$. Then, the map $t \mapsto \mu_t$ plots a curve in $\mathcal{P}_2(\mathbb{R}^m)$. According to the Otto calculus (Villani, 2009, § 23), this curve coincides with a functional gradient flow in $\mathcal{P}_2(\mathbb{R}^m)$, called the Wasserstein gradient flow, with respect to some *potential functional* $F : \mathcal{P}_2(\mathbb{R}^m) \to \mathbb{R}$.

Specifically, we further assume that the vector field $\boldsymbol{v}_t$ is given by the gradient vector field ∇V_t of a potential function $V_t : \mathbb{R}^m \to \mathbb{R}$.

Fact 3 *Assume that μ_t satisfies the continuity equation with the gradient vector field,*

$$\partial_t \mu_t = -\nabla \cdot [\mu_t \nabla V_t], \tag{10}$$

and that we have found F that satisfies the following equation:

$$\frac{\mathrm{d}}{\mathrm{d}t} F[\mu_t] = \int_{\mathbb{R}^m} \nabla V_t(\boldsymbol{x}) [\partial_t \mu_t](\boldsymbol{x}) \mathrm{d}\boldsymbol{x}. \tag{11}$$

Then, the Wasserstein gradient flow

$$\frac{\mathrm{d}}{\mathrm{d}t} \mu_t = -\mathsf{grad}\, F[\mu_t], \tag{12}$$

coincides with the continuous equation.

Here, grad denotes the gradient operator on L^2-Wasserstein space $\mathcal{P}_2(\mathbb{R}^m)$ explained in Section 1.3.3. While (12) is an evolution equation or an ODE in $\mathcal{P}_2(\mathbb{R}^m)$, (9) is a PDE in $\mathbb{R}^m$. Hence, we use different notations for the time derivatives, $\frac{\mathrm{d}}{\mathrm{d}t}$ and ∂_t.

3. Denoising Autoencoder

We formulate the denoising autoencoder (DAE) as a variational problem, and we show that the minimizer $\boldsymbol{g}^*$ or the training result is a transport map. Even though the term "DAE" refers to a training procedure of neural networks, we refer to the minimizer of DAE also as a "DAE." We further investigate the initial velocity vector field $\partial_t \boldsymbol{g}_{t=0}$ for mass transportation, and we show that the data distribution μ_t evolves according to the continuity equation.

For the sake of simplicity, we assume that the hidden unit number of NNs is sufficiently large (or infinite), and thus the NNs can always attain the minimum. Furthermore, we assume the the size of data set is sufficiently large (or infinite). In the case when the hidden unit number and the size of data set are both finite, we understand the DAE $\boldsymbol{g}$ is composed of the minimizer $\boldsymbol{g}^*$ and the residual term $\boldsymbol{h}$. Namely, $\boldsymbol{g} = \boldsymbol{g}^* + \boldsymbol{h}$. However, theoretical investigations on the approximation and estimation error $\boldsymbol{h}$ remain as our future work.

3.1. Training Procedure of DAE

Let $\boldsymbol{x}$ be an m-dimensional random vector that is distributed according to the data distribution μ_0, and let $\widetilde{\boldsymbol{x}}$ be its corruption defined by

$$\widetilde{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \nu_t$$

where ν_t denotes the noise distribution parametrized by variance $t \geq 0$. A basic example of ν_t is the Gaussian noise with mean 0 and variance t, i.e., $\nu_t = N(0, tI)$.

The DAE is a function that is trained to remove corruption $\widetilde{\boldsymbol{x}}$ and restore it to the original $\boldsymbol{x}$; this is equivalent to finding a function $\boldsymbol{g}$ that minimizes an objective function, i.e.,

$$L[\boldsymbol{g}] := \mathbb{E}_{\boldsymbol{x},\widetilde{\boldsymbol{x}}} |\boldsymbol{g}(\widetilde{\boldsymbol{x}}) - \boldsymbol{x}|^2. \tag{13}$$

Note that as long as $\boldsymbol{g}$ is a universal approximator and can thus attain the minimum, it need not be a neural network. Specifically, our analysis in this section and the next section is applicable to a wide range of learning machines. Typical examples of $\boldsymbol{g}$ include neural networks with a sufficiently large number of hidden units, splines (Wahba, 1990), kernel machines (Shawe-Taylor and Cristianini, 2004) and ensemble models (Schapire and Freund, 2012).

3.2. Transport Map of DAE

Theorem 4 *(Modification of Theorem 1 by Alain and Bengio, 2014). The global minimum $\boldsymbol{g}_t^*$ of $L[\boldsymbol{g}]$ is attained at*

$$\boldsymbol{g}_t^*(\widetilde{\boldsymbol{x}}) = \frac{1}{\nu_t * \mu_0(\widetilde{\boldsymbol{x}})} \int_{\mathbb{R}^m} \boldsymbol{x}\nu_t(\widetilde{\boldsymbol{x}} - \boldsymbol{x})\mu_0(\boldsymbol{x})\mathrm{d}\boldsymbol{x}, \tag{14}$$

$$= \widetilde{\boldsymbol{x}} - \underbrace{\frac{1}{\nu_t * \mu_0(\widetilde{\boldsymbol{x}})} \int_{\mathbb{R}^m} \boldsymbol{\varepsilon}\nu_t(\boldsymbol{\varepsilon})\mu_0(\widetilde{\boldsymbol{x}} - \boldsymbol{\varepsilon})\mathrm{d}\boldsymbol{\varepsilon}}_{=: \boldsymbol{f}_t(\widetilde{\boldsymbol{x}})}, \tag{15}$$

where $*$ denotes the convolution operator.

Here, the second equation is simply derived by changing the variable $\boldsymbol{x} \leftarrow \widetilde{\boldsymbol{x}} - \boldsymbol{\varepsilon}$ (see Appendix A for the complete proof, where we used the calculus of variations). Note that this calculation first appeared in Alain and Bengio (2014, Theorem 1), where the authors obtained (14).

The DAE $\boldsymbol{g}_t^*(\boldsymbol{x})$ is composed of the identity term $\boldsymbol{x}$ and the denoising term $\boldsymbol{f}_t(\boldsymbol{x})$. If we assume that $\nu_t \to \delta_t$ as $t \to 0$, then in the limit $t \to 0$, the denoising term $\boldsymbol{f}_t(\boldsymbol{x})$ vanishes and DAE reduces to a traditional autoencoder. We reinterpret the DAE $\boldsymbol{g}_t^*(x)$ as a *transport map with transport time t* that transports the mass at $\boldsymbol{x} \in \mathbb{R}^m$ toward $\boldsymbol{x} + \boldsymbol{f}_t(\boldsymbol{x}) \in \mathbb{R}^m$ with displacement vector $\boldsymbol{f}_t(\boldsymbol{x})$.

3.3. Statistical Interpretation of DAE

In statistics, (15) is known as Brown's representation of the posterior mean (George et al., 2006). This is not just a coincidence, because the DAE $\boldsymbol{g}_t^*$ is an estimator of the mean. Recall that a DAE is trained to retain the original vector $\boldsymbol{x}$, given its corruption $\widetilde{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{\varepsilon}$. At least in principle, this is nonsense because to retain $\boldsymbol{x}$ from $\widetilde{\boldsymbol{x}}$ means to reverse the random walk $\widetilde{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{\varepsilon}$ (in Figure 4, the multimodal distributions $\mu_{0.5}$ and $\mu_{1.0}$ indicate its difficulty). Obviously, this is an inverse problem or a statistical estimation problem of the latent vector $\boldsymbol{x}$, given the noised observation $\widetilde{\boldsymbol{x}}$ with the observation model $\widetilde{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{\varepsilon}$. According to a fundamental fact of estimation theory, the minimum mean squared error (MMSE) estimator of $\boldsymbol{x}$ given $\widetilde{\boldsymbol{x}}$ is given by the posterior mean $\mathbb{E}[\boldsymbol{x}|\widetilde{\boldsymbol{x}}]$. In our case, the posterior mean equals $\boldsymbol{g}_t^*$.

$$\mathbb{E}[\boldsymbol{x}|\widetilde{\boldsymbol{x}}] = \frac{\int_{\mathbb{R}^m} \boldsymbol{x}p(\widetilde{\boldsymbol{x}} \mid \boldsymbol{x})p(\boldsymbol{x})\mathrm{d}\boldsymbol{x}}{\int_{\mathbb{R}^m} p(\widetilde{\boldsymbol{x}} \mid \boldsymbol{x}')p(\boldsymbol{x}')\mathrm{d}\boldsymbol{x}'} = \frac{1}{\nu_t * \mu_0(\widetilde{\boldsymbol{x}})} \int_{\mathbb{R}^m} \boldsymbol{x}\nu_t(\widetilde{\boldsymbol{x}} - \boldsymbol{x})\mu_0(\boldsymbol{x})\mathrm{d}\boldsymbol{x} = \boldsymbol{g}_t^*(\widetilde{\boldsymbol{x}}). \tag{16}$$

Similarly, we can interpret the denoising term $\boldsymbol{f}_t(\widetilde{\boldsymbol{x}})$ as the posterior mean $\mathbb{E}[\boldsymbol{\varepsilon}|\widetilde{\boldsymbol{x}}]$ of noise $\boldsymbol{\varepsilon}$ given observation $\widetilde{\boldsymbol{x}}$.

3.4. Examples: Gaussian DAE

When the noise distribution is Gaussian with mean 0 and covariance tI, i.e.,

$$\nu_t(\boldsymbol{\varepsilon}) = \frac{1}{(2\pi t)^{m/2}} e^{-|\boldsymbol{\varepsilon}|^2/2t},$$

the transport map is calculated as follows.

Theorem 5 *The transport map $\boldsymbol{g}_t^*$ of Gaussian DAE is given by*

$$\boldsymbol{g}_t^*(\widetilde{\boldsymbol{x}}) = \widetilde{\boldsymbol{x}} + t\nabla \log[\nu_t * \mu_0](\widetilde{\boldsymbol{x}}). \tag{17}$$

Proof The proof is straightforward by using Stein's identity,

$$-t\nabla\nu_t(\boldsymbol{\varepsilon}) = \boldsymbol{\varepsilon}\,\nu_t(\boldsymbol{\varepsilon}),$$

which is known to hold only for Gaussians.

$$\begin{aligned}
\boldsymbol{g}_t^*(\widetilde{\boldsymbol{x}}) &= \widetilde{\boldsymbol{x}} - \frac{1}{\nu_t * \mu_0(\widetilde{\boldsymbol{x}})} \int_{\mathbb{R}^m} \boldsymbol{\varepsilon}\nu_t(\boldsymbol{\varepsilon})\mu_0(\widetilde{\boldsymbol{x}} - \boldsymbol{\varepsilon})\mathrm{d}\boldsymbol{\varepsilon} \\
&= \widetilde{\boldsymbol{x}} + \frac{1}{\nu_t * \mu_0(\widetilde{\boldsymbol{x}})} \int_{\mathbb{R}^m} t\nabla\nu_t(\boldsymbol{\varepsilon})\mu_0(\widetilde{\boldsymbol{x}} - \boldsymbol{\varepsilon})\mathrm{d}\boldsymbol{\varepsilon} \\
&= \widetilde{\boldsymbol{x}} + \frac{t\nabla\nu_t * \mu_0(\widetilde{\boldsymbol{x}})}{\nu_t * \mu_0(\widetilde{\boldsymbol{x}})} \\
&= \widetilde{\boldsymbol{x}} + t\nabla \log[\nu_t * \mu_0(\widetilde{\boldsymbol{x}})].
\end{aligned}$$

■

Theorem 6 *At the initial moment $t \to 0$, the pushforward μ_t of Gaussian DAE satisfies the* backward heat equation

$$\partial_t \mu_{t=0}(\boldsymbol{x}) = -\triangle\mu_0(\boldsymbol{x}), \quad \boldsymbol{x} \in \mathbb{R}^m, \tag{18}$$

where $\triangle$ denotes the Laplacian.

Proof The initial velocity vector is given by the *Fisher score*

$$\partial_t \boldsymbol{g}_{t=0}^*(\boldsymbol{x}) = \lim_{t\to 0} \frac{\boldsymbol{g}_t^*(\boldsymbol{x}) - \boldsymbol{x}}{t} = \nabla \log \mu_0(\boldsymbol{x}). \tag{19}$$

Hence, by substituting the score (19) in the continuity equation (9), we have

$$\partial_t \mu_{t=0}(\boldsymbol{x}) = -\nabla \cdot [\mu_0(\boldsymbol{x})\nabla \log \mu_0(\boldsymbol{x})] = -\nabla \cdot [\nabla\mu_0(\boldsymbol{x})] = -\triangle\mu_0(\boldsymbol{x}).$$

■

The backward heat equation (BHE) rarely appears in nature. However, of course, the present result is not an error. As mentioned in Section 3.3, the DAE solves an estimation problem. Therefore, in the sense of the mean, the DAE behaves as time reversal. We remark that, as shown by Figure 4, a training result of a DAE with a real NN on a finite data set does not converge to a perfect time reversal of a diffusion process.

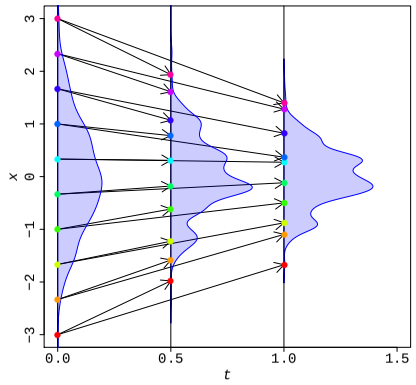

Figure 4: Shallow Gaussian DAE, which is one of the most fundamental versions of DNNs, transports mass, from the left to the right, to decrease the Shannon entropy of data. The x-axis represents the 1-dimensional input/output space, the t-axis represents the variance of the Gaussian noise, and t is the transport time. The leftmost distribution depicts the original data distribution $\mu_0 = N(0,1)$. The middle and rightmost distributions depict the pushforward $\mu_t = \boldsymbol{g}_{t\sharp}\mu_0$, associated with the transportation by two DAEs with noise variance $t = 0.5$ and $t = 1.0$, respectively. As t increases, the variance of the pushforward decreases.

4. Deep DAEs

We introduce the composition $\boldsymbol{g}_L \circ \cdots \circ \boldsymbol{g}_0$ of DAEs $\boldsymbol{g}_\ell : \mathbb{R}^m \to \mathbb{R}^m$ and its continuum limit: the continuous DAE $\boldsymbol{\varphi}_t : \mathbb{R}^m \to \mathbb{R}^m$. We can understand the composition of DAEs as the *Euler scheme* or the *broken line approximation* of a continuous DAE.

For the sake of simplicity, we assume that the hidden unit number of NNs is infinite, and that the size of data set is infinite.

4.1. Composition of DAEs

We write $0 = t_0 < t_1 < \cdots < t_{L+1} = t$. We assume that the input vector $\boldsymbol{x}_0 \in \mathbb{R}^m$ is subject to a data distribution μ_0. Let $\boldsymbol{g}_0 : \mathbb{R}^m \to \mathbb{R}^m$ be a DAE that is trained on μ_0 with noise variance $t_1 - t_0$. Then, let $\boldsymbol{x}_1 := \boldsymbol{g}_0(\boldsymbol{x}_0)$, which is a random vector in $\mathbb{R}^m$ that is subject to the pushforward $\mu_1 := \boldsymbol{g}_{0\sharp}\mu_0$. We train another DAE $\boldsymbol{g}_1 : \mathbb{R}^m \to \mathbb{R}^m$ on μ_1 with noise variance $t_2 - t_1$. By repeating the procedure, we obtain $\boldsymbol{g}_\ell(\boldsymbol{x}_\ell)$ from $\boldsymbol{x}_{\ell-1}$ that is subject to $\mu_\ell := \boldsymbol{g}_{(\ell-1)\sharp}\mu_{\ell-1}$.

For the sake of generality, we assume that each component DAE is given by

$$\boldsymbol{g}_\ell(\boldsymbol{x}) = \boldsymbol{x} + (t_{\ell+1} - t_\ell)\nabla V_{t_\ell}(\boldsymbol{x}), \quad (\ell = 0, \dots, L) \tag{20}$$

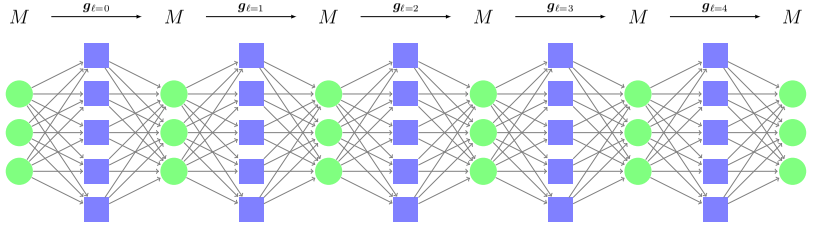

Figure 5: Composition of DAEs $\boldsymbol{g}^t_{0:4} : M \to M$, or the composite of five shallow DAEs $M \to M$, where $M = \mathbb{R}^3$

where V_{t_ℓ} denotes a certain potential function. For example, the Gaussian DAE satisfies the requirement because $V_{t_\ell} = \log[\nu_{t_\ell} * \mu_{t_\ell}]$.

We abbreviate the composition of DAEs by

$$\boldsymbol{g}^t_{0:L}(\boldsymbol{x}) := \boldsymbol{g}_L \circ \cdots \circ \boldsymbol{g}_0(\boldsymbol{x}). \tag{21}$$

By definition, the "velocity" of a composition of DAEs coincides with the vector field

$$\frac{\boldsymbol{g}^{t_{\ell+1}}_{0:\ell}(\boldsymbol{x}) - \boldsymbol{g}^{t_\ell}_{0:(\ell-1)}(\boldsymbol{x})}{t_{\ell+1} - t_\ell} = \nabla V_{t_\ell}(\boldsymbol{x}). \tag{22}$$

4.2. Continuous DAE

We fix the total time t, take the limit $L \to \infty$ of the layer number L, and introduce the continuous DAE as the limit of the "infinite composition of DAEs" $\lim_{L\to\infty} \boldsymbol{g}^t_{0:L}$.

Definition 4 *We call the solution operator or flow $\boldsymbol{\varphi}_t : \mathbb{R}^m \to \mathbb{R}^m$ of the following dynamical systems as the* continuous DAE *associated with vector field ∇V_t.*

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{x}(t) = \nabla V_t(\boldsymbol{x}(t)), \quad t \geq 0. \tag{23}$$

Proof According to the Cauchy-Lipschitz theorem or the Picard-Lindelöf theorem, when the vector field ∇V_t is continuous in t and Lipschitz in $\boldsymbol{x}$, the limit $\lim_{L\to\infty} \boldsymbol{g}_{0:L}$ converges to a continuous DAE (23) because the trajectory $t \mapsto \boldsymbol{g}_{0:L}(x_0)$ corresponds to a broken line approximation of the integral curve $t \mapsto \boldsymbol{\varphi}_t(x)$. ■

The following properties are immediate from Fact 2 and Fact 3. Let $\boldsymbol{\varphi}_t : \mathbb{R}^m \to \mathbb{R}^m$ be the continuous DAE associated with vector field ∇V_t. Given the data distribution μ_0, the pushforward $\mu_t := (\boldsymbol{\varphi}_t)_\sharp\mu_0$ evolves according to the continuity equation

$$\partial_t \mu_t(\boldsymbol{x}) = -\nabla \cdot [\mu_t(\boldsymbol{x})\nabla V_t(\boldsymbol{x})], \quad t \geq 0 \tag{24}$$

and the Wasserstein gradient flow

$$\frac{\mathrm{d}}{\mathrm{d}t}\mu_t = -\mathsf{grad}\, F[\mu_t], \quad t \geq 0 \tag{25}$$

where F is given by (11).

4.3. Example: Gaussian DAE

We consider a continuous Gaussian DAE $\boldsymbol{\varphi}_t$ trained on $\mu_0 \in \mathcal{P}_2(\mathbb{R}^m)$. Specifically, it satisfies

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{x}(t) = \nabla \log[\mu_t(\boldsymbol{x}(t))], \quad t \geq 0 \tag{26}$$

with $\mu_t := \boldsymbol{\varphi}_{t\sharp}\mu_0$.

Theorem 7 *The pushforward $\mu_t := \boldsymbol{\varphi}_{t\sharp}\mu_0$ of the continuous Gaussian DAE $\boldsymbol{\varphi}_t$ is the solution to the initial value problem of the backward heat equation (BHE)*

$$\partial_t \mu_t(\boldsymbol{x}) = -\triangle \mu_t(\boldsymbol{x}), \quad \mu_{t=0}(\boldsymbol{x}) = \mu_0(\boldsymbol{x}). \tag{27}$$

The proof is immediate from Theorem 6.

As mentioned after Theorem 6, the BHE appears because the DAE solves an estimation problem. We remark that the BHE is equivalent to the following *final value problem* for the ordinary heat equation:

$$\partial_t u_t(\boldsymbol{x}) = \triangle u_t(\boldsymbol{x}), \quad u_{t=T}(\boldsymbol{x}) = \mu_0(\boldsymbol{x}) \quad \text{for some } T$$

where u_t denotes a probability measure on $\mathbb{R}^m$. Indeed, $\mu_t(\boldsymbol{x}) = u_{T-t}(\boldsymbol{x})$ solves (27). In other words, the backward heat equation describes the time reversal of an ordinary diffusion process.

According to Wasserstein geometry, an ordinary heat equation corresponds to a Wasserstein gradient flow that *increases* the Shannon entropy functional $H[\mu] := -\int \mu(\boldsymbol{x}) \log \mu(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}$ (Villani, 2009, Th. 23.19). Consequently, we can conclude that the continuous Gaussian DAE is a transport map that *decreases* the Shannon entropy of the data distribution.

Theorem 8 *The pushforward $\mu_t := \boldsymbol{\varphi}_{t\sharp}\mu_0$ evolves according to the Wasserstein gradient flow with respect to the Shannon entropy*

$$\frac{\mathrm{d}}{\mathrm{d}t}\mu_t = -\mathsf{grad}\, H[\mu_t], \quad \mu_{t=0} = \mu_0. \tag{28}$$

Proof When $F = H$, then $V_t = -\log \mu_t$; thus,

$$\mathsf{grad}\, H[\mu_t] = \nabla \cdot [\mu_t \nabla \log \mu_t] = \nabla \cdot [\nabla \mu_t] = \triangle \mu_t,$$

which means that the continuity equation reduces to the backward heat equation. ■

4.4. Example: Renyi Entropy

Similarly, when F is the Renyi entropy

$$H^\alpha[\mu] := \int_{\mathbb{R}^m} \frac{\mu^\alpha(\boldsymbol{x}) - \mu(\boldsymbol{x})}{\alpha - 1} \mathrm{d}\boldsymbol{x},$$

then $\mathsf{grad}\, H^\alpha[\mu_t] = \triangle \mu_t^\alpha$ (see Ex. 15.6 in Villani, 2009, for the proof) and thus the continuity equation reduces to the *backward porous medium equation*

$$\partial_t \mu_t(\boldsymbol{x}) = -\triangle \mu_t^\alpha(\boldsymbol{x}). \tag{29}$$

5. Further Investigations on Shallow and Deep DAEs through Examples

5.1. Analytic Examples

We list analytic examples of shallow and continuous DAEs (see Appendix D for further details, including proofs). In all the settings, the continuous DAEs attain a singular measure at some finite $t > 0$ with various singular supports that reflect the initial data distribution μ_0, while the shallow DAEs accept any $t > 0$ and degenerate to a point mass as $t \to \infty$.

5.1.1. Univariate Normal Distribution

When the data distribution is a univariate normal distribution $N(m_0, \sigma_0)$, the transport map and pushforward for the *shallow* DAE are given by

$$g_t(x) = \frac{\sigma_0^2}{\sigma_0^2 + t} x + \frac{t}{\sigma_0^2 + t} m_0, \tag{30}$$

$$\mu_t = N\left(m_0, \frac{\sigma_0^2}{(1 + t/\sigma_0^2)^2}\right), \tag{31}$$

and those of the *continuous* DAE are given by

$$g_t(x) = \sqrt{1 - 2t/\sigma_0^2}(x - m_0) + m_0, \tag{32}$$

$$\mu_t = N(m_0, \sigma_0^2 - 2t). \tag{33}$$

5.1.2. Multivariate Normal Distribution

When the data distribution is a multivariate normal distribution $N(\boldsymbol{m}_0, \Sigma_0)$, the transport map and pushforward for the *shallow* DAE are given by

$$\boldsymbol{g}_t(\boldsymbol{x}) = (I + t\Sigma_0^{-1})^{-1}\boldsymbol{x} + (I + t^{-1}\Sigma_0)^{-1}\boldsymbol{m}_0, \tag{34}$$

$$\mu_t = N(\boldsymbol{m}_0, \Sigma_0(I + t\Sigma_0^{-1})^{-2}), \tag{35}$$

and those of the *continuous* DAE are given by

$$\boldsymbol{g}_t(\boldsymbol{x}) = \sqrt{I - 2t\Sigma_0^{-1}}(\boldsymbol{x} - \boldsymbol{m}_0) + \boldsymbol{m}_0, \tag{36}$$

$$\mu_t = N(\boldsymbol{m}_0, \Sigma_0 - 2tI). \tag{37}$$

5.1.3. Mixture of Multivariate Normal Distributions

When the data distribution is a mixture of multivariate normal distributions $\sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k)$ with the assumption that it is *well separated*, the transport map and pushforward for the *shallow* DAE are given by

$$\boldsymbol{g}_t(\boldsymbol{x}) = \sum_{k=1}^K \gamma_{kt}(\boldsymbol{x}) \left\{ (I + t\Sigma_k^{-1})^{-1}\boldsymbol{x} + (I + t^{-1}\Sigma_k)^{-1}\boldsymbol{m}_k \right\}, \tag{38}$$

$$\mu_t \approx \sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k(I + t\Sigma_k^{-1})^{-2}), \tag{39}$$

with responsibility function

$$\gamma_{kt}(\boldsymbol{x}) := \frac{w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k + tI)}{\sum_{k=1}^K w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k + tI)}, \tag{40}$$

and those of the *continuous* DAE are given by

$$\boldsymbol{g}_t(\boldsymbol{x}) \approx \sqrt{I - 2t\Sigma_k^{-1}}(\boldsymbol{x} - \boldsymbol{m}_k) + \boldsymbol{m}_k, \tag{41}$$

$$\mu_t = \sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k - 2tI), \tag{42}$$

with responsibility function

$$\gamma_{kt}(\boldsymbol{x}) := \frac{w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k - 2tI)}{\sum_{k=1}^K w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k - 2tI)}. \tag{43}$$

Here, we say that the mixture $\sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k)$ is well separated when for every cluster center $\boldsymbol{m}_k$, there exists a neighborhood Ω_k of $\boldsymbol{m}_k$ such that $N(\Omega_k; \boldsymbol{m}_k, \Sigma_k) \approx 1$ and $\gamma_{kt} \approx \mathbf{1}_{\Omega_k}$.

5.2. Numerical Example of Trajectories

We employed 2-dimensional examples, in order to visualize the difference of vector fields between the shallow and deep DAEs. In the examples below, every trajectories are drawn into attractors, however the shape of the attractors and the speed of trajectories are significantly different between shallow and deep.

5.2.1. Bivariate Normal Distribution

Figure 6 compares the trajectories of four DAEs trained on the common data distribution

$$\mu_0 = N\left([0,0], \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}\right). \tag{44}$$

The transport maps for computing the trajectories are given by (34) for the shallow DAE and composition of DAEs, and by (36) for the continuous DAE. Here, we applied (34) multiple times for the composition of DAEs.

The continuous DAE converges to an attractor lying on the x-axis at $t = 1/2$. By contrast, the shallow DAE slows down as $t \to \infty$ and never attains the singularity in finite time. As L tends to infinity, $\boldsymbol{g}_{0:L}^t$ plots a trajectory similar to that of the continuous DAE $\boldsymbol{\varphi}_t$; the curvature of the trajectory changes according to Δt.

5.2.2. Mixture of Bivariate Normal Distributions

Figure 7, 8, and 9 compare the trajectories of four DAEs trained on the three common data distributions

$$\mu_0 = 0.5\, N\left([-1,0], \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\right) + 0.5\, N\left([1,0], \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\right), \tag{45}$$

$$\mu_0 = 0.2\, N\left([-1,0], \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\right) + 0.8\, N\left([1,0], \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\right), \tag{46}$$

$$\mu_0 = 0.2\, N\left([-1,0], \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\right) + 0.8\, N\left([1,0], \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}\right). \tag{47}$$

respectively.

The transport maps for computing the trajectories are given by (38) for the shallow DAE and composition of DAEs. For the continuous DAE, we compute the trajectories by numerically solving the definition of the continuous Gaussian DAE: $\dot{\boldsymbol{x}} = \nabla \log \mu_t(\boldsymbol{x})$.

In any case, the continuous DAE converges to an attractor at some $t > 0$, but the shape of the attractors and the basins of attraction change according to the initial data distribution. The shallow DAE converges to the origin as $t \to \infty$, and the composition of DAEs plots a curve similar to that of the continuous DAE as L tends to infinity, $\boldsymbol{g}_{0:L}^t$. In particular, in Figure 8, some trajectories of the continuous DAE intersect, which implies that the velocity vector field $\boldsymbol{v}_t$ is time-dependent.

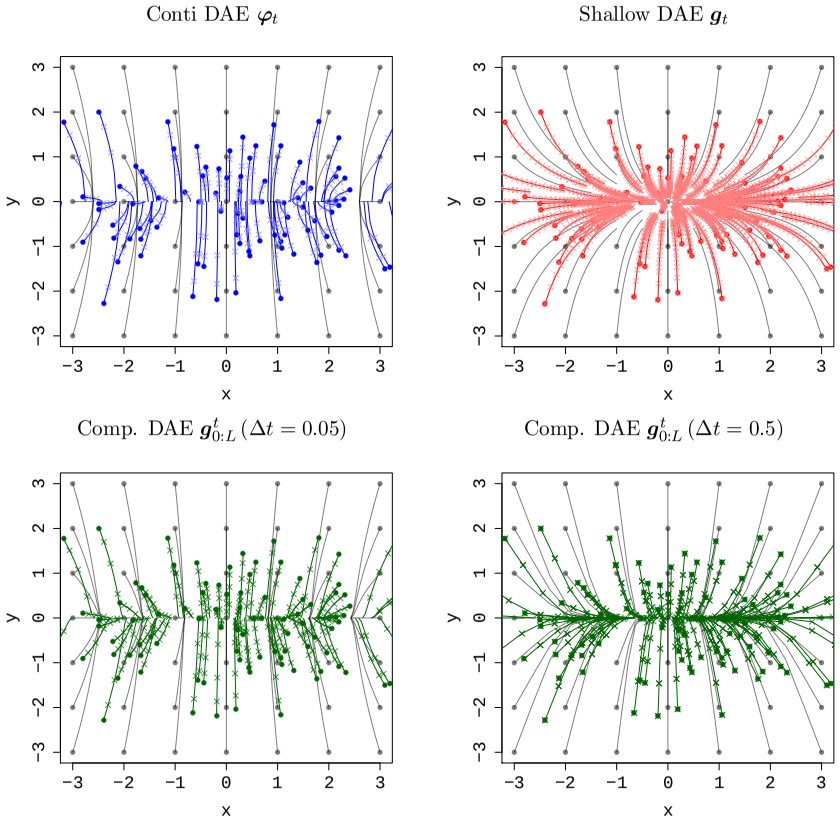

Figure 6: Trajectories of DAEs trained on the common data distribution (44) ($\mu_0 = N([0,0], \mathsf{diag}\,[2,1])$). The **gray lines** start from the regular grid. The **colored lines** start from the samples drawn from μ_0. The **midpoints** are plotted every $\Delta t = 0.2$. Every lines are drawn into attractors.

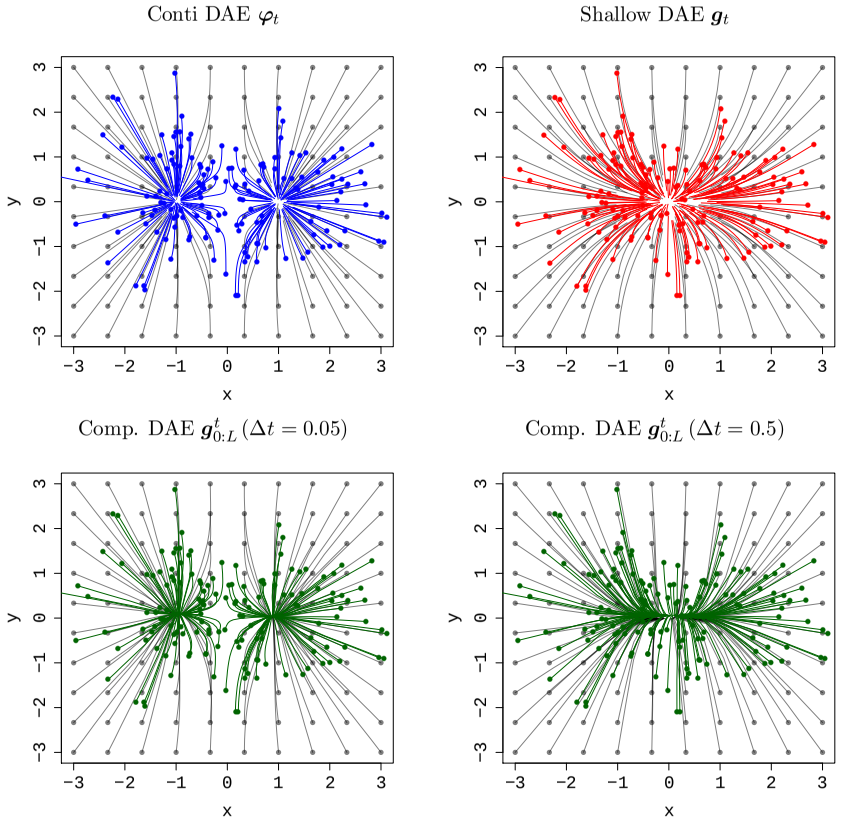

Figure 7: Trajectories of DAEs trained on the common data distribution (45) (a GMM with uniform weight and covariance). The **gray lines** start from the regular grid. The **colored lines** start from the samples drawn from μ_0. Every lines are drawn into attractors.

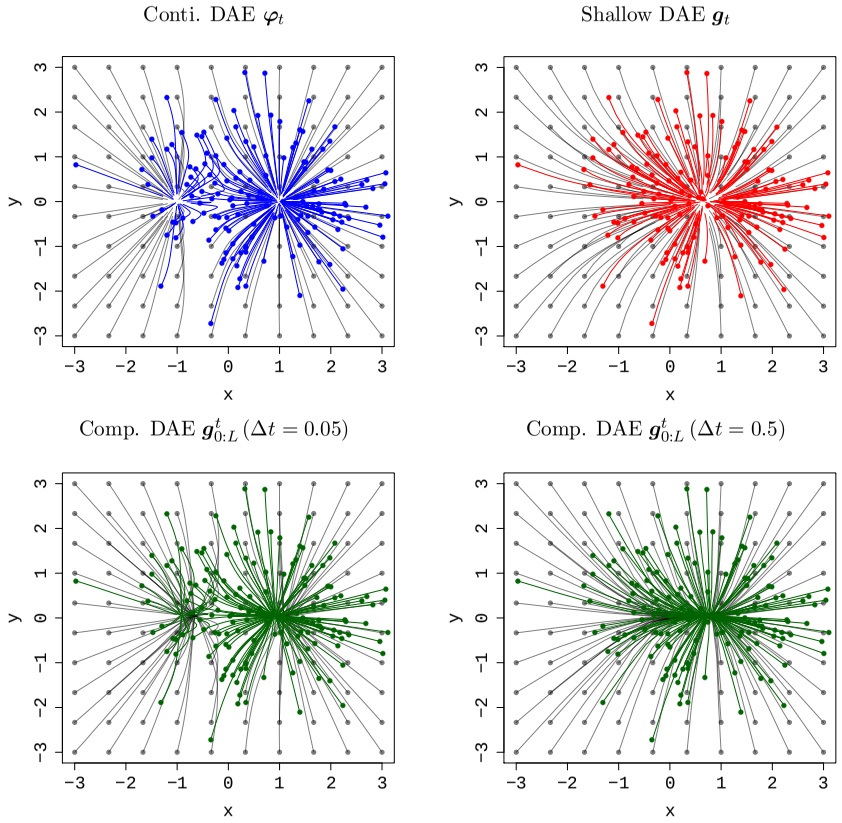

Figure 8: Trajectories of DAEs trained on the common data distribution (46) (a GMM with non-uniform weight and uniform covariance). The **gray lines** start from the regular grid. The **colored lines** start from the samples drawn from μ_0. Every lines are drawn into attractors.

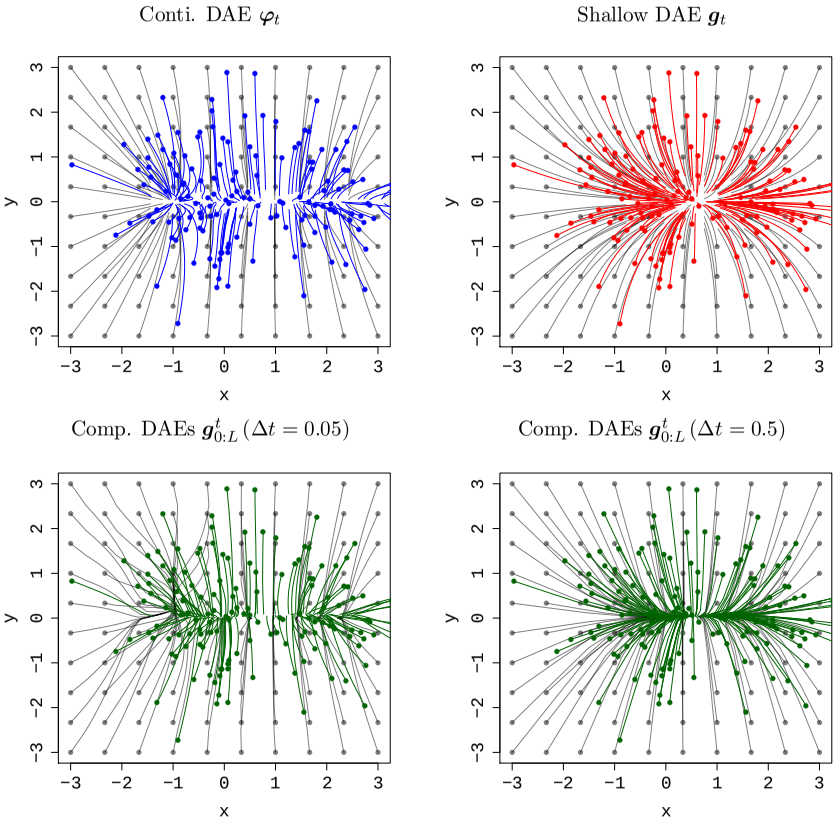

Figure 9: Trajectories of DAEs trained on the common data distribution (47) (a GMM with non-uniform weight and covariance). The **gray lines** start from the regular grid. The **colored lines** start from the samples drawn from μ_0. Every lines are drawn into attractors.

5.3. Numerical Example of Trajectories in Wasserstein Space

We consider the space $\mathcal{Q}$ of bivariate Gaussians:

$$\mathcal{Q} := \left\{ N\left([0,0], \begin{bmatrix} \sigma_1^2 & 0 \\ 0 & \sigma_2^2 \end{bmatrix}\right) \,\middle|\, \sigma_1, \sigma_2 > 0 \right\}. \tag{48}$$

Obviously, $\mathcal{Q}$ is a 2-dimensional subspace of L^2-Wasserstein space, and it is closed in the actions of the continuous DAE and shallow DAE because the pushforwards are given by (37) and (35), respectively.

We employ (σ_1, σ_2) as the coordinate of $\mathcal{Q}$. This is reasonable because, in this coordinate, the L^2-Wasserstein distance $W_2(\mu, \nu)$ between two points $\mu = (\sigma_1, \sigma_2)$ and $\nu = (\tau_1, \tau_2)$ is simply given by the "Euclidean distance" $W_2(\mu, \nu) = \sqrt{(\sigma_1 - \tau_1)^2 + (\sigma_2 - \tau_2)^2}$ (see Takatsu, 2011, for the proof). The Shannon entropy is given by

$$H(\sigma_1, \sigma_2) = (1/2) \log |\mathsf{diag}\,[\sigma_1^2, \sigma_2^2]| + const. = \log \sigma_1 + \log \sigma_2 + const. \tag{49}$$

Figure 10 compares the trajectories of the pushforward by DAEs in $\mathcal{Q}$. In the left, we calculated the theoretical trajectories according to the analytic formulas (37) and (35). In the right, we trained real NNs as the composition of DAEs according to the training procedure described in Section 4.1. Even though we always assumed the infinite number of hidden units and the infinite size of data set, the results suggest that our calculus is a good approximation to finite settings.

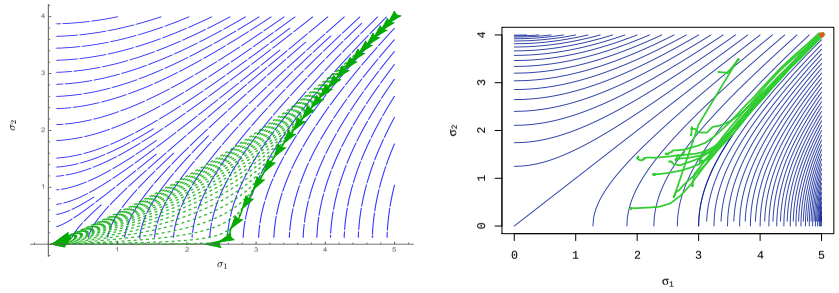

Figure 10: Trajectories of pushforward measures in a space $\mathcal{Q}$ of bivariate Gaussians $N([0,0], \mathsf{diag}\,[\sigma_1^2, \sigma_2^2])$. In **both** sides, the **blue** lines represent the Wasserstein gradient flow with respect to the Shannon entropy. The continuous Gaussian DAE $t \mapsto \boldsymbol{\varphi}_{t\sharp}\mu_0$ always coincides with the blue lines. In the **left-hand side**, the **dashed green** lines represent theoretical trajectories of the shallow DAE $t \mapsto \boldsymbol{g}_{t\sharp}\mu_0$ and the **solid green** line represents a theoretical trajectory of the composition of DAEs $t \mapsto \boldsymbol{g}^t_{0:L\sharp}\mu_0$. Both the green lines gradually leave the gradient flow. In the **right-hand side**, the **solid green** lines represent the trajectories of the composition of DAEs calculated by training real NNs (10 trials). In particular, in the early stage, the trajectories are parallel to the gradient flow.

6. Equivalence between Stacked DAE and Compositions of DAEs

As an application of transport analysis, we shed light on the equivalence of the stacked DAE (SDAE) and the composition of DAEs (CDAE), provided that the definition of DAEs is generalized to *L-DAE*, which is defined below. In SDAE, we apply the DAE to the features vectors obtained from the hidden layer of an NN to obtain higher-order feature vectors. Therefore, the feature vectors obtained from the SDAE and CDAE are different from each other. Nevertheless, we can prove that the trajectories generated by the SDAE and CDAE are *topologically conjugate*, which means that there exists a homeomorphism between the trajectories. Moreover, we can transform the trajectory of an SDAE into that of a CDAE by using a *linear map*, which is obtained from the decoder of the SDAE. Thus, we can synthesize the feature vectors of the SDAE by using CDAEs.

6.1. Definitions

To begin with, we introduce a generalized version of shallow DAE.

Definition 5 (L-DAE) *Let L be an elliptic operator on the domain Ω in $\mathbb{R}^m$, μ be a probability density on Ω, and D be a positive definite matrix. The L-DAE with diffusion coefficient D and initial data μ is defined by*

$$\mathsf{id} + tD\nabla \log e^{tL}\mu, \quad t > 0. \tag{50}$$

Here, e^{tL} is the semigroup generated by the elliptic operator L. Specifically, let $\mu_t := e^{tL}\mu$; then, μ_t satisfies the parabolic equation $\partial_t \mu_t = L\mu_t$. The original Gaussian DAE corresponds to a special case when $D \equiv I$ and $L = \triangle$.

By dae, we denote a DAE realized by a shallow NN (Figure 11). Specifically,

$$\mathsf{dae}(\boldsymbol{x}) = \sum_{j=1}^{p} \boldsymbol{c}_j \sigma(\boldsymbol{a}_j \cdot \boldsymbol{x} - b_j). \tag{51}$$

By enc and dec, we denote the encoder and decoder of dae, respectively. Specifically,

$$\mathsf{enc}_j(\boldsymbol{x}) = \sigma(\boldsymbol{a}_j \cdot \boldsymbol{x} - b_j), \quad j = 1, \ldots, p \tag{52}$$

$$\mathsf{dec}(\boldsymbol{z}) = \sum_{j=1}^{p} \boldsymbol{c}_j z_j, \tag{53}$$

Figure 11: enc and dec correspond to the hidden layer and output layer, respectively.

where z_j denotes the j-th element of $\boldsymbol{z} = \mathsf{enc}(\boldsymbol{x})$. Obviously, $\mathsf{dae} = \mathsf{dec} \circ \mathsf{enc}$.

For the sake of simipicity, even though we introduced the finite number p of hidden units, we assume that p is large, and thus dae approximately equals L-DAE for some L.

6.2. Training Procedure of Stacked DAE (SDAE)

Let $M := \mathbb{R}^m$ be the space of input vectors with probability density μ, and let $\mathsf{dae} : M \to M$ be a shallow NN with p hidden units. We assume that dae is trained as the Gaussian DAE with μ, and it thus approximates the DAE $\mathsf{id} + t\nabla \log[e^{t\triangle}\mu]$. Let $H := \mathbb{R}^p$. Then, the encoder and decoder of dae are the maps $\mathsf{enc} : M \to H$ and $\mathsf{dec} : H \to M$, respectively.

In the SDAE, we apply the DAE to $\boldsymbol{z}$. Specifically, let $\widetilde{\mu}$ be the density of hidden feature vectors $\boldsymbol{z} = \mathsf{enc}(\boldsymbol{x})$, and let $\widetilde{\mathsf{dae}} : H \to H$ be a shallow NN with $\widetilde{p}$ hidden units,

$$\widetilde{\mathsf{dae}}(\boldsymbol{z}) := \sum_{\widetilde{\jmath}=1}^{\widetilde{p}} \widetilde{\boldsymbol{c}}_{\widetilde{\jmath}} \sigma(\widetilde{\boldsymbol{a}}_{\widetilde{\jmath}} \cdot \boldsymbol{z} - \widetilde{b}_{\widetilde{\jmath}}).$$

We train $\widetilde{\mathsf{dae}}$ by using the Gaussian DAE with $\widetilde{\mu}$, where the network is decomposed as $\widetilde{\mathsf{dae}} = \widetilde{\mathsf{dec}} \circ \widetilde{\mathsf{enc}}$ with $\widetilde{\mathsf{enc}} : H \to \widetilde{H}$ and $\widetilde{\mathsf{dec}} : \widetilde{H} \to H$, and we obtain the feature vectors $\widetilde{\boldsymbol{z}} := \widetilde{\mathsf{enc}}(\boldsymbol{z}) \in \widetilde{H} = \mathbb{R}^{\widetilde{p}}$. By iterating the stacking procedure, we can obtain more abstract feature vectors (Figure 12).

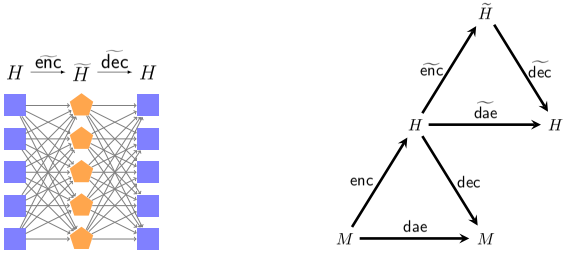

Figure 12: The (feature map of) SDAE $\widetilde{\mathsf{enc}} \circ \mathsf{enc}$ is built on the hidden layer.

Technically speaking, $\widetilde{\mu}$ is (the density of) the pushforward $\mathsf{dae}_\sharp\mu$, and its support is contained in the image $\widetilde{M} := \mathsf{enc}(M)$. In general, we assume that $\dim \widetilde{M} (= \dim M) \leq \dim H$; thus, the support of $\widetilde{\mu}$ is singular (i.e., the density vanishes outside $\widetilde{M}$) (see Fact 1 for further details).

6.3. Topological Conjugacy

The transport map of the feature vector $\widetilde{\mathsf{enc}} \circ \mathsf{enc} : M \to H \to \widetilde{H}$ is somewhat unclear. According to Theorem 9 and 10, the transport map of $\widetilde{\mathsf{enc}} \circ \mathsf{enc}$ can be transformed or projected to the ground space M by applying $\mathsf{dec} \circ \widetilde{\mathsf{dec}}$ (Figure 13). Specifically, there exists an L-DAE $\mathsf{dae}' : M \to M$ such that

$$\mathsf{dec} \circ \widetilde{\mathsf{dec}} \circ \widetilde{\mathsf{enc}} \circ \mathsf{enc} = \mathsf{dae}' \circ \mathsf{dae}. \tag{54}$$

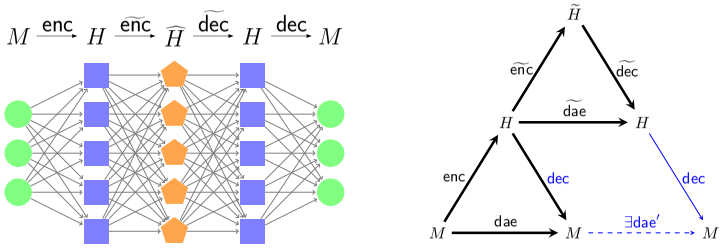

Figure 13: By reusing dec, we can transform the SDAE $\widetilde{\mathsf{enc}} \circ \mathsf{enc}$ into a CDAE $\mathsf{dae}' \circ \mathsf{dae}$.

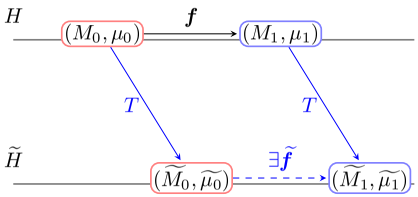
Theorem 9 *Let H and $\widetilde{H}$ be vector spaces, $\dim H \geq \dim \widetilde{H}$, let M_0 be an m-dimensional smooth Riemannian manifold embedded in H, and let μ_0 be a C^2 probability density on M_0. Let $\boldsymbol{f} : H \to H$ be an L_t-DAE:*



$$\boldsymbol{f} := \mathsf{id}_H + tD\nabla \log e^{tL_t}\mu_0,$$

with diffusion coefficient D and time-dependent elliptic operator L_t on H, where ∇ is the gradient operator in H.

Let $T : H \to \widetilde{H}$ be a linear map. If $T|_M$ is injective, then there exists an $\widetilde{L}_t$-DAE $\widetilde{\boldsymbol{f}} : \widetilde{H} \to \widetilde{H}$ with diffusion coefficient $\widetilde{D}$ such that

$$T \circ \boldsymbol{f}|_M = \widetilde{\boldsymbol{f}} \circ T|_M. \tag{55}$$

In other words, the following diagram commutes. Here we denoted $M_1 := \boldsymbol{f}(M_0)$ and

$\mu_1 := \boldsymbol{f}_\sharp\mu_0$. See Appendix C for the proof. The statement is general in that the choice of a linear map T is independent of the DAEs, as long as it is injective.

We note that the trajectory of the equivalent DAE $\widetilde{\boldsymbol{f}}$ may be complicated, because the "equivalence" we mean here is simply the topological conjugacy. Actually, as the proof suggests, $\widetilde{D}$ and $\widetilde{L}_t$ contain the non-linearity of activation functions via the pseudo-inverse $T^\dagger$ of T. Nevertheless, $\widetilde{\boldsymbol{f}}$ may not be much complicated because it is simply a linear projection of the high-dimensional trajectory of L_t-DAE. According to Theorem 6, a Gaussian DAE solves backward heat equation (at least when $t \to 0$). Hence, its projection to low dimension should also solve backward heat equation in low dimension spaces.

6.4. Equivalence between SDAE and CDAE

To clarify the statement, we prepare the notation. Figure 14 summarizes the symbols and procedures.

First, we rewrite the input vector as $\boldsymbol{z}^0$ instead of $\boldsymbol{x}$, the input space as $H^0 = M_0^0 (= \mathbb{R}^m)$ instead of M, and the density as μ_0^0 instead of μ. We iteratively train the ℓ-th NN $\mathsf{dae}_\ell^\ell : H^\ell \to H^\ell$ with a data distribution μ_ℓ^ℓ, obtain the encoder $\mathsf{enc}^\ell : H^\ell \to H^{\ell+1}$ and decoder $\mathsf{dec}^\ell : H^{\ell+1} \to H^\ell$, and update the feature $\boldsymbol{z}^{\ell+1} := \mathsf{enc}^\ell(\boldsymbol{z}^\ell)$, the image $M_{\ell+1}^{\ell+1} := \mathsf{enc}^\ell(M_\ell^\ell) \subset H^{\ell+1}$, and the distribution $\mu_{\ell+1}^{\ell+1} := (\mathsf{enc}^\ell)_\sharp \mu_\mu^\ell$.

For simplicity, we abbreviate

$$\mathsf{enc}^{\ell:n} := \mathsf{enc}^n \circ \cdots \circ \mathsf{enc}^\ell,$$
$$\mathsf{dec}^{n:\ell} := \mathsf{dec}^\ell \circ \cdots \circ \mathsf{dec}^n.$$

In addition, we introduce auxiliary objects.

$$M_{\ell+1}^n := \mathsf{dec}^{\ell:n}(M_{\ell+1}^{\ell+1}), \quad n = 0, \cdots, \ell$$
$$\mu_{\ell+1}^n := \mathsf{dec}_\sharp^{\ell:n} \mu_{\ell+1}^{\ell+1}, \quad n = 0, \cdots, \ell.$$

By construction, M_n^ℓ is an at most m-dimensional submanifold in H^ℓ, and the support of μ_n^ℓ is in M_n^ℓ.

Finally, we denote the map $\mathsf{dae}_n^\ell : M_n^\ell \to M_{n+1}^\ell$ that is (not "trained by DAE" but) defined by

$$\mathsf{dae}_n^\ell := (\mathsf{dec}^{n:\ell} \circ \mathsf{enc}^{0:n}) \circ (\mathsf{dec}^{(n-1):\ell} \circ \mathsf{enc}^{0:(n-1)})^{-1} : M_n^\ell \to M_{n+1}^\ell.$$

By Theorem 9, if $\mathsf{dae}_n^{\ell+1}$ is an $L_n^{\ell+1}$-DAE, then dae_n^ℓ exists and it is an L_n^ℓ-DAE.

Theorem 10 *If every* $\mathsf{enc}^\ell|_{M_\ell^\ell}$ *is a continuous injection and every* $\mathsf{dec}^\ell|_{M_n^{\ell+1}}$ *is an injection, then*

$$\mathsf{dec}^{L:0} \circ \mathsf{enc}^{0:L} = \mathsf{dae}_L^0 \circ \cdots \circ \mathsf{dae}_0^0. \tag{56}$$

Proof By repeatedly applying the topological conjugacy in Theorem 9,

$$\mathsf{dec}^\ell \circ \mathsf{dae}_n^{\ell+1} = \mathsf{dae}_n^\ell \circ \mathsf{dec}^\ell,$$

we have

$$\begin{aligned}
&\mathsf{dec}^{L:0} \circ \mathsf{enc}^{0:L} \\
&= \mathsf{dec}^{(L-2):0} \circ \mathsf{dec}^{L-1} \circ \mathsf{dae}_L^L \circ \mathsf{enc}^{L-1} \circ \mathsf{enc}^{0:(L-2)} \\
&= \mathsf{dec}^{(L-2):0} \circ \mathsf{dae}_L^{L-1} \circ \mathsf{dec}^{L-1} \circ \mathsf{enc}^{L-1} \circ \mathsf{enc}^{0:(L-2)} \\
&= \mathsf{dec}^{(L-2):0} \circ \mathsf{dae}_L^{L-1} \circ \mathsf{dae}_{L-1}^{L-1} \circ \mathsf{enc}^{0:(L-2)} \\
&\cdots \\
&= \mathsf{dae}_L^0 \circ \mathsf{dae}_{L-1}^0 \circ \cdots \circ \mathsf{dae}_0^0.
\end{aligned}$$

■

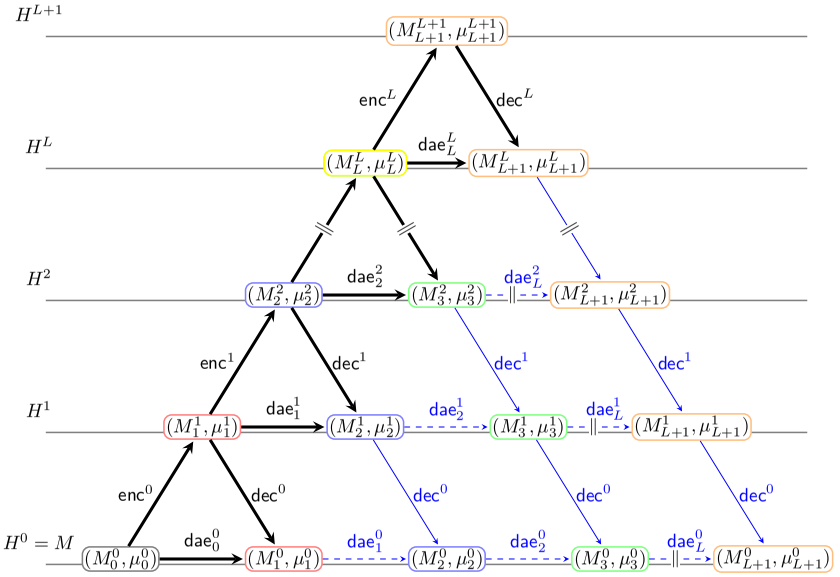


Figure 14: By using decoders, an SDAE is transformed or projected into a CDAE. The leftmost arrows correspond to the SDAE $\mathsf{enc}^{0:L}$, the rightmost arrows correspond to the decoders $\mathsf{dec}^{L:0}$, and the bottom arrows correspond to the CDAE $\mathsf{dae}_L^0 \circ \cdots \circ \mathsf{dae}_0^0$.

6.5. Numerical Example

Figure 15 compares the transportation results of the 2-dimensional swissroll data by the DAEs. In both the cases, the swissroll becomes thinner by the action of transportation. We remark that to test the topological conjugacy by numerical experiments is difficult. Here, we display Figure 15 to see typical trajectories by an SDAE and a CDAE.

In the left-hand side, we trained an SDAE $\mathsf{enc}^1 \circ \mathsf{enc}^0$ by using real NNs. Specifically, we first trained a shallow DAE dae_0^0 on the swissroll data $\boldsymbol{x}_0$. Second, writing $\mathsf{dae}_0^0 = \mathsf{dec}_0 \circ \mathsf{enc}_0$ and letting $\boldsymbol{z}^1 := \mathsf{enc}_0(\boldsymbol{x}_0)$, we trained a shallow DAE dae_1^1 on the feature vectors $\boldsymbol{z}^1$. Then, writing $\mathsf{dae}_1^1 = \mathsf{dec}_1 \circ \mathsf{enc}_1$, we obtained $\boldsymbol{x}_1 := \mathsf{dae}_0^0(\boldsymbol{x}_0)$ and $\boldsymbol{x}_2 := \mathsf{dec}^0 \circ \mathsf{dec}^1 \circ \mathsf{enc}^1 \circ \mathsf{enc}^0$. The black points represent the input vectors $\boldsymbol{x}_0$, and the red and blue points represent the first and second transportation results $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, respectively. In other words, the distribution of $\boldsymbol{x}_0, \boldsymbol{x}_1$ and $\boldsymbol{x}_2$ correspond to μ_0^0, μ_1^0 and μ_2^0 in Figure 14, respectively.

In the right-hand side, we trained a CDAE $\mathsf{dae}_0^1 \circ \mathsf{dae}_0^0$ by using real NNs. Specifically, we first trained a shallow DAE dae_0^0 on the swissroll data $\boldsymbol{x}_0$. Second, writing $\boldsymbol{x}_1 := \mathsf{dae}_0^0(\boldsymbol{x}_0)$, we trained a shallow DAE dae_1^0 on the transported vectors $\boldsymbol{x}_1^0$. Then, we obtained $\boldsymbol{x}_2 := \mathsf{dae}_0^1(\boldsymbol{x}_1) = \mathsf{dae}_0^1 \circ \mathsf{dae}_0^0(\boldsymbol{x}_0)$. The black points represent the input vectors $\boldsymbol{x}_0$, and the red and blue points represent the first and second transportation results $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, respectively.

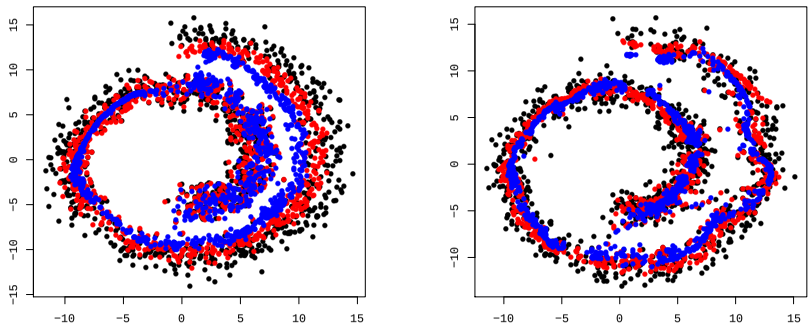

Figure 15: Typical transportation results of the 2-dimensional swissroll data by an SDAE (left) and a CDAE (right). In **both** the sides, the **black** points represent the input vectors $\boldsymbol{x}_0 \in \mathbb{R}^2$, and the **red** and **blue** points represent the first and second transportation results $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, respectively.

7. Integral Representation of the Flow Representation

In this section, we aim to develop the double continuum limit: a combination of the depth continuum limit, or the flow representation, and the width continuum limit, or the integral representation.

To facilitate visualization, we write the hidden parameters as $\boldsymbol{\theta}$ instead of $(\boldsymbol{a}, b)$, the k-th element of the coefficient function as $\gamma(\boldsymbol{\theta}, k)$ or $\gamma_k(\boldsymbol{\theta})$ instead of the boldface $\boldsymbol{\gamma}(\boldsymbol{\theta})$, and the integral representation as

$$S[\gamma_k](\boldsymbol{x}) = \int \gamma(\boldsymbol{\theta}, k)\sigma(\boldsymbol{x}; \boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}. \tag{57}$$

Furthermore, by using a singular measure $\gamma_k^p(\boldsymbol{\theta}) := \sum_{j=1}^p c_{jk}\delta_{\boldsymbol{\theta}_j}(\boldsymbol{\theta})$, we write an ordinary shallow NN as

$$S[\gamma_k^p](\boldsymbol{x}) = \int \gamma^p(\boldsymbol{\theta}, k)\sigma(\boldsymbol{x}; \boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta} = \sum_{j=1}^p c_{jk}\sigma(\boldsymbol{x}; \boldsymbol{\theta}_j). \tag{58}$$

If there is no risk of confusion, we omit writing the superscript p. Specifically, we write "$S[\gamma_k]$" without distinction between an infinite NN (57) and a finite NN (58).

7.1. Encoder and Decoder in the Integral Representation

First, we consider a finite case. Suppose that a shallow DAE is realized by a finite NN $\sum_{j=1}^p c_{jk}\sigma(\boldsymbol{x}; \boldsymbol{\theta}_j)$. Then, the encoder is given by

$$z(\boldsymbol{\theta}_j) = \mathsf{enc}(\boldsymbol{x}, \boldsymbol{\theta}_j) = \sigma(\boldsymbol{x}; \boldsymbol{\theta}_j), \quad j = 1, \dots, p;$$

and the decoder is given by

$$\mathsf{dec}(\boldsymbol{z}, k) = \sum_{j=1}^p c_{jk} z(\boldsymbol{\theta}_j).$$

Therefore, supposing that a shallow DAE is realized by $S[\gamma]$, the encoder and decoder in the integral representation are given by

$$\mathsf{enc}(\boldsymbol{x}, \boldsymbol{\theta}) := \sigma(\boldsymbol{x}; \boldsymbol{\theta}), \tag{59}$$

$$\mathsf{dec}(\boldsymbol{z}, k) := \int \gamma(\boldsymbol{\theta}, k) z(\boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}, \tag{60}$$

where "the $\boldsymbol{\theta}$-th element" of $\boldsymbol{z}$ is given by $z(\boldsymbol{\theta})$.

Next, we consider the stacked DAE built on $\boldsymbol{z}$. Suppose that the stacked DAE is realized by $S[\widetilde{\gamma}_{\boldsymbol{\theta}}](\boldsymbol{z}) = \int \widetilde{\gamma}(\boldsymbol{\omega}, \boldsymbol{\theta})\sigma(\boldsymbol{z}; \boldsymbol{\omega})\mathrm{d}\boldsymbol{\omega}$; then, the encoder and decoder are given by

$$\widetilde{\mathsf{enc}}(\boldsymbol{z}, \boldsymbol{\omega}) := \sigma(\boldsymbol{z}; \boldsymbol{\omega}), \tag{61}$$

$$\widetilde{\mathsf{dec}}(\boldsymbol{u}, \boldsymbol{\theta}) := \int \widetilde{\gamma}(\boldsymbol{\omega}, \boldsymbol{\theta}) u(\boldsymbol{\omega})\mathrm{d}\boldsymbol{\omega}, \tag{62}$$

where the $\boldsymbol{\omega}$-th element of $\boldsymbol{u}$ is given by $u(\boldsymbol{\omega})$, and the $\boldsymbol{\theta}$-th element of $\boldsymbol{\omega}$ is given by $\omega(\boldsymbol{\theta})$.

In this notation, for example, the topological conjugacy (55) claims that there exists γ' such that

$$\int \gamma(\boldsymbol{\theta}, k) \int \widetilde{\gamma}(\boldsymbol{\omega}, \boldsymbol{\theta})\sigma(\sigma(\boldsymbol{x}; \cdot); \boldsymbol{\omega})\mathrm{d}\boldsymbol{\omega}\mathrm{d}\boldsymbol{\theta} = \int \gamma'(\boldsymbol{\theta}', k)\sigma\left(\int \gamma(\boldsymbol{\theta}, \cdot)\sigma(\boldsymbol{x}; \boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}; \boldsymbol{\theta}'\right)\mathrm{d}\boldsymbol{\theta}'. \tag{63}$$

7.2. Ridgelet Transform of Flows

Let $\boldsymbol{\varphi}_t : \mathbb{R}^m \to \mathbb{R}^m$ be a flow that satisfies $\boldsymbol{\varphi}_t \circ \boldsymbol{\varphi}_s = \boldsymbol{\varphi}_{t+s}$. Then, the following formula holds:

$$\int R[\boldsymbol{\varphi}_t](\boldsymbol{\theta}, k)\sigma\left(\int R[\boldsymbol{\varphi}_s](\boldsymbol{\theta}, \cdot)\sigma(\boldsymbol{x}; \boldsymbol{\theta}')\mathrm{d}\boldsymbol{\theta}'\right)\mathrm{d}\boldsymbol{\theta} = \int R[\boldsymbol{\varphi}_{t+s}](\boldsymbol{\theta}, k)\sigma(\boldsymbol{x}; \boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}. \tag{64}$$

In other words, $S[R[\boldsymbol{\varphi}_t]] \circ S[R[\boldsymbol{\varphi}_s]] = S[R[\boldsymbol{\varphi}_{t+s}]]$. According to Barron's bound (Kůrková, 2012, Cor.5.4), the discretization error $\|S[\gamma] - S[\gamma^p]\|_2$ between $S[\gamma]$ and $S[\gamma^p]$ is bounded by $\|\gamma\|_1/\sqrt{p}$. Hence, $\|R[\boldsymbol{\varphi}_t]\|_1 + \|R[\boldsymbol{\varphi}_s]\|_1 \leq \|R[\boldsymbol{\varphi}_{t+s}]\|_1$ for some t and s, which implies the expressive efficiency of the DNN.

Consider a special case when $\boldsymbol{\varphi} : \mathbb{R}^m \to \mathbb{R}^m$ is given by the gradient of a potential function V. Specifically, $\boldsymbol{\varphi} = \nabla V$. We note that according to the polar decomposition theorem by Brenier (1991), any optimal transport map $\boldsymbol{\varphi}_t : [0, 1] \times \mathbb{R}^m \to \mathbb{R}^m$ can be written as $\boldsymbol{\varphi}_t = \mathsf{id} + t\nabla U$ with some potential function U. Hence, by letting $V = |\cdot|^2/2 + U$, we can understand $\boldsymbol{\varphi} := \boldsymbol{\varphi}_1 = \nabla V$ as an optimal transport map.

Then, we have an integration-by-parts formula for the vector ridgelet transform.

Theorem 11 *Let $K \subset \mathbb{R}^m$ be a compact set with smooth boundary ∂K. Given that a smooth scalar potential V is supported in K, the ridgelet transform of the potential vector field ∇V is calculated by*

$$R_\rho[\nabla V](\boldsymbol{a}, b) = -\boldsymbol{a} R_{\rho'}[V](\boldsymbol{a}, b). \tag{65}$$

Here, R_ρ and $R_{\rho'}$ denote the ridgelet transform with respect to ρ and ρ', respectively.

Proof

$$\begin{aligned} R_\rho[\nabla V](\boldsymbol{a}, b) &= \int_K \nabla V(\boldsymbol{x}) \overline{\rho(\boldsymbol{a} \cdot \boldsymbol{x} - b)} \mathrm{d}\boldsymbol{x} \\ &= \left[\int_{\partial K} V(\boldsymbol{x}) \overline{\rho(\boldsymbol{a} \cdot \boldsymbol{x} - b)} \boldsymbol{n}(\boldsymbol{x}) \mathrm{d}S - \boldsymbol{a} \int_K V(\boldsymbol{x}) \overline{\rho'(\boldsymbol{a} \cdot \boldsymbol{x} - b)} \mathrm{d}\boldsymbol{x} \right] \\ &= 0 - \boldsymbol{a}\, R_{\rho'}[V](\boldsymbol{a}, b). \end{aligned}$$

■

The left-hand side (LHS) of (65) denotes a vector ridgelet transform defined by element-wise mapping, whereas the right-hand side (RHS) consists of a scalar ridgelet transform. We can understand the RHS given that the network shares common knowledge among element-wise tasks.

7.3. Example: Autoencoder

As the most fundamental transport map, we consider a smooth "truncated" autoencoder $\mathsf{id}_{r,\delta}$. We denote by $\mathbb{B}^m(\boldsymbol{z}; r)$ a closed ball in $\mathbb{R}^m$ with center $\boldsymbol{z}$ and radius r. We assume that $\mathsf{id}_{r,\delta}$ is (1) smooth, (2) equal to the identity map id when it is restricted to $\mathbb{B}^m(r)$, and (3) truncated to be supported in $\mathbb{B}^m(r+\delta)$ with a small positive number $\delta > 0$. Let $\nabla V_{r,\delta}$ be a smooth function that satisfies

$$V_{r,\delta}(\boldsymbol{x}) := \begin{cases} \frac{1}{2}|\boldsymbol{x}|^2 & \boldsymbol{x} \in \mathbb{B}^m(0; r), \\ (\text{smooth map}) & \boldsymbol{x} \in \mathbb{B}(0; r+\delta) \setminus \mathbb{B}(0; r), \\ 0 & \boldsymbol{x} \notin \mathbb{B}^m(0; r+\delta), \end{cases}$$

and let

$$\mathsf{id}_{r,\delta} := \nabla V_{r,\delta}.$$

Note that we can construct $\mathsf{id}_{r,\delta}$ and $\nabla V_{r,\delta}$ by using mollifiers; thus, such maps exist.

The ridgelet transform of the truncated autoencoder is given by

$$R_\rho[\mathsf{id}_{r,\delta}](\boldsymbol{a}, b) \approx -K \boldsymbol{a} \overline{\rho'(-b)} \quad \text{as} \quad \delta \to 0 \tag{66}$$

with a certain constant K (see Appendix E for the proof).

8. Discussion

We performed transport analysis of denoising autoencoders by introducing the flow representation. The flow representation $\boldsymbol{\varphi}_t$ is the depth continuum limit of a DNN, specified by an ODE with vector field $\boldsymbol{v}_t$. We interpreted an ordinary DNN $\boldsymbol{g}_t$ as a transport map or an Euler broken line approximation of $\boldsymbol{\varphi}_t$. The advantages of the flow representation are that it provides the coordinate-free treatment of DNNs, avoiding the redundancy of the ordinary parametrization of DNNs, and that it facilitates our understanding of what DNNs do—it is the mass transportation controlled by $\boldsymbol{v}_t$. In addition, the advantage of the interpretation as mass transportation is that it can handle function composition. In the transport analysis, we analyzed a flow in three aspects: a dynamical system described by a transport map or vector field, a pushforward measure described by a continuity equation, and Wasserstein gradient flow. From the results in Wasserstein geometry, these aspects are closely connected, and the hyperparameter $\boldsymbol{v}_t$ plays a central role as an intermediary. For example, in the transport analysis of continuous DAEs, the potential functional of the Wasserstein gradient flow often facilitates our understanding of the flow because it is the Shannon entropy, which is a fundamental quantity in statistics and machine learning.

In Section 3 and 4, we specified the transport maps of shallow, deep, and infinitely deep DAEs, and we gave their statistical interpretations. The shallow DAE is an estimator of the mean, while the deep DAE transports data points to decrease the Shannon entropy of the data distribution, which gives a partial answer to our research question "what do hidden layers do?" In Section 5, according to analytic and numerical experiments, we showed that deep DAEs converge faster and that the extracted features are different from each other, which gives a partial answer to the other question "why do DNNs perform better?" In Section 6, we proved the equivalence between the stacked DAE and the composition of DAEs. Because of the peculiar construction, it is difficult to formulate and understand stacking. Nevertheless, by tracking the flow, we succeeded in formulating the stacked DAE. In Section 7, we developed the double continuum limits, or the width continuum limit of the depth continuum limit. We presented some examples of the integral representation of the flow, such as encoder, decoder, and traditional autoencoder.

As a consequence of the equivalence, we can understand the so-called *pre-training* and *fine-tuning* strategy (Bengio et al., 2007; Erhan et al., 2010) as an *optimal control* problem. Namely, write a DNN as a composite $\boldsymbol{\psi} \circ \boldsymbol{\varphi}_t$ of classifier $\boldsymbol{\psi} : \mathbb{R}^m \to [0,1]^n$ and flow $\boldsymbol{\varphi}_t : \mathbb{R}^m \to \mathbb{R}^m$. If $\boldsymbol{\varphi}_t$ stays closer to the identity, $\boldsymbol{\psi}$ has to be more complex—and vice versa. The pre-training regularizes the behavior of hidden layers by

$$\frac{\mathrm{d}}{\mathrm{d}t} \boldsymbol{\varphi}_t(\boldsymbol{x}) = \boldsymbol{v}_t(\boldsymbol{\varphi}_t(\boldsymbol{x})), \quad \boldsymbol{x} \in \mathbb{R}^m,\, t > 0 \tag{67}$$

and the fine-tuning specifies the relation between input and output by

$$\text{Minimize} \quad \mathbb{E}_{X,Y} |Y - \boldsymbol{\psi} \circ \boldsymbol{\varphi}_{t=1}(X)|^2 \quad \text{w.r.t NN } \boldsymbol{\psi} \circ \boldsymbol{\varphi}_{t=1}. \tag{68}$$

Overall, we can understand the strategy as the control problem of system (67) under restriction (68). Owing to ridgelet transform, shallow NNs are interpretable and principled. Development of a "solution operator" to the control problem in the flow representation would open the way to the interpretable and principled alternative to DNNs.

Acknowledgments

The authors thank the editor and reviewers for their supportive and insightful comments, which have improved the clarity of the argument significantly. The authors also acknowledge fruitful discussions with Dr. Shotaro Akaho, Dr. Kohei Yatabe, Dr. Keisuke Yano, and Mr. Kentaro Minami. This work was supported by JSPS KAKENHI (15J07517 and 18K18113).

Appendix A. Proof of Theorem 4

By $L^1_{\mathrm{loc}}(\mathbb{R}^m)$ and $C^\infty_c(\mathbb{R}^m)$, we denote the spaces of locally integrable functions and compactly supported smooth functions, respectively. We assume that $\boldsymbol{g} : \mathbb{R}^m \to \mathbb{R}^m$ is locally integrable (L^1_{loc}).

Proof The proof follows from the calculus of variations. Let

$$\begin{aligned} L[\boldsymbol{g}] &= \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} |\boldsymbol{g}(\boldsymbol{x}+\boldsymbol{\varepsilon}) - \boldsymbol{x}|^2 \mu_0(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\ &= \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} [|\boldsymbol{g}(\boldsymbol{x}') - \boldsymbol{x}' + \boldsymbol{\varepsilon}|^2 \mu_0(\boldsymbol{x}' - \boldsymbol{\varepsilon})] \mathrm{d}\boldsymbol{x}', \quad \boldsymbol{x}' \leftarrow \boldsymbol{x} + \boldsymbol{\varepsilon}. \end{aligned}$$

Here, $L[\boldsymbol{g}]$ always exists because $\boldsymbol{g} \in L^1_{\mathrm{loc}}(\mathbb{R}^m) \subset L^2(\mu * \nu)$. Then, for an arbitrary function $\boldsymbol{h} \in C^\infty_c(\mathbb{R}^m)$, the first variation $\delta L[\boldsymbol{h}]$ is given by

$$\begin{aligned} \delta L[\boldsymbol{h}] &= \frac{d}{ds} L[\boldsymbol{g} + s\boldsymbol{h}]\Big|_{s=0} \\ &= \int_{\mathbb{R}^m} \frac{\partial}{\partial s} \mathbb{E}_{\boldsymbol{\varepsilon}} [|\boldsymbol{g}(\boldsymbol{x}) + s\boldsymbol{h}(\boldsymbol{x}) - \boldsymbol{x} + \boldsymbol{\varepsilon}|^2 \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] \mathrm{d}\boldsymbol{x}\Big|_{s=0} \\ &= 2 \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} [(\boldsymbol{g}(\boldsymbol{x}) - \boldsymbol{x} + \boldsymbol{\varepsilon}) \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] \boldsymbol{h}(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}. \end{aligned}$$

At a critical point $\boldsymbol{g}^*$ of L, $\delta L[\boldsymbol{h}] \equiv 0$ for every $\boldsymbol{h}$. Hence,

$$\mathbb{E}_{\boldsymbol{\varepsilon}} [(\boldsymbol{g}^*(\boldsymbol{x}) - \boldsymbol{x} + \boldsymbol{\varepsilon}) \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] = 0, \quad \mathsf{a.e.}\, \boldsymbol{x},$$

by the fundamental lemma of calculus of variations for integrable functions, and we have

$$\begin{aligned} \boldsymbol{g}^*(\boldsymbol{x}) &= \frac{\mathbb{E}_{\boldsymbol{\varepsilon}} [(\boldsymbol{x} - \boldsymbol{\varepsilon}) \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})]}{\mathbb{E}_{\boldsymbol{\varepsilon}} [\mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})]} = (14) \\ &= \boldsymbol{x} - \frac{\mathbb{E}_{\boldsymbol{\varepsilon}} [\boldsymbol{\varepsilon} \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})]}{\mathbb{E}_{\boldsymbol{\varepsilon}} [\mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})]} = (15). \end{aligned}$$

Note that $\boldsymbol{g}^*$ attains the global minimum, because, for every function $\boldsymbol{h}$,

$$\begin{aligned} L[\boldsymbol{g}^* + \boldsymbol{h}] &= \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} [|\boldsymbol{\varepsilon} - \mathbb{E}_t[\boldsymbol{\varepsilon}|\boldsymbol{x}] + \boldsymbol{h}(\boldsymbol{x})|^2 \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] \mathrm{d}\boldsymbol{x} \\ &= \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} [|\boldsymbol{\varepsilon} - \mathbb{E}_t[\boldsymbol{\varepsilon}|x]|^2 \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] \mathrm{d}\boldsymbol{x} + \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} [|\boldsymbol{h}(\boldsymbol{x})|^2 \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] \mathrm{d}\boldsymbol{x} \\ &\quad + 2 \int_{\mathbb{R}^m} \mathbb{E}_{\boldsymbol{\varepsilon}} [(\boldsymbol{\varepsilon} - \mathbb{E}_t[\boldsymbol{\varepsilon}|\boldsymbol{x}]) \mu_0(\boldsymbol{x} - \boldsymbol{\varepsilon})] \boldsymbol{h}(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\ &= L[\boldsymbol{g}^*] + L[\boldsymbol{h}] + 2 \cdot 0 \geq L[\boldsymbol{g}^*]. \end{aligned}$$

■

Appendix B. Proof of Fact 2

For simplicity, we assume that $\boldsymbol{g}$, $\boldsymbol{v}$, and μ are smooth. See Ambrosio et al. (2008, § 8.1) for more generalized conditions on the continuity equation.

Proof To facilitate visualization, we write $\boldsymbol{g}(\boldsymbol{x}, t)$, $\boldsymbol{v}(\boldsymbol{x}, t)$, and $\mu(\boldsymbol{x}, t)$ instead of $\boldsymbol{g}_t(\boldsymbol{x})$, $\boldsymbol{v}_t(\boldsymbol{x})$, and $\mu_t(\boldsymbol{x})$, respectively.

By definition,

$$\begin{cases} \partial_t \boldsymbol{g}(\boldsymbol{g}(\boldsymbol{x}, t), t) = \boldsymbol{v}(\boldsymbol{g}(\boldsymbol{x}, t), t), & \boldsymbol{x} \in \mathbb{R}^m,\ t > 0 \\ \boldsymbol{g}(\boldsymbol{x}, 0) = 0, & \boldsymbol{x} \in \mathbb{R}^m. \end{cases}$$

In particular,

$$\nabla \boldsymbol{g}(\boldsymbol{x}, 0) = I.$$

According to the change-of-variables formula, for any $\boldsymbol{x} \in \mathbb{R}^m$ and $t > s > 0$,

$$\mu(\boldsymbol{g}(\boldsymbol{x}, t), t) \cdot |\nabla \boldsymbol{g}(\boldsymbol{x}, t)| = \mu(\boldsymbol{x}, s),$$

where $|\cdot|$ denotes the determinant.

Take the logarithm on both sides and then differentiate with respect to t. Then, the RHS vanishes and the LHS is calculated as follows:

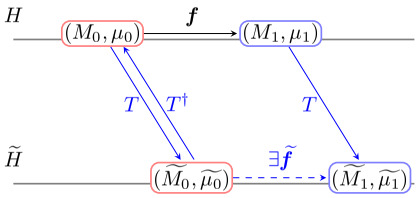
$$\begin{aligned} \partial_t \log[\mu(\boldsymbol{g}(\boldsymbol{x}, t), t) \cdot |\nabla \boldsymbol{g}(\boldsymbol{x}, t)|] &= \frac{\partial_t [\mu(\boldsymbol{g}(\boldsymbol{x}, t), t)]}{\mu(\boldsymbol{g}(\boldsymbol{x}, t), t)} + \partial_t \log |\nabla \boldsymbol{g}(\boldsymbol{x}, t)| \\ &= \frac{(\nabla \mu)(\boldsymbol{g}(\boldsymbol{x}, t), t) \cdot \partial_t \boldsymbol{g}(\boldsymbol{x}, t) + (\partial_t \mu)(\boldsymbol{g}(\boldsymbol{x}, t), t)}{\mu(\boldsymbol{g}(\boldsymbol{x}, t), t)} \\ &\quad + \mathsf{tr}\,[(\nabla \boldsymbol{g}(\boldsymbol{x}, t))^{-1} \nabla \partial_t \boldsymbol{g}(\boldsymbol{x}, t)], \end{aligned}$$

where the second term follows a differentiation formula by Petersen and Pedersen (2012, Eq. 43)

$$\partial \log |J| = \mathsf{tr}\,[J^{-1} \partial J].$$

By letting $t \to s + 0$,

$$\frac{\nabla \mu(\boldsymbol{x}, t) \cdot \boldsymbol{v}(\boldsymbol{x}, t) + (\partial_t \mu)(\boldsymbol{x}, t)}{\mu(\boldsymbol{x}, t)} + \mathsf{tr}\,[\nabla \boldsymbol{v}(\boldsymbol{x}, t)] = 0,$$



which gives

$$\partial_t \mu(\boldsymbol{x}, t) = -\nabla \cdot [\mu(\boldsymbol{x}, t) \boldsymbol{v}(\boldsymbol{x}, t)].$$

■

Appendix C. Proof of Theorem 9

We show that the diagram commutes. Observe that $\boldsymbol{f} = \mathsf{id} + tD\nabla \log e^{tL_t} \mu$ is the sum of the present position id and the gradient ∇V of potential $V = \log e^{tL_t} \mu$. We calculate the pushforward $\widetilde{\nabla} \widetilde{V}$ and show that it coincides with $\widetilde{L}_t$-DAE.

Proof We suppose that L_t is expressed as

$$L_t u := \boldsymbol{a}_t^\top (\nabla^2 u) \boldsymbol{a}_t + \boldsymbol{b}_t^\top \nabla u + c_t u, \quad u \in C^2(H) \tag{69}$$

and T is expressed as

$$T(\boldsymbol{z}) = A\boldsymbol{z} \tag{70}$$

with a matrix A.

By the assumption that the restriction $T|_{M_0}$ is injective, it has a left inverse $T^\dagger$ such that $T^\dagger \circ T|_{M_0} = \mathsf{id}_{M_0}$. Note that it is not a linear map but an abstract nonlinear map, which means that there is no matrix A that realizes $T^\dagger$.

Step. 1

We show that

$$T \circ \boldsymbol{f} \circ T^\dagger = \mathsf{id} + t\widetilde{D}\widetilde{\nabla}\widetilde{V} \quad \text{in } \widetilde{M}_0 \tag{71}$$

where $\widetilde{D} = ADA^\top$ and $\widetilde{V} = V \circ T^\dagger$.

For an arbitrary $U \in C^2(M_0)$, write $T_* U := U \circ T^\dagger \in C^2(\widetilde{M}_0)$, and

$$\nabla U(T^\dagger(\boldsymbol{x})) = A^\top \widetilde{\nabla} T_* U(\boldsymbol{x}), \quad \boldsymbol{x} \in \widetilde{M}_0 \tag{72}$$

because the i-th element of $\widetilde{\nabla} T_* U$ is given by

$$\frac{\partial U \circ T^\dagger}{\partial x_i}(\boldsymbol{x}) = \sum_p \frac{\partial U}{\partial z_p}(T^\dagger(\boldsymbol{x})) \frac{\partial T_p^\dagger}{\partial x_i}(\boldsymbol{x}).$$

Thus, the q-th element of $A^\top \widetilde{\nabla} T_* U$ is given by

$$\begin{aligned}\sum_i A_{iq} \frac{\partial U \circ T^\dagger}{\partial x_i}(\boldsymbol{x}) &= \sum_p \frac{\partial U}{\partial z_p}(T^\dagger(\boldsymbol{x})) \sum_i A_{iq} \frac{\partial T_p^\dagger}{\partial x_i}(\boldsymbol{x}) \\ &= \sum_p \frac{\partial U}{\partial z_p}(T^\dagger(\boldsymbol{x})) \delta_{pq} \\ &= \frac{\partial U}{\partial z_q}(T^\dagger(\boldsymbol{x})).\end{aligned}$$

Therefore, by substituting U with $V = \log e^{tL_t}\mu_0$,

$$\begin{aligned}T \circ \boldsymbol{f} \circ T^\dagger(\boldsymbol{x}) &= \boldsymbol{x} + A(tD\nabla V(T^\dagger(\boldsymbol{x}))) \\ &= \boldsymbol{x} + tADA^\top \widetilde{\nabla} T_* V(\boldsymbol{x})) \\ &= \boldsymbol{x} + t\widetilde{D}\widetilde{\nabla}\widetilde{V}(\boldsymbol{x}).\end{aligned}$$

Step. 2

We show that

$$\widetilde{V} = \log e^{t\widetilde{L}_t}\widetilde{\mu}_0 + (const.), \quad \text{in } M_0 \tag{73}$$

where

$$\widetilde{L}_t \widetilde{u} := \widetilde{\boldsymbol{a}}_t^\top (\widetilde{\nabla}^2 \widetilde{u}) \widetilde{\boldsymbol{a}}_t + \widetilde{\boldsymbol{b}}_t^\top \widetilde{\nabla} \widetilde{u} + \widetilde{c}_t \widetilde{u}, \quad \widetilde{u} \in C^2(\widetilde{H}) \tag{74}$$

with $\widetilde{\boldsymbol{a}}_t = A\boldsymbol{a}_t \circ T^\dagger, \widetilde{\boldsymbol{b}}_t = A\boldsymbol{b}_t \circ T^\dagger$, and $\widetilde{c}_t = c_t \circ T^\dagger$.

Let

$$u_t := e^{tL_t}\mu_0. \tag{75}$$

By the definition of semigroup e^{tL_t}, $u_0 = \mu_0$ and $\partial_t u_t = L_t u_t$ (however, u_1 is different from μ_1).

Given u_t, let

$$\widetilde{u}_t := T_\sharp u_t. \tag{76}$$

According to the change-of-variables formula (7),

$$\widetilde{u}_t = [A]^{-1} T_* u_t, \tag{77}$$

where $[A] := \sqrt{\det |A^\top A|}$ and $T_* u_t := u_t \circ T^\dagger$. In particular, $\widetilde{u}_0 = \widetilde{\mu}_0$ and $\log \widetilde{u}_t = \widetilde{V}$.

Furthermore,

$$\partial_t \widetilde{u}_t = \widetilde{L}_t \widetilde{u}_t, \quad \text{in } \widetilde{M}_0, \tag{78}$$

because

$$\begin{aligned}\partial_t \widetilde{u}_t(\boldsymbol{x}) &= [A]^{-1} \partial_t [u_t(T^\dagger(\boldsymbol{x}))] \\ &= [A]^{-1} L_t[u_t](T^\dagger(\boldsymbol{x})),\end{aligned}$$

and

$$\begin{aligned}&[A]^{-1} \boldsymbol{a}_t(T^\dagger(\boldsymbol{x}))^\top (\nabla^2 u_t(T^\dagger(\boldsymbol{x}))) \boldsymbol{a}_t(T^\dagger(\boldsymbol{x})) \\ &\quad = \boldsymbol{a}_t(T^\dagger(\boldsymbol{x}))^\top (A^\top \widetilde{\nabla}^2 [[A]^{-1} T_* u_t](\boldsymbol{x}) A) \boldsymbol{a}_t(T^\dagger(\boldsymbol{x})) \\ &\quad = \widetilde{\boldsymbol{a}}_t(\boldsymbol{x})^\top (\widetilde{\nabla}^2 [\widetilde{u}_t](\boldsymbol{x})) \widetilde{\boldsymbol{a}}_t(\boldsymbol{x}), \\ &[A]^{-1} \boldsymbol{b}_t(T^\dagger(\boldsymbol{x}))^\top \nabla u_t(T^\dagger(\boldsymbol{x})) \\ &\quad = \boldsymbol{b}_t(T^\dagger(\boldsymbol{x}))^\top A^\top \widetilde{\nabla} [[A]^{-1} T_* u_t](\boldsymbol{x}) \\ &\quad = \widetilde{\boldsymbol{b}}_t(\boldsymbol{x})^\top \widetilde{\nabla} \widetilde{u}_t(\boldsymbol{x}), \\ &[A]^{-1} c_t(T^\dagger(\boldsymbol{x})) u_t(T^\dagger(\boldsymbol{x})) \\ &\quad = \widetilde{c}_t(\boldsymbol{x}) \widetilde{u}_t(\boldsymbol{x}).\end{aligned}$$

Thus,

$$\partial_t \widetilde{u}_t(\boldsymbol{x}) = [A]^{-1} L_t[u_t](T^\dagger(\boldsymbol{x})) = \widetilde{L}_t \widetilde{u}_t(\boldsymbol{x}).$$

Hence, $\widetilde{u}_t$ is the solution of the initial value problem $\partial_t \widetilde{u}_t = \widetilde{L}_t \widetilde{u}_t$ with $\widetilde{u}_0 = \widetilde{\mu}_0$. By the uniqueness of the solution, $\widetilde{u}_t = e^{t\widetilde{L}_t}\widetilde{\mu}_0$. On the other hand, $\log \widetilde{u}_t = \widetilde{V}$. Therefore, $\widetilde{V} = \log \widetilde{u}_t = e^{t\widetilde{L}_t}\widetilde{\mu}_0$.

To sum up the two steps,

$$T \circ \boldsymbol{f} \circ T^\dagger = \mathsf{id} + t\widetilde{D}\widetilde{\nabla} \log e^{t\widetilde{L}_t}\widetilde{\mu}_0 =: \widetilde{\boldsymbol{f}},$$

and we have the topological conjugacy

$$T \circ \boldsymbol{f} = \widetilde{\boldsymbol{f}} \circ T. \qquad \blacksquare$$

Appendix D. Proofs for Analytic Examples

D.1. Univariate Normal Distribution

We calculate the case for a univariate normal distribution $N(m_0, \sigma_0^2)$.

D.1.1. Shallow DAE

We show that

$$g_t(x) = \frac{\sigma_0^2}{\sigma_0^2 + t} x + \frac{t}{\sigma_0^2 + t} m_0, \tag{30}$$

$$\mu_t = N\left(m_0, \frac{\sigma_0^2}{(1 + t/\sigma_0^2)^2}\right). \tag{31}$$

Proof The proof is immediate from (17). First, write $\phi_t(x, y) = (4\pi t)^{-1/2} \exp(-|x-y|^2/4t)$,

$$\phi_{t/2} * N(m_0, \sigma_0^2) = N(m_0, \sigma_0^2 + t).$$

Hence,

$$g_t(x) = x + t\nabla \log[N(m_0, \sigma_0^2 + t)] = \frac{\sigma_0^2}{\sigma_0^2 + t} x + \frac{t}{\sigma_0^2 + t} m_0.$$

As g_t is affine, the pushforward is immediate. $\blacksquare$

D.1.2. Continuous DAE

We show that

$$g_t(x) = \sqrt{1 - 2t/\sigma_0^2}(x - m_0) + m_0, \tag{32}$$

$$\mu_t = N(m_0, \sigma_0^2 - 2t), \quad 0 \le t < \sigma_0^2/2. \tag{33}$$

Proof [μ_t] Write the pushforward as $N(m_t, \sigma_t^2)$. By using the heat kernel $\phi_t(\boldsymbol{x}, \boldsymbol{y}) = (4\pi t)^{-m/2} \exp(-|\boldsymbol{x} - \boldsymbol{y}|^2/4t)$, for some $T > 0$,

$$\begin{aligned} N(m_t, \sigma_t^2) &= \phi_{T-t} * N(m_T, \sigma_T^2) \\ &= N(m_T, \sigma_T^2 + 2(T - t)). \end{aligned}$$

By eliminating T by the initial conditions, we have

$$N(m_t, \sigma_t^2) = N(m_0, \sigma_0^2 - 2t).$$

By the positivity of σ_t^2, we can determine the largest possible T as $T = \sigma_0^2/2$. $\blacksquare$

Proof [g_t] Fix an arbitrary point x_0. Write $x_t := g_t(x_0)$ and $\dot{x}_t := \partial_t g_t(x_0)$. Recall that $\dot{m}_t \equiv 0$, because m_t is a constant. According to (24),

$$\dot{x}_t = -\frac{x_t - m_t}{\sigma_t^2}.$$

By dividing both sides by x_t and integrating them,

$$\begin{aligned} \log\left|\frac{x_t - m_t}{x_0 - m_0}\right| &= -\int_0^t \frac{\mathrm{d}s}{\sigma_s^2} \\ &= \frac{1}{2}\int_0^t \frac{\mathrm{d}s}{s - T} \\ &= \frac{1}{2}\log\left|\frac{T - t}{T}\right|, \end{aligned}$$

which concludes the proof. $\blacksquare$

D.2. Multivariate Normal Distribution

We calculate the case for a multivariate normal distribution $N(\boldsymbol{m}_0, \Sigma_0)$.

D.2.1. Shallow DAE

We show that

$$\boldsymbol{g}_t(\boldsymbol{x}) = (I + t\Sigma_0^{-1})^{-1}\boldsymbol{x} + (I + t^{-1}\Sigma_0)^{-1}\boldsymbol{m}_0, \tag{34}$$

$$\mu_t = N(\boldsymbol{m}_0, \Sigma_0(I + t\Sigma_0^{-1})^{-2}). \tag{35}$$

Proof Calculate (17) directly as in the univariate case. First, by writing $\phi_t(\boldsymbol{x}, \boldsymbol{y}) = (4\pi t)^{-m/2} \exp(-|\boldsymbol{x} - \boldsymbol{y}|^2/4t)$,

$$\phi_{t/2} * N(\boldsymbol{m}_0, \Sigma_0) = N(\boldsymbol{m}_0, \Sigma_0 + tI).$$

Hence,

$$\begin{aligned}\boldsymbol{g}_t(\boldsymbol{x}) &= \boldsymbol{x} + t\nabla \log[N(\boldsymbol{m}_0, \Sigma_0 + tI)] \\ &= \boldsymbol{x} + t\nabla\left[-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{m}_0)^\top(\Sigma_0+tI)^{-1}(\boldsymbol{x}-\boldsymbol{m}_0)\right] \\ &= (I + t\Sigma_0^{-1})^{-1}\boldsymbol{x} + (I + t^{-1}\Sigma_0)^{-1}\boldsymbol{m}_0.\end{aligned}$$

As $\boldsymbol{g}_t$ is affine, the pushforward is immediate. ■

D.2.2. Continuous DAE

We show that

$$\boldsymbol{g}_t(\boldsymbol{x}) = \sqrt{I - 2t\Sigma_0^{-1}}(\boldsymbol{x}-\boldsymbol{m}_0) + \boldsymbol{m}_0, \tag{36}$$

$$\mu_t = N(\boldsymbol{m}_0, \Sigma_0 - 2tI). \tag{37}$$

Proof Write $\phi_t(\boldsymbol{x}, \boldsymbol{y}) = (4\pi t)^{-m/2}\exp(-|\boldsymbol{x}-\boldsymbol{y}|^2/4t)$, and recall that $\phi_t * N(\boldsymbol{m}, \Sigma) = N(\boldsymbol{m}, \Sigma + 2tI)$. Thus, the pushforward $N(\boldsymbol{m}_t, \Sigma_t)$ is obtained as follows in a manner similar to the univariate case.

$$N(\boldsymbol{m}_t, \Sigma_t) = N\left(\boldsymbol{m}_0, \Sigma_0 - 2tI\right).$$

Suppose that $\boldsymbol{g}_t(\boldsymbol{x})$ is an affine transform $A_t(\boldsymbol{x}-\boldsymbol{m}_0)+\boldsymbol{m}_0$ analogous to the univariate case. Recall that, if $X \sim N(\boldsymbol{m}, \Sigma)$, then $AX+b \sim N(A\boldsymbol{m}+b, A\Sigma A^\top)$. Hence, for our case, $\Sigma_t = A_t\Sigma_0 A_t^\top$ and we can determine

$$A_t = \sqrt{\Sigma_t\Sigma_0^{-1}} = \sqrt{I - 2t\Sigma_0^{-1}}.$$

Finally, we check whether $\boldsymbol{g}_t$ satisfies (24). As Σ_0 is symmetric, we can always diagonalize $\Sigma_0 = UD_0U^\top$ with an orthogonal matrix U and a diagonal matrix D_0. Observe that with the same U, we can simultaneously diagonalize Σ_t and A_t as

$$\begin{aligned}\Sigma_t &= UD_tU^\top, \quad D_t := D_0 - 2tI \\ A_t &= UD_t^{1/2}D_0^{-1/2}U^\top.\end{aligned}$$

Without loss of generality, we can assume that $U = I$; therefore, Σ_t and A_t are diagonal and $\boldsymbol{m}_t \equiv 0$. Fix an index j and denote the j-th diagonal element of Σ_t and A_t by σ_t^2 and a_t, respectively. Then, our goal is reduced to showing that $\partial_t[a_t x] = \nabla \log \mu_t(a_t x)$ for every fixed $x \in \mathbb{R}$.

By definition,

$$\begin{aligned}\sigma_t^2 &= \sigma_0^2 - 2t, \\ a_t &= \sigma_t\sigma_0^{-1} = \sqrt{1 - 2t\sigma_0^{-2}}.\end{aligned}$$

Thus, the LHS is

$$\partial_t[a_t x] = -\frac{1}{\sigma_0\sqrt{\sigma_0^2 - 2t}}x = -\sigma_0^{-1}\sigma_t^{-1}x,$$

and the RHS is

$$\nabla \log \mu_t(a_t x) = -\frac{a_t x}{\sigma_t^2} = -\sigma_0^{-1}\sigma_t^{-1}x.$$

Hence, the LHS equals the RHS. ■

D.3. Mixture of Multivariate Normal Distributions

We calculate the case for the mixture of multivariate normal distributions $\sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k)$, with the assumption that it is *well separated* (see Section 5.1.3 for the definition).

D.3.1. Shallow DAE

We show that

$$\boldsymbol{g}_t(\boldsymbol{x}) = \sum_{k=1}^K \gamma_{kt}(\boldsymbol{x})\left\{(I + t\Sigma_k^{-1})^{-1}\boldsymbol{x} + (I + t^{-1}\Sigma_k)^{-1}\boldsymbol{m}_k\right\}, \tag{38}$$

$$\mu_t \approx \sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k(I + t\Sigma_k^{-1})^{-2}), \quad \text{if well separated} \tag{39}$$

with the responsibility function

$$\gamma_{kt}(\boldsymbol{x}) := \frac{w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k + tI)}{\sum_{k=1}^K w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k + tI)}. \tag{40}$$

Proof Directly calculate (17). By the linearity of the heat kernel,

$$\begin{aligned}\boldsymbol{g}_t &:= \mathsf{id} + t\sum_{k=1}^K \frac{w_k \nabla N(\boldsymbol{m}_k, \Sigma_k + tI)}{\sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k + tI)}, \\ &= \mathsf{id} + \sum_{k=1}^K \frac{w_k N(\boldsymbol{m}_k, \Sigma_k + tI)}{\sum_{k=1}^K w_k N(\boldsymbol{m}_k, \Sigma_k + tI)} \cdot t\nabla \log N(\boldsymbol{m}_k, \Sigma_k + tI), \\ &= \mathsf{id} + \sum_{k=1}^K \gamma_{kt}(\boldsymbol{g}_{kt} - \mathsf{id}), \\ &= \sum_{k=1}^K \gamma_{kt}\boldsymbol{g}_{kt},\end{aligned}$$

where $\boldsymbol{g}_{kt}$ exactly coincides with the flow induced by the individual k-th component.

To calculate the pushforward, we introduce some auxiliary variables. Write $w(k) := w_k$, $\gamma(k \mid \cdot) := \gamma_{kt}(\cdot)$ and

$$\mu_t(\cdot \mid k) := N(\boldsymbol{m}_k, \Sigma_k + tI),$$
$$\mu_t := \sum_k w(k)\mu_t(\cdot \mid k).$$

Let $\tau_k(\cdot \mid \boldsymbol{x})$ be a probability measure that satisfies

$$\int_M \tau_k(y \mid \boldsymbol{x})\mu_0(\boldsymbol{x} \mid k)\mathrm{d}\boldsymbol{x} = \mu_t(y \mid k).$$

Note that τ_k is not unique. Recall that by definition, if $X \sim \mu_0(\cdot \mid k)$, then $Y = \boldsymbol{g}_{kt}(X) \sim \mu_t(\cdot \mid k)$. Hence, τ_k is a stochastic alternative to $\boldsymbol{g}_{kt}$.

Consider a probability measure

$$\sigma(\cdot \mid \boldsymbol{x}) := \sum_{k=1}^K \gamma(k \mid \boldsymbol{x})\tau_k(\cdot \mid \boldsymbol{x}).$$

Clearly, this is a stochastic alternative to $\boldsymbol{g}_t$. We show that

$$\int_M \sigma(y \mid \boldsymbol{x})\mu_0(\boldsymbol{x})\mathrm{d}\boldsymbol{x} \approx \mu_t(y).$$

The LHS is reduced to

$$\begin{aligned}\int_M \sigma(y \mid \boldsymbol{x})\mu_0(\boldsymbol{x})\mathrm{d}\boldsymbol{x} &= \int_M \sum_{k=1}^K \gamma(k \mid \boldsymbol{x})\tau_k(y \mid \boldsymbol{x}) \sum_\ell w(\ell)\mu_0(\boldsymbol{x} \mid \ell)\mathrm{d}\boldsymbol{x} \\ &= \sum_\ell w(\ell) \sum_{k=1}^K \int_M \gamma(k \mid \boldsymbol{x})\tau_k(y \mid \boldsymbol{x})\mu_0(\boldsymbol{x} \mid \ell)\mathrm{d}\boldsymbol{x}. \end{aligned} \tag{79}$$

Suppose that $\gamma(k \mid \boldsymbol{x})$ is an indicator function of a domain Ω_k, where $\int_{\Omega_k} \mu_0(\cdot \mid k) \approx 1$. Then,

$$\begin{aligned}(79) &\approx \sum_\ell w(\ell) \int_{\Omega_\ell} \tau_k(y \mid \boldsymbol{x})\mu_0(\boldsymbol{x} \mid \ell)\mathrm{d}\boldsymbol{x} \\ &\approx \sum_\ell w(\ell)\mu_t(y \mid \ell) = \mu_t(y).\end{aligned}$$

This concludes the claim. ■

D.3.2. Continuous DAE

We show that

$$\boldsymbol{g}_t(\boldsymbol{x}) \approx \sqrt{I - 2t\Sigma_k^{-1}}\,(\boldsymbol{x} - \boldsymbol{m}_k) + \boldsymbol{m}_k, \quad \boldsymbol{x} \in \Omega_k, \text{ if well separated} \tag{41}$$

$$\mu_t = \sum_{k=1}^K w_k N\left(\boldsymbol{m}_k, \Sigma_k - 2tI\right), \tag{42}$$

with the responsibility function

$$\gamma_{kt}(\boldsymbol{x}) := \frac{w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k - 2tI)}{\sum_{k=1}^K w_k N(\boldsymbol{x}; \boldsymbol{m}_k, \Sigma_k - 2tI)}. \tag{43}$$

Proof The pushforward is immediate by the linearity of the heat kernel. The dynamical system (24) for our case is reduced to

$$\partial_t \boldsymbol{g}_t(\boldsymbol{x}) = -\sum_{k=1}^K \gamma_{kt} \circ \boldsymbol{g}_t(\boldsymbol{x})(\Sigma_k - 2tI)^{-1}(\boldsymbol{g}_t(\boldsymbol{x}) - \boldsymbol{m}_k).$$

By the assumption that μ_0 is well separated, we can take an open neighborhood Ω_k of $\boldsymbol{m}_k$ and an open time interval I that contains t such that $\gamma_{kt} \circ \boldsymbol{g}_t(\boldsymbol{x}) \equiv 1$ for every $(\boldsymbol{x}, t) \in \Omega_k \times I$. In this restricted domain, the dynamical system is reduced to a single-component version:

$$\partial_t \boldsymbol{g}_t(\boldsymbol{x}) = -(\Sigma_k - 2tI)^{-1}(\boldsymbol{g}_t(\boldsymbol{x}) - \boldsymbol{m}_k), \quad (\boldsymbol{x}, t) \in \Omega_k \times I.$$

According to the previous results, we have exactly

$$\boldsymbol{g}_t(\boldsymbol{x}) = \sqrt{I - 2t\Sigma_k^{-1}}(\boldsymbol{x} - \boldsymbol{m}_k) + \boldsymbol{m}_k, \quad (\boldsymbol{x}, t) \in \Omega_k \times I. \qquad ■$$

Appendix E. Proof of (66)

Let $\delta \to 0$. Then, the ridgelet transform of the truncated autoencoder $\mathsf{id}_{r,\delta}$ is given by

$$R_\rho[\mathsf{id}_{r,0}](\boldsymbol{a}, b) = -\frac{A_{m-1}}{2(m+1)} \int_{|p|<r} (r^2 - p^2)^{\frac{m-1}{2}} \left\{ \frac{2}{m-1}p^2 + r^2 \right\} \overline{\rho'(|\boldsymbol{a}|p - b)}\boldsymbol{a}\mathrm{d}p \tag{80}$$

$$\approx -K\boldsymbol{a}\overline{\rho'(-b)}, \tag{81}$$

where $A_{m-1} := \frac{2\pi^{\frac{m-1}{2}}}{\Gamma(\frac{m-1}{2})}$ is the surface area of $\mathbb{S}^{m-1}$, and K is given by (87).

Proof Let $\delta \to 0$. Then, the connecting annulus $\mathbb{B}(0; r+\delta) \setminus \mathbb{B}(0; r)$ vanishes as follows:

$$\begin{aligned}R_\rho[\mathsf{id}_{r,\delta}](\boldsymbol{a}, b) &= -\boldsymbol{a}R_{\rho'}[V_{r,\delta}](\boldsymbol{a}, b) \\ &\to -\boldsymbol{a}\int_{\mathbb{B}^m(r)} \frac{1}{2}|\boldsymbol{x}|^2\overline{\rho'(\boldsymbol{a}\cdot\boldsymbol{x} - b)}\mathrm{d}\boldsymbol{x} \\ &= -\boldsymbol{a}R_{\rho'}[V_{r,0}](\boldsymbol{a}, b).\end{aligned}$$

Hence, we omit considering the annulus.

In the following, we use a spherical coordinate defined by

$$\boldsymbol{u} := \boldsymbol{a}/|\boldsymbol{a}|, \quad \alpha := 1/|\boldsymbol{a}|, \quad \beta := b/|\boldsymbol{a}|,$$

where $\boldsymbol{u} \in \mathbb{S}^{m-1}$ denotes the direction, $\alpha \in \mathbb{R}_+$ denotes the scale, and $\beta \in \mathbb{R}$ denotes the (scaled) shift parameters.

The ridgelet transform in the spherical coordinate (Sonoda and Murata, 2017a) is given by

$$R_\rho f(\boldsymbol{u}/\alpha, \beta/\alpha) = \int_{\mathbb{R}} \mathrm{Rad}[f](\boldsymbol{u}, p)\overline{\rho_\alpha(p-\beta)}\mathrm{d}p,$$

where $\mathrm{Rad}[f](\boldsymbol{u}, p)$ denotes the Radon transform

$$\mathrm{Rad}[f](\boldsymbol{u}, p) \coloneqq \int_{(\mathbb{R}\boldsymbol{u})^\perp} f(p\boldsymbol{u}+\boldsymbol{y})\mathrm{d}\boldsymbol{y}$$

of the function $f \in L^1(\mathbb{R}^m)$ at direction $\boldsymbol{u} \in \mathbb{S}^{m-1}$ and position $p \in \mathbb{R}$, and

$$\rho_\alpha(p) \coloneqq \rho(p/\alpha).$$

The Radon transform $\mathrm{Rad}[V_{r,0}](\boldsymbol{u}, p)$ for $|p| < r$ is calculated as follows. Because $V_{r,\delta}$ is a radial function, $\mathrm{Rad}[V_{r,0}](\boldsymbol{u}, p)$ does not depend on the direction $\boldsymbol{u}$. Hence, it is sufficient to consider a special case when $(\mathbb{R}\boldsymbol{u})^\perp = \mathbb{R}^{m-1}$. Therefore,

$$\begin{aligned}
\mathrm{Rad}[V_{r,0}](\boldsymbol{u}, p) &= \int_{\mathbb{R}^{m-1}} V_{r,0}(p\boldsymbol{u}+y)\mathrm{d}\boldsymbol{y}, \quad \boldsymbol{u} \perp \boldsymbol{y} \\
&= \int_{\mathbb{R}^{m-1}} \frac{1}{2}|p\boldsymbol{u}+\boldsymbol{y}|^2 \mathbf{1}_{\mathbb{B}^m(0;r)}(p\boldsymbol{u}+\boldsymbol{y})\mathrm{d}\boldsymbol{y} \\
&= \frac{1}{2}\int_{\mathbb{B}^{m-1}\left(0;\sqrt{r^2-p^2}\right)} \left\{p^2+|\boldsymbol{y}|^2\right\}\mathrm{d}\boldsymbol{y}, \qquad (82)
\end{aligned}$$

where the third equation follows by the orthogonality $|p\boldsymbol{u}+\boldsymbol{y}|_m^2 = p^2 + |\boldsymbol{y}|_{m-1}^2$ and a geometric consideration as follows:

$$\begin{aligned}
\int_{\mathbb{R}^{m-1}} [\,\cdot\,]\mathbf{1}_{\mathbb{B}^m(0;r)}(p\boldsymbol{u}+\boldsymbol{y})\mathrm{d}\boldsymbol{y} &= \int_{\mathbb{R}^{m-1}} [\,\cdot\,]\mathbf{1}_{\mathbb{B}^m(-p\boldsymbol{u};r)}(\boldsymbol{y})\mathrm{d}\boldsymbol{y} \\
&= \int_{\mathbb{R}^{m-1}\cap\mathbb{B}^m(-p\boldsymbol{u};r)} [\,\cdot\,]\mathrm{d}\boldsymbol{y} \\
&= \int_{\mathbb{B}^{m-1}(0;\sqrt{r^2-p^2})} [\,\cdot\,]\mathrm{d}\boldsymbol{y}.
\end{aligned}$$

The first integral in (82) is calculated as follows:

$$\begin{aligned}
\int_{\mathbb{B}^{m-1}\left(0;\sqrt{r^2-p^2}\right)} p^2\mathrm{d}\boldsymbol{y} &= p^2\,\mathsf{vol}\left[\mathbb{B}^{m-1}(0;\sqrt{r^2-p^2})\right] \\
&= \frac{\pi^{\frac{m-1}{2}}}{2\Gamma\left(\frac{m-1}{2}+1\right)} p^2(r^2-p^2)^{\frac{m-1}{2}}. \qquad (83)
\end{aligned}$$

The second integral in (82) is calculated as follows:

$$\begin{aligned}
\int_{\mathbb{B}^{m-1}\left(0;\sqrt{r^2-p^2}\right)} |\boldsymbol{y}|^2\mathrm{d}\boldsymbol{y} &= \int_{\mathbb{S}^{m-2}}\int_0^{\sqrt{r^2-p^2}} |\rho\omega|^2\rho^{m-2}\mathrm{d}\rho\mathrm{d}\omega \\
&= \int_{\mathbb{S}^{m-2}}\mathrm{d}\omega \int_0^{\sqrt{r^2-p^2}} \rho^m\mathrm{d}\rho \\
&= \frac{\pi^{\frac{m-1}{2}}}{(m+1)\Gamma\left(\frac{m-1}{2}\right)}(r^2-p^2)^{\frac{m+1}{2}}. \qquad (84)
\end{aligned}$$

Hence, by combining the first and second integrals, we have

$$\mathrm{Rad}[V_{r,0}](\boldsymbol{u}, p) = \begin{cases} \frac{A_{m-1}}{2(m+1)}(r^2-p^2)^{\frac{m-1}{2}}\left\{\frac{2}{m-1}p^2+r^2\right\} & |p| < r \\ 0 & |p| \geq r. \end{cases} \qquad (85)$$

The ridgelet transform $R_{\rho'}[V_{r,0}]$ is given by

$$R_{\rho'}[V_{r,0}](\boldsymbol{u}/\alpha, \beta/\alpha) = \int_{|p|<r} k(p)\overline{\rho'_\alpha(p-\beta)}\mathrm{d}p, \qquad (86)$$

where we define

$$k(p) \coloneqq \mathrm{Rad}[V_{r,0}](\boldsymbol{u}, p).$$

Recall that $\mathrm{Rad}[V_{r,0}](\boldsymbol{u}, p)$ does not depend on the direction $\boldsymbol{u}$; thus, the definition of k is reasonable. According to (85), k is a compactly supported bump function. Consequently, k is summable; thus, the integral

$$K \coloneqq \int_{\mathbb{R}} k(p)\mathrm{d}p \qquad (87)$$

always exists. Recall that the convolution results in smoothing, i.e.,

$$\int_{|p|<r} k(p)\overline{\rho'_\alpha(p-\beta)}\mathrm{d}p \approx K\overline{\rho'_\alpha(-\beta)}. \qquad (88)$$

In summary, we have presented the following:

$$R_\rho[\mathsf{id}_{r,0}](\boldsymbol{a}, b) = -\boldsymbol{a}R_{\rho'}[V_{r,0}](\boldsymbol{a}, b) \approx -K\boldsymbol{a}\overline{\rho'(-b)}. \qquad \blacksquare$$

Abstract

Despite their attractiveness, popular perception is that techniques for nonparametric function approximation do not scale to streaming data due to an intractable growth in the amount of storage they require. To solve this problem in a memory-affordable way, we propose an online technique based on functional stochastic gradient descent in tandem with supervised sparsification based on greedy function subspace projections. The method, called *parsimonious online learning with kernels* (POLK), provides a controllable tradeoff between its solution accuracy and the amount of memory it requires. We derive conditions under which the generated function sequence converges almost surely to the optimal function, and we establish that the memory requirement remains finite. We evaluate POLK for kernel multi-class logistic regression and kernel hinge-loss classification on three canonical data sets: a synthetic Gaussian mixture model, the MNIST hand-written digits, and the Brodatz texture database. On all three tasks, we observe a favorable trade-off of objective function evaluation, classification performance, and complexity of the nonparametric regressor extracted by the proposed method.

Keywords: kernel methods, online learning, stochastic optimization, supervised learning, orthogonal matching pursuit, nonparametric regression

1. Introduction

Reproducing kernel Hilbert spaces (RKHS) provide the ability to approximate functions using nonparametric functional representations. Although the structure of the space is determined by the choice of kernel, the set of functions that can be represented is still sufficiently rich so as to permit close approximation of a large class of functions. This resulting expressive power makes RKHS an appealing choice in many learning problems where we want to estimate an unknown function that is specified as optimal with respect to some empirical risk. When learning these optimal function representations in a RKHS, the representer theorem is used to transform the search over functions into a search over parameters, where the number of parameters grows with each new observation that is processed (Wheeden et al., 1977; Norkin and Keyzer, 2009). This growth is what endows the representation with expressive power. However, this growth also results in function descriptions that are as complex as the number of processed observations, and, more importantly, in training algorithms that exhibit a cost per iteration that grows with each new iterate (Pontil et al., 2005; Kivinen et al., 2004). The resulting unmanageable training cost renders RKHS learning approaches inefficient for large data sets and outright inapplicable in streaming applications. This is a well-known limitation which has motivated the development of several heuristics to reduce the growth in complexity. These heuristics typically result in suboptimal functional approximations (Richard et al., 2009).

This paper proposes a new technique for learning nonparametric function approximations in a RKHS that respects optimality and ameliorates the complexity issues described above. We accomplish this by: (i) shifting the goal from that of finding an approximation that is optimal to that of finding an approximation that is optimal within a class of parsimonious (sparse) kernel representations; (ii) designing a training method that follows a trajectory of intermediate representations that are also parsimonious. The proposed technique, *parsimonious online learning with kernels* (POLK), provides a controllable tradeoff between complexity and optimality and we provide theoretical guarantees that neither factor becomes untenable.

Formally, we propose solving expected risk minimization problems, where the goal is to learn a regressor that minimizes a loss function quantifying the merit of a statistical model averaged over a data set. We focus on the case when the number of training examples, N, is either very large, or the training examples arrive sequentially. Further, we assume that these input-output examples, $(\mathbf{x}_n, \mathbf{y}_n)$, are i.i.d. realizations drawn from a stationary joint distribution over the random pair $(\mathbf{x}, \mathbf{y}) \in \mathcal{X} \times \mathcal{Y}$. This problem class is popular in many fields and particularly ubiquitous in text (Sampson et al., 1990), image (Mairal et al., 2007), and genomic (Taşan et al., 2014) processing. Here, we consider finding regressors that are not vector valued parameters, but rather functions $f \in \mathcal{H}$ in a hypothesized function class $\mathcal{H}$. This function estimation task allows one to learn nonlinear statistical models and is known to yield better results in applications where linearity of a given statistical model is overly restrictive such as computer vision and object recognition (Mukherjee and Nayar, 1996; Li et al., 2014). The adequacy of the regressor function f is evaluated by the convex loss function $\ell : \mathcal{H} \times \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ that quantifies the merit of the estimator $f(\mathbf{x})$ evaluated at feature vector $\mathbf{x}$. This loss is averaged over all possible training examples to define the statistical loss $L(f) := \mathbb{E}_{\mathbf{x},\mathbf{y}}[\ell(f(\mathbf{x}), y)]$, which we combine with a Tikhonov regularizer to

construct the regularized loss $R(f) := \operatorname{argmin}_{f\in\mathcal{H}} L(f) + (\lambda/2)\|f\|^2_{\mathcal{H}}$ (Shalev-Shwartz et al., 2010; Evgeniou et al., 2000). We then define the optimal function as

$$f^* = \operatorname*{argmin}_{f\in\mathcal{H}} R(f) := \operatorname*{argmin}_{f\in\mathcal{H}} \mathbb{E}_{\mathbf{x},\mathbf{y}}\Big[\ell(f(\mathbf{x}), y)\Big] + \frac{\lambda}{2}\|f\|^2_{\mathcal{H}} \tag{1}$$

The optimization problem in (1) is intractable in general. However, when $\mathcal{H}$ is equipped with a *reproducing kernel* $\kappa : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, a nonparametric function estimation problem of the form (1) may be reduced to a parametric form via the representer theorem (Wheeden et al., 1977; Norkin and Keyzer, 2009). This theorem states that the optimal argument of (1) is in the span of kernel functions that are centered at points in the given training data set, and it reduces the problem to that of determining the N coefficients of the resulting linear combination of kernels (Section 2). This results in a function description that is data driven and flexible, alas very complex. As we consider problems with larger training sets, the representation of f requires a growing number of kernels (Norkin and Keyzer, 2009). In the case of streaming applications this number would grow unbounded and the kernel matrix as well as the coefficient vector would grow to infinite dimension and an infinite amount of memory would be required to represent f. It is therefore customary to reduce this complexity by forgetting training points or otherwise requiring that f^* admit a parsimonious representation in terms of a sparse subset of kernels. This overcomes the difficulties associated with a representation of unmanageable complexity but a steeper difficulty is the *determination* of this optimal parsimonious representation as we explain in the following section

1.1. Context

To understand the challenge in determining optimal parsimonious representations, recall that kernel optimization methods borrow techniques from vector valued (i.e., without the use of kernels) stochastic optimization in the sense that they seek to optimize (1) by replacing the descent direction of the objective with that of a stochastic estimate (Bottou, 1998; Robbins and Monro, 1951). Stochastic optimization is well understood in vector valued problems to the extent that recent efforts are concerned with improving convergence properties through the use of variance reduction (Schmidt et al., 2013; Johnson and Zhang, 2013; Defazio et al., 2014), or stochastic approximations of Newton steps (Schraudolph et al., 2007; Bordes et al., 2009; Mokhtari and Ribeiro, 2014, 2015). Stochastic optimization in kernel spaces, however, exhibits two peculiarities that make it more challenging:

i. The implementation of stochastic methods for expected risk minimization in a RKHS requires storage of kernel matrices and weight vectors that together are cubic in the iteration index. This is true even if we require that the solution f^* admit a sparse representation because, while it may be true that the asymptotic solution admits a sparse representation, the intermediate iterates are not necessarily sparse; see, e.g., Kivinen et al. (2004).

ii. The problem in (i) makes it necessary to use sparse approximations of descent directions. However, these sparse approximates are not guaranteed to be valid stochastic descent directions. Consequently, there are no guarantees that a path of sparse approximation learns the optimal sparse approximation.

Issue (i) is a key point of departure between kernel stochastic optimization and its vector valued counterpart. It implies that redefining f^* to encourage sparsity may make it easier to work with the RKHS representation after it has been learnt. However, the stochastic gradient iterates that need to be computed to find such representation have a complexity that grows with the order of the iteration index (Kivinen et al., 2004), precluding the use of sparsity-encouraging penalties (Fu, 1998). Works on stochastic optimization in a RKHS have variously ignored the intractable growth of the parametric representation of $f \in \mathcal{H}$ (Ying and Zhou, 2006; Liu et al., 2008; Pontil et al., 2005; Dieuleveut and Bach, 2014), addressed it indirectly through probabilistic (Rahimi and Recht, 2008, 2009; Dai et al., 2014) or computational (Williams and Seeger, 2001; Zhang et al., 2008) approximations of the kernel, or have augmented the learned function to limit the memory issues associated with kernelization using online sparsification procedures. These approaches focus on limiting the growth of the kernel dictionary through forgetting factors (Kivinen et al., 2004), random dropping (Zhang et al., 2013; Le et al., 2016b), compressive sensing (Engel et al., 2004; Richard et al., 2009; Honeine, 2012), greedy search (Bordes et al., 2005) and projection (Zhao et al., 2012; Zhao and Hoi, 2012; Wang et al., 2012). These approaches overcome Issue (i) but they do so at the cost of dropping optimality [cf. Issue (ii)]. This is because these sparsification techniques introduce a bias in the stochastic gradient which nullifies convergence guarantees, and empirically leads to instability.

Past works that have considered *supervised* sparsification (addressing issues (i)-(ii)) have only been developed for special cases such as online support vector machines (SVM) (Wang et al., 2012), off-line logistic regression Zhu and Hastie (2005), and off-line SVM (Joachims and Yu, 2009). The works perhaps most similar to ours, but developed only for SVM (Wang et al., 2012)) fixes the number of kernel dictionary elements, or the model order, in advance rather tuning the kernel dictionary to guarantee stochastic descent, i.e. determining which kernel dictionary elements are most important for representing f^*. Further, the analysis of the resulting bias induced by sparsification requires overly restrictive assumptions and is conducted in terms of time-average objective sub-optimality, a looser criterion than almost sure convergence. For specialized classes of loss functions, the bias of the descent direction induced by unsupervised sparsification techniques using random sub-sampling does not prevent the derivation of bounds on the time-average sub-optimality (regret) (Zhang et al., 2013); however, this analysis omits important cases such as support vector machines and kernel ridge regression.

1.2. Contributions

In this work, we build upon past works which combine functional generalizations of first-order stochastic optimization methods operating in tandem with supervised sparsification. In particular, descending along the gradient of the objective in (1) is intractable when the sample size N is not necessarily finite, and thus stochastic methods are necessary. In Section 3, we build upon Kivinen et al. (2004) in deriving the generalization of stochastic gradient method called functional SGD (Section 3.1). The complexity of this online functional iterative optimization is on the order of the iteration index, a complicating factor of kernel methods which is untenable for streaming settings.

Thus, we project the FSGD iterates onto sparse subspaces, which, rather than being fixed independent of the problem (Zhu et al., 2009), are adaptively constructed from the span of a small number of kernel dictionary elements (Section 3.2). To find these sparse subspaces of the RKHS, we make use of greedy sampling methods based on matching pursuit (Pati et al., 1993). The use of this technique is motivated by: (i) The fact that kernel matrices induced by arbitrary data streams will not, in general, satisfy requisite conditions for methods that enforce sparsity through convex relaxation (Candes, 2008); (ii) That having function iterates that exhibit small model order is of greater importance than exact recovery since SGD iterates are not the goal signal but just a noisy stepping stone to the optimal f^*. Therefore, we construct these instantaneous sparse subspaces by making use of kernel orthogonal matching pursuit (Vincent and Bengio, 2002), a greedy search routine which, given a function and an approximation budget ϵ, returns its a sparse approximation and guarantees its output to be in a specific Hilbert-norm neighborhood of its function input. Greedy sampling methods appear in prior works for constructing RKHS subspaces in recursive mini-batching procedures (Keerthi et al., 2006) or with FSGD (Zhao et al., 2012), but in a manner that avoids addressing how to merge greedy compression with obtaining optimal function representations.

To guarantee stochastic descent, we tie the size of the error neighborhood induced by sparse projections to the magnitude of the functional stochastic gradient and other problem parameters, thereby keeping only those kernel dictionary elements necessary for convergence (Section 4). The result is that we are able to conduct stochastic gradient descent using only sparse projections of the stochastic gradient, maintaining a convergence path of moderate complexity towards the optimal f^* (1). When the data and target domains ($\mathcal{X}$ and $\mathcal{Y}$, respectively) are compact, for a certain approximation budget depending on the stochastic gradient algorithm step-size, we show that the sparse stochastically projected FSGD sequence still converges almost surely to the optimum of (5) under both attenuating and constant learning rate schemes. Moreover, the model order of this sequence remains finite for a given choice of constant step-size and approximation budget, and is, in the worst-case, comparable to the covering number of the data domain (Zhou, 2002; Pontil, 2003).

In Section 5 we present numerical results on synthetic and empirical data for large-scale kernelized supervised learning tasks. We observe stable convergence behavior of POLK comparable to vector-valued first-order stochastic methods in terms of objective function evaluation, punctuated by a state of the art trade-off between test set error and number of samples processed. Further, the proposed method reduces the complexity of training kernel regressors by orders of magnitude. In Section 6 we discuss our main findings. In particular, we suggest that there is a path forward for kernel methods as an alternative to neural networks that provides a more interpretable mechanism for inference with nonlinear statistical models and that one may achieve high generalization capability without losing convexity, an essential component for efficient training.

Relative to (Koppel et al., 2017), this paper provides detailed derivations of the algorithms and proofs to all theorems, including auxiliary and technical lemmas. Moreover, a thorough accounting of computational complexity and extensive experimentation with several state of the art alternatives, both offline and online, are provided.

2. Statistical Optimization in Reproducing Kernel Hilbert Spaces

Supervised learning is often formulated as an optimization problem that computes a set of parameters $\theta \in \Theta$ to minimize the average of a loss function $l : \Theta \times \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ for training examples $(\mathbf{x}_n, \mathbf{y}_n) \in \mathcal{X} \times \mathcal{Y}$. When the number of training examples N is finite, this goal is referred to as *empirical risk minimization* (Tewari and Bartlett, 2014), and may be solved using batch optimization techniques. The optimal $\boldsymbol{\theta}$ is the one that minimizes the regularized average loss, $\tilde{R}(\theta; \{\mathbf{x}_n, y_n\}_{n=1}^N) = \frac{1}{N}\sum_{n=1}^N l(\boldsymbol{\theta}; (\mathbf{x}_n, y_n))$, over the set of training data $\mathcal{S} = \{\mathbf{x}_n, y_n\}_{n=1}^N$, i.e.,

$$\theta^* = \operatorname*{argmin}_{\boldsymbol{\theta}\in\Theta} \tilde{R}(\boldsymbol{\theta}; \mathcal{S}) = \operatorname*{argmin}_{\boldsymbol{\theta}\in\Theta} \frac{1}{N}\sum_{n=1}^N l(\boldsymbol{\theta}; \mathbf{x}_n, y_n) + \frac{\lambda}{2}\|\boldsymbol{\theta}\|^2 \,. \tag{2}$$

We focus on the case when the inputs are vectors $\mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^p$ and the target domain $\mathcal{Y} \subseteq \{0, 1\}$ in the case of classification or $\mathcal{Y} \subseteq \mathbb{R}$ in the case of regression.

2.1. Supervised Kernel Learning

In the case of supervised kernel learning (Müller et al., 2013; Li et al., 2014), Θ is taken to be a Hilbert space, denoted here as $\mathcal{H}$. Elements of $\mathcal{H}$ are *functions*, $f : \mathcal{X} \to \mathcal{Y}$, that admit a representation in terms of elements of $\mathcal{X}$ when $\mathcal{H}$ has a special structure. In particular, equip $\mathcal{H}$ with a unique *kernel function*, $\kappa : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, such that:

$$(i)\ \langle f, \kappa(\mathbf{x}, \cdot)\rangle_{\mathcal{H}} = f(\mathbf{x}) \quad \text{for all } \mathbf{x} \in \mathcal{X}\,, \qquad (ii)\ \mathcal{H} = \overline{\operatorname{span}\{\kappa(\mathbf{x}, \cdot)\}} \quad \text{for all } \mathbf{x} \in \mathcal{X}\,. \tag{3}$$

where $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ denotes the Hilbert inner product for $\mathcal{H}$. We further assume that the kernel is positive semidefinite, i.e. $\kappa(\mathbf{x}, \mathbf{x}') \geq 0$ for all $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$. Function spaces with this structure are called reproducing kernel Hilbert spaces (RKHS).

In (3), property (i) is called the reproducing property of the kernel, and is a consequence of the Riesz Representation Theorem (Wheeden et al., 1977). Replacing f by $\kappa(\mathbf{x}', \cdot)$ in (3) (i) yields the expression $\langle \kappa(\mathbf{x}', \cdot), \kappa(\mathbf{x}, \cdot)\rangle_{\mathcal{H}} = \kappa(\mathbf{x}, \mathbf{x}')$, which is the origin of the term "reproducing kernel." This property provides a practical means by which to access a nonlinear transformation of the input space $\mathcal{X}$. Specifically, denote by $\phi(\cdot)$ a nonlinear map of the feature space that assigns to each $\mathbf{x}$ the kernel function $\kappa(\cdot, \mathbf{x})$. Then the reproducing property of the kernel allows us to write the inner product of the image of distinct feature vectors $\mathbf{x}$ and $\mathbf{x}'$ under the map ϕ in terms of kernel evaluations only: $\langle \phi(\mathbf{x}), \phi(\mathbf{x}')\rangle_{\mathcal{H}} = \kappa(\mathbf{x}, \mathbf{x}')$. This is commonly referred to as the *kernel trick*, and it provides a computationally efficient tool for learning nonlinear functions.

Moreover, property (3) (ii) states that any function $f \in \mathcal{H}$ may be written as a linear combination of kernel evaluations. For kernelized and regularized empirical risk minimization, the Representer Theorem (Kimeldorf and Wahba, 1971; Schölkopf et al., 2001) establishes that the optimal f in the hypothesis function class $\mathcal{H}$ may be written as an expansion of kernel evaluations *only* at elements of the training set as

$$f(\mathbf{x}) = \sum_{n=1}^N w_n \kappa(\mathbf{x}_n, \mathbf{x}) \,. \tag{4}$$

where $\mathbf{w} = [w_1, \cdots, w_N]^T \in \mathbb{R}^N$ denotes a set of weights. The upper summand index N in (4) is henceforth referred to as the model order. Common choices κ include the polynomial kernel and the radial basis kernel, i.e., $\kappa(\mathbf{x}, \mathbf{x}') = \left(\mathbf{x}^T\mathbf{x}' + b\right)^c$ and $\kappa(\mathbf{x}, \mathbf{x}') = \exp\left\{-\frac{\|\mathbf{x}-\mathbf{x}'\|_2^2}{2c^2}\right\}$, respectively, where $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$.

We may now formulate the kernel variant of the empirical risk minimization problem as the one that minimizes the loss functional $L : \mathcal{H} \times \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ plus a complexity-reducing penalty. The loss functional L may be written as an average over instantaneous losses $\ell : \mathcal{H} \times \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$, each of which penalizes the average deviation between $f(\mathbf{x}_n)$ and the associated output y_n over the training set $\mathcal{S}$. We denote the data loss and complexity loss as $R : \mathcal{H} \to \mathbb{R}$, and consider the problem

$$f^* = \operatorname*{argmin}_{f\in\mathcal{H}} R(f;\mathcal{S}) = \operatorname*{argmin}_{f\in\mathcal{H}} \frac{1}{N}\sum_{n=1}^{N} \ell(f(\mathbf{x}_n), y_n) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 \,. \tag{5}$$

The above problem, referred to as Tikhonov regularization (Evgeniou et al., 2000), is one in which we aim to learn a general nonlinear relationship between $\mathbf{x}_n$ and y_n through a function f. Throughout, we assume ℓ is convex with respect to its first argument $f(\mathbf{x})$. By substituting the Representer Theorem expansion in (4) into (5), the optimization problem amounts to finding an optimal set of coefficients $\mathbf{w}$ as

$$\begin{aligned} f^* &= \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^N} \frac{1}{N}\sum_{n=1}^{N} \ell(\sum_{m=1}^{N} w_m\kappa(\mathbf{x}_m, \mathbf{x}_n), y_n) + \frac{\lambda}{2}\|\sum_{n,m=1}^{N} w_n w_m \kappa(\mathbf{x}_m, \mathbf{x}_n)\|_{\mathcal{H}}^2 \\ &= \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^N} \frac{1}{N}\sum_{n=1}^{N} \ell(\mathbf{w}^T\boldsymbol{\kappa}_{\mathbf{X}}(\mathbf{x}_n), y_n) + \frac{\lambda}{2}\mathbf{w}^T\mathbf{K}_{\mathbf{X},\mathbf{X}}\mathbf{w} \end{aligned} \tag{6}$$

where we have defined the Gram matrix (variously referred to as the *kernel matrix*) $\mathbf{K}_{\mathbf{X},\mathbf{X}} \in \mathbb{R}^{N\times N}$, with entries given by the kernel evaluations between $\mathbf{x}_m$ and $\mathbf{x}_n$ as $[\mathbf{K}_{\mathbf{X},\mathbf{X}}]_{m,n} = \kappa(\mathbf{x}_m, \mathbf{x}_n)$. We further define the vector of kernel evaluations $\boldsymbol{\kappa}_{\mathbf{X}}(\cdot) = [\kappa(\mathbf{x}_1, \cdot) \dots \kappa(\mathbf{x}_N, \cdot)]^T$, which are related to the kernel matrix as $\mathbf{K}_{\mathbf{X},\mathbf{X}} = [\boldsymbol{\kappa}_{\mathbf{X}}(\mathbf{x}_1) \dots \boldsymbol{\kappa}_{\mathbf{X}}(\mathbf{x}_N)]$. The dictionary of training points associated with the kernel matrix is defined as $\mathbf{X} = [\mathbf{x}_1, \ \dots \ , \mathbf{x}_N]$.

Observe that by exploiting the Representer Theorem, we transform a nonparametric infinite dimensional optimization problem in $\mathcal{H}$ (5) into a finite N-dimensional parametric problem (6). Thus, for empirical risk minimization, the RKHS provides a principled framework to solve nonparametric regression problems as via search over $\mathbb{R}^N$ for an optimal set of coefficients. A motivating example is presented next to clarify the setting of supervised kernel learning.

Example 1 *(Kernel Logistic Regression)* Consider the case of *kernel logistic regression* (KLR), with feature vectors $\mathbf{x}_n \in \mathcal{X} \subseteq \mathbb{R}^p$ and binary class labels $y_n \in \{0, 1\}$. We seek to learn a function $f \in \mathcal{H}$ that allows us to best approximate the distribution of an unknown class label given a training example $\mathbf{x}$ under the assumed model

$$\mathbb{P}\left(y = 0 \mid \mathbf{x}\right) = \frac{\exp\left\{f(\mathbf{x})\right\}}{1 + \exp\left\{f(\mathbf{x})\right\}} \,. \tag{7}$$

In classical logistic regression, we assume that f is linear, i.e., $f(\mathbf{x}) = \mathbf{c}^T\mathbf{x} + b$. In KLR, on the other hand, we instead seek a nonlinear function of the form given in (4). By making use of (7) and (4), we may formulate a maximum-likelihood estimation (MLE) problem to find the optimal function f on the basis of $\mathcal{S}$ by solving for the $\mathbf{w}$ that maximizes the λ-regularized average negative log likelihood over $\mathcal{S}$, i.e.,

$$\begin{aligned} f^* &= \operatorname*{argmin}_{f\in\mathcal{H}} \frac{1}{N}\sum_{n=1}^{N}\left[-\log\mathbb{P}(y = y_n \mid \mathbf{x} = \mathbf{x}_n) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2\right] \\ &= \operatorname*{argmin}_{f\in\mathcal{H}} \frac{1}{N}\sum_{n=1}^{N}\left[\log\left(1 + \exp\{f(\mathbf{x}_n)\}\right) - \mathbb{1}(y_n = 1) - f(\mathbf{x}_n)\mathbb{1}(y_n = 0) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2\right] \\ &= \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^N} \frac{1}{N}\sum_{n=1}^{N}\left[\log\left(1+\exp\{\mathbf{w}^T\boldsymbol{\kappa}_{\mathbf{X}}(\mathbf{x}_n)\}\right) - \mathbb{1}(y_n = 1) - \mathbf{w}^T\boldsymbol{\kappa}_{\mathbf{X}}(\mathbf{x}_n)\mathbb{1}(y_n = 0) + \frac{\lambda}{2}\mathbf{w}^T\mathbf{K}_{\mathbf{X},\mathbf{X}}\mathbf{w}\right] , \end{aligned} \tag{8}$$

where $\mathbb{1}(\cdot)$ represents the indicator function. Solving (8) amounts to finding a function f that, given a feature vector $\mathbf{x}$ and the model outlined by (7), best represents the class-conditional probabilities that the corresponding label y is either 0 or 1.

2.2. Online Kernel Learning

The goal of this paper is to solve problems of the form (5) when training examples $(\mathbf{x}_n, \mathbf{y}_n)$ either become sequentially available or their total number is not necessarily finite. To do so, we consider the case where $(\mathbf{x}_n, \mathbf{y}_n)$ are independent realizations from a stationary joint distribution of the random pair $(\mathbf{x}, \mathbf{y}) \in \mathcal{X} \times \mathcal{Y}$ (Slavakis et al., 2013). In this case, the objective in (5) may be written as an expectation over this random pair as

$$\begin{aligned} f^* = \operatorname*{argmin}_{f\in\mathcal{H}} R(f) :&= \operatorname*{argmin}_{f\in\mathcal{H}} \mathbb{E}_{\mathbf{x},\mathbf{y}}[\ell(f(\mathbf{x}), y)] + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 \\ &= \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^{\mathcal{I}}} \mathbb{E}_{\mathbf{x},\mathbf{y}}[\ell(\sum_{n\in\mathcal{I}} w_n\kappa(\mathbf{x}_n, \mathbf{x}), y)] + \frac{\lambda}{2}\|\sum_{n,m\in\mathcal{I}} w_n w_m\kappa(\mathbf{x}_m, \mathbf{x}_n)\|_{\mathcal{H}}^2 \,. \end{aligned} \tag{9}$$

where we define the average loss as $L(f) := \mathbb{E}_{\mathbf{x},\mathbf{y}}[\ell(f(\mathbf{x}), y)]$. In the second equality in (1), we substitute in the expansion of f given by the Representer Theorem generalized to the infinite sample-size case established in (Norkin and Keyzer, 2009), with $\mathcal{I}$ as some countably infinite indexing set.

3. Algorithm Development

We turn to deriving an algorithmic solution to the kernelized expected risk minimization problem stated in (1). To do so, two complexity bottlenecks must be overcome. The first is that in order to develop a numerical optimization scheme such as gradient descent, we must compute the functional gradient (Frechét derivative) of the expected risk $L(f)$ with respect to f, which requires infinitely many realizations of the random pair $(\mathbf{x}, y)$. This bottleneck is handled via stochastic approximation, as detailed in Section 3.1. The second issue is that when making use of the stochastic gradient method in the RKHS setting,

the resulting parametric updates require memory storage whose complexity is cubic in the iteration index (the curse of kernelization), which rapidly becomes unaffordable. To alleviate this memory explosion, we introduce our sparse stochastic projection scheme based upon kernel orthogonal matching pursuit in Section 3.2.

3.1. Functional Stochastic Gradient Descent

Following Kivinen et al. (2004), we derive the generalization of the stochastic gradient method for the RKHS setting. The resulting procedure is referred to as *functional stochastic gradient descent* (FSGD). First, given an independent realization $(\mathbf{x}_t, y_t)$ of the random pair $(\mathbf{x}, y)$, we compute the stochastic functional gradient (Frechét derivative) of $L(f)$, stated as

$$\nabla_f \ell(f(\mathbf{x}_t), y_t)(\cdot) = \frac{\partial \ell(f(\mathbf{x}_t), y_t)}{\partial f(\mathbf{x}_t)} \frac{\partial f(\mathbf{x}_t)}{\partial f}(\cdot) \tag{10}$$

where we have applied the chain rule. Now, define the short-hand notation $\ell'(f(\mathbf{x}_t), y_t) := \partial \ell(f(\mathbf{x}_t), y_t)/\partial f(\mathbf{x}_t)$ for the derivative of $\ell(\mathbf{f}(\mathbf{x}_t), y_t)$ with respect to its first scalar argument $f(\mathbf{x}_t)$ evaluated at $\mathbf{x}_t$. To evaluate the second term on the right-hand side of (10), differentiate both sides of the expression defining the reproducing property of the kernel [cf. (3)(i)] with respect to f to obtain

$$\frac{\partial f(\mathbf{x}_t)}{\partial f} = \frac{\partial \langle f, \kappa(\mathbf{x}_t, \cdot) \rangle_{\mathcal{H}}}{\partial f} = \kappa(\mathbf{x}_t, \cdot) \tag{11}$$

With this computation in hand, we present the stochastic gradient method for the kernelized λ-regularized expected risk minimization problem in (1) as

$$f_{t+1} = (1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t) = (1 - \eta_t \lambda) f_t - \eta_t \ell'(f_t(\mathbf{x}_t), y_t) \kappa(\mathbf{x}_t, \cdot) \, , \tag{12}$$

where $\eta_t > 0$ is an algorithm step-size either chosen as diminishing with $\mathcal{O}(1/t)$ or a small constant – see Section 4. We further require that, given $\lambda > 0$, the step-size satisfies $\eta_t < 1/\lambda$ and the sequence is initialized as $f_0 = 0 \in \mathcal{H}$. Given this initialization, by making use of the Representer Theorem (4), at time t, the function f_t may be expressed as an expansion in terms of feature vectors $\mathbf{x}_t$ observed thus far as

$$f_t(\mathbf{x}) = \sum_{n=1}^{t-1} w_n \kappa(\mathbf{x}_n, \mathbf{x}) = \mathbf{w}_t^T \boldsymbol{\kappa}_{\mathbf{X}_t}(\mathbf{x}) \, . \tag{13}$$

On the right-hand side of (13) we have introduced the notation $\mathbf{X}_t = [\mathbf{x}_1, \ldots, \mathbf{x}_{t-1}] \in \mathbb{R}^{p \times (t-1)}$ and $\boldsymbol{\kappa}_{\mathbf{X}_t}(\cdot) = [\kappa(\mathbf{x}_1, \cdot), \ \ldots \ , \kappa(\mathbf{x}_{t-1}, \cdot)]^T$. Moreover, observe that the kernel expansion in (13), taken together with the functional update (12), yields the fact that performing the stochastic gradient method in $\mathcal{H}$ amounts to the following parametric updates on the kernel dictionary $\mathbf{X}$ and coefficient vector $\mathbf{w}$:

$$\mathbf{X}_{t+1} = [\mathbf{X}_t, \ \ \mathbf{x}_t], \quad \mathbf{w}_{t+1} = [(1 - \eta_t \lambda)\mathbf{w}_t, \ \ -\eta_t \ell'(f_t(\mathbf{x}_t), y_t)] \, , \tag{14}$$

Observe that this update causes $\mathbf{X}_{t+1}$ to have one more column than $\mathbf{X}_t$. We define the *model order* as number of data points M_t in the dictionary at time t (the number of columns of $\mathbf{X}_t$). FSGD is such that $M_t = t - 1$, and hence grows unbounded with iteration index t.

3.2. Model Order Control via Stochastic Projection

To mitigate the model order issue described above, we shall generate an approximate sequence of functions by orthogonally projecting functional stochastic gradient updates onto subspaces $\mathcal{H}_{\mathbf{D}} \subseteq \mathcal{H}$ that consist only of functions that can be represented using some dictionary $\mathbf{D} = [\mathbf{d}_1, \ \ldots, \ \mathbf{d}_M] \in \mathbb{R}^{p \times M}$, i.e., $\mathcal{H}_{\mathbf{D}} = \{f \ : \ f(\cdot) = \sum_{n=1}^{M} w_n \kappa(\mathbf{d}_n, \cdot) = \mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\} = \text{span}\{\kappa(\mathbf{d}_n, \cdot)\}_{n=1}^{M}$. For convenience we have defined $[\boldsymbol{\kappa}_{\mathbf{D}}(\cdot) = \kappa(\mathbf{d}_1, \cdot) \ldots \kappa(\mathbf{d}_M, \cdot)]$, and $\mathbf{K}_{\mathbf{D},\mathbf{D}}$ as the resulting kernel matrix from this dictionary. We will enforce parsimony in function representation by selecting dictionaries $\mathbf{D}$ that $M_t \ll t$.

We first show that, by selecting $\mathbf{D} = \mathbf{X}_{t+1}$ at each iteration, the sequence (12) derived in Section 3.1 may be interpreted as carrying out a sequence of orthogonal projections. To see this, rewrite (12) as the quadratic minimization

$$\begin{aligned} f_{t+1} &= \operatorname*{argmin}_{f \in \mathcal{H}} \left\| f - \Big((1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t) \Big) \right\|_{\mathcal{H}}^2 \\ &= \operatorname*{argmin}_{f \in \mathcal{H}_{\mathbf{X}_{t+1}}} \left\| f - \Big((1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t) \Big) \right\|_{\mathcal{H}}^2 , \end{aligned} \tag{15}$$

where the first equality in (15) comes from ignoring constant terms which vanish upon differentiation with respect to f, and the second comes from observing that f_{t+1} can be represented using only the points $\mathbf{X}_{t+1}$, using (14). Notice now that (15) expresses f_{t+1} as the orthogonal projection of the update $(1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t)$ onto the subspace defined by dictionary $\mathbf{X}_{t+1}$.

Rather than select dictionary $\mathbf{D} = \mathbf{X}_{t+1}$, we propose instead to select a different dictionary, $\mathbf{D} = \mathbf{D}_{t+1}$, which is extracted from the data points observed thus far, at each iteration. The process by which we select $\mathbf{D}_{t+1}$ will be discussed shortly, but is of dimension $p \times M_{t+1}$, with $M_{t+1} \ll t$. As a result, we shall generate a function sequence f_t that differs from the functional stochastic gradient method presented in Section 3.1. The function f_{t+1} is parameterized by dictionary $\mathbf{D}_{t+1}$ and weight vector $\mathbf{w}_{t+1}$. We denote columns of $\mathbf{D}_{t+1}$ as $\mathbf{d}_n$ for $n = 1, \ldots, M_{t+1}$, where the time index is dropped for notational clarity but may be inferred from the context.

To be specific, we propose replacing the update (15) in which the dictionary grows at each iteration by the stochastic projection of the functional stochastic gradient sequence onto the subspace $\mathcal{H}_{\mathbf{D}_{t+1}} = \text{span}\{\kappa(\mathbf{d}_n, \cdot)\}_{n=1}^{M_{t+1}}$ as

$$\begin{aligned} f_{t+1} &= \operatorname*{argmin}_{f \in \mathcal{H}_{\mathbf{D}_{t+1}}} \left\| f - \Big((1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t) \Big) \right\|_{\mathcal{H}}^2 \\ &:= \mathcal{P}_{\mathcal{H}_{\mathbf{D}_{t+1}}} \Big[(1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t) \Big] . \end{aligned} \tag{16}$$

where we define the projection operator $\mathcal{P}$ onto subspace $\mathcal{H}_{\mathbf{D}_{t+1}} \subset \mathcal{H}$ by the update (16).

Coefficient update The update (16), for a fixed dictionary $\mathbf{D}_{t+1} \in \mathbb{R}^{p \times M_{t+1}}$, may be expressed in terms of the parameter space of coefficients only. In order to do so, we first define the stochastic gradient update without projection, given function f_t parameterized by dictionary $\mathbf{D}_t$ and coefficients $\mathbf{w}_t$, as

$$\tilde{f}_{t+1} = (1 - \eta_t \lambda) f_t - \eta_t \nabla_f \ell(f_t; \mathbf{x}_t, \mathbf{y}_t). \tag{17}$$

This update may be represented using dictionary and weight vector

$$\tilde{\mathbf{D}}_{t+1} = [\mathbf{D}_t, \;\; \mathbf{x}_t], \quad \tilde{\mathbf{w}}_{t+1} = [(1-\eta_t\lambda)\mathbf{w}_t, \;\; -\eta_t \ell'(f_t(\mathbf{x}_t), y_t)] \; . \tag{18}$$

Observe that $\tilde{\mathbf{D}}_{t+1}$ has $\tilde{M} = M_t + 1$ columns, which is also the length of $\tilde{\mathbf{w}}_{t+1}$. For a fixed dictionary $\mathbf{D}_{t+1}$, the stochastic projection in (16) amounts to a least-squares problem on the coefficient vector. To see this, make use of the Representer Theorem to rewrite (16) in terms of kernel expansions, and that the coefficient vector is the only free parameter to write

$$\begin{aligned} &\operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^{M_{t+1}}} \frac{1}{2\eta_t} \Big\| \sum_{n=1}^{M_{t+1}} w_n \kappa(\mathbf{d}_n, \cdot) - \sum_{m=1}^{\tilde{M}} \tilde{w}_m \kappa(\tilde{\mathbf{d}}_m, \cdot) \Big\|_{\mathcal{H}}^2 \qquad (19) \\ &= \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^{M_{t+1}}} \frac{1}{2\eta_t} \left(\sum_{n,n'=1}^{M_{t+1}} w_n w_{n'} \kappa(\mathbf{d}_n, \mathbf{d}_{n'}) - 2 \sum_{n,m=1}^{M_{t+1},\tilde{M}} w_n \tilde{w}_m \kappa(\mathbf{d}_n, \tilde{\mathbf{d}}_m) + \sum_{m,m'=1}^{\tilde{M}} \tilde{w}_m \tilde{w}_{m'} \kappa(\tilde{\mathbf{d}}_m, \tilde{\mathbf{d}}_{m'}) \right) \\ &= \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^{M_{t+1}}} \frac{1}{2\eta_t} \Big(\mathbf{w}^T \mathbf{K}_{\mathbf{D}_{t+1},\mathbf{D}_{t+1}} \mathbf{w} - 2\mathbf{w}^T \mathbf{K}_{\mathbf{D}_{t+1},\tilde{\mathbf{D}}_{t+1}} \tilde{\mathbf{w}}_{t+1} + \tilde{\mathbf{w}}_{t+1} \mathbf{K}_{\tilde{\mathbf{D}}_{t+1},\tilde{\mathbf{D}}_{t+1}} \tilde{\mathbf{w}}_{t+1} \Big) := \mathbf{w}_{t+1} \; . \end{aligned}$$

In (19), the first equality comes from expanding the square, and the second comes from defining the cross-kernel matrix $\mathbf{K}_{\mathbf{D}_{t+1},\tilde{\mathbf{D}}_{t+1}}$ whose $(n,m)^{\text{th}}$ entry is given by $\kappa(\mathbf{d}_n, \tilde{\mathbf{d}}_m)$. The other kernel matrices $\mathbf{K}_{\tilde{\mathbf{D}}_{t+1},\tilde{\mathbf{D}}_{t+1}}$ and $\mathbf{K}_{\mathbf{D}_{t+1},\mathbf{D}_{t+1}}$ are similarly defined. Note that M_{t+1} is the number of columns in $\mathbf{D}_{t+1}$, while $\tilde{M} = M_t + 1$ is the number of columns in $\tilde{\mathbf{D}}_{t+1}$ [cf. (18)]. The explicit solution of (19) may be obtained by noting that the last term is a constant independent of $\mathbf{w}$, and thus by computing gradients and solving for $\mathbf{w}_{t+1}$ we obtain

$$\mathbf{w}_{t+1} = \mathbf{K}_{\mathbf{D}_{t+1}\mathbf{D}_{t+1}}^{-1} \mathbf{K}_{\mathbf{D}_{t+1}\tilde{\mathbf{D}}_{t+1}} \tilde{\mathbf{w}}_{t+1} \; , \tag{20}$$

Given that the projection of $\tilde{f}_{t+1}$ onto the stochastic subspace $\mathcal{H}_{\mathbf{D}_{t+1}}$, for a fixed dictionary $\mathbf{D}_{t+1}$, amounts to a simple least-squares multiplication, we turn to detailing how the kernel dictionary $\mathbf{D}_{t+1}$ is selected from the data sample path $\{\mathbf{x}_u, y_u\}_{u\le t}$.

Dictionary Update The selection procedure for the kernel dictionary $\mathbf{D}_{t+1}$ is based upon greedy sparse approximation, a topic studied extensively in the compressive sensing community (Needell et al., 2008). The function $\tilde{f}_{t+1} = (1-\eta_t) f_t - \eta_t \nabla_f \ell(f_t; \mathbf{x}_t, \mathbf{y}_t)$ defined by stochastic gradient method without projection is parameterized by dictionary $\tilde{\mathbf{D}}_{t+1}$ [cf. (18)], whose model order is $\tilde{M} = M_t + 1$. We form $\mathbf{D}_{t+1}$ by selecting a subset of M_{t+1} columns from $\tilde{\mathbf{D}}_{t+1}$ that are best for approximating $\tilde{f}_{t+1}$ in terms of error with respect to the Hilbert norm. As previously noted, numerous approaches are possible for seeking a sparse representation. We make use of *kernel orthogonal matching pursuit* (KOMP) (Vincent and Bengio, 2002) with allowed error tolerance ϵ_t to find a kernel dictionary matrix $\mathbf{D}_{t+1}$ based on the one which adds the latest sample point $\tilde{\mathbf{D}}_{t+1}$. This choice is due to the fact that we can tune its stopping criterion to guarantee stochastic descent, and guarantee the model order of the learned function remains finite – see Section 4 for details. Similar ideas have independently appeared in a prior work but without any analysis Zhao et al. (2012).

We now describe the variant of KOMP we propose using, called Destructive KOMP with Pre-Fitting (see Vincent and Bengio (2002), Section 2.3), which is summarized in

Algorithm 1 Destructive Kernel Orthogonal Matching Pursuit (KOMP)

Require: function $\tilde{f}$ defined by dict. $\tilde{\mathbf{D}} \in \mathbb{R}^{p\times\tilde{M}}$, coeffs. $\tilde{\mathbf{w}} \in \mathbb{R}^{\tilde{M}}$, approx. budget $\epsilon_t > 0$
initialize $f = \tilde{f}$, dictionary $\mathbf{D} = \tilde{\mathbf{D}}$ with indices $\mathcal{I}$, model order $M = \tilde{M}$, coeffs. $\mathbf{w} = \tilde{\mathbf{w}}$.

while candidate dictionary is non-empty $\mathcal{I} \neq \emptyset$ **do**
  for $j = 1, \ldots, \tilde{M}$ **do**
    Find minimal approximation error with dictionary element $\mathbf{d}_j$ removed

$$\gamma_j = \min_{\mathbf{w}_{\mathcal{I}\setminus\{j\}}\in\mathbb{R}^{M-1}} \|\tilde{f}(\cdot) - \sum_{k\in\mathcal{I}\setminus\{j\}} w_k \kappa(\mathbf{d}_k, \cdot)\|_{\mathcal{H}} \; .$$

  end for
  Find dictionary index minimizing approximation error: $j^* = \operatorname{argmin}_{j\in\mathcal{I}} \gamma_j$
  if minimal approximation error exceeds threshold $\gamma_{j^*} > \epsilon_t$
    stop
  else
    Prune dictionary $\mathbf{D} \leftarrow \mathbf{D}_{\mathcal{I}\setminus\{j^*\}}$
    Revise set $\mathcal{I} \leftarrow \mathcal{I} \setminus \{j^*\}$ and model order $M \leftarrow M - 1$.
    Compute updated weights $\mathbf{w}$ defined by current dictionary $\mathbf{D}$

$$\mathbf{w} = \operatorname*{argmin}_{\mathbf{w}\in\mathbb{R}^M} \|\tilde{f}(\cdot) - \mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\|_{\mathcal{H}}$$

  end
end while
return $f, \mathbf{D}, \mathbf{w}$ of model order $M \le \tilde{M}$ such that $\|f - \tilde{f}\|_{\mathcal{H}} \le \epsilon_t$

Algorithm 1. This flavor of KOMP takes as an input a candidate function $\tilde{f}$ of model order $\tilde{M}$ parameterized by its kernel dictionary $\tilde{\mathbf{D}} \in \mathbb{R}^{p\times\tilde{M}}$ and coefficient vector $\tilde{\mathbf{w}} \in \mathbb{R}^{\tilde{M}}$. The method then seeks to approximate $\tilde{f}$ by a parsimonious function $f \in \mathcal{H}$ with a lower model order. Initially, this sparse approximation is the original function $f = \tilde{f}$ so that its dictionary is initialized with that of the original function $\mathbf{D} = \tilde{\mathbf{D}}$, with corresponding coefficients $\mathbf{w} = \tilde{\mathbf{w}}$. Then, the algorithm sequentially removes dictionary elements from the initial dictionary $\tilde{\mathbf{D}}$, yielding a sparse approximation f of $\tilde{f}$, until the error threshold $\|f - \tilde{f}\|_{\mathcal{H}} \le \epsilon_t$ is violated, in which case it terminates.

At each stage of KOMP, a single dictionary element j of $\mathbf{D}$ is selected to be removed which contributes the least to the Hilbert-norm approximation error $\min_{f\in\mathcal{H}_{\mathbf{D}\setminus\{j\}}} \|\tilde{f} - f\|_{\mathcal{H}}$ of the original function $\tilde{f}$, when dictionary $\mathbf{D}$ is used. Since at each stage the kernel dictionary is fixed, this amounts to a computation involving weights $\mathbf{w} \in \mathbb{R}^{M-1}$ only; that is, the error of removing dictionary point $\mathbf{d}_j$ is computed for each j as $\gamma_j = \min_{\mathbf{w}_{\mathcal{I}\setminus\{j\}}\in\mathbb{R}^{M-1}} \|\tilde{f}(\cdot) - \sum_{k\in\mathcal{I}\setminus\{j\}} w_k \kappa(\mathbf{d}_k, \cdot)\|$. We use the notation $\mathbf{w}_{\mathcal{I}\setminus\{j\}}$ to denote the entries of $\mathbf{w} \in \mathbb{R}^M$ restricted to the sub-vector associated with indices $\mathcal{I} \setminus \{j\}$. Then, we define the dictionary element which contributes the least to the approximation error as $j^* = \operatorname{argmin}_j \gamma_j$. If the error associated with removing this kernel dictionary element exceeds the given approximation budget $\gamma_{j^*} > \epsilon_t$, the algorithm terminates. Otherwise, this dictionary element $\mathbf{d}_{j^*}$ is removed, the weights $\mathbf{w}$ are revised based on the pruned dictionary as

Algorithm 2 Parsimonious Online Learning with Kernels (POLK)

Require: $\{\mathbf{x}_t, \mathbf{y}_t, \eta_t, \epsilon_t\}_{t=0,1,2,\ldots}$

initialize $f_0(\cdot) = 0, \mathbf{D}_0 = [], \mathbf{w}_0 = []$, i.e. initial dictionary, coefficient vectors are empty

for $t = 0, 1, 2, \ldots$ **do**

Obtain independent training pair realization $(\mathbf{x}_t, y_t)$

Compute unconstrained functional stochastic gradient step [cf. (17)]

$$\tilde{f}_{t+1}(\cdot) = (1 - \eta_t\lambda) f_t - \eta_t \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot)$$

Revise dictionary $\tilde{\mathbf{D}}_{t+1} = [\mathbf{D}_t, \ \mathbf{x}_t]$ and weights $\tilde{\mathbf{w}}_{t+1} \leftarrow [(1-\eta_t\lambda)\mathbf{w}_t, \ -\eta_t\ell'(f_t(\mathbf{x}_t), y_t)]$

Compute sparse function approximation via Algorithm 1

$$(f_{t+1}, \mathbf{D}_{t+1}, \mathbf{w}_{t+1}) = \mathbf{KOMP}(\tilde{f}_{t+1}, \tilde{\mathbf{D}}_{t+1}, \tilde{\mathbf{w}}_{t+1}, \epsilon_t)$$

end for

$\mathbf{w} = \operatorname{argmin}_{\mathbf{w}\in\mathbb{R}^M} \|\tilde{f}(\cdot) - \mathbf{w}^T\boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\|_{\mathcal{H}}$, and the process repeats as long as the current function approximation is defined by a nonempty dictionary.

With Algorithm 1 stated, we may summarize the key steps of the proposed method in Algorithm 2 for solving (1) while maintaining a finite model order, thus breaking the "curse of kernelization." The method, Parsimonious Online Learning with Kernels (POLK), executes the stochastic projection of the functional stochastic gradient iterates onto sparse subspaces $\mathcal{H}_{\mathbf{D}_{t+1}}$ stated in (16). The initial function is set to null $f_0 = 0$, meaning that it has empty kernel dictionary $\mathbf{D}_0 = []$ and coefficient vector $\mathbf{w}_0 = []$. The notation $[]$ is used to denote the empty matrix or vector respective size $p \times 0$ or 0. Then, at each step, given an independent training example $(\mathbf{x}_t, y_t)$ and step-size η_t, we compute the *unconstrained* functional stochastic gradient iterate $\tilde{f}_{t+1}(\cdot) = (1 - \eta_t\lambda)f_t - \eta_t\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot)$ which admits the parametric representation $\tilde{\mathbf{D}}_{t+1}$ and $\tilde{\mathbf{w}}_{t+1}$ as stated in (18). These parameters are then fed into KOMP with approximation budget ϵ_t, such that $(f_{t+1}, \mathbf{D}_{t+1}, \mathbf{w}_{t+1}) = \text{KOMP}(\tilde{f}_{t+1}, \tilde{\mathbf{D}}_{t+1}, \tilde{\mathbf{w}}_{t+1}, \epsilon_t)$.

In the next section, we discuss the analytical properties of Algorithm 2 for solving online nonparametric regression problems of the form (1). We close here with an example algorithm derivation for the kernel logistic regression problem stated in Example 1 and a remark regarding the selection of KOMP to execute the greedy compression.

Example 2 *(Kernel Logistic Regression)* Returning to the case of kernel logistic regression stated in Example 1, with feature vectors $\mathbf{x}_n \in \mathcal{X} \subseteq \mathbb{R}^p$ and binary class labels $y_n \in \{0, 1\}$, we may perform sparse function estimation in $\mathcal{H}$ that fits a a training example $\mathbf{x}$ to its associated label y under the logistic model [cf. (7)] of the odds-ratio of the given class label. The associated λ-regularized maximum-likelihood estimation (MLE) is given as (8). Provided that a particular kernel map $\kappa(\cdot, \cdot)$, regularizer λ, and step-size η_t have been chosen, the only specialization of Algorithm 2 to this case is the computation of $\tilde{f}_t$, which requires computing the stochastic gradient of (7) with respect to an instantaneous training

example $(\mathbf{x}_t, y_t)$. Doing so specializes (17) to

$$\tilde{f}_{t+1}(\cdot) = (1 - \eta_t\lambda)f_t - \eta_t \frac{\exp\{-\tilde{f}_t(\mathbf{x}_t)\}}{[1 + \exp\{-\tilde{f}_t(\mathbf{x}_t)\}]^2}\kappa(\mathbf{x}_t, \cdot)\ . \tag{21}$$

The resulting dictionary and parameter updates implied by (21), given in (18), are then fed into KOMP (Algorithm 1) which returns their greedy sparse approximation for a fixed budget ϵ_t.

Remark 1 *(On the Choice of Compression Method)* Many penalty-based compression methods (Fu, 1998; Zou and Hastie, 2005) in principle could be used to reduce the complexity of the nonparametric regressor through the introduction of sparsity-promiting terms that are added to the objective in (1). However, given the infinite sample size setting of the problem considered in this work, it is not enough to sparsify the solution, since (1) must be solved with FSGD [cf. (12)]. The per-iteration complexity of FSGD [cf. (14)] that is necessary to actually solve the optimization problem means that it will still be untenably computationally burdensome even to find a sparsified solution. Thus, it is necessary to apply sparsification in an *online manner* to the FSGD sequence, akin to Algorithm 2. However, compressing the FSGD sequence may violate the descent properties of the optimization algorithm, which motivates us to address how to compress the parameterization while preserving stochastic descent. In POLK, this is done by identifying the relationship between the projected and un-projected stochastic gradient, and noting that the directional error in this relationship may be controlled by tying compression budget ϵ_t to the choice of algorithm learning rate η_t.

Therefore, to ensure that we actually attain the minimizer of the expected risk functional (1) almost surely, we need to sparsify FSGD while preserving the validity of the descent direction in the function space. In principle, it is possible to do this with *any method* that sparsifies FSGD while guaranteeing the function sequence moves in a Hilbert-norm error neighborhood of the true functional stochastic gradient. The reason we select KOMP in particular is that it easily admits a Hilbert-norm error neighborhood stopping criterion in conjunction with its compression procedure, and we were not aware of lower complexity alternatives that meet this stringent criterion. The result is that the complexity of the function sequence is then tailored to solve the learning task at hand and the model order is directly modified on the fly by that which is necessary to represent f^*, rather than arbitrarily fixed in advance of training.

Alternative online sparsification methods based on sliding windows (Kivinen et al., 2004), fixed-size subspace projections (Wang and Vucetic, 2010a; Wang et al., 2012; Zhao and Hoi, 2012), approximate linear dependence tests (Engel et al., 2004; Richard et al., 2009), or random dropping methods Zhang et al. (2013); Le et al. (2016b) cannot directly control the directional error/bias induced by sparsification so that the algorithm approximately behaves like FSGD. This is because the descent direction is intrinsically tied to its parameterization associated with a sequentially expanding kernel dictionary (14) (see Section 3.1), and these methods are proposed to reduce the complexity of the kernel representation *independently* of the optimization sequence to which they are applied.

4. Convergence Analysis

We turn to studying the theoretical performance of Algorithm 2 developed in Section 3. In particular, we establish that the method, when a diminishing step-size is chosen, is guaranteed to converge to the optimum of (1). We further obtain that when a sufficiently small constant step-size is chosen, the limit infimum of the iterate sequence is within a neighborhood of the optimum. In both cases, the convergence behavior depends on the approximation budget used in the online sparsification procedure detailed in Algorithm 1.

We also perform a worst-case analysis of the model order of the instantaneous iterates resulting from Algorithm 2, and show that asymptotically the model order depends on that of the optimal $f^* \in \mathcal{H}$. Before proceeding with the analysis, we define key quantities to simplify the analysis and introduce standard assumptions which are necessary to establish convergence. First, define the regularized stochastic functional gradient as

$$\hat{\nabla}_f \ell(f_t(\mathbf{x}_t), y_t) = \nabla_f \ell(f_t(\mathbf{x}_t), y_t) + \lambda f_t \tag{22}$$

Further define the projected stochastic functional gradient associated with the update in (16) as

$$\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t), y_t) = \Big(f_t - \mathcal{P}_{\mathcal{H}_{\mathbf{D}_{t+1}}} \Big[f_t - \eta_t \hat{\nabla}_f \ell(f_t(\mathbf{x}_t), y_t) \Big] \Big) / \eta_t \tag{23}$$

such that the Hilbert space update of Algorithm 2 [cf. (16)] may be expressed as a stochastic descent using projected functional gradients

$$f_{t+1} = f_t - \eta_t \tilde{\nabla}_f \ell(f_t(\mathbf{x}_t), y_t) \; . \tag{24}$$

The definitions (23) - (22) will be used to analyze the convergence behavior of the algorithm. Before doing so, observe that the stochastic functional gradient in (22), based upon the fact that $(\mathbf{x}_t, y_t)$ are independent and identically distributed realizations of the random pair $(\mathbf{x}, y)$, is an unbiased estimator of the true functional gradient of the regularized expected risk $R(f)$ in (1), i.e.

$$\mathbb{E}[\hat{\nabla}_f \ell(f_t(\mathbf{x}_t), y_t) \,|\, \mathcal{F}_t] = \nabla_f R(f_t) \tag{25}$$

for all t. Next, we formally state technical conditions on the loss functions, data domain, and stochastic approximation errors that are necessary to establish convergence.

Assumption 1 *The feature space $\mathcal{X} \subset \mathbb{R}^p$ and target domain $\mathcal{Y} \subset \mathbb{R}$ are compact, and the reproducing kernel map may be bounded as*

$$\sup_{\mathbf{x} \in \mathcal{X}} \sqrt{\kappa(\mathbf{x}, \mathbf{x})} = X < \infty \tag{26}$$

Assumption 2 *The instantaneous loss $\ell : \mathcal{H} \times \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ is uniformly C-Lipschitz continuous for all $z \in \mathbb{R}$ for a fixed $y \in \mathcal{Y}$*

$$|\ell(z, y) - \ell(z', y)| \leq C|z - z'| \tag{27}$$

Assumption 3 *The loss function $\ell(f(\mathbf{x}), y)$ is convex and differentiable with respect to its first (scalar) argument $f(\mathbf{x})$ on $\mathbb{R}$ for all $\mathbf{x} \in \mathcal{X}$ and $y \in \mathcal{Y}$.*

Assumption 4 *Let $\mathcal{F}_t$ denote the sigma algebra which measures the algorithm history for times $u < t$, i.e. $\mathcal{F}_t = \{\mathbf{x}_u, y_u, u_u\}_{u=1}^t$. The projected functional gradient of the regularized instantaneous risk in (22) has finite conditional second moments for each t, that is,*

$$\mathbb{E}[\|\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t), y_t)\|_{\mathcal{H}}^2 \mid \mathcal{F}_t] \leq \sigma^2 \tag{28}$$

Assumption 1 holds in most practical settings by the data domain itself, and justifies the bounding of the loss in Assumption 2. Taken together, these conditions permit bounding the optimal function f^* in the Hilbert norm, and imply that the worst-case model order is guaranteed to be finite. Variants of Assumption 2 appear in the analysis of stochastic descent methods in the kernelized setting (Pontil et al., 2005; Ying and Zhou, 2006). Assumption 3 is satisfied for supervised learning problems such as logistic regression, support vector machines with the square-hinge-loss, the square loss, among others. Moreover, it is a standard condition in the analysis of descent methods (see Boyd and Vanderberghe (2004)). Assumption 4 is common in stochastic approximation literature, and ensures that the variance of the stochastic approximation error is finite. Under these conditions, we establish technical results in Appendix A which are used to establish our main convergence results in the following subsection.

4.1. Iterate Convergence

As is customary in the analysis of stochastic algorithms, we establish that under a diminishing algorithm step-size scheme (non-summable and square-summable), with the sparse approximation budget selection

$$\sum_{t=1}^{\infty} \eta_t = \infty \; , \quad \sum_{t=1}^{\infty} \eta_t^2 < \infty \; , \quad \epsilon_t = \eta_t^2 \; , \tag{29}$$

Algorithm 2 converges exactly to the optimal function f^* in stated in (1) almost surely. We use the abbreviation a.s. for an event that occurs almost surely, or with probability 1.

Theorem 2 *Consider the sequence generated $\{f_t\}$ by Algorithm 2 with $f_0 = 0$, and denote f^* as the minimizer of the regularized expected risk stated in (1). Let Assumptions 1-4 hold and suppose the step-size rules and approximation budget are diminishing as in (29) with regularizer such that $\eta_t < 1/\lambda$ for all t. Then the objective function error sequence converges to null in infimum almost surely as*

$$\liminf_{t \to \infty} R(f_t) - R(f^*) = 0 \qquad a.s. \tag{30}$$

Moreover, the sequence of functions $\{f_t\}$ converges almost surely to the optimum f^* as

$$\lim_{t \to \infty} \|f_t - f^*\|_{\mathcal{H}}^2 = 0 \qquad a.s. \tag{31}$$

Proof: See Appendix B. ■

The result in Theorem 2 states that when a diminishing algorithm step-size is chosen as, e.g. $\eta_t = \mathcal{O}(1/t)$, and the approximation budget that dictates the size of the sparse stochastic subspaces onto which the iterates are projected is selected as $\epsilon_t = \eta_t^2$, we obtain

exact convergence to the optimizer of the regularized expected risk in (1). However, in obtaining exact convergence behavior, we require the approximation budget to approach null asymptotically, which means that the model order of the resulting function sequence may grow arbitrarily, unless f^* is sparse and the magnitude of the stochastic gradient reduces sufficiently quickly, i.e., comparable to $\epsilon_t = \mathcal{O}(1/t^2)$.

If instead we consider a constant algorithm step-size $\eta_t = \eta$ and the approximation budget $\epsilon_t = \epsilon$ is chosen as a constant which satisfies $\epsilon_t = \epsilon = \mathcal{O}(\eta^{3/2})$, we obtain that the iterates converge in infimum to a neighborhood of the optimum, as we state next.

Theorem 3 *Denote $\{f_t\}$ as the sequence generated by Algorithm 2 with $f_0 = 0$, and denote f^* as the minimizer of the regularized expected risk stated in (1). Let Assumptions 1-4 hold, and given regularizer $\lambda > 0$, suppose a constant algorithm step-size $\eta_t = \eta$ is chosen such that $\eta < 1/\lambda$, and the sparse approximation budget satisfies $\epsilon = K\eta^{3/2} = \mathcal{O}(\eta^{3/2})$, where K is a positive scaler. Then the algorithm converges to a neighborhood almost surely as*

$$\liminf_{t\to\infty} \|f_t - f^*\|_{\mathcal{H}} \leq \frac{\sqrt{\eta}}{\lambda}\left(K + \sqrt{K^2 + \lambda\sigma^2}\right) = \mathcal{O}(\sqrt{\eta}) \qquad a.s. \tag{32}$$

Proof: See Appendix C. ■

Theorem 3 states that when a sufficiently small constant step-size is used together with a bias tolerance induced by sparsification chosen as $\epsilon = \mathcal{O}(\eta^{3/2})$, Algorithm 2 converges in infimum to a neighborhood of the optimum which depends on the chosen step-size, the parsimony constant K which scales the approximation budget ϵ, the regularization parameter λ, as well as the variance of the stochastic gradient σ^2. This result again is typical of convergence results in stochastic gradient methods. However, the use of a constant learning rate allows use to guarantee the model order of the resulting function sequence is always bounded, as we establish in the following subsection.

4.2. Model Order Control

In this subsection, we establish that the sequence of functions $\{f_t\}$ generated by Algorithm 2, when a constant algorithm step-size is selected, is parameterized by a kernel dictionary which is guaranteed to have finitely many elements, i.e., its the model order remains bounded. We obtain that the worst-case bound on the model order of f_t depends by the topological properties of the feature space $\mathcal{X}$, the Lipschitz constant of the instantaneous loss, and the radius of convergence $\Delta = (\sqrt{\eta}/\lambda)(K + \sqrt{K^2 + \lambda\sigma^2})$ defined in Theorem 3.

Theorem 4 *Denote f_t as the function sequence defined by Algorithm 2 with constant step-size $\eta_t = \eta < 1/\lambda$ and approximation budget $\epsilon = K\eta^{3/2}$ where $K > 0$ is an arbitrary positive scalar. Let M_t be the model order of f_t i.e., the number of columns of the dictionary $\mathbf{D}_t$ which parameterizes f_t. Then there exists a finite upper bound M^∞ such that, for all $t \geq 0$, the model order is always bounded as $M_t \leq M^\infty$. Consequently, the model order of the limiting function $f^\infty = \lim_t f_t$ is finite.*

Proof: See Appendix D.1. ■

The number of kernel dictionary elements in the function sequence f_t generated by Algorithm 2 is in the worst-case determined by the packing number of the kernel transformation

Table 1: Summary of convergence results for different parameter selections.

	Diminishing	Constant
Step-size/Learning rate	$\eta_t = \mathcal{O}(1/t)$	$\eta_t = \eta > 0$
Sparse Approximation Budget	$\epsilon_t = \eta_t^2$	$\epsilon = \mathcal{O}(\eta^{3/2})$
Regularization Condition	$\eta_t < 1/\lambda$	$\eta < 1/\lambda$
Convergence Result	$f_t \to f^*$ a.s.	$\liminf_t \|f_t - f^*\| = \mathcal{O}(\sqrt{\eta})$ a.s.
Model Order Guarantee	None	Finite

of the feature space $\phi(\mathcal{X}) = \kappa(\mathcal{X}, \cdot)$, as shown in the proof of Theorem 4. Moreover, the online sparsification procedure induced by KOMP reduces to a condition on the scale of the packing number of $\phi(\mathcal{X})$ as stated in (76). Specifically, as the radius $\frac{K\sqrt{\eta}}{C}$ increases, the packing number of the kernelized feature space decreases, and hence the required model order to fill $\phi(\mathcal{X})$ decreases. This radius depends on the constant K which scales the approximation budget selection η, the learning rate η, and the constant C bounding the gradient of the regularized instantaneous loss.

We have established that Algorithm 2 yields convergent behavior for the problem (1) in both diminishing and constant step-size regimes. When the learning rate η_t satisfies $\eta_t < 1/\lambda$, where $\lambda > 0$ is the regularization parameter, and is attenuating such that $\sum_t \eta_t = \infty$ and $\sum_t \eta_t^2 < \infty$, i.e., $\eta_t = \mathcal{O}(1/t)$, the approximation budget ϵ_t of Algorithm 1 must satisfy $\epsilon_t = \eta_t^2$ [cf. (29)]. Practically speaking, this means that asymptotically the iterates generated by Algorithm 2 may have a very large model order in the diminishing step-size regime, since the approximation budget is vanishing as $\epsilon_t = \mathcal{O}(1/t^2)$. On the other hand, when a constant algorithm step-size $\eta_t = \eta$ is chosen to satisfy $\eta < 1/\lambda$, then we only require the constant approximation budget $\epsilon_t = \epsilon$ to satisfy $\epsilon = \mathcal{O}(\eta^{3/2})$. This means that in the constant learning rate regime, we obtain a function sequence which converges to a neighborhood of the optimal f^* defined by (1) and is guaranteed to have a finite model order. These results are summarized in Table 1.

Remark 5 *(Sparsity of f^*)* Algorithm 2 provides a method to avoid keeping an unnecessarily large number of kernel dictionary elements along the convergence path towards f^* [cf. (1)], solving the classic scalability problem of kernel methods in stochastic programming. However, if the optimal function admits a low dimensional representation $|\mathcal{I}| \ll \infty$, then in addition to extracting memory efficient instantaneous iterates, POLK will obtain the optimal function exactly. In Section 5, we illustrate this property via a multi-class classification problem where the data is generated from Gaussian mixture models.

4.3. Complexity Analysis

We now study the per-iteration computational complexity of Algorithm 2. Throughout the following discussion, we shall use M_t to denote the model order at iteration t, and p to

denote the dimension of the input (feature) space. For convenience of analysis, Algorithm 2 can be thought of as operating in two distinct phases:

i. **Append**: augment the dictionary and weights so as to take the true FSGD step (i.e., such that they represent $\tilde{f}_{t+1}$).

ii. **Prune**: use matching pursuit to reduce the model order (i.e., compute the approximation f_{t+1}).

In analyzing the append phase, there are two major operations to consider. The first is the computation of the coefficient $\ell'(f(\mathbf{x}_t), y_t)$ for the new point, which requires M_t kernel evaluations, $\{\kappa(\mathbf{d}_j, \mathbf{x}_t)\}_{j=1}^{M_t}$, to be weighted and summed. Computing the kernel values exhibits complexity $\mathcal{O}(pM_t^2)$ (the complexity of a kernel evaluation scales at least linearly with p), and the weighting and summing exhibits complexity $\mathcal{O}(M_t)$. The second major operation that takes place in the append phase is that of augmenting the kernel matrix. However, for computational efficiency, a copy of the inverse of this kernel matrix is also kept, which can be updated in $O(M_t^2)$ time using classical rank-one, block-inverse update rules, based on the Sherman-Woodbury-Morrison identity (see, e.g., KRLS in Engel et al. (2004)). Therefore, the total computational complexity of the append phase is $\mathcal{O}(M_t^2)$.

To analyze the pruning phase, we first introduce some additional notation. Let Z_t denote the total number of the outer iterations of Algorithm 1 that actually take place at time t, i.e., the number of points removed from $\tilde{\mathbf{D}}$. Using an efficient implementation of Algorithm 1 inspired by Vincent and Bengio (2002), each of these Z_t iterations exhibits a computational complexity of $\mathcal{O}(M_t^2)$. After the stopping criterion has been met, the augmented function is projected onto the subspace spanned by the pruned dictionary, which also exhibits a complexity of $\mathcal{O}(M_t^2)$. Finally, the new kernel matrix and its inverse are updated, which, too, incurs a computational cost of $\mathcal{O}(M_t^2)$, bringing the overall complexity of the pruning phase to $\mathcal{O}(Z_t M_t^2)$. A pessimistic estimate of Z_t is M_t, although in practice it is always less than the mini-batch size B.

Combining the terms from each phase, the total complexity of Algorithm 2 at iteration t comes out to $O(Z_t M_t^2)$. In the steady-state, $Z = 1$ (i.e., $M_{t+1} = M_t$), which further reduces the expression to $\mathcal{O}(M_t^2)$, exactly the complexity of KRLS (Engel et al., 2004). Observe that the complexity of FSGD is $\mathcal{O}(t)$, which means that POLK is computationally advantageous whenever $t > Z_t M_t^2$. Since $\lim_t M_t$ is guaranteed to be finite, and usually $Z_t \leq B$, the mini-batch size.Thus, POLK is justified whenever t is large. This is typical of the online methods for kernel learning that we compare against experimentally in the following section.

Remark 6 *(Cheaper Projections)* Both theoretically and in practice, it is possible to cheapen the cost of projections by replacing the argmin in KOMP by a scheme that drops kernel dictionary elements *uniformly at random* until the function hits the boundary of a Hilbert-norm error neighborhood. Such a scheme's convergence would still be guaranteed by the preceding theoretical analysis, and the cost of pruning points would be significantly cheaper. Specifically, it would be at most linear in the dictionary size $\mathcal{O}(M_t Z_t)$. However, the price of pursuing this route would be lower quality estimates of f^*. We have left the investigation of these random approximated projections to future work. However, we note that several

alternatives in the literature adopt a version of this approach, but with *fixed* subspace sizes (Wang and Vucetic, 2010a; Wang et al., 2012; Zhao and Hoi, 2012; Zhang et al., 2013; Le et al., 2016b; Lu et al., 2016) rather than error-neighborhood budgets, as is done in this work, which is not enough to establish almost sure convergence.

5. Experiments

In this section, we evaluate POLK by considering its performance on two supervised learning tasks trained for three streaming data sets. The specific tasks we consider are those of (a) training a multi-class kernel logistic regressor (KLR), and (b) training a multi-class kernel support vector machine (KSVM). The three data sets we use are (i) `multidist`, a synthetic data set we constructed using two-dimensional Gaussian mixture models; (ii) `mnist`, the MNIST handwritten digits (Lecun and Cortes, 2009); and (iii) `brodatz`, image textures drawn from a subset of the Brodatz texture database (Brodatz, 1966).

Where possible, we compare our technique with competing methods. Specifically, for the online support vector machine case, we compare with budgeted stochastic gradient descent (BSGD) Wang et al. (2012), a fixed subspace projection method, which requires a maximum model order *a priori*; Dual Space Gradient Descent (Dual) (Le et al., 2016a), which executes a hybrid combination of functional stochastic gradient method together with a hybrid random feature representation of the regression function; nonparametric budgeted stochastic gradient descent (NPBSGD) Le et al. (2016b), which combines a fixed subspace projection with random dropping, Naive Online R_{reg} Minimization Algorithm (NORMA) (Kivinen et al., 2004), which does a greedy objective function value based truncation to a fixed budget, and an instantiation of Budgeted Passive-Aggressive (BPA) algorithm based on k-nearest neighbor merging of incoming points (Wang and Vucetic, 2010a). We note that all the aforementioned methods fix the model order except Dual (Le et al., 2016a). Further, for logistic regression, from the preceding list, we omit BPA and BSGD since they are derived specifically for the SVM setting. We compare all of these online methods on our first data set but then only compare POLK and BSGD on the later benchmark data domains, since the trends we observe for the former directly scale up to the later.

For off-line (batch) KLR, we compare with the import vector machine (IVM) (Zhu and Hastie, 2005), a sparse second-order method. We also compare with the batch techniques of LIBSVM (Chang and Lin, 2011), applicable to KSVM only, an L-BFGS solver (Nocedal, 1980), and methods which approximate the kernel matrix using either Fourier transforms (Rahimi and Recht, 2008, 2009) or Nyström approximation (Williams and Seeger, 2001; Zhang et al., 2008).

5.1. Tasks

The tasks we consider are those of multi-class classification, which is a problem that admits approaches based on probabilistic and geometric criteria. In what follows, we use $\mathbf{x}_n \in \mathcal{X} \subset \mathbb{R}^p$ to denote the n^{th} feature vector in a given data set, and $y_n \in \{1, \ldots, C\}$ to denote its corresponding label.

Multi-class Kernel Support Vector Machines (Multi-KSVM) The first task we consider is that of training a multi-class kernel support vector machine, in which the merit of a particular regressor is defined by its ability to maximize its classification margin. In

particular, define a set of class-specific activation functions $f_c : \mathcal{X} \to \mathbb{R}$, and denote them jointly as $\mathbf{f} \in \mathcal{H}^C$. In Multi-KSVM, points are assigned the class label of the activation function that yields the maximum response. KSVM is trained by taking the instantaneous loss ℓ to be the multi-class hinge function which defines the margin separating hyperplane in the kernelized feature space, i.e.,

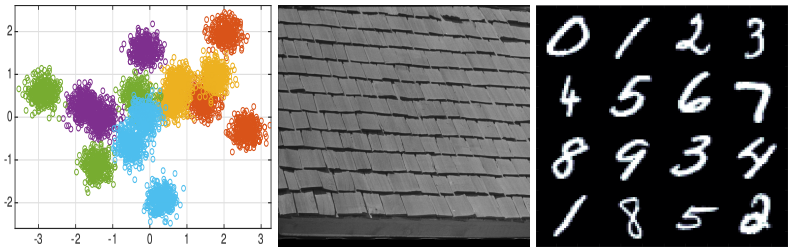
$$\ell(\mathbf{f}, \mathbf{x}_n, y_n) = \max(0, 1 + f_r(\mathbf{x}_n) - f_{y_n}(\mathbf{x}_n)) + \lambda \sum_{c'=1}^{C} \|f_{c'}\|_{\mathcal{H}}^2 \,, \tag{33}$$

where $r = \operatorname{argmax}_{c' \neq y} f_{c'}(\mathbf{x})$. Further details may be found in Murphy (2012).

Multi-class Kernel Logistic Regression (Multi-KLR) The second task we consider is that of kernel logistic regression, wherein, instead of maximizing the margin which separates sample points in the kernelized feature space, we instead adopt a probabilistic model on the odds ratio that a sample point has a specific label relative to all others. Using the same notation as above for the class-specific activation functions, we adopt the probabilistic model:

$$P(y = c \,|\, \mathbf{x}) \triangleq \frac{\exp(f_c(\mathbf{x}))}{\sum_{c'} \exp(f_{c'}(\mathbf{x}))}. \tag{34}$$

which models the odds ratio of a given sample point being in class c versus all others. We use the negative log likelihood pertaining to the above model as the instantaneous loss (see, e.g., Murphy (2012)), i.e.,



$$\begin{aligned} \ell(\mathbf{f}, \mathbf{x}_n, y_n) &= -\log P(y = y_n | \mathbf{x}_n) + \frac{\lambda}{2} \sum_c \|f_c\|_{\mathcal{H}}^2 \\ &= \log \left(\sum_{c'} \exp(f_{c'}(\mathbf{x}_n)) \right) - f_{y_n}(\mathbf{x}_n) + \frac{\lambda}{2} \sum_c \|f_c\|_{\mathcal{H}}^2 \,. \end{aligned} \tag{35}$$

Observe that the loss (35) substituted into the empirical risk minimization problem in Example 1 is its generalization to multi-class classification. For a given set of activation functions, the classification decision $\tilde{c}$ for $\mathbf{x}$ is given by the class that yields the maximum likelihood, i.e., $\tilde{c} = \operatorname{argmax}_{c \in \{1,\ldots,C\}} f_c(\mathbf{x})$.

5.2. Data Sets

We evaluate Algorithm 2 for the Multi-KLR and Multi-KSVM tasks described above using the `multidist`, `mnist`, `brodatz` data sets.

`multidist`
In a manner similar to (Zhu and Hastie, 2005), we generate the `multidist` data set using a set of Gaussian mixture models. The data set consists $N = 5000$ feature-label pairs for training and 2500 for testing. Each label y_n was drawn uniformly at random from the label set. The corresponding feature vector $\mathbf{x}_n \in \mathbb{R}^p$ was then drawn from a planar ($p = 2$), equitably-weighted Gaussian mixture model, i.e., $\mathbf{x} \,|\, y \sim (1/3) \sum_{j=1}^{3} \mathcal{N}(\boldsymbol{\mu}_{y,j}, \sigma_{y,j}^2 \mathbf{I})$ where $\sigma_{y,j}^2 = 0.2$ for all values of y and j. The means $\boldsymbol{\mu}_{y,j}$ are themselves realizations of their own Gaussian distribution with class-dependent parameters, i.e., $\boldsymbol{\mu}_{y,j} \sim \mathcal{N}(\boldsymbol{\theta}_y, \sigma_y^2 \mathbf{I})$, where

(a) `multidist` data (b) `brodatz` example texture (c) `mnist` examples

Figure 1: Visualizations of the data sets used in experiments.

$\{\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_C\}$ are equitably spaced around the unit circle, one for each class label, and $\sigma_y^2 = 1.0$. We fix the number of classes $C = 5$, meaning that the feature distribution has, in total, 15 distinct modes. The data points are plotted in Figure 1(a).

`mnist`
The `mnist` data set we use is the popular MNIST data set (Lecun and Cortes, 2009), which consists of $N = 60000$ feature-label pairs for training and 10000 for testing. Feature vectors are $p = 784$-dimensional, where each dimension captures a single grayscale pixel value (scaled to lie within the unit interval) that corresponds to a unique location in a 28-pixel-by-28-pixel image of a cropped, handwritten digit. Labels indicate which digit is written, i.e., there are $C = 10$ classes total, corresponding to digits $0, \ldots, 9$ – examples are given in Figure 1(c).

`brodatz`
We generated the `brodatz` data set using a subset of the images provided in Brodatz (1966). Specifically, we used 13 texture images (i.e., $C = 13$), and from them generated a set of 256 textons (Leung and Malik, 1999). Next, for each overlapping patch of size 24-pixels-by-24-pixels within these images, we took the feature to be the associated $p = 256$-dimensional texton histogram. The corresponding label was given by the index of the image from which the patch was selected. When then randomly selected $N = 10000$ feature-label pairs for training and 5000 for testing. An example texture image can be seen in Figure 1(b).

5.3. Parameter Selection

For the choice of kernel, some intuition regarding the data domain is helpful, but typically the Gaussian kernel is a good starting point, and therefore is our selection for all of the experiments. For bandwidth selection $\tilde{\sigma}^2$, we find that choosing it according to the sample variance of a cross-validation training subset to be reasonably effective, and this strategy was used in our implementation. The mini-batch size of 32 was selected based on reducing the noise of stochastic approximation error once steady state is achieved, and was done through trial and error by starting at batch sizes of 1 and doubling until the computational burden of a mini-batch exceeded its benefits in terms of noise reduction. We find the regularizer λ has little effect when the data does not have an untenably large variance, and therefore fix

it as a small constant. For problems with worse conditioning, however, larger regularizers may be useful.

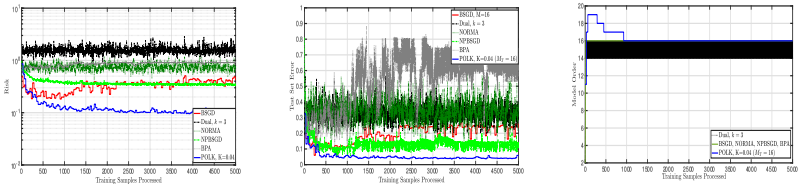
The selection of the algorithm step-size and parsimony constant in our experiments is done through a simple trial and error procedure. We begin with a small step-size, between 0.01 and 0.1, to test whether the algorithm converges, with parsimony constant $K = 0.001$. Convergence, however, may occur while the model order grows untenably. So, we progressively increase the parsimony constant until the bias in the stochastic gradient becomes unmanageable and the algorithm diverges. We select the parsimony constant to be as large as possible while still preserving convergence of the algorithm. Then, we exploit knowledge of the trade-off between learning rate and step-size selection: smaller step-sizes yield slower learning and smaller asymptotic error. In light of this fact, we increment the step-size to increase the learning rate, and then ramp up the parsimony constant to its maximum value that preserves convergence. This trial and error procedure only needed to be repeated a few times for each data set/problem instance to obtain the POLK results presented in this section.

5.4. Results

For each task and data set described above, we implemented POLK (Algorithm 2) along with the competing methods described at the beginning of the section. For some of the tasks, only a subset of the competing methods are applicable, and in some cases such as online logistic regression, none are. Here, we shall describe the details of each experimental setting and the corresponding results.

`multidist` Results

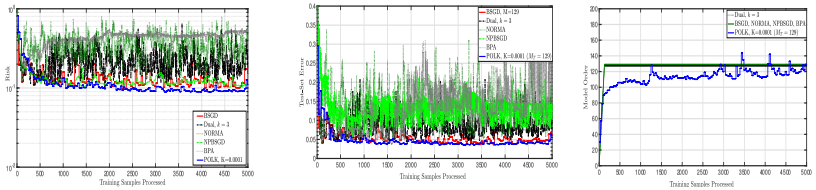
Sparse SVM Due to the small size of our synthetic `multidist` data set, we were able to generate results for the Multi-KSVM task using each of the methods specified earlier except for IVM. For POLK, we used the following specific parameter values: we select the Gaussian/RBF kernel with bandwidth $\tilde{\sigma}^2 = 0.6$, constant learning rate $\eta = 6.0$, parsimony constant $K = 0.04$, and regularization constant $\lambda = 10^{-6}$. Further, we processed streaming samples in mini-batches of size 32. For BSGD, Dual, NORMA, NPBSGD, and BPA, we used the same $\tilde{\sigma}^2$ and λ, but achieved the best results with smaller constant learning rate $\eta = 1.0$ (perhaps due, in part, to the fact that it is unclear how to fold mini-batching into their implementation). For Dual, we set $k = 3$, which determines the how many model points we search over to omit from the dictionary and instead contribute to the random feature functional representation. For NPBSGD, we set the Bernoulli parameter $p = \min(1, \beta/t)$ with $\beta = (45/70)N$ as in the experiments of Le et al. (2016b). In order to compare with POLK, we set the competing methods' pre-specified model orders or budget parameters to be 16, i.e., the steady-state model orders of POLK parameterized with the value of K specified above.



In Figure 2 we plot the empirical results of this experiment for POLK and its competitors, and observe that POLK outperforms many of its competitors by an order of magnitude in terms of objective evaluation (Fig. 2(a)) and test-set error rate (Fig 2(b)). The notable exception is NPBSGD which comes close in terms of objective evaluation but still falls short in terms of test error. Moreover, because the marginal feature density of `multidist` contains 15 modes, the optimal model order is $M^* = 15$, which is approximately *learned* by

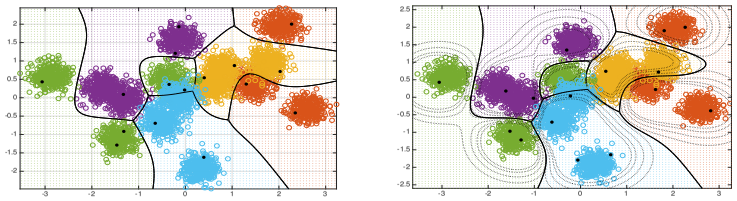
	`multidist`	
Algorithm	Multi-KSVM (risk/error/model order)	Multi-Logistic (risk/error/model order)
LIBSVM	−/3.92/656	−/−/−
L-BFGS	0.0854/4.08/5000	0.0854/4.04/5000
IVM	−/−/−	0.0894/4.08/16
Fourier	−/3.88/5000	−/3.80/5000
Nyström	−/3.67/1000	−/3.72/1000
BSGD	0.385/21.8/16	−/−/−
Dual	1.598/30.5.8/15	1.417/48.4/15
NORMA	0.751/33.1/16	1.26/29.3/16
NPBSGD	0.334/11.6/16	0.101/3.92/16
BPA	0.947/64.1/16	−/−/−
POLK	**0.0919/3.98/16**	**0.120/4.36/16**

Table 2: Comparison of different methods on the `multidist` data set for extracting the optimally sparse functional representation, i.e., $K = 0.04$ for POLK and $M = 16$ for online competitors. Reported risk and error values for POLK and BSGD were averaged over the final 5% of processed training examples. Dashes indicate where the method could not be used to generate results because it is not defined for that task. LIBSVM is used as a baseline, but note that it uses a fundamentally different model for multi-class problems (a separate one-vs-all classifier is trained for each class, and then at test time, a majority vote is executed), and so a comparable risk value can not computed.



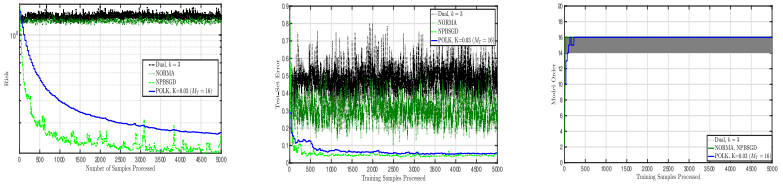
POLK for $K = 0.04$ (i.e., $M_T = 16$) (Fig. 2(c)). Several alternatives initialized with this parameter, on the other hand, do not converge. Observe that for this task POLK exhibits a state of the art trade off between test set accuracy and number of samples processed – reaching below 4% error after only 1249 samples. The final decision surface $\mathbf{f}_T$ of this trial of POLK is shown in Fig. 4(a), where it can be seen that the selected kernel dictionary elements concentrate near the modes of the marginal feature density.

We can also see from Table 2 that POLK compares favorably to the batch techniques for Multi-KSVM on the `multidist` data set. It achieves approximately the same error rate as LIBSVM with significantly fewer model points (support vectors) and even outperforms our (dense) L-BFGS batch solver in terms of test-set error, while adding the ability to process data in an online fashion. Compared to approximate batch solvers such as Random Fourier Features with $d = 1000$ features and all $N = 5000$ sample points, we observe POLK obtains a 0.1% error increase with a 99% reduction in model complexity. We also implement Nyström approximation with k-means sampled landmark points with $k = 1000$ (Zhang et al., 2008), and observe similar accuracy results to random features, which increased complexity associated with computing k means over the entire training set. We still report a model order equal to the sample size for these methods, however, since they require the full training set in order to implement their approximation procedure.



(a) Empirical risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 2: Comparison of POLK and its competitors on the `multidist` data set for the Multi-KSVM task for extracting a optimally sparse kernel regressor. Observe that POLK achieves lower risk and higher accuracy when we seek to learn a statistical model of comparable complexity to the class-conditional density ($M = 15$ total modes). Competing methods yield slower learning and higher test-set error rates.

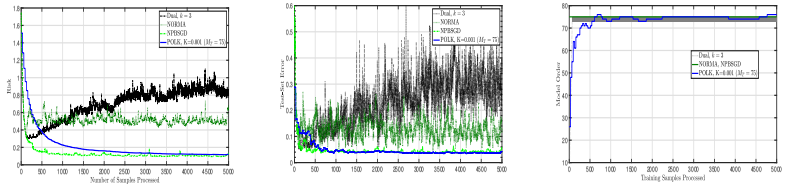


(a) Empirical risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 3: Comparison of POLK and its competitors on the `multidist` data set for the Multi-KSVM task when the model order parameter is fixed for the competitors at $M = 129$ and the parsimony constant of POLK is set to $K = 10^{-4}$. Observe that POLK achieves lower risk and higher accuracy than its competitors on this problem instance, but the gap is less relative to the sparser model extraction problem.

(a) $\mathbf{f}_T$ (hinge loss) (b) $\mathbf{f}_T$ (logistic loss)

Figure 4: Visualization of the decision surfaces yielded by POLK for the Multi-KSVM and Multi-Logisitic tasks on the `multidist` data set. Training examples from distinct classes are assigned a unique color. Grid colors represent the classification decision by $\mathbf{f}_T$. Bold black dots are kernel dictionary elements, which concentrate at the modes of the data distribution. Solid lines are drawn to denote class label boundaries, and dashed lines in 4(b) are drawn to denote confidence intervals.



(a) Empirical risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 5: Empirical behavior of the POLK algorithm applied to the `multidist` data set for the Multi-Logistic task. Observe that the algorithm converges to a low risk value ($R(f_t) < 10^{-1}$) and achieves test set accuracy between 4% and 5% depending on choice of parsimony constant K, which respectively corresponds to a model order between 75 and 16.

Dense SVM We now repeat the previous experiment with the same parameters except for a different parsimony constant $K = 10^{-4}$ for POLK and a model order of $M = 129$ for its competitors, given that this is the value extracted by POLK for this parameter selection. The results of this experiment are given in Figure 3. Observe that NORMA and Dual appear to not converge for this experiment, while POLK converges stably, although its learning rate is exceeded by NPBSGD. This trend is observed both in terms of the risk functional (Fig. 3(a)) and test-set error (Fig 3(b)). We believe NPBSGD performs better for this case due to the smoothness of the logistic loss relative to the hinge loss. However, the test errors of these methods stabilize to similar levels of accuracy (below 4% error rate).

Sparse KLR For the Multi-Logisitic task on this data set, we were able to generate results for each method except BSGD, BPA, and LIBSVM, which are specifically tailored to the SVM task. For POLK, we used the following parameter values: Gaussian kernel with bandwidth $\tilde{\sigma}^2 = 0.6$, constant learning rate $\eta = 6.0$, parsimony constant $K = 0.03$, and

(a) Empirical risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 6: Empirical behavior of the POLK algorithm applied to the `multidist` data set for the Multi-Logistic task. Observe that the algorithm converges to a low risk value ($R(f_t) < 10^{-1}$) and achieves test set accuracy between 4% and 5% depending on choice of parsimony constant K, which respectively corresponds to a model order between 75 and 16.

regularization constant $\lambda = 10^{-6}$. As in Multi-KSVM, we processed the streaming samples in mini-batches of size 32. The empirical behavior of POLK for the Multi-Logistic task can be seen in Figure 5 and the final decision surface is presented in Figure 4(b). Observe that POLK is exhibits comparable convergence to the SVM problem, but a smoother descent due to the differentiability of the multi-logistic loss. The competing methods, initialized with a model order of $M = 16$ do not converge, except for NPBSGD, which attains comparable test error to POLK. In Table 2 we present final accuracy and risk values on the logistic task, and note that it performs comparably, or in some cases, favorably, to the batch techniques (IVM, L-BFGS, Random Features, Nyström with k-means sampled points), while processing streaming data. The final model f_T extracted by POLK attains comparable performance to off-line methods while reducing the model complexity by several orders of magnitude.

Dense KLR Now, we re-rerun the previous experiment but modify the parsimony constant of POLK as $K = 0.001$, which yields a limiting model of order $M = 75$. The competing methods are then run with this selection. The results of this experiment are given in Figure 6: observe that NORMA and Dual diverge, while NPBSGD converges slightly faster albeit more noisily than POLK. The later two methods attain comparable test accuracy near 96% by the end of training.

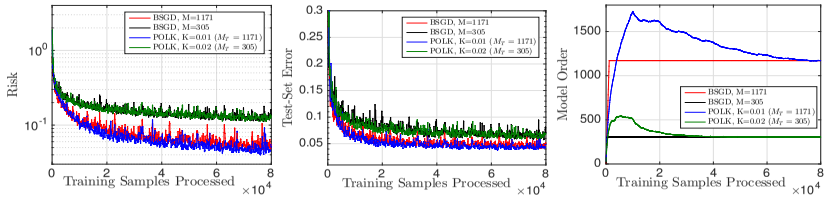
`mnist` and `brodatz` Results

By construction, the `multidist` data set above yields optimal activation functions that are themselves sparse (i.e., $\mathbf{f}^*$ has a low model order due to the marginal feature density). Here, we analyze the performance of POLK on more realistic data sets where the optimal solutions are not sparse, i.e., where one might desire a sparse approximation. Due to the increased size and dimensionality of these data sets, we were unable to generate results for `mnist` using the batch L-BFGS technique, and unable to generate results for either data set using IVM. With Random Fourier Features on `mnist`, we use a bandwidth of 0.0095 with $d = 1000$ randomly chosen features for both SVM and KLR. For `brodatz`, we use a larger bandwidth of $\tilde{\sigma}^2 = 4.0$, with $d = 10^4$ Random Features both for KSVM and KLR. For Nyström approximation, we set $k = 1000$ since larger choices of k cause memory problems.

	`mnist`		`brodatz`	
Algorithm	Multi-KSVM (risk/error/model order)	Multi-Logistic (risk/error/model order)	Multi-KSVM (risk/error/model order)	Multi-Logistic (risk/error/model order)
LIBSVM	$-/1.50/16118$	$-/-/-$	$-/3.72/4777$	$-/-/-$
Fourier	$-/3.83/60000$	$-/3.87/60000$	$-/5.88/10000$	$-/6.18/10000$
Nyström	$-/2.89/60000$	$-/2.94/60000$	$-/5.13/10000$	$-/5.86/10000$
L-BFGS	$-/-/-$	$-/-/-$	$0.0319/4.44/10000$	$0.0572/4.00/10000$
BSGD	$0.0731/2.67/1086$	$-/-/-$	$0.0560/4.72/1171$	$-/-/-$
POLK	$\mathbf{0.0684/2.46/1086}$	$\mathbf{0.116/2.68/2326}$	$\mathbf{0.0507/4.53/1171}$	$\mathbf{0.0871/4.41/1833}$

Table 3: Comparison of POLK, BSGD, IVM, L-BFGS, and LIBSVM results on the `mnist` and `brodatz` data sets. Reported risk and error values for POLK and BSGD were averaged over the final 5% of processed training examples. Dashes indicate where the method could not be used to generate results either because it is not defined for the task or because the size of the problem was too large for that data set. For these reasons, IVM was not able to generate results for these data sets on either task, and so is omitted here. LIBSVM is used as a baseline, but note that it uses a fundamentally different model for multi-class problems (1v1 + majority vote), and so a comparable risk value can not be computed.

For Multi-KSVM on `mnist`, we used the following parameter values for POLK: Gaussian kernel with bandwidth $\tilde{\sigma}^2 = 4.0$, constant learning rate $\eta = 24.0$, parsimony constant $K \in \{0.16, 0.24\}$, and regularization constant $\lambda = 10^{-6}$. We again processed data in mini-batches of size 32. For `brodatz`, we used identical parameters except for changing the kernel bandwith $\tilde{\sigma}^2 = 0.1$ and parsimony constant $K \in \{0.01, 0.02\}$. For BSGD, we again found $\eta = 1.0$ to yield the best results on both datasets, and pre-specified model orders of $\{324, 1086\}$ and $\{305, 1171\}$ on `mnist` and `brodatz`, respectively, for comparison to POLK.

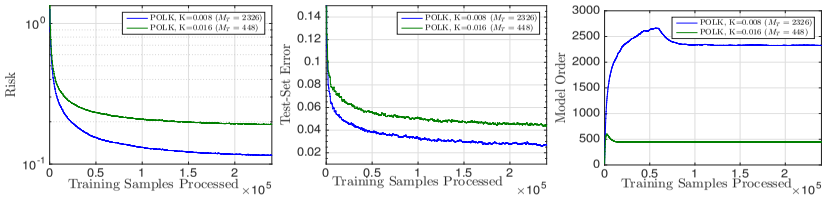


In Figures 7 and 8 we plot the empirical results of these experiments for POLK and BSGD. We observe that POLK is able to outperform the comparable BSGD trial in terms of convergence speed and steady-state risk and test-set error. The strength of the proposed technique is further demonstrated in Table 3, where we can see that POLK is able to achieve test-set error within 1-2% of LIBSVM while requiring a number of support vectors (model points) that is significantly-less than LIBSVM, *while* adding the ability to process streaming data.

For the Multi-Logistic task on `mnist`, we ran POLK using a Gaussian kernel with bandwidth $\tilde{\sigma}^2 = 4.0$, constant learning rate $\eta = 24.0$, parsimony constant $K \in \{0.08, 0.16\}$, and regularization constant $\lambda = 10^{-6}$. Data was processed in mini-batches of size 32 here as well. For `brodatz`, we again change the kernel bandwidth $\tilde{\sigma}^2 = 0.1$ and used different parsimony constants $K = \{0.005, 0.015\}$. The empirical behavior of POLK on this task can be seen in Figures 9 and 10. Observe that for this task the descent is smoother due to the differentiability of the logistic loss, although the asymptotic test accuracy is lower than that of KSVM.

(a) Expected risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

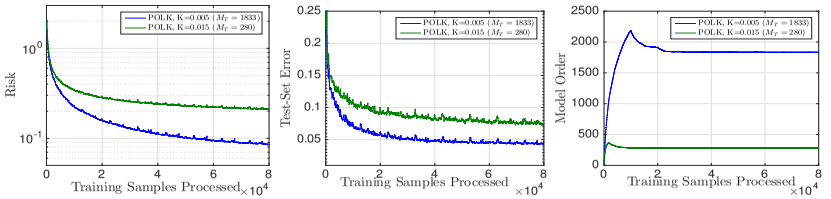
Figure 7: Comparison of POLK and BSGD on `mnist` data set for the Multi-KSVM task. Observe that POLK achieves lower risk and higher accuracy on this task, and extracts a model order directly from the feature space that yields convergence.



(a) Expected risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 8: Comparison of POLK and BSGD on `brodatz` data set for the Multi-KSVM task. We observe that POLK behaves similarly to BSGD for this task, stabilizing at an accuracy near 96%. For this dense data domain, larger model orders are needed to achieve convergence.

The overall performance is summarized in Table 3. Note that the only other technique that was able to generate results for this task was L-BFGS, and even there only on the `brodatz` data set, since the complexity bottleneck in the sample size for `mnist` is prohibitive for batch optimization. We see from this comparison that POLK yields a test-set error within 0.5% of the batch solution while using an order of magnitude fewer model points. Additionally, POLK is able to run *online*, with streaming data, whereas L-BFGS requires all the data points to be operated on at each step.



6. Discussion

Over the past several years, parametric function approximation has largely dominated the machine learning landscape. Deep learning is perhaps currently the most prominent parametric paradigm (Haykin, 1994). One must first specify a network structure, thereby fixing the parametric representation of the function to be learned, before proceeding to determine the coefficients linking neurons in different layers. Given this parametric representation, training techniques proceed by searching over the predefined parameter space for the op-

(a) Expected risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 9: Empirical behavior of the POLK algorithm applied to `mnist` data set for the Multi-Logistic task. The algorithm exhibits smoother convergence due to the differentiability of the logistic loss, and achieves asymptotic test error 2.6%. We again observe due to the dense data domain, larger model orders are needed to exhibit competitive classification performance.

(a) Expected risk $R(\mathbf{f}_t)$ (b) Error rate (c) Model order M_t

Figure 10: Empirical behavior of the POLK algorithm applied to the `brodatz` data set for the Multi-Logistic task. We observe convergent behavior, and a clear trade off between higher model order and increased accuracy. Due to this data domain being a more challenging task than the `mnist` digits, we observe asymptotic test accuracy of approximately 4.4%.

timal parameter values that minimize the error between the function and observed input-output pairs. The main reason for the popularity of parametric function approximation is its success in solving practical problems, but there are other factors that have fostered their adoption. One such factor is the availability of workable, if not necessarily efficient, optimization techniques for the determination of the optimal parameter values, in the form of stochastic gradient descent and its variants. Parametric stochastic gradient descent processes training examples sequentially and has a per-iteration complexity that is linear on the number of parameters but independent of the size of the training set.

Despite the success of parametric techniques, nonparametric function approximation has the advantage of expressive power in the sense that they are allowed to select the approximating function from a more general set of functions than those that admit a parametric form chosen *a priori*. This advantage is seen, e.g., in the improved classification accuracy of (nonparametric) kernel support vector machines (SVMs) relative to (parametric) linear SVMs (Evgeniou et al., 2000). This is not to say that nonparametric methods are necessarily better. Neural networks, e.g., have proven to be very adept parametric representations in image classification problems (Krizhevsky et al., 2012). However, it is nonetheless true that the better expressive power of nonparametric representations is of importance in some applications.

The importance of expressiveness notwithstanding, nonparametric approaches are relatively less popular. This is partly explained by the fact that, contrary to parametric approaches, workable algorithms for the minimization of functional costs are not as well-developed. Indeed, nonparametric models involve function representations that depend on an infinite number of parameters. This is a challenge not only because optimal function descriptions can become computationally intractable but, more importantly, because finding these optimal representations is itself intractable.

This work represents the first attempt at comprehensively addressing this intractability. In particular, we have proposed solving general convex expected risk minimization problems over a Hilbert space that defines nonparametric regression functions in a way that guarantees the model order of the learned function does not grow unnecessarily large. In doing so, we addressed challenges (i) - (ii) as follows: we considered the generalization of stochastic gradient descent to the kernelized expected risk setting and we compressed the learned decision function in a way that guarantees stochastic descent by tuning a greedy sparse approximation error criterion to the underlying optimization sequence. The result is an almost-sure convergent function sequence with moderate complexity that is able to operate in true online settings.

Indeed, our experiments have shown that POLK performs comparably to batch kernel methods in terms of accuracy, while its model complexity is reduced by orders of magnitude. Additionally, we observe state-of-the-art performance in terms of test-set accuracy relative to the number of samples processed. Such performance is key to achieving reasonable performance in many applications of interest, e.g., when learning on robotics platforms operating in unknown environments. In this case, the online nature of the problem is intrinsic and due to a lack of prior information on their operating domain (Koppel et al., 2016).

On the other hand, it must be noted that POLK, and even batch kernel methods, for certain large-scale supervised learning tasks, have not met the high bar of asymptotic

test set accuracy set forth by batch approaches to deep learning (Krizhevsky et al., 2012). We believe this discrepancy is on account of the single-layer nature of the nonparametric regressor, which is tied to the choice of reproducing kernel used in our experiments. Of course, more complicated multi-layer composite kernels may be used, based on the fact that a composition and positive linear combination of kernels is still a kernel (Theodoridis, 2015, Ch. 11). However, the scalable development of online nonparametric methods based on such composite kernels is not straight-forward, and left to future work.

Appendix A. Technical Results

Next we establish an auxiliary result needed to prove Theorems 2 and 3 which bounds the magnitude of the iterates of Algorithm 2 in the Hilbert norm.

Proposition 7 *Let Assumptions 1-4 hold and denote $\{f_t\}$ as the sequence generated by Algorithm 2 with $f_0 = 0$. Further denote f^* as the optimum defined by* (1)*. Both quantities are bounded by the constant $K := CX/\lambda$ in Hilbert norm for all t as*

$$\|f_t\|_{\mathcal{H}} \leq \frac{CX}{\lambda}\,, \qquad \|f^*\|_{\mathcal{H}} \leq \frac{CX}{\lambda} \tag{36}$$

Proof: First, since we repeatedly use the Cauchy-Schwartz inequality together with the reproducing kernel property in the following analysis, we here note that for all $g \in \mathcal{H}$, $|g(\mathbf{x}_t)| \leq |\langle g, \kappa(\mathbf{x}_t, \cdot)\rangle_{\mathcal{H}}| \leq X\|g\|_{\mathcal{H}}$. Now, consider the magnitude of f_1 in the Hilbert norm, given $f_0 = 0$

$$\begin{aligned}\|f_1\|_{\mathcal{H}} &= \left\|\mathcal{P}_{\mathcal{H}_{\mathbf{D}_1}}\left[\eta_0 \nabla_f \ell(0, y_0)\right]\right\|_{\mathcal{H}} \\ &\leq \eta_0 \|\nabla_f \ell(0, y_0)\|_{\mathcal{H}} \leq \eta_0 |\ell'(0, y_0)| \|\kappa(\mathbf{x}_0, \cdot)\|_{\mathcal{H}} \\ &\leq \eta_0 CX < \frac{CX}{\lambda}\end{aligned} \tag{37}$$

The first equality comes from substituting in $f_0 = 0$ and the second inequality comes from the definition of optimality condition of the projection operator and the homogeneity of the Hilbert norm, and the third uses the derivation of the functional stochastic gradient in (10) with the Cauchy-Schwartz inequality. Lastly, we make use of Assumptions 1 and 2 to bound the scalar derivative ℓ' using the Lipschitz constant, and the boundedness of the kernel map [cf. (26)]. The final strict inequality in (37) comes from applying the step-size condition $\eta_0 < 1/\lambda$.

Now we consider the induction step. Given the induction hypothesis $\|f_t\|_{\mathcal{H}} \leq CX/\lambda$, consider the magnitude of the iterate at the time $t+1$ as

$$\begin{aligned}\|f_{t+1}\|_{\mathcal{H}} &= \left\|\mathcal{P}_{\mathcal{H}_{\mathbf{D}_{t+1}}}\left[(1-\eta_t\lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t)\right]\right\|_{\mathcal{H}} \\ &\leq \|(1-\eta_t\lambda) f_t - \eta_t \nabla_f \ell(f_t(\mathbf{x}_t), y_t)\|_{\mathcal{H}} \\ &\leq (1-\eta_t\lambda)\|f_t\| + \eta_t \|\nabla_f \ell(f_t(\mathbf{x}_t), y_t)\|_{\mathcal{H}}\,,\end{aligned} \tag{38}$$

where we have applied the non-expansion property of the projection operator for the first inequality on the right-hand side of (38), and the triangle inequality for the second. Now,

apply the induction hypothesis $\|f_t\|_{\mathcal{H}} \leq CX/\lambda$ to the first term on the right-hand side of (38), and the chain rule together with the triangle inequality to the second to obtain

$$\begin{aligned}\|f_{t+1}\|_{\mathcal{H}} &\leq (1-\eta_t\lambda)\frac{CX}{\lambda} + \eta_t|\ell'(f_t(\mathbf{x}_t),y_t)|\|\kappa(\mathbf{x}_t,\cdot)\|_{\mathcal{H}} \\ &\leq (\frac{1}{\lambda}-\eta_t)CX + \eta_t CX = \frac{CX}{\lambda} \end{aligned} \tag{39}$$

where we have made use of Assumptions 1 and 2 to bound the scalar derivative ℓ' using the Lipschitz constant, and the boundedness of the kernel map [cf. (26)] as in the base case for f_1, as well as the fact that $\eta_t < 1/\lambda$. The same bound holds for f^* by applying the result of Section V-B of Kivinen et al. (2004) with $m \to \infty$.

■

Next we introduce a proposition which quantifies the error due to our sparse stochastic projection scheme in terms of the ratio of the sparse approximation budget to the algorithm step-size.

Proposition 8 *Given independent identical realizations $(\mathbf{x}_t, y_t)$ of the random pair $(\mathbf{x}, y)$, the difference between the projected stochastic functional gradient and the stochastic functional gradient of the regularized instantaneous risk defined by* (23) *and* (22)*, respectively, is bounded for all t as*

$$\|\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t) - \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\|_{\mathcal{H}} \leq \frac{\epsilon_t}{\eta_t} \tag{40}$$

where $\eta_t > 0$ denotes the algorithm step-size and $\epsilon_t > 0$ is the approximation budget parameter of Algorithm 1.

Proof: Consider the square-Hilbert-norm difference of $\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)$ and $\hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)$ defined in (22) and (23), respectively,

$$\begin{aligned}&\|\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t) - \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\|_{\mathcal{H}}^2 \\ &\quad= \left\| \Big(f_t - \mathcal{P}_{\mathcal{H}_{\mathbf{D}_{t+1}}}\Big[f_t - \eta_t \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\Big]\Big)/\eta_t - \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\right\|_{\mathcal{H}}^2 \end{aligned} \tag{41}$$

Multiply and divide $\hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)$, the last term, by η_t, and reorder terms to write

$$\begin{aligned}&\left\| \Big(f_t - \mathcal{P}_{\mathcal{H}_{\mathbf{D}_{t+1}}}\Big[f_t - \eta_t \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\Big]\Big)/\eta_t - \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\right\|_{\mathcal{H}}^2 \\ &\quad= \left\| \frac{1}{\eta_t}\Big(f_t - \eta_t \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\Big) - \frac{1}{\eta_t}\mathcal{P}_{\mathcal{H}_{\mathbf{D}_{t+1}}}\Big[f_t - \eta_t \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\Big]\right\|_{\mathcal{H}}^2 \\ &\quad= \frac{1}{\eta_t^2}\|\tilde{f}_{t+1} - f_{t+1}\|_{\mathcal{H}}^2 \end{aligned} \tag{42}$$

where we have substituted the definition of $\tilde{f}_{t+1}$ and f_{t+1} in (17) and (15), respectively, and pulled the nonnegative scalar η_t outside the norm. Now, observe that the KOMP residual stopping criterion in Algorithm 1 is $\|\tilde{f}_{t+1} - f_{t+1}\|_{\mathcal{H}} \leq \epsilon_t$, which we may apply to the last term on the right-hand side of (42) to conclude (40).

■

Lemma 9 *(Stochastic Descent) Consider the sequence generated $\{f_t\}$ by Algorithm 2 with $f_0 = 0$. Under Assumptions 1-4, the following expected descent relation holds.*

$$\mathbb{E}\left[\|f_{t+1} - f^*\|_{\mathcal{H}}^2 \,\middle|\, \mathcal{F}_t\right] \leq \|f_t - f^*\|_{\mathcal{H}}^2 - 2\eta_t[R(f_t) - R(f^*)] + 2\epsilon_t\|f_t - f^*\|_{\mathcal{H}} + \eta_t^2\sigma^2 \,. \tag{43}$$

Proof: Begin by considering the square of the Hilbert-norm difference between f_{t+1} and f^* defined by (1), and expand the square to write

$$\begin{aligned}\|f_{t+1} - f^*\|_{\mathcal{H}}^2 &= \|f_t - \eta_t\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\|_{\mathcal{H}}^2 \\ &= \|f_t - f^*\|_{\mathcal{H}}^2 - 2\eta_t\langle f_t - f^*, \tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\rangle_{\mathcal{H}} + \eta_t^2\|\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\|_{\mathcal{H}}^2 \end{aligned} \tag{44}$$

Add and subtract the gradient of the regularized instantaneous risk $\hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)$ defined in (22) to the second term on the right-hand side of (44) to obtain

$$\begin{aligned}\|f_{t+1} - f^*\|_{\mathcal{H}}^2 = \|f_t - f^*\|_{\mathcal{H}}^2 &- 2\eta_t\langle f_t - f^*, \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\rangle_{\mathcal{H}} \\ &- 2\eta_t\langle f_t - f^*, \tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t) - \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\rangle_{\mathcal{H}} + \eta_t^2\|\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\|_{\mathcal{H}}^2 \end{aligned} \tag{45}$$

We deal with the third term on the right-hand side of (45), which represents the directional error associated with the sparse stochastic projections, by applying the Cauchy-Schwartz inequality together with Proposition 8 to obtain

$$\begin{aligned}\|f_{t+1} - f^*\|_{\mathcal{H}}^2 \leq \|f_t - f^*\|_{\mathcal{H}}^2 &- 2\eta_t\langle f_t - f^*, \hat{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\rangle_{\mathcal{H}} \\ &+ 2\epsilon_t\|f_t - f^*\|_{\mathcal{H}} + \eta_t^2\|\tilde{\nabla}_f \ell(f_t(\mathbf{x}_t),y_t)\|_{\mathcal{H}}^2 \end{aligned} \tag{46}$$

Now compute the expectation of (46) conditional on the algorithm history $\mathcal{F}_t$

$$\mathbb{E}\left[\|f_{t+1} - f^*\|_{\mathcal{H}}^2 \,\middle|\, \mathcal{F}_t\right] \leq \|f_t - f^*\|_{\mathcal{H}}^2 - 2\eta_t\langle f_t - f^*, \nabla_f R(f_t)\rangle_{\mathcal{H}} + 2\epsilon_t\|f_t - f^*\|_{\mathcal{H}} + \eta_t^2\sigma^2 \,, \tag{47}$$

where we have applied the fact that the stochastic functional gradient in (22) is an unbiased estimator [cf. (25)] for the functional gradient of the expected risk in (1), as well as the fact that the variance of the functional projected stochastic gradient is finite stated in (28) (Assumption 4). Observe that since $R(f)$ is an expectation of a convex function, it is also convex, which allows us to write

$$R(f_t) - R(f^*) \leq \langle f_t - f^*, \nabla_f R(f_t)\rangle_{\mathcal{H}} \,, \tag{48}$$

which we substitute into the second term on the right-hand side of the relation given in (47) to obtain

$$\mathbb{E}\left[\|f_{t+1} - f^*\|_{\mathcal{H}}^2 \,\middle|\, \mathcal{F}_t\right] \leq \|f_t - f^*\|_{\mathcal{H}}^2 - 2\eta_t[R(f_t) - R(f^*)] + 2\epsilon_t\|f_t - f^*\|_{\mathcal{H}} + \eta_t^2\sigma^2 \,. \tag{49}$$

Thus the claim in Lemma 9 is valid. ■

Appendix B. Proof of Theorem 2

Apply the iterate bound stated in Proposition 7 to the third term on the right-hand side of (43) (Lemma 9) to write

$$\mathbb{E}\left[\|f_{t+1}-f^*\|_{\mathcal{H}}^2 \,\middle|\, \mathcal{F}_t\right] \leq \|f_t-f^*\|_{\mathcal{H}}^2 - 2\eta_t[R(f_t)-R(f^*)] + \eta_t^2\left(\frac{4CX}{\lambda}+\sigma^2\right) . \tag{50}$$

where we also have applied the approximation budget condition $\epsilon_t = \eta_t^2$. We use the relation in (50) to construct a martingale difference sequence. In particular, define the nonnegative stochastic processes α_t and β_t as

$$\alpha_t = \|f_t-f^*\|_{\mathcal{H}}^2 + \left(\frac{4CX}{\lambda}+\sigma^2\right)\sum_{u=t}^{\infty}\eta_u^2 , \qquad \beta_t = 2\eta_t[R(f_t)-R(f^*)] \tag{51}$$

Observe that α_t is finite almost surely, since $\sum_{u=t}^{\infty}\eta_u^2 \leq \sum_{u=0}^{\infty}\eta_u^2$. Given the definitions of α_t and β_t in (51), we may write

$$\mathbb{E}\left[\alpha_{t+1}\,\middle|\,\mathcal{F}_t\right] \leq \alpha_t - \beta_t , \tag{52}$$

together with the fact that α_t and β_t are nonnegative, whereby the conditions of the Supermartingale Convergence Theorem (Solo and Kong, 1995) are satisfied. Therefore, we obtain that (i) α_t has a finite limit almost surely; and (ii) the series $\sum_{t=1}^{\infty}\beta_t < \infty$ is almost surely finite. The later result, taken together with the non-summability of the step-sizes stated in (29), implies that the almost surely the limit infimum of $R(f_t)-R(f^*)$ is null, i.e.

$$\liminf_{t\to\infty} R(f_t)-R(f^*) = 0 \qquad \text{a.s.} \tag{53}$$

Now, using the consequence of the Supermartingale Convergence Theorem, α_t almost surely has a limit. Observe that the sum $\sum_{u=t}^{\infty}\eta_u^2$ is a deterministic quantity whose limit is null (we sum over less and less terms over time, asymptotically summing over zero terms). Taken with the finiteness of the limit of α_t, we conclude

$$\lim_{t\to\infty}\|f_t-f^*\|_{\mathcal{H}}^2 = 0 \qquad \text{a.s.} \tag{54}$$

Appendix C. Proof of Theorem 3

Proof: The use of the regularizing term $(\lambda/2)\|f\|_{\mathcal{H}}^2$ in (1) implies that the regularized expected risk is λ-strongly convex with respect to $f \in \mathcal{H}$, which allows us to write

$$\frac{\lambda}{2}\|f_t-f^*\|_{\mathcal{H}}^2 \leq R(f_t)-R(f^*) \tag{55}$$

Substituting the relation (55) into the second term on the right-hand side of the expected descent relation stated in Lemma 9, with constant step-size $\eta_t = \eta$ and approximation budget $\epsilon_t = \epsilon$, yields

$$\mathbb{E}\left[\|f_{t+1}-f^*\|_{\mathcal{H}}^2 \,\middle|\, \mathcal{F}_t\right] \leq (1-\eta\lambda)\|f_t-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_t-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 . \tag{56}$$

We use the expression in (56) to construct a stopping stochastic process, which tracks the suboptimality of $\|f_t-f^*\|_{\mathcal{H}}^2$ until it reaches a specific threshold. In doing so, we obtain convergence to a neighborhood. We aim to define a stochastic process δ_t that qualifies as a supermartingale, i.e. $\mathbb{E}\left[\delta_{t+1}\,\middle|\,\mathcal{F}_t\right] \leq \delta_t$. To do so, consider (56) and solve for the appropriate threshold by analyzing when the following holds true

$$\mathbb{E}\left[\|f_{t+1}-f^*\|_{\mathcal{H}}^2 \,\middle|\, \mathcal{F}_t\right] \leq (1-\eta\lambda)\|f_t-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_t-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 \leq \|f_t-f^*\|_{\mathcal{H}}^2 . \tag{57}$$

Re-arrange the above expression to obtain the sufficient condition

$$-\eta\lambda\|f_t-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_t-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 \leq 0 . \tag{58}$$

Observe that (58) defines a quadratic polynomial in $\|f_t-f^*\|_{\mathcal{H}}$, which, using the quadratic formula, has roots

$$\|f_t-f^*\|_{\mathcal{H}} = \frac{-2\epsilon \pm \sqrt{4\epsilon^2-(-4\lambda\eta)(\eta^2\sigma^2)}}{-2\lambda\eta} = \frac{\epsilon \pm \sqrt{\epsilon^2+\lambda\eta^3\sigma^2}}{\lambda\eta} \tag{59}$$

The quadratic polynomnial defined by (58) opens downward, and $\|f_t-f^*\|_{\mathcal{H}} \geq 0$, so we focus on the positive root, substituting the approximation budget selection $\epsilon = K\eta^{3/2}$ to define the radius of convergence as

$$\Delta := \frac{\epsilon+\sqrt{\epsilon^2+\lambda\eta^3\sigma^2}}{\lambda\eta} = \frac{\sqrt{\eta}}{\lambda}\left(K+\sqrt{K^2+\lambda\sigma^2}\right) \tag{60}$$

The definition (60) allows us to construct a stopping process. In particular, define the stochastic process δ_t as

$$\delta_t = \|f_t-f^*\|_{\mathcal{H}}\mathbb{1}\left\{\min_{u\leq t} -\eta\lambda\|f_u-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_u-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 > \Delta\right\} \tag{61}$$

where $\mathbb{1}\{E\}$ denotes the indicator process of event $E \in \mathcal{F}_t$. Note that $\delta_t \geq 0$ for all t, since both $\|f_t-f^*\|_{\mathcal{H}}$ and the indicator function are nonnegative. Observe that, given the definition (61), either $\min_{u\leq t} -\eta\lambda\|f_u-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_u-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 > \Delta$ holds, in which case we may compute the square root of the condition in (57) to write

$$\mathbb{E}[\delta_{t+1}\,|\,\mathcal{F}_t] \leq \delta_t \tag{62}$$

Alternatively, $\min_{u\leq t} -\eta\lambda\|f_u-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_u-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 \leq \Delta$, in which case the indicator function is null for all subsequent times, due to the use of the minimum inside the indicator in the definition of (61). Thus in either case, (62) holds, which implies that δ_t converges almost surely to null, which, as a consequence we obtain the fact that either $\lim_{t\to\infty}\|f_t-f^*\|_{\mathcal{H}} - \Delta = 0$ or the indicator function is null for large t, i.e. $\lim_{t\to\infty}\mathbb{1}\{\min_{u\leq t} -\eta\lambda\|f_u-f^*\|_{\mathcal{H}}^2 + 2\epsilon\|f_u-f^*\|_{\mathcal{H}} + \eta^2\sigma^2 > \Delta\} = 0$ almost surely. Therefore, we obtain that

$$\liminf_{t\to\infty}\|f_t-f^*\|_{\mathcal{H}} \leq \Delta = \frac{\sqrt{\eta}}{\lambda}\left(K+\sqrt{K^2+\lambda\sigma^2}\right) \qquad \text{a.s.} \tag{63}$$

which is as stated in Theorem 3. ■

Appendix D. Proofs Leading to Theorem 4

Before proving Theorem D, we present a lemma which allows us to relate the stopping criterion of our sparsification procedure to a Hilbert subspace distance.

Lemma 10 *Define the distance of an arbitrary feature vector* $\mathbf{x}$ *evaluated by the feature transformation* $\phi(\mathbf{x}) = \kappa(\mathbf{x}, \cdot)$ *to* $\mathcal{H}_{\mathbf{D}} = span\{\kappa(\mathbf{d}_n, \cdot)\}_{n=1}^{M}$*, the subspace of the Hilbert space spanned by a dictionary* $\mathbf{D}$ *of size* M*, as*

$$dist(\kappa(\mathbf{x}, \cdot), \mathcal{H}_{\mathbf{D}}) = \min_{f \in \mathcal{H}_{\mathbf{D}}} \|\kappa(\mathbf{x}, \cdot) - \mathbf{v}^T \boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\|_{\mathcal{H}} \,. \tag{64}$$

This set distance simplifies to following least-squares projection when $\mathbf{D} \in \mathbb{R}^{p \times M}$ *is fixed*

$$dist(\kappa(\mathbf{x}, \cdot), \mathcal{H}_{\mathbf{D}}) = \left\|\kappa(\mathbf{x}, \cdot) - [\mathbf{K}_{\mathbf{D},\mathbf{D}}^{-1} \boldsymbol{\kappa}_{\mathbf{D}}(\mathbf{x})]^T \boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\right\|_{\mathcal{H}} . \tag{65}$$

Proof: The distance to the subspace $\mathcal{H}_{\mathbf{D}}$ is defined as

$$\text{dist}(\kappa(\mathbf{x}, \cdot), \mathcal{H}_{\mathbf{D}_t}) = \min_{f \in \mathcal{H}_{\mathbf{D}}} \|\kappa(\mathbf{x}, \cdot) - \mathbf{v}^T \boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\|_{\mathcal{H}} = \min_{\mathbf{v} \in \mathbb{R}^M} \|\kappa(\mathbf{x}, \cdot) - \mathbf{v}^T \boldsymbol{\kappa}_{\mathbf{D}}(\cdot)\|_{\mathcal{H}} \,, \tag{66}$$

where the first equality comes from the fact that the dictionary $\mathbf{D}$ is fixed, so $\mathbf{v} \in \mathbb{R}^M$ is the only free parameter. Now plug in the minimizing weight vector $\tilde{\mathbf{v}}^* = \mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1} \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t)$ into (66) which is obtained in an analogous manner to the logic which yields (19) - (20). Doing so simplifies (66) to the following

$$\text{dist}(\kappa(\mathbf{x}_t, \cdot), \mathcal{H}_{\mathbf{D}_t}) = \left\|\kappa(\mathbf{x}_t, \cdot) - [\mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1} \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t)]^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)\right\|_{\mathcal{H}} . \tag{67}$$

■

D.1. Proof of Theorem 4

Proof: The proof proceeds by the following logic. We begin by considering the model order at two arbitrary subsequent iterates of Algorithm 2, and reduce model order growth at a given time to a criterion involving the approximation error γ_{M_t+1} associated with removing the most recent feature vector $\mathbf{x}_t$, and then analyze the conditions under which this simplified criterion is not satisfied for all subsequent times, meaning that the model order does not grow beyond a certain point. To do so, we prove that this quantity reduces to a weighted set distance to the Hilbert subspace $\mathcal{H}_{\mathbf{D}_t}$ defined by dictionary $\mathbf{D}_t$, and thus we are able to invoke point-set topological properties of the compact feature space $\mathcal{X}$, specifically, its packing number, which guarantee that the number of dictionary elements remains finite, in a manner similar to the proof of Theorem 3.1 in Engel et al. (2004).

Consider the model order of the function iterates f_t and f_{t+1} generated by Algorithm 2 denoted by M_t and M_{t+1}, respectively, at two arbitrary subsequent times t and $t+1$. Assume a constant algorithm step-size η has been chosen such that $\eta < 1/\lambda$ and the approximation budget ϵ satisfies $\epsilon = K\eta^{3/2}$ for some positive scalar $K > 0$. Suppose the model order of the function f_{t+1} is less than or equal to that of f_t, i.e. $M_{t+1} \leq M_t$. This relation holds when the stopping criterion of KOMP (Algorithm 1), stated as $\min_{j=1,\ldots,M_t+1} \gamma_j > \epsilon$, *is*

not satisfied for the kernel dictionary matrix with the newest sample point $\mathbf{x}_t$ appended: $\tilde{\mathbf{D}}_{t+1} = [\mathbf{D}_t; \mathbf{x}_t]$ [cf. (18)], which is of size $M_t + 1$. Thus, the negation of the termination condition of Algorithm 1 must hold for this case, stated as

$$\min_{j=1,\ldots,M_t+1} \gamma_j \leq \epsilon \,. \tag{68}$$

Observe that the left-hand side of (68) lower bounds the approximation error γ_{M_t+1} of removing the most recent feature vector $\mathbf{x}_t$ due to the minimization over j, that is, $\min_{j=1,\ldots,M_t+1} \gamma_j \leq \gamma_{M_t+1}$. Consequently, if $\gamma_{M_t+1} \leq \epsilon$, then (68) holds and the model order does not grow. Thus it suffices to consider γ_{M_t+1}.

The definition of γ_{M_t+1} with the substitution of $\tilde{f}_{t+1}$ in (17) allows us to write

$$\begin{aligned}\gamma_{M_t+1} &= \min_{\mathbf{u} \in \mathbb{R}^{M_t}} \left\|(1-\eta\lambda) f_t - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot) - \sum_{k \in \mathcal{I} \setminus \{M_t+1\}} u_k \kappa(\mathbf{d}_k, \cdot)\right\|_{\mathcal{H}} \\ &= \min_{\mathbf{u} \in \mathbb{R}^{M_t}} \left\|(1-\eta\lambda) \sum_{k \in \mathcal{I} \setminus \{M_t+1\}} w_k \kappa(\mathbf{d}_k, \cdot) - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot) - \sum_{k \in \mathcal{I} \setminus \{M_t+1\}} u_k \kappa(\mathbf{d}_k, \cdot)\right\|_{\mathcal{H}} ,\end{aligned} \tag{69}$$

where we denote the k^{th} column of $\mathbf{D}_t$ as $\mathbf{d}_k$. The minimal error is achieved by considering the square of the expression inside the minimization and expanding terms to obtain

$$\begin{aligned}&\left\|(1-\eta\lambda) \sum_{k \in \mathcal{I} \setminus \{M_t+1\}} w_k \kappa(\mathbf{d}_k, \cdot) - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot) - \sum_{k \in \mathcal{I} \setminus \{M_t+1\}} u_k \kappa(\mathbf{d}_k, \cdot)\right\|_{\mathcal{H}}^2 \\ &= (1-\eta\lambda)^2 \mathbf{w}^T \mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t} \mathbf{w} + \eta^2 \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)^2 \kappa(\mathbf{x}_t, \mathbf{x}_t) + \mathbf{u}^T \mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t} \mathbf{u} \\ &\quad - 2(1-\eta\lambda)\eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)^2 \mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t) + 2\eta^2 \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t) \mathbf{u}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t) - 2(1-\eta\lambda) \mathbf{w}^T \mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t} \mathbf{u}.\end{aligned} \tag{70}$$

To obtain the minimum, we compute the stationary solution of (70) with respect to $\mathbf{u} \in \mathbb{R}^{M_t}$ and solve for the minimizing $\tilde{\mathbf{u}}^*$, which in a manner similar to the logic in (19) - (20), is given as

$$\tilde{\mathbf{u}}^* = (1-\eta\lambda)\mathbf{w} - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t) \mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1} \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t) \,. \tag{71}$$

Plug $\tilde{\mathbf{u}}^*$ in (71) into the expression in (69) and using the short-hand notation $f_t(\cdot) = \mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)$ and $\sum_k u_k \kappa(\mathbf{d}_k, \cdot) = \mathbf{u}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)$. Doing so simplifies (69) to

$$\begin{aligned}&\left\|(1-\eta\lambda)\mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot) - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot) - \mathbf{u}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)\right\|_{\mathcal{H}} \\ &= \Big\|(1-\eta\lambda)\mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot) - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot) \\ &\quad - [(1-\eta\lambda)\mathbf{w} - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t) \mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1} \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t)]^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)\Big\|_{\mathcal{H}}.\end{aligned} \tag{72}$$

The above expression may be simplified by cancelling like terms $(1-\eta\lambda)\mathbf{w}^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)$ and pulling out a common factor of $\eta|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|$ outside the norm as

$$\begin{aligned}&\Big\| - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)\kappa(\mathbf{x}_t, \cdot) - \eta \ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)[\mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1} \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t)]^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)\Big\|_{\mathcal{H}} \\ &\qquad = \eta|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)| \left\|\kappa(\mathbf{x}_t, \cdot) - [\mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1} \boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t)]^T \boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)\right\|_{\mathcal{H}} .\end{aligned} \tag{73}$$

Notice that the right-hand side of (73) may be identified as the distance to the subspace $\mathcal{H}_{\mathbf{D}_t}$ in (67) defined in Lemma 10 scaled by a factor of $\eta|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|$. We may upper-bound the right-hand side of (73) as

$$\eta|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|\left\|\kappa(\mathbf{x}_t, \cdot) - [\mathbf{K}_{\mathbf{D}_t,\mathbf{D}_t}^{-1}\boldsymbol{\kappa}_{\mathbf{D}_t}(\mathbf{x}_t)]^T\boldsymbol{\kappa}_{\mathbf{D}_t}(\cdot)\right\|_{\mathcal{H}} \leq \eta|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|\text{dist}(\kappa(\mathbf{x}_t, \cdot), \mathcal{H}_{\mathbf{D}_t}) \tag{74}$$

where we have applied (65) regarding the definition of the subspace distance on the right-hand side of (74) to replace the Hilbert-norm term. Now, when the KOMP stopping criterion is violated, i.e., (68) holds, which implies $\gamma_{M_t+1} \leq \epsilon$. Therefore, the right-hand side of (74) is upper-bounded by ϵ, which we select as $\epsilon = K\eta^{3/2}$.

$$\text{dist}(\kappa(\mathbf{x}_t, \cdot), \mathcal{H}_{\mathbf{D}_t}) \leq \frac{K\sqrt{\eta}}{|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|}\ , \tag{75}$$

where we have divided both sides by $|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|$ and cancelled out a common factor of η. Observe that if (75) holds, then $\gamma_{M_t+1} \leq \epsilon$ holds, but since $\gamma_{M_t+1} \geq \min_j \gamma_j$, we may conclude that (68) is satisfied. Consequently the model order at the subsequent step does not grow $M_{t+1} \leq M_t$ whenever (75) is valid.

Now, let's take the contrapositive of the preceding expressions to observe that growth in the model order ($M_{t+1} = M_t + 1$) implies that the condition

$$\text{dist}(\kappa(\mathbf{x}_t, \cdot), \mathcal{H}_{\mathbf{D}_t}) > \frac{K\sqrt{\eta}}{|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|} \tag{76}$$

holds. Therefore, each time a new point is added to the model, the corresponding kernel function is guaranteed to be at least a distance of $\frac{K\sqrt{\eta}}{|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|}$ from every other kernel function in the current model.

By the C-Lipschitz continuity of the instantaneous loss (Assumption 2): specifically $1/|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)| \geq 1/C$, we can lower-bound the threshold condition in (76) as

$$\frac{K\sqrt{\eta}}{|\ell'(f_t(\mathbf{x}_t), \mathbf{y}_t)|} \geq \frac{K\sqrt{\eta}}{C} \tag{77}$$

Therefore, the KOMP stopping criterion is violated for the newest point whenever distinct dictionary points $\mathbf{d}_k$ and $\mathbf{d}_j$ for $j, k \in \{1, \ldots, M_t\}$, satisfy the condition $\|\phi(\mathbf{d}_j) - \phi(\mathbf{d}_k)\|_2 > \frac{K\sqrt{\eta}}{C}$. We shall now proceed in a manner similar to the proof of Theorem 3.1 in Engel et al. (2004). Since $\mathcal{X}$ is compact and κ is continuous, the range $\phi(\mathcal{X})$ (where $\phi(\mathbf{x}) = \kappa(\mathbf{x}, \cdot)$ for $\mathbf{x} \in \mathcal{X}$) of the kernel transformation of feature space $\mathcal{X}$ is compact. Therefore, the number of balls of radius δ (here, $\delta = \frac{K\sqrt{\eta}}{C}$) needed to cover the set $\phi(\mathcal{X})$ is finite (see, e.g., Anthony and Bartlett (2009)). Therefore, for some finite M^∞, if $M_t = M^\infty$, the left-hand side of (**??**) holds, which implies (68) is true for all t. We conclude that $M_t \leq M^\infty$ for all t. ■

Abstract

In this paper we propose a modified version of the simulated annealing algorithm for solving a stochastic global optimization problem. More precisely, we address the problem of finding a global minimizer of a function with noisy evaluations. We provide a rate of convergence and its optimized parametrization to ensure a minimal number of evaluations for a given accuracy and a confidence level close to 1. This work is completed with a set of numerical experimentations and assesses the practical performance both on benchmark test cases and on real world examples.

Keywords: Simulated Annealing, Stochastic Optimization, Markov Process, Convergence Rate, Aircraft Trajectory Optimization

1. Introduction

We are interested in an algorithm that solves the stochastic global optimization problem:

$$\text{Find} \quad x^\star = \arg\min_{x \in E} \mathbb{E}_\omega(U(x,\omega)), \tag{*}$$

where x is a decision variable belonging to some large space E, ω is a random variable and U is the cost, a positive and bounded real valued function. We do not make any assumption on the regularity of U. We only expect it to be rapidly evaluable: typically, U is the result of some short numerical simulation. We do not make any distribution assumption for the random inputs ω themselves but only on the outputs U. We assume the code has some robustness property in the sense that, at some point x, it is either infinite for all ω or bounded uniformly in ω.
This problem is twofold: we must both estimate and minimize the expectation of the cost. A simple and general approach consists in the minimization of a sample average of Monte Carlo estimators:

$$\widehat{\mathbb{E}}_{\omega,N}(U(x,\omega)) := \frac{1}{N}\sum_{i=1}^{N} U(x,\omega_i),$$

for any given i.i.d. sample $(\omega_i)_{1\leq i\leq N}$ of size N distributed according to the distribution $P_\Omega(x)$ of ω and for any $x \in E$. Such an estimator consistently estimates $\mathbb{E}_\omega(U(x,\omega))$ for any given x. Nevertheless, its accuracy is directly linked to N and thus to the computational effort. One can thus wonder if a computationally efficient procedure using that estimator can return a solution to the initial problem given a certain level of accuracy ϵ.

1.1. Previous Works: Different Types of Algorithms

There were many attempts to solve this stochastic problem across several research communities. We give a brief survey of them in what follows.
In the case E is finite and U takes its values in $[0,1]$, problem (*) is labelled as a "simple regret bandit optimization problem" by the bandit community. Indeed it can be seen as the problem of choosing, among a small finite set of slot machines providing random rewards, the one with the best expected reward by playing a minimal number of times. This is not the classical setting of bandit optimization which usually seeks for the "cumulative regret". As algorithm proposals for the simple regret context often extends cumulative regret concepts (Audibert and Bubeck, 2010), we focus on them first. The Upper Confidence Bound (UCB, Auer et al. 2002) algorithm aimed at building sequences of confidence bounds around the estimated expected cost of each element of the search space. If the space is too large this can be prohibitive. These were several attempts to bypass this issue by adding some assumptions on the regularity of the cost function around its optimum. We can mention HOO (Bubeck et al., 2011) that produced guarantees about the cumulative regret for a continuous Lipschitz cost function with known Lipschitz constant. In the same framework StoSOO (Munos, 2014) relaxed this last assumption. Both algorithms were however not very efficient in practice if the search space is multidimensional. Indeed they still required some uniform exploration of the state space in the first phase. This could lead to numerical difficulties when the dimension was growing. The Adaptive-treed bandit algorithm (Bull et al., 2015) partially solved this issue by adapting the exploration step using a Lipschitz constant per dimension.
These algorithms could all be viewed as stochastic variations around the classical *branch and bound* algorithm (Little et al., 1963), which was extensively studied by the optimization community. We can mention the very popular DIRECT algorithm (Jones et al., 1993), from which the StoSOO procedure was inspired.
Finally, let us mention the computer experiment community that introduced another popular global optimization method for dealing with the stochastic case, the so called Efficient Global Optimization (EGO, Jones et al. 1998) based on expected improvement. The convergence rate of this method was already investigated in Bull (2011) in a noise free context. This algorithm focused on minimizing the number of cost evaluations because it considered a setting where the cost evaluations were very time consuming. As a result, in order to select each evaluation point, it required a higher computational effort and memory storage per iteration than other optimization methods. Such a method could therefore turn out to under-perform in a setting where the computational cost ratio between selection and evaluation was inverted.
A typical algorithm that was known to perform well in the case of time-cheap cost evaluations was the simulated annealing (SA) as mentioned by Locatelli in Horst and Pardalos

(2013): *"The latter algorithms* (mainly EGO) *often outperform SA algorithms from the point of view of the number of function evaluations to reach a given relative accuracy on the standard test functions from Dixon and Szegö (1978), but usually require a higher computational effort per iteration. Typical advantages of SA algorithms are their very mild memory requirements and the small computational effort per iteration. If the cost of a function evaluation is very high, then even a considerable computational effort per iteration may be negligible with respect to the cost of a function evaluation, and algorithms which require few function evaluations are preferable; otherwise, also the computational effort per iteration should be taken into account, and from this point of view SA algorithms are often better than other algorithms."*

However SA algorithms have been designed and extensively studied in a context where the exact cost could be observed. We recall below some basic facts in the noiseless case (Section 1.2) and then present the noisy case which is the setting addressed in this paper (Section 1.3).

1.2. Simulated Annealing without Noise

Let E be some finite search space and $J : E \to \mathbb{R}_+$ a function that we want to minimize, called cost thereafter.

Simulated Annealing is a classical global optimization method. It aims at building a sequence of elements from E whose last element is drawn from a uniform probability law on the subset of *global* minima of J. In other words it aims at sampling from the following distribution

$$\mu^\star = \frac{\mathbb{1}_{S_{opt}}}{|S_{opt}|} ,$$

where $S_{opt} = \{x, J(x) = \min_{y\in E} J(y)\}$ and $|.|$ denotes the cardinality of a set. Such a sampling is of course not straightforward but one can notice that this distribution can be rewritten in the following form:

$$\forall x \in E,\ \mu^\star(x) = \lim_{T\to 0} \frac{e^{\frac{-J(x)}{T}}}{\sum_{y\in E} e^{\frac{-J(y)}{T}}} ,$$

and it is well-known that the Gibbs distributions of the form $\mu_T = e^{\frac{-J}{T}} / \sum e^{\frac{-J}{T}}$ are efficiently sampled for reasonably low temperatures $T \in \mathbb{R}_+$ using the Metropolis-Hastings algorithm (Aarts and Korst, 1988). A quite natural attempt is therefore to build a sequence of sequences obtained using Metropolis-Hastings algorithm for a set of decreasing temperatures. In particular, at a very low temperature, the Metropolis-Hastings algorithm generates exploratory moves that are accepted with very low probabilities, which makes it a very bad sampler. Therefore it is necessary to first encourage exploration by using a sampling at higher temperatures. A lower bound on the temperature at each step ensuring a convergence in probability of the algorithm has been provided by Hajek (1988). At the same time another proof of convergence using modern semi-group representation of Markov processes has been obtained by Holley and Stroock (1988). The obtained bounds are less explicit but contain information about the convergence rate and the proof scheme is much more general. We set our work in the continuity of this last work and use similar notations.

1.3. Simulated Annealing with Noisy Evaluations

As mentioned previously, our main interest is to extend such a method of simulated annealing to the stochastic case:

$$\text{Find} \quad x^\star = \arg\min_{x\in E} \mathbb{E}_\omega(U(x,\omega))$$

where ω is a random input of a bounded cost function U whose expectation can only be numerically estimated through Monte Carlo simulations. In other words, we consider $J(.) = \mathbb{E}_\omega(U(.,\omega))$. This question is not novel and several attempts were made to address this problem theoretically in the 90's. Gelfand and Mitter (1989) were probably the first ones to introduce the notion of simulated annealing with noisy measurements. They assumed an additive Gaussian noise independent of the evaluation point and gave a sufficient condition for the decrease of the variance σ_k^2 of this noise, to ensure convergence of the algorithm to the optimal set. Gutjahr and Pflug (1996) extended the results to distributions that are more peaked around zero than the Gaussian distribution. Their convergence result can be stated roughly as follows:

Theorem 1 (Gutjahr and Pflug 1996) *Let $(X_k)_{k\in\mathbb{N}}$ denote the sequence of states in E visited by the simulated annealing algorithm with Monte Carlo sampling of the noisy measurements. If:*

(i) the convergence conditions from (Hajek, 1988) are satisfied

(ii) $\exists\epsilon > 0$ such that the standard error of the noise at step k of the algorithm $\sigma_k^2 = \mathcal{O}(k^{-(2+\epsilon)})$

then $\forall x \in E$, $\lim_{k\to+\infty} \mathbb{P}(X_k = x) = \mu^\star(x)$, where $\mu^\star$ is the uniform distribution on the global minima of the expected cost. ■

This result provided a first answer to our question about the convergence of the algorithm in the stochastic case. However the convergence statement above did not give any information about the convergence rate of the algorithm. Following the noise-free proof of Aarts and Korst (1988), Homem-de Mello (2000) provided an extension of this statement to the noisy case with bounded variance and introducing a state dependent noise. He obtained the same constraint on the decrease of the variance and the same convergence statement. He also highlighted the need for an extended result concerning the rate of convergence and for numerical experiments. Indeed on this second point we can mention the works of Fink (1998) and Branke et al. (2008) that addressed this issue. Fink (1998) made a very interesting proposition in the framework of Gaussian noise. He proposed to use the noise of measurement to drive the simulated annealing, *i.e.*, accept a move if the estimated cost of the proposed solution is lower than the one of the current solution. Using an analogy with the Glauber acceptance mechanism, which is a symmetric alternative to the Metropolis-Hasting mechanism (Aarts and Korst, 1988), he proposed a far more efficient criteria for the variance decrease, *i.e.*, $\sigma_k = \mathcal{O}(log(k)^{-2})$. Unfortunately he only provided a few numerical examples to validate his statement and a theoretical proof is still missing.

1.4. Main Contributions

In this paper we consider a simulated annealing algorithm based on mini-batches of increasing size. More precisely, at each iteration, the expected cost is estimated by Monte Carlo sampling of increasing sizes. The estimated cost at step k of the algorithm is thus $\widehat{\mathbb{E}}_\omega(U(x_k,\omega)) = 1/N_k \sum_{i=1}^{N_k} U(x_k,\omega_i)$, where N_k is an increasing sequence and ω_i are i.i.d. random variables having the same law as ω. The cost can be written also as $\widehat{\mathbb{E}}_\omega(U(x_k,\omega)) = \mathbb{E}_\omega(U(x_k,\omega)) + \zeta_\omega(x_k)$, where $\zeta_\omega(x_k)$ is some bounded random variable. We denote $\sigma_k^2 := \mathrm{Var}(\zeta_\omega(x_k))$, the variance of post-sampling noise. As it is directly linked to the number of measurements made during the mini-batch, it can be tuned by the user.

Rate of convergence for all variances of polynomial decay. In the sequel we first show that theoretical guarantees of Theorem 1 can be extended to sub-Gaussian random variables (e.g., bounded noise distributions) with stronger convergence results for this algorithm. Indeed we show that convergence can be ensured if the number of measurements is chosen such that $\sigma_k = \mathcal{O}(k^{-(\alpha/2)})$ with $\alpha > 0$, which corresponds to N_k of the order k^α. One can observe that, as opposed to Gutjahr and Pflug (1996), the convergence still holds for $\alpha \leq 2$. This is summarized in Theorem 3.

We derive the rate of convergence of the procedure (Theorem 5) and optimize it (Corollary 1) with respect to the noisy simulated annealing algorithm parameters in order to provide a minimal total number of measurements at given accuracy and confidence requirements. This leads to the optimal value $\alpha = 2$ for which the number of cost evaluations increases fast enough to ensure almost the same convergence rate as in the noise-free case. This shows that the convergence rate is limited by the concentration speed of the Gibbs measure around its modes. According to our concentration result, increasing the estimation effort cannot increase the performance of the algorithm above this limit. On the other hand the convergence still holds for a decreased estimation effort ($\alpha < 2$) as soon as the cooling schedule is slowed consequently.

Computational cost in the general case. Finally, we derive an upper bound on the computational time-complexity of our simulated annealing algorithm (with noisy measurements). This quantity is roughly of the order of:

$$e^{\frac{C_1 \log \frac{1}{\delta}}{\epsilon}},$$

where C_1 is some constant depending on the cost function itself as detailed in Corollary 1. The provided bound exhibit an exponential dependency in $1/\epsilon$ and $\log 1/\delta$. This is comprehensive regarding the generality of the considered problem.

Computational cost in the absence of local minimum If the function has no local minimum apart from the global minimum (e.g., a convex function evaluated on a finite set) the temperature schedule can be adapted and the computational cost becomes of the order of:

$$\left(\frac{C_2 \log \frac{1}{\delta}}{\epsilon}\right)^3,$$

where C_2 is a constant detailed in Corollary 2. This second bound increases in a polynomial way with respect to $1/\epsilon$ and $\log 1/\delta$. This is a very positive result as it shows that the noisy simulated annealing algorithm recovers the state-of-the-art convergence guaranties if stronger hypotheses on the cost are considered.

Numerical experiments. We provide numerical evidence indicating that the numerically observed requirements in Fink (1998), *i.e.*, $\sigma_k = \mathcal{O}(\log(k))$, do not hold for a Metropolis-Hastings Acceptance criteria. We apply the noisy simulated annealing on classical non convex optimization test cases with different level of noise, but also perform a test on a real-world example, *i.e.*, an aircraft trajectory optimization problem using a black-box aircraft performance model.

1.5. Aircraft Trajectory Optimization

As a leading example for this setting, we consider the problem of optimizing commercial aircraft trajectories with respect to a combination of fuel consumption and flight duration:.

$$\begin{aligned} \text{Find } u^\star = \arg\min_u\ & g(x(t_f),t_f) + \int_{t_0}^{t_f} -\dot{m}(x(s),u(s))ds \\ s.t.\ \forall t > t_0\ & \dot{x}(t) = f(x(t),u(t)) \\ & x(t_0) = x_0 \\ & d(t_f) = d_f, \end{aligned}$$

where x is the state of the aircraft, m its mass, $\dot{m}$ its instantaneous fuel consumption, d the ground distance it has flown over, u the path control, f the instantaneous dynamic and g the terminal cost function. The path control u is the combination of the thrust rating δ_T and the lift coefficient C_l.

$$u = \begin{pmatrix} C_l \\ \delta_T \end{pmatrix}$$

Estimates of the cost of trajectories are usually obtained through numerical integration of the flight dynamic equations, f:

$$\dot{x} = \begin{pmatrix} \dot{V} \\ \dot{\gamma} \\ \dot{h} \\ \dot{d} \\ \dot{m} \end{pmatrix} = \begin{pmatrix} (T(h,V,\delta_T) - D(h,V,C_L))\frac{1}{m} - g\sin\gamma \\ (L(h,V,C_L) - mg\cos\gamma)\frac{1}{mV} \\ V\sin(\gamma) \\ V\cos(\gamma) \\ \eta T(h,V) \end{pmatrix}$$

where T is the thrust, D the drag, L the lift, η the specific fuel consumption, γ the path angle, V the speed of the aircraft and h its height. These equations involve some terms

like the aerodynamic drag coefficient (C_D) or maximal propulsion effort (T_{max}) who are estimated using interpolation of experimental local measurements.

$$T(h, V, \delta_T) = \delta_T T_{max}(h, V)$$
$$L(h, V, C_L) = \frac{1}{2}\rho(h, V)SV^2 C_L$$
$$D(h, V, C_L) = \frac{1}{2}\rho(h, V)SV^2 C_D(C_L, V)$$

No analytic solution is therefore available nor conceivable. Moreover the relation between cost and trajectory control parameters cannot reasonably be assumed to be convex. At last, the cost estimation relies on some predicted flight conditions including atmospheric ones. Hence, real-flight costs can thus deviate substantially from their predictions and some uncertainty propagation method must be applied to obtain an accurate estimate of the expected flight costs. In other words the function we want to minimize can only be evaluated with a certain random error, which corresponds exactly to the setting of this paper. Finally, the computational efficiency is a key ingredient as it must be performed only a few hours before the planned flight. For more information about aircraft trajectory optimization we refer to Betts (1998).
This example completely fits our requirement as the computation of the cost of one single complete trajectory is quite fast, *i.e.*, less than a second. Therefore, the EGO algorithm (Jones et al., 1998) would not be suited for this application. On the other hand formulations based on the DIRECT algorithm (Jones et al., 1993) would suffer strongly from the dimension of the problem. An additional element that motivates the use of simulated annealing is the fact that in the case of trajectory optimization the set of admissible controls is not known in advance as it is path dependent. We can only ensure that this set is connected. This implies in particular that no projection on the constraints can be performed and excludes the projected stochastic gradient descent for example. In the case of simulated annealing, a very simple step can bypass this issue. By setting the value of the cost to infinity when the trajectory evaluator returns an error we ensure staying in the admissible domain. Consequently, a feasible solution and a conservative approximation of the admissible domain are the only requirements to initiate the algorithm in this setting.

1.6. Outline of the Paper

Our paper is organized as follows. In Section 2 we present the noisy simulated algorithm and our main theoretical result. In Sections 3, 4 and 5 we provide the proof of this statement. More precisely, in Section 3 we compute the infinitesimal generator of the noisy simulated annealing algorithm. In Section 4 we compare it to the one of the noise-free simulated annealing algorithm from Holley and Stroock (1988). This enables us to derive a differential inequality for a L^2 distance between the distributions of the two previously mentioned processes. Integrating by applying Grönwall's Lemma Section 5, we obtain obtain our convergence result. In the same section, we show how to tune the parameters of the algorithm in order to optimize the performance bound and give the corresponding computational cost. In Section 6 we propose some numerical insight on synthetic and real data experiments.

Acknowledgments.

We thank Sébastien Gadat for introducing this topic to us, making this collaboration possible and for fruitful discussions and helpful insights, and Sébastien Gerchinovitz for all his constructive advice and ideas.

2. Noisy Simulated Annealing Algorithm: Statement and Convergence Result

We first present our extended version of the simulated annealing to the stochastic case, whose pseudo-code can be found in Algorithm 1.

2.1. Noisy Simulated Annealing algorithm (NSA)

Algorithm 1 Noisy Simulated Annealing

procedure NSA(**Inputs:** Neighbourhoods structure $(S_x)_{x\in S}$, Initial guess x_0, increasing function $\beta : \mathbb{R}_+ \to \mathbb{R}_+$, Function $t \mapsto n_t$)

Initialize time $t_0 = 0$
$\beta_0 = \beta(t_0)$

for k from 0 to Maximal number of iterations **do**
Draw one solution candidate: $\widetilde{x}_{t_k} \in S_{x_{t_k}}$ according to $q_0(x_k, \cdot)$
Draw $N_{t_k} \sim \mathcal{P}oisson(n_{t_k}) + 1$
Draw $2N_{t_k}$ simulation conditions independently:
$(\omega_1^k, ..., \omega_{N_{t_k}}^k) \sim (P_\Omega(x_{t_k}))^{\otimes N_{t_k}}$ and $(\widetilde{\omega}_1^k, ..., \widetilde{\omega}_{N_{t_k}}^k) \sim (P_\Omega(\widetilde{x}_{t_k}))^{\otimes N_{t_k}}$
Compute estimates $\widehat{J}(x_t)$ and $\widehat{J}(\widetilde{x}_t)$ using the N_{t_k} conditions:
$\widehat{J}(x_{t_k}) = \frac{1}{N_{t_k}} \sum_{i=1}^{N_{t_k}} U(x_{t_k}, \omega_i^k)$,
$\widehat{J}(\widetilde{x}_{t_k}) = \frac{1}{N_{t_k}} \sum_{i=1}^{N_{t_k}} U(\widetilde{x}_{t_k}, \widetilde{\omega}_i^k)$

Draw an exponential random variable ξ_{k+1} of parameter 1
Update time $t_{k+1} := t_k + \xi_{k+1}$

With probability $e^{-\beta_k \lfloor \widehat{J}(\widetilde{x}_{t_k}) - \widehat{J}(x_{t_k}) \rfloor_+}$: [1]
set $x_{t_{k+1}} := \widetilde{x}_{t_k}$
Otherwise set $x_{t_{k+1}} := x_{t_k}$

Increase the inverse of the temperature $\beta_{k+1} := \beta(t_{k+1})$
end for
return $x_{t_{k+1}}$
end procedure

[1] $\lfloor x \rfloor_+ = 0$ if $x \leq 0$ and x if not.

As in the deterministic setting, the algorithm requires an initial feasible solution x_{t_0}, a temperature schedule T_t (we will mostly use its inverse $\beta_t = 1/T_t$), and a good neighbourhood structure. What we mean by good will be specified in the definition of q_0. The algorithm explores the state space in the following manner. After k iterations, at time t_k, it selects a random neighbouring solution $\widetilde{x}_{t_k} \in S_{x_{t_k}}$ (S_{x_t} being the set of neighbours of x_{t_k}) according to a proposition law. Then it compares the estimate $\widehat{J}(\widetilde{x}_{t_k})$ of the cost of this new solution to the estimated cost $\widehat{J}(x_{t_k})$ of the current solution and then it decides to substitute (or not) the new to the current:

- if the estimated cost of the new state is lower than the current one, *i.e.*, $\widehat{J}(\widetilde{x}_{t_k}) \leq \widehat{J}(x_{t_k})$, the move is accepted, *i.e.*, $x_{t_{k+1}} \leftarrow \widetilde{x}_{t_k}$
- if not, it is only accepted with a probability $\exp(-\beta_{t_k}(\widehat{J}(\widetilde{x}_{t_k}) - \widehat{J}(x_{t_k}))$.

The time t is then updated using independent exponential random variables, enabling us to consider the NSA as a continuous time Markov process.

Remark 2 *As one can see in line 8 of Algorithm 1, the sample size at each step is random. This is a technical choice that will ease the convergence study of the underlying process. However in practice we did not observe any significant difference between using, at step k, a random sample size N_{t_k} and its expected value, namely $n_{t_k} + 1$.*

2.2. General Setting and Notations

To state the convergence of Algorithm 1, we first need to describe formally the framework we are working in. Notations introduced in this section are valid for the whole paper unless mentioned explicitly.

- Regarding the noise structure and the estimation procedure, we denote:

  $(\widehat{J})$ the estimated cost: $\widehat{J} : E \to \mathbb{R}_+$, such that $\forall\ x \in E, \widehat{J}(x) = \frac{1}{N}\sum_{i=1}^{N} U(x, \omega_i)$, where: $(\omega_1, ..., \omega_N)$ is a N i.i.d. vectors sequence drawn from distribution $P_\Omega(x)$

  (ξ_k) the time increments: $(\xi_k)_{k\in\mathbb{N}}$ is a sequence of i.i.d. exponential random variables of parameter 1

  (t_k) the jumping times: $\forall k \in\ \mathbb{N}, \quad t_k = \sum_{i=1}^{k} \xi_i$.

  (n_t) the samplig intensity: n_t a continuous increasing function.

  (N_{t_k}) the sample sizes: $N_{t_1}, N_{t_2}, \ldots N_{t_n}$ are independent for all $n \in \mathbb{N}$ and all $0 < t_1 < t_2 \ldots < t_n$ and

  $$N_{t_k} \sim \mathcal{P}oisson(n_{t_k}) + 1,$$

  We can make a few remarks about the different notations. The construction of N_t ensures that its value is a strictly positive integer at all times. The reason why we choose to have a randomly sized sample for the Monte Carlo estimation procedure is rather technical. It enables generating a continuous transition probability as it can be noticed in Equation (3) and ease the formulation of the infinitesimal generator (Equation (7)).

- About the state space, we denote:

  (E) a finite state space.

  (S) a neighbourhood structure such that E is connected with respect to it, *i.e.*, S is a connected graph containing all the points in E. For any x in E, we denote S_x the set of its direct neighbours.

  (μ_0) the initial distribution, a probability measure that charges every point of a subset of interest $E' \subset E$ defined more precisely in (U) ,

  (q_0) the proposition law, an irreducible and $\mu_0 - reversible$ transition probability, *i.e.*, $\forall x, y \in E$, $\sum_{n=0}^{\infty} q_0^{(n)}(x, y) = \infty$ and $\mu_0(x)q_0(x, y) = \mu_0(y)q_0(y, x)$. In addition we assume that for any x in E, we have $q_0(x, S_x) = 1$

  Considering a finite search space E enables us to easily derive the spectral gap inequality in Theorem 4 and overcome differentiation-under-the-integral-sign issues in Equation (15). Nevertheless, it could be replaced by coercivity assumptions on the function J, which could be more general but not really well suited for the application we are looking for. It is our most restrictive assumption. Nevertheless it is in line with previous works on noisy global optimization for example: Gutjahr and Pflug (1996), Homem-de Mello (2000) or Fink (1998). It corresponds to a historical use of simulated annealing for problems with huge finite search space like for the traveling salesman problem (Aarts and Korst, 1989). Mimicking Holley and Stroock (1988), we might however relax this assumption of finiteness. Nevertheless it requires more technicalities as in Aarts and Korst (1988) and this is left for future work.

  We assume that the algorithm can visit and start from every point in the solution space through the connection assumption S and the definition of μ_0. The proposition law q_0 defines the way a new solution $\widetilde{x}$ is proposed to the NSA at each iteration. The irreducibility of q_0 implies the fact that one can go from any state x to any other state y using the neighbourhood structure S, in a finite number of steps. The $\mu_0-reversibility$ is used to simplify the notations. A classical choice (Aarts and Korst, 1988) for q_0 and μ_0 is: $\forall\ x, y\ \in\ E,\ \mu_0(x) = \frac{1}{|E|}$ and $q_0(x, y) = \frac{1}{|S_x|}$, assuming every point in E to have the same number of neighbors. However there are other possible choices for μ_0 and q_0. This last two assumptions are inherited from the classical Metropolis-Hasting sampling algorithm which corresponds to the NSA algorithm with no cooling mechanism and no noise. They ensure that a run in this setting, starting from any point of the search space, converges to a stationary distribution which is the Gibbs measure associated to J.

- About the cost function, we consider:

  (U) the underlying cost: $\exists M > 0$ and $\exists E' \subset E$, such that U is bounded and non-negative on E', i.e. $\forall x\ \in\ E', \forall\omega$, $0 \leq U(x, \omega) \leq M$ and U is infinite on $E\backslash E'$, *i.e.*,$\forall x \in E\backslash E'$, $\forall\omega$, $U(x, \omega) = +\infty$.

The assumption about U being bounded is not restrictive. It reflects the practical setting where a simulation code crashes out of the definition domains. We associate infinite costs to crashes and thus (U) is rather a consequence of (E).

- About the algorithm parametrization, we denote

  (β_t) the inverse of the temperature: a positive increasing real function of t,

  (α) the sampling size (expected number of simulations): $\exists \alpha \in \mathbb{R}_+$ such that $n_t = (t+1)^\alpha$,

  β_t is usually chosen such that $\forall t \in \mathbb{R}_+$, $\frac{d\beta_t}{dt} = \frac{bd}{1+td}$ for some $b, d \in \mathbb{R}_+$, as it was shown by (Hajek, 1988) and (Holley and Stroock, 1988) to be a necessary condition to ensure the convergence of the simulated annealing algorithm for any cost function. There is no reason to expect that the noisy context would be more favorable than the deterministic one. As suggested by the definition of α, we choose a polynomial growth of the number of simulations for the cost estimation. We show later on in this work that this ensures the convergence of the noisy simulated annealing for a good choice of α and b.

2.3. Tool for the Analysis: the NSA Process

We now present the mathematical formalization of the NSA algorithm's underlying stochastic process. First, for pedagogical purposes, we omit the temperature evolution and noisy measurements. The NSA algorithm then becomes a simpler Markov chain exploring the state space E according to the Markovian transition matrix whose elements are of the form:

$$\mathbb{P}(x \to y) = q_\beta(x,y) = \begin{cases} q_0(x,y) e^{-\beta \lfloor J(y) - J(x) \rfloor_+} & \text{if } y \neq x \\ 1 - \sum\limits_{z \in E \setminus x} q_\beta(x,z) & \text{if } y = x, \end{cases} \tag{1}$$

This reflects the transition mechanism introduced at the beginning of this section. As the process is in fact a continuous one, we must also consider the time component. NSA jumps happen at stochastic times and the probability of acceptance depends on these times. Combining the law of the jumping times and the previous mechanism, we can make their joint transition probability explicit:

- Let $(\widetilde{\chi}_k, T_k)_{k \in \mathbb{N}}$ a $E \times \mathbb{R}_+$-valued Markov chain such that $\forall k \in \mathbb{N}$, $\forall y \in E$, $\forall u \in \mathbb{R}_+$:

$$\mathbb{P}(\widetilde{\chi}_{k+1} = y, T_{k+1} \geq u | \widetilde{\chi}_k, T_k) = \int_u^{+\infty} \widetilde{q}_{\beta_\tau}(\widetilde{\chi}_k, y) \mathbb{1}_{[T_k, +\infty[}(\tau) e^{-(\tau - T_k)} d\tau, \tag{2}$$

  where

$$\widetilde{q}_{\beta_t}(x,y) = \begin{cases} q_0(x,y) \mathbb{E}_{N_t} \mathbb{E}_{\omega_1, \ldots, \omega_{N_t}} \left(e^{-\frac{\beta_t}{N_t} \lfloor \sum_{i=1}^{N_t} U(y,\omega_i) - U(x,\omega_i) \rfloor_+} \right) & \text{if } y \neq x \\ 1 - \sum\limits_{x \neq z} \widetilde{q}_{\beta_t}(x,z) & \text{if } y = x \end{cases} \tag{3}$$

This is a similar construction to the one of the classical simulated annealing process (Hajek, 1988). The state transition mechanism must also reflect the estimation procedure, therefore the form of Equation (3) differs from Equation (1). As mentioned before the function $t \mapsto \beta_t$ represents the inverse of the temperature schedule and N_t is the random process described by N_{t_k}. The jumping times, or evaluation times of the process happen at times defined by the sequence T_k (*cf.* the definition of t_k).

The chain $(\widetilde{\chi}_k)_{k \geq 0}$ explores the state space E using a transition probability $\widetilde{q}_{\beta_t}$ constructed in a same way as the classical one, replacing the exact value of $-\beta_{T_k}(J(y) - J(x))_+$ by its Monte Carlo estimation. The expected value from the formula comes from the fact that, as mentioned in the definition of $\widehat{J}$ and in Algorithm 1, we use a random number of Monte Carlo shootings for the estimations.

Finally, we obtain the NSA process by associating the two sub-processes as follows:

- Let $\left(\widetilde{X}_t\right)_{t \geq 0}$ be the inhomogeneous Markov Process such that $\widetilde{X}_t = \widetilde{\chi}_k$ if $T_k \leq t < T_{k+1}$. One can see that this process is piecewise constant and jumps at exponential times from one candidate solution to another, in other words $(\widetilde{X}_t)_{t \geq 0}$ is just the continuous-time version of the noisy simulated annealing discrete time process,$(\widetilde{\chi}_k)_{k \geq 0}$.

  Note that, if $y \in E \setminus E'$ then $\forall x \in E'$, $\widetilde{q}_{\beta_t}(x,y) = 0$. Hence, if the initial solution $\widetilde{X}_0$ is chosen in E', then $\forall t \geq 0$, $\widetilde{X}_t \in E'$.

2.4. Convergence Result

We denote:

- $m^\star$ the maximum depth of a well not containing a fixed global minimum of the function J. To be more precise, we call a path from x to y any finite sequence $x_0 = x, x_1, \ldots, x_n = y$ such that for all i, $x_{i+1} \in S_{x_i}$. Let P_{xy} be the set of paths from x to y.
  For a given path $p \in P_{x,y}$, the elevation of the function J on p is $\max\limits_{z \in p} J(z)$. Minimizing this quantity over the set of possible paths $P_{x,y}$, gives us the elevation of the cheapest path going from x to y. Denote this elevation by:

$$H_{x,y} = \min_{p \in P_{xy}} \left\{ \max_{z \in p} J(z) \right\}$$

  Then

$$m^\star := \max_{x,y \in E} \{ H_{x,y} - \max(J(y), J(x)) \} \tag{4}$$

  As represented on Figure 1, $m^\star$ can also be understood as the highest energy barrier to climb to go from one point to another in the search space in the easiest direction. As mentioned before, it also represents the maximal depth of a well not containing a fixed global minimum. If $x^\star$ is a global minimum then:

$$m^\star = \max_{y \in E} \{ H_{x^\star, y} - J(y) \}.$$

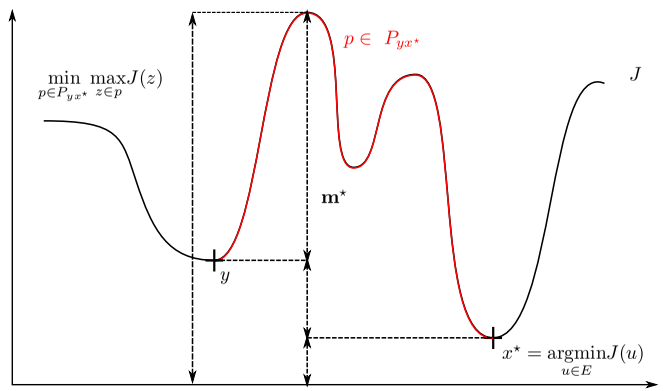

Figure 1: $m^\star$, maximal depth of local minima

The definition provided here is equivalent to the classical one, *i.e.*, the one provided in Hajek (1988) and Holley and Stroock (1988). A proof of this statement can be found in Appendix B.

- $\gamma(\beta)$ the spectral gap between 0 and the rest of the $L^2(\mu_\beta)$ spectrum of $-L_\beta$, where L_β is the generator of the classical simulated annealing (for more details about L_β see Section 3):

$$\gamma(\beta) := \inf\left\{-\int \phi L_\beta \phi d\mu_\beta \text{ s.t. } \int |\phi|^2 d\mu_\beta = 1 \text{ and } \int \phi d\mu_\beta = 0\right\} \tag{5}$$

Following Holley and Stroock (1988), we know that given E, μ_0 and U, there exists a constant c such that:

$$\forall \beta \geq 0, \quad \gamma(\beta) \geq c e^{-m^\star \beta}$$

Remark that this lower bound is mainly informative for small values of β. In addition set:

$$\forall x \in E,\ J(x) = \mathbb{E}_\omega(U(x,\omega)) \text{ and } J^\star = \min_{x\in E} \mathbb{E}_\omega(U(x,\omega)).$$

We define χ_ϵ the set of ϵ-optimal points in E, *i.e.*,

$$\chi_\epsilon = \{x : J(x) \leq J^\star + \epsilon\}, \tag{6}$$

and denote ${}^c\chi_\epsilon = E\backslash\chi_\epsilon$, its complementary in E. We also write $a \wedge b = \min a, b$.

Theorem 3 *Consider the settings of Section 2.2, if* $\beta_t = b\log(td+1)$ *and* $n_t = (t+1)^\alpha$, *with:*

$$\{m^\star b < 1 \wedge \alpha/2\} \text{ or } \{m^\star b = 1,\ \alpha > 2 \text{ and } d < 2cm^\star/M\},$$

then there exits $C > 0$ *such that,* $\forall t \in \mathbb{R}_+,\ \forall \epsilon > 0, \quad \mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) \leq C(\mu_{\beta_t}({}^c\chi_\epsilon))^{1/2}.$ ■

This theorem is a natural extension of the result provided by Holley and Stroock (1988). There are two main interesting facts to point out. First, we obtain a balance between the expected number of Monte Carlo simulations at each step of the algorithm and the inverse of the temperature, *i.e.*, $\{m^\star b < 1 \wedge \alpha/2\}$ or $\{m^\star b = 1,\ \alpha > 2$ and $d < 2cm^\star/M\}$. Reducing the growth rate α of the number of simulations below the quadratic rate should be compensated by decreasing accordingly the temperature factor b. Second, the convergence is stated in terms of a bound on the probability of not returning an optimal solution. Using the concentration speed of the Gibbs measure one can deduce a rate of convergence of the algorithm. Also the theorem provides an insight on how the algorithm could be used in practice. A run of parallel noisy simulated annealing would have a probability of returning a bad solution that would decrease in the power of the number of runs. Nevertheless this benefit should be traded with an additional selection cost. Indeed, if we obtain K solutions retrieved by K parallel NSA realization, we still face the problem of selecting the best one. We only access estimates of the costs associated to each solution.

Remark 1 *Taking* $n_t = (t+1)^\alpha$, *implies that the sample size at step* k, *is of the order* t_k^α. *The value* $\alpha = 2$ *minimizes the number of measurements used by the algorithm in order to return an estimation of a given accuracy and confidence level (see Corollary 1). In practice generating samples of sizes growing at this rate might be overwhelming. However, for some well-behaved cost functions and low noise levels one can afford a sub-optimal evaluation number as shown in Figure 3. On the other hand, when this is not the case, using fewer measurements at each step can decrease the performance of the algorithm as suggested in Figure 5.*

Sketch of the proof The proof of this theorem is divided into three parts. First, in Section 3, we compute the infinitesimal generator of the classical (Equation (11)) and noisy simulated annealing (Equation (7)). Second, in Section 4, we compare them (Lemma 1) and third, in Section 5, we conclude about the convergence using the Grönwall lemma (Equation (18)) and the convergence of the classical simulated annealing (Equation (24)).

Convergence rate In the case $m^\star b < 1$ a finer bound can be deduced from Grönwall's lemma and one can obtain a more precise convergence rate for the algorithm (Theorem 5), which is roughly of the order of:

$$\mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) \leq \Gamma\ t^{((m^\star-\epsilon)b - \min(1,\alpha/2))/2}$$

where Γ is some constant detailed in Theorem 5. In particular this implies that for fixed $\epsilon, \delta > 0$ we can find $T^\star$ such that $\mathbb{P}(\widetilde{X}_T^\star \in {}^c\chi_\epsilon) \leq \delta$. This leads to a bound (Lemma 6) on the computational complexity, $\mathbb{E}\left(N_{call}^{T^*}\right)$, of the order of:

$$\mathbb{E}\left(N_{call}^{T^*}\right) \leq \left(\frac{\Gamma}{\delta}\right)^{2(\alpha+1)/(\min(1,\alpha/2)-(m^\star-\epsilon)b)}.$$

3. Proof, Part 1: Infinitesimal Generator

In this section we use the semi-group characterization of the generator in order to prove that as soon as $\widetilde{q}_{\beta_t}$ defined in Equation (3) is continuous with respect to t then the infinitesimal generator $\widetilde{L}_{\beta_t}$ of the Markov process $\widetilde{X}_t$ can be written as:

$$\widetilde{L}_{\beta_t} f(x) = \sum_{y \in E} \Big(f(y) - f(x) \Big) \widetilde{q}_{\beta_t}(x, y). \tag{7}$$

We briefly recall the definition of the semi-group associated to a Markov process.

Definition 1 *The semi-group $(P_{t,t+s})_{t\geq 0, s\geq 0}$ associated to the Markov process $(X_t)_{t\geq 0}$ is a family of probability kernels such that for all non-negative borelian functions:*

$$\forall t, s \in \mathbb{R}_+ \quad P_{t,t+s} f(x) = \mathbb{E}(f(X_{t+s}) | X_t = x)$$

Let $(P_{t,t+s})_{t\geq 0, s\geq 0}$ be the semi-group associated to the Markov process $(X_t)_{t\geq 0}$. The semi-group characterization of its generator is given in the following definition:

Definition 2 *The infinitesimal generator L_t of the Markov process $(X_t)_{t\geq 0}$ is defined as the operator such that for any bounded function f:*

$$L_t f(x) = \lim_{s \to 0} \frac{P_{t,t+s} f(x) - P_{t,t} f(x)}{s}$$

We start by computing the infinitesimal generator L_{β_t} of the process associated to the SA algorithm, *i.e.*, with no measurement noise, and then deduce the infinitesimal generator of the NSA algorithm. Using similar notations to the ones of Section 2.3, we consider the noise free inhomogeneous Markov process, $(X_t)_{t\geq 0}$ constructed from the inhomogeneous Markov chain $(\chi_k)_{k\in\mathbb{N}}$ whose one step transition probability is:

$$\forall x, y \in E, \quad q_{\beta_{T_k}}(x, y) = \begin{cases} q_0(x, y) e^{-\beta_{T_k}(J(y) - J(x))_+} & \text{if } y \neq x \\ 1 - \sum\limits_{z \in E \setminus \{x\}} q_{\beta_{T_k}}(x, z) & \text{if y=x} \end{cases}$$

This is the natural extension of the simulated annealing process with discrete jumping times (Hajek, 1988) to the continuous time process. In this configuration, the jumping times are drawn from an i.i.d. sequence of exponential random variables of parameter 1. In the homogeneous configuration, *i.e.*, $\beta_t = \beta$, the infinitesimal generator has a classical form: $L_\beta = Q_\beta - Id$ where Q_β is the transition matrix associated to q_β and Id denotes the identity. The extension to the generator of the non-homogeneous process is not straightforward. Therefore we propose to detail the computations.

By definition, for any bounded function f:

$$\begin{aligned} L_{\beta_t} f(x) &= \lim_{s \to 0} \frac{P_{t,t+s} f(x) - P_{t,t} f(x)}{s} \\ &= \lim_{s \to 0} \frac{\sum\limits_{y \in E} f(y) \mathbb{P}(X_{t+s} = y | X_t = x) - f(x)}{s} \\ &= \lim_{s \to 0} \frac{\sum\limits_{y \in E} f(y) \mathbb{P}(X_{t+s} = y, H_{t+s} - H_t \geq 0 | X_t = x) - f(x)}{s}, \end{aligned} \tag{8}$$

where $H_t = \max\{k \in \mathbb{N} : T_k < t\}$ denotes the number of jumps before time t. Since T_k is a sum of independent exponential variables of parameter 1, one can remark that H_t is in fact a Poisson process of parameter 1.

In order to compute the above limit, we begin by calculating a more explicit form of the probabilities above. We can divide these computations into three parts according to the number of jumps between t and $t + s$:

$$\begin{aligned} \mathbb{P}(X_{t+s} = y, H_{t+s} - H_t \geq 0 | X_t = x) = \mathbb{P}(X_{t+s} = y, H_{t+s} - H_t = 0 | X_t = x) \\ + \mathbb{P}(X_{t+s} = y, H_{t+s} - H_t = 1 | X_t = x) \\ + \mathbb{P}(X_{t+s} = y, H_{t+s} - H_t \geq 2 | X_t = x). \end{aligned}$$

The first case is straightforward, if there is no jump between t and $t + s$, the process will not change its position and we thus have:

$$\mathbb{P}(X_{t+s} = y,\ H_{t+s} - H_t = 0 | X_t = x) = \delta_x(y) e^{-s}.$$

The second case is slightly more involved. Using the stationarity and the definition of Poisson processes, the event that the algorithm goes from x to y, having only one jump between t and $t + s$, can be written as:

$$\mathbb{P}(X_{t+s} = y, H_{t+s} - H_t = 1 | X_t = x) = \mathbb{P}(X_{t+s} = y, \xi_1' < s, s - \xi_1' < \xi_2' | X_t = x)$$

where ξ_1' and ξ_2' are two independent exponential random variables of parameter one.
Let $\xi = (\xi_1', \xi_2')$ and $D_s = \{(h_1, h_2) \in \mathbb{R}^2 | h_1 < s \text{ and } h_2 > s - h_1\}$. Also in what follows, for a random variable Y we denote f_Y its probability distribution. Using these notations and the fact that ξ is independent of X_t, we can write:

$$\begin{aligned} \mathbb{P}(X_{t+s} = y, \xi \in D_s | X_t = x) &= \int_{D_s} f_{(X_{t+s}, \xi) | X_t = x}(y, h) \mathrm{d}h \\ &= \int_{D_s} f_{X_{t+s} | \xi = h, X_t = x}(y) f_\xi(h) \mathrm{d}h \\ &= \int_0^s \int_{s - h_1}^{+\infty} q_{\beta_{t+h_1}}(x, y) e^{-h_1} e^{-h_2} \mathrm{d}h_1 \mathrm{d}h_2 \end{aligned}$$

The previous equality yields:

$$\mathbb{P}(X_{t+s} = y,\ H_{t+s} - H_t = 1 | X_t = x) = e^{-s} \int_0^s q_{\beta_{t+h_1}}(x, y) \mathrm{d}h_1. \tag{9}$$

In the following we use the classical $\mathcal{O}(.)$ and $o(.)$ notations: for all functions f and g defined on some subset of $\mathbb{R}$,

- $f(x) = \mathcal{O}(g(x))$ as $x \to 0^+ \iff \exists \sigma, x_0 > 0, |f(x)| \leq \ \sigma |g(x)|$ for all $0 < x \leq x_0$
- $f(x) = o(g(x))$ as $x \to 0^+ \iff \lim\limits_{x \to 0^+} \frac{f(x)}{g(x)} = 0.$

For the third term we can see that:

$$\mathbb{P}(X_{t+s} = y,\ H_{t+s} - H_t \geq 2 | X_t = x) \leq \mathbb{P}(H_{t+s} - H_t \geq 2) \leq \mathbb{P}(H_s \geq 2)$$

Since H_s is a Poisson Process of parameter 1, one can check that for all s close to zero we have that $\mathbb{P}(H_s \geq 2) = 1 - \mathbb{P}(H_s = 0) - \mathbb{P}(H_s = 1) = 1 - e^{-s} - se^{-s} = \mathcal{O}(s^2)$.

This implies that when s is close to zero, the probability that the process goes from x to y between t and $t+s$, with more than one jump is small in comparison to s:

$$\mathbb{P}(X_{t+s} = y,\ H_{t+s} - H_t \geq 2 | X_t = x) = \mathcal{O}(s^2) \tag{10}$$

Putting all the terms together and replacing them in Equation (2), we can rewrite the infinitesimal generator as follows:

$$\begin{aligned} L_{\beta_t} f(x) = \lim_{s\to 0} \frac{1}{s} \quad & \left[\sum_{y\in E} f(y) \left[\delta_x(y) e^{-s} + e^{-s} \int_0^s q_{\beta(t+\tau)}(x,y) d\tau \right] - f(x) \right] \\ + \lim_{s\to 0} \frac{1}{s} & \sum_{y\in E} f(y) \mathbb{P}(X_{t+s} = y, H_{t+s} - H_t \geq 2 | X_t = x) \end{aligned}$$

Using the fact that f is bounded, E finite and the upper bound given by Equation (10), one can easily check that the second term is zero. Hence we obtain:

$$\begin{aligned} L_{\beta_t} f(x) &= \lim_{s\to 0} \frac{1}{s} \quad \left[e^{-s} \left[f(x) + \sum_{y\in E} f(y) \int_0^s q_{\beta(t+\tau)}(x,y) d\tau \right] - f(x) \right] \\ &= \lim_{s\to 0} \frac{f(x)(e^{-s} - 1)}{s} + \lim_{s\to 0} \frac{e^{-s}}{s} \left(\sum_{y\in E} f(y) \int_0^s q_{\beta(t+\tau)}(x,y) d\tau \right) \end{aligned}$$

Noting the fact that q_{β_t} is continuous with respect to t and the following identity

$$e^{-s} = 1 - s + \mathcal{O}(s^2),$$

we easily obtain the simplest form for the infinitesimal generator of the inhomogeneous Markov chain:

$$L_{\beta_t} f(x) = \sum_{y\in E} \Big(f(y) - f(x) \Big) q_{\beta_t}(x,y). \tag{11}$$

We can remark that the explicit form of the transition probability q_{β_t} does not appear in the proof, hence the result is completely general. The only necessary property of this transition probability is its continuity with respect to t.

The fact that n_t and β_t are continuous functions ensures the continuity of transition probability $\widetilde{q}_{\beta_t}$, defined in Equation (3) . Therefore, following the same argument,one can deduce (7). Here we can see the relevance of the randomness of N_t. An increasing deterministic sequence would generate a discontinuous $\widetilde{q}_{\beta_t}$ and would make difficult the use of derivations above.

4. Proof, Part 2: Generators Comparison

The fact that for a temperature schedule that decreases slowly enough, the process generated by the classical Simulated Annealing converges to the set of global minima of J is well known. The Noisy Simulated Annealing is a similar algorithm, built on the same principles except that the values of the function J are replaced by an estimation each time its computation is needed. Therefore a tight relation exists between both approaches. Furthermore, as we will show in this section, for a well chosen couple (β_t, n_t) the generators of the two algorithms will be 'close' at large times. This is a key element of the proof as it will imply a first condition for the ratio β_t/n_t.

Using the relations given by Equation (11) and Equation (7), the quantity of interest is:

$$\widetilde{L}_{\beta_t} f(x) = L_{\beta_t} f(x) + \sum_{y\in E} (f(y) - f(x))(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y).$$

Hence quantifying the difference between the two generators can be reduced to bounding the difference between the two probability transitions q_{β_t} and $\widetilde{q}_{\beta_t}$. Thus the main result of this section is the following lemma.

Lemma 1 *Let $\beta_t/\sqrt{n_t} \underset{\infty}{\to} 0$. There exist two functions ϵ_t^- and ϵ_t^+ such that*

$$\forall\ t\ \in\ \mathbb{R}_+,\ \forall\ x\ \in\ E',\ \forall\ y\ \in\ E, \quad \epsilon_t^- q_{\beta_t}(x,y) \leq (\widetilde{q}_{\beta_t} - q_{\beta_t})(x,y) \leq \epsilon_t^+ q_{\beta_t}(x,y)$$

and

$$\lim_{t\to+\infty} \epsilon_t^- = \lim_{t\to+\infty} \epsilon_t^+ = 0.$$

Before going into the proof of this lemma, we present some preliminaries. First it can be noticed that for all $x, y \in E$, $x \neq y$ we have:

$$\begin{aligned} &(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y) \\ &= q_{\beta_t}(x,y) \left(\frac{\widetilde{q_{\beta_t}}}{q_{\beta_t}} - 1 \right)(x,y) \\ &= q_{\beta_t}(x,y) \left(\mathbb{E}_{N_t} \mathbb{E}_{\omega_1,\dots,\omega_{N_t}} \left(\frac{e^{-\frac{\beta}{N_t} \lfloor \sum_{i=1}^{N_t} U(y,\omega_i) - U(x,\omega_i) \rfloor_+}}{e^{-\beta_t \lfloor \mathbb{E}(U(y,\Omega)) - \mathbb{E}(U(x,\Omega)) \rfloor_+}} - 1 \right) \right). \end{aligned}$$

Unless specified otherwise, in this section we always consider $x \neq y$. The case $x = y$ is handled at the end of the section. To simplify the notations we denote $X_i^{x,y} := U(y,\omega_i) - U(x,\omega_i) - \mathbb{E}(U(y,\omega_i) - U(x,\omega_i))$ and $K^{x,y} = \mathbb{E}(U(y,\omega_i) - U(x,\omega_i))$. Hence,

$$\begin{aligned} &(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y) \\ &= q_{\beta_t}(x,y) \left(\mathbb{E}_{N_t} \mathbb{E}_{\omega_1,\dots,\omega_{N_t}} \left(e^{-\beta_t \left(\lfloor \frac{1}{N_t} \sum_{i=1}^{N_t} X_i^{x,y} + K^{x,y} \rfloor_+ + \lfloor K^{x,y} \rfloor_+ \right)} - 1 \right) \right). \end{aligned}$$

Noticing that,

$$\forall\ a, b \in \mathbb{R}, \quad -|a| \leq -\lfloor a + b \rfloor_+ + \lfloor b \rfloor_+ \leq |a|,$$

we obtain the following bounds for $(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y)$:

$$\mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}-1\right) \geq (\frac{\widetilde{q_{\beta_t}} - q_{\beta_t}}{q_{\beta_t}})(x,y) \geq \mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}-1\right). \tag{12}$$

In order to obtain a bound for the expectation of a function of N_t we need an estimation of the probability that N_t takes values 'far' from its expectation.

Lemma 2 *There exist $\delta \in (0,1)$ and $a = |(1-\delta)(1-\log(1-\delta))-1|$ such that for all $t>0$ we have:*

$$\mathbb{P}(N_t \leq (1-\delta)n_t) \leq e^{-an_t}.$$

Proof. We remind the reader that, as mentioned in the definition N_{t_k}, at a fixed time t the process N_t can be written as $1+H$, where H is a Poisson random variable of parameter n_t.

Fix $t \in \mathbb{R}$ and $\delta \in (0,1)$. We provide an upper bound for $\mathbb{P}(N_t \leq (1-\delta)n_t)$ using the Cramer-Chernoff method.

First we see that for any $\lambda > 0$, applying Markov's inequality we have:

$$\mathbb{P}(N_t \leq (1-\delta)n_t) = \mathbb{P}(e^{-\lambda N_t} > e^{\lambda(\delta-1)n_t}) \leq \frac{\mathbb{E}_{N_t}[e^{-\lambda N_t}]}{e^{\lambda(\delta-1)n_t}}..$$

For t fixed $N_t - 1$ has the distribution of a Poisson random variable of parameter n_t. Therefore by direct computations we have:

$$\begin{aligned}\mathbb{E}_{N_t}[e^{-\lambda N_t}] &= \sum_{k>0}(e^{-\lambda(k+1)}e^{-n_t}\frac{n_t^k}{k!}) \\ &= e^{-n_t-\lambda}\sum_{k>0}\frac{(e^{-\lambda}n_t)^k}{k!} \\ &= e^{-n_t-\lambda}e^{e^{-\lambda}n_t}\end{aligned}$$

Putting all these elements together yields:

$$\mathbb{P}(N_t \leq (1-\delta)n_t) \leq \exp([-\lambda(\delta-1)-1+e^{-\lambda}]n_t)$$

The idea is to choose λ and δ in order to obtain the smallest possible value for $-\lambda(\delta-1)-1+e^{-\lambda}$. For $\delta \in (0,1)$, the minimum is reached at $\lambda = -\log(1-\delta)$ which is strictly positive. For such λ and δ, we denote $a = |(1-\delta)(1-\log(1-\delta))-1|$ and conclude the proof. ■

Now we have what we need in order to start the proof of Lemma 1.

4.1. Proof of Lemma 1.

First, recall that if $y \in E\backslash E'$ then $\forall x \in E'$, $\widetilde{q}_{\beta_t}(x,y) = q_{\beta_t}(x,y) = 0$. Hence Lemma Equation (1) is trivially verified for $x \in E$ and $y \in E\backslash E'$.
Considering the inequalities given by Equation (12), the proof can be divided in two parts by studying separately the upper bound $\mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}\right)$ and the lower bound $\mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}\right)$.

4.1.1. Upper Bound

We have:

$$(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y) \leq q_{\beta_t}(x,y)\left(\mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}-1\right)\right).$$

First we will provide an estimate of $\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left[e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right]$ for all N_t.

We start by rewriting this expectation as:

$$\begin{aligned}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left[e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right] &= \int_{\mathbb{R}_+}\mathbb{P}\left(e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|} > u|N_t\right)du \\ &= \int_{\mathbb{R}_+}\mathbb{P}\left(\left|\sum_{i=1}^{N_t}X_i^{x,y}\right| > \frac{\log(u)N_t}{\beta_t}|N_t\right)du.\end{aligned}$$

Since $X_i^{x,y} = U(y,\omega_i) - U(x,\omega_i) - \mathbb{E}_{N_t}\mathbb{E}_{\omega_i}(U(y,\omega_i)-U(x,\omega_i))$ is a centered random variable and U is bounded on E' (see the definition of U) there exists σ such that $|X_i^{x,y}| \leq \sigma$ (for example set $\sigma = 2M$), almost surely for all i. Therefore $(X_i^{x,y})_{1\leq i\leq N_t}$ are sub-gaussian random variables ((Boucheron et al., 2013)) with variance factor σ^2, *i.e.*,

$$\forall u \geq 0,\ \max\left(\mathbb{P}(X_i^{x,y} > u), \mathbb{P}(-X_i^{x,y} > u)\right) \leq e^{-\frac{u^2}{2\sigma^2}}.$$

Considering that $(X_i^{x,y})_{i\leq N_t}$ is a sequence of independent sub-Gaussian variables, their sum is still a sub-Gaussian variable. As $\mathrm{Var}(X_i^{x,y}) \leq \sigma^2$ for all i we have that $\mathrm{Var}\left(\sum_{i=1}^{N_t}X_i^{x,y}\right) \leq N_t\sigma^2$ and therefore:

$$\forall u \geq 0,\ \max\left(\mathbb{P}\left(\sum_{i=1}^{N_t}X_i^{x,y} > u\right), \mathbb{P}\left(-\sum_{i=1}^{N_t}X_i^{x,y} > u\right)\right) \leq e^{-\frac{u^2}{2\sigma^2N_t}}.$$

For more details about sub-gaussian variables we refer to (Boucheron et al., 2013). We use this property of concentration in order to get an estimate of the expectation:

$$\begin{aligned}
&\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left[e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right] \\
&\quad=\int_0^1 \mathbb{P}\left(\left|\sum_{i=1}^{N_t}X_i^{x,y}\right|>\frac{\log(u)N_t}{\beta_t}|N_t\right)du+\int_1^{+\infty}\mathbb{P}\left(\left|\sum_{i=1}^{N_t}X_i^{x,y}\right|>\frac{\log(u)N_t}{\beta_t}|N_t\right)du \\
&\quad\leq 1+2\int_1^{+\infty}e^{-\frac{1}{2\sigma^2}\left(\frac{\log(u)\sqrt{N_t}}{\beta_t}\right)^2}du.
\end{aligned}$$

Using a simple variable substitution $s=\frac{\log(u)}{\lambda_t}$ with $\lambda_t=\frac{\sigma\beta_t}{\sqrt{N_t}}$, we get:

$$\begin{aligned}
\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left[e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right] &\leq 1+2\lambda_t\int_0^{+\infty}e^{\lambda_t s}e^{-\frac{s^2}{2}}du \\
&\leq 1+2\lambda_t e^{\frac{\lambda_t^2}{2}}\int_0^{+\infty}e^{-\frac{(s-\lambda_t)^2}{2}}ds \\
&\leq 1+2\lambda_t e^{\frac{\lambda_t^2}{2}}\int_{-\lambda_t}^{+\infty}e^{-\frac{u^2}{2}}du \\
&\leq 1+2\sqrt{2\pi}\lambda_t e^{\frac{\lambda_t^2}{2}}\mathbb{P}(G>-\lambda_t) \\
&\leq 1+2\sqrt{2\pi}\lambda_t e^{\frac{\lambda_t^2}{2}}(1-\mathbb{P}(G>\lambda_t)).
\end{aligned}$$

where G is a standard Gaussian. Thanks to the Taylor formula, we know that there exists a constant $0<\theta<1$, such that:

$$\begin{aligned}
\mathbb{P}(G>\lambda_t)&=\mathbb{P}(G>0)+\lambda_t\frac{e^{\frac{-(\theta\lambda_t)^2}{2}}}{\sqrt{2\pi}} \\
&=\frac{1}{2}+\lambda_t\frac{e^{\frac{-(\theta\lambda_t)^2}{2}}}{\sqrt{2\pi}} \\
&\geq\frac{1}{2}+\lambda_t\frac{e^{\frac{-(\lambda_t)^2}{2}}}{\sqrt{2\pi}}.
\end{aligned}$$

This leads to:

$$\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left[e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right]\leq 1+(\sqrt{2\pi}e^{\frac{\lambda_t^2}{2}})\lambda_t.$$

Thus, replacing λ_t by its definition we see that we need an estimate of:

$$\mathbb{E}_{N_t}\left[1+(\sqrt{2\pi}e^{\frac{\sigma^2\beta_t^2}{2N_t}})\frac{\sigma\beta_t}{\sqrt{N_t}}\right].$$

In order to simplify the notations we denote: $g_t=\sigma\beta_t$. Using the bound given by Lemma 2 we get:

$$\begin{aligned}
&\mathbb{E}_{N_t}\left[1+\sqrt{2\pi}e^{\frac{g_t^2}{2\sqrt{N_t}}}\frac{g_t}{\sqrt{N_t}}\right] \\
&\quad=1+\mathbb{E}_{N_t}\left[\sqrt{2\pi}e^{\frac{g_t^2}{2\sqrt{N_t}}}\frac{g_t}{\sqrt{N_t}}\right] \\
&\quad\leq 1+\mathbb{E}_{N_t}\left[\sqrt{2\pi}e^{\frac{g_t^2}{2\sqrt{N_t}}}\frac{g_t}{\sqrt{N_t}}(\mathbb{1}_{[1,(1-\delta)n_t]}+\mathbb{1}_{[(1-\delta)n_t,+\infty)})\right] \\
&\quad\leq 1+\sqrt{2\pi}g_t\left[\frac{e^{\frac{g_t^2}{2(1-\delta)n_t}}}{\sqrt{(1-\delta)n_t}}+e^{g_t^2-an_t}\right]
\end{aligned}$$

Finally we have obtained that under assumptions of Section 2.2:

$$\begin{aligned}
(\widetilde{q_{\beta_t}}-q_{\beta_t})(x,y)&\leq q_{\beta_t}(x,y)\left(\mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}-1\right)\right) \\
&\leq q_{\beta_t}(x,y)\sqrt{2\pi}g_t\left[\frac{e^{\frac{g_t^2}{2(1-\delta)n_t}}}{\sqrt{(1-\delta)n_t}}+e^{g_t^2-an_t}\right]
\end{aligned}$$

Hence it is natural to define ϵ_t^+ as:

$$\epsilon_t^+=\sqrt{2\pi}\beta_t\sigma\left[\frac{e^{\frac{\beta_t^2\sigma^2}{2(1-\delta)n_t}}}{\sqrt{(1-\delta)n_t}}+e^{\beta_t^2\sigma^2-an_t}\right].$$

Since $\beta_t/\sqrt{n_t}\underset{\infty}{\to}0$ one can check that ϵ_t^+ goes to 0 when t goes to infinity. Here we can see once more the importance of the balance between the two parameters β_t and n_t.

4.1.2. Lower Bound

Considering the left-hand side of Equation (12) we have:

$$(\widetilde{q_{\beta_t}}-q_{\beta_t})(x,y)\geq q_{\beta_t}(x,y)\left(\mathbb{E}_{N_t}\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}-1\right)\right).$$

In a similar way we start by obtaining a lower bound for $\mathbb{E}_{\omega_1,\dots,\omega_{N_t}}\left(e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right)$ and after we improve it using the probabilistic properties of N_t. First observe that:

$$\begin{aligned}
\mathbb{E}_{\omega_1,..,\omega_{N_t}}\left[e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right] &= \int_{\mathbb{R}_+}\mathbb{P}\left(e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}>u|N_t\right)du\\
&= \int_{\mathbb{R}_+}\mathbb{P}\left(-\left|\sum_{i=1}^{N_t}X_i^{x,y}\right|>\frac{\log(u)N_t}{\beta_t}|N_t\right)du\\
&= \int_0^1\mathbb{P}\left(\left|\sum_{i=1}^{N_t}X_i^{x,y}\right|<\frac{-\log(u)N_t}{\beta_t}|N_t\right)du\\
&= \int_0^1 1-\mathbb{P}\left(\left|\sum_{i=1}^{N_t}X_i^{x,y}\right|>\frac{-\log(u)N_t}{\beta_t}|N_t\right)du\\
&\geq 1-2\int_0^1 e^{-\frac{N_t}{2\sigma^2}\left(\frac{-\log(u)}{\beta_t}\right)^2}du
\end{aligned}$$

Again, this is due to the fact that the sum of $X_i^{x,y}$ is sub-Gaussian with variance factor $N_t\sigma^2$.

Using the same variable substitution as above: $s=\frac{\log(u)}{\lambda_t}$ with $\lambda_t=\frac{\sigma\beta_t}{\sqrt{N_t}}$, we get:

$$\begin{aligned}
\mathbb{E}_{\omega_1,..,\omega_{N_t}}\left[e^{-|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right] &\geq 1-2\lambda_t\int_{-\infty}^0 e^{\lambda_t s}e^{-\frac{s^2}{2}}du\\
&\geq 1-2\lambda_t e^{\frac{\lambda_t^2}{2}}\int_{-\infty}^0 e^{-\frac{(s-\lambda_t)^2}{2}}ds\\
&\geq 1-2\lambda_t e^{\frac{\lambda_t^2}{2}}\int_{-\infty}^{-\lambda_t} e^{-\frac{u^2}{2}}du\\
&\geq 1-2\sqrt{2\pi}\lambda_t e^{\frac{\lambda_t^2}{2}}\mathbb{P}(G>\lambda_t)
\end{aligned}$$

where G is a standard $N(0,1)$ Gaussian. As seen before there exists some $0<\theta<1$, such that:

$$\mathbb{P}(G>\lambda_t)\geq\frac{1}{2}+\lambda_t\frac{e^{\frac{-(\lambda_t)^2}{2}}}{\sqrt{2\pi}}.$$

This leads to

$$\mathbb{E}_{\omega_1,..,\omega_{N_t}}\left[e^{|\frac{\beta_t}{N_t}\sum_{i=1}^{N_t}X_i^{x,y}|}|N_t\right]\geq 1-(\sqrt{2\pi}e^{\frac{\lambda_t^2}{2}})\lambda_t.$$

This expression has exactly the symmetric form to the one obtained in the upper bound part. Thus, the lower bound is obtained the same way as the upper bound. We directly get:

$$\begin{aligned}
&\mathbb{E}_{N_t}\left[1-(\sqrt{2\pi}e^{\frac{g_t^2}{2N_t}})\frac{g_t}{\sqrt{N_t}}\right]\\
&\quad\geq 1-\sqrt{2\pi}g_t\left[\frac{e^{\frac{g_t^2}{2(1-\delta)n_t}}}{\sqrt{(1-\delta)n_t}}+e^{g_t^2-an_t}\right]
\end{aligned}$$

Now we define ϵ_t^-:

$$\epsilon_t^- = -\sqrt{2\pi}\beta_t\sigma\left[\frac{e^{\frac{\beta_t^2\sigma^2}{2(1-\delta)n_t}}}{\sqrt{(1-\delta)n_t}}+e^{\beta_t^2\sigma^2-an_t}\right].$$

It is easy to see that ϵ_t^- goes to 0 when t goes to infinity as soon as $\beta_t/\sqrt{n_t}\underset{\infty}{\to}0$. This completes the proof of Lemma 1. ■

5. Proof, Last Part: Rate of Convergence in the General Case

We first complete the proof of convergence as stated in Theorem 3 and then deduce the convergence rate (Theorem 5) from it. This enables us to provide an upper bound on the minimal number of cost function evaluations in Section 5.3.

5.1. Proof of Theorem 3

The proof of Theorem 3 follows the roadmap of Holley and Strook (Holley and Stroock, 1988) and relies on the use of the Grönwall lemma. We derive a differential inequality for the $L^2_{\mu_{\beta_t}}$-norm of the density measure of the NSA process with respect to μ_{β_t} and deduce an integrated version of it using the lemma. We then show that bounding the $L^2_{\mu_{\beta_t}}$-norm of this density implies the convergence of the process to the optimal state space χ_ϵ.

Proof. **[Proof of Theorem 3]** Our goal is to show that when t goes to infinity, the noisy simulated annealing gets "close enough" to the classical simulated annealing. Therefore we denote by f_t the Radon-Nikodym derivative of the probability density of the noisy simulated annealing process $\widetilde{X}_t$ with respect to the Gibbs measure μ_{β_t}, *i.e.*:

$$f_t=\frac{\mathrm{d}m_t}{\mathrm{d}\mu_{\beta_t}} \tag{13}$$

where m_t is the distribution of $(\widetilde{X}_s)_{s\geq0}$ at time t. A first remark is that $f_t(x)=0$ for all $t\geq0$ and all $x\in E\setminus E'$, since our process, by construction does not accept states out of E'.

Using the results obtained in Section 3 one can see that $\mathbb{R}_+\ni t\to\widetilde{L}_{\beta_t}$ is continuous and therefore the semi-group $(P_{s,t})_{0\leq s\leq t}$ is smooth . Also by their definition the operators $(P_{s,t})_{0\leq s\leq t}$ are linear and have the following semi-group property: $P_{s,t+h}=P_{s,t}\circ P_{t,t+h}$, for all $0\leq s<t$ and $h>0$. Hence, for all $0\leq s\leq t$, we have:

$$\frac{\mathrm{d}}{\mathrm{d}t}P_{s,t}=P_{s,t}L_t. \tag{14}$$

For details about the infinitesimal generator see Section 1.4. of (Bakry et al., 2013).

As shown in Equation (23), bounding the L^2-norm of f_t w.r.t. μ_{β_t}, *i.e.*, $\|f_t\|_{\mu_{\beta_t}}$, ensures convergence of the NSA algorithm. However it does not provide enough information about

the convergence of m_t to μ_{β_t} to deduce a fine convergence rate. This is why we study the evolution of $\|f_t - 1\|_{\mu_{\beta_t}}$ which controls the distance between the two measures. If this quantity is bounded then we obtain the convergence of the NSA algorithm. If moreover it converges to zero, it implies a stronger convergence rate. In order to prove that, we deduce a differential inequality for $\|f_t - 1\|^2_{\mu_{\beta_t}}$. We start by computing its derivative:

$$\begin{aligned}\partial_t \|f_t - 1\|^2_{\mu_{\beta_t}} = \partial_t \|f_t\|^2_{\mu_{\beta_t}} =& \partial_t \sum_{x\in E} f_t^2(x)\mu_{\beta_t}(x) \\ &= 2\sum_{x\in E} f_t(x)\partial_t m_t(x) + \sum_{x\in E} f_t(x)\partial_t \mu_{\beta_t}(x).\end{aligned}$$

Using the backward Kolmogorov equation given by Equation (14), for the first term we have:

$$\begin{aligned}\sum_{x\in E} f_t(x)\partial_t\left[\frac{m_t}{\mu_{\beta_t}}\right](x)\mu_{\beta_t}(x) &= \sum_{x\in E} f_t(x)\partial_t\left[\frac{m_t}{\mu_{\beta_t}}\right](x)\mu_{\beta_t}(x) + \sum_{x\in E} f_t(x)\partial_t\mu_{\beta_t}(x) \qquad (15)\\ &= \sum_{x\in E}\left[\widetilde{L}_{\beta_t} f_t(x)\right] m_t(x) - \sum_{x\in E} f_t(x)\frac{m_t}{\mu_{\beta_t}}(x)\partial_t\mu_{\beta_t}(x).\end{aligned}$$

Denote $\langle J\rangle_{\mu_{\beta_t}} := \int J d\mu_{\beta_t}$ the mean of J with respect to μ_{β_t}. One can check that:

$$\partial_t \mu_{\beta_t}(x) = -\beta_t'\left[J(x) - \langle J\rangle_{\mu_{\beta_t}}\right]\mu_{\beta_t}(x).$$

Thus, we easily obtain the following equality:

$$\partial_t \|f_t - 1\|^2_{\mu_{\beta_t}} = 2\sum_{x\in E} f_t(x)(\widetilde{L}_{\beta_t} f_t)(x)\mu_{\beta_t}(x) + \beta_t'\sum_{x\in E}(J(x) - \langle J\rangle_{\mu_{\beta_t}})f_t^2(x)\mu_{\beta_t}. \qquad (16)$$

First, we focus on the first term of the right hand side of Equation (16). Since we try to control the generator of the noisy simulated annealing by the generator of the classical one, it is natural to write $\widetilde{L}_{\beta_t}$ as $L_{\beta_t} + \widetilde{L}_{\beta_t} - L_{\beta_t}$. This comparison leads to the computation:

$$\begin{aligned}&\sum_{x\in E} f_t(x)(\widetilde{L}_{\beta_t} f_t)(x)\mu_{\beta_t}(x)\\ &= \sum_x f_t(x)(L_{\beta_t} f_t)(x)\mu_{\beta_t}(x) + \sum_{x\in E} f_t(x)\left(\sum_{y\in E}(f_t(y) - f_t(x))(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y)\right)\mu_{\beta_t}(x).\end{aligned}$$

We rewrite the last part of the second term using Lemma 1:

$$\begin{aligned}&\sum_{y\in E}(f_t(y) - f_t(x))(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y)\\ &= \sum_{y\in E} f_t(y)(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y) - \sum_{y\in E} f_t(x))(\widetilde{q_{\beta_t}} - q_{\beta_t})(x,y)\\ &\le \epsilon_t^+\sum_{y\in E} f_t(y)q_{\beta_t}(x,y) - \epsilon_t^+\sum_{y\in E} f_t(x)q_{\beta_t}(x,y) + \epsilon_t^+\sum_{y\in E} f_t(x)q_{\beta_t}(x,y) - \epsilon_t^-\sum_{y\in E} f_t(x)q_{\beta_t}(x,y)\\ &\le \epsilon_t^+\sum_{y\in E}(f_t(y) - f_t(x))q_{\beta_t}(x,y) + (\epsilon_t^+ - \epsilon_t^-)f_t(x)\\ &\le \epsilon_t^+ L_{\beta_t} f_t(x) + (\epsilon_t^+ - \epsilon_t^-)f_t(x).\end{aligned}$$

Inserting this in the previous inequality, we get:

$$\begin{aligned}&\sum_{x\in E} f_t(x)(\widetilde{L}_{\beta_t} f_t)(x)\mu_{\beta_t}(x)\\ &\le (1+\epsilon_t^+)\sum_x f_t(x)(L_{\beta_t} f_t)(x)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-)\sum_{x\in E} f_t^2(x)\mu_{\beta_t}(x)\\ &\le (1+\epsilon_t^+)\sum_x f_t(x)(L_{\beta_t} f_t)(x)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-)\sum_{x\in E}(f_t^2(x) - 1)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-).\end{aligned}$$

Therefore, using Equation (16), we obtain the following inequality:

$$\begin{aligned}&\frac{d}{dt}\|f_t - 1\|^2_{\mu_{\beta t}}\\ &\le 2\left[(1+\epsilon_t^+)\sum_x f_t(x)(L_{\beta_t} f_t)(x)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-)\sum_{x\in E}(f_t^2(x) - 1)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-)\right]\\ &\quad + \beta_t'\sum_{x\in E}(J(x) - \langle J\rangle_{\mu_{\beta_t}})f_t^2(x)\mu_{\beta_t}\\ &\le 2\left[(1+\epsilon_t^+)\sum_x f_t(x)(L_{\beta_t} f_t)(x)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-)\sum_{x\in E}(f_t^2(x) - 1)\mu_{\beta_t}(x) + (\epsilon_t^+ - \epsilon_t^-)\right]\\ &\quad + \beta_t'\sum_{x\in E}(J(x) - \langle J\rangle_{\mu_{\beta_t}})(f_t(x) - 1)^2\mu_{\beta_t}(x) + 2\beta_t'\sum_{x\in E}(J(x) - \langle J\rangle_{\mu_{\beta_t}})(f_t(x) - 1)\mu_{\beta_t(x)}.\end{aligned}$$

In order to deal with the first sum we use an estimate of the spectral gap of L_{β_t}. This is provided by Theorem 2.1 of Holley and Strook(Holley and Stroock, 1988).

Theorem 4 (Holley and Strook 88) *Under assumptions of 2.2, there exist two positive constants $0 < c \le C < +\infty$ such that $\forall\ \beta \in \mathbb{R}_+$,*

$$ce^{-\beta m^\star} \le \gamma(\beta) \le Ce^{-\beta m^\star}$$

where $\gamma(\beta) = \inf\{-\int \phi L_\beta \phi\ d\mu_\beta : \|\phi\|_{\mu_\beta} = 1$ and $\int \phi d\mu_\beta = 0\}$ and $m^\star$ is the maximum depth of a well containing a local minimum defined in Equation(4). ■

Remark 2 *The constant $m^\star$ is always strictly positive as soon as the function has a strict local minimum that is not global. This is generally the case in our setting. Also, we always have $m^\star \leq M$.*

Following of the Proof. Using the definition of f_t, one can see that $\int f_t d\mu_{\beta_t} = 1$, hence applying the theorem for $\phi = \dfrac{f_t - 1}{\|f_t - 1\|_{\mu_{\beta_t}}}$ gives:

$$-\sum_x \phi(L_{\beta_t}\phi)(x)\mu_{\beta_t}(x) \geq ce^{-\beta_t m^\star}.$$

This and the definition of L_{β_t} imply:

$$\sum_x f_t(x)(L_{\beta_t}f_t)(x)\mu_{\beta_t}(x) \leq -ce^{-\beta_t m^\star}\|f_t - 1\|^2_{\mu_{\beta_t}}.$$

J is a positive function bounded by M on E'. For all $x \in E \setminus E'$, the only points where $J > M$, we have that $J(x) = +\infty$ and therefore $\mu_{\beta_t}(x) = 0$. This implies that for all measurable functions g,

$$\sum_{x\in E}(J(x) - \langle J\rangle_{\mu_{\beta_t}})g(x)\mu_{\beta_t} \leq M\|g\|_{\mu_{\beta_t}}.$$

Putting all these terms together gives:

$$\begin{aligned}\frac{d}{dt}\|f_t - 1\|^2_{\mu_{\beta_t}} \leq 2\left[-ce^{-\beta_t m^\star}(1+\epsilon_t^+) + (\epsilon_t^+ - \epsilon_t^-) + \frac{M}{2}\beta_t'\right]\|f_t - 1\|^2_{\mu_{\beta_t}} \\ + 2M\beta_t'\|f_t - 1\|_{\mu_{\beta_t}} \\ + 2(\epsilon_t^+ - \epsilon_t^-).\end{aligned} \tag{17}$$

We denote $u_t = \|f_t - 1\|^2_{\mu_{\beta_t}}$. Considering the fact that ϵ_t^+ is a positive function we have:

$$\begin{aligned}u_t' \leq 2\left[-ce^{-\beta_t m^\star} + (\epsilon_t^+ - \epsilon_t^-) + \frac{M}{2}\beta_t'\right]u_t \\ + 2M\beta_t'\sqrt{u_t} \\ + 2(\epsilon_t^+ - \epsilon_t^-).\end{aligned} \tag{18}$$

Using that, $\forall x \in \mathbb{R}$, $\frac{1}{4}x^2 + 1 \geq x$, we get:

$$\begin{aligned}u_t' \leq 2\left[-ce^{-\beta_t m^\star} + (\epsilon_t^+ - \epsilon_t^-) + (\frac{M}{2} + \frac{M}{4})\beta_t'\right]u_t \\ + 2M\beta_t' + 2(\epsilon_t^+ - \epsilon_t^-).\end{aligned} \tag{19}$$

Let $A_t = 2ce^{-\beta_t m^\star}$ and $B_t = 2(\epsilon_t^+ - \epsilon_t^-) + 2M\beta_t'$.

Applying Grönwall's Lemma for the previous relation gives:

$$u_t \leq u_0 e^{\int_0^t -A_s + B_s \mathrm{d}s} + \int_0^t B_s e^{\int_s^t -A_h + B_h \mathrm{d}h}\mathrm{d}s. \tag{20}$$

Under Assumptions 2.2, there exist $b, d > 0$ such that $\beta_t = b\log(1+td)$. This implies:

$$\beta_t' = \frac{bd}{1+td} \text{ and } e^{-m^\star\beta_t} = \left(\frac{1}{1+td}\right)^{m^\star b}.$$

Using the definition of $\epsilon_t^+, \epsilon_t^-$ and the fact that $n_t = (1+t)^\alpha$ one can check that:

$$A_t = \mathcal{O}\left(\frac{1}{t^{m^\star b}}\right) \text{ and } B_t = \mathcal{O}\left(\frac{1}{t} \vee \frac{\log t}{t^{\alpha/2}}\right)$$

We can see that if $B_t = o(A_t)$ the second term of Equation (20) is bounded and gives us a finite upper bound on u_t. This happens as soon as:

$$m^\star b < 1 \wedge \alpha/2 \tag{21}$$

However, the condition given by Equation (21) is sufficient yet not necessary. For $\alpha > 2$, B_t becomes of the order $\mathcal{O}(1/t)$ and thus we can choose d in a way that preserves a finite upper bound of Equation (20) even for $m^\star b = 1$. One can check by direct computation that this is true for any $d < cm^\star/M$.

Let β_t and n_t be chosen in order to comply to one of the two previously mentioned conditions. Then there exists a constant K' such that

$$u_t \leq K' \text{ for all } t \in \mathbb{R}^+ \tag{22}$$

To complete the proof of Theorem 3 one can observe that for all $t \in \mathbb{R}_+$, and all $\epsilon > 0$:

$$\mathbb{P}(\widetilde{X}_t \in {}^{\mathsf{c}}\chi_\epsilon) = \mathbb{E}(\mathbb{1}_{[J^\star+\epsilon,+\infty)}(J(\widetilde{X}_t))).$$

Using the Cauchy-Schwarz inequality and the upper bound given by Equation (22) we obtain:

$$\begin{aligned}\mathbb{E}(\mathbb{1}_{[J^\star+\epsilon,+\infty}(J(\widetilde{X}_t))) &= \int_{\mathbb{R}} \mathbb{1}_{[J^\star+\epsilon,+\infty}(J(x))f_t d\mu_{\beta_t}(x) \\ &\leq \left(\int_{\mathbb{R}}(f_t)^2 d\mu_{\beta_t}(x)\right)^{\frac{1}{2}}\left(\int_{\mathbb{R}}\mathbb{1}^2_{[J^\star+\epsilon,+\infty)}(J(x))d\mu_{\beta_t}(x)\right)^{\frac{1}{2}} \\ &\leq \|f_t\|_{L^2_{\mu_{\beta_t}}}(\mu_{\beta_t}({}^{\mathsf{c}}\chi_\epsilon))^{1/2} \\ &\leq K(\mu_{\beta_t}({}^{\mathsf{c}}\chi_\epsilon))^{1/2}\end{aligned} \tag{23}$$

with $K = \sqrt{K'+1}$. This completes the proof of Theorem 3. ■

5.2. Convergence Rate

A first rate of convergence can be deduced from Theorem 3 using the concentration speed of the Gibbs measure on χ_ϵ.

$$\begin{aligned}\mu_{\beta_t}({}^c\chi_\epsilon) &= \frac{\sum_{x\in{}^c\chi_\epsilon} e^{-\beta_t J(x)}}{\sum_{x\in E} e^{-\beta_t J(x)}} \\ &= \frac{\sum_{x\in{}^c\chi_\epsilon} e^{-\beta_t J(x)}}{\sum_{x\in{}^c\chi_\epsilon} e^{-\beta_t J(x)} + \sum_{x\in\chi_\epsilon} e^{-\beta_t J(x)}} \\ &\leq \frac{(|E|-|\chi_\epsilon|)e^{-\beta_t(J^\star+\epsilon)}}{0+|\chi_\epsilon|e^{-\beta_t J^\star}} \\ &\leq \left(\frac{|E|}{|\chi_\epsilon|}-1\right)(1+td)^{-b\epsilon} \end{aligned} \tag{24}$$

As the dependency of K (Theorem 3) in b and α is not explicit, we can however not deduce an optimal choice of (b,α) from this bound. This can be achieved if we assume that Equation (21) holds and distinguish the two cases $\alpha \leq 2$ and $\alpha > 2$. Indeed, we can then improve the bound on u_t and derive a more accurate convergence rate of the algorithm. This rate can then be optimized to obtain either an upper bound of the probability of convergence to χ_ϵ for a fixed computational budget or the minimal computational budget at a fixed risk of convergence out of χ_ϵ.

Theorem 5 *Under assumptions of Section 2.2, suppose:* $\beta_t = b\log(td+1)$, $n_t = (1+td)^\alpha$ *and* $m^\star b < \min(\alpha/2, 1)$*:*

- *if* $\alpha \geq 2$, *let* b *be such that* $m^\star b < 1$ *and let* $\gamma \in (0, \alpha/2 - m^\star b)$, *Then, there exist* $\Gamma_\gamma, \Gamma_2 > 0$ *such that for* t *large enough, for all* $\epsilon > 0$,

$$\mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) \leq \Gamma_\gamma\Gamma_2(1+td)^{(m^\star b-1-b\epsilon)/2} + \Gamma_2(1+td)^{-b\epsilon}$$

- *if* $\alpha < 2$, *let* b *be such that* $m^\star b < \alpha/2$ *and let* $\gamma \in (0, \alpha/2 - m^\star b)$, *Then, there exist* $\Gamma_\gamma, \Gamma_2 > 0$ *such that for* t *large enough, for all* $\epsilon > 0$,

$$\mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) \leq \Gamma_\gamma\Gamma_2(1+td)^{(m^\star b-\alpha/2+\gamma-b\epsilon)/2} + \Gamma_2(1+td)^{-b\epsilon}$$

■

Remark 3 γ *is not a new parameter of the NSA algorithm. This is a technical element that enables the tuning of the computational complexity bounds of Section 5.3. As shown in the Appendix A,* Γ_γ *is of the order of* $1/\gamma$.

Remark 4 *This two bounds display the trade off between the convergence rate of the Gibbs measure to the uniform distribution over the global minima and the rate of convergence of the NSA process to the Gibbs measure. For the first bound, considering* $\alpha > 2$ *we recover the classical rate of convergence of the simulated annealing in the noise free case. This corresponds to the result of Gutjahr and Pflug (1996). The second bound provides the rate of convergence for a choice of* $\alpha < 2$. *It can be seen that* b *will have to be reduced to ensure the convergence and thus this bound exhibits clearly the trade off between cooling and estimation.*

Proof. Under assumptions of Theorem 5, the following bound on u_t can be derived from Grönwall's Lemma (for details see Appendix A):

$$u_t \leq \begin{cases}\Gamma_\gamma(1+td)^{m^\star b-1} & \text{if } \alpha \geq 2 \\ \Gamma_\gamma(1+td)^{m^\star b-\alpha/2+\gamma} & \text{if } \alpha < 2\end{cases} \tag{25}$$

Thus we can compute a new bound on the probability that $\widetilde{X}_t$ does not belong to the optimal set χ_ϵ (*cf.* 6):

$$\begin{aligned}\mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) &= \int_{\mathbb{R}} \mathbb{1}_{{}^c\chi_\epsilon}(J(x))f_t d\mu_{\beta_t}(x) \\ &= \int_{\mathbb{R}} \mathbb{1}_{{}^c\chi_\epsilon}(J(x))(f_t-1)d\mu_{\beta_t}(x) + \int_{\mathbb{R}_+} \mathbb{1}_{{}^c\chi_\epsilon}(J(x))d\mu_{\beta_t}(x) \\ &\leq \left(\int_{\mathbb{R}_+}(f_t-1)^2 d\mu_{\beta_t}(x)\int_{\mathbb{R}_+}\mathbb{1}^2_{{}^c\chi_\epsilon}(J(x))d\mu_{\beta_t}(x)\right)^{1/2} + \mu_{\beta_t}({}^c\chi_\epsilon) \\ &\leq \sqrt{u_t\mu_{\beta_t}({}^c\chi_\epsilon)} + \mu_{\beta_t}({}^c\chi_\epsilon) \end{aligned} \tag{26}$$

This means that if there exist (α, b) such that $u_t = \mathcal{O}(\mu_{\beta_t})$ the convergence rate in the noisy case will be of the same order as in the classical one, but for a smaller b.

Using the previous inequality, Equation (25) and the concentration rate of the Gibbs measure given by Equation (24) we have:

$$\mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) \leq \begin{cases}\Gamma_\gamma\Gamma_2(1+td)^{\frac{m^\star b-1-b\epsilon}{2}} + \Gamma_2(1+td)^{-b\epsilon} & \text{if } \alpha \geq 2 \\ \Gamma_\gamma\Gamma_2(1+td)^{\frac{m^\star b-\alpha/2+\gamma-b\epsilon}{2}} + \Gamma_2(1+td)^{-b\epsilon} & \text{if } \alpha < 2\end{cases}$$

where $\Gamma_2 = \frac{|E|}{|\chi_\epsilon|} - 1$. ■

5.3. Computational Complexity of NSA

Given the convergence rate of the algorithm, we can define $T^\star$ such that the confidence inequality constraint is satisfied at time $T^\star$.

Let N^T_{call} be the number of cost function evaluations made by the NSA until time T. This is a random variable. We define the computational cost of the algorithm as the expectation of this random variable. It can be written as:

$$\mathbb{E}\left(N^T_{call}\right) = \mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T}N_{T_k}\right).$$

Lemma 6 *Let* $\delta, \epsilon > 0$, $\gamma \in (0, \alpha/2 - m^\star b)$ *and*

$$T^\star = \frac{1}{d}\left(\max\left(\left(\frac{2\Gamma_\gamma}{\delta}\right)^{2/(\min(1,\frac{\alpha}{2}-\gamma)-m^\star b+b\epsilon)}, \left(\frac{2\Gamma_2}{\delta}\right)^{1/b\epsilon}\right) - 1\right).$$

Then, for all $t \geq T^\star$, $\mathbb{P}(\widetilde{X}_t \in {}^c\chi_\epsilon) \leq \delta$ and the computational cost up to time $T^\star$ is bounded:

$$\mathbb{E}\left(N_{call}^{T^*}\right) \leq \frac{1}{d}\max\left(\left(\frac{2\Gamma_\gamma}{\delta}\right)^{2(\alpha+1)/(\min(1,\frac{\alpha}{2}-\gamma)-m^\star b+b\epsilon)}, \left(\frac{2\Gamma_2}{\delta}\right)^{(\alpha+1)/b\epsilon}\right).$$

■

Proof. In order to prove this statement, we use the inequalities from Theorem 5 treating each term separately.
We consider T_1, T_2 such that $\Gamma_\gamma\Gamma_2(1+dT_1)^{m^\star b-\min(1,\frac{\alpha}{2}-\gamma)-b\epsilon} = \delta/2$ and $\Gamma_2(1+dT_2)^{-b\epsilon} = \delta/2$. This implies:

$$1+dT_1 = \left(\frac{2\Gamma_\gamma}{\delta}\right)^{2/(\min(1,\frac{\alpha}{2}-\gamma)-m^\star b+b\epsilon)} \text{ and } 1+dT_2 = \left(\frac{2\Gamma_2}{\delta}\right)^{1/b\epsilon}. \tag{27}$$

Now we can define $T^\star$, the time after which the current state of the NSA belongs to χ_ϵ with probability at least $1-\delta$, *i.e.*, $\forall t > T^\star,\ \mathbb{P}(\widetilde{X}_t \in \chi_\epsilon) \geq 1-\delta$:

$$T^\star = \max(T_1, T_2).$$

We are interested in the computational cost up to time $T^\star$, more precisely the expected number of Monte Carlo simulations used up to $T^\star$. This is given by $\mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}N_{T_k}\right)$. The value of this quantity cannot be computed exactly, but it can easily be upper bounded.

$$\begin{aligned}\mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}N_{T_k}\right) =& \mathbb{E}\left(\mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}N_{T_k}\right)|(T_k)_{k=1\cdots+\infty}\right)\\ =& \mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}n_{T_k}\right)\\ \leq& \mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}\right)n_{T^\star}\end{aligned}$$

The last inequality is implied by the fact that n_t is an increasing function. Since $\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}$ is a Poisson variable of parameter $T^\star$, using the definition of n_t one can see that:

$$\begin{aligned}\mathbb{E}\left(\sum_{k\geq 1}\mathbb{1}_{T_k<T^\star}N_{T_k}\right) \leq& T^\star(1+dT^\star)^\alpha \\ \leq& \frac{1}{d}(1+dT^\star)^{\alpha+1}.\end{aligned} \tag{28}$$

We conclude using Equation (27). ■

The rate of growth of the total computation number is mainly driven by the exponent of $\frac{1}{\delta}$ in the cost function. We are looking for the couple (α, b) that minimizes this quantity and fulfills the requirements of Theorem 5. We can split the problem into two sub-problems:

Case 1: $\frac{\alpha}{2}-\gamma > 1$

$$\begin{aligned}&\min_{b,\alpha}\ \max\left(\frac{2(\alpha+1)}{1-m^\star b+b\epsilon}, \frac{\alpha+1}{b\epsilon}\right)\\ &s.t.\\ &\quad m^\star b < 1 \text{ and } \alpha - 2\gamma > 2\end{aligned} \tag{29}$$

Case 2: $\frac{\alpha}{2} \leq 1$

$$\begin{aligned}&\min_{b,\alpha}\ \max\left(\frac{2(\alpha+1)}{\alpha/2-\gamma-m^\star b+b\epsilon}, \frac{\alpha+1}{b\epsilon}\right)\\ &s.t.\\ &\quad 0 < \gamma < \frac{\alpha}{2} - m^\star b \text{ and } \alpha - 2\gamma \leq 2\end{aligned} \tag{30}$$

The solution of Equation (29) is obvious, the minimal value for α and the maximal for b, *i.e*, α must be as close to 2 as possible and $b = \frac{1}{m^\star+\epsilon}$. As for Equation (30), we consider two sub-cases. First suppose that:

$$\frac{2(\alpha+1)}{\alpha/2-\gamma-m^\star b+b\epsilon} \geq \frac{\alpha+1}{b\epsilon} \iff \alpha/2-\gamma-m^\star b \leq b\epsilon. \tag{31}$$

The function we want to minimize is strictly decreasing in α and strictly increasing in b, so its minimum value is attained for the maximal value of α and the minimal value of b, under the domain constraints given by Equation (30) and Equation (31), so the solution is:

$$\alpha = 2(1+\gamma) \text{ and } b > \frac{1}{m^\star+\epsilon}. \tag{32}$$

In the second sub-case, supposing that the inequality Equation (31) is inverted, the problem can be resumed at minimizing $(\alpha+1)/b\epsilon$, a decreasing function with respect to b, for

$$b \leq \frac{\alpha/2-\gamma}{(m^\star+\epsilon)} \text{ and } \alpha \leq 2.$$

Replacing b by its maximal value the objective function becomes a decreasing function in α, and therefore we obtain the same solution as before, defined in Equation (32). This is a quite comprehensive result, as it indicates that the lower the required accuracy in the solution space is, *i.e.*, ϵ increases and thus the size of χ_ϵ does too, the faster the temperature can decrease to zero. We need to explore less the state space.

Corollary 1 *For the optimal parameters choice defined in Equation (32), an ϵ-optimal solution is returned by NSA with probability $1-\delta$ at a computational cost at most :*

$$\frac{1}{d}\left(\frac{2\Gamma_\gamma}{\delta}\right)^{\frac{m^\star+\epsilon}{\epsilon}(3+2\gamma)},$$

where Γ_γ is defined in Theorem 5.

This is rather costly but represents a general bound with few constraints on the function J. However, if the function J has additional properties the bound can be significantly improved:

Corollary 2 *Suppose that J has no well containing a local minimum, apart from the one containing the global minimum, i.e. $m^\star = 0$, then an ϵ-optimal solution is returned by NSA with probability $1-\delta$ at a computational cost at most :*

$$\left(\frac{2\log\frac{1}{\delta}}{d\epsilon}\right)^3.$$

Remark 5 *We recover the polynomial dependency in $1/\epsilon$ and $\log 1/\delta$ of the state-of-the-art complexity results (c.f. Woodroofe 1972 and Nemirovski et al. 1982) which are of the order of $\epsilon^{-2}\log(\frac{1}{\delta})$ for strongly convex cost functions. As we relax this assumption and only consider cost functions with no local minimum, it seems coherent to observe a slight degradation of the complexity.*

Proof. In order to have an estimate of the computational cost in this setting we follow the same method as before and highlight only the main steps of the proof. First remark that in this case, Theorem 4 states that there exist $C, c > 0$ such that $\forall \beta \in \mathbb{R}^+$:

$$c \leq \gamma(\beta) \leq C \tag{33}$$

This changes the differential inequality obtained for $u_t = \|f_t - 1\|^2_{\mu_{\beta_t}}$ and thus Equation (19) becomes :

$$u'_t \leq 2\left[-c + (\epsilon_t^+ - \epsilon_t^-) + (\frac{M}{2} + \frac{M}{4})\beta'_t\right] u_t + 2M\beta'_t + 2(\epsilon_t^+ - \epsilon_t^-).$$

We can apply Grönwall's Lemma and obtain the same type of inequality as before:

$$u_t \leq u_0 e^{\int_0^t -A_s + B_s \mathrm{d}s} + \int_0^t B_s e^{\int_s^t -A_h + B_h \mathrm{d}h}\mathrm{d}s. \tag{34}$$

where B_t has the same form as before, $B_t = 2(\epsilon_t^+ - \epsilon_t^-) + 2M\beta'_t$ and $A_t = 2c$.

The convergence of u_t towards 0 can be proved now for a larger class of functions n_t, β_t, since:

$$A_t = \mathcal{O}(1) \text{ and } B_t = \mathcal{O}(\beta_t/\sqrt{n_t} \vee \beta'_t).$$

We no longer need to impose $\beta_t = \mathcal{O}(\log_t)$. Let $\alpha, b, d > 0$. Define

$$n_t = (1+t)^\alpha \text{ and } \beta_t = d(1+t)^b.$$

Using Equation (34) one can check that we have a finite upper bound on u_t as soon as:

$$\{b < \alpha/2 \wedge 1, d > 0\} \text{ or } \{b = 1, \alpha \geq 2, 0 < d < c\}.$$

This in particular implies that the NSA algorithm converges a.s. to the set of global minimums of J. Furthermore for the first set of conditions one can prove using the same technique as in Appendix A that :

$$u_t = \mathcal{O}(t^{\max(b-1, b-\alpha/2)}).$$

This means that there exits $\Gamma'_\gamma > 0$ such that for t large enough $u_t \leq \Gamma'_\gamma t^{-\gamma}$, where $\gamma = -\max(b-1, b-\alpha/2)$. Using this, Equation (26) and Equation (24), for t large enough, we get:

$$\begin{aligned}\mathbb{P}(\widetilde{X}_t \in {}^{\mathsf{c}}\chi_\epsilon) &\leq \Gamma'_\gamma t^{-\gamma/2} e^{-\epsilon d(1+t)^b/2} + \Gamma_2 e^{-\epsilon d(1+t)^b} \\ &\leq e^{-\epsilon d(1+t)^b/2}(\Gamma'_\gamma t^{-\gamma/2} + \Gamma_2 e^{-\epsilon d(1+t)^b/2}) \\ &\leq e^{-\epsilon d(1+t)^b/2}\end{aligned}$$

The last inequality is valid as soon as $t > \max\left[\left(\frac{2\log(2\Gamma_2)}{\epsilon d}\right)^{\frac{1}{b}} - 1, \left(2\Gamma'_\gamma\right)^{\frac{2}{\gamma}}\right]$. This is not a restrictive condition. Take for example the minimization of the $\|.\|_1$ over the subset subset $E = \{x \in \mathbb{Z}^p, \|x\|_\infty \leq n\}$ for some $n \in \mathbb{N}$. As $\Gamma_2 = \|E\| - 1 = (n+1)^p - 1$, the time for which the first part of the condition is fulfilled only grows linearly with the dimension of the search space. We show latter on that the optimal choice for b is one and thus the second part of the condition can be omitted.

Let $\delta > 0$ be a fixed. Using the previous inequality one can compute $T^\star$ such that the confidence inequality constraint is satisfied:

$$T^\star_{\epsilon,\delta} = \left(-\frac{2\log\delta}{d\epsilon}\right)^{1/b} - 1.$$

Regarding the computational cost we remind the reader that Equation (28) implies:

$$\mathbb{E}(N^{T^\star}_{call}) \leq n_{T^\star} T^\star \leq \left(-\frac{2\log\delta}{d\epsilon}\right)^{\frac{1+\alpha}{b}}.$$

We can optimize this bound with respect to α and b in the same way as for Corollary 1. This leads to $\alpha = 2$ and $b < 1$ and thus to the desired results:

$$\mathbb{E}(N^{T^\star}_{call}) \leq \left(-\frac{2\log\delta}{d\epsilon}\right)^3.$$

■

6. Numerical Experiments

In this section we first present some test cases, for which we use an additive Gaussian noise at each evaluation. We recover the theoretical results introduced by Gutjahr and Pflug (1996). In a second part we present some results for the aircraft trajectory optimization problem. In this case the solution of the problem is unknown. We can only observe the total cost improvement in comparison with a trajectory optimized for a similar but deterministic setting.

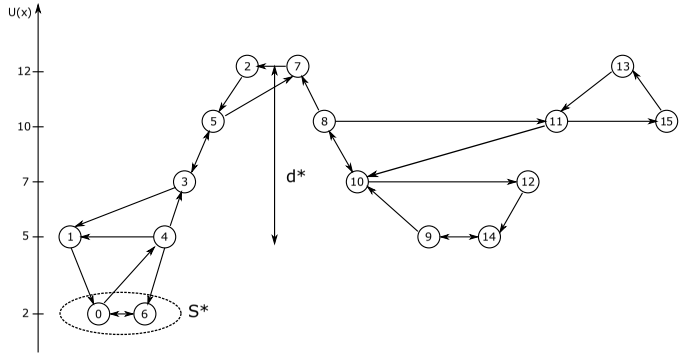

Figure 2: B. Hajek test case for the simulated annealing in a deterministic environment

6.1. Basic Exemple

The first experimental setting we consider, was introduced in (Hajek, 1988). The cost function and the neighbourhood structure are represented on Figure 2. This is of particular interest as the function has two basins from which it is hard to escape. B. Hajek has shown that the following holds:

Theorem 7 (Hajek 1988)
If $\beta_k = b\ log(k+2)$, then $b \leq d^\star \Leftrightarrow \lim_{k\to\infty} \mathbb{P}(X_k \in S^\star) = 1$, *where $d^\star$ is the maximum depth of a cup containing a local but not global minima. The depth of a cup is the maximal energy difference between two of it states and $(X_k)_{k\in\mathbb{N}}$ denotes the Markov chain generated by the classical simulated annealing.* ■

For a complete definition of $d^\star$, see Hajek (1988).

We add Gaussian noises to the cost function of Figure 2 with different variance levels to highlight the fact that if only one sampling is performed the simulated annealing performance becomes rapidly very poor as the variance increases. On the other hand it appears that the performance of the NSA for a linear increase of the mean number of samples is as good a quadratic one. These results are summarized on Figure 3.

6.2. Ackley Test Function

We introduce a second test case to further asses these observations. We consider the uniformly (2000 points) discretized version of the Ackley function in one dimension on $[-100, 100]$. This function has many local minima as shown on Figure 4.

Figures 5 displays the convergence results on this test case for different levels of variance of the added Gaussian noise, for each estimation schedule introduced in this paper. As before, the success ratio of the algorithm is established using 1000 Monte Carlo runs for each noise level and estimation schedule, by comparing at every run the returned value with

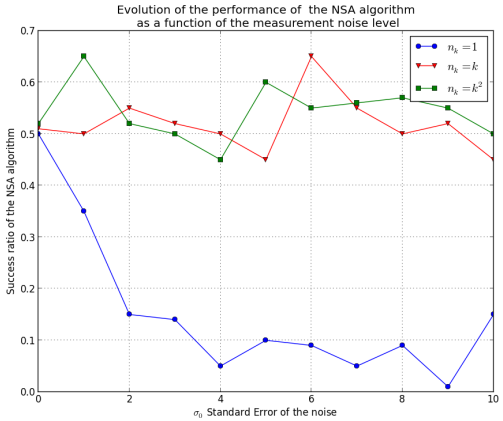

Figure 3: Convergence performance of NSA for the Hajek setting. Each line represents the evolution of the success ratio of the algorithm when the variance of the noise added to the cost function increases. The success ratio is measured over 1000 Monte Carlo simulations for each level of noise. A run is considered successful if the algorithm returns a true optimal value. One can see that the performance in the case where the mean sample number is generated using $n_k = k^2$ (green curve) or $n_k = k$ (red curve) is similar and quite stable, as opposed to case of only one sample used at each step (blue curve), where the success ratio decreases rapidly.

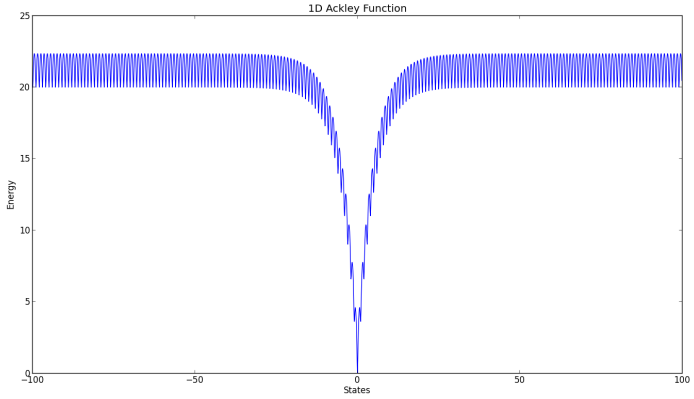

Figure 4: Ackley 1D Test Function

the true optimizer of the cost function. We observe that the only case where the convergence is not impacted by the noise variance increase is the $n_t = t^2$ case (corresponding to the use of approximately k^2 measurements at each step k). Although, when the variance of the noise is rather small (equal to 1), the algorithm's performance using the linear schedule ($n_t = t$) or the quadratic one ($n_t = t^2$) is quite similar, a clear gap is highlighted between the two schedules as soon as the variance increases.

These results also highlight the fact that a logarithmic sampling schedule is not appropriate for any cost function, even in the Gaussian case. This invalidates partially the hypotheses introduced in Fink (1998).

6.3. Aircraft Trajectory Optimization

We use a black box trajectory evaluator for a long range commercial aircraft. We consider a direct shooting method for optimizing the vertical part of the trajectory. As displayed on Figure 6, the vertical path is made of a sequence of flight segments at constant altitude called steps. The transitions between those steps are called step climbs. This has been put in place by the international authorities to ease the air traffic control. Aircraft can only fly at a finite set of altitudes. The steps climbs are transition phases that must be very short. The Figure 6 is a conceptual. It does not reflect the real scale of the different phases. Our optimization variables are the vectors of position of the steps and the vector of steps' altitude, denoted respectively x and h on Figure 6. The structure of this airspace strongly limits the number of steps. We will only consider the problem with an *a priori* number of steps. There are two main reasons why the aircraft might vary its altitude during a flight

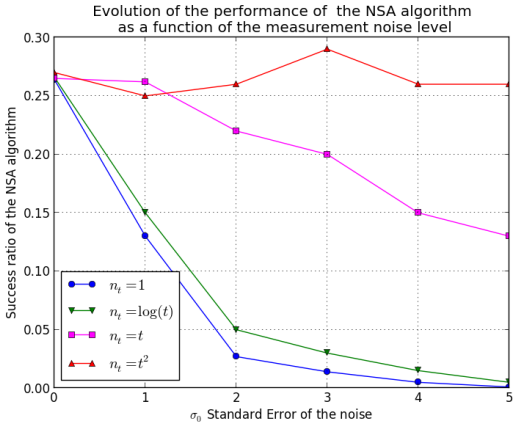

Figure 5: Performance of the NSA algorithm as a function of the level of noise on the evaluation of the cost function.

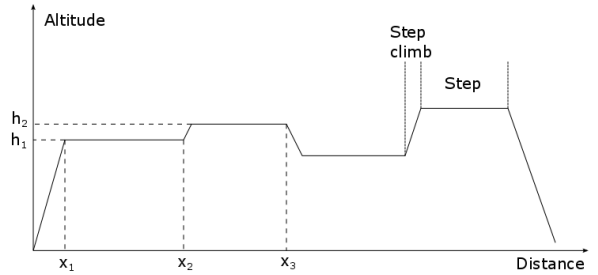

Figure 6: Aircraft trajectory, structure of the vertical path

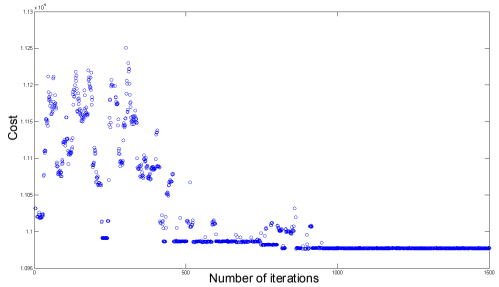

Figure 7: NSA descent: Aircraft trajectory optimization problem

(optimizing fuel consumption and air traffic control). Because of fuel consumption, the aircraft weight is decreasing during the flight. Analyzing the laws of flight physics, it can be shown that there exists an altitude at which the fuel consumption per flown distance unit is minimal. It can also be shown that this altitude increases as the weight decreases. This last statement is however only true if there is no wind. It is easily understandable that for some particular wind map configuration it might be preferable to target lower altitudes at lower weights.
The choice of the vertical path must be declared to the authorities before the flight to ensure traffic manageability. Airlines operating aircraft have therefore a stochastic optimization problem to solve. This is a stochastic problem for two main reasons. First, they only access predicted weather conditions that suffer some uncertainty. Second, the airspace is not empty and sometimes air traffic controllers might refuse some altitude changes because of the presence of other aircraft. As the weather, the traffic is not known in advance.
We applied NSA to the problem of finding an optimal 3 steps configuration. An example of the current solution cost evolution with respect to the number of iterations is displayed on Figure 7.

We observe a very quick convergence to a low cost trajectory. We do not claim it is a general behaviour. It might be due to the structure of the cost function. Figure 8, shows how the cost evolves with respect to the ground position of the first step. It is obviously not convex but has some regularity. We can observe some flat parts. This explains why gradient based methods would fail solving this problem. However, we are not aware of any other study solving the Aircraft trajectory optimization problem under uncertainty using a Black box aircraft model and are thus unable to provide more advance appreciation of the performance of such an approach.

As for the previous problems we have observed that the increase sampling condition must be satisfied to ensure a good behaviour of the algorithm.

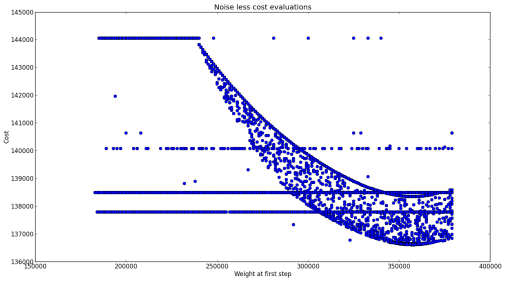

Figure 8: Sampling of the cost function along the first step position for a 3 step vertical path

Appendix A. Proof of Bound Equation (25)

Proof.[Proof of Theorem 5]
Let $\beta_t = b\log(td+1)$ and $n_t = (1+td)^\alpha$.
Recall Equation (18):

$$u'_t \leq 2\left[-ce^{-\beta_t m^\star} + (\epsilon^+ - \epsilon^-) + \left(\frac{M}{2} + \frac{M}{4}\right)\beta'_t\right] u_t + 2M\beta'_t + 2(\epsilon^+ - \epsilon^-)$$

Let $A_t = 2ce^{-\beta_t m^\star}$ and $B_t = 2(\epsilon^+ - \epsilon^-) + 2M\beta'_t$.

Applying Grönwall's Lemma for the previous relation gives:

$$u_t \leq u_0 e^{\int_0^t -A_s + B_s \mathrm{d}s} + \int_0^t B_s e^{\int_s^t -A_h + B_h \mathrm{d}h} \mathrm{d}s$$

Under Assumptions 2.2, there exist $b, d > 0$ such that $\beta_t = b\log(1+td)$. This implies:

$$\beta'_t = \frac{bd}{1+td} \text{ and } e^{-m^\star \beta_t} = \left(\frac{1}{1+td}\right)^{m^\star b}.$$

Using the definition of ϵ^-, ϵ^+ we have:

$$\epsilon^+ - \epsilon^-_t = 2\sqrt{2\pi}\beta_t\sigma\left[\frac{e^{\frac{\beta_t^2\sigma^2}{2(1-\delta)n_t}}}{\sqrt{(1-\delta)n_t}} + e^{\beta_t^2\sigma^2 - an_t}\right].$$

This implies that when t goes to infinity:

$$A_t = \mathcal{O}\left(\frac{1}{t^{m^\star b}}\right) \text{ and } B_t = \mathcal{O}\left(\frac{1}{t} \vee \frac{\log t}{t^{\alpha/2}}\right)$$

In order to highlight the mains ideas of the proof we will try to simplify the notations as much as possible. First observe that for all $\alpha > 0$ and all $0 < \gamma < \alpha/2$, $\frac{\log t}{t^{\alpha/2}} = o\left(\frac{1}{t^{\alpha/2-\gamma}}\right)$.

Hence we can assume there exist $A, B > 0$ and δ_1, δ_2 such that:

$$A_t = A\frac{d}{(1+td)^{\delta_1}} \text{ and } B_t \leq B\frac{d}{(1+td)^{\delta_2}}$$

where $\delta_1 = m^\star b$ and $\delta_2 = \min(1, -\gamma + \alpha/2)$. Since $\min(1, \alpha/2) > m^\star b$, and γ can be chosen arbitrarily close to 0, we choose it such that $\delta_1 < \delta_2$. This means that $0 < \gamma < \alpha/2 - m^\star b$.

Remark 6 *The choice of γ influences the choice of B. If $B_t = \mathcal{O}\left(\frac{\log t}{t^{\alpha/2}}\right)$, there exists $C_B > 0$ such that $B_t \leq C_B\frac{\log t}{t^{\alpha/2}}, \forall t$. The constant B is then such that $\forall t$, $C_B\frac{\log t}{t^\gamma} \leq B$. Hence we can choose:*

$$B = \frac{C_B}{e\gamma}. \tag{35}$$

Let $T_t^1 = u_0 e^{\int_0^t -A_s + B_s \mathrm{d}s}$ and $T_t^2 = \int_0^t B_s e^{\int_s^t -A_h + B_h \mathrm{d}h}\mathrm{d}s$.

The first term T_t^1 is always easy to deal with and one can check that under the theorem's assumptions we always have $T_t^1 = o(1/t^{\delta_1 - \delta_2})$ when t goes to infinity. As for the second term, using a substitution gives:

$$\begin{aligned} T_t^2 &\leq \int_1^{1+td} \frac{B}{s^{\delta_2}} e^{\int_s^{1+td} -\frac{A}{h^{\delta_1}} + \frac{B}{h^{\delta 2}}\mathrm{d}h}\mathrm{d}s \\ &\leq e^{-\frac{A(1+td)^{1-\delta_1}}{1-\delta_1} + \frac{B(1+td)^{1-\delta_2}}{1-\delta_2}} \int_1^{1+td} \frac{B}{s^{\delta_2}} e^{\frac{As^{1-\delta_1}}{1-\delta_1} - \frac{Bs^{1-\delta_2}}{1-\delta_2}}\mathrm{d}s \end{aligned} \tag{36}$$

For the last inequality we assume $\delta_2 \neq 1$ which corresponds to the case $\alpha \leq 2$.

Let $I_t = \int_1^{1+td} \frac{B}{s^{\delta_2}} e^{\frac{As^{1-\delta_1}}{1-\delta_1} - \frac{Bs^{1-\delta_2}}{1-\delta_2}}\mathrm{d}s$ and $f_s = \frac{As^{1-\delta_1}}{1-\delta_1} - \frac{Bs^{1-\delta_2}}{1-\delta_2}$. Let T_0 be such that for all $s \geq T_0$, $s^{\delta_2-\delta_1} \geq \frac{B+1}{A}$ (for instance $T_0 = (\frac{B}{A}+1)^{1/(\delta_2-\delta_1)}$). We can write I_t as follows:

$$\begin{aligned} I_t &= \int_1^{T_0} \frac{B}{s^{\delta_2}} e^{f_s}\mathrm{d}s + \int_{T_0}^{1+td} \frac{B}{s^{\delta_2}} e^{f_s}\mathrm{d}s \\ &= K_{T_0} + \int_{T_0}^{1+td} \frac{B}{s^{\delta_2}(As^{-\delta_1} - Bs^{-\delta_2})} e^{f_s} f_s' \mathrm{d}s \\ &= K_{T_0} + \left[\frac{B}{As^{\delta_2-\delta_1} - B} e^{f_s}\right]_{T_0}^{1+td} + \int_{T_0}^{1+td} \frac{AB(\delta_2-\delta_1)s^{\delta_2-\delta_1-1}}{(As^{\delta_2-\delta_1}-B)^2} e^{f_s}\mathrm{d}s \end{aligned}$$

Since $\delta_1 < \delta_2$, $\frac{A(\delta_2-\delta_1)s^{-\delta_1-1}}{(As^{\delta_2-\delta_1}-B)^2}$ goes to 0 when s goes to infinity. Moreover one can check that for all $s \geq T_0$ this quantity is smaller than $1/2$. Using this we get:

$$I_t \leq K_{T_0} + \left[\frac{B}{As^{\delta_2-\delta_1} - B} e^{f_s}\right]_{T_0}^{1+td} + \frac{1}{2} I_t$$

and therefore for all $t \geq T_0$:

$$I_t \leq 2\left[\frac{B}{As^{\delta_2-\delta_1} - B} e^{f_s}\right]_1^{1+td} + 2K_{T_0}$$

This gives:

$$\begin{aligned} T_t^2 &\leq 2e^{-f_{1+td}}\left(\left[\frac{B}{As^{\delta_2-\delta_1} - B} e^{f_s}\right]_1^{1+td} + K_{T_0}\right) \\ &\leq 2\left[\frac{B}{A(1+td)^{\delta_2-\delta_1} - B}\right] + 2\left(K_{T_0} - \frac{B}{A-B}e^{f_1}\right)e^{-f_{1+td}} \end{aligned}$$

Regrouping the terms we obtain for all $t \geq T_0$:

$$u_t \leq \left[u_0 + 2\left(K_{T_0} - \frac{B}{A-B}e^{f_1}\right)\right]e^{-f_{1+td}} + \frac{2B}{A(1+td)^{\delta_2-\delta_1} - B} \tag{37}$$

Since the first term is a $\mathcal{O}(e^{-f_t})$ and therefore a $o(t^{\delta_1-\delta_2})$ it is obvious that:

$$u_t = \mathcal{O}\left(\frac{1}{t^{\delta_2-\delta_1}}\right) \text{ when } t \to \infty \tag{38}$$

This means that for all $\gamma \in (0, \alpha/2 - m^\star b)$ there exists $\Gamma_\gamma > 0$ such that:

$$u_t \leq \Gamma_\gamma t^{-\alpha/2 + m^\star b + \gamma} \text{ for all } t \geq T_0. \tag{39}$$

Since $f_t = \mathcal{O}(t^{1-\delta_1})$, $e^{-f_t}t^{\delta_1-\delta_2}$ goes very fast to zero and therefore the size of Γ_γ is mainly driven by $\frac{2B}{A}$. Using Equation (35) one can see that:

$$\Gamma_\gamma \simeq \frac{1}{\gamma}.$$

If $\alpha > 2$, $\delta_2 = 1$ and Equation (36) becomes of the form:

$$T_t^2 \leq e^{-\frac{A(1+td)^{1-\delta_1}}{1-\delta_1} + B\log(1+td)} \int_1^{1+td} \frac{B}{s^{1+B}} e^{\frac{As^{1-\delta_1}}{1-\delta_1}}\mathrm{d}s.$$

Using a similar procedure one can check that in this case we also have an inequality similar to Equation (37) , T_2^t remains a $\mathcal{O}\left(\frac{1}{t^{1-\delta_1}}\right)$, and Equation (38) and Equation (39) still hold.

Remark 7 *In this case one can choose $\gamma = \alpha/2 - 1$, this way $\min(1, \frac{\alpha}{2} - \gamma) = 1$ and Γ_γ is minimal.*

■

Appendix B. Definition of $m^\star$

In this section we prove that the definition of $m^\star$, *i.e.* Equation (4), is equivalent to the definition provided by Holley and Stroock (1988).

Lemma 3 *Let,* $m^\star_{HS} := \max_{x,y\in E}\left\{\min_{p\in P_{xy}}\left\{\max_{z\in p} J(z)\right\} - J(y) - J(x) + \min_u J(u)\right\}$.
Then

$$m^\star = m^\star_{HS}$$

■

Proof. Let $x, y \in E$ and denote $H_{xy} := \min_{p\in P_{xy}}\left\{\max_{z\in p} J(z)\right\}$.
First it can be noticed that if x is a global minimum of J then we have

$$H_{x,y} - J(y) - J(x) + \min_u J(u) = H_{x,y} - J(y) \tag{40}$$

Thus $m^\star_{HS} \geq H_{x^\star,y} - J(y)$ for any y in E, where $x^\star$ is a global minimum of J.

Recall that $m^\star = \max_{x,y\in E}\{H_{xy} - \max(J(y), J(x))\}$. As the set of paths going from x to y containing a global minimum $x^\star$ is a subset of the paths going from x to y, we have:

$$H_{xy} \leq \max(H_{x^\star x}, H_{x^\star y})$$

Let $x, y \in E$ such that $m^\star = H_{xy} - \max(J(y), J(x))$,

$$\begin{aligned} m^\star &\leq \max(H_{x^\star x}, H_{x^\star y}) - \max(J(y), J(x)) \\ &\leq \max(H_{x^\star x} - J(x), H_{x^\star y} - J(y)) \\ &\leq m^\star_{HS} \end{aligned}$$

On the other hand, as $\forall\, x, y \in E$, we have $-\min(J(y), J(x)) + \min_u J(u) \leq 0$, so

$$H_{xy} - J(y) - J(x) + \min_u J(u) \leq H_{xy} - \max(J(y), J(x))$$

This implies $m^\star_{HS} \leq m^\star$, which completes the proof. ■

Abstract

In this paper, we consider the problem of learning high-dimensional tensor regression problems with low-rank structure. One of the core challenges associated with learning high-dimensional models is computation since the underlying optimization problems are often non-convex. While convex relaxations could lead to polynomial-time algorithms they are often slow in practice. On the other hand, limited theoretical guarantees exist for non-convex methods. In this paper we provide a general framework that provides theoretical guarantees for learning high-dimensional tensor regression models under different low-rank structural assumptions using the projected gradient descent algorithm applied to a potentially non-convex constraint set Θ in terms of its *localized Gaussian width* (due to Gaussian design). We juxtapose our theoretical results for non-convex projected gradient descent algorithms with previous results on regularized convex approaches. The two main differences between the convex and non-convex approach are: (i) from a computational perspective whether the non-convex projection operator is computable and whether the projection has desirable contraction properties and (ii) from a statistical error bound perspective, the non-convex approach has a superior rate for a number of examples. We provide three concrete examples of low-dimensional structure which address these issues and explain the pros and cons for the non-convex and convex approaches. We supplement our theoretical results with simulations which show that, under several common settings of generalized low rank tensor regression, the projected gradient descent approach is superior both in terms of statistical error and run-time provided the step-sizes of the projected descent algorithm are suitably chosen.

Keywords: tensors, non-convex optimization, high-dimensional regression, low-rank;

1. Introduction

Parameter estimation in high-dimensional regression has received substantial interest over the past couple of decades. See, e.g., Buhlmann and van de Geer (2011); Hastie et al. (2015). One of the more recent advances in this field is the study of problems where the parameters and/or data take the form of a multi-way array or *tensor*. Such problems arise in many practical settings (see, e.g., Cohen and Collins, 2012; Li and Li, 2010; Semerci et al., 2014; Sidiropoulos and Nion, 2010) and present a number of additional challenges that do not arise in the vector or matrix setting. In particular, one of the challenges associated with high-dimensional tensor regression models is how to define low-dimensional structure since the notion of rank is ambiguous for tensors (see, e.g., Koldar and Bader, 2009). Different approaches on how to impose low-rank and sparsity structure that lead to implementable algorithms have been considered. See, e.g., Gandy et al. (2011); Mu et al. (2014); Raskutti and Yuan (2015); Tomioka et al. (2013); Yuan and Zhang (2014), and references therein. All of the previously mentioned approaches have relied on penalized convex relaxation schemes and in particular, many of these different approaches have been encompassed by Raskutti and Yuan (2015). The current work complements these earlier developments by studying the non-convex projected gradient descent (PGD) approaches to generalized low-rank tensor regression.

While convex approaches are popular since greater theoretical guarantees have been provided for them, non-convex approaches have gained popularity as recently more theoretical guarantees have been provided for specific high-dimensional settings. See, e.g., Fan and Li (2001); Jain et al. (2014, 2016); Loh and Wainwright (2015). Furthermore, even though non-convex problems do not in general lead to polynomial-time computable methods, they often work well in practice. In particular, inspired by the recent work of Jain et al. (2014, 2016) who demonstrated the effectiveness of non-convex projected gradient descent approaches for high-dimensional linear regression and matrix regression, we consider applying similar techniques to high-dimensional low-rank tensor regression problems with a generalized linear model loss function.

Low-rankness in higher order tensors may occur in a variety of ways (see e.g. Koldar and Bader (2009) for examples). To accommodate these different notions of low-rankness, we develop a general framework which provides theoretical guarantees for projected gradient descent algorithms applied to tensors residing in general low-dimensional subspaces. Our framework relies on two properties ubiquitous in low-rank tensor regression problems: (i) that the parameter space is a member of a class of subspaces super-additive when indexed over a partially ordered set; and (ii) there exists an approximate projection onto each subspace satisfying a contractive property. Assuming that the coefficient tensor lies in a low-dimensional subspace Θ satisfying these properties, we establish general risk bounds for non-convex projected gradient descent based methods applied to a generalized tensor regression model with covariates with Gaussian design. By developing this general framework in terms of these properties, we only need to verify that our set satisfies these properties and also demonstrate that these properties are fundamental to providing theoretical results for projected gradient descent.

Our main theoretical result shows that the Frobenius norm scales as $n^{-1/2} w_G[\Theta \cap \mathbb{B}_F(1)]$, where n is the sample size, $\mathbb{B}_F(1) := \{A : \|A\|_F \leq 1\}$ refers to the Frobenius-norm ball with radius 1 and $w_G[\Theta \cap \mathbb{B}_F(1)]$ refers to the *localized Gaussian width* of Θ. While statistical rates in terms of Gaussian widths are already established for convex regularization approaches (see, e.g., Chandrasekaran et al., 2012; Raskutti and Yuan, 2015), this to the best of our knowledge is the first general error bound for non-convex projected gradient descent in terms of a localized Gaussian width.

Another major contribution we make is to provide a comparison both in terms of statistical error rate and computation to existing convex approaches to low rank tensor regression. Using our statistical error bound for non-convex projected gradient descent which is stated in terms of the localized Gaussian width of Θ, we show explicitly that our error bound for the non-convex approach is no larger (up to a constant) than those for convex regularization schemes (see, e.g., Theorem 1 of Raskutti and Yuan, 2015), and in some cases is smaller. To make this comparison more concrete, we focus on three particular examples of low-rank tensor structure: (i) sum of ranks of each slice of a tensor being small; (ii) sparsity and low-rank structure for slices; and (iii) low Tucker rank. In case (i), both approaches are applicable and achieve the same rate of convergence. For case (ii), the non-convex approach is still applicable whereas a convex regularization approach is not naturally applicable. In case (iii) again both approaches are applicable but a superior statistical performance can be achieved via the non-convex method. We supplement our theoretical comparison with a simulation comparison. Our simulation results show that our non-convex projected gradient descent based approach compares favorably to the convex regularization approach using a generic `cvx` solver in terms of both run-time and statistical performance provided optimal step-size choices in the projected gradient descent and regularization parameters in the convex regularization approach are used. Furthermore the projected gradient descent scales to much larger-scale data than generic convex solvers.

1.1. Our contributions

To summarize, we make the following three contributions in our paper:

- Firstly, we provide general error bounds for projected gradient descent applied to generalized tensor regression problems in terms of the localized Gaussian width of the constraint set Θ. In particular, we provide three novel results. Theorem 1 provides an upper bound for projected gradient descent with tensor parameters and applies to any Θ satisfying the super-additivity and contractive properties described above and explained in greater detail in Section 3. Theorem 1 substantially generalizes prior results in Jain et al. (2014, 2016) which focus on sparse vectors and low-rank matrices. Theorem 2 and 3 apply the general result in Theorem 1 to generalized linear models and Gaussian linear models respectively. Significantly, Theorems 2 and 3 show that the localized Gaussian width for the constraint set for Θ play a crucial role in the mean-squared error bound. This is the first analysis we are aware of that expresses the statistical error of PGD in terms of localized Gaussian width which allows us to deal with PGD in a more unified manner.

- Using Theorem 3, our second major contribution is to provide a comparison in terms of mean-squared error to standard convex regularization schemes studied in Raskutti and Yuan (2015). We show using the comparison of Gaussian widths in the convex and non-convex cases that unlike for vector and matrix problems where convex regularization schemes provably achieve the same statistical error bounds as non-convex approaches, the more complex structure of tensors means that our non-convex approach could yield a superior statistical error bound in some examples compared to convex regularization schemes. We also prove that our non-convex error bound is no larger than the convex regularization bound developed in Raskutti and Yuan (2015).

- Lastly, we demonstrate in Section 5 the benefits of the non-convex approach compared to existing convex regularization schemes for various low-rank tensor regression problems. We also show through simulations the benefit of using low-rank tensor regularization schemes compared to using a low-rank matrix scheme.

The remainder of the paper is organized as follows: Section 2 introduces the basics of the low-rank tensor regression models we consider and introduces the projected gradient descent algorithm. Section 3 presents the general theoretical results for non-convex projected gradient descent and specific examples are discussed in Section 4. A simulation comparison between the convex and non-convex approach is provided in Section 5 and proofs are provided in Section 7.

2. Methodology

Consider a generalized tensor regression framework where the conditional distribution of a scalar response Y given a covariate tensor $X \in \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$ is given by

$$p(Y|X,T) = h(Y)\exp\left\{Y\langle X,T\rangle - a(\langle X,T\rangle)\right\}, \tag{1}$$

where $a(\cdot)$ is a strictly convex and differentiable log-partition function, $h(\cdot)$ is a nuisance parameter, and $T \in \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$ is the parameter tensor of interest. Typical examples of $a(\cdot)$ include $a(\theta) = \frac{1}{2}\theta^2$ leading to the usual normal linear regression, $a(\theta) = \log(1+e^\theta)$ corresponding to logistic regression, and $a(\theta) = e^\theta$ which can be identified with Poisson regression where θ is a scalar. The goal is to estimate tensor T based on the training data $\{(X^{(i)}, Y^{(i)}) : 1 \le i \le n\}$. For convenience we assume $(X^{(i)}, Y^{(i)})$'s are independent copies of (X,Y). Hence the negative log-likelihood risk objective, for any $A \in \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$, is:

$$\mathcal{L}(A) = \frac{1}{n}\sum_{i=1}^{n}\left[a(\langle X^{(i)}, A\rangle) - Y^{(i)}\langle X^{(i)}, A\rangle - \log h(Y^{(i)})\right]. \tag{2}$$

The notation $\langle\cdot,\cdot\rangle$ will refer throughout this paper to the standard inner product taken over appropriate Euclidean spaces. Hence, for $A \in \mathbb{R}^{d_1 \times \cdots \times d_N}$ and $B \in \mathbb{R}^{d_1 \times \cdots \times d_N}$:

$$\langle A, B\rangle = \sum_{j_1=1}^{d_1}\cdots\sum_{j_N=1}^{d_N} A_{j_1,\ldots,j_N}B_{j_1,\ldots,j_N} \in \mathbb{R}.$$

Using the standard notion of inner product, for a tensor A, $\|A\|_{\mathrm{F}} = \langle A, A\rangle^{1/2}$. And the empirical norm $\|\cdot\|_n$ for a tensor $A \in \mathbb{R}^{d_1 \times \cdots \times d_N}$ is define as:

$$\|A\|_n^2 := \frac{1}{n}\sum_{i=1}^{n}\langle A, X^{(i)}\rangle^2.$$

Also, for any linear subspace $\mathcal{A} \subset \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$, $A_{\mathcal{A}}$ denotes the projection of a tensor A onto $\mathcal{A}$. More precisely

$$A_{\mathcal{A}} := \arg\min_{M \in \mathcal{A}} \|A - M\|_{\mathrm{F}}.$$

2.1. Background on tensor algebra

One of the major challenges associated with low-rank tensors is that the notion of higher-order tensor decomposition and rank is ambiguous. See, e.g., Koldar and Bader (2009) for a review. There are two standard decompositions, the so-called canonical polyadic (CP) decomposition and the Tucker decomposition. In addition to that, there are various notions of tensor low-rankness considered in the application. In order to simplify notation, we focus our discussion on third-order tensors ($N = 3$) but point out that many of the notions generalize to $N > 3$. Our general theorem in Section 3 works for general $N \geq 3$.

The CP decomposition of a third-order tensor is defined as the smallest number r of rank-one tensors needed to represent a tensor $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$:

$$A = \sum_{k=1}^{r} u_{k,1} \otimes u_{k,2} \otimes u_{k,3} \tag{3}$$

where $u_{k,m} \in \mathbb{R}^{d_m}$, for $1 \leq k \leq r$ and $1 \leq m \leq 3$.

A second popular decomposition is the so-called Tucker decomposition. The Tucker decomposition of a tensor $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ is of the form:

$$A_{j_1 j_2 j_3} = \sum_{k_1=1}^{r_1} \sum_{k_2=1}^{r_2} \sum_{k_3=1}^{r_3} S_{k_1 k_2 k_3} U_{j_1 k_1,1} U_{j_2 k_2,2} U_{j_3 k_3,3}$$

so that $U_m \in \mathbb{R}^{d_m \times r_m}$ for $1 \leq m \leq 3$ are factors matrices (which are usually orthogonal) and $S \in \mathbb{R}^{r_1 \times r_2 \times r_3}$ is the so-called core tensor (see, e.g., Koldar and Bader, 2009). The vector (r_1, r_2, r_3) is referred to as the Tucker ranks of A. It is not hard to see that if (3) holds, then the Tucker ranks (r_1, r_2, r_3) can be equivalently interpreted as the dimensionality of the linear spaces spanned by $\{u_{k,1} : 1 \leq k \leq r\}$, $\{u_{k,2} : 1 \leq k \leq r\}$, and $\{u_{k,3} : 1 \leq k \leq r\}$ respectively.

A convenient way to represent low Tucker ranks of a tensor is through *matricization*. Denote by $\mathcal{M}_1(\cdot)$ the mode-1 matricization of a tensor, that is $\mathcal{M}_1(A)$ is the $d_1 \times (d_2 d_3)$ matrix whose column vectors are the mode-1 fibers of $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. A fiber is defined by fixing every index but one, which is the first index in the case of mode-1 fiber. Here A has $d_2 d_3$ mode-1 fibers. $\mathcal{M}_2(\cdot)$, $\mathcal{M}_3(\cdot)$ are defined in the same fashion. By defining

$$\text{rank}(\mathcal{M}_m(A)) = r_m(A),$$

it follows that $(r_1(A), r_2(A), r_3(A))$ represent the Tucker ranks of A. For later discussion, define $\mathcal{M}_i^{-1}(\cdot)$ to be the inverse of mode-i matricization, so

$$\mathcal{M}_1^{-1} : \mathbb{R}^{d_1 \times (d_2 \cdot d_3)} \to \mathbb{R}^{d_1 \times d_2 \times d_3},$$
$$\mathcal{M}_2^{-1} : \mathbb{R}^{d_2 \times (d_1 \cdot d_3)} \to \mathbb{R}^{d_1 \times d_2 \times d_3},$$
$$\mathcal{M}_3^{-1} : \mathbb{R}^{d_3 \times (d_1 \cdot d_2)} \to \mathbb{R}^{d_1 \times d_2 \times d_3},$$

such that $\mathcal{M}_i^{-1}(\mathcal{M}_i(A)) = A$. Also, a tensor can be vectorized via collapsing all its dimensions sequentially, i.e. $\text{vec}(A) \in \mathbb{R}^{d_1 \cdot d_2 \cdot d_3}$ for $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, and A's $(j_1, j_2, j_3)^{th}$ element is placed in the position of $\sum_{i=1}^{3}[(j_i - 1)\Pi_{l=i+1}^{3} d_l] + 1$ in $\text{vec}(A)$.

Further, we define *slices* of a tensor as follows. For an order-3 tensor A, the $(1, 2)$ slices of A are the collection of d_3 matrices of $d_1 \times d_2$

$$\{A_{\cdot\cdot j_3} := (A_{j_1 j_2 j_3})_{1 \leq j_1 \leq d_1, 1 \leq j_2 \leq d_2} : 1 \leq j_3 \leq d_3\}.$$

2.2. Low-dimensional structural assumptions

As mentioned earlier, there is not a unique way of defining tensor and there are multiple ways to impose low-rankness/low-dimensionality on a tensor space. Given the ambiguity of tensor low-rankness, one of the goals of the paper is to develop a general framework that applies to many different notions of low-rankness. To be more concrete, we focus on three specific examples of low-rank structure. These three examples fall in the general framework of our analysis of the PGD algorithm applied to low-dimensional tensor regression. Among the three, the first two are closely related to viewing the tensor as slices of matrix or lower order tensor (e.g. 4th order tensor has 'slices' of 3rd order tensor), and hence measuring hybrid of group sparsity and lower order low-rankness. The third is the maximum of the standard Tucker ranks. For simplicity, we focus on the case when $N = 3$ and then discuss potential generalization to higher order.

Firstly we place low-rank structure on the matrix slices. In particular first define:

$$\Theta_1(r) = \left\{ A \in \mathbb{R}^{d_1 \times d_2 \times d_3} : \sum_{j_3=1}^{d_3} \text{rank}(A_{\cdot\cdot j_3}) \leq r \right\}.$$

We can view $\Theta_1(r)$ as a specific rank-r or less subset of 3rd order tensor space with the rank defined to be the sum of the rank of the matrix slices. To connect to matrices, an alternative way to parameterize $\Theta_1(r)$ is as the set of $\mathbb{R}^{d_1 . d_3 \times d_2 . d_3}$ block diagonal matrices, where each block corresponds to the matrix slice $A_{\cdot\cdot j_3} \in \mathbb{R}^{d_1 \times d_2}$ and $1 \leq j_3 \leq d_3$. The rank constraint in $\Theta_1(r)$, corresponds exactly to placing a rank constraint on the corresponding $\mathbb{R}^{d_1 . d_3 \times d_2 . d_3}$ matrix.

Secondly we can impose a related notion where we bound the maximum of the rank of each slice and sparsity along the matrix slices.

$$\Theta_2(r, s) = \left\{ A \in \mathbb{R}^{d_1 \times d_2 \times d_3} : \max_{j_3} \text{rank}(A_{\cdot\cdot j_3}) \leq r, \sum_{j_3=1}^{d_3} \mathbb{I}(A_{\cdot\cdot j_3} \neq 0) \leq s \right\}.$$

We can view $\Theta_2(r, s)$ as a specific rank-(r,s) or less subset of the third-order tensor. One natural example where imposing this combination of low-rankness and sparsity for is vector auto-regressive (VAR) models (see e.g. Basu and Michailidis (2015)). For example, if we have an M-variate time series and consider a VAR(p) model, $d_1 = d_2 = M$ and $d_3 = p$. We want each auto-regressive matrix slice $A_{\cdot\cdot j_3}$ to have low-rank and the total number of lags involved in the problem to be sparse (e.g. to account for immediate effects and seasonal effects).

Finally, we impose the assumption that Tucker ranks are upper bounded:

$$\Theta_3(r_1, r_2, r_3) = \left\{ A \in \mathbb{R}^{d_1 \times d_2 \times d_3} : r_i(A) \leq r_i \text{ for } i = 1, 2, 3 \right\}.$$

Note that all these low-dimensional structural assumptions $\Theta_1(r)$, $\Theta_2(r,s)$ and $\Theta_3(r_1,r_2,r_3)$ are non-convex sets. Note that $\Theta_2(r,s)$ and $\Theta_3(r_1,r_2,r_3)$ have two parameters (r,s) and three parameters (r_1,r_2,r_3) respectively and our framework deals with this. In the next subsection we introduce a general projected gradient descent (PGD) algorithm for minimizing the generalized linear model objective (2) subject to the parameter tensor A belonging to a potentially non-convex constraint set Θ. Also note that it is straightforward to extend $\Theta_3(r_1,r_2,r_3)$ to $N>3$.

2.3. Projected Gradient Descent (PGD)

In this section we introduce the non-convex projected gradient descent (PGD) approaches developed in Jain et al. (2014, 2016) adapted to a general tensor space Θ. The problem we are interested in is minimizing the generalized linear model objective (2) subject to A belonging to a potentially non-convex set. The PGD algorithm for minimizing a general loss function $f(A)$ subject to the constraint $A\in\Theta$ is as follows:

Algorithm 1 Projected Gradient Descent

1: **Input :** data $\mathbf{Y},\mathbf{X}$, parameter space Θ, iterations K, step size η
2: **Initialize :** $k=0$, $\widehat{T}_0\in\Theta$
3: **for** $k=1,2,\ldots,K$ **do**
4: $\quad g_k=\widehat{T}_k-\eta\nabla f(\widehat{T}_k)$ (gradient step)
5: $\quad \widehat{T}_{k+1}=P_\Theta(g_k)$ or $\widehat{T}_{k+1}=\widehat{P}_\Theta(g_k)$ ((approximate) projection step)
6: **end for**
7: **Output :** $\widehat{T}_K$

The notation $\widehat{P}_\Theta(\cdot)$ refers to an approximate projection on to Θ if an exact projection is not implementable. The PGD algorithm has been widely used for both convex and non-convex objectives and constraint sets. In our setting, we choose the negative log-likelihood for the generalized linear model as the functions $f(A)$ to minimize.

An important question associated with projected gradients is whether the projection on to Θ is implementable. The projections we consider for $\Theta_1(r)$, $\Theta_2(r,s)$ and $\Theta_3(r_1,r_2,r_3)$ can all be implemented approximately as combinations of projections on to matrix or vector subspaces defined in Jain et al. (2014, 2016). By using sparsity and low-rankness projections in the vector and matrix respectively, the projections in Θ_1, Θ_2 and Θ_3 are implementable.

In particular, for a vector $v\in\mathbb{R}^d$, we define the projection operator $\tilde{P}_s(v)$ as the projection on to the set of s-sparse vectors by selecting the s largest elements of v in ℓ_2-norm. That is:

$$\tilde{P}_s(v):=\underset{\|z\|_{\ell_0}\le s}{\arg\min}\|z-v\|_{\ell_2}.$$

For a matrix $M\in\mathbb{R}^{d_1\times d_2}$, let $\bar{P}_r(M)$ denote the rank-r projection:

$$\bar{P}_r(M):=\underset{\mathrm{rank}(Z)\le r}{\arg\min}\|Z-M\|_{\mathrm{F}}.$$

As mentioned in Jain et al. (2014, 2016), both projections are computable. $\tilde{P}_s(v)$ is the thresholding operator which selects the s largest elements of v in ℓ_2-norm and $\bar{P}_r(M)$ can

be selecting the top r singular vectors of M. For the remainder of this paper we use both of these projection operators for vectors and matrices respectively.

3. Main Results

In this section we present our general theoretical results where we provide a statistical guarantee for the PGD algorithm applied to a low-dimensional space Θ.

3.1. Properties for Θ and its projection

To ensure the PGD algorithm converges for a given subspace Θ, we view it as a member of a collection of subspaces $\{\Theta(t):t\in\Xi\}$ for some $\Xi\subset\mathbb{Z}_+^k$ and require some general properties for this collection. The index t typically represents a sparsity and/or low-rank index and may be multi-dimensional. For example, $\Theta_1(r)$ is indexed by rank r where

$$\Xi=\{0,\ldots,d_3\cdot\min\{d_1,d_2\}\}.$$

Similarly, $\Theta_2(r,s)$ is indexed by $t=(r,s)$ so that

$$\Xi=\{(0,0),\ldots,(\min\{d_1,d_2\},d_3)\},$$

and $\Theta_3(r_1,r_2,r_3)$ is indexed by rank (r_1,r_2,r_3) so that

$$\Xi=\{(0,0,0),\ldots,(\min\{d_1,d_2d_3\},\min\{d_2,d_1d_3\},\min\{d_3,d_1d_2\})\}.$$

Note that the Ξ is partially ordered where $a\ge(\le,<,>)b$ for two vectors a and b of conformable dimension means the inequality holds in an element-wise fashion, i.e. the inequality holds for each element of a and its counterparty in b.

Definition 1. A set $\{\Theta(t):t\in\Xi\}$ is a *superadditive and partially ordered collection of symmetric cones* if

(1) each member $\Theta(t)$ is a *symmetric cone* in that if $z\in\Theta(t)$, then $cz\in\Theta(t)$ for any $c\in\mathbb{R}$;

(2) the set is *partially ordered* in that for any $t_1\le t_2$, $\Theta(t_1)\subset\Theta(t_2)$;

(3) the set is *superadditive* in that $\Theta(t_1)+\Theta(t_2)\subset\Theta(t_1+t_2)$.

The first two properties basically state that we have a set of symmetric cones in the tensor space with a partial ordering indexed by t. The last property requires that the collection of subspaces be superadditive in that the Minkowski sum of any two subspaces is contained in the subspace of dimension that is the sum of the two lower dimensions. All three properties are essential for deriving theoretical guarantees for the PGD algorithm. By relying on these properties alone, we obtain a general result that provides a unified way of dealing with $\Theta_1(r),\Theta_2(r,s)$ and $\Theta_3(r_1,r_2,r_3)$ as well as many other collections of subspaces.

Furthermore, we introduce the following property of contractive projection, for P_Θ or $\widehat{P}_\Theta$ in Algorithm 1, that is essential for the theoretical performance of the PGD algorithm. Again, we shall view these operators as members of a collection of operators $Q_{\Theta(t)}$:

$\cup_t \Theta(t) \mapsto \Theta(t)$. The contractive projection property says that, when $Q_{\Theta(t)} : \cup_t \Theta(t) \mapsto \Theta(t)$ are viewed as projections, projection onto a larger "dimension" incurs less approximation error *per dimension* compared to projection onto a smaller dimension, up to a constant factor. This property is adopted from earlier study on vector/matrix case. (see, e.g., Jain et al., 2014, 2016). The difference here is that in the tensor case, the constant factor δ is no longer one as in vector/matrix case. And later theorems will show that any finite δ can guarantee linear convergence with error bound expressed in Gaussian width for PGD in tensor case. This means that certain low-cost approximate low-rank projections in the tensor case are sufficient for PGD and later we will see Tucker rank is the case.

Definition 2. We say that a set $\{\Theta(t) : t \geq 0\}$ and corresponding operators $Q_{\Theta(t)} : \cup_t \Theta(t) \mapsto \Theta(t)$ satisfy the *contractive projection property* for some $\delta > 0$, denoted by CPP(δ), if for any $t_1 < t_2 < t_0$, $Y \in \Theta(t_1)$, and $Z \in \Theta(t_0)$:

$$\|Q_{\Theta(t_2)}(Z) - Z\|_{\mathrm{F}} \leq \delta \left\| \frac{t_0 - t_2}{t_0 - t_1} \right\|_{\ell_\infty}^{1/2} \cdot \|Y - Z\|_{\mathrm{F}}.$$

Here, when $\Theta(t)$ is indexed by multi-dimensional t, the division $\frac{t_0 - t_2}{t_0 - t_1}$ refers to a vector with the jth element to be $\frac{(t_0)_j - (t_2)_j}{(t_0)_j - (t_1)_j}$.

It is clear that $\Theta_1(r)$ is isomorphic to rank-r block diagonal matrices with diagonal blocks $A_{\cdot\cdot 1}$, $A_{\cdot\cdot 2}$,..., $A_{\cdot\cdot d_3}$ so that $\{\Theta_1(r)\}$ satisfies Definition 1. It is also easy to verify that $\{\Theta_1(r)\}$ and its projections $\{P_{\Theta_1(r)}\}$ which applies $\bar{P}_r(.)$ to the $d_1.d_3 \times d_2.d_3$ block-diagonal matrix described earlier obeys CPP(1). Later, we will see in Lemmas 2 and 3 that these two properties are also satisfied by $\{\Theta_2(r, s)\}$ and $\{\Theta_3(r_1, r_2, r_3)\}$, and their appropriate (approximate) projections.

3.2. Restricted strong convexity

Now we state some general requirements on the loss function, namely the restricted strong convexity and smoothness conditions (RSCS), that is another essential part for the guarantee of PGD performance (see, e.g., Jain et al., 2014, 2016). Recall that for $f(A)$, a function of tensor A, we can abuse the notation to view $f(A)$ as a function of vectorized tensor, i.e. $f(A) = f(\mathrm{vec}(A))$and use $\nabla^2 f(A)$ to denote the Hessian of function f on vectorized tensor. Please refer to Section 2.1 for the formal definition of vectorization of a tensor.

Definition 3. We say that a function f satisfies *restricted strong convexity and smoothness conditions* $RSCS(\Theta, C_l, C_U)$ for a set Θ, and $0 < C_l < C_u < \infty$ if for any $A \in \Theta$, $\nabla^2 f(A)$ is positive semidefinite such that for any $B \in \Theta$

$$C_l \cdot \|B\|_{\mathrm{F}} \leq \|\nabla^2 f(A) \cdot \mathrm{vec}(B)\|_{\ell_2} \leq C_u \cdot \|B\|_{\mathrm{F}},$$

for some constants $C_l < C_u$. Note that $RSCS(\Theta, C_l, C_U)$ reduces to restricted strong convexity and restricted smoothness assumptios for vectors and matrices (see e.g. Jain et al. (2014, 2016)) when A and B are vectors and matrices. We first state the following Theorem about the PGD performance under general loss function which is a tensor version of the results in Jain et al. (2014, 2016).

Theorem 1 ***(PGD Error Bound for General Loss Function)*** *Suppose that $\{\Theta(t) : t \geq 0\}$ is a superadditive and partially ordered collection of symmetric cones, together with operators $\{P_{\Theta(t)} : t \geq 0\}$ which obey CPP(δ) for some constant $\delta > 0$, and f satisfies $RSCS(\Theta(t_0), C_l, C_u)$ for some constants C_l and C_u. Let $\widehat{T}_K$ be the output from the Kth iteration of applying PGD algorithm with step size $\eta = 1/C_u$, and projection $P_{\Theta(t_1)}$ where*

$$t_1 = \left\lceil \frac{4\delta^2 C_u^2 C_l^{-2}}{1 + 4\delta^2 C_u^2 C_l^{-2}} \cdot t_0 \right\rceil.$$

Then

$$\sup_{T \in \Theta(t_0 - t_1)} \|\widehat{T}_K - T\|_{\mathrm{F}} \leq 4\eta C_u C_l^{-1} \cdot \sup_{A \in \Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)} \langle \nabla f(T), A \rangle + \epsilon,$$

for any

$$K \geq 2C_u C_l^{-1} \log\left(\frac{\|T\|_{\mathrm{F}}}{\epsilon} \right).$$

Basically, Theorem 1 guarantees that the PGD applied to general loss minimization problem with general low-rank constraint enjoys linear convergence rate with statistical error bounded by the restricted norm of the gradient of loss function evaluation at the true parameter. Note that we are taking a supremum over the set $\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)$ which relates to the local Gaussian width which we define shortly. More insight arises when we specialize f to the generalized linear model.

3.3. Generalized linear models

To use Theorem 1 for a specific f and collection of $\{\Theta(t) : t \geq 0\}$, we need to verify the conditions on $\{\Theta(t) : t \geq 0\}$, $\{P_{\Theta(t)} : t \geq 0\}$ and f satisfying $RSCS(\Theta, C_l, C_U)$, and choose the step-size in the PGD accordingly.

First we turn our attention to the covariate tensor $(X^{(i)})_{i=1}^n$ where $X^{(i)} \in \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$ and how it relates to the $RSCS(\Theta, C_l, C_U)$. With slight abuse of notation, write

$$\mathrm{vec}(X^{(i)}) \in \mathbb{R}^{d_1 d_2 \cdots d_N}$$

for $1 \leq i \leq n$ which is the vectorization of each tensor covariate $X^{(i)}$. For convenience let $D_N = d_1 d_2 \cdots d_N$. Further as mentioned for technical convenience we assume a Gaussian design of independent sample tensors $X^{(i)}$ s.t.

$$\mathrm{vec}(X^{(i)}) \sim \mathcal{N}(0, \Sigma) \text{ where } \Sigma \in \mathbb{R}^{D_N \times D_N}. \tag{4}$$

With more technical work our results may be extended beyond random Gaussian designs. We shall assume that Σ has bounded eigenvalues. Let $\lambda_{\min}(\cdot)$ and $\lambda_{\max}(\cdot)$ represent the smallest and largest eigenvalues of a matrix, respectively. In what follows, we shall assume that

$$c_\ell^2 \leq \lambda_{\min}(\Sigma) \leq \lambda_{\max}(\Sigma) \leq c_u^2, \tag{5}$$

for some constants $0 < c_\ell \leq c_u < \infty$. For our analysis of the non-convex projected gradient descent algorithm, we define the condition number $\kappa = c_u / c_l$.

A quantity that emerges from our analysis is the *Gaussian width* (see, e.g., Gordon, 1988) of a set $S \subset \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$ which is defined to be:

$$w_G(S) := \mathbb{E}\left(\sup_{A \in S} \langle A, G \rangle\right),$$

where $G \in \mathbb{R}^{d_1 \times d_2 \times \ldots \times d_N}$ is a tensor whose entries are independent $\mathcal{N}(0,1)$ random variables. The Gaussian width is a standard notion of size or complexity of a subset of tensors S.

In addition to the positive semi-definiteness of the Hessian in the GLM, the following Lemma extends a restricted upper and lower eigenvalue condition to the sample version of Σ and hence guarantees the RSCS for the GLM with Gaussian covariates with quite general covariance structure.

Lemma 1 *Assume that* (4) *and* (5) *hold. For any $\tau > 1$, there exist constants $c_1, c_2, c_3 > 0$ such that if $n \geq c_1 w_G^2[\Theta \cap \mathbb{B}_{\mathrm{F}}(1)]$, then with probability at least $1 - c_2 \exp(-c_3 w_G^2[\Theta \cap \mathbb{B}_{\mathrm{F}}(1)])$,*

$$\left(\tau^{-1} c_l\right)^2 \|A\|_{\mathrm{F}}^2 \leq \frac{1}{n} \sum_{i=1}^{n} \langle X^{(i)}, A \rangle^2 \leq (\tau c_u)^2 \|A\|_{\mathrm{F}}^2, \qquad \forall A \in \Theta.$$

Lemma 1 is a direct consequence of Theorem 6 in Banerjee et al. (2015). Using these definitions, we are in a position to state the main result for generalized linear models.

Theorem 2 ***(PGD Error Bound for Generalized Linear Model)*** *Suppose that $\{\Theta(t) : t \geq 0\}$ is a superadditive and partially ordered collection of symmetric cones, and together with operators $\{P_{\Theta(t)} : t \geq 0\}$ which obey CPP(δ) for some constant $\delta > 0$. Assume that $\{(X^{(i)}, Y^{(i)}) : i = 1, \ldots, n\}$ follow the generalized linear model* (1) *and $X^{(i)}$'s satisfy* (4) *and* (5)*, $\mathbb{E}|Y^{(i)}|^q \leq M_Y$ for some $q > 2$ and $M_Y > 0$, $1/\tau_0^2 \leq Var(Y^{(i)}) \leq \tau_0^2$ for $i = 1, \ldots, n$ and some $\tau_0 > 0$, and $n > c_1 w_G^2[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]$ for some t_0 and $c_1 > 0$. Let $\widehat{T}_K$ be the output from the K^{th} iteration of applying PGD algorithm to* (2) *with step size $\eta = (\tau c_u)^{-2}$ and projection $P_{\Theta(t_1)}$ where*

$$t_1 = \left\lceil \frac{4\delta^2 \tau^8 \kappa^4}{1 + 4\delta^2 \tau^8 \kappa^4} \cdot t_0 \right\rceil,$$

for any given $\tau > \tau_0$. Then there exist constants $c_2, c_3, c_4, c_5 > 0$ such that

$$\sup_{T \in \Theta(t_0 - t_1)} \|\widehat{T}_K - T\|_{\mathrm{F}} \leq \frac{c_5 \eta \tau^4 \kappa^2 c_u M_Y^{1/q}}{\sqrt{n}} \cdot w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)] + \epsilon,$$

with probability at least

$$1 - K c_2 \exp\left\{-c_3 w_G^2[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]\right\} - K c_4 n^{-(q/2-1)} \log^q n,$$

for any

$$K \geq 2\tau^4 \kappa^2 \log\left(\frac{\|T\|_{\mathrm{F}}}{\epsilon}\right).$$

Notice that the statistical error we have is related to the Gaussian width of the intersection of a unit Frobenius ball and an (often non-convex) subset of low-dimensional structure $w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]$. The intersection of $\Theta(t_0)$ with $\mathbb{B}_{\mathrm{F}}(1)$ means we are *localizing* the Gaussian width to a unit Frobenius norm ball around T. *Localization* of the Gaussian width means a sharper statsitical error bound can be proven and the benefits of localization in empirical risk minimization have been previously discussed in Bartlett et al. (2005). Later we will see how the main result leads to sample complexity bounds applied to $\Theta_2(r,s)$ and $\Theta_3(r_1, r_2, r_3)$. To the best of our knowledge this is the first general result that provides statistical guarantees in terms of the local Gaussian width of $\Theta(t_0)$ for the projected gradient descent algorithm. Expressing the error bound in terms of the Gaussian width allows an easy comparison to already established error bounds for convex regularization schemes which we discuss in Section 3.4.

The moment conditions on the response in Theorem 2 are in place to ensure that the restricted strong convexity and restricted smoothness conditions are satisfied for a non-quadratic loss. When specialized to normal linear regression, these conditions could be further removed.

3.4. Gaussian model and comparison to convex regularization

Consider the Gaussian linear regression setting which corresponds to the GLM in Equation (1) with $a(\theta) = \frac{\theta^2}{2}$. In particular

$$Y^{(i)} = \langle X^{(i)}, T \rangle + \zeta^{(i)}, \tag{6}$$

where $\zeta^{(i)}$'s are independent $\mathcal{N}(0, \sigma^2)$ random variables. Furthermore, substituting $a(\theta) = \frac{\theta^2}{2}$ into the GLM objective (2), we have the least-squares objective:

$$f(A) = \frac{1}{2n} \sum_{i=1}^{n} (Y^{(i)} - \langle X^{(i)}, A \rangle)^2. \tag{7}$$

Now we state our main result for the normal linear regression.

Theorem 3 ***(PGD Error Bound for Normal Linear Regression)*** *Suppose that $\{\Theta(t) : t \geq 0\}$ is a superadditive and partially ordered collection of symmetric cones, and together with operators $\{P_{\Theta(t)} : t \geq 0\}$ which obey CPP(δ) for some constant $\delta > 0$. Assume that $\{(X^{(i)}, Y^{(i)}) : i = 1, \ldots, n\}$ follow the Gaussian linear model* (6) *where $n > c_1 w_G^2[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]$ for some t_0 and $c_1 > 0$. Let $\widehat{T}_K$ be the output from the K^{th} iteration of applying PGD algorithm to* (2) *with step size $\eta = (\tau c_u)^{-2}$ and projection $P_{\Theta(t_1)}$ where*

$$t_1 = \left\lceil \frac{4\delta^2 \tau^8 \kappa^4}{1 + 4\delta^2 \tau^8 \kappa^4} \cdot t_0 \right\rceil,$$

for any given $\tau > 1$. Then there exist constants $c_2, c_3 > 0$ such that

$$\sup_{T \in \Theta(t_0 - t_1)} \|\widehat{T}_K - T\|_{\mathrm{F}} \leq \frac{8\eta \tau^4 \kappa^2 c_u \sigma}{\sqrt{n}} w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)] + \epsilon,$$

with probability at least

$$1 - Kc_2 \exp\left\{-c_3 w_G^2[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]\right\},$$

for any

$$K \geq 2\tau^4\kappa^2 \log\left(\frac{\|T\|_{\mathrm{F}}}{\epsilon}\right).$$

One of the contributions of this paper outlined in the introduction is to compare the non-convex PGD approach in tensor regression to the existing convex regularization approach analyzed in Raskutti and Yuan (2015) applied to the Gaussian linear model (6). In this section we first summarize the general result from Raskutti and Yuan (2015) and then provide a comparison to the error bound for the non-convex PGD approach. In particular, the following estimator for T is considered in Raskutti and Yuan (2015):

$$\widehat{T} \in \underset{A \in \mathbb{R}^{d_1 \times \cdots \times d_N}}{\arg\min} \left\{ \frac{1}{2n} \sum_{i=1}^{n} \|Y^{(i)} - \langle A, X^{(i)} \rangle\|_{\mathrm{F}}^2 + \lambda \mathcal{R}(A) \right\}, \tag{8}$$

where the convex regularizer $\mathcal{R}(\cdot)$ is a norm on $\mathbb{R}^{d_1 \times \cdots \times d_N}$, and $\lambda > 0$ is a tuning parameter. The *convex conjugate* for $\mathcal{R}$ (see e.g. Rockafellar (1970) for details) is given by:

$$\mathcal{R}^*(B) := \sup_{A \in \mathbb{B}_{\mathcal{R}}(1)} \langle A, B \rangle.$$

For example if $\mathcal{R}(A) = \|A\|_*$, then $\mathcal{R}^*(B) = \|B\|_s$. Following Negahban et al. (2012), for a subspace Θ of $\mathbb{R}^{d_1 \times \cdots \times d_N}$, define its compatibility constant $s(\Theta)$ as

$$s(\Theta) := \sup_{A \in \Theta / \{0\}} \frac{\mathcal{R}^2(A)}{\|A\|_{\mathrm{F}}^2},$$

which can be interpreted as a notion of low-dimensionality of Θ.

Raskutti and Yuan (2015) show that if $\widehat{T}$ is defined by (8) and the regularizer $\mathcal{R}(\cdot)$ is *decomposable* with respect to Θ, then if

$$\lambda \geq 2 w_G(\mathbb{B}_{\mathcal{R}}(1)), \tag{9}$$

where recall that $w_G(\mathbb{B}_{\mathcal{R}}(1)) = \mathbb{E}\big(\sup_{A \in \mathbb{B}_{\mathcal{R}}(1)} \langle A, G \rangle\big)$. Then according to Theorem 1 in Raskutti and Yuan (2015),

$$\max\left\{ \|\widehat{T} - T\|_n, \|\widehat{T} - T\|_{\mathrm{F}} \right\} \lesssim \frac{\sqrt{s(\Theta)}\lambda}{\sqrt{n}}. \tag{10}$$

with probability at least $1 - \exp(-cn)$ for some constant $c > 0$. In particular setting $\lambda = 2w_G(\mathbb{B}_{\mathcal{R}}(1))$,

$$\max\left\{ \|\widehat{T} - T\|_n, \|\widehat{T} - T\|_{\mathrm{F}} \right\} \lesssim \frac{\sqrt{s(\Theta)} w_G(\mathbb{B}_{\mathcal{R}}(1))}{\sqrt{n}}.$$

The error bound boils down to bounding two quantities, $s(\Theta)$ and $w_G(\mathbb{B}_{\mathcal{R}}(1))$, noting that for comparison pursposes the subpace Θ in the convex case refers to $\Theta(t_0)$ in the non-convex case. In the next section we provide a comparison between the error bound for the non-convex PGD approach and the convex regularization approach. To be clear, Raskutti and Yuan (2015) consider multi-response models where the response $Y^{(i)}$ can be a tensor which are not considered in this paper.

The error bound for the convex regularization scheme scales as $\sqrt{s(\Theta(t_0))} w_G[\mathbb{B}_{\mathcal{R}}(1)]/\sqrt{n}$ while we recall that the error bound we prove in this paper for the non-convex PGD approach scales as $w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]/\sqrt{n}$. Hence how the Frobenius error for the non-convex and convex approach scales depends on which of the quantities $\sqrt{s(\Theta(t_0))} w_G[\mathbb{B}_{\mathcal{R}}(1)]/\sqrt{n}$ or $w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]/\sqrt{n}$ is larger. It follows easily that $w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)] \leq \sqrt{s(\Theta(t_0))} w_G[\mathbb{B}_{\mathcal{R}}(1)]$ since

$$\begin{aligned} w_G[\Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)] &= \mathbb{E}\big[\sup_{A \in \Theta(t_0), \|A\|_{\mathrm{F}} \leq 1} \langle A, G \rangle \big] \\ &\leq \mathbb{E}\big[\sup_{\mathcal{R}(A) \leq \sqrt{s(\Theta(t_0))}} \langle A, G \rangle \big] \\ &= \sqrt{s(\Theta(t_0))}\, \mathbb{E}\big[\sup_{\mathcal{R}(A) \leq 1} \langle A, G \rangle \big] = \sqrt{s(\Theta(t_0))} w_G[\mathbb{B}_{\mathcal{R}}(1)]. \end{aligned}$$

The first inequality follows from the subspace compatibility constant since for all $A \in \Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)$, $\mathcal{R}(A) \leq \sqrt{s(\Theta(t_0))} \|A\|_{\mathrm{F}} \leq \sqrt{s(\Theta(t_0))}$ and the final equality follows since $\mathcal{R}(\cdot)$ is a convex function. Therefore the non-convex error bound is always no larger than the convex error bound and the important question is whether there is a gap between the convex and non-convex bounds which implies a superior bound in the non-convex case. For examples involving sparse vectors and low-rank matrices as studied in e.g., Buhlmann and van de Geer (2011); Jain et al. (2014, 2016), these two quantities end up being identical up to a constant. On the other hand for tensors, as we see in this paper for $\Theta_3(r_1, r_2, r_3)$, the Gaussian width using the non-convex approach is smaller which presents an additional benefit for the non-convex projection approach.

In terms of implementation, the regularizer $\mathcal{R}(\cdot)$ needs to be defined in the convex approach and the important question is whether the convex regularizer is implementable for the low-dimensional structure of interest. For the non-convex approach, the important implementation issue is whether exact or approximate projection that satisfies the contractive projection property is implementable. These implementation issues have been resolved in the vector and matrix cases (see, e.g., Jain et al., 2014, 2016). In Section 5 in this paper, we focus on whether they apply in the low-rank tensor case under the low-dimensional structure Θ_1, Θ_2 and Θ_3.

4. Specific low rank structure

In this section, we apply Theorem 3 (and by extension Theorem 2) to $\Theta_1(r)$, $\Theta_2(r, s)$ and $\Theta_3(r_1, r_2, r_3)$ and compare our theoretical result to the theoretical bound achieved by the convex regularization approach. Recall that $\Theta_1(r)$ is isomorphic to rank-r block diagonal matrices with diagonal blocks $A_{\cdot\cdot 1}$, $A_{\cdot\cdot 2}, \ldots, A_{\cdot\cdot d_3}$ so that its treatment is identical to the case of low rank matrix estimation. See Jain et al. (2016) for further discussions. Hence we

will focus on $\Theta_2(r,s)$ and $\Theta_3(r_1,r_2,r_3)$. To prove error bounds using Theorem 3 we find an exact or approximate projection $P_{\Theta(t)}$, prove the contractive projection property and then find an error bound on the Gaussian width $w_G[\Theta(t)\cap\mathbb{B}_{\mathrm{F}}(1)]$.

4.1. Low-rank structure for matrix slices

Recall that

$$\Theta_2(r,s)=\left\{A\in\mathbb{R}^{d_1\times d_2\times d_3}:\max_{j_3}\operatorname{rank}(A_{\cdot\cdot j_3})\le r,\sum_{j_3=1}^{d_3}\mathbb{I}(A_{\cdot\cdot j_3}\neq 0)\le s\right\}.$$

For the projection, we define the two-step projection $P_{\Theta_2(r,s)}$:

(1) for each matrix slice $A_{\cdot\cdot j_3}$ where $1\le j_3\le d_3$, let $\tilde{A}_{\cdot\cdot j_3}:=\bar{P}_r(A_{\cdot\cdot j_3})$ be the best rank r approximation of $A_{\cdot\cdot j_3}$;

(2) to impose sparsity, retain s out of d_3 slices with the largest magnitude $\|\tilde{A}_{\cdot\cdot j_3}\|_{\mathrm{F}}$, and zero out all other slices.

As discussed earlier both steps are easily computable using thresholding and SVD operators as discussed in Jain et al. (2014, 2016).The following lemma proves that the contractive property of projection onto $\Theta_2(r,s)$ holds for our $P_{\Theta_2(r,s)}$.

Lemma 2 *Let the projection operator $P_{\Theta_2(r,s)}$ be defined above. Suppose $Z\in\Theta_2(r_0,s_0)$, and $r_1<r_2<r_0, s_1<s_2<s_0$. Then for any $Y\in\Theta_2(r_1,s_1)$, we have*

$$\|P_{\Theta_2(r_2,s_2)}(Z)-Z\|_{\mathrm{F}}\le(\alpha+\beta+\alpha\beta)\cdot\|Y-Z\|_{\mathrm{F}}.$$

where $\alpha=\sqrt{(s_0-s_2)/(s_0-s_1)}$, $\beta=\sqrt{(r_0-r_2)/(r_0-r_1)}$.

Consequently we have the following Theorem:

Theorem 4 *Let $\{X^{(i)},Y^{(i)}\}_{i=1}^n$ follow a Gaussian linear model as defined by (6) with $T\in\Theta_2(r,s)$ and*

$$n\ge c_1\cdot sr(d_1+d_2+\log d_3)$$

for some constant $c_1>0$. Then, applying the PGD algorithm with step size $\eta=(\tau c_u)^{-2}$ and projection $P_{\Theta(r',s')}$ where

$$s'=\lceil 36\tau^8\kappa^4 s\rceil,\qquad\text{and}\qquad r'=\lceil 36\tau^8\kappa^4 r\rceil,$$

guarantees that, with probability at least $1-Kc_2\exp\{-c_3\max(d_1,d_2,\log d_3)\}$, after $K\ge 2\tau^4\kappa^2\log(\|T\|_{\mathrm{F}}/\epsilon)$ iterations,

$$\|\widehat{T}_K-T\|_{\mathrm{F}}\le c_4\sigma\sqrt{\frac{sr\max\{d_1,d_2,\log(d_3)\}}{n}}+\epsilon$$

for any $\tau>1$, and some constants $c_2,c_3,c_4>0$.

The convex regularization approach defined by Raskutti and Yuan (2015) is not directly applicable for $\Theta_2(r,s)$ since there is no suitable choice of regularizer that imposes both low-rankness of each slice and sparsity. Therefore we discuss the convex regularization approach applied to the parameter space $\Theta_1(r)$ for which a natural choice of regularizer is:

$$\mathcal{R}_1(A)=\sum_{j_3=1}^{d_3}\|A_{\cdot\cdot j_3}\|_*,$$

where $\|\cdot\|_*$ refers to the standard nuclear norm of a matrix. Let $\widehat{T}$ be an estimator corresponding to the minimizer of the regularized least-squares estimator defined by (8) with regularizer $\mathcal{R}_1(A)$. Lemma 6 in Raskutti and Yuan (2015) proves that

$$\|\widehat{T}-T\|_{\mathrm{F}}\lesssim\sqrt{\frac{r\max(d_1,d_2,\log d_3)}{n}}.$$

Notice that both $\Theta_1(r)$ and $\Theta_2(r,s)$ focus on the low-rankness of matrix slices of a tensor, and actually $\Theta_1(\cdot)$ can be seen as relaxation of $\Theta_2(\cdot,\cdot)$ since $\Theta_2(s,r)\subset\Theta_1(sr)$. Theorem 4 guarantees that, under the restriction of sparse slices of low-rank matrices, PGD achieves the linear convergence rate with the statistical error of order

$$\sqrt{\frac{sr\max\{d_1,d_2,\log(d_3)\}}{n}}.$$

If we compare this result with the risk bound of the convex regularization approach where the true tensor parameter lies in $\Theta_1(r)$ we see that replacing r by sr yields the same rate which makes intuitive sense in light of the observation that $\Theta_2(s,r)\subset\Theta_1(sr)$.

4.2. Low Tucker rank

We now consider the general set of tensors with low Tucker rank:

$$\Theta_3(r_1,r_2,r_3)=\left\{A\in\mathbb{R}^{d_1\times d_2\times d_3}:r_i(A)\le r_i\text{ for }i=1,2,3\right\}.$$

Although we focus on $N=3$, note that $\Theta_3(r_1,r_2,r_3)$ can be easily extended to general N and we also consider $N=4$ in the simulations.

To define the projection $P_{\Theta_3(r_1,r_2,r_3)}$ on to $\Theta_3(r_1,r_2,r_3)$, we exploit the connection between Tucker ranks and ranks of different matricizations mentioned earlier. Recall that the matricization operator $\mathcal{M}_j$ maps a tensor to a matrix and the inverse operator $\mathcal{M}_j^{-1}$ maps a matrix back to a tensor. Let $\bar{P}_r(M)$ be the low-rank projection operator that maps a matrix M to its best rank r approximation. Then we can define the approximate projection $\widehat{P}_{\Theta_3(r_1,r_2,r_3)}$ as follows:

$$\widehat{P}_{\Theta_3(r_1,r_2,r_3)}(A):=(\mathcal{M}_3^{-1}\circ\bar{P}_{r_3}\circ\mathcal{M}_3)\circ(\mathcal{M}_2^{-1}\circ\bar{P}_{r_2}\circ\mathcal{M}_2)\circ(\mathcal{M}_1^{-1}\circ\bar{P}_{r_1}\circ\mathcal{M}_1)(A).\quad(11)$$

The order of which matricization is performed is nonessential. Similar to before, we have the following projection lemma to be essential in the analysis of PGD applied to the restricted parameter space Θ_3.

Lemma 3 *Suppose* $Z \in \Theta_3(r_1^{(0)}, r_2^{(0)}, r_3^{(0)})$, *and* $r_i^{(1)} < r_i^{(2)} < r_i^{(0)}$ *for* $i = 1, 2, 3$. *Then for any* $Y \in \Theta_3(r_1^{(1)}, r_2^{(1)}, r_3^{(1)})$, *we have*

$$\|\widehat{P}_{\Theta_3(r_1,r_2,r_3)}(Z) - Z\|_{\mathrm{F}} \leq [(\beta_1+1)(\beta_2+1)(\beta_3+1) - 1]\|Y - Z\|_{\mathrm{F}}$$

where $\beta_i = \sqrt{(r_i^{(0)} - r_i^{(2)})/(r_i^{(0)} - r_i^{(1)})}$.

This allows us to derive the following result for the PGD algorithm applied with projection operator $\widehat{P}_{\Theta_3(r_1',r_2',r_3')}(\cdot)$. Basically, the sequential matrix low-rank projection, as an approximate projection onto low Tucker rank subset, could achieve the same order error rate as the exact low Tucker rank projection which might involve expensive iterative computation.

Theorem 5 *Let* $\{X^{(i)}, Y^{(i)}\}_{i=1}^n$ *follow a Gaussian linear model as defined by* (6) *with* $T \in \Theta_3(r_1, r_2, r_3)$ *and*

$$n \geq c_1 \cdot \min\{r_1(d_1 + d_2d_3), r_2(d_2 + d_1d_3), r_3(d_3 + d_1d_2)\},$$

for some constant $c_1 > 0$. *Then, applying the PGD algorithm with step size* $\eta = (\tau c_u)^{-2}$ *and projection* $\widehat{P}_{\Theta_3(r_1',r_2',r_3')}$ *where*

$$r_i' = \lceil 196\tau^8\kappa^4 r_i \rceil \text{ for } i = 1, 2, 3$$

guarantees that, with probability at least $1 - Kc_2 \exp\{-c_3 \min(d_1+d_2d_3, d_2+d_1d_3, d_3+d_1d_2)\}$, *after* $K \geq 2\tau^4\kappa^2 \log(\|T\|_{\mathrm{F}}/\epsilon)$ *iterations,*

$$\|\widehat{T}_K - T\|_{\mathrm{F}} \leq c_4\sigma\sqrt{\frac{\min\{r_1(d_1 + d_2d_3), r_2(d_2 + d_1d_3), r_3(d_3 + d_1d_2)\}}{n}} + \epsilon$$

for any $\tau > 1$, *and some constants* $c_2, c_3, c_4 > 0$.

In Raskutti and Yuan (2015), the following convex low-rankness regularizer is considered for the space $\Theta_3(r)$:

$$\mathcal{R}_2(A) = \frac{1}{3}\left(\|\mathcal{M}_1(A)\|_* + \|\mathcal{M}_2(A)\|_* + \|\mathcal{M}_3(A)\|_*.\right).$$

Let $\widehat{T}$ be an estimator corresponding to the minimizer of the regularized least-squares estimator defined by (8) with regularizer $\mathcal{R}_2(A)$. An adaptation of the proof of Lemma 10 in Raskutti and Yuan (2015) to $\Theta_3(r_1, r_2, r_3)$ proves that:

$$\|\widehat{T} - T\|_{\mathrm{F}} \lesssim \sqrt{\frac{\max(r_1, r_2, r_3) \cdot \max(d_1 + d_2d_3, d_2 + d_1d_3, d_3 + d_1d_2)}{n}}.$$

This shows that convex relaxation in this particular case has greater mean-squared error since the minimum is replaced by the maximum. The underlying reason is that the non-convex PGD approach selects the optimal choice of matricization whereas the convex regularization approach takes an average of the three matricizations which is sub-optimal. While it may be argued that one could use the regularizer corresponding with only the optimal $\mathcal{M}_1(.)$, $\mathcal{M}_2(.)$, or $\mathcal{M}_3(.)$, since the Tucker ranks (r_1, r_2, r_3) are unknown, it is impossible to know which matricization to use in the convex case.

5. Simulations

In this section, we provide a simulation study that firstly verifies that the non-convex PGD algorithm performs well in solving least-squares, logistic and Poisson regression problems, compares the non-convex PGD approach with the convex regularization approach we discussed earlier, and also compares using tensor regularization and naive matricization schemes. Our simulation study includes both third and fourth order tensors. For the purpose of illustration, we consider the balanced-dimension situation where $d = d_1 = d_2 = d_3 (= d_4)$, and hence the number of elements is $p = d^3$ for a third order tensor and $p = d^4$ for a fourth order tensor.

5.1. Data generation

We first describe three different ways of generating random tensor coefficient T with different types of low tensor rank structure.

1. (Low CP rank) Generate three independent groups of r independent random vectors of unit length, $\{u_{k,1}\}_{k=1}^r$, $\{u_{k,2}\}_{k=1}^r$ and $\{u_{k,3}\}_{k=1}^r$. To do this we perform the SVD of a Gaussian random matrix three times and keep the r leading singular vectors, and then compute the outer-product

   $$T = \sum_{k=1}^r u_{k,1} \otimes u_{k,2} \otimes u_{k,3}.$$

   The T produced in this way is guaranteed to have CP rank at most r. This can easily be extended to $N = 4$.

2. (Low Tucker rank) Generate $M_{d\times d\times d}$ with i.i.d. $\mathcal{N}(0, 1)$ elements and then do approximate Tucker rank-r projection (successive low rank approximation of mode-1, mode-2 and mode-3 matricization) to get $T = \widehat{P}_{\Theta_3(r,r,r)}(M)$. The T produced in this way is guaranteed to have largest element of Tucker rank at most r. Once again this is easily extended to the $N = 4$ case.

3. (Sparse slices of low-rank matrices) In this case $N = 3$. Generate s slices of random rank-r matrices, (with eigenvalues all equal to one and random eigenvectors), and fill up the remaining $d - s$ slices with zero matrices to get $d \times d \times d$ tensor T. The T produced in this way is guaranteed to fall in $\Theta_2(r, s)$.

Then we generate covariates $\{X^{(i)}\}_{i=1}^n$ to be i.i.d random matrices filled with i.i.d $\mathcal{N}(0, 1)$ entries. Finally, we simulate three GLM model, the Gaussian linear model, logistic regression and Poisson regression as follows.

1. (Gaussian linear model) We simulated noise $\{\epsilon^{(i)}\}_{i=1}^n$ independently from $\mathcal{N}(0, \sigma^2)$ and we vary σ^2. The noisy observation is then

   $$Y^{(i)} = \langle X^{(i)}, T\rangle + \epsilon^{(i)}.$$

2. (Logistic regression) We simulated Binomial random variables:

   $$Y^{(i)} \sim \text{Binomial}(m, p_i), \text{ where } p_i = \text{logit}(\alpha \cdot \langle X^{(i)}, T\rangle).$$

3. (Poisson regression) We simulated

$$Y^{(i)} \sim \text{Poisson}(\lambda_i), \text{ where } \lambda_i = m \exp(\alpha \cdot \langle X^{(i)}, T \rangle).$$

5.2. Convergence of PGD under restricted tensor regression

The first set of simulations investigates the convergence performance of PGD under various constraints and step-size choices for three different types of low-rankness. One of the important challenges when using the projected gradient descent algorithm is choosing the step-sizes (just like selecting the regularization parameter for convex regularization schemes) and the step-size choices stated in Theorem 2 depend on non-computable parameters (e.g. $c_u, c_\ell, ...$). In practice, the step is very important in that large step size would lead to divergence and small step size could cause slow convergence. We suggest either start with relatively large step size and continuously decrease the step size if divergence behavior is observed until tolerable step size is found, or start with relatively small step size that can guarantee convergence and gradually increase step size along the way while going back to small step size when divergence behavior is observed, which is similar to warm start strategy usually used to speed up convergence. In all our simualtions, the step-size η is set as a constant specified in each plot.

5.2.1. Third-order tensors

In the first two cases (see cases below), PGD with approximate projection $\widehat{P}_{\Theta_3(r',r',r')}$ were applied with different choices of (r', η) while in the third case the PGD with exact projection $P_{\Theta_2(r',s')}$ were adopted with different choices of (r', s', η).

Case 1a: (Gaussian) Low CP Rank with $p = 50^3$, $n = 4000$, $r = 5$, $\sigma = 0.5$ (SNR ≈ 4.5);

Case 2a: (Gaussian) Low Tucker Rank with $p = 50^3$, $n = 4000$, $r = 5$, $\sigma = 5$ (SNR ≈ 7.2);

Case 3a: (Gaussian) Slices of Low-rank Matrices with $p = 50^3$, $n = 4000$, $r = 5$, $s = 5$, $\sigma = 1$ (SNR ≈ 5.2).

Figures 1, 2 and 3 plot normalized rooted mean squared error (rmse) $\|\widehat{T} - T\|_{\text{F}}/\|T\|_{\text{F}}$ versus number of iterations, showing how fast rmse decreases as the number of iterations increases, under different (r', η) or (r', s', η). Notice that here we plot the average rmse with error bar to be the standard deviation for ten runs for Cases 1a, 2a and 3a.

Overall, the plots show the convergence of rmse's, and that the larger the r' or s' is, the greater the converged rmse will be, meaning that misspecification of rank/sparsity will do harm to the performance of PGD. In terms of the choice of step size, the experiments inform us that if η is too large, the algorithm may not converge and the range of tolerable step-size choices varies in different cases. In general, the more misspecified the constraint parameter(s) is(are), the lower the tolerance for step size will be. On the other hand, as we can see in all cases, given η under a certain tolerance level, the larger the η is, the faster the convergence will be.

5.2.2. Fourth-order tensors

Although we have focused on third order tensor for brevity, our method applies straightforwardly to higher order tensors. For illustration, we considered the following two examples which focus on estimating fourth order low rank tensors.

Case 4a: (Gaussian) Low CP Rank with $p = 20^4$, $n = 4000$, $r = 5$, $\sigma = 0.5$ (SNR ≈ 4.4);

Case 5a: (Gaussian) Low Tucker Rank with $p = 20^4$, $n = 4000$, $r = 5$, $\sigma = 5$ (SNR ≈ 7.4).

Figure 4 plots average rmse (with s.d. as error bar) for ten runs vs number of iterations for Case 4a and Case 5a using $\eta = 0.2$ under various choices of low-rankness constraint parameter r'. In general the convergence behavior for Case 4a and Case 5a are similar to those for Case 1a and Case 2a.

5.2.3. Logistic and Poisson regression

In the next set of simulations, we study the convergence behavior of the PGD applied to logistic and Poisson regression situation.

Case 1b: (Logistic) Low CP Rank with $p = 50^3$, $n = 4000$, $r = 5$, $m = 10$, $\alpha = 0.1$ (SNR ≈ 3.8);

Case 1c: (Poisson) Low CP Rank with $p = 30^3$, $n = 4000$, $r = 5$, $m = 5$, $\alpha = 0.5$ (SNR ≈ 4.8).

The results presented in Figures 5 and 6 exhibit similar pattern of convergence as in Figure 1. We observe also that in the case of low Tucker rank and sparse slices of low-rank matrices, logistic and Poisson regression have similar convergence behavior to least-squares regression. In general, a relaxed projection step is inferior to using the true rank parameter for projection. Once again as the step-size increases, the convergence will speed up until the step size becomes too large to guarantee convergence.

5.3. Comparison of non-convex PGD to convex regularization

Next, we compare the PGD method with convex regularization methods (implemented via `cvx`). In general, the `cvx` based regularization algorithm is significantly slower than the PGD method. This is partly due to the fact that the infrastructure of generic `cvx` is not tailored to solve the specific convex optimization problems. On the other hand, the PGD is much easier to implement and enjoys fast rates of convergence, which may also contribute to its improved performance in terms of run-time. Besides, `cvx` cannot handle p as large as those in Cases 1a, 2a and 3a. Hence, in order to do comparison in terms of the estimation error, we resort to moderate p so that `cvx` runs to completion. The simulation setup is as follows:

Case 6a: (Gaussian) Low CP Rank with $p = 10^3$, $n = 1000$, $r = 5$, $\sigma = 0.5, 1,$ or 2 (SNR $\approx$ 4.8, 2.4 or 1.2);

Case 7a: (Gaussian) Low Tucker Rank with $p = 10^3$, $n = 1000$, $r = 5$, $\sigma = 2.5, 5,$ or 10 (SNR $\approx$ 7.2, 3.6, or 1.8);

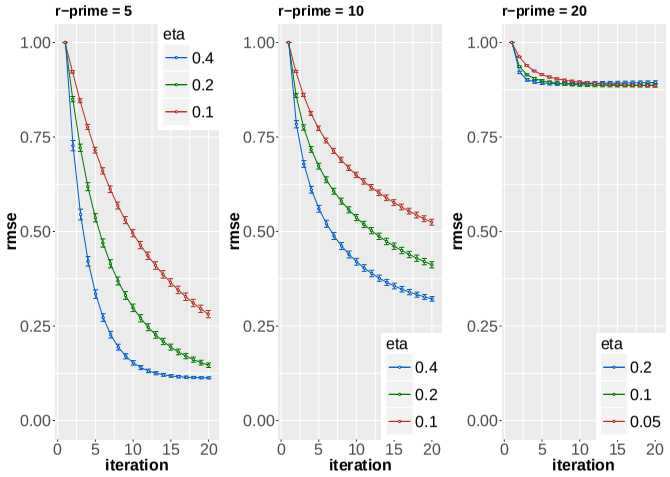

Figure 1: Case 1a: Low CP rank

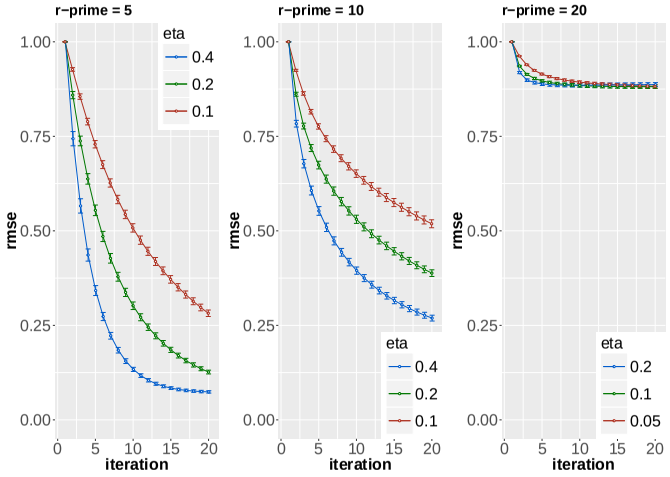

Figure 2: Case 2a: Low Tucker rank

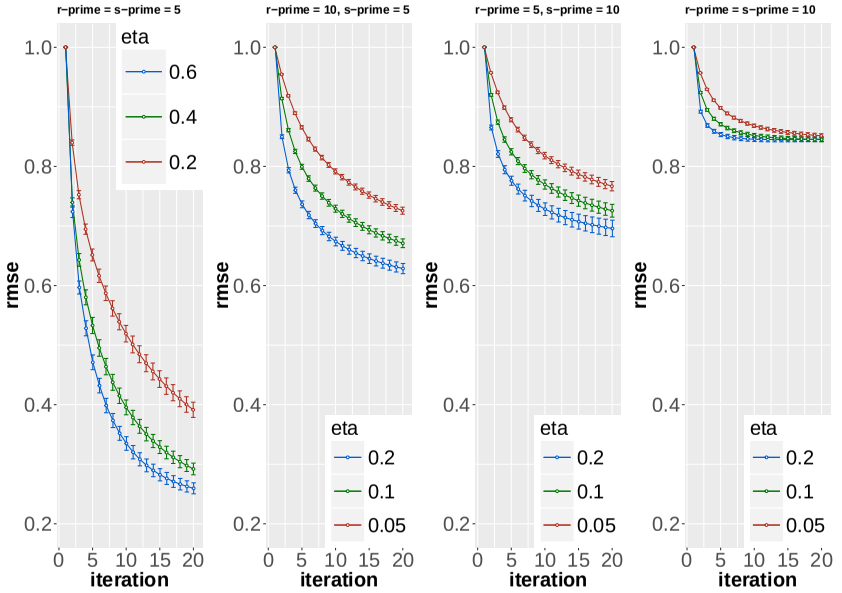

Figure 3: Case 3a: Sparse slices of low-rank matrices

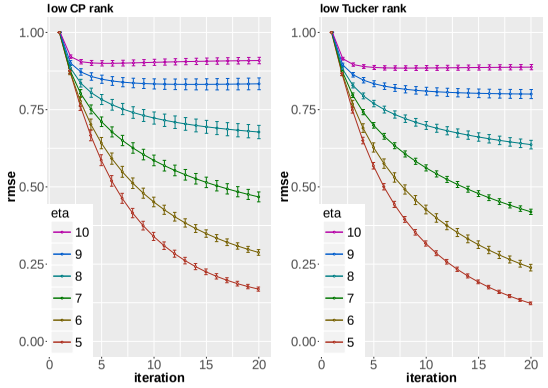

Figure 4: Case 4a, 5a: 4th order tensor

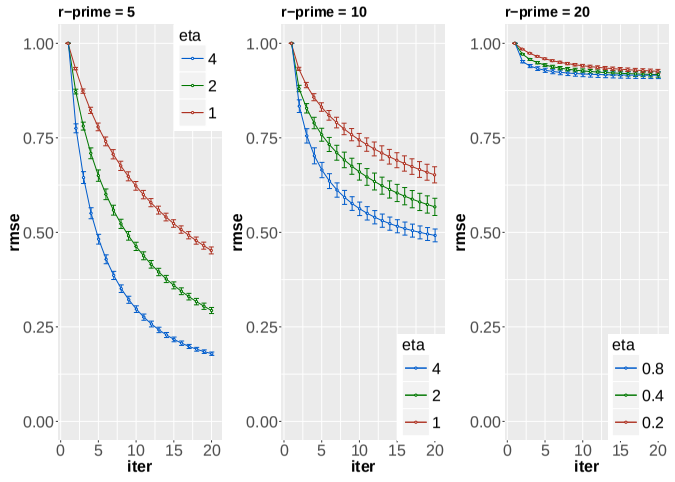

Figure 5: Case 1b: (Logistic) Low CP rank

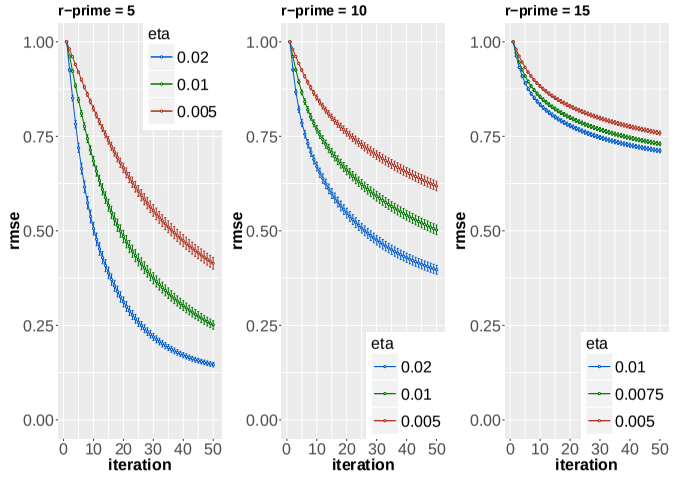

Figure 6: Case 1c: (Poisson) Low CP rank

Case 8a: (Gaussian) Slices of Low-rank Matrices with $p = 10^3$, $n = 1000$, $r = 5$, $s = 5$, $\sigma = 0.5, 1,$ or 2 (SNR $\approx$ 9.6, 4.8, or 2.4);

Case 6b: (Logistic) Low CP Rank with $p = 10^3$, $n = 1000$, $\alpha = 3.5$, $r = 5$, $m = 20, 5,$ or 1 (SNR $\approx$ 9.0, 4.5 or 2.0);

Case 7b: (Logistic) Low Tucker Rank with $p = 10^3$, $n = 1000$, $\alpha = 0.5$, $r = 5$, $m = 20, 5,$ or 1 (SNR $\approx$ 9.6 , 4.9 or 2.2);

Case 8b: (Logistic) Slices of Low-rank Matrices with $p = 10^3$, $n = 1000$, $\alpha = 1.2$, $r = 5$, $s = 5$, $m = 20, 5,$ or 1 (SNR $\approx$ 7.7 , 3.8 , or 1.7);

Case 6c: (Poisson) Low CP Rank with $p = 10^3$, $n = 1000$, $\alpha = 0.5$, $r = 5$, $m = 20, 5,$ or 1 (SNR $\approx$ 9.6 , 4.7, or 2.1);

Case 7c: (Poisson) Low Tucker Rank with $p = 10^3$, $n = 1000$, $\alpha = 0.06$, $r = 5$, $m = 20, 5,$ or 1 (SNR $\approx$ 9.0, 4.5 or 2.0);

Case 8c: (Poisson) Slices of Low-rank Matrices with $p = 10^3$, $n = 1000$, $\alpha = 0.25$, $r = 5$, $s = 5$, $m = 30, 10,$ or 5 (SNR $\approx$ 15.4, 8.8 or 6.2).

Cases 6(a,b,c), 7(a,b,c) and 8(a,b,c) were constructed to represent different types of tensor low-rankness structure in least-square, logistic and Poisson regression. In each case, three levels of SNR(high, moderate and low) are considered. For each setting, we simulated 50 groups of (T, ϵ, X) and run PGD and convex-regularization methods for the recovery of T to get average rmse with standard deviation for the two approaches respectively. Here we are comparing the best performance achieved by the PGD and convex regularization method respectively: for the PGD we use true parameter as the constraint parameter $r' = r$ (and $s' = s$); for convex regularization method, we do a grid search to choose the tuning parameter that yields the smallest rmse.

The results are summarized in Table 1. These results show that in general, the PGD method produces smaller rmse's than convex regularization methods regardless of the noise level of the data.

5.4. Comparison of tensor low-rankness approach and simple matricization approach

Finally, we display the value of considering low-rank tensors rather than a naive low-rank matricazation scheme. To begin, we consider the following low tensor ranks schemes.

Case 9a: (Gaussian) Low Tucker Rank with $p = 30^3$, $n = 4000$, $r = 5$, $\sigma = 5, 10,$ or 20 (SNR $\approx$ 5.9, 2.9 or 1.5);

Case 10a: (Gaussian) Low CP Rank with $p = 30^3$, $n = 4000$, $r = 5$, $\sigma = 0.5, 1, 2$ or (SNR $\approx$ 4.5, 2.2, or 1.1);

Case 11a: (Gaussian) Slices of Low-rank Matrices with $p = 30^3$, $n = 4000$, $r = 5$, $s = 5$, $\sigma = 1, 2,$ or 4 (SNR $\approx$ 5.0, 2.5 or 1.3).

	Low	**0.57 (0.02)**	0.83 (0.01)

Table 2: rmse of approximate Tucker projection vs naive matricization

Case 9a and Case 10a is when the true tensor parameter has low Tucker rank or low CP rank. Case 11a is when the true tensor parameter is sparse slices of low-rank matrices. Three levels of SNR(high, moderate and low) are considered. For each setting, we simulated 50 groups of (T, ϵ, X) and run two approaches to recover T. The first approach we use is the PGD with our tensor low-rank (approximate) projection. In the Case 9a and 10a, tensor Tucker low-rankness is used via sequential matrix low rank projection, i.e. the approximate low Tucker rank projection $\hat{\Theta}_3(r', r', r')$ with $r' = 5$. While in Case 11a we exploit combination of group-sparsity and matrix low-rankness via $\Theta_2(r', s')$ with $r' = s' = 5$. The second approach is to naively use the matricization where we view the $p \times p \times p$ tensor simply as a $p \times p^2$ matrix and then impose low-rank structure. For naive matricization approach, we report the results of matrix rank-r' projection with $r' = 5$ which yields the best performance of its kind. Table 2 summarizes the average rmse with standard deviation of the two approaches for 50 random runs respectively. Hence we can see that if we partially discard the tensor structure by using only the low-rankness after matricization, the performance is greatly inferior to the low Tucker approximate projection approach. This applies to all three cases considered here, i.e. Tucker, CP and sparse slices of low-rank matrices.

6. Conclusion

In this paper, we provide a general framework that offers theoretical guarantees for learning high-dimensional tensor regression models under different low-rank structural assumptions using the PGD algorithm applied to a potentially non-convex constraint set Θ in terms of its *localized Gaussian width*. Our framework is the first general theory for PGD applied to tensor problems and given that the notion of low-rank structure is ambiguous for tensors, our general framework applies treats them in a unified way.

By providing statistical guarantees in terms of localized Gaussian width, we prove that the PGD approach has mean-squared error that is no worse than the convex regularization counter-part studied in Raskutti and Yuan (2015). We also provided three concrete examples Θ_1, Θ_2 and Θ_3 of low-dimensional tensor structure and provide implementable (approximate) projections and provide mean-squared error guarantees. For Θ_1 and Θ_2 we

provide a convex regularization scheme that achieves the same rate, while for Θ_3 we show that the non-convex PGD approach achieves superior mean-squared error.

We supplement our theoretical results with simulations which show that, under several common settings of generalized low rank tensor regression, the projected gradient descent approach is superior both in terms of statistical error and run-time compared to convex approaches provided the step-sizes of the projected descent algorithm are suitably chosen. Additional simulation results show that PGD with tensor low-rankness constraint also outperforms naive matricization approaches.

7. Proofs

7.1. Proof of general results

We first prove the results of Section 3: Theorems 1, 2 and 3. In particular, we first provide a proof for Theorem 1. For convenience we first state the proof for the Gaussian case (Theorem 3) and then describe the necessary changes needed for the more general GLM case (Theorem 2).

7.1.1. Proof of Theorem 1

The proof follows very similar steps to those developed in Jain et al. (2014, 2016). Recall that $\widehat{T}_{k+1} = P_{\Theta(t_1)}(g_k)$ where $g_k = \widehat{T}_k - \eta \nabla f(\widehat{T}_k)$. For $\widehat{T}_{k+1} \in \Theta(t_1)$ and any $T \in \Theta(t_0 - t_1)$, the superadditivity condition guarantees that there exists a linear subspace $\mathcal{A} = \{\alpha_1 \widehat{T}_{k+1} + \alpha_2 T \mid \alpha_1, \alpha_2 \in \mathbb{R}\}$ such that $\widehat{T}_{k+1} \in \mathcal{A}$, $T \in \mathcal{A}$ and $\mathcal{A} \subset \Theta(t_0)$.

The contractive projection property CPP(δ) implies that for any $T \in \Theta(t_0 - t_1)$,

$$\|(\widehat{T}_{k+1} - g_k)_{\mathcal{A}}\|_{\mathrm{F}} \leq \delta \left\| \frac{t_0 - t_1}{t_1} \right\|_{\ell_\infty}^{1/2} \cdot \|(T - g_k)_{\mathcal{A}}\|_{\mathrm{F}}.$$

Since $t_1 = \left\lceil \frac{4\delta^2 C_u^2 C_l^{-2}}{1+4\delta^2 C_u^2 C_l^{-2}} \cdot t_0 \right\rceil$,

$$\delta \left\| \frac{t_0 - t_1}{t_1} \right\|_{\ell_\infty}^{1/2} \leq (2C_u C_l^{-1})^{-1}.$$

Hence,

$$\begin{aligned}
\|\widehat{T}_{k+1} - T\|_{\mathrm{F}} &\leq \|\widehat{T}_{k+1} - g_k\|_{\mathrm{F}} + \|T - g_k\|_{\mathrm{F}} \\
&\leq \left(1 + \delta \left\| \frac{t_0 - t_1}{t_1} \right\|_{\ell_\infty}^{1/2}\right) \|(T - g_k)_{\mathcal{A}}\|_{\mathrm{F}} \\
&\leq (1 + (2C_u C_l^{-1})^{-1}) \|(T - g_k)_{\mathcal{A}}\|_{\mathrm{F}} \\
&\leq \left(1 + \frac{C_l}{2C_u}\right) \|[T - \widehat{T}_k - \eta(\nabla f(T) - \nabla f(\widehat{T}_k))]_{\mathcal{A}}\|_{\mathrm{F}} + 2\eta \|[\nabla f(T)]_{\mathcal{A}}\|_{\mathrm{F}},
\end{aligned}$$

where the final inequality follows from the triangle inequality. If we define the Hessian matrix of the function f of a vectorized tensor as

$$H(A) = \nabla^2 f(A),$$

the Mean Value Theorem implies that

$$\mathrm{vec}(\nabla f(T) - \nabla f(\widehat{T}_k)) = H(\widehat{T}_k + \alpha(T - \widehat{T}_k)) \cdot (T - \widehat{T}_k),$$

for some $0 < \alpha < 1$, and

$$\begin{aligned}
\|\widehat{T}_{k+1} - T\|_{\mathrm{F}} \leq (1 + (2C_u C_l^{-1})^{-1}) \|[(I - \eta H(\widehat{T}_k + \alpha(T - \widehat{T}_k)))\mathrm{vec}(\widehat{T}_k - T)]_{\mathrm{vec}(\mathcal{A})}\|_{\ell_2} \\
+ 2\eta \|[\nabla f(T)]_{\mathcal{A}}\|_{\mathrm{F}}.
\end{aligned}$$

We now appeal to the following lemma:

Lemma 4 *Suppose $\mathcal{S}$ is a linear subspace of $\mathbb{R}^d$, and H is an $d \times d$ positive semidefinite matrix. For any given $0 < c < 1$, if for any $x \in \mathcal{S}$,*

$$c x^\top x \leq x^\top H x \leq (2 - c) x^\top x, \tag{12}$$

then for any $z \in \mathcal{S}$, we have

$$\|[(I - H)z]_{\mathcal{S}}\|_{\ell_2} \leq (1 - c)\|z\|_{\ell_2},$$

$(\cdot)_{\mathcal{S}}$ stands for the projection onto the subspace $\mathcal{S}$.

Proof [Proof of Lemma 4] Suppose the orthonomal basis of $\mathcal{S}$ is $e_1 \ldots, e_q$, and then

$$\mathbb{R}^d = \{ce_1 | c \in \mathbb{R}\} \oplus \ldots \oplus \{ce_q | c \in \mathbb{R}\} \oplus \mathcal{S}^\perp$$

For positive semidefinite H, it can be decomposed as follows

$$H = D^\top D.$$

Hence we can decompose the rows of D to get

$$D = \sum_{i=1}^{q} \lambda_i e_i^\top + (y_1, \ldots, y_n)^\top$$

where $y_1, \ldots, y_n \in \mathcal{S}^\perp$, and $\lambda_i \in \mathbb{R}^n$ for $i = 1, \ldots, q$. Therefore,

$$D^\top D = \sum_{i=1}^{q}\sum_{j=1}^{q} (\lambda_i^\top \lambda_j) e_i e_j^\top + \sum_{k=1}^{n} y_k y_k^\top + (y_1, \ldots, y_n) \sum_{i=1}^{q} \lambda_i e_i^\top + \sum_{i=1}^{q} e_i \lambda_i^\top \cdot (y_1, \ldots, y_n)^\top.$$

Now for any $(\alpha_1, \ldots, \alpha_q)^\top \in \mathbb{R}^q$, we have $x = \sum_{i=1}^{q} \alpha_i e_i \in \mathcal{S}$, and hence

$$x^\top D^\top D x = (\sum_{i=1}^{q} \alpha_i e_i)^\top D^\top D (\sum_{i=1}^{q} \alpha_i e_i) = \sum_{i=1}^{q}\sum_{j=1}^{q} (\lambda_i^\top \lambda_j) \alpha_i \alpha_j.$$

The equation 12 then implies that the matrix

$$\Lambda = \{\Lambda_{i,j}\}_{i,j=1}^{q} \text{ where } \Lambda_{i,j} = \lambda_i^\top \lambda_j$$

has eigenvalues bounded by c from below and $2-c$ from above. Next, notice that for any $z \in \mathcal{S}$, we have $z = \sum_{i=1}^{q} \beta_i e_i$ for some $(\beta_1, \ldots, \beta_q)^\top \in \mathbb{R}^q$, and hence due to the fact that $y_1, \ldots y_n \in \mathcal{S}^\perp$

$$(I - D^\top D)z = \left(I - \sum_{i=1}^{q}\sum_{j=1}^{q} (\lambda_i^\top \lambda_j) e_i e_j^\top + (y_1, \ldots, y_n) \sum_{i=1}^{q} \lambda_i e_i^\top \right) \sum_{i=1}^{q} \beta_i e_i,$$

and furthermore

$$\begin{aligned} [(I - D^\top D)z]_{\mathcal{S}} &= \left(I - \sum_{i=1}^{q}\sum_{j=1}^{q} (\lambda_i^\top \lambda_j) e_i e_j^\top \right) \sum_{i=1}^{q} \beta_i e_i \\ &= (e_1, \ldots, e_q)(I_{q\times q} - \Lambda)(\beta_1, \ldots \beta_q)^\top, \end{aligned}$$

and

$$\|[(I - D^\top D)z]_{\mathcal{S}}\|_{\ell_2}^2 = (\beta_1, \ldots \beta_q)(I_{q\times q} - \Lambda)(\beta_1, \ldots \beta_q)^\top,$$

which completes the proof. ■

Condition $RSCS(\Theta(t_0), C_l, C_u)$ guarantees the condition of Lemma 4 is satisfied with $H = \eta H(\widehat{T}_k + \alpha(T - \widehat{T}_k))$, $c = (C_u C_l^{-1})^{-1}$ and $\mathcal{S} = \mathcal{A}$. Hence Lemma 4 implies that

$$\|\widehat{T}_{k+1} - T\|_{\mathrm{F}} \leq (1 + (2C_u C_l^{-1})^{-1}) \left(1 - (C_u C_l^{-1})^{-1}\right) \|\widehat{T}_k - T\|_{\mathrm{F}} + 2\eta \|[\nabla f(T)]_{\mathcal{A}}\|_{\mathrm{F}}.$$

Therefore for any k,

$$\|\widehat{T}_{k+1} - T\|_{\mathrm{F}} \leq (1 - (2C_u C_l^{-1})^{-1}) \|\widehat{T}_k - T\|_{\mathrm{F}} + 2\eta Q,$$

where

$$Q = \sup_{\mathcal{A}_0 \subset \Theta(t_0)} \|(\nabla f(T))_{\mathcal{A}_0}\|_{\mathrm{F}},$$

where $\mathcal{A}_0$ is any linear subspace of $\Theta(t_0)$.We then appeal to the following result.

Lemma 5 *Suppose $\mathcal{A}$ is a linear subspace of tensor space Ω. For any $L \in \Omega$,*

$$\|(L)_{\mathcal{A}}\|_{\mathrm{F}} = \sup_{A \in \mathcal{A} \cap \mathbb{B}_{\mathrm{F}}(1)} \langle A, L \rangle$$

Proof [Proof of Lemma 5] First, we are going to show that

$$\|(L)_{\mathcal{A}}\|_{\mathrm{F}} \leq \sup_{A \in \mathcal{A} \cap \mathbb{B}_{\mathrm{F}}(1)} \langle A, L \rangle$$

Suppose we have $(L)_{\mathcal{A}} = P \in \mathcal{A}$. Since for any $\alpha > -1$, $P + \alpha P \in \mathcal{A}$, and hence

$$\|P + \alpha P - L\|_{\mathrm{F}} = \|P - L\|_{\mathrm{F}} + \alpha^2 \|P\|_{\mathrm{F}} + \alpha \langle P, P - L \rangle \leq \|P - L\|_{\mathrm{F}}$$

we must have $\langle P, P - L \rangle = 0$, i.e. $\langle P, L \rangle = \langle P, P \rangle$. (otherwise α of small magnitude with the same sign of $\langle P, P - L \rangle$ will violate the inequality). Therefore,

$$\sup_{A \in \mathcal{A} \cap \mathbb{B}_{\mathrm{F}}(1)} \langle A, L \rangle \geq \left\langle \frac{P}{\|P\|_{\mathrm{F}}}, L \right\rangle = \|P\|_{\mathrm{F}} = \|(L)_{\mathcal{A}}\|_{\mathrm{F}}$$

What remains is to show

$$\|(L)_{\mathcal{A}}\|_{\mathrm{F}} \geq \sup_{A \in \mathcal{A} \cap \mathbb{B}_{\mathrm{F}}(1)} \langle A, L \rangle$$

For any $D \in \mathcal{A} \cap \mathbb{B}_{\mathrm{F}}(1)$, let D_α be the projection of L onto $\{\alpha D | \alpha \geq 0\}$, and hence

$$\langle D_\alpha, L \rangle = \langle D_\alpha, D_\alpha \rangle \leq \langle P, P \rangle.$$

Therefore, we have

$$\langle D, L \rangle \leq \left\langle \frac{D}{\|D\|_{\mathrm{F}}}, L \right\rangle = \left\langle \frac{D_\alpha}{\|D_\alpha\|_{\mathrm{F}}}, L \right\rangle \leq \|P\|_{\mathrm{F}}$$

which completes the proof. ■

Lemma 5 then implies

$$Q = \sup_{\mathcal{A}_0 \subset \Theta(t_0)} \|(\nabla f(T))_{\mathcal{A}_0}\|_{\mathrm{F}} = \sup_{\mathcal{A}_0 \subset \Theta(t_0)} \sup_{A \in \mathcal{A}_0 \cap \mathbb{B}_{\mathrm{F}}(1)} \langle \nabla f(T), A \rangle \leq \sup_{A \in \Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)} \langle \nabla f(T), A \rangle .$$

Therefore, after

$$K = \lceil 2C_u C_l^{-1} \log \frac{\|T\|_{\mathrm{F}}}{\epsilon} \rceil$$

iterations,

$$\|\widehat{T}_k - T\|_{\mathrm{F}} \leq \epsilon + 4\eta C_u C_l^{-1} \sup_{A \in \Theta(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)} \langle \nabla f(T), A \rangle ,$$

which completes the proof.

7.1.2. Proof of Theorem 3

Recall that the original least-squares objective is

$$f(A) = \frac{1}{2n} \sum_{i=1}^{n} (Y^{(i)} - \langle X^{(i)}, A \rangle)^2.$$

Hence, the gradient at true tensor coefficient T is :

$$\nabla f(T) = \frac{1}{n} \sum_{i=1}^{n} X^{(i)} \otimes [\langle T, X^{(i)} \rangle - Y^{(i)}] = -\frac{1}{n} \sum_{i=1}^{n} X^{(i)} \zeta^{(i)}$$

for the least-squares objective we consider. Further

$$\nabla^2 f(T) = \frac{1}{n} \sum_{i=1}^{n} X^{(i)} \otimes X^{(i)}.$$

Through vectorization, the Hessian matrix H is

$$H = \sum_{i=1}^{n} \text{vec}(X^{(i)})\text{vec}(X^{(i)})^\top.$$

Lemma 1 then implies that given $n \geq c_1 w_G^2[\Theta(t_0) \cap \mathbb{B}_{\text{F}}(1)]$, with probability at least

$$1 - c_2/2 \exp(-c_3 w_G^2[\Theta(t_0) \cap \mathbb{B}_{\text{F}}(1)]),$$

we have, for any $A \in \Theta(t_0)$,

$$\left(\tau^{-1}c_l\right)^2 \langle A, A\rangle \leq \frac{1}{n}\sum_{i=1}^{n}\langle X^{(i)}, A\rangle^2 \leq (\tau c_u)^2\langle A, A\rangle,$$

which guarantees the $RSCS(\Theta(t_0), C_l, C_u)$ condition with $C_u = \tau c_u$ and $C_l = \tau^{-1}c_l$. Thus Theorem 1 implies that

$$\|\widehat{T}_k - T\|_{\text{F}} \leq \epsilon + 4\eta\tau^2\kappa \sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \left\langle \frac{1}{n}\sum_{i=1}^{n}\zeta^{(i)}X^{(i)}, A\right\rangle.$$

The last step is to show that

$$\sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \left\langle \frac{1}{n}\sum_{i=1}^{n}\zeta^{(i)}X^{(i)}, A\right\rangle \leq 2c_u\sigma n^{-1/2} w_G[\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)],$$

with probability at least

$$1 - c_2/2\exp\left\{-c_3 w_G^2[\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)]\right\}.$$

This can be shown by simply applying Lemma 11 in Raskutti and Yuan (2015) and replacing $\{A|\mathcal{R}(A) \leq 1\}$ with $\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)$. Note that all the proof steps for Lemma 11 in Raskutti and Yuan (2015) are identical for $\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)$ since the sets $\Theta(t)$'s are symmetric.

7.1.3. Proof of Theorem 2

The proof follows the same flow as Theorem 3 but we requires an important concentration result from Mendelson (2014). Recall that in the GLM setting, according to (2),

$$f(A) = \frac{1}{n}\sum_{i=1}^{n}\left(a(\langle X^{(i)}, A\rangle) - Y^{(i)}\langle X^{(i)}, A\rangle\right).$$

Hence the gradient at true coefficient T is

$$\nabla f(T) = \frac{1}{n}\sum_{i=1}^{n}(\mu_i - Y^{(i)})X^{(i)},$$

where $\mu_i = a'(\langle X^{(i)}, T\rangle)$, and the Hessian matrix at vectorized tensor T is

$$\nabla^2 f(T) = \sum_{i=1}^{n} W_{ii}\text{vec}(X^{(i)})\text{vec}(X^{(i)})^\top.$$

where $W_{ii} = a''(\langle X^{(i)}, T\rangle)$.

Since $\text{Var}(Y^{(i)}) = a''(\langle X^{(i)}, T\rangle) = W_{ii}$, the moment assumption $1/\tau_0^2 \leq \text{Var}(Y^{(i)}) \leq \tau_0^2$ guarantees that

$$\frac{1}{\tau_0^2} \leq W_{ii} \leq \tau_0^2.$$

Plus, for any $\tau > \tau_0$, Lemma 1 guarantees that when $n > c_1 w_G^2[\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)]$,

$$\left((\tau/\tau_0)^{-1}c_l\right)^2\langle A, A\rangle \leq \frac{1}{n}\sum_{i=1}^{n}\langle X^{(i)}, A\rangle^2 \leq ((\tau/\tau_0)c_u)^2\langle A, A\rangle.$$

Therefore $RSCS(\Theta(t_0), C_l, C_u)$ condition holds with $C_l = \tau^{-1}c_l$ and $C_u = \tau c_u$. Thus Theorem 1 implies that

$$\|\widehat{T}_k - T\|_{\text{F}} \leq \epsilon + 4\eta\tau^2\kappa \sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \left\langle \frac{1}{n}\sum_{i=1}^{n}(Y^{(i)} - \mu_i)X^{(i)}, A\right\rangle.$$

For the last step, by applying a concentration result on the following multiplier empirical process

$$\sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \left\langle \frac{1}{n}\sum_{i=1}^{n}(Y^{(i)} - \mu_i)X^{(i)}, A\right\rangle = \sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \frac{1}{n}\sum_{i=1}^{n}(Y^{(i)} - \mu_i)\left\langle X^{(i)}, A\right\rangle,$$

we can bound the quantity by the Gaussian width with large probability, up to some constant.

More specifically, denote

$$\omega^{(i)} = \Sigma^{-1/2}\text{vec}(X^{(i)})$$

then $\{\omega^{(i)}\}_{i=1}^n$ are i.i.d Gaussian random vectors and hence

$$\begin{aligned}
&\sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \frac{1}{n}\sum_{i=1}^{n}(Y^{(i)} - \mu_i)\left\langle X^{(i)}, A\right\rangle \\
=\ &\sup_{F\in\text{vec}(\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1))} \frac{1}{n}\sum_{i=1}^{n}(Y^{(i)} - \mu_i)\text{vec}(X^{(i)})^\top F \\
=\ &\sup_{F\in\Sigma^{1/2}\cdot\text{vec}(\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1))} \frac{1}{n}\sum_{i=1}^{n}(Y^{(i)} - \mu_i)(\omega^{(i)})^\top F \\
\leq\ &c_5 M_Y^{1/q} \sup_{F\in\Sigma^{1/2}\cdot\text{vec}(\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1))} \frac{1}{n}\sum_{i=1}^{n}(\omega^{(i)})^\top F \\
=\ &c_5 M_Y^{1/q} \sup_{A\in\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)} \frac{1}{n}\sum_{i=1}^{n}\left\langle X^{(i)}, A\right\rangle \\
\leq\ &\frac{c_5 M_Y^{1/q} c_u}{\sqrt{n}} w_G^2[\Theta(t_0)\cap\mathbb{B}_{\text{F}}(1)],
\end{aligned}$$

where the first inequality follows from Theorem 1.9 of Mendelson (2014), and the second inequality holds in view of Lemma 11 of Raskutti and Yuan (2015), and both inequalities hold with probability greater than

$$1 - c_2\exp\left\{-c_3 w_G^2[\Theta(\theta' + \theta)\cap\mathbb{B}_{\text{F}}(1)]\right\} - c_4 n^{-(q/2-1)}\log^q n.$$

7.2. Proofs of results in Section 4

We now present the proofs for the two main examples $\Theta_2(r,s)$ and $\Theta_3(r)$. Our proofs involve: (i) proving that the projection properties hold for both sets of cones and (ii) finding an error bound for the Gaussian width $w_G[\Theta(t)\cap\mathbb{B}_{\mathrm{F}}(1)]$.

7.2.1. Proof of Theorem 4

First, it is straightforward to verify that $\{\Theta_2(r,s)\}$ is a superadditive family of symmetric cones. We then verify the contraction properties as stated by Lemma 2.

Proof [Proof of Lemma 2] We need to develop an error bound for $\|P_{\Theta_2(r_2,s_2)}(Z)-Z\|_{\mathrm{F}}$ for a general tensor $Z\in\Theta_2(r_0,s_0)$. Let $\tilde{Z}\in\mathbb{R}^{d_1\times d_2\times d_3}$ denote the tensor whose slices $\tilde{Z}_{\cdot\cdot j_3}$, $(j_3=1,\ldots,d_3)$ are the rank-r_2 approximation of the corresponding slices of Z. First, it follows from the contraction property of low rank matrix projector (see, e.g., Jain et al., 2016) that for all $1\le j_3\le d_3$, for any $Y_{\cdot\cdot j_3}$ such that $\mathrm{rank}(Y_{\cdot\cdot j_3})\le r_1$

$$\|\tilde{Z}_{\cdot\cdot j_3}-Z_{\cdot\cdot j_3}\|_{\mathrm{F}}\le\beta\|Y_{\cdot\cdot j_3}-Z_{\cdot\cdot j_3}\|_{\mathrm{F}}.$$

By summing over j_3 it follows that for any $Y\in\mathbb{R}^{d_1\times d_2\times d_3}$ where $\mathrm{rank}(Y_{\cdot\cdot j_3})\le r_1$ for all j_3

$$\|\tilde{Z}-Z\|_{\mathrm{F}}\le\beta\|Y-Z\|_{\mathrm{F}}.$$

The projection $P_{\Theta_2(r_2,s_2)}(Z)$ involves zeroing out the slices of $\tilde{Z}$ with the smallest magnitude. Let $v_{\tilde{Z}}:=\mathrm{vec}(\|\tilde{Z}_{\cdot\cdot 1}\|_{\mathrm{F}},\|\tilde{Z}_{\cdot\cdot 2}\|_{\mathrm{F}},\ldots,\|\tilde{Z}_{\cdot\cdot d_3}\|_{\mathrm{F}})$. As shown by Jain et al. (2014), for all Y where $v_Y=\mathrm{vec}(\|Y_{\cdot\cdot 1}\|_{\mathrm{F}},\|Y_{\cdot\cdot 2}\|_{\mathrm{F}},\ldots,\|Y_{\cdot\cdot d_3}\|_{\mathrm{F}})$ and $\|v_Y\|_{\ell_0}\le s_1$,

$$\|\tilde{P}_s(v_{\tilde{Z}})-v_{\tilde{Z}}\|_{\ell_2}\le\alpha\|v_Y-v_{\tilde{Z}}\|_{\ell_2}.$$

Therefore

$$\begin{aligned}\|P_{\Theta_2(r_2,s_2)}(Z)-\tilde{Z}\|_{\mathrm{F}} &\le \alpha\|Y-\tilde{Z}\|_{\mathrm{F}}\\ &\le \alpha(\|Y-Z\|_{\mathrm{F}}+\|\tilde{Z}-Z\|_{\mathrm{F}})\\ &\le (\alpha+\alpha\beta)\|Y-Z\|_{\mathrm{F}}.\end{aligned}$$

Hence using the triangle inequality:

$$\|P_{\Theta_2(r_2,s_2)}(Z)-Z\|_{\mathrm{F}}\le\|\tilde{Z}-Z\|_{\mathrm{F}}+\|P_{\Theta_2(r_2,s_2)}(Z)-\tilde{Z}\|_{\mathrm{F}}\le(\alpha+\beta+\alpha\beta)\cdot\|Y-Z\|_{\mathrm{F}},$$

which completes the proof. ■

Lemma 2 guarantees that $P_{\Theta_2(r,s)}$ satisfies the contractive projection property CPP(δ) with $\delta=3$. Hence, by setting $t_1=(r',s')$ and $t_0=(r'+r,s'+s)$, Theorem 3 directly implies the linear convergence rate result with statistical error of order

$$n^{-1/2}w_G[\Theta_2(r'+r,s'+s)\cap\mathbb{B}_{\mathrm{F}}(1)].$$

It remains to calibrate the Gaussian width. Recall the definition of the convex regularizer:

$$\mathcal{R}_1(A)=\sum_{j_3=1}^{d_3}\|A_{\cdot\cdot j_3}\|_*.$$

It is straightforward to show that

$$\Theta_2(r'+r,s'+s)\cap\mathbb{B}_{\mathrm{F}}(1)\subset\mathbb{B}_{\mathcal{R}_1}(\sqrt{(r'+r)(s'+s)}).$$

Then Lemma 5 of Raskutti and Yuan (2015) implies that

$$\begin{aligned}w_G[\Theta_2(r'+r,s'+s)\cap\mathbb{B}_{\mathrm{F}}(1)] &\le w_G[\mathbb{B}_{\mathcal{R}_1}(\sqrt{(r'+r)(s'+s)})]\\ &\le \sqrt{(s'+s)(r'+r)}\,w_G[\mathbb{B}_{\mathcal{R}_1}(1)]\\ &\le \sqrt{(s'+s)(r'+r)}\sqrt{6(d_1+d_2+\log d_3)}\end{aligned}$$

which completes the proof.

7.2.2. Proof of Theorem 5

Once again, it is straightforward to verify that $\{\Theta_3(r_1,r_2,r_3)\}$ is a superadditive family of symmetric cones. We now verify the contraction properties

Proof [Proof of Lemma 3] To develop an error bound for $\|\widehat{P}_{\Theta_3(r_1^{(2)},r_2^{(2)},r_3^{(2)})}(Z)-Z\|_{\mathrm{F}}$ for a general tensor $Z\in\Theta_3(r_1^{(0)},r_2^{(0)},r_3^{(0)})$, we introduce the following three tensors (recursively):

$$\begin{aligned}Z_{(1)} &:= (\mathcal{M}_1^{-1}\circ\bar{P}_{r_1}\circ\mathcal{M}_1)(Z)\\ Z_{(2)} &:= (\mathcal{M}_2^{-1}\circ\bar{P}_{r_2}\circ\mathcal{M}_2)(Z_{(1)})\\ Z_{(3)} &:= (\mathcal{M}_3^{-1}\circ\bar{P}_{r_3}\circ\mathcal{M}_3)(Z_{(2)}),\end{aligned}$$

where we recall that $\mathcal{M}_1(\cdot)$, $\mathcal{M}_2(\cdot)$ and $\mathcal{M}_3(\cdot)$ are the mode-1, mode-2 and mode-3 matricization operators. Therefore $\widehat{P}_{\Theta_3(r_1^{(2)},r_2^{(2)},r_3^{(2)})}(Z)=Z_{(3)}$ and:

$$\|\widehat{P}_{\Theta_3(r_1^{(2)},r_2^{(2)},r_3^{(2)})}(Z)-Z\|_{\mathrm{F}}\le\|\widehat{P}_{\Theta_3(r_1^{(2)},r_2^{(2)},r_3^{(2)})}(Z)-Z_{(2)}\|_{\mathrm{F}}+\|Z_{(2)}-Z_{(1)}\|_{\mathrm{F}}+\|Z_{(1)}-Z\|_{\mathrm{F}}.$$

Next note that

$$\|Z_{(1)}-Z\|_{\mathrm{F}}=\|(\mathcal{M}_1^{-1}\circ\bar{P}_{r_1}\circ\mathcal{M}_1)(Z)-Z\|_{\mathrm{F}}=\|\bar{P}_{r_1}(\mathcal{M}_1(Z))-\mathcal{M}_1(Z)\|_{\mathrm{F}}.$$

As shown by Jain et al. (2016), for any Y such that $r_1(Y)\le r_1^{(1)}$,

$$\|Z_{(1)}-Z\|_{\mathrm{F}}\le\beta_1\|Y-Z\|_{\mathrm{F}}.$$

Using a similar argument and the triangle inequality

$$\|Z_{(2)}-Z_{(1)}\|_{\mathrm{F}}\le\beta_2\|Y-Z_{(1)}\|_{\mathrm{F}}\le\beta_2(\|Y-Z\|_{\mathrm{F}}+\|Z_{(1)}-Z\|_{\mathrm{F}})\le(\beta_2+\beta_1\beta_2)\|Y-Z\|_{\mathrm{F}}.$$

Furthermore,

$$\begin{aligned}\|Z_{(3)}-Z_{(2)}\|_{\mathrm{F}} &\le \beta_3\|Y-Z_{(2)}\|_{\mathrm{F}}\\ &\le \beta_3(\|Y-Z\|_{\mathrm{F}}+\|Z_{(2)}-Z\|_{\mathrm{F}})\\ &\le \beta_3(1+\beta_1+\beta_2+\beta_1\beta_2)\|Y-Z\|_{\mathrm{F}}.\end{aligned}$$

Therefore for all $Y \in \Theta_3(r_1^{(1)}, r_2^{(1)}, r_3^{(1)})$

$$\begin{aligned}\|\widehat{P}_{\Theta_3(r_1^{(2)},r_2^{(2)},r_3^{(2)})}(Z) - Z\|_{\mathrm{F}} &= \|\widehat{P}_{\Theta_3(r_1^{(2)},r_2^{(2)},r_3^{(2)})}(Z) - Z_{(2)}\|_{\mathrm{F}} + \|Z_{(2)} - Z_{(1)}\|_{\mathrm{F}} + \|Z_{(1)} - Z\|_{\mathrm{F}} \\ &\leq [(\beta_1+1)(\beta_2+1)(\beta_3+1) - 1]\|Y - Z\|_{\mathrm{F}}.\end{aligned}$$

■

Lemma 2 guarantees the approximate projection $\widehat{P}_{\Theta_3(r_1,r_2,r_3)}$ fulfills the contractive projection property CPP(δ) with $\delta = 7$. And hence via setting $t_1 = (r_1', r_2', r_3')$ and $t_0 = (r_1' + r_1, r_2' + r_2, r_3' + r_3)$, Theorem 3 directly implies the linear convergence rate result with statistical error of order $n^{-1/2} w_G[\Theta_3(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)]$. To upper bound the Gaussian width, we define the following nuclear norms:

$$\mathcal{R}_{(i)}(A) = \|\mathcal{M}_i(A)\|_*,$$

where $1 \leq i \leq 3$ and $\|.\|_*$ is the standard nuclear norm. Then it clearly follows that

$$\Theta_3(t_0) \cap \mathbb{B}_{\mathrm{F}}(1) \subset \cap_{i=1}^3 \mathbb{B}_{\mathcal{R}_{(i)}}(\sqrt{r_i' + r_i}).$$

Lemma 5 in Raskutti and Yuan (2015) then implies that

$$\begin{aligned} w_G[\Theta_3(t_0) \cap \mathbb{B}_{\mathrm{F}}(1)] &\leq w_G[\cap_i \mathbb{B}_{\mathcal{R}_{(i)}}(\sqrt{r_i' + r_i})] \\ &\leq \min_i w_G[\mathbb{B}_{\mathcal{R}_{(i)}}(\sqrt{r_i' + r_i})] \\ &\leq \min_i \sqrt{r_i' + r_i}\, w_G[\mathbb{B}_{\mathcal{R}_{(i)}}(1)] \\ &\leq \sqrt{6 \min\{(r_1'+r_1)(d_1 + d_2 d_3), (r_2'+r_2)(d_2 + d_1 d_3), (r_3'+r_3)(d_3 + d_1 d_2)\}}\end{aligned}$$

which completes the proof.

Abstract

The scikit-multilearn is a Python library for performing multi-label classification. It is compatible with the scikit-learn and scipy ecosystems and uses sparse matrices for all internal operations; provides native Python implementations of popular multi-label classification methods alongside a novel framework for label space partitioning and division and includes modern algorithm adaptation methods, network-based label space division approaches, which extracts label dependency information and multi-label embedding classifiers. The library provides Python wrapped access to the extensive multi-label method stack from Java libraries and makes it possible to extend deep learning single-label methods for multi-label tasks. The library allows multi-label stratification and data set management. The implementation is more efficient in problem transformation than other established libraries, has good test coverage and follows PEP8. Source code and documentation can be downloaded from `http://scikit.ml` and also via `pip`. The project is BSD-licensed.

Keywords: Python, multi-label classification, label-space clustering, multi-label embedding, multi-label stratification

1. Introduction

The Python language with its machine learning library stack has grown to become one of the leading technologies of building models for the industry and developing new methods for the researchers. While the Python community boasts with the excellent culture of development, well-defined API traditions and well-performing implementations of methods from most machine learning areas it did not have a high-quality solution for multi-label classification.

In this paper we introduce scikit-multilearn, a well-tested, multi-platform, Python 3 compatible, BSD-licensed library with bleeding edge approaches for multi-label problems, which is actively developed and has a growing user base. We also show that it is faster than its competition in other languages. It is also entirely compatible with the scientific/machine learning ecosystem of well-known Python libraries which allows it to fill the niche of the missing multi-label classification solution, while also benefits from complementary solutions present in the scikit-learn community, while providing it with efficient implementations of missing classification methods, data stratification, dataset access and manipulation.

We start with a summary of what multi-label classification is in Section 2. Followed by Section 3 where we present related work and a description of the machine learning ecosystem that scikit-multilearn fits in. In Section 4 we describe what scikit-multilearn brings to the community. We evaluate how scikit-multilearn performs in comparison to libraries implemented in other languages in Section 5 and present conclusions and future ideas in Section 6.

2. Multi-label classification

Multi-label classification deals with the problem of assigning a subset of available labels to a given observation. Such problems appear in multiple domains - article and website classification, multimedia annotation, music categorization, the discovery of genomics functionalities and are performed either by transforming a problem into a single/multi-class classification problem or by adapting a single/multi-class method to take multi-label information into account. An excellent introduction to the field has been provided by Tsoumakas et al. (2009).

Madjarov et al. (2012) divide approaches multi-label classification into three groups: method adaptation, problem transformation and ensembles thereof. The first idea is to adapt single-label methods to multi-label classification by modifying label assigning fragments in a single-label method. An example of this is introducing a multi-label version of a decision function in Decision Trees (ex. Kocev et al., 2013).

Problem transformation concentrates on converting the multi-label problem to one or more single-label problems. The most prominent examples include classifying each label separately such as Binary Relevance or Classifier Chains (Read et al., 2009) and treating each label combination as a separate class in one multi-class problem as in the Label Powerset case.

Both of these approaches suffer not only from standard problems of machine learning such as over- and under-fitting but also from the issue of label imbalance (Sun et al., 2009) or numerical anomalies related to label ordering when Bayesian approaches are used for taking correlations into account. Ensemble methods aim to correct this by learning multiple classifiers trained on label subspaces (ex. RAkEL by Tsoumakas et al., 2011a), observation subsets with pruning and replacement, or analyzing various label orderings in chains (ex. Probabilistic Classifier Chains by Dembczynski et al., 2010).

Multi-label embedding techniques emerged as a response the need to cope with a large label space; these include label space dimensionality reduction techniques that turned Most multi-label embedding methods turn multi-label classification into multivariate regression problem followed by a rule-based or classifier-based correction step. Embedding methods also vary by the principle of how the embedding is performed, these include: Principle Label Space Transformation (Tai and Lin, 2012) based on Principal Component Analysis; Conditional Principal Label Space Transformation (Chen and Lin, 2012) with Canonical Com-

ponent Analysis; Feature-aware Implicit Label Space Encoding (Lin et al., 2014) based on matrix decompositions; SLEEC (Bhatia et al., 2015) which uses k-means clustering and per cluster embedding; CLEMS (Huang and Lin, 2017) which performs Multi-Dimensional Scaling (see Kruskal, 1964) with extra multi-label quality measure optimization; and LNEMLC (Szymański et al., 2018) which embeds label networks using network embeddings such as LINE or node2vec. Most of these use linear, ridge or random forest regressors to predict embeddings for unseen samples and a variant of kNN to classify them with labels. CLEMS and LNEMLC are among the best performing multi-label embeddings at this time.

Multi-label advances in recent years also include developments in a sub-area called extreme multi-label where new methods emerged such as deep-learning based domain-specific approaches for: image classification frameworks (Zhao et al., 2015; Wang et al., 2016; Wei et al., 2016) or text (Liu et al., 2017; Yen et al., 2017). The field also includes tree-based (Prabhu and Varma, 2014) or embedding-based (Bhatia et al., 2015) approaches. While extreme multi-label is an interesting task it differs strongly from classical multi-label classification in performance expectations, benchmark datasets and quality measures and falls beyond the main focus of scikit-multilearn but its methods can be used to classify these scale of problems.

3. Related work

As with every applied science, research requires environments for performing experiments. The most prominent multi-label classification stack to date (regarding method count and popularity) is implemented in Java: MULAN (Tsoumakas et al., 2011b) and MEKA (Read et al., 2016). Both depend heavily on the famous WEKA library (Hall et al., 2009) which implements a plethora of classification and regression methods for single-label classification. MULAN and MEKA are large multi-purpose libraries which support not only multi-label classification tasks but also regression and multi-instance/multi-output tasks.

Python's scientific ecosystem's philosophy (Oliphant, 2007) is a different one, instead of having few large multi-purpose libraries, it provides a foundation of libraries that deliver most important approaches and a network of smaller and more specialized libraries that interact thanks to a well-defined API, coding and documentation standards set out for common machine learning tasks such as prediction or data transformation. With numpy (Oliphant, 2006), scipy (Jones et al., 2001) as numerical operation and data structure foundations. The machine-learning foundation provided by scikit-learn (Pedregosa et al., 2011) follows a different approach than WEKA as it does not aim at being a large mono-library where all functionality is gathered. Instead, it concentrates on implementing most cited well-established methods alongside a stable API design.

The rudimentary multi-label methods provided by scikit-learn do not support sparse representations of label matrices apart from the multi output classifier: algorithm adaptation approaches such as k nearest neighbors, CART trees and random forests and perceptrons; problem transformation methods Binary Relevance, Classifier Chains and one-vs-rest or one-vs-all usage of multi-class classifiers such as Support Vector Machines (Hearst et al., 1998). However all of these are the most rudimentary variants of listed methods and have been superseded by more modern approaches. The kNN approach from scikit-learn has been improved by ML-kNN (Zhang and Zhou, 2007), deep learning is used much more

often than perceptrons, and new tree-based classifiers like fastXML (Prabhu and Varma, 2014) outperform traditional random forests of multi-label trees. One-vs-all/rest multi-class classifiers can now be replaced with inherently multi-label variants of the methods, ex. SVM classification scheme has been enhanced by multi-label SVM approaches such as MLTSVM (Chen et al., 2016). Binary Relevance provides worse performance than data-driven label space division (Szymański et al., 2016) or stacking (Montañes et al., 2014). Classifier chains have been extended in multiple ways to overcome artifacts related to sample distribution changes between label orderings either by learning shorter chains via data-driven label space divisions or chain sampling methods (PCC by Dembczynski et al., 2010), (MCC by Read et al., 2013). However scikit-learn's classifiers are extremely useful when used as a base for more comprehensive methods in scikit-mutlilearn such as label space partitioning ensembles or multi-label embedding.

The scikit-learn project also forms a hub of a large network of complementary libraries for more specific tasks, new techniques or emergent sub-fields. Such libraries include among many others scikit-multiflow and imbalanced-learn.

The scikit-multiflow library (Montiel et al., 2018) concerns multi-label streams, which differs from the traditional multi-label setting where a method is trained once to predict data - in multi-label streams the methods are retrained or adopted as new samples arrive. Even though scikit-multiflow provides reimplementations selected methods of scikit-learn, the authors note that scikit-learn's implementations should be applied while using the library. Authors claim that the provided implementations are less optimal (kNN) or masks over the original scikit-learn code for internal purposes. more Modern version of classifier chains (PCC, MCC) and stream classifiers are the core contribution of the library. They are optimized towards partial updating as new evidence arrives. The library is well unit-tested and should be used for multi-label stream tasks which scikit-multilearn does not handle out of the box. However, scikit-multilearn provides more vibrant and various offering of state of the art methods optimized for the classic multi-label problem formulation.

The imbalanced-learn library (Lemaître et al., 2017) is dedicated to overcoming class imbalance problems in single-label tasks by a variety of under/over-sampling strategies. As many problem transformation approaches transform the problem to a multi-class problem imbalanced-learn can be used to improve learning capabilities of scikit-multilearn classifiers by fitting them to resampled data.

Domain and sub-field related deep neural networks with multi-label classification support are also available such as magpie[1], CNN-RNN for images or a variety of different models for biological data[2] for text classification.

Multi-label classification problems can also be addressed in general purse deep learning libraries such as Tensorflow (Abadi et al., 2015) or Keras (Chollet et al., 2015). However, deep neural networks often do not demonstrate an appropriate level of robustness and require significant differences in architecture to accommodate a concrete problem. This introduces an additional level of complication while applying deep learning to multi-label problems. While these libraries are instrumental in their areas, scikit-multilearn is dedicated to providing domain-independent solutions as efficient per domain specialization is rarely possible in one unified code base. However, scikit-multilearn does provide support for using

Table 1: Comparison of multi-label classification libraries and their features. Letter P denotes partial functionality: scikit-learn can generate multi-label datasets, but does not offer methods to lead them and manipulate them; sparse support is implemented only for Binary Relevance (MultiOutputClassifier). MLC toolbox offers some of its classifiers Windows-only. Output format from scikit-multilearn's classifiers is compatible with scikit-learn's quality measures.

Keras-compatible models for multi-label classification independent of the backend used by Keras (i.e. Tensorflow, CNTK) or PyTorch (via the skorch[3] library).

The scikit-multilearn project fits in the Python community similarly as to how MEKA or MULAN fit to the Java machine learning projects network, however, it is focused on multi-label classification problems to provide state of the art approaches and efficient implementation of more advanced methods.

Recently multi-label classification libraries were made available in R (R Core Team, 2013) and Matlab/Octave (Eaton et al., 2017): utiml (Rivolli and de Carvalho, 2018) R library built on top of the dataset management library mldr (Charte and Charte, 2015) and offers a larger variety of available methods than other R libraries and a more welcoming API; MLC Toolbox (Kimura et al., 2017) provides multi-label methods for Matlab/Octave communities.

Table 1 provides a general point of view on the functionality offered by multi-label classification methods in Java, Python, R and Matlab/Octave.

4. The scikit-multilearn library

The proposed library follows the idea of building a multi-label classification library on top of an existing classification solution. In the case of Python, the obvious choice for a base library is the scipy stack with scikit-learn. The concept of scikit-learn compatible projects (scikits in short, not to mistake with the old scipy notion of scikits), has been present for several years in many formats, most prominently exemplified in scikit-contrib. We follow the ideas of these communities, the scikit-learn API principles and licensing.

The primary goal of scikit-multilearn is to provide an efficient Python implementation of as many multi-label classification algorithms as possible both to the open source community and commercial users of the Python data science stack. With such focus in mind, we concentrate on delivering a library dedicated to provide domain-independent solutions for solving multi-label classification problems, allowing other toolkits to excel in their areas such as: scikit-multiflow when it comes to multi-label streams or imbalanced-learn when it comes to handling imbalance multi-class data or many deep learning approaches described in the previous section.

Extensions of scikit-learn. The scikit-multilearn library extends the multi-label classification offering of scikit-learn by:

- extending the family of classifiers available to the Python community with more advanced algorithm adaptation and problem transformation (label space division) approaches
- implementing multi-label embedding-based classification methods
- providing additional features too specific for scikit-learn such as the general framework for classification based on label space division or the wrapper for MEKA,
- implementing non-classification tools for multi-label classification, including multi-label dataset manipulation from ARFF, loading and saving sparse representations of

3. `https://github.com/dnouri/skorch`

these datasets and the only Python implementations of multi-label data stratification methods (see work by (Sechidis et al., 2011), (Szymański and Kajdanowicz, 2017))

Advanced Multi-label Adapted Algorithms. Within scikit-multilearn we provide implementations of recent multi-label algorithm adaptation methods, that do not meet the selectiveness criteria of scikit-learn due to their novelty. These include:

- ML-ARAM: the hierarchical multi-label adaptive resonance associative map (Benites and Sapozhnikova, 2015)
- BR-kNN and ML-kNN: Binary Relevance kNN (Spyromitros et al., 2008) and multi-label kNN (Zhang and Zhou, 2007) - their scikit-multilearn implementations are built on top of scikit-learn's NearestNeighbors multiclass classifier,
- MLTSVM: the multi-label twin support vector machine (Chen et al., 2016) which does not require a training quadratic number of SVM classifiers.

Problem Transformation with Label Space Division. One of the significant contributions of the library is a framework for performing ensemble classification with different label space division strategies. The library provides ways to divide the label space based on:

- clustering of the label matrix representations, using any of the scikit-learn compatible clusterers (i.e. classes that inherit scikit-learn's `ClusterMixin` base class). The clusterer is executed on a transposed label assignment matrix and detected clustering is used as the label space division for the ensemble method. An example of this approach is the k-means clustering of labels which has been applied by many approaches (Tsoumakas et al., 2008; Yu et al., 2017)).
- communities detected in a network which embeds information about relations between labels. In scikit-multilearn there is a general API for defining graph generators based on the label matrix, such graphs can exploit relations based on co-occurrence, correlation or any other pairwise measure defined over labels. The library supports community detection methods based on three popular graph/network packages in Python: (NetworkX, BSD by Hagberg et al., 2008)), (igraph, GPL by Csardi and Nepusz, 2006), (graphtool, GPL by Peixoto, 2014). An example of this approach is the label space division based on label co-occurrence graphs (Szymański et al., 2016).
- random division, present in the random k-label sets (RAkEL) approaches
- predefined fixed division obtained from expert knowledge

In scikit-multilearn a partitioning and a voting majority ensemble approach are provided, in both a sub-classifier is trained on every label subset from a label space partition. In the partitioning variant, the predicted results are the union of results from each of the classifiers. In the voting ensemble, the label is assigned if the majority of classifiers trained on a label subspace which contain the label have assigned it to a given sample.

Multi-Label Embeddings. Another significant contribution of the library is a framework for multi-label classification using multi-label embeddings and scikit-multilearn is the first Python library to provide a general multi-label embedding scheme with an embedding regressor and embedding-based classifier. Currently two state of the art embedding approaches are provided Cost-Sensitive Label Embedding with Multidimensional Scaling (CLEMS)(Huang and Lin, 2017), Label Network Embeddings for Multi-Label Classification (LNEMLC)(Szymański et al., 2018) alongside a general embedder that can use any scikit-learn manifold learning or dimension reduction to embed the output space.

Compatibility. The scikit-multilearn project aims to be compatible with the Python data science stack. It follows the scikit-learn API and requirements specified in check_estimator code. Multi-label classifiers in scikit-multilearn inherit scikit-learn's `BaseEstimator` and `ClassifierMixin` classes. They can be thus easily incorporated into scikit-learn pipelines and cross-validations, evaluation measures, and feature space transformators. It is easy to use scikit-learn's extensive feature-space manipulation methods, single-label classifiers and classification evaluation functions with scikit-multilearn.

BSD licensing. As innovations in machine learning happen in both academia and companies, it is important to create a library that allows both communities to grow and profit from common work. Thus, scikit-multilearn is released under the BSD license to permit the for-profit ecosystem to use the library while opening the possibility of sharing development and maintenance tasks. While most of scikit-multilearn's functionality is available via BSD licensed libraries, the package also allows using GPL-licensed libraries to be used for label space division such as igraph or graphtool. Importing from `skmultilearn.cluster.igraph` or `skmultilearn.cluster.graphtool` will require your code to submit to GPL licensing requirements.

Access to the Java stack. The library provides scikit-compatible wrapper to reference libraries such as MEKA, MULAN and WEKA through MEKA when a need arises to use methods that have not yet been implemented in Python natively. Using these libraries via scikit-multilearn wrapper does not induce a licensing (GPL-BSD) conflict. Support for MULAN is limited to methods available via MEKA's `meka.classifiers.multilabel.MULAN` classifier[4].

Using Deep Learning models. Scikit-multilearn provides a wrapper that allows using any Keras (Chollet et al., 2015) compatible backend such as Tensorflow (Abadi et al., 2015) CNTK (Seide and Agarwal, 2016) or PyTorch (Paszke et al., 2017), to provide a single-class or multi-class model that can be used to solve multi-label problems through problem transformation approaches.

Sparsity. Multi-label classification problems often do not provide cases for all possible label combinations - in most benchmark sets there are less than 5% labels per row on average. The output space is thus very sparse. As opposed to MULAN and MEKA, scikit-multilearn operates on sparse matrices internally yielding a large memory boost as displayed in Figure 1.

4. `http://meka.sourceforge.net/api-1.9/meka/classifiers/multilabel/MULAN.html#setMethod-java.lang.String-`

Using scikit-multilearn. The steps for using scikit-multilearn are very simple: loading the data, selecting the method and performing classification. The library supports loading matrices from all well-established formats thanks to scipy and operates on scipy/numpy representations internally, converting to dense matrices or lists of lists only if required by a scikit-base classifier, if one is employed in the problem transformation scenario.

Other output types and subproblems. Scikit-multilearn does not support multi-label regression or multi-output prediction at the moment. Multi-label regression is considered for future releases, while multi-output approaches will not be supported due to scikit-multilearn's concentration on efficient sparse matrix usage throughout the codebase. Extreme Multi-label Classification is not the main focus of scikit-multilearn but both the label network embedding methods and label space partitioning methods are capable of handling extreme multi-label datasets. Keras-based deep learning models can also be deployed with the label partitioning strategy to solve extreme multi-label problems.

Structure of scikit-multilearn. Scikit-multilearn provides three subpackages following the established categorization of multi-label methods: method adaptation approach (in `skmultilearn.adapt`), problem transformation approach (in `skmultilearn.pt`) and ensembles of the two (in `skmultilearn.ensemble`). The label space division methods and label relationship graph builders are present in `skmultilearn.cluster`. To use multi-label-adapted version of a single-label method one only needs to import it and instantiate an object of the class. A problem transformation approach takes a scikit-learn compatible base classifier and optional information whether the base classifier supports sparse input. Ensemble methods require a classifier and relevant method's parameters. The classifier is trained using the fit method, which takes the training input and output matrices, and classification is performed using the predict method on test observations - just as in scikit-learn. The MEKA wrapper provides a scikit-learn compatible classifier class in `skmultilearn.meka`. Dataset download, loading and manipulation tools are available in `skmultilearn.dataset`. Multi-label data stratification methods and dataset fold division quality measures are available in `skmultilearn.model_selection`. Multi-label embedding approaches are located in `skmultilearn.embeddings`.

4.1. Documentation and Availability

Scikit-multilearn is hosted on GitHub and managed via the fork and pull-request paradigm. Both user and developer documentation is available at `http://scikit.ml/`. After 4 years of development, in July 2018, the library has reached a stable 0.1.0 release. The newest version - 0.2.0 - was released in December 2018. The code is released under BSD licence using GitHub and releases are available via PyPI. Implementation follows PEP8 and is maintained with a high level of test coverage (82% for the 0.2.0 release). The development undergoes continuous integration on Windows, Ubuntu Linux and Mac OS X, with Python 2.7 and Python 3.3. At the moment of the 0.2.0 release scikit-multilearn has been starred 242 times and forked 72 times. Development is managed on the GitHub repository `scikit-multilearn`[5] and is accompanied with communication and discussion in the Slack channel[6]. All commits undergo continuous testing on Windows, Ubuntu and Mac OS X, both under Python 2.7 and 3.3. The library also has its tag[7] on StackOverflow.

5. `https://github.com/scikit-multilearn/scikit-multilearn`

5. Benchmark

We found that scikit-multilearn is faster than its competition. We have tested MEKA, MULAN and scikit-multilearn on 12 well-cited benchmark multi-label classification datasets using two comparison scenarios: Binary Relevance and Label Powerset. The two selected problem transformation approaches are widely used both in regular classification tasks and as the base for more sophisticated methods. We did not test algorithm adaptation methods as there are no algorithm adaptation methods present in all three libraries. We use these methods to illustrate two aspects of the classification performance of the libraries: the cost of using many classifiers with splitting operations performed on the label space matrix and the cost of using a single classifier which requires to access all label combinations to perform the transformation. To minimize the impact of base classifiers, we have decided to use a fast Random Forest base classifier with 10 trees. As Octave does not provide Matlab's random forest implementation, we used the one provided by the shogun toolbox (Sonnenburg et al., 2017). We have checked the classification quality and did not find significant differences between Hamming Loss, Jaccard and Accuracy scores between the outputs. The benchmark is performed with scikit-multilearn 0.1.0, MEKA 1.9.2, MULAN 1.5.0, scikit-learn 0.19.2, Octave 4.2.2, shogun 6.1.3, MLC Toolbox for Matlab/Octave code from GitHub master commit hash `e798779`, R 3.4.1, utiml 0.1.2. As utiml does not provide a Label Powerset implementation, we do not evaluate it in this subexperiment.

Figure 1 presents the time and memory required to perform classification, including loading the ARFF dataset (or Matlab export in case of the toolbox) and measuring errors, i.e. a complete classification use case scenario. As different datasets require a different amount of time and memory we decided to normalize the charts. The results on the chart are normalized for each dataset separately. To normalize we calculated the median of every library's time or memory performance and selected the highest of the medians in the dataset as the normalization point, i.e. 100% is the worst median performance. We present the best, median, and worst performance of each library per dataset, normalized performance with the worst median performance on that dataset. The closer the library is to point 0, the better it performed, thus the smaller area inside the library curve, the better.

All the libraries were forced to use a single core using the `taskset` command to minimize parallelization effects on the comparison. Time and memory results were obtained using the `time -v` command and represent User time, and Maximum resident set size respectively. All results taken into consideration reported that 100% of their CPU core had been assigned to the process which performed the classification scenario.

We notice that in both classification schemes scikit-multilearn always uses less or, in a few edge cases the same amount of, memory than MEKA or MULAN due to its sparse matrix support. In most cases scikit-multilearn also operates faster than MEKA, MULAN.

When it comes to label space division approaches modeled in the experiment by Binary Relevance, scikit-multilearn is the most efficient choice on every data set. With Label Pow-

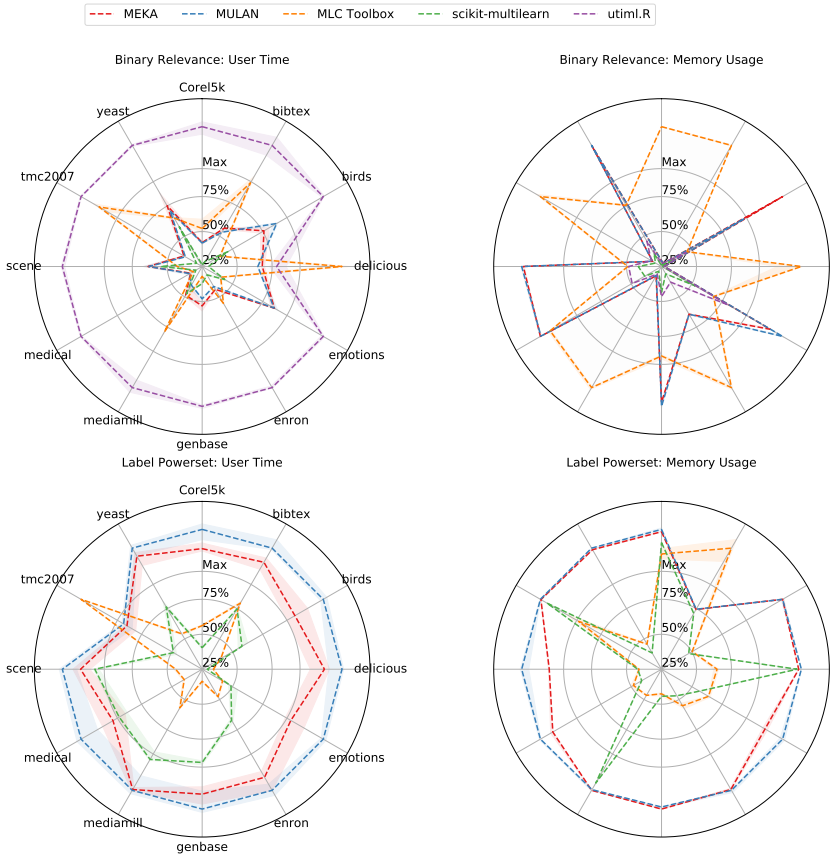

Figure 1: User running time (s) and memory usage ranks of utiml, MLC Toolbox, scikit-multilearn, MEKA and MULAN, with RandomForest, and two different multi-label classifiers.

erset multi-class transformation it is in most cases more efficient than MEKA and MULAN and outperforms the MLC Toolbox on datasets with larger numbers of label combinations while on smaller data sets the MLC Toolbox tends to be more efficient.

We have also compared Binary Relevance from scikit-learn to Binary Relevance from scikit-multilearn. The only difference between the two implementations is the fact that

scikit-learn does not convert the output matrix to a Compressed Sparse Column matrix[8] while scikit-multilearn does. The observed results were that scikit-learn's implementation was always slightly faster than scikit-multilearn's, while it always used a slightly larger amount of memory, both changes can be attributed to a difference between formats used for the output space. We, therefore, do not report this comparison in extensive detail.

As there is no statistical procedure that allows performing a non-parametric repeated measure tests on multiple measurements per test, we decided to compare the worst case time/memory usage of scikit-multilearn against the best case MEKA/MULAN/utiml/MLC

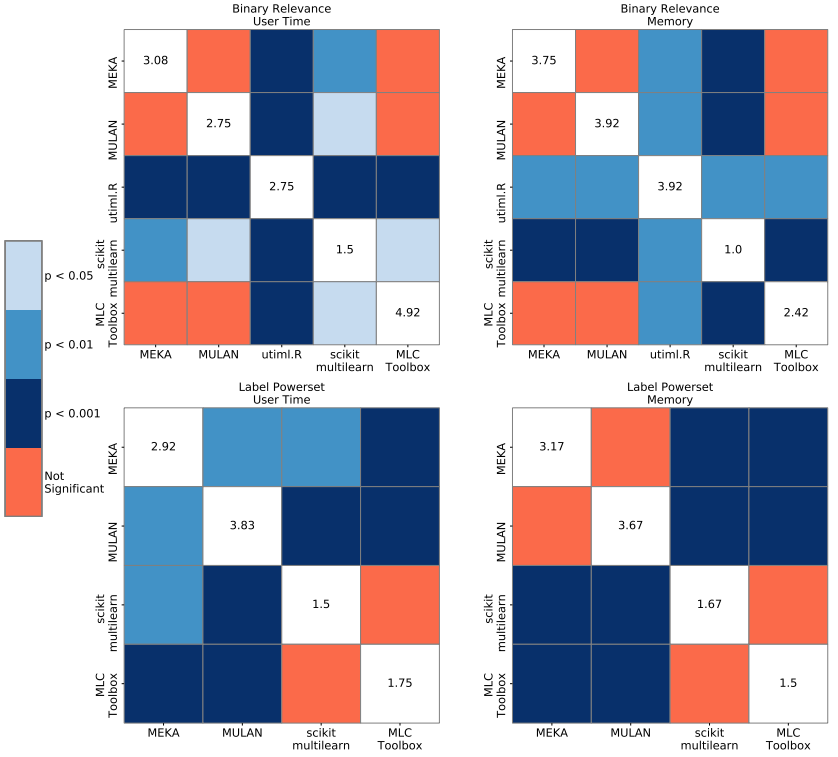

Figure 2: User running time (s) and memory usage ranks of utiml, MLC Toolbox, scikit-multilearn, MEKA and MULAN, with RandomForest, with RandomForest, and different multi-label classifiers. There are mean ranks on diagonal.

Toolbox performance. We used the Quade test with Bergmann-Hommel post hoc multiple hypothesis testing scenario (as laid out by García et al., 2010), the significances of rank difference and mean ranks of each libraries performance are provided in Figure 2.

We see that even in this negative averaging scenario scikit-multilearn is statistically significantly more efficient the other libraries when label space division approach (Binary Relevance) is deployed.

When Label Powerset multi-class transformation is used both scikit-multilearn and MLC Toolbox perform better than MULAN/MEKA with statistical significance. In terms of speed scikit-multilearn ranks slightly higher than the MLC Toolbox but consumes a little more memory. The differences between scikit-multilearn and the MLC Toolbox in this approach are not statistically significant.

6. Conclusions

The presented library - scikit-multilearn - is the most extensive scikit-learn compatible multi-label classification library. It provides implementations of both the most popular algorithms and new families of methods such as network-based label space division approaches. It is fast thanks to performing transformations on sparse matrices internally and using well-optimized methods from scikit-learn as base classifiers, and also integrates well with the Python data science stack of scipy. It also provides wrappers to Keras models which allows quick adaptation of deep learning approaches to multi-label classification via problem-transformation approaches, and MEKA/WEKA with parts of MULAN - the standard Java classification stack - and allows easy use of those methods with the rest of the Python stack.

Acknowledgments

We would like to thank Wojciech Stachowski for initial versions of BR/ML-kNN & Classifier Chains implementations, Christian Schulze for asking multiple questions, reporting and fixing bugs, Felipe Almeida for bug fixes and testing, Fernando Benites for providing the implementation of ML-ARAM (Brucker et al., 2011), and Jose Perez-Parras Toledano for his implementation of balanced k-means clustering and other contributions. The work was partially supported by The National Science Centre the research projects no. 2016/21/N/ST6/02382 and 2016/21/D/ST6/02948, by the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 691152 (RENOIR); the Polish Ministry of Science and Higher Education fund for supporting internationally co-financed projects in 2016-2019 (agreement no. 3628/H2020/2016/2) and by the Faculty of Computer Science and Management, Wrocław University of Science and Technology statutory funds.

Abstract

In stochastic optimization, the population risk is generally approximated by the empirical risk which is in turn minimized by an iterative algorithm. However, in the large-scale setting, empirical risk minimization may be computationally restrictive. In this paper, we design an efficient algorithm to approximate the population risk minimizer in generalized linear problems such as binary classification with surrogate losses and generalized linear regression models. We focus on large-scale problems where the iterative minimization of the empirical risk is computationally intractable, i.e., the number of observations n is much larger than the dimension of the parameter p ($n \gg p \gg 1$). We show that under random sub-Gaussian design, the true minimizer of the population risk is approximately proportional to the corresponding ordinary least squares (OLS) estimator. Using this relation, we design an algorithm that achieves the same accuracy as the empirical risk minimizer through iterations that attain up to a quadratic convergence rate, and that are computationally cheaper than any batch optimization algorithm by at least a factor of $\mathcal{O}(p)$. We provide theoretical guarantees for our algorithm, and analyze the convergence behavior in terms of data dimensions. Finally, we demonstrate the performance of our algorithm on well-known classification and regression problems, through extensive numerical studies on large-scale datasets, and show that it achieves the highest performance compared to several other widely used optimization algorithms.

Keywords: Generalized Linear Problems, Stochastic optimization, Subsampling, Dimension reduction in optimization.

1. Introduction

We consider the following stochastic optimization problem

$$\underset{\beta\in\mathbb{R}^p}{\text{minimize}}\ R(\beta) \coloneqq \mathbb{E}\left[\Psi\left(\langle x,\beta\rangle\right) - y\langle x,\beta\rangle\right]\ , \tag{1}$$

where $\Psi : \mathbb{R} \to \mathbb{R}$ is a non-linear function, $y \in \mathcal{Y} \subset \mathbb{R}$ denotes the response variable, $x \in \mathcal{X} \subset \mathbb{R}^p$ denotes the predictor (or covariate), and the expectation is over the joint distribution of (y, x). The above minimization is called a generalized linear problem in its canonical representation, and it is commonly encountered in statistical learning. Celebrated examples include binary classification with smooth surrogate losses (Buja et al., 2005; Reid and Williamson, 2010), and generalized linear models (GLMs) such as Poisson regression, logistic regression, ordinary least squares, multinomial regression with many applications involving graphical models (Nelder and Baker, 1972; McCullagh and Nelder, 1989; Wainwright and Jordan, 2008; Koller and Friedman, 2009). These methods play a crucial role in numerous machine learning and statistics problems, and they provide a miscellaneous framework for many regression and classification tasks.

The exact minimization of the stochastic optimization problem (1) requires the knowledge of the underlying distribution of the variables (y, x). In practice, however, the joint distribution of the pair is not available; therefore, after observing n independent data points (y_i, x_i), the standard approach is to minimize the following surrogate of (1), often referred to as empirical risk approximation

$$\underset{\beta\in\mathbb{R}^p}{\text{minimize}}\ \widehat{R}(\beta) \coloneqq \frac{1}{n}\sum_{i=1}^{n} \Psi\left(\langle x_i,\beta\rangle\right) - y_i\langle x_i,\beta\rangle. \tag{2}$$

In the case of GLMs, the empirical risk minimization given in (2) is equivalent to the maximum likelihood estimation (MLE), whereas in the case of binary classification, it is generally referred to as surrogate loss minimization. Due to the non-linear structure of the optimization task given in (2), minimizing the empirical risk requires iterative methods. The first-order approximation of the non-linear risk yields the gradient descent algorithm, which attains a (local) linear convergence rate under certain conditions with $\mathcal{O}(np)$ per-iteration cost. Although its convergence rate is slow compared to that of the second-order methods, its modest per-iteration cost makes it practical for large-scale problems. Regardless of the problem formulation, the most commonly used optimization method for computing the MLE is the Newton-Raphson method, which may be viewed as a reweighted least squares algorithm (McCullagh and Nelder, 1989; Buja et al., 2005). This method uses a second-order approximation to benefit from the curvature of the log-likelihood and achieves locally quadratic convergence. A drawback of this approach is its excessive per-iteration cost of $\mathcal{O}(np^2)$. To remedy this, Hessian-free Krylov sub-space based methods such as conjugate gradient can be used, but the resulting direction is imprecise (Hestenes and Stiefel, 1952; Paige and Saunders, 1975; Martens, 2010). In the regime $n \gg p$, another popular optimization technique is the class of Quasi-Newton methods (Bishop, 1995; Nesterov, 2004), which can attain a per-iteration cost of $\mathcal{O}(np)$, and the convergence rate is locally super-linear; a well-known member of this class of methods is the BFGS algorithm (Broyden, 1970; Fletcher, 1970; Goldfarb, 1970; Shanno, 1970).

In this paper, we take an alternative approach for minimizing (1), based on an identity that is well-known in some areas of statistics, but appears to have received relatively little attention for its computational implications in large-scale problems. Let β^{pop} denote the true minimizer of the population risk given in (1), and let β^{ols} denote the corresponding ordinary least squares (OLS) coefficients defined as $\beta^{\mathsf{ols}} = \mathbb{E}\left[xx^T\right]^{-1}\mathbb{E}\left[xy\right]$. Then, under

certain random predictor (design) models,

$$\beta^{\mathsf{pop}} \propto \beta^{\mathsf{ols}}. \tag{3}$$

For logistic regression with Gaussian design (which is equivalent to Fisher's discriminant analysis), (3) was noted by Fisher in the 1930s (Fisher, 1936); a more general formulation for models with Gaussian design is given in Brillinger (1982). The relationship (3) suggests that if the constant of proportionality is known, then β^{pop} can be estimated by computing the OLS estimator, which may be substantially simpler than minimizing the empirical risk. In fact, in some applications like binary classification, it may not be necessary to find the constant of proportionality in (3). Our work in this paper builds on this idea.

Our contributions can be summarized as follows.

1. We show that β^{pop} is approximately proportional to β^{ols} in the random design setting, regardless of the covariate (predictor) distribution. That is, we prove

$$\left\| \beta^{\mathsf{pop}} - c_\Psi \times \beta^{\mathsf{ols}} \right\|_\infty \lesssim c \frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}},$$

   for some $c_\Psi \in \mathbb{R}$ which depends on the non-linearity Ψ. We note that above rate is the *relative* decay, and it is obtained under the assumption that $\mathbb{E}[\langle x, \beta^{\mathsf{pop}} \rangle^2] \lesssim c^2$. Our generalization uses zero-bias transformations (Goldstein and Reinert, 1997). We also show that the relation (3) still holds under certain types of regularization.

2. We design a computationally efficient estimator for β^{pop} by first estimating the OLS coefficients, and then estimating the proportionality constant c_Ψ via line search. We refer to the resulting estimator as the Scaled Least Squares (SLS) estimator and denote it by $\hat{\beta}^{\mathsf{sls}}$. After estimating the OLS coefficients, the second step of our algorithm involves finding a root of a real valued function; this can be accomplished using iterative methods with up to a quadratic convergence rate and only $\mathcal{O}(n)$ per-iteration cost. This is computationally cheaper than the classical batch methods such as gradient descent by at least a factor of $\mathcal{O}(p)$.

3. For random design with sub-Gaussian predictors and bounded $\Psi^{(2)}$, we show that

$$\left\| \hat{\beta}^{\mathsf{sls}} - \beta^{\mathsf{pop}} \right\|_\infty \lesssim \frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}} + \sqrt{\frac{p}{n}}.$$

   This bound characterizes the performance of the proposed estimator in terms of data dimensions, and justifies the use of the algorithm in the large-scale setting where $n \gg p \gg 1$. We also provide theoretical guarantees when subsampling is utilized in the algorithm for further efficiency.

4. We demonstrate how to transform a binary classification problem with smooth surrogate loss into a generalized linear problem, and how our methods can be applied to obtain a computationally efficient optimization scheme.

5. We propose a scalable optimization method for converting one generalized linear problem to another by exploiting the proportionality relation (3). The proposed algorithm requires only $\mathcal{O}(n)$ computations per each iteration, with no additional one-time cost. We further discuss the canonicalization of the square loss, which may be of independent interest for non-convex optimization.

6. We empirically study the statistical and computational performance of $\hat{\beta}^{\mathsf{sls}}$, and compare it to that of the empirical risk minimizer (using several well-known implementations), on a variety of large-scale datasets.

The rest of the paper is organized as follows: Section 1.1 surveys the related work and Section 2 introduces the required background and the notation. In Section 3, we provide the intuition behind the relationship (3), which are based on exact calculations for the Gaussian design setting. In Section 4, we propose our algorithm and discuss its computational properties. Theoretical results are given in Section 5. In Section 6, we propose an algorithm to convert one GLM type to another. We discuss how a binary classification problem can be cast as a generalized linear problem in Section 7, and in Section 7.1 we propose a method to canonicalize the square loss. Section 8 provides a thorough comparison between the proposed algorithm and other existing methods. Finally, we conclude with a brief discussion in Section 9.

1.1. Related work

As mentioned in Section 1, the relationship (3) is well-known in several forms in statistics literature. Brillinger (1982) derived (3) for models with Gaussian predictors using Stein's lemma. Li and Duan (1989) studied model misspecification problems in statistics and derived (3) when the predictor distribution has linear conditional means (this is a slight generalization of Gaussian predictors). The relation (3) has led to various techniques for dimension reduction (Li, 1991; Li and Dong, 2009), and more recently, it has been studied by Plan and Vershynin (2016); Thrampoulidis et al. (2015) in the context of compressed sensing. It has been shown that the standard lasso estimator may be very effective when used in models where the relationship between the expected response and the signal is nonlinear, and the predictors (i.e. the design or sensing matrix) are Gaussian. A common theme for all of this previous work is that it focuses solely on settings where (3) holds exactly and the predictors (covariates) are Gaussian (or, in the case of Li and Duan (1989), very nearly Gaussian).

The proportionality relation is solely based on Stein's lemma and its variants. There are recent studies using Stein's lemma in various machine learning and optimization tasks such as second-order optimization (Erdogdu, 2015, 2016, 2017), Bayesian inference (Liu and Wang, 2016), measuring sample quality and model evaluation tasks (Gorham and Mackey, 2015; Liu et al., 2016).

Two key novelties of the present paper are (i) our focus on the computational benefits following from (3) for large scale problems with $n \gg p \gg 1$; and (ii) our rigorous finite sample analysis of models with non-Gaussian predictors, where (3) is shown to be approximately valid. To the best of our knowledge, the present paper and its earlier version Erdogdu et al. (2016) are the first to consider the relation (3) in the context of optimization.

2. Preliminaries and Notation

We assume a random design setting, where the observed data consists of n random iid pairs (y_1, x_1), (y_2, x_2), ..., (y_n, x_n); $y_i \in \mathcal{Y} \subset \mathbb{R}$ is the response variable and $x_i = (x_{i1}, \cdots, x_{ip})^T \in \mathcal{X} \subset \mathbb{R}^p$ is the vector of predictors or covariates. We focus on problems where the minimization (1) is desirable, but we allow model misspecification, and do not need to assume that (y_i, x_i) are actually drawn from a particular parametric model. In other words, the joint distribution of (y_i, x_i) can be arbitrary.

$$\beta^{\mathsf{pop}} = \underset{\beta \in \mathbb{R}^p}{\operatorname{argmin}} \ \mathbb{E}\left[\Psi(\langle x_i, \beta\rangle) - y_i \langle x_i, \beta\rangle\right]. \tag{4}$$

While we make no assumptions on Ψ beyond smoothness, note that when the optimization problem is GLM, and Ψ is the cumulant generating function for $y_i \mid x_i$, then the problem reduces to the standard GLM with canonical link and regression parameters β^{pop} (McCullagh and Nelder, 1989). Examples of GLMs in this form include logistic regression with $\Psi(w) = \log\{1 + e^w\}$, Poisson regression with $\Psi(w) = e^w$, and linear regression (least squares) with $\Psi(w) = w^2/2$.

Our objective is to find a computationally efficient estimator for β^{pop}. The alternative estimator for β^{pop} proposed in this paper is related to the OLS coefficient vector, which is defined by $\beta^{\mathsf{ols}} := \mathbb{E}[x_i x_i^T]^{-1}\mathbb{E}[x_i y_i]$; the corresponding OLS estimator is $\hat{\beta}^{\mathsf{ols}} := (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T y$, where $\mathbf{X} = (x_1, \ldots, x_n)^T$ is the $n \times p$ design matrix and $y = (y_1, \ldots, y_n)^T \in \mathbb{R}^n$.

Additionally, throughout the text we let $[m] = \{1, 2, ..., m\}$, for positive integers m, and we denote the size of a set S by $|S|$. The m-th derivative of a function $g : \mathbb{R} \to \mathbb{R}$ is denoted by $g^{(m)}$. For a vector $u \in \mathbb{R}^p$ and a $n \times p$ matrix $\mathbf{U}$, we let $\|u\|_q$ and $\|\mathbf{U}\|_q$ denote the ℓ_q-vector and -operator norms, respectively. If $S \subseteq [n]$, let $\mathbf{U}_S$ denote the $|S| \times p$ matrix obtained from $\mathbf{U}$ by extracting the rows that are indexed by S. For a symmetric matrix $\mathbf{M} \in \mathbb{R}^{p\times p}$, $\lambda_{\max}(\mathbf{M})$ and $\lambda_{\min}(\mathbf{M})$ denote the maximum and minimum eigenvalues, respectively, and $\rho_q(\mathbf{M})$ for $q \in \{1, 2, \infty\}$ denotes the condition number of $\mathbf{M}$ with respect to ℓ_q-norm. We denote by N_p the p-variate normal distribution, and all expectations are over all randomness inside the brackets. Finally, we use $a \lesssim b$ and $a \leq \mathcal{O}(b)$ interchangeably, whichever is convenient (where $\mathcal{O}(\cdot)$ refers to the big O notation).

3. From OLS to the True Minimizer: Gaussian Case

To motivate our methodology, we assume in this section that the covariates are multivariate normal, as in Brillinger (1982). These distributional assumptions will be relaxed to a certain extent in Section 5.

Proposition 1 *Assume that the covariates are multivariate normal with mean 0 and covariance matrix $\mathbf{\Sigma}$, i.e. $x_i \sim \mathsf{N}_p(0, \mathbf{\Sigma})$. Then β^{pop} can be written as*

$$\beta^{\mathsf{pop}} = c_\Psi \times \beta^{\mathsf{ols}}, \tag{5}$$

where $c_\Psi \in \mathbb{R}$ is the fixed point of the mapping

$$z \to \mathbb{E}\left[\Psi^{(2)}(\langle x_i, \beta^{\mathsf{ols}}\rangle z)\right]^{-1}. \tag{6}$$

Proof [of Proposition 1] The stationary point of the minimization problem in (4) satisfies the following normal equations,

$$\mathbb{E}[y_i x_i] = \mathbb{E}\left[x_i \Psi^{(1)}(\langle x_i, \beta\rangle)\right] \quad \text{for} \quad i = 1, 2, ..., p. \tag{7}$$

Now, denote by $\phi(x \mid \mathbf{\Sigma})$ the multivariate normal density with mean 0 and covariance matrix $\mathbf{\Sigma}$. We recall the well-known property of Gaussian density $\mathrm{d}\phi(x \mid \mathbf{\Sigma})/\mathrm{d}x = -\mathbf{\Sigma}^{-1}x\phi(x \mid \mathbf{\Sigma})$. Using this and the integration by parts on the right hand side of the above equation, we obtain for $i = 1, 2, ..., p$

$$\begin{aligned}\mathbb{E}\left[x_i \Psi^{(1)}(\langle x_i, \beta\rangle)\right] &= \int x\Psi^{(1)}(\langle x, \beta\rangle)\phi(x \mid \mathbf{\Sigma})\, \mathrm{d}x, \\ &= \mathbf{\Sigma}\beta \ \underbrace{\mathbb{E}\left[\Psi^{(2)}(\langle x_i, \beta\rangle)\right]}_{\in \mathbb{R}},\end{aligned} \tag{8}$$

which is basically the Stein's lemma. Combining this with the normal equations (7) and multiplying both side with $\mathbf{\Sigma}^{-1}$, we obtain the desired result. ■

Proposition 1 and its proof provide the main intuition behind our proposed method. Observe that in our derivation, we only worked with the right hand side of the normal equations (7) which does not depend on the response variable y_i. Therefore, the equivalence will hold regardless of the joint distribution of (y_i, x_i). This is the main difference from the proof of Brillinger (1982) where y_i is assumed to follow a single index model. In Section 5, where we extend the method to non-Gaussian predictors, the identity (8) is generalized via the zero-bias transformations from Goldstein and Reinert (1997).

3.1. Regularization

A version of Proposition 1 incorporating regularization — an important tool for datasets where p is large relative to n or the predictors are highly collinear — is also possible, as outlined briefly in this section. We focus on ℓ^2-regularization (ridge regression) in this section; some connections with lasso (ℓ^1-regularization) are discussed in Section 5 and Corollary 6.

For $\lambda \geq 0$, define the ℓ_2-regularized empirical risk minimizer,

$$\beta_\lambda^{\mathsf{pop}} = \underset{\beta \in \mathbb{R}^p}{\operatorname{argmin}} \ \mathbb{E}\left[\Psi(\langle x_i, \beta\rangle) - y_i\langle x_i, \beta\rangle\right] + \frac{\lambda}{2}\|\beta\|_2^2 \tag{9}$$

and the corresponding ℓ^2-regularized OLS coefficients $\beta_\lambda^{\mathsf{ols}} = \left(\mathbb{E}\left[x_i x_i^T\right] + \lambda\mathbf{I}\right)^{-1}\mathbb{E}\left[x_i y_i\right]$ (so $\beta^{\mathsf{pop}} = \beta_0^{\mathsf{pop}}$ and $\beta^{\mathsf{ols}} = \beta_0^{\mathsf{ols}}$). The same argument as above implies that

$$\beta_\lambda^{\mathsf{pop}} = c_\Psi \times \beta_\gamma^{\mathsf{ols}}, \quad \text{where} \quad \gamma = \lambda c_\Psi. \tag{10}$$

This suggests that the ordinary ridge regression for the linear model can be used to estimate the ℓ^2-regularized empirical risk minimizer $\beta_\lambda^{\mathsf{pop}}$. Further pursuing these ideas for problems where regularization is a critical issue may be an interesting area for future research.

Algorithm 1 SLS: Scaled Least Squares Estimator

Input: Data $(y_i, x_i)_{i=1}^n$

Step 1. Compute the least squares estimator: $\hat{\beta}^{\mathsf{ols}}$ **and** $\hat{y} = \mathbf{X}\hat{\beta}^{\mathsf{ols}}$**.**

For a sub-sampling based OLS estimator, let $S \subset [n]$ be a random subset and take $\hat{\beta}^{\mathsf{ols}} = \frac{|S|}{n}(\mathbf{X}_S^T\mathbf{X}_S)^{-1}\mathbf{X}^T y$.

Step 2. Solve the following equation for $c \in \mathbb{R}$**:** $1 = \frac{c}{n}\sum_{i=1}^n \Psi^{(2)}(c\,\hat{y}_i)$**.**

Use Newton's root-finding method:

Initialize c;

Repeat until convergence:

$$c \leftarrow c - \frac{c\,\frac{1}{n}\sum_{i=1}^n \Psi^{(2)}(c\,\hat{y}_i) - 1}{\frac{1}{n}\sum_{i=1}^n \left\{\Psi^{(2)}(c\,\hat{y}_i) + c\,\hat{y}_i\Psi^{(3)}(c\,\hat{y}_i)\right\}}.$$

Output: $\hat{\beta}^{\mathsf{sls}} = c \times \hat{\beta}^{\mathsf{ols}}$.

4. SLS: Scaled Least Squares Estimator

Motivated by the results in the previous section, we design a computationally efficient algorithm that approximates the stochastic optimization problem (1) that is as simple as solving the least squares problem; it is described in Algorithm 1. The algorithm has two basic steps. First, we estimate the OLS coefficients, and then in the second step we estimate the proportionality constant via a simple root-finding algorithm.

There are numerous fast optimization methods to solve the least squares problem, and even a superficial review of these could go beyond the page limits of this paper. We emphasize that this step (finding the OLS estimator) does not have to be iterative and it is the main computational cost of the proposed algorithm. We suggest using a sub-sampling based estimator for β^{ols}, where we only use a subset of the observations to estimate the covariance matrix. Let $S \subset [n]$ be a random sub-sample and denote by $\mathbf{X}_S$ the sub-matrix formed by the rows of $\mathbf{X}$ in S. Then the sub-sampled OLS estimator is given as $\hat{\beta}^{\mathsf{ols}} = \left(\frac{1}{|S|}\mathbf{X}_S^T\mathbf{X}_S\right)^{-1}\frac{1}{n}\mathbf{X}^T y$. Properties of sub-sampling and sketching based estimators have been well-studied (Vershynin, 2010; Dhillon et al., 2013; Erdogdu and Montanari, 2015; Pilanci and Wainwright, 2015; Roosta-Khorasani and Mahoney, 2016a,b). For sub-Gaussian covariates, it suffices to use a sub-sample size of $\mathcal{O}(p\log(p))$ (Vershynin, 2010). Hence, this step requires a single time computational cost of $\mathcal{O}\left(|S|p^2 + p^3 + np\right) \approx \mathcal{O}\left(p\max\{p^2\log(p), n\}\right)$. For other approaches, we refer reader to Rokhlin and Tygert (2008); Drineas et al. (2011); Dhillon et al. (2013); Erdogdu and Montanari (2015) and the references therein.

The second step of Algorithm 1 involves solving a simple root-finding problem. As with the first step, there are numerous methods available for completing this task. Newton's root-finding method with quadratic convergence or Halley's method with cubic convergence may be appropriate choices. We highlight that this step costs only $\mathcal{O}(n)$ per-iteration and that we can attain fast convergence rates of higher order algorithms. The resulting per-iteration cost is cheaper than commonly used batch algorithms by at least a factor of $\mathcal{O}(p)$ — indeed, the cost of computing the gradient is $\mathcal{O}(np)$. For simplicity, we use Newton's root-finding method. We also note that in certain classification problems, only the direction of β^{pop} is needed to make a prediction, so there is no need to compute the scaling constant.

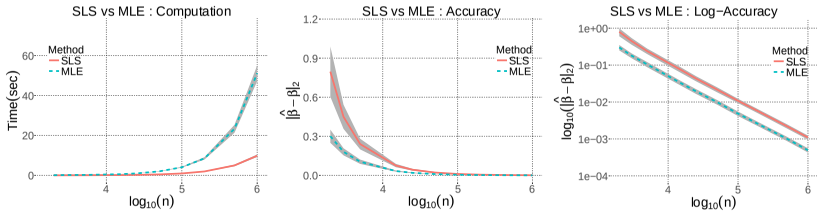

Figure 1: Logistic regression with iid standard Gaussian design. The left plot shows the computational cost (time) for finding the MLE and SLS as n grows and $p = 200$. The middle and the right plots depict the accuracy of the estimators in standard and log scales, respectively. In the regime where the MLE is expensive to compute, the SLS is found much more rapidly and has the same accuracy. R's built-in functions are used to find the MLE.

Correct initialization of the scaling constant c depends on the optimization problem. For example, in the case of GLM problems, assuming that the GLM is a good approximation to the true conditional distribution, by the law of total variance and basic properties of GLMs, we have

$$\mathrm{Var}(y_i) = \mathbb{E}\left[\mathrm{Var}(y_i \mid x_i)\right] + \mathrm{Var}\left(\mathbb{E}[y_i \mid x_i]\right) \approx c_\Psi^{-1} + \mathrm{Var}\big(\Psi^{(1)}(\langle x_i, \beta\rangle)\big). \tag{11}$$

It follows that the initialization $c = 2/\mathrm{Var}(y_i)$ is reasonable as long as we have $c_\Psi^{-1} \approx \mathbb{E}\left[\mathrm{Var}(y_i \mid x_i)\right]$ not much smaller than $\mathrm{Var}\big(\Psi^{(1)}(\langle x_i, \beta\rangle)\big)$. Our experiments show that SLS is very robust to initialization.

In Figure 1, we compare the performance of our SLS estimator to that of the MLE in a GLM optimization problem, when both are used to analyze synthetic data generated from a logistic regression model under general Gaussian design with randomly generated covariance matrix. The left plot shows the computational cost of obtaining both estimators as n increases for fixed $p = 200$. The middle and the right plots show the accuracy of the estimators where the latter is in log-scale. In the regime $n \gg p \gg 1$ — where the MLE is hard to compute — the MLE and the SLS achieve the same accuracy, yet SLS has significantly smaller computation time. We refer the reader to Section 5 for theoretical results characterizing the finite sample behavior of the SLS.

5. Theoretical Results

In this section, we use the zero-bias transformations (Goldstein and Reinert, 1997) to generalize the equivalence relation given in the previous section to the settings where the covariates are non-Gaussian.

Definition 2 *Let z be a random variable with mean 0 and variance σ^2. Then, there exists a random variable z^* that satisfies $\mathbb{E}[zf(z)] = \sigma^2\mathbb{E}[f^{(1)}(z^*)]$, for all differentiable functions f. The distribution of z^* is said to be the z-zero-bias distribution.*

The existence of z^* in Definition 2 is a consequence of Riesz representation theorem (Goldstein and Reinert, 1997). The normal distribution is the unique distribution whose zero-bias

transformation is itself (i.e. the normal distribution is a fixed point of the operation mapping the distribution of z to that of z^* – which is basically Stein's lemma).

To provide some intuition behind the usefulness of the zero-bias transformation, we refer back to the proof of Proposition 1. For simplicity, assume that the covariate vector x_i has iid entries with mean 0, and variance 1. Then the zero-bias transformation applied to the j-th normal equation in (7) yields

$$\underbrace{\mathbb{E}\left[y_i x_{ij}\right] = \mathbb{E}\left[x_{ij}\Psi^{(1)}\big(x_{ij}\beta_j + \Sigma_{k\neq j} x_{ik}\beta_k\big)\right]}_{j\text{-th normal equation}} = \underbrace{\beta_j \mathbb{E}\left[\Psi^{(2)}\left(x^*_{ij}\beta_j + \Sigma_{k\neq j} x_{ik}\beta_{ik}\right)\right]}_{\text{Zero-bias transformation}}. \tag{12}$$

The distribution of x^*_{ij} is the x_{ij}-zero-bias distribution and is entirely determined by the distribution of x_{ij}; general properties of x^*_{ij} can be found, for example, in Chen et al. (2010). If β is well spread, it turns out that taken together, with $j = 1, \ldots, p$, the far right-hand side in (12) behaves similar to the right side of (8), with $\mathbf{\Sigma} = \mathbf{I}$; that is, the behavior is similar to the Gaussian case, where the proportionality relationship given in Proposition 1 holds. This argument leads to an approximate proportionality relationship for problems with non-Gaussian predictors, which, when carried out rigorously, yields the following result.

Theorem 3 *Suppose that the whitened covariates $w_i = \mathbf{\Sigma}^{-1/2}x_i$ are independent random vectors with mean 0, covariance $\mathbf{I}$, and sub-Gaussian norm κ_x. Furthermore, w_i's have constant first and second conditional moments, i.e., $\forall j \in [p]$ and $\tilde{\beta} = \mathbf{\Sigma}^{1/2}\beta^{\mathsf{pop}}$, $\mathbb{E}[w_{ij}|\Sigma_{k\neq j}\tilde{\beta}_k w_{ik}]$ and $\mathbb{E}[w^2_{ij}|\Sigma_{k\neq j}\tilde{\beta}_k w_{ik}]$ are deterministic, and the function $\Psi^{(2)}$ is Lipschitz continuous with constant k. Then, for $c_\Psi = 1/\mathbb{E}\left[\Psi^{(2)}(\langle x_i, \beta^{\mathsf{pop}}\rangle)\right]$, we have*

$$\left\| \frac{1}{c_\Psi} \times \beta^{\mathsf{pop}} - \beta^{\mathsf{ols}} \right\|_\infty \leq \eta \|\mathbf{\Sigma}^{1/2}\beta^{\mathsf{pop}}\|_\infty \|\beta^{\mathsf{pop}}\|_\infty, \quad \textit{where} \quad \eta = 8k\kappa_x^3\rho_\infty. \tag{13}$$

Theorem 3 is proved in Section 10 of the Appendix. It implies that the population parameters β^{ols} and β^{pop} are approximately equivalent up to a scaling factor, with a *relative* error bound of $\mathcal{O}(\|\mathbf{\Sigma}^{1/2}\beta^{\mathsf{pop}}\|_\infty)$. For the above analysis to provide a decreasing bound in the dimension p, one needs a tractability assumption on either one of the terms in the error bound. The most common way to achieve this is to introduce a structure on the inner product between x and β^{pop}, e.g. $\mathbb{E}[\langle x, \beta^{\mathsf{pop}}\rangle^2]^{1/2} = o\left(\sqrt{p}\right)$ suffices to get a decay in (13). We emphasize that it is common practice to standardize the response and the features before training any model; therefore this preliminary procedure can provide the required order and consequently the desired decay in p.

Below, we discuss two commonly encountered settings in the literature as two corollaries.

Corollary 4 *Let the assumptions of Theorem 3 hold. If we further assume that the covariates x_i are supported on a ball of radius r, and $\Sigma^{1/2}$ is diagonally dominant, we have*

$$\left\| \frac{1}{c_\Psi} \times \beta^{\mathsf{pop}} - \beta^{\mathsf{ols}} \right\|_\infty \leq \eta \frac{\|\beta^{\mathsf{pop}}\|^2_\infty}{\sqrt{p}}, \quad \textit{where} \quad \eta = 16kr\kappa_x^3\sqrt{\rho_2}\rho_\infty. \tag{14}$$

Note that we do not require an underlying model assumption between y and x. Therefore, one can always perform under the finite support assumption by first scaling the design

matrix appropriately, and then using the proposed estimator. This assumption is common in many fields, yet can appear in different forms. For example in the machine learning literature, the standard convention (the same setting in Corollary 4) is to assume that $\|x_i\|_2 \leq r$, and that $\|\beta^{\mathsf{pop}}\|_2 = \mathcal{O}\left(\sqrt{p}\right)$ (Kalai and Sastry, 2009; Shalev-Shwartz et al., 2009; Kakade et al., 2011), or the inner product is supported on an interval $|\langle x, \beta^{\mathsf{pop}}\rangle| \leq b$ almost surely (Alquier and Biau, 2013), where the latter is a more strict assumption. In the compressed sensing and other areas in statistics, a similar assumption is imposed on the covariance matrix $\mathbb{E}\left[xx^T\right] = \tilde{\mathbf{\Sigma}}/p$ which provides us with $\mathbb{E}[\|x\|_2^2] = \mathcal{O}(1)$ (Donoho et al., 2009; Bayati and Montanari, 2012; Bayati et al., 2013; Su and Candes, 2016).

On the other hand, the standard convention in the dimension reduction techniques is to assume that the covariates have norm of order $\sqrt{p}$, i.e. $\mathbb{E}\left[\|x\|_2\right] = \mathcal{O}\left(\sqrt{p}\right)$, and the coefficients have norm of order 1, i.e. $\|\beta\|_2 = \tau = \mathcal{O}(1)$ (Duan and Li, 1991; Hall and Li, 1993; Hristache et al., 2001). This setting again yields that the inner product between those two vectors are tractable and provides us with a decay in the latter term, i.e. $\|\beta^{\mathsf{pop}}\|_\infty = \mathcal{O}\left(1/\sqrt{p}\right)$. In this setting, Theorem 3 yields the following corollary.

Corollary 5 *Let the assumptions of Theorem 3 hold. If we further assume that β^{pop} is r-well-spread in the sense that for $\|\beta^{\mathsf{pop}}\|_2 = \tau$, we have $\tau/\|\beta^{\mathsf{pop}}\|_\infty = r\sqrt{p}$ for some $r \leq 1$,*

$$\left\| \frac{1}{c_\Psi} \times \beta^{\mathsf{pop}} - \beta^{\mathsf{ols}} \right\|_\infty \leq \eta \frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}}, \quad \textit{where} \quad \eta = 8k\kappa_x^3\rho_\infty(\tau/r)\|\mathbf{\Sigma}^{1/2}\|_\infty. \tag{15}$$

In the above bound, the decay is in fact $1/p$, but we chose to state the *relative decay*. We emphasize that both settings in Corollaries 4 and 5 are equivalent and both assumptions lead a tractable inner product $\langle x, \beta^{\mathsf{pop}}\rangle$. The constants κ_x, ρ_k are invariant to the scalings considered in both settings.

The assumption that β^{pop} is well-spread can be relaxed with minor modifications. For example, if we have a sparse coefficient vector, where $\mathrm{supp}(\beta^{\mathsf{pop}}) = \{j;\ \beta^{\mathsf{pop}}_j \neq 0\}$ is the support set of β^{pop}, then Corollary 5 holds with p replaced by the size of the support set.

The assumptions on the conditional moments are the relaxed versions of assumptions that are commonly encountered in dimension reduction techniques. For example, sliced inverse regression methods assume that the first conditional moment $\mathbb{E}\left[x|\langle x, \beta\rangle\right]$ is linear in x for all β (Li and Duan, 1989; Li, 1991), which is satisfied by elliptically distributed random vectors. An important case that is not covered by these methods is the independent coordinate case, i.e., when the whitened covariates have independent, but not necessarily identical entries. This is made possible by introducing additional approximation error (i.e. suboptimality due to non-Gaussian design). We refer reader to Li and Dong (2009), for a good review of dimension reduction techniques and their corresponding assumptions. We also highlight that our moment assumptions can be relaxed further, at the expense of introducing some additional complexity into the results.

An interesting consequence of Theorem 3 and the corollaries following the theorem is that whenever an entry of β^{pop} is zero, the corresponding entry of β^{ols} has to be small, and conversely. For $\lambda \geq 0$, define the lasso coefficients

$$\beta^{\mathsf{lasso}}_\lambda = \underset{\beta\in\mathbb{R}^p}{\mathrm{argmin}} \ \frac{1}{2}\mathbb{E}\left[(y_i - \langle x_i, \beta\rangle)^2\right] + \lambda\|\beta\|_1. \tag{16}$$

Corollary 6 *Let* $\text{supp}(\beta)$ *denote the support of* β*, i.e., the set* $\{i \in [p] : \beta_i \neq 0\}$*. Given* $\|\frac{1}{c_\Psi}\beta^{\mathsf{pop}} - \beta^{\mathsf{ols}}\|_\infty \leq \delta$*, and for any* $\lambda \geq \delta$*, if* $\mathbb{E}[x_i] = 0$ *and* $\mathbb{E}\left[x_i x_i^T\right] = \mathbf{I}$*, we have*

$$\text{supp}(\beta^{\mathsf{lasso}}) \subset \text{supp}(\beta^{\mathsf{pop}}).$$

Further, if λ *and* β^{pop} *also satisfy that* $\forall j \in \text{supp}(\beta^{\mathsf{pop}})$*,* $|\beta_j^{\mathsf{pop}}| > c_\Psi(\lambda + \delta)$*, then we have* $\text{supp}(\beta^{\mathsf{lasso}}) = \text{supp}(\beta^{\mathsf{pop}})$.

We note that δ above can be obtained using Theorem 3 or its corollaries. So far in this section, we have only discussed properties of the population parameters, such as β^{pop} and β^{ols}. In the remainder of this section, we turn our attention to the results on the estimators that are the main focus of this paper; these results ultimately build on our earlier results, i.e. Theorem 3. We will be considering the setting in Corollary 5 in the rest of this section, i.e., $\|x\|_2 = \mathcal{O}\left(\sqrt{p}\right)$ and $\|\beta^{\mathsf{pop}}\|_2 = \mathcal{O}(1)$. Results presented below can be easily generalized to the setting in Corollary 4 as well.

In order to precisely describe the performance of $\hat{\beta}^{\mathsf{sls}}$, we first need bounds on the OLS estimator. The OLS estimator has been studied extensively in the literature; however, for our purposes, we find it convenient to derive a new bound on its accuracy. While we have not seen this exact bound elsewhere, it is very similar to Theorem 5 of Dhillon et al. (2013).

Proposition 7 *Assume that* $\mathbb{E}[x_i] = 0$*,* $\mathbb{E}\left[x_i x_i^T\right] = \mathbf{\Sigma}$*, and that* $\mathbf{\Sigma}^{-1/2}x_i$ *and* y_i *are sub-Gaussian with norms* κ *and* γ*, respectively. For* λ_{min} *denoting the smallest eigenvalue of* $\mathbf{\Sigma}$*, and* $|S| > \eta p$*,*

$$\left\|\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}}\right\|_2 \leq \eta \lambda_{min}^{-1/2}\sqrt{\frac{p}{|S|}}, \tag{17}$$

with probability at least $1 - 3e^{-p}$*, where* η *depends only on* γ *and* κ*.*

Proposition 7 is proved in Section 10. Our main result on the performance of $\hat{\beta}^{\mathsf{sls}}$ is given next.

Theorem 8 *Let the assumptions of Theorem 3, Corollary 5, and Proposition 7 hold. Further assume that* $\left|\Psi^{(2)}\right| \leq b$ *and for some* $\bar{c}$ *and* ϵ *the function* $f(z) = z\mathbb{E}\left[\Psi^{(2)}(\langle x, \beta^{\mathsf{ols}}\rangle z)\right]$ *satisfies* $f(\bar{c}) > 1 + \epsilon$*, and the derivative of* f *in the interval* $[0, \bar{c}]$ *does not change sign, i.e., its absolute value is lower bounded by* $\upsilon > 0$*. Then, for* n *and* $|S|$ *sufficiently large, with probability at least* $1 - 4e^{-p}$*, we have*

$$\left\|\hat{\beta}^{\mathsf{sls}} - \beta^{\mathsf{pop}}\right\|_\infty \leq \eta_1 \frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}} + \eta_2\sqrt{\frac{p}{|S|}}, \tag{18}$$

where the constants η_1 *and* η_2 *are defined by*

$$\eta_1 = \eta k\bar{c}\rho_\infty(\tau/r)\|\mathbf{\Sigma}^{1/2}\|_\infty \tag{19}$$

$$\eta_2 = \eta\bar{c}\left(\lambda_{min}^{-1/2} + k\upsilon^{-1}\max\left\{(\|\Sigma^{1/2}\beta^{\mathsf{ols}}\|_2 + 1)\|\Sigma\|_2 + b/k, \bar{c}\right\}\right), \tag{20}$$

and $\eta > 0$ *is a constant depending on* κ *and* γ*.*

Note that the convergence rate of the upper bound in (18) depends on the sum of the two terms, both of which are functions of the data dimensions n and p. The first term on the right in (18) comes from Theorem 3 and Corollary 5, which bounds the discrepancy between $c_\Psi \times \beta^{\mathsf{ols}}$ and β^{pop}. This term is small when p is large, and it does not depend on the number of observations n. If n and p grow together, then p has to grow at a smaller rate to achieve convergence. We note that the actual decay of this term is $\mathcal{O}(1/p)$ (since $\|\beta^{\mathsf{pop}}\|_\infty = \mathcal{O}\left(1/\sqrt{p}\right)$), but we state the relative decay which is $\mathcal{O}\left(1/\sqrt{p}\right)$.

The second term in the upper bound (18) comes from estimating β^{ols} and c_Ψ. This term is increasing in p, which reflects the fact that estimating β^{pop} is more challenging when p is large. As expected, this term is decreasing in n and $|S|$, i.e. larger sample size yields better estimates. When the full OLS solution is used ($|S| = n$), the second term becomes $\mathcal{O}(\sqrt{p/n})$, which suggests that the sample size should be at least of order p for good performance. We note that in the case of Gaussian covariates, $\sqrt{n}$-consistency follows since we don not have a bias term.

In certain loss functions, the uniform boundedness assumption on $\Psi^{(2)}$ may be too strict. However, this assumption can be removed by making an additional assumption that the covariates have bounded support. This yields the same decay rate $\mathcal{O}\left(\sqrt{p/n}\right)$ in the second term. However, if one needs to preserve the sub-Gaussian assumption on the covariates, then the above analysis – when carried out without the uniform bound assumption on $\Psi^{(2)}$ – yields the following result. We note that we still require the uniform Lipschitz assumption but one can always utilize the local Lipschitz properties of the function $\Psi^{(2)}$.

Theorem 9 *Let the assumptions of Theorem 3, Corollary 5, and Proposition 7 hold with* $\mathbb{E}[\|\mathbf{\Sigma}^{-1/2}x\|_2] = \tilde{\mu}\sqrt{p}$*. Further assume that* $\sup_{\beta:\|\beta - \Sigma^{1/2}\beta^{\mathsf{ols}}\|_2 \leq 1}\|\Psi^{(2)}(\langle x_i, \beta\rangle)\|_{\psi_2} \leq \kappa_g$ *and for some* $\bar{c}$ *and* ϵ *the function* $f(z) = z\mathbb{E}\left[\Psi^{(2)}(\langle x, \beta^{\mathsf{ols}}\rangle z)\right]$ *satisfies* $f(\bar{c}) > 1 + \epsilon$*, and the derivative of* f *in the interval* $[0, \bar{c}]$ *does not change sign, i.e., its absolute value is lower bounded by* $\upsilon > 0$*. Then, for* n *and* $|S|$ *sufficiently large, with probability at least* $1 - 5e^{-p}$*, we have*

$$\left\|\hat{\beta}^{\mathsf{sls}} - \beta^{\mathsf{pop}}\right\|_\infty \leq \eta_1 \frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}} + \eta_2\sqrt{\frac{p}{\min\{n/\log(n), |S|\}}}, \tag{21}$$

where the constants η_1 *and* η_2 *are defined by*

$$\eta_1 = \eta k\bar{c}\rho_\infty(\tau/r)\|\mathbf{\Sigma}^{1/2}\|_\infty \tag{22}$$

$$\eta_2 = \eta\bar{c}\left(\lambda_{min}^{1/2} + \upsilon^{-1}\|\beta^{\mathsf{ols}}\|_\infty\max\{(\kappa_g + k/\tilde{\mu}), k\bar{c}\kappa_x\}\right), \tag{23}$$

and $\eta > 0$ *is a constant depending on* κ_x *and* γ*.*

We observe that this time when the full OLS solution is used ($|S| = n$), the second term becomes $\mathcal{O}(\sqrt{p\log(n)/n})$, which is worse than the rate given in Theorem 8 by a logarithmic factor. In this setting, we require that $n/\log(n)$ should be at least of order p for good performance. Also, note that there is a theoretical threshold for the sub-sampling size $|S|$, namely $\mathcal{O}(n/\log(n))$, beyond which further sub-sampling provides no improvement.

When the covariates are Gaussian, the Lipschitz assumption on the function $\Psi^{(2)}$ is enough the guarantee the sub-Gaussianity of $\Psi^{(2)}(\langle x_i, \beta\rangle)$. However, we note that the condition given in the Theorem is more general.

5.1. Convergence in ℓ_2-norm

In the sequel, we assume that the full OLS solution is used ($|S| = n$). Using Proposition 7 and Lemma 16, we can show that the ℓ_2-distance between the estimator $\hat{\beta}^{\mathsf{sls}}$ and the population parameter $c_\Psi \beta^{\mathsf{ols}}$ converges to 0 with rate $\sqrt{n}$ when p is fixed. It is straightforward to see that under Gaussian design, this leads to consistency in ℓ_2-norm with convergence rate $\sqrt{n}$. However, the quantity $c_\Psi \beta^{\mathsf{ols}}$ is in general different from β^{pop} under general sub-Gaussian design; thus, in such cases consistency cannot be achieved in the classical setting where p is fixed (see i.e. Claim 1 in Chen and Banerjee (2017)). In such a scenario, Theorem 3 can be used to obtain an upper bound on the suboptimality resulting from general sub-Gaussian design.

In order to talk about consistency when $n, p \to \infty$ under ℓ_2-norm, a normalization by one of the growing dimensions is required, see e.g. Bayati and Montanari (2012); Bayati et al. (2013). Hence, in this regime, we focus on the quantity $\frac{1}{\sqrt{p}}\|\hat{\beta}^{\mathsf{sls}} - \beta^{\mathsf{pop}}\|_2$ under the assumptions of Corollary 4 with $\mathbf{\Sigma} = \mathbf{I}$. Since we have $\sqrt{n}$-convergence of our estimator to the population parameter $c_\Psi \beta^{\mathsf{ols}}$, consistency reduces to showing that the suboptimality term $\frac{1}{\sqrt{p}}\left\|c_\Psi \beta^{\mathsf{ols}} - \beta^{\mathsf{pop}}\right\|_2$ converges to 0. This term can be controlled with additional sparsity-type structural assumptions on the problem. Below, we discuss two scenarios that may lead to such a setting.

Sparsity. Assume that β^{pop} has s non-zero terms, i.e., $\|\beta^{\mathsf{pop}}\|_0 = s$. Following the same proof technique of Theorem 3, we can show that

$$\frac{1}{\sqrt{p}}\left\|c_\Psi \beta^{\mathsf{ols}} - \beta^{\mathsf{pop}}\right\|_2 \le C\sqrt{\frac{s}{p}}\|\beta^{\mathsf{pop}}\|_\infty, \tag{24}$$

for some constant $C > 0$. As long as the non-sparsity level satisfies $s = o(p)$, we can attain consistency in ℓ_2-norm. The rate of convergence will be determined by the growing rates of $n, p(n)$ and $s(n)$. For example, to attain $\sqrt{n}$-convergence, one needs $s = \mathcal{O}(1)$ and $p = \mathcal{O}(n)$, but milder growth conditions can still lead to consistency at the expense of slower convergence.

Normality. Similarly, one can assume that a subset of features with size s follow a non-Gaussian distribution, and the remaining $p - s$ features are normally distributed. The same argument above can also provides consistency in ℓ_2-norm – again in this case and the convergence rate will be determined by the ratio $\sqrt{s/p}$.

5.2. Verifying the key assumptions

The assumption on $f(z) = z\mathbb{E}\left[\Psi^{(2)}(\langle x, \beta^{\mathsf{ols}}\rangle, z)\right]$ appears in both theorems and depends both on the function Ψ and the underlying covariate distribution. Therefore, in order to verify this assumption rigorously, one needs to know the distribution of the covariates which is not always available. However, a straightforward way to verify this assumption is to use the sample mean estimate $\hat{f}(z) = z\frac{1}{n}\sum_{i=1}^n \Psi^{(2)}(\langle x_i, \hat{\beta}^{\mathsf{ols}}\rangle z)$ using the dataset at hand to estimate $f(z)$. In Figure 2, we use this technique to verify that our assumptions are valid for two commonly used loss functions, namely, boosting and logistic regression when the covariates are normally distributed $x \sim \mathsf{N}(0, \frac{1}{p}\mathbf{I})$ and $\|\beta^{\mathsf{ols}}\|_2 = \sqrt{p}/4$. We observe through the figure that for both loss functions, one can easily verify that the conditions are satisfied.

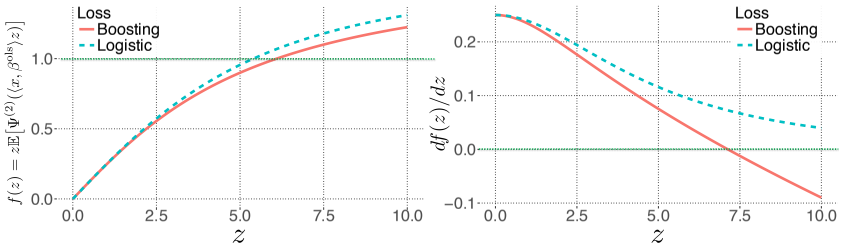

Figure 2: We demonstrate how to validate our assumption on $f(z) = z\mathbb{E}\left[\Psi^{(2)}(\langle x, \beta^{\mathsf{ols}}\rangle z)\right]$ on two commonly used loss functions. Left plot shows $f(z)$, whereas right plots shows its derivative. In these plots, covariates are generated from $x \sim \mathsf{N}(0, \mathbf{I}/p)$, and $\|\beta^{\mathsf{ols}}\|_2 = \sqrt{p}/4$.

The assumption on $f(z)$ can be verified by a more rigorous treatment. For simplicity, we again consider the compressed sensing setting where we assume $x \sim \mathsf{N}(0, \frac{1}{p}\mathbf{I})$, and this time we let $\|\beta^{\mathsf{pop}}\|_2 = c_\Psi \left\|\beta^{\mathsf{ols}}\right\|_2 \approx \sqrt{p}$. In order to obtain a scaling constant $c_\Psi \le 20$, assume that we have $\left\|\beta^{\mathsf{ols}}\right\|_2 = \sqrt{p}/20$.

Boosting loss: In this case, we have $\Psi(z) = z/2 + \sqrt{1 + z^2/4}$ which yields

$$\Psi^{(2)}(z) = \frac{1}{4}(1 + z^2/4)^{-3/2} \quad \text{and} \quad \Psi^{(4)}(z) = \frac{3}{64}\frac{5z^2(1 + z^2/4)^{-2} - 4}{(1 + z^2/4)^{5/2}}. \tag{25}$$

We notice that both of these functions are even, i.e., $\Psi^{(2)}(z) = \Psi^{(2)}(-z)$, and $\Psi^{(4)}(z) = \Psi^{(4)}(-z)$. We use the local convexity for $z \ge 0$ around $z = 2$, and obtain $\Psi^{(2)}(z) \ge a - bz$ where $a = \Psi^{(2)}(2) - 2\Psi^{(3)}(2)$ and $b = -\Psi^{(3)}(2)$. For $W \sim \mathsf{N}(0, 1)$ and ϕ denoting the standard normal density, we write

$$\begin{aligned} f(z) =& z\mathbb{E}\left[\Psi^{(2)}(\langle x, \beta^{\mathsf{ols}}\rangle z)\right] = z\mathbb{E}\left[\Psi^{(2)}(Wz/20)\right], \\ =& 2z\int_0^\infty \Psi^{(2)}(wz/20)\phi(w)dw \ge 2z\int_0^{20a/bz}(a - bwz/20)\phi(w)dw, \\ &= 2z\left\{a\Phi(20a/bz) - \frac{a}{2} - \frac{bz}{20\sqrt{2\pi}}(1 - e^{-200a^2/b^2z^2})\right\}. \end{aligned} \tag{26}$$

Using the above bound, we observe that for $\bar{c} = 6$ and $\delta = .23$, we have $f(\bar{c}) > 1 + \delta$.

Next, we verify the derivative condition on f, that is, $f^{(1)}$ does not change sign in the interval $[0, \bar{c}]$. By the Stein's lemma, we write

$$f^{(1)}(z) = \mathbb{E}\left[\Psi^{(2)}(Wz/20)\right] + (z/20)^2\mathbb{E}\left[\Psi^{(4)}(Wz/20)\right]. \tag{27}$$

Using the previous inequalities together with the above expression, we have

$$\begin{aligned} f^{(1)}(z) \ge& \mathbb{E}\left[\Psi^{(2)}(Wz/20)\right] - \frac{9}{100}\left|\Psi^{(4)}\right| \\ \ge& 2\left\{a\Phi(20a/bz) - \frac{a}{2} - \frac{bz}{20\sqrt{2\pi}}(1 - e^{-200a^2/b^2z^2})\right\} - \frac{27}{1600} \ge 0.188, \end{aligned} \tag{28}$$

which verifies the derivative assumption on $f(z)$.

Logistic regression: In this case, we have $\Psi(z) = \log(1 + e^z)$ which yields

$$\Psi^{(2)}(z) = \frac{e^z}{(1+e^z)^2} \quad \text{and} \quad \Psi^{(4)}(z) = \frac{e^z(1 - 4e^z + e^{2z})}{(1+e^z)^4}. \tag{29}$$

As before, both $\Psi^{(2)}$ and $\Psi^{(4)}$ are even functions. Again, appealing to the local convexity properties, for $z \geq 0$ around $z = 2.5$, we obtain $\Psi^{(2)}(z) \geq a - bz$ where $a = \Psi^{(2)}(2.5) - 2.5\Psi^{(3)}(2.5)$ and $b = -\Psi^{(3)}(2.5)$. Using (26), we obtain

$$f(z) \geq 2z \left\{ a\Phi\big(20a/bz\big) - \frac{a}{2} - \frac{bz}{20\sqrt{2\pi}}(1 - e^{-200a^2/b^2z^2}) \right\}. \tag{30}$$

Using the above bound, we see that for $\bar{c} = 6$, and $\delta = .22$ we have $f(\bar{c}) > 1 + \delta$.

For the derivative bound, we again use (27), and obtain that for $z \in [0, \bar{c}]$,

$$f^{(1)}(z) \geq \mathbb{E}\left[\Psi^{(2)}(Wz/20)\right] - \frac{9}{100}\left|\Psi^{(4)}\right| \geq \mathbb{E}\left[\Psi^{(2)}(Wz/20)\right] - \frac{9}{800} \geq 0.19, \tag{31}$$

which verifies the assumption.

6. Converting One GLM to Another

In this section, we assume that one has already obtained a set of coefficients by minimizing a certain GLM loss, but wants to minimize another GLM loss using the same dataset. It is often the case that a practitioner would like to change the loss function (or equivalently the model) based on its performance. However, when the dataset is large, training a new model from scratch is extremely time consuming. In the following, we will use the proportionality relation to transition between different loss functions.

Assume that a practitioner fitted a GLM using the loss function (or cumulant generating function) Ψ_1, but they would like to train a new model based on the second loss function Ψ_2. Instead of minimizing the new loss based on Ψ_2, one can exploit the proportionality relation and obtain the coefficients for the new GLM problem. Denote by β_1^{pop} and β_2^{pop} the GLM coefficients corresponding to the loss functions Ψ_1 and Ψ_2, respectively. Using the results in the previous sections, we have

$$\frac{1}{c_{\Psi_1}}\beta_1^{\mathsf{pop}} = \frac{1}{c_{\Psi_2}}\beta_2^{\mathsf{pop}} = \beta^{\mathsf{ols}},$$

for the normal case, that is, both coefficients are proportional to the OLS coefficients which does not depend on the loss function. Therefore, these coefficients β_1^{pop} and β_2^{pop} are also proportional to each other and we can write

$$\beta_2^{\mathsf{pop}} = \frac{c_{\Psi_2}}{c_{\Psi_1}}\,\beta_1^{\mathsf{pop}} \coloneqq \rho\,\beta_1^{\mathsf{pop}}, \tag{32}$$

where the proportionality constant between two different GLM types turns out to be the ratio between c_{Ψ_1} and c_{Ψ_2}, i.e. $\rho = c_{\Psi_2}/c_{\Psi_1}$. Using the definition of c_{Ψ_2}, we write

$$\begin{aligned} 1 &= c_{\Psi_2}\,\mathbb{E}\left[\Psi_2^{(2)}(\langle x, \beta_2^{\mathsf{pop}}\rangle)\right], \\ &= c_{\Psi_1}\rho\,\mathbb{E}\left[\Psi_2^{(2)}(\langle x, \beta_1^{\mathsf{pop}}\rangle\rho)\right]. \end{aligned}$$

Algorithm 2 Conversion from one GLM to another

Input: Data $(y_i, x_i)_{i=1}^n$, and $\hat{\beta}_1^{\mathrm{glm}}$

Step 1. Compute $\hat{y} = \mathbf{X}\hat{\beta}_1^{\mathrm{glm}}$, and $\kappa = \frac{1}{n}\sum_{i=1}^n \Psi_1^{(2)}(\hat{y}_i)$.

Step 2. Solve the following equation for $\rho \in \mathbb{R}$: $\kappa = \frac{\rho}{n}\sum_{i=1}^n \Psi_2^{(2)}(\hat{y}_i\rho)$

Use Newton's root-finding method:

Initialize $\rho = 1$;

Repeat until convergence:

$$\rho \leftarrow \rho - \frac{\rho\,\frac{1}{n}\sum_{i=1}^n \Psi_2^{(2)}(\rho\,\hat{y}_i) - \kappa}{\frac{1}{n}\sum_{i=1}^n \left\{\Psi_2^{(2)}(\rho\,\hat{y}_i) + \rho\,\hat{y}_i\Psi_2^{(3)}(\rho\,\hat{y}_i)\right\}}.$$

Output: $\hat{\beta}_2^{\mathrm{glm}} = \rho \times \hat{\beta}_1^{\mathrm{glm}}$.

Dividing the both sides by c_{Ψ_1} and using the equality $c_{\Psi_1}^{-1} = \mathbb{E}\left[\Psi_1^{(2)}(\langle x, \beta_1^{\mathsf{pop}}\rangle)\right]$, we obtain

$$\mathbb{E}\left[\Psi_1^{(2)}(\langle x, \beta_1^{\mathsf{pop}}\rangle)\right] = \rho\,\mathbb{E}\left[\Psi_2^{(2)}(\langle x, \beta_1^{\mathsf{pop}}\rangle\rho)\right].$$

The above equation only involves β_1^{pop} as the coefficients (which is assumed to be already known/obtained by the practitioner). Therefore, if we solve it for the ratio ρ, we can estimate β_2^{pop} by simply using the proportionality relation given in (32).

The procedure described above is summarized as Algorithm 2. We emphasize that this procedure does not require the computation of the OLS estimator which was the main cost of SLS, and it only requires a per-iteration cost of $\mathcal{O}(n)$. In other words, conversion from one GLM type to another is easier compared to obtaining the GLM coefficients from scratch.

7. Binary Classification with Proper Scoring Rules

In this section, we assume that for $i \in [n]$, the response is binary $y_i \in \{0, 1\}$. The binary classification problem can be described by the following minimization of an empirical risk

$$\underset{\beta \in \mathbb{R}^p}{\text{minimize}}\ \frac{1}{n}\sum_{i=1}^n \ell(y_i; q(\langle x_i, \beta\rangle)), \tag{33}$$

where ℓ and q are referred to as the loss and the link functions, respectively. There are various loss functions that are used in practice. Examples include log-loss, boosting loss, square loss etc (See Table 1). As before, we constrain our analysis on the canonical links. The concept of canonical links for binary classification is introduced by Buja et al. (2005), and it is quite similar to the generalized linear problems.

For any given loss function, we define the partial losses $\ell_k(\cdot) = \ell(y = k; \cdot)$ for $k \in \{0, 1\}$. Since we have a binary response variable, we can write any loss in the following format

$$\begin{aligned} \ell(y; q) =& y\ell_1(q) + (1 - y)\ell_0(q), \\ =& y\,(\ell_1(q) - \ell_0(q)) + \ell_0(q). \end{aligned}$$

Table 1: Common loss functions and their inverse canonical links

Name	Loss function: $\ell(y;q)$	Weight: $w(q)$	Inverse Canonical link: q
Log-loss	$-y\log(q)-(1-y)\log(1-q)$	$\frac{1}{q(1-q)}$	$\frac{1}{1+\exp(-z)}$
Boosting loss	$y(q^{-1}-1)^{1/2}+(1-y)(q^{-1}-1)^{-1/2}$	$\frac{1}{[q(1-q)]^{3/2}}$	$\frac{1}{2}+\frac{z/4}{2(z^2/4+1)^{1/2}}$
Square loss	$y(1-q)^2+(1-y)q^2$	1	$\frac{1+z}{2}$

The above formulation is of the form of a generalized linear problem. Before moving forward, we recall the concept of proper scoring in binary classification, which is sometimes referred to as Fisher consistency.

Definition 10 (Proper scoring rules) *Assume that $y \sim$ Bernoulli(η). If the expected loss $\mathbb{E}[\ell(y,q)]$ is minimized by $q=\eta$ for all $\eta\in(0,1)$, we call the loss function a proper scoring rule.*

The following theorem by Schervish (1989) provides a methodology for constructing a loss function for the proper scoring rules.

Theorem 11 (Schervish (1989)) *Let $w(dt)$ be a positive measure on $(0,1)$ that is finite on interval $(\epsilon,1-\epsilon)$ $\forall\epsilon>0$. Then the following defines a proper scoring rule*

$$\ell_1(q)=\int_q^1(1-t)w(dt),\ \text{and}\ \ell_0(q)=\int_0^q tw(dt).$$

The measure $w(dt)$ uniquely defines the loss function (generally referred to as the weight function, since all losses can be written as weighted average of cost weighted misclassification error (Buja et al., 2005; Reid and Williamson, 2010)). Examples of weight functions is given in Table 1. The above theorem has many interesting interpretations; one that is most useful to us is that $\ell_0^{(1)}(q)=qw(q)$.

The notion of canonical links for proper scoring rules are introduced by Buja et al. (2005), which corresponds to the notion of matching loss (Helmbold et al., 1999; Reid and Williamson, 2010). The derivation of canonical links stems from the Hessian of the above minimization, which remedies two potential problems: non-convexity and asymptotic variance inflation. It turns out that by setting $w(q)q^{(1)}$ as constant, one can remedy both problems (Buja et al., 2005). We will skip the derivation and, without loss of generality, assume that the canonical link-loss pair satisfies $w(q)q^{(1)}=1$. Note that any loss function has a natural canonical link. The following Theorem summarizes this concept.

Theorem 12 (Buja et al. (2005)) *For proper scoring rules with $w>0$, there exists a canonical link function which is unique up to addition and multiplication by constants. Conversely, any link function is canonical for a unique proper scoring rule.*

The canonical link for a given loss function can be explicitly derived from the equation $w(q)q^{(1)}=1$. We have provided some examples in Table 1. Using the definition of canonical

link for proper scoring rules, we write the normal equations $\frac{\mathrm{d}}{\mathrm{d}\beta}\mathbb{E}\left[\ell(y,q(\langle x,\beta\rangle))\right]=0$ as

$$\begin{aligned}
&\mathbb{E}\left[xq^{(1)}(\langle x,\beta\rangle)\ell_0^{(1)}(q(\langle x,\beta\rangle))\right]=\mathbb{E}\left[yxq^{(1)}(\langle x,\beta\rangle)\left(\ell_0^{(1)}(q(\langle x,\beta\rangle))-\ell_1^{(1)}(q(\langle x,\beta\rangle))\right)\right],\\
&\implies \mathbb{E}\left[xq^{(1)}(\langle x,\beta\rangle)q(\langle x,\beta\rangle)w(q(\langle x,\beta\rangle))\right]=\mathbb{E}\left[yxq^{(1)}(\langle x,\beta\rangle)w(q(\langle x,\beta\rangle))\right],\\
&\implies \mathbb{E}\left[xq(\langle x,\beta\rangle)\right]=\mathbb{E}\left[yx\right],\\
&\implies \boldsymbol{\Sigma}\beta\mathbb{E}\left[q^{(1)}(\langle x,\beta\rangle)\right]=\mathbb{E}\left[yx\right].
\end{aligned}$$

The last equation provides us with the analog of the proportionality relation we observed in generalized linear problems. In this case, we observe that the proportionality constant becomes $1/\mathbb{E}\left[q^{(1)}(\langle x,\beta\rangle)\right]$. Therefore, our algorithm can be used to obtain a fast training procedure for the binary classification problems under canonical links as well.

7.1. Canonicalization of the Square Loss

Consider a minimization problem of the following form

$$\underset{\beta}{\text{minimize}}\ \frac{1}{n}\sum_{i=1}^n[y_i-f(\langle x_i,\beta\rangle)]^2. \tag{34}$$

The above problem is commonly encountered in many machine learning tasks – specifically, in the context of neural networks, the function f is called the activation function. Here, we consider a toy example to demonstrate how our methodology can be useful in a minimization problem of the above form.

We first use Taylor series expansion around a point θ (which should be close to $\langle x,\beta\rangle$), in order to approximate the function $f(z)$ with a linear function around $f(\theta)$. We write

$$\min_\beta\mathbb{E}\left[(y-f(\langle x,\beta\rangle))^2\right]\approx\min_\beta\mathbb{E}\left[f(\langle x,\beta\rangle)^2-2y\langle x,\beta\rangle f'(\theta)\right]. \tag{35}$$

The above approximation yields

$$\Psi(z)=\frac{f(z)^2}{2f'(\theta)}, \tag{36}$$

and the proportionality relation given in previous sections would hold for the approximation, which will be accurate when the activation function is smooth around the user-specified point θ. This method can be used to derive proportionality relations for GLMs with non-canonical links (conditional on the link being nice), and also may be of interest in non-convex optimization, e.g., reliable initialization.

8. Experiments

8.1. Numerical Analysis of Convergence

This section contains the results of numerical studies that demonstrate the convergence results presented in Section 5. We first demonstrate the convergence of the population

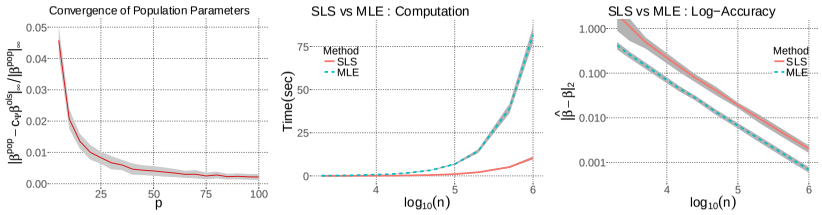

Figure 3: Logistic regression with iid Bernoulli ± 1 design. The left plot shows the relative error between the population parameters. The middle plot shows the computational cost (time) for finding the MLE and SLS as n grows and $p = 200$. The right plot depict the accuracy of the estimators in log scale. In the regime where the MLE is expensive to compute, the SLS is found much more rapidly and has the same accuracy. `R`'s built-in functions are used to find the MLE.

parameters with respect to the dimension. In this experiment, we estimate the relative error $\left\|\beta^{\mathsf{pop}} - c_\Psi \beta^{\mathsf{ols}}\right\|_\infty / \left\|\beta^{\mathsf{pop}}\right\|_\infty$ using a Monte-Carlo simulation. The dimension takes values from $p \in \{5, 10, 15, ..., 100\}$, and for each fixed p, we choose the sample size $n(p) = Kp$ where $K = 10{,}000$. $\beta^{\mathsf{pop}} = (1, 1, ..., 1)/\sqrt{p}$ is fixed throughout this experiment. Covariates are generated from a Bernoulli distribution $\mathbb{P}(x_{ij} = \pm 1) = 0.5$, and the response is generated from the logistic model. We estimate β^{ols} using coordinatewise average of the ordinary least squares estimator over the whole dataset. The scaling constant is estimated by the inverse of $\frac{1}{n}\sum_{i=1}^n \Psi^{(2)}(\langle x_i, \beta^{\mathsf{pop}}\rangle)$. We repeat this experiment 100 times for each p, and the results are reported in left plot in Figure 3. We observe that the relative error decreases with increasing dimension.

The second experiment demonstrates the effect of sample size. In this experiment, we fix $p = 200$, and the sample size varies $n \in 10^3 \times \{2, 3, 5, 15, 25, 50, 100, 200, 500, 1000\}$. Covariates are again generated from Bernoulli distribution $\mathbb{P}(x_{ij} = \pm 1) = 0.5$, and the response is generated from the logistic model. Maximum likelihood estimator is obtained through `R`'s built-in function `glm`. We report the computation time of these estimators as well as their estimation error in the middle and the right plots in Figure 3, respectively. We observe that MLE performs consistently better in terms of test error, yet it is significantly expensive to compute when n gets larger. In the large-scale regime, the difference between the achieved test errors becomes negligible as seen in the right plot. This is the regime that SLS provides significant advantage. We also emphasize that MLE and SLS has the same convergence rate as can be observed in the right plot.

8.2. Comparisons With Other Optimization Methods

This section contains the results of a variety of numerical studies, which show that the Scaled Least Squares estimator reaches its minimum achievable test error substantially faster than commonly used batch algorithms for finding the MLE. Both logistic and Poisson regression models (two types of GLMs) are utilized in our analyses, which are based on several synthetic and real datasets.

Below, we briefly describe the optimization algorithms for the MLE that were used in the experiments.

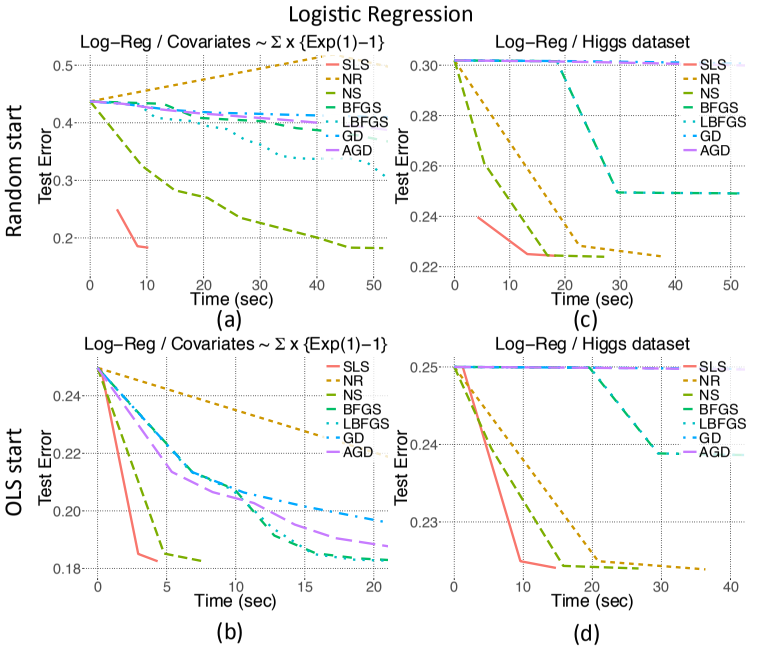

Figure 4: We compared the performance of SLS to that of MLE for the logistic regression problem on several datasets. MLE optimization is solved by various optimization algorithms. SLS is represented with red straight line. The details are provided in Table 2.

1. **Newton-Raphson (NR)** achieves locally quadratic convergence by scaling the gradient by the inverse of the Hessian evaluated at the current iterate. Computing the Hessian has a per-iteration cost of $\mathcal{O}\left(np^2\right)$, which makes it impractical for large-scale datasets.

2. **Newton-Stein (NS)** is a recently proposed second-order batch algorithm specifically designed for GLMs (Erdogdu, 2015, 2016). The algorithm uses Stein's lemma and sub-sampling to efficiently estimate the Hessian with a cost of $\mathcal{O}\left(np\right)$ per-iteration, achieving near quadratic rates.

3. **Broyden-Fletcher-Goldfarb-Shanno (BFGS)** is the most popular and stable quasi-Newton method (Nesterov, 2004). At each iteration, the gradient is scaled by a matrix that is formed by accumulating information from previous iterations and gradient computations. The convergence is locally super-linear with a per-iteration cost of $\mathcal{O}\left(np\right)$.

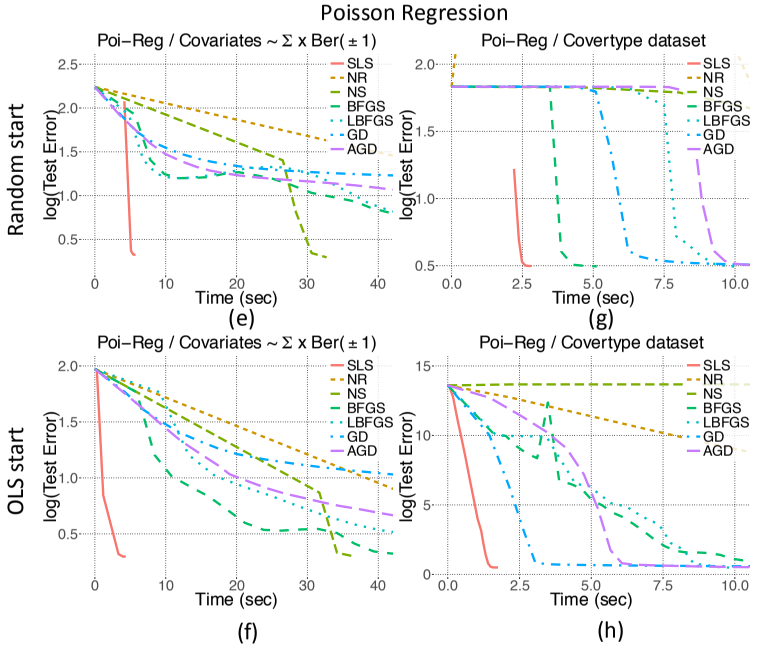

Figure 5: We compared the performance of SLS to that of MLE for the Poisson regression problem on several datasets. MLE optimization is solved by various optimization algorithms. SLS is represented with red straight line. Details are given in Table 2.

4. **Limited memory BFGS (LBFGS)** is a variant of BFGS, which uses only the recent iterates and gradients to approximate the Hessian, providing significant improvement in terms of memory usage. LBFGS has many variants; we use the formulation given in Bishop (1995).

5. **Gradient descent (GD)** takes a step in the opposite direction of the gradient, evaluated at the current iterate. Its performance strongly depends on the condition number of the design matrix. Under certain assumptions, the convergence is linear with $\mathcal{O}(np)$ per-iteration cost.

6. **Accelerated gradient descent (AGD)** is a modified version of gradient descent with an additional "momentum" term (Nesterov, 1983). Its per iteration cost is $\mathcal{O}(np)$ and its performance strongly depends on the smoothness of the objective function.

For all the algorithms for computing the MLE, the step size at each iteration is chosen via the backtracking line search (Boyd and Vandenberghe, 2004).

Table 2: Details of the experiments shown in Figures 4 and 5 with simulated and real datasets HIGGS (Baldi et al., 2014), and Covertype (Blackard and Dean, 1999)

Recall that the proposed Algorithm 1 is composed of two steps; the first finds an estimate of the OLS coefficients. This up-front computation is not needed for any of the MLE algorithms described above. On the other hand, each of the MLE algorithms requires some initial value for β, but no such initialization is needed to find the OLS estimator in Algorithm 1. This raises the question of how the MLE algorithms should be initialized, in order to compare them fairly with the proposed method. We consider two scenarios in our experiments: first, we use the OLS estimator computed for Algorithm 1 to initialize the MLE algorithms; second, we use a random initial value.

On each dataset, the main criterion for assessing the performance of the estimators is how rapidly the minimum test error is achieved. The test error is measured as the mean squared error of the estimated mean using the current parameters at each iteration on a test dataset, which is a randomly selected (and set-aside) 10% portion of the entire dataset. As noted previously, the MLE is more accurate for small n (see Figure 1). However, in the regime considered here ($n \gg p \gg 1$), the MLE and the SLS perform very similarly in terms of their error rates; for instance, on the Higgs dataset, the SLS and MLE have test error rates of 22.40% and 22.38%, respectively. For each dataset, the minimum achievable test error is set to be the maximum of the final test errors, where the maximum is taken over all of the estimation methods. Let $\mathbf{\Sigma}^{(1)}$ and $\mathbf{\Sigma}^{(2)}$ be two randomly generated covariance matrices. The datasets we analyzed were: (i) a synthetic dataset generated from a logistic regression model with iid {exponential(1)-1} predictors scaled by $\mathbf{\Sigma}^{(1)}$; (ii) the Higgs dataset (logistic regression) Baldi et al. (2014); (iii) a synthetic dataset generated from a Poisson regression model with iid binary(±1) predictors scaled by $\mathbf{\Sigma}^{(2)}$; (iv) the Covertype dataset (Poisson regression) Blackard and Dean (1999).

In all cases, the SLS outperformed the alternative algorithms for finding the MLE by a large margin, in terms of computation. Detailed results may be found in Figures 4 and 5, and Table 2. We provide additional experiments with different datasets in Section 12.

9. Discussion

In this paper, we showed that the true minimizer of a generalized linear problem and the OLS estimator are approximately proportional under the general random design setting. Using this relation, we proposed a computationally efficient algorithm for large-scale problems that achieves the same accuracy as the empirical risk minimizer by first estimating the OLS coefficients and then estimating the proportionality constant through iterations that can attain quadratic or cubic convergence rate, with only $\mathcal{O}(n)$ per-iteration cost.

We briefly mentioned that the proportionality between the coefficients holds even when there is regularization in Section 3.1. Further pursuing this idea may be interesting for large-scale problems where regularization is crucial. Another interesting line of research is to find similar proportionality relations between the parameters in other large-scale optimization problems such as support vector machines. Such relations may reduce the problem complexity significantly.

10. Proof of Main Results

In this section, we provide the details and the proofs of our technical results. For convenience, we briefly state the following definitions.

Definition 13 (Sub-Gaussian) *For a given constant κ, a random variable $x \in \mathbb{R}$ is said to be* sub-Gaussian *if it satisfies $\sup_{m\geq 1} m^{-1/2}\mathbb{E}\left[|x|^m\right]^{1/m} \leq \kappa$. Smallest such κ is the sub-Gaussian norm of x and it is denoted by $\|x\|_{\psi_2}$. Similarly, a random vector $y \in \mathbb{R}^p$ is a* sub-Gaussian vector *if there exists a constant κ' such that $\sup_{v\in S^{p-1}} \|\langle y, v\rangle\|_{\psi_2} \leq \kappa'$.*

Definition 14 (Sub-exponential) *For a given constant κ, a random variable $x \in \mathbb{R}$ is called* sub-exponential *if it satisfies $\sup_{m\geq 1} m^{-1}\mathbb{E}\left[|x|^m\right]^{1/m} \leq \kappa$. Smallest such κ is the sub-exponential norm of x and it is denoted by $\|x\|_{\psi_1}$. Similarly, a random vector $y \in \mathbb{R}^p$ is a* sub-exponential vector *if there exists a constant κ' such that $\sup_{v\in S^{p-1}} \|\langle y, v\rangle\|_{\psi_1} \leq \kappa'$.*

The proof of Theorem 3 is given next.

Proof [of Theorem 3] For simplicity, we denote the whitened covariate by $w = \mathbf{\Sigma}^{-1/2}x$. Since w is sub-Gaussian with norm κ, its j-th entry w_j has bounded third moment. That is,

$$\kappa = \sup_{\|u\|_2=1} \|\langle u, w\rangle\|_{\psi_2} \geq \|w_j\|_{\psi_2} = \sup_{m\geq 1} m^{-1/2}\mathbb{E}\left[|w_j|^m\right]^{1/m} \geq \frac{1}{\sqrt{3}}\mathbb{E}\left[|w_j|^3\right]^{1/3}, \tag{37}$$

where in the first step, we used $u = e_j$, the j-th standard basis vector. Hence, we obtain a bound on the third moment, i.e,

$$\max_j \mathbb{E}\left[|w_j|^3\right] \leq 3^{3/2}\kappa^3. \tag{38}$$

Using the normal equations, we write

$$\begin{aligned}\mathbb{E}\left[yx\right] = \mathbb{E}\left[x\Psi^{(1)}(\langle x, \beta\rangle)\right] =& \mathbf{\Sigma}^{1/2}\mathbb{E}\left[w\Psi^{(1)}(\langle w, \mathbf{\Sigma}^{1/2}\beta\rangle)\right], \\ =& \mathbf{\Sigma}^{1/2}\mathbb{E}\left[w\Psi^{(1)}(\langle w, \tilde{\beta}\rangle)\right],\end{aligned} \tag{39}$$

where we defined $\tilde{\beta} = \mathbf{\Sigma}^{1/2}\beta$. By multiplying both sides with $\mathbf{\Sigma}^{-1}$, we obtain

$$\beta^{\mathsf{ols}} = \mathbf{\Sigma}^{-1/2}\mathbb{E}\left[w\Psi^{(1)}(\langle w, \tilde{\beta}\rangle)\right]. \tag{40}$$

Now we define the partial sums $W_{-i} = \sum_{j\neq i}\tilde{\beta}_j w_j = \langle\tilde{\beta}, w\rangle - \tilde{\beta}_i w_i$. We will focus on the i-th entry of the above expectation given in (40). Denoting the zero biased transformation of w_i conditioned on W_{-i} by w_i^*, we have

$$\begin{aligned}\mathbb{E}\left[w_i\Psi^{(1)}(\langle w, \tilde{\beta}\rangle)\right] =& \mathbb{E}\left[\mathbb{E}\left[w_i\Psi^{(1)}\left(\tilde{\beta}_i w_i + W_{-i}\right)\big|W_{-i}\right]\right], \\ =& \tilde{\beta}_i\mathbb{E}\left[\Psi^{(2)}(\tilde{\beta}_i w_i^* + W_{-i})\right], \\ =& \tilde{\beta}_i\mathbb{E}\left[\Psi^{(2)}(\tilde{\beta}_i(w_i^* - w_i) + \langle w, \tilde{\beta}\rangle)\right],\end{aligned} \tag{41}$$

where in the second step, we used the assumption on conditional moments. Let $\mathbf{D}$ be a diagonal matrix with diagonal entries $\mathbf{D}_{ii} = \mathbb{E}\left[\Psi^{(2)}(\tilde{\beta}_i(w_i^* - w_i) + \langle w, \tilde{\beta}\rangle)\right]$. Using (40) together with (41), we obtain the equality

$$\beta^{\mathsf{ols}} = \mathbf{\Sigma}^{-1/2}\mathbf{D}\tilde{\beta} = \mathbf{\Sigma}^{-1/2}\mathbf{D}\mathbf{\Sigma}^{1/2}\beta. \tag{42}$$

Now, using the Lipschitz continuity assumption of the variance function, we have

$$\left|\mathbb{E}\left[\Psi^{(2)}(\tilde{\beta}_i(w_i^* - w_i) + \langle w, \tilde{\beta}\rangle)\right] - \mathbb{E}\left[\Psi^{(2)}(\langle w, \tilde{\beta}\rangle)\right]\right| \leq k|\tilde{\beta}_i|\mathbb{E}\left[|w_i^* - w_i|\right]. \tag{43}$$

In the following, we will use the properties of zero-biased transformations. Consider the quantity

$$r = \sup \frac{\mathbb{E}\left[|w_i^* - w_i|\big|W_{-i}\right]}{\mathbb{E}\left[|w_i|^3\big|W_{-i}\right]} \tag{44}$$

where w_i^* has w_i-zero biased distribution (conditioned on W_{-i}) and the supremum is taken with respect to all random variables with mean 0, standard deviation 1 and finite third moment, and w_i^* is achieving the minimal ℓ_1 coupling to w_i conditioned on W_{-i}. It is shown in Goldstein (2007) that the above bound holds for $r = 1.5$ for the unconditional zero-bias transformations. Here, we take a similar approach to show that the same bound holds for the conditional case as well. By using the triangle inequality, we have

$$\begin{aligned}\mathbb{E}\left[|w_i^* - w_i|\big|W_{-i}\right] \leq& \mathbb{E}\left[|w_i^*|\big|W_{-i}\right] + \mathbb{E}\left[|w_i|\big|W_{-i}\right] \\ \leq& \frac{1}{2}\mathbb{E}\left[|w_i|^3\big|W_{-i}\right] + \mathbb{E}\left[|w_i|^3\big|W_{-i}\right]^{1/3}.\end{aligned} \tag{45}$$

Since $\mathbb{E}\left[|w_i|^2\big|W_{-i}\right]$ is constant, it is equal to $\mathbb{E}\left[|w_i|^2\right] = 1$. This yields that the second term in the last line is upper bounded by $\mathbb{E}\left[|w_i|^3\big|W_{-i}\right]$. Consequently, by taking expectations over both hand sides we obtain that

$$\mathbb{E}\left[|w_i^* - w_i|\right] \leq 1.5\ \mathbb{E}\left[|w_i|^3\right]. \tag{46}$$

Then the right hand side of (43) can be upper bounded by

$$k|\tilde{\beta}_i|\mathbb{E}\left[|w_i^* - w_i|\right] \leq rk \max_i \left\{|\tilde{\beta}_i|\mathbb{E}\left[|w_i|^3\right]\right\} \leq 8k\kappa^3 \|\mathbf{\Sigma}^{1/2}\beta\|_\infty, \tag{47}$$

where in the second step we used the bound on the third moment given in (38). The last inequality provides us with the following result,

$$\max_i \left|\mathbf{D}_{ii} - \frac{1}{c_\Psi}\right| \leq 8k\kappa^3 \|\mathbf{\Sigma}^{1/2}\beta\|_\infty. \tag{48}$$

Finally, combining this with (40) and (42), we obtain

$$\begin{aligned}
\left\|\beta^{\mathsf{ols}} - \frac{1}{c_\Psi}\beta\right\|_\infty &= \left\|\mathbf{\Sigma}^{-1/2}\mathbf{D}\mathbf{\Sigma}^{1/2}\beta - \frac{1}{c_\Psi}\beta\right\|_\infty \\
&= \left\|\mathbf{\Sigma}^{-1/2}\left(\mathbf{D} - \frac{1}{c_\Psi}\mathbf{I}\right)\mathbf{\Sigma}^{1/2}\beta\right\|_\infty, \\
&\leq \max_i \left|\mathbf{D}_{ii} - \frac{1}{c_\Psi}\right| \left\|\mathbf{\Sigma}^{1/2}\right\|_\infty \left\|\mathbf{\Sigma}^{-1/2}\right\|_\infty \|\beta\|_\infty, \\
&\leq 8k\kappa^3 \rho_\infty \|\mathbf{\Sigma}^{1/2}\|_\infty \|\beta^{\mathsf{pop}}\|_\infty^2,
\end{aligned} \tag{49}$$

which completes the proof. ■

Proof [of Corollary 4] Due to diagonal dominance property, we have

$$\|\Sigma^{1/2}\|_\infty = \max_i \sum_{j=1}^p \left|\Sigma_{ij}^{1/2}\right| \leq 2 \max_i \Sigma_{ii}^{1/2} \leq 2\|\Sigma\|_2^{1/2}. \tag{50}$$

Since we have $\|x\|_2 \leq r$, we write

$$r^2 \geq \mathbb{E}\left[\|x\|_2^2\right] = \mathrm{Tr}\left(\Sigma\right) \geq p\|\Sigma\|_2 / \rho_2. \tag{51}$$

Combining this with the previous inequality we obtain

$$\|\Sigma^{1/2}\|_\infty \leq 2r\sqrt{\rho_2/p}. \tag{52}$$

Finally, the result follows from using the last bound in Theorem 3. ■

Proof [of Corollary 5] The result directly follows from using the r-well-spreadness assumption in Theorem 3. ■

Proof [of Proposition 7] For convenience, we denote the whitened covariates by $w_i = \mathbf{\Sigma}^{-1/2}x_i$. We have $\mathbb{E}\left[w_i\right] = 0$, $\mathbb{E}\left[w_i w_i^T\right] = \mathbf{I}$, and $\|w_i\|_{\psi_2} \leq \kappa$. Also denote the sub-sampled covariance matrix with $\widehat{\mathbf{\Sigma}} = \frac{1}{|S|}\sum_{i\in S} x_i x_i^T$, and its whitened version as $\widetilde{\mathbf{\Sigma}} = \frac{1}{|S|}\sum_{i\in S} w_i w_i^T$. Further, define $\hat{\zeta} = \frac{1}{n}\sum_{i=1}^n w_i y_i$ and $\zeta = \mathbb{E}\left[wy\right]$. Then, we have

$$\hat{\beta}^{\mathsf{ols}} = \widehat{\mathbf{\Sigma}}^{-1}\mathbf{\Sigma}^{1/2}\hat{\zeta} \quad \text{and} \quad \beta^{\mathsf{ols}} = \mathbf{\Sigma}^{-1/2}\zeta.$$

For now, we work on the event that $\widehat{\mathbf{\Sigma}}$ is invertible. We will see that this event holds with very high probability. We write

$$\begin{aligned}
\left\|\mathbf{\Sigma}^{1/2}(\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}})\right\|_2 &= \left\|\mathbf{\Sigma}^{1/2}\widehat{\mathbf{\Sigma}}^{-1}\mathbf{\Sigma}^{1/2}\hat{\zeta} - \mathbf{\Sigma}^{-1/2}\zeta\right\|_2, \\
&= \left\|\widetilde{\mathbf{\Sigma}}^{-1}\left\{\hat{\zeta} - \zeta + \left(\mathbf{I} - \mathbf{\Sigma}^{-1/2}\widehat{\mathbf{\Sigma}}\mathbf{\Sigma}^{-1/2}\right)\zeta\right\}\right\|_2, \\
&\leq \left\|\widetilde{\mathbf{\Sigma}}^{-1}\right\|_2 \left\{\left\|\hat{\zeta} - \zeta\right\|_2 + \left\|\mathbf{I} - \widetilde{\mathbf{\Sigma}}\right\|_2 \|\zeta\|_2\right\},
\end{aligned} \tag{53}$$

where we used the triangle inequality and the properties of the operator norm.

For the first term on the right hand side of (53), we write

$$\left\|\widetilde{\mathbf{\Sigma}}^{-1}\right\|_2 = \frac{1}{\lambda_{\min}(\widetilde{\mathbf{\Sigma}})} \leq \frac{1}{1-\delta},$$

where we assumed that such a $\delta > 0$ exists. In fact, when $\delta < 0.5$, we obtain a bound of 2 on the right hand side, which also justifies the invertibility assumption of $\widehat{\mathbf{\Sigma}}$. By Corollary 5.50 of Vershynin (2010) and the following remark, we have with probability at least $1 - 2\exp\{-p\}$,

$$\left\|\widetilde{\mathbf{\Sigma}} - \mathbf{I}\right\|_2 \leq c\sqrt{\frac{p}{|S|}},$$

where c is a constant depending only on κ. When $|S| > 4c^2 p$, we obtain

$$\left|\lambda_{\min}(\widetilde{\mathbf{\Sigma}}) - 1\right| \leq \left\|\widetilde{\mathbf{\Sigma}} - \mathbf{I}\right\|_2 \leq 0.5,$$

where the first inequality follows from the Lipschitz property of the eigenvalues.

Next, we bound the difference between $\hat{\zeta}$ and its expectation ζ. We write the bounds on the sub-exponential norm

$$\begin{aligned}
\|wy\|_{\psi_1} &= \sup_{\|v\|_2=1} \sup_{m\geq 1} m^{-1}\mathbb{E}\left[|\langle v, w\rangle y|^m\right]^{1/m}, \\
&\leq \sup_{\|v\|_2=1} \sup_{m\geq 1} m^{-1}\mathbb{E}\left[|\langle v, w\rangle|^{2m}\right]^{1/2m} \mathbb{E}\left[|y|^{2m}\right]^{1/2m}, \\
&\leq \sup_{\|v\|_2=1} \sup_{m\geq 1} m^{-1/2}\mathbb{E}\left[|\langle v, w\rangle|^{2m}\right]^{1/2m} \sup_{m\geq 1} m^{-1/2}\mathbb{E}\left[|y|^{2m}\right]^{1/2m}, \\
&\leq 2\|w\|_{\psi_2}\|y\|_{\psi_2} = 2\gamma\kappa.
\end{aligned} \tag{54}$$

Hence, we have $\max_i \|w_i y_i - \mathbb{E}\left[w_i y_i\right]\|_{\psi_1} \leq 4\gamma\kappa$. Further, let e_j denote the j-th standard basis, and notice that each entry of w is also sub-Gaussian with norm upper bounded by κ, i.e.,

$$\kappa = \|w\|_{\psi_2} = \sup_{\|u\|_2=1} \|\langle u, w\rangle\|_{\psi_2} \geq \|\langle e_j, w\rangle\|_{\psi_2} = \|w_j\|_{\psi_2}.$$

Also, we can write

$$\begin{aligned} 2\gamma\kappa \geq \|wy\|_{\psi_1} &= \sup_{\|u\|_2=1} \sup_{m\geq 1} m^{-1}\mathbb{E}\left[|\langle u, w\rangle y|^m\right]^{1/m}, \\ &\geq \sup_{\|u\|_2=1} \mathbb{E}\left[|\langle u, w\rangle y|\right], \\ &\geq \sup_{\|u\|_2=1} \mathbb{E}\left[\langle u, w\rangle y\right] = \sup_{\|u\|_2=1} \langle u, \zeta\rangle = \|\zeta\|_2, \end{aligned} \tag{55}$$

where in the last step, we used the fact that dual norm of ℓ_2 norm is itself.

Next, we apply Lemma 17 to $\hat{\zeta} - \zeta$, and obtain with probability at least $1 - \exp\{-p\}$

$$\left\|\hat{\zeta} - \zeta\right\|_2 \leq c\gamma\kappa\sqrt{\frac{p}{n}},$$

whenever $n > c^2 p$ for an absolute constant c.

Combining the above results in (53), we obtain with probability at least $1 - 3\exp\{-p\}$

$$\left\|\mathbf{\Sigma}^{1/2}(\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}})\right\|_2 \leq 2\left\{c_1\gamma\kappa\sqrt{\frac{p}{n}} + c_2\gamma\kappa\sqrt{\frac{p}{|S|}}\right\} \leq \eta\sqrt{\frac{p}{|S|}} \tag{56}$$

where η depends only on κ and γ, and $|S| > \eta p$. Finally, we write

$$\begin{aligned} \left\|\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}}\right\|_2 &\leq \lambda_{\min}^{-1/2}\left\|\mathbf{\Sigma}^{1/2}(\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}})\right\|_2, \\ &\leq \eta\lambda_{\min}^{-1/2}\sqrt{\frac{p}{|S|}}, \end{aligned}$$

with probability at least $1 - 3\exp\{-p\}$, whenever $|S| > \eta p$. ■

The following lemma – combined with the Proposition 7 – provides the necessary tools to prove Theorem 9.

Lemma 15 *For a given function $\Psi^{(2)}$ that is Lipschitz continuous with constant k, we define the function $f : \mathbb{R} \times \mathbb{R}^p \to \mathbb{R}$ as $f(c, \beta) = c\ \mathbb{E}\left[\Psi^{(2)}(\langle x, \beta\rangle c)\right]$, and its empirical counterpart as*

$$\hat{f}(c, \beta) = c\ \frac{1}{n}\sum_{i=1}^{n} \Psi^{(2)}(\langle x_i, \beta\rangle c).$$

For the ball centered around β^{ols} with radius δ,

$$\mathcal{B}^{\delta}(\tilde{\beta}^{\mathsf{ols}}) = \left\{\beta : \left\|\beta - \tilde{\beta}^{\mathsf{ols}}\right\|_2 \leq \delta\right\}, \quad \textit{with} \quad \tilde{\beta}^{\mathsf{ols}} = \Sigma^{1/2}\beta^{\mathsf{ols}},$$

assume that $\sup_{\beta\in\mathcal{B}^{\delta}(\tilde{\beta}^{\mathsf{ols}})}\left\|\Psi^{(2)}(\langle x, \beta\rangle)\right\|_{\psi_2} \leq \kappa_g$, and $\left\|\Sigma^{-1/2}x_i\right\|_{\psi_2} \leq \kappa_x$. Further, for some $\epsilon, \bar{c} > 0$, assume that $f(\bar{c}, \beta^{\mathsf{ols}}) \geq 1+\epsilon$. Then, $\exists c_\Psi > 0$ satisfying the equation $1 = f(c_\Psi, \beta^{\mathsf{ols}})$.

Further, assume that for some $\tilde{\epsilon} > 0$, we have $\epsilon = \tilde{\epsilon}\sqrt{p}$, and n and $|S|$ sufficiently large, i.e.,

$$\min\left\{\frac{n}{\log(n)}, |S|\right\} > K^2/\tilde{\epsilon}^2$$

for $K = \eta\bar{c}\max\{b + \kappa/\tilde{\mu}, k\bar{c}\kappa\}$. Then, with probability $1-5\exp\{-p\}$, there exists a constant $\hat{c}_\Psi \in (0, \bar{c})$ satisfying the equation

$$1 = \hat{c}_\Psi\ \frac{1}{n}\sum_{i=1}^{n} \Psi^{(2)}(\langle x_i, \hat{\beta}^{\mathsf{ols}}\rangle\hat{c}_\Psi).$$

Moreover, if the derivative of $z \to f(z, \beta^{\mathsf{ols}})$ is bounded below in absolute value (i.e. does not change sign) by $\upsilon > 0$ in the interval $z \in [0, \bar{c}]$, then with probability $1 - 5\exp\{-p\}$, we have

$$|\hat{c}_\Psi - c_\Psi| \leq C\sqrt{\frac{p}{\min\{n/\log(n), |S|\}}},$$

where $C = K/\upsilon$.

Proof [of Lemma 15] First statement is obvious. We notice that $f(c, \beta^{\mathsf{ols}})$ is a continuous function in its first argument with $f(0, \beta^{\mathsf{ols}}) = 0$ and $f(\bar{c}, \beta^{\mathsf{ols}}) \geq 1 + \delta$. Hence, there exists $c_\Psi > 0$ such that $f(c_\Psi, \beta^{\mathsf{ols}}) = 1$. If there are many solutions to the above equation, we choose the one that is closest to zero. The condition on the derivative will guarantee the uniqueness of the solution.

Next, we will show the existence of $\hat{c}_\Psi$ using a uniform concentration given by Lemma 18. Define the event $\mathcal{E}$ that $\hat{\beta}^{\mathsf{ols}}$ falls into $\mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})$, i.e., $\mathcal{E} = \left\{\hat{\beta}^{\mathsf{ols}} \in \mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})\right\}$. By Proposition 7 and the inequality given in (56), whenever $|S| > \eta p$, we obtain

$$\mathbb{P}\left(\mathcal{E}^C\right) \leq 3\exp\{-p\},$$

where $\mathcal{E}^C$ denotes the complement of the event $\mathcal{E}$, and η is a constant depending only on κ_x and γ, and $\delta = \eta\sqrt{p/|S|}$. For any $c \in [0, \bar{c}]$, on the event $\mathcal{E}$, we have

$$\left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \hat{\beta}^{\mathsf{ols}})\right| \leq \sup_{\beta\in\mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})}\left|\hat{f}(c, \beta) - f(c, \beta)\right|.$$

Hence, we obtain the following inequality

$$\begin{aligned} &\mathbb{P}\left(\sup_{c\in[0,\bar{c}]}\left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \hat{\beta}^{\mathsf{ols}})\right| > \epsilon\right) \\ &\leq \mathbb{P}\left(\sup_{c\in[0,\bar{c}]}\left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \hat{\beta}^{\mathsf{ols}})\right| > \epsilon; \mathcal{E}\right) + \mathbb{P}\left(\mathcal{E}^C\right), \\ &\leq \mathbb{P}\left(\sup_{c\in[0,\bar{c}]}\sup_{\beta\in\mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})}\left|\hat{f}(c, \beta) - f(c, \beta)\right| > \epsilon\right) + 3\exp\{-p\}. \end{aligned}$$

In the following, we will use Lemma 18 for the first term in the last line above. Denoting by w, the whitened covariates, we have $\langle x, \beta\rangle = \langle w, \mathbf{\Sigma}^{1/2}\beta\rangle$. Therefore,

$$\begin{aligned}&\sup_{c\in[0,\bar{c}]}\sup_{\beta\in\mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})}\left|\hat{f}(c,\beta)-f(c,\beta)\right|\\&\leq \bar{c}\sup_{c\in[0,\bar{c}]}\sup_{\beta\in\mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})}\left|\frac{1}{n}\sum_{i=1}^{n}\Psi^{(2)}(\langle w_i,\mathbf{\Sigma}^{1/2}\beta\rangle c)-\mathbb{E}\left[\Psi^{(2)}(\langle w,\mathbf{\Sigma}^{1/2}\beta\rangle c)\right]\right|.\end{aligned}$$

Next, define the ball centered around $\tilde{\beta}^{\mathsf{ols}} = \mathbf{\Sigma}^{1/2}\beta^{\mathsf{ols}}$, with radius δ as $\mathcal{B}_\delta(\tilde{\beta}^{\mathsf{ols}}) = \mathbf{\Sigma}^{1/2}\mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})$. We have $\beta \in \mathcal{B}^{\delta}_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})$ if and only if $\mathbf{\Sigma}^{1/2}\beta \in \mathcal{B}_\delta(\tilde{\beta}^{\mathsf{ols}})$. Then, the right hand side of the above inequality can be written as

$$\begin{aligned}&\bar{c}\sup_{c\in[0,\bar{c}]}\sup_{\beta\in\mathcal{B}_{\delta}(\tilde{\beta}^{\mathsf{ols}})}\left|\frac{1}{n}\sum_{i=1}^{n}\Psi^{(2)}(\langle w_i,\beta\rangle c)-\mathbb{E}\left[\Psi^{(2)}(\langle w,\beta\rangle c)\right]\right|,\\&=\bar{c}\sup_{\beta\in\mathcal{B}_{\bar{c}\delta}(\tilde{\beta}^{\mathsf{ols}})}\left|\frac{1}{n}\sum_{i=1}^{n}\Psi^{(2)}(\langle w_i,\beta\rangle)-\mathbb{E}\left[\Psi^{(2)}(\langle w,\beta\rangle)\right]\right|.\end{aligned}$$

Then, by Lemma 18, we obtain

$$\mathbb{P}\left(\sup_{c\in[0,\bar{c}]}\left|\hat{f}(c,\hat{\beta}^{\mathsf{ols}})-f(c,\hat{\beta}^{\mathsf{ols}})\right|>c'\bar{c}(\kappa_g+\kappa_x/\tilde{\mu})\sqrt{\frac{p}{n/\log(n)}}\right)\leq 5\exp\{-p\}\tag{57}$$

whenever $np > 51\max\left\{\chi,\chi^{-1}\right\}$ where $\chi = (\kappa_g+\kappa_x/\tilde{\mu})^2/(c'\delta^2k^2\bar{c}^2\tilde{\mu}^2)$.

Also, by the Lipschitz condition for $\Psi^{(2)}$, we have for any $c\in[0,\bar{c}]$, and β_1,β_2,

$$\begin{aligned}|f(c,\beta_1)-f(c,\beta_2)|\leq& kc^2\mathbb{E}\left[\left|\langle w,\mathbf{\Sigma}^{1/2}(\beta_1-\beta_2)\rangle\right|\right]\\\leq& k\bar{c}^2\kappa_x\left\|\mathbf{\Sigma}^{1/2}(\beta_1-\beta_2)\right\|_2.\end{aligned}$$

Applying the above bound for $\beta_1=\hat{\beta}^{\mathsf{ols}}$ and $\beta_2=\beta^{\mathsf{ols}}$, we obtain with probability $1-3\exp\{-p\}$

$$\left|f(c,\hat{\beta}^{\mathsf{ols}})-f(c,\beta^{\mathsf{ols}})\right|\leq\eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}},\tag{58}$$

where the last step follows from Proposition 7 and the inequality given in (56).

Combining this with the previous bound, and taking into account that $\mu=\tilde{\mu}\sqrt{p}$, for any $c\in[0,\bar{c}]$, with probability $1-5\exp\{-p\}$, we obtain

$$\begin{aligned}\left|\hat{f}(c,\hat{\beta}^{\mathsf{ols}})-f(c,\beta^{\mathsf{ols}})\right|\leq& c'\bar{c}(\kappa_g+\kappa_x/\tilde{\mu})\sqrt{\frac{p}{n/\log(n)}}+\eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}}\\\leq& K\sqrt{\frac{p}{\min\{n/\log(n),|S|\}}}\end{aligned}$$

where $K=\eta\bar{c}\max\{\kappa_g+\kappa_x/\tilde{\mu},k\bar{c}\kappa_x\}$. Here, η depends only on κ_x and γ.

In particular, for $c=\bar{c}$ we observe that

$$\begin{aligned}\hat{f}(\bar{c},\hat{\beta}^{\mathsf{ols}})\geq& f(\bar{c},\beta^{\mathsf{ols}})-K\sqrt{\frac{p}{\min\{n/\log(n),|S|\}}}\\\geq& 1+\epsilon-K\sqrt{\frac{p}{\min\{n/\log(n),|S|\}}}.\end{aligned}$$

Therefore, for sufficiently large n and $|S|$ satisfying $\min\left\{\frac{n}{\log(n)},|S|\right\}>K^2/\bar{\epsilon}^2$ we obtain $\hat{f}(\bar{c},\hat{\beta}^{\mathsf{ols}})>1$. Since this function is continuous and $\hat{f}(0,\hat{\beta}^{\mathsf{ols}})=0$, we obtain the existence of $\hat{c}_\Psi\in[0,\bar{c}]$ with probability at least $1-5\exp\{-p\}$.

Now, since $\hat{c}_\Psi$ and c_Ψ satisfy the equations $\hat{f}(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})=f(c_\Psi,\beta^{\mathsf{ols}})=1$ (with high probability), by the inequality given in (57), with probability at least $1-5\exp\{-p\}$, we obtain

$$\left|1-f(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})\right|=\left|\hat{f}(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})-f(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})\right|\leq c'\bar{c}(\kappa_g+\kappa_x/\tilde{\mu})\sqrt{\frac{p}{n/\log(n)}}.$$

Also, by the same argument in (60), and Proposition 7, we get

$$\left|f(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})-f(\hat{c}_\Psi,\beta^{\mathsf{ols}})\right|\leq k\bar{c}^2\kappa\left\|\mathbf{\Sigma}(\hat{\beta}^{\mathsf{ols}}-\beta^{\mathsf{ols}})\right\|_2\leq\eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}}.$$

Now, using the Taylor's series expansion of $c\to f(c,\beta^{\mathsf{ols}})$ around c_Ψ, and the assumption on the derivative of f with respect to its first argument, we obtain

$$\begin{aligned}\upsilon\left|\hat{c}_\Psi-c_\Psi\right|\leq&\left|f(\hat{c}_\Psi,\beta^{\mathsf{ols}})-f(c_\Psi,\beta^{\mathsf{ols}})\right|\\\leq&\left|f(\hat{c}_\Psi,\beta^{\mathsf{ols}})-f(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})\right|+\left|f(\hat{c}_\Psi,\hat{\beta}^{\mathsf{ols}})-1\right|\\\leq&\eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}}+c'\bar{c}(\kappa_g+\kappa_x/\tilde{\mu})\sqrt{\frac{p}{n/\log(n)}}\\\leq&K\sqrt{\frac{p}{\min\{n/\log(n),|S|\}}}\end{aligned}$$

with probability at least $1-5\exp\{-p\}$. Here, the constant K is the same as before $K=\eta\bar{c}\max\{\kappa_g+\kappa_x/\tilde{\mu},k\bar{c}\kappa_x\}$.

■

Lemma 16 *For a given function $\Psi^{(2)}$ that is Lipschitz continuous with constant k, and uniformly bounded by b, we define the functions f, $\hat{f}$, and the constants $\epsilon, c_\Psi, \bar{c}$ as in Lemma 15. Assume that x_i's are i.i.d. sub-Gaussian with $\|x_i\|_{\psi_2}\leq\kappa_x$. Then, with probability $1-4\exp\{-p\}$, there exists a constant $\hat{c}_\Psi\in(0,\bar{c})$ satisfying the equation*

$$1=\hat{c}_\Psi\ \frac{1}{n}\sum_{i=1}^{n}\Psi^{(2)}(\langle x_i,\hat{\beta}^{\mathsf{ols}}\rangle\hat{c}_\Psi).$$

Moreover, if the derivative of $z \to f(z, \beta^{\mathsf{ols}})$ is bounded below in absolute value (i.e. does not change sign) by $\upsilon > 0$ in the interval $z \in [0, \bar{c}]$, then with probability $1 - 4\exp\{-p\}$, we have

$$|\hat{c}_\Psi - c_\Psi| \leq K\sqrt{\frac{p}{|S|}},$$

where $K = \eta\upsilon^{-1}\bar{c}k \max\left\{(1 + \|\tilde{\beta}\|_2)\|\Sigma\|_2 + b/k, \bar{c}\right\}$, η depends only on γ and κ_x, and $|S|$ is sufficiently large.

Proof [of Lemma 16] The proof follows from the same steps in Lemma 15. First statement is obvious.

Next, we will show the existence of $\hat{c}_\Psi$ using a uniform concentration given by Lemma 19. Let the ellipsoids $\mathcal{B}^\delta_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})$ and $\mathcal{B}^\delta(\tilde{\beta}^{\mathsf{ols}})$, and the event $\mathcal{E}$ be as in Lemma 15. By Proposition 7 and the inequality given in (56), whenever $|S| > \eta p$, we obtain

$$\mathbb{P}\left(\mathcal{E}^C\right) \leq 3\exp\{-p\},$$

where $\mathcal{E}^C$ denotes the complement of the event $\mathcal{E}$, and η is a constant depending only on κ_x and γ. For any $c \in [0, \bar{c}]$, on the event $\mathcal{E}$, we have

$$\left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \hat{\beta}^{\mathsf{ols}})\right| \leq \sup_{\beta \in \mathcal{B}^\delta_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})} \left|\hat{f}(c, \beta) - f(c, \beta)\right|.$$

Using the same arguments as in the previous lemma that led to (57), we obtain the following inequality

$$\begin{aligned}
&\mathbb{P}\left(\sup_{c\in[0,\bar{c}]} \left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \hat{\beta}^{\mathsf{ols}})\right| > \epsilon\right) \\
&\leq \mathbb{P}\left(\sup_{c\in[0,\bar{c}]} \sup_{\beta \in \mathcal{B}^\delta_{\mathbf{\Sigma}}(\beta^{\mathsf{ols}})} \left|\hat{f}(c, \beta) - f(c, \beta)\right| > \epsilon\right) + 3\exp\{-p\}, \\
&\leq \mathbb{P}\left(\sup_{\beta \in \mathcal{B}_{\bar{c}\delta}(\tilde{\beta}^{\mathsf{ols}})} \left|\frac{1}{n}\sum_{i=1}^n \Psi^{(2)}(\langle w_i, \beta\rangle) - \mathbb{E}\left[\Psi^{(2)}(\langle w, \beta\rangle)\right]\right| > \epsilon/\bar{c}\right) + 3\exp\{-p\}
\end{aligned}$$

where $\mathcal{B}_{\bar{c}\delta}(\tilde{\beta}^{\mathsf{ols}})$ is the ball centered around $\tilde{\beta}^{\mathsf{ols}} = \mathbf{\Sigma}^{1/2}\beta^{\mathsf{ols}}$ with radius $\delta = \eta\sqrt{p/|S|}$.

Then, using Lemma 19, we obtain

$$\mathbb{P}\left(\sup_{c\in[0,\bar{c}]} \left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \hat{\beta}^{\mathsf{ols}})\right| > 2\bar{c}\left(k\left\{\|\tilde{\beta}\|_2 + \eta\sqrt{\frac{p}{|S|}}\right\}\|\Sigma\|_2 + b\right)\sqrt{\frac{p}{n}}\right) \leq 4\exp\{-p\}. \tag{59}$$

By the Lipschitz property of $\Psi^{(2)}$ as well as sub-Gaussian property of x, we have for any $c \in [0, \bar{c}]$, and β_1, β_2,

$$\begin{aligned}
|f(c, \beta_1) - f(c, \beta_2)| \leq& kc^2\mathbb{E}\left[\left|\langle w, \mathbf{\Sigma}^{1/2}(\beta_1 - \beta_2)\rangle\right|\right] \\
\leq& k\bar{c}^2\kappa_x\left\|\mathbf{\Sigma}^{1/2}(\beta_1 - \beta_2)\right\|_2.
\end{aligned}$$

Applying the above bound for $\beta_1 = \hat{\beta}^{\mathsf{ols}}$ and $\beta_2 = \beta^{\mathsf{ols}}$, we obtain with probability $1 - 3\exp\{-p\}$

$$\left|f(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \beta^{\mathsf{ols}})\right| \leq \eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}}, \tag{60}$$

where the last step follows from Proposition 7 and the inequality given in (56).

Combining this with the previous bound, for any $c \in [0, \bar{c}]$, with probability $1 - 4\exp\{-p\}$, we obtain

$$\begin{aligned}
\left|\hat{f}(c, \hat{\beta}^{\mathsf{ols}}) - f(c, \beta^{\mathsf{ols}})\right| \leq& 2\bar{c}\left(k\|\tilde{\beta}\|_2\|\Sigma\|_2 + \eta k\|\Sigma\|_2\sqrt{\frac{p}{|S|}} + b\right)\sqrt{\frac{p}{n}} + \eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}} \\
=& 2\bar{c}k\left\{\|\tilde{\beta}\|_2\|\Sigma\|_2\sqrt{\frac{p}{n}} + \eta\|\Sigma\|_2\frac{p}{\sqrt{|S|n}} + b\sqrt{\frac{p}{n}} + \eta\bar{c}\kappa_x\sqrt{\frac{p}{|S|}}\right\} \\
\leq& \eta\bar{c}k\max\left\{(1 + \|\tilde{\beta}\|_2)\|\Sigma\|_2 + b/k, \bar{c}\right\}\sqrt{\frac{p}{|S|}} = K\sqrt{\frac{p}{|S|}}
\end{aligned}$$

where $K = \eta\bar{c}k\max\left\{(1 + \|\tilde{\beta}\|_2)\|\Sigma\|_2 + b/k, \bar{c}\right\}$, and $|S| > \eta p$. Here, η depends only on the constants κ_x and γ. In particular, for $c = \bar{c}$ we observe that

$$\begin{aligned}
\hat{f}(\bar{c}, \hat{\beta}^{\mathsf{ols}}) \geq& f(\bar{c}, \beta^{\mathsf{ols}}) - K\sqrt{\frac{p}{|S|}} \\
\geq& 1 + \epsilon - K\sqrt{\frac{p}{|S|}}.
\end{aligned}$$

Therefore, for sufficiently large $|S|$ satisfying $|S| > K^2 p$, we obtain $\hat{f}(\bar{c}, \hat{\beta}^{\mathsf{ols}}) > 1$. Since this function is continuous and $\hat{f}(0, \hat{\beta}^{\mathsf{ols}}) = 0$, we obtain the existence of $\hat{c}_\Psi \in [0, \bar{c}]$ with probability at least $1 - 4\exp\{-p\}$.

Now, since $\hat{c}_\Psi$ and c_Ψ satisfy the equations $\hat{f}(\hat{c}_\Psi, \hat{\beta}^{\mathsf{ols}}) = f(c_\Psi, \beta^{\mathsf{ols}}) = 1$ (with high probability), by the inequality given in (59), with probability at least $1 - 4\exp\{-p\}$, we obtain

$$\left|1 - f(\hat{c}_\Psi, \hat{\beta}^{\mathsf{ols}})\right| = \left|\hat{f}(\hat{c}_\Psi, \hat{\beta}^{\mathsf{ols}}) - f(\hat{c}_\Psi, \hat{\beta}^{\mathsf{ols}})\right| \leq 2\bar{c}\left(k\left\{\|\tilde{\beta}\|_2 + \eta\sqrt{\frac{p}{|S|}}\right\}\|\Sigma\|_2 + b\right)\sqrt{\frac{p}{n}}.$$

Now, using the Taylor's series expansion of $c \to f(c, \beta^{\mathsf{ols}})$ around c_Ψ, and the assumption on the derivative of f with respect to its first argument, we obtain

$$\begin{aligned}
\upsilon\,|\hat{c}_\Psi - c_\Psi| \leq& \left|f(\hat{c}_\Psi, \beta^{\mathsf{ols}}) - f(c_\Psi, \beta^{\mathsf{ols}})\right| \\
\leq& \left|f(\hat{c}_\Psi, \beta^{\mathsf{ols}}) - f(\hat{c}_\Psi, \hat{\beta}^{\mathsf{ols}})\right| + \left|f(\hat{c}_\Psi, \hat{\beta}^{\mathsf{ols}}) - 1\right| \\
\leq& \eta k\bar{c}^2\kappa_x\sqrt{\frac{p}{|S|}} + 2\bar{c}\left(k\left\{\|\tilde{\beta}\|_2 + \eta\sqrt{\frac{p}{|S|}}\right\}\|\Sigma\|_2 + b\right)\sqrt{\frac{p}{n}} \\
\leq& K\sqrt{\frac{p}{|S|}}
\end{aligned}$$

with probability at least $1-4\exp\{-p\}$. Here, the constant K is the same as before $K = \eta\bar{c}k\max\left\{(1+\|\tilde{\beta}\|_2)\,\|\Sigma\|_2 + b/k, \bar{c}\right\}$. ■

Proof [of Theorem 8] We have

$$\left\|\hat{\beta}^{\mathsf{sls}} - \beta^{\mathsf{pop}}\right\|_\infty \leq \left\|c_\Psi\beta^{\mathsf{ols}} - \beta^{\mathsf{pop}}\right\|_\infty + \left\|\hat{c}_\Psi\hat{\beta}^{\mathsf{ols}} - c_\Psi\beta^{\mathsf{ols}}\right\|_\infty, \tag{61}$$

where we used the triangle inequality for the ℓ_∞ norm. The first term on the right hand side can be bounded using Theorem 3 and Corollary 5. We write

$$\left\|c_\Psi\beta^{\mathsf{ols}} - \beta^{\mathsf{pop}}\right\|_\infty \leq \eta_1\,\frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}}, \tag{62}$$

for $\eta_1 = 8k\bar{c}\kappa^3\rho_\infty\|\mathbf{\Sigma}^{1/2}\|_\infty(\tau/r)$.

For the second term, we write

$$\begin{aligned}\left\|\hat{c}_\Psi\hat{\beta}^{\mathsf{ols}} - c_\Psi\beta^{\mathsf{ols}}\right\|_\infty &= \left\|\hat{c}_\Psi\hat{\beta}^{\mathsf{ols}} \pm \hat{c}_\Psi\beta^{\mathsf{ols}} - c_\Psi\beta^{\mathsf{ols}}\right\|_\infty, \\ &\leq |\hat{c}_\Psi|\left\|\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}}\right\|_\infty + |\hat{c}_\Psi - c_\Psi|\left\|\beta^{\mathsf{ols}}\right\|_\infty,\end{aligned} \tag{63}$$

where the first step follows from triangle inequality. By Lemma 16, for sufficiently large n and $|S|$, with probability $1-4\exp\{-p\}$, the constant $\hat{c}_\Psi$ exists and it is in the interval $(0,\bar{c}]$. By the same lemma, with probability $1-4\exp\{-p\}$, we have

$$|\hat{c}_\Psi - c_\Psi| \leq \eta_4\sqrt{\frac{p}{|S|}}, \tag{64}$$

where $\eta_4 = \eta' v^{-1}\bar{c}k\max\left\{(\|\Sigma^{1/2}\beta^{\mathsf{ols}}\|_2+1)\|\Sigma\|_2 + b/k, \bar{c}\right\}$ for some constant η' depending on the sub-Gaussian norms κ and γ.

Also, by the norm equivalence and Proposition 7, we have with probability $1-4\exp\{-p\}$

$$\left\|\hat{\beta}^{\mathsf{ols}} - \beta^{\mathsf{ols}}\right\|_\infty \leq \eta_3\sqrt{\frac{p}{|S|}}, \tag{65}$$

for $\eta_3 = \eta''\lambda_{\min}^{-1/2}$, where η'' is constant depending only on γ and κ.

Finally, combining all these inequalities with the last line of (61), we have with probability $1-4\exp\{-p\}$,

$$\begin{aligned}\left\|\hat{\beta}^{\mathsf{sls}} - \beta^{\mathsf{pop}}\right\|_\infty &\leq \eta_1\frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}} + \eta_3\bar{c}\,\sqrt{\frac{p}{|S|}} + \eta_4\left\|\beta^{\mathsf{ols}}\right\|_\infty\sqrt{\frac{p}{|S|}}, \\ &\leq \eta_1\frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}} + \left(\eta_3\bar{c} + \eta_4\left\|\beta^{\mathsf{ols}}\right\|_\infty\right)\sqrt{\frac{p}{|S|}}, \\ &= \eta_1\frac{\|\beta^{\mathsf{pop}}\|_\infty}{\sqrt{p}} + \eta_2\sqrt{\frac{p}{|S|}},\end{aligned} \tag{66}$$

where

$$\begin{aligned}\eta_1 &= \eta k\bar{c}\rho_\infty(\tau/r)\|\mathbf{\Sigma}^{1/2}\|_\infty \\ \eta_2 &= \eta_3\bar{c} + \eta_4\left\|\beta^{\mathsf{ols}}\right\|_\infty = \eta\bar{c}\left(\lambda_{\min}^{-1/2} + kv^{-1}\max\left\{(\|\Sigma^{1/2}\beta^{\mathsf{ols}}\|_2+1)\|\Sigma\|_2 + b/k, \bar{c}\right\}\right)\end{aligned} \tag{67}$$

■

Proof [of Theorem 9] Proof is essentially the same as that of Theorem 8, where this time we use Lemma 16 instead of Lemma 15. ■

Proof [of Corollary 6] The normal equations for the lasso minimization yields

$$\mathbb{E}\left[xx^T\right]\beta_\lambda^{\mathsf{lasso}} - \beta^{\mathsf{ols}} + \lambda s = 0,$$

where $s \in \partial\left\|\beta_\lambda^{\mathsf{lasso}}\right\|_1$. It is well-known that under the orthogonal design where the covariates have i.i.d. entries, the above equation reduces to $\mathsf{soft}(\beta^{\mathsf{ols}};\lambda) = \beta_\lambda^{\mathsf{lasso}}$, where $\mathsf{soft}(\,\cdot\,;\lambda)$ denotes the soft thresholding operator at level λ. For any $\beta\in\mathbb{R}^p$, let $\mathrm{supp}(\beta)$ denote the support of β, i.e., the set $\{i\in[p]:\beta_i\neq 0\}$. We have

$$\mathrm{supp}(\beta_\lambda^{\mathsf{lasso}}) = \{i\in[p]:\beta_{\lambda,i}^{\mathsf{lasso}}\neq 0\} = \{i\in[p]:|\beta_i^{\mathsf{ols}}|>\lambda\}$$

By Theorem 3, we have $|\beta_i^{\mathsf{ols}}| \leq \frac{1}{c_\Psi}|\beta_i^{\mathsf{pop}}| + \delta$, which implies that

$$\mathrm{supp}(\beta_\lambda^{\mathsf{lasso}}) \subset \left\{i\in[p]:\frac{1}{c_\Psi}|\beta_i^{\mathsf{pop}}| + \delta \geq \lambda\right\}.$$

Hence, whenever $\lambda\geq\delta$, we have $\mathrm{supp}(\beta_\lambda^{\mathsf{lasso}})\subset\mathrm{supp}(\beta^{\mathsf{pop}})$. Further, we have by Theorem 3

$$\frac{1}{c_\Psi}|\beta_i^{\mathsf{pop}}| \leq |\beta_i^{\mathsf{ols}}| + \delta.$$

Hence, whenever $|\beta_i^{\mathsf{pop}}| > c_\Psi\,(\lambda+\delta)$, we get $|\beta_i^{\mathsf{ols}}|>\lambda$. If this condition is satisfied for any entry in the support of β^{pop}, the corresponding lasso coefficient will be non-zero. Therefore, we get $\mathrm{supp}(\beta^{\mathsf{pop}})\subset\mathrm{supp}(\beta_\lambda^{\mathsf{lasso}})$ under this assumption. Combining this with the previous result, we conclude the proof. ■

11. Auxiliary Lemmas

Lemma 17 (Sub-exponential vector concentration) *Let $x_1, x_2, ..., x_n$ be independent centered sub-exponential random vectors with $\max_i\|x_i\|_{\psi_1} = \kappa$. Then we have*

$$\mathbb{P}\left(\left\|\frac{1}{n}\sum_{i=1}^n x_i\right\|_2 > c\kappa\sqrt{\frac{p}{n}}\right) \leq \exp\{-p\}. \tag{68}$$

whenever $n > 4c^2p$ for an absolute constant c.

Proof [of Lemma 17] For a vector $z \in \mathbb{R}^p$, we have $\|z\|_2 = \sup_{\|u\|_2=1} \langle u, z\rangle$ since the dual of ℓ_2 norm is itself. Therefore, we write

$$\mathbb{P}\left(\left\|\frac{1}{n}\sum_{i=1}^n x_i\right\|_2 > t\right) = \mathbb{P}\left(\sup_{\|u\|_2=1} \frac{1}{n}\sum_{i=1}^n \langle u, x_i\rangle > t\right).$$

Now, let $\mathcal{N}_\epsilon$ be an ϵ-net over $\mathcal{S}^{p-1} = \{u \in \mathbb{R}^p : \|u\|_2 = 1\}$, and observe that

$$\max_{u\in\mathcal{N}_\epsilon} \langle u, x\rangle \geq (1-\epsilon) \sup_{\|u\|_2=1} \langle u, x\rangle \quad = (1-\epsilon)\|x\|_2,$$

with $|\mathcal{N}_\epsilon| \leq (1+2/\epsilon)^p$. Hence, we may write

$$\begin{aligned}\mathbb{P}\left(\sup_{\|u\|_2=1} \frac{1}{n}\sum_{i=1}^n \langle u, x_i\rangle > t\right) \leq& \mathbb{P}\left(\max_{u\in\mathcal{N}_\epsilon} \frac{1}{n}\sum_{i=1}^n \langle u, x_i\rangle > t(1-\epsilon)\right),\\ \leq& |\mathcal{N}_\epsilon|\, \mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \langle u, x_i\rangle > t(1-\epsilon)\right).\end{aligned}$$

For any $u \in \mathcal{S}^{p-1}$, we have $\|\langle u, x_i\rangle\|_{\psi_1} \leq \kappa$. Then, by the Bernstein-type inequality for sub-exponential random variables (Vershynin, 2010), we have

$$\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \langle u, x_i\rangle > t(1-\epsilon)\right) \leq \exp\left\{-cn\min\left\{\frac{t^2(1-\epsilon)^2}{\kappa^2}, \frac{t(1-\epsilon)}{\kappa}\right\}\right\},$$

for an absolute constant c. Therefore, the probability on the left hand side of (68) can be bounded by

$$\left(1+\frac{2}{\epsilon}\right)^p \exp\left\{-cn\frac{t^2(1-\epsilon)^2}{\kappa^2}\right\} = \exp\left\{-cn\frac{t^2(1-\epsilon)^2}{\kappa^2} + p\log\left(1+\frac{2}{\epsilon}\right)\right\},$$

whenever $t < \kappa/(1-\epsilon)$. Choosing $\epsilon = 0.5$ and for an absolute constant $c' > 3.24/c$ and letting $t = c'\kappa\sqrt{\frac{p}{n}}$, we conclude the proof. ■

Lemma 18 *Let $B(\tilde\beta)$ denote the ball centered around $\tilde\beta$ with radius δ, i.e.,*

$$B(\tilde\beta) = \left\{\beta : \left\|\beta - \tilde\beta\right\|_2 \leq \delta\right\}.$$

For $i = 1, ..., n$, let $x_i \in \mathbb{R}^p$ be i.i.d. sub-Gaussian random vectors with $\|x_i\|_{\psi_2} \leq \kappa_x$. Given a function $g : \mathbb{R} \to \mathbb{R}$ that is Lipschitz continuous with k, and satisfying $\sup_{\beta\in B(\tilde\beta)} \|g(\langle x_i, \beta\rangle)\|_{\psi_2} \leq \kappa_g$, we have

$$\mathbb{P}\left(\sup_{\beta\in B}\left|\frac{1}{n}\sum_{i=1}^n g(\langle x_i, \beta\rangle) - \mathbb{E}\left[g(\langle x, \beta\rangle)\right]\right| > c(\kappa_g + \kappa_x/\tilde\mu)\sqrt{\frac{p}{n/\log(n)}}\right) \leq 2\exp\{-p\},$$

whenever $np > 51\max\{\chi, \chi^{-1}\}$ for $\chi = (\kappa_g + \kappa_x/\tilde\mu)^2/(c\delta^2k^2\tilde\mu^2)$. Above, c is an absolute constant.

Proof [of Lemma 18] Let $\mathbb{E}[\|x\|_2] = \mu = \tilde\mu\sqrt{p}$ and for $\epsilon > 0$, $\beta \in B(\tilde\beta)$ and $w \in \mathbb{R}^p$ define the bounding functions

$$l_\beta(w) = g(\langle w, \beta\rangle) - \epsilon\|w\|_2/4\mu, \quad u_\beta(w) = g(\langle w, \beta\rangle) + \epsilon\|w\|_2/4\mu.$$

Let $\mathcal{N}_\Delta$ be a net over $B(\tilde\beta)$ in the sense that for any $\beta_1 \in B(\tilde\beta)$, $\exists\beta_2 \in \mathcal{N}_\Delta$ such that $\|\beta_1 - \beta_2\|_2 \leq \Delta$. We fix $\Delta_* = \epsilon/(4k\mu)$ and write $\forall\beta_1 \in B$, $\exists\beta_2 \in \mathcal{N}_{\Delta_*}$,

1. an upper bound of the form:

$$\begin{aligned}g(\langle w, \beta_1\rangle) \leq& g(\langle w, \beta_2\rangle) + k\left|\langle w, \beta_1 - \beta_2\rangle\right|,\\ \leq& g(\langle w, \beta_2\rangle) + k\left\|w\right\|_2\Delta_* = u_{\beta_2}(w),\end{aligned}$$

2. and a lower bound of the form:

$$\begin{aligned}g(\langle w, \beta_1\rangle) \geq& g(\langle w, \beta_2\rangle) - k\left|\langle w, \beta_1 - \beta_2\rangle\right|,\\ \geq& g(\langle w, \beta_2\rangle) - k\left\|w\right\|_2\Delta_* = l_{\beta_2}(w),\end{aligned}$$

where the second steps in the above inequalities follow from the Cauchy-Schwarz inequality. These functions are called *bracketing functions* in the context of empirical process theory.

Hence, we can write that $\forall\beta_1 \in B(\tilde\beta)$, $\exists\beta_2 \in \mathcal{N}_{\Delta_*}$ such that

$$\begin{aligned}\frac{1}{n}\sum_{i=1}^n l_{\beta_2}(x_i) - \mathbb{E}\left[l_{\beta_2}(x)\right] - \epsilon/2 \leq& \frac{1}{n}\sum_{i=1}^n g(\langle x_i, \beta_1\rangle) - \mathbb{E}\left[g(\langle x, \beta_1\rangle)\right],\\ \leq& \frac{1}{n}\sum_{i=1}^n u_{\beta_2}(x_i) - \mathbb{E}\left[u_{\beta_2}(x)\right] + \epsilon/2.\end{aligned}$$

The above inequalities translate to the following conclusion: Whenever the following event happens,

$$\left\{\left|\frac{1}{n}\sum_{i=1}^n g(\langle x_i, \beta_1\rangle) - \mathbb{E}\left[g(\langle x, \beta_1\rangle)\right]\right| > \epsilon\right\},$$

at least one of the following events happens

$$\left\{\frac{1}{n}\sum_{i=1}^n u_{\beta_2}(x_i) - \mathbb{E}\left[u_{\beta_2}(x)\right] > \epsilon/2\right\} \quad \text{or} \quad \left\{\frac{1}{n}\sum_{i=1}^n l_{\beta_2}(x_i) - \mathbb{E}\left[l_{\beta_2}(x)\right] < -\epsilon/2\right\}.$$

Therefore, using the union bound on the above events, we may obtain

$$\begin{aligned}&\mathbb{P}\left(\sup_{\beta\in B(\tilde\beta)}\left|\frac{1}{n}\sum_{i=1}^n g(\langle x_i, \beta\rangle) - \mathbb{E}\left[g(\langle x, \beta\rangle)\right]\right| > \epsilon\right) \qquad (69)\\ &\leq \mathbb{P}\left(\max_{\beta\in\mathcal{N}_{\Delta_*}} \frac{1}{n}\sum_{i=1}^n u_\beta(x_i) - \mathbb{E}\left[u_\beta(x)\right] > \epsilon/2\right)\\ &\quad + \mathbb{P}\left(\max_{\beta\in\mathcal{N}_{\Delta_*}} \frac{1}{n}\sum_{i=1}^n l_\beta(x_i) - \mathbb{E}\left[l_\beta(x)\right] < -\epsilon/2\right).\end{aligned}$$

Note that the right hand side of the above inequality has two terms both of which are of the same form. For simplicity, we bound only the first one. The bound for the second one follows from the exact same steps.

The relation between sub-Gaussian and sub-exponential norms (Vershynin, 2010) allows us to write

$$\|\|x\|_2\|_{\psi_2}^2 \leq \|\|x\|_2^2\|_{\psi_1} \leq \sum_{i=1}^{p} \|x_i^2\|_{\psi_1} \leq 2\sum_{i=1}^{p} \|x_i\|_{\psi_2}^2 \leq 2\kappa_x^2 p, \tag{70}$$

where the second step follows from the triangle inequality. Hence, we conclude that $\|x\|_2 - \mathbb{E}[\|x\|_2]$ is a centered sub-Gaussian random variable with norm upper bounded by $3\kappa_x\sqrt{p}$.

For $\epsilon < 4/3$, we notice that the random variable $u_\beta(x) = g(\langle x, \beta\rangle) + \epsilon\|x\|_2/4\mu$ is also sub-Gaussian with norm

$$\|u_\beta(x)\|_{\psi_2} \leq \kappa_g + \frac{\epsilon}{4\tilde{\mu}} 3\kappa_x \leq \kappa_g + \kappa_x/\tilde{\mu},$$

and consequently, the centered random variable $u_\beta(x) - \mathbb{E}[u_\beta(x)]$ has the sub-Gaussian norm upper bounded by $2\kappa_g + 2\kappa_x/\tilde{\mu}$.

Then, by the Hoeffding-type inequality for the sub-Gaussian random variables, we obtain

$$\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^{n} u_\beta(x_i) - \mathbb{E}[u_\beta(x)] > \epsilon/2\right) \leq \exp\left\{-cn\frac{\epsilon^2}{(\kappa_g + \kappa_x/\tilde{\mu})^2}\right\}$$

for an absolute constant $c > 0$.

By the same argument above, one can obtain the same result for the function $l_\beta(x)$. Using Hoeffding bounds in (69) along with the union bound over the net, we immediately obtain

$$\mathbb{P}\left(\sup_{\beta\in B(\tilde{\beta})} \left|\frac{1}{n}\sum_{i=1}^{n} g(\langle x_i, \beta\rangle) - \mathbb{E}[g(\langle x, \beta\rangle)]\right| > \epsilon\right) \leq 2|\mathcal{N}_{\Delta_*}| \exp\left\{-cn\frac{\epsilon^2}{(\kappa_g + \kappa_x/\tilde{\mu})^2}\right\}$$

for some absolute constant c.

Using a standard covering argument over the net $\mathcal{N}_{\Delta_*}$ as given in Erdogdu (2015), we have

$$|\mathcal{N}_{\Delta_*}| \leq \left(\frac{\delta\sqrt{p}}{\Delta_*}\right)^p = \left(\frac{4\delta k\tilde{\mu}p}{\epsilon}\right)^p.$$

Combining this with the previous bound, and choosing

$$\epsilon^2 = \frac{p}{n}\frac{(\kappa_g + \kappa_x/\tilde{\mu})^2}{2c}\log\left(\frac{32c\delta^2k^2\tilde{\mu}^2pn}{(\kappa_g + \kappa_x/\tilde{\mu})^2}\right)$$

we get

$$\begin{aligned}
&2\left(\frac{4\delta k\tilde{\mu}p}{\epsilon}\right)^p \exp\left\{-cn\frac{\epsilon^2}{(\kappa_g + \kappa_x/\tilde{\mu})^2}\right\} \\
&= 2\exp\left\{-\frac{p}{2}\log\log\left(\frac{32c\delta^2k^2\tilde{\mu}^2pn}{(\kappa_g + \kappa_x/\tilde{\mu})^2}\right)\right\} \leq 2\exp\{-p\},
\end{aligned}$$

whenever $np > 51\max\{\chi, \chi^{-1}\}$ for $\chi = (\kappa_g + \kappa_x/\tilde{\mu})^2/(c\delta^2k^2\tilde{\mu}^2)$. ■

Lemma 19 *Let $B(\tilde{\beta})$ denote the ball centered around $\tilde{\beta}$ with radius δ, i.e.,*

$$B(\tilde{\beta}) = \left\{\beta : \left\|\beta - \tilde{\beta}\right\|_2 \leq \delta\right\}.$$

For $i = 1, ..., n$, let $x_i \in \mathbb{R}^p$ be i.i.d. random vectors with a covariance matrix Σ. Given a function $g : \mathbb{R} \to \mathbb{R}$ that is uniformly bounded by $b > 0$, and Lipschitz continuous with k,

$$\mathbb{P}\left(\sup_{\beta\in B(\tilde{\beta})} \left|\frac{1}{n}\sum_{i=1}^{n} \Psi^{(2)}(\langle x_i, \beta\rangle) - \mathbb{E}\left[\Psi^{(2)}(\langle x, \beta\rangle)\right]\right| \geq 2\left\{k(\|\tilde{\beta}\|_2 + \delta)\|\Sigma\|_2 + b\right\}\sqrt{\frac{p}{n}}\right) \leq e^{-p}. \tag{71}$$

Proof [of Lemma 19] This is a standard result in the theory of Rademacher complexity – see for example Bartlett and Mendelson (2002). Define the following empirical process

$$G(x_1, ..., x_n) = \sup_{\beta\in B(\tilde{\beta})} \left|\frac{1}{n}\sum_{i=1}^{n} g(\langle x_i, \beta\rangle) - \mathbb{E}[g(\langle x, \beta\rangle)]\right|. \tag{72}$$

We notice that for any i, we have

$$\left|G(.., x_i, ..) - G(.., x_i', ..)\right| \leq \frac{2b}{n}, \tag{73}$$

due to boundedness of the function g. By the McDiarmid's inequality (Azuma), we have

$$\mathbb{P}(G > \epsilon) \leq \exp\left\{-\frac{(\epsilon - \mathbb{E}[G])^2 n}{2b^2}\right\}. \tag{74}$$

The above inequality – when stated differently – reads that with probability at least $1 - \exp\{-p\}$, we have

$$G < \mathbb{E}[G] + b\sqrt{\frac{2p}{n}}. \tag{75}$$

For $\sigma_1, ..., \sigma_n$ i.i.d. random variables with $\mathbb{P}(\sigma_i = \pm 1) = 0.5$, we have

$$\mathbb{E}[G] \leq \frac{2}{n}\mathbb{E}\left[\sup_{\beta\in B(\tilde{\beta})} \sum_{i=1}^{n} \sigma_i g(\langle x_i, \beta\rangle)\right] = \mathcal{R}(g \circ \mathcal{B}(\tilde{\beta})), \tag{76}$$

where $\mathcal{R}$ denoting the Rademacher complexity. Since g is Lipschitz continuous with constant k, we have $\mathcal{R}(g \circ B(\tilde{\beta})) \leq k\mathcal{R}(B(\tilde{\beta}))$ by the Ledoux-Talagrand contraction inequality. We

write

$$\begin{aligned}\mathcal{R}(B(\tilde{\beta})) =& \frac{2}{n}\mathbb{E}\left[\sup_{\beta\in B(\tilde{\beta})}\sum_{i=1}^{n}\sigma_i\langle x_i,\beta\rangle\right] \leq \frac{2}{n}\mathbb{E}\left[\sup_{\beta\in B(\tilde{\beta})}\left\|\sum_{i=1}^{n}\sigma_i x_i\right\|_2\|\beta\|_2\right], \\ \leq& (\|\tilde{\beta}\|_2+\delta)\frac{2}{n}\mathbb{E}\left[\left\|\sum_{i=1}^{n}\sigma_i x_i\right\|_2^2\right]^{1/2} = (\|\tilde{\beta}\|_2+\delta)\frac{2}{n}\left(\sum_{i=1}^{n}\mathbb{E}\left[\|x_i\|_2^2\right]\right)^{1/2}, \\ \leq& 2(\|\tilde{\beta}\|_2+\delta)\|\Sigma\|_2\sqrt{\frac{p}{n}}.\end{aligned} \tag{77}$$

Combining this with the previous results, we obtain

$$\mathbb{P}\left(\sup_{\beta\in B(\tilde{\beta})}\left|\frac{1}{n}\sum_{i=1}^{n}\Psi^{(2)}(\langle x_i,\beta\rangle)-\mathbb{E}\left[\Psi^{(2)}(\langle x,\beta\rangle)\right]\right| \geq 2\left\{k(\|\tilde{\beta}\|_2+\delta)\|\Sigma\|_2+b\right\}\sqrt{\frac{p}{n}}\right) \leq e^{-p}.$$

■

12. Additional Experiments

In this section, we provide additional experiments. The overall setting is the same as Section 8. The only difference is that we change the sampling distribution of the datasets, which are stated in the title of each plot. As in Section 8, SLS estimator outperforms its competitors by a large margin in terms of the computation time.

The results are provided in Figures 7 and 6, and Table 3.

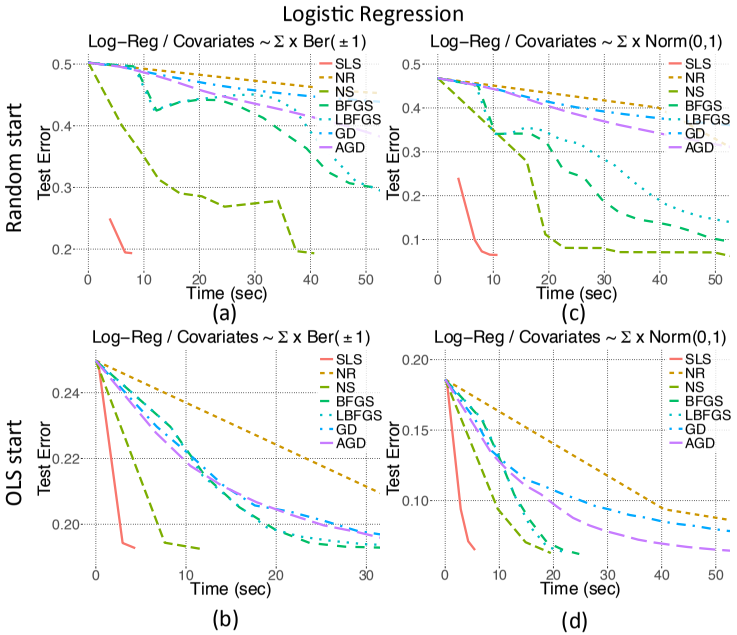

Figure 6: Additional experiments comparing the performance of SLS to that of MLE obtained with various optimization algorithms on several datasets. SLS is represented with red straight line. The details are provided in Table 3

Table 3: Details of the experiments shown in Figures 7 and 6.

Abstract

Forward-backward selection is one of the most basic and commonly-used feature selection algorithms available. It is also general and conceptually applicable to many different types of data. In this paper, we propose a heuristic that significantly improves its running time, while preserving predictive performance. The idea is to temporarily discard the variables that are conditionally independent with the outcome given the selected variable set. Depending on how those variables are reconsidered and reintroduced, this heuristic gives rise to a family of algorithms with increasingly stronger theoretical guarantees. In distributions that can be faithfully represented by Bayesian networks or maximal ancestral graphs, members of this algorithmic family are able to correctly identify the Markov blanket in the sample limit. In experiments we show that the proposed heuristic increases computational efficiency by about 1-2 orders of magnitude, while selecting fewer or the same number of variables and retaining predictive performance. Furthermore, we show that the proposed algorithm and feature selection with LASSO perform similarly when restricted to select the same number of variables, making the proposed algorithm an attractive alternative for problems where no (efficient) algorithm for LASSO exists.

Keywords: Feature Selection, Forward Selection, Markov Blanket Discovery, Bayesian Networks, Maximal Ancestral Graphs

1. Introduction

The problem of feature selection (a.k.a. variable selection) in supervised learning tasks can be defined as the problem of selecting a minimal-size subset of the variables that leads to an optimal, multivariate predictive model for a target variable (outcome) of interest (Tsamardinos and Aliferis, 2003). Thus, the feature selection's task is to filter out irrelevant variables and variables that are superfluous given the selected ones (that is, weakly relevant variables, see (John et al., 1994; Tsamardinos and Aliferis, 2003)).

Solving the feature selection problem has several advantages. Arguably, the most important one is knowledge discovery: by removing superfluous variables it improves intuition and understanding about the data-generating mechanisms. This is no accident as solving the feature selection problem has been linked to the data-generating causal network (Tsamardinos and Aliferis, 2003). In fact, *it is often the case that the primary goal of data analysis is feature selection* and not the actual resulting predictive model. This is particularly true in medicine and biology where the features selected may direct future experiments and studies. Feature selection is also employed to reduce the cost of measuring the features to make operational a predictive model; for example, it can reduce the monetary cost or inconvenience to a patient of applying a diagnostic model by reducing the number of medical tests and measurements required to perform on a subject for providing a diagnosis. Feature selection also often improves the predictive performance of the resulting model in practice, especially in high-dimensional settings. This is because a good-quality selection of features facilitates modeling, particularly for algorithms susceptible to the curse of dimensionality. There has been a lot of research on feature selection methods in the statistical and machine learning literature. An introduction to the topic, as well as a review of many, prominent methods can be found in (Guyon and Elisseeff, 2003), while the connections between feature selection, the concept of relevancy, and probabilistic graphical models is in (John et al., 1994; Tsamardinos and Aliferis, 2003).

We will focus on forward and backward selection algorithms, which are specific instances of stepwise methods (Kutner et al., 2004; Weisberg, 2005). These methods are some of the oldest, simplest and most commonly employed feature selection methods. An attractive property of stepwise methods is that they are very general, and are applicable to different types of data. For instance, stepwise methods using conditional independence tests can be directly applied to (a) mixed continuous and categorical predictors, (b) cross-sectional or time course data, (c) continuous, nominal, ordinal or time-to-event outcomes, among others, (d) with non-linear tests, such as kernel-based methods (Zhang et al., 2011), and (e) to heteroscedastic data using robust tests; many of the aforementioned tests, along with others have been implemented in the MXM R package (Lagani et al., 2017). The main drawback of forward selection is its computational cost. In order to select k variables, it performs $O(pk)$ tests for variable inclusion, where p is the total number of variables in the input data. This is acceptable for low-dimensional datasets, but becomes unmanageable with increasing dimensionality. Another issue is that forward selection suffers from multiple testing problems and thus may select a large number of irrelevant variables (Flom and Cassell, 2007).

In computer science, forward-backward selection has re-appeared in the context of Markov blanket discovery and Bayesian network learning (Margaritis and Thrun, 2000; Tsamardinos et al., 2003b; Margaritis, 2009), and has been shown to be optimal for distributions that can be faithfully represented by causal graphs. In the signal processing community forward selection is known as orthogonal least squares (Chen et al., 1989). Other algorithms, such as LASSO (Tibshirani, 1996), least-angle regression (LARS) (Efron et al., 2004), forward stagewise regression (FSR) (Efron et al., 2004) and orthogonal matching pursuit (OMP) (Pati et al., 1993; Davis et al., 1994) are all variations of the basic stepwise selection algorithm, while information-theoretic feature selection methods are all approximations of the forward phase using discrete data (Brown et al., 2012). A detailed comparison between LASSO, LARS and FSR is given in (Efron et al., 2004), a comparison between LARS and OMP can be found in (Hameed, 2012), while a comparison between OMP and forward selection (called orthogonal least squares) can be found in (Blumensath and Davies, 2007). We proceed with a brief high-level comparison of the above with the forward selection algorithm. All of the above methods select the next feature using some selection criterion and are equipped with a stopping criterion. Intuitively, they all select the feature that provides the most information for the errors (residuals) of the current model. Forward selection on the other hand, selects the feature that leads to a model providing

the most additional information, given all selected variables. In LASSO, both forward and backward steps can be performed at each iteration. After a feature is selected, forward selection and OMP create a new unrestricted model that also contains the newly selected feature. LASSO, LARS and FSR create a new model by updating the previous one, constraining the coefficients of the new model. LASSO has a stopping criterion based on the L1-norm of the coefficients of the current variables. *Given this synthetic view and connections between the algorithms, we would like to note that any extension to stepwise methods, such as the one proposed in this work, can be translated and directly applied with any of the above feature selection algorithms.*

In this work we extend the forward selection algorithm to deal with the problems above. In Section 3 we propose **early dropping**, a simple heuristic to speed-up forward selection, without sacrificing its quality and maintaining its theoretical guarantees. The idea is, in each iteration of the forward search, to filter out variables that are deemed conditionally independent of the target given the current set of selected variables. After termination, the algorithm is allowed to run up to K additional times, every time initializing the set of selected variables to the ones selected in the previous run. Finally, backward selection is applied on the result of the forward phase. We call this algorithm **Forward-Backward selection with Early Dropping** (FBED^K)[1]. This heuristic is inspired by the theory of Bayesian networks and maximal ancestral graphs (Spirtes et al., 2000; Richardson and Spirtes, 2002), and similar ideas have been successfully applied for feature selection (Aliferis et al., 2010). In Section 3.2 we show that (a) FBED^0 returns a superset of the adjacent nodes in any Bayesian network or maximal ancestral graph that faithfully represents the data distribution (if there exists one and assuming perfect statistical independence tests), (b) FBED^1 returns the Markov blanket of the data distribution, provided the distribution is faithful to a Bayesian network, and (c) FBED$^\infty$ returns the Markov blanket of the data distribution provided the distribution is faithful to a maximal ancestral graph, or equivalently, it is faithful to a Bayesian network where some variables are unobserved (latent). In the experimental evaluation presented in Section 4, we show that FBED^K is 1-2 orders of magnitude faster than FBS, while at the same time selecting a similar number of features and having similar predictive performance. In a comparison between different members of the FBED^K family and FBS we show that FBED^0 and FBED^1 also reduce the number of false variable selections, when the data consist of irrelevant variables only. We also investigated the behavior of FBED^K with increasing number of runs K, showing that a relatively small K is sufficient in most cases to reach optimal predictive performance. Afterwards, we compare FBED^K to FBS, feature selection with LASSO (Tibshirani, 1996) and to the Max-Min Parents and Children algorithm (MMPC) (Tsamardinos et al., 2003a) and show that it often has comparable predictive performance while selecting the fewest variables overall. Finally, we compare FBED^K to feature selection with LASSO (Tibshirani, 1996) when both algorithms are limited to select the same number of variables, showing that both algorithms perform similarly. This, along with the generality of FBED^K makes it an interesting alternative to LASSO, especially for problems where LASSO requires specialized algorithms (like the group LASSO algorithm for logistic regression (Meier et al., 2008), LASSO for mixed-effects linear models (Schelldorfer et al., 2011), and the LASSO and group LASSO methods for functional Poisson regression (Ivanoff et al., 2016)), which may be non-convex (as is the case for mixed-effects linear models (Schelldorfer et al., 2011) or for temporal-longitudinal data (Groll and Tutz, 2014; Tsagris et al., 2018)) and computationally demanding (taking several days to terminate on datasets with just 1000 predictors using Cox's proportional hazards model (Fan et al., 2010)).

1. The early dropping heuristic has also used by an extension of FBED for Big Data settings and map-reduce architectures (Tsamardinos et al., 2018a). However, the main idea and motivation behind it, its theoretical properties and a thorough experimental evaluation are presented in this work.

2. Notation and Preliminaries

We start by introducing the notation and terminology used throughout the paper. We use upper-case letters to denote single variables (for example, X), and bold upper-case letters to denote sets of variables (for example, $\mathbf{Z}$). The terms variable, feature or predictor will be used interchangeably. We will use p and n to refer to the number of variables and samples in a dataset $\mathcal{D}$, respectively. The set of variables in $\mathcal{D}$ will be denoted as $\mathbf{V}$. The target variable (also called outcome) will be referred to as T. Next, we proceed with the basics about stepwise feature selection methods (Kutner et al., 2004; Weisberg, 2005).

2.1. Stepwise Feature Selection

Stepwise methods start with some set of selected variables and try to improve it in a greedy fashion, by either including or excluding a single variable at each step. There are various ways to combine those operations, leading to different members of the stepwise algorithmic family. Two popular members of the stepwise family are the **forward selection** and **backward selection** (also known as backward elimination) algorithms. Forward selection starts with a (usually empty) set of variables and adds variables to it, until some stopping criterion is met. Similarly, backward selection starts with a (usually complete) set of variables and then excludes variables from that set, again, until some stopping criterion is met. Typically, both methods try to include or exclude the variable that offers the highest performance increase. We will call each step of selecting (removing) a variable a forward (backward) **iteration**. Executing forward (backward) iterations until termination will be called a forward (backward) **phase** respectively. An instance of the stepwise family, which we focus on hereafter, is the **Forward-Backward Selection** algorithm (FBS), which first performs a forward phase and then a backward phase on the selected variables. This algorithm is not new; similar algorithms have appeared in the literature before (Margaritis and Thrun, 2000; Tsamardinos et al., 2003b; Margaritis, 2009).

FBS is shown in Algorithm 1. The function Perf evaluates a set of variables and returns their performance relative to some statistical model. Examples are the log-likelihood for logistic regression, the partial log-likelihood for Cox regression and the F-score for linear regression, or their AIC (Akaike, 1973) or BIC (Schwarz et al., 1978) penalized variants. The **selection criterion** C compares the performance of two sets of variables as computed by Perf. For instance, in the previous example C could perform a likelihood ratio test and use a predetermined significance level α to make a decision [2]; we will describe such selection criteria in the next subsection. We will use the predicates $\underset{\text{C}}{>}$, $\underset{\text{C}}{\geq}$ and $\underset{\text{C}}{=}$ to compare two sets

2. In general, the type of criteria used in practice are not limited to that. For example, one may also stop after a fixed number of variables have been selected.

Algorithm 1 Forward-Backward Selection (FBS)

Input: Dataset $\mathcal{D}$, Target T
Output: Selected Variables $\mathbf{S}$

$\mathbf{S} \leftarrow \emptyset$ *//Set of selected variables*
$\mathbf{R} \leftarrow \mathbf{V}$ *//Set of remaining candidate variables*

//Forward phase: iterate until $\mathbf{S}$ *does not change*
while $\mathbf{S}$ changes **do**
  //Identify the best variable V_{best} *out of all remaining variables* $\mathbf{R}$*, according to* Perf
  $V_{best} \leftarrow \underset{V \in \mathbf{R}}{\text{argmax}}\ \textsc{Perf}(\mathbf{S} \cup V)$
  //Select V_{best} *if it increases performance according to criterion* C
  if $\textsc{Perf}(\mathbf{S} \cup V_{best}) \underset{\text{C}}{>} \textsc{Perf}(\mathbf{S})$ **then**
    $\mathbf{S} \leftarrow \mathbf{S} \cup V_{best}$
    $\mathbf{R} \leftarrow \mathbf{R} \setminus V_{best}$
  end if
end while

//Backward phase: iterate until $\mathbf{S}$ *does not change*
while $\mathbf{S}$ changes **do**
  //Identify the worst variable V_{worst} *out of all selected variables* $\mathbf{S}$*, according to* Perf
  $V_{worst} \leftarrow \underset{V \in \mathbf{S}}{\text{argmax}}\ \textsc{Perf}(\mathbf{S} \setminus V)$
  //Remove V_{worst} *if it does not decrease performance according to criterion* C
  if $\textsc{Perf}(\mathbf{S} \setminus V_{worst}) \underset{\text{C}}{\geq} \textsc{Perf}(\mathbf{S})$ **then**
    $\mathbf{S} \leftarrow \mathbf{S} \setminus V_{worst}$
  end if
end while
return $\mathbf{S}$

of variables; they are true if the left-hand-side value is greater, greater or equal, or equal than the right-hand-side value respectively, according to the criterion C.

2.2. Criteria for Variable Selection

Next we will briefly describe some performance functions and selection criteria that are employed in practice; for more details see (Kutner et al., 2004; Weisberg, 2005). The most common choices are statistical tests, information criteria and cross-validation. We will focus on statistical tests, as we use them in the remainder of the paper. We will also describe information criteria and contrast them to statistical tests, but will not further consider cross-validation, mainly because of its high computational cost.

2.2.1. Statistical Tests

Since the models tested at each iteration are nested, one can employ a likelihood-ratio (LR) test (or asymptotically equivalent approximations thereof such as score tests and Wald

tests) for nested models as a selection criterion. We next describe the likelihood-ratio test in more depth. For the LR test, the performance Perf is related to the log-likelihood (LL) and the criterion C tests the hypothesis that both models are equivalent with respect to some pre-specified significance level α. Let $\textsc{Dev}(T|\mathbf{X}) \equiv -2 \cdot \text{LL}(T|\mathbf{X})$ and $\textsc{Par}(T|\mathbf{X})$ be the deviance and number of parameters respectively of a model for target T using variables $\mathbf{X}$. Then, the test statistic of a nested test for models with variables $\mathbf{X}$ (null model) and $\mathbf{X} \cup \mathbf{Y}$ (alternative model) is computed as the difference in deviance of both models, that is, $\textsc{Dev}(T|\mathbf{X}) - \textsc{Dev}(T|\mathbf{X} \cup \mathbf{Y})$, and follows asymptotically a χ^2 distribution with $\textsc{Par}(T|\mathbf{X} \cup \mathbf{Y}) - \textsc{Par}(T|\mathbf{X})$ degrees of freedom (Wilks, 1938) [3].

Tests for nested models are essentially **conditional independence tests**, relative to some statistical model (for example, using linear regression without interaction terms tests for linear dependence), and assuming that the model is correctly specified. If the null model contains the predictors $\mathbf{X}$ and the alternative model contains $\mathbf{X} \cup \mathbf{Y}$, the nested test tests the hypothesis that the coefficients of $\mathbf{Y}$ are zero, or equivalently, that $\mathbf{Y}$ is conditionally independent of the target T given $\mathbf{X}$. We denote **conditional independence** of two non-empty sets $\mathbf{X}$ and $\mathbf{Y}$ given a (possibly empty) set $\mathbf{Z}$ as $(\mathbf{X} \perp \mathbf{Y} \mid \mathbf{Z})$. Finally, we note that one is not limited to likelihood-ratio based conditional independence tests, but can use any appropriate conditional independence test, such as a kernel-based test (Zhang et al., 2011).

A problem when using statistical tests for feature selection is that, due to multiple testing, the test statistics do not have the claimed distribution (Hastie et al., 2009) and the resulting p-values are too small (Harrell, 2001; Flom and Cassell, 2007), leading to a high false discovery rate. Approaches to deal with problem include methods that dynamically adjusting significance levels (Hwang and Hu, 2015), or methods that directly deal with the problem of sequential testing of stepwise procedures (G'Sell et al., 2016; Tibshirani et al., 2016). In order to perform tests on the model returned by stepwise selection, one can use resampling-based procedures to correct the p-values (Finos et al., 2010). In addition to the above problems, we note that the model returned by stepwise selection is sub-optimal, as it will have inflated coefficients (Flom and Cassell, 2007), reducing its predictive ability. If the main focus is to obtain a predictive model, methods performing regularization (like L1, L2 or elastic net) are more appropriate. In any case, procedures like cross-validation should be used to estimate out-of-sample predictive performance of the final model. We will not consider the above in this paper; we note however that our proposed algorithm is orthogonal to those methods and could be used in conjunction with them.

2.2.2. Information Criteria

Another way to compare two (or more) competing models is to use information criteria, such as the Akaike information criterion (AIC) (Akaike, 1973) or the Bayesian information criterion (BIC) (Schwarz et al., 1978). Information criteria are based on the fit of a model but additionally penalize the model by its complexity (that is, the number of parameters).

3. This result assumes that the larger hypothesis is correctly specified. In case of model misspecification, the statistic follows a different distribution (Foutz and Srivastava, 1977). Methods to handle model misspecification have been proposed by White (1982) and Vuong (1989). A method for dealing with model misspecification in model selection with information criterion is presented in (Lv and Liu, 2014). As this problem is out of this paper's scope, we did not further consider it.

The AIC and BIC scores of a model for T based on $\mathbf{X}$ are defined as follows:

$$\text{AIC}(T|\mathbf{X}) \equiv \textsc{Dev}(T|\mathbf{X}) + 2 \cdot \textsc{Par}(T|\mathbf{X})$$
$$\text{BIC}(T|\mathbf{X}) \equiv \textsc{Dev}(T|\mathbf{X}) + \log(n) \cdot \textsc{Par}(T|\mathbf{X})$$

where n is the number of samples. In the framework described above, information criteria can be applied by using the information criterion value as the performance function Perf, and a selection criterion C that simply compares the performance of two models, giving preference to the one with the lowest value. Alternatively, one could check that the difference in scores is larger than some threshold.

Neither AIC nor BIC are designed for cases where the number of predictors p is larger than the number of samples n (Chen and Chen, 2008), and thus also suffer from a high false discovery rate, similar to statistical tests. There have been several extensions to handle this problem, like the extended Bayesian information criterion (EBIC) (Chen and Chen, 2008), the generalized information criterion (GIC) (Fan and Tang, 2013; Kim et al., 2012), and the corrected risk information criterion (RIC_c) (Zhang and Shen, 2010), to name a few.

Compared to statistical tests, information criteria are somewhat limited as they can only be computed for models where the model complexity is known (like generalized linear models). An example where information criteria are not applicable are kernel-based tests (Zhang et al., 2011). Thus, statistical tests are inherently more general than information criteria. We will show next how, in case of nested models, using BIC directly corresponds to a likelihood-ratio test for some significance level α; the same reasoning can be applied to AIC and all information criteria that are computed based on the model likelihood and a penalty term. Let $\mathbf{X}$ and $\mathbf{X} \cup \mathbf{Y}$ be two candidate variables sets. $\mathbf{X} \cup \mathbf{Y}$ is selected (that is, the null hypothesis is rejected) if $\text{BIC}(T|\mathbf{X} \cup \mathbf{Y}) < \text{BIC}(T|\mathbf{X})$, or equivalently if $\textsc{Dev}(T|\mathbf{X}) - \textsc{Dev}(T|\mathbf{X} \cup \mathbf{Y}) > \log(n) \cdot (\textsc{Par}(T|\mathbf{X} \cup \mathbf{Y}) - \textsc{Par}(T|\mathbf{X}))$. Note that the left-hand side term equals the statistic of a likelihood-ratio test, whereas the right-hand size corresponds to the critical value. The statistic follows a χ^2 distribution with $k = \textsc{Par}(T|\mathbf{X} \cup \mathbf{Y}) - \textsc{Par}(T|\mathbf{X})$ degrees of freedom, and thus, the significance level equals $\alpha = 1 - F(\log(n) \cdot k; k)$, where $F(v; k)$ is the χ^2 cdf with k degrees of freedom at value v.

2.3. Markov Blankets in Bayesian Networks and Maximal Ancestral Graphs

The proposed algorithm is inspired by the theory of Markov blankets in Bayesian networks and maximal ancestral graphs. Next, we will provide a brief introduction of them; more details can be found in Appendix A. For a comprehensive introduction to Bayesian networks and maximal ancestral graphs we refer the reader to (Pearl, 1988; Spirtes et al., 2000; Richardson and Spirtes, 2002).

A **directed acyclic graph** (DAG) is a graph that only contains directed edges ($\rightarrow$) and has no directed cycles. A **directed mixed graph** is a graph that, in addition to directed edges also contains bi-directed edges ($\leftrightarrow$). A triplet of vertices $\langle X, Y, Z \rangle$ is called a **collider** if there are directed or bi-directed edges from X and Z to Y. A path p is called a **collider path** if every non-endpoint vertex is a collider on p.

Bayesian networks (BNs) consist of a DAG $\mathcal{G}$ and a probability distribution $\mathcal{P}$ over a set of variables $\mathbf{V}$. A DAG $\mathcal{G}$ is Markov and faithful to $\mathcal{P}$ if (a) each variable is conditionally independent of its non-descendants given its parents, and (b) all and only those conditional

independencies in $\mathcal{P}$ are entailed by $\mathcal{G}$. BNs are not closed under marginalization, that is, they are not able to encode latent confounders. BNs have been extended to represent such marginal distributions, and are called **directed maximal ancestral graphs** (DMAGs) (Richardson and Spirtes, 2002). The graphical structure of a DMAG is a directed mixed graph with the following restrictions: (i) it contains no directed cycles, (ii) it contains no almost directed cycles, that is, if $X \leftrightarrow Y$ then neither X nor Y is an ancestor of the other, and (iii) there is no path p such that each non-endpoint on p is a collider and every collider is an ancestor of an endpoint vertex of p.

A **Markov blanket** of a variable T is a **minimal** set of variables $\mathbf{MB}(T)$ that renders T conditionally independent of all remaining variables $\mathbf{V} \setminus \mathbf{MB}(T)$. In case the distribution can be faithfully represented by a BN or DMAG, then the Markov blanket of T is **unique**, and is defined as follows (see Appendix A for a proof sketch).

Definition 1 (Markov blanket) *The Markov blanket of T in a BN or DMAG consists of all vertices adjacent to T, as well as all vertices that are reachable from T through a collider path.*

In case of Bayesian networks, this simplifies to the set of parents, children, and parents of children of T.

3. Speeding-up Forward-Backward Selection

The standard FBS algorithm has two main issues. The first is that it is slow: at each forward iteration, all remaining variables are reconsidered to find the best next candidate. If k is the total number of selected variables and p is the number of input variables, the number of model evaluations (or in our case, independence tests) FBS performs is of the order of $O(kp)$. Although relatively low-dimensional datasets are manageable, it can be very slow for modern datasets which often contain thousands of variables. The second problem is that it suffers from multiple testing issues, resulting in overfitting and a high false discovery rate. This happens because it reconsiders all remaining variables at each iteration; variables will often happen to seem important simply by chance, if they are given enough opportunities to be selected. As a result, it will often select a significant number of false positive variables (Flom and Cassell, 2007). This behavior is further magnified in high-dimensional settings and with larger significance levels α. Next, we describe a simple modification of FBS, improving its running time while reducing the problem of multiple testing.

3.1. The Early Dropping Heuristic

We propose the following modification: after each forward iteration, remove all variables that do not satisfy the criterion C for the current set of selected variables $\mathbf{S}$ from the remaining variables $\mathbf{R}$. In our case, those variables are the ones that are conditionally independent of T given $\mathbf{S}$. The idea is to quickly reduce the number of candidate variables $\mathbf{R}$, while keeping many (possibly) relevant variables in it. The forward phase terminates if no more variables can be selected, either because there is no informative variable or because $\mathbf{R}$ is empty; to distinguish between forward and backward phases, we will call a forward phase

Algorithm 2 Forward-Backward Selection with Early Dropping (FBED^K)

Input: Dataset $\mathcal{D}$, Target T, Maximum Number of Runs K
Output: Selected Variables $\mathbf{S}$

$\mathbf{S} \leftarrow \emptyset$ *//Set of selected variables*
$K_{cur} \leftarrow 0$ *//Initializing current number of runs to 0*

//Forward phase: iterate until (a) run limit reached, or (b) $\mathbf{S}$ *does not change*
while $K_{cur} \leq K \wedge \mathbf{S}$ changes **do**
    $\mathbf{S} \leftarrow$ OneRun$(\mathcal{D}, T, \mathbf{S})$
    $K_{cur} \leftarrow K_{cur} + 1$
end while

//Perform backward selection and return result
return BackwardSelection$(\mathcal{D}, \mathbf{T}, \mathbf{S})$

function OneRun($\mathcal{D}$, T, $\mathbf{S}$)
    $\mathbf{R} \leftarrow \mathbf{V} \setminus \mathbf{S}$ *//Set of remaining candidate variables*

    //Forward phase: iterate until $\mathbf{R}$ *is empty*
    while $|\mathbf{R}| > 0$ **do**
        //Identify best variable V_{best} *out of* $\mathbf{R}$*, according to* Perf
        $V_{best} \leftarrow \underset{V \in \mathbf{R}}{\text{argmax}}$ Perf$(\mathbf{S} \cup V)$
        //Select V_{best} *if it increases performance according to criterion* C
        if Perf$(\mathbf{S} \cup V_{best}) \underset{C}{>}$ Perf$(\mathbf{S})$ **then**
            $\mathbf{S} \leftarrow \mathbf{S} \cup V_{best}$
        end if
        //Drop all variables from $\mathbf{R}$ *not satisfying* C
        $\mathbf{R} \leftarrow \{V : V \in \mathbf{R} \wedge V \neq V_{best} \wedge$ Perf$(\mathbf{S} \cup V) \underset{C}{>}$ Perf$(\mathbf{S})\}$
    end while
    return S
end function

with early dropping a **run**. Extra runs can be performed to reconsider variables dropped previously. This is done by retaining the previously selected variables $\mathbf{S}$ and initializing the set of remaining variables to all variables which have not been selected yet, that is $\mathbf{R} = \mathbf{V} \setminus \mathbf{S}$. The backward phase employed afterwards is identical to the standard backward-selection algorithm (see Algorithm 1). Depending on the number of additional runs K, this defines a family of algorithms, which we call **Forward Backward Selection with Early Dropping** (FBED^K), shown in Algorithm 2. The function OneRun shown in the bottom of Algorithm 2, performs one run until no variables remain in $\mathbf{R}$. Three interesting members of this family are the FBED^0, FBED^1 and FBED$^\infty$ algorithms. FBED^0 performs the first run until termination, FBED^1 performs one additional run and FBED$^\infty$ performs runs until no more variables can be selected. We will focus on those three algorithms hereafter.

The heuristic is inspired by the theory of Bayesian networks and maximal ancestral graphs (Spirtes et al., 2000; Richardson and Spirtes, 2002). Similar heuristics have been applied by Markov blanket based algorithms such as the Max-Min Parents and Children (MMPC) algorithm (Tsamardinos et al., 2003a) and HITON (Aliferis et al., 2003) successfully in practice and in extensive comparative evaluations (Aliferis et al., 2010). These algorithms also remove variables from consideration, and specifically the ones that are conditionally independent given some **subset** of the selected variables. In contrast, FBED^K reconsiders variables dropped during previous runs, while existing methods do not. Thus, *FBED^K bridges two types of algorithms to combine their advantages*: those that condition on all currently selected variables (such as FBS, grow-shrink (Margaritis and Thrun, 2000) and incremental association Markov blanket (Tsamardinos et al., 2003b)), and those that condition on subsets of variables to drop some of them (like MMPC (Tsamardinos et al., 2003a) and HITON (Aliferis et al., 2003)). Doing so, FBED^K manages to have the theoretical properties of the former (as shown in the next subsection), while obtaining speed-ups similar to the latter.

3.2. Comparing the Theoretical Properties of FBED^K to FBS

Due to early dropping of variables, the distributions under which FBED^K and FBS perform optimally are not the same. For all versions of FBED^K, with the exception of FBED$^\infty$, it is relatively straightforward to construct examples where FBS is able to identify variables that can not be identified by FBED^K. We give an example for FBED^0. FBED^0 may remove variables that seem uninformative at first, but become relevant if considered in conjunction with other variables. For example, let $X = T + Y$, with T and Y being independent Gaussian random variables, and assume that T is the outcome for which variable selection is performed. When no variables have been selected (first iteration), X will be dependent with T, while Y will be independent of T as it does not give any information about T by itself, and thus will be dropped. However, after selecting X, Y becomes conditionally dependent again (as $T = X - Y$), but FBED^0 will not select it as it was dropped in the first iteration. Surprisingly, in practice this does not seem to significantly affect the quality of FBED^0. In contrast, FBED^0 often gives better results, while also selecting fewer variables than FBS (see Section 4.4).

As mentioned above, it is not clear how FBS and FBED$^\infty$ are related in the general case. What can be shown is that both identify a minimal set of variables, although the identified solutions may not necessarily be the same.

Definition 2 (Minimal Variable Set) *Let* $\mathbf{V}$ *be the set of all variables and* $\mathbf{S}$ *a set of selected variables. We call a set of variables* $\mathbf{S}$ *minimal with respect to some outcome* T*, if:*

1. *No variable can be removed from* $\mathbf{S}$ *given the rest of the selected variables, that is,* $\forall V_i \in \mathbf{S}, (T \not\perp V_i \mid \mathbf{S} \setminus V_i)$ *holds.*

2. *Let* $\mathbf{R} = \mathbf{V} \setminus \mathbf{S}$*. No variable from* $\mathbf{R}$ *can be included in* $\mathbf{S}$*, that is,* $\forall V_i \in \mathbf{R}, (T \perp V_i \mid \mathbf{S})$ *holds.*

Corollary 3 *Any set of variables* $\mathbf{S}$ *selected by FBS is minimal.*

Proof See Appendix B. ■

Corollary 4 *Any set of variables* $\mathbf{S}$ *selected by FBED*$^{\infty}$ *is minimal.*

Proof See Appendix B. ■

In words, a minimal set is a set such that no single variable can be included to or removed from using forward and backward iterations respectively, that is, it is a local optimum for stepwise algorithms. Note that, although no single variable is informative for T if looked at separately, there may be sets of variables that are informative if considered jointly. A simple example is if all variables are binary and $T = X \oplus Y$, where $\oplus$ is the logical XOR operator. In this case $\mathbf{S} = \emptyset$ is minimal, as neither X nor Y are dependent with T, even though the set $\{X, Y\}$ fully determines T. Thus, none of the algorithms gives a globally optimal solution in all distributions.

We next consider the special case in which distributions can be represented by Bayesian networks or maximal ancestral graphs. We show that FBED^1 and FBED$^{\infty}$ identify the Markov blanket of a BN and DMAG respectively, assuming (a) that the distribution can be faithfully represented by the respective graph, and (b) that the algorithms have access to an **independence oracle**[4], which correctly determines whether a given conditional (in)dependence holds. This also holds for FBS but will not be shown here; proofs for similar algorithms exist (Margaritis and Thrun, 2000; Tsamardinos et al., 2003b) and can be easily adapted to FBS. For FBED^0 it can be shown that it selects a superset of the variables that are adjacent to T in the graph; this can be shown using the fact that, under the Markov and faithfulness assumptions, adjacent variables are dependent with T given any subset of the remaining variables.

Theorem 5 *If the distribution can be faithfully represented by a Bayesian network, then FBED*^{1} *identifies the Markov blanket of the target* T*.*

Proof See Appendix B. ■

Theorem 6 *If the distribution can be faithfully represented by a directed maximal ancestral graph, then FBED*$^{\infty}$ *identifies the Markov blanket of the target* T*.*

4. Assuming access to an independence oracle allows one to analyze whether the strategy used by FBED^K for identifying a Markov blanket is correct; thus, in practice, any errors in the output are due to statistical errors of the tests and not due to the heuristics or strategy used by FBED^K. Furthermore, it allows one to analyze the asymptotic behavior of algorithms without parametric distributional assumptions (for example, multivariate normality), but structural assumptions (for example, faithfulness). Assuming a conditional independence oracle is a standard assumption for the theoretical analysis of Markov blanket and causal discovery algorithms (for example, see (Spirtes et al., 2000; Aliferis et al., 2010)). In practice, FBED^K will not have access to an oracle, but will perform conditional independence tests to decide (in)dependence. There exist tests that, in the sample limit, will correctly identify (in)dependence. Examples include the partial correlation test for multivariate Gaussian data, and the G-test (Agresti, 2002) for multinomial data.

Proof See Appendix B. ■

3.3. Limitations and Practical Considerations

We have shown that FBED^K is able to solve the feature selection problem (that is, identify the Markov blanket of T) for distributions that are faithful to causal graphs. In practice, FBED^K may fail to identify the Markov blanket for several reasons. Naturally, in case the distribution can't be faithfully modeled with causal graphs, there is no guarantee of how close the solution will be to the optimal solution. However, previous comparisons show that forward selection performs as well as best subset selection, and is competitive with lasso (Hastie et al., 2017), indicating that its solutions are reasonably good approximations to the best subset solution, which we also confirm in the experimental section. Another, more subtle issue is if the conditional independence tests used are not appropriate to capture the dependencies present in the distribution. For instance, if all relations are non-linear and linear tests are used, there is no guarantee that any of the important variables will be selected. However, this is an issue with all feature selection algorithms (and predictive algorithms in general) and is not specific to FBED^K. Finally, if sample size is too low, or if the significance level is not set appropriately, dependencies may be incorrectly labeled as independencies and vice versa. Again, this is a general problem with all algorithms and can be handled by increasing sample size (if possible) and by appropriately setting or tuning the significance level. For example, for the task of learning Bayesian networks from Gaussian data using the PC algorithm (Spirtes et al., 2000), Kalisch and Bühlmann (2007) have shown that (under mild conditions) the significance level can be set in a way to ensure consistency asymptotically (Kalisch and Bühlmann, 2007, Theorem 1). The problem of learning Bayesian networks and Markov blanket discovery are closely related, and such results can possibly be translated and used by algorithms such as FBED^K, but it is out of the scope of the current paper.

We proceed with additional considerations regarding the sample size required to use FBED^K. FBED^K identifies the next variable to select conditional on all currently selected variables. Because of this, it can in principle take complex multivariate dependencies into consideration when selecting a variable. The complexity depends on the conditional independence test used (for example, non-linear tests can model more complex relations than linear tests). However, there is a clear trade-off between the complexity of dependencies that can be identified, and the sample size required to do so. For instance, if all variables are binary, the G-test of conditional independence (Agresti, 2002) can be used, which can identify any type of interaction between variables. In this case, the number of parameters increases exponentially with the number of selected variables: for k selected variables, the number of parameters is in the order of $O(2^k)$, and consequently, the number of samples required to have sufficient power also increases exponentially. Using linear models (for example, linear, logistic or Cox regression for continuous, categorical or time-to-event outcomes respectively), simpler, linear dependencies can be identified, and the number of samples required increases only linearly with the number of parameters. Rules of thumb for setting the minimum sample size for linear models are given in (Peduzzi et al., 1996; Harrell, 2001; Vittinghoff and McCulloch, 2007). For binary logistic regression, one recommendation is to

use at least $s = c/\min(p_0, p_1) \cdot k$ samples (Peduzzi et al., 1996), where p_0 and p_1 are the proportion of negative and positive classes of T respectively, k is the number of parameters in the model and c is a user-set parameter, which is usually recommended to be between 5 and 20, with larger values leading to more accurate results. Thus, multivariable methods like FBED^K should only be used when sufficient sample size is available; alternatively, one can use rules of thumb as stopping criteria (that is, to determine when to stop selecting variables).

Next, we make a few recommendations based on the above considerations; exact rules are hard to devise, as they depend on the specific problem at hand. In case sample size is very low (a few tens or hundreds of samples), sample-efficient methods like the max-min parents and children algorithm (Tsamardinos et al., 2003a) (which condition only on small subsets of variables), information-theoretic feature selection methods (Brown et al., 2012) (which only condition on up to 1 variable), or univariate feature selection methods are more preferable than methods like FBED^K. Otherwise, we recommend using linear multivariable methods like OMP (Pati et al., 1993; Davis et al., 1994), LASSO (Tibshirani, 1996) or FBED^K with linear tests, and if sample size allows to also consider FBED^K using non-linear tests. Finally, we believe it is also worth considering robust tests (Lagani et al., 2017) for FBED^K, as outliers often exist in practice and may negatively impact tests which do not take them into account.

4. Experimental Evaluation

In this section we evaluate FBED^K, and compare it to the standard FBS algorithm[5], feature selection with LASSO (called LASSO-FS hereafter) (Tibshirani, 1996), the Max-Min Parents and Children algorithm (MMPC) (Tsamardinos et al., 2003a), and no feature selection (NO-FS), which was used as the baseline method. We note that MMPC is designed specifically for low-sample size and high-dimensional settings, and thus may not perform optimally in the datasets considered here. The reason we compare against it is because, it belongs in the same category of algorithms as FBED^K (that is, is also inspired by causal graphs).

We implemented all algorithms in Matlab except for LASSO, for which we used the glmnet implementation (Qian et al., 2013). We used 12 binary classification datasets, with sample sizes ranging from 200 to 16772 and number of variables between 166 and 100000. The datasets were selected from various competitions (Guyon et al., 2004, 2006a) and the UCI repository (Dietterich et al., 1994), and were selected to cover a wide range of variable and sample sizes. A summary of the datasets is shown in Table 1. All experiments were performed in Matlab, running on a desktop computer with an Intel i7-7700K processor and 32GB of RAM.

5. We want to point out that, although the early dropping heuristic only affects the forward phase of the algorithm, we chose evaluate FBED^K and FBS with the backward phase. This is done mainly as FBED^K and FBS require the backward phase to have provable theoretical guarantees, and because that is how the algorithms are presented throughout the paper. To ensure that this will not significantly affect the results, we performed a few preliminary anecdotal experiments, and observed that (a) the number of features removed by backward selection is typically small, and (b) the predictive performance is very similar when backward selection is used.

Table 1: Binary classification datasets used in the experimental evaluation. n is the number of samples, p is the number of predictors and $P(T = 1)$ is the proportion of instances where $T = 1$.

Dataset	n	p	P(T = 1)	Type	Domain	Source

The remainder of this section is organized as follows. First, we describe in detail the experimental setup, that is, all algorithms used, their hyper-parameters, and how we performed model selection and performance estimation. We proceed by evaluating how the running time, number of selected variables and predictive performance of FBED^K is affected by the number of runs K. Afterwards, we compare FBED^K to FBS, to show the effects of the early dropping heuristic. Next, we evaluate FBED^K in a realistic scenario with other feature selection methods, where hyper-parameters of the feature selection and classification algorithms are optimized. Then, we compare FBED^K and LASSO in terms of predictive ability when the number of variables to select is fixed so that all algorithms produce solutions of equal size. This is done for two reasons: (a) because LASSO tends to select many variables otherwise, giving it an advantage over FBED^K in terms of predictive performance, and (b) because this allows us to evaluate how well FBED^K orders the variables in comparison to LASSO. Finally, we compare FBED^0, FBED^1, FBED$^\infty$ and FBS on simulated data containing only irrelevant variables, investigating how is each algorithm is affected by multiple testing in terms of the falsely selected variables.

4.1. Experimental Setup

We present an overview of the experimental setup next. Additional details for each specific experiment are described in the respective section.

4.1.1. Feature selection algorithms

First of all we note that, although the early dropping heuristic only affects the forward phase of the algorithm, we will use FBED^K and FBS with their backward phase in the experiments. This is done mainly as FBED^K and FBS require the backward phase to have provable theoretical guarantees, and because that is how they are presented throughout the paper.

As selection criteria for FBED^K, FBS and MMPC we used a nested likelihood-ratio independence test based on logistic regression. For FBED^K and MMPC, the significance level α of the conditional independence test was set to $\{0.001, 0.005, 0.01, 0.05, 0.1\}$, covering a range of commonly used values, while for FBS we explored a total of 100 values, uniformly spaced in $[0.001, 0.01]$. For the K value of FBED^K we used $\{0, 1, \ldots, \infty\}$, while the maximum conditioning size $maxK$ of MMPC was set to $\{1, 2, 3, 4\}$. For LASSO-FS we set all parameters to their default values and set the maximum number of λ values, λ_{max}, to 100. Thus, we used 5 hyper-parameter combinations for each value K of FBED^K, 100 for FBS and LASSO-FS, and 20 for MMPC.

Unfortunately, for MMPC there were 2 datasets where not all hyper-parameter combinations were executed, as they were taking too long to terminate (see results about running time in Appendix D); we stopped execution if a time limit of 2 days was exceeded. Specifically, for the gisette and nova datasets MMPC was only executed with $maxK \leq 2$

We would like to point out that for a given value K for FBED^K, all solutions with fewer runs (smaller K) can be computed with minimal computational overhead, as the forward phases have already been computed and only the backward phases need to be performed separately. As the number of variables selected is relatively small, the computational cost of the backward phases is usually negligible. Thus, FBED^K required a single execution with $K = \infty$ for a given α. Unfortunately, something similar can not be done with MMPC, and thus it has to be executed for each hyper-parameter value separately [6].

4.1.2. Predictive models

We used both, linear and non-linear predictive models. As linear models we used elastic net regularized logistic regression (Zou and Hastie, 2005), using $\lambda_{max} = 100$ and the mixture parameter α set to $\{0, 0.25, 0.5, 0.75, 1\}$ ($\alpha = 0$ corresponds to L2 regularization and $\alpha = 1$ to L1 regularization), leading to a total of 500 hyper-parameter combinations. We remind the reader that regularization is important, especially after feature selection has been performed, in order to improve predictive performance due to inflated coefficients (Flom and Cassell, 2007) (see also Section 2.2). As non-linear models we used Gaussian support vector machines (SVM) (Cortes and Vapnik, 1995) and random forests (RF) (Breiman, 2001). For SVMs we used the LIBSVM (Chang and Lin, 2011) implementation, while for RFs we used the TreeBagger implementation in Matlab. The cost hyper-parameter C of SVMs was set to $\{2^{-10}, 2^{-9}, \ldots, 2^9\}$ (a total of 20 values), while the remaining hyper-parameters were set to their default values. For RFs the number of trees was set to 500, the minimum leaf node size was set to $\{1, 5, 9\}$ and the number of variables to split at each node was set to $\{0.5, 1, 1.5\} \cdot \sqrt{p}$ (9 combinations in total).

6. This is only partially true, as for FBED^K, FBS and MMPC we implemented a caching mechanism to avoid fitting the same logistic regression model more than once. This mechanism was not used however for experiments measuring the running time of the algorithms.

4.1.3. Linear vs non-linear models

Throughout the section, we will report results obtained by using only linear models or a combination of linear and non-linear models. The former is done to evaluate the ability of the feature selection methods of identifying features that are linearly (or possibly monotonically) related to the outcome. The reason for that is that all evaluated methods can only identify such types of dependencies; we note that all algorithms (except for LASSO) can be trivially adapted to also handle non-linear dependencies by using an appropriate conditional independence test. Non-linear models were also considered to better simulate a realistic scenario, as such methods would be used in a typical analysis. Furthermore, it is interesting to see whether there are any significant differences between linear and non-linear modeling for any of the considered feature selection algorithms.

4.1.4. Model selection and performance estimation protocols

Ideally, we would like to evaluate each feature selection algorithm using an optimal predictive model, in order to measure how informative the selected features are. As an optimal model is not available in practice, we approximate this by using a variety of predictive algorithms as well as multiple hyper-parameter value combinations for each (see above), and perform hyper-parameter optimization (also called tuning or model selection) to find a good approximate model; interested readers may refer to (Feurer and Hutter, 2018; Tsamardinos et al., 2018b) for more details. We proceed with a description of the model selection and performance estimation protocols we used.

As the performance metric we optimize and report the area under the ROC curve (AUC). For model selection and performance estimation we used a 60/20/20 stratified split of the data, using 60% as a training set, 20% as a validation set and the remaining 20% as a test set. A hyper-parameter configuration is defined as a combination of a feature selection algorithm and its hyper-parameters, as well as a modeling algorithm and its hyper-parameters. Given a set of configurations, the best one is chosen by training models for all of them on the training set and selecting the configuration of the model with the highest performance on the validation set. Finally, the predictive performance of that configuration is obtained by training a final model on the pooled training and validation sets, and evaluating it on the test set. To account for the variation due to the data splitting, we repeated this procedure multiple times for different splits and report averages over repetitions. For datasets with more than 1000 samples the number of repetitions was set to 10, and to 50 for the rest.

4.2. Effect of the Number of Runs K

We performed an experiment to measure the effect of K on the running time, number of selected variables and predictive performance of FBED^K. For the running time and number of selected variables we executed FBED^K once for each hyper-parameter value on

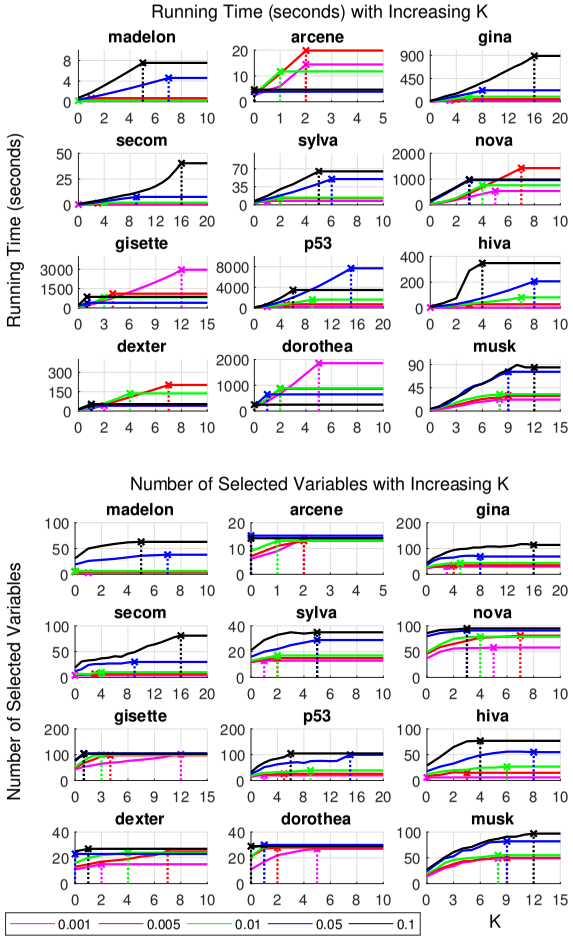

Figure 1: The figure shows how the running time (top) and the number of selected variables (bottom) vary with an increasing number of runs K for different values of the threshold parameter α. The vertical lines indicate the value of K for which FBED^K has converged. We can see that running time increases almost linearly with increasing K. Also, most progress is made in the first few runs, and any additional runs increase running time while only selecting a few more variables.

the complete datasets, while for the predictive performance we used the model selection and performance estimation protocols described previously and report averages over multiple repetitions of the experiment.

Figure 1 shows how the number of runs K affects the running time and the number of selected variables. Vertical lines show the value of K for which the algorithm has converged (that is, after that point more runs do not select any more variables). We can see that running time increases almost linearly with an increasing number of runs K, meaning that any additional run has a roughly linear computational cost with respect to the size of the dataset. Furthermore, convergence is typically achieved in less than 10 runs, although for a few cases up to 16 runs are required. As expected, the number of selected variables increases with K, as well as with the threshold α. In the majority of cases however, most progress is made in the first few runs, and further runs increase the number of selected variables only marginally. *Based on those results, we recommend considering relatively small values of K, up to $K < 10$.*

Figure 2 shows how the area under the ROC curve (AUC) varies with an increasing number of runs K, for 5 different values of the threshold parameter α of FBED^K. We observe that, although AUC often tends to increase with K, this is not always the case. For instance, for the nova and dexter datasets, AUC actually decreases with K for some values of α. The maximum AUC is typically achieved with relatively small values of K, further suggesting that considering higher values for K is not necessary. Also, there are no clear relationships between AUC, the value of α and the type of predictive models used. Depending on the dataset different values of α or predictive models may be optimal. *Thus, in practice we recommend considering several combinations of α and K.* Optimizing over both α and K will be considered in Section 4.4.

4.3. FBED^K vs FBS

In this section we compare FBED^K to the standard FBS algorithm in terms of predictive performance, number of selected variables and running time. The algorithms were compared on the same hyper-parameters (for example, FBS vs FBED^0 with $\alpha = 0.01$); results when also optimizing over hyper-parameters are shown in Section 4.4. Model selection and performance estimation was performed for each feature selection algorithm and each hyper-parameter value separately, following the procedure described in the experimental setup. *The main goal of this comparison is to show that FBED^K and FBS perform similarly for the same hyper-parameters, with the former being faster.* A summary of the results is presented next.

Figure 3 shows how the algorithms compare in terms of predictive performance, number of selected variables and running time. Each column shows the distribution of the respective metric across all thresholds and datasets, as well as the mean and median values. The difference in AUC is computed is AUC(FBED^K) - AUC(FBS), the relative number of selected variables is computed as the ratio of variables selected by FBED^K compared to FBS, and the speed-up is computed as Time(FBS) / Time(FBED^K). The y-axis corresponds to different values of K used by FBED^K. Only the first few values ($K \leq 9$), as well as the last one ($K = \infty$) are shown, as the left-out ones were almost identical to $K = \infty$.

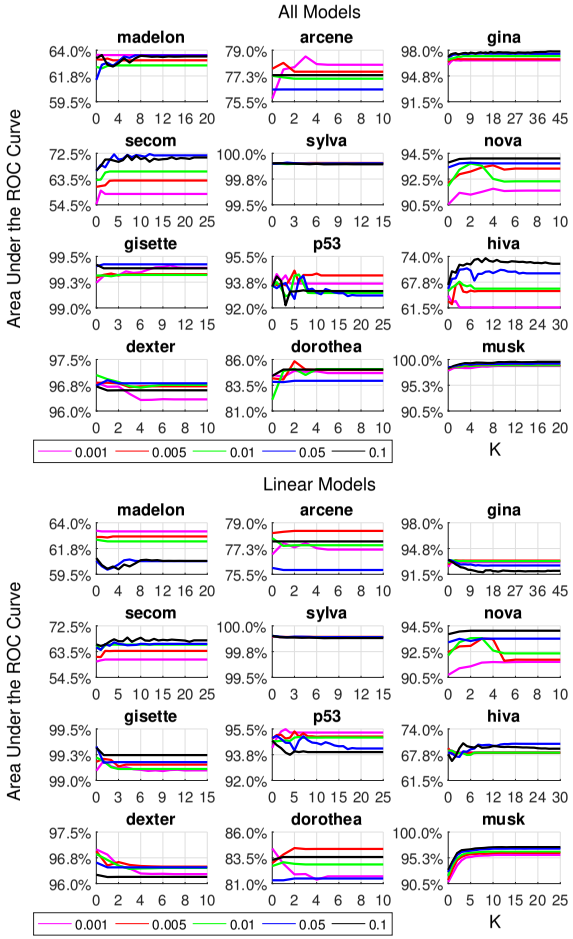

Figure 2: The figure shows how the AUC varies with an increasing number of runs K for different values of the threshold parameter α, using non-linear and linear models (top) or linear models only (bottom). There is no clear pattern for which thresholds or values of K to prefer, but the optimal values depend on the specific dataset, as well as on the predictive models used. However, in most cases only a few runs are required to achieve maximal AUC.

Regarding predictive performance, FBED^K performs as good as FBS on average, irrespective of the type of predictive models used. For FBED^K with $K < 3$, the average

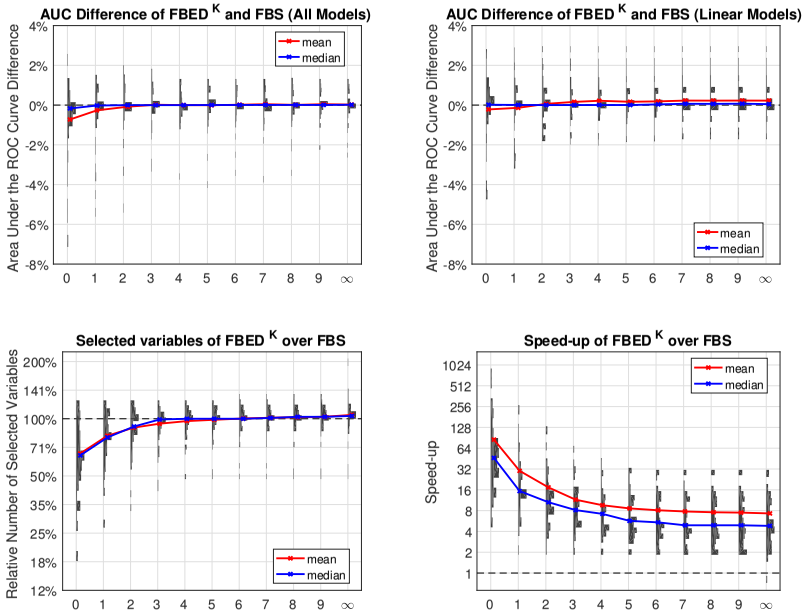

Figure 3: The x-axis of the figures on the top row shows the difference in AUC between FBED^K and FBS, with positive values indicating that FBED^K performs better than FBS. The AUC of the top left figure is computed by optimizing over all models, while for the one of the top right figure only linear models were considered. The relative number of selected variables (bottom left) shows the number of variables selected by FBED^K compared to the ones selected by FBS. The speed-up (bottom right) is computed as the one obtained by FBED^K over FBS. For all cases, the distribution over all thresholds and datasets is shown, as well as the mean and median values. The y-axis on all figures is the value of K used by FBED^K. Overall, FBED^K has a virtually identical performance with FBS, while being on average between 1 and 2 orders of magnitude faster.

difference in AUC is less than 1% while the median difference is close to 0, and for all other K the performance is almost identical to FBS. We note that all those lower-performing cases are also the ones where FBED^K selected much fewer variables than FBS. In terms of the number of selected variables, FBED^K produces smaller solutions for $K < 3$, and tends to select the same number as FBS with increasing K. Finally, in terms of running time, FBED^K is significantly faster than FBS, being about 1-2 orders of magnitude faster on average in all cases.

An interesting case is for FBED^3, where the number of selected variables and AUC between both algorithms is almost identical, while being around 10 times faster than FBS. If

speed and small solutions are important, FBED^0 and FBED^1 are good choices, as they are ∼30-100 times faster than FBS, selecting only ∼70%-80% of the variables with a minimal drop in AUC. Therefore, if the number of variables is high, FBED^0 and FBED^1 are preferable due to their low computational lost. Furthermore, in low sample settings the smaller solutions of FBED^0 and FBED^1 are important, as selecting many variables leads to loss of power and overfitting. If on the other hand the sample size is large and the number of variables is relatively small, both FBS and FBED^K with higher values of K are reasonable choices, with the latter being more attractive, as it is around 1 order of magnitude faster and thus can scale to higher variable sizes.

4.4. Comparison of FBED^K with other Feature Selection Methods

We performed an experiment where we also optimize over the hyper-parameter values of feature selection algorithms. *The main objective of this comparison is to compare FBED^K to other feature selection algorithms in a realistic scenario, where hyper-parameter values are optimized.* For this comparison we focus on the predictive performance and number of selected variables; additional results showing the running time of each algorithm can be found in Appendix D.

4.4.1. Setup

For FBED^K optimization is performed over the threshold α and the number of runs K. We examine four versions of FBED^K: FBED^0, FBED$^{\leq 1}$, FBED$^{\leq 3}$ and FBED$^{\leq \infty}$. FBED$^{\leq K}$ means that optimization was performed for all results up to K runs. Thus, the number of hyper-parameter configurations used were 5, 10, 20 and around 50 (for most cases) for FBED^0, FBED$^{\leq 1}$, FBED$^{\leq 3}$ and FBED$^{\leq \infty}$ respectively. The hyper-parameter values for FBS, MMPC and LASSO-FS are the ones described in Section 4.1.1 (a total of 100, 20 and 100 respectively). We also included results when no feature selection was performed (NO-FS). Finally, we remind the reader that we used two sets of classification algorithms and hyper-parameters, one containing only linear algorithms (elastic net regularized logistic regression) and one also containing non-linear ones in addition to the linear ones (Gaussian support vector machines and random forests). For brevity, we will refer to linear models as LM and to the combination of linear and non-linear models as NLM hereafter.

4.4.2. Results

A summary of the results averaged over repetitions, measuring the AUC and number of selected variables is shown in Tables 2 and 3. For each algorithm, we computed a score which is the average rank of that algorithm over all datasets. The final rank of an algorithm is then computed based on that score. We used a bootstrap-based procedure to compute the probability of an algorithm being significantly better or worse than all competitors, and used a threshold of 95%. The procedure is described in more detail in Appendix C. In the tables, algorithms that are statistically significantly better than all others are shown in bold, whereas algorithms that are worse than the rest are shown in italic.

Overall, performing no feature selection has the highest AUC. Out of all feature selection methods, LASSO-FS offers the best predictive performance, statistically significantly outperforming the rest in 4 datasets. MMPC outperforms the rest in 2 and 3 datasets using

Table 2: Area under the ROC curve and number of selected variables for all feature selection algorithms using linear and non-linear models. The results are obtained after optimizing the hyper-parameters of the feature selection and modeling algorithms. Bold and italic entries denote that the method is significantly better or worse than all other feature selection methods (excluding NO-FS) respectively. The score is the average rank of each method over all datasets and the final rank is computed using those scores. Methods that select more variables tend to also perform better (Spearman correlation between AUC and variable rankings is -0.976).

NLM and LM respectively. In two cases FBED^0 is significantly worse than the rest (musk and gina), while FBS is the worst in 1 dataset. However, in terms of the number of selected

variables, LASSO-FS selects statistically significantly more in 7 and 5 cases for NLM and LM, while MMPC selects the most variables in 5 datasets for both NLM and LM. FBED^K and FBS on the other hand tend to select fewer variables. Thus, *there is a clear trade-off between model interpretability (number of selected variables) and predictive performance (AUC)*. Specifically, there is a -0.976 and -0.595 Spearman correlation between the AUC and selected variables ranks for NLM and LM respectively. For that reason, we performed an additional experiment, comparing the AUC between FBED^K, FBS and LASSO-FS by constraining the total number of variables to select, presented in Section 4.5.

A strong outlier in the NLM case is the difference in performance of LASSO-FS compared to the other methods on the madelon dataset, where LASSO-FS reaches an AUC that is $17.3 - 19.5\%$ higher, which is also close to the AUC of NO-FS. The main reason why all methods fail is because the madelon dataset has been constructed in a way that makes it hard for linear methods (FBED^K, FBS and MMPC using the logistic regression test). Specifically, the outcome variable has been artificially constructed to be a XOR-type problem of 5 variables (Guyon et al., 2006b). Further evidence for the hardness of this problem is the fact that using LM and NO-FS achieves an AUC of only 59.5 (even lower than all feature selection methods). LASSO-FS, although also linear, is able to pick up the signal as it basically performs no feature selection, selecting 495.4 out of 500 variables on average. This happens because LASSO-FS explores up to 100 values for λ, some of which correspond to very dense solutions. In contrast, due to the experimental setup, none of the remaining methods selects that many variables in this case.

An interesting observation is the fact that FBED^0 and FBED$^{\leq 1}$, the forward selection methods selecting the fewest variables, are ranked higher in terms of AUC than FBED$^{\leq 3}$, FBED$^{\leq \infty}$ and FBS when using LM. Thus, they are better suited to pick out linear trends in the data, producing solutions that are smaller and more predictive compared to algorithms of the same type. Using NLM gives an even bigger advantage to methods selecting more variables, as this increases the chance to also capture some non-linear signals in the data.

Finally, we performed a statistical test between all pairs of methods to identify cases where a method outperforms others, both in terms of AUC and number of selected variables. Again, we used a bootstrap-based test, computing the joint probability that method A has a higher AUC and selecting fewer variables than method B, using the same procedure as described in Appendix C. A method is considered to dominate another, if that probability is higher than 95%. The results are summarized in Figure 4. Each node corresponds to a feature selection method, and a directed edge from method A to B with weight w denotes that A dominates B in w datasets. We observe that, except for a single case where FBED$^{\leq \infty}$ gets dominated by FBS in 1 dataset for LM, FBED^K is never dominated by any other method, neither for the NLM nor for the LM case. In both NLM and LM cases, FBED^K dominates the competitors in 1-3 cases, while LASSO-FS and MMPC only dominate each other in 1-3 cases. Especially interesting is the fact that for NLM, FBED$^{\leq 3}$, FBED$^{\leq \infty}$ and FBS (that is, the forward-selection algorithms typically selecting the most variables) are the only algorithms that dominate others, while also not getting dominated. On the other hand, using LM only FBED^0 and FBED$^{\leq 1}$ both dominate others and are not getting dominated. This agrees with the observation made before, that FBED^0 and FBED$^{\leq 1}$ are particularly well suited to identify compact and linearly predictive solutions.

(a) Dominating Relationships (All Models) (b) Dominating Relationships (Linear Models)

Figure 4: The figures show how often a feature selection method dominates another (that is, has a higher AUC while selecting fewer variables), using non-linear models (left) and linear models (right). An edge from method A to B with weight w indicates that A dominates B in w datasets. Except for FBED$^{\leq \infty}$ for linear models, which gets dominated by FBS in 1 dataset, methods in the FBED^K family are never dominated by FBS, MMPC or LASSO-FS, while typically dominating them in 1-3 datasets.

Overall, *there is no clear winner, and the choice depends solely on the goal*. If the goal is predictive performance, LASSO-FS or MMPC are clearly preferable. If on the other hand one is interested in interpretability, then methods from the FBED^K family with small values of K are preferable. Regarding FBS, there is no scenario where it is preferable over one of the other algorithms. We must note that those results are somewhat artificial, as the performance of FBED^K and FBS highly depends on the hyper-parameter values chosen for the experiment, while LASSO-FS is not as sensitive to those choices. Furthermore, the fact that hyper-parameters are optimized based on performance naturally tends to favor methods that select more variables, putting LASSO-FS at a disadvantage in terms of interpretability.

4.5. Fixing the Number of Selected Variables

As confirmed by the previous experiment, there are two main trade-offs for feature selection algorithms: (a) the number of selected variables, with fewer variables leading to more interpretable results, and (b) the predictive ability of the selected variables, with more variables typically leading to better results. In general, algorithms that select more variables also tend to perform better in terms of predictive performance. Because of that, *we performed a comparison where algorithms are forced the select the same number of variables. That way, the predictive performance of algorithms can be compared on equal footing.*

We will compare FBED^K and LASSO-FS, when both are limited to select the same number of features. FBS is not included in the comparison, as we have already shown in

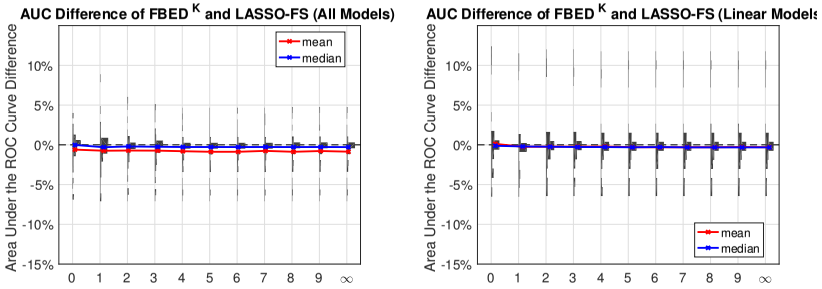

Figure 5: **LASSO-FS with limit on selected variables:** The x-axis shows the distribution of the difference in AUC of FBED^K and LASSO-FS, with positive values indicating that FBED^K performs better. The y-axis corresponds to value of K used by FBED^K. The mean and median values are shown in red and blue respectively. The average difference using non-linear models is 0.78%, and 0.23% when using only linear models. The difference can be explained by the arcene dataset, where LASSO-FS outperforms FBED^K even when selecting the same number of variables. A more detailed explanation is given in the main text.

Section 4.3 that FBS and FBED^K exhibit similar predictive performance with a similar number of selected features, with FBED^K being orders of magnitude faster. MMPC was not included, because neither MMPC nor FBED^K allow to set the number of features to select.

In order to perform the comparison, we executed FBED^K for multiple hyper-parameter values (the ones given in the experimental setup) and then executed LASSO-FS with the constraint to select the same number of variables as FBED^K did. As it was not always possible to select the exact same number of variables, we identified the solution of LASSO-FS with at least as many variables as FBED^K. Except for a few cases where LASSO-FS selected 1 more variable than FBED^K, both methods selected the same number of variables. As a final comment, we note that the above experiment does not favor FBED^K over LASSO-FS, as no optimization over its hyper-parameter values is performed. The reason we did not use a fixed number of variables M to select is because there is no easy way to select exactly M variables using FBED^K.

The comparison was performed similarly to the one between FBED^K and FBS in Section 4.3. Specifically, for a given K and threshold α, we computed the difference in AUC obtained by FBED^K and LASSO-FS. Thus, the only hyper-parameter optimization performed was over predictive models and not over the hyper-parameters of FBED^K. The results are shown in Figure 5. The x-axis corresponds to the difference in AUC between FBED^K and LASSO-FS, while the y-axis indicates the value K of FBED^K. We can see that, overall, both methods perform very similarly, regardless of whether linear models or non-linear models were used. For non-linear models, LASSO-FS outperforms FBED^K on average (over all K and α) by 0.78%, while using linear models the difference drops to

0.23%. In terms of median difference in AUC, a metric which is more stable with the respect to the datasets and hyper-parameter values used, both algorithms perform almost identically. Those results also agree with previous comparisons between forward selection and LASSO-FS (Hastie et al., 2017).

We investigated the difference in performance and found that it can be attributed to the arcene dataset. By removing this dataset, LASSO-FS outperforms FBED^K by 0.32% on average using non-linear models, while for linear models FBED^K performs better by 0.22%. Note that, arcene is the dataset which contains the fewest number of samples, while also containing a large number of variables. It contains 200 samples and 10000 variables, and only 120/160 are used for training and validation respectively. Theoretical results by Ng (2004) show that LASSO performs well in settings with low sample size and many irrelevant variables, as is the case for the arcene dataset. One possible explanation for the lower performance of FBED^K on arcene is that forward selection based procedures use more effective degrees of freedom (Hastie et al., 2017, Figure 1), thus requiring more sample size to have sufficient statistical power to pick up weak signals. It would be interesting to study this effect in more depth, but it is out of the scope of the current paper. In summary, *LASSO-FS and FBED^K perform similarly when the number of variables to select is the same.*

4.6. Simulation Study on the Multiple Testing Problem

The idea of early dropping of variables used by FBED^K does not only reduce the running time, but also reduces the problem of multiple testing, in some sense. Specifically, it reduces the number of variables falsely selected due to type I errors. In general, the number of false selections is related to the total number of variables considered in all forward iterations. Thus, the effect highly depends on the value of K used by FBED^K, with higher values of K leading to more false selections. We show this for FBED^0 by considering a simple scenario, where none of the candidate variables are predictive for the outcome. Then, in the worst case, FBED^0 will select about $\alpha \cdot p$ of the variables on average (where α is the significance level), since all other variables will be dropped in the first iteration. This stems from the fact that, under the null hypothesis of conditional independence, the p-values are uniformly distributed. In practice, the number of selected variables will be even lower, as FBED^0 will keep dropping variables after each variable inclusion. On the other hand, FBS may select a much larger number of variables, since each variable is given the chance to be included in the output at each iteration and will often do so, simply by chance.

We performed a small simulation to investigate the behavior of FBED^0, FBED^1, FBED$^\infty$ and how they compare to FBS. We generated 500 normally distributed datasets with 1000 samples each, a uniformly distributed random binary outcome, and considered different variable sizes $p \in \{100, 200, 300, 400, 500\}$ and 5 significance levels α uniformly spaced in $[0.01, 0.1]$. All variables are generated randomly, and there is no dependency between any of them. Thus, a false positive rate of about α is expected, if no adjustment is done to control the false discovery rate. For each setting, we computed the ratio of false positives with respect to the expected number of false positives.

Figure 6 (top) shows how the ratio varies for sample sizes 100 and 500 with increasing α, and Figure 6 (bottom) shows how the ratio varies for α 0.01 and 0.1 with increasing number

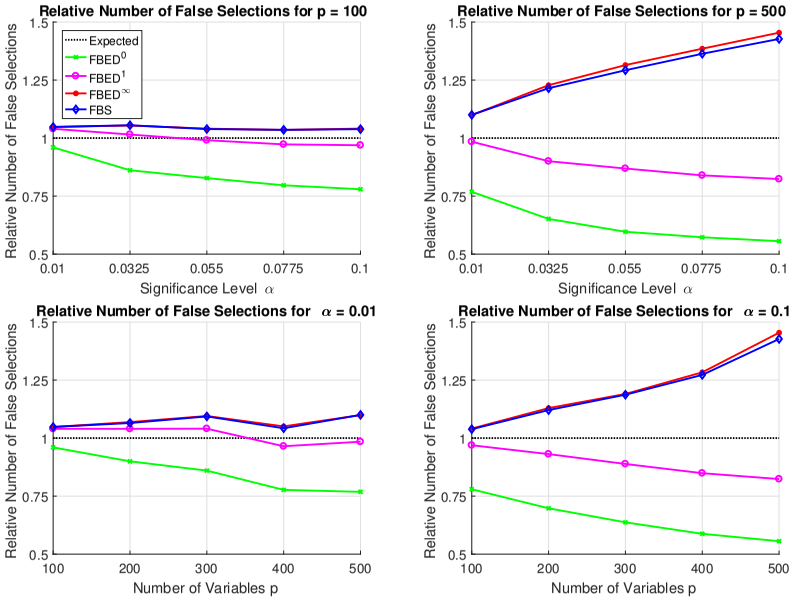

Figure 6: The figures show the relative number of false selections by each algorithm on randomly generated data. The expected number of false selections is $\alpha \cdot p$, where α is the significance level and p the number of variables. The numbers are computed as the ratio between the average number of selected variables to the expected false positives. FBED^0 and FBED^1 typically select fewer variables than expected, and their behavior improves with increasing α and p. FBED$^\infty$ and FBS on the other hand select more false positive variables, getting worse with larger values of α or on datasets with more variables.

of variables. In all cases, FBED^0 and FBED^1 select fewer false positives than expected, and their behavior improves both with increasing α and number of variables. FBED$^\infty$ and FBS perform almost identically, and tend to select more variables. We also observe that the number of false positives increases both with α and with the number of variables. Thus, *in case one is interested to limit the number of false selection, we recommend running FBED^K with a small value of K.*

5. Conclusion

We presented the early dropping heuristic to speed-up the forward-backward feature selection algorithm, which gives rise to a family of algorithms, called forward-backward selection with early dropping (FBED^K). Early dropping is a simple heuristic that leads to orders of magnitude speed-up, especially in high-dimensional datasets, while still maintaining the

theoretical guarantees of forward-backward selection. We prove that FBED^1 and FBED$^\infty$ identify the optimal solution (Markov blanket) if the distribution of the data can be faithfully represented by a Bayesian network or maximal ancestral graph respectively, similar to the standard forward-backward selection (FBS).

A useful property of FBED^K is that it is a general algorithm that can be adapted to handle different variable types (for example, continuous, categorical, ordinal), cross-sectional and time-course data, linear and non-linear dependencies, as well as different analysis tasks (for example, regression, classification, survival analysis) by using an appropriate conditional independence test. In contrast, algorithms like LASSO (Tibshirani, 1996), although being computationally fast and performing well in terms of predictive performance for common problems like regression and classification, are not as general (Meier et al., 2008; Schelldorfer et al., 2011; Ivanoff et al., 2016) and are computationally demanding for some problems (Fan et al., 2010; Groll and Tutz, 2014; Tsagris et al., 2018).

In experiments we demonstrate that FBED^K behaves similarly to FBS in terms of predictive performance and number of selected variables, while being 1-2 orders of magnitude faster. Compared to other feature selection algorithms like LASSO (Tibshirani, 1996) and MMPC (Tsamardinos et al., 2003a), FBED^K has competitive predictive performance, while selecting the fewest variables, which is especially important if feature selection is performed for knowledge discovery. An interesting result is that FBED^K and LASSO perform about equally well, when limited to select the same number of variables. This, combined with the fact that FBED^K is more general, makes it an attractive alternative to LASSO, especially for problems where no efficient solution to the LASSO problem exists.

Appendix A. Bayesian Networks and Maximal Ancestral Graphs

We will briefly introduce Bayesian networks and maximal ancestral graphs, which we will use to show theoretical properties of FBED^K.

A **directed acyclic graph** (DAG) is a graph that only contains directed edges ($\rightarrow$) and has no directed cycles. A **directed mixed graph** is a graph that, in addition to directed edges also contains bi-directed edges ($\leftrightarrow$). The graphs contain no self-loops, and vertices can be connected only by a single edge. Two vertices are called **adjacent** if they are connected by an edge. An edge between X and Y is called **into** Y if $X \rightarrow Y$ or $X \leftrightarrow Y$. A **path** in a graph is a sequence of unique vertices $\langle V_1, \ldots, V_k \rangle$ such that each consecutive pair of vertices is adjacent. The first and last vertices in a path are called **endpoints**. A path is called directed if $\forall 1 \leq i \leq k$, $V_i \rightarrow V_{i+1}$. If $X \rightarrow Y$ is in a graph, then X is a **parent** of Y and Y a **child** of X. A vertex W is a **spouse** of X, if both share a common child. A vertex X is an **ancestor** of Y, and Y is a **descendant** of X, if $X = Y$ or there is a directed path from X to Y. A triplet $\langle X, Y, Z \rangle$ is called a **collider** if Y is adjacent to X and Z, and both, X and Z are into Y. A triplet $\langle X, Y, Z \rangle$ is called **unshielded** if Y is

adjacent to X and Z, but X and Z are not adjacent. A path p is called a **collider path** if every non-endpoint vertex is a collider on p.

Bayesian networks (BNs) consist of a DAG $\mathcal{G}$ and a probability distribution $\mathcal{P}$ over a set of random variables $\mathbf{V}$. Each such variable is represent by a vertex in $\mathcal{G}$, and thus, the terms variable and vertex will be used interchangeably. The DAG represents dependency relations between variables in $\mathbf{V}$ and is linked with $\mathcal{P}$ through the **Markov condition**, which states that each variable is conditionally independent of its non-descendants given its parents. Those are not the only independencies encoded in the DAG; the Markov condition entails additional independencies, which can be read from the DAG using a graphical criterion called **d-separation** (Verma and Pearl, 1988; Pearl, 1988). In order to present the d-separation criterion we first introduce the notion of blocked paths. A (not necessarily directed) path p between two nodes X and Y is called **blocked** by a set of nodes $\mathbf{Z}$ if there is a node V on p that is a collider and, neither V nor any of its descendants are in $\mathbf{Z}$, or if V is not a collider and it is in $\mathbf{Z}$. If all paths between X and Y are blocked by $\mathbf{Z}$, then X and Y are **d-separated** given $\mathbf{Z}$; otherwise X and Y are **d-connected** given $\mathbf{Z}$. The **faithfulness condition** states that all and only those conditional independencies in $\mathcal{P}$ are entailed by the Markov condition applied to $\mathcal{G}$. In other words, the faithfulness condition requires that two variables X and Y are d-separated given a set of variables $\mathbf{Z}$ if and only if they are conditionally independent given $\mathbf{Z}$.

Bayesian networks are not closed under marginalization: a marginalized DAG, containing only a subset of the variables of the original DAG, may not be able to exactly represent the conditional independencies of the marginal distribution (Richardson and Spirtes, 2002). **Directed maximal ancestral graphs** (DMAGs) (Richardson and Spirtes, 2002) are an extension of BNs, which are able to represent such marginal distributions, that is, they admit the presence of latent confounders. The graphical structure of a DMAG is a directed mixed graph with the following restrictions: (i) it contains no directed cycles, (ii) it contains no almost directed cycles, that is, if $X \leftrightarrow Y$ then neither X nor Y is an ancestor of the other, and (iii) there is no primitive inducing path between any two non-adjacent vertices, that is, there is no path p such that each non-endpoint on p is a collider and every collider is an ancestor of an endpoint vertex of p. The d-separation criterion analogue for DMAGs is called the **m-separation criterion**, and follows the same definition.

A **Markov blanket** of a variable T is a **minimal** set of variables $\mathbf{MB}(T)$ that renders T conditionally independent of all remaining variables $\mathbf{V} \setminus \mathbf{MB}(T)$. In case faithfulness holds, and the distribution can be represented by a BN or DMAG, then the Markov blanket is **unique**. For a BN, the Markov blanket of T consists of its parents, children and spouses. For DMAGs it is slightly more complicated: the Markov blanket of T consists of its parents, children and spouses, as well as its district (all vertices that are reachable by bi-directed edges), the districts of its children and the parents of all districts (Richardson, 2003). An alternative definition is given next.

Definition 1 The Markov blanket of T in a BN or DMAG consists of all vertices adjacent to T, as well as all vertices that are reachable from T through a collider path.

A proof sketch follows. Recall that a collider path of length $k-1$ is of the form $X_1 * \rightarrow X_2 \dots X_{k-1} \leftarrow * X_k$, where the path between X_2 and X_{k-1} contains only bi-directed edges. Given this, it is easy to see that Definition 1 includes vertices directly adjacent to T, its spouses (collider path of length 2), and in the case of DMAGs, vertices D in the district of

T ($T \leftrightarrow \dots \leftrightarrow D$), vertices D in the district of any children C of T ($T \rightarrow C \leftrightarrow \dots \leftrightarrow D$), and all parents P of any vertex D in some district ($T* \rightarrow \dots \leftrightarrow D \leftarrow P$). As the previous cases capture exactly all possibilities of nodes reachable from T through a collider path, Definition 1 does not include any additional variables that are not in the Markov blanket of T.

Appendix B. Proofs

We proceed by listing some axioms about conditional independence (Pearl, 2000), called **semi-graphoid** axioms, which will be useful later on. Those axioms are general, as they hold for any probability distribution. For all of the proofs we assume that the algorithms have access to an **independence oracle** that can perfectly determine whether a given conditional dependence or independence holds. Furthermore, in all proofs we will use the terms d-connected/m-connected (d-separated/m-separated) and dependent (independent) interchangeably; this is possible due to the faithfulness assumption.

Symmetry	$(\mathbf{X} \perp \mathbf{Y} \mid \mathbf{Z}) \Rightarrow (\mathbf{Y} \perp \mathbf{X} \mid \mathbf{Z})$
Decomposition	$(\mathbf{X} \perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \Rightarrow (\mathbf{X} \perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp \mathbf{W} \mid \mathbf{Z})$
Weak Union	$(\mathbf{X} \perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z}) \Rightarrow (\mathbf{X} \perp \mathbf{Y} \mid \mathbf{Z} \cup \mathbf{W})$
Contraction	$(\mathbf{X} \perp \mathbf{Y} \mid \mathbf{Z}) \wedge (\mathbf{X} \perp \mathbf{W} \mid \mathbf{Y} \cup \mathbf{Z}) \Rightarrow (\mathbf{X} \perp \mathbf{Y} \cup \mathbf{W} \mid \mathbf{Z})$

Using those axioms we prove the following lemma.

Lemma 7 *Let A, T be variables and $\mathbf{B}$, $\mathbf{C}$ sets of variables. Then $(T \perp A \mid \boldsymbol{B} \cup \mathbf{C}) \wedge (T \perp \boldsymbol{B} \mid \mathbf{C}) \Rightarrow (T \perp A \mid \mathbf{C})$ holds for any such variables.*

Proof

$(T \perp A \mid \mathbf{B} \cup \mathbf{C}) \wedge (T \perp \mathbf{B} \mid \mathbf{C}) \Rightarrow$ (**Contraction**)
$(T \perp A \cup \mathbf{B} \mid \mathbf{C}) \Rightarrow$ (**Decomposition**)
$(T \perp A \mid \mathbf{C}) \wedge (T \perp \mathbf{B} \mid \mathbf{C})$

■

The following lemma will be useful for proving some of the theorems.

Lemma 8 *Let $\mathbf{S}$ be a set of variables selected for some target T and $\mathbf{R} = \mathbf{V} \setminus \mathbf{S}$. Assume that $\forall V_r \in \mathbf{R}$ $(T \perp V_r \mid \mathbf{S})$ holds. Then, if $\exists V_s \in \mathbf{S}$ such that $(T \perp V_s \mid \mathbf{S} \setminus V_s)$ holds, $\forall V_r \in \mathbf{R}$ $(T \perp V_r \mid \mathbf{S} \setminus V_s)$ also holds.*

Proof We are given that $\forall V_r \in \mathbf{R}$ $(T \perp V_r \mid \mathbf{S})$ holds. By applying Lemma 7 to each variable in $V_r \in \mathbf{R}$ with $A = V_r$, $\mathbf{B} = \{V_s\}$ and $\mathbf{C} = \mathbf{S} \setminus V_s$, we get that $(T \perp V_r \mid V_s \cup (\mathbf{S} \setminus V_s)) \wedge (T \perp V_s \mid \mathbf{S} \setminus V_s) \Rightarrow (T \perp V_r \mid \mathbf{S} \setminus V_s)$ holds for any such V_r, which concludes the proof. ■

To put it simple, Lemma 8 states that if we remove any variable V_s from a set of selected variables $\mathbf{S}$ by conditioning on $\mathbf{S} \setminus V_s$, no variable that is not in $\mathbf{S}$ becomes conditionally dependent with T given $\mathbf{S} \setminus V_s$. In practice this means that removing variables using backward selection from a set of variables selected by forward selection will not create any additional conditional dependencies, meaning that we do not have to reconsider them again.

Proof of Corollary 3
Proof To show that $\mathbf{S}$ is minimal, we have to show the following

i $\forall V_s \in \mathbf{S}$ $(T \not\perp V_s \mid \mathbf{S} \setminus V_s)$ (*No variable can be removed*)

ii $\forall V_r \in \mathbf{V_D} \setminus \mathbf{S}, (T \perp V_r \mid \mathbf{S})$ (*No variable can be added*)

Proof of (i): This holds trivially, as backward selection removes any variable $V_s \in \mathbf{S}$ if $(T \perp V_s \mid \mathbf{S} \setminus V_s)$ holds.
Proof of (ii): We know that after the termination of forward selection, no variable can be added, that is, $\forall V_r \in \mathbf{R}$ $(T \perp V_r \mid \mathbf{S})$ holds. Given that, Lemma 8 can be repeatedly applied after each variable removal by backward selection, and thus no variable in $\mathbf{R}$ can be added to $\mathbf{S}$. ■

Proof of Corollary 4
Proof As is the case with FBS, the forward selection phase of FBED$^\infty$ stops if no more variables can be included. Using this fact, the proof is identical to the one of Theorem 3. ■

Proof of Theorem 5
Proof In the first run of FBED^1, all variables that are adjacent to T (that is, its parents and children) will be selected, as none of them can be d-separated from T by any set of variables. In the next run, all variables connected through a collider path of length 2 (that is, the spouses of T) will become d-connected with T, since the algorithm conditions on all selected variables (including its children), and thus will be selected. The resulting set of variables includes the Markov blanket of T, but may also include additional variables. Next we show that all additional variables will be removed by the backward selection phase. Let MB(T) be the Markov blanket of T and $\mathbf{S_{ind}} = \mathbf{S} \setminus$MB($T$) be all selected variables not in the Markov blanket of T. By definition, $(T \perp \mathbf{X} \mid MB(T))$ holds for any set of variables $\mathbf{X}$ not in MB(T), and thus also for variables $\mathbf{S_{ind}}$. By applying the weak union graphoid axiom, one can infer that $\forall S_i \in \mathbf{S_{ind}}, (T \perp S_i \mid MB(T) \cup \mathbf{S_{ind}} \setminus S_i)$ holds, and thus some variable S_j will be removed in the first iteration. Using the same reasoning and the definition of a Markov blanket, it can be shown that all variables in $\mathbf{S_{ind}}$ will be removed from MB(T) at some iteration. To conclude, it suffices to use the fact that variables in MB(T) will not be removed by the backward selection, as they are not conditionally independent of T given the remaining variables in MB(T). ■

Proof of Theorem 6
Proof In the first run of FBED$^\infty$, all variables that are adjacent to T (that is, its parents, children and variables connected with T by a bi-directed edge) will be selected, as none

of them can be m-separated from T by any set of variables. After each run additional variables may become admissible for selection. Specifically, after k runs all variables that are connected with T by a collider path of length k will become m-connected with T, and thus will be selected; we prove this next. Assume that after k runs all variables connected with T by a collider path of length at most $k-1$ have been selected. By conditioning on all selected variables, all variables that are into some selected variable connected with T by a collider path will become m-connected with T. This is true because conditioning on a variable Y in a collider $\langle X, Y, Z \rangle$ m-connects X and Z. By applying this on each variable on some collider path, it is easy to see that its end-points become m-connected. Finally, after applying the backward selection phase, all variables that are not in the Markov blanket of T will be removed; the proof is identical to the one used in the proof of Theorem 5 and thus will be omitted. ■

Appendix C. Bootstrap Test For Comparing Algorithms

We used bootstrapping to compute the probability that algorithm A_i is better/worse or equal than all others in terms of some measure of interest f (for example, AUC), that is $P(\wedge_{j \neq i} f(A_i) \geq f(A_j))$. The procedure is described next. Let $f_{i,k}$ denote the measure of interest of algorithm i on test set k. We resample with replacement $B = 100000$ times the test sets and compute f, denoted as $f_{i,k,b}$ for the b-th sample of algorithm i and test set k. Then, $f_{i,k,b}$ are averaged over test sets, obtaining $\hat{f}_{i,b}$. The probability $P(\wedge_{j \neq i} f(A_i) \geq f(A_j))$ is then computed as $1/B \sum_b I(\hat{f}_{i,b} \geq \max_j \hat{f}_{j,b})$, where I is the indicator function.

Appendix D. Running Times of FBED^K, FBS, MMPC and LASSO

Table 4 shows the running time of each feature selection algorithm and configuration, on all datasets. The values correspond to a single run on the complete dataset. All runs were performed on a single machine, and no runs were performed simultaneously. For FBED^K we only show running times for $K \in \{0, 1, 3, \infty\}$, and for LASSO-FS we show results for $\lambda_{max} \in \{25, 100, 500\}$. MMPC for a given value of $maxK$ is denoted as MMPC^{maxK}.

It can clearly be seen that LASSO-FS is the fastest in large datasets, irrespective of the number of λ values used. For smaller datasets (musk, sylva, madelon, secom, gina and hiva), FBED^0 and FBED^1 are often at least as fast as LASSO-FS. FBS and MMPC with $maxK \geq 3$ are the slowest among all algorithms. For the gisette and nova datasets, MMPC with $maxK \geq 3$ fails to terminate after a timeout limit of 2 days. For $maxK \leq 2$ MMPC often has competitive performance with the other algorithms. We note that MMPC was designed specifically for low sample sizes and high dimensional data, such as data from biological domains which contain a few tens or hundreds of samples and tens of thousands of variables, explaining the high running times on the datasets considered in our experiments, most of which contain thousands of samples.

The large difference between the running time of LASSO-FS and the other algorithms can largely be attributed to their implementations. For LASSO-FS the glmnet implementation was used, which is highly optimized and written in FORTRAN. In contrast, for FBED^K, FBS and MMPC we used a custom logistic regression implementation written in Matlab.

A difference of 1-2 orders of magnitude can be expected between the same implementation in a low-level language such as FORTRAN, C or C++ and higher-level languages such as Matlab. Therefore, we would expect that an implementation in a lower-level language would perform similarly to LASSO-FS. Of course, LASSO-FS has the advantage that it returns the whole solution path, and thus would still be faster in practice if hyper-parameter optimization is also performed.

Table 4: Running times in seconds on the full datasets.

Editor: Peter Auer

Abstract

We study the pricing problem faced by a firm that sells a large number of products, described via a wide range of features, to customers that arrive over time. Customers independently make purchasing decisions according to a general choice model that includes products features and customers' characteristics, encoded as d-dimensional numerical vectors, as well as the price offered. The parameters of the choice model are a priori unknown to the firm, but can be learned as the (binary-valued) sales data accrues over time. The firm's objective is to maximize its revenue. We benchmark the performance using the classic regret minimization framework where the regret is defined as the expected revenue loss against a clairvoyant policy that knows the parameters of the choice model in advance, and always offers the revenue-maximizing price. This setting is motivated in part by the prevalence of online marketplaces that allow for real-time pricing.

We assume a structured choice model, parameters of which depend on s_0 out of the d product features. Assuming that the market noise distribution is known, we propose a dynamic policy, called Regularized Maximum Likelihood Pricing (RMLP) that leverages the (sparsity) structure of the high-dimensional model and obtains a logarithmic regret in T. More specifically, the regret of our algorithm is of $O(s_0 \log d \cdot \log T)$. Furthermore, we show that no policy can obtain regret better than $O(s_0(\log d + \log T))$. In addition, we propose a generalization of our policy to a setting that the market noise distribution is unknown but belongs to a parametrized family of distributions. This policy obtains regret of $O(\sqrt{(\log d)T})$. We further show that no policy can obtain regret better than $\Omega(\sqrt{T})$ in such environments.

Keywords: Revenue Management, Dynamic Pricing, High-dimensional Regression, Maximum Likelihood, Regret, Sparsity

1. Introduction

A central challenge in revenue management is determining the optimal pricing policy when there is uncertainty about customers' willingness to pay. Due to its importance, this problem has been studied extensively (Kleinberg and Leighton, 2003; Besbes and Zeevi, 2009; Badanidiyuru et al., 2013; Wang et al., 2014; Broder and Rusmevichientong, 2012; Keskin and Zeevi, 2014; den Boer and Zwart, 2014; Cohen et al., 2016). Most of these models are built around the following classic setting: customers arrive over time; the seller posts a price for each customer; if the customer's valuation is above the posted price, a sale occurs and the seller collects a revenue in the amount of the posted price; otherwise, no sale occurs and no revenue is generated. Based on this and the previous feedbacks, the seller updates the posted price. Therefore, the seller is involved in the realm of exploration-exploitation as he needs to choose between learning about the valuations and exploiting what has been learned so far to collect revenue.

In this work, we consider a setting with a large number of products which are defined via a wide range of features. The valuations are given by $v(\theta, x)$ with x being the (observable) feature vectors of products and θ_0 representing the customer's characteristics true parameters of the choice model, which is initially unknown to the seller, cf. (Amin et al., 2014; Cohen et al., 2016). An important special case of this setting is the linear model in which

$$v(\theta, x) = \theta_0 \cdot x + z\,, \tag{1}$$

where z captures the idiosyncratic noise in valuations.

Our setting is motivated in part by applications in online marketplaces. For instance, a company such as Airbnb recommends prices to hosts based on many features including the space (number of rooms, beds, bathrooms, etc.), amenities (AC, WiFi, washer, parking, etc.), the location (accessibility to public transportation, walk score of the neighborhood, etc.), house rules (pet-friendly, non-smoking, etc.), as well as the prediction of the demand which itself depends on many factors including the date, events in the area, availability and prices of near-by hotels, etc. (Airbnb Documentation, 2015). Therefore, the vector describing each property can have hundreds of features. Another important application comes from online advertising. Online publishers set the (reserve) price of ads based on many features including user's demographic, browsing history, the context of the webpage, the size and location of the ad on the page, etc.

In this work, we propose *Regularized Maximum Likelihood Pricing* (RMLP) policy for dynamic pricing in high-dimensional environments. As suggested by its name, the policy uses maximum likelihood method to estimate the true parameters of the choice model. In addition, using an (ℓ_1-norm) regularizer, our policy exploits the structure of the optimal solution; namely, the performance of the RMLP policy significantly improves if the valuations are essentially determined by a small subset of features. More formally, the difference between the revenue obtained by our policy and the benchmark policy that knows in advance the true parameters of the choice model, θ_0, is bounded by $O\big(s_0 \log d \cdot \log T\big)$, where T, d, and s_0 respectively denote the length of the horizon, number of the features, and sparsity (i.e., number of non-zero elements of θ_0). We show that our results are nearly optimal and no policy can obtain regret better than $O\big(s_0(\log d + \log T)\big)$.

In the RMLP policy it is assumed that the noise distribution (distribution of term z in valuation model (1)) is known to the seller. We also consider the setting that the noise distribution is unknown but belongs to a parametrized family of distributions. We propose RMLP-2 policy for such setting and prove that it achieves a regret of $O(\sqrt{(\log d)T})$. We further how that no policy can get regret better than $\Omega(\sqrt{T})$ in this setting.

We point out that our results can be applied to applications where the features dimension is larger than the time horizon of interest. A powerful pricing policy for these applications should obtain regret that scales gracefully with the dimension. Note that in general, little can be learned about the model parameters θ_0 if $T < d$, because the number of degrees of freedom d exceeds the number of observations T, and therefore, any estimator can be arbitrary erroneous. However, when there is prior knowledge about the structure of unknown parameter θ_0, (e.g., sparsity), then accurate estimations are attainable even when $T < d$.

1.1. Organization and Contributions

In the remaining part of the introduction, we discuss how our work is positioned with respect to the literature on dynamic pricing and high-dimensional statistics. The rest of the paper presents the following contributions:

- Section 2. We formally present our model and discuss the technical assumptions and the benchmark policy.
- Section 3. We present the RMLP policy that uses a regularized maximum likelihood function to estimate the parameters of the choice model and subsequently sets the best prices based on the obtained estimates. The RMLP policy assumes that the market noise distribution is known and forms the log-likelihood function based on this knowledge.
- Section 4. We analyze the regret of the RMLP policy with respect to a clairvoyant who knows the parameters of the choice model in advance. We show that it achieves a regret of $O(s_0 \log d \cdot \log T)$.
- Section 5. We provide a lower bound on the regret of any policy that does not know the parameters of the choice model in advance. Namely, we show that no policy can obtain regret better than $O(s_0(\log d + \log T))$.
- Section 6. We generalize the RMLP policy to non-linear valuations functions and show that, similar to the case of linear valuations, it achieves a regret of $O(s_0 \log d \cdot \log T)$.
- Section 7. We consider a setting where the exact underlying noise distribution is not known but it is assumed to belong to a known class of log-concave distributions. We propose the RMLP-2 policy, so-named, for this setting whose regret is $O(\sqrt{(\log d)T})$. We also argue that no policy can get better than $O(\sqrt{T})$ regret in this setting.
- Section 8. We provide the proofs of our main theorems and results.

We conclude our work along with some future directions in Section 9. Proof of technical lemmas are deferred to the appendices.

1.2. Related Work

Our work contributes to the literature on dynamic pricing as well as high dimensional statistics. In the following, we briefly overview the work closest to ours in these contexts.

Dynamic pricing and learning. The literature on dynamic pricing and learning has been growing over the past few years, motivated in part by the advances in big data technology that allow firms to easily collect and utilize information. We briefly discuss some of the recent lines of research in this literature. We refer to den Boer (2015) for an excellent survey on this topic.

Parametric Approach. A natural approach to capture uncertainty about the customers' valuations is to model the uncertainty using a small number of parameters, and then estimate those parameters using classical statistical methods such as maximum likelihood (Broder and Rusmevichientong, 2012; den Boer and Zwart, 2013, 2014; Chen et al., 2015) or least square estimation (Keskin, 2014; Bastani and Bayati, 2016). Our work is similar to this line of work, in that we assume a parametric model for customer's valuations and apply the maximum likelihood method using the randomness of the idiosyncratic noise in valuations. However, the parameter vector θ is high-dimensional, whose dimension d (that can even exceed the time horizon of interest T). We use *regularized* maximum-likelihood in order to promote sparsity structure in the estimated parameter. Further, our pricing policy has an episodic theme which makes the posted prices p_t in each episode independent of the idiosyncratic noise in valuations, z_t, in that episode. This is in contrast to other policies based on maximum-likelihood, such as MLE-GREEDY (Broder and Rusmevichientong, 2012), or greedy iterative least square (GILS) (Keskin, 2014; den Boer and Zwart, 2014; Qiang and Bayati, 2016) that use the entire history of observations to update the estimate for the model parameters at each step.

Bayesian Approach. One of the earliest work on Bayesian parametric approach in this context is by (Rothschild, 1974) who consider a Bayesian framework where the firm can choose from two prices with unknown demand and show that (myopic) Bayesian policies may lead to "incomplete learning." However, carefully designed variations of the myopic policies can (optimally) learn the optimal price (Harrison et al., 2012); see also Keller and Rady (1999); Araman and Caldentey (2009).

Non-Parametric models. An early work in non-parametric setting is by Kleinberg and Leighton (2003). They model the dynamic pricing problem as a multi-armed bandit (MAB) where each arm corresponds to a (discretized) posted price. They propose an $O(\sqrt{T})$-algorithm where T is the length of the horizon. Similar results have been obtained in more general settings (Badanidiyuru et al., 2013; Agrawal and Devanur, 2014) including setting with inventory constraints (Besbes and Zeevi, 2009; Babaioff et al., 2012; Wang et al., 2014).

Feature-based Models. Recent papers on dynamic pricing consider models with features/covariates. Amin et al. (2014), in a model similar to ours, present an algorithm that obtains regret $O(T^{2/3})$; they also study dynamic incentive compatibility in repeated auctions. Another closely related work to ours is by Cohen et al. (2016). Their model differs from ours in two main aspects: *i*) their model is deterministic (no idiosyncratic noise) *ii*) the arrivals (of features vectors) is modeled as adversarial. They propose a clever binary-search approach using the Ellipsoid method which obtains regret of $O(d^2 \log(T/d))$. Recently, Golrezaei et al. (2018) studied the problem of dynamic pricing when a group of strategic buyers competes with each other in repeated contextual auctions. To the extent of our knowledge, ours is the first work that highlights the role of structure/sparsity in dynamic pricing.

Qiang and Bayati (2016) study a model where the seller can observe the demand itself, not a binary signal as in our setting. They show that a myopic policy based on least-square estimations can obtain a logarithmic regret. Bastani and Bayati (2016) study a multi-armed bandit setting, with discrete arms, and high-dimensional covariates, generalizing results of Goldenshluger and Zeevi (2013). More precisely, the decision-maker has access to K arms (decisions), where each arm i has an unknown sparse parameter vector $\beta_i \in \mathbb{R}^d$. Upon pulling arm i at time t, the decision-maker gets reward $x_t \cdot \beta_i + z_t$. The authors present an algorithm, using a LASSO estimator, that obtains regret $O\left(K(\log T + \log d)^2\right)$ where K denotes the number of arms. By contrast, in our setting decisions (prices) can take continuous values and also the resulting rewards do not follow a similar relationship with the covariates and the decisions.

High-dimensional statistics. There has been a great deal of work on regularized estimator under the high-dimensional scaling; see e.g., Van de Geer (2008). Closer to the spirit of our work is the problem of 1-bit compressed sensing (Plan and Vershynin, 2013; Bhaskar and Javanmard, 2015). In this problem, linear measurements are observed for an unknown parameter of interest but only the sign of these measurements are observed. Note that in our problem, the seller is involved in both the learning task and also the policy design. Specifically, he should decide on the prices, which directly affect collected revenue and also indirectly influence the difficulty of the learning task. The market values are then compared with the posted prices, in contrast to 1-bit compressed sensing where the measurements are compared with zero (sign information). In addition, the pricing problem has an online nature while the 1-bit compressed sensing is mostly studied for offline setting. Finally, note that prices are set based on customer's purchase behavior, and hence introduce dependency among the collected information about the model parameters.

1.3. Notations

For a vector v, $\mathrm{supp}(v)$ represents the positions of nonzero entries of v. Further, for a vector v and a subset J, v_J is the restriction of v to indices in J. We write $\|v\|_p$ for the standard ℓ_p norm of a vector v, i.e., $\|v\|_p = (\sum_i |v_i|^p)^{1/p}$ and $\|v\|_0$ for the umber of nonzero entries of v. If the subscript p is omitted, it should be deemed as ℓ_2 norm. For two vectors $a, b \in \mathbb{R}^d$, the notation $a \cdot b = \sum_{i=1}^d a_i b_i$ represents the standard inner product. For two functions $f(n)$ and $g(n)$, the notation $f(n) = O(g(n))$ means that f is bounded above by g asymptotically, namely, $f(n) \le Cg(n)$ for some fixed positive constant $C > 0$. Throughout, $\phi(x) = e^{-x^2/2}/\sqrt{2\pi}$ is the Gaussian density and $\Phi(x) \equiv \int_{-\infty}^{x} \phi(u)\mathrm{d}u$ is the Gaussian distribution.

2. Choice Model

We consider a seller, who has a product for sale in each period $t = 1, 2, \cdots, T$, where T denotes the length of the horizon and may be unknown the to the seller. Each product is represented by an *observable* vector of features (covariates) $x_t \in \mathcal{X} \subseteq \mathbb{R}^d$. Products may vary across periods and we assume that feature vectors x_t are sampled independently from a fixed, but a priori *unknown*, distribution $\mathbb{P}_X$, supported on a bounded set $\mathcal{X}$.

The product at time t has a market value $v_t = v(x_t)$, which is *not observed* by the seller and function v is (a priori) unknown. At each period t, the seller posts a price p_t. If $p_t \le v_t$, a sale occurs, and the seller collects revenue p_t. If the price is set higher than the market value, $p_t > v_t$, no sale occurs and no revenue is obtained. The goal of the seller is to design a pricing policy that maximizes the collected revenue.

We first assume that the market value of a product is a linear function of its covariates, namely

$$v(x_t) = \theta_0 \cdot x_t + z_t\,, \tag{2}$$

where $a \cdot b$ denotes the inner product of vectors a and b. Here, $\{z_t\}_{t\ge 1}$ are idiosyncratic shocks, referred to as noise, which are drawn independently and identically from a distribution with mean zero and cumulative function F, with density $f(x) = F'(x)$, cf. (Keskin and Zeevi, 2014). The noise can account for the features that are not measured. We generalize our model to non-linear valuation functions in Section 6. Parameter θ_0 is a priori unknown to the seller. Therefore, the seller is involved in the realm of exploration-exploitation as he needs to choose between learning θ_0 and exploiting what has been learned so far to collect revenue.

Let y_t be the response variable that indicates whether a sale has occurred at period t:

$$y_t = \begin{cases} +1 & \text{if } v_t \ge p_t\,, \\ -1 & \text{if } v_t < p_t\,. \end{cases} \tag{3}$$

Note that the above model can be represented as the following probabilistic model:

$$y_t = \begin{cases} +1 & \text{with probability } \ 1 - F\left(p_t - \theta_0 \cdot x_t\right)\,, \\ -1 & \text{with probability } \ F\left(p_t - \theta_0 \cdot x_t\right)\,. \end{cases} \tag{4}$$

Our proposed algorithm exploits the structure (sparsity) of the feature space to improve its performance. To this aim, let s_0 denote the number of nonzero coordinates of θ_0, i.e., $s_0 = \|\theta_0\|_0 = \sum_{j=1}^d \mathbb{I}(\theta_{0j} \neq 0)$. We remark that s_0 is a priori unknown to the seller.

2.1. Technical Assumptions

To simplify the presentation, we assume that $\|x_t\|_\infty \le 1$, for all $x_t \in \mathcal{X}$, and $\|\theta_0\|_1 \le W$ for a known constant $W \ge 1$, where for a vector $u = (u_1, \ldots, u_d)$, $\|u\|_\infty = \max_{i\in[d]} |u_i|$ denotes the maximum absolute value of its entries and $\|u\|_1 = \sum_{i=1}^d |u_i|$. We denote by Ω the set of feasible parameters, i.e.,

$$\Omega = \left\{\theta \in \mathbb{R}^{d+1} : \|\theta\|_0 \le s_0\,,\ \|\theta\|_1 \le W\right\}. \tag{5}$$

We also make the following assumption on the distribution of noise F.

Assumption 1 *The function $F(v)$ is strictly increasing. Further, $F(v)$ and $1 - F(v)$ are log-concave in v.*

Log-concavity is a widely-used assumption in the economics literature (Bagnoli and Bergstrom, 2005). Note that if the density f is symmetric and the distribution F is log-concave, then $1-F$ is also log-concave. Assumption 1 is satisfied by several common probability distributions including normal, uniform, Laplace, exponential, and logistic. Note that the cumulative distribution function of all log-concave densities is also log-concave (Boyd and Vandenberghe, 2004).

Our second assumption is on the product feature vectors.

Assumption 2 *Product feature vectors are generated independently from a fixed unknown distribution $\mathbb{P}_X$ with a bounded support $\mathcal{X} \in \mathbb{R}^d$. We denote by $\Sigma = \mathbb{E}(x_t x_t^\intercal)$ the second moment matrix of distribution $\mathbb{P}_X$, and assume that Σ is a positive definite matrix. Namely, all of its eigenvalues are bounded from below by a constant $C_{\min} > 0$. We also denote the maximum eigenvalue of Σ by $C_{\max}$.*

The above assumption holds for many common probability distributions, such as uniform, truncated normal, and in general truncated version of many more distributions. Generally, if $\mathbb{P}_X$ is bounded below from zero on an open set around the origin, then it has a positive definite second moment matrix. Let us stress that the seller knows neither the distribution $\mathbb{P}_X$, nor its second moment Σ.

2.2. Clairvoyant Policy and Performance Metric

We evaluate the performance of our algorithm using the common notion of regret: the expected revenue loss compared with the optimal pricing policy that knows θ_0 in advance (but not the realizations of $\{z_t\}_{t\geq 1}$). Let us first characterize this benchmark policy.

Using Eq. (2), the expected revenue from a posted price p is equal to

$$p \times \mathbb{P}(v_t \geq p) = p(1 - F(p - \theta_0 \cdot x_t))\,.$$

Therefore, using first order conditions, for the optimal posted price, denoted by p^*, we have

$$p^*(x_t) = \frac{1 - F(p^* - \theta_0 \cdot x_t)}{f(p^* - \theta_0 \cdot x_t)}\,. \tag{6}$$

To simplify the presentation, let $p_t^* = p^*(x_t)$ denote the optimal price at time t.

We now define $\varphi(v) \equiv v - (1-F(v))/f(v)$ corresponding to the *virtual valuation* function commonly used in mechanism design (Myerson, 1981). By Assumption 1, φ is injective and hence we can define function g as follows

$$g(v) \equiv v + \varphi^{-1}(-v)\,. \tag{7}$$

It is easy to verify that g is non-negative. Note that by Eq. (6), for the optimal price we have

$$\theta_0 \cdot x_t + \varphi(p^* - \theta_0 \cdot x_t) = 0\,.$$

Therefore, by rearranging the terms for the optimal price at time t we have

$$p_t^* = g(\theta_0 \cdot x_t)\,. \tag{8}$$

We can now formally define the regret of a policy. Let π be the seller's policy that sets price p_t at period t, and p_t can depend on the history of events up to time t. The worst-case regret is defined as:

$$\mathsf{Regret}_\pi(T) \equiv \max_{\substack{\theta_0 \in \Omega \\ \mathbb{P}_X \in Q(\mathcal{X})}} \mathbb{E}\left[\sum_{t=1}^{T}\Big(p_t^* \mathbb{I}(v_t \geq p_t^*) - p_t \mathbb{I}(v_t \geq p_t)\Big)\right], \tag{9}$$

where the expectation is with respect to the distributions of idiosyncratic noise, z_t, and $\mathbb{P}_X$, the distribution of feature vectors. Also, $Q(\mathcal{X})$ represents the set of probability distributions supported on a bounded set $\mathcal{X}$.

Our algorithm uses the sparsity structure of θ_0 and learns the model with order of magnitude less data compared to a structure-ignorant algorithm. In Section 4, we show that our pricing scheme achieves a regret bound of $O\big(s_0 \log d \cdot \log T\big)$.

Note that the setting with known market noise distribution is equivalent to positing a parametric choice model on the users' behavior. Several parametric choice models have been widely used by practitioners and have been analyzed by researchers. Perhaps the most well-known example is the multinomial logit (MNL) model, which has quite a long history in economic and transportation research (McFadden, 2001), as well as marketing (Hauser and Koppelman, 1979; Gensch and Recker, 1979; Louviere and Woodworth, 1983; Guadagni and Little, 2008). Note that the MNL model corresponds to the case where customers are offered multiple products at each round and the market noise is coming from the Gumbel distribution (Talluri and Van Ryzin, 2006). In the case of single product offered at each round (similar to our setting), this reduces to noise coming from the logistic distribution. Other prominent MNL models include Nested MNL, latent-class MNL, random-parameter mixed MNL, and hierarchical Bayesian MNL (Elshiewy et al., 2017).

In Section 7 we relax the assumption of knowing the market noise distribution.

3. A Regularized Maximum Likelihood Pricing (RMLP) Policy

In this section, we present our dynamic pricing policy. Our policy runs in an episodic fashion. Episodes are indexed by k and time periods are indexed by t. The length of episode k is denoted by τ_k. Throughout episode k, we set the prices equal to $p_t = g(x_t \cdot \widehat{\theta}^k)$ where $\widehat{\theta}^k$ denotes the estimate of θ_0 which is obtained from the observations $\{(x_t, y_t, p_t)\}$ in the *previous* episode. Note that by Eq. (7), p_t is the optimal posted price if $\widehat{\theta}^k$ was the true underlying parameter of the model.

We estimate θ_0 using a regularized maximum-likelihood estimator; see Eq. (10) where the (normalized) negative log-likelihood function for θ is given by Eq. (11). We note that as a consequence of the log concavity assumption on F and $1-F$, the optimization problem (10) is a convex problem. There is a large toolkit of various optimization methods (e.g., alternating direction method of multipliers (ADMM), fast iterative shrinkage-thresholding algorithm (FISTA), accelerated projected gradient descent, among many others) that can be used to solve this optimization problem. There are also recent developments on distributed solvers for ℓ_1 regularized cost function (Boyd et al., 2011).

Observe that by design, prices posted in the k-th episode are independent from the market value noises in this period, i.e., $\{z_t\}_{t=\tau_k}^{\tau_{k+1}-1}$. This allows us to estimate θ_0 for each

Input: (at time 0) function g, regularizations λ_k, W (bound on $\|\theta_0\|_1$),
Input: (arrives over time) covariate vectors $\{x_t\}_{t\in\mathbb{N}}$
Output: prices $\{p_t\}_{t\in\mathbb{N}}$

1: $\tau_1 \leftarrow 1$, $p_1 \leftarrow 0$, $\widehat{\theta}^1 \leftarrow 0$
2: **for** each episode $k = 2, 3, \ldots$ **do**
3: Set the length of k-th episode: $\tau_k \leftarrow 2^{k-1}$.
4: Update the model parameter estimate $\widehat{\theta}^k$ using the regularized ML estimator obtained
from observations in the previous episode:

$$\widehat{\theta}^k = \underset{\|\theta\|_1 \le W}{\arg\min} \left\{ \mathcal{L}(\theta) + \lambda_k \|\theta\|_1 \right\}, \tag{10}$$

with

$$\mathcal{L}(\theta) = -\frac{1}{\tau_{k-1}} \sum_{t=\tau_{k-1}}^{\tau_k - 1} \Big\{ \mathbb{I}(y_t = 1) \log(1 - F(p_t - \theta \cdot x_t)) + \mathbb{I}(y_t = -1) \log(F(p_t - \theta \cdot x_t)) \Big\}. \tag{11}$$

5: For each period t during the k-th episode, set

$$p_t \leftarrow g(\widehat{\theta}^k \cdot x_t). \tag{12}$$

Algorithm 1: RMLP policy for dynamic pricing

episode separately; see Proposition 10 in Section 8.1. Comparing to policies that use the entire data sale history in making decisions, some remarks are in order:

- *Perishability of data:* In practical applications, the unknown demand parameters will change over time, raising the concern of perishability of data. Namely, collected data becomes obsolete after a while and cannot be relied on for estimating the model parameters (Keskin and Zeevi, 2016; Javanmard, 2017). Common policies to mitigate this problem (discussed in (Keskin and Zeevi, 2016)) include moving windows and decaying weights which use only recent data to learn the model parameters. By contrast, methods that use the entire historical data, with equal weight, suffers from this problem.

- *Simplicity and efficiency:* In RMLP policy, estimates of the model parameters are updated only at the first period of each episode ($\log T$ updates). Further, at each update, the policy uses only the historical data from the previous episode. These two ideas together, not only allow for a neat analysis of the statistical dependency among samples but also decrease the computational cost. Scalability of the pricing policy is indispensable in practical applications as the sales data is collected at an unprecedented rate.

- *The impact on regret:* By using half of the historical data at each update, our policy loses at most a factor 2 in the total regret. (This becomes clear shortly when we discuss the estimation error rate in terms of number of samples.)

The lengths of episodes in our algorithm increase geometrically ($\tau_k = 2^{k-1}$), allowing for more accurate estimate of θ_0 as the episode index grows. The algorithm terminates at the end of the horizon (period T), but note that it does not need to know the length of the horizon in advance.

The regularization parameter λ_k constrains the ℓ_1 norm of the estimator $\widehat{\theta}^k$. Selecting the value of λ_k is of crucial importance as it affects the estimator error. We set it as $\lambda_k = O\left(\sqrt{(\log d)/\tau_{k-1}}\right)$. More precisely, define

$$u_F \equiv \sup_{|x|\le 3W} \Big\{ \max\Big\{ \log' F(x), -\log'(1 - F(x)) \Big\} \Big\},$$

where the derivatives are w.r.t. x. By the log-concavity property of F and $1 - F$, we have

$$u_F = \max\Big\{ \log' F(-2W), -\log'(1 - F(2W)) \Big\}. \tag{13}$$

Hence, u_F captures the steepness of $\log F$. In order to minimize the regret, we run the RMLP policy with

$$\lambda_k = 4u_F \sqrt{\frac{\log d}{\tau_{k-1}}}. \tag{14}$$

Note that exploration and exploitation tasks are mixed in our algorithm. In the beginning of each episode, we use what is learned from previous episode to improve the estimation of θ_0 and then we exploit this estimate throughout the current episode to incur little regret. Meanwhile, the observations gathered in the current episode are used to update our estimate of θ_0 for the next episode.

The knowledge of the market noise distribution is used by the RMLP policy, in estimating the model parameters (constructing the log-likelihood function and choosing the regularization λ_k) as well as in setting the prices. (The pricing function g is defined based on the noise distribution F.)

In the next section we analyze the regret of the RMLP policy.

4. Regret Analysis

The following theorem bounds the regret of our dynamics pricing policy.

Theorem 3 (Regret Upper Bound) *Suppose Assumptions 1 and 2 hold and the . Then, the regret of the RMLP policy is of* $O\left(\frac{W}{C_{\min}^2} s_0 \log d \cdot \log T\right)$.

Let us stress again that the RMLP policy does not need to know the sparsity s_0, although its regret scales linearly with s_0. Further, the RMLP is assumed to know the market noise distribution F. [1] Below we provide an outline for the proof of Theorem 3 and defer its complete proof to Section 8.1.

1. It is useful to compare Theorem 3 with the result of Chen et al. (2015), [Theorem 5.4], which also uses a maximum likelihood estimator without exploiting sparsity structure and achieves regret $O\left(\frac{d}{C_{\min}} \sqrt{\log(Td)T}\right)$.

1. In RMLP, the updates in the model parameter estimation only occurs at the beginning of each episode, with using only the samples collected in the previous episode. Therefore, the prices posted in each episode are independent from the market value noises in that episode. This observation also verifies that $\mathcal{L}(\theta)$ given by (11), is indeed the negative log-likelihood of the samples collected in k-th episode. Note that this independence is not a mere serendipity, rather it holds because of the specific design of RMLP policy. Using this property, we use tools from high-dimensional statistics to bound the estimation error. To bound the error term $\|\theta^k - \theta_0\|_2$, we compare the function values $\mathcal{L}(\theta^k)$ and $\mathcal{L}(\theta_0)$. The main challenge here is that $\mathcal{L}(\theta)$ is not strictly convex in θ.[2] Hence, there can be, in principle, parameter vectors θ_1 and θ_2 that are close to each other and nevertheless the values of function $\mathcal{L}$ at these points are far from each other.

   To cope with this challenge, we show that a so-called *restricted eigenvalue condition* holds for the feature products. This notion implies that $\mathcal{L}(\theta)$ is strictly convex on the set of sparse vectors.[3] Using the restricted eigenvalue condition, we show the following ℓ_2 error for the regularized log-likelihood estimate in the k-th episode, $\widehat{\theta}^k$, holds true

$$\|\widehat{\theta}^k - \theta_0\|_2 = O(\sqrt{s_0}\lambda_k) = O\left(\sqrt{\frac{s_0 \log d}{\tau_{k-1}}}\right).$$

   As expected, the estimate gets more accurate as the episode's length increases; see Section 8.1 for more details.

2. For any $p \geq 0$, denote by $\mathsf{rev}_t(p) = p(1-F(p-x_t\cdot\theta_0))$, the expected revenue under price p. We bound reg_t in terms of $\mathsf{rev}_t(p_t^*) - \mathsf{rev}_t(p_t)$. Since $p_t^* \in \arg\max\{\mathsf{rev}_t(p)\}$, we have $\mathsf{rev}_t'(p_t^*) = 0$, and by Taylor expansion of rev_t around p_t^*, we obtain $\mathsf{rev}_t(p_t^*) - \mathsf{rev}_t(p_t) = O((p_t^* - p_t)^2)$.

3. For t in the k-th episode, namely $\tau_{k-1} \leq t \leq \tau_k - 1$, we have

$$p_t^* - p_t = g(\theta_0 \cdot x_t) - g(\widehat{\theta}^k \cdot x_t) \leq |(\theta_0 - \widehat{\theta}^k) \cdot x_t|,$$

   which follows by showing that g is 1-Lipschitz. Further, by Assumption 2 (without loss of generality assume $C_{\max} > 1$), we have

$$\mathbb{E}[((\theta_0 - \widehat{\theta}^k) \cdot x_t)^2] = \mathbb{E}[(\theta_0 - \widehat{\theta}^k)^\mathsf{T} \Sigma (\theta_0 - \widehat{\theta}^k)] \leq C_{\max} \mathbb{E}[\|\widehat{\theta}^k - \theta_0\|_2^2],$$

   where the equality holds because x_t is independent of $\widehat{\theta}^k$, and the last step follows since the maximum eigenvalue of the second moment matrix $\Sigma = \mathbb{E}(x_t x_t^\mathsf{T})$ is at most $C_{\max} > 0$.

2. Note that $\nabla^2_\theta \mathcal{L} = (-1/\tau_{k-1}) \sum_{t=\tau_{k-1}}^{\tau_k - 1} (\partial^2/\partial_{u_t}^2 \mathcal{L}) x_t x_t^\mathsf{T}$, where $u_t = p_t - \theta \cdot x_t - \alpha_0$. Therefore, $\nabla^2_\theta \mathcal{L}$ is a $d \times d$ matrix of rank at most $\tau_k - \tau_{k-1}$. Hence, $\mathcal{L}(\theta)$ is strictly convex in θ only if $\tau_k - \tau_{k-1} \geq d$. However, since we are not updating our estimates in the middle of an episode, episodes of length d yield the regret to scale linearly in d, which is not desired.

3. It is strictly convex over the set of s_0 sparse vectors in d-dimension if the number of samples is above $cs_0 \log d$ for a suitable constant $c > 0$.

   Let reg_t be the regret occurred at step t. Combining the above bounds (step 2 and 3), we arrive at $\mathbb{E}[\mathsf{reg}_t] = O(s_0(\log d)/\tau_{k-1})$. Therefore, the cumulative expected regret in episode k works out at $O(s_0 \log d)$. Since the length of episodes increase geometrically, there are $O(\log T)$ episodes by time T. This implies that the total expected regret by time T is $O(s_0 \log d \log T)$.

4.1. Comparison with the "Common" Regret of Bound $\Omega(\sqrt{T})$

There is an often-seen regret bound $\Omega(\sqrt{T})$ in the literature of online decision making, which can be improved to a logarithmic regret bound if some type of "separability assumption" holds true (Dani et al., 2008; Abbasi-Yadkori et al., 2012). Separability assumption posits that there is a positive constant gap between the rewards of the best and the second best actions. In our framework, the parameter θ belongs to a continuous set in $\mathbb{R}^{d+1}$ and therefore the separability assumption cannot be enforced because by choosing θ arbitrary close to θ_0, one can obtain suboptimal (but arbitrary close to optimal) reward. However, the regret of our policy scales only logarithmically with T. Here, we contrast our logarithmic regret bound with the folklore lower bound $\Omega(\sqrt{T})$, to build further insight on our results.

Uninformative prices and $\Omega(\sqrt{T})$ lower-bound. We focus on (Broder and Rusmevichientong, 2012) which has a close framework to ours in that it considers a dynamic pricing policy from purchasing decisions and presents a pricing policy based on maximum likelihood estimation with regret $O(\sqrt{T})$. Adopting their notation, it is assumed that market values v_t are independent and identically distributed random variables coming from a distribution function that belongs to some family parametrized by $\mathbf{z}$. Denote by $d(p;\mathbf{z})$ the demand curve. This curve determines the probability of a purchase at a given price, i.e., $d(p;\mathbf{z}) = \mathbb{P}_\mathbf{z}(v_t \geq p)$. (Broder and Rusmevichientong, 2012) show that the worst-case regret of any pricing policy must be at least $\Omega(\sqrt{T})$ (see Theorem 3.1 therein). The bound is proved by considering a specific family of demand curves $d(p;\mathbf{z})$, such that all demand curves in this family intersect at a common price. Further, the common price is the optimal price for a specific choice of parameter $\mathbf{z}_0$, i.e, $p^*(\mathbf{z}_0)$.[4] Therefore, the price $p^*(\mathbf{z}_0)$ is "uninformative" since no policy can gain information about the demand parameter $\mathbf{z}$, while pricing $p^*(\mathbf{z}_0)$. The idea behind the derived lower bound for the worst-case regret is that for a policy to learn the underlying demand curve fast enough, it must necessarily choose prices that are away from (the uninformative) price $p^*(\mathbf{z}_0)$ and this leads to a large regret when the true demand curve is indeed $\mathbf{z}_0$.

Intuition behind our results. In contrast to the previous case, for our framework there is no such uninformative price. First, note that the for a choice model with parameters $\theta_0 = (\theta_0, \alpha_0)$, the demand curve at time t is given by

$$d_t(p;\theta_0) = 1 - F(p - \theta_0 \cdot x_t),$$

For $n \geq 1$, we define the aggregate demand function up to time n as $d_1^n = (d_1, d_2, \ldots, d_n)$. In the following, we argue that under our setting, there is no uninformative price. For any

4. Specifically, they consider $d(p;\mathbf{z}) = 0.5 + \mathbf{z} - \mathbf{z}p$. Hence $d(1;\mathbf{z}) = 1$, for all $\mathbf{z}$ and it is shown that $p^*(\mathbf{z}_0) = 1$ for $\mathbf{z}_0 = 0.5$.

price p and any θ_1, θ_2, we have

$$\frac{1}{n}\|d_1^n(p,\theta_1) - d_1^n(p,\theta_2)\|_2^2 = \frac{c^2}{n}\sum_{\ell=1}^{n}((\theta_1-\theta_2)\cdot x_t)^2$$
$$= \frac{c^2}{n}\|X(\theta_1-\theta_2)\|_2^2\,,$$

where X is the matrix with rows x_ℓ, for $1 \le \ell \le t$. We also used the fact that $f(z) \ge c > 0$ for some constant c because F is strictly increasing by Assumption 1. As we show in Appendix A, for $n \ge c_0 s_0 \log d$ (with c_0 a proper constant), X satisfy a so-called "restricted eigenvalue", by which we have

$$\frac{1}{n}\|X(\theta_1-\theta_2)\|_2^2 \ge \frac{C_{\min}}{2}\|\theta_1-\theta_2\|_2^2\,. \tag{15}$$

Therefore, for any fixed price p, if we vary the demand parameters θ_1 to some other value θ_2, then the aggregate demand at price p also changes by an amount proportional to $\|\theta_1-\theta_2\|_2$. Hence, any price in this setting is informative about the model parameters.

To build further insight, let us consider a more general choice model, where the utility of the customer from buying a product with feature vectors x_t at price p is given by

$$u(x_t) = \theta_0 \cdot x_t - \beta_0 p + z_t\,, \tag{16}$$

where θ_0, β_0 are unknown model parameters and z_t is the noise term. The customer buys the product iff $u(x_t) \ge 0$. Note that the model we studied in this paper (see Equation (3)) is a special case when the price sensitivity β_0 is known and hence can be normalized to 1. We next argue that in case of unknown β_0, the uninformative prices do exist and hence the $\Omega(\sqrt{T})$ is still in place.

To see this, let $\theta_{0,i} = 0$ for $2 \le i \le d$. Fix arbitrary a, and set $\beta_0 = g(a) - a + \theta_{0,1}$. Also, let $x_{t,1} = 1$, for all t. Then, the demand curves will be unaltered over time and are given by

$$d_t(p,\theta) = 1 - F(\beta_0 p - \theta_{0,1}) = 1 - F\left((g(a) - a + \theta_{0,1})p - \theta_{0,1}\right)\,.$$

We next verify that $p^* = 1$ is the optimal price for the specific choice of $\theta_{0,1} = a$. In this case, the expected revenue form a posted price p is given by

$$p \times d_t(p,\theta) = p\left(1 - F\left(g(a)p - a\right)\right)\,. \tag{17}$$

By definition of the pricing function g, given by (7), it is easy to see that $p^* = 1$ sets the gradient of the expected revenue to zero.

Next note that all the demand curves, regardless of value $\theta_{0,1}$, intersect at $p^* = 1$ (they all have the value $1 - F(g(a) - a)$ at this price). Therefore, p^* is an uninformative price and no policy can gain information about $\theta_{0,1}$ by pricing at p^*. However, when $\theta_{0,1} = a$, choosing prices that are away from this informative price leads to a large regret. Prices that are close to p^* does not have any information gain, and contrasting these two points, it can be shown that the worst case regret is of order $\Omega(\sqrt{T})$. A formal proof follows the same lines of the proof of (Broder and Rusmevichientong, 2012, Theorem 3.1) and is omitted.

Finally, it is worth noting that the rate of learning demand parameter θ_0 is chiefly derived by three factors:

- Non-smoothness of distribution function F, as it controls the amount of information obtained about $x_t \cdot \theta_0$ at each t.
- The rate by which the feature vectors x_t span the parameter space. This is controlled through the minimum eigenvalue of Σ, i.e., $C_{\min}$. If $C_{\min}$ is small, the randomly generated features are relatively aligned and one requires larger sample size to estimate θ_0 within specified accuracy.
- Complexity of θ_0. This is captured through the sparsity measure s_0.

Later in Proposition 10, we see how these factors contribute to the learning rate of θ_0.

4.2. Role of $C_{\min}$

In establishing our results, we relied on Assumption 2 which requires the population covariance of features to be positive definite. The lower bound on its eigenvalues, denoted by $C_{\min}$, appears in our regret bound as a factor $1/C_{\min}^2$.

As evident from the proof of Proposition 10, Assumption 1 can be replaced by the weaker *restricted eigenvalue condition* (Bühlmann and van de Geer, 2011; Candes and Tao, 2007), which is a common assumption in high-dimensional statistical learning. While assumption $C_{\min} > 0$ allows for a fast learning rate of model parameters and a regret bound $O(\log T)$, RMLP policy can still provably achieve regret $O(\sqrt{T})$, even when $C_{\min} = 0$.

Theorem 4 *Suppose that product feature vectors are generated independently from a probability distribution $\mathbb{P}_X$ with a bounded support $\mathcal{X} \in \mathbb{R}^d$. Also, assume that the choice model parameters $\theta_0 \in \Omega$, where the set Ω is given by* (5)*. Under Assumption 1, the regret of RMLP policy is of $O(W^3\sqrt{(\log d)T})$.*

Proof of Theorem 4 is given in Section 8.2. We remark that the regret bound in Theorem 4 is independent of the sparsity s_0 and scales logarithmically with the feature dimension d. From the technical point of view, this is due to the fact that in our analysis instead of bounding the estimation errors $\|\theta_0 - \widehat{\theta}^k\|_2$, we directly bound the prediction errors $\|X^{(k-1)}(\theta_0 - \widehat{\theta}^k)\|_2$, where $X^{(k-1)}$ is the matrix obtained by putting the feature vectors in episode $(k-1)$ as its rows. We then connect the total regret in each episode to the corresponding prediction error. By this analysis, we are able to remove the requirement $C_{\min} > 0$ and obtain a regret that is independent of the sparsity s_0, at the cost of getting $O(\sqrt{T})$ regret bound.

5. Lower Bound on Regret

As discussed in Section 2.2, if the true parameter θ_0 is known, the optimal policy (in terms of expected revenue) is the one that sets prices as $p_t = g(x_t \cdot \theta_0)$. Let $\mathcal{H}_t = \{x_1, x_2, \ldots, x_t, z_1, z_2, \ldots, z_t\}$ denote the history set up to time t, and recall that Ω denotes the set of feasible parameters, i.e., $\Omega = \{\theta \in \mathbb{R}^d : \|\theta\|_0 \le s_0\,,\ \|\theta\|_1 \le W\}$. We consider the following set of policies, Π:

$$\Pi = \Big\{\pi : \pi(p_t) = g(x_t \cdot \theta_t),\ \text{for some } \theta_t \in \Omega,\ \text{such that } \theta_t \text{ is } \mathcal{H}_{t-1}\text{-measurable}\Big\}\,. \tag{18}$$

Here $\pi(p_t)$ denotes the price posted by policy π at time t.

We provide a lower bound on the achievable regret by any policy in set Π. Indeed this lower bound applies to an oracle who fully observes the market values after the price is either accepted or rejected. Compared to our setting, where the seller observes only the binary feedbacks (purchase/no purchase), this oracle appears exceedingly powerful at first sight but surprisingly, the derived lower bound matches the regret of our dynamic policy, up to a logarithmic factor.

Theorem 5 *Consider linear model* (2) *where the market values $v(x_t)$, $1 \le t \le T$, are fully observed. We further assume that market value noises are generated as $z_t \sim \mathsf{N}(0, \sigma^2)$. Let Π be the set of policies given by* (18)*. Then, there exists constant $C' > 0$ (depending on W and σ), such that the following holds true for all $T \in \mathbb{N}$.*

$$\min_{\pi \in \Pi} \mathsf{Regret}_\pi(T) \ge C' \left\{ s_0 \log\left(\frac{T}{s_0}\right) + \min\left[\frac{T}{s_0}, s_0 \log\left(\frac{d}{s_0}\right)\right]\right\}. \tag{19}$$

In the following we give an outline for the proof of Theorem 5, summarizing its main steps and defer the complete proof to Section 8.3.

1. We derive a lower bound for regret in terms of the minimax estimation error. Specifically, for $t \in \mathbb{N}$, let

$$\mathsf{reg}_t \equiv p_t^* \mathbb{I}(v_t \ge p_t^*) - p_t \mathbb{I}(v_t \ge p_t) \tag{20}$$

be the regret at period t. We show that

$$\max_{\theta_0 \in \Omega} \mathbb{E}(\mathsf{reg}_t) \ge c \max_{\theta_0 \in \Omega} \mathbb{E}\{\min(\|\theta_t - \theta_0\|_2^2, C)\}, \tag{21}$$

for some constants $c, C > 0$.

2. Let $\theta_1^T = (\theta_t)_{t=1}^T$ and define $\mathsf{d}(\theta_1^T, \theta) \equiv \sum_{t=1}^T \min(\|\theta_t - \theta\|_2^2, C)$. We use a standard argument (Le Cam's method) that relates the minimax ℓ_2 risk, $\min_{\theta_1^T} \max_{\theta_0 \in \Omega} \mathbb{E}[\mathsf{d}(\theta_1^T, \theta_0)]$, in terms of the error in multi-way hypothesis problem (Tsybakov, 2008). We first construct a maximal set of points in Ω, such that minimum pairwise distances among them is at least δ. (Such set is usually referred to as a δ-packing in the literature). Here δ is a free parameter to be determined in the proof. We then use a standard reduction to show that any estimator with small minimax risk should necessarily solve a hypothesis testing problem over the packing set, with small error probability. More specifically, suppose that nature chooses one point from the packing set uniformly at random and conditional on nature's choice of the parameter vector, say θ_0, the market value are generated according to $\langle x_t, \theta_0 \rangle + z_t$ with $z_t \sim \mathsf{N}(0, \sigma^2)$. The problem is reduced to lower bounding the error probability in distinguishing θ_0 among the candidates in the packing set using the observed market values.

3. We apply Fano's inequality from information theory to lower bound the probability of error (Tsybakov, 2008). The Fano's bound involves the logarithm of the cardinality of the δ-packing set as well as the mutual information between the observations (market values) and the random parameter vector θ_0 chosen uniformly at random from the packing set. Le Cam's method is used to derive minimal risk lower bound for an estimator $\widehat{\theta}$, while here we have a sequence of estimators and need to adjust the Le Cam's method to get the lower bound for $\mathsf{d}(\theta_1^T, \theta_0)$.

6. Nonlinear Valuation Function

In previous sections, we focused exclusively on linear valuation function given by Eq (2). Here, we extend our results and assume that the market valuations are modeled by a *nonlinear* function that depends on products' features and an independent noise term. Specifically, the market value of a product with feature vector x_t is given by

$$v(x_t) = \psi(\theta_0 \cdot \phi(x_t) + z_t), \tag{22}$$

where the original features x_t are transformed by a feature mapping $\phi : \mathbb{R}^d \mapsto \mathbb{R}^d$, and function $\psi : \mathbb{R} \mapsto \mathbb{R}$ is a general function that is log-concave and strictly increasing. Important examples of this model include log-log model ($\psi(x) = e^x$, $\phi(x) = \ln(x)$), semi-log model ($\psi(x) = e^x$, $\phi(x) = x$), and logistic model ($\psi(x) = e^x/(1+e^x)$, $\psi(x) = x$).

Model (22) allows us to capture correlations and non-linear dependencies on the features. We next state our assumption on the feature mapping ϕ and then discuss our dynamic pricing policy and its regret bound for the general setting (22).

Assumption 6 *Let p_X be an (unknown) distribution from which the original features x_t are sampled independently. Suppose that the feature mapping ϕ has continuous derivative and denote by $\Sigma_\phi \equiv \mathbb{E}(\phi(x) \cdot \phi(x)^\mathsf{T})$ the second moment matrix of $\phi(x)$ under $\mathbb{P}_X$. We assume that there exist constants $C_{\min}$ and $C_{\max}$ such that for every eigenvalue σ of Σ_ϕ, we have $0 < C_{\min} \le \sigma < C_{\max} < \infty$.*

Invoking Assumption 1, $\mathbb{P}_X$ has a bounded support $\mathcal{X}$ and since ϕ has continuous derivative, it is Lipschitz on $\mathcal{X}$ and hence the image of $\mathcal{X}$ under ϕ remains bounded. Therefore, the new features $\phi(x_t)$ are also sampled independently from a bounded set. The condition on Σ_ϕ is analogous to that on Σ, as required by Assumption 2 for the linear setting.

Based on feature mapping ϕ, validity of Assumption 6 may depend on all moments of distribution $\mathbb{P}_X$. We provide an alternative to this assumption, which only depends on feature mapping ϕ and the second moment of $\mathbb{P}_X$. In stating the assumption, we use the notation $\mathcal{D}_\phi$ to denote the derivative matrix of a feature mapping ϕ. Precisely, for $\phi = (\phi_1, \ldots, \phi_d)$, with ϕ_i real-valued function defined on $\mathbb{R}^d$, we write $\mathcal{D}_\phi = (\partial \phi_i / \partial x_j)_{1 \le i \le j \le d}$.

Assumption 7 ***(alternative to Assumption 6)*** *Suppose that feature mapping ϕ has continuous derivative and its derivative $\mathcal{D}_\phi(x)$ is full-rank for almost all x. In addition, there exist constants $C_{\min}$ and $C_{\max}$ such that for every eigenvalue σ of covariance Σ, we have $0 < C_{\min} \le \sigma < C_{\max} < \infty$.*

Recall that the noise terms $\{z_t\}_{t \ge 1}$ are drawn independently and identically from a distribution with cumulative function F and density $f(x)$. Let $\lambda(v) = f(v)/(1 - F(v))$ be the hazard rate function for distribution F. For a log-concave function ψ, we define

$$g_\psi^{-1}(v) \equiv v - \lambda^{-1}\Big(\frac{\psi'(v)}{\psi(v)}\Big). \tag{23}$$

Input: (at time 0) function g, regularizations λ_k, W (bound on $\|\theta_0\|_1$)
Input: (arrives over time) covariate vectors $\{\tilde{x}_t = \phi(x_t)\}_{t\in\mathbb{N}}$
Output: prices $\{p_t\}_{t\in\mathbb{N}}$

1: $\tau_1 \leftarrow 1$, $p_1 \leftarrow 0$, $\widehat{\theta}^1 \leftarrow 0$
2: **for** each episode $k = 2, 3, \ldots$ **do**
3: Set the length of k-th episode: $\tau_k \leftarrow 2^{k-1}$.
4: Update the model parameter estimate $\widehat{\theta}^k$ using the regularized ML estimator obtained
from observations in the previous episode:

$$\widehat{\theta}^k = \underset{\|\theta\|_1 \le W}{\arg\min} \ \{\mathcal{L}(\theta) + \lambda_k \|\theta\|_1\} \ , \tag{24}$$

where $\mathcal{L}(\theta)$ is given by:

$$\mathcal{L}(\theta) = -\frac{1}{\tau_{k-1}} \sum_{t=\tau_{k-1}}^{\tau_k - 1} \Big\{ \mathbb{I}(y_t = 1) \log(1 - F(\psi^{-1}(p_t) - \theta \cdot \tilde{x}_t)) + \mathbb{I}(y_t = -1) \log(F(\psi^{-1}(p_t) - \theta \cdot \tilde{x}_t)) \Big\} . \tag{25}$$

5: For each period t during the k-th episode, set

$$p_t \leftarrow \psi(g_\psi(\widehat{\theta}^k \cdot \tilde{x}_t)) . \tag{26}$$

Algorithm 2: RMLP Policy for dynamic pricing under the nonlinear setting

Note that $\psi'(v)/\psi(v) = \log' \psi(v)$ and since ψ is log-concave, this term is decreasing. Further, since $1 - F$ is log-concave then its hazard rate λ is increasing (See proof of Lemma C.1.) Combining these observations, we have that $-\lambda^{-1}(\psi'(v)/\psi(v))$ is increasing. Consequently,

- Right-hand side of (23) is strictly increasing and hence, g_ψ^{-1} is well-defined.
- We have $(g_\psi^{-1})'(v) \ge 1$, for all v. This implies that $0 < g'_\psi(v) \le 1$, for all v.

It is worth noting that for $\psi(v) = v$ (linear model), we have $g_\psi = g$, where g is defined by (7). Our pricing policy for the nonlinear model is conceptually similar to the linear setting: The policy runs in an episodic manner. During episode k, the prices are set as $p_t = \psi(g_\psi(\widehat{\theta}^k \cdot x_t))$, where $\widehat{\theta}^k$ denotes the estimate of the true parameter vector θ_0, using a regularized maximum-likelihood estimator applied to observations in the *previous* episode, and $\tilde{x}_t = \phi(x_t)$.

We describe our (modified) RMLP policy in Algorithm 2. There a few differences between Algorithm 2 and Algorithm 1: Firstly, the features x_t are replaced by $\tilde{x}_t = \phi(x_t)$. Secondly, in the regularized estimator, prices p_t are replaced by $\psi^{-1}(p_t)$. Thirdly, in the last step of algorithm prices are set as $\psi(g_\psi(\widehat{\theta}^k \cdot x_t))$, with g_ψ defined by Equation (23).

Our next theorem bounds the regret of our pricing policy (Algorithm 2).

Theorem 8 *Let ψ be log-concave and strictly increasing. Suppose that Assumptions 1 and 6 (or its alternative, Assumption 7) hold. Then, regret of the RMLP policy described as Algorithm 2 is of $O(s_0 \log d \cdot \log T)$.*

Proof of Theorem 8 is given in Appendix 8.4. Here, we summarize its key ingredients.

1. By increasing property of ψ, a sale occurs at period t when $z_t \ge \psi^{-1}(p_t) - \theta_0 \cdot \tilde{x}_t$. Hence, the log-likelihood estimator for this setting reads as (25). By virtue of Assumption 6 (or its alternative, Assumption 7) we get a similar estimation error for the regularized estimator to the one in Proposition 10.

2. Similar to our derivation for linear setting, we show that the optimal pricing policy that knows θ_0 in advance is given by $p_t^* = \psi(g_\psi(\theta_0 \cdot \tilde{x}_t))$, where g_ψ is defined based on Equation (23).

3. The difference between the posted price and the optimal price can be bounded as $p_t - p_t^* = \psi(g_\psi(\widehat{\theta}^k \cdot \tilde{x}_t)) - \psi(g_\psi(\theta_0 \cdot \tilde{x}_t)) \le L|\tilde{x}_t \cdot (\widehat{\theta}^k - \theta_0)|$, for a constant $L > 0$. This bound is similar to the corresponding bound for the linear setting, and following the same lines of our regret analysis for that case, we get $R(T) = O(s_0 \log d \cdot \log T)$.

7. Knowledge of Market Noise Distribution

The proposed RMLP policy has assumed that the market noise distribution F is known to the seller. Knowledge of F has been used both in estimating the model parameters θ_0 and in setting the prices p_t. On the other hand, the benchmark policy is also assumed to have access to model parameters and the distribution F. Therefore, the regret bound established in Theorem 3 essentially measures how much the seller loses in revenue due to lack of knowledge of the underlying model parameters. In practice, however, the underlying distribution of valuations is not given and this raises the question of *distribution-independent* pricing policy.

It is worth mentioning that in some applications, although the underlying distribution of valuations is unknown, it belongs to a known class of distributions. For example, lognormal distributions have proved to be a good fit for the distribution of valuations of advertisers in online advertising markets (Edelman et al., 2007; Lahaie and Pennock, 2007; Xiao et al., 2009; Balseiro et al., 2014). In Section 7.1, we consider a setting where the underlying distribution belongs to a known class of log-concave distributions and propose a policy whose regret is $O(\sqrt{T})$. We also argue that no policy can get a better regret bound.

7.1. Unknown Distribution from a Known Class

Suppose that the market noises are generated from a log-concave distribution $F_{m,\sigma}$ (e.g., Log-normal), with unknown mean m and unknown variance σ^2. Without loss of generality, we can assume that $m = 0$; otherwise, in the valuation model (2), m can be absorbed in the features as the intercept term. We next explain how the RMLP policy can be adapted to this case.

Input: Pricing function g (corresponding to $F_{0,1}$), regularizations λ_k, W
Input: (arrives over time) covariate vectors $\{x_t\}_{t\in\mathbb{N}}$
Output: prices $\{p_t\}_{t\in\mathbb{N}}$

1: $\tau_1 \leftarrow 1$, $p_1 \leftarrow 0$, $\widehat{\theta}^1 \leftarrow 0$
2: **for** each episode $k = 2, 3, \dots$ **do**
3: Set the length of k-th episode: $\tau_k \leftarrow 2^{k-1}$.
4: Update the model parameter estimate $\widehat{\mu}^k$ using the regularized ML estimator:

$$(\widehat{\mu}^k, \widehat{\beta}^k) = \underset{\|(\mu/\beta,\beta)\|_1 \le W}{\arg\min} \{\mathcal{L}(\mu,\beta) + \lambda_k \|\mu\|_1\}\,, \tag{28}$$

where $\mathcal{L}(\mu,\beta)$ is given by:

$$\mathcal{L}(\mu,\beta) = -\frac{1}{\tau_{k-1}} \sum_{t=\tau_{k-1}}^{\tau_k-1} \Big\{ \mathbb{I}(y_t = 1)\log\left(1 - F(\beta p_t - \mu\cdot x_t)\right) + \mathbb{I}(y_t = -1)\log\left(F(\beta p_t - \mu\cdot x_t)\right) \Big\}. \tag{29}$$

5: For each period t during the k-th episode, set

$$p_t \leftarrow \frac{1}{\widehat{\beta}^k} g(\widehat{\mu}^k \cdot x_t)\,. \tag{30}$$

Algorithm 3: RMLP-2 policy for dynamic pricing

Define $\beta_0 = 1/\sigma$ and consider the transformation $\tilde{v}_t = \beta_0 v_t$, $\mu_0 = \beta_0\theta_0$, $\tilde{z}_t = \beta_0 z_t$. Then, the valuation model (2) can be written as

$$\tilde{v}_t = x_t \cdot \mu_0 + \tilde{z}_t\,, \tag{27}$$

where $\tilde{z}_t$ are drawn from $F_{0,1}$. To lighten the notation, we use the shorthand $F \equiv F_{0,1}$. The response variables y_t are then given by $y_t = \mathbb{I}(\tilde{v}_t \ge \beta_0 p_t)$.

We propose a variant of RMLP policy, called RMLP-2 for this case. The RMLP-2 policy is very similar to RMLP except that the maximum log-likelihood is formed to estimate the parameter vector (μ_0, β_0) jointly. Likewise, the regularizations are set as $\lambda_k = 4u_F\sqrt{(\log d)/\tau_{k-1}}$, where u_F is defined based on the distribution $F \equiv F_{0,1}$ as in Equation (13). The policy then offers the optimal prices based on the current parameter estimates at the time. Specifically, for episode k, we set $p_t = (1/\widehat{\beta}^k)g(\widehat{\mu}^k \cdot x_t)$, where the pricing function g, given by (7), is defined based on the distribution $F \equiv F_{0,1}$. A formal description of RMLP-2 is given in Algorithm 3.

Our next result bounds the regret of RMLP-2.

Theorem 9 *Consider the valuation model* (2)*, where noises z_t are generated from a distribution $F_{m,\sigma}$, with unknown mean m and variance σ^2. Assuming that distribution $F_{m,\sigma}$ satisfies Assumption 1, the regret of RMLP-2 policy is of $O(\sqrt{(\log d)T})$. Further, regret of any pricing policy in this case is $\Omega(\sqrt{T})$.*

We refer to Section 8.5 for the proof of Theorem 9. As discussed in the proof, the lower bound $\Omega(\sqrt{T})$ applies to this case due to the existence of non-informative prices; See also Section 4.1.

8. Proof of Theorems

8.1. Proof of Theorem 3

Following step 1 of the proof outline mentioned in Section 4, we consider the problem of estimating θ_0 based on observations from previous episode. Before we proceed, let us emphasize once again that the way RMLP is designed, posted prices at each episode are statistically independent from the market noises in that episode. This can be easily observed because $p_t = g(x_t \cdot \widehat{\theta}^k)$ for t belonging in the k-th episode, and $\widehat{\theta}^k$ is estimated based on the samples in the $(k-1)$-th episode.

We fix $k \ge 1$ and to lighten the notation, we use the indices $1, 2, \dots, n$ to correspond to periods in the k-the episode, i.e., $t = \tau_k, \tau_k + 1, \dots, \tau_{k+1} - 1$.

Using probabilistic model (4), θ_0 is estimated by solving a regularized maximum likelihood (ML) optimization problem. The (normalized) negative log-likelihood function for θ reads as

$$\mathcal{L}(\theta) = -\frac{1}{n}\sum_{t=1}^{n} \Big\{ \mathbb{I}(y_t = 1)\log(1 - F(p_t - \theta\cdot x_t)) + \mathbb{I}(y_t = -1)\log(F(p_t - \theta\cdot x_t)) \Big\}. \tag{31}$$

Parameter θ is estimated as the solution of the following program:

$$\widehat{\theta} = \underset{\|\theta\|_1 \le W}{\arg\min}\ \mathcal{L}(\theta) + \lambda\|\theta\|_1\,. \tag{32}$$

Define ℓ_F as follows which corresponds to "flatness" of function $\log F$:

$$\ell_F \equiv \inf_{|x|\le 3W} \Big\{ \min\Big\{ -\log'' F(x), -\log''(1 - F(x)) \Big\} \Big\}\,. \tag{33}$$

By Assumption 1, the log-concavity property of F and $1 - F$, we have $\ell_F > 0$.

The next theorem upper bounds the estimation error of the proposed regularized estimator.

Proposition 10 (Estimation Error) *Consider linear model* (2) *with $\theta_0 \in \Omega$, under Assumptions 1 and 2. Let $\widehat{\theta}$ be the solution of optimization problem* (32) *with $\lambda \ge 4u_F\sqrt{(\log d)/n}$. Then, there exist positive constants c_0 and C such that, for $n \ge c_0 s_0 \log(d)$, the following inequality holds with probability at least $1 - 1/d - 2e^{-n/(c_0 s_0)}$:*

$$\|\widehat{\theta} - \theta_0\|_2^2 \le \frac{16 s_0 \lambda^2}{\ell_F^2 C_{\min}^2}\,. \tag{34}$$

We refer to Appendix A for the proof of Proposition 10.

As we see the ℓ_2 estimation error scales linearly with the sparsity level s_0. As s_0 increases, the number of parameters to be estimated becomes larger and this makes the estimation problem harder, leading to worse ℓ_2 bound for a fixed number of samples, n. Further,

choosing $\lambda \sim \sqrt{(\log d)/n}$ (where $\sim$ indicates equality up to a constant factor), our ℓ_2 bound scales logarithmically in the dimension of the demand space, d. This allows to deal with high-dimensional applications and obtain a regret that scales logarithmically in d. Further, the estimation error shrinks as $\sim 1/n$; getting more samples with fixed value of s_0 and d leads to better estimation accuracy. Finally, note that for small values of ℓ_F, the log-likelihood function is very flat and there can be, in principle, vectors θ of log-likelihood value very close to the optimum and nevertheless far from the optimum. In other words, estimation task becomes harder as ℓ_F gets smaller and this is clearly reflected in the derived estimation bound.

We next use Proposition 10 to bound the expected estimation error.

Corollary 11 *Under assumptions of Proposition 10, the following holds true:*

$$\mathbb{E}(\|\widehat{\theta}-\theta_0\|_2^2) \le \frac{16 s_0 \lambda^2}{\ell_F^2 C_{\min}^2} + 4W^2\left(\frac{1}{d} + 2e^{-n/(c_0 s_0)}\right). \tag{35}$$

Proof of Corollary 11 is straightforward and is omitted.

In the next proposition, we improve bound (35) for $n \ge c_1 d$, for a constant $c_1 > 0$. As we will see, the following result is useful to develop sharper upper bound for regret of RMLP policy.

Proposition 12 *Under assumptions of Proposition 10, there exist constants $c, c_1 > 0$, such that for $n \ge c_1 d$, the following holds true:*

$$\mathbb{E}(\|\widehat{\theta}-\theta_0\|_2^2) \le \frac{16(s_0+1)\lambda^2}{\ell_F^2 C_{\min}^2} + 4W^2 e^{-cn^2}. \tag{36}$$

Proposition 12 is proved in Appendix B.

We next establish some useful properties of the virtual valuation function φ and the price function g.

Lemma 13 *If $1-F$ is log-concave, then the virtual valuation function φ is strictly monotone increasing.*

Lemma 14 *If $1-F$ is log-concave, then the price function g satisfies $0 < g'(v) < 1$, for all values of $v \in \mathbb{R}$.*

Proofs of Lemma 13 and 14 are given in Appendix C.1 and C.2, respectively.

Given that $\|\widehat{\theta}^k\|_1 \le W$ and $|x_t \cdot \widehat{\theta}^k| \le W$ for all t, k,

$$p_t = g(x_t \cdot \widehat{\theta}^k) \le 2|x_t \cdot \widehat{\theta}^k| \le 2W, \tag{37}$$

where in the first inequality we used the fact that $\varphi(v)$ is increasing as per Lemma 13 and hence $g(v) = v + \varphi^{-1}(-v) \le v + |v| \le 2|v|$. Similarly, we have $p_t^* \le 2W$ for all t.

We are now ready to bound the regret of our policy. For $t \ge 1$, let

$$\mathsf{reg}_t \equiv p_t^* \mathbb{I}(v_t \ge p_t^*) - p_t \mathbb{I}(v_t \ge p_t) \tag{38}$$

be the regret at period t. Further, let $\mathcal{H}_t = \{x_1, x_2, \dots, x_t, z_1, z_2, \dots, z_t\}$ be the history set, up to time t (more precisely, $\mathcal{H}_t$ is the filtration generated by $\{x_1, x_2, \dots, x_t, z_1, z_2, \dots, z_t\}$). We also define $\bar{\mathcal{H}}_t = \mathcal{H}_t \cup \{x_{t+1}\}$ as the filtration obtained after augmenting by the new feature x_{t+1}.

We write

$$\begin{aligned}\mathbb{E}(\mathsf{reg}_t|\bar{\mathcal{H}}_{t-1}) &= \mathbb{E}(p_t^*\mathbb{I}(v_t \ge p_t^*)|\bar{\mathcal{H}}_{t-1}) - \mathbb{E}(p_t\mathbb{I}(v_t \ge p_t)|\bar{\mathcal{H}}_{t-1}) \\ &= p_t^*(1-F(p_t^* - x_t\cdot\theta_0)) - p_t(1-F(p_t - x_t\cdot\theta_0)).\end{aligned} \tag{39}$$

Define $\mathsf{rev}_t(p) \equiv p(1-F(p - x_t\cdot\theta_0))$ as the expected revenue under price p. Note that $p_t^* \in \arg\max \mathsf{rev}_t(p)$ and thus $r_t'(p_t^*) = 0$. By Taylor expansion,

$$\mathsf{rev}_t(p_t) = \mathsf{rev}_t(p_t^*) + \frac{1}{2} r_t''(p)(p_t - p_t^*)^2, \tag{40}$$

for some p between p_t and p_t^*.

We next show that $|r_t''(p)| \le 2(B + WB')$, with $B = \max_v f(v)$, and $B' = \max_v f'(v)$. To see this, we write

$$|r_t''(p)| = |2f(p - x_t\cdot\theta_0) + pf'(p - x_t\cdot\theta_0)| \le 2B + 2WB', \tag{41}$$

where we use the fact that $p_t, p_t^* \le 2W$ and consequently $p \le 2W$. We let $C = 2\max(B, B')$. Then, combining Equations (39), (40), (41), along with 1-Lipschitz property of g gives

$$\begin{aligned}\mathbb{E}(\mathsf{reg}_t|\bar{\mathcal{H}}_{t-1}) &\le (B+WB')(p_t^* - p_t)^2 \\ &\le CW(p_t^* - p_t)^2 \\ &= CW(g(\theta_0\cdot x_t) - g(\widehat{\theta}^k\cdot x_t))^2 \\ &\le CW\,|x_t\cdot(\theta_0 - \widehat{\theta}^k)|^2.\end{aligned} \tag{42}$$

Here, in the second inequality we used the fact that $W \ge 1$. Given that x_t is independent of $\mathcal{H}_{t-1}$, we have

$$\mathbb{E}(\mathsf{reg}_t|\mathcal{H}_{t-1}) \le CW\langle\widehat{\theta}^k - \theta_0, \Sigma(\widehat{\theta}^k - \theta_0)\rangle, \tag{43}$$

where $\Sigma = \mathbb{E}(x_t x_t^{\mathsf{T}})$. Since the maximum eigenvalue of Σ is bounded by $C_{\max}$, we obtain

$$\mathbb{E}(\mathsf{reg}_t) = \mathbb{E}\left(\mathbb{E}(\mathsf{reg}_t|\mathcal{H}_{t-1})\right) \le CC_{\max}W\mathbb{E}(\|\widehat{\theta}^k - \theta_0\|_2^2). \tag{44}$$

Now, since the length of episodes grows exponentially, the number of episodes by period T is logarithmic in T. Specifically, T belongs to episode $K = \lfloor \log T \rfloor + 1$. Hence,

$$\mathsf{Regret}(T) = \sum_{k=1}^{K} \mathsf{Regret}(k\text{th Episode}). \tag{45}$$

We bound the total regret over each episode by considering three separate cases:

- $2^{k-2} \le c_0 s_0 \log d$: Here, c_0 is the constant in the statement of Proposition 10. In this case, episodes are not large enough to estimate θ_0 accurately enough, and thus we use a naive bound on regret. Clearly, by (37), we have $\mathbb{E}(\mathsf{reg}_t) \le p_t^* \le 2W$. Since the length of k th episode is $2^{k-1} \le 2c_0 s_0 \log d$, the total regret incurred during episode k is at most $4c_0 W s_0 \log d$.

- $c_0 s_0 \log d \le 2^{k-2} \le c_1 d$: Here, c_1 is the constant in the statement of Proposition 12. Continuing from Equation (44) and applying Corollary 11 to episode k, we obtain

$$\begin{aligned}
\mathsf{Regret}(k\text{th Episode}) &= \sum_{t=\tau_k}^{\tau_{k+1}-1} \mathbb{E}(\mathsf{reg}_t) \\
&\le C C_{\max} W \sum_{t=\tau_k}^{\tau_{k+1}-1} \mathbb{E}(\|\widehat{\theta}^k - \theta_0\|_2^2) \\
&\le C C_{\max} W \left\{ \frac{16 s_0 \lambda_k^2}{\ell_F^2 C_{\min}^2} \tau_k + 4W^2 \left(\frac{\tau_k}{d} + 2\tau_k e^{-\tau_{k-1}/(c_0 s_0)} \right) \right\} \\
&\le C C_{\max} W \left\{ \left(\frac{16 u_F}{\ell_F C_{\min}} \right)^2 2 s_0 \log d + 8W^2 \left(2c_1 + 2\tau_{k-1} e^{-\frac{\tau_{k-1}}{c_0 s_0}} \right) \right\},
\end{aligned} \tag{46}$$

  where in the last step we used $\tau_k = 2\tau_{k-1}$ and $\tau_k = 2^{k-1} \le 2c_1 d$. Therefore, in this case

$$\mathsf{Regret}(k\text{th Episode}) \le \frac{C' W}{C_{\min}^2} s_0 \log d\,, \tag{47}$$

  where C' hides various constants in the right-hand side of (46).

- $c_1 d < 2^{k-2}$: Continuing from Equation (44) and applying Proposition 12 to episode k, we obtain

$$\begin{aligned}
\mathsf{Regret}(k\text{th Episode}) &= \sum_{t=\tau_k}^{\tau_{k+1}-1} \mathbb{E}(\mathsf{reg}_t) \\
&\le C C_{\max} W \sum_{t=\tau_k}^{\tau_{k+1}-1} \mathbb{E}(\|\widehat{\theta}^k - \theta_0\|_2^2) \\
&\le C C_{\max} W \left\{ \frac{16(s_0+1)\lambda_k^2}{\ell_F^2 C_{\min}^2} \tau_k + 4\tau_k W^2 e^{-c\tau_{k-1}^2} \right\} \\
&\le C C_{\max} W \left\{ \left(\frac{16 u_F}{\ell_F C_{\min}} \right)^2 2(s_0+1) \log d + 8W^2 \tau_{k-1} e^{-c\tau_{k-1}^2} \right\},
\end{aligned} \tag{48}$$

  Therefore, in this case

$$\mathsf{Regret}(k\text{th Episode}) \le \frac{C' W}{C_{\min}^2} s_0 \log d\,, \tag{49}$$

where C' hides various constants in the right-hand side of (48).

Combining the above three cases into Equation (45), we get

$$\mathsf{Regret}(T) \le K \frac{C' W}{C_{\min}^2} s_0 \log d = O\Big(\frac{W}{C_{\min}^2} s_0 \log d \cdot \log T \Big)\,, \tag{50}$$

which concludes the proof.

8.2. Proof of Theorem 4

By using Equation (43), we have

$$\mathbb{E}(\mathsf{reg}_t) \le \frac{C}{2} \mathbb{E}\left(\left\langle \widehat{\theta}^k - \theta_0, \Sigma(\widehat{\theta}^k - \theta_0) \right\rangle \right)\,, \tag{51}$$

with $\Sigma = \mathbb{E}(x_t x_t^{\mathsf{T}})$ and $C = 2(B + WB')$, where $B = \max_v f(v)$ and $B' = \max_v f'(v)$. Therefore, letting $K = \lfloor \log T \rfloor + 1$, we get

$$\mathsf{Regret}(T) = \sum_{k=1}^{K} \mathsf{Regret}(k\text{th Episode}) \le \frac{C}{2} \sum_{k=1}^{K} \mathbb{E}\left(\left\langle \widehat{\theta}^k - \theta_0, \Sigma(\widehat{\theta}^k - \theta_0) \right\rangle \right) \tau_k\,. \tag{52}$$

We next bound the right-hand side of the above bound. Let $X^{(k)} \in \mathbb{R}^{\tau_k \times d}$ be the matrix obtained by stacking feature vectors in episode k as rows. By applying bound (91) to samples in episode $(k-1)$, we get that with probability at least $1 - 1/d$,

$$\frac{2\ell_F}{\tau_{k-1}} \left\| X^{(k-1)}(\theta_0 - \widehat{\theta}^k) \right\|^2 + 2\lambda_k \|\widehat{\theta}^k\|_1 \le \lambda_k \|\widehat{\theta}^k - \theta_0\|_1 + 2\lambda_k \|\theta_0\|_1\,. \tag{53}$$

Hence,

$$\frac{2\ell_F}{\tau_{k-1}} \left\| X^{(k-1)}(\theta_0 - \widehat{\theta}^k) \right\|^2 \le \lambda_k \|\widehat{\theta}^k - \theta_0\|_1 + 2\lambda_k \|\theta_0\|_1 - 2\lambda_k \|\widehat{\theta}^k\|_1 \le 3\lambda_k \|\widehat{\theta}^k - \theta_0\|_1\,. \tag{54}$$

For $k \ge 1$, let $S^{(k)} \in \mathbb{R}^{d \times d}$ be the empirical second moment of $X^{(k)}$, and define $E^{(k)} = \Sigma - S^{(k)}$. Then,

$$\left\langle \widehat{\theta}^k - \theta_0, \Sigma(\widehat{\theta}^k - \theta_0) \right\rangle = \left\langle \widehat{\theta}^k - \theta_0, S^{(k-1)}(\widehat{\theta}^k - \theta_0) \right\rangle + \left\langle \widehat{\theta}^k - \theta_0, E^{(k-1)}(\widehat{\theta}^k - \theta_0) \right\rangle\,. \tag{55}$$

The first term is bounded using Equation (54) as follows:

$$\left\langle \widehat{\theta}^k - \theta_0, S^{(k-1)}(\widehat{\theta}^k - \theta_0) \right\rangle = \frac{1}{\tau_{k-1}} \left\| X^{(k-1)}(\theta_0 - \widehat{\theta}^k) \right\|^2 \le \frac{3\lambda_k}{2\ell_F} \|\widehat{\theta}^k - \theta_0\|_1 \le \frac{3W}{\ell_F} \lambda_k\,, \tag{56}$$

with probability at least $1 - 1/d$.

The second term can be bounded by virtue of the following lemma, whose proof is deferred to Appendix C.8

Lemma 15 *For any $k \geq 1$ and any vector $v \in \mathbb{R}^d$, we have*

$$\langle v, E^{(k)} v \rangle \leq 3\sqrt{\frac{\log d}{\tau_k}}\, \|v\|_1^2\,,$$

with probability at least $1 - 8/d^2$.

By Lemma 15, we have

$$\left\langle \widehat{\theta}^k - \theta_0, E^{(k-1)}(\widehat{\theta}^k - \theta_0) \right\rangle \leq 12\sqrt{\frac{\log d}{\tau_{k-1}}} W^2\,, \tag{57}$$

with probability at least $1 - 8/d^2$.

Combining Equations (56) and (57), with probability at least $1 - 9/d$ we have

$$\left\langle \widehat{\theta}^k - \theta_0, \Sigma(\widehat{\theta}^k - \theta_0) \right\rangle \leq \frac{3W}{\ell_F}\lambda_k + 12\sqrt{\frac{\log d}{\tau_{k-1}}} W^2 = 12\left(\frac{W u_F}{\ell_F} + W^2\right)\sqrt{\frac{\log d}{\tau_{k-1}}}\,. \tag{58}$$

Following a similar argument as in Section 8.1 (see Equation (45) and onwards) we have that the following holds for a suitable constant $C > 0$:

$$\begin{aligned}\mathsf{Regret}(T) &\leq CW^3 \sum_{k=2}^{K} \sqrt{\frac{\log d}{\tau_{k-1}}} \cdot \tau_k \\ &\leq \sqrt{2} CW^3 \sum_{k=2}^{K} \sqrt{(\log d)\tau_{k-1}} = O(W^3\sqrt{(\log d)T})\,,\end{aligned}$$

which completes the proof.

8.3. Proof of Theorem 5

The regret benchmark (9) is defined as the maximum gap between a policy and the oracle policy over different $\theta_0 \in \Omega$ and $p_X \in Q(\mathcal{X})$. Without loss of generality, we assume $\mathcal{X} = [-1, 1]^d$. In order to obtain a lower bound on the regret, it suffices to consider a specific distribution in $Q(\mathcal{X})$. We consider a distribution p_X that selects coordinates x_i, $1 \leq i \leq d$, uniformly at random from $\{-1, 1\}$ and independent of each other. We further assume $\theta_0 \in \Omega$, with Ω given by (5).

Fix an arbitrary policy π in family Π. By definition of policy set Π, we have $\pi(p_t) = g(x_t \cdot \theta_t)$, for some $\theta_t \in \Omega$, which is $\mathcal{H}_{t-1}$-measurable . Recalling our notation in the proof of Theorem 3, reg_t denotes the regret occurred at step t and by Equations (39), (40), we have

$$\mathbb{E}(\mathsf{reg}_t | \bar{\mathcal{H}}_{t-1}) = \mathsf{rev}_t(p_t^*) - \mathsf{rev}_t(p_t) = -\frac{1}{2}\mathsf{rev}_t''(p)(p_t - p_t^*)^2\,, \tag{59}$$

for some p between p_t and p_t^*.

Our first lemma will be used in lower bounding $\mathbb{E}(\mathsf{reg}_t | \bar{\mathcal{H}}_{t-1})$.

Lemma 16 *There exists a constant $c_1 > 0$ (depending on W and σ) such that, with probability one*[5]*, $r_t''(p_t^*) \leq -c_1$, for all $t \geq 1$. Further, there exists constant $\delta > 0$ (depending on W and σ) such that $r_t''(p) \leq -c_1/4$ for $p \in [p_t^* - \delta, p_t^* + \delta]$, with probability one.*

Proof of Lemma 16 is given in Appendix C.3.

Continuing from Equation (59), we consider two separate cases:

- $|p_t - p_t^*| \leq \delta$: We have $p \in [p_t^* - \delta, p_t^* + \delta]$ and therefore by applying Lemma 16 we obtain

$$\mathbb{E}(\mathsf{reg}_t | \bar{\mathcal{H}}_{t-1}) = \mathsf{rev}_t(p_t^*) - \mathsf{rev}_t(p_t) \geq \frac{c}{8}(p_t - p_t^*)^2\,. \tag{60}$$

- $|p_t - p_t^*| > \delta$: Since function rev_t has only one local maximum, namely p_t^*, the function is increasing before p_t^* and decreasing afterward. Therefore, if $p_t \leq p_t^* - \delta$ then

$$\mathsf{rev}_t(p_t) \leq \mathsf{rev}_t(p_t^* - \delta) = \mathsf{rev}_t(p_t^*) + \frac{1}{2}\mathsf{rev}_t''(p)\delta^2 \leq \mathsf{rev}_t(p_t^*) - \frac{c_1}{8}\delta^2\,, \tag{61}$$

where p is some point in $[p_t^* - \delta, p_t^*]$ and we applied Lemma 16 in the last step.

Similarly, for $p_t \geq p_t^* + \delta$ we obtain

$$\mathsf{rev}_t(p_t) \leq \mathsf{rev}_t(p_t^* + \delta) = \mathsf{rev}_t(p_t^*) + \frac{1}{2}\mathsf{rev}_t''(p)\delta^2 \leq \mathsf{rev}_t(p_t^*) - \frac{c_1}{8}\delta^2\,, \tag{62}$$

where $p \in [p_t^* - \delta, p_t^*]$ this time. Combining these two inequalities, we get that $\mathsf{rev}_t(p_t^*) - \mathsf{rev}_t(p_t) \geq c_1\delta^2/8$, if $|p_t^* - p_t| \geq \delta$.

Writing the bounds in the two cases together, we get

$$\mathbb{E}(\mathsf{reg}_t | \bar{\mathcal{H}}_{t-1}) \geq \mathsf{rev}_t(p_t^*) - \mathsf{rev}_t(p_t) \geq \begin{cases} \frac{c_1}{8}(p_t - p_t^*)^2\,, & \text{if } |p_t - p_t^*| \leq \delta\,, \\ \frac{c_1}{8}\delta^2\,, & \text{if } |p_t - p_t^*| > \delta\,. \end{cases} \tag{63}$$

We proceed by relating the lower bound to the error in estimation θ_0.

$$\begin{aligned}\mathbb{E}(\mathsf{reg}_t | \bar{\mathcal{H}}_{t-1}) &\geq \frac{c_1}{8}\min\left((p_t - p_t^*)^2, \delta^2\right) = \frac{c_1}{8}\min\left((g(x_t \cdot \theta_t) - g(x_t \cdot \theta_0))^2, \delta^2\right) \\ &\geq \frac{c_1}{8}\min\left(c_2^2\,|x_t \cdot (\theta_t - \theta_0)|^2, \delta^2\right),\end{aligned} \tag{64}$$

where we used the fact that by Lemma 14, $g'(v) > c_2$ over the bounded interval $[-W, W]$, for some constant $c_2 > 0$. We recall the definition of history set $\mathcal{H}_t \equiv \bar{\mathcal{H}}_t \backslash \{x_{t+1}\} = \{x_1, x_2, \ldots, x_t, z_1, z_2, \ldots, z_t\}$. Since $\mathcal{H}_t \subseteq \bar{\mathcal{H}}_t$, by iterated law of expectation, we get

$$\mathbb{E}(\mathsf{reg}_t | \mathcal{H}_{t-1}) = \mathbb{E}(\mathbb{E}(\mathsf{reg}_t | \bar{\mathcal{H}}_{t-1}) | \mathcal{H}_{t-1}) \geq \frac{c_1}{8}\mathbb{E}\Big(\min\left(c_2^2 |x_t \cdot (\theta_t - \theta_0)|_2^2, \delta^2\right)\Big| \mathcal{H}_{t-1}\Big)\,. \tag{65}$$

Note that x_t is independent of $\mathcal{H}_{t-1}$ and $\theta_t - \theta_0$ is $\mathcal{H}_{t-1}$-measurable.

We use the following lemma to lower bound the right-hand side of (65).

5. The randomness comes from randomness in prices which in turn comes from randomness in features x_t.

Lemma 17 *Let $x \in \mathbb{R}^d$ be a random vector such that its coordinates are chosen independently and uniformly at random from $\{-1, 1\}$. Further, suppose that $v \in \mathbb{R}^d$ and $\delta > 0$ are deterministic. Then,*

$$\mathbb{E}\Big(\min\big((x \cdot v)^2, \delta^2\big)\Big) \geq 0.1 \min(\|v\|_2^2, \delta^2)\,. \tag{66}$$

Proof of Lemma 17 is given in Appendix C.4.

Applying Lemma 17 to bound (65), we obtain

$$\mathbb{E}(\mathsf{reg}_t|\mathcal{H}_{t-1}) \geq \frac{c_1 c_2^2}{80}\mathbb{E}\Big(\min\Big(\|\theta_t - \theta_0\|_2^2, \delta^2/c_2^2\Big)\Big|\mathcal{H}_{t-1}\Big)\,. \tag{67}$$

Now, taking expectation from both sides with respect to $\mathcal{H}_{t-1}$, we arrive at

$$\mathbb{E}(\mathsf{reg}_t) \geq \frac{c_1 c_2^2}{80}\mathbb{E}\Big(\min\Big(\|\theta_t - \theta_0\|_2^2, \delta^2/c_2^2\Big)\Big)\,. \tag{68}$$

Equation (68) lower bounds the expected regret at each step to the ℓ_2 estimation error.

We continue by establishing a minimax lower bound on ℓ_2-risk of estimation.

Lemma 18 *Consider linear model (2), with $\alpha_0 = 0$, and assume that the market values $v(x_t)$, $1 \leq t \leq T$, are fully observed and the feature vectors are generated according to p_X, described above. We further assume that the noise in market value is generated as $z_t \sim \mathsf{N}(0, \sigma^2)$. For a sequence of estimators θ_t, we let $\theta_1^t = (\theta_1, \theta_2, \ldots, \theta_t)$. Then, for any fixed value $C > 0$, there exists a nonnegative constant $\widetilde{C}$, depending on C, σ, W, such that*

$$\min_{\theta_1^T} \max_{\theta_0 \in \Omega} \sum_{t=1}^T \mathbb{E}\left(\min\left(\|\theta_t - \theta_0\|_2^2, C\right)\Big| x_1, \ldots, x_T\right) \geq \widetilde{C}\Big\{ s_0 \log\Big(\frac{T}{s_0}\Big) + \min\Big[\frac{T}{s_0}, s_0 \log\Big(\frac{d}{s_0}\Big)\Big]\Big\}\,. \tag{69}$$

Proof of Lemma 18 is given in Appendix C.5.

We are now ready to lower bound the regret of any policy in Π.

$$\begin{aligned}\mathsf{Regret}(T) &\geq \max_{\theta_0 \in \Omega} \sum_{t=1}^T \mathbb{E}(\mathsf{reg}_t) \geq \frac{c_1 c_2^2}{80} \sum_{t=1}^T \mathbb{E}\Big(\min\Big(\|\theta_t - \theta_0\|_2^2, \delta^2/c_2^2\Big)\Big) \\ &\geq \widetilde{C}\frac{c_1 c_2^2}{80}\Big\{ s_0 \log\Big(\frac{T}{s_0}\Big) + \min\Big[\frac{T}{s_0}, s_0 \log\Big(\frac{d}{s_0}\Big)\Big]\Big\}\,. \end{aligned} \tag{70}$$

where the last step follows from Lemma 18.

8.4. Proof of Theorem 8

Let $\tilde{x}_t = \phi(x_t)$ denote the transformed features under the feature-map. Also, let $\tilde{p}_t = \psi^{-1}(p_t)$. We first show that Assumption 7 implies Assumption 6, and therefore it suffices to prove the theorem under Assumption 6.

Lemma 19 *Suppose that Assumption 1 hold true. Then, Assumption 7 implies Assumption 6.*

Proof of Lemma 19 is given in Appendix C.6.

By Assumption 1, the support of $\mathbb{P}_X$ is a bounded set $\mathcal{X}$. Given that ϕ has a continuous derivative, it is Lipschitz on the bounded set $\mathcal{X}$ and ergo the image of $\mathcal{X}$ remains bounded under the feature-map ϕ. Putting differently, features $\tilde{x}_t$ are sampled from a bounded set in $\mathbb{R}^d$. Without loss of generality, we assume $\|\tilde{x}_t\|_\infty \leq 1$. Further, as per Assumption 6, the covariance of the underlying distribution Σ_ϕ is positive definite with bounded eigenvalues.

On a different note, since ψ is strictly increasing, a sale occurs at period t when $\theta_0 \cdot \tilde{x}_t + z_t \geq \psi^{-1}(p_t) = \tilde{p}_t$. Therefore the (negative) log-likelihood function for θ reads as

$$\mathcal{L}(\theta) = -\frac{1}{\tau_{k-1}} \sum_{t=\tau_{k-1}}^{\tau_k - 1} \Big\{ \mathbb{I}(y_t = 1)\log(1 - F(\tilde{p}_t - \theta \cdot \tilde{x}_t)) + \mathbb{I}(y_t = -1)\log(F(\tilde{p}_t - \theta \cdot \tilde{x}_t))\Big\}\,.$$

The estimation bound (34) also holds for this setting and the proof goes along the same lines of the proof of Proposition 10, with slight modifications: (i) the features x_t and prices p_t should be replaced by $\tilde{x}_t$ and $\tilde{p}_t$. (ii) Quantity u_F and ℓ_F in the statement of Proposition 10 should be set as $M = (1/3)g_\psi(0) + (2/3)W$. This follows from the bounds below

$$\tilde{p}_t = g_\psi(\tilde{x}_t \cdot \widehat{\theta}^k) \leq g_\psi(0) + |\tilde{x}_t \cdot \widehat{\theta}^k| \leq g_\psi(0) + W\,, \tag{71}$$

where we used the facts that g_ψ is 1-Lipschitz and increasing as explained below Equation (23).

We next characterize the optimal policy when the true parameter θ_0 is known. The expected revenue from a posted price p works out at $p(1 - F(\psi^{-1}(p) - \theta_0 \cdot \tilde{x}_t))$. Writing this in terms of $\tilde{p} = \psi^{-1}(p)$, the first order condition for the optimal price reads as

$$\lambda(\tilde{p}^* - \theta_0 \cdot \tilde{x}_t) \equiv \frac{f(\tilde{p}^* - \theta_0 \cdot \tilde{x}_t)}{1 - F(\tilde{p}^* - \theta_0 \cdot \tilde{x}_t)} = \frac{\psi'(\tilde{p}^*)}{\psi(\tilde{p}^*)}\,, \tag{72}$$

where λ denotes the hazard rate function. Equivalently

$$\theta_0 \cdot \tilde{x}_t = \tilde{p}^* - \lambda^{-1}\Big(\frac{\psi'(\tilde{p}^*)}{\psi(\tilde{p}^*)}\Big)\,. \tag{73}$$

By definition of function g_ψ as per Equation (23), we get $\tilde{p}^* = g_\psi(\theta_0 \cdot \tilde{x}_t)$ and thus $p^* = \psi(g_\psi(\theta_0 \cdot \tilde{x}_t))$.

We are now ready to bound the regret of the algorithm. Similar to Equation (42), we have

$$\begin{aligned}\mathbb{E}(\mathsf{reg}_t|\overline{\mathcal{H}}_{t-1}) \leq \frac{C}{2}(p_t^* - p_t)^2 &= \frac{C}{2}\Big[\psi(g_\psi(\theta_0 \cdot \tilde{x}_t)) - \psi(g_\psi(\widehat{\theta}^k \cdot \tilde{x}_t))\Big]^2 \\ &\leq \frac{C}{2}L(g_\psi(\theta_0 \cdot \tilde{x}_t)) - g_\psi(\widehat{\theta}^k \cdot \tilde{x}_t))^2 \leq \frac{LC}{2}|\tilde{x}_t \cdot (\theta_0 - \widehat{\theta}^k)|^2\,, \end{aligned} \tag{74}$$

where $L \equiv \max_{|v| \leq \psi(M)} |\psi'(v)|$ (since ψ is continuously differentiable, it attains a maximum over a bounded set.) In addition, we used the fact that $g'_\psi(v) \leq 1$ as explained below Equation (23). The inequalities above then follow from the mean-value theorem.

Given that $\tilde{x}_t$ is independent of $\mathcal{H}_{t-1}$, we have

$$\mathbb{E}(\mathsf{reg}_t|\mathcal{H}_{t-1}) \leq \frac{LC}{2}\langle \widehat{\theta}^k - \theta_0, \Sigma_\phi(\widehat{\theta}^k - \theta_0)\rangle\,, \tag{75}$$

where $\Sigma_\phi = \mathbb{E}(x_t x_t^\mathsf{T})$. Using Assumption 6,

$$\mathbb{E}(\mathsf{reg}_t) = \mathbb{E}\left(\mathbb{E}(\mathsf{reg}_t|\mathcal{H}_{t-1})\right) \le \frac{1}{2} LCC_{\max}\mathbb{E}(\|\widehat{\theta}^k - \theta_0\|_2^2)\,. \tag{76}$$

Rest of the proof is similar to proof of Theorem 8.1 (see after Equation (45)).

8.5. Proof of Theorem 9

We consider representation (27) of the valuations. Letting $\tilde{x}_t = (-x_t; p_t)$ and $\eta = (\mu; \beta)$ vectors in $\mathbb{R}^{(d+1)\times 1}$, we can write the log-likelihood loss as:

$$\mathcal{L}(\eta) = -\frac{1}{\tau_{k-1}} \sum_{t=\tau_{k-1}}^{\tau_k - 1} \Big\{ \mathbb{I}(y_t = 1)\log\left(1 - F\left(\tilde{x}_t \cdot \eta\right)\right) + \mathbb{I}(y_t = -1)\log\left(F\left(\tilde{x}_t \cdot \eta\right)\right) \Big\}\,. \tag{77}$$

We let $p^{(k)} = (p_{\tau_{k-1}}, \ldots, p_{\tau_k - 1})^\mathsf{T}$ be the vector of prices posted in episode k. We also construct feature matrix $X^{(k)}$ by putting features x_t that arrive in episode k, as its rows. Matrix $\widetilde{X}^{(k)}$ is constructed likewise by stacking augmented features x_t. Hence, $\widetilde{X}^{(k)} = [-X^{(k)}, p^{(k)}]$.

The next lemma is a technical lemma that will be used later in bounding the regret. We refer the reader to Appendix C.9 for its proof.

Lemma 20 *Assume that the product features $x_t \in \mathbb{R}^d$ are generated independently from an unknown distribution with bounded support in $\mathbb{R}^d$. Then, with the choice of regularization parameters $\lambda_k = 4u_F\sqrt{(\log d)/\tau_{k-1}}$ in the RMLP-2 policy, the following inequalities hold true:*

$$\frac{1}{\tau_{k-1}}\|X^{(k-1)}(\mu_0 - \widehat{\mu}^k)\|^2 \;\le\; \frac{4W}{\ell_F}\lambda_k\,, \tag{78}$$

$$(\beta_0 - \widehat{\beta}^k)^2 \;\le\; \frac{c_W}{\ell_F}\lambda_k\,, \tag{79}$$

where $c_W > 0$ is a constant that depends on W.

We next figure out the clairvoyant policy.

Lemma 21 *Let g be the pricing function corresponding to distribution $F = F_{0,1}$, given by $g(v) = v + \varphi^{-1}(-v)$, where $\varphi(v) = v - (1 - F(v))/f(v)$ is the virtual valuation function. Then, under model (27), the clairvoyant optimal prices are given by*

$$p_t^* = \frac{1}{\beta_0} g(x_t \cdot \mu_0)\,. \tag{80}$$

Proof of Lemma 21 is given in Appendix C.7.

We next bound the regret at other periods of the episode. Let $\bar{\mathcal{H}}_t = \{\tilde{x}_1, \ldots, \tilde{x}_t, \tilde{x}_{t+1}, z_1, \ldots, z_t\}$ be the history set up to time t. Similar to (42), we write

$$\begin{aligned}
\mathbb{E}(\mathsf{reg}_t|\bar{\mathcal{H}}_{t-1}) &\le CW(p_t^* - p_t)^2 \\
&= CW\Big(\frac{1}{\beta_0}g(x_t\cdot\mu_0) - \frac{1}{\widehat{\beta}^k}g(x_t\cdot\widehat{\mu}^k)\Big)^2 \\
&\le \frac{2CW}{\beta_0^2}\Big(g(x_t\cdot\mu_0) - g(x_t\cdot\widehat{\mu}^k)\Big)^2 + 2CW\Big(\frac{1}{\beta_0} - \frac{1}{\widehat{\beta}^k}\Big)^2 g(x_t\cdot\widehat{\mu}^k)^2 \\
&\le \frac{2CW}{\beta_0^2}|x_t\cdot(\mu_0 - \widehat{\mu}^k)|^2 + \frac{8CW^3}{\beta_0^2}(\widehat{\beta}^k - \beta_0)^2\,.
\end{aligned} \tag{81}$$

In the last step, the first term is bounded by using 1-Lipschitz property of g and the second term is bounded by using the following chain of inequalities:

$$\frac{1}{\widehat{\beta}^k}g(x_t\cdot\widehat{\mu}^k) \le \frac{2}{\widehat{\beta}^k}|x_t\cdot\widehat{\mu}^k| \le \frac{2}{\widehat{\beta}^k}\|x_t\|_\infty\|\widehat{\mu}^k\|_1 \le 2W\,.$$

Note that in the first inequality we used the fact that $\varphi(v)$ is increasing for log-concave distributions and hence $g(v) = v + \varphi^{-1}(-v) \le v + |v| \le 2|v|$. The last inequality holds because $\|\widehat{\mu}^k/\widehat{\beta}^k\| \le W$ by the optimization constraint in (28).

Recalling our notation $\mathcal{H}_t = \bar{\mathcal{H}}_t\backslash\{\tilde{x}_{t+1}\}$ and applying the law of iterated expectations, we have

$$\begin{aligned}
\mathbb{E}(\mathsf{reg}_t|\mathcal{H}_{t-1}) &\le \frac{2CW}{\beta_0^2}\Big\langle\widehat{\mu}^k - \mu_0, \Sigma(\widehat{\mu}^k - \mu_0)\Big\rangle + \frac{8CW^3}{\beta_0^2}(\widehat{\beta}^k - \beta_0)^2 \\
&\le C_1W^3\Big(\Big\langle\widehat{\mu}^k - \mu_0, \Sigma(\widehat{\mu}^k - \mu_0)\Big\rangle + (\widehat{\beta}^k - \beta_0)^2\Big)\,,
\end{aligned} \tag{82}$$

with $C_1 = 8CW/\beta_0^2$. Following a similar derivation to (58) we get

$$\Big\langle\widehat{\mu}^k - \mu_0, \Sigma(\widehat{\mu}^k - \mu_0)\Big\rangle \le 16\left(\frac{Wu_F}{\ell_F} + W^2\right)\sqrt{\frac{\log d}{\tau_{k-1}}}\,. \tag{83}$$

Using Equations (83) and (79) in Equation (82), we get

$$\mathbb{E}(\mathsf{reg}_t) \le \underbrace{C_1W^3\left[16\left(\frac{Wu_F}{\ell_F} + W^2\right) + 4\frac{u_Fc_W}{\ell_F}\right]}_{C_2}\sqrt{\frac{\log d}{\tau_{k-1}}}\,. \tag{84}$$

Following a similar argument as in Section 8.1 (see Equation (45) and onwards) we have that the following holds for a suitable constant $C > 0$:

$$\begin{aligned}
\mathsf{Regret}(T) &\le C_2\sum_{k=2}^{K}\sqrt{\frac{\log d}{\tau_{k-1}}}\cdot\tau_k \\
&\le \sqrt{2}C_2\sum_{k=2}^{K}\sqrt{(\log d)\tau_{k-1}} = O(\sqrt{(\log d)T})\,,
\end{aligned}$$

where we used $\tau_k = 2\tau_{k-1}$.

For the lower bound $\Omega(\sqrt{T})$, note that under model (27) we can define the (scaled) customer's utility as

$$\tilde{u}(x_t) = \mu_0 \cdot x_t - \beta_0 p + \tilde{z}_t \,. \tag{85}$$

Then, a purchase occurs if $\tilde{u}(x_t) > 0$. Following our discussion in Section 4.1 (see after Equation (16)), since β_0 is unknown, the uninformative prices do exist and therefore $\Omega(\sqrt{T})$ applies to this case.

9. Conclusion

In this work, we leverage tools from statistical learning to design a dynamic pricing policy for a setting wherein the products are described via high-dimensional features. Our policy is computationally efficient and by exploiting the structure of demand parameters, it obtains a regret that scales gracefully with the features dimension and the time horizon. Namely, the regret of our algorithm scales linearly with the sparsity of the optimal solution and logarithmically with the dimension. We also show an $O(\log T)$ dependence of the regret on the length of the horizon. On the flip side, we provide a lower-bound of $O(\log T)$ on the regret of any algorithm that does not know the true parameters of the model in advance.

A natural next step is providing a tight bound on the regret, closing the gap between the derived upper and lower bounds. Another step would be assuming that θ^* is not exactly sparse, but it can be well approximated by a sparse vector, i.e, $\|\theta_0 - \theta_{s_0}\|_1 \leq \delta$ for some s_0-sparse vector θ_{s_0}. An interesting question is to figure out how the regret scales with δ.

The choice model that proposed in this work assumes one product arrived at each period, and describes the customer's purchase behavior based on the product features and the posted price. A more general choice model would be the one that assumes multiple products at each period. More specifically, each customer has a "consideration" set which includes products left after the customer has narrowed down her choices based on her own personal screening criteria, and then chooses the product from this set which brings maximum utility. We model the no purchase option as an extra product. This generalization is the focus of a future work.

We also believe the ideas and techniques developed in this work can be be applied to other settings such as personalized pricing where information about the buyers can be used for price differentiation or optimizing reserve prices in online ad auctions. Another application would be assortment optimization and learning consumer choice models both in terms of the role of the structure (Farias et al., 2013; Kallus and Udell, 2016) as well as inventory-constrained environments (Golrezaei et al., 2014; Ferreira et al., 2018; Cheung et al., 2018).

Appendix A. Proof of Proposition 10

We start by reviewing the notion of *restricted eigenvalue* (RE) which is commonplace in high-dimensional statistical estimation.

Definition 22 *For a given matrix $A \in \mathbb{R}^{d\times d}$ and some integer s such that $1 \le s_0 \le d$ and a positive number c, we say that* Restricted Eigenvalue *(RE) condition is met if*

$$\kappa^2(A, s_0, c) \equiv \min_{\substack{J\subseteq[p]\\ |J|\le s_0}} \min_{\substack{v\neq 0\\ \|v_{J^c}\|_1\le c\|v_J\|_1}} \frac{v^\mathsf{T} A v}{\|v_J\|_2^2} > 0\,.$$

It is shown in (Bühlmann and van de Geer, 2011) and (Rudelson and Zhou, 2013) that when two matrices A_0, A_1 are close to each other (in the maximum element-wise norm) compared to sparsity s_0, the RE condition for A_0 implies the RE condition for A_1. This is particularly useful when A_0 is a population second moment matrix and A_1 is a corresponding empirical second moment matrix. To apply this result to our case, let $X \in \mathbb{R}^{n\times d}$ be the feature matrix with rows x_t, corresponding to n products. Let $\Sigma = \mathbb{E}(x_t x_t^\mathsf{T})$ be the empirical second moment. By Assumption 2, we have $\Sigma \succeq C_{\min}\mathrm{I}$ and therefore, Σ satisfies RE condition with $\kappa^2(\widetilde{\Sigma}, s_0, 3) \ge C_{\min}$. By using the following result, we conclude that $\widehat{\Sigma} = (X^\mathsf{T}X)/n$ also satisfies RE condition with $\kappa^2(\widehat{\Sigma}, s_0, 3) \ge C_{\min}/2$.

Proposition 23 *Let $\widehat{\Sigma} = (X^\mathsf{T}X)/n$ and let $S = \mathrm{supp}(\theta_0)$ be the support of θ_0. Under Assumption 2, $\widehat{\Sigma}$ satisfies the restricted eigenvalue condition with constant $\kappa(\widehat{\Sigma}, s_0, 3) \ge \sqrt{C_{\min}/2}$, with probability $1 - e^{-2n/(c_0 s_0)}$ and $c_0 = 768/C_{\min}^2$, provided that $n \ge c_0 s_0 \log d$,*

Proposition 23 follows from the results established in (Bühlmann and van de Geer, 2011) and (Rudelson and Zhou, 2013). We outline the main steps of its proof in Appendix A.1 for the reader's convenience.

By the second-order Taylor's theorem, expanding around θ_0 we have

$$\mathcal{L}(\theta_0) - \mathcal{L}(\widehat{\theta}) = -\langle \nabla\mathcal{L}(\theta_0), \widehat{\theta} - \theta_0\rangle - \frac{1}{2}\langle \widehat{\theta} - \theta_0, \nabla^2\mathcal{L}(\tilde{\theta})(\widehat{\theta} - \theta_0)\rangle\,, \tag{86}$$

for some $\tilde{\theta}$ on the line segment between θ_0 and $\widehat{\theta}$. Invoking (31), we have

$$\nabla\mathcal{L}(\theta) = \frac{1}{n}\sum_{t=1}^n \xi_t(\theta) x_t\,, \quad \nabla^2\mathcal{L}(\theta) = \frac{1}{n}\sum_{t=1}^n \eta_t(\theta) x_t x_t^\mathsf{T}\,, \tag{87}$$

where ∇ and ∇^2 represents the gradient and the hessian w.r.t θ. Further,

$$\begin{aligned}\xi_t(\theta) &= -\frac{f(u_t(\theta))}{F(u_t(\theta))}\mathbb{I}(y_t = -1) + \frac{f(u_t(\theta))}{1 - F(u_t(\theta))}\mathbb{I}(y_t = +1)\\ &= -\log' F(u_t(\theta))\mathbb{I}(y_t = -1) - \log'(1 - F(u_t(\theta)))\mathbb{I}(y_t = +1)\,.\end{aligned}$$

$$\begin{aligned}\eta_t(\theta) &= \left(\frac{f(u_t(\theta))^2}{F(u_t(\theta))^2} - \frac{f'(u_t(\theta))}{F(u_t(\theta))}\right)\mathbb{I}(y_t = -1) + \left(\frac{f(u_t(\theta))^2}{(1 - F(u_t(\theta)))^2} + \frac{f'(u_t(\theta))}{1 - F(u_t(\theta))}\right)\mathbb{I}(y_t = +1)\\ &= -\log'' F(u_t(\theta))\mathbb{I}(y_t = -1) - \log''(1 - F(u_t(\theta)))\mathbb{I}(y_t = +1)\,,\end{aligned}$$

where $u_t(\theta) = p_t - \langle x_t, \theta\rangle$, and $\log' F(x)$ and $\log'' F(x)$ represent first and second derivative w.r.t x, respectively.

By Equation (37), we have

$$|u_t(\theta_0)| \le |p_t| + \|x_t\|_\infty\|\theta_0\|_1 \le 3W\,.$$

Further, recall that the sequences $\{p_t\}_{t=1}^n$ and $\{x_t\}_{t=1}^n$ are independent of $\{z_t\}_{t=1}^n$. Therefore, $\{u_t(\theta_0)\}_{t=1}^T$ and $\{z_t(\theta_0)\}_{t=1}^T$ are independent and by (4), we have $\mathbb{E}[\xi_t(\theta_0)] = \mathbb{E}[\mathbb{E}[\xi_t(\theta_0)|u_t(\theta_0)]] = 0$. Further, by definition of u_F, cf. Equation (13), we have $|\xi_t(\theta_0)| \le u_F$.

We next introduce the set

$$\mathcal{F} \equiv \left\{\|\nabla\mathcal{L}(\theta_0)\|_\infty \le 2u_F\sqrt{\frac{\log d}{n}}\right\}. \tag{88}$$

By applying Azuma-Hoeffding inequality followed by union bounding over d coordinates of feature vectors, we obtain $\mathbb{P}(\mathcal{F}) \ge 1 - 1/d$.

On the other note, $\|\theta_0\|_1, \|\tilde{\theta}\|_1 \le W$ and hence $\|\tilde{\theta}\|_1 \le W$. This implies that $|u_t(\tilde{\theta})| \le 3W$. Therefore, by definition of ℓ_F, cf. Equation (33), we have $\eta_t(\tilde{\theta}) \ge \ell_F$. Recalling Equation (87), we get $\nabla^2\mathcal{L}(\tilde{\theta}) \succeq \ell_F(\widetilde{X}^\mathsf{T}\widetilde{X}/n)$.

By optimality of $\widehat{\theta}$, we write

$$\mathcal{L}(\widehat{\theta}) + \lambda\|\widehat{\theta}\|_1 \le \mathcal{L}(\theta_0) + \lambda\|\theta_0\|_1\,, \tag{89}$$

and by rearranging the terms and using (86), we arrive at

$$\frac{\ell_F}{n}\|X(\theta_0 - \widehat{\theta})\|^2 + \lambda\|\widehat{\theta}\|_1 \le \|\nabla\mathcal{L}(\theta_0)\|_\infty\|\widehat{\theta} - \theta_0\|_1 + \lambda\|\theta_0\|_1\,. \tag{90}$$

Form now on, the analysis is exactly similar to the oracle inequality for Lasso estimator. We bring the analysis here for the reader's convenience.

Choosing $\lambda \ge 4u_F\sqrt{(\log d)/n}$, we have on $\mathcal{F}$

$$\frac{2\ell_F}{n}\|X(\theta_0 - \widehat{\theta})\|^2 + 2\lambda\|\widehat{\theta}\|_1 \le \lambda\|\widehat{\theta} - \theta_0\|_1 + 2\lambda\|\theta_0\|_1\,. \tag{91}$$

Let $S = \mathrm{supp}(\theta_0)$. On the left-hand side using triangle inequality, we have

$$\|\widehat{\theta}\|_1 = \|\widehat{\theta}_S\|_1 + \|\widehat{\theta}_{S^c}\|_1 \ge \|\widehat{\theta}_S\|_1 - \|\widehat{\theta}_S - \theta_{0,S}\|_1 + \|\widehat{\theta}_{S^c}\|_1\,.$$

On the right-hand side, we have

$$\|\widehat{\theta} - \theta_0\|_1 = \|\widehat{\theta}_S - \theta_{0,S}\|_1 + \|\widehat{\theta}_{S^c}\|_1\,.$$

Using these two inequalities in (91), we get

$$\frac{2\ell_F}{n}\|X(\theta_0 - \widehat{\theta})\|^2 + \lambda\|\widehat{\theta}_{S^c}\|_1 \le 3\lambda\|\widehat{\theta}_S - \theta_{0,S}\|_1\,. \tag{92}$$

We next write

$$\begin{aligned}\frac{2\ell_F}{n}\|X(\theta_0-\widehat{\theta})\|^2+\lambda\|\widehat{\theta}-\theta_0\|_1 &= \frac{2\ell_F}{n}\|X(\theta_0-\widehat{\theta})\|^2+\lambda\|\widehat{\theta}_S-\theta_{0,S}\|_1+\lambda\|\widehat{\theta}_{S^c}\|_1\\ &\overset{(a)}{\le} 4\lambda\|\widehat{\theta}_S-\theta_{0,S}\|_1 \overset{(b)}{\le} 4\lambda\sqrt{s_0}\|\widehat{\theta}_S-\theta_{0,S}\|_2\\ &\overset{(c)}{\le} \frac{4\lambda\sqrt{2s_0}}{\sqrt{nC_{\min}}}\|X(\widehat{\theta}-\theta_0)\|_2\\ &\overset{(d)}{\le} \frac{\ell_F}{n}\|X(\widehat{\theta}-\theta_0)\|_2^2+\frac{8\lambda^2 s_0}{\ell_F C_{\min}}\,,\end{aligned}$$

where (a) follows from Equation (92); (b) holds by Cauchy-Shwarz inequality; (c) follows form the RE condition, which holds for $\widehat{\Sigma}=(X^\mathsf{T}X)/n$ as stated by Proposition 23, with $\kappa(\widehat{\Sigma},s_0,3)\ge\sqrt{C_{\min}/2}$, and recalling the inequality $\|\widehat{\theta}_{S^c}-\theta_{0,S^c}\|_1=\|\widehat{\theta}_{S^c}\|_1\le 3\|\widehat{\theta}_S-\theta_{0,S}\|$ as per Equation (92); Finally (d) follows from the inequality $2\sqrt{ab}\le a^2+b^2$. Rearranging the terms, we obtain

$$\frac{\ell_F}{n}\|X(\theta_0-\widehat{\theta})\|^2+\lambda\|\widehat{\theta}-\theta_0\|_1\le\frac{8\lambda^2 s_0}{\ell_F C_{\min}}\,. \tag{93}$$

Applying the RE condition again to the l.h.s of (93), we get

$$C_{\min}\frac{\ell_F}{2}\|\theta_0-\widehat{\theta}\|_2^2\le\frac{\ell_F}{n}\|X(\theta_0-\widehat{\theta})\|^2\le\frac{8\lambda^2 s_0}{\ell_F C_{\min}}\,, \tag{94}$$

and therefore,

$$\|\theta_0-\widehat{\theta}\|_2^2\le\frac{16 s_0\lambda^2}{\ell_F^2 C_{\min}^2}\,. \tag{95}$$

The result follows.

A.1. Proof of Proposition 23

The proof follows by combining two lemmas from (Bühlmann and van de Geer, 2011).

We show the desired result holds for a more general case, namely for X with subgaussian entries. Before stating the proof, we recall a few definitions and notations.

Definition 24 *A random variable ν is subgaussian if there exist constants L,σ_0 such that*

$$\mathbb{E}(e^{\frac{\nu^2}{L^2}})\le\frac{\sigma_0^2}{L^2}+1\,.$$

Note that bounded random variables are subgaussian. Specifically, if $|\nu|\le\nu_{\max}$, then ν is subgaussian with $L=\nu_{\max}$ and $\sigma_0=\nu_{\max}\sqrt{e-1}$.

For a matrix A, we let $\|A\|_\infty$ denote its (element wise) maximum norm, i.e., $\|A\|_\infty=\max_{i,j}|A_{ij}|$. The next lemma shows that if two matrices are close enough in maximum norm and if the compatibility condition holds for one of them then it would also hold for the other one.

Lemma 25 *Suppose that the restricted eigenvalue (RE) condition holds for Σ_0 with constant $\kappa(\Sigma_0,s_0,3)>0$. If*

$$\|\Sigma_0-\Sigma_1\|_\infty\le\frac{\kappa^2(\Sigma_0,s_0,3)}{32 s_0}\,,$$

then the RE condition holds for Σ_1 with constant $\kappa(\Sigma_1,s_0,3)\ge\kappa(\Sigma_0,s_0,3)/\sqrt{2}$.

Proof Proof of Lemma 25 We refer to Problem 6.10 of (Bühlmann and van de Geer, 2011). ■

Lemma 26 *Consider $X\in\mathbb{R}^{n\times p}$ with i.i.d. rows generated from a distribution with covariance $\Sigma\in\mathbb{R}^{d\times d}$. Let $\widehat{\Sigma}=X^\mathsf{T}X/n$ be the corresponding empirical second moment. Further, suppose that the entries of X are uniformly subgaussian with parameters L,σ_0. If $n\ge c_0 L s_0\log d$ with $c_0=768L/\kappa^2(\Sigma,s_0,3)$, then*

$$\mathbb{P}\left[\|\widehat{\Sigma}-\Sigma\|_\infty\ge\frac{\kappa^2(\Sigma,s_0,3)}{384 s_0}\Big(2+\frac{7\sigma_0}{L}\Big)\right]\le e^{-\frac{2n}{cs_0}}\,. \tag{96}$$

Proof Proof of Lemma 26 The result follows readily from Problem 14.3 on page 535 of (Bühlmann and van de Geer, 2011). ■

Next we note that Σ satisfies the restricted eigenvalue condition with constant $\kappa^2(\Sigma,s_0,3)\ge C_{\min}$ because of Assumption 2. Further, since $\|x_t\|_\infty\le 1$, we can apply the result of Lemma 26 with $L=1$, $\sigma_0=\sqrt{e-1}$. Proposition 23 then follows from Lemma 25.

Appendix B. Proof of Proposition 12

Define the event $\mathcal{B}_n$ as follows:

$$\mathcal{B}_n\equiv\Big\{X\in\mathbb{R}^{n\times d}:\ \sigma_{\min}(X^\mathsf{T}X/n)>C_{\min}/2\Big\}\,. \tag{97}$$

Using concentration bounds on the spectrum of random matrices with subgaussian rows (see (Vershynin, 2010, Equation (5.26))), there exist constants $c,c_1>0$ such that for $n>c_1 d$, we have $\mathbb{P}(\mathcal{B}_n)\ge 1-e^{-cn^2}$.

For $\gamma>0$, we define the event $\mathcal{F}_\gamma=\{\|\nabla\mathcal{L}(\theta_0)\|_\infty\le\gamma\}$. Using characterization (87), and by applying Azuma-Hoeffding inequality (similar to our argument after Equation (88)), we obtain

$$\mathbb{P}(\mathcal{F}_\gamma)\ge 1-d\exp\Big(-\frac{n\gamma^2}{2u_F^2}\Big)\,. \tag{98}$$

We also let $\mathcal{E}_{1,n}\equiv\mathcal{B}_n\cap\mathcal{F}_{\lambda/2}$, $\mathcal{E}_{2,n}\equiv\mathcal{B}_n\cap\mathcal{F}^c_{\lambda/2}$. To lighten the notation, we use the shorthand $D\equiv\|\widehat{\theta}-\theta_0\|_2^2$.

We then have

$$\mathbb{E}(D)=\mathbb{E}(D\cdot\mathbb{I}(\mathcal{B}_n^c))+\mathbb{E}(D\cdot\mathbb{I}(\mathcal{E}_{1,n}))+\mathbb{E}(D\cdot\mathbb{I}(\mathcal{E}_{2,n}))\,. \tag{99}$$

We treat each of the terms on the right-hand side separately.

- **Term 1:** We have

$$\mathbb{E}(D\cdot\mathbb{I}(\mathcal{B}_n^c))\le 4W^2\mathbb{P}(\mathcal{B}_n^c)\le 4W^2e^{-cn^2}\,. \tag{100}$$

- **Term 2:** Similar to proof of Proposition 10, on $\mathcal{E}_{1,n}$, we have $D\le 16s_0\lambda^2/(\ell_F^2C_{\min}^2)$. Hence,

$$\mathbb{E}(D\cdot\mathbb{I}(\mathcal{E}_{1,n}))\le\frac{16s_0\lambda^2}{\ell_F^2C_{\min}^2}\,. \tag{101}$$

- **Term 3:** To bound term 3, we first prove the following lemma.

  Lemma 27 *On event $\mathcal{E}_n(\gamma)\equiv\mathcal{B}_n\cap\mathcal{F}_\gamma$, with $\gamma>\lambda/2$, we have*

$$D\le\Big(\frac{36}{C_{\min}^2\ell_F^2}\Big)\gamma^2 d.$$

  Lemma 27 is proved in Section B.1.

We next bound term 3 as follows. Let $L=9\lambda^2d/(C_{\min}^2\ell_F^2)$.

$$\begin{aligned}\mathbb{E}(D\cdot\mathbb{I}(\mathcal{E}_{2,n}))&=\int_0^\infty\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>\alpha\Big)\mathrm{d}\alpha\\&=L\int_0^\infty\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>Lc\Big)\mathrm{d}c\\&=L\int_0^1\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>Lc\Big)\mathrm{d}c+L\int_1^\infty\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>Lc\Big)\mathrm{d}c\,.\end{aligned} \tag{102}$$

For the first term on the right-hand side we write

$$L\int_0^1\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>Lc\Big)\mathrm{d}c\le L\int_0^1\mathbb{P}(\mathcal{E}_{2,n})\le L\mathbb{P}(\mathcal{F}_{\lambda/2}^c)\le\frac{L}{d}\,, \tag{103}$$

where the last step holds from Equation (98) with $\gamma=\lambda/2$.

We next upper bound the second term. For arbitrary fixed $c>1$, let $\gamma=\sqrt{Lc/(d\kappa)}$, with $\kappa=36/(\ell_F^2C_{\min}^2)$. It is easy to verify that $\gamma=\sqrt{c}\lambda/2>\lambda/2$. Further, by virtue of Lemma 27, on $\mathcal{E}(\gamma)$ we have $D\le\kappa\gamma^2d=Lc$. Hence,

$$\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>Lc\Big)\le\mathbb{P}\Big(\mathcal{E}(\gamma)^c\cap\mathcal{E}_{2,n}\Big)\le\mathbb{P}(\mathcal{F}_\gamma^c\cap\mathcal{B}_n)\le\mathbb{P}(\mathcal{F}_\gamma^c)\,. \tag{104}$$

Further, applying Equation (98) and plugging for γ, we obtain

$$\mathbb{P}(\mathcal{F}_\gamma^c)\le d\exp\Big(-\frac{nLc}{2u_F^2\kappa d}\Big)=d\exp\Big(-\frac{n\lambda^2}{8u_F^2}\Big)\le d^{1-2c}\,. \tag{105}$$

Here, the second step follows from definition of L and the last step holds because $\lambda\ge 4u_F\sqrt{(\log d)/n}$.

Combining Equations (104) and (105), we have

$$L\int_1^\infty\mathbb{P}\Big(D\cdot\mathbb{I}(\mathcal{E}_{2,n})>Lc\Big)\mathrm{d}c\le L\int_1^\infty d^{1-2c}\,\mathrm{d}c\le\frac{L}{2d\log d}\,. \tag{106}$$

Using bounds (103) and (106) in Equation (102), we obtain

$$\mathbb{E}(D\cdot\mathbb{I}(\mathcal{E}_{2,n}))\le\frac{L}{d}\left(1+\frac{1}{2\log d}\right)\le\frac{3L}{2d}<\frac{16\lambda^2}{\ell_F^2C_{\min}^2}\,. \tag{107}$$

The result follows by putting the upper bounds on the three terms together.

B.1. Proof of Lemma 27

We start by rewriting Equation (90), which follows from optimality of $\widehat{\theta}$ and log-concave property of the loss function:

$$\frac{\ell_F}{n}\|X(\theta_0-\widehat{\theta})\|^2+\lambda\|\widehat{\theta}\|_1\le\|\nabla\mathcal{L}(\theta_0)\|_\infty\|\widehat{\theta}-\theta_0\|_1+\lambda\|\theta_0\|_1\,. \tag{108}$$

On event $\mathcal{E}_n(\gamma)$, Equation (108) implies that

$$\frac{1}{2}C_{\min}\ell_F\|\theta_0-\widehat{\theta}\|_2^2+\lambda\|\widehat{\theta}\|_1\le\gamma\|\widehat{\theta}-\theta_0\|_1+\lambda\|\theta_0\|_1\,. \tag{109}$$

Using the assumption $\gamma>\lambda/2$ and our shorthand $D\equiv\|\widehat{\theta}-\theta_0\|_2^2$, we get

$$\begin{aligned}\frac{1}{2}C_{\min}\ell_F\|\widehat{\theta}-\theta_0\|_2^2&\le\gamma\|\widehat{\theta}-\theta_0\|_1+\lambda\|\theta_0\|_1-\lambda\|\widehat{\theta}\|_1\\&\le(\gamma+\lambda)\|\widehat{\theta}-\theta_0\|_1\\&\le 3\gamma\|\widehat{\theta}-\theta_0\|_1\le 3\gamma\sqrt{d}\|\widehat{\theta}-\theta_0\|_2\,.\end{aligned}$$

Writing the above bound in terms of our shorthand $D\equiv\|\widehat{\theta}-\theta_0\|_2^2$, we obtain the desired result.

Appendix C. Proof of Technical Lemmas

C.1. Proof of Lemma 13

We write the virtual valuation function as $\varphi(v)=v-1/\lambda(v)$ where $\lambda(v)=\frac{f(v)}{1-F(v)}=-\log'(1-F(v))$ is the hazard rate function. Since $1-F$ is log-concave, the hazard function $\lambda(v)$ is increasing which implies that φ is strictly increasing. Indeed, by this argument $\varphi'(v)>1$.

C.2. Proof of Lemma 14

Recalling the definition $g(v)=v+\varphi^{-1}(-v)$, we have $g'(v)=1-1/\varphi'(\varphi^{-1}(-v))$. Since φ is strictly increasing by Lemma 13, we have $g'(v)<1$. The claim $g'(v)>0$ follows if we show $\varphi'(\varphi^{-1}(-v))>1$. For this we refer to the proof of Lemma 13, where we showed that $\varphi'(v)>1$ for all v.

C.3. Proof of Lemma 16

Let $\phi(v)$ and $\Phi(v)$ respectively denote the density and the distribution function of standard normal variable. Function h_t and its derivatives read as

$$\mathsf{rev}_t(p) = p\Big(1-\Phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)\Big)\,, \tag{110}$$

$$\mathsf{rev}_t'(p) = 1-\Phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)-\frac{p}{\sigma}\phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)\,, \tag{111}$$

$$\mathsf{rev}_t''(p) = \frac{1}{\sigma}\Big[\frac{p}{\sigma}\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)-2\Big]\phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)\,. \tag{112}$$

Define $\xi\equiv p_t^*-x_t\cdot\theta_0=g(x_t\cdot\theta_0)-x_t\cdot\theta_0$. Writing $\mathsf{rev}_t''(p_t^*)$ in term of ξ, we obtain

$$r_t''(p_t^*) = \frac{1}{\sigma}\Big[\frac{\xi}{\sigma}\Big(\frac{1-\Phi(\xi/\sigma)}{\phi(\xi/\sigma)}\Big)-2\Big]\phi(\xi/\sigma)\,. \tag{113}$$

By tail bound inequality for Gaussian distribution $1-\Phi(\xi/\sigma)\le(\sigma/\xi)\phi(\xi/\sigma)$ for $\xi\ge 0$. Therefore,

$$\frac{\xi}{\sigma}\Big(\frac{1-\Phi(\xi/\sigma)}{\phi(\xi/\sigma)}\Big)-2\le -1\,, \tag{114}$$

and the same bound obviously holds for $\xi<0$.

By definition of function g, $|\xi|\le 3W$ with φ being the virtual valuation fusion corresponding to the Gaussian distribution. Hence, $\phi(\xi/\sigma)\ge\phi(3W/\sigma)$. Putting this together with (114), we get $\mathsf{rev}_t''(p_t^*)\le -c_1$ with $c_1=(1/\sigma)\phi(3W/\sigma)$.

For the second part of the Lemma statement, set $\delta=\min\Big\{3W,\sigma^2/(18W),\sigma^2\phi(3W/\sigma)\Big\}$. For $p\in[p_t^*-\delta,p_t^*+\delta]$, we have

$$\Big|\frac{p}{\sigma}\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)-\frac{p_t^*}{\sigma}\Big(\frac{p_t^*-x_t\cdot\theta_0}{\sigma}\Big)\Big|\le\frac{1}{\sigma^2}|p-p_t^*|\cdot|p+p_t^*-x_t\cdot\theta_0|\le\frac{1}{\sigma^2}\delta(5W+\delta)\le\frac{1}{2}\,. \tag{115}$$

Using Equation (114) we get $p(p-x_t\cdot\theta_0)/\sigma^2\le -1/2$. Further,

$$\Big|\phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)-\phi\Big(\frac{p_t^*-x_t\cdot\theta_0}{\sigma}\Big)\Big|\le\frac{|p-p_t^*|}{2\sigma^2}\le\frac{\delta}{2\sigma^2}\le\frac{1}{2}\phi(3W/\sigma)\,. \tag{116}$$

Therefore,

$$\phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)\ge\phi(\xi/\sigma)-\frac{1}{2}\phi(3W/\sigma)\ge\frac{1}{2}\phi(3W/\sigma)\,. \tag{117}$$

Combining (115), (117) we obtain

$$\mathsf{rev}_t''(p) = \frac{1}{\sigma}\Big[\frac{p}{\sigma}\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)-2\Big]\phi\Big(\frac{p-x_t\cdot\theta_0}{\sigma}\Big)\le-\frac{1}{4\sigma}\phi(3W/\sigma)=-\frac{c_1}{4}\,. \tag{118}$$

The result follows.

C.4. Proof of Lemma 17

Let $Z=x\cdot v$ and $\tilde{Z}=Z/\|v\|_2$. Note that $\mathrm{Var}(\tilde{Z})=1$. Write the expectation in terms of the tail probability

$$\mathbb{E}(\min(Z^2,\delta^2)) = \int_0^{\delta^2}\mathbb{P}(Z^2\ge t)\mathrm{d}t=\int_0^{\delta^2}\mathbb{P}\Big(|\tilde{Z}|\ge\frac{\sqrt{t}}{\|v\|_2}\Big)\mathrm{d}t\,. \tag{119}$$

We consider two cases:

- $\delta\le\|v\|_2$: The right-hand side in (119) can be lower bounded as

$$\int_0^{\delta^2}\mathbb{P}\Big(|\tilde{Z}|\ge\frac{\sqrt{t}}{\|v\|_2}\Big)\mathrm{d}t\ge\int_0^{\delta^2}\mathbb{P}\Big(|\tilde{Z}|\ge\frac{\sqrt{t}}{\delta}\Big)\mathrm{d}t=2\delta^2\int_0^1 t\,\mathbb{P}(|\tilde{Z}|\ge t)\mathrm{d}t\,. \tag{120}$$

  In the sequel, we provide two separate lower bounds for the right-hand side.

  Let $\xi\equiv\mathbb{P}(|\tilde{Z}|\ge 1)$. We have

$$\int_0^1 t\,\mathbb{P}\Big(|\tilde{Z}|\ge t\Big)\mathrm{d}t\ge\int_0^1 t\,\xi\mathrm{d}t\ge\frac{\xi}{2}\,. \tag{121}$$

  We proceed to obtain another bound which utilizes the fact $\mathrm{Var}(\tilde{Z})=1$.

$$\begin{aligned}\int_0^1 t\,\mathbb{P}(|\tilde{Z}|\ge t)\mathrm{d}t&=\int_0^\infty t\,\mathbb{P}(|\tilde{Z}|\ge t)\mathrm{d}t-\int_1^\infty t\,\mathbb{P}(|\tilde{Z}|\ge t)\mathrm{d}t\\&=\frac{1}{2}\mathrm{Var}(\tilde{Z})-\int_1^\infty t\,\mathbb{P}(|\tilde{Z}|\ge t)\mathrm{d}t\,.\end{aligned} \tag{122}$$

  For $t\ge 1$, we have $\mathbb{P}(|\tilde{Z}|\ge t)\le\xi$. Further, by applying Chernoff bound, we get

$$\begin{aligned}\mathbb{P}(|\tilde{Z}|\ge t)&=2\mathbb{P}(\tilde{Z}\ge t)=2\mathbb{P}(e^{\lambda\tilde{Z}}\ge e^{\lambda t})\le e^{-\lambda t}\mathbb{E}(e^{\lambda\tilde{Z}})\\&=2e^{-\lambda t}\prod_{i=1}^d\Big(\frac{e^{\lambda\frac{v_i}{\|v\|_2}}+e^{-\lambda\frac{v_i}{\|v\|_2}}}{2}\Big)\le 2e^{-\lambda t}\prod_{i=1}^d e^{\lambda^2\frac{v_i^2}{2\|v\|_2^2}}=2e^{\frac{\lambda^2}{2}-\lambda t}\,.\end{aligned}$$

  Setting $\lambda=t$ leads to $\mathbb{P}(|\tilde{Z}|\ge t)\le 2e^{-\frac{t^2}{2}}$. Combining these bounds into (121), we obtain

$$\int_0^1 t\,\mathbb{P}(|\tilde{Z}|\ge t)\mathrm{d}t\ge\frac{1}{2}-\int_1^\infty t\,\min(2e^{-\frac{t^2}{2}},\xi)\mathrm{d}t=\frac{1-\xi}{2}-\xi\log\Big(\frac{2}{\xi}\Big)\,. \tag{123}$$

  We summarize bounds (121) and (123) as in

$$\int_0^1 t\,\mathbb{P}\Big(|\tilde{Z}|\ge t\Big)\mathrm{d}t\ge\min_{\xi\in[0,1]}\max\Big(\xi,\frac{1-\xi}{2}-\xi\log\Big(\frac{2}{\xi}\Big)\Big)>0.05\,. \tag{124}$$

  Turning back to Equation (120), in this case we have

$$\int_0^{\delta^2}\mathbb{P}\Big(|\tilde{Z}|\ge\frac{\sqrt{t}}{\|v\|_2}\Big)\mathrm{d}t\ge 0.1\delta^2\,. \tag{125}$$

- $\delta \geq \|v\|_2$: Similar to the previous case, the right-hand side in (119) can be lower bounded as

$$\int_0^{\delta^2} \mathbb{P}\Big(|\tilde{Z}| \geq \frac{\sqrt{t}}{\|v\|_2}\Big)\mathrm{d}t \geq \int_0^{\|v\|_2^2} \mathbb{P}\Big(|\tilde{Z}| \geq \frac{\sqrt{t}}{\|v\|_2}\Big)\mathrm{d}t\,. \geq 0.1\|v\|_2^2 \tag{126}$$

The above two cases can be summarized as $\mathbb{E}(\min(Z^2, \delta^2)) \geq 0.1\min(\|v\|_2^2, \delta^2)$.

C.5. Proof of Lemma 18

We use a standard argument that relates minimax ℓ_2-risk in terms of the error in multi-way hypothesis testing problem; See e.g. (Yang and Barron, 1999; Yu, 1997). Let $\{\tilde{\theta}_1, \ldots, \tilde{\theta}_m\}$ be a δ-packing of set Ω, meaning that their pairwise distances are all at least δ. Parameter δ is free for now and its value will be determined later in the proof. We further let P_j denote the induced probability on market values $(v(x_1), \ldots, v(x_T))$, conditional on $(x_1, \ldots, x_T)$ and for $\theta_0 = \tilde{\theta}_j$. In other words, in defining distributions P_j we treat feature vectors fixed. Let ν be random variable uniformly distributed on the hypothesis set $\{1, 2, \ldots, m\}$ which indicates the index of the true parameter, i.e, $\nu = j$ means $\theta_0 = \tilde{\theta}_j$.

Define $\mathsf{d}(\theta_1^T, \theta) \equiv \sum_{t=1}^T \min(\|\theta_t - \theta\|_2^2, C)$ and let μ be the value of j for which $\mathsf{d}(\theta_1^T, \tilde{\theta}_j)$ is a minimum. Suppose that δ is chosen such that $\delta^2 \leq C$. If $\mathsf{d}(\theta_1^T, \tilde{\theta}_j) < \delta^2 T/4$ then $\mu = j$, because assuming otherwise, we have $\mu = j' \neq j$, and by triangle inequality

$$\begin{aligned}\min(\|\tilde{\theta}_{j'} - \tilde{\theta}_j\|_2^2, C) &\leq \min(2\|\theta_t - \tilde{\theta}_j\|_2^2 + 2\|\theta_t - \tilde{\theta}_{j'}\|_2^2, C) \\ &\leq \min(2\|\theta_t - \tilde{\theta}_j\|_2^2, C) + \min(2\|\theta_t - \tilde{\theta}_{j'}\|_2^2, C)\,,\end{aligned} \tag{127}$$

for all t, where we used the inequality $\min(a+b, c) \leq \min(a, c) + \min(b, c)$ for $a, b, c \geq 0$. Summing over $t = 1, 2, \ldots, T$, we get

$$T\min(\|\tilde{\theta}_{j'} - \tilde{\theta}_j\|_2^2, C) \leq 2\mathsf{d}(\theta_1^T, \tilde{\theta}_j) + 2\mathsf{d}(\theta_1^T, \tilde{\theta}_{j'}) \leq 4\mathsf{d}(\theta_1^T, \tilde{\theta}_j) < \delta^2 T\,,$$

where we used the assumption $\mu = j'$. But this is a contradiction because $\|\tilde{\theta}_{j'} - \tilde{\theta}_j\|_2 \geq \delta$ (they form a δ-packing of Ω) and $\delta^2 \leq C$.

Using Markov inequality, we can write

$$\begin{aligned}\max_j \mathbb{E}_{P_j}\mathsf{d}(\theta_1^T, \tilde{\theta}_j) &\geq \frac{\delta^2 T}{4}\max_j \mathbb{P}\Big(\mathsf{d}(\theta_1^T, \tilde{\theta}_j) \geq \frac{\delta^2 T}{4}\Big|\nu = j\Big) \\ &\geq \frac{\delta^2 T}{4m}\sum_{j=1}^m \mathbb{P}(\mu \neq j|\nu = j) = \frac{\delta^2 T}{4}\mathbb{P}(\mu \neq \nu)\,.\end{aligned} \tag{128}$$

We use Fano's inequality to lower bound the error probability on the right-hand side. We first construct a δ-packing of Ω similar to the one proposed in (Raskutti et al., 2011, proof of Theorem 1).

Let $s = s_0/2 \leq d/2$ and define

$$\mathcal{A} = \{q \in \{-1, 0, 1\}^d : \ \|q\|_0 = s\}\,.$$

As proved in (Raskutti et al., 2011, Lemma 5), there exists a subset $\tilde{\mathcal{A}} \subseteq \mathcal{A}$ of cardinality $|\tilde{\mathcal{A}}| \geq \exp(\frac{s}{2}\log\frac{d-s/2}{s})$ such that the Hamming distance between any two elements in $\tilde{\mathcal{A}}$ is at least $s/2$. Next, consider the set $\sqrt{\frac{2}{s}}\delta\tilde{\mathcal{A}}$ for some $\delta \leq W/\sqrt{2s}$ whose exact value to be determined later. Then, for q in this set, $\|q\|_1 = \sqrt{2s}\delta \leq W$ and hence $\sqrt{\frac{2}{s}}\delta\tilde{\mathcal{A}} \subseteq \Omega$. Further, for $q, q' \in \sqrt{\frac{2}{s}}\delta\tilde{\mathcal{A}}$, we have the following bounds:

$$\|q - q'\|_2^2 \geq \delta^2\,, \tag{129}$$

$$\|q - q'\|_2^2 \leq 8\delta^2\,. \tag{130}$$

By (129), the set $\sqrt{\frac{2}{s}}\delta\tilde{\mathcal{A}}$ forms a δ-packing for Ω with size $|\tilde{\mathcal{A}}|$.

We now turn back to bound (128). Left-hand side can be lower bounded using Fano's inequality. We omit the details here as it is a standard argument and instead we refer to (Raskutti et al., 2011, proof of Theorem 1) for details. Using Fano's inequality and bound (130), we get

$$\mathbb{P}(\mu \neq \nu) = 1 - \frac{\frac{8T}{2\sigma^2}\delta^2 + \log(2)}{\frac{s}{2}\log(\frac{d-s/2}{s})}\,. \tag{131}$$

Choosing $\delta^2 \leq \delta_1^2 \equiv \frac{\sigma^2 s}{32T}\log(\frac{d-s/2}{s})$, we obtain $\mathbb{P}(\mu \neq \nu) \geq 1/4$. Therefore, setting $\delta^2 = \min(\frac{W^2}{2s}, \delta_1^2, C)$ and combining with bound (128), we conclude that

$$\min_{\theta_1^T}\max_{\theta_0 \in \Omega}\mathbb{E}(\mathsf{d}(\theta_1^T, \theta_0)) \geq \frac{\delta^2 T}{16} = \frac{1}{16}\min\left\{\frac{W^2 T}{2s}, \frac{\sigma^2 s}{32}\log\Big(\frac{d-s/2}{s}\Big), CT\right\}. \tag{132}$$

Now since $s = s_0/2 \leq d/2$, we have $\log((d-s/2)/s) \geq c\log(d/s)$ with some constant $c > 0$. Therefore, by using Equation (132) and substituting for $s = s_0/2$, we obtain

$$\min_{\theta_1^T}\max_{\theta_0 \in \Omega}\mathbb{E}(\mathsf{d}(\theta_1^T, \theta_0)) \geq L_1\,, \tag{133}$$

with

$$L_1 \equiv \frac{1}{16}\min\left\{\frac{W^2 T}{s_0}, \frac{c\sigma^2 s_0}{64}\log\Big(\frac{d}{s_0}\Big), CT\right\}. \tag{134}$$

We next derive another separate lower bound for minimax risk, by assuming that an oracle gives us the true support of θ_0. In this case, the least square estimator, applied to the observed features restricted to the true support S, achieves the optimal minimax ℓ_2 rate. This implies that $\|\theta_t - \theta_0\|_2^2 \geq c\sigma^2 s_0/t$, for $t \geq s_0$ and a constant $c > 0$. Therefore,

$$\min_{\theta_1^T}\max_{\theta_0 \in \Omega}\mathbb{E}(\mathsf{d}(\theta_1^T, \theta_0)) \geq \sum_{t=1}^T \min\Big(c\sigma^2\frac{s_0}{t}, C\Big)\,, \tag{135}$$

from which we obtain

$$\min_{\theta_1^T}\max_{\theta_0 \in \Omega}\mathbb{E}(\mathsf{d}(\theta_1^T, \theta_0)) \geq L_2 \equiv c' s_0\,\log(T/s_0)\,, \tag{136}$$

for some constant $c' > 0$, depending on σ and C.

Combining bounds in (134) and (136), we have

$$\min_{\theta_1^T} \max_{\theta_0 \in \Omega} \mathbb{E}(\mathsf{d}(\theta_1^T, \theta_0)) \geq \frac{1}{2}(L_1 + L_2) \geq \widetilde{C}\left\{ s_0 \log\left(\frac{T}{s_0}\right) + \min\left[\frac{T}{s_0}, s_0 \log\left(\frac{d}{s_0}\right)\right]\right\}, \tag{137}$$

for a constant $\widetilde{C}$ that depends on C, σ, W. The proof is complete.

C.6. Proof of Lemma 19

We recall the notion of 0-*property* established by (Ponomarev, 1987).

Definition 28 *A continuous function has the* 0-property*, if the pre-image of any set of probability zero is a set of probability zero.*

As proved in (Ponomarev, 1987, Theorem 1), if a function $\phi : \mathcal{X} \subseteq \mathbb{R}^d \mapsto \mathbb{R}^d$ is continuously differentiable, then it satisfies 0-property if and only if its derivative $\mathcal{D}\phi$ is full rank for almost all $x \in \mathcal{X}$. Therefore, we need to show that under Assumption 1, if ϕ has 0-property, then Assumption 6 holds true.

Supposing otherwise, there exists a nonzero $v \in \mathbb{R}^d$ such that $v^\mathsf{T}\Sigma_\phi v = 0$. Therefore, $\mathbb{E}((z \cdot \phi(x))^2) = 0$ which implies that $z \cdot \phi(x) = 0$, almost surely. Define $S \equiv \{z \in \mathbb{R}^d : z \cdot \phi(x) = 0\}$. Space S is $(d-1)$-dimensional and all the points in $\phi(\mathcal{X})$ belong to S almost surely, i.e., $\mathbb{P}(\phi(\mathcal{X}) \cap S^c) = 0$. However, since Σ is positive definite (with all of its eigenvalues target than $C_{\min}$, by Assumption 1), $\mathbb{P}_X(S) = 0$. Combining these observations, $\mathbb{P}(\phi(\mathcal{X})) \leq \mathbb{P}(S) + \mathbb{P}(\phi(\mathcal{X}) \cap S^c) = 0$. Since ϕ has the 0-property, this implies that $\mathbb{P}_X(\mathcal{X}) = 0$, which is a contradiction because $\mathcal{X}$ is the support of $\mathbb{P}_X$ and thus $\mathbb{P}_X(\mathcal{X}) = 1$. The result follows.

C.7. Proof of Lemma 21

Under model (27), a purchase occurs at time t with the posted price price p if $\tilde{v}_t \geq \beta_0 p$. This is equivalent to $\tilde{z}_t \geq \beta_0 p - x_t \cdot \mu_0$. Therefore, the expected revenue from a posted price p is given by

$$p \times \mathbb{P}(\tilde{v}_t \geq \beta_0 p) = p(1 - F(\beta_0 p - \mu_0 \cdot x_t)). \tag{138}$$

By setting the first order conditions, the optimal price p_t^* is given by the solution of the following equation:

$$\beta_0 p_t^* = \frac{1 - F(\beta_0 p_t^* - \mu_0 \cdot x_t)}{f(\beta_0 p_t^* - \mu_0 \cdot x_t)}. \tag{139}$$

It is straightforward to verify that the solution p_t^* of the above equation is given by $p_t^* = (1/\beta_0) g(\mu_0 \cdot x_t)$.

C.8. Proof of Lemma 15

Recall the notation $\|E^{(k)}\|_\infty = \max_{i,j} |E_{ij}^{(k)}|$. Note that

$$\langle v, E^{(k)} v\rangle = \sum_{i,j=1}^{d+1} |E_{ij}^{(k)}||v_i||v_j| \leq \|E^{(k)}\|_\infty \sum_{i,j=1}^{d+1} |v_i|\,|v_j| \leq \|E^{(k)}\|_\infty \left(\sum_{i=1}^{d} |v_i|\right)^2 = \|E^{(k)}\|_\infty \|v\|_1^2. \tag{140}$$

Therefore, we only need to bound $\|E^{(k)}\|_\infty$. Fix $1 \leq i, j \leq d+1$. We then have

$$E_{ij}^{(k)} = \Sigma_{ij}^{(k)} - S_{ij}^{(k)} = \frac{1}{\tau_k} \sum_{\ell=1}^{\tau_k} \left\{ \mathbb{E}(X_{\ell i} X_{\ell j}) - X_{\ell i} X_{\ell j} \right\}. \tag{141}$$

Let $u_\ell^{(ij)} = X_{\ell i} X_{\ell j}$. Then, $|u_\ell^{(ij)}| \leq 1$ because $\|x_\ell\|_\infty \leq 1$. By applying Hoeffding's inequality,

$$\mathbb{P}\left(|E_{ij}^{(k)}| \geq 3\sqrt{\frac{\log d}{\tau_k}} \right) \leq \frac{2}{d^4}. \tag{142}$$

Therefore, by union bonding over all indices $1 \leq i, j \leq d+1$, we obtain that $\|E^{(k)}\|_\infty \leq 3\sqrt{(\log d)/\tau_k}$, with probability at least $1 - 8/d^2$. The claim follows from this result along with (140).

C.9. Proof of Lemma 20

Define parameter vectors $\eta_{0,0} = (\mu_0; \beta_0)$, $\eta_{0,\wedge} = (\mu_0; \widehat{\beta}^k)$, $\eta_{\wedge,0} = (\widehat{\mu}^k; \beta_0)$, and $\eta_{\wedge,\wedge} = (\widehat{\mu}^k; \widehat{\beta}^k)$ all in $\mathbb{R}^{d+1}$. By optimality of $\eta_{\wedge,\wedge}$, we have $\nabla_\mu \mathcal{L}(\widehat{\mu}^k) + \lambda_k \nu^k = 0$ and $\nabla_\beta \mathcal{L}(\widehat{\beta}^k) + \lambda_k \rho^k = 0$, where ν^k is a subgradient of ℓ_1 norm at $\widehat{\mu}^k$ and ρ^k is a subgradient of the absolute value function at $\widehat{\beta}^k$. Therefore,

$$\begin{aligned} \nabla\mathcal{L}(\eta_{0,\wedge}) &= (\nabla_\mu \mathcal{L}(\mu_0); \nabla_\beta \mathcal{L}(\widehat{\beta}^k)) = (\nabla_\mu \mathcal{L}(\mu_0); -\lambda_k \rho^k), \\ \nabla\mathcal{L}(\eta_{\wedge,0}) &= (\nabla_\mu \mathcal{L}(\widehat{\mu}^k); \nabla_\beta \mathcal{L}(\beta_0)) = (-\lambda_k \nu^k; \nabla_\mu \mathcal{L}(\beta_0)). \end{aligned} \tag{143}$$

By a similar argument following (88), we have $\|\nabla\mathcal{L}(\eta_{0,0})\|_\infty \leq \lambda_k/2$, with probability at least $1 - 1/d$. Hence, invoking relations (143), we get

$$\|\nabla\mathcal{L}(\eta_{0,\wedge})\|_\infty \leq \lambda_k, \quad \|\nabla\mathcal{L}(\eta_{\wedge,0})\|_\infty \leq \lambda_k. \tag{144}$$

By optimality of $\eta_{\wedge,\wedge}$, we have

$$\mathcal{L}(\eta_{\wedge,\wedge}) + \lambda_k \|\eta_{\wedge,\wedge}\|_1 \leq \mathcal{L}(\eta_{0,\wedge}) + \lambda_k \|\eta_{0,\wedge}\|_1.$$

Following a similar argument to (91), we have

$$\frac{2\ell_F}{\tau_{k-1}} \|\widetilde{X}^{(k-1)}(\eta_{0,\wedge} - \eta_{\wedge,\wedge})\|^2 + 2\lambda_k \|\eta_{\wedge,\wedge}\|_1 \leq 2\lambda_k \|\eta_{\wedge,\wedge} - \eta_{0,\wedge}\|_1 + 2\lambda_k \|\eta_{0,\wedge}\|_1.$$

Applying triangle inequality and rearranging the terms, this yields to the following inequality:

$$\frac{2\ell_F}{\tau_{k-1}}\|\widetilde{X}^{(k-1)}(\eta_{0,\wedge}-\eta_{\wedge,\wedge})\|^2 \le 4\lambda_k\|\eta_{\wedge,\wedge}-\eta_{0,\wedge}\|_1 \le 8W\lambda_k\,. \tag{145}$$

By substituting for $\eta_{0,\wedge}$ and $\eta_{\wedge,\wedge}$, we get Equation (79).

Likewise, we can write (145) with $\eta_{\wedge,0}$ instead of $\eta_{0,\wedge}$:

$$\frac{2\ell_F}{\tau_{k-1}}\|\widetilde{X}^{(k-1)}(\eta_{\wedge,0}-\eta_{\wedge,\wedge})\|^2 \le 8W\lambda_k\,. \tag{146}$$

By substituting for $\eta_{\wedge,0}$ and $\eta_{0,0}$ we obtain

$$\frac{2\ell_F}{\tau_{k-1}}(\beta_0-\widehat{\beta}^k)^2\|p^{(k-1)}\|^2 = \frac{2\ell_F}{\tau_{k-1}}\|\widetilde{X}^{(k-1)}(\eta_{\wedge,0}-\eta_{\wedge,\wedge})\|^2 \le 8W\lambda_k\,, \tag{147}$$

where $p^{(k)}=(p_{\tau_{k-1}},\ldots,p_{\tau_k-1})^{\mathsf{T}}$ is the vector of prices offered in episode $(k-1)$. Hence, in order to prove (79), it suffices to show that $p_t \ge \tilde{c}_W$ for all t. To see this, note that since $g(v)>0$ it attains its minimum over any bounded interval. Therefore, there exists a constant $c'_W>0$, such that $g(v)>c'_W$ for $v\in[-W,W]$. Further, by the constraint in the optimization (28) we have $|\widehat{\beta}^{(k-1)}|\le W$. Combining these two facts, we get

$$p_t = \frac{1}{\widehat{\beta}^{(k-1)}}g(x_t\cdot\widehat{\mu}^{(k-1)}) \ge \frac{c'_W}{W} \equiv \tilde{c}_W\,. \tag{148}$$

The result follows from (147) and setting $c_W = 4W/\tilde{c}_W^2$.

Abstract

Graphical Lasso (GL) is a popular method for learning the structure of an undirected graphical model, which is based on an l_1 regularization technique. The objective of this paper is to compare the computationally-heavy GL technique with a numerically-cheap heuristic method that is based on simply thresholding the sample covariance matrix. To this end, two notions of sign-consistent and inverse-consistent matrices are developed, and then it is shown that the thresholding and GL methods are equivalent if: (i) the thresholded sample covariance matrix is both sign-consistent and inverse-consistent, and (ii) the gap between the largest thresholded and the smallest un-thresholded entries of the sample covariance matrix is not too small. By building upon this result, it is proved that the GL method—as a conic optimization problem—has an explicit closed-form solution if the thresholded sample covariance matrix has an acyclic structure. This result is then generalized to arbitrary sparse support graphs, where a formula is found to obtain an approximate solution of GL. Furthermore, it is shown that the approximation error of the derived explicit formula decreases exponentially fast with respect to the length of the minimum-length cycle of the sparsity graph. The developed results are demonstrated on synthetic data, functional MRI data, traffic flows for transportation networks, and massive randomly generated data sets. We show that the proposed method can obtain an accurate approximation of the GL for instances with the sizes as large as $80,000 \times 80,000$ (more than 3.2 billion variables) in less than 30 minutes on a standard laptop computer running MATLAB, while other state-of-the-art methods do not converge within 4 hours.

Keywords: Graphical Lasso, Graphical Model, Sparse Graphs, Optimization

1. Introduction

There has been a pressing need in developing new and efficient computational methods to analyze and learn the characteristics of high-dimensional data with a structured or randomized nature. Real-world data sets are often overwhelmingly complex, and therefore it is important to obtain a simple description of the data that can be processed efficiently. In an effort to address this problem, there has been a great deal of interest in sparsity-promoting techniques for large-scale optimization problems (Coleman and Li 1990; Bach et al. 2012; Benson et al. 2000). These techniques have become essential to the tractability of big-data analyses in many applications, including data mining (Garcke et al. 2001; Muthukrishnan 2005; Wu et al. 2014), pattern recognition (Wright et al. 2010; Qiao et al. 2010), human brain functional connectivity (Sojoudi and Doyle 2014), distributed controller design (Fardad et al. 2011; Fattahi and Lavaei 2017), and compressive sensing (Candes and Romberg 2007; Foucart and Rauhut 2013). Similar approaches have been used to arrive at a parsimonious estimation of high-dimensional data. However, most of the existing statistical learning techniques in data analytics are contingent upon the availability of a sufficient number of samples (compared to the number of parameters), which is difficult to satisfy for many applications (Bühlmann and Van De Geer 2011; Fan and Lv 2010). To remedy the aforementioned issues, a special attention has been paid to the augmentation of these problems with sparsity-inducing penalty functions to obtain sparse and easy-to-analyze solutions.

Graphical lasso (GL) is one of the most commonly used techniques for estimating the inverse covariance matrix (Friedman et al. 2008; Banerjee et al. 2008; Yuan and Lin 2007). GL is an optimization problem that shrinks the elements of the inverse covariance matrix towards zero compared to the maximum likelihood estimates, using an l_1 regularization. There is a large body of literature suggesting that the solution of GL is a good estimate for the unknown graphical model, under a suitable choice of the regularization parameter (Friedman et al. 2008; Banerjee et al. 2008; Yuan and Lin 2007; Liu et al. 2010; Krämer et al. 2009; Danaher et al. 2014). It is known that Graphical Lasso is computationally expensive for large-scale problems. An alternative computationally-cheap heuristic method for estimating graphical models is based on thresholding the sample covariance matrix.

In this paper, we develop a mathematical framework to analyze the relationship between the GL and thresholding techniques. The paper Sojoudi (2016) offers a set of conditions for the equivalence of these two methods, and argues the satisfaction of these conditions in the case where the regularization coefficient is large or equivalently a sparse graph is sought. Although the conditions derived in Sojoudi (2016) shed light on the performance of the GL, they depend on the optimal solution of the GL and cannot be verified without solving the problem. Nonetheless, it is highly desirable to find conditions for the equivalence of the GL and thresholding that are directly in terms of the sample covariance matrix. To this end, two notions of *sign-consistent* and *inverse-consistent* matrices are introduced, and their properties are studied for different types of matrices. It is then shown that the GL and thresholding are equivalent if three conditions are satisfied. The first condition requires a certain matrix formed based on the sample covariance matrix to have a positive-definite completion. The second condition requires this matrix to be sign-consistent and inverse-consistent. The third condition needs a separation between the largest thresholded and the smallest un-thresholded entries of the sample covariance matrix. These conditions can be easily verified for acyclic graphs and are expected to hold for sparse graphs. By building upon these results, an explicit closed-form solution is obtained for the GL method in the case where the thresholded sample covariance matrix has an acyclic support graph. Furthermore, this result is generalized to sparse support graphs to derive a closed-form formula that can serve either as an approximate solution of the GL or the optimal solution of the GL with a perturbed sample covariance matrix. The approximation error (together with the corresponding perturbation in the sample covariance matrix) is shown to be related to the lengths of the cycles in the graph.

The remainder of this paper is organized as follows. The main results are presented in Section 3, followed by numerical examples and case studies in Section 4. Concluding remarks are drawn in Section 5. Most of the technical proofs are provided in Appendix.

Notations: Lowercase, bold lowercase and uppercase letters are used for scalars, vectors and matrices, respectively (say $x, \mathbf{x}, X$). The symbols $\mathbb{R}^d$, $\mathbb{S}^d$ and $\mathbb{S}^d_+$ are used to denote the sets of $d\times 1$ real vectors, $d\times d$ symmetric matrices and $d\times d$ symmetric positive-semidefinite matrices, respectively. The notations $\mathrm{trace}(M)$ and $\log\det(M)$ refer to the trace and the logarithm of the determinant of a matrix M, respectively. The $(i,j)^{\text{th}}$ entry of the matrix M is denoted by M_{ij}. Moreover, I_d denotes the $d\times d$ identity matrix. The sign of a scalar x is shown as $\mathrm{sign}(x)$. The notations $|x|$, $\|M\|_1$ and $\|M\|_F$ denote the absolute value of the scalar x, the induced norm-1 and Frobenius norm of the matrix M, respectively. The inequalities $M\succeq 0$ and $M\succ 0$ mean that M is positive-semidefinite and positive-definite, respectively. The symbol $\mathrm{sign}(\cdot)$ shows the sign operator. The ceiling function is denoted as $\lceil\cdot\rceil$. The cardinality of a discrete set $\mathcal{D}$ is denoted as $|\mathcal{D}|_0$. Given a matrix $M\in\mathbb{S}^d$, define

$$\|M\|_{1,\text{off}} = \sum_{i=1}^{d}\sum_{j=1}^{d}|M_{ij}| - \sum_{i=1}^{d}|M_{ii}|,$$
$$\|M\|_{\max} = \max_{i\neq j}|M_{ij}|.$$

Definition 1 *Given a symmetric matrix $S\in\mathbb{S}^d$, the* **support graph or sparsity graph** *of S is defined as a graph with the vertex set $\mathcal{V}:=\{1,2,...,d\}$ and the edge set $\mathcal{E}\subseteq\mathcal{V}\times\mathcal{V}$ such that $(i,j)\in\mathcal{V}$ if and only if $S_{ij}\neq 0$, for every two different vertices $i,j\in\mathcal{V}$. The support graph of S captures the sparsity pattern of the matrix S and is denoted as* $\mathrm{supp}(S)$.

Definition 2 *Given a graph $\mathcal{G}$, define $\mathcal{G}^{(c)}$ as the complement of $\mathcal{G}$, which is obtained by removing the existing edges of $\mathcal{G}$ and drawing an edge between every two vertices of $\mathcal{G}$ that were not originally connected.*

Definition 3 *Given two graphs $\mathcal{G}_1$ and $\mathcal{G}_2$ with the same vertex set, $\mathcal{G}_1$ is called a subgraph of $\mathcal{G}_2$ if the edge set of $\mathcal{G}_1$ is a subset of the edge set of $\mathcal{G}_2$. The notation $\mathcal{G}_1\subseteq\mathcal{G}_2$ is used to denote this inclusion.*

Finally, a symmetric matrix M is said to have a **positive-definite completion** if there exists a positive-definite $\tilde{M}$ with the same size such that $\tilde{M}_{ij}=M_{ij}$ for every $(i,j)\in\mathrm{supp}(M)$.

2. Problem Formulation

Consider a random vector $\mathbf{x}=(x_1,x_2,...,x_d)$ with a multivariate normal distribution. Let $\Sigma_*\in\mathbb{S}^d_+$ denote the covariance matrix associated with the vector $\mathbf{x}$. The inverse of the covariance matrix can be used to determine the conditional independence between the

random variables $x_1,x_2,...,x_d$. In particular, if the $(i,j)^{\text{th}}$ entry of Σ_*^{-1} is zero for two disparate indices i and j, then x_i and x_j are conditionally independent given the rest of the variables. The graph $\mathrm{supp}\big(\Sigma_*^{-1}\big)$ (i.e., the sparsity graph of Σ_*^{-1}) represents a graphical model capturing the conditional independence between the elements of $\mathbf{x}$. Assume that Σ_* is nonsingular and that $\mathrm{supp}\big(\Sigma_*^{-1}\big)$ is a sparse graph. Finding this graph is cumbersome in practice because the exact covariance matrix Σ_* is rarely known. More precisely, $\mathrm{supp}\big(\Sigma_*^{-1}\big)$ should be constructed from a given sample covariance matrix (constructed from n samples), as opposed to Σ_*. Let Σ denote an arbitrary $d\times d$ positive-semidefinite matrix, which is provided as an estimate of Σ_*. Consider the convex optimization problem

$$\min_{S\in\mathbb{S}^d_+} -\log\det(S)+\mathrm{trace}(\Sigma S). \tag{1}$$

It is easy to verify that the optimal solution of the above problem is equal to $S^{\text{opt}}=\Sigma^{-1}$. However, there are two issues with this solution. First, since the number of samples available in many applications is small or modest compared to the dimension of Σ, the matrix Σ is ill-conditioned or even singular. Under such circumstances, the equation $S^{\text{opt}}=\Sigma^{-1}$ leads to large or undefined entries for the optimal solution of (1). Second, although Σ_*^{-1} is assumed to be sparse, a small random difference between Σ_* and Σ would make S^{opt} highly dense. In order to address the aforementioned issues, consider the problem

$$\min_{S\in\mathbb{S}^d_+} -\log\det(S)+\mathrm{trace}(\Sigma S)+\lambda\|S\|_{1,\text{off}}, \tag{2}$$

where $\lambda\in\mathbb{R}_+$ is a regularization parameter. This problem is referred to as *Graphical Lasso* (GL). Intuitively, the term $\|S\|_{1,\text{off}}$ in the objective function serves as a surrogate for promoting sparsity among the off-diagonal entries of S, while ensuring that the problem is well-defined even with a singular input Σ. Henceforth, the notation S^{opt} will be used to denote a solution of the GL instead of the unregularized optimization problem (1).

Suppose that it is known *a priori* that the true graph $\mathrm{supp}\big(\Sigma_*^{-1}\big)$ has k edges, for some given number k. With no loss of generality, assume that all nonzero off-diagonal entries of Σ have different magnitudes. Two heuristic methods for finding an estimate of $\mathrm{supp}\big(\Sigma_*^{-1}\big)$ are as follows:

- **Graphical Lasso:** We solve the optimization problem (2) repeatedly for different values of λ until a solution S^{opt} with exactly $2k$ nonzero off-diagonal entries are found.
- **Thresholding:** Without solving any optimization problem, we simply identify those $2k$ entries of Σ that have the largest magnitudes among all off-diagonal entries of Σ. We then replace the remaining d^2-d-2k off-diagonal entries of Σ with zero and denote the thresholded sample covariance matrix as Σ_k. Note that Σ and Σ_k have the same diagonal entries. Finally, we consider the sparsity graph of Σ_k, namely $\mathrm{supp}(\Sigma_k)$, as an estimate for $\mathrm{supp}\big(\Sigma_*^{-1}\big)$.

Definition 4 *It is said that the* **sparsity structures of Graphical Lasso and thresholding are equivalent** *if there exists a regularization coefficient λ such that* $\mathrm{supp}(S^{opt})=\mathrm{supp}(\Sigma_k)$.

Recently, we have verified in several simulations that the GL and thresholding are equivalent for electrical circuits and functional MRI data of 20 subjects, provided that k is on the order of n (Sojoudi 2016). This implies that a simple thresholding technique would obtain the same sparsity structure as the computationally-heavy GL technique. In this paper, it is aimed to understand under what conditions the easy-to-find graph $\text{supp}(\Sigma_k)$ is equal to the hard-to-obtain graph $\text{supp}(S^{\text{opt}})$, without having to solve the GL. Furthermore, we will show that the GL problem has a simple closed-form solution that can be easily derived merely based on the thresholded sample covariance matrix, provided that its underlying graph has an acyclic structure. This result will then be generalized to obtain an approximate solution for the GL in the case where the thresholded sample covariance matrix has an arbitrary sparsity structure. This closed-form solution converges to the exact solution of the GL as the length of the minimum-length cycle in the support graph of the thresholded sample covariance matrix grows. The derived closed-form solution can be used for two purposes: (1) as a surrogate to the exact solution of the computationally heavy GL problem, and (2) as an initial point for common numerical algorithms to numerically solve the GL (see Friedman et al. (2008); Hsieh et al. (2014)). The above results unveil fundamental properties of the GL in terms of sparsification and computational complexity. Although conic optimization problems almost never benefit from an exact or inexact explicit formula for their solutions and should be solved numerically, the formula obtained in this paper suggests that sparse GL and related graph-based conic optimization problems may fall into the category of problems with closed-form solutions (similar to least squares problems).

3. Main Results

In this section, we present the main results of the paper. In order to streamline the presentation, most of the technical proofs are postponed to Appendix.

3.1. Equivalence of GL and Thresholding

In this subsection, we derive sufficient conditions to guarantee that the GL and thresholding methods result in the same sparsity graph. These conditions are only dependent on λ and Σ, and are expected to hold whenever λ is large enough or a sparse graph is sought.

Definition 5 *A matrix $M \in \mathbb{S}^d$ is called* **inverse-consistent** *if there exists a matrix $N \in \mathbb{S}^d$ with zero diagonal elements such that*

$$\begin{aligned} &M + N \succ 0, \\ &\text{supp}(N) \subseteq (\text{supp}(M))^{(c)}, \\ &\text{supp}\left((M+N)^{-1}\right) \subseteq \text{supp}(M). \end{aligned}$$

The matrix N is called **inverse-consistent complement** *of M and is denoted as $M^{(c)}$.*

The next Lemma will shed light on the definition of inverse-consistency by introducing an important class of such matrices that satisfy this property, namely the *set of matrices with positive-definite completions.*

Lemma 6 *Any arbitrary matrix with positive-definite completion is inverse-consistent and has a unique inverse-consistent complement.*

Proof: Consider the optimization problem

$$\begin{aligned} \min_{S \in \mathbb{S}^n} \quad & \text{trace}(MS) - \text{logdet}(S) && \text{(4a)} \\ \text{subject to} \quad & S_{ij} = 0, \qquad \forall (i,j) \in (\text{supp}(M))^{(c)} && \text{(4b)} \\ & S \succeq 0, && \text{(4c)} \end{aligned}$$

and its dual

$$\begin{aligned} \max_{\Pi \in \mathbb{S}^n} \quad & \det(M + \Pi) && \text{(5a)} \\ \text{subject to} \quad & M + \Pi \succeq 0 && \text{(5b)} \\ & \text{supp}(\Pi) \subseteq (\text{supp(M)})^{(c)} && \text{(5c)} \\ & \Pi_{ii} = 0, \qquad i = 1, ..., d. && \text{(5d)} \end{aligned}$$

Note that Π_{ij} is equal to the Lagrange multiplier for (4b) and every $(i,j) \in (\text{supp}(M))^{(c)}$, and is zero otherwise. Since the matrix M has a positive-definite completion, the dual problem is strictly feasible. Moreover, $S = I_d$ is a feasible solution of (4). Therefore, strong duality holds and the primal solution is attainable. On the other hand, the objective function (4a) is strictly convex, which makes the solution of the primal problem unique. Let S^{opt} denote the globally optimal solution of (4). It follows from the first-order optimality conditions that

$$S^{\text{opt}} = (M + \Pi^{\text{opt}})^{-1}.$$

This implies that

$$\begin{aligned} &\text{supp}(\Pi^{\text{opt}}) \subseteq (\text{supp}(M))^{(c)} \\ &\text{supp}((M + \Pi^{\text{opt}})^{-1}) \subseteq \text{supp}(M) \\ &M + \Pi^{\text{opt}} \succ 0. \end{aligned}$$

As a result, $M \in \mathbb{S}^d$ is inverse-consistent and Π^{opt} is its complement. To prove the uniqueness of the inverse-consistent complement of M, let Π denote an arbitrary complement of M. It follows from Definition 5 and the first-order optimality conditions that $(M+\Pi)^{-1}$ is a solution of (4). Since S^{opt} is the unique solution of (4), it can be concluded that $\Pi = \Pi^{\text{opt}}$. This implies that M has a unique inverse-consistent complement. ■

Remark 7 *Two observations can be made based on Lemma 6. First, the positive-definiteness of a matrix is sufficient to guarantee that it belongs to the cone of matrices with positive-definite completion. Therefore, positive-definite matrices are inverse-consistent. Second, upon existence, the inverse-consistent complement of a matrix with positive-definite completion is equal to the difference between the matrix and its unique* ***maximum determinant completion****.*

Definition 8 *An inverse-consistent matrix M is called* **sign-consistent** *if the (i,j) entries of M and $(M+M^{(c)})^{-1}$ are nonzero and have opposite signs for every $(i,j) \in \text{supp}(M)$.*

Example 1 (An inverse- and sign-consistent matrix) To illustrate Definitions 5 and 8, consider the matrix

$$M = \begin{bmatrix} 1 & 0.3 & 0 & 0 \\ 0.3 & 1 & -0.4 & 0 \\ 0 & -0.4 & 1 & 0.2 \\ 0 & 0 & 0.2 & 1 \end{bmatrix}.$$

The graph $\text{supp}(M)$ is a path graph with the vertex set $\{1,2,3,4\}$ and the edge set $\{(1,2),(2,3),(3,4)\}$. To show that M is inverse-consistent, let the matrix $M^{(c)}$ be chosen as

$$M^{(c)} = \begin{bmatrix} 0 & 0 & -0.120 & -0.024 \\ 0 & 0 & 0 & -0.080 \\ -0.120 & 0 & 0 & 0 \\ -0.024 & -0.080 & 0 & 0 \end{bmatrix}.$$

The inverse matrix $(M+M^{(c)})^{-1}$ is equal to

$$\begin{bmatrix} \frac{1}{0.91} & \frac{-0.3}{0.91} & 0 & 0 \\ \frac{-0.3}{0.91} & 1+\frac{0.09}{0.91}+\frac{0.16}{0.84} & \frac{0.4}{0.84} & 0 \\ 0 & \frac{0.4}{0.84} & 1+\frac{0.16}{0.84}+\frac{0.04}{0.96} & \frac{-0.2}{0.96} \\ 0 & 0 & \frac{-0.2}{0.96} & \frac{1}{0.96} \end{bmatrix}.$$

Observe that:

- M and $M+M^{(c)}$ are both positive-definite.
- The sparsity graphs of M and $M^{(c)}$ are complements of each other.
- The sparsity graphs of M and $(M+M^{(c)})^{-1}$ are identical.
- The nonzero off-diagonal entries of M and $(M+M^{(c)})^{-1}$ have opposite signs.

The above properties imply that M is both inverse-consistent and sign-consistent, and $M^{(c)}$ is its complement.

Definition 9 *Given a graph $\mathcal{G}$ and a scalar α, define $\beta(\mathcal{G},\alpha)$ as the maximum of $\|M^{(c)}\|_{\max}$ over all matrices M with positive-definite completions and with the diagonal entries all equal to 1 such that $\text{supp}(M) = \mathcal{G}$ and $\|M\|_{\max} \leq \alpha$.*

Consider the dual solution Π^{opt} introduced in the proof of Lemma 6 and note that it is a function of M. Roughly speaking, the function $\beta(\mathcal{G},\alpha)$ in the above definition provides an upper bound on $\|\Pi^{\text{opt}}\|_{\max}$ over all matrices M with positive-definite completions and with the diagonal entries equal to 1 such that $\text{supp}(M) = \mathcal{G}$ and $\|M\|_{\max} \leq \alpha$. As will be shown later, this function will be used as a *certificate* to verify the optimality conditions for the GL.

Since Σ_* is non-singular and we have a finite number of samples, the elements of the upper triangular part of Σ (excluding its diagonal elements) are all nonzero and distinct with probability one. Let $\sigma_1, \sigma_2, ..., \sigma_{d(d-1)/2}$ denote the absolute values of those upper-triangular entries such that

$$\sigma_1 > \sigma_2 > ... > \sigma_{d(d-1)/2} > 0.$$

Definition 10 *Consider an arbitrary positive regularization parameter λ that does not belong to the discrete set $\{\sigma_1, \sigma_2, ..., \sigma_{d(d-1)/2}\}$. Define the index k associated with λ as an integer number satisfying the relation $\lambda \in (\sigma_{k+1}, \sigma_k)$. If λ is greater than σ_1, then k is set to 0.*

Throughout this paper, the index k refers to the number introduced in Definition 10, which depends on λ.

Definition 11 *Define the* **residue of Σ relative to λ** *as a matrix $\Sigma^{\text{res}}(\lambda) \in \mathbb{S}^d$ such that the (i,j) entry of $\Sigma^{\text{res}}(\lambda)$ is equal to $\Sigma_{ij} - \lambda \times \text{sign}(\Sigma_{ij})$ if $i \neq j$ and $|\Sigma_{ij}| > \lambda$, and it is equal to 0 otherwise. Furthermore, define* **normalized residue of Σ relative to λ** *as*

$$\tilde{\Sigma}^{\text{res}}(\lambda) = D^{-1/2} \times \Sigma^{\text{res}}(\lambda) \times D^{-1/2},$$

where D is diagonal matrix with $D_{ii} = \Sigma_{ii}$ for every $i \in \{1, ..., d\}$.

Notice that $\Sigma^{\text{res}}(\lambda)$ is in fact the soft-thresholded sample covariance matrix with the threshold λ. For notational simplicity, we will use Σ^{res} or $\tilde{\Sigma}^{\text{res}}$ instead of $\Sigma^{\text{res}}(\lambda)$ or $\tilde{\Sigma}^{\text{res}}(\lambda)$ whenever the equivalence is implied by the context. One of the main theorems of this paper is presented below.

Theorem 12 *The sparsity structures of the thresholding and GL methods are equivalent if the following conditions are satisfied:*

- **Condition 1-i:** *$I_d + \tilde{\Sigma}^{\text{res}}$ has a positive-definite completion.*
- **Condition 1-ii:** *$I_d + \tilde{\Sigma}^{\text{res}}$ is sign-consistent.*
- **Condition 1-iii:** *The relation*

$$\beta\left(\text{supp}(\Sigma^{\text{res}}), \|\tilde{\Sigma}^{\text{res}}\|_{\max}\right) \leq \min_{\substack{i \neq j \\ |\Sigma_{ij}| \leq \lambda}} \frac{\lambda - |\Sigma_{ij}|}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}$$

holds.

A number of observations can be made based on Theorem 12. First note that, due to Lemma 6, Condition (1-i) guarantees that $I_d + \tilde{\Sigma}^{\text{res}}$ is inverse-consistent; in fact it holds when $I_d + \tilde{\Sigma}^{\text{res}}$ itself is positive-definite. Note that the positive-definiteness of $I_d + \tilde{\Sigma}^{\text{res}}$ is guaranteed to hold if the eigenvalues of the normalized residue of the matrix Σ relative to λ are greater than -1. Recall that $\lambda \in (\sigma_{k+1}, \sigma_k)$ for some integer k and the off-diagonal entries of $I_d + \tilde{\Sigma}^{\text{res}}$ are in the range $[-1, 1]$. In the case where the number k

is significantly smaller than d^2, the residue matrix has many zero entries. Hence, the satisfaction of Condition (1-i) is expected for a large class of residue matrices; this will be verified extensively in our case studies on the real-world and synthetically generated data sets. Specifically, this condition is automatically satisfied if $I_d+\tilde{\Sigma}^{\text{res}}$ is diagonally dominant. Conditions (1-ii) and (1-iii) of Theorem 12 are harder to check. These conditions depend on the support graph of the residue matrix $\tilde{\Sigma}^{\text{res}}$ and/or how small the nonzero entries of $\tilde{\Sigma}^{\text{res}}$ are. The next two lemmas further analyze these conditions to show that they are expected to be satisfied for large λ.

Lemma 13 *Given an arbitrary graph $\mathcal{G}$, there is a strictly positive constant number $\zeta(\mathcal{G})$ such that*

$$\beta(\mathcal{G},\alpha)\leq \zeta(\mathcal{G})\alpha^2, \qquad \forall\ \alpha\in(0,1) \tag{7}$$

and therefore, Condition (1-iii) is reduced to

$$\zeta(\text{supp}(\Sigma^{\text{res}}))\times \max_{\substack{k\neq l\\ |\Sigma_{kl}|>\lambda}}\left(\frac{|\Sigma_{kl}|-\lambda}{\sqrt{\Sigma_{kk}\Sigma_{ll}}}\right)^2\leq \min_{\substack{i\neq j\\ |\Sigma_{ij}|\leq\lambda}}\frac{\lambda-|\Sigma_{ij}|}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}.$$

Lemma 14 *Consider a matrix M with a positive-definite completion and with unit diagonal entries. Define $\alpha=\|M\|_{\max}$ and $\mathcal{G}=\text{supp}(M)$. There exist strictly positive constant numbers $\alpha_0(\mathcal{G})$ and $\gamma(\mathcal{G})$ such that M is sign-consistent if $\alpha\leq\alpha_0(\mathcal{G})$ and the absolute value of the off-diagonal nonzero entries of M is lower bounded by $\gamma(\mathcal{G})\alpha^2$. This implies that Condition (i-ii) is satisfied if $\|\tilde{\Sigma}^{\text{res}}\|_{\max}\leq\alpha_0(\text{supp}(\Sigma^{\text{res}}))$ and*

$$\gamma(\text{supp}(\Sigma^{\text{res}}))\times \max_{\substack{k\neq l\\ |\Sigma_{kl}|>\lambda}}\left(\frac{|\Sigma_{kl}|-\lambda}{\sqrt{\Sigma_{kk}\Sigma_{ll}}}\right)^2\leq \min_{\substack{i\neq j\\ |\Sigma_{ij}|>\lambda}}\frac{|\Sigma_{ij}|-\lambda}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}. \tag{8}$$

For simplicity of notation, define $r=\frac{\max_i\Sigma_{ii}}{\min_j\Sigma_{jj}}$ and $\Sigma_{\max}=\max_i\Sigma_{ii}$. Assuming that $\|\tilde{\Sigma}^{\text{res}}\|_{\max}\leq\alpha_0(\text{supp}(\Sigma^{\text{res}}))$, Conditions (1-ii) and (1-iii) of Theorem 12 are guaranteed to be satisfied if

$$\zeta(\text{supp}(\Sigma^{\text{res}}))\leq\frac{1}{r^2}\cdot\frac{\frac{\lambda-\sigma_{k+1}}{\Sigma_{\max}}}{\left(\frac{\sigma_1-\lambda}{\Sigma_{\max}}\right)^2}, \qquad \gamma(\text{supp}(\Sigma^{\text{res}}))\leq\frac{1}{r^2}\cdot\frac{\frac{\sigma_k-\lambda}{\Sigma_{\max}}}{\left(\frac{\sigma_1-\lambda}{\Sigma_{\max}}\right)^2}, \tag{9}$$

which is equivalent to

$$\max\left\{\gamma(\text{supp}(\Sigma^{\text{res}})),\zeta(\text{supp}(\Sigma^{\text{res}}))\right\}\leq\frac{2}{r^2}\cdot\frac{\frac{\sigma_k-\sigma_{k+1}}{\Sigma_{\max}}}{\left(\frac{2\sigma_1-\sigma_k-\sigma_{k+1}}{\Sigma_{\max}}\right)^2}.$$

for the choice $\lambda=\frac{\sigma_k+\sigma_{k+1}}{2}$. Consider the set

$$\mathcal{T}=\left\{|\Sigma_{ij}|\ \middle|\ i=1,2,...,d-1,\ j=i+1,...,d\right\}.$$

This set has $\frac{d(d-1)}{2}$ elements. The cardinality of $\{\sigma_1,...,\sigma_{d-1}\}$, as a subset of $\mathcal{T}$, is smaller than the cardinality of $\mathcal{T}$ by a factor of $\frac{d}{2}$. Combined with the fact that $|\sigma_i|<\Sigma_{\max}$ for

every $i=1,...,\frac{d(d-1)}{2}$, this implies that the term $\frac{2\sigma_1-\sigma_{d-1}-\sigma_d}{\Sigma_{\max}}$ is expected to be small and its square is likely to be much smaller than 1, provided that the elements of $\mathcal{T}$ are sufficiently spread. If the number $(2\sigma_1-\sigma_{d-1}-\sigma_d)$ is relatively smaller than the gap $\sigma_{d-1}-\sigma_d$ and $k=O(d)$, then (7) and as a result Conditions (1-ii) and (1-iii) would be satisfied. The satisfaction of this condition will be studied for acyclic graphs in the next section.

3.2. Closed-form Solution: Acyclic Sparsity Graphs

In the previous subsection, we provided a set of sufficient conditions for the equivalence of the GL and thresholding methods. Although these conditions are merely based on the known parameters of the problem, i.e., the regularization coefficient and sample covariance matrix, their verification is contingent upon knowing the value of $\beta(\text{supp}(\Sigma^{\text{res}}),\|\tilde{\Sigma}^{\text{res}}\|_{\max})$ and whether $I_d+\tilde{\Sigma}^{\text{res}}$ is sign-consistent and has a positive-definite completion. The objective of this part is to greatly simplify the conditions in the case where the thresholded sample covariance matrix has an acyclic support graph. First, notice that if $I_d+\tilde{\Sigma}^{\text{res}}$ is positive-definite, it has a trivial positive-definite completion. Furthermore, we will prove that $\zeta(\text{supp}(\Sigma^{\text{res}}))$ in Lemma 13 is equal to 1 when $\text{supp}(\Sigma^{\text{res}})$ is acyclic. This reduces Condition (1-iii) to the simple inequality

$$\|\tilde{\Sigma}^{\text{res}}\|_{\max}^2\leq\min_{\substack{i\neq j\\ |\Sigma_{ij}|\leq\lambda}}\frac{\lambda-|\Sigma_{ij}|}{\sqrt{\Sigma_{ii}\Sigma_{jj}}},$$

which can be verified efficiently and is expected to hold in practice (see Section 4). Then, we will show that the sign-consistency of $I_d+\tilde{\Sigma}^{\text{res}}$ is automatically implied by the fact that it has a positive-definite completion if $\text{supp}(\Sigma^{\text{res}})$ is acyclic.

Lemma 15 *Given an arbitrary acyclic graph $\mathcal{G}$, the relation*

$$\beta(\mathcal{G},\alpha)\leq\alpha^2 \tag{10}$$

holds for every $0\leq\alpha<1$. Furthermore, strict equality holds for (10) if $\mathcal{G}$ includes a path of length at least 2.

Sketch of the Proof: In what follows, we will provide a sketch of the main idea behind the proof of Lemma 15. The detailed analysis can be found in the Appendix. Without loss of generality, one can assume that $\mathcal{G}$ is connected. Otherwise, the subsequent argument can be made for every connected component of $\mathcal{G}$. Consider a matrix M that satisfies the conditions delineated in Definition 9, i.e. 1) it has a positive-definite completion and hence, is inverse-consistent (see Lemma 6), 2) it has unit diagonal entries, 3) the absolute value of its off-diagonal elements is upper bounded by α, and 4) $\text{supp}(M)=\mathcal{G}$. The key idea behind the proof of Lemma 15 lies in the fact that, due to the acyclic structure of $\mathcal{G}$, one can explicitly characterize the inverse-consistent complement of M. In particular, it can be shown that the inverse-consistent complement of M has the following explicit formula: for every $(i,j)\notin\mathcal{G}$, $M^{(c)}_{ij}$ is equal to the multiplication of the off-diagonal elements of M corresponding to the edges in the unique path between the nodes i and j in $\mathcal{G}$. This key insight immediately results in the statement of Lemma 15: the length of the path between

nodes i and j is lower bounded by 2 and therefore, $M_{ij}^{(c)} \leq \alpha^2$. Furthermore, it is easy to see that if $\mathcal{G}$ includes a path of length at least 2, M can be chosen such that for some $(i,j) \notin \mathcal{G}$, we have $M_{ij}^{(c)} = \alpha^2$. ■

Lemma 15 is at the core of our subsequent arguments. It shows that the function $\beta(\mathcal{G}, \alpha)$ has a simple and explicit formula since its inverse-consistent complement can be easily obtained. Furthermore, it will be used to derive *approximate* inverse-consistent complement of the matrices with sparse, but not necessarily acyclic support graphs.

Lemma 16 *Condition (1-ii) of Theorem 12 is implied by its Condition (1-i) if the graph* $\text{supp}(\Sigma^{\text{res}})$ *is acyclic.*

Proof: Consider an arbitrary matrix $M \in \mathbb{S}^d$ with a positive-definite completion. It suffices to show that if $\text{supp}(M)$ is acyclic, then M is sign-consistent. To this end, consider the matrix Π^{opt} introduced in the proof of Lemma 6, which is indeed the unique inverse-consistent complement of M. For an arbitrary pair $(i,j) \in \text{supp}(M)$, define a diagonal matrix $\Phi \in \mathbb{S}^n$ as follows:

- Consider the graph $\text{supp}(M)\backslash\{(i,j)\}$, which is obtained from the acyclic graph $\text{supp}(M)$ by removing its edge (i,j). The resulting graph is disconnected because there is no path between nodes i and j.
- Divide the disconnected graph $\text{supp}(M)\backslash\{(i,j)\}$ into two groups 1 and 2 such that group 1 contains node i and group 2 includes node 2.
- For every $l \in \{1,...,n\}$, define Φ_{ll} as 1 if l is in group 1, and as -1 otherwise.

In light of Lemma 6, $(M+\Pi)^{-1}$ is the unique solution of (4). Similarly, $\Phi(M+\Pi)^{-1}\Phi$ is a feasible point for (4). As a result, the following inequality must hold

$$\Big\{\text{trace}(M(M+\Pi^{\text{opt}})^{-1}) - \text{logdet}((M+\Pi^{\text{opt}})^{-1})\Big\}$$
$$-\Big\{\text{trace}(M\Phi(M+\Pi^{\text{opt}})^{-1}\Phi) - \text{logdet}(\Phi(M+\Pi^{\text{opt}})^{-1}\Phi)\Big\} < 0.$$

It is easy to verify that the left side of the above inequality is equal to twice the product of the (i,j) entries of M and $(M+\Pi)^{-1}$. This implies that the (i,j) entries of M and $(M+\Pi)^{-1}$ have opposite signs. As a result, M is sign-consistent. ■

Definition 17 *Define* $T(\lambda)$ *as a* $d \times d$ *symmetric matrix whose* $(i,j)^{th}$ *entry is equal to* $\Sigma_{ij} + \lambda \times sign(S_{ij}^{opt})$ *for every* $(i,j) \in supp(S^{opt})$*, and it is equal to zero otherwise.*

The next result of this paper is a consequence of Lemmas 15 and 16 and Theorem 12.

Theorem 18 *Assume that the graph* $supp(S^{opt})$ *is acyclic and the matrix* $D + T(\lambda)$ *is positive-definite. Then, the relation* $\mathcal{E}^{opt} \subseteq \mathcal{E}^{\text{res}}$ *holds and the optimal solution* S^{opt} *of the GL can be computed via the explicit formula*

$$S_{ij}^{opt} = \begin{cases} \frac{1}{\Sigma_{ii}}\left(1 + \sum_{(i,m)\in\mathcal{E}^{opt}} \frac{(\Sigma_{im}^{\text{res}})^2}{\Sigma_{ii}\Sigma_{mm}-(\Sigma_{im}^{\text{res}})^2}\right) & \text{if} \quad i=j, \\ \frac{-\Sigma_{ij}^{\text{res}}}{\Sigma_{ii}\Sigma_{jj}-(\Sigma_{ij}^{\text{res}})^2} & \text{if} \quad (i,j)\in\mathcal{E}^{opt}, \\ 0 & \text{otherwise}, \end{cases} \tag{11}$$

where $\mathcal{E}^{opt}$ *and* $\mathcal{E}^{\text{res}}$ *denote the edge sets of* $\text{supp}(S^{opt})$ *and* $\text{supp}(\Sigma^{\text{res}})$*, respectively.*

When the regularization parameter λ is large, the graph $\text{supp}(S^{\text{opt}})$ is expected to be sparse and possibly acyclic. In this case, the matrix $T(\lambda)$ is sparse with small nonzero entries. If $D + T(\lambda)$ is positive-definite and $\text{supp}(S^{\text{opt}})$ is acyclic, Theorem 18 reveals two important properties of the solution of the GL: 1) its support graph is contained in the sparsity graph of the thresholded sample covariance matrix, and 2) the entries of this matrix can be found using the explicit formula (11). However, this formula requires to know the locations of the nonzero elements of S^{opt}. In what follows, we will replace the assumptions of the above theorem with easily verifiable rules that are independent from the optimal solution S^{opt} or the locations of its nonzero entries. Furthermore, it will be shown that these conditions are expected to hold when λ is large enough, i.e., if a sparse matrix S^{opt} is sought.

Theorem 19 *Assume that the following conditions are satisfied:*

- **Condition 2-i.** *The graph* $supp(\Sigma^{\text{res}})$ *is acyclic.*
- **Condition 2-ii.** $I_d + \tilde{\Sigma}^{\text{res}}$ *is positive-definite.*
- **Condition 2-iii.** $\|\tilde{\Sigma}^{\text{res}}\|_{\max}^2 \leq \min\limits_{\substack{i\neq j \\ |\Sigma_{ij}|\leq\lambda}} \frac{\lambda - |\Sigma_{ij}|}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}$.

Then, the sparsity pattern of the optimal solution S^{opt} *corresponds to the sparsity pattern of* Σ^{res} *and, in addition,* S^{opt} *can be obtained via the explicit formula* (11)*.*

The above theorem states that if a sparse graph is sought, then as long as some easy-to-verify conditions are met, there is an explicit formula for the optimal solution. It will later be shown that Condition (2-i) is exactly or approximately satisfied if the regularization coefficient is sufficiently large. Condition (2-ii) implies that the eigenvalues of the normalized residue of Σ with respect to λ should be greater than -1. This condition is expected to be automatically satisfied since most of the elements of $\tilde{\Sigma}^{\text{res}}$ are equal to zero and the nonzero elements have small magnitude. In particular, this condition is satisfied if $I_d + \tilde{\Sigma}^{\text{res}}$ is diagonally dominant. Finally, using (8), it can be verified that Condition (2-iii) is satisfied if

$$\frac{\left(\frac{2\sigma_1-\sigma_k-\sigma_{k+1}}{\Sigma_{\max}}\right)^2}{\frac{\sigma_k-\sigma_{k+1}}{\Sigma_{\max}}} \leq \frac{2}{r^2}. \tag{12}$$

Similar to the arguments made in the previous subsection, (12) shows that Condition (2-iii) is satisfied if $\frac{2\sigma_1-\sigma_k-\sigma_{k+1}}{\Sigma_{\max}}$ is small. This is expected to hold in practice since the choice of λ

entails that $2\sigma_1 - \sigma_k - \sigma_{k+1}$ is much smaller than $\Sigma_{\max}$. Under such circumstances, one can use Theorem 19 to obtain the solution of the GL without having to solve (2) numerically.

Having computed the sample covariance matrix, we will next show that checking the conditions in Theorem 19 and finding S^{opt} using (11) can all be carried out efficiently.

Corollary 20 *Given Σ and λ, the total time complexity of checking the conditions in Theorem 19 and finding S^{opt} using* (11) *is $\mathcal{O}(d^2)$.*

Another line of work has been devoted to studying the connectivity structure of the optimal solution of the GL. In particular, Mazumder and Hastie (2012) and Witten et al. (2011) have shown that the connected components induced by thresholding the covariance matrix and those in the support graph of the optimal solution of the GL lead to the same vertex partitioning. Although this result does not require any particular condition, it cannot provide any information about the edge structure of the support graph and one needs to solve (2) for each connected component using an iterative algorithm, which may take up to $\mathcal{O}(d^3)$ per iteration (Friedman et al. 2008; Banerjee et al. 2008; Mazumder and Hastie 2012). Corollary 20 states that this complexity could be reduced significantly for sparse graphs.

Remark 21 *The results introduced in Theorem 12 can indeed be categorized as a set of "safe rules" that correctly determine sparsity pattern of the optimal solution of the GL. These rules are subsequently reduced to a set of easily verifiable conditions in Theorem 19 to safely obtain the correct sparsity pattern of the acyclic components in the optimal solution. On the other hand, there is a large body of literature on simple and cheap safe rules to prescreen and simplify the sparse learning and estimation problems, including Lasso, logistic regression, support vector machine, group Lasso, etc(Ghaoui et al. (2010); Tibshirani et al. (2012); Fercoq et al. (2015); Ndiaye et al. (2015)). Roughly speaking, these methods are based on constructing a sequence of safe regions that encompass the optimal solution for the dual of the problem at hand. These safe regions, together with the Karush—Kuhn—Tucker (KKT) conditions, give rise to a set of rules that facilitate inferring the sparsity pattern of the optimal solution. Our results are similar to these methods since we also analyze the special structure of the KKT conditions and resort to the dual of the GL to obtain the correct sparsity structure of the optimal solution. However, according to the seminal work Ndiaye et al. (2015), most of the developed results on safe screening rules rely on strong Lipschitz assumptions on the objective function; an assumption that is violated in the GL. This calls for a new machinery to derive theoretically correct rules for this problem; a goal that is at the core of Theorems 12 and 19.*

3.3. Approximate Closed-form Solution: Sparse Graphs

In the preceding subsection, it was shown that, under some mild assumptions, the GL has an explicit closed-form solution if the support graph of the thresholded sample covariance matrix is acyclic. In this part, a similar approach will be taken to find approximate solutions of the GL with an arbitrary underlying sparsity graph. In particular, by closely examining the hard-to-check conditions of Theorem 12, a set of simple and easy-to-verify surrogates will be introduced which give rise to an approximate closed-form solution for the general sparse GL. Furthermore, we will derive a strong upper bound on the approximation error

and show that it decreases exponentially fast with respect to the length of the minimum-length cycle in the support graph of the thresholded sample covariance matrix. Indeed, the formula obtained earlier for acyclic graphs could be regarded as a by-product of this generalization since the length of the minimum-length cycle can be considered as infinity for such graphs. The significance of this result is twofold:

- Recall that the support graph corresponding to the optimal solution of the GL is sparse (but not necessarily acyclic) for a large regularization coefficient. In this case, the approximate error is provably small and the derived closed-form solution can serve as a good approximation for the exact solution of the GL. This will later be demonstrated in different simulations.

- The performance and runtime of numerical (iterative) algorithms for solving the GL heavily depend on their initializations. It is known that if the initial point is chosen close enough to the optimal solution, these algorithms converge to the optimal solution in just a few iterations (Friedman et al. 2008; Hsieh et al. 2014; Zhang and Lavaei 2017). The approximate closed-form solution designed in this paper can be used as an initial point for the existing numerical algorithms to significantly improve their runtime.

The proposed approximate solution for the GL with an arbitrary support graph has the following form:

$$A_{ij} = \begin{cases} \frac{1}{\Sigma_{ii}} \left(1 + \sum\limits_{(i,m)\in\mathcal{E}^{\text{opt}}} \frac{(\Sigma^{\text{res}}_{im})^2}{\Sigma_{ii}\Sigma_{mm} - (\Sigma^{\text{res}}_{im})^2} \right) & \text{if} \quad i = j, \\ \frac{-\Sigma^{\text{res}}_{ij}}{\Sigma_{ii}\Sigma_{jj} - (\Sigma^{\text{res}}_{ij})^2} & \text{if} \quad (i,j) \in \mathcal{E}^{\text{res}}, \\ 0 & \text{otherwise.} \end{cases} \tag{13}$$

The definition of this matrix does not make any assumption on the structure of the graph $\mathcal{E}^{\text{res}}$. Recall that Σ^{res} in the above formula is the shorthand notation for $\Sigma^{\text{res}}(\lambda)$. As a result, the matrix A is a function of λ. To prove that the above matrix is an approximate solution of the GL, a few steps need to be taken. First, recall that—according to the proof of Lemma 15—it is possible to explicitly build the inverse-consistent complement of the thresholded sample covariance matrix if its sparsity graph is acyclic. This matrix serves as a *certificate* to confirm that the explicit solution (13) indeed satisfies the KKT conditions for the GL. By adopting a similar approach, it will then be proved that if the support graph of the thresholded sample covariance matrix is sparse, but not necessarily acyclic, one can find an approximate inverse-consistent complement of the proposed closed-form solution to approximately satisfy the KKT conditions.

Definition 22 *Given a number $\epsilon \geq 0$, a $d \times d$ matrix B is called an ϵ-**relaxed inverse** of matrix A if $A \times B = I_d + E$ such that $|E_{ij}| \leq \epsilon$ for every $(i,j) \in \{1,2,...,d\}^2$.*

The next lemma offers optimality (KKT) conditions for the unique solution of the GL.

Lemma 23 (Sojoudi (2016)) *A matrix S^{opt} is the optimal solution of the GL if and only if it satisfies the following conditions for every $i, j \in \{1, 2, ..., d\}$*

$$(S^{opt})^{-1}_{ij} = \Sigma_{ij} \qquad \text{if} \quad i = j, \tag{14a}$$
$$(S^{opt})^{-1}_{ij} = \Sigma_{ij} + \lambda \times \text{sign}(S^{opt}_{ij}) \qquad \text{if} \quad S^{opt}_{ij} \neq 0, \tag{14b}$$
$$\Sigma_{ij} - \lambda \leq (S^{opt})^{-1}_{ij} \leq \Sigma_{ij} + \lambda \qquad \text{if} \quad S^{opt}_{ij} = 0, \tag{14c}$$

where $(S^{opt})^{-1}_{ij}$ denotes the $(i,j)^{th}$ entry of $(S^{opt})^{-1}$.

The following definition introduces a relaxed version of the first-order optimality conditions given in (14).

Definition 24 *Given a number $\epsilon \geq 0$, it is said that the $d \times d$ matrix A satisfies the **ϵ-relaxed KKT conditions** for the GL problem if there exists a $d \times d$ matrix B such that*

- *B is an ϵ-relaxed inverse of the matrix A.*
- *The pair (A, B) satisfies the conditions*

$$B_{ij} = \Sigma_{ij} \qquad \text{if} \quad i = j, \tag{15a}$$
$$|B_{ij} - (\Sigma_{ij} + \lambda \times \text{sign}(A_{ij}))\,| \leq \epsilon \qquad \text{if} \quad A_{ij} \neq 0, \tag{15b}$$
$$|B_{ij} - \Sigma_{ij}| \leq \lambda + \epsilon \qquad \text{if} \quad A_{ij} = 0. \tag{15c}$$

By leveraging the above definition, the objective is to prove that the explicit solution introduced in (13) satisfies the ϵ-relaxed KKT conditions for some number ϵ to be defined later.

Definition 25 *Given a graph $\mathcal{G}$, define the function $c(\mathcal{G})$ as the length of the minimum-length cycle of $\mathcal{G}$ (the number $c(\mathcal{G})$ is set to $+\infty$ if $\mathcal{G}$ is acyclic). Let $\deg(\mathcal{G})$ refer to the maximum degree of $\mathcal{G}$. Furthermore, define $\mathcal{P}_{ij}(\mathcal{G})$ as the set of all simple paths between nodes i and j in $\mathcal{G}$, and denote the maximum of $|\mathcal{P}_{ij}(\mathcal{G})|_0$ over all pairs (i,j) as $P_{\max}(\mathcal{G})$.*

Define $\Sigma_{\max}$ and $\Sigma_{\min}$ as the maximum and minimum diagonal elements of Σ, respectively.

Theorem 26 *Under the assumption $\lambda < \sigma_1$, the explicit solution (13) satisfies the ϵ-relaxed KKT conditions for the GL with ϵ chosen as*

$$\epsilon = \max\left\{\Sigma_{\max}, \sqrt{\frac{\Sigma_{\max}}{\Sigma_{\min}}}\right\} \cdot \delta \cdot (P_{\max}(\text{supp}(\Sigma^{\text{res}})) - 1) \cdot \left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\left\lceil \frac{c(\text{supp}(\Sigma^{\text{res}}))}{2} \right\rceil}, \tag{16}$$

where

$$\delta = 1 + \frac{\deg(\text{supp}(\Sigma^{\text{res}})) \cdot \|\tilde{\Sigma}^{\text{res}}\|^2_{\max}}{1 - \|\tilde{\Sigma}^{\text{res}}\|^2_{\max}} + \frac{(\deg(\text{supp}(\Sigma^{res})) - 1)}{1 - \|\tilde{\Sigma}^{\text{res}}\|^2_{\max}}, \tag{17}$$

if the following conditions are satisfied:

- **Condition 3-i.** *$I_d + \tilde{\Sigma}^{\text{res}}$ is positive-definite.*

- **Condition 3-ii.** $\|\tilde{\Sigma}^{\text{res}}\|^2_{\max} \leq \min\limits_{\substack{i \neq j \\ (i,j) \notin \text{supp}(\Sigma^{\text{res}})}} \frac{\lambda - |\Sigma_{ij}|}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}$.

The number ϵ given in Theorem 26 is comprised of different parts:

- $\|\tilde{\Sigma}^{\text{res}}\|_{\max}$: Notice that $\|\tilde{\Sigma}^{\text{res}}\|_{\max}$ is strictly less than 1 and λ is large when a sparse graph is sought. Therefore, $\|\tilde{\Sigma}^{\text{res}}\|_{\max}$ is expected to be small for sparse graphs. Under this assumption, we have $0 \leq \|\tilde{\Sigma}^{\text{res}}\|_{\max} \ll 1$.
- $c(\text{supp}(\Sigma^{\text{res}}))$: It is straightforward to verify that $c(\text{supp}(\Sigma^{\text{res}}))$ is a non-decreasing function of λ. This is due to the fact that as λ increases, $\Sigma^{\text{res}}(\lambda)$ becomes sparser and this results in a support graph with fewer edges. In particular, if $d \geq 3$, then $c(\text{supp}(\Sigma^{\text{res}})) = 3$ for $\lambda = 0$ and $c(\text{supp}(\Sigma^{\text{res}})) = +\infty$ for $\lambda = \sigma_1$ almost surely.
- $P_{\max}(\text{supp}(\Sigma^{\text{res}}))$ and $\deg(\text{supp}(\Sigma^{\text{res}}))$: These two parameters are also non-decreasing functions of λ and likely to be small for large λ. For a small λ, the numbers $P_{\max}(\text{supp}(\Sigma^{\text{res}}))$ and $\deg(\text{supp}(\Sigma^{\text{res}}))$ could be on the order of $\mathcal{O}(d!)$ and $\mathcal{O}(d)$, respectively. However, these values are expected to be small for sparse graphs. In particular, it is easy to verify that for nonempty and acyclic graphs, $P_{\max}(\text{supp}(\Sigma^{\text{res}})) = 1$.

The above observations imply that if λ is large enough and the support graph of Σ^{res} is sparse, (13) serves as a good approximation of the optimal solution of the GL. In other words, it results from (16) that if $\text{supp}(\Sigma^{\text{res}})$ has a structure that is close to an acyclic graph, i.e., it has only a few cycles with moderate lengths, we have $\epsilon \approx 0$. In Section 4, we will present illustrative examples to show the accuracy of the closed-form approximate solution with respect to the size of the cycles in the sparsity graph.

Consider the matrix A given in (13), and let $\mu_{\min}(A)$ and $\mu_{\max}(A)$ denote its minimum and maximum eigenvalues, respectively. If $\lambda = \sigma_1$, then $A = D^{-1}$ (recall that D collects the diagonal entries of Σ) and subsequently $\mu_{\min}(A) > 0$. Since $\mu_{\min}(\cdot)$ is a continuous function of λ, there exists a number λ_0 in the interval $(0, 1)$ such that the matrix A (implicitly defined based on λ) is positive-definite for every $\lambda \geq \lambda_0$. The following theorem further elaborates on the connection between the closed-form formula and the optimal solution of the GL.

Theorem 27 *There exists an strictly positive number λ_0 such that, for every $\lambda \geq \lambda_0$, the matrix A given in (13) is the optimal solution of the GL problem after replacing Σ with some perturbed matrix $\hat{\Sigma}$ that satisfies the inequality*

$$\|\Sigma - \hat{\Sigma}\|_2 \leq d_{\max}(A) \left(\frac{1}{\mu_{\min}(A)} + 1\right) \epsilon, \tag{18}$$

where $d_{\max}(A)$ is the maximum vertex cardinality of the connected components in the graph $\text{supp}(A)$ and ϵ is given in (16). Furthermore, 18 implies that

$$f(A) - f^* \leq \left(\mu_{\max}(A) + \mu_{\max}(S^{\text{opt}})\right) d_{\max}(A) \left(\frac{1}{\mu_{\min}(A)} + 1\right) \epsilon, \tag{19}$$

where $f(A)$ and f^* are the objective functions of the GL evaluated at A and the optimal solution, respectively.

As mentioned before, if a sparse solution is sought for the GL, the regularization coefficient would be large and this helps with the satisfaction of the inequality $\lambda \geq \lambda_0$. In fact, it will be shown through different simulations that λ_0 is small in practice and hence, this condition is not restrictive. Under this circumstance, Theorem 27 states that the easy-to-construct matrix A is 1) the exact optimal solution of the GL problem with a perturbed sample covariance matrix, and 2) it is the approximate solution of the GL with the original sample covariance matrix. The magnitudes of this perturbation and approximation error are a function of $d_{\max}(A)$, $\mu_{\min}(A)$, $\mu_{\max}(A)$, $\mu_{\max}(S^{\text{opt}})$, and ϵ. Furthermore, it should be clear that A and ϵ are functions of λ and Σ (we dropped this dependency for simplicity of notation). Recall that the disjoint components (or the vertex partitions) of $\text{supp}(A)$ satisfy a nested property: given $1 \geq \lambda_1 > \lambda_2 \geq 0$, the components of $\text{supp}(A)$ for $\lambda = \lambda_1$ are nested within the components of $\text{supp}(A)$ for $\lambda = \lambda_2$ (see Mazumder and Hastie (2012) for a simple proof of this statement). This implies that $d_{\max}(A)$ is a decreasing function of λ. In particular, it can be observed that $d_{\max}(A) = d$ if $\lambda = 0$ and $d_{\max}(A) = 1$ if $\lambda = \sigma_1$. Now, consider $\mu_{\min}(A)$, $\mu_{\max}(A)$, and $\mu_{\max}(S^{\text{opt}})$. First, note that if $\lambda = \sigma_1$, then $A = S^{\text{opt}} = D^{-1}$. Furthermore, it is easy to verify that both A and S^{opt} are continuous functions of λ. Therefore, for large values of λ, $\mu_{\min}(A)$, $\mu_{\max}(A)$, and $\mu_{\max}(S^{\text{opt}})$ are expected to be close to $1/\Sigma_{\max}$, $1/\Sigma_{\min}$, and $1/\Sigma_{\min}$, respectively. In addition, as discussed earlier, ϵ is a decreasing function of λ and vanishes when λ is large enough. Based on these observations, it can be concluded that the upper bound presented in (18) is small if λ is chosen to be large.

Notice that although the aforementioned value of ϵ in (16) and the upper bound in (18) were essential in the study of the effect of the sparsity of the support graph on the accuracy of the presented closed-form solution, they are conservative in practice. These numbers may be tightened significantly for specific sample covariance matrices. We will further discuss the approximation error of the closed-form solution in Section 4.

Warm-start algorithm As delineated before, one of the main strengths of the proposed closed-form solution is that it can be used as an initial point (warm-start) for the numerical algorithms specialized for solving the GL. To this goal, the following warm-start procedure is proposed.

Algorithm 1: Warm-start algorithm

Data: data samples ($\mathbf{x}$), and regularization coefficient (λ)
Result: Solution of the GL (S^{opt})

```
Obtain the residue matrix Σ^res based on Definition 11 and the closed-form solution
  A from (13);
for each component i in supp(Σ^res) do
    if Conditions 2-i, 2-ii, 2-iii are satisfied then
        S^opt[i] ← A[i];
    else
        Find S^opt[i] by numerically solving the GL for component i with initial
          point A[i];
    end
end
```

In the above algorithm, $S^{\text{opt}}[i]$ and $A[i]$ are the submatrices of S^{opt} and A corresponding to the i^{th} component of $\text{supp}(\Sigma_{\text{res}})$. The warm-start algorithm is based on the key fact that the GL decomposes over the disjoint components of $\text{supp}(\Sigma_{\text{res}})$ (Mazumder and Hastie 2012; Witten et al. 2011). In particular, in the first step, the warm-start algorithm obtains the residue matrix according to Definition 11. Next, for every disjoint component of the residue matrix, if its support graph is acyclic and the conditions of Theorem 19 are satisfied, then the corresponding component in S^{opt} is found using the closed-form solution (11). Otherwise, this closed-form solution is provided as an initial point to a numerical algorithm, such as GLASSO and QUIC Friedman et al. (2008); Hsieh et al. (2014), in order to boost the runtime of solving the GL for the considered component. The results of the warm-start algorithm will be evaluated in the next section.

Remark 28 *The statistical analysis of the GL entails that λ should converge to zero as the number of samples grows to infinity. It is worthwhile to mention that our results may not be applicable in the high sampling regime, where λ is close to zero and consequently the thresholded sample covariance matrix is dense. However, notice that the main strength of the GL lies in the high dimensional-low sampling regime where n is much smaller than d and is in the order of $\log d$. Under such circumstances, the proposed explicit formula results in highly accurate solutions for the GL. In fact, it will be shown through massive-scale simulations that in practice, the required conditions on λ—such as the positive-definiteness of $I_d + \tilde{\Sigma}^{\text{res}}$—for the validity of the presented results are much more relaxed than the known conditions on λ to guarantee the statistical consistency of the GL.*

4. Numerical Results

In this section, we will demonstrate the effectiveness of the proposed methods on synthetically generated data, as well as on real data collected from the brain networks and transportation systems.

4.1. Case Study on Synthetic Data

Given a nonnegative number ω, consider an arbitrary sample covariance matrix Σ with the following properties:

- Its diagonal elements are normalized to 1.
- The entries corresponding to an arbitrary spanning tree of $\text{supp}(\Sigma)$ belong to the union of the intervals $[-0.85, -0.95]$ and $[0.85, 0.95]$.
- The off-diagonal entries that do not belong to the spanning tree are in the interval $[-0.85 + \omega, 0.85 - \omega]$.

The goal is to find conditions on λ, ω and the size of the covariance matrix such that Theorem 19 can be used to obtain a closed-form solution for the GL problem. One can choose the value of λ to be greater than σ_d to ensure that the graph $\text{supp}(\Sigma^{\text{res}})$ is acyclic. In particular, if we pick λ in the interval (σ_d, σ_{d-1}), the graph $\text{supp}(\Sigma^{\text{res}})$ becomes a spanning tree.

Select λ as $0.85 - \epsilon$ for a sufficiently small number ϵ and consider Condition (2-ii) in Theorem 19. One can easily verify that $I_d + \Sigma^{\text{res}}$ is positive-definite if the inequality

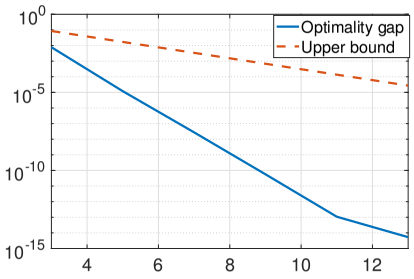

Figure 1: The optimality gap between the closed-form and optimal solutions for the GL

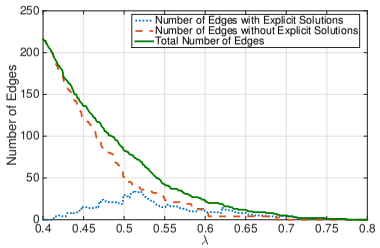
$\frac{1}{\deg(v)} > (\sigma_1 - \lambda)^2$ holds for every node v in $\text{supp}(\Sigma^{\text{res}})$, where $\deg(v)$ is the degree of node v. This condition is guaranteed to be satisfied for all possible acyclic graphs if $(\deg(v))(0.95 - 0.85)^2 < 1$ or equivalently $\deg(v) \leq 100$ for every node v. Regarding Condition (2-iii), it can be observed that the relation $(\sigma_1 - \lambda)^2 \leq \lambda - \sigma_{k+1}$ holds if $(0.95 - 0.85)^2 < 0.85 - (0.85 - \omega)$. This implies that the inequality $\omega > 0.01$ guarantees the satisfaction of Condition (2-iii) for every acyclic graph $\text{supp}(\Sigma^{\text{res}})$. In other words, one can find the optimal solution of the GL problem using the explicit formula in Theorem 19 as long as: 1) a spanning tree structure for the optimal solution of the GL problem is sought, 2) the degree of each node in the spanning tree is not greater than 100, and (3) the difference between σ_{d-1} and σ_d is greater than 0.01. Note that Condition (2) is conservative and can be dropped for certain types of graphs (e.g., path graphs). In practice, the positive-definiteness of $I_d + \Sigma^{\text{res}}$ is not restrictive; we have verified that this matrix is positive-definite for randomly generated instances with the sizes up to $d = 200,000$ even when $\deg(v) > 100$.

Now, consider the following modifications in the experiment:

- The elements of Σ corresponding to a cycle of length d are randomly set to -0.8 or 0.8 with equal probability.
- The off-diagonal entries that do not correspond to the above cycle are in the interval $[-0.7, 0.7]$.

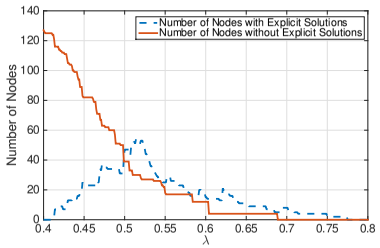
If λ is chosen as 0.75, then the graph $\text{supp}(\Sigma^{\text{res}})$ coincides with a cycle of length d. Furthermore, $I_d + \Sigma^{\text{res}}$ is diagonally dominant and hence positive-definite for every d. Figure 1 shows the optimality gap of the proposed closed-form solution and its derived theoretical upper bound (i.e. the left and right hand sides of (19), respectively) with respect to the length of the cycle d in log-linear scale. (note that $\deg(\text{supp}(\Sigma^{\text{res}}))$ and $P_{\max}(\text{supp}(\Sigma^{\text{res}}))$ in (19) are both equal to 2). Two important observations can be made based on this figure.

- In practice, the performance of the derived closed-form solution is significantly better than its theoretical upper bounds. In fact, this error is less than 10^{-6} when the length of the minimum-length cycle is at least 6. The high accuracy of the closed-form solution will become more evident in the subsequent case studies on large-scale problems.



- It can be seen that the logarithm of the optimality gap is approximately a linear function of the cycle length. This matches the behavior of the theoretical bounds introduced in Theorems 26 and 27: the approximation error is exponentially decreasing with respect to the length of the minimum-length cycle.

4.2. Case Study on Brain Networks



Consider the problem of estimating the brain functional connectivity network based on a set of resting state functional MRI (fMRI) data collected from 20 individual subjects (Vértes et al., 2012). The data for each subject correspond to disjoint brain activities and are correlated due to the underlying functional connectivity structure of the brain. In order to represent these dependencies, each disjoint region of the brain can be considered as a node and the correlation between two different regions can be resembled by an edge between the nodes. The data set for each subject consists of 134 samples of low frequency oscillations taken from 140 different cortical brain regions. We construct a normalized sample covariance matrix by combining the data sets of all 20 subjects (note that the data for each individual is limited and not informative enough, but the combined data provides rich information about the brain network). The goal is to use the GL to estimate the underlying functional connectivity network of different regions of the brain based on the obtained 140×140 sample covariance matrix. We study the thresholded sample covariance matrix and the derived closed-form solution for different values of the regularization coefficient in order to analyze their accuracy.

Figure 2a shows the number of edges in the sparsity graph of the thresholded sample covariance matrix that belong to those connected components satisfying the conditions in Theorem 19. The formula derived in this paper is able to find the optimal values of the entries of the solution corresponding to these edges. It can be observed that if λ is greater than 0.51, then almost half of the edges in the sparsity graph of the optimal solution can be found using the proposed explicit formula. This is due to the fact that the corresponding entries in the residue matrix belong to the acyclic components of its sparsity graph and satisfy the conditions of Theorem 19. Figure 2b depicts the number of nodes that belong to the components (with sizes greater than 1) for which the corresponding submatrices of the solution of the GL have an explicit formula. Note that those entries in the optimal solution that correspond to isolated nodes are trivially equal to 0. Therefore, in order to better reflect the significance of the derived solution, we have only considered the components with at least two nodes. It can be observed that if λ is greater than 0.5, then the number of nodes belonging to the components with explicit formula is greater than the number of those nodes associated with inexact closed-form solutions. Figure 2c demonstrates the number of edges in the sparsity graph of the optimal solution, together with the number of mismatches in the edge sets of the sparsity graphs of the optimal and thresholded solutions. Notice that the number of mismatches is less than 10% when λ is greater than 0.35 and is almost 0 when λ is greater than 0.5.

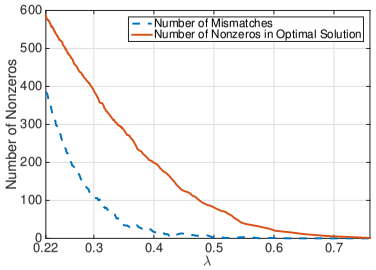


Figure 2d shows the minimum eigenvalues of the optimal and closed-form approximate solutions for different values of λ. The approximate solution is positive-definite when λ is greater than 0.37. This implies that λ_0 in Corollary 27 is equal to 0.37. Figures 2e and 2f depict the 2-norm of the approximation error (the difference between the optimal and closed-

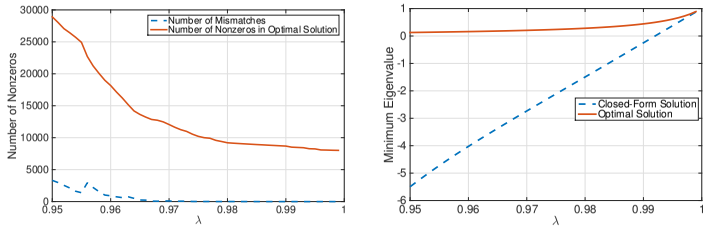
Figure 2: a) Number of edges in the sparsity graph of the closed-form approximate solution whose corresponding entries are guaranteed to be equal to those in the sparsity graph of the optimal solution due to Theorem 19. b) Number of nodes that belong to the components for which the corresponding submatrices of the optimal solution have explicit formulas. c) Number of edges in the sparsity graph of the optimal solution, compared to the number of mismatches. d) Minimum eigenvalues of the optimal and closed-form approximate solutions. e) The 2-norm of the difference between the optimal and approximate solutions. f) The similarity degree between the optimal and approximate solutions.

form approximate solutions) and the similarity degree between these two solutions, which is defined as

$$\text{similarity degree} = \frac{\text{trace}(\tilde{S}^{\text{opt}} \times \tilde{A})}{\|\tilde{S}^{\text{opt}}\|_F \times \|\tilde{A}\|_F},$$

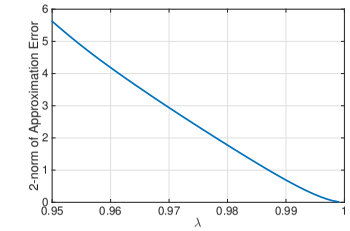
where $\tilde{S}^{\text{opt}} = S^{\text{opt}} - I_d$ and $\tilde{A} = A - I_d$. Subtracting the identity matrix from A and S^{opt} is due to the observation that both matrices have diagonal entries close to 1 when the support graph is sparse. This leads to an artificially inflated similarity degree between A and S^{opt}. Therefore, in order to have a better assessment of the similarity between the closed-form and optimal solutions, we measure the similarity between A and S^{opt} after softening the effect of their diagonal entries. The similarity degree of 1 means that the optimal and approximate solutions are exactly equal.



It can be observed that the approximation error is small and the similarity degree is high for a wide range of values of λ. For instance, if λ is greater than 0.4, then the 2-norm of the approximation error is less than 0.37 and the similarity degree is greater than 0.98. For these values of λ, the number of edges in the sparsity graph of the optimal solution ranges from 200 to 0. In all of these cases, the structure and values of the optimal solution can be estimated efficiently, without solving the optimization problem numerically.

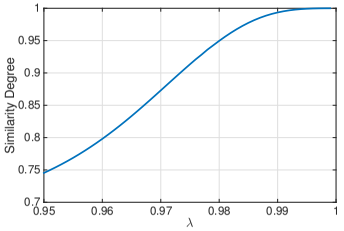
4.3. Case Study on Transportation Networks

In recent years, the problem of short- and long-term traffic flow prediction and control has attracted much attention in Intelligent Transportation Systems (ITSs) (Figueiredo et al. 2001). Estimating the correlation between the traffic flows on different links of a transportation network is one of the crucial steps toward the traffic congestion control in the network; it can also serve as an initial block in different traffic forecasting methods. Substantial research has been devoted to extracting these dependencies and performing predictions based on the measured data (see Yin et al. (2017); Nassiri and Aghamohammadi (2017); Sun et al. (2012) and the references therein). In this case study, the objective is to construct a sparse matrix representing the conditional covariance between the traffic flows of different links in the network. The data is collected from the Caltrans Performance Measurement System (PeMS) database, which consists of traffic information of freeways on the a statewide scale across California (PeM 2017). We consider the data measured by the stations deployed in District 3 of California, which is collected and aggregated every 5 minutes from 1277 stations during March 6^{th} to March 12^{th} of the year 2017 (one-week interval). Due to the malfunctioning of some of the detectors, a non-negligible portion of the traffic flows was missing from the raw data set. Therefore, the following steps were taken before solving the GL problem in order to obtain a useful representation of the raw data:



- Since 228 stations did not have sufficient number of measurements during the one-week period, they were removed from the sampled data.
- In a few stations, the detectors did not measure the traffic flow for some periods of time. For these data samples, we used a linear interpolation method to estimate the missing values.

After performing the aforementioned data-cleaning steps, a 1049×1049 normalized sample covariance matrix was constructed from the combined 2016 data samples (288 samples for



(a) Number of nonzeros and mismatches

(b) Minimum eigenvalue

(c) 2-norm of the approximation error

(d) Similarity degree

Figure 3: a) Number of edges in the sparsity graph of the optimal solution, compared to the number of mismatches. b) Minimum eigenvalues of the optimal and closed-form approximate solutions. c) The 2-norm of the difference between the optimal and approximate solutions. d) The similarity degree between the optimal and approximate solutions.

each day of the week). In Figure 3, the accuracy of the thresholding technique and its corresponding closed-form approximate solution is compared to the optimal solution of the GL problem for different values of the regularization coefficient.

Since the number of entries in the upper triangular part of the sample covariance matrix is large (roughly 550,000 entries), we have only considered large values of λ in order to obtain a sparse solution for the GL. Figure 3a shows the number of edges in the sparsity graph of the optimal solution, compared to the number of mismatches between the edge sets of the sparsity graphs of the optimal and closed-form solutions. It can be observed that as λ increases, the support graph of the optimal solution becomes sparser and the number of mismatches decreases. In particular, the number of mismatches is almost zero if λ is chosen to be greater than 0.97. Figure 3b depicts the minimum eigenvalues of the optimal and closed-form approximate solutions of the GL with respect to λ. The approximate solution becomes positive-definite if λ is greater than 0.991. Furthermore, Figures 3c and 3d show that, for those values of λ between 0.991 and 0.999, the 2-norm of the approximation error is between 0.5 and 0.01, and that the similarity degree is greater than 0.99. For this range of λ, the number of edges in the sparsity graph of the optimal solution is 7.82 to 7.40 times higher the number of nodes.

4.4. Case Study on Large-Scale Data

In this case study, we evaluate the performance of the proposed closed-form solution on massive randomly generated data sets. Given d (the dimension of each sample) and similar to Hsieh et al. (2014) and Yun and Toh (2011), a sparse inverse covariance matrix is generated for each test case according to the following procedure: first, a sparse matrix $U \in \mathbb{R}^{d\times d}$ is generated whose nonzero elements are randomly set to $+1$ or -1, with equal probability. Then, the inverse covariance matrix is set to $UU^\top + 2I$. Depending on the test case, the number of nonzero elements in U is controlled so that the resulted inverse covariance matrix has approximately $5d$ or $10d$ nonzero elements. $n = d/2$ number of i.i.d. samples are drawn from the corresponding multivariate Gaussian distribution in all experiments, except for the largest test case with $d = 80000$. This instance has more than 3.2 billion variables and only $n = 20000$ samples are collected to solve the GL due to the memory limitations. Furthermore, the regularization coefficient is chosen such that the estimated solution has approximately the same number of nonzero elements as the ground truth.

Table 1 reports the runtime of the closed-form solution, compared to two state-of-the-art methods for solving the GL, namely QUIC (Hsieh et al. 2014) and GLASSO (Friedman et al. 2008) algorithms, as well as elementary estimator (Yang et al. 2014). The GLASSO is the most widely-used algorithm for the GL, while the QUIC algorithm is commonly regarded as the fastest available solver for this problem. The elementary estimator is recently proposed in lieu of the GL to remove its computational burden, while preserving its desired high-dimensional properties. We use the source codes for latest versions of QUIC and GLASSO in our simulations. In particular, we use the QUIC 1.1 (available in `http://bigdata.ices.utexas.edu/software/1035/`) which is implemented in $C++$ with MATLAB interface. The GLASSO is downloaded from `http://statweb.stanford.edu/~tibs/glasso/` and is implemented in FORTRAN with MATLAB interface. We implemented the elementary estimator and the proposed closed-form solution in MATLAB using its sparse package. A time limit of 4 hours is considered in all experiments. Table 1 has the following columns:

- d: The dimension of the samples.
- m: The number of nonzero elements in the true inverse covariance matrix.
- Closed-form: The runtime of the proposed method.
- QUIC-C and GLASSO-C: The runtime of the QUIC and GLASSO without initialization.
- QUIC-W and GLASSO-W: The runtime of the QUIC and GLASSO using the warm-start Algorithm 1.
- Elem.: The runtime of the elementary estimator.

In all of the test cases, the resulted closed-form solution is positive-definite and hence, feasible. It can be seen that the proposed method significantly outperforms QUIC, GLASSO and elementary estimator in terms of its runtime. In particular, the presented method is on average 6, 36, and 951 times faster than elementary, QUIC, and GLASSO methods, respectively, provided that they can obtain the solution within the predefined time limit.

80000	401798	1450.4	⋆	⋆	⋆	⋆	⋆

Table 1: The runtime of different methods.

Furthermore, for the cases where the GL can be solved to optimality using QUIC, the relative optimality gap of the closed-form solution, i.e., $(f(A) - f^*)/f^*$, is 2.1×10^{-3} on average. For the cases with $d = 40000$ and $d = 80000$, none of these methods converge to a meaningful solution, while the proposed method can obtain an accurate solution in less than 30 minutes. On the other hand, the warm-start Algorithm 1 accompanied by QUIC and GLASSO yields up to 2.35 and 4.45 times speedups in their runtime, respectively. Moreover, the warm-start algorithm doubles the size of the instances that are solvable using the GLASSO.

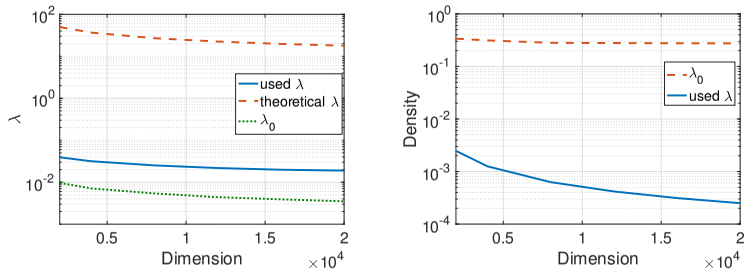

Table 2 compares the accuracy of the estimated inverse covariance matrix using different methods. This table includes the following columns:

- ℓ_F: The Frobenius norm of the difference between the true and estimated inverse covariance matrices, normalized by the Frobenius norm of the true inverse covariance matrix.
- TPR and FPR: The true positive rate (TPR) and false positive rate (FPR) defined as

$$\text{TPR} = \frac{\left|(i,j) : i \neq j, S_{ij} \neq 0, (\Sigma_*^{-1})_{ij} \neq 0\right|_0}{\left|(i,j) : i \neq j, (\Sigma_*^{-1})_{ij} \neq 0\right|_0},$$
$$\text{FPR} = \frac{\left|(i,j) : i \neq j, S_{ij} \neq 0, (\Sigma_*^{-1})_{ij} = 0\right|_0}{\left|(i,j) : i \neq j, (\Sigma_*^{-1})_{ij} = 0\right|_0},$$

  where S corresponds to the explicit formula, the optimal solution of the GL, or the elementary estimator.

It can be seen that, while the elementary estimator has slightly better estimation error, its TPR is significantly outperformed by the those of the GL and closed-form solutions. Furthermore, it can be seen that the closed-form estimator has almost the same accuracy as the optimal solution of the GL. The superiority of the proposed closed-form solution

(a) Different values of λ

(b) Density of the thresholded sample covariance matrix

Figure 4: a) Values of λ_0, used λ, and theoretical λ, b) The density of the true inverse and thresholded sample covariance matrices.

over the other methods becomes more evident in the larger instances, where it (almost) exactly recovers the true sparsity pattern of the inverse covariance matrix and results in small estimation error, while becoming the only viable method for estimating the inverse covariance matrix.

Finally, we show that the requirement $\lambda \geq \lambda_0$ in Theorem 27 does not impose any restriction on the practicality of this theorem under the finite-sampling regime. In particular, we show that in practice, the lower bound λ_0 on λ is significantly smaller than the theoretical value of λ that is derived for the high-dimensional consistency of the GL. To this goal, we compare λ_0 with the theoretical value of λ introduced in the seminal paper Ravikumar et al. (2011). In particular, Ravikumar et al. (2011) shows that the following value for λ is sufficient to guarantee consistency

$$\lambda = \frac{8}{\alpha}\sqrt{128(1+4\sigma^2)^2 \max(\Sigma_*)_{ii}^2}\sqrt{\frac{\log d + \log 4}{n}}, \tag{20}$$

where α is the mutual incoherence parameter, σ is the sub-Gaussian parameter of normalized random variables, and $(\Sigma_*)_{ii}$ is the i^{th} diagonal element of the true covariance matrix. Figure 4a shows the values for λ_0, theoretical λ defined as (20), and λ used in our simulations with respect to the dimension of the problem. On average, λ_0 is 640 and 6 times smaller than the theoretical and used λ, respectively. Furthermore, Figure 4b shows the density (the number of nonzero elements, normalized by the total number of entries) of the thresholded sample covariance matrix when λ is set to λ_0, compared to the density of the true inverse covariance matrix. Note that when $\lambda = \lambda_0$, the density of the thresholded sample covariance matrix is close to 0.3 on average while the average density of the true inverse covariance matrix is less than 0.0009. Based on these simulations, one can infer that λ_0 is an underestimator for the values of the regularization coefficient that correctly promote sparsity in the estimated solution, and the requirement $\lambda \geq \lambda_0$ is extremely mild for large-scale instances of the GL.

5. Conclusions

Graphical Lasso (GL) is a popular method for finding the conditional independence between the entries of a random vector. This technique aims at learning the sparsity pattern of the inverse covariance matrix from a limited number of samples, based on the regularization of a positive-definite matrix. Motivated by the computational complexity of solving the GL for large-scale problems, this paper provides conditions under which the GL behaves the same as the simple method of thresholding the sample covariance matrix. The conditions make direct use of the sample covariance matrix and are not based on the solution of the GL. More precisely, it is shown that the GL and thresholding techniques are equivalent if: (i) a certain matrix formed based on the sample covariance matrix is both sign-consistent and inverse-consistent, and (ii) the gap between the largest thresholded and the smallest un-thresholded entries of the sample covariance matrix is not too small. Although the GL is believed to be a difficult conic optimization problem, it is proved that it indeed has a closed-form solution in the case where the sparsity pattern of the solution is known to be acyclic. This result is then extended to general sparse graphs and an explicit formula is derived as an approximate solution of the GL, where the approximation error is also quantified in terms of the structure of the sparsity graph. The significant speedup and graceful scalability of the proposed explicit formula compared to other state-of-the-art methods is showcased on different real-world and randomly generated data sets.

Appendix

In what follows, the omitted technical proofs will be presented. A number of lemmas are required for this purpose.

Before presenting the proof of Theorem 12, consider the *normalized GL*, defined as

$$\min_{S\in\mathbb{S}^d_+} -\log\det(S)+\text{trace}(\tilde{\Sigma}S)+\sum_{i\neq j}\tilde{\lambda}_{ij}|S_{ij}|, \tag{21}$$

where $\tilde{\Sigma}$ is the normalized sample covariance, i.e., $\tilde{\Sigma}_{ij}=\frac{\Sigma_{ij}}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}$ for every $(i,j)\in\{1,2,...,d\}^2$ (also known as sample correlation matrix). Similarly, $\tilde{\lambda}_{ij}$ is defined as $\frac{\lambda}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}$. Upon denoting the optimal solution of the normalized GL as $\tilde{S}$, we consider the relationship between $\tilde{S}$ and S^{opt}. Recall that D is defined as a matrix collecting the diagonal elements of Σ.

Lemma 29 *We have* $S^{\text{opt}}=D^{-1/2}\tilde{S}D^{-1/2}$.

Proof Notice that the GL (2) can be re-written as follows

$$\min_{S\in\mathbb{S}^d_+} -\log\det(S)+\text{trace}(\tilde{\Sigma}D^{1/2}SD^{1/2})+\sum_{i\neq j}\lambda|S_{ij}|, \tag{22}$$

where we have used the equality

$$\text{trace}(\Sigma S)=\text{trace}(D^{1/2}\tilde{\Sigma}D^{1/2}S)=\text{trace}(\tilde{\Sigma}D^{1/2}SD^{1/2}).$$

Upon defining

$$\tilde{S}=D^{1/2}SD^{1/2} \tag{23}$$

and following some algebra, one can verify that (22) is equivalent to

$$\min_{\tilde{S}\in\mathbb{S}^d_+} -\log\det(\tilde{S})+\text{trace}(\tilde{\Sigma}\tilde{S})+\sum_{i\neq j}\tilde{\lambda}_{ij}|\tilde{S}_{ij}|+\log\det(D). \tag{24}$$

Dropping the constant term in (24) gives rise to the normalized GL (21). Therefore, $S^{\text{opt}}=D^{-1/2}\tilde{S}D^{-1/2}$ holds in light of 23. This completes the proof. ■

Proof of Theorem 12 Note that, due to the Definition 11 and Lemma 29, $\tilde{\Sigma}^{\text{res}}$ and $\tilde{S}$ have the same sparsity pattern as Σ^{res} and S^{opt}, respectively. Therefore, it suffices to show that the sparsity structures of $\tilde{\Sigma}^{\text{res}}$ and $\tilde{S}$ are the same.

To verify this, we focus on the optimality conditions for optimization (21). Define M as $I_d+\tilde{\Sigma}^{\text{res}}$. Due to Condition (1-i) and Lemma 6, M is inverse-consistent and has a unique inverse-consistent complement, which is denoted by N. First, will show that $(M+N)^{-1}$ is the optimal solution of (21). For an arbitrary pair $(i,j)\in\{1,...,d\}^2$, the KKT conditions, introduced in Lemma 23, imply that one of the following cases holds:

1) $i=j$: We have $(M+N)_{ij}=M_{ii}=\tilde{\Sigma}_{ii}$.

2) $(i,j) \in \text{supp}(\tilde{\Sigma}^{\text{res}})$: In this case, we have

$$(M+N)_{ij} = M_{ij} = \tilde{\Sigma}_{ij} - \tilde{\lambda}_{ij} \times \text{sign}(\tilde{\Sigma}_{ij}).$$

Note that since $|\Sigma_{ij}| > \lambda$, we have that $\text{sign}(M_{ij}) = \text{sign}(\tilde{\Sigma}_{ij})$. On the other hand, due to the sign-consistency of M, we have $\text{sign}(M_{ij}) = -\text{sign}\left(\left((M+N)^{-1}\right)_{ij}\right)$. This implies that

$$(M+N)_{ij} = M_{ij} = \tilde{\Sigma}_{ij} + \tilde{\lambda}_{ij} \times \text{sign}((M+N)^{-1}).$$

3) $(i,j) \notin \text{supp}(\tilde{\Sigma}^{\text{res}})$: One can verify that $(M+N)_{ij} = N_{ij}$. Therefore, due to Condition (1-iii), we have

$$\begin{aligned} |(M+N)_{ij}| &\leq \beta\left(\text{supp}(\tilde{\Sigma}^{\text{res}}), \|\tilde{\Sigma}^{\text{res}}\|_{\max}\right) \\ &\leq \min_{\substack{k\neq l \\ (k,l)\notin \text{supp}(\Sigma^{\text{res}})}} \frac{\lambda - |\Sigma_{kl}|}{\sqrt{\Sigma_{kk}\Sigma_{ll}}} \\ &= \min_{\substack{k\neq l \\ (k,l)\notin \text{supp}(\Sigma^{\text{res}})}} \tilde{\lambda}_{kl} - |\tilde{\Sigma}_{kl}|. \end{aligned} \tag{25}$$

This leads to

$$|(M+N)_{ij} - \tilde{\Sigma}_{ij}| \leq |(M+N)_{ij}| + |\tilde{\Sigma}_{ij}| \leq \min_{\substack{k\neq l \\ (k,l)\notin \text{supp}(\Sigma^{\text{res}})}} \left(\tilde{\lambda}_{kl} - |\tilde{\Sigma}_{kl}|\right) + |\tilde{\Sigma}_{ij}| \leq \tilde{\lambda}_{ij}. \tag{26}$$

Therefore, it can be concluded that $(M+N)^{-1}$ satisfies the KKT conditions for (21)[1]. On the other hand, note that $\text{supp}((\text{M}+\text{N})^{-1}) = \text{supp}(\tilde{\Sigma}^{\text{res}})$. This concludes the proof. ■

To proceed with the proof of Lemma 13, we need the following lemma.

Lemma 30 *Consider a matrix $M \in \mathbb{S}^d$ with positive-definite completion. Assume that $\|M^{(c)}\|_1 \leq \eta\|M - I_d\|_1$ and $\|M - I_d\|_1 < \frac{1}{\eta+1}$, for some number η. The relation*

$$\|M^{(c)}\|_1 \leq (1+\eta)^2 \frac{\|M - I_d\|_1^2}{1 - (\eta+1)\|M - I_d\|_1}$$

holds.

Proof Note that $M \in \mathbb{S}^d$ has a positive-definite completion and hence, is inverse-consistent due to Lemma 6. One can write

$$\|(M - I_d) + M^{(c)}\|_1 \leq \|M - I_d\|_1 + \|M^{(c)}\|_1 \leq (\eta+1)\|M - I_d\|_1 < 1.$$

Therefore,

$$\begin{aligned} (M + M^{(c)})^{-1} = (I_d + (M - I_d + M^{(c)}))^{-1} + I_d - (M - I_d + M^{(c)}) \\ + (M - I_d + M^{(c)})^2 \times \sum_{i=0}^{\infty} (-M + I_d - M^{(c)})^i. \end{aligned}$$

1. The KKT conditions for the normalized GL are equivalent to (14) after replacing λ with $\tilde{\lambda}_{ij}$

Since $\text{supp}((M + M^{(c)})^{-1}) \subseteq \text{supp}(M)$, it can be concluded that the (i,j) entries of $M^{(c)}$ and

$$(M - I_d + M^{(c)})^2 \times \sum_{i=0}^{\infty} (-M + I_d - M^{(c)})^i$$

are equal for every $(i,j) \in \text{supp}(M^{(c)})$. Since the (i,j) entry of $M^{(c)}$ is zero if $(i,j) \notin \text{supp}(M^{(c)})$, we have

$$\|M^{(c)}\|_1 \leq \left\| (M - I_d + M^{(c)})^2 \sum_{i=0}^{\infty} (M - I_d + M^{(c)})^i \right\|_1.$$

Since 1-norm is sub-multiplicative, the above inequality can be simplified as

$$\begin{aligned} \|M^{(c)}\|_1 &\leq (\|M - I_d\|_1 + \|M^{(c)}\|_1)^2 \times \sum_{i=0}^{\infty} (\|M - I_d\|_1 + \|M^{(c)}\|_1)^i \\ &= \frac{(\|M - I_d\|_1 + \|M^{(c)}\|_1)^2}{1 - \|M - I_d\|_1 - \|M^{(c)}\|_1} \\ &\leq \frac{(\|M - I_d\|_1 + \eta\|M - I_d\|\|_1)^2}{1 - \|M - I_d\|_1 - \eta\|M - I_d\|\|_1} \\ &= (1+\eta)^2 \frac{\|M - I_d\|_1^2}{1 - (\eta+1)\|M - I_d\|_1}. \end{aligned}$$

This completes the proof. ■

Proof of Lemma 13 Given an arbitrary graph $\mathcal{G}$, consider a matrix variable M with 1's on the diagonal such that $\text{supp}(M) \subseteq \mathcal{G}$. The first objective is to find a matrix in terms of M, denoted by the matrix function $N(M)$, satisfying the following properties

$$\begin{aligned} &\text{supp}\left((M + N(M))^{-1}\right) \subseteq \mathcal{G}, \\ &\text{supp}(N(M)) \subseteq \mathcal{G}^{(c)}. \end{aligned}$$

To this end, define the matrix function $A(M)$ as

$$A(M) = (M + N(M))^{-1}.$$

Observe that

- As long as $A(M)$ exists and $\text{supp}(A(M)) \subseteq \mathcal{G}$, there is a continuously differentiable mapping from $A(M)$ to M because M can be found by setting those entries of $A(M)^{-1}$ corresponding to the edges of $\mathcal{G}^{(c)}$ to zero. Moreover, the Jacobian of this mapping has full rank at $M = I_d$. Due to the inverse function theorem, the mapping from M to $A(M)$ exists and is continuously differentiable.
- Similarly, as long as $A(M)$ exists and $\text{supp}(A(M)) \subseteq \mathcal{G}$, there is a continuously differentiable mapping from $A(M)$ to $N(M)$.

- If $M = I_d$, then $N(M) = 0$.

It follows from the above properties that if M is sufficiently small, the function $N(M)$ exists and satisfies the following properties: (i) $0 = N(I_d)$, and (ii) $N(\cdot)$ is differentiable at $M = I_d$. This implies that there are sufficiently small nonzero numbers η and α_0 such that $\|N(M)\|_1 \leq \eta \|M - I_d\|_1$ whenever $\|M\|_{\max} \leq \alpha_0$. Now, it follows from Lemma 30 that

$$\|N(M)\|_1 \leq (1+\eta)^2 \frac{\|M - I_d\|_1^2}{1 - (\eta+1)\|M - I_d\|_1},$$

or

$$\|N(M)\|_{\max} \leq \frac{(1+\eta)^2 \times (\deg(\mathcal{G}))^2}{1 - (\eta+1)\alpha_0 \times \deg(\mathcal{G})} \|M\|_{\max}^2,$$

if $\|M\|_{\max} \leq \alpha_0$. The inequality (7) is satisfied for the number ζ defined as the maximum of

$$\frac{(1+\eta)^2 \times (\deg(\mathcal{G}))^2}{1 - (\eta+1)\alpha_0 \times \deg(\mathcal{G})}$$

and the finite number

$$\max \left\{ \frac{\beta(\mathcal{G}, \alpha)}{\alpha^2} \middle| \alpha \in (\alpha_0, 1) \right\}.$$

This completes the proof. ■

Proof of Lemma 14 It can be easily verified that

$$(M + M^{(c)})^{-1} = I - (M + M^{(c)} - I) + (M + M^{(c)})^{-1}(M + M^{(c)} - I)^2.$$

This implies that, for a given pair $(i, j) \in \mathcal{G}$, one can write

$$\left((M + M^{(c)})^{-1}\right)_{ij} = -M_{ij} + \left((M + M^{(c)})^{-1}\right)_{i:} \left((M + M^{(c)} - I)^2\right)_{:j}, \tag{28}$$

where $\left((M + M^{(c)})^{-1}\right)_{i:}$ and $\left((M + M^{(c)} - I)^2\right)_{:j}$ are the i^{th} row and j^{th} column of $(M + M^{(c)})^{-1}$ and $(M + M^{(c)} - I)^2$, respectively. Based on (28), the (i, j) entries of M and $(M + M^{(c)})^{-1}$ have opposite signs if

$$|M_{ij}| > \left| \left((M + M^{(c)})^{-1}\right)_{i:} \left((M + M^{(c)} - I)^2\right)_{:j} \right|. \tag{29}$$

To streamline the presentation, $\|M\|_{\max}$ is redefined as $\max_{i,j} |M_{ij}|$ in the rest of the proof. One can write

$$\begin{aligned}
\left\|(M+M^{(c)}-I)^2\right\|_{\max} &\leq \left\|(M-I)^2\right\|_{\max} + \left\|\left(M^{(c)}\right)^2\right\|_{\max} + \left\|M^{(c)}(M-I)\right\|_{\max} + \left\|(M-I)M^{(c)}\right\|_{\max} \\
&\leq \deg(\mathcal{G})\alpha^2 + (d - \deg(\mathcal{G}))\zeta(\mathcal{G})^2\alpha^4 + 2\deg(\mathcal{G})\zeta(\mathcal{G})\alpha^3 \\
&\leq 3\deg(\mathcal{G}) \max\{\alpha^2, \zeta(\mathcal{G})\alpha^3\} + (d - \deg(\mathcal{G}))\zeta(\mathcal{G})^2\alpha^4 \\
&\leq K\alpha^2,
\end{aligned} \tag{30}$$

for some K that only depends on $\deg(\mathcal{G}), \zeta(\mathcal{G})$, and d. Furthermore, assume that

$$\alpha \leq \frac{1}{2\deg(\mathcal{G})\sqrt{\zeta(\mathcal{G})}} = \alpha_0(\mathcal{G}). \tag{31}$$

Note that

$$(M + M^{(c)})^{-1} = I - (M + M^{(c)} - I)(M + M^{(c)})^{-1},$$

which implies that

$$\left\|(M + M^{(c)})^{-1}\right\|_{\max} = 1 + \deg(\mathcal{G}) \max\{\alpha, \zeta(\mathcal{G})\alpha^2\} \left\|(M + M^{(c)})^{-1}\right\|_{\max}, \tag{32}$$

where we have used the fact that $\text{supp}((M + M^{(c)})^{-1}) \subseteq \mathcal{G}$ and hence, its maximum degree is upper bounded by $\deg(\mathcal{G})$. (32), together with the assumption (31) implies that

$$\left\|(M + M^{(c)})^{-1}\right\|_{\max} \leq \frac{1}{1 - \deg(\mathcal{G}) \max\{\alpha, \zeta(\mathcal{G})\alpha^2\}} \leq 2. \tag{33}$$

Combining (30) and (33) with (29) completes the proof. ■

Proof of Lemma 15 Without loss of generality, assume that $\mathcal{G}$ is a tree. Note that if there are disjoint components, the argument made in the sequel can be applied to each connected component of $\mathcal{G}$ separately. Let d_{ij} denote the unique path between every two disparate nodes i and j in $\mathcal{G}$. Furthermore, define $\mathcal{N}(i)$ as the set of all neighbors of node i in $\mathcal{G}$. Consider a matrix M with positive-definite completion and with diagonal elements equal to 1 such that $\|M\|_{\max} \leq \alpha$ and $\text{supp}(M) = \mathcal{G}$. Let N be a matrix with the following entries

$$N_{ij} = \begin{cases} \prod_{(m,t) \in d_{ij}} M_{mt} & \text{if} \quad (i,j) \in (\text{supp}(M))^{(c)}, \\ 0 & \text{otherwise.} \end{cases} \tag{34}$$

Moreover, define

$$A_{ij} = \begin{cases} 1 + \sum_{m \in \mathcal{N}(i)} \frac{M_{mi}^2}{1 - M_{mi}^2} & \text{if} \quad i = j, \\ \frac{-M_{ij}}{1 - M_{ij}^2} & \text{if} \quad (i,j) \in \text{supp}(M), \\ 0 & \text{otherwise.} \end{cases} \tag{35}$$

The goal is to show that the matrix N is the unique inverse-consistent complement of M. First, note that $\text{supp}(N) = (\text{supp}(M))^{(c)}$ and $\text{supp}(M) = \text{supp}(A)$. Next, it is desirable to prove that $(M + N)^{-1} = A$ or equivalently $(M + N)A = I$. Upon defining $T = (M + N)A$, one can write

$$T_{ii} = \sum_{m=1}^{d} (M_{im} + \mathcal{N}_{im}) A_{mi} = 1 + \sum_{m \in \mathcal{N}(i)} \frac{M_{mi}^2}{1 - M_{mi}^2} - \sum_{m \in \mathcal{N}(i)} \frac{M_{mi}^2}{1 - M_{mi}^2} = 1.$$

Moreover, for every pair of nodes i and j, define D_{ij} as $\prod_{(k,t) \in d_{ij}} M_{kt}$ if $i \neq j$ and as 1 if $i = j$.

Consider a pair of distinct nodes i and j. Let t denote the node adjacent to j in d_{ij} (note that we may have $t = i$). It can be verified that

$$T_{ij} = \sum_{m=1}^{d}(M_{im}+N_{im})A_{mj} = D_{ij}\left(1+\sum_{m\in\mathcal{N}(j)}\frac{M_{mj}^2}{1-M_{mj}^2}\right) - D_{it}\left(\frac{M_{tj}}{1-M_{tj}^2}\right) - \sum_{\substack{m\in\mathcal{N}(j)\\ m\neq t}} D_{im}\frac{M_{mj}}{1-M_{mj}^2}. \tag{36}$$

Furthermore,

$$\begin{aligned} D_{ij} &= D_{it}M_{tj}, \\ D_{im} &= D_{it}M_{tj}M_{jm}, \qquad \forall\ m\in\mathcal{N}(j),\ m\neq t. \end{aligned} \tag{37}$$

Plugging (37) into (36) yields that

$$T_{ij} = D_{it}M_{tj}\left(\frac{1}{1-M_{tj}^2}+\sum_{\substack{m\in\mathcal{N}(j)\\ m\neq t}}\frac{M_{mj}^2}{1-M_{mj}^2}\right) - D_{it}\left(\frac{M_{tj}}{1-M_{tj}^2}\right) - D_{it}M_{tj}\sum_{\substack{m\in\mathcal{N}(j)\\ m\neq t}}\frac{M_{mj}^2}{1-M_{mj}^2} = 0.$$

Hence, $T = I$. Finally, we need to show that $M + N \succ 0$. To this end, it suffices to prove that $A \succ 0$. Note that A can be written as $I + \sum_{(i,j)\in\mathcal{G}} L^{(i,j)}$, where $L^{(i,j)}$ is defined as

$$L_{rl}^{(i,j)} = \begin{cases} \frac{M_{ij}^2}{1-M_{ij}^2} & \text{if} \quad r = l = i \text{ or } j, \\ \frac{-M_{ij}}{1-M_{ij}^2} & \text{if} \quad (r,l) = (i,j), \\ 0 & \text{otherwise.} \end{cases}$$

Consider the term x^TAx for an arbitrary vector $x\in\mathbb{R}^d$. One can verify that

$$\begin{aligned} x^TAx =& \sum_{i=1}^{d}x_i^2 + \sum_{(i,j)\in\mathcal{G}} x^TL^{(i,j)}x \\ =& \sum_{i=1}^{d}x_i^2 + \sum_{(i,j)\in\mathcal{G}}\left(\frac{M_{ij}^2}{1-M_{ij}^2}\right)x_i^2 + \left(\frac{M_{ij}^2}{1-M_{ij}^2}\right)x_j^2 - \left(\frac{2M_{ij}}{1-M_{ij}^2}\right)x_ix_j. \end{aligned} \tag{38}$$

Without loss of generality, assume that the graph is a rooted tree with the root at node d. Assume that each edge (i,j) defines a direction that is toward the root. Then, it follows from (38) that

$$\begin{aligned} x^TAx =& x_d^2 + \sum_{(i,j)\in\mathcal{G}} x_i^2 + \left(\frac{M_{ij}^2}{1-M_{ij}^2}\right)x_i^2 + \left(\frac{M_{ij}^2}{1-M_{ij}^2}\right)x_j^2 - \left(\frac{2M_{ij}}{1-M_{ij}^2}\right)x_ix_j \\ =& x_d^2 + \sum_{(i,j)\in\mathcal{G}}\left(\frac{1}{1-M_{ij}^2}\right)x_i^2 + \left(\frac{M_{ij}^2}{1-M_{ij}^2}\right)x_j^2 - \left(\frac{2M_{ij}}{1-M_{ij}^2}\right)x_ix_j \\ =& x_d^2 + \sum_{(i,j)\in\mathcal{G}}\frac{(x_i - M_{ij}x_j)^2}{1-M_{ij}^2} \geq 0. \end{aligned}$$

Therefore, $M + N \succeq 0$ and subsequently $M + N \succ 0$ (because it is invertible). Hence, according to Definition 5 and Lemma 6, the matrix N is the unique inverse-consistent compliment of M. On the other hand, it follows from the definition of N that $\|N\|_{\max} \leq \alpha^2$ and consequently $\beta(\mathcal{G},\alpha) \leq \alpha^2$. Now, suppose that $\mathcal{G}$ includes a path of length at least 2, e.g., the edges $(1,2)$ and $(2,3)$ belong to $\mathcal{G}$. By setting $M_{12} = M_{23} = \alpha$ and choosing sufficiently small values for those entries of M corresponding to the remaining edges in $\mathcal{G}$, the matrix M becomes positive-definite with a trivial positive-definite completion and we obtain $\|N\|_{\max} = \alpha^2$. This completes the proof. ■

Proof of Theorem 18 To prove this theorem, first consider the following matrix

$$\hat{S}_{ij} = \begin{cases} 1 + \sum\limits_{(i,m)\in\mathcal{E}^{\text{opt}}} \frac{(\tilde{\Sigma}_{im}^{\text{res}})^2}{1-(\tilde{\Sigma}_{im}^{\text{res}})^2} & \text{if} \quad i = j, \\ \frac{-\tilde{\Sigma}_{ij}^{\text{res}}}{1-(\tilde{\Sigma}_{ij}^{\text{res}})^2} & \text{if} \quad (i,j)\in\mathcal{E}^{\text{opt}}, \\ 0 & \text{otherwise.} \end{cases} \tag{39}$$

In what follows, we will show that $\hat{S} = \tilde{S}$, where $\tilde{S}$ is the optimal solution for the normalized GL. This, together with Lemma 29 implies that (11) is indeed optimal for the GL.

First, note that there exists a matrix N such that $\tilde{S}^{-1} = M + N$, where M is defined as

$$M_{ij} = \begin{cases} \tilde{\Sigma}_{ij} + \tilde{\lambda}_{ij}\times\text{sign}(\tilde{S}_{ij}) & \text{if} \quad (i,j)\in\text{supp}(\tilde{S}), \\ 1 & \text{if} \quad i = j, \\ 0 & \text{otherwise.} \end{cases} \tag{40}$$

Clearly, $\text{supp}(\tilde{S}) = \text{supp}(M)$. Furthermore, $M = I_d + \tilde{T}(\lambda)$, where $(i,j)^{\text{th}}$ entry of $\tilde{T}(\lambda)$ is equal to $\tilde{\Sigma}_{ij} + \tilde{\lambda}_{ij}\text{sign}(S_{ij}^{\text{opt}})$ for every $(i,j)\in\text{supp}(S^{\text{opt}})$ and it is equal to zero otherwise. Subsequently, $M = D^{-1/2}(D + T(\lambda))D^{-1/2}$ and hence, $D + T(\lambda) \succ 0$ implies $M \succ 0$. By combining $N = (\tilde{S})^{-1} - M$ with (40) and exploiting the optimality conditions in (14), one can verify that $\text{supp}(N) \subseteq (\text{supp}(M))^{(c)}$ and $\text{supp}(\tilde{S}) = \text{supp}\left((M+N)^{-1}\right) \subseteq \text{supp}(M)$. Therefore, according to Lemma 6, the matrix N is the unique inverse-complement of M. Moreover, since M is sign-consistent, the equation $\text{sign}(M_{ij}) = -\text{sign}(\tilde{S}_{ij})$ holds for every $(i,j)\in\text{supp}(\tilde{S})$. This leads to the relations $\text{sign}(\Sigma_{ij}) = -\text{sign}(\tilde{S}_{ij})$ and

$$M_{ij} = \tilde{\Sigma}_{ij}^{\text{res}}, \tag{41a}$$

$$|\tilde{\Sigma}_{ij}| > \tilde{\lambda}_{ij}, \tag{41b}$$

for every $(i,j)\in\text{supp}(\tilde{S})$. Part 1 of the theorem is an immediate consequence of (41b). On the other hand, based on the argument made in the proof of Lemma 15, the matrix N can be obtained as

$$N_{ij} = \begin{cases} \prod_{(m,t)\in d_{ij}} M_{mt} & \text{if} \quad d_{ij}\neq\emptyset \text{ and } (i,j)\in(\text{supp}(M))^{(c)}, \\ 0 & \text{otherwise,} \end{cases} \tag{42}$$

where d_{ij} denotes the unique path between nodes i and j in $\text{supp}(\tilde{S})$ if they belong to the same connected component in $\text{supp}(\tilde{S})$, and d_{ij} is empty if there is no path between nodes

i and j. Similar to the proof of Lemma 15, one can show that (11) is equal to $(M+N)^{-1}$. This completes the proof of the second part of the theorem. ■

Proof of Theorem 19 Based on Lemmas 15 and 16, the conditions introduced in Theorem 12 can be reduced to conditions (2-ii) and (2-iii) in Theorem 19 if $\text{supp}(\Sigma^{\text{res}})$ is acyclic and therefore, $\mathcal{E}^{\text{opt}} = \mathcal{E}^{\text{res}}$. Moreover, suppose that M is set to $I_d + \tilde{\Sigma}^{\text{res}}$, and that the matrices N and A are defined as (34) and (35), respectively. Similar to the proof of Theorem 12, it can be verified that (39) satisfies all the KKT conditions for the normalized GL (21). Therefore, due to Lemma 29, (11) is the unique solution of the GL. The details are omitted for brevity. ■

Proof of Corollary 20 Given Σ and λ, the matrix Σ^{res} can be computed in $\mathcal{O}(d^2)$. Moreover, Condition (2-i) in Theorem 19 can be checked using the Depth-First-Search algorithm, which has the time complexity of $\mathcal{O}(d^2)$ in the worst case (Ahuja et al., 1993). If the graph is cyclic, Theorem 19 cannot be used. Otherwise, we consider Condition (2-ii). For matrices with acyclic support graphs, the Cholesky Decomposition can be computed in $\mathcal{O}(d)$, from which the positive-definiteness of the matrix can be checked (Vandenberghe and Andersen 2015). The complexity of checking Condition (2-iii) is equivalent to that of finding its left and right hand sides, which can be done in $\mathcal{O}(d)$ and $\mathcal{O}(d^2)$, respectively. Finally, since (11) can be used only if the support graph of Σ^{res} is acyclic, one can easily verify that the complexity of obtaining S^{opt} using (11) is at most $\mathcal{O}(d)$. This completes the proof of Corollary 20. ■

The remainder of this section is devoted to proving approximation bounds for the derived closed-form solution when the acyclic assumption on the support graph of the thresholded sample covariance matrix is not necessarily acyclic. The shorthand notations c, deg, $\mathcal{P}_{ij}$ and $P_{\max}$ will be used instead of $c(\text{supp}(\Sigma^{\text{res}}))$, $\deg(\text{supp}(\Sigma^{\text{res}}))$, $\mathcal{P}_{ij}(\text{supp}(\Sigma^{\text{res}}))$ and $P_{\max}(\text{supp}(\Sigma^{\text{res}}))$, respectively. First, the approximation error of the closed-form solution for the normalized GL will be analyzed. Then, the result will be generalized to the GL via the key equality in Lemma 29. To prove Theorem 26, the first step is to generalize the definition of the matrix N in (42) and show that this generalized matrix is an approximate inverse-consistent complement of $I_d + \tilde{\Sigma}^{\text{res}}$. Without loss of generality, assume that $\text{supp}(\Sigma^{\text{res}})$ is connected. If there are disjoint components in $\text{supp}(\Sigma^{\text{res}})$, the argument made in the sequel can be used for every connected component due to the decomposition rule for the GL (see Mazumder and Hastie (2012)). Let M be equal to $I_d + \tilde{\Sigma}^{\text{res}}$. Consider the matrix N as

$$N_{ij} = \begin{cases} \sum_{d_{ij} \in \mathcal{P}_{ij}} \prod_{(m,t) \in d_{ij}} M_{mt} & \text{if} \quad (i,j) \in (\text{supp}(M))^{(c)}, \\ \sum_{d_{ij} \in \mathcal{P}_{ij} \setminus \{(i,j)\}} \prod_{(m,t) \in d_{ij}} M_{mt} & \text{if} \quad (i,j) \in (\text{supp}(M)), \\ 0 & \text{otherwise.} \end{cases} \tag{43}$$

It can be verified that $M + N = R$, where

$$R_{ij} = \begin{cases} \sum_{d_{ij} \in \mathcal{P}_{ij}} \prod_{(m,t) \in d_{ij}} M_{mt} & \text{if} \quad i \neq j, \\ 1 & \text{if} \quad i = j. \end{cases} \tag{44}$$

For each simple path between the pair of nodes i and j, define its length as the multiplication of the entries of M corresponding to the edges of the path. Based on this definition, R_{ij} is

equal to the sum of the lengths of all nonidentical simple paths between nodes i and j in $\text{supp}(M)$. Denote d^s_{ij} as any shortest path between nodes i and j in $\text{supp}(M)$ (recall that $\text{supp}(M)$ is unweighted), and let R^s be given by

$$R^s_{ij} = \begin{cases} \prod_{(m,t) \in d^s_{ij}} M_{mt} & \text{if} \quad i \neq j, \\ 1 & \text{if} \quad i = j. \end{cases}$$

Note that R^s collects the length of the shortest path between every two nodes in $\text{supp}(M)$. The following lemmas are crucial to prove Theorem 26.

Lemma 31 *Given two nodes i and j in $\text{supp}(\Sigma^{\text{res}})$, suppose that $\mathcal{P}_{ij} \backslash d^s_{ij}$ is non-empty. Then, the length of every path d_{ij} in $\mathcal{P}_{ij} \backslash d^s_{ij}$ is at least $\lceil c/2 \rceil$.*

Proof Consider a path d_{ij} in $\mathcal{P}_{ij} \backslash d^s_{ij}$. The subgraph $d_{ij} \cup d^s_{ij}$ has a cycle. Since the length of this cycle is at least c, the segment of this cycle that resides in d_{ij} should have the length of at least $\lceil c/2 \rceil$; otherwise d^s_{ij} is not the shortest path between the nodes i and j. This implies that the length of d_{ij} is at least $\lceil c/2 \rceil$. ■

Lemma 32 *Let M be equal to $I_d + \tilde{\Sigma}^{\text{res}}$. The inequalities*

$$\left| R_{ij} - R^s_{k'j} M_{ik'} \right| \leq (|\mathcal{P}_{ij}|_0 - 1) \left(\|\tilde{\Sigma}^{\text{res}}\|_{\max} \right)^{\lceil \frac{c}{2} \rceil}, \tag{45a}$$

$$\left| R_{kj} - R^s_{k'j} M_{ik'} M_{ik} \right| \leq (|\mathcal{P}_{kj}|_0 - 1) \left(\|\tilde{\Sigma}^{\text{res}}\|_{\max} \right)^{\lceil \frac{c}{2} \rceil - 1} \tag{45b}$$

hold if $i \neq j$, where k' is the node adjacent to i in d^s_{ij} and $k \in \mathcal{N}(i) \backslash k'$.

Proof First, we show the validity of (45a). Due to (44), one can write

$$R_{ij} = R^s_{ij} + \sum_{d_{ij} \in \mathcal{P}_{ij} \backslash d^s_{ij}} \prod_{(m,t) \in d_{ij}} M_{mt}. \tag{46}$$

If $\mathcal{P}_{ij} \backslash d^s_{ij}$ is empty, then the equation $R_{ij} = R^s_{k'j} M_{ik'}$ and therefore (45a) hold. Now, assume that $\mathcal{P}_{ij} \backslash d^s_{ij}$ is not empty. Due to Lemma 31, we have

$$-\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max} \right)^{\lceil \frac{c}{2} \rceil} \leq \prod_{(m,t) \in d_{ij}} M_{mt} \leq \left(\|\tilde{\Sigma}^{\text{res}}\|_{\max} \right)^{\lceil \frac{c}{2} \rceil},$$

for every $d_{ij} \in \mathcal{P}_{ij} \backslash d^s_{ij}$. The above inequalities, together with (46) and the equation $R^s_{ij} = R^s_{k'j} M_{ik'}$, result in (45a). To prove (45b), define $\hat{d}_{kj}$ as $d^s_{ij} \cup \{(i,k)\}$ (note that $\hat{d}_{kj}$ is not necessarily equal to d^s_{kj}). It yields that

$$R_{kj} = R^s_{ij} M_{ik} + \sum_{d_{kj} \in \mathcal{P}_{kj} \backslash \hat{d}_{kj}} \prod_{(m,t) \in d_{kj}} M_{mt}. \tag{47}$$

In light of Lemma 31, the length of every path $d_{kj} \in \mathcal{P}_{kj} \backslash \hat{d}_{kj}$ is lower bounded by $\lceil c/2 \rceil - 1$. This implies that

$$-\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil \frac{c}{2} \rceil - 1} \leq \prod_{(m,t)\in d_{ij}} M_{mt} \leq \left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil \frac{c}{2} \rceil - 1}, \tag{48}$$

for every $d_{kj} \in \mathcal{P}_{kj} \backslash \hat{d}_{kj}$. Combining $R^s_{ij} M_{ik} = R^s_{k'j} M_{ik'} M_{ik}$ with (47) and (48) leads to the inequality (45b). ■

Lemma 33 *The following inequality holds*

$$\frac{\deg}{1 - \|\tilde{\Sigma}^{\text{res}}\|^2_{\max}} \leq \delta,$$

where δ defined as (17).

Proof The proof is straightforward and is omitted for brevity. ■

Proof of Theorem 26 Consider the normalized GL and define the following explicit formula for $\tilde{A}$

$$\tilde{A}_{ij} = \begin{cases} 1 + \sum\limits_{(i,m)\in\mathcal{E}^{\text{opt}}} \frac{(\tilde{\Sigma}^{\text{res}}_{im})^2}{1-(\tilde{\Sigma}^{\text{res}}_{im})^2} & \text{if} \quad i = j, \\ \frac{-\tilde{\Sigma}^{\text{res}}_{ij}}{1-(\tilde{\Sigma}^{\text{res}}_{ij})^2} & \text{if} \quad (i,j) \in \mathcal{E}^{\text{res}}, \\ 0 & \text{otherwise.} \end{cases} \tag{49}$$

Let M be equal to $I_d + \tilde{\Sigma}^{\text{res}}$. Furthermore, define

$$\tilde{\epsilon} = \delta \cdot (P_{\max}(\text{supp}(\Sigma^{\text{res}})) - 1) \cdot \left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\left\lceil \frac{c(\text{supp}(\Sigma^{\text{res}}))}{2} \right\rceil}.$$

In order to prove the theorem, we use the matrix N defined in (43), and first show that $M + N$ is an $\tilde{\epsilon}$-relaxed inverse of $\tilde{A}$ and that the pair $(\tilde{A}, M + N)$ satisfies the $\tilde{\epsilon}$-relaxed KKT conditions.

Consider the matrix T defined as $T = \tilde{A}(M + N)$ and recall that $M + N = R$. One can write

$$T_{ii} = \sum_{m=1}^{d} \tilde{A}_{im} R_{mi} = \left(1 + \sum_{m\in\mathcal{N}(i)} \frac{{M_{im}}^2}{1 - {M_{im}}^2}\right) - \sum_{m\in\mathcal{N}(i)} \frac{M_{im}}{1 - {M_{im}}^2} R_{mi}. \tag{50}$$

Note that since $\{(m,i)\} \in \mathcal{P}_{mi}$ for every $m \in \mathcal{N}(i)$, we have

$$R_{mi} = M_{mi} + \sum_{d_{mi}\in\mathcal{P}_{mi}\backslash\{(m,i)\}} \prod_{(r,t)\in d_{mi}} M_{rt}.$$

If $\mathcal{P}_{mi}\backslash\{(m,i)\}$ is empty, then $R_{mi} = M_{mi}$ and $T_{ii} = 1$. Otherwise, since the length of the minimum-length cycle is c, the length of every path $d_{mi} \in \mathcal{P}_{mi}\backslash\{(m,i)\}$ is at least $c - 1$. This yields that

$$M_{mi} - (|\mathcal{P}_{mi}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{c-1} \leq R_{mi} \leq M_{mi} + (|\mathcal{P}_{mi}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{c-1}. \tag{51}$$

Combining (51) and (50) leads to

$$|T_{ii} - 1| \leq (|\mathcal{P}_{mi}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{c-1}\left(\sum_{m\in\mathcal{N}(i)} \frac{M_{im}}{1 - {M_{im}}^2}\right) \leq \deg(P_{\max} - 1)\frac{\|\tilde{\Sigma}^{\text{res}}\|^c_{\max}}{1 - \|\tilde{\Sigma}^{\text{res}}\|^2_{\max}} \leq \tilde{\epsilon}, \tag{52}$$

where the last inequality is due to Lemma 33 and the fact that $\lceil \frac{c}{2} \rceil \leq c$ for $c \geq 3$. Now, consider T_{ij} for a pair (i,j) such that $i \neq j$. We have

$$T_{ij} = \sum_{m=1}^{d} \tilde{A}_{im} R_{mj} = \left(1 + \sum_{m\in\mathcal{N}(i)} \frac{{M_{im}}^2}{1 - {M_{im}}^2}\right) R_{ij} - \sum_{m\in\mathcal{N}(i)} \frac{M_{im}}{1 - {M_{im}}^2} R_{mj}. \tag{53}$$

According to Lemma 31, one can write

$$R^s_{m'j} M_{im'} - (|\mathcal{P}_{ij}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil \frac{c}{2} \rceil} \leq R_{ij} \leq R^s_{m'j} M_{im'} + (|\mathcal{P}_{ij}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil \frac{c}{2} \rceil}, \tag{54a}$$

$$\begin{aligned} R^s_{m'j} M_{im'} M_{im} - (|\mathcal{P}_{mj}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil \frac{c}{2} \rceil - 1} &\leq R_{mj} \\ &\leq R^s_{m'j} M_{im'} M_{im} + (|\mathcal{P}_{mj}|_0 - 1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil \frac{c}{2} \rceil - 1}, \end{aligned} \tag{54b}$$

where m' is the node adjacent to i in d^s_{ij} and $m \in \mathcal{N}(i)\backslash m'$. Note that if $\mathcal{N}(i)\backslash m'$ is empty, then $R_{ij} = R^s_{m'j} M_{im'}$ and $R_{mj} = R^s_{m'j} M_{im'} \tilde{\Sigma}^{\text{res}}_{im}$. In this case, an argument similar to the proof of Lemma 15 can be made to show that $T_{ij} = 0$. Now, assume that $\mathcal{N}(i)\backslash m'$ is not empty. One can write

$$|T_{ij} - F_{ij}| \overset{(a)}{=} |T_{ij}| \overset{(b)}{\leq} \tilde{\epsilon}, \tag{55}$$

where

$$\begin{aligned} F_{ij} = &\left(\frac{1}{1 - {M_{im'}}^2} + \sum_{m\in\mathcal{N}(i)\backslash m'} \frac{{M_{im}}^2}{1 - {M_{im}}^2}\right) R^s_{m'j} M_{im'} - \frac{M_{im'}}{1 - {M_{im'}}^2} R^s_{m'j} \\ &- \sum_{m\in\mathcal{N}(i)\backslash m'} \frac{{M_{im}}^2}{1 - {M_{im}}^2} R^s_{m'j} M_{im'} M_{im}. \end{aligned}$$

Note that the relation (a) can be verified by the fact that $F_{ij} = 0$ and the inequality (b) is obtained by combining (53) with (54a) and (54b). The inequalities (52) and (55) imply that $M + N$ is an $\tilde{\epsilon}$-relaxed inverse of $\tilde{A}$.

Now, it will be shown that the pair $(\tilde{A}, M+N)$ satisfies the $\tilde{\epsilon}$-relaxed KKT conditions. Note that $M_{ii}+N_{ii}=M_{ii}=\tilde{\Sigma}_{ii}$ and, hence, (15a) is satisfied. To prove (15b), since $\text{sign}(\tilde{A}_{ij})=-\text{sign}(M_{ij})=-\text{sign}(\tilde{\Sigma}_{ij})$, it can be concluded that

$$M_{ij}+N_{ij}=(\tilde{\Sigma}_{ij}-\tilde{\lambda}_{ij}\times\text{sign}(\Sigma_{ij}))+N_{ij}=(\tilde{\Sigma}_{ij}+\tilde{\lambda}_{ij}\times\text{sign}(\tilde{A}_{ij}))+N_{ij},$$

for every (i,j) such that $i\neq j$ and $\tilde{A}_{ij}\neq 0$. Due to the definition of N and the fact that $(i,j)\in\text{supp}(M)$, we have $|N_{ij}|\leq(P_{\max}-1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{c-1}$. Hence,

$$|M_{ij}+N_{ij}-(\tilde{\Sigma}_{ij}+\tilde{\lambda}_{ij}\times\text{sign}(\tilde{A}_{ij}))|\leq\epsilon,$$

for every (i,j) such that $i\neq j$ and $\tilde{A}_{ij}\neq 0$. Therefore, the pair $(\tilde{A}, M+N)$ satisfies (15b). Finally, consider a pair (i,j) such that $i\neq j$ and $\tilde{A}_{ij}=0$. One can write

$$M_{ij}+N_{ij}=R^s_{ij}+\sum_{d_{ij}\in\mathcal{P}_{ij}\backslash d^s_{ij}}\prod_{(m,t)\in d_{ij}}\tilde{\Sigma}^{\text{res}}_{mt}.$$

If $\mathcal{P}_{ij}\backslash d^s_{ij}$ is empty, a set of inequalities similar to (25) and (26) can be obtained to prove (15c). Now, assume that $\mathcal{P}_{ij}\backslash d^s_{ij}$ is not empty. The length of d^s_{ij} is at least 2 since there is no direct edge between nodes i and j. Hence, $|R^s_{ij}|\leq\|\tilde{\Sigma}^{\text{res}}\|^2_{\max}$. Furthermore, due to Lemma (31), the length of every path $d_{ij}\in\mathcal{P}_{ij}\backslash d^s_{ij}$ is at least $\lceil c/2\rceil$. This leads to

$$\begin{aligned}|M_{ij}+N_{ij}|&\leq\|\tilde{\Sigma}^{\text{res}}\|^2_{\max}+(P_{\max}-1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil\frac{c}{2}\rceil}\\&\leq\min_{\substack{k\neq l\\(k,l)\notin\text{supp}(\Sigma^{\text{res}})}}(\tilde{\lambda}_{kl}-|\tilde{\Sigma}^{\text{res}}_{kl}|)+(P_{\max}-1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil\frac{c}{2}\rceil}\\&\leq\tilde{\lambda}_{ij}-|\tilde{\Sigma}^{\text{res}}_{ij}|+(P_{\max}-1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil\frac{c}{2}\rceil},\end{aligned}$$

where the last inequality follows from Condition (2-ii) in the theorem. Therefore,

$$\begin{aligned}|M_{ij}+N_{ij}-\tilde{\Sigma}_{ij}|\leq|M_{ij}+N_{ij}|+|\tilde{\Sigma}_{ij}|&\leq\tilde{\lambda}_{ij}-|\tilde{\Sigma}^{\text{res}}_{ij}|+|\tilde{\Sigma}^{\text{res}}_{ij}|+(P_{\max}-1)\left(\|\tilde{\Sigma}^{\text{res}}\|_{\max}\right)^{\lceil\frac{c}{2}\rceil}\\&\leq\tilde{\lambda}_{ij}+\tilde{\epsilon}.\end{aligned}$$

This shows that $(\tilde{A}, M+N)$ indeed satisfies the $\tilde{\epsilon}$-relaxed KKT conditions for the normalized GL. Finally, we consider the explicit solution A defined as (13). The following statements hold:

1. the matrix $D^{1/2}(M+N)D^{1/2}$ is ϵ-relaxed inverse of A. To see this, note that

$$\begin{aligned}A\left(D^{1/2}(M+N)D^{1/2}\right)&=D^{-1/2}\tilde{A}D^{-1/2}D^{1/2}(M+N)D^{1/2}\\&=D^{-1/2}TD^{1/2}\\&=I_d+E,\end{aligned}$$

where $\|E\|_{\max}\leq\sqrt{\frac{\Sigma_{\max}}{\Sigma_{\min}}}\tilde{\epsilon}\leq\epsilon$.

2. The pair $(A, D^{1/2}(M+N)D^{1/2})$ satisfies the ϵ-relaxed KKT conditions. Note that it is already shown that $(\tilde{A}, M+N)$ satisfies the following inequalities

$$\begin{aligned}&(M+N)_{ij}=\tilde{\Sigma}_{ij} && \text{if}\quad i=j, && (56a)\\&\left|(M+N)_{ij}-\left(\tilde{\Sigma}_{ij}+\tilde{\lambda}_{ij}\times\text{sign}(\tilde{A}_{ij})\right)\right|\leq\tilde{\epsilon} && \text{if}\quad \tilde{A}_{ij}\neq 0, && (56b)\\&\left|(M+N)_{ij}-\tilde{\Sigma}_{ij}\right|\leq\tilde{\lambda}_{ij}+\tilde{\epsilon} && \text{if}\quad \tilde{A}_{ij}=0. && (56c)\end{aligned}$$

Replacing $M+N$ with $D^{1/2}(M+N)D^{1/2}$ and modifying (56) accordingly, one can verify that $(A, D^{1/2}(M+N)D^{1/2})$ satisfies ϵ-relaxed KKT conditions for the GL, where

$$\epsilon=\max\left\{\Sigma_{\max},\sqrt{\frac{\Sigma_{\max}}{\Sigma_{\min}}}\right\}\tilde{\epsilon}.$$

This completes the proof. ■

Proof of Theorem 27 Due to Theorem 26, the equation

$$D^{1/2}(M+N)D^{1/2}=A^{-1}+A^{-1}E \tag{57}$$

holds for every λ greater than or equal to λ_0, where $\|E\|_{\max}\leq\epsilon$. Since the pair $(A, D^{1/2}(M+N)D^{1/2})$ satisfies the ϵ-relaxed KKT conditions, it follows from (57) that

$$\begin{aligned}&(A)^{-1}_{ij}=\Sigma_{ij}-(A^{-1}E)_{ij}=\hat{\Sigma}_{ij} && \text{if}\quad i=j, && (58a)\\&(A)^{-1}_{ij}=\underbrace{\Sigma_{ij}+t_{ij}\epsilon-(A^{-1}E)_{ij}}_{\hat{\Sigma}_{ij}}+\lambda\times\text{sign}(A_{ij}) && \text{if}\quad A_{ij}\neq 0, && (58b)\\&\underbrace{\Sigma_{ij}+s_{ij}\epsilon-(A^{-1}E)_{ij}}_{\hat{\Sigma}_{ij}}-\lambda\leq(A)^{-1}_{ij}\leq\underbrace{\Sigma_{ij}+s_{ij}\epsilon-(A^{-1}E)_{ij}}_{\hat{\Sigma}_{ij}}+\lambda && \text{if}\quad A_{ij}=0, && (58c)\end{aligned}$$

for some numbers t_{ij} and s_{ij} in the interval $[-1,1]$. To complete the proof, it suffices to show that the matrix F defined as

$$\Sigma_{ij}-\hat{\Sigma}_{ij}=F_{ij}=\begin{cases}-(A^{-1}E)_{ij} & \text{if}\quad i=j,\\ t_{ij}\epsilon-(A^{-1}E)_{ij} & \text{if}\quad A_{ij}\neq 0,\\ s_{ij}\epsilon-(A^{-1}E)_{ij} & \text{if}\quad A_{ij}=0\end{cases} \tag{59}$$

satisfies the inequality $\|F\|_2\leq d_{\max}\left(1/\mu_{\min}(A)+1\right)\epsilon$. To this end, it is enough to prove that $\|A^{-1}E\|_2\leq(d_{\max}/\mu_{\min}(A))\epsilon$, since $\|F-A^{-1}E\|_2\leq d_{\max}(A)\epsilon$. One can write

$$\|A^{-1}E\|_2\leq\|A^{-1}\|_2\|E\|_2\leq d_{\max}(A)\|A^{-1}\|_2\|E\|_{\max}=\left(\frac{d_{\max}(A)}{\mu_{\min}(A)}\right)\epsilon,$$

which shows the validity of (18).

Next, we prove the inequality (19). The following chain of inequalities hold

$$\begin{aligned}
-\log\det(A)+\operatorname{trace}(\hat{\Sigma}A)+\lambda\|A\|_{1,\text{off}} &= \underbrace{-\log\det(A)+\operatorname{trace}(\Sigma A)+\lambda\|A\|_{1,\text{off}}}_{f(A)} \\
&\quad +\operatorname{trace}((\hat{\Sigma}-\Sigma)A) \\
&\overset{(a)}{\leq} -\log\det(S^{\text{opt}})+\operatorname{trace}(\hat{\Sigma}S^{\text{opt}})+\lambda\|S^{\text{opt}}\|_{1,\text{off}} \\
&= \underbrace{-\log\det(S^{\text{opt}})+\operatorname{trace}(\Sigma S^{\text{opt}})+\lambda\|S^{\text{opt}}\|_{1,\text{off}}}_{f^*} \\
&\quad +\operatorname{trace}((\hat{\Sigma}-\Sigma)S^{\text{opt}}),
\end{aligned}$$

where (a) is due to the fact that A is optimal for the GL with the perturbed sample covariances. This implies that

$$\begin{aligned}
f(A)-f^* &\leq \operatorname{trace}((\tilde{\Sigma}-\Sigma)(S^{\text{opt}}-A)) \\
&\leq \|\tilde{\Sigma}-\Sigma\|_2(\|S^{\text{opt}}\|_2+\|A\|_2) \\
&\leq \left(\mu_{\max}(A)+\mu_{\max}(S^{\text{opt}})\right) d_{\max}(A)\left(\frac{1}{\mu_{\min}(A)}+1\right)\epsilon.
\end{aligned}$$

Abstract

In this paper, the problem of one-bit compressed sensing (OBCS) is formulated as a problem in probably approximately correct (PAC) learning. It is shown that the Vapnik-Chervonenkis (VC-) dimension of the set of half-spaces in $\mathbb{R}^n$ generated by k-sparse vectors is bounded below by $k(\lfloor \lg(n/k) \rfloor + 1)$ and above by $\lfloor 2k \lg(en) \rfloor$. By coupling this estimate with well-established results in PAC learning theory, we show that a consistent algorithm can recover a k-sparse vector with $O(k \lg n)$ measurements, given only the signs of the measurement vector. This result holds for *all* probability measures on $\mathbb{R}^n$. The theory is also applicable to the case of noisy labels, where the signs of the measurements are flipped with some unknown probability.

1. Introduction

The field of "compressed sensing" has become very popular in recent years, with an explosion in the number of papers. Stated briefly, the core problem in compressed sensing is to recover a high-dimensional sparse (or nearly sparse) vector x from a small number of measurements of x. In the traditional problem formulation, the measurements are *linear*, consisting of m real numbers $y_i = \langle a_i, x \rangle, i = 1, \ldots, m$, where the measurement vectors $a_i \in \mathbb{R}^n$ are chosen by the learner. More recently, attention has focused on so-called one-bit compressed sensing, referred to hereafter as OBCS in the interest of brevity. In OBCS the measurements consist, not of the inner products $\langle a_i, x \rangle$, but rather *just the signs of these inner products*, i.e., a "one-bit" representation of these measurements. In much of the OBCS literature, the vectors a_i are chosen at random from some specified probability distribution, often Gaussian. Because the sign of $\langle a_i, x \rangle$ is unchanged if x is replaced by any positive multiple of x, it is obvious that under this model, one can at best aspire to recover the unknown vector x only to within a positive multiple, or equivalently, to recover the normalized vector $x/\|x\|_2$. This limitation can be overcome by choosing the measurements to consist of the signs of inner products $\langle a_i, x \rangle + b_i$, where again a_i, b_i are selected at random.

The current status of OBCS is that while several algorithms have been proposed, theoretical analysis is available for only a few algorithms. Moreover, in cases where theoretical analysis is available, the sample complexity is extremely high. In the present paper, we interpret OBCS as a problem in probably approximately correct (PAC) learning theory, which is a well-established branch of statistical learning theory. By doing so, we are able to draw from the wealth of results that are already available, and thereby address some of the currently outstanding issues. In PAC learning theory, a central role is played by the so-called Vapnik-Chervonenkis (VC) dimension of the collection of concepts to be learned. The principal result of the present paper is that the VC-dimension of the set of half-planes in $\mathbb{R}^n$ generated by k-sparse vectors is bounded below by $k \lg(n/k)$ and above by $2k \lg(en)$, plus some roundoff terms. Using this bound, we are able to establish the following results for the case where $x \in \mathbb{R}^n$ has no more than k nonzero components:

- In principle, OBCS is possible whenever the measurement vector (a_i, b_i) is drawn at random from *any arbitrary* probability distribution. Moreover, if a consistent algorithm[1] can be devised, then the number of measurements is $O(k \lg n)$.
- There is also a *lower bound* on the OBCS problem. Specifically, there exists a probability distribution on $\mathbb{R}^n$ such that, if (a_i, b_i) is drawn at random from this distribution, then the number of measurements required to learn each k-sparse n-dimensional vector is bounded *below* by $\Omega(k \ln(n/k))$.
- It is shown that OBCS is possible under random flipping of the signs of the measurements. This finding builds on earlier results on PAC learning with noisy labels.
- If the samples a_i are not independent, but are β-mixing, learning is still possible, and explicit estimates are available for the rate of learning.

The paper is organized as follows: In Section 2, a brief review is given of some recent papers in OBCS. In Section 3, some parts of PAC learning theory that are relevant to OBCS are reviewed. In particular, it is shown how OBCS can be formulated as a problem in PAC learning, so that OBCS can be addressed by finding upper bounds on the VC-dimension of half-spaces generated by k-sparse vectors. In Section 4, both upper and lower bounds are derived for the VC-dimension of half-spaces generated by k-sparse vectors. In Section 5, the case where the sign measurements are flipped at random is examined. Finally, Section 6 contains a discussion of some issues that merit further investigation.

2. Brief Review of One-Bit Compressed Sensing

By now there is a substantial literature regarding the traditional compressed sensing formulation, out of which only a few references are cited here in the interests of brevity. Book-length treatments of compressed sensing can be found in (Elad, 2010; Foucart and Rauhut, 2013; Rish and Grabarnik, 2015; Hastie et al., 2015). Amongst these, (Foucart

and Rauhut, 2013) contains a thorough discussion of virtually all aspects of compressed sensing theory. A recent volume (Eldar and Kutyniok, 2012) is a compendium of articles on a variety of topics. The first paper in this volume (Davenport et al., 2012) is a survey of the basic results in compressed sensing. Another paper (Negabhan et al., 2012) provides a very general framework for sparse regression that can be used, among other things, to analyze compressed sensing algorithms. Each of these papers contains an extensive bibliography.

Throughout this paper, n denotes some fixed and large integer. For $x \in \mathbb{R}^n$, let $\text{supp}(x)$ denote the support of a vector, and let Σ_k denote the set of k-sparse vectors in $\mathbb{R}^n$; that is,

$$\text{supp}(x) := \{i : x_i \neq 0\}, \Sigma_k := \{x \in \mathbb{R}^n : |\text{supp}(x)| \leq k\}.$$

Suppose $x \in \mathbb{R}^n$ is k-sparse, that is, $x \in \Sigma_k$, where both n and k are known integers with $k \ll n$. The basic problem in compressed sensing is to design an $m \times n$ matrix A where $m \ll n$, together with a decoder map $\Delta : \mathbb{R}^m \to \mathbb{R}^n$ such that $\Delta(Ax) = x$ for all $x \in \Sigma_k$, that is, x can be recovered exactly from the m-dimensional vector of linear measurements $y = Ax$. Variations of the problem include the case where x is not exactly sparse, and/or $y = Ax + \eta$ where η is a measurement noise. Given a vector $x \in \mathbb{R}^n$, an integer $k < n$, define

$$\sigma_k(x, \|\cdot\|_1) := \min_{z \in \Sigma_k} \|x - z\|_1$$

to be the k-**sparsity index** of the vector x. It is clear that $x \in \Sigma_k$ if and only if $\sigma_k(x, \|\cdot\|_1) = 0$. By far the most popular method for recovering a sparse vector is ℓ_1-norm minimization. If $y = Ax + \eta$, the approach is to define the "decoder" map $\Delta : \mathbb{R}^m \to \mathbb{R}^n$ by

$$\Delta(y) = \hat{x} := \underset{z}{\text{argmin}} \|z\|_1 \text{ s.t. } \|y - Az\|_2 \leq \epsilon, \tag{1}$$

where ϵ is a known upper bound on $\|\eta\|_2$. In a series of papers by Candès, Tao, Donoho, and others, it is demonstrated that if the matrix A is chosen so as to satisfy the so-called Restricted Isometry Property (RIP), then the decoder Δ defined in (1) produces a good approximation to x in the following sense: There exist constants C, D that depend on the measurement matrix A but not on the unknown vector x, such that

$$\|\hat{x} - x\|_1 \leq C\sigma_k(x, \|\cdot\|_1) + D\epsilon.$$

In particular, ℓ_1-norm minimization recovers x exactly if $x \in \Sigma_k$ and $\eta = 0$. See for example (Candès and Tao, 2005; Candès et al., 2006; Donoho, 2006a,b), as well as the survey paper (Davenport et al., 2012) and the comprehensive book (Foucart and Rauhut, 2013). Further, it is shown in (Candès and Tao, 2005) that if the elements of A are samples of independent and identically distributed (i.i.d.) normal random variables (denoted by $a_{ij} \sim \mathcal{N}(0, 1)$), then the resulting normalized matrix $(1/\sqrt{m})A$ satisfies the RIP with probability that can be made arbitrarily close to one by increasing the number of measurements.

The remainder of the section is devoted to a discussion of the one-bit compressed sensing (OBCS) problem. One bit compressed sensing is introduced in (Boufounos and Baraniuk, 2008). In that paper, it is assumed that the measurement y_i equals the bipolar quantity $y_i = \text{sign}(\langle a_i, x\rangle)$, as opposed to the real number $\langle a_i, x\rangle$. Because the measurements remain invariant if x is replaced by any positive multiple of x, there is no loss of generality in

assuming that $\|x\|_2 = 1$. A greedy algorithm called "renormalized fixed point iteration" is introduced, as follows:

$$\hat{x} := \underset{z}{\text{argmin}} \|z\|_1 + \lambda \sum_{i=1}^{m} f(|(YA)_i|) \text{ s.t. } \|z\|_2 = 1,$$

where $y_1, \ldots, y_m$ are some constants, $Y = \text{Diag}(y_1, \ldots, y_m)$, and the regularizing function $f(\cdot)$ is defined by

$$f(\alpha) := \begin{cases} \alpha^2/2 & \text{if } \alpha < 0, \\ 0 & \text{if } \alpha \geq 0. \end{cases}$$

The optimization problem is non-convex due to the constraint $\|z\|_2 = 1$. Only simulations are provided, but no theoretical results.

In (Gupta et al., 2010), the focus is on recovering the support set of the unknown vector x from noise-corrupted measurements of the form $\text{sign}(\langle a_i, x\rangle + \eta_i)$, where the noise vector $\boldsymbol{\eta}$ consists of pairwise independent Gaussian signals. A non-adaptive algorithm is presented that makes use of Hoeffding's inequality applied to the expected value of the covariance of the signs of two Gaussian random variables. An adaptive algorithm is also presented. In (Boufounos, 2009), a new greedy algorithm is presented called "matched signed pursuit." The optimization problem is not convex; as a result there are no theoretical resuts. The algorithm is similar to the CoSaMP algorithm for the conventional compressed sensing problem (Needell and Tropp, 2009).

In (Jacques et al., 2013), the authors introduce a constant

$$\epsilon_{\text{opt}} := \frac{k}{2em + 2k^{3/2}},$$

where e denotes the base of the natural logarithm, and show that it is the minimum achievable error no matter what reconstruction method is used. Next, they choose any $\epsilon \geq \epsilon_{\text{opt}}$ and show the following result: Let $A \sim \mathcal{N}^{m \times n}(0, 1)$ consist of mn pairwise independent normal random variables, and let $y_i = \text{sign}(\langle a_i, x\rangle)$. Fix $\delta \in (0, 1)$. If the number of measurements m satisfies

$$m \geq \frac{2}{\epsilon}\left(2k \ln n + 4k \ln \frac{17}{\epsilon} + \ln \frac{1}{\delta}\right).$$

then for every pair $x, s \in \Sigma_k$,

$$\text{sign}(Ax) = \text{sign}(As) \implies \|x - s\|_2 \leq \epsilon,$$

with probability $\geq 1 - \delta$. In words, this result means that if we can find a k-sparse vector s that is consistent with the observation vector y, then s is close to x. In fact, s can be made as close to x as desired by increasing the number of measurements m. Unfortunately, this result is not practical because finding such a vector s is equivalent to finding a minimal ℓ_0-norm solution consistent with the observations, which is known to be an NP-hard problem (Natarajan, 1995).

In (Plan and Vershynin, 2013a), the authors focus on vectors $x \in \mathbb{R}^n$ that satisfy an inequality of the form $\|x\|_1/\|x\|_2 \leq s$. Note that if x is s-sparse, then it satisfies the above

inequality, though of course the converse is not true. Thus they use the ratio $\|x\|_1/\|x\|_2$ as a proxy for $\|x\|_0$. They choose measurement vectors $a_i \in \mathbb{R}^n$ according to the Gaussian distribution, or more generally, any radially invariant distribution; this means that, under the chosen probability distribution on the vector $a \in \mathbb{R}^n$, the normalized vector $a/\|a\|_2$ is uniformly distributed on the sphere $S^{n-1} \subseteq \mathbb{R}^n$. With these randomly generated measurement vectors, the measured quantities are $y_i = \text{sign}(\langle a_i, x\rangle)$. The authors propose to estimate x via

$$\hat{x} := \underset{z}{\text{argmin}} \|z\|_1 \text{ s.t. } \text{sign}(\langle a_i, z\rangle) = y_i \ \forall i, \sum_{i=1}^{m} |\langle a_i, z\rangle| = m, \tag{2}$$

where m is the number of measurements. They show that if

$$\epsilon > C\left(\frac{s}{m}\ln(2n/s)\ln(2n/m + 2m/n)\right)^{1/5}$$

for some universal constant C, then with probability $\geq 1 - \exp(-c\epsilon m)$ where c is another universal constant, it is true that

$$\left\| \frac{x}{\|x\|_2} - \frac{\hat{x}}{\|\hat{x}\|_2} \right\|_2 \leq \epsilon \tag{3}$$

for all $x \in \mathbb{R}^n$ such that $\|x\|_1/\|x\|_2 \leq \sqrt{s}$. Although this is the first proposed convex algorithm to recover x, the number of measurement m is $O(\delta^{-5})$. From (3) we see that if we are able to carry out the ℓ_0-norm minimization, then m is $O(\delta^{-1})$. It is still an open question whether or not a practical algorithm can achieve this optimal dependence on δ in (3). In (Ai et al., 2014) the theory is extended to non-Gaussian noise signals that are sub-Gaussian.

In (Plan and Vershynin, 2013b), it is assumed that the measurements $y_i \in \{0, 1\}$ are drawn at random with the property that the expected value $E(y_i)$ satisfies

$$E(y_i) = \theta(\langle a_i, x\rangle),$$

where $\theta : \mathbb{R} \to [-1, 1]$ is an unknown function. If $\theta(\alpha) = \tanh(\alpha/2)$, then the problem is one of logistic regression, whereas if $\theta(\alpha) = \text{sign}(\alpha)$, then the problem becomes OBCS. A probabilistic approach is proposed in (Plan and Vershynin, 2013b), which has the advantage that the resulting optimization problem is convex. However, the disadvantage is that the number of measurements m is $O(\delta^{-6})$ where δ is the probability that the algorithm may fail. The large negative exponent of δ makes the algorithm somewhat impractical.

In all of the papers discussed until now, the measurement vector y_i equals $\text{sign}(\langle a_i, x\rangle)$ for suitably generated random vectors a_i. As mentioned above, with such a set of measurements one can at best aspire to recover only the normalized unknown vector $x/\|x\|_2$. In (Knudson et al., 2016), it is proposed to overcome this limitation by changing the *linear* measurements to *affine* measurements. Specifically, the measurements in (Knudson et al., 2016) are of the form $y_i = \text{sign}(\langle a_i, x\rangle + b_i)$, where $a_{ij} \sim \mathcal{N}(0, 1)$,[2] and $b_i \sim \mathcal{N}(0, \tau^2)$ where τ is some

2. Recall that each a_i is an n-vector.

specified constant. If a prior upper bound R for $\|x\|_2$ is available, then it is possible to choose $\tau = R$. Then the optimization problem in (2) is modified to[3]

$$(\hat{x}, \hat{v}) := \underset{z,v}{\text{argmin}}[\|z\|_1 + \tau|v|] \text{ s.t. } \text{sign}(\langle a_i, z\rangle + b_i v) = y_i \ \forall i, \sum_{i=1}^{m} |\langle a_i, z\rangle + b_i v| = m. \tag{4}$$

It is evident that the above formulation is similar to the formulation in (Plan and Vershynin, 2013a) applied to the augmented vector $(x, v) \in \mathbb{R}^{n+1}$. The following result is shown in (Knudson et al., 2016, Theorem 4): Fix τ, R, α such that $\alpha < \min\{1, \tau/2\}$. If

$$m \geq C\left(\frac{\sqrt{R^2 + \tau^2}}{\alpha}\right)^5 \log^2\left(\frac{2n}{x}\right),$$

then for all vectors $x \in \mathbb{R}^n$ with $\|x\|_1/\|s\|_2 \leq \sqrt{s}$, the solution $(\hat{x}, \hat{v})$ to the optimization problem in (4) satisfies

$$\|(\hat{x}/\hat{v}) - x\|_2 \leq \frac{4\sqrt{R^2 + \tau^2}}{\tau}\alpha,$$

with a probability exceeding

$$1 - C\exp\left(-\frac{c\alpha m}{\sqrt{R^2 + \tau^2}}\right),$$

where C and c are universal constants. If R is a known prior upper bound for $\|x\|_2$, then one can choose $\tau = R$ in the above, in which the bound simplifies to

$$\|(\hat{x}/\hat{v}) - x\|_2 \leq 4\sqrt{2}\alpha.$$

3. Preliminaries

In this section we present some preliminary results, while the main results are presented in the next section. As shown below, the one-bit compressed sensing (OBCS) problem can be naturally formulated as a problem in probably approximately correct (PAC) learning. In fact, several of the approaches proposed thus far for solving the OBCS problem are similar to existing methods in PAC learning, but do not take full advantage of the power and generality of PAC learning theory. Some of the things that "come for free" in PAC learning theory are: explicit estimates for the number of measurements m, ready extension to the case where successive measurement vectors a_i are not independent but form a β-mixing process, and ready extension to the case of noisy measurements. The negative is that the PAC learning approach does not always address the *efficiently computability* of the algorithms. In (Valiant, 1984) which launched PAC learning theory, efficient computability of the algorithm is a central consideration. However, subsequent literature does not always pay full attention to this aspect.

3. Note that v here equals u/τ in (Knudson et al., 2016, Eq. (6)). Also, since δ is used to denote the confidence of a PAC learning algorithm later in the paper, we use α instead of δ as in the cited equation.

3.1. Brief Introduction to the PAC Learning Problem

In this subsection, we give a brief introduction to PAC learning theory. By now the fundamentals of PAC learning theory are well-developed, and several book-length treatments are available, including (Vapnik, 1998; Anthony and Bartlett, 1999; Vidyasagar, 1997, 2003). The theory encompasses a wide variety of learning situations. However, OBCS is aligned closely with the most basic version of PAC learning, known as concept learning, which is formally described next.

The concept learnig problem is formulated over a metric space X (usually taken as $\mathbb{R}^n$ for some integer n), together with the associated Borel σ-algebra $\mathcal{S}$; a collection of sets $\mathcal{C} \subseteq \mathcal{S}$, known as the **concept class**; and a family $\mathcal{P}$ of probability measures on $(X, \mathcal{S})$. If $\mathcal{P} = \mathcal{P}^*$, the set of *all* probability measures on $(X, \mathcal{S})$, the problem is known as one of "distribution-free learning."

Learning takes place as follows: A fixed but unknown set $T \in \mathcal{C}$, known as the "target concept," is chosen, along with an unknown probability measure $P \in \mathcal{P}$. Then random samples $\{c_1, c_2, \ldots\}$ are generated independently in accordance with the chosen distribution P. This is the basic version of PAC learning studied in (Vapnik, 1998; Anthony and Bartlett, 1999; Vidyasagar, 1997). The case where the sample sequence can exhibit dependence, for example if they come from a Markov process with the stationary distribution P, is studied in (Vidyasagar, 2003). Using the sample c_i, an "oracle" generates a "label" $y_i \in \{0, 1\}$. In the case of noise-free measurements, $y_i = I_T(c_i)$, where T is the fixed but unknown target concept, and $I_T(\cdot)$ denotes the indicator function of the set T. In the case of noisy measurements, the label y_i equals $I_T(c_i)$ flipped with an unknown probability α. This situation is studied in Section 5. After m such samples are drawn and labelled, the available information $\{(c_i, y_i)\}_{i=1}^m \in (X \times \{0, 1\})^m$ is passed through an "algorithm" to generate a "hypothesis," or an approximation to the unknown target concept T. For present purposes, an "algorithm" is any indexed collection of maps $\{A_m\}_{m \geq 1}$ where

$$A_m : (X \times \{0, 1\})^m \to \mathcal{C}.$$

In other words, an algorithm is any systematic procedure for taking a finite sequence of labelled samples, and returning an element of the concept class $\mathcal{C}$. The concept

$$G_m(T; \mathbf{c}) := A_m\left(\{(c_i, y_i)\}_{i=1}^m\right)$$

is called the "hypothesis" generated by the first m samples when the sample sequence is $\mathbf{c} = (c_1, \ldots, c_m)$, and the label sequence is $\mathbf{y} = (y_1, \ldots, y_m)$. In the interests of reducing clutter, we will use G_m in the place of $G_m(T; \mathbf{c})$ unless the full form is needed for clarity. Note that A_m is a deterministic map, but the hypothesis G_m is random because it depends on the random learning sequence $\{c_i\}$.

To measure how well the hypothesis G_m approximates the unknown target concept T, we use the **generalization error** defined by

$$J(T, G_m) = E[|I_T(x) - I_{G_m}(x)|, P]. \tag{5}$$

Thus $J(T, G_m)$ is the expected value of the difference between the indicator function $I_T(\cdot)$ and the label generated by the oracle with the input $I_{G_m}(\cdot)$. Note that both I_T and I_{G_m}

assume values in $\{0, 1\}$. Hence $J(T, G_m)$ is also the probability that, when a random test sample $x \in X$ is generated in accordance with the probability distribution P, the sample is *misclassified* by the hypothesis G_m, in the sense that $I_T(x) \neq I_{G_m}(x)$. In particular, if the hypothesis G_m differs from the target concept T by a set of measure zero, then the generalization error would be zero.

The key quantity in PAC learning theory is the **learning rate**, defined by

$$r(m, \epsilon) := \sup_{P \in \mathcal{P}} \sup_{T \in \mathcal{C}} P^m\{\mathbf{c} \in X^m : J(T, G_m) > \epsilon\}. \tag{6}$$

Therefore $r(m, \epsilon)$ is the worst-case measure, over all probability distributions in $\mathcal{P}$ and all target concepts in $\mathcal{C}$, of the set of "bad" samples $\mathbf{c} = (c_1, \ldots, c_m)$ for which the corresponding hypothesis G_m has a generalization error larger than a prespecifie threshold ϵ. Thus, after m samples are generated together with their labels, and the hypothesis G_m is generated using the algorithm, it can be asserted with confidence $1 - r(m, \epsilon)$ that G_m will correctly classify the next randomly generated test sample with probability of at least $1 - \epsilon$.

Definition 1 *An algorithm $\{A_m\}$ is said to be* **probably approximately correct (PAC)** *if $r(m, \epsilon) \to 0$ as $m \to \infty$, for every fixed $\epsilon > 0$. The concept class $\mathcal{C}$ is said to be* **PAC learnable** *under the family of probability measures $\mathcal{P}$ if there exists a PAC algorithm.*

The objective of statistical learning theory is to determine conditions under which there exists a PAC algorithm for a given concept class, and if so, to find upper bounds for the learning rate $r(m, \epsilon)$.

3.2. OBCS as a Problem in PAC Learning

In order to embed the problem of one-bit compressed sensing into the framework of concept learning, we proceed as follows. We begin with the case where the measurements are of the form $\text{sign}(\langle a_i, x \rangle)$ where the a_i are chosen at random according to some arbitrary probability distribution, *which need not be the Gaussian.* Observe now that the closed half-space

$$H(x) := \{z \in \mathbb{R}^n : \langle z, x \rangle \geq 0\}$$

determines the vector x uniquely to within a positive scalar multiple, because x is the normal to the half-space. Conversely, the vector x uniquely determines the corresponding half-space $H(x)$, which remains invariant if x is replaced by a positive multiple of x. Thus the OBCS problem can be posed as that of determining the half-space $H(x)$ given the measurements $\text{sign}(\langle a_i, x \rangle), i = 1, \ldots, m$ where the a_i are selected at random in accordance with some probability measure P. Moreover, the one-bit measurement $\text{sign}(\langle a_i, x \rangle)$ equals $2I_{H(x)}(a_i) - 1$, where $I_{H(x)}(\cdot)$ denotes the indicator function of the half-space $H(x)$. Therefore, to within a simple affine transformation, the OBCS problem becomes that of determining an unknown half-space $H(x)$ from labelled samples $(a_i, I_{H(x)}(a_i)), i = 1, \ldots, m$, where the samples a_i are generated at random according to some prespecified probability measure. This is a PAC learning problem where the underlying space X is $\mathbb{R}^n$, with $\mathcal{S}$ being the associated Borel σ-algebra. The concept class $\mathcal{C}$ is the collection of all half-spaces $\{H_k^n(x)\}$ where

$$H_k^n(x) = \{a \in \mathbb{R}^n : \langle a, x \rangle \geq 0\} \tag{7}$$

as x varies over Σ_k, the set of k-sparse vectors in $\mathbb{R}^n$. The family of probability measures $\mathcal{P}$ can either be a singleton $\{P\}$ where P is specified *a priori*, or $\mathcal{P}^*$, the family of *all* probability measures on $\mathbb{R}^n$, or anything in-between.

When measurements are of the type $\text{sign}(\langle a_i, x\rangle)$, it is inherently impossible to determine the unknown vector x, except to within a positive scalar multiple. This is addressed by changing the measurements to be of the form $\text{sign}(\langle a_i, x\rangle + b_i)$, as suggested in (Knudson et al., 2016). Some slight modifications are required to address this modified formulation. In this case theunderlying space X is $\mathbb{R}^{n+1}$, and $\mathcal{S}$ is the associated σ-algebra. The concept class $\mathcal{C}$ is the collection of all half-spaces $\{H_k^{n+1}\}$ where

$$H_k^{n+1}(x) = \{(a,b) \in \mathbb{R}^{n+1} : \langle a, x\rangle + b \geq 0\} \tag{8}$$

as x varies over Σ_k. Finally, the family of probability measures $\mathcal{P}$ can either be a singleton $\{P\}$ where P is specified *a priori*, or $\mathcal{P}^*$, the family of *all* probability measures on $\mathbb{R}^n$, or anything in-between.

For a given $x \in \Sigma_k$, if $a \in \mathbb{R}^n$ belongs to the half-space $H_k^n(x)$, then the vector $(a,0) \in \mathbb{R}^{n+1}$ belongs to $H_k^{n+1}(x)$. However, the half-space $H_k^{n+1}(x)$ can also contain vectors of the form (a,b) with $b \neq 0$.

3.3. Interpretation of the Generalization Error

Suppose P is a probability measure on $(X, \mathcal{S})$, and define the quantity

$$d_P(A,B) := P(A \Delta B),\ \forall A, B \in \mathcal{S}.$$

Then d_P is a pseudometric on $\mathcal{S}$, in that d_P satisfies all the axioms of a metric, except that $d_P(A\Delta B) = 0$ does not necessarily imply that $A = B$, only that $A\Delta B$ has measure zero under P. In the traditional PAC learning problem formulation, the quantity of interest is the generalization error defined in (5). It is easy to see that an alternate expression for the generalization error is

$$J(T, G_m) = P(A\Delta B) = d_P(A,B).$$

Therefore the traditional PAC learning formulation does not distinguish between two concept classes that differ by a set of measure zero.

The above discussion explains the limitations of one-bit compressed sensing as described in (Plan and Vershynin, 2013b). In their case, they choose two vectors in $\mathbb{R}^2$, namely $x_1 = [\ 1 \quad 0\ ]$ and $x_1 = [\ 1 \quad 0.5\ ]$.[4] Their choice for P is the Bernoulli distribution on $\mathbb{R}^2$, which is purely atomic and assigns a weight of 0.25 to the four points $(1,1), (1,-1), (-1,1), (-1,-1)$. Now let us plot the half-planes H_{x_1}, H_{x_2} and their symmetric difference, which is the shaded region shown in Figure 1. Because none of the four points $(1,1), (1,-1), (-1,1), (-1,-1)$ (shown as red circles) belongs to the symmetric difference, x_1 and x_2 are indistinguishable in OBCS under this probability measure. In (Plan and Vershynin, 2013a), the authors conclude that OBCS cannot always recover an unknown vector x, depending on what P is. Indeed, x_1 and x_2 would be indistinguishable under *any* probability measure that assigns a value of zero to $H_{x_1} \Delta H_{x_2}$. Therefore, one must be careful to draw the right conclusion: When subsequent theorems in this paper show that OBCS is possible under *all* probability

4. They append a whole lot of zero components which are neglected here.

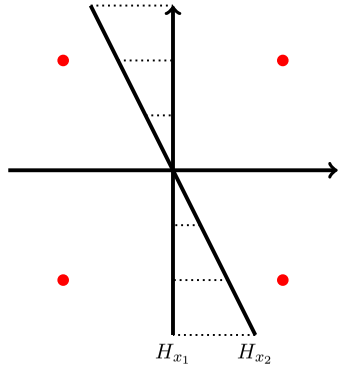

Figure 1: The half-planes H_{x_1}, H_{x_2}, and their symmetric difference.

measures on $\mathbb{R}^n$, *including* all purely atomic probability measures, what this means is that if $x \in \Sigma_k$, then OBCS will return a vector $\hat{x}$ such that $P(H_x \Delta H_{\hat{x}}) = 0$ whatever be P, and *not* that $x = \hat{x}$.

Now we examine the relationship of the generalization error $J(\hat{x}, x)$ to a couple of other quantities that are widely used in OBCS as error measures. First, define

$$\rho(\hat{x}, x) := E[|\text{sign}(\langle a, \hat{x}\rangle) - \text{sign}(\langle a, x\rangle)|, P], \tag{9}$$

where x is the true vector, $\hat{x}$ is its estimate. Note that $|\text{sign}(\langle a, \hat{x}\rangle) - \text{sign}(\langle a, x\rangle)|$ equals 0 or 2. Therefore we can also write

$$\rho(\hat{x}, x) = 2J(H_{\hat{x}}, H_x).$$

Next, we examine the relationship of $\rho(\hat{x}, x)$ to $\|\hat{x} - x\|_2$. Without loss of generality it can be assumed that both x and $\hat{x}$ have unit Euclidean norm. This can be achieved using some results from (Goemans and Williamson, 1995). Define

$$\alpha := \min_{\theta \in [0, 2\pi]} \frac{2}{\pi} \frac{\theta}{1 - \cos\theta} > 0.87856. \tag{10}$$

Then we have the following results.

Lemma 2 *Let P be any radially invariant probability measure on $\mathbb{R}^n$, and suppose $a \in \mathbb{R}^n$ is drawn at random according to P. Suppose $\|x\|_2 = \|\hat{x}\|_2 = 1$, and let $J(\hat{x}, x)$ denote the generalization error defined in* (5)*. Then*

$$\|\hat{x} - x\|_2^2 \leq \frac{4}{\alpha} J(\hat{x}, x). \tag{11}$$

Proof We make use of a couple of results from (Goemans and Williamson, 1995). First, (Goemans and Williamson, 1995, Lemma 3.2) states that

$$\Pr\{\text{sign}(\langle a, \hat{x}\rangle) \neq \text{sign}(\langle a, x\rangle)\} = \frac{1}{\pi}\arccos(\hat{x}^\top x),$$

Note that

$$J(\hat{x}, x) = \Pr\{\text{sign}(\langle a, \hat{x}\rangle) \neq \text{sign}(\langle a, x\rangle)\}.$$

Therefore the above is equivalent to

$$J(\hat{x}, x) = \frac{1}{\pi}\arccos(\hat{x}^\top x).$$

Second, (Goemans and Williamson, 1995, Lemma 3.4) states that

$$\frac{1}{\pi}\arccos(\hat{x}^\top x) \geq \frac{\alpha}{2}(1 - \hat{x}^\top x),$$

or equivalently

$$1 - \hat{x}^\top x \leq \frac{2}{\alpha}\arccos(\hat{x}^\top x).$$

Now note that, when both $\hat{x}$ and x are unit vectors, we have

$$\|\hat{x} - x\|_2^2 = \|\hat{x}\|_2^2 + \|x\|_2^2 - 2\hat{x}^\top x = 2(1 - \hat{x}^\top x).$$

Therefore

$$\begin{aligned} \|\hat{x} - x\|_2^2 &= 2(1 - \hat{x}^\top x) \\ &\leq \frac{4}{\alpha}\arccos(\hat{x}^\top x) = \frac{4}{\alpha}J(\hat{x}, x). \end{aligned}$$

■

3.4. PAC Learning via the Vapnik-Chervonenkis (VC) Dimension

One of the most useful concepts in PAC learning theory is defined next.

Definition 3 *A set $S \subseteq X$ of finite cardinality is said to be* **shattered** *by the concept class $\mathcal{C}$ if, for every subset $B \subseteq S$, there exists a concept $A \in \mathcal{C}$ such that $S \cap A = B$. The* **Vapnik-Chervonenkis- or VC-dimension** *of the concept class $\mathcal{C}$ is the largest integer d such that there exists a set S of cardinality d that is shattered by $\mathcal{C}$.*

Therefore a concept class $\mathcal{C}$ has VC-dimension d if two statements hold: (i) There exists a set of cardinality d that is shattered by $\mathcal{C}$, and *no set* of cardinality larger than d is shattered by $\mathcal{C}$. If there exist sets of arbitarily large cardinality that are shattered by $\mathcal{C}$, then its VC-dimension is defined to be infinite.

If a concept class has finite VC-dimension, then it is PAC learnable under *every probability distribution* on X. An algorithm is said to be **consistent** if it always produces a

hypothesis that classifies all the training samples correctly. In other words, an algorithm is consistent if the hypothesis G_m produced by applying the algorithm to the sequence $\{(c_i, I_T(c_i))\}_{i\geq 1}$ has the property that $I_T(c_i) = I_{G_m}(c_i)$ for all i and m. Note that a consistent algorithm always exists if the axiom of choice is assumed. However, in some situations, it is NP-hard or NP-complete to find a consistent algorithm.

With these notions in place, we have the following very fundamental result.

Theorem 4 *((Blumer et al., 1989); see also (Vidyasagar, 2003, Theorem 7.6)) Suppose a concept class $\mathcal{C}$ has finite VC-dimension. Then $\mathcal{C}$ is PAC learnable for every probability measure on X. Suppose that d is an upper bound for VC-dim($\mathcal{C}$), and let $\{A_m\}$ be any consistent algorithm. Moreover, the learning rate is bounded by*

$$r(m, \epsilon) \leq 2\left(\frac{2em}{d}\right)^d 2^{-m\epsilon/2},$$

where e denotes the base of the natural logarithm. Therefore $r(m, \epsilon) \leq \delta$ if

$$m \geq \max\left\{\frac{8d}{\epsilon}\lg\frac{8e}{\epsilon}, \frac{4}{\epsilon}\lg\frac{2}{\delta}\right\} \tag{12}$$

samples are chosen.

Note that the number of samples required to achieve an accuracy of ϵ with confidence $1 - \delta$ is $O((1/\epsilon)\ln(1/\delta))$. However, the main challenge in applying this result is in finding a consistent algorithm.

Theorem 4 shows that the finiteness of the VC-dimension of a concept class is a *sufficient* condition for PAC learnability. The next result shows that the condition is also necessary.

Theorem 5 *((Blumer et al., 1989; Ehrenfeucht et al., 1989); see also (Vidyasagar, 2003, Theorem 7.7)) Suppose a concept class $\mathcal{C}$ has VC-dimension $d \geq 2$. Then there exist probability measures on X such that any algorithm requires at least*

$$m \geq \left\{\frac{d-1}{32\epsilon}, \frac{1-\epsilon}{\epsilon}\ln\frac{1}{\delta}\right\} \tag{13}$$

samples, in order to learn to accuracy ϵ and confidence δ.

4. Estimates of the VC-Dimension

This section contains the main results of the paper, namely, to obtain explicit estimates of the VC-dimension of half-spaces generated by k-sparse vectors.

Theorem 6 *Let $\mathcal{H}_k^n$ denote the set of half-spaces $H_k^n(x)$ in $\mathbb{R}^n$ generated by k-sparse vectors, as defined in* (7)*. Then*

$$k(\lfloor\lg(n/k)\rfloor + 1) \leq \textit{VC-dim}(\mathcal{H}_k^n) \leq \lfloor 2k\lg(ne)\rfloor. \tag{14}$$

Remark: In (Neylon, 2006, Theorem 20), it is shown that if $k < 0.45\sqrt{n}$, then

$$\text{VC-dim}(\mathcal{H}_k^n) < 2k \lg n.$$

The right side of (14) can be rewritten as

$$\text{VC-dim}(\mathcal{H}_k^n) \leq 2k(\lg n + \lg e) \approx 2k(\lg n + 1.4).$$

Clearly, as n becomes larger, the additional term becomes insignificant. Moreover, there is no restriction on the magnitude of k in Theorem 6, as there is in (Neylon, 2006, Theorem 20). Also, the present Theorem 6 contains a lower bound on the VC-dimension in addition to an upper bound, which is not previously available in the literature.

Proof We begin with the upper bound in (14). It is shown that if a set $U = \{u_1, \ldots, u_l\} \subseteq \mathbb{R}^n$ is shattered by the collection of half-spaces $\mathcal{H}_k^n$, then $l \leq \lfloor 2k \lg(en) \rfloor$. The proof combines a few ideas that are standard in PAC learning theory, which are stated next.

The first result needed is (Dudley, 1978, Theorem 7.2).[5] It states the following: Suppose that $\mathcal{F}$ is a collection of functions mapping a given set Z into $\mathbb{R}$, such that $\mathcal{F}$ is a k-dimensional real vector space over the field $\mathbb{R}$. Define the associated collection of subsets of X by

$$\text{Pos}(f) := \{z \in Z : f(z) \geq 0\}, \text{Pos}(\mathcal{F}) := \{\text{Pos}(f), f \in \mathcal{F}\}.$$

Then VC-dim(Pos($\mathcal{F}$)) $= k$. To apply the above theorem to this particular instance, we fix the integer k as well as a support set $S \subseteq \{1, \ldots, n\}$ such that $|S| = k$, and choose $\mathcal{F}$ to be the set of functions $\{f(z) = \langle z, x \rangle : \text{supp}(x) \subseteq S\}$. This family of functions is clearly a k-dimensional linear space because the adjustable parameter here is the k-sparse vector x with support in the fixed set S. Therefore it follows that, if we define $\mathcal{H}_S = \{H_k^n(x) : \text{supp}(x) \subseteq S\}$, then VC-dim$(\mathcal{H}_S) = k$.

The next result needed is Sauer's lemma (Sauer, 1972), which states the following: Suppose $\mathcal{C}$ is a collection of subsets of X with finite VC-dimension d, and that $U = \{u_1, \ldots, u_l\} \subseteq X$ with $l > d$. Let $\mathcal{C} \cap U$ denote the collection $\{A \cap B : A \in \mathcal{C}, B \subseteq U\}$. Then

$$|\mathcal{C} \cap U| \leq \sum_{i=0}^{d} \begin{pmatrix} l \\ i \end{pmatrix} \leq \left(\frac{el}{d}\right)^d,$$

where e denotes the base of the natural logarithm. Strictly speaking, Sauer's lemma is the first inequality, which states that the number of subsets of U that can be generated by taking intersections with sets in the collection $\mathcal{C}$ is bounded by the summation shown. The second bound is derived in (Blumer et al., 1989). By applying Sauer's lemma to the problem at hand, it can be seen that, for a fixed support set S, the number of subsets of U that can be generated by intersecting with the collection of half-spaces $\mathcal{H}_S$ is bounded by $(el/k)^k$, because $\mathcal{H}_S$ has VC-dimension k. Note that a similar bound is derived in (Jacques et al., 2013), but without any reference to Sauer's lemma. Also, the result in (Jacques et al., 2013) is specifically for collections of half-spaces, whereas Sauer's lemma is applicable to completely general collections of sets.

5. Note that the definition of VC-dimension used in this reference is the VC-dimension as defined in Definition 3 *plus one*.

Now observe that $\mathcal{H}_k^n$ is just the union of the collections $\mathcal{H}_S$ as S ranges over all subsets of $\{1, \ldots, n\}$ with $|S| = k$. The number of such sets S is the combinatorial parameter n choose k, which is bounded by n^k.[6] Moreover, for each fixed support set S, the collection of subsets $\mathcal{H}_S \cap U$ has cardinality no larger than $(en/k)^k$, as shown above. Therefore

$$|\mathcal{H}_k^n \cap U| \leq \begin{pmatrix} n \\ k \end{pmatrix} \left(\frac{el}{k}\right)^k \leq \left(\frac{nel}{k}\right)^k.$$

The final step in the proof comes from (Vidyasagar, 2003, Lemma 4.6), which states the following (see specifically item 2 of this lemma): Suppose $\alpha, \beta > 0$, $\alpha\beta > 4$ and $l \geq 1$. Then

$$l \leq \alpha \lg(\beta l) \implies l < 2\alpha \lg(\alpha\beta). \tag{15}$$

In the present instance, the collection of sets $\mathcal{H}_k^n \cap U$ has cardinality no larger $(nel/k)^k$, whereas U has 2^l subsets in all. Therefore, if U is shattered by the collection $\mathcal{H}_k^n$, then we must have

$$2^l \leq \left(\frac{nel}{k}\right)^k,$$

or, after taking binary logarithms,

$$l \leq k \lg \frac{nel}{k},$$

which is of the form (15) with $\alpha = k, \beta = ne/k$. Substituting these values into (15) leads to the conclusion that

$$l \leq 2k \lg(ne),$$

provided $\alpha\beta = ne \geq 4$, which holds if $n \geq 2$. Because l is an integer, we can replace the right side by its integer part, which leads to the upper bound in (14).

Now we turn our attention to the lower bound. First we consider the simple case where $k = 1$. Given n, define $l = \lfloor \lg n \rfloor + 1$, so that $n \geq 2^{l-1}$. The first step is to show that the set of half-spaces $\mathcal{H}_1^n$ generated by "one-sparse vectors" has VC-dimension l. Let $s = l - 1 = \lfloor \lg n \rfloor$, and enumerate the 2^s bipolar row vectors in $\{-1, 1\}^s$ in some order, call them $v_1, \ldots v_{2^s}$. Now define the $n \times l$ matrix

$$M = \left[\begin{array}{c|c} 1 & v_1 \\ \vdots & \vdots \\ 1 & v_{2^s} \\ 0_{(n-2^s)\times 1} & 0_{(n-2^s)\times s} \end{array}\right] \in \mathbb{R}^{n \times l}. \tag{16}$$

In other words, the matrix M has a first column of ones, and then the 2^s bipolar vectors in $\{-1, 1\}^s$ in some order, padded by a block of zeros in case $n > 2^{l-1}$. As we shall see below, the "padding" is not used. Now define $U = \{u_0, u_1, \ldots, u_s\}$ denote the $s + 1 = l$ columns of the matrix M. Note that for notational convenience we start numbering the columns with 0 rather than 1. It is claimed that the collection of half-spaces $\mathcal{H}_1^n$ shatters this set U, thus showing that VC-dim$(\mathcal{H}_1^n) \geq l$.

6. Actually n^k is a pretty crude estimate, but as we shall see, it is good enough.

To show that the set U is shattered, let $B \subseteq U$ be an arbitrary subset. Thus B consists of some columns of the matrix M. We examine two cases separately. First, suppose $u_0 \in B$. Then we associate a unique integer r between 1 and 2^s as follows. Define a bipolar vector $\mathbf{i}_B \in \{-1,1\}^s$ by $i_j = 1$ if $u_j \in B$, and $i_j = -1$ if $u_j \notin B$. This bipolar vector $\mathbf{i}_B$ must be one of the vectors $v_1, \ldots, v_{2^s}$. Let r be the unique integer such that $\mathbf{i}_B = v_r$. Define the vector $x \in \mathbb{R}^n$ such that $x_r = 1$, and the remaining elements of x are all zero, and note that $x \in \Sigma_1$. Then $\langle u_0, x\rangle = 1$, while $\langle u_j, x\rangle = 1$ if $u_j \in B$ and $\langle u_j, x\rangle = -1$ if $u_j \notin B$. Therefore the associated half-space $H(x)$ includes precisely the elements of the specified set B. Next, suppose $u_0 \notin B$; in this case we basically flip the signs. Thus the bipolar vector $\mathbf{i}_B \in \{-1,1\}^s$ is chosen such that $i_j = -1$ if $u_j \in B$, and $i_j = 1$ if $u_j \notin B$. If this bipolar vector corresponds to row r in the ordering of $\{-1,1\}^s$, we choose $x \in \Sigma_1$ to have a -1 in row r and zeros elsewhere. This argument shows that the set $\mathcal{H}_1^n$ generated by all one-sparse vectors x has VC-dimension of at least $\lfloor \lg n \rfloor + 1$, which is consistent with the left side of (14) when $k = 1$.

To extend the above argument to general values of k, suppose n and k are specified, and define $l = \lfloor \lg(n/k) \rfloor + 1$ and $s = l - 1 = \lfloor \lg(n/k) \rfloor$. Then $n/k \geq 2^s$, or equivalently, $n \geq k2^s$. Define matrices $M_1, \ldots, M_k \in \{-1,1\}^{2^s \times l}$ in analogy with (16). Then define a matrix $M \in \{0,1\}^{n \times kl}$ as a block-diagonal matrix containing $M_1, \ldots, M_k$ on the diagonal blocks, padded by an appropriate number of zero rows so that the number of rows equals n. In other words, M has the form

$$M = \begin{bmatrix} M_1 & 0_{2^s \times l} & \ldots & 0_{2^s \times l} \\ 0_{2^s \times l} & M_2 & \ldots & 0_{2^s \times l} \\ \vdots & \vdots & \vdots & \vdots \\ 0_{2^s \times l} & \ldots & 0_{2^s \times l} & M_k \\ & & 0_{(n-k2^s) \times kl} & \end{bmatrix} \in \mathbb{R}^{n \times kl}.$$

Define U to be the set of columns of the matrix M, and note that $|U| = kl = k(\lfloor \lg(n/k) \rfloor + 1)$. It is now shown that the set U is shattered by the collection $\mathcal{H}_k^n$ of half-spaces generated by k-sparse vectors. Partition U as $U_1 \cup U_2 \cup \ldots \cup U_k$, where each U_i consists of l column vectors. Then any specified subset $B \subseteq U$ can be expressed as a union $B_1 \cup \cdots \cup B_k$ where $B_i \subseteq U_i$ for each i. Now it is possible to mimic the arguments of the previous paragraph to show that the set U can be shattered by the collection of half-spaces $\mathcal{H}_k^n$. For each subset B_i, identify an integer r_i between 1 and 2^s such that the bipolar vector $\mathbf{i}_{B_i}$ is the r_i-th in the enumeration of $\{-1,1\}^s$. For each index i between 1 and k, let $x_i \in \mathbb{R}^{2^s}$ contain a 1 in row r_i and zeros elsewhere. Define $x \in \mathbb{R}^n$ by stacking x_1 through x_k, followed by $n - k2^s$ zeros. This shows that it is possible to shatter a set of cardinality $k(1 + \lfloor \lg(n/k) \rfloor)$, which is the right inequality in (14). ■

Theorem 6 is applicable to the case where measurements are of the form $\text{sign}(\langle a_i, x\rangle)$. Such measurements can at best lead to the recovery of the direction of a k-sparse vector x, but not its magnitude. In situations where it is desired to recover a sparse vector in its entirety, the measurements are changed to

$$y_i = \text{sign}(\langle a_i, x\rangle + b_i\theta), \tag{17}$$

where x varies over $\Sigma_k \subseteq \mathbb{R}^n$ and $\theta \in \mathbb{R}$. The concept class in this case is given by

$$H_k^{n+1}(x, \theta) = \{(a, b) \in \mathbb{R}^{n+1} : \langle a, x\rangle + b\theta \geq 0\}. \tag{18}$$

By inspecting the equation (17), we deduce that

$$\mathcal{H}_k^n(x) \subseteq \mathcal{H}_k^{n+1}(x) \subseteq \mathcal{H}_{k+1}^{n+1}([x\ \theta]^\top), \tag{19}$$

where $x \in \Sigma_k$ and $\theta \in \mathbb{R}$ so that the vector $[x\ \theta]^\top$ is $k+1$-sparse. We are now ready to state a bound on the VC-dimenstion of the collection of half-spaces $\mathcal{H}_k^{n+1}$.

Theorem 7 *Let $\mathcal{H}_k^{n+1}$ denote the set of half-spaces $H_k^n(x)$ in $\mathbb{R}^n$ as defined in (17). Then*

$$k(1 + \lfloor \lg(n/k) \rfloor) \leq \textit{VC-dim}(\mathcal{H}_k^{n+1}) \leq \lfloor 2(k+1)\lg(e(n+1)) \rfloor. \tag{20}$$

Proof From (19) we conclude that

$$\text{VC-dim}(H_k^n) \leq \text{VC-dim}(\mathcal{H}_k^{n+1}) \leq \text{VC-dim} H_{k+1}^{n+1}([x\ \theta]^\top),$$

then the desired result follows Theorem 6. ■

5. OBCS with Noisy Measurements

In this section we study the one-bit compressed sensing problem when the information available to the learner is a randomly "flipped" version of the true output $\text{sign}(\langle a_i, x\rangle)$ or $\text{sign}(\langle a_i, x\rangle + b_i)$, where x is an unknown k-sparse vector. A study of the problem of PAC learning with noisy measurements was initiated in (Valiant, 1985), shortly after the publication of (Valiant, 1984). Over the years several different models of PAC learning with noisy labels have been studied. Rather than present an exhaustive listing of these, we focus on just a few papers that are most germane to the version of the problem studied here.

In the case of noise-free measurements, the results on learnability were stated in terms of a consistent algorithm, which always exists if one were to assume the axiom of choice. In contrast, in the case where the labels are noisy, it might not be possible to construct a hypothesis that is consistent with the data. Therefore the notion of consistency is replaced by the notion of minimizing empirical risk. Suppose we are given a labelled sample sequence $\{(c_i, y_i) \in X \times \{0,1\}\}_{i \geq 1}$. Suppose $F \in \mathcal{C}$ is a hypothesis. Then the **empirical risk** of the hypothesis with respect to this labelled sequence, after m samples, is defined as

$$\hat{J}_m(T, F) := \frac{1}{m} \sum_{i=1}^{m} |y_i - I_F(c_i)|. \tag{21}$$

Definition 8 *An algorithm $\{A_m\}_{m \geq 1}$ is said to **minimize empirical risk**, or to be a **MER algorithm**, if for all sample sequences $\{(c_i, y_i) \in X \times \{0,1\}\}_{i \geq 1}$, and all integers m, it is the case that*

$$\hat{J}_m(G_m) = \min_{F \in \mathcal{C}} \hat{J}_m(F), \tag{22}$$

where

$$G_m = A_m((c_1, y_1), \ldots (c_m, y_m))$$

is the output of the algorithm after m samples, given the sequence $\{(c_i, y_i) \in X \times \{0,1\}\}_{i \geq 1}$.

Note that if the labels are noise-free, then $y_i = I_T(c_i)$, and

$$\hat{J}_m(T,F) := \frac{1}{m}\sum_{i=1}^{m} |I_T(c_i) - I_F(c_i)|$$

is the empirical estimate of the distance $D_P(T,F)$. In this case, a MER algorithm becomes a consistent algorithm.

We begin by summarizing some relevant results from (Angluin and Laird, 1988). In this paper, the probability of a 1 turning into 0 is assumed to be the same as the probability of a 0 turning into a 1; call it α. Clearly α must be < 0.5 in order for the problem to be learnable, because if the labels are flipped with probability 0.5, then the labels are pure noise and do not convey any information. In this paper, it is *not* assumed that the flipping probability α is known; rather, it is assumed that an upper bound $\bar{\alpha} < 0.5$ for α is known. Moreover, a procedure is given for generating such an upper bound. Suppose $\epsilon, \delta \in (0,1)$ are specified, where ϵ is the accuracy and δ is the confidence, and the objective is to choose the number of samples m to be sufficiently large that $r(m,\epsilon) \leq \delta$, where the learning rate $r(m,\epsilon)$ is defined in (6). The procedure given in this paper generates an upper bound $\bar{\alpha} < 0.5$ for α with confidence $\geq 1 - \delta/2$ using $r = 1 + \lceil \lg[(1-2\alpha)^{-1}] \rceil$ rounds. In case the concept class $\mathcal{C}$ has finite cardinality, say $|\mathcal{C}| \leq N$, then the following result can be established.

Theorem 9 *(See (Angluin and Laird, 1988, Theorem 2).) Given $\epsilon, \delta > 0$, draw*

$$m \geq \frac{2}{\epsilon^2(1-2\bar{\alpha})^2} \ln \frac{2N}{\delta} \tag{23}$$

i.i.d. samples according to an unknown probability measure $\mathcal{P} \in \mathcal{P}^*$. Let $T \in \mathcal{C}$ be any unknown target concept, and let G_m denote the output of a MER algorithm based on m noisy labels. Then

$$\sup_{P \in \mathcal{P}^*} \max_{T \in \mathcal{C}} P^m\{x \in X^m : d_P(G_m, T) \geq \epsilon\} \leq \delta. \tag{24}$$

If an infinite concept class $\mathcal{C}$ has finite VC-dimension, then for each $\epsilon > 0$ and $P \in \mathcal{P}^*$, $\mathcal{C}$ has a finite ϵ-cover with respect to the metric d_P, whose cardinality does not depend on $P \in \mathcal{P}^*$. Using this fact and Theorem 9, it is possible to prove bounds analogous to those in (25) for concept classes with finite VC-dimension. This is done in (Laird, 1988).

Next we discuss the paper (Natarajan et al., 2013). In this paper, the probability of a 1 becoming 0 is *not* assumed to equal the probability of a 0 becoming a 1. However, it is assumed that *both probabilities are known*. This allows the authors to construct an unbiased estimator for the true label, which may not be possible if only bounds for these probabilities are known.

Finally, we mention in passing the paper (Simon, 1996), even though the learning problem studied there is more general than the one studied here. Let $\mathcal{F} \subseteq [0,1]^X$ be a family of functions mapping X into $[0,1]$, and let $f \in \mathcal{F}$ be fixed but unknown. Let $P \in \mathcal{P}^*(X)$ be an unknown probability measure on X, and generate samples $x_1, \ldots, x_m$ in X that are i.i.d. according to P. For each sample x_j, a corresponding label $l_j \in \{0,1\}$ is generated according to

$$l_j = \begin{cases} 1, & \text{w.p. } f(x_j), \\ 0, & \text{w.p. } 1 - f(x_j). \end{cases}$$

From the data $\{(x_j, l_j)\}_{i=1}^m$, the objective is to cconstruct an approximation to $f(\cdot)$.

Now we come to the objective of the present section. By focusing on the *prediction error* (defined below) instead of the distance $d_P(G_m, T)$, it is possible to streamline the statement of the theorem.

To make the problem formulation precise, we use the notation in Section 3.1, whereby X is a set, $\mathcal{S}$ is a σ-algebra of subsets of X, and P is a probability measure on X. To incorporate the randomness, we enlarge X by defining $X_N = X \times \{0,1\}$ as the sample space; define $\mathcal{S}_N$ to be the σ-algebra of subsets in X_N generated by cylinder sets of the form $S \times \{0\}$ and $S \times \{1\}$ for all $S \in \mathcal{S}$; and define a probability measure P_N on X_N by defining

$$P_N(S \times \{0\}) = (1-\alpha)P(S), P_N(S \times \{1\}) = \alpha P(S). \tag{25}$$

Let (c, L) denote a typical element in the sample space X_N. Then

$$\Pr\{L = 0\} = P_N(X \times \{0\}) = 1 - \alpha, \Pr\{L = 1\} = P_N(X \times \{1\}) = \alpha.$$

Here the event $L = 0$ corresponds to the label not being flipped, while the event $L = 1$ corresponds to the label being flipped. It is clear that P_N is a product measure, so that the flipping of labels is independent of the generation of training samples.

Learning takes place as follows: Independent samples $\{(c_i, \omega_i) \in X \times \{0,1\}\}_{i \geq 1}$ are generated in accordance with the above probability measure P_N. Let T be a fixed but unknown target concept. Then for each i, a label y_i is generated as

$$y_i = |I_T(c_i) - \omega_i|. \tag{26}$$

This is equivalent to saying that $y_i = I_T(c_i)$ with probability $1 - \alpha$ and $y_i = 1 - I_T(c_i)$ with probability α. As before, an algorithm is an indexed family of maps $A_m : (X \times \{0,1\})^m \to \mathcal{C}$ for each $m \geq 1$. The algorithm A_m is applied to the set of labelled samples $\{(c_i, y_i)\}_{i=1}^m$, giving rise to a hypothesis G_m.

To assess how well a hypothesis F (however it is derived) approximates the unknown target concept T, we generate a random test input $x \in X$ according to P, and then predict that the oracle output on x will be $I_F(x)$. The error criterion therefore is the **prediction error**, and equals

$$J_N(T,F) := E[|f(I_T(x)) - I_F(x)|, P_N], \tag{27}$$

where $f(I_T(x))$ is the noisy label and $I_F(x)$ is the indicator function of F. The premise in the above definition is that, while the oracle output is noisy, our prediction is not noisy.

Note that, for a given $x \in X$, the quantity $|f(I_T(x)) - I_F(x)|$ equals $|I_T(x) - I_F(x)|$ with probability $1 - \alpha$, and equals $1 - |I_T(x) - I_F(x)|$ with probabilty α. Therefore

$$\begin{aligned} J_N(T,F) &= \int_X [(1-\alpha)|I_T(x) - I_F(x)| + \alpha(1 - |I_T(x) - I_F(x)|)]P(dx) \\ &= \alpha + (1-2\alpha)\int_X |I_T(x) - I_F(x)|P(dx) \\ &= \alpha + (1-2\alpha)d_P(T,F). \end{aligned} \tag{28}$$

Therefore, if we were to define the minimum achievable prediction error $J_N^*(T)$ as

$$J_N^*(T) = \min_{F \in \mathcal{C}} J_N(T,F),$$

then $J_N^*(T) = \alpha$ for each $T \in \mathcal{C}$. Therefore, to quantify the performance of a learning algorithm, we compare the actual prediction error $J_N(G_m, T)$ with $J_N^*(T)$, where G_m is the output of the algorithm based on m samples. With these observations, we can state the following result.

Theorem 10 *Suppose $\mathcal{C}$ is a concept class of subsets of X with VC-dim$(\mathcal{C}) \leq d$, and let $T \in \mathcal{C}$ be a fixed but unknown target concept. Suppose $P \in \mathcal{P}^*$ is a fixed but unknown probability measure on X, $c_1, \ldots, c_m \in X$ are i.i.d. samples drawn according to P, and let G_m be the output of a MER algorithm. Then*

$$\Pr\{J_N(T, G_m) > J_N^*(T) + \epsilon\} \leq c(m, \epsilon), \tag{29}$$

where

$$c(m, \epsilon) = \left[4\left(\frac{0.2em}{d}\right)^{10d} + 1\right] \exp(-0.08m\epsilon^2). \tag{30}$$

Because the estimates derived above are broadly similar to those in (Angluin and Laird, 1988; Laird, 1988), we omit the proof of Theorem 10. The proof can be found in (Ahsen and Vidyasagar, 2017).

Note that the bound for the learning rate in Theorem 10 is qualitatively similar to that in Theorem 4. Therefore the bound (30) can be used to show the following: The quantity $\Pr\{J_N(T, G_m) > J_N^*(T) + \epsilon\}$ can be made smaller than a specified constant δ by choosing

$$m \geq \max\{O((1/\epsilon)\lg(1/\epsilon)), O((1/\epsilon)\lg(1/\delta))\} \tag{31}$$

samples.

Note that the error rate α does not appear explicitly in the right side of (30). However, if we examine (28), we see that α *does* appear in the estimate for the error $d_P(G_m, T)$. Specifically

$$d_P(G_m, T) = \frac{J_N(G_m, T) - J_N^*(T)}{1 - 2\alpha}.$$

Therefore

$$d_P(G_m, T) \leq \epsilon \iff J_N(G_m, T) - J_N^*(T) \leq (1 - 2\alpha)\epsilon. \tag{32}$$

Substituting this into Theorem 10 gives the following estimate.

Corollary 11 *Let all symbols be as in Theorem 10. Then*

$$\Pr\{d_P(G_m, T) \geq \epsilon\} \leq c(m, (1 - 2\alpha)\epsilon) = c(m, \bar{\epsilon}), \tag{33}$$

where $\bar{\epsilon} = (1 - 2\alpha)\epsilon)$, and $c(\cdot, \cdot)$ is defined in (30).

In view of Corollary 11, we infer that, in order to make the quantity $\Pr\{d_P(G_m, T) \geq \epsilon\}$ smaller than a specified constant δ, it is sufficient to choose

$$m \geq \max\{O((1/\bar{\epsilon})\lg(1/\bar{\epsilon})), O((1/\bar{\epsilon})\lg(1/\delta))\} \tag{34}$$

samples. Thus, for a fixed mislabelling probability α, the rate of growth of the sample complexity with respect to ϵ and δ is of the same order as in the noise-free case. However, as $\alpha \to 0.5^-$, the constant under the O symbol becomes larger and larger.

Note that Corollary 11 continues to hold if α is replaced by any upper bound for α.

6. Discussion

In this paper, the problem of one-bit compressed sensing (OBCS) has been formulated as a problem in probably approximately correct (PAC) learning theory. In particular, it has been shown that the VC-dimension of the set of half-spaces in $\mathbb{R}^n$ generated by k-sparse vectors is bounded by $O(k \lg n)$. Therefore, in principle at least, the OBCS problem can be solved using only $O(k \lg n)$ samples. This is possible in principle even when the measurements are corrupted by noise, except that as the mislabelling probability α approaches 0.5, the constant under the O symbol becomes larger and larger. However, in general, it is NP-hard to find a consistent algorithm when measurements are free from noise, and to find an algorithm that minimizes empirical risk when measurements are noisy.

One of the main advantages of formulating OBCS as a problem in PAC learning is that extending these results to the case where the samples $\{a_i\}$ (or $\{(a_i, b_i)\}$ as the case may be) are not i.i.d. essentially "comes for free." It is now known that, if a concept class has finite VC-dimension, then empirical means converge to their true values not only for i.i.d. samples $\{a_i\}$ (or $\{(a_i, b_i)\}$ as the case may be), but also when the samples come from a β-mixing stochastic process, e.g., from a Markov process. The convergence result is established in (Nobel and Dembo, 1993), and explicit rates of convergence are proved in (Karandikar and Vidyasagar, 2002). As it is fairly straight-forward to adapt the various theorems given here to the case of β-mixing processes using the above-mentioned results, the details are omitted.

Abstract

Kernel k-means clustering can correctly identify and extract a far more varied collection of cluster structures than the linear k-means clustering algorithm. However, kernel k-means clustering is computationally expensive when the non-linear feature map is high-dimensional and there are many input points.

Kernel approximation, e.g., the Nyström method, has been applied in previous works to approximately solve kernel learning problems when both of the above conditions are present. This work analyzes the application of this paradigm to kernel k-means clustering, and shows that applying the linear k-means clustering algorithm to $\frac{k}{\epsilon}(1+o(1))$ features constructed using a so-called rank-restricted Nyström approximation results in cluster assignments that satisfy a $1+\epsilon$ approximation ratio in terms of the kernel k-means cost function, relative to the guarantee provided by the same algorithm without the use of the Nyström method. As part of the analysis, this work establishes a novel $1+\epsilon$ relative-error trace norm guarantee for low-rank approximation using the rank-restricted Nyström approximation.

Empirical evaluations on the 8.1 million instance MNIST8M dataset demonstrate the scalability and usefulness of kernel k-means clustering with Nyström approximation. This work argues that spectral clustering using Nyström approximation—a popular and computationally efficient, but theoretically unsound approach to non-linear clustering—should be replaced with the efficient and theoretically sound combination of kernel k-means clustering with Nyström approximation. The superior performance of the latter approach is empirically verified.

Keywords: kernel k-means clustering, the Nyström method, randomized linear algebra

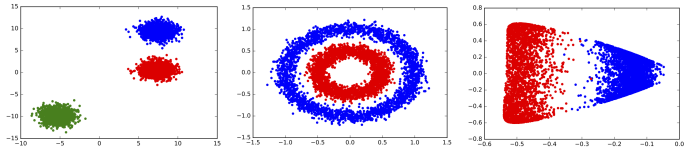
1. Introduction



Cluster analysis divides a data set into several groups using information found only in the data points. Clustering can be used in an exploratory manner to discover meaningful groupings within a data set, or it can serve as the starting point for more advanced analyses. As such, applications of clustering abound in machine learning and data analysis, including, *inter alia*: genetic expression analysis (Sharan et al., 2002), market segmentation (Chaturvedi et al., 1997), social network analysis (Handcock et al., 2007), image segmentation (Haralick and Shapiro, 1985), anomaly detection (Chandola et al., 2009), collaborative filtering (Ungar and Foster, 1998), and fast approximate learning of non-linear models (Si et al., 2014).

Linear k-means clustering is a standard and well-regarded approach to cluster analysis that partitions input vectors $\{\mathbf{a}_1,\dots,\mathbf{a}_n\}\subset\mathbb{R}^d$ into k clusters, in an unsupervised manner, by assigning each vector to the cluster with the nearest centroid. Formally, linear k-means clustering seeks to partition the set $[n]=\{1,\dots,n\}$ into k disjoint sets $\mathcal{J}_1,\dots,\mathcal{J}_k$ by solving

$$\underset{\mathcal{J}_1,\dots,\mathcal{J}_k}{\operatorname{argmin}} \frac{1}{n}\sum_{i=1}^{k}\sum_{j\in\mathcal{J}_i}\left\|\mathbf{a}_j-\frac{1}{|\mathcal{J}_i|}\sum_{l\in\mathcal{J}_i}\mathbf{a}_l\right\|_2^2. \tag{1}$$

Lloyd's algorithm (Lloyd, 1982) is a standard approach for finding local minimizers of (1), and is a staple in data mining and machine learning.

Despite its popularity, linear k-means clustering is not a universal solution to all clustering problems. In particular, linear k-means clustering strongly biases the recovered clusters towards isotropy and sphericity. Applied to the data in Figure 1(a), Lloyd's algorithm is perfectly capable of partitioning the data into three clusters which fit these assumptions. However, the data in Figure 1(b) do not fit these assumptions: the clusters are ring-shaped and have coincident centers, so minimizing the linear k-means objective does not recover these clusters.

(a) (b) (c)

Figure 1: Figures 1(a) and 1(b) show two sets of two-dimensional points, with different colors indicating different clusters. Figure 1(a) is separable using linear k-means; Figures 1(b) is inseparable using linear k-means. Figure 1(c) shows the first two dimensions of the feature vectors $\mathbf{k}_1,\dots,\mathbf{k}_n\in\mathbb{R}^n$ derived from a kernel.

To extend the scope of k-means clustering to include anistotropic, non-spherical clusters such as those depicted in Figure 1(b), Schölkopf et al. (1998) proposed to perform linear k-means clustering in a nonlinear feature space instead of the input space. After choosing a feature function $\boldsymbol{\phi}:\mathbb{R}^d\mapsto\mathcal{F}$ to map the input vectors non-linearly into feature vectors,

they propose minimizing the objective function

$$\underset{\mathcal{J}_1,\ldots,\mathcal{J}_k}{\operatorname{argmin}} \frac{1}{n}\sum_{i=1}^{k}\sum_{j\in\mathcal{J}_i}\left\|\boldsymbol{\phi}(\mathbf{a}_j) - \frac{1}{|\mathcal{J}_i|}\sum_{l\in\mathcal{J}_i}\boldsymbol{\phi}(\mathbf{a}_l)\right\|_2^2, \tag{2}$$

where $\{\mathcal{J}_1,\ldots,\mathcal{J}_k\}$ denotes a k-partition of $[n]$. The "kernel trick" enables us to minimize this objective without explicitly computing the potentially high-dimensional features, as inner products in feature space can be computed implicitly by evaluating the kernel function

$$\kappa\big(\mathbf{a}_i,\,\mathbf{a}_j\big) \;=\; \big\langle\boldsymbol{\phi}(\mathbf{a}_i),\,\boldsymbol{\phi}(\mathbf{a}_j)\big\rangle.$$

Thus the information required to solve the kernel k-means problem (2), is present in the kernel matrix $\mathbf{K} = [\kappa(\mathbf{a}_i,\mathbf{a}_j)]_{ij} \in \mathbb{R}^{n\times n}$.

Let $\mathbf{K} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^T$ be the full eigenvalue decomposition (EVD) of the kernel matrix and $\mathbf{k}_1,\ldots,\mathbf{k}_n \in \mathbb{R}^n$ be the rows of $\mathbf{V}\mathbf{\Lambda}^{1/2} \in \mathbb{R}^{n\times n}$. It can be shown (see Appendix B.3) that the solution of (2) is identical to the solution of

$$\underset{\mathcal{J}_1,\ldots,\mathcal{J}_k}{\operatorname{argmin}} \frac{1}{n}\sum_{i=1}^{k}\sum_{j\in\mathcal{J}_i}\left\|\mathbf{k}_j - \frac{1}{|\mathcal{J}_i|}\sum_{l\in\mathcal{J}_i}\mathbf{k}_l\right\|_2^2. \tag{3}$$

To demonstrate the power of kernel k-means clustering, consider the dataset in Figure 1(b). We use the Gaussian RBF kernel

$$\kappa(\mathbf{a},\mathbf{a}') = \exp\big(-\tfrac{1}{2\sigma^2}\|\mathbf{a}-\mathbf{a}'\|_2^2\big)$$

with $\sigma = 0.3$, and form the corresponding kernel matrix of the data in Figure 1(b). Figure 1(c) scatterplots the first two coordinates of the feature vectors $\mathbf{k}_1,\ldots,\mathbf{k}_n$. Clearly, the first coordinate of the feature vectors already separates the two classes well, so k-means clustering using the non-linear features $\mathbf{k}_1,\cdots,\mathbf{k}_n$ has a better chance of separating the two classes.

Although it is more generally applicable than linear k-means clustering, kernel k-means clustering is computationally expensive. As a baseline, we consider the cost of optimizing (3). The formation of the kernel matrix $\mathbf{K}$ given the input vectors $\mathbf{a}_1,\ldots,\mathbf{a}_n \in \mathbb{R}^d$ costs $\mathcal{O}(n^2d)$ time. The objective in (3) can then be (approximately) minimized using Lloyd's algorithm at a cost of $\mathcal{O}(n^2k)$ time per iteration. This requires the n-dimensional non-linear feature vectors obtained from the full EVD of $\mathbf{K}$; computing these feature vectors takes $\mathcal{O}(n^3)$ time, because $\mathbf{K}$ is, in general, full-rank. Thus, approximately solving the kernel k-means clustering problem by optimizing (3) costs $\mathcal{O}(n^3 + n^2d + Tn^2k)$ time, where T is the number of iterations of Lloyd's algorithm.

Kernel approximation techniques, including the Nyström method (Nyström, 1930; Williams and Seeger, 2001; Gittens and Mahoney, 2016) and random feature maps (Rahimi and Recht, 2007), have been applied to decrease the cost of solving kernelized machine learning problems: the idea is to replace $\mathbf{K}$ with a low-rank approximation, which allows for more efficient computations. Chitta et al. (2011, 2012) proposed to apply kernel approximations to efficiently approximate kernel k-means clustering. Although kernel approximations mitigate the computational challenges of kernel k-means clustering, the aforementioned works do not provide guarantees on the clustering performance: how

accurate must the low-rank approximation of $\mathbf{K}$ be to ensure near optimality of the approximate clustering obtained via this method?

We propose a provable approximate solution to the kernel k-means problem based on the Nyström approximation. Our method has three steps: first, extract c ($c \ll n$) features using the Nyström method; second, reduce the features to s dimensions ($k \le s < c$) using the truncated SVD;[1] third, apply any off-the-shelf linear k-means clustering algorithm upon the s-dimensional features to obtain the final clusters. The total time complexity of the first two steps is $\mathcal{O}(ndc + nc^2)$. The time complexity of the third step depends on the specific linear k-means algorithm; for example, using Lloyd's algorithm, the per-iteration complexity is $\mathcal{O}(nsk)$, and the number of iterations may depend on s.[2]

Our method comes with a strong approximation ratio guarantee. Suppose we set $s = k/\epsilon$ and $c = \tilde{\mathcal{O}}(\mu s/\epsilon)$ for any $\epsilon \in (0,1)$, where $\mu \in [1, \frac{n}{s}]$ is the coherence parameter of the dominant s-dimensional singular space of the kernel matrix $\mathbf{K}$. Also suppose the standard kernel k-means and our approximate method use the same linear k-means clustering algorithm, e.g., Lloyd's algorithm or some other algorithm that comes with different provable approximation guarantees. As guaranteed by Theorem 2, when the quality of the clustering is measured by the cost function defined in (2), with probability at least 0.9, our algorithm returns a clustering that is at most $1+\mathcal{O}(\epsilon)$ times worse than the standard kernel k-means clustering. Our theory makes explicit the trade-off between accuracy and computation: larger s and c lead to high accuracy and also high computational cost.

Spectral clustering (Shi and Malik, 2000; Ng et al., 2002) is a popular alternative to kernel k-means clustering that can also partition non-linearly separable data such as those in Figure 1(b). Unfortunately, because it requires computing an $n\times n$ affinity matrix and the top k eigenvectors of the corresponding graph Laplacian, spectral clustering is inefficient for large n. Fowlkes et al. (2004) applied the Nyström approximation to increase the scalability of spectral clustering. Since then, spectral clustering with Nyström approximation has been used in many works, e.g., (Arikan, 2006; Berg et al., 2004; Chen et al., 2011; Wang et al., 2016b; Weiss et al., 2009; Zhang and Kwok, 2010). Despite its popularity in practice, this approach does not come with guarantees on the approximation ratio for the obtained clustering. Our algorithm, which combines kernel k-means with Nyström approximation, is an equally computationally efficient alternative that comes with strong bounds on the approximation ratio, and can be used wherever spectral clustering is applied.

1.1. Contributions

Using tools developed in (Boutsidis et al., 2015; Cohen et al., 2015; Feldman et al., 2013), we rigorously analyze the performance of approximate kernel k-means clustering with the Nyström approximation, and show that a rank-$\frac{k}{\epsilon}$ Nyström approximation delivers a $1+\mathcal{O}(\epsilon)$

1. This is why our variant is called the rank-restricted Nyström approximation. The rank-restriction serves two purposes. First, although we do not know whether the rank-restriction is necessary for the $1+\epsilon$ bound, we are unable to establish the bound without it. Second, the rank-restriction makes the third step, linear k-means clustering, much less costly. For the computational benefit, previous works (Boutsidis et al., 2009, 2010, 2015; Cohen et al., 2015; Feldman et al., 2013) have considered dimensionality reduction for linear k-means clustering.
2. Without the rank-restriction, the per-iteration cost would be $\mathcal{O}(nck)$, and the number of iterations may depend on c.

approximation ratio guarantee, relative to the guarantee provided by the same algorithm without the use of the Nyström method.

As part of the analysis of kernel k-means with Nyström approximation, we establish the first relative-error bound for rank-restricted Nyström approximation,[3] which has independent interest.

Kernel k-means clustering and spectral clustering are competing solutions to the nonlinear clustering problem, neither of which scales well with n. Fowlkes et al. (2004) introduced the use of Nyström approximations to make spectral clustering scalable; this approach has become popular in machine learning. We identify fundamental mathematical problems with this heuristic. These concerns and an empirical comparison establish that our proposed combination of kernel k-means with rank-restricted Nyström approximation is a theoretically well-founded and empirically competitive alternative to spectral clustering with Nyström approximation.

Finally, we demonstrate the scalability of this approach by measuring the performance of an Apache Spark implementation of a distributed version of our approximate kernel k-means clustering algorithm using the MNIST8M data set, which has 8.1 million instances and 10 classes.

1.2. Relation to Prior Work

The key to our analysis of the proposed approximate kernel k-means clustering algorithm is a novel relative-error trace norm bound for a *rank-restricted* Nyström approximation. We restrict the rank of the Nyström approximation in a non-standard manner (see Remark 1). Our relative-error trace norm bound is not a simple consequence of the existing bounds for non-rank-restricted Nyström approximation such as the ones provided by Gittens and Mahoney (2016). The relative-error bound which we provide for the rank-restricted Nyström approximation is potentially useful in other applications involving the Nyström method.

The projection-cost preservation (PCP) property (Cohen et al., 2015; Feldman et al., 2013) is an important tool for analyzing approximate linear k-means clustering. We apply our novel relative-error trace norm bound as well as existing tools in (Cohen et al., 2015) to prove that the rank-restricted Nyström approximation enjoys the PCP property. We do not rule out the possibility that the non-rank-restricted (rank-c) Nyström approximation satisfies the PCP property and/or also enjoys a $1+\epsilon$ approximation ratio guarantee when applied to kernel k-means clustering. However, the cost of the linear k-means clustering step in the algorithm is proportional to the dimensionality of the feature vectors, so the rank-restricted Nyström approximation, which produces s-dimensional feature vectors, where $s < c$, is more computationally desirable.

Musco and Musco (2017) similarly establishes a $1+\epsilon$ approximation ratio for the kernel k-means objective when a Nyström approximation is used in place of the full kernel matrix. Specifically, Musco and Musco (2017) shows that when $c = \mathcal{O}(\frac{k}{\epsilon}\log\frac{k}{\epsilon})$ columns of $\mathbf{K}$ are sampled using *ridge leverage score (RLS) sampling* (Alaoui and Mahoney, 2015; Cohen et al., 2017; Musco and Musco, 2017) and are used to form a Nyström approximation,

3. Similar relative-error bounds were independently developed by contemporaneous work of Tropp et al. (2017), in service of the analysis of a novel streaming algorithm for fixed-rank approximation of positive semidefinite matrices. Preliminary versions of this work and theirs were simultaneously submitted to arXiv in June 2017.

Table 1: Commonly used parameters. It holds that $k \le s \le c \le n$.

Notation	Definition
n	number of samples
d	number of features (attributes)
k	number of clusters
s	target rank of the Nyström approximation
c	sketch size of the Nyström approximation

then applying linear k-means clustering to the c-dimensional Nyström features returns a clustering that has objective value at most $1+\epsilon$ times as large as the objective value of the best clustering. Our theory is independent of that in Musco and Musco (2017), and differs in that (1) Musco and Musco (2017) applies specifically to Nyström approximations formed using RLS sampling, whereas our guarantees apply to any sketching method that satisfies the "subspace embedding" and "matrix multiplication" properties (see Lemma 10 for definitions of these two properties); (2) Musco and Musco (2017) establishes a $1+\epsilon$ approximation ratio for the non-rank-restricted RLS-Nyström approximation, whereas we establish a $1+\epsilon$ approximation ratio for the (more computationally efficient) rank-restricted Nyström approximation.

1.3. Paper Organization

In Section 2, we start with a definition of the notation used throughout this paper as well as a background on matrix sketching methods. Then, in Section 3, we present our main theoretical results: Section 3.1 presents an improved relative-error rank-restricted Nyström approximation; Section 3.2 presents the main theoretical results on kernel k-means with Nyström approximation; and Section 3.3 studies kernel k-means with kernel principal component analysis. Section 4 discusses and evaluates the theoretical and empirical merits of kernel k-means clustering versus spectral clustering, when each is approximated using Nyström approximation. Section 5 empirically compares the Nyström method and the random feature maps for the kernel k-means clustering on medium-scale data. Section 6 presents a large-scale distributed implementation in Apache Spark and its empirical evaluation on a data set with 8.1 million points. Section 7 provides a brief conclusion. Proofs are provided in the Appendices.

2. Notation

This section defines the notation used throughout this paper. A set of commonly used parameters is summarized in Table 1.

Matrices and vectors. We take $\mathbf{I}_n$ to be the $n \times n$ identity matrix, $\mathbf{0}$ to be a vector or matrix of all zeros of the appropriate size, and $\mathbf{1}_n$ to be the n-dimensional vector of all ones.

Sets. The set $\{1, 2, \cdots, n\}$ is written as $[n]$. We call $\{\mathcal{J}_1, \cdots, \mathcal{J}_k\}$ a k-partition of $[n]$ if $\mathcal{J}_1 \cup \cdots \cup \mathcal{J}_k = [n]$ and $\mathcal{J}_p \cap \mathcal{J}_q = \emptyset$ when $p \neq q$. Let $|\mathcal{J}|$ denote the cardinality of the set $\mathcal{J}$.

Singular value decomposition (SVD). Let $\mathbf{A} \in \mathbb{R}^{n\times d}$ and $\rho = \text{rank}(\mathbf{A})$. A (compact) singular value decomposition (SVD) is defined by

$$\mathbf{A} \;=\; \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T \;=\; \textstyle\sum_{i=1}^{\rho} \sigma_i(\mathbf{A})\mathbf{u}_i\mathbf{v}_i^T,$$

where $\mathbf{U}$, $\mathbf{\Sigma}$, $\mathbf{V}$ are an $n \times \rho$ column-orthogonal matrix, a $\rho \times \rho$ diagonal matrix with nonnegative entries, and a $d \times \rho$ column-orthogonal matrix, respectively. If $\mathbf{A}$ is symmetric positive semi-definite (SPSD), then $\mathbf{U} = \mathbf{V}$, and this decomposition is also called the (reduced) eigenvalue decomposition (EVD). By convention, we take $\sigma_1(\mathbf{A}) \geq \cdots \geq \sigma_\rho(\mathbf{A})$.

Truncated SVD. The matrix $\mathbf{A}_s = \sum_{i=1}^{s} \sigma_i(\mathbf{A})\mathbf{u}_i\mathbf{v}_i^T$ is a rank-s truncated SVD of $\mathbf{A}$, and is an optimal rank-s approximation to $\mathbf{A}$ when the approximation error is measured in a unitarily invariant norm.

The Moore-Penrose inverse of $\mathbf{A}$ is defined by $\mathbf{A}^\dagger = \mathbf{V}\mathbf{\Sigma}^{-1}\mathbf{U}^T$.

Leverage score and coherence. Let $\mathbf{U} \in \mathbb{R}^{n\times\rho}$ be defined in the above and $\mathbf{u}_i$ be the i-th row of $\mathbf{U}$. The row leverage scores of $\mathbf{A}$ are $l_i = \|\mathbf{u}_i\|_2^2$ for $i \in [n]$. The row coherence of $\mathbf{A}$ is $\mu(\mathbf{A}) = \frac{n}{\rho}\max_i \|\mathbf{u}_i\|_2^2$. The leverage scores for a matrix $\mathbf{A}$ can be computed exactly in the time it takes to compute the matrix $\mathbf{U}$; and the leverage scores can be approximated (in theory (Drineas et al., 2012) and in practice (Gittens and Mahoney, 2016)) in roughly the time it takes to apply a random projection matrix to the matrix $\mathbf{A}$.

Matrix norms. We use three matrix norms in this paper:

$$\begin{aligned}
\text{Frobenius Norm:} \quad & \|\mathbf{A}\|_F \;=\; \sqrt{\textstyle\sum_{i,j} a_{ij}^2} \;=\; \sqrt{\textstyle\sum_i \sigma_i^2(\mathbf{A})};\\
\text{Spectral Norm:} \quad & \|\mathbf{A}\|_2 \;=\; \max_{\|\mathbf{x}\|_2=1} \left\|\mathbf{A}\mathbf{x}\right\|_2 \;=\; \sigma_1(\mathbf{A});\\
\text{Trace Norm:} \quad & \|\mathbf{A}\|_* \;=\; \textstyle\sum_i \sigma_i(\mathbf{A}).
\end{aligned}$$

Any square matrix satisfies $\text{tr}(\mathbf{A}) \leq \|\mathbf{A}\|_*$. If additionally $\mathbf{A}$ is SPSD, then $\text{tr}(\mathbf{A}) = \|\mathbf{A}\|_*$.

Matrix sketching Here, we briefly review matrix sketching methods that are commonly used within randomized linear algebra (RLA) (Mahoney, 2011).

Given a matrix $\mathbf{A} \in \mathbb{R}^{m\times n}$, we call $\mathbf{C} = \mathbf{A}\mathbf{P} \in \mathbb{R}^{m\times c}$ (typically $c \ll n$) a *sketch* of $\mathbf{A}$ and $\mathbf{P} \in \mathbb{R}^{n\times c}$ a *sketching matrix*. Within RLA, sketching has emerged as a powerful primitive, where one is primarily interested in using random projections and random sampling to construct randomzed sketches (Mahoney, 2011; Drineas and Mahoney, 2016). In particular, sketching is useful as it allows large matrices to be replaced with smaller matrices which are more amenable to efficient computation, but provably retain almost optimal accuracy in many computations (Mahoney, 2011; Woodruff, 2014). The columns of $\mathbf{C}$ typically comprise a rescaled subset of the columns of $\mathbf{A}$, or random linear combinations of the columns of $\mathbf{A}$; the former type of sketching is called *column selection* or *random sampling*, and the latter is referred to as *random projection*.

Column selection forms $\mathbf{C} \in \mathbb{R}^{m\times c}$ using a randomly sampled and rescaled subset of the columns of $\mathbf{A} \in \mathbb{R}^{m\times n}$. Let $p_1, \cdots, p_n \in (0, 1)$ be the sampling probabilities associated

with the columns of $\mathbf{A}$ (so that, in particular, $\sum_{i=1}^n p_i = 1$). The columns of the sketch are selected identically and independently as follows: each column of $\mathbf{C}$ is randomly sampled from the columns of $\mathbf{A}$ according to the sampling probabilities and rescaled by $\frac{1}{\sqrt{cp_i}}$, where i is the index of the column of $\mathbf{A}$ that was selected. In our matrix multiplication formulation for sketching, column selection corresponds to a sketching matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$ that has exactly one non-zero entry in each column, whose position and magnitude correspond to the index of the column selected from $\mathbf{A}$. *Uniform sampling* is column sampling with $p_1 = \cdots = p_n = \frac{1}{n}$, and *leverage score sampling* takes $p_i = \frac{l_i}{\sum_j l_j}$ for $i \in [n]$, where l_i is the i-th leverage score of some matrix (typically $\mathbf{A}$, $\mathbf{A}_k$, or an randomized approximation thereto) (Drineas et al., 2012).

Gaussian projection is a type of random projection where the sketching matrix is taken to be $\mathbf{P} = \frac{1}{\sqrt{c}}\mathbf{G} \in \mathbb{R}^{n\times c}$; here the entries of $\mathbf{G}$ are i.i.d. $\mathcal{N}(0, 1)$ random variables. Gaussian projection is inefficient relative to column sampling: the formation of a Gaussian sketch of a dense $m \times n$ matrix requires $\mathcal{O}(mnc)$ time. The *Subsampled Randomized Hadamard Transform (SRHT)* is a more efficient alternative that enjoys similar properties to the Gaussian projection (Drineas et al., 2011; Lu et al., 2013; Tropp, 2011), and can be applied to a dense $m \times n$ matrix in only $\mathcal{O}(mn \log c)$ time. The *CountSketch* is even more efficient: it can be applied to any matrix $\mathbf{A}$ in $\mathcal{O}(\text{nnz}(\mathbf{A}))$ time (Clarkson and Woodruff, 2013; Meng and Mahoney, 2013; Nelson and Nguyên, 2013), where $\text{nnz}(\cdot)$ denotes the number of nonzero entries in a matrix.

3. Our Main Results: Improved SPSD Matrix Approximation and Kernel k-means Approximation

In this section, we present our main theoretical results. We start, in Section 3.1, by presenting Theorem 1, a novel result on SPSD matrix approximation with the rank-restricted Nyström method. This result is of independent interest, and so we present it in detail, but in this paper we will use it to establish our main result. Then, in Section 3.2, we present Theorem 2, which is our main result for approximate kernel k-means with the Nyström approximation. In Section 3.3, we establish novel guarantees on kernel k-means with dimensionality reduction.

3.1. The Nyström Method

The Nyström method (Nyström, 1930) is the most popular kernel approximation method in the machine learning community. Let $\mathbf{K} \in \mathbb{R}^{n\times n}$ be an SPSD matrix and $\mathbf{P} \in \mathbb{R}^{n\times c}$ be a sketching matrix. The Nyström method approximates $\mathbf{K}$ with $\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T$, where $\mathbf{C} = \mathbf{K}\mathbf{P}$ and $\mathbf{W} = \mathbf{P}^T\mathbf{K}\mathbf{P}$. The Nyström method was introduced to the machine learning community by Williams and Seeger (2001); since then, numerous works have studied its theoretical properties, e.g., (Drineas and Mahoney, 2005; Gittens and Mahoney, 2016; Jin et al., 2013; Kumar et al., 2012; Wang and Zhang, 2013; Yang et al., 2012).

Empirical results in (Gittens and Mahoney, 2016; Wang et al., 2016b; Yang et al., 2012) demonstrated that the accuracy of the Nyström method significantly increases when the spectrum of $\mathbf{K}$ decays fast. This suggests that the Nyström approximation captures the dominant eigenspaces of $\mathbf{K}$, and that error bounds comparing the accuracy of the Nyström

Table 2: Sufficient sketch sizes for several sketching methods used to construct Nyström approximations to the matrix $\mathbf{K}$. Let $\mathbf{K}_s = \mathbf{V}_s\mathbf{\Sigma}_s\mathbf{V}_s^T$ be the truncated SVD of $\mathbf{K}$, then μ denotes the row coherence of $\mathbf{V}_s \in \mathbb{R}^{n\times s}$ and the leverage score sampling is done using the row leverage scores of $\mathbf{V}_s$.

sketching	**sketch size** (c)	**time complexity** (T)
uniform sampling	$\mathcal{O}(\mu s/\epsilon + \mu s \log s)$	$\mathcal{O}(nc)$
leverage sampling	$\mathcal{O}(s/\epsilon + s\log s)$	$\tilde{\mathcal{O}}(n^2 s)$
Gaussian projection	$\mathcal{O}(s/\epsilon)$	$\mathcal{O}(n^2 c)$
SRHT	$\mathcal{O}((s+\log n)(\epsilon^{-1}+\log s))$	$\mathcal{O}(n^2 \log c)$
CountSketch	$\mathcal{O}(s/\epsilon + s^2)$	$\mathcal{O}(n^2)$

approximation of $\mathbf{K}$ to that of the best rank-s approximation $\mathbf{K}_s$ (for $s < c$) would provide a meaningful measure of the performance of the Nyström kernel approximation. Gittens and Mahoney (2016) established the first relative-error bounds showing that for sufficiently large c, the trace norm error $\|\mathbf{K} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\|_*$ is comparable to $\|\mathbf{K} - \mathbf{K}_s\|_*$. Such results quantify the benefits of spectral decay to the performance of the Nyström method, and are sufficient to analyze the performance of Nyström approximations in applications such as kernel ridge regression (Alaoui and Mahoney, 2015; Bach, 2013) and kernel support vector machines (Cortes et al., 2010).

However, Gittens and Mahoney (2016) did not analyze the performance of rank-restricted Nyström approximations; they compared the approximation accuracies of the rank-c matrix $\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T$ and the rank-s matrix $\mathbf{K}_s$ (recall $s < c$). In our application to approximate kernel k-means clustering, it is the rank-s matrix $(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s$ that is of relevance. Given $\mathbf{C}$ and $\mathbf{W}$, the truncated SVD $\left((\mathbf{W}^\dagger)^{1/2}\mathbf{C}^T\right)_s = \tilde{\mathbf{U}}_s\tilde{\mathbf{\Sigma}}_s\tilde{\mathbf{V}}_s^T$ can be found using $\mathcal{O}(nc^2)$ time. Then the rank-s Nyström approximation can be written as

$$(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s \;=\; \left(\mathbf{C}(\mathbf{W}^\dagger)^{1/2}\right)_s\left(\mathbf{C}(\mathbf{W}^\dagger)^{1/2}\right)_s^T \;=\; \tilde{\mathbf{V}}_s\tilde{\mathbf{\Sigma}}_s^2\tilde{\mathbf{V}}_s^T. \tag{4}$$

Theorem 1 provides a relative-error trace norm approximation guarantee for the sketch (4) and is novel; a proof is provided in Appendix A.

Theorem 1 (Relative-Error Rank-Restricted Nyström Approximation) *Let $\mathbf{K} \in \mathbb{R}^{n\times n}$ be an SPSD matrix, s be the target rank, and $\epsilon \in (0,1)$ be an error parameter. Let $\mathbf{P} \in \mathbb{R}^{n\times c}$ be a sketching matrix corresponding to one of the sketching methods listed in Table 2. Let $\mathbf{C} = \mathbf{K}\mathbf{P}$ and $\mathbf{W} = \mathbf{P}^T\mathbf{K}\mathbf{P}$. Then*

$$\left\|\mathbf{K} - (\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s\right\|_* \;\leq\; (1+\epsilon)\left\|\mathbf{K} - \mathbf{K}_s\right\|_*$$

holds with probability at least 0.9. In addition, there exists an $n \times s$ column orthogonal matrix $\mathbf{Q}$ such that $(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s = \mathbf{K}^{1/2}\mathbf{Q}\mathbf{Q}^T\mathbf{K}^{1/2}$.

Remark 1 (Rank Restrictions) *The traditional rank-restricted Nyström approximation, $\mathbf{C}(\mathbf{W}_s)^\dagger\mathbf{C}^T$, (Drineas and Mahoney, 2005; Fowlkes et al., 2004; Gittens and Mahoney, 2016; Li et al., 2015) is not known to satisfy a relative-error bound of the form guaranteed in Theorem 1. Pourkamali-Anaraki and Becker (2016) pointed out the drawbacks of the traditional rank-restricted Nyström approximation and proposed the use of the rank-restricted Nyström approximation $(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s$ in applications requiring kernel approximations, but provided only empirical evidence of its performance. This work provides guarantees on the approximation error of the rank-restricted Nyström approximation $(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s$, and applies this approximation to the kernel k-means clustering problem. The contemporaneous work Tropp et al. (2017) provides similar guarantees on the approximation error of $(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s$, and uses this Nyström approximation as the basis of a streaming algorithm for fixed-rank approximation of positive-semidefinite matrices.*

3.2. Main Result for Approximate Kernel k-means

In this section we establish the approximation ratio guarantees for the objective function of kernel k-means clustering. We first define γ-approximate k-means algorithms (where $\gamma \geq 1$), then present our main result in Theorem 2.

Let $\mathbf{A}$ be a matrix with n rows $\mathbf{a}_1, \cdots, \mathbf{a}_n$. The objective function for linear k-means clustering over the rows of $\mathbf{A}$ is

$$f(\mathcal{J}_1, \cdots, \mathcal{J}_k; \mathbf{A}) \;=\; \frac{1}{n}\sum_{i=1}^{k}\sum_{j\in\mathcal{J}_i}\left\|\mathbf{a}_j \;-\; \frac{1}{|\mathcal{J}_i|}\sum_{l\in\mathcal{J}_i}\mathbf{a}_l\right\|_2^2.$$

The minimization of f w.r.t. the k-partition $\{\mathcal{J}_1, \cdots, \mathcal{J}_k\}$ is NP-hard (Garey et al., 1982; Aloise et al., 2009; Dasgupta and Freund, 2009; Mahajan et al., 2009; Awasthi et al., 2015), but approximate solutions can be obtained in polynomial time. γ-approximate algorithms capture one useful notion of approximation.

Definition 1 (γ-Approximate Algorithms) *A linear k-means clustering algorithm $\mathcal{A}_\gamma$ takes as input a matrix $\mathbf{Z}$ with n rows and outputs $\{\mathcal{J}_1', \cdots, \mathcal{J}_k'\}$. We call $\mathcal{A}_\gamma$ a γ-approximate algorithm if, for any such matrix $\mathbf{Z}$,*

$$f(\mathcal{J}_1', \cdots, \mathcal{J}_k'; \mathbf{Z}) \;\leq\; \gamma \cdot \min_{\mathcal{J}_1, \cdots, \mathcal{J}_k} f(\mathcal{J}_1, \cdots, \mathcal{J}_k; \mathbf{Z}).$$

Here $\{\mathcal{J}_1, \cdots, \mathcal{J}_k\}$ and $\{\mathcal{J}_1', \cdots, \mathcal{J}_k'\}$ are k-partitions of $[n]$.

Many $(1+\epsilon)$-approximation algorithms have been proposed, but they are computationally expensive (Chen, 2009; Har-Peled and Mazumdar, 2004; Kumar et al., 2004; Matousek, 2000). There are also relatively efficient constant factor approximate algorithms, e.g., (Arthur and Vassilvitskii, 2007; Kanungo et al., 2002; Song and Rajasekaran, 2010).

Let $\boldsymbol{\phi}$ be a feature map, $\mathbf{\Phi}$ be the matrix with rows $\phi(\mathbf{a}_1), \ldots, \phi(\mathbf{a}_n)$, and $\mathbf{K} = \mathbf{\Phi}\mathbf{\Phi}^T \in \mathbf{R}^{n\times n}$ be the associated kernel matrix. Analogously, we denote the objective function for kernel k-means clustering by

$$f(\mathcal{J}_1, \cdots, \mathcal{J}_k\,;\,\mathbf{\Phi}) \;=\; \frac{1}{n}\sum_{i=1}^{k}\sum_{j\in\mathcal{J}_i}\left\|\boldsymbol{\phi}(\mathbf{a}_j) \;-\; \frac{1}{|\mathcal{J}_i|}\sum_{l\in\mathcal{J}_i}\boldsymbol{\phi}(\mathbf{a}_l)\right\|_2^2,$$

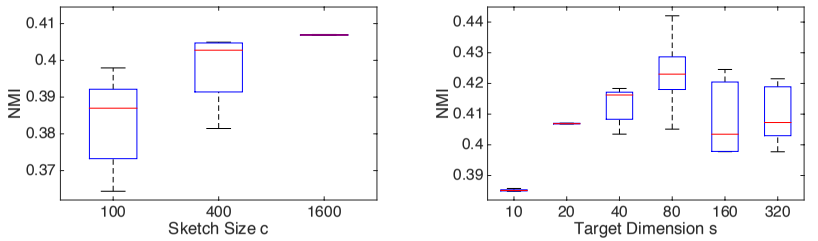
where $\{\mathcal{J}_1, \cdots, \mathcal{J}_k\}$ is a k-partition of $[n]$.

Theorem 2 (Kernel k-Means with Nyström Approximation) *Choose a sketching matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$ and sketch size c consistent with Table 2. Let $\mathbf{CW}^{\dagger}\mathbf{C}^T$ be the previously defined Nyström approximation of $\mathbf{K}$. Let $\mathbf{B} \in \mathbb{R}^{n\times s}$ be any matrix satisfying $\mathbf{BB}^T = (\mathbf{CW}^{\dagger}\mathbf{C}^T)_s$. Let the k-partition $\{\tilde{\mathcal{J}}_1, \cdots, \tilde{\mathcal{J}}_k\}$ be the output of a γ-approximate algorithm applied to the rows of $\mathbf{B}$. With probability at least 0.9,*

$$f(\tilde{\mathcal{J}}_1, \cdots, \tilde{\mathcal{J}}_k\,;\,\mathbf{\Phi}) \;\;\leq\;\; \gamma\big(1+\epsilon+\tfrac{k}{s}\big)\cdot \min_{\mathcal{J}_1,\cdots,\mathcal{J}_k} f(\mathcal{J}_1, \cdots, \mathcal{J}_k\,;\,\mathbf{\Phi}).$$

Remark 2 *Kernel k-means clustering is an NP-hard problem. Therefore, instead of comparing with $\min f$, we compare with clusterings obtained using γ-approximate algorithms. Theorem 2 shows that, when uniform sampling to form the Nyström approximation, if $s = \mathcal{O}(\frac{k}{\epsilon})$ and $c = \tilde{\mathcal{O}}(\frac{\mu s}{\epsilon})$, then the returned clustering has an objective value that is at most a factor of ϵ larger than the objective value of the kernel k-means clustering returned by the γ-approximate algorithm.*

Remark 3 *Assume we are in a practical setting where c, the budget of column samples one can use to form a Nyström approximation, and k, the number of desired cluster centers, are fixed. The pertinent question is how to choose s to produce a high-quality approximate clustering. Theorem 2 shows that for uniform sampling, the error ratio is*



$$1+\epsilon+\tfrac{k}{s} \;=\; 1+\tilde{\mathcal{O}}(\tfrac{s\mu}{c})+\tfrac{k}{s}.$$

To balance the two sources of error, s must be larger than k, but not too large a fraction of c. To minimize the above error ratio, s should be selected on the order of $\sqrt{kc/\mu}$. Since the matrix coherence μ (≥ 1) is unknown, it can be heuristically treated as a constant.

We empirically study the effect of the values of c and s using a data set comprising 8.1 million samples. Note that computing the kernel k-means clustering objective function requires the formation of the entire kernel matrix $\mathbf{K}$, which is infeasible for a data set of this size; instead, we use normalized mutual information (NMI) (Strehl and Ghosh, 2002)—a standard measure of the performance of clustering algorithms— to measure the quality of the clustering obtained by approximating kernel k-means clustering using Nyström approximations formed through uniform sampling. NMI scores range from zero to one, with a larger score indicating better performance. We report the results in Figure 2. The complete details of the experiments, including the experimental setting and time costs, are given in Section 6.

From Figure 2(a) we observe that larger values of c lead to better and more stable clusterings: the mean of the NMI increases and its standard deviation decreases. This is reasonable and in accordance with our theory. However, larger values of c incur more computations, so one should choose c to trade off computation and accuracy.

Figure 2(b) shows that for fixed k and c, the clustering performance is not monotonic in s, which matches Theorem 2 (see the discussion in Remark 3). Setting s as small as k results in poor performance. Setting s over-large not only incurs more computations, but also negatively affects clustering performance; this may suggest the necessity of rank-restriction. Furthermore, in this example, $\sqrt{kc} = 126.5$, which corroborates the suggestion made in Remark 3 that setting s around $\sqrt{kc/\mu}$ (where μ is unknown but can be treated as a constant larger than 1) can be a good choice.

(a) Fix $s = 20$ and vary c. (b) Fix $c = 1600$ and vary s.

Figure 2: Performance of approximate kernel k-means clustering on the MNIST8M data set, for which $n = 8.1 \times 10^6$, $d = 784$, and $k = 10$. We use Nyström approximations formed using uniform sampling, and the built-in k-means algorithm of Spark MLlib (a parallelized variant of the k-means++ method) with the setting MaxIter $= 100$.

Remark 4 *Musco and Musco (2017) established a $1+\epsilon$ approximation ratio for the kernel k-means objective value when a non-rank-restricted Nyström approximation is formed using ridge leverage scores (RLS) sampling; their analysis is specific to RLS sampling and does not extend to other sketching methods. By way of comparison, our analysis covers several popular sampling schemes and applies to rank-restricted Nyström approximations, but does not extend to RLS sampling.*

3.3. Approximate Kernel k-Means with KPCA and Power Method

The use of dimensionality reduction to increase the computational efficiency of k-means clustering has been widely studied, e.g. in (Boutsidis et al., 2010, 2015; Cohen et al., 2015; Feldman et al., 2013; Zha et al., 2002). Kernel principal component analysis (KPCA) is particularly well-suited to this application (Dhillon et al., 2004; Ding et al., 2005). Applying Lloyd's algorithm on the rows of $\mathbf{\Phi}$ or $\mathbf{K}^{-1/2}$ has an $\mathcal{O}(n^2k)$ per-iteration complexity; if s features are extracted using KPCA and Lloyd's algorithm is applied to the resulting s-dimensional feature map, then the per-iteration cost reduces to $\mathcal{O}(nsk)$. Proposition 3 states that, to obtain a $1+\epsilon$ approximation ratio in terms of the kernel k-means objective function, it suffices to use $s = \frac{k}{\epsilon}$ KPCA features. This proposition is a simple consequence of (Cohen et al., 2015).

Proposition 3 (KPCA) *Let $\mathbf{\Phi}$ be a matrix with n rows, and $\mathbf{K} = \mathbf{\Phi}\mathbf{\Phi}^T \in \mathbf{R}^{n\times n}$ be the corresponding kernel matrix. Let $\mathbf{K}_s = \mathbf{V}_s\mathbf{\Lambda}_s\mathbf{V}_s^T$ be the truncated SVD of $\mathbf{K}$ and take $\mathbf{B} = \mathbf{V}_s\mathbf{\Lambda}_s^{1/2} \in \mathbb{R}^{n\times s}$. Let the k-partition $\{\tilde{\mathcal{J}}_1, \cdots, \tilde{\mathcal{J}}_k\}$ be the output of a γ-approximate algorithm applied to the rows of $\mathbf{B}$. Then*

$$f(\tilde{\mathcal{J}}_1, \cdots, \tilde{\mathcal{J}}_k\,;\,\mathbf{\Phi}) \;\;\leq\;\; \gamma\,(1+\tfrac{k}{s})\cdot \min_{\mathcal{J}_1,\cdots,\mathcal{J}_k} f(\mathcal{J}_1, \cdots, \mathcal{J}_k\,;\,\mathbf{\Phi}).$$

Algorithm 1 Approximate Kernel k-Means using the Power Method.

Input: kernel matrix $\mathbf{K} \in \mathbb{R}^{n\times n}$, number of clusters k, target dimension s ($\geq k$), sketch size c ($\geq s$), number of iterations t (≥ 1)
Draw a Gaussian projection matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$;
for all $j \in [t]$ **do**
  $\mathbf{P} \longleftarrow \mathbf{KP}$;
end for
Orthogonalize $\mathbf{P}$ to obtain $\mathbf{U} \in \mathbb{R}^{n\times c}$;
Compute $\mathbf{C} = \mathbf{KU}$ and $\mathbf{W} = \mathbf{U}^T\mathbf{KU}$;
Compute a $\mathbf{B} \in \mathbb{R}^{n\times s}$ satisfying $(\mathbf{CW}^\dagger\mathbf{C}^T)_s = \mathbf{BB}^T$;
return $\mathbf{B}$.

In practice, the truncated SVD (equivalently EVD) of $\mathbf{K}$ is computed using the power method or Krylov subspace methods. These numerical methods do not compute the exact decomposition $\mathbf{K}_s = \mathbf{V}_s\mathbf{\Lambda}_s\mathbf{V}_s^T$, so Proposition 3 is not directly applicable. It is useful to have a theory that captures the effect of realisticly inaccurate estimates like $\mathbf{K}_s \approx \tilde{\mathbf{V}}_s\tilde{\mathbf{\Lambda}}_s\tilde{\mathbf{V}}_s^T$ on the clustering process. As one particular example, consider that general-purpose implementations of the truncated SVD attempt to mitigate the fact that the computed decompositions are inaccurate by returning very high-precision solutions, e.g. solutions that satisfy $\|(\mathbf{I}_n - \mathbf{V}_s\mathbf{V}_s^T)\tilde{\mathbf{V}}_s\|_2 \leq 10^{-10}$. Understanding the trade-off between the precision of the truncated SVD solution and the impact on the approximation ratio of the approximate kernel k-means solution allows us to more precisely manage the computational complexity of our algorithms. Are such high-precision solutions necessary for kernel k-means clustering?

Theorem 4 answers this question by establishing that highly accurate eigenspaces are not significantly more useful in approximate kernel k-means clustering than eigenspace estimates with lower accuracy. A low-precision solution obtained by running the power iteration for a few rounds suffices for kernel k-means clustering applications. We prove Theorem 4 in Appendix C.

Theorem 4 (The Power Method) *Let $\mathbf{\Phi}$ be a matrix with n rows, $\mathbf{K} = \mathbf{\Phi}\mathbf{\Phi}^T \in \mathbb{R}^{n\times n}$ be the corresponding kernel matrix, and σ_i be the i-th singular value of $\mathbf{K}$. Fix an error parameter $\epsilon \in (0,1)$. Run Algorithm 1 with $t = \mathcal{O}(\frac{\log(n/\epsilon)}{\log(\sigma_s/\sigma_{s+1})})$ to obtain $\mathbf{B} \in \mathbb{R}^{n\times s}$. Let the k-partition $\{\tilde{\mathcal{J}}_1, \cdots, \tilde{\mathcal{J}}_k\}$ be the output of a γ-approximate algorithm applied to the rows of $\mathbf{B}$. If $c = s + \mathcal{O}(\log\frac{1}{\delta})$, then*

$$f(\tilde{\mathcal{J}}_1, \cdots, \tilde{\mathcal{J}}_k\,;\,\mathbf{\Phi}) \;\leq\; \gamma\left(1+\epsilon+\tfrac{k}{s}\right)\cdot \min_{\mathcal{J}_1,\cdots,\mathcal{J}_k} f(\mathcal{J}_1, \cdots, \mathcal{J}_k\,;\,\mathbf{\Phi}).$$

holds with probability at least $1-\delta$. If $c = s$, then the above inequality holds with probability $0.9 - \mathcal{O}(s^{-\tau})$, where τ is a positive constant (Tao and Vu, 2010).

Note that the power method requires forming the entire kernel matrix $\mathbf{K} \in \mathbb{R}^{n\times n}$, which may not fit in memory even in a distributed setting. Therefore, in practice, the power method may not be as efficient as the Nyström approximation with uniform sampling, which avoids forming $\mathbf{K}$.

Theorem 2, Proposition 3, and Theorem 4 are highly interesting from a theoretical perspective. These results demonstrate that $s = \frac{k}{\epsilon}\big(1 + o(1)\big)$ features are sufficient to

ensure a $(1+\epsilon)$ approximation ratio. Prior work (Dhillon et al., 2004; Ding et al., 2005) set $s = k$ and did not provide approximation ratio guarantees. Indeed, a lower bound in the linear k-means clustering case due to (Cohen et al., 2015) shows that $s = \Omega(\frac{k}{\epsilon})$ is necessary to obtain a $1+\epsilon$ approximation ratio.

4. Comparison to Spectral Clustering with Nyström Approximation

In this section, we provide a brief discussion and empirical comparison of our clustering algorithm, which uses the Nyström method to approximate kernel k-means clustering, with the popular alternative algorithm that uses the Nyström method to approximate spectral clustering.

4.1. Background

Spectral clustering is a method with a long history (Cheeger, 1969; Donath and Hoffman, 1972, 1973; Fiedler, 1973; Guattery and Miller, 1995; Spielman and Teng, 1996). Within machine learning, spectral clustering is more widely used than kernel k-means clustering (Ng et al., 2002; Shi and Malik, 2000), and the use of the Nyström method to speed up spectral clustering has been popular since Fowlkes et al. (2004). Both spectral clustering and kernel k-means clustering can be approximated in time linear in n by using the Nyström method with uniform sampling. Practitioners reading this paper may ask:

> *How does the approximate kernel k-means clustering algorithm presented here, which uses Nyström approximation, compare to the popular heuristic of combining spectral clustering with Nyström approximation?*

Based on our theoretical results and empirical observations, our answer to this reader is:

> *Although they have equivalent computational costs, kernel k-means clustering with Nyström approximation is both more theoretically sound and more effective in practice than spectral clustering with Nyström approximation.*

We first formally describe spectral clustering, and then substantiate our claim regarding the theoretical advantage of our approximate kernel k-means method. Our discussion is limited to the normalized and symmetric graph Laplacians used in Fowlkes et al. (2004), but spectral clustering using asymmetric graph Laplacians encounters similar issues.

4.2. Spectral Clustering with Nyström Approximation

The input to the spectral clustering algorithm is an affinity matrix $\mathbf{K} \in \mathbb{R}_+^{n\times n}$ that measures the pairwise similarities between the points being clustered; typically $\mathbf{K}$ is a kernel matrix or the adjacency matrix of a weighted graph constructed using the data points as vertices. Let $\mathbf{D} = \mathsf{diag}(\mathbf{K}\mathbf{1}_n)$ be the diagonal degree matrix associated with $\mathbf{K}$, and $\mathbf{L} = \mathbf{I}_n - \mathbf{D}^{-1/2}\mathbf{K}\mathbf{D}^{-1/2}$ be the associated normalized graph Laplacian matrix. Let $\mathbf{V}_k \in \mathbb{R}^{n\times k}$ denote the bottom k eigenvectors of $\mathbf{L}$, or equivalently, the top k eigenvectors of $\mathbf{D}^{-1/2}\mathbf{K}\mathbf{D}^{-1/2}$. Spectral clustering groups the data points by performing linear k-means clustering on the normalized rows of $\mathbf{V}_k$. Fowlkes et al. (2004) popularized the application of the Nyström approximation to spectral clustering. This algorithm computes an approximate spectral

clustering by: (1) forming a Nyström approximation to $\mathbf{K}$, denoted by $\tilde{\mathbf{K}}$; (2) computing the degree matrix $\tilde{\mathbf{D}} = \mathsf{diag}(\tilde{\mathbf{K}}\mathbf{1}_n)$ of $\tilde{\mathbf{K}}$; (3) computing the top k singular vectors $\tilde{\mathbf{V}}_k$ of $\tilde{\mathbf{D}}^{-1/2}\tilde{\mathbf{K}}\tilde{\mathbf{D}}^{-1/2}$, which are equivalent to the bottom k eigenvectors of $\tilde{\mathbf{L}} = \mathbf{I}_n - \tilde{\mathbf{D}}^{-1/2}\tilde{\mathbf{K}}\tilde{\mathbf{D}}^{-1/2}$; (4) performing linear k-means over the normalized rows of $\tilde{\mathbf{V}}_k \in \mathbb{R}^{n\times k}$.

To the best of our knowledge, spectral clustering with Nyström approximation does not have a bounded approximation ratio relative to exact spectral clustering. In fact, it seems unlikely that the approximation ratio could be bounded, as there are fundamental problems with the application of the Nyström approximation to the affinity matrix.

- The affinity matrix $\mathbf{K}$ used in spectral clustering must be elementwise nonnegative. However, the Nyström approximation of such a matrix can have numerous negative entries, so $\tilde{\mathbf{K}}$ is, in general, not proper input for the spectral clustering algorithm. In particular, the approximated degree matrix $\tilde{\mathbf{D}} = \mathsf{diag}(\tilde{\mathbf{K}}\mathbf{1}_n)$ may have negative diagonal entries, so $\tilde{\mathbf{D}}^{-1/2}$ is not guaranteed to be a real matrix; such exceptions must be handled heuristically. The approximate asymmetric Laplacian $\tilde{\mathbf{L}} = \mathbf{I}_n - \tilde{\mathbf{K}}\tilde{\mathbf{D}}^{-1}$ does avoid the introduction of complex values; however, the negative entries in $\tilde{\mathbf{D}}^{-1}$ negate whole columns of $\tilde{\mathbf{K}}$, leading to less meaningful negative similarities/distances.

- Even if $\tilde{\mathbf{D}}^{-1/2}$ is real, the matrix $\tilde{\mathbf{L}} = \mathbf{I}_n - \tilde{\mathbf{D}}^{-1/2}\tilde{\mathbf{K}}\tilde{\mathbf{D}}^{-1/2}$ may not be SPSD, much less a Laplacian matrix. Thus the bottom eigenvectors of $\tilde{\mathbf{L}}$ cannot be viewed as useful coordinates for linear k-means clustering in the same way that the eigenvectors of $\mathbf{L}$ can be.

- Such approximation is also problematic in terms of matrix approximation accuracy. Even when $\tilde{\mathbf{K}}$ approximates $\mathbf{K}$ well, which can be theoretically guaranteed, the approximate Laplacian $\tilde{\mathbf{L}} = \mathbf{I}_n - \tilde{\mathbf{D}}^{-1/2}\tilde{\mathbf{K}}\tilde{\mathbf{D}}^{-1/2}$ can be far from $\mathbf{L}$. This is because a small perturbation in $\tilde{\mathbf{D}}$ can have an out-sized influence on the eigenvectors of $\tilde{\mathbf{L}}$.

- One may propose to approximate $\mathbf{N} = \mathbf{D}^{-1/2}\mathbf{K}\mathbf{D}^{-1/2}$, rather than $\mathbf{K}$, with a Nyström approximation $\tilde{\mathbf{N}}$; this ensures that the approximate normalized graph Laplacian $\tilde{\mathbf{L}} = \mathbf{I}_n - \tilde{\mathbf{N}}$ is SPSD. However, this approach requires forming the entirety of $\mathbf{K}$ in order to compute the degree matrix $\mathbf{D}$, and thus has quadratic (with n) time and memory costs. Furthermore, although the resulting approximation, $\tilde{\mathbf{L}}$, is SPSD, it is not a graph Laplacian: its off-diagonal entries are not guaranteed to be non-positive, and its smallest eigenvalue may be nonzero.

In summary, spectral clustering using the Nyström approximation (Fowlkes et al., 2004), which has proven to be a useful heuristic, and which is composed of theoretically principled parts, is less principled when viewed in its entirety. Approximate kernel k-means clustering using Nyström approximation is an equivalently efficient, but theoretically more principled alternative.

4.3. Empirical Comparison with Approximate Spectral Clustering using Nyström Approximation

To complement our discussion of the relative merits of the two methods, we empirically compared the performance of our novel method of approximate kernel k-means clustering

Table 3: Summary of the data sets used in our comparisons.

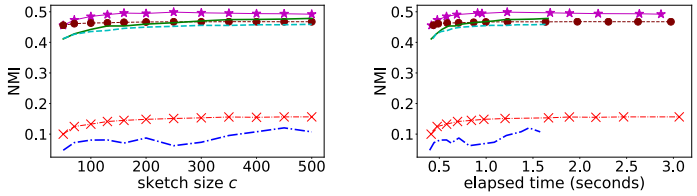
dataset	**#instances** (n)	**#features** (d)	**#clusters** (k)
MNIST (LeCun et al., 1998)	60,000	780	10
Mushrooms (Frank and Asuncion, 2010)	8,124	112	2
PenDigits (Frank and Asuncion, 2010)	7,494	16	10

using the Nyström method with the popular method of approximate spectral clustering using the Nyström method. We used three classification data sets, described in Table 3. The data sets used are available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`.

Let $\mathbf{a}_1, \ldots, \mathbf{a}_n \in \mathbb{R}^d$ be the input vectors. We take both the affinity matrix for spectral clustering and the kernel matrix for kernel k-means to be the RBF kernel matrix $\mathbf{K} = [\kappa(\mathbf{a}_i, \mathbf{a}_j)]_{ij} \in \mathbb{R}^{n\times n}$, where $\kappa(\mathbf{a}, \mathbf{a}') = \exp\left(-\frac{1}{2\sigma^2}\|\mathbf{a} - \mathbf{a}'\|_2^2\right)$ and σ is the kernel width parameter. We choose σ based on the average interpoint distance in the data sets as

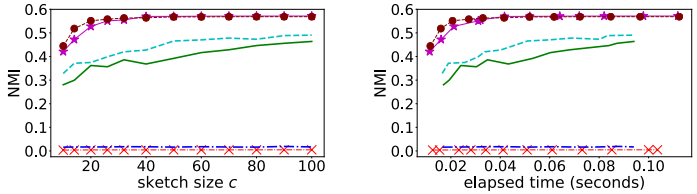
$$\sigma \quad = \quad \beta \cdot \sqrt{\tfrac{1}{n^2}\textstyle\sum_{i=1}^n \sum_{j=1}^n \|\mathbf{a}_i - \mathbf{a}_j\|_2^2}, \tag{5}$$

where we take $\beta = 0.2$, 1, or 5.



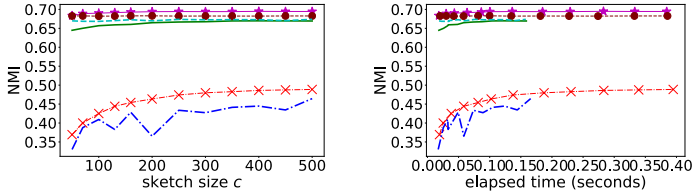
The algorithms under comparison are all implemented in Python 3.5.2. Our implementation of approximate spectral clustering follows the code in (Fowlkes et al., 2004). To compute linear k-means clusterings, we use the function `sklearn.cluster.KMeans` present in the scikit-learn package. Our algorithm for approximate kernel k-means clustering is described in more detail in Section 5.1. We ran the computations on a MacBook Pro with a 2.5GHz Intel Core i7 CPU and 16GB of RAM.

We compare approximate spectral clustering (SC) with approximate kernel k-means clustering (KK), with both using the rank-restricted Nyström method with uniform sampling.[4] We used normalized mutual information (NMI) (Strehl and Ghosh, 2002) to evaluate clustering performance: the NMI falls between 0 (representing no mutual information between the true and approximate clusterings) and 1 (perfect correlation of the two clusterings), so larger NMI indicates better performance. The target dimension s is taken to be k; and, for each method, the sketch size c is varied from $5s$ to $50s$. We record the time cost of the two methods, excluding the time spent on the k-means clustering required in both algorithms.[5] We repeat this procedure 100 times and report the averaged NMI and average elapsed time.



We note that, at small sketch sizes c, exceptions often arise during approximate spectral clustering due to negative entries in the degree matrix. (This is an example, as discussed in Section 4.2, of when approximate spectral clustering heuristics do not perform well.) We discard the trials where such exceptions occur.

Our results are summarized in Figure 3. Figure 3 illustrates the NMI of SC and KK as a function of the sketch size c and as a function of elapsed time for both algorithms. While



4. Uniform sampling is appropriate for the value of σ used in Eqn. (5); see Gittens and Mahoney (2016) for a detailed discussion of the effect of varying σ.
5. For both SC and KK with Nyström approximation, the extracted feature matrices have dimension $n \times k$, so the k-means clusterings required by both SC and KK have identical cost.

(a) M $n = 60,000$, $d = 780$, $k = 10$.

(b) Mushroom $n = 8,124$, $d = 112$, $k = 2$.

(c) en igits $n = 7,494$, $d = 16$, $k = 10$.

Figure 3: Comparisons between the runtimes and accuracies of approximate spectral clustering (SC) and approximate kernel k-means clustering (KK), both using uniform column sampling Nyström approximation.

Algorithm 2 Approximate Kernel k-Means Clustering using Nyström Approximation.

Input: data set $\mathbf{a}_1, \ldots, \mathbf{a}_n \in \mathbb{R}^d$, number of clusters k, target dimension s ($\geq k$), arbitrary integer ℓ ($> s$), sketch size c ($> \ell$), kernel function κ.
// Step 1: The Nyström Method
Form sketches $\mathbf{C} = \mathbf{KP} \in \mathbb{R}^{n\times c}$ and $\mathbf{W} = \mathbf{P}^T\mathbf{C} \in \mathbb{R}^{c\times c}$, where $\mathbf{K} = [\kappa(\mathbf{a}_i, \mathbf{a}_j)]_{ij} \in \mathbb{R}^{n\times n}$ is the kernel matrix and $\mathbf{P} \in \mathbb{R}^{n\times c}$ is some sketching matrix, e.g., uniform sampling;
Compute a matrix $\mathbf{R} \in \mathbb{R}^{n\times \ell}$ such that $\mathbf{RR}^T = \mathbf{CW}_\ell^{-1}\mathbf{C}^T$;
// Step 2: Dimensionality Reduction
Compute the rank-s truncated SVD $\mathbf{R}_s = \tilde{\mathbf{U}}_s\tilde{\mathbf{\Sigma}}_s\tilde{\mathbf{V}}_s^T$;
Let $\mathbf{B} = \tilde{\mathbf{U}}_s\tilde{\mathbf{\Sigma}}_s (= \mathbf{R}\tilde{\mathbf{V}}_s) \in \mathbb{R}^{n\times s}$;
// Step 3: Linear k-Means Clustering
Perform k-means clustering over the rows of $\mathbf{B}$;
return the clustering results.

there are quantitative differences between the results on the three data sets, the plots all show that KK is more accurate as a function of the sketch size or elapsed time than SC.

5. Single-Machine Medium-Scale Experiments

In this section, we empirically compare the Nyström method and random feature maps (Rahimi and Recht, 2007) for kernel k-means clustering. We conduct experiments on the data listed in Table 3. For the Mushrooms and PenDigits data, we are able to evaluate the objective function value of kernel k-means clustering.

5.1. Single-Machine Implementation of Approximate Kernel k-Means

Our algorithm for approximate kernel k-means clustering comprises three steps: **Nyström approximation**, **dimensionality reduction**, and **linear k-means clustering**. Both the single-machine as well as the distributed variants of the algorithm are governed by three parameters: s, the number of features used in the clustering; ℓ, a regularization parameter; and c, the sketch size. These parameters satisfy $k \leq s < \ell \leq c \ll n$.

1. **Nyström approximation.** Let c be the sketch size and $\mathbf{P} \in \mathbb{R}^{n\times c}$ be a sketching matrix. Let $\mathbf{C} = \mathbf{KP}$ and $\mathbf{W} = \mathbf{P}^T\mathbf{KP} = \mathbf{P}^T\mathbf{C}$. The standard Nyström approximation is $\mathbf{CW}^\dagger\mathbf{C}^T$; small singular values in $\mathbf{W}$ can lead to instability in the Moore-Penrose inverse, so a widely used heuristic is to choose $\ell < c$ and use $\mathbf{CW}_\ell^{-1}\mathbf{C}^T$ instead of the standard Nyström approximation.[6] We set $\ell = \lceil c/2 \rceil$ (arbitrarily). Let $\mathbf{W}_\ell = \mathbf{U}_{\mathbf{W},\ell}\mathbf{\Lambda}_{\mathbf{W},\ell}\mathbf{U}_{\mathbf{W},\ell}^T$ be the truncated SVD of $\mathbf{W}$ and return $\mathbf{R} = \mathbf{CU}_{\mathbf{W},\ell}\mathbf{\Lambda}_{\mathbf{W},\ell}^{-1/2} \in \mathbb{R}^{n\times\ell}$ as the output of the Nyström method.

6. The Nyström approximation $\mathbf{CW}^\dagger\mathbf{C}^T$ is correct in theory, but the Moore-Penrose inverse often causes numerical errors in practice. The Moore-Penrose inverse drops all the zero singular values, however, due to the finite numerical precision, it is difficult to determine whether a singular value, say 10^{-12}, should be zero or not, and this makes the computation unstable: if such a small singular value is believed to be zero, it will be dropped; otherwise, the Moore-Penrose inverse will invert it to obtain a singular value of 10^{12}. Dropping some portion of the smallest singular values is a simple heuristic that avoids this instability. This is why we heuristically use $\mathbf{CW}_\ell^{-1}\mathbf{C}^T$ instead of $\mathbf{CW}^\dagger\mathbf{C}^T$. Currently we do not have theory for this heuristic. Chiu and Demanet (2013) considers the theoretical implications of this regularization heuristic, but their results do not apply to our problem.

2. **Dimensionality reduction.** Let $\tilde{\mathbf{V}}_s \in \mathbb{R}^{\ell \times s}$ contain the dominant s right singular vectors of $\mathbf{R}$. Let $\mathbf{B} = \mathbf{R}\tilde{\mathbf{V}}_s \in \mathbb{R}^{n \times s}$. It can be verified that $\mathbf{B}\mathbf{B}^T = (\mathbf{C}\mathbf{W}_\ell^{-1}\mathbf{C}^T)_s$, which is our desired rank-restricted Nyström approximation.

3. **Linear k-means clustering.** With $\mathbf{B} \in \mathbb{R}^{n \times s}$ at hand, use an arbitrary off-the-shelf linear k-means clustering algorithm to cluster the rows of $\mathbf{B}$.

See Algorithm 2 for the single-machine version of this approximate kernel k-means clustering algorithm. Observe that we can use uniform sampling to form $\mathbf{C}$ and $\mathbf{W}$, and thereby avoid computing most of $\mathbf{K}$.

Let $\mathbf{R} \in \mathbb{R}^{n \times c}$ be the feature matrix computed by random feature maps (RFM). To make the comparison fair, we perform **dimensionality reduction** for RFM (Rahimi and Recht, 2007) in the same way as described in Algorithm 2 to compute $\mathbf{B} = \mathbf{R}\tilde{\mathbf{V}}_s$, and apply linear k-means clustering on the rows of $\mathbf{B}$.

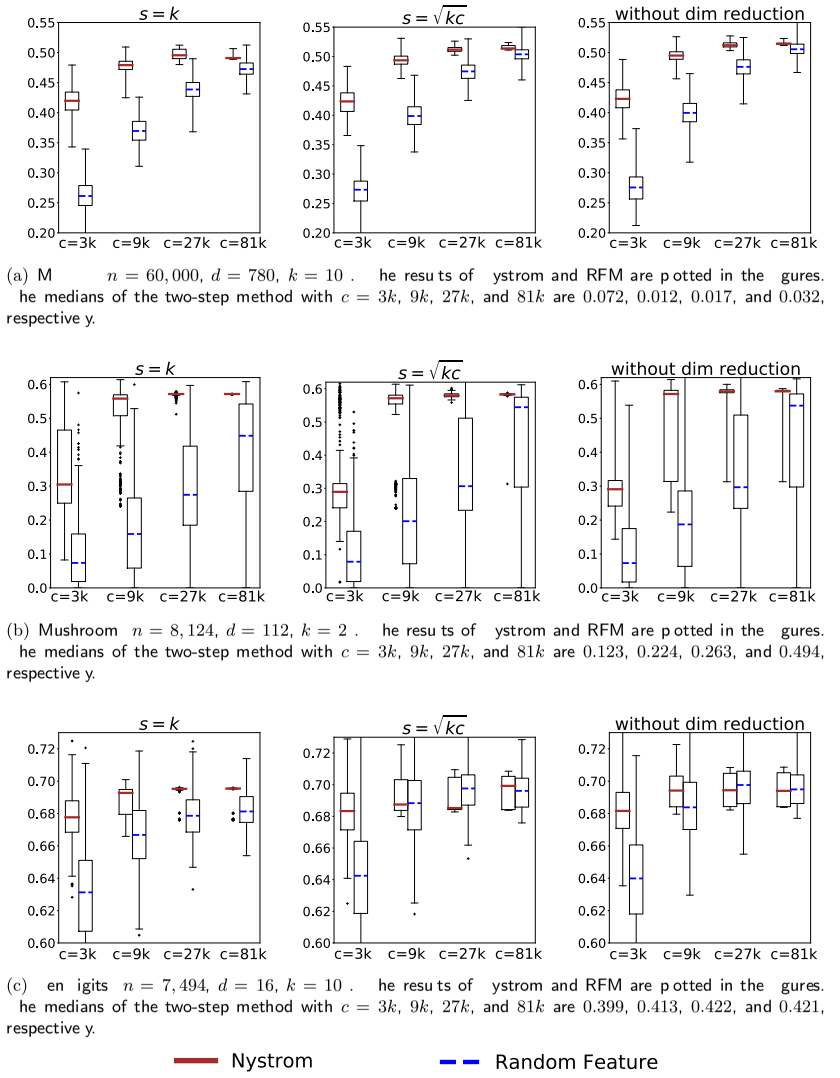
5.2. Comparing Nyström, Random Feature Maps, and Two-Step Method

We empirically compare the clustering performances of kernel approximations formed using Nyström, random feature map (RFM) (Rahimi and Recht, 2007), and the two-step method (Chitta et al., 2011) on the data sets detailed in Table 3.

We use the RBF kernel with width parameter given by (5); Figure 3 indicates that $\beta = 1$ is a good choice for these data sets. We conduct dimensionality reduction for both Nyström and RFM to obtain s-dimensional features, and consider three choices: $s = k$, $s = \lceil \sqrt{ck} \rceil$, and without dimensionality reduction (equivalently, $s = c$).

The quality of the clusterings is quantified using both normalized mutual information (NMI) (Strehl and Ghosh, 2002) and the objective function value:

$$\frac{1}{n} \sum_{i=1}^{k} \sum_{j \in \mathcal{J}_i} \left\| \mathbf{k}_j - \frac{1}{|\mathcal{J}_i|} \sum_{l \in \mathcal{J}_i} \mathbf{k}_l \right\|_2^2, \tag{6}$$



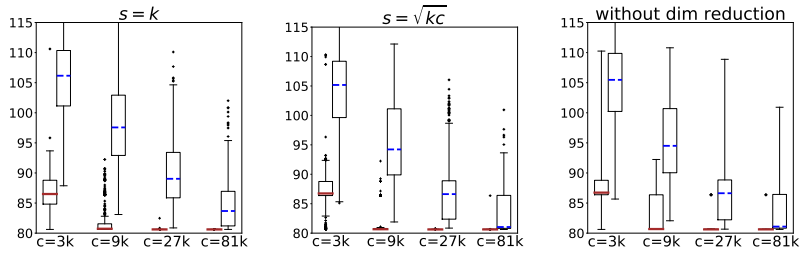
where $\mathbf{k}_1, \cdots, \mathbf{k}_n \in \mathbb{R}^n$ are the columns of the kernel matrix $\mathbf{K}$, and the disjoint sets $\mathcal{J}_1, \cdots, \mathcal{J}_k$ reflect the clustering.

We repeat the experiments 500 times and report the results in Figures 4 and 5. The experiments show that as measured by both NMIs and objective values, the Nyström method outperforms RFM in most cases. Both the Nyström method and RFM are consistently superior to the two-step method of (Chitta et al., 2011), which requires a large sketch size. All the compared methods improve as the sketch size c increases.

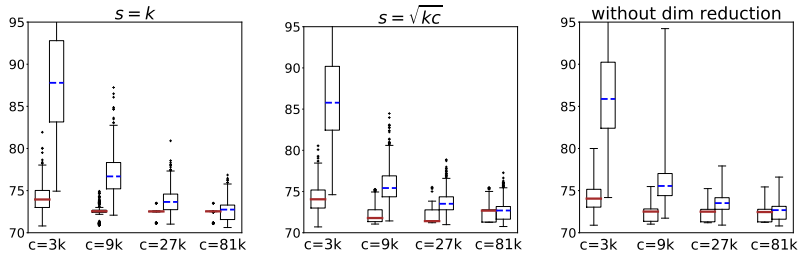
Judging from these medium-scale experiments, the target rank s has little impact on the NMI and clustering objective value. This phenomenon is not general; in the large-scale experiments of the next section we see that setting s properly allows one to obtain a better NMI than an over-small or over-large s.

6. Large-Scale Experiments using Distributed Computing

In this section, we empirically study our approximate kernel k-means clustering algorithm on large-scale data. We state a distributed version of the algorithm, implement it in Apache



(a) M $n = 60{,}000$, $d = 780$, $k = 10$. he resu ts of ystrom and RFM are p otted in the gures. he medians of the two-step method with $c = 3k$, $9k$, $27k$, and $81k$ are 0.072, 0.012, 0.017, and 0.032, respective y.



(b) Mushroom $n = 8{,}124$, $d = 112$, $k = 2$. he resu ts of ystrom and RFM are p otted in the gures. he medians of the two-step method with $c = 3k$, $9k$, $27k$, and $81k$ are 0.123, 0.224, 0.263, and 0.494, respective y.

(c) en igits $n = 7{,}494$, $d = 16$, $k = 10$. he resu ts of ystrom and RFM are p otted in the gures. he medians of the two-step method with $c = 3k$, $9k$, $27k$, and $81k$ are 0.399, 0.413, 0.422, and 0.421, respective y.

Figure 4: Quality of approximate kernel k-means clusterings using Nyström, random feature maps (Rahimi and Recht, 2007), and the two-step method (Chitta et al., 2011). (Dimensionality reduction is not applicable to the two-step method). The y-axis reports the normalized mutual information (NMI).

(a) Mushroom $n = 8,124$, $d = 112$, $k = 2$. he resu ts of ystrom and RFM are p otted in the gures. he medians of the objective va ues of the two-step method with $c = 3k$, $9k$, $27k$, and $81k$ are 101.5, 92.8, 89.5, and 85.3, respective y. random partition resu ts in a median objective function va ue of 119.5.

(b) en igits $n = 7,494$, $d = 16$, $k = 10$. he resu ts of ystrom and RFM are p otted in the gures. he medians of the two-step method with $c = 3k$, $9k$, $27k$, and $81k$ are 210.5, 198.2, 193.5, and 193.4, respective y. random partition resu ts in a median objective function va ue of 395.4.

Figure 5: Quality of approximate kernel k-means clusterings obtained using rank-restricted Nyström, RFMs (Rahimi and Recht, 2007), and the two-step method (Chitta et al., 2011). (Dimensionality reduction is not applicable to the two-step method). The y-axis reports the kernel k-means clustering objective function value.

Algorithm 3 Distributed Approximate Kernel k-Means Clustering using Nyström Approximation.

Input: data set $\mathbf{a}_1, \ldots, \mathbf{a}_n \in \mathbb{R}^d$ distributed among m machines, number of clusters k, target dimension s ($\geq k$), arbitrary integer $\ell > s$, sketch size c ($> \ell$), kernel function κ.
// **Step 1: The Nyström Method**
Sample c vectors from $\mathbf{a}_1, \ldots, \mathbf{a}_n$ to form $\mathbf{a}'_1, \ldots, \mathbf{a}'_c$ and send to the driver;
Driver computes $\mathbf{W} = [\kappa(a'_i, a'_j)]_{ij} \in \mathbb{R}^{c \times c}$ and a matrix $\mathbf{Z} \in \mathbb{R}^{c \times \ell}$ satisfying $\mathbf{Z}\mathbf{Z}^T = \mathbf{W}_\ell^{-1}$;
Broadcast $\mathbf{Z}$ and $\mathbf{a}'_1, \ldots, \mathbf{a}'_c$ to all executors;
for all $j \in [n]$ **do**
  Each executor locally computes $\mathbf{c}_j = [\kappa(\mathbf{a}_j, \mathbf{a}'_1); \ldots; \kappa(\mathbf{a}_j, \mathbf{a}'_c)] \in \mathbb{R}^c$ and $\mathbf{r}_j = \mathbf{Z}^T\mathbf{c}_j \in \mathbb{R}^\ell$;
end for
// **Step 2: Dimensionality Reduction**
Let $\tilde{\mathbf{V}}_s$ contain the dominant s right singular vectors of the distributed row matrix $\mathbf{R} = [\mathbf{r}_1, \ldots, \mathbf{r}_n]^T \in \mathbb{R}^{n \times \ell}$ (computed using a distributed truncated SVD algorithm);
Broadcast $\tilde{\mathbf{V}}_s \in \mathbb{R}^{\ell \times s}$ to all executors;
for all $j \in [n]$ **do**
  Each executor locally computes $\mathbf{b}_j = \tilde{\mathbf{V}}_s^T\mathbf{r}_j \in \mathbb{R}^s$;
end for
// **Step 3: Linear k-Means Clustering**
Perform k-means clustering over the Nyström features $\mathbf{b}_1, \ldots, \mathbf{b}_n \in \mathbb{R}^s$ (using a distributed linear k-means clustering algorithm).
return the clustering results.

Spark[7], and evaluate its performance on NERSC's Cori supercomputer. We investigate the effect of increased parallelism, sketch size c, and target dimension s.

Algorithm 3 is a distributed version of our method described in Section 5.1. Again, we use uniform sampling to form $\mathbf{C}$ and $\mathbf{W}$ to avoid computing most of $\mathbf{K}$. We mainly focus on the **Nyström approximation** step, as the other two steps are well supported by distributed computing systems such as Apache Spark.

6.1. Experimental Setup

We implemented Algorithm 3 in the Apache Spark framework (Zaharia et al., 2010, 2012), using the Scala API. We computed the Nyström approximation using the matrix operations provided by Spark, and invoked the MLlib library for machine learning in Spark (Meng et al., 2016) to perform the dimensionality reduction and linear k-means clustering steps. For the linear k-means clustering, we set the maximum number of iterations to 100.

We ran our experiments on Cori Phase I, a NERSC supercomputer, located at Lawrence Berkeley National Laboratory. Cori Phase I is a Cray XC40 system with 1632 compute nodes, each of which has two 2.3GHz 16-core Haswell processors and 128GB of DRAM. The Cray Aries high-speed interconnect linking the compute nodes is configured in a dragonfly topology.

We used the MNIST8M data set to conduct our empirical evaluations; this data set has $n = 8.1 \times 10^6$ instances, $d = 784$ features, and $k = 10$ clusters. We vary c and s and set $\ell = \frac{c}{2}$. We chose the RBF kernel width parameter according to (5) with $\beta = 1.0$. We use

7. This implementation is available at `https://github.com/wangshusen/SparkKernelKMeans.git`.

Table 4: The mean and standard deviation of the runtimes of Algorithm 3, in seconds, as a function of the number of compute nodes. We report the total runtime as well as the runtimes of the three stages: **Nyström approximation**, **dimensionality reduction (DR)**, and **linear k-means clustering**. The total time is the sum of the three stages and all the Spark overheads, e.g., Spark initialization. We fix $k = 10$ and $c = 400$. In the upper table, we set $s = 20$, and the NMI is 0.400 ± 0.009; in the lower table, we set $s = 80$, and the NMI is 0.410 ± 0.010.

	8 Nodes	16 Nodes	32 Nodes	64 Nodes	128 Nodes
Nyström	2998.6 ± 263.9	1268.8 ± 106.4	665.2 ± 39.6	369.7 ± 126.1	181.4 ± 22.2

Cori's default setting of Spark configurations. For each setting of parameters, we repeated the experiments 10 times and recorded the NMIs and elapsed time.

6.2. Effect of Increased Parallelism

We varied the number of nodes to test the impact of increased parallelism on each of the three steps in Algorithm 3. We set the sketch size to $c = 400$ and the target dimension to $s = 20$ or 80. Table 4 reports the mean and standard deviation of the elapsed times. As a reference point, using 32 nodes, our algorithm takes 15 minutes on average to group the 8.1 million input instances into 10 clusters. We also plot the elapsed times in Figure 6.

The **Nyström method** scales very well with the increase of nodes: its elapsed time is inversely proportional to the number of nodes. This is because the **Nyström method** requires only 2 rounds of communications; the elapsed time is spent mostly on computation on the executors.

Dimensionality reduction (DR) and **linear k-means clustering** are highly iterative and thus have high latency, incur straggler delays, and have large scheduler and communication overheads. See (Gittens et al., 2016) for an in-depth discussion of the performance concerns when using Spark for distributed matrix computations. As the number of nodes increases from 32 to 64 and higher, **DR** and **k-means** exhibit anti-scaling behavior: as the number of nodes goes up, their runtimes increase rather than decrease. For **DR**, the input dimension is $\ell = \frac{c}{2} = 200$, and the target dimension is $s = 20$ or 80; while for **k-means**, the input dimension is $s = 20$ or 80. Clearly, the issue here is not that **DR** and **k-means** are computationally intensive. Instead, as the number of nodes increase, although the per-node computational time decreases, the Spark communications overheads are increasing, making **DR** and **k-means** less performant. Such

(a) $k = 10$, $s = 20$, $c = 400$. (b) $k = 10$, $s = 80$, $c = 400$.

Figure 6: The mean of the runtimes of Algorithm 3, in seconds, as a function of the number of compute nodes.

behavior has been characterized and studied in other Spark implementations of linear algebra algorithms (Gittens et al., 2016).

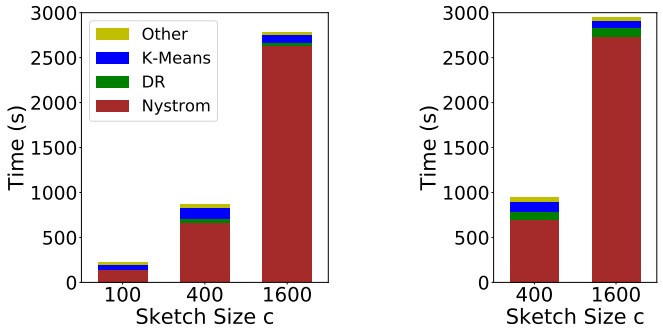

Table 5: The NMI and elapsed time (seconds) for varying sketch sizes c. Here "T" denotes the elapsed time. We use 32 nodes. In the upper table, we set $s = 20$; in the lower table, we set $s = 80$.

	$c = 100$	$c = 400$	$c = 1,600$
NMI	0.3833 ± 0.0117	0.3975 ± 0.0112	0.4069 ± 0.0001

T(Total)	940.6 ± 139.3	2952.2 ± 174.5

6.3. Effect of Sketch Size c

We executed our Spark implementation using 32 compute nodes, setting $s = 20$ or 80, and varying the target dimension c. Table 5 reports the observed normalized mutual information

(a) $k = 10$ and $s = 20$.

(b) $k = 10$ and $s = 80$.

Figure 7: The mean of the runtimes of Algorithm 3, in seconds, as a function of the sketch size c.

(NMI) (Strehl and Ghosh, 2002) and elapsed times. As predicted by our theory, for fixed k and s, larger c always leads to better performance.

In Figure 7 we plot the runtime as a function of the sketch size c. The plots shows the significant influence of c on the running time. In Figure 7, the runtime of Nyström grows superlinearly with c. According to our analysis, the computational and communication costs of Nyström are both superlinear in c. Therefore, the user should keep in mind this trade-off between the clustering performance and the computational cost.

6.4. Effect of Target Dimension s

We executed our Spark implementation using 32 computational nodes, fixing $k = 10$ and $c = 1600$ and varying the target dimension s. Table 6 reports the observed NMIs and elapsed times. For fixed k and c, a moderately large s leads to better clustering performance. However, as s grows, $\frac{k}{s}$ decreases but $\frac{s}{c}$ increases, so as predicted in Remark 3, the clustering performance is nonmonotonic in s. Indeed, as s grows from 80 to 160, the NMI deteriorates. In practice, for fixed k and c, one should set s moderately large, but not over-large.

In Figure 8 we plot the runtime as a function of the target dimension s. Note that s does not affect the time cost of the Nyström method. As s grows, the time costs of dimensionality reduction and linear k-means clustering both increase. This implies that a moderate s is good for computational purpose. Previously, in Figure 2, we plot the NMI as a function of s while fixing k and c. Figure 2 shows that a proper s leads to better NMI than an over-large or over-small s. In sum, setting s properly has both computational and accuracy benefits, which corroborates our theory.

Table 6: The NMI and elapsed time (seconds) for varying target dimensions s. Here "T" denotes the elapsed time. We use 32 nodes and fix $c = 1600$.

	$s = 10$	$s = 20$	$s = 40$	$s = 80$	$s = 160$	$s = 320$
NMI	0.3852 ± 0.0003	0.4069 ± 0.0001	0.4130 ± 0.0062	0.4233 ± 0.0131	0.4086 ± 0.0125	0.4099 ± 0.0098
T(Nyström)	2702.2 ± 131.6	2634.5 ± 94.4	2815.3 ± 403.6	2728.1 ± 190.3	2849.9 ± 511.2	2757.1 ± 271.9
T(DR)	21.1 ± 3.2	31.3 ± 6.6	57.5 ± 9.2	97.9 ± 20.6	168.2 ± 29.0	570.5 ± 151.0

T(Total)	2840.9 ± 132.0	2785.4 ± 83.2	3003.4 ± 413.7	2952.2 ± 174.5	3157.5 ± 549.2	3537.5 ± 256.3

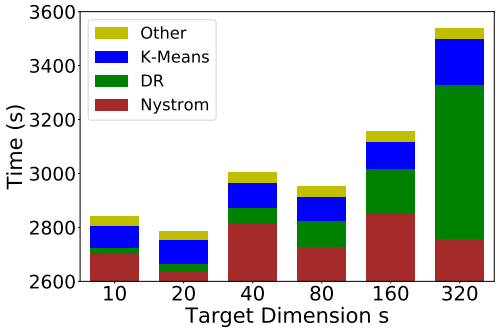

Figure 8: The mean of the runtimes of Algorithm 3, in seconds, as a function of the target dimension s. We use 32 nodes and fix $k = 10$ and $c = 1600$.

7. Conclusion

We provided principled algorithms for computing approximate kernel k-means clusterings. In particular, we showed that the combination of linear k-means with rank-restricted Nyström approximation is theoretically sound, practically useful, and scalable to large data sets. This should be contrasted with approximate spectral clustering using Nyström approximation. Although the latter is a widely-used approach to scalable non-linear clustering, it has theoretical deficiencies and practical limitations. Experiments demonstrated that approximate kernel k-means clustering using the rank-restricted Nyström approximation consistently outperforms approximate spectral clustering.

Our analysis uses the concept of projection-cost preservation and builds upon the existing theory of randomized linear algebra. Our main result is a $1+\epsilon$ approximation ratio guarantee for kernel k-means clustering: when $s = \frac{k}{\epsilon}$ Nyström features are used, a $1 + \mathcal{O}(\epsilon)$ approximation ratio is guaranteed with high probability. As an intermediate theoretical result of independent interest, we introduced a novel rank-restricted Nyström approximation and proved that it gives a $1+\epsilon$ relative-error low-rank approximation guarantee in the trace norm.

To complement our theory, we investigated the performance of the rank-restricted Nyström approximation when applied to kernel k-means clustering. We produced an Apache Spark implementation of a distributed version of our approximate kernel k-means algorithm, and applied it to cluster 8.1 million vectors; the results demonstrate the usefulness and simplicity of kernel k-means with rank-restricted Nyström approximation for clustering moderately large-scale data sets. Combined with recent work on user-friendly frameworks for distributed computing systems (Zaharia et al., 2010, 2012), large-scale machine learning (Meng et al., 2016), and large-scale randomized linear algebra (Gittens et al., 2016), our results suggest the use of kernel k-means with rank-restricted Nyström approximations for simple, computationally efficient, and theoretically principled clustering of large-scale data sets.

Acknowledgments

We thank the authors of Musco and Musco (2017) for bringing to our attention their results on approximate kernel k-means clustering through the use of ridge leverage score Nyström approximations, the authors of Tropp et al. (2017) for informing us of their contemporaneous guarantees on the approximation error of rank-restricted Nyström approximations, and the anonymous reviewers for their helpful suggestions. We would like to acknowledge ARO, DARPA, NSF, and ONR for providing partial support of this work.

Appendix A. Proof of Theorem 1

In this section, we will provide a proof of Theorem 1, our main quality-of-approximation result for rank-restricted Nyström approximation. We will start, in Section A.1, by establishing three technical lemmas; then, in Section A.2, we will establish an important structural result on the rank-restricted Nyström approximation as well as key approximate matrix multiplication properties for low-rank matrix approximation; and finally, in Section A.3, we will use these results to prove Theorem 1.

A.1. Technical Lemmas

Lemma 5 is a very well known result. See (Boutsidis et al., 2014; Zhang, 2015). Here we offer a simplified proof.

Lemma 5 *Let $\mathbf{A} \in \mathbb{R}^{n\times m}$ be any matrix and $\mathbf{U} \in \mathbb{R}^{n\times c}$ have orthonormal columns. Let s be any positive integer no greater than c. Then*

$$(\mathbf{U}^T\mathbf{A})_s \;=\; \operatorname*{argmin}_{\operatorname{rank}(\mathbf{Z})\le s} \big\|\mathbf{A}-\mathbf{U}\mathbf{Z}\big\|_F^2.$$

Proof Let $\mathbf{U}^\perp \in \mathbb{R}^{n\times(n-c)}$ be the orthogonal complement of $\mathbf{U}$. It holds that

$$\begin{aligned}
\big\|\mathbf{A}-\mathbf{U}\mathbf{Z}\big\|_F^2 &= \left\|\mathbf{A} - \begin{bmatrix}\mathbf{U} & \mathbf{U}^\perp\end{bmatrix}\begin{bmatrix}\mathbf{Z}\\ \mathbf{0}\end{bmatrix}\right\|_F^2\\
&= \left\|\begin{bmatrix}\mathbf{U}^T\\ (\mathbf{U}^\perp)^T\end{bmatrix}\mathbf{A} - \begin{bmatrix}\mathbf{Z}\\ \mathbf{0}\end{bmatrix}\right\|_F^2\\
&= \left\|\begin{bmatrix}\mathbf{U}^T\mathbf{A}-\mathbf{Z}\\ (\mathbf{U}^\perp)^T\mathbf{A}\end{bmatrix}\right\|_F^2\\
&= \big\|\mathbf{U}^T\mathbf{A}-\mathbf{Z}\big\|_F^2 + \big\|(\mathbf{U}^\perp)^T\mathbf{A}\big\|_F^2,
\end{aligned}$$

where the second equality follows from the unitary invariance of the Frobenius norm. Then

$$\operatorname*{argmin}_{\operatorname{rank}(\mathbf{Z})\le s} \big\|\mathbf{A}-\mathbf{U}\mathbf{Z}\big\|_F^2 \;=\; \operatorname*{argmin}_{\operatorname{rank}(\mathbf{Z})\le s} \big\|\mathbf{U}^T\mathbf{A}-\mathbf{Z}\big\|_F^2 \;=\; (\mathbf{U}^T\mathbf{A})_s,$$

by which the lemma follows. ■

Lemma 6 is a new result established in this work. The lemma plays an important role in analyzing the rank-restricted Nyström method.

Lemma 6 *Let $\mathbf{A} \in \mathbb{R}^{n\times m}$ be any matrix and $\mathbf{U} \in \mathbb{R}^{n\times c}$ has orthonormal columns. Let $s \le c$ be arbitrary integer. Let $\mathbf{Q} \in \mathbb{R}^{n\times s}$ be the orthonormal bases of the rank s matrix $\mathbf{U}(\mathbf{U}^T\mathbf{A})_s \in \mathbb{R}^{n\times m}$. Then $\mathbf{Q}\mathbf{Q}^T\mathbf{A} = \mathbf{U}(\mathbf{U}^T\mathbf{A})_s$.*

Proof Let $\mathbf{Z}^\star = \mathbf{Q}^T\mathbf{U}(\mathbf{U}^T\mathbf{A})_s \in \mathbb{R}^{s\times m}$. By the definition of $\mathbf{Q}$, we have

$$\mathbf{Q}\mathbf{Q}^T\mathbf{U}(\mathbf{U}^T\mathbf{A})_s \;=\; \mathbf{U}(\mathbf{U}^T\mathbf{A})_s. \tag{7}$$

It holds that

$$\big\|\mathbf{U}(\mathbf{U}^T\mathbf{A})_s-\mathbf{A}\big\|_F^2 \;=\; \min_{\operatorname{rank}(\mathbf{X})\le s}\big\|\mathbf{U}\mathbf{X}-\mathbf{A}\big\|_F^2 \;\le\; \min_{\operatorname{rank}(\mathbf{Z})\le s}\big\|\mathbf{Q}\mathbf{Z}-\mathbf{A}\big\|_F^2 \;\le\; \big\|\mathbf{Q}\mathbf{Z}^\star-\mathbf{A}\big\|_F^2,$$

where the equality follows from Lemma 5; the former inequality follows from that $\operatorname{range}(\mathbf{Q}) \subset \operatorname{range}(\mathbf{U})$. Because $\mathbf{U}(\mathbf{U}^T\mathbf{A})_s = \mathbf{Q}\mathbf{Z}^\star$ by (7), the lefthand and righthand sides are equal, and thereby

$$\min_{\operatorname{rank}(\mathbf{Z})\le s}\big\|\mathbf{Q}\mathbf{Z}-\mathbf{A}\big\|_F^2 \;=\; \big\|\mathbf{Q}\mathbf{Z}^\star-\mathbf{A}\big\|_F^2.$$

Since $\mathbf{Z}$ is $s\times m$, it follows that

$$\min_{\mathbf{Z}}\big\|\mathbf{Q}\mathbf{Z}-\mathbf{A}\big\|_F^2 \;=\; \min_{\operatorname{rank}(\mathbf{Z})\le s}\big\|\mathbf{Q}\mathbf{Z}-\mathbf{A}\big\|_F^2 \;=\; \big\|\mathbf{Q}\mathbf{Z}^\star-\mathbf{A}\big\|_F^2. \tag{8}$$

Let $\mathbf{Q}^\perp \in \mathbb{R}^{n\times(n-s)}$ be the orthogonal complement of $\mathbf{Q}$. It holds that

$$\begin{aligned}\left\|\mathbf{A}-\mathbf{QZ}\right\|_F^2 &= \left\|\mathbf{A}-\begin{bmatrix}\mathbf{Q} & \mathbf{Q}^\perp\end{bmatrix}\begin{bmatrix}\mathbf{Z}\\ \mathbf{0}\end{bmatrix}\right\|_F^2\\ &= \left\|\begin{bmatrix}\mathbf{Q}^T\\ (\mathbf{Q}^\perp)^T\end{bmatrix}\mathbf{A}-\begin{bmatrix}\mathbf{Z}\\ \mathbf{0}\end{bmatrix}\right\|_F^2\\ &= \left\|\begin{bmatrix}\mathbf{Q}^T\mathbf{A}-\mathbf{Z}\\ (\mathbf{Q}^\perp)^T\mathbf{A}\end{bmatrix}\right\|_F^2\\ &= \left\|\mathbf{Q}^T\mathbf{A}-\mathbf{Z}\right\|_F^2+\left\|(\mathbf{Q}^\perp)^T\mathbf{A}\right\|_F^2,\end{aligned}$$

where the second equality follows from the unitary invariance of the Frobenius norm. Obviously, $\mathbf{Z}=\mathbf{Q}^T\mathbf{A}$ is the unique minimizer of $\min_{\mathbf{Z}}\|\mathbf{QZ}-\mathbf{A}\|_F^2$; otherwise $\mathbf{Q}^T\mathbf{A}-\mathbf{Z}$ in the righthand side is non-zero, making the objective function increase.

On the one hand, Eqn. (8) shows that $\mathbf{Z}^\star=\mathbf{Q}^T\mathbf{U}(\mathbf{U}^T\mathbf{A})_s\in\mathbb{R}^{s\times m}$ is one minimizer of $\min_{\mathbf{Z}}\|\mathbf{QZ}-\mathbf{A}\|_F^2$. On the other hand, we have that $\mathbf{Z}=\mathbf{Q}^T\mathbf{A}$ is the unique minimizer of $\min_{\mathbf{Z}}\|\mathbf{QZ}-\mathbf{A}\|_F^2$. By the uniqueness, we have

$$\mathbf{Z}^\star \;=\; \mathbf{Q}^T\mathbf{U}(\mathbf{U}^T\mathbf{A})_s \;=\; \mathbf{Q}^T\mathbf{A}.$$

It follows that

$$\mathbf{QQ}^T\mathbf{U}(\mathbf{U}^T\mathbf{A})_s \;=\; \mathbf{QQ}^T\mathbf{A}.$$

The lemma follows from (7) and the above equality. ■

Lemma 7 is a new result established by this work. Let $\mathbf{A}$ be any symmetric matrix. Lemma 7 analyzes the power scheme: using $\mathbf{A}^t\mathbf{P}$, instead of $\mathbf{AP}$, as a sketch of $\mathbf{A}$. The lemma shows that the power scheme leads to an improvement of $\left(\frac{\sigma_{s+1}^2}{\sigma_s^2}\right)^{t-1}$, where σ_i is the i-th biggest singular value of $\mathbf{A}$. Lemma 7 with $t=1$ is identical to (Boutsidis et al., 2014, Lemma 9). The power scheme has been studied by Gittens and Mahoney (2016); Halko et al. (2011); Woodruff (2014); their results do not allow the rank restriction $\mathrm{rank}(\mathbf{X})\le s$. To prove Theorem 1, we only need $t=1$; we will use Lemma 7 to extend Theorem 1 to the power method.

Lemma 7 *Let $\mathbf{A}\in\mathbb{R}^{n\times n}$ be any SPSD matrix and $\mathbf{A}_s=\mathbf{V}_s\mathbf{\Sigma}_s\mathbf{V}_s^T$ be the truncated SVD. Let $\mathbf{P}\in\mathbb{R}^{n\times c}$ satisfy that $\mathbf{P}^T\mathbf{V}_s\in\mathbb{R}^{c\times s}$ has full column rank. Let $t\ge 1$ be any integer and $\mathbf{C}=\mathbf{A}^t\mathbf{P}$. Then for $\xi=2$ or F,*

$$\min_{\mathrm{rank}(\mathbf{X})\le s}\left\|\mathbf{A}-\mathbf{CX}\right\|_\xi^2 \;\le\; \left\|\mathbf{A}-\mathbf{A}_s\right\|_\xi^2+\left(\tfrac{\sigma_{s+1}^2}{\sigma_s^2}\right)^{t-1}\left\|(\mathbf{A}-\mathbf{A}_s)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\right\|_\xi^2,$$

where σ_i is the i-th largest singular value of $\mathbf{A}$.

Proof We construct the rank s matrix $\tilde{\mathbf{A}}_s=\mathbf{C}(\mathbf{V}_s^T\mathbf{P})^\dagger\mathbf{\Sigma}_s^{1-t}\mathbf{V}_s^T$ and use it to facilitate our proof. Since $\tilde{\mathbf{A}}_s$ has rank s, and its column space is in range$(\mathbf{C})$, it holds that

$$\begin{aligned}&\min_{\mathrm{rank}(\mathbf{X})\le s}\left\|\mathbf{A}-\mathbf{CX}\right\|_\xi^2 \;\le\; \left\|\mathbf{A}-\tilde{\mathbf{A}}_s\right\|_\xi^2\\ &=\; \left\|(\mathbf{A}-\mathbf{A}_s)+(\mathbf{A}_s-\tilde{\mathbf{A}}_s)\right\|_\xi^2 \;\le\; \left\|\mathbf{A}-\mathbf{A}_s\right\|_\xi^2+\left\|\mathbf{A}_s-\tilde{\mathbf{A}}_s\right\|_\xi^2.\end{aligned}$$

The latter inequality follows from that the row space of $\mathbf{A}_s-\tilde{\mathbf{A}}_s$ is in range$(\mathbf{V}_s)$, that $(\mathbf{A}-\mathbf{A}_s)\mathbf{V}_s=\mathbf{0}$, and the matrix Pythagorean theorem. By the assumption $\mathrm{rank}(\mathbf{V}_s^T\mathbf{P})=s$, it holds that $(\mathbf{V}_s^T\mathbf{P})(\mathbf{V}_s^T\mathbf{P})^\dagger=\mathbf{I}_s$. We have

$$\begin{aligned}\left\|\mathbf{A}_s-\tilde{\mathbf{A}}_s\right\|_\xi^2 &= \left\|\mathbf{A}_s-(\mathbf{A}_s^t+\mathbf{A}^t-\mathbf{A}_s^t)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\mathbf{\Sigma}_s^{1-t}\mathbf{V}_s^T\right\|_\xi^2\\ &= \left\|\mathbf{A}_s-\mathbf{V}_s\mathbf{\Sigma}_s^t\underbrace{(\mathbf{V}_s^T\mathbf{P})}_{s\times c}\underbrace{(\mathbf{V}_s^T\mathbf{P})^\dagger}_{c\times s}\mathbf{\Sigma}_s^{1-t}\mathbf{V}_s^T-(\mathbf{A}^t-\mathbf{A}_s^t)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\mathbf{\Sigma}_s^{1-t}\mathbf{V}_s^T\right\|_\xi^2\\ &= \left\|\mathbf{A}_s-\mathbf{V}_s\mathbf{\Sigma}_s\mathbf{V}_s^T-(\mathbf{A}^t-\mathbf{A}_s^t)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\mathbf{\Sigma}_s^{1-t}\mathbf{V}_s^T\right\|_\xi^2\\ &= \left\|(\mathbf{A}^t-\mathbf{A}_s^t)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\mathbf{\Sigma}_s^{1-t}\mathbf{V}_s^T\right\|_\xi^2\\ &\le \left\|(\mathbf{A}-\mathbf{A}_s)^{t-1}\right\|_2^2\left\|\mathbf{\Sigma}_s^{1-t}\right\|_2^2\left\|(\mathbf{A}-\mathbf{A}_s)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\right\|_\xi^2\\ &= \left(\tfrac{\sigma_{s+1}^2}{\sigma_s^2}\right)^{t-1}\left\|(\mathbf{A}-\mathbf{A}_s)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^\dagger\right\|_\xi^2,\end{aligned}$$

by which the lemma follows. ■

A.2. Structural Result and Approximate Matrix Multiplication Properties

Lemma 8 is a structural result of independent interest that is important for establishing Theorem 1. By *structural result*, we mean that it is a linear algebraic result that holds for any matrix $\mathbf{P}$, and in particular for any matrix $\mathbf{P}$ that is a randomized sketching matrix. In particular, given this structural result, randomness in an algorithm enters only via $\mathbf{P}$. The importance of establishing such structural results within randomized linear algebra has been highlighted previously (Drineas et al., 2011; Mahoney, 2011; Gittens and Mahoney, 2016; Mahoney and Drineas, 2016; Wang et al., 2017).

Lemma 8 *Let $\mathbf{K}\in\mathbb{R}^{n\times n}$ be any SPSD matrix, $\mathbf{P}\in\mathbb{R}^{n\times c}$ be any matrix, and $s\le c$ be any positive integer. Let $\mathbf{D}=\mathbf{K}^{1/2}\mathbf{P}\in\mathbb{R}^{n\times c}$, $\rho=\mathrm{rank}(\mathbf{D})\le c$, and $\mathbf{U}\in\mathbb{R}^{n\times\rho}$ be the left singular vectors of $\mathbf{D}$. Let $\mathbf{Q}\in\mathbb{R}^{n\times s}$ be any orthonormal bases of $\mathbf{U}(\mathbf{U}^T\mathbf{K}^{1/2})_s$. It holds that*

$$\begin{aligned}\left(\mathbf{CW}^\dagger\mathbf{C}^T\right)_s &= \mathbf{K}^{1/2}\mathbf{QQ}^T\mathbf{K}^{1/2},\\ \left\|\mathbf{K}-\left(\mathbf{CW}^\dagger\mathbf{C}^T\right)_s\right\|_* &= \min_{\mathrm{rank}(\mathbf{Z})\le s}\left\|\mathbf{K}^{1/2}-(\mathbf{K}^{1/2}\mathbf{P})\mathbf{Z}\right\|_F^2.\end{aligned}$$

Proof Let $\mathbf{D}=\mathbf{K}^{1/2}\mathbf{P}=\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T\in\mathbb{R}^{n\times c}$ be the SVD of $\mathbf{D}$. It holds that $\mathbf{C}=\mathbf{KP}=\mathbf{K}^{1/2}\mathbf{D}$ and $\mathbf{W}=\mathbf{P}^T\mathbf{KP}=\mathbf{D}^T\mathbf{D}$. It follows the SVD of $\mathbf{D}$ that

$$\mathbf{C}(\mathbf{W}^\dagger)^{1/2} \;=\; \mathbf{K}^{1/2}\mathbf{D}\left((\mathbf{D}^T\mathbf{D})^\dagger\right)^{1/2} \;=\; \mathbf{K}^{1/2}(\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T)\left(\mathbf{V}\mathbf{\Sigma}^{-2}\mathbf{V}^T\right)^{1/2} \;=\; \mathbf{K}^{1/2}\mathbf{U}\mathbf{V}^T.$$

We need the following lemma to prove Lemma 8. The following lemma is not hard to prove.

Lemma 9 *Let the integers n,c,ρ,s satisfy $n\ge c\ge\rho\ge s$. Let $\mathbf{A}\in\mathbb{R}^{n\times\rho}$ be any matrix with rank at least s and $\mathbf{V}\in\mathbb{R}^{c\times\rho}$ has orthonormal columns. Then $(\mathbf{AV}^T)_s=\mathbf{A}_s\mathbf{V}^T$.*

If $\mathrm{rank}(\mathbf{K}^{1/2}\mathbf{U}) < s$, then obviously $\mathbf{K}^{1/2}\mathbf{U}\mathbf{V}^T = (\mathbf{K}^{1/2}\mathbf{U}\mathbf{V}^T)_s = (\mathbf{K}^{1/2}\mathbf{U})_s\mathbf{V}^T$. We thus assume $\mathrm{rank}(\mathbf{K}^{1/2}\mathbf{U}\mathbf{V}^T) \geq s$ and can apply the above lemma to show $(\mathbf{K}^{1/2}\mathbf{U}\mathbf{V}^T)_s = (\mathbf{K}^{1/2}\mathbf{U})_s\mathbf{V}^T$. In either case, we have

$$(\mathbf{K}^{1/2}\mathbf{U}\mathbf{V}^T)_s \;=\; (\mathbf{K}^{1/2}\mathbf{U})_s\mathbf{V}^T.$$

It follows from (9) that $\big(\mathbf{C}(\mathbf{W}^\dagger)^{1/2}\big)_s = (\mathbf{K}^{1/2}\mathbf{U})_s\mathbf{V}^T$. Thus

$$\big(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\big)_s \;=\; (\mathbf{K}^{1/2}\mathbf{U})_s(\mathbf{U}^T\mathbf{K}^{1/2})_s \;=\; (\mathbf{K}^{1/2}\mathbf{U})_s\mathbf{U}^T\mathbf{U}(\mathbf{U}^T\mathbf{K}^{1/2})_s$$

Let $\mathbf{Q} \in \mathbb{R}^{n\times s}$ be the orthonormal bases of the rank s matrix $\mathbf{U}(\mathbf{U}^T\mathbf{K}^{1/2})_s$. Lemma 6 ensures that

$$\mathbf{Q}\mathbf{Q}^T\mathbf{K}^{1/2} \;=\; \mathbf{U}(\mathbf{U}^T\mathbf{K}^{1/2})_s.$$

It follows that

$$\big(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\big)_s \;=\; \mathbf{K}^{1/2}\mathbf{Q}\mathbf{Q}^T\mathbf{K}^{1/2}, \tag{9}$$

by which the former conclusion of the lemma follows.

It is well known that $\|\mathbf{Y}\|_* = \mathrm{tr}(\mathbf{Y})$ for any SPSD matrix $\mathbf{Y}$ and that $\mathrm{tr}(\mathbf{A}^T\mathbf{A}) = \|\mathbf{A}\|_F^2$ for any matrix $\mathbf{A}$. It follows from (9) that

$$\begin{aligned}
&\big\|\mathbf{K} - \big(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\big)_s\big\|_* \;=\; \big\|\mathbf{K}^{1/2}\big(\mathbf{I}_n - \mathbf{Q}\mathbf{Q}^T\big)\mathbf{K}^{1/2}\big\|_* \\
&= \mathrm{tr}\Big(\mathbf{K}^{1/2}\big(\mathbf{I}_n - \mathbf{Q}\mathbf{Q}^T\big)\big(\mathbf{I}_n - \mathbf{Q}\mathbf{Q}^T\big)\mathbf{K}^{1/2}\Big) \\
&= \big\|\big(\mathbf{I}_n - \mathbf{Q}\mathbf{Q}^T\big)\mathbf{K}^{1/2}\big\|_F^2 \;=\; \big\|\mathbf{K}^{1/2} - \mathbf{U}(\mathbf{U}^T\mathbf{K}^{1/2})_s\big\|_F^2;
\end{aligned}$$

here the second equality holds because $\mathbf{K}^{1/2}(\mathbf{I}_n - \mathbf{Q}\mathbf{Q}^T)\mathbf{K}^{1/2}$ is SPSD and $(\mathbf{I}_n - \mathbf{Q}\mathbf{Q}^T)$ is orthogonal projection matrix; the last equality follows from Lemma 6. It follows from Lemma 5 that

$$\begin{aligned}
&\big\|\mathbf{K} - \big(\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\big)_s\big\|_* \;=\; \big\|\mathbf{K}^{1/2} - \mathbf{U}(\mathbf{U}^T\mathbf{K}^{1/2})_s\big\|_F^2 \\
&= \min_{\mathrm{rank}(\mathbf{X})\leq s}\big\|\mathbf{K}^{1/2} - \mathbf{U}\mathbf{X}\big\|_F^2 \;=\; \min_{\mathrm{rank}(\mathbf{Z})\leq s}\big\|\mathbf{K}^{1/2} - \mathbf{D}\mathbf{Z}\big\|_F^2,
\end{aligned}$$

by which the latter conclusion of the lemma follows. ■

Lemma 10 formally defines the key *approximate matrix multiplication properties* (subspace embedding property and approximate orthogonality property) which—when sketching dimensions are chosen appropriately (see Table 7)—are shared by the uniform sampling, leverage score sampling, Gaussian projection, SRHT, and CountSketch sketching methods. Establishing approximate matrix multiplication bounds is the key step in proving many approximate regression and low-rank approximation results (Mahoney, 2011), and this lemma will be used crucually in the proof of Theorem 1.

Lemma 10 (Key Approximate Matrix Multiplication Properties for a Sketch) *Let $\eta, \epsilon, \delta_1, \delta_2 \in (0,1)$ be fixed parameters. Fix $\mathbf{Y} \in \mathbb{R}^{n\times d}$ and let $\mathbf{V} \in \mathbb{R}^{n\times s}$ have orthonormal columns. Let $\mathbf{P} \in \mathbb{R}^{n\times c}$ be one of the sketching methods listed in Table 7. When c is larger than the quantity in the middle column of the corresponding row of Table 7, the subspace embedding property*

$$\big\|\mathbf{V}^T\mathbf{P}\mathbf{P}^T\mathbf{V} - \mathbf{I}_s\big\|_2 \;\leq\; \eta$$

holds with probability at least $1-\delta_1$. When c is larger than the quantity in the right-hand column of the corresponding row of Table 7, the matrix multiplication property

$$\big\|\mathbf{V}^T\mathbf{P}\mathbf{P}^T\mathbf{Y} - \mathbf{V}^T\mathbf{Y}\big\|_F^2 \;\leq\; \epsilon\|\mathbf{Y}\|_F^2$$

holds with probability at least $1-\delta_2$.

Table 7: Sufficient sketching dimensions for the sketching properties of Lemma 10 to hold. The leverage score sampling referred to here is with respect to the leverage scores of the matrix $\mathbf{V}$ described in Lemma 10. Similarly, μ is the row coherence of $\mathbf{V}$.

Sketching	Subspace Embedding	Matrix Multiplication
Leverage Score Sampling	$\frac{s}{\eta^2}\log\frac{s}{\delta_1}$	$\frac{s}{\epsilon\delta_2}$
Uniform Sampling	$\frac{\mu s}{\eta^2}\log\frac{s}{\delta_1}$	$\frac{\mu s}{\epsilon\delta_2}$
SRHT	$\frac{s+\log n}{\eta^2}\log\frac{s}{\delta_1}$	$\frac{s+\log n}{\epsilon\delta_2}$
Gaussian Projection	$\frac{s+\log(1/\delta_1)}{\eta^2}$	$\frac{s}{\epsilon\delta_2}$
CountSketch	$\frac{s^2}{\delta_1\eta^2}$	$\frac{s}{\epsilon\delta_2}$

Proof This lemma is a reproduction of (Wang et al., 2016b, Lemma 2), and is a collation of heterogenously stated results from the literature. The random sampling estimates were established by Drineas et al. (2008); Wang et al. (2016a); Woodruff (2014). The Gaussian projection was firstly analyzed by Johnson and Lindenstrauss (1984); see Woodruff (2014) for a proof of the stated sufficient sketching dimensions. The SRHT estimates are from Drineas et al. (2011); Lu et al. (2013); Tropp (2011). The CountSketch estimates are from Meng and Mahoney (2013); Nelson and Nguyên (2013). ■

A.3. Completing the Proof of Theorem 1

Proof Let $\mathbf{K}_s = \mathbf{V}_s\mathbf{\Lambda}_s\mathbf{V}_s^T \in \mathbb{R}^{n\times n}$ be the truncated SVD of $\mathbf{K}$. It follows from Lemma 10 and the sketch sizes defined in Table 2 that

$$\begin{aligned}
\big\|\mathbf{V}_s^T\mathbf{P}\mathbf{P}^T\mathbf{V}_s - \mathbf{I}_s\big\|_2 &\leq \eta, \\
\big\|(\mathbf{K}^{1/2} - \mathbf{K}_s^{1/2})\mathbf{P}\mathbf{P}^T\mathbf{V}_s\big\|_F^2 &\leq \epsilon\big\|\mathbf{K}^{1/2} - \mathbf{K}_s^{1/2}\|_F^2
\end{aligned}$$

hold simultaneously with probability at least 0.9.

It follows from Lemma 8 that

$$\begin{aligned}\left\|\mathbf{K}-\left(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^{T}\right)_{s}\right\|_{*} &= \min_{\mathrm{rank}(\mathbf{Z})\leq s}\left\|\mathbf{K}^{1/2}-(\mathbf{K}^{1/2}\mathbf{P})\mathbf{Z}\right\|_{F}^{2}\\ &\leq \left\|\mathbf{K}^{1/2}-\mathbf{K}_{s}^{1/2}\right\|_{F}^{2}+\left\|(\mathbf{K}^{1/2}-\mathbf{K}_{s}^{1/2})\mathbf{P}(\mathbf{V}_{s}^{T}\mathbf{P})^{\dagger}\right\|_{F}^{2}\\ &= \left\|\mathbf{K}-\mathbf{K}_{s}\right\|_{*}+\left\|(\mathbf{K}^{1/2}-\mathbf{K}_{s}^{1/2})\mathbf{P}\mathbf{P}^{T}\mathbf{V}_{s}(\mathbf{V}_{s}^{T}\mathbf{P}\mathbf{P}^{T}\mathbf{V}_{s})^{\dagger}\right\|_{F}^{2}\\ &\leq \left\|\mathbf{K}-\mathbf{K}_{s}\right\|_{*}+\sigma_{s}^{-2}\left(\mathbf{V}_{s}^{T}\mathbf{P}\mathbf{P}^{T}\mathbf{V}_{s}\right)\left\|(\mathbf{K}^{1/2}-\mathbf{K}_{s}^{1/2})\mathbf{P}\mathbf{P}^{T}\mathbf{V}_{s}\right\|_{F}^{2},\end{aligned}$$

where the former inequality follows from Lemma 7 (with $t=1$). It follows that

$$\left\|\mathbf{K}-\left(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^{T}\right)_{s}\right\|_{*} \leq \left\|\mathbf{K}-\mathbf{K}_{s}\right\|_{*}+\tfrac{\epsilon}{(1-\eta)^{2}}\left\|\mathbf{K}-\mathbf{K}_{s}\right\|_{*}.$$

We let η be a constant and obtain the former claim of Theorem 1. The latter claim of Theorem 1 follows from Lemma 8. ■

Appendix B. Proof of Theorem 2

In this section, we will provide a proof of Theorem 2, our main result for kernel k-means approximation. We will start, in Sections B.1, B.2, and B.3, by presenting several technical tools of independent interest (Lemmas 11, 12, and 13, respectively). Then, in Section B.4, we will use use these tools to prove Theorem 2.

The proof of Theorem 2 will proceed by combining Theorem 1 with Lemmas 11, 12, and 13. For convenience, the structure of proof is given in Figure 9.

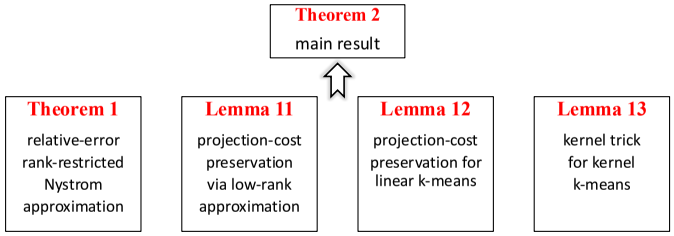

Figure 9: The structure of the proof of Theorem 2.

We use the notation of *orthogonal projection matrix* throughout this section. A matrix $\mathbf{M}\in\mathbb{R}^{n\times n}$ is an orthogonal projection matrix if and only if there exists a matrix $\mathbf{Q}$ with orthonormal columns such that $\mathbf{M}=\mathbf{Q}\mathbf{Q}^{T}$. It follows that $\mathbf{M}^{T}=\mathbf{M}$, $\mathbf{M}\mathbf{M}=\mathbf{M}$, $\mathbf{M}\preceq\mathbf{I}_{n}$ and that $\mathbf{I}_{n}-\mathbf{M}$ is also an orthogonal projection matrix.

B.1. Projection-Cost Preservation via Low-Rank Approximation

We first define projection-cost preservation, then show that certain low-rank approximations are projection-cost preserving. Projection-cost preservation was named and systematized by Cohen et al. (2015), but the idea has been used in earlier works (Boutsidis et al., 2010, 2015; Feldman et al., 2013; Liang et al., 2014).

Definition 2 (Rank k Projection-Cost Preservation) *Fix a matrix $\mathbf{A}\in\mathbb{R}^{n\times d}$ and error parameters $\epsilon_1,\epsilon_2>0$. The matrix $\mathbf{B}\in\mathbb{R}^{n\times d}$ has the rank k projection-cost preserving property with respect to $\mathbf{A}$ if for any rank k orthogonal projection matrices $\mathbf{\Pi}\in\mathbb{R}^{n\times n}$,*

$$(1-\epsilon_1)\left\|\mathbf{A}-\mathbf{\Pi}\mathbf{A}\right\|_{F}^{2} \leq \left\|\mathbf{B}-\mathbf{\Pi}\mathbf{B}\right\|_{F}^{2}+\alpha \leq (1+\epsilon_2)\left\|\mathbf{A}-\mathbf{\Pi}\mathbf{A}\right\|_{F}^{2},$$

for some fixed non-negative α that can depend on $\mathbf{A}$ and $\mathbf{B}$ but is independent of $\mathbf{\Pi}$.

The next lemma provides a way to construct a projection-cost preserving sketch of $\mathbf{A}$. It states that if a rank-s matrix $\tilde{\mathbf{A}}_s$ in the span of $\mathbf{A}$ is constructed so that $\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^{T}$ approximates $\mathbf{A}\mathbf{A}^{T}$ sufficiently well in terms of the trace norm, then $\tilde{\mathbf{A}}_s$ has the projection-cost preserving property. Observe that this lemma explicitly relates projection-cost preserving sketches to approximate matrix multiplication (Drineas et al., 2006; Mahoney, 2011), where the latter is measures with respect to the trace norm (Gittens and Mahoney, 2016). We provide a proof of Lemma 11 in Appendix D.

Lemma 11 (Projection-Cost Preservation via Low-Rank Approximation) *Fix an error parameter $\epsilon\in(0,1)$. Let $\mathbf{A}\in\mathbb{R}^{n\times d}$ and choose a rank-s matrix $\tilde{\mathbf{A}}_s$ that satisfies the following conditions:*

(i) there is an orthogonal projection matrix $\mathbf{M}$ such that $\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^{T}=\mathbf{A}\mathbf{M}\mathbf{A}^{T}$, and

(ii) $\|\mathbf{A}\mathbf{A}^{T}-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^{T}\|_{*}\leq(1+\epsilon)\left\|\mathbf{A}\mathbf{A}^{T}-\mathbf{A}_s\mathbf{A}_s^{T}\right\|_{*}$.

Then there exists a fixed $\alpha\geq 0$ such that, for any rank k projection matrices $\mathbf{\Pi}\in\mathbb{R}^{n\times n}$,

$$\left\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\right\|_{F}^{2} \leq \left\|(\mathbf{I}_n-\mathbf{\Pi})\tilde{\mathbf{A}}_s\right\|_{F}^{2}+\alpha \leq \left(1+\epsilon+\tfrac{k}{s}\right)\left\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\right\|_{F}^{2}.$$

B.2. Linear k-Means Clustering and Projection-Cost Preservation

Linear k-means clustering is formally defined by the optimization problem (1). To relate the linear k-means clustering problem to the projection-cost preservation property, we use an equivalent formulation of (1) as an optimization over the set of rank-k projection matrices of the form $\mathbf{X}\mathbf{X}^{T}$, where $\mathbf{X}$ is a *cluster indicator matrix*. This approach was adopted by Boutsidis et al. (2009, 2010, 2015); Cohen et al. (2015); Ding et al. (2005). Following them, we define the cluster indicator matrix in the following and give an example in Figure 10.

Definition 3 (Cluster Indicator Matrices) *Let n and k be given, and let $\mathcal{J}_1,\ldots,\mathcal{J}_k$ be a k-partition of the set $[n]$. The cluster indicator matrix corresponding to $\mathcal{J}_1,\ldots,\mathcal{J}_k$ is the $n\times k$ matrix $\mathbf{X}$ defined by*

$$x_{ij} = \begin{cases}\frac{1}{\sqrt{|\mathcal{J}_j|}} & \text{if } i\in\mathcal{J}_j;\\ 0 & \text{otherwise.}\end{cases}$$

We take $\mathcal{X}_{n,k}$ to be the collection of cluster indicator matrices corresponding to all the k-partitions of $[n]$.

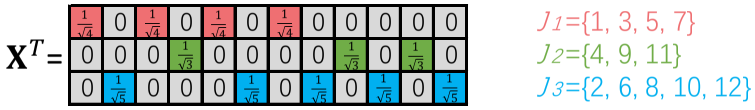

Figure 10: An example of a cluster indicator matrix $\mathbf{X} \in \mathcal{X}_{n,k}$. In this example, $n = 12$, $k = 3$, and $\mathbf{X}$ corresponds to the indicated 3-partition $\mathcal{J}_1$, $\mathcal{J}_2$, $\mathcal{J}_3$.

A cluster indicator matrix $\mathbf{X}$ has exactly one non-zero entry in each row and has orthonormal columns. That is, because of the normalization of the non-zero entries, a cluster indicator matrix $\mathbf{X}$ is an orthogonal matrix, but one with the additional constraint that there is only one non-zero entry in each row. (Indeed, the insight of Boutsidis et al. (2009, 2010, 2015) was that the rank-constrained optimization over all orthonormal matrices, which provides the usual PCA/SVD-based low-rank approximation, is a relaxation of the optimization over this smaller set of orthonormal matrices.) Among other things, it follows that $\mathbf{X}\mathbf{X}^T$ is a rank-k projection matrix.

Given this, assume $i \in \mathcal{J}_j$; it can be verified that the i-th row of $\mathbf{X}\mathbf{X}^T\mathbf{A} \in \mathbb{R}^{n\times d}$ is the centroid of $\mathcal{J}_j$:

$$(\mathbf{X}\mathbf{X}^T\mathbf{A})_{i:} \;=\; \mathbf{x}_{i:}\mathbf{X}^T\mathbf{A} \;=\; \frac{1}{|\mathcal{J}_j|}\sum_{l\in\mathcal{J}_j}\mathbf{a}_{l:}.$$

Consider the objective function of (1). When $\mathbf{X}$ is the cluster indicator matrix corresponding to the input k-partition, this objective can be rewritten in terms of $\mathbf{X}\mathbf{X}^T$ as

$$\sum_{j=1}^{k}\sum_{i\in\mathcal{J}_j}\left\|\mathbf{a}_{i:} - \frac{1}{|\mathcal{J}_j|}\sum_{l\in\mathcal{J}_j}\mathbf{a}_{l:}\right\|_2^2 = \sum_{j=1}^{k}\sum_{i\in\mathcal{J}_j}\left\|\mathbf{a}_{i:} - (\mathbf{X}\mathbf{X}^T\mathbf{A})_{i:}\right\|_2^2$$
$$= \sum_{i=1}^{n}\left\|\mathbf{a}_{i:} - (\mathbf{X}\mathbf{X}^T\mathbf{A})_{i:}\right\|_2^2 \;=\; \left\|\mathbf{A} - \mathbf{X}\mathbf{X}^T\mathbf{A}\right\|_F^2.$$

Therefore, the linear k-means clustering problem (1) is equivalent to the optimization problem

$$\operatorname*{argmin}_{\mathbf{X}\in\mathcal{X}_{n,k}} \frac{1}{n}\left\|\mathbf{A} - \mathbf{X}\mathbf{X}^T\mathbf{A}\right\|_F^2. \tag{10}$$

In the remainder of this section, we use this equivalence between k-partitionings of $[n]$ and cluster indicator matrices without comment; e.g., we refer to the outputs of linear k-means clustering algorithms as cluster indicator matrices. Because the linear k-means clustering problem (10) is NP-hard, in practice it is solved by variants of Lloyd's algorithm.

Definition 4 defines an appropriate notion of approximation for linear k-means clustering algorithms. Definition 4 is an equivalent statement of Definition 1.

Definition 4 (γ-Approximate Algorithms) *We call an algorithm $\mathcal{A}_\gamma$ ($\gamma \geq 1$) a γ-approximate linear k-means algorithm if it produces a cluster indicator matrix $\tilde{\mathbf{X}}$ such that*

$$\left\|\mathbf{A} - \tilde{\mathbf{X}}\tilde{\mathbf{X}}^T\mathbf{A}\right\|_F^2 \;\leq\; \gamma\cdot\min_{\mathbf{X}\in\mathcal{X}_{n,k}}\left\|\mathbf{A} - \mathbf{X}\mathbf{X}^T\mathbf{A}\right\|_F^2$$

for any conformal matrix $\mathbf{A}$.

Given this, we now state Lemma 12, which relates projection-cost preservation to linear k-means clustering. Let $\mathbf{A} \in \mathbb{R}^{n\times d}$ be the input matrix and $\mathbf{B} \in \mathbb{R}^{n\times s}$ be a smaller matrix ($s < d$) satisfying the projection-cost preservation property. The projection-cost preserving property ensures that the k-partition obtained by applying linear k-means clustering to the rows of $\mathbf{B}$, instead of $\mathbf{A}$, is a good k-partition for the rows of $\mathbf{A}$. This lemma was established by Cohen et al. (2015). To make this paper self-contained, we provide a proof of Lemma 12 in Appendix E.

Lemma 12 (Projection-Cost Preservation for Linear k-Means) *Fix $\mathbf{A} \in \mathbb{R}^{n\times d}$ and assume $\mathbf{B} \in \mathbb{R}^{n\times s}$ satisfies the rank k projection-cost preservation property in Definition 2 with probability at least $1-\delta$. Let the error parameters $\epsilon_1, \epsilon_2 \in (0,1)$ be as in Definition 2. If $\tilde{\mathbf{X}}_\mathbf{B}$ is the result of applying a γ-approximate linear k-means clustering algorithm to the rows of $\mathbf{B}$, then with probability at least $1-2\delta$,*

$$\left\|\mathbf{A} - \tilde{\mathbf{X}}_\mathbf{B}\tilde{\mathbf{X}}_\mathbf{B}^T\mathbf{A}\right\|_F^2 \;\leq\; \gamma\cdot\tfrac{1+\epsilon_2}{1-\epsilon_1}\cdot\min_{\mathbf{X}\in\mathcal{X}_{n,k}}\left\|\mathbf{A} - \mathbf{X}\mathbf{X}^T\mathbf{A}\right\|_F^2.$$

B.3. Kernel k-Means Clustering

Given input vectors $\mathbf{a}_1, \ldots, \mathbf{a}_n$, the kernel k-means clustering algorithm applies linear k-means clustering to feature vectors $\boldsymbol{\phi}(\mathbf{a}_1), \ldots, \boldsymbol{\phi}(\mathbf{a}_n)$. For convenience, we let $\boldsymbol{\phi}(\mathbf{a}_1)^T, \ldots, \boldsymbol{\phi}(\mathbf{a}_n)^T$ constitute the rows of the matrix $\boldsymbol{\Phi}$. Lemma 13 argues that all the information in $\boldsymbol{\Phi}$ relevant to the kernel k-means clustering problem is present in the kernel matrix $\mathbf{K} = \boldsymbol{\Phi}\boldsymbol{\Phi}^T$. Variants of this lemma are well-known (Schölkopf and Smola, 2002).

Lemma 13 (Kernel Trick for Kernel k-Means) *Let $\boldsymbol{\Phi}$ be a matrix with n rows and let $\mathbf{K} = \boldsymbol{\Phi}\boldsymbol{\Phi}^T \in \mathbb{R}^{n\times n}$. Let $\mathbf{K} = \mathbf{V}\boldsymbol{\Lambda}\mathbf{V}^T$ be the EVD of $\mathbf{K}$. Then for any matrix $\mathbf{X}$ with orthonormal columns,*

$$\left\|\boldsymbol{\Phi} - \mathbf{X}\mathbf{X}^T\boldsymbol{\Phi}\right\|_F^2 \;=\; \left\|(\mathbf{V}\boldsymbol{\Lambda}^{1/2}) - \mathbf{X}\mathbf{X}^T(\mathbf{V}\boldsymbol{\Lambda}^{1/2})\right\|_F^2.$$

Proof Because $\mathbf{X}$ has orthonormal columns, $\mathbf{X}\mathbf{X}^T$ is an orthogonal projection matrix, and $(\mathbf{I}_n - \mathbf{X}\mathbf{X}^T)$ is the orthogonal projection onto the complementary space. It follows that, as claimed,

$$\left\|\boldsymbol{\Phi} - \mathbf{X}\mathbf{X}^T\boldsymbol{\Phi}\right\|_F^2 \;=\; \mathrm{tr}\Big((\boldsymbol{\Phi}^T(\mathbf{I}_n - \mathbf{X}\mathbf{X}^T)\boldsymbol{\Phi}\Big) \;=\; \mathrm{tr}\Big((\mathbf{I}_n - \mathbf{X}\mathbf{X}^T)\mathbf{K}\Big)$$
$$= \mathrm{tr}\Big((\mathbf{I}_n - \mathbf{X}\mathbf{X}^T)\mathbf{V}\boldsymbol{\Lambda}^{1/2}\boldsymbol{\Lambda}^{1/2}\mathbf{V}(\mathbf{I}_n - \mathbf{X}\mathbf{X}^T)\Big) \;=\; \left\|(\mathbf{V}\boldsymbol{\Lambda}^{1/2}) - \mathbf{X}\mathbf{X}^T(\mathbf{V}\boldsymbol{\Lambda}^{1/2})\right\|_F^2.$$

The equalities are justified by, respectively, the definition of the squared Frobenius norm and the idempotence of projections; the cyclicity of the trace and the fact that $\mathbf{K} = \boldsymbol{\Phi}\boldsymbol{\Phi}^T$; the cyclicity of the trace and the EVD of $\mathbf{K}$; and the definition of the squared Frobenius norm. ■

B.4. Completing the Proof of Theorem 2

To complete the proof of Theorem 2, we first establish Lemma 14, and then use it to prove Theorem 15, which is equivalent to Theorem 2. Let $\mathbf{\Phi}$ be a matrix with n rows, and $\mathbf{K} = \mathbf{\Phi}\mathbf{\Phi}^T \in \mathbb{R}^{n\times n}$ be the corresponding kernel matrix.

Lemma 14 *Assume that $\mathbf{B} \in \mathbb{R}^{n\times s}$ satisfies*

$$\mathrm{tr}\big(\mathbf{K} - \mathbf{B}\mathbf{B}^T\big) \;\le\; (1+\epsilon)\big\|\mathbf{K} - \mathbf{K}_s\big\|_* \tag{11}$$

and that there is an orthogonal projection matrix $\mathbf{M}$ such that

$$\mathbf{B}\mathbf{B}^T \;=\; \mathbf{K}^{1/2}\mathbf{M}\mathbf{K}^{1/2}. \tag{12}$$

Use the rows of $\mathbf{B}$ as input to a γ-approximation algorithm (see Definition 4) and let $\tilde{\mathbf{X}}_\mathbf{B}$ be the output cluster indicator matrix (see Definition 3), then

$$\big\|\mathbf{\Phi} - \tilde{\mathbf{X}}_\mathbf{B}\tilde{\mathbf{X}}_\mathbf{B}^T\mathbf{\Phi}\big\|_F^2 \;\le\; \gamma\big(1+\epsilon+\tfrac{k}{s}\big)\cdot \min_{\mathbf{X}\in\mathcal{X}_{n,k}} \big\|\mathbf{\Phi} - \mathbf{X}\mathbf{X}^T\mathbf{\Phi}\big\|_F^2.$$

Proof Because assumptions (11) and (12) are satisfied, Lemma 11 ensures that $\mathbf{B}$ is a rank k projection-cost preserving sketch of $\mathbf{K}$. That is, there exists a constant $\alpha \ge 0$ independent of $\mathbf{\Pi}$ such that

$$\big\|(\mathbf{I}_n - \mathbf{\Pi})\mathbf{K}^{1/2}\big\|_F^2 \;\le\; \big\|(\mathbf{I}_n - \mathbf{\Pi})\mathbf{B}\big\|_F^2 + \alpha \;\le\; \big(1+\epsilon+\tfrac{k}{s}\big)\big\|(\mathbf{I}_n - \mathbf{\Pi})\mathbf{K}^{1/2}\big\|_F^2$$

holds for any rank-k orthogonal projection matrix $\mathbf{\Pi}$. It follows by Lemma 12 that $\tilde{\mathbf{X}}_\mathbf{B}$ gives an almost optimal linear k-means clustering over the rows of $\mathbf{K}^{1/2}$:

$$\big\|\mathbf{K}^{1/2} - \tilde{\mathbf{X}}_\mathbf{B}\tilde{\mathbf{X}}_\mathbf{B}^T\mathbf{K}^{1/2}\big\|_F^2 \;\le\; \gamma\big(1+\epsilon+\tfrac{k}{s}\big)\cdot \min_{\mathbf{X}\in\mathcal{X}_{n,k}} \big\|\mathbf{K}^{1/2} - \mathbf{X}\mathbf{X}^T\mathbf{K}^{1/2}\big\|_F^2.$$

Finally, Lemma 13 states that clustering the rows of $\mathbf{K}^{1/2}$ is equivalent to clustering the rows of $\mathbf{\Phi}$, so we reach the desired conclusion that

$$\big\|\mathbf{\Phi} - \tilde{\mathbf{X}}_\mathbf{B}\tilde{\mathbf{X}}_\mathbf{B}^T\mathbf{\Phi}\big\|_F^2 \;\le\; \gamma\big(1+\epsilon+\tfrac{k}{s}\big)\cdot \min_{\mathbf{X}\in\mathcal{X}_{n,k}} \big\|\mathbf{\Phi} - \mathbf{X}\mathbf{X}^T\mathbf{\Phi}\big\|_F^2.$$

■

Finally, we state and prove Theorem 15. Theorem 15 shows that approximate kernel k-means clustering using the Nyström method exhibits a $1+\epsilon+\frac{k}{s}$ approximation ratio. Observe that Theorem 15 is equivalent to Theorem 2, and thus establishing it also establishes Theorem 2. Recall the Nyström approximation is $\mathbf{K} \approx \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T$, where $\mathbf{C} = \mathbf{K}\mathbf{P}$, $\mathbf{W} = \mathbf{P}^T\mathbf{K}\mathbf{P}$, and $\mathbf{P}$ is a sketching matrix.

Theorem 15 *Choose a sketching sketching matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$ and sketch size c consistent with Table 2. Let $\mathbf{B} \in \mathbb{R}^{n\times s}$ be any matrix satisfying $\mathbf{B}\mathbf{B}^T = (\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s$. Let the cluster indicator matrix $\mathbf{X}_\mathbf{B}$ be the output of any γ-approximate k-means clustering algorithm applied to the rows of $\mathbf{B}$. With probability at least 0.9,*

$$\big\|\mathbf{\Phi} - \mathbf{X}_\mathbf{B}\mathbf{X}_\mathbf{B}^T\mathbf{\Phi}\big\|_F^2 \;\le\; \gamma\big(1+\epsilon+\tfrac{k}{s}\big)\min_{\mathbf{X}\in\mathcal{X}_{n,k}} \big\|\mathbf{\Phi} - \mathbf{X}\mathbf{X}^T\mathbf{\Phi}\big\|_F^2.$$

Proof Theorem 1 shows that (11) holds with probability at least 0.9. Theorem 1 also shows that $\mathbf{B}\mathbf{B}^T = \mathbf{K}^{1/2}\mathbf{Q}\mathbf{Q}^T\mathbf{K}^{1/2}$ where $\mathbf{Q}$ is a $n\times s$ matrix with orthonormal columns, so (12) holds surely. The theorem now follows from Lemma 14. ■

Appendix C. Proof of Theorem 4

Section C.1 analyzes rank-restricted Nystöm with power method. Section C.2 completes the proof of Theorem 4. Here we re-state the algorithm of Theorem 4: first, set any $c \ge s$ and draw a Gaussian projection matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$; second, run the power iteration $\mathbf{P} \longleftarrow \mathbf{K}\mathbf{P}$ for t times; third, orthogonalize $\mathbf{P} \in \mathbb{R}^{n\times c}$ to obtain $\mathbf{U} \in \mathbb{R}^{n\times c}$; fourth, compute $\mathbf{C} = \mathbf{K}\mathbf{U}$ and $\mathbf{W} = \mathbf{U}^T\mathbf{K}\mathbf{U}$; last, find any $\mathbf{B} \in \mathbb{R}^{n\times s}$ satisfying $\mathbf{B}\mathbf{B}^T = (\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s$.

C.1. Rank-Restricted Nyström with Power Method

Theorem 16 analyzes the rank-restricted Nyström with power method. The theorem will be used to prove Theorem 4.

Theorem 16 *Let $\mathbf{K} \in \mathbb{R}^{n\times n}$ be an SPSD matrix, s be the target rank, c ($\ge s$) be arbitrary, and $\epsilon \in (0,1)$ be an approximation parameter. Let $\mathbf{C} \in \mathbb{R}^{n\times c}$ and $\mathbf{W} \in \mathbb{R}^{c\times c}$ be computed by the above algorithm with $t = \mathcal{O}(\frac{\log(n/\epsilon)}{\log(\sigma_s/\sigma_{s+1})})$ power iterations, where σ_i is the i-th singular value of $\mathbf{K}$. If $c = s + \mathcal{O}(\log\frac{1}{\delta})$, then*

$$\big\|\mathbf{K} - (\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T)_s\big\|_* \;\le\; (1+\epsilon)\big\|\mathbf{K} - \mathbf{K}_s\big\|_*$$

with probability at least $1-\delta$. If $c = s$, then this bound holds with a constant probability (that depends on s).

Proof Let $\mathbf{V}_{-s} \in \mathbb{R}^{n\times(n-s)}$ be the orthogonal complement of $\mathbf{V}_s$. Let $\mathbf{P}$ be an $n\times c$ standard Gaussian matrix. Then $\mathbf{V}_{-s}^T\mathbf{P}$ is $(n-s)\times c$ standard Gaussian matrix, and $\mathbf{V}_s^T\mathbf{P}$ is $s\times c$ standard Gaussian matrix.

It is well known that the largest singular value of an $(n-s)\times c$ standard Gaussian matrix is at most $\sqrt{n-s}+\sqrt{c}+\zeta$ with probability $1-\exp(-\zeta^2/2)$. See (Vershynin, 2010).

Consider $c > s$. The least singular value of an $s\times c$ standard Gaussian matrix is at least $\sqrt{c}-\sqrt{s}-\zeta$ with probability $1-\exp(-\zeta^2/2)$. Combining the above results, we have that

$$\frac{\sigma_1^2(\mathbf{V}_{-s}^T\mathbf{P})}{\sigma_s^2(\mathbf{V}_s^T\mathbf{P})} \;\le\; \frac{\sqrt{n-s}+\sqrt{c}+\sqrt{2\log(1/\delta)}}{\sqrt{c}-\sqrt{s}-\sqrt{2\log(1/\delta)}}$$

holds with probability $1-2\delta$.

Consider $c = s$. Rudelson and Vershynin (2008); Tao and Vu (2010) showed that the least singular value of an $s\times s$ standard Gaussian matrix $\mathbf{G}$ satisfy

$$\mathbb{P}\big\{\sigma_s(\mathbf{G}) \le \tfrac{\delta_1}{\sqrt{s}}\big\} \;=\; \delta_1 + \mathcal{O}(s^{-\tau}),$$

where $\tau > 0$ is a constant. It follows that

$$\frac{\sigma_1^2(\mathbf{V}_{-s}^T\mathbf{P})}{\sigma_s^2(\mathbf{V}_s^T\mathbf{P})} \;\le\; \frac{\sqrt{n-s}+\sqrt{s}+\sqrt{2\log(1/\delta_2)}}{\delta_1/\sqrt{s}}$$

holds with probability $1-\delta_1-\delta_2-\mathcal{O}(s^{-\tau})$.

For either $c>s$ or $c=s$, it follows from Lemma 17, which will be proved subsequently, that

$$\begin{aligned}\left\|\mathbf{K}-(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T)_s\right\|_* &\leq \left\|\mathbf{K}-\mathbf{K}_s\right\|_* + \tfrac{\sigma_1^2(\mathbf{V}_{-s}^T\mathbf{P})}{\sigma_s^2(\mathbf{V}_s^T\mathbf{P})}\left(\tfrac{\sigma_{s+1}(\mathbf{K})}{\sigma_s(\mathbf{K})}\right)^{2t}\left\|\mathbf{K}-\mathbf{K}_s\right\|_* \\ &\leq \left\|\mathbf{K}-\mathbf{K}_s\right\|_* + \mathcal{O}(ns)\left(\tfrac{\sigma_{s+1}(\mathbf{K})}{\sigma_s(\mathbf{K})}\right)^{2t}\left\|\mathbf{K}-\mathbf{K}_s\right\|_*\end{aligned}$$

holds with constant probability, by which the theorem follows. ■

Lemma 17 *Let $\mathbf{K}\in\mathbb{R}^{n\times n}$ be any fixed SPSD matrix, s and t be any positive integer, and $\mathbf{V}_s\in\mathbb{R}^{n\times s}$ be the top s singular vectors of $\mathbf{K}$. Let $\mathbf{P}\in\mathbb{R}^{n\times c}$ satisfy that $\mathbf{P}^T\mathbf{V}_s\in\mathbb{R}^{c\times s}$ has full column rank. Let $\mathbf{U}\in\mathbb{R}^{n\times c}$ be the orthonormal bases of $\mathbf{K}^t\mathbf{P}$. Let $\mathbf{C}=\mathbf{K}\mathbf{U}$ and $\mathbf{W}=\mathbf{U}^T\mathbf{K}\mathbf{U}$. Then*

$$\left\|\mathbf{K}-(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T)_s\right\|_* \leq \left\|\mathbf{K}-\mathbf{K}_s\right\|_* + \left(\tfrac{\sigma_{s+1}(\mathbf{K})}{\sigma_s(\mathbf{K})}\right)^{2t}\tfrac{\sigma_1^2(\mathbf{V}_{-s}^T\mathbf{P})}{\sigma_s^2(\mathbf{V}_s^T\mathbf{P})}\left\|\mathbf{K}-\mathbf{K}_s\right\|_*.$$

Here $\mathbf{V}_{-s}\in\mathbb{R}^{n\times(n-s)}$ is the orthogonal complement of $\mathbf{V}_s$.

Proof It follows from Lemma 8 that

$$\begin{aligned}\left\|\mathbf{K}-\left(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T\right)_s\right\|_* &= \min_{\mathrm{rank}(\mathbf{Z})\leq s}\left\|\mathbf{K}^{1/2}-(\mathbf{K}^{1/2}\mathbf{U})\mathbf{Z}\right\|_F^2 \\ &= \min_{\mathrm{rank}(\mathbf{Z})\leq s}\left\|\mathbf{A}-(\mathbf{A}\mathbf{U})\mathbf{Z}\right\|_F^2\end{aligned}$$

where we let $\mathbf{A}=\mathbf{K}^{1/2}$. By definition, $\mathbf{U}$ contains the orthonormal bases of $\mathbf{K}^t\mathbf{P}=\mathbf{A}^{2t}\mathbf{P}$, and thus there exists an $s\times s$ non-singular matrix $\mathbf{R}$ such that $\mathbf{A}^{2t}\mathbf{P}=\mathbf{U}\mathbf{R}$. It follows that

$$\begin{aligned}\left\|\mathbf{K}-\left(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T\right)_s\right\|_* &= \min_{\mathrm{rank}(\mathbf{Z})\leq s}\left\|\mathbf{A}-(\mathbf{A}\mathbf{A}^{2t}\mathbf{P}\mathbf{R}^{-1})\mathbf{Z}\right\|_F^2 \\ &= \min_{\mathrm{rank}(\mathbf{Y})\leq s}\left\|\mathbf{A}-(\mathbf{A}^{2t+1}\mathbf{P})\mathbf{Y}\right\|_F^2,\end{aligned}$$

where the latter equality follows from that the column spaces of $\mathbf{A}^{2t+1}\mathbf{P}$ and $\mathbf{A}^{2t+1}\mathbf{P}\mathbf{R}^{-1}$ are the same. It follows from Lemma 7 that

$$\begin{aligned}&\left\|\mathbf{K}-\left(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T\right)_s\right\|_* = \min_{\mathrm{rank}(\mathbf{Y})\leq s}\left\|\mathbf{A}-(\mathbf{A}^{2t+1}\mathbf{P})\mathbf{Y}\right\|_F^2 \\ &\leq \left\|\mathbf{A}-\mathbf{A}_s\right\|_F^2 + \left(\tfrac{\sigma_{s+1}^2(\mathbf{A})}{\sigma_s^2(\mathbf{A})}\right)^{2t}\left\|(\mathbf{A}-\mathbf{A}_s)\mathbf{P}(\mathbf{V}_s^T\mathbf{P})^{\dagger}\right\|_F^2 \\ &\leq \left\|\mathbf{A}-\mathbf{A}_s\right\|_F^2 + \left(\tfrac{\sigma_{s+1}^2(\mathbf{A})}{\sigma_s^2(\mathbf{A})}\right)^{2t}\left\|\mathbf{A}-\mathbf{A}_s\right\|_F^2\left\|\mathbf{V}_{-s}^T\mathbf{P}\right\|_2^2\left\|(\mathbf{V}_s^T\mathbf{P})^{\dagger}\right\|_2^2,\end{aligned}$$

where we define $\mathbf{V}_{-s}\in\mathbb{R}^{n\times(n-s)}$ as the orthogonal complement of $\mathbf{V}_s$. By our definition $\mathbf{A}=\mathbf{K}^{1/2}$, it follows that

$$\begin{aligned}&\left\|\mathbf{K}-\left(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T\right)_s\right\|_* \\ &\leq \left\|(\mathbf{K}-\mathbf{K}_s)^{1/2}\right\|_F^2 + \left(\tfrac{\sigma_{s+1}(\mathbf{K})}{\sigma_s(\mathbf{K})}\right)^{2t}\tfrac{\sigma_1^2(\mathbf{V}_{-s}^T\mathbf{P})}{\sigma_s^2(\mathbf{V}_s^T\mathbf{P})}\left\|(\mathbf{K}-\mathbf{K}_s)^{1/2}\right\|_F^2 \\ &= \left\|\mathbf{K}-\mathbf{K}_s\right\|_* + \left(\tfrac{\sigma_{s+1}(\mathbf{K})}{\sigma_s(\mathbf{K})}\right)^{2t}\tfrac{\sigma_1^2(\mathbf{V}_{-s}^T\mathbf{P})}{\sigma_s^2(\mathbf{V}_s^T\mathbf{P})}\left\|\mathbf{K}-\mathbf{K}_s\right\|_*,\end{aligned}$$

by which the lemma follows. ■

C.2. Completing the Proof of Theorem 4

Finally, we state and prove Theorem 18. Observe that Theorem 18 is equivalent to Theorem 4, and thus establishing it also establishes Theorem 4.

Theorem 18 *Let c, t, and $\mathbf{B}\in\mathbb{R}^{n\times s}$ be defined in the begining of this section. Set $t=\mathcal{O}(\frac{\log(n/\epsilon)}{\log(\sigma_s/\sigma_{s+1})})$. Let the cluster indicator matrix $\mathbf{X}_\mathbf{B}$ be the output of any γ-approximate k-means clustering algorithm applied to the rows of $\mathbf{B}$. If $c=s+\mathcal{O}(\log\frac{1}{\delta})$, then*

$$\left\|\mathbf{\Phi}-\mathbf{X}_\mathbf{B}\mathbf{X}_\mathbf{B}^T\mathbf{\Phi}\right\|_F^2 \leq \gamma\left(1+\epsilon+\tfrac{k}{s}\right)\min_{\mathbf{X}\in\mathcal{X}_{n,k}}\left\|\mathbf{\Phi}-\mathbf{X}\mathbf{X}^T\mathbf{\Phi}\right\|_F^2$$

holds with probability at least $1-\delta$. If $c=s$, then the above inequality holds with probability $0.9-\mathcal{O}(s^{-\tau})$, where τ is a constant.

Proof Since $\mathbf{B}\mathbf{B}^T=(\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^T)_s$ by definition, Theorem 16 ensures that (11) holds with some constant probability. Theorem 1 shows that $\mathbf{B}\mathbf{B}^T=\mathbf{K}^{1/2}\mathbf{Q}\mathbf{Q}^T\mathbf{K}^{1/2}$ where $\mathbf{Q}$ is a $n\times s$ matrix with orthonormal columns, so (12) holds surely. The theorem now follows from Lemma 14. ■

Appendix D. Proof of Lemma 11

To prove Lemma 11, we first establish a key lemma, Lemma 19. This lemma will make use of the following two assumptions.

Assumption 1 *Assume that $\tilde{\mathbf{A}}_s$ satisfies $\mathrm{tr}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\leq(1+\epsilon)\left\|\mathbf{A}\mathbf{A}^T-\mathbf{A}_s\mathbf{A}_s^T\right\|_*$.*

Assumption 2 *Assume there exists such an orthogonal projection matrix $\mathbf{M}$ that $\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T=\mathbf{A}\mathbf{M}\mathbf{A}^T$.*

Lemma 19 *Let $\mathbf{A}\in\mathbb{R}^{n\times d}$ be any fixed matrix. Fix an error parameter $\epsilon\in(0,1)$. Let the rank s matrix $\tilde{\mathbf{A}}_s$ satisfy Assumptions 1 and 2. Then for any rank k orthogonal projection matrix $\mathbf{\Pi}\in\mathbb{R}^{n\times n}$,*

$$\mathrm{tr}\Big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\Big) \leq \left(\epsilon+\tfrac{k}{s}\right)\left\|\mathbf{A}-\mathbf{\Pi}\mathbf{A}\right\|_F^2.$$

Proof It holds that

$$\begin{aligned}&\mathrm{tr}\Big((\mathbf{I}_n-\mathbf{\Pi})\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\Big) \\ &= \mathrm{tr}\Big(\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)-\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\Big) \\ &= \mathrm{tr}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)-\mathrm{tr}\big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\big) \\ &\leq (1+\epsilon)\left\|\mathbf{A}\mathbf{A}^T-\mathbf{A}_s\mathbf{A}_s^T\right\|_*-\mathrm{tr}\big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\big),\end{aligned}$$

where the inequality follows from Assumption 1. It can be equivalently written as

$$\begin{aligned}&\mathrm{tr}\Big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\Big)\\&\leq\ (1+\epsilon)\big\|\mathbf{A}\mathbf{A}^T-\mathbf{A}_s\mathbf{A}_s^T\big\|_*-\mathrm{tr}\Big((\mathbf{I}_n-\mathbf{\Pi})\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)(\mathbf{I}_n-\mathbf{\Pi})\Big).\end{aligned}$$

Let $\mathbf{M}$ be an orthogonal projection matrix defined in Assumption 2; by this assumption, it holds that $\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T=\mathbf{A}\mathbf{M}\mathbf{A}^T$ and $\mathrm{rank}(\mathbf{M}\mathbf{A})=s$. It follows that

$$\begin{aligned}&\mathrm{tr}\Big((\mathbf{I}_n-\mathbf{\Pi})\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)(\mathbf{I}_n-\mathbf{\Pi})\Big)\ =\ \mathrm{tr}\Big((\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}(\mathbf{I}-\mathbf{M})\mathbf{A}^T(\mathbf{I}_n-\mathbf{\Pi})\Big)\\&=\ \big\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}(\mathbf{I}-\mathbf{M})\big\|_F^2\ =\ \Big\|\mathbf{A}-\underbrace{\mathbf{\Pi}\mathbf{A}}_{\text{rank }k}-\underbrace{(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\mathbf{M}}_{\text{rank }s}\Big\|_F^2\\&\geq\ \min_{\mathrm{rank}(\mathbf{Y})\leq s+k}\big\|\mathbf{A}-\mathbf{Y}\big\|_F^2\ =\ \big\|\mathbf{A}-\mathbf{A}_{s+k}\big\|_F^2,\end{aligned}$$

where the inequality follows from that matrix rank is subadditive function. It follows that

$$\begin{aligned}&\mathrm{tr}\Big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\Big)\\&\leq\ (1+\epsilon)\big\|\mathbf{A}\mathbf{A}^T-\mathbf{A}_s\mathbf{A}_s^T\big\|_*-\big\|\mathbf{A}-\mathbf{A}_{s+k}\big\|_F^2\\&=\ (1+\epsilon)\big\|\mathbf{A}-\mathbf{A}_s\big\|_F^2-\big\|\mathbf{A}-\mathbf{A}_{s+k}\big\|_F^2\\&=\ \epsilon\big\|\mathbf{A}-\mathbf{A}_s\big\|_F^2+\sum_{i=s+1}^{n}\sigma_i^2(\mathbf{A})-\sum_{i=s+k+1}^{n}\sigma_i^2(\mathbf{A})\\&=\ \epsilon\big\|\mathbf{A}-\mathbf{A}_s\big\|_F^2+\sum_{i=s+1}^{s+k}\sigma_i^2(\mathbf{A})\\&\leq\ \epsilon\big\|\mathbf{A}-\mathbf{A}_s\big\|_F^2+\frac{k}{s}\sum_{i=k+1}^{s+k}\sigma_i^2(\mathbf{A}),\end{aligned}$$

where the last inequality follows by the decrease of the singular values. Finally, we obtain that

$$\mathrm{tr}\Big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\Big)\ \leq\ \epsilon\big\|\mathbf{A}-\mathbf{A}_k\big\|_F^2+\tfrac{k}{s}\big\|\mathbf{A}-\mathbf{A}_k\big\|_F^2\ \leq\ \big(\epsilon+\tfrac{k}{s}\big)\big\|\mathbf{A}-\mathbf{\Pi}\mathbf{A}\big\|_F^2,$$

by which the lemma follows. ■

Given Lemma 19, we now provide the proof of Lemma 11.

Proof For any orthogonal projection matrix $\mathbf{M}$, it holds that $\mathbf{M}=\mathbf{M}\mathbf{M}$. It follows that

$$\begin{aligned}&\big\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\big\|_F^2-\big\|(\mathbf{I}_n-\mathbf{\Pi})\tilde{\mathbf{A}}_s\big\|_F^2\ =\ \mathrm{tr}\big((\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\mathbf{A}^T\big)-\mathrm{tr}\big((\mathbf{I}_n-\mathbf{\Pi})\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\\&=\ \mathrm{tr}\big((\mathbf{I}_n-\mathbf{\Pi})(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T)\big)\ =\ \mathrm{tr}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)-\mathrm{tr}\big(\mathbf{\Pi}(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T)\big)\\&=\ \alpha-\mathrm{tr}\big(\mathbf{\Pi}(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T)\big),\end{aligned}$$

where the last equality follows by letting $\alpha=\mathrm{tr}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\geq 0$ which is independent of $\mathbf{\Pi}$. The above equality can be equivalently written as

$$\big\|(\mathbf{I}_n-\mathbf{\Pi})\tilde{\mathbf{A}}_s\big\|_F^2+\alpha\ \ =\ \ \big\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\big\|_F^2+\mathrm{tr}\big(\mathbf{\Pi}(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T)\mathbf{\Pi}\big).\tag{13}$$

Under Assumption 2 that $\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\preceq\mathbf{A}\mathbf{A}^T$, it follows from (13) that

$$\begin{aligned}&\big\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\big\|_F^2\\&\leq\ \big\|(\mathbf{I}_n-\mathbf{\Pi})\tilde{\mathbf{A}}_s\big\|_F^2+\alpha\\&=\ \big\|(\mathbf{I}_n-\mathbf{\Pi})\mathbf{A}\big\|_F^2+\mathrm{tr}\big(\mathbf{\Pi}(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T)\mathbf{\Pi}\big).\end{aligned}$$

Under Assumptions 1 and 2, we can apply Lemma 19 to bound the right-hand side:

$$\mathrm{tr}\Big(\mathbf{\Pi}\big(\mathbf{A}\mathbf{A}^T-\tilde{\mathbf{A}}_s\tilde{\mathbf{A}}_s^T\big)\mathbf{\Pi}\Big)\ \leq\ \big(\epsilon+\tfrac{k}{s}\big)\big\|\mathbf{A}-\mathbf{\Pi}\mathbf{A}\big\|_F^2,$$

by which the lemma follows. ■

Appendix E. Proof of Lemma 12

Because $\mathbf{B}$ enjoys the projection-cost preservation property, there exists a constant $\alpha\geq 0$ such that for any rank k orthogonal projection matrices $\mathbf{\Pi}_1$ and $\mathbf{\Pi}_2$, the two inequalities

$$(1-\epsilon_1)\big\|\mathbf{A}-\mathbf{\Pi}_1\mathbf{A}\big\|_F^2\ \leq\ \big\|\mathbf{B}-\mathbf{\Pi}_1\mathbf{B}\big\|_F^2+\alpha,\tag{14}$$

$$\big\|\mathbf{B}-\mathbf{\Pi}_2\mathbf{B}\big\|_F^2+\alpha\ \leq\ (1+\epsilon_2)\big\|\mathbf{A}-\mathbf{\Pi}_2\mathbf{A}\big\|_F^2\tag{15}$$

hold simultaneously with probability at least $1-2\delta$. Let $\mathbf{\Pi}_1=\tilde{\mathbf{X}}_{\mathbf{B}}\tilde{\mathbf{X}}_{\mathbf{B}}^T$ and $\mathbf{X}_{\mathbf{A}}^\star=\mathrm{argmin}_{\mathbf{X}\in\mathcal{X}_{n,k}}\|\mathbf{A}-\mathbf{X}\mathbf{X}^T\mathbf{A}\|_F^2$. It follows from (14) and the definition of γ-approximate k-means algorithm that

$$\begin{aligned}&(1-\epsilon_1)\big\|\mathbf{A}-\tilde{\mathbf{X}}_{\mathbf{B}}\tilde{\mathbf{X}}_{\mathbf{B}}^T\mathbf{A}\big\|_F^2\ \leq\ \big\|\mathbf{B}-\tilde{\mathbf{X}}_{\mathbf{B}}\tilde{\mathbf{X}}_{\mathbf{B}}^T\mathbf{B}\big\|_F^2+\alpha\\&\leq\ \gamma\cdot\min_{\mathbf{X}\in\mathcal{X}_{n,k}}\big\|\mathbf{B}-\mathbf{X}\mathbf{X}^T\mathbf{B}\big\|_F^2+\alpha\ \leq\ \gamma\big\|\mathbf{B}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{B}\big\|_F^2+\alpha.\end{aligned}$$

Let $\mathbf{\Pi}_2=\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T$. It follows from (15) that

$$\big\|\mathbf{B}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{B}\big\|_F^2+\alpha\ \leq\ (1+\epsilon_2)\big\|\mathbf{A}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{A}\big\|_F^2.$$

Combining the above results, we have that

$$\begin{aligned}&(1-\epsilon_1)\big\|\mathbf{A}-\tilde{\mathbf{X}}_{\mathbf{B}}\tilde{\mathbf{X}}_{\mathbf{B}}^T\mathbf{A}\big\|_F^2\ \leq\ \gamma\big\|\mathbf{B}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{B}\big\|_F^2+\alpha\\&\leq\ \gamma\big(\big\|\mathbf{B}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{B}\big\|_F^2+\alpha\big)\ \leq\ \gamma(1+\epsilon_2)\big\|\mathbf{A}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{A}\big\|_F^2,\end{aligned}$$

where the second inequality follows from that $\gamma\geq 1$ and $\alpha\geq 0$. It follows that

$$\big\|\mathbf{A}-\tilde{\mathbf{X}}_{\mathbf{B}}\tilde{\mathbf{X}}_{\mathbf{B}}^T\mathbf{A}\big\|_F^2\ \leq\ \gamma\tfrac{1+\epsilon_2}{1-\epsilon_1}\big\|\mathbf{A}-\mathbf{X}_{\mathbf{A}}^\star{\mathbf{X}_{\mathbf{A}}^\star}^T\mathbf{A}\big\|_F^2\ =\ \gamma\tfrac{1+\epsilon_2}{1-\epsilon_1}\min_{\mathbf{X}\in\mathcal{X}_{n,k}}\big\|\mathbf{A}-\mathbf{X}\mathbf{X}^T\mathbf{A}\big\|_F^2$$

This concludes our proof.

Abstract

Structured prediction is used in areas including computer vision and natural language processing to predict structured outputs such as segmentations or parse trees. In these settings, prediction is performed by MAP inference or, equivalently, by solving an integer linear program. Because of the complex scoring functions required to obtain accurate predictions, both learning and inference typically require the use of approximate solvers. We propose a theoretical explanation for the striking observation that approximations based on linear programming (LP) relaxations are often tight (exact) on real-world instances. In particular, we show that learning with LP relaxed inference encourages integrality of training instances, and that this training tightness generalizes to test data.

1. Introduction

Many applications of machine learning can be formulated as prediction problems over structured output spaces (Bakir et al., 2007; Nowozin et al., 2014). In such problems output variables are predicted *jointly* in order to take into account mutual dependencies between them, such as high-order correlations or structural constraints (e.g., matchings or spanning trees). Unfortunately, the improved expressive power of these models comes at a computational cost, and indeed, exact prediction and learning become NP-hard in general. Despite this worst-case intractability, efficient approximations often achieve very good performance in practice. In particular, one type of approximation which has proved effective in many applications is based on *linear programming (LP) relaxation*. In this approach the prediction problem is first cast as an integer LP (ILP), and then the integrality constraints are relaxed to obtain a tractable program. In addition to achieving high prediction accuracy, it has been observed that LP relaxations are often *tight* in practice. That is, the solution to the relaxed program happens to be optimal for the original hard problem (i.e., an *integral* solution is found). This is particularly surprising since the LPs have complex scoring functions that are not constrained to be from any tractable family. It has been an interesting open question to understand why these real-world instances behave so differently from the theoretical worst case.

This paper addresses this question and aims to provide a theoretical explanation for the frequent tightness of LP relaxations in the context of structured prediction. In particular, we show that an *approximate* training objective, although designed to produce accurate predictors, also induces tightness of the LP relaxation as a byproduct. Interestingly, our analysis also suggests that exact training may have the opposite effect. To explain tightness on future (i.e., test) instances, we prove several generalization bounds relating average tightness on the training data to expected tightness with respect to the generating distribution. Our bounds imply that if many predictions on training instances are tight, then predictions on test instances are also likely to be tight. Moreover, if predictions on training instances are *close to* integral solutions (in terms of L1 distance), then predictions on test instances will likely be similarly close to integral solutions. Our results help to understand previous empirical findings, and to our knowledge provide the first theoretical justification for the widespread success of LP relaxations for structured prediction in settings where the training data is not (algorithmically) separable.

2. Background

In this section we review the formulation of the structured prediction problem, its LP relaxation, and the associated learning problem. Consider a prediction task where the goal is to map a real-valued input vector x to a discrete output vector $y = (y_1, \ldots, y_n)$. In this work we focus on a simple class of models based on linear classifiers.[1] Particularly, in this setting prediction is performed via a linear discriminant rule: $y(x; w) = \arg\max_{y'} w^\top \phi(x, y')$, where $\phi(x, y) \in \mathbb{R}^d$ is a function mapping input-output pairs to feature vectors, and $w \in \mathbb{R}^d$ is the corresponding weight vector. Since the output space is often huge (exponential in n), it will generally be intractable to maximize over all possible outputs.

In many applications the score function has a particular structure. Specifically, we will assume that the score decomposes as a sum of simpler score functions: $w^\top \phi(x, y) = \sum_c w_c^\top \phi_c(x, y_c)$, where y_c is an assignment to a (non-exclusive) subset of the variables. For example, it is common to use such a decomposition that assigns scores to single and pairs of output variables corresponding to nodes and edges of a graph G: $w^\top \phi(x, y) = \sum_{i \in V(G)} w_i^\top \phi_i(x, y_i) + \sum_{ij \in E(G)} w_{ij}^\top \phi_{ij}(x, y_i, y_j)$. Viewing this as a function of y, we can write the prediction problem as:

$$\max_y \sum_c \theta_c(y_c; x, w) \ , \tag{1}$$

where $\theta_c(y_c; x, w) = w_c^\top \phi_c(x, y_c)$ (we will sometimes omit the dependence on x and w in the sequel).

Due to its combinatorial nature, the prediction problem is generally NP-hard, but fortunately, efficient approximations have been proposed. Here we will be particularly interested in approximations based on LP relaxations. We begin by formulating prediction

1. Most of our results also hold more generally for non-linear models (e.g., deep neural factors).

as the following ILP:[2]

$$\max_{\substack{\mu\in\mathcal{M}_L\\ \mu\in\{0,1\}^q}} \sum_c \sum_{y_c} \mu_c(y_c)\theta_c(y_c) + \sum_i \sum_{y_i} \mu_i(y_i)\theta_i(y_i) \quad = \theta^\top \mu \ , \tag{2}$$

$$\text{where } \mathcal{M}_L = \left\{ \mu \geq 0 : \begin{array}{ll} \sum_{y_{c\setminus i}} \mu_c(y_c) = \mu_i(y_i) & \forall c, i \in c, y_i \\ \sum_{y_i} \mu_i(y_i) = 1 & \forall i \end{array} \right\}.$$

Here, $\mu_c(y_c)$ is an indicator variable for a factor c and local assignment y_c, and q is the total number of factor assignments (dimension of μ). The set $\mathcal{M}_L$ is known as the local marginal polytope (Wainwright and Jordan, 2008), and $\sum_{y_{c\setminus i}} \mu_c(y_c)$ is the marginalization of μ_c w.r.t. variable i. First, notice that there is a one-to-one correspondence between feasible μ's and assignments y's, which is obtained by setting μ to indicators over local assignments (y_c and y_i) consistent with y. Second, while solving ILPs is NP-hard in general, it is easy to obtain a tractable program by relaxing the integrality constraints ($\mu \in \{0,1\}^q$), which may introduce fractional solutions to the LP. This relaxation, sometimes called the *basic linear programming relaxation* (Thapper and Živný, 2012), is the first level of the Sherali-Adams hierarchy (Sherali and Adams, 1990). This hierarchy provides successively tighter LP relaxations of an ILP. Notice that since the relaxed program is obtained by removing constraints from the original problem, its optimal value upper bounds the ILP optimum. Finally, we note that most of our results below also hold for cases where more complex constraints than those in Eq. (2) are used. For example, some assignments may be forbidden since they do not correspond to feasible global structures such as spanning trees (e.g., Martins et al., 2009b; Koo et al., 2010).

In order to achieve high prediction accuracy, the parameters w are learned from training data. In this supervised learning setting, the model is fit to labeled examples $\{(x^{(m)}, y^{(m)})\}_{m=1}^M$, where the goodness of fit is measured by a task-specific loss $\Delta(y(x^{(m)}; w), y^{(m)})$. We assume that $\Delta(y, y') \geq 0$ for all y, y', and that $\Delta(y, y) = 0$. For example, a commonly used task-loss is the Hamming distance: $\Delta_{\text{Hamming}}(y, y') = \frac{1}{n}\sum_i \mathbb{1}[y_i \neq y'_i]$.

In the *structured SVM* (SSVM) framework (Taskar et al., 2003; Tsochantaridis et al., 2004), the empirical risk is upper bounded by a convex surrogate called the structured hinge loss, which yields the training objective:

$$\min_w \ \sum_m \max_y \left[w^\top \Big(\phi(x^{(m)}, y) - \phi(x^{(m)}, y^{(m)}) \Big) + \Delta(y, y^{(m)}) \right] \ . \tag{3}$$

For brevity, we have omitted the standard regularization term from Eq. (3), however, all of our results below in sections 4—6 still hold with regularization.[3] The objective in Eq. (3) is a convex function of w and hence can be optimized in various ways. But, notice that the objective includes a maximization over outputs y for each training example. This loss-augmented prediction task needs to be solved repeatedly during training (e.g., to evaluate subgradients), which makes training intractable in general (see also Sontag et al., 2010). Similar to prediction, LP relaxation can be applied to the structured loss (Taskar et al., 2003; Kulesza and Pereira, 2007), which yields the relaxed training objective:

$$\min_w \ \sum_m \max_{\mu\in\mathcal{M}_L} \left[\theta_m^\top(\mu - \mu_m) + {\ell_m}^\top \mu \right] \ , \tag{4}$$

where $\theta_m \in \mathbb{R}^q$ is a score vector in which each entry represents $w_c^\top \phi_c(x^{(m)}, y_c)$ for some c and y_c, and μ_m is the integral vector corresponding to $y^{(m)}$. Assuming that the task-loss decomposes as the model score, $\Delta(y, y') = \sum_c \Delta_c(y_c, y'_c)$, we define the vector $\ell_m \in \mathbb{R}^q$ with entries $\ell_{m,c,y_c} = \Delta_c(y_c^{(m)}, y_c)$ for each value y_c. Notice that ℓ has the same dimension as μ, and we can define $\Delta(y^{(m)}, y) = \sum_c \sum_{y'_c} \Delta_c(y_c^{(m)}, y'_c)\mu_c(y'_c) = {\ell_m}^\top \mu$, where μ is the vector of indicators corresponding to y (i.e., $\mu_c(y'_c) = \mathbb{1}\{y'_c = y_c\}$). With this definition, ℓ generalizes Δ to any $\mu \in \mathcal{M}_L$.

After reviewing related work in Section 3, we propose a theoretical justification for the observed tightness of LP relaxations for structured prediction. To this end, we make two complementary arguments: in Section 4 we argue that optimizing the relaxed training objective of Eq. (4) also has the effect of encouraging tightness of training instances; then, in sections 5 and 6 we show that tightness generalizes from train to test data.

3. Related Work

Many structured prediction problems can be expressed as ILPs (Roth and Yih, 2005; Martins et al., 2009a; Rush et al., 2010). Despite being NP-hard in general (Roth, 1996; Shimony, 1994), various effective approximations have been proposed. These approximations include search-based methods (Daumé III et al., 2009; Zhang et al., 2014) and natural LP relaxations to the hard ILPs (Schlesinger, 1976; Koster et al., 1998; Chekuri et al., 2004; Wainwright et al., 2005). Tightness of LP relaxations for special classes of problems has been studied extensively in recent years and has been demonstrated by restricting either the structure of the model or its score function. For example, the pairwise LP relaxation is known to be tight for tree-structured models or for supermodular scores (see, e.g., Wainwright and Jordan, 2008; Thapper and Živný, 2012); certain stability conditions guarantee tightness of LP relaxations for Ferromagnetic Potts models (Lang et al., 2018); and the cycle relaxation (for binary pairwise models) is known to be tight both for planar Ising models with no external field (Barahona, 1993) and for almost balanced models (Weller et al., 2016). Hybrid conditions, combining structure and score, by forbidding signed minors have recently been shown to also guarantee tight relaxations (Rowland et al., 2017; Weller, 2016). To facilitate efficient prediction, one could restrict the model class to be tractable. For example, Taskar et al. (2004) learn supermodular scores, and Meshi et al. (2013) learn tree structures.

However, the sufficient conditions mentioned above are by no means necessary, and indeed, many score functions that are useful in practice do not satisfy them but still produce integral solutions (Roth and Yih, 2004; Lacoste-Julien et al., 2006; Sontag et al., 2008; Finley and Joachims, 2008; Martins et al., 2009b; Koo et al., 2010). For example, Martins et al. (2009b) showed that predictors that are learned with LP relaxations yield tight LPs for 92.88% of the test data on a dependency parsing problem (see Table 2 therein). Koo et al. (2010) observed similar behavior for dependency parsing on a number of languages, as can

2. For convenience we introduce singleton factors θ_i, which could be set to 0 if needed.
3. In particular, our bounds apply to the maximization over y in Eq. (3), so still hold when regularization w.r.t. w is added.

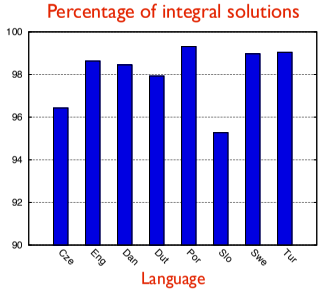

Figure 1: Percentage of integral solutions for dependency parsing from Koo et al. (2010).

be seen in Fig. 1.[4] Lacoste-Julien et al. (2006) found that about 80% of test instances had tight LP relaxations in a quadratic assignment formulation for word alignment, with only 0.2% fractional values overall. The same phenomenon has been observed for a multi-label classification task, where test integrality reached 100% (Finley and Joachims, 2008, Table 3).

Learning structured output predictors from labeled data was proposed in various forms by Collins (2002); Taskar et al. (2003); Tsochantaridis et al. (2004). These formulations generalize training methods for binary classifiers, such as the Perceptron algorithm and support vector machines (SVMs), to the case of structured outputs. The learning algorithms repeatedly perform prediction, necessitating the use of approximate inference within training as well as at test time. A common approach, introduced right at the inception of structured SVMs by Taskar et al. (2003), is to use LP relaxations for this purpose.

The closest work to ours is by Kulesza and Pereira (2007), which showed that not all approximations are equally good, and that it is important to match the inference algorithms used at train and test time. The authors defined the concept of *algorithmic separability* which refers to the case where an approximate inference algorithm achieves zero loss on a data set. The authors studied the use of LP relaxations for structured learning, giving generalization bounds for the true risk of LP-based prediction. However, since the generalization bounds in Kulesza and Pereira (2007) are focused on prediction *accuracy*, the only settings in which tightness on test instances can be guaranteed are when the training data is algorithmically separable, which is seldom the case in real-world structured prediction tasks (the models are far from perfect). In contrast, our paper's main result (Theorem 1), guarantees that the expected fraction of test instances for which an LP relaxation is tight is close to that which was achieved on training data. This then allows us to talk about the generalization of *computation*. For example, suppose one uses LP relaxation-based algorithms that iteratively tighten the relaxation, such as Sontag and Jaakkola (2008); Sontag et al. (2008), and observes that 20% of the instances in the training data are integral using the basic relaxation and that after tightening the remaining 80% are now integral too. Our generalization bound then guarantees that approximately the same ratio will hold at test time (assuming sufficient training data).

4. Kindly provided by the authors.

Finley and Joachims (2008) also studied the effect of various approximate inference methods in the context of structured prediction. Their theoretical and empirical results support the superiority of LP relaxations in this setting. Martins et al. (2009b) established conditions which guarantee algorithmic separability for LP relaxed training, and derived risk bounds for a learning algorithm which uses a combination of exact and relaxed inference.

Finally, Globerson et al. (2015) recently studied the performance of structured predictors for 2D grid graphs with binary labels from an information-theoretic perspective. They proved lower bounds on the minimum achievable expected Hamming error in this setting, and proposed a polynomial-time algorithm that achieves this error. Our work is different since we focus on LP relaxations as an approximation algorithm, we handle a general form of the problem without making any assumptions on the model or error measure (except score decomposition), and we concentrate solely on the computational aspects while ignoring any accuracy concerns.

4. Tightness at Training

In this section we show that the *relaxed* training objective in Eq. (4), although designed to achieve high accuracy, also induces tightness of the underlying LP relaxation. In fact, although we focus here on the basic LP relaxation (first-level), the results below hold for higher-level LP relaxations as well.[5]

In order to simplify notation we focus on a single training instance and drop the index m. Denote the solutions to the relaxed and integer LPs as:

$$\mu_L \in \arg\max_{\mu \in \mathcal{M}_L} \theta^\top \mu \qquad \mu_I \in \arg\max_{\substack{\mu \in \mathcal{M}_L \\ \mu \in \{0,1\}^q}} \theta^\top \mu \ , \tag{5}$$

respectively. Also, let μ_T be the integral vector corresponding to the ground-truth output $y^{(m)}$. Now consider the following decomposition:

$$\underset{\text{relaxed-hinge}}{\theta^\top(\mu_L - \mu_T)} = \underset{\text{integrality gap}}{\theta^\top(\mu_L - \mu_I)} + \underset{\text{exact-hinge}}{\theta^\top(\mu_I - \mu_T)} \tag{6}$$

This equality states that the difference in scores between the relaxed optimum and ground-truth (*relaxed-hinge*) can be written as a sum of the *integrality gap* and the difference in scores between the exact optimum and the ground-truth (*exact-hinge*); notice that all three terms are non-negative. This simple decomposition has several interesting implications.

First, we can immediately derive the following bound on the integrality gap:

$$\begin{aligned} \theta^\top(\mu_L - \mu_I) &= \theta^\top(\mu_L - \mu_T) - \theta^\top(\mu_I - \mu_T) && (7)\\ &\leq \theta^\top(\mu_L - \mu_T) && (8)\\ &\leq \theta^\top(\mu_L - \mu_T) + \ell^\top \mu_L && (9)\\ &\leq \max_{\mu \in \mathcal{M}_L} \left(\theta^\top(\mu - \mu_T) + \ell^\top \mu\right), && (10) \end{aligned}$$

where Eq. (10) is precisely the relaxed training objective from Eq. (4). Therefore, optimizing the approximate training objective of Eq. (4) minimizes an upper bound on the integrality

5. Similar analysis for SDP and quadratic relaxations is left as future work—see recent work by Lê-Huu and Paragios (2018).

gap. Hence, driving down the approximate objective may also reduce the integrality gap of training instances, although in Section 4.1 we also study cases where loose bounds can lead to non-zero integrality gap. One case where the integrality gap becomes zero is when the data is algorithmically separable (i.e., $\mu_L = \mu_T$, so Eq. (8) equals 0). In this case the relaxed-hinge term vanishes (the exact-hinge must also vanish), and training integrality is assured.

Second, Eq. (6) holds for *any integral* μ, and not just the ground-truth μ_T. In other words, the only property of μ_T used here is its integrality. Indeed, in Section 7 we verify empirically that training a model using *random labels* still attains the same level of tightness as training with the ground-truth labels.[6] On the other hand, accuracy drops drastically, as expected. This analysis suggests that *tightness is not coupled with accuracy* of the predictor. Finley and Joachims (2008) explained tightness of LP relaxations by noting that fractional solutions always incur a loss during training. Our analysis suggests an alternative explanation, emphasizing the difference in scores (Eq. (7)) rather than the loss, and decoupling tightness from accuracy.

Third, the results above still hold in the presence of global constraints. Often such constraints can be expressed as linear inequalities, so in this case the local polytope $\mathcal{M}_L$ can be redefined by adding these constraints to those in Eq. (2) to form a tighter polytope. In particular, Eq. (8) holds since μ_T satisfies the global constraints.

Finally, we do not make any assumption here about the form of the model scores θ. Therefore, these results apply more generally, even when factor scores are obtained from non-linear functions of the inputs, such as deep neural networks (e.g., Chen et al., 2015).

4.1. When Relaxed Training is Better than Exact Training

Unfortunately, the bound in Eq. (10) might sometimes be loose. Indeed, to get the bound we have discarded the exact-hinge term (Eq. (8)), added the task-loss (Eq. (9)), and maximized the loss-augmented objective (Eq. (10)). At the same time, Eq. (7) provides a precise characterization of the integrality gap. Specifically, the gap is determined by the difference between the relaxed-hinge and the exact-hinge terms. This implies that even when the relaxed-hinge is not zero, a small integrality gap can still be attained if the exact-hinge is also large. In fact, the *only way* to get a large integrality gap is by setting the exact-hinge much smaller than the relaxed-hinge. But when can this happen? As we now show, it is less likely to happen when training with relaxed inference than when training with exact inference.

A key point is that the relaxed and exact hinge terms are upper bounded by the relaxed and exact *training objectives* respectively (the latter additionally depend on the task loss Δ). Therefore, minimizing the training objective will also likely reduce the corresponding hinge term (this is also demonstrated empirically in Section 7). Using this insight, we observe that relaxed training reduces the relaxed-hinge term without directly reducing the exact-hinge term, and thereby induces a small integrality gap. On the other hand, this also suggests that *exact training may actually increase the integrality gap*, since it reduces the exact-hinge without also reducing directly the relaxed-hinge term. This finding is consistent with previous empirical evidence. Specifically, Martins et al. (2009b, Table 2) showed that on

6. This is not true for random models (w), which often yield loose relaxations.

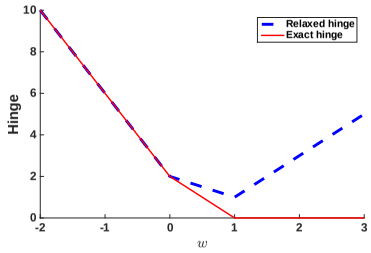

Figure 2: Exact- and relaxed- hinge (see Eq. (6)) as a function of w for the learning scenario in Section 4.1.

a dependency parsing problem, training with the relaxed objective achieved 92.9% integral solutions, while exact training achieved only 83.5% integral solutions. An even stronger effect was observed by Finley and Joachims (2008, Table 3) for multi-label classification, where relaxed training resulted in 99.6% integral instances, with exact training attaining only 17.7% ('Yeast' dataset).

In Section 7 we provide further empirical support for our explanation, however, we next show its possible limitation by providing a counter-example. The counter-example demonstrates that despite training with a relaxed objective, the exact-hinge can in some cases actually be *substantially smaller* than the relaxed-hinge, leading to a loose relaxation. Although this illustrates the limitations of the explanation above, we point out that the corresponding learning task is far from natural.

We construct a learning scenario where relaxed training obtains zero exact-hinge and non-zero relaxed-hinge, so the relaxation is not tight. Consider a model where $x \in \mathbb{R}^3$, $y \in \{0,1\}^3$, and the prediction is given by:

$$y(x;w) = \arg\max_y \Big(x_1 y_1 + x_2 y_2 + x_3 y_3 + w\left[\mathbb{1}\{y_1 \neq y_2\} + \mathbb{1}\{y_1 \neq y_3\} + \mathbb{1}\{y_2 \neq y_3\}\right] \Big). \tag{11}$$

The corresponding LP relaxation is then:

$$\max_{\mu \in \mathcal{M}_L} \Big(x_1\mu_1(1) + x_2\mu_2(1) + x_3\mu_3(1) + w\left[\mu_{12}(01) + \mu_{12}(10) + \mu_{13}(01) + \mu_{13}(10) + \mu_{23}(01) + \mu_{23}(10)\right] \Big). \tag{12}$$

Next, we construct a training set where the first instance is: $x^{(1)} = (2,2,2), y^{(1)} = (1,1,0)$, and the second is: $x^{(2)} = (0,0,0), y^{(2)} = (1,1,0)$. Fig. 2 shows the relaxed and exact losses as a function of w, obtained by plugging Eq. (11) and Eq. (12) in Eq. (3) and Eq. (4), respectively.[7] Observe that $w = 1$ minimizes the relaxed objective (Eq. (4)). However, with this weight vector the relaxed-hinge for the second instance $(x^{(2)}, y^{(2)})$ is equal to 1, while the exact-hinge for this instance is 0 (the data is separable with $w = 1$). Consequently, there is an integrality gap of 1 for the second instance, and the relaxation is loose (the first

7. For simplicity we use $\ell = 0$ in this example, but a similar result holds with $\ell = 1/2 \cdot \ell_{\text{Hamming}}$.

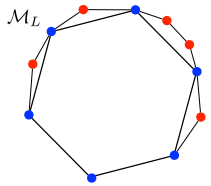

Figure 3: Illustration of the local marginal polytope $\mathcal{M}_L$, with its vertices partitioned into integral vertices $\mathcal{V}_I$ (blue), and fractional vertices $\mathcal{V}_F$ (red).

instance is actually tight). Notice that in this data the same output corresponds to two very different inputs.

5. Generalization of Tightness

Our argument in Section 4 concerns only the tightness of train instances. However, the empirical evidence discussed above pertains to test data. To bridge this gap, in this section we prove a generalization bound which shows that train tightness implies test tightness.

We first define a loss function which measures the lack of integrality (or, fractionality) of the LP solution for a given instance. To this end, we consider the discrete set of *vertices* of the local polytope $\mathcal{M}_L$ (excluding its convex hull), denoting by $\mathcal{V}_I$ and $\mathcal{V}_F$ the sets of fully-integral and non-integral (i.e., fractional) vertices,[8] respectively (so $\mathcal{V}_I \cap \mathcal{V}_F = \emptyset$, and $\mathcal{V}_I \cup \mathcal{V}_F$ consists of all vertices of $\mathcal{M}_L$);[9] see Fig. 3. Considering only vertices does not reduce generality, since the solution to a linear program is always at a vertex.

Next, let

$$I^*(w,x) \triangleq \max_{\mu \in \mathcal{V}_I} \theta(x;w)^\top \mu \qquad \text{and} \qquad F^*(w,x) \triangleq \max_{\mu \in \mathcal{V}_F} \theta(x;w)^\top \mu \tag{13}$$

denote the respective best integral and fractional scores. By convention, we set $F^*(w,x) \triangleq -\infty$ whenever $\mathcal{V}_F = \emptyset$. The fractionality of inference with (w,x) can be measured by the quantity

$$D(w,x) \triangleq F^*(w,x) - I^*(w,x). \tag{14}$$

Observe that $D(w,x) > 0$ whenever the LP has a fractional solution that is better than the integral solution. We can now define the *integrality loss*,

$$\mathcal{L}_0(w,x) \triangleq \begin{cases} 1 & D(w,x) > 0 \\ 0 & \text{otherwise} \end{cases}. \tag{15}$$

8. It is enough that one coordinate is fractional to belong to $\mathcal{V}_F$.
9. We assume that all feasible integral solutions are vertices of $\mathcal{M}_L$, which is the case for the type of relaxations considered here (see Wainwright and Jordan, 2008).

This loss function equals 1 if and only if the optimal fractional solution has a (strictly) higher score than the optimal integral solution. The loss will be 0 whenever the non-integral and integral optima are equal—that is, for our purpose we consider the relaxation to be tight in this case. The expected integrality loss measures the probability of obtaining a fractional LP solution (over draws of an input, x). Note that this loss ignores the ground truth assignment.

To support our generalization analysis, we define a related loss function, which we call the *integrality ramp loss*. For a predetermined margin parameter, γ, the integrality ramp loss is given by

$$\mathcal{L}_\gamma(w,x) \triangleq \begin{cases} 1 & D(w,x) > 0 \\ 1 + D(w,x)/\gamma & -\gamma < D(w,x) \leq 0 \\ 0 & D(w,x) \leq -\gamma \end{cases}. \tag{16}$$

Importantly, the integrality ramp loss upper-bounds the integrality loss. For the ramp loss to be zero, the best integral solution has to be better than the best fractional solution by a margin of at least γ, which is a stronger requirement than mere tightness. In Appendix A we give examples of models that are guaranteed to satisfy this requirement, and in Section 7 we also show this often happens in practice.

We point out that both $\mathcal{L}_0(w,x)$ and $\mathcal{L}_\gamma(w,x)$ are generally hard to compute, a point which we address in Section 6. For the time being, we are only interested in proving that tightness is a generalizing property, so we will not worry about computational efficiency.

We are now ready to state the main theorem of this section, a generalization bound for tightness. Our proof (deferred to Appendix B.1) uses a PAC-Bayesian analysis, similar to London et al. (2016), though the main result is stated for a deterministic predictor.

Theorem 1. *Let $\mathbb{D}$ denote a distribution over $\mathcal{X}$. Let $\phi : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$ denote a feature mapping such that $\sup_{x,y} \|\phi(x,y)\|_2 \leq B < \infty$. Then, for any $\gamma > 0$, $\delta \in (0,1)$ and $m \geq 1$, with probability at least $1-\delta$ over draws of $(x^{(1)}, \ldots, x^{(m)}) \in \mathcal{X}^m$, according to $\mathbb{D}^m$, every weight vector, w, with $\|w\|_2 \leq R < \infty$, satisfies*

$$\mathop{\mathbb{E}}_{x \sim \mathbb{D}}[\mathcal{L}_0(w,x)] \leq \frac{1}{m} \sum_{i=1}^{m} \mathcal{L}_\gamma(w, x^{(i)}) + \frac{8}{m} + 2\sqrt{\frac{d \ln(mBR/\gamma) + \ln \frac{2}{\delta}}{2m}}. \tag{17}$$

Theorem 1 shows that if we observe high integrality (equivalently, low fractionality) on a finite sample of training data, then it is likely that integrality of test data will not be much lower, provided sufficient number of samples. It is worth noting that, though we focus on linear models to simplify our presentation, it is possible to extend this result to accommodate non-linear models (e.g., scores θ computed by a deep neural network), provided some assumptions are made on the smoothness of the model and loss.

As the following corollary states, Theorem 1 actually applies more generally to any two disjoint sets of vertices, and is not limited to $\mathcal{V}_I$ and $\mathcal{V}_F$.

Corollary 1. *Let $\mathcal{V}_\alpha$ be any set of vertices of $\mathcal{M}_L$ with at most α fractional values (where $0 \leq \alpha \leq 1$), and let $\bar{\mathcal{V}}_\alpha$ be the rest of the vertices of $\mathcal{M}_L$. Then Theorem 1 holds with $\mathcal{V}_\alpha$ and $\bar{\mathcal{V}}_\alpha$ replacing $\mathcal{V}_I$ and $\mathcal{V}_F$ in the definition of I^* and F^* in Eq. (13), respectively.*

For example, we can set $\mathcal{V}_\alpha$ to be any set of vertices with at most 10% fractional values, and $\bar{\mathcal{V}}_\alpha$ to be the rest of the vertices of $\mathcal{M}_L$. This gives a different meaning to the integrality loss, but the rest of our analysis holds unchanged. Consequently, our generalization result implies that it is likely to observe a similar portion of instances with at most 10% fractional values at test time as we did at training.

Moreover, Theorem 1 also holds in the presence of global constraints (e.g., spanning tree constraints). As mentioned in Section 4, the polytope $\mathcal{M}_L$ is replaced by its intersection with the global constraints polytope, but the rest of our derivation remains unchanged.

Note that the loss function in Eq. (15) does not measure the actual number of fractional values, nor their *distance* to integrality. In Section 6, we analyze a notion of tightness that accounts for the L1 distance to integrality.

Compared to the generalization bound of Kulesza and Pereira (2007), our bounds only consider the tightness of a prediction, ignoring label errors. Thus, for example, if learning happens to settle on a set of parameters in a tractable regime (e.g., supermodular potentials or stable instances (Makarychev et al., 2014)) for which the LP relaxation is tight for most training instances, our generalization bound guarantees that with high probability the LP relaxation will also be tight on most test instances. In contrast, in Kulesza and Pereira (2007), tightness on test instances can only be guaranteed when the training data is algorithmically separable (i.e., LP-relaxed inference predicts perfectly).

5.1. γ-Tight Relaxations

In this section we study the stronger notion of tightness required by our surrogate fractionality loss (Eq. (16)), and show examples of models that satisfy it.

Definition 1. An LP relaxation is called γ-*tight* if $I^*(w,x) \geq F^*(w,x) + \gamma$ (so $\mathcal{L}_\gamma(w,x) = 0$). That is, the best integral value is larger than the best non-integral value by at least γ.[10]

We focus on binary pairwise models and show two cases where the model is guaranteed to be γ-tight. Proofs are provided in Appendix A. Our first example involves *balanced* models, which are binary pairwise models that have supermodular scores, or can be made supermodular by "flipping" a subset of the variables (for more details, see Appendix A).

Proposition 1. *A balanced model with a unique optimum is* $(\alpha/2)$*-tight, where* α *is the difference between the best and second-best (integral) solutions.*

This result is of particular interest when learning structured predictors where the edge scores depend on the input. Whereas one could learn supermodular models by enforcing linear inequalities (Taskar et al., 2004), we know of no tractable means of ensuring the model is balanced. Instead, one could learn over the full space of models using LP relaxation. If the learned models are balanced on the training data, Proposition 1 together with Theorem 1 tell us that the LP relaxation is likely to be tight on test data as well.

Our second example regards models with singleton scores that are much stronger than the pairwise scores. Consider a binary pairwise model[11] in minimal representation, where $\bar{\theta}_i$ are node scores and $\bar{\theta}_{ij}$ are edge scores in this representation (see Appendix A for full details). Further, for each variable i, define the set of neighbors with *attractive* edges $N_i^+ = \{j \in N_i | \bar{\theta}_{ij} > 0\}$, and the set of neighbors with *repulsive* edges $N_i^- = \{j \in N_i | \bar{\theta}_{ij} < 0\}$.

10. Notice that scaling up $\theta(w,x)$ will also increase γ, but our bound in Eq. (17) also grows with the norm of $\theta(w,x)$ (via the term BR). Therefore, we assume here that $\|\theta(w,x)\|_2$ is bounded.
11. This case easily generalizes to variables with more than 2 possible values.

Proposition 2. *If all variables satisfy the condition:*

$$\bar{\theta}_i \geq -\sum\nolimits_{j \in N_i^-} \bar{\theta}_{ij} + \beta, \quad \text{or} \quad \bar{\theta}_i \leq -\sum\nolimits_{j \in N_i^+} \bar{\theta}_{ij} - \beta$$

for some $\beta > 0$*, then the model is* $(\beta/2)$*-tight.*

Finally, we point out that in both of the examples above, the conditions can be verified efficiently and if they hold, the value of γ can be computed efficiently.

6. Analysis of the Integrality Distance

For structured prediction, the maximizer, μ_L, is often more important than the maximum value, $\theta^\top \mu_L$. That is, we do not really care whether the optimum of the relaxed problem equals that of the integral one; we just want relaxed inference to yield the optimal integral assignment—or, lacking that, an assignment that is "close to" the optimal integral one. If we assume that the relaxed problem has a unique solution, then an integrality gap of zero implies that the assignments are the same. However, lacking this assumption, there may be multiple, disparate solutions, so the assignments may differ. In general, it is difficult to characterize the distance between relaxed and exact assignments as a function of a nonzero integrality gap.

Thus, in addition to studying the integrality gap, we are also interested in what we will call the *integrality distance*, defined as $\|\mu_L - \mu_I\|_1$, which is the Manhattan distance between the maximizers of the relaxed and exact programs. The integrality distance is conceptually similar to *persistence* (see Wainwright and Jordan, 2008 for definition) in that a persistent fractional solution will have a subset of variables with zero integrality distance. The integrality distance is also related to the integrality gap, although the distance could sometimes be more useful: when the integrality distance is small, the relaxed solution is close to the exact solution, which is what we may ultimately care about; moreover, when the integrality distance is zero, the integrality gap must also be zero, regardless of whether we assume uniqueness.

In this section, we relate the integrality distance to several loss functions that are commonly analyzed in the literature on structured prediction. We then show that, similar to the integrality gap, the integrality distance also generalizes from an empirical sample to the population average. Moreover, we show that the integrality distance is upper-bounded by a constant multiple of the structured hinge loss—a convex loss function that is commonly used for training. Importantly, unlike the bound in Theorem 1, this bound is computationally tractable. Combining these results, we obtain a high-probability bound on the expected integrality distance that can be efficiently evaluated from training data, and whose additive error decreases with the number of examples. Finally, a simple argument shows how this bound applies to an integral rounding of a fractional solution.

6.1. Structured Loss Functions

We will focus on the integrality distance of the singleton (i.e., node) marginals, denoted $\mu_{\mathrm{u}} \triangleq (\mu_i)_{i=1}^n$, since they are sufficient for decoding a labeling, y. Let

$$D_1(\mu, \mu') \triangleq \frac{1}{2n} \left\| \mu_{\mathrm{u}} - \mu'_{\mathrm{u}} \right\|_1 \tag{18}$$

denote the normalized Manhattan distance. When both inputs are integral, D_1 is equivalent to the normalized Hamming distance.

Given a model, w, an input, x, and an assignment, μ, let

$$\mathcal{L}_1(w, x, \mu) \triangleq D_1\left(\mu, \mu_L(x; w)\right) \tag{19}$$

denote the L_1 *loss*. This loss function is a generalization of the Hamming loss, which is commonly used to measure the prediction error of exact inference. If the third argument is a reference (i.e., "ground truth") labeling, μ_T, then $\mathcal{L}_1(w, x, \mu_T)$ measures the prediction error of approximate inference. However, if the third argument is the exact, integral MAP state, μ_I, then $\mathcal{L}_1(w, x, \mu_I)$ is the normalized integrality distance. This latter quantity is what we will focus on upper-bounding.

Let

$$\mathcal{L}_{\mathrm{h}}(w, x, \mu) \triangleq \max_{\mu' \in \mathcal{M}_L} D_1(\mu, \mu') + \theta^\top \left(\mu' - \mu\right). \tag{20}$$

denote a loss function commonly referred to as the (relaxed) *structured hinge loss*. This loss is minimized when μ scores higher than all alternate assignments, μ', by a margin that is at least $D_1(\mu, \mu')$. Note that when μ is the exact MAP state, the structured hinge loss computes a *loss-augmented* integrality gap, using Manhattan distance for loss augmentation (see Eq. (4)).

A related loss function is the (relaxed) *structured ramp loss*,

$$\mathcal{L}_{\mathrm{r}}(w, x, \mu) \triangleq \max_{\mu' \in \mathcal{M}_L} D_1(\mu, \mu') + \theta^\top \left(\mu' - \mu_L(x; w)\right), \tag{21}$$

which can be considered a normalized version of the hinge loss. $\mathcal{L}_{\mathrm{r}}$ is bounded by $[0, 1]$, whereas $\mathcal{L}_{\mathrm{h}}$ might be unbounded (depending on the features and weights).

The hinge loss is often used in max-margin training, since it is convex in w. The ramp loss is not convex in w, but it is bounded, Lipschitz, and has a convenient relationship to the L_1 (or Hamming) and hinge losses:

$$\mathcal{L}_1(w, x, \mu) \leq \mathcal{L}_{\mathrm{r}}(w, x, \mu) \leq \mathcal{L}_{\mathrm{h}}(w, x, \mu). \tag{22}$$

Thus, the ramp loss is often used as an analytical tool to derive generalization bounds, such as those that follow.

6.2. Generalization Bound

Similar to Section 5, we now show that the integrality distance on a training sample generalizes to the data distribution. Like Theorem 1, the proof (in Appendix B.2) uses PAC-Bayesian analysis.

Theorem 2. *Let $\mathbb{D}$ denote a distribution over $\mathcal{X}$. Let $\phi : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$ denote a feature mapping such that $\sup_{x,y} \|\phi(x, y)\|_2 \leq B < \infty$; and μ_I is defined in Eq. (5). Then, for any $\delta \in (0, 1)$ and $m \geq 1$, with probability at least $1 - \delta$ over draws of $(x^{(1)}, \ldots, x^{(m)}) \in \mathcal{X}^m$, according to $\mathbb{D}^m$, every weight vector, w, with $\|w\|_2 \leq R < \infty$, satisfies*

$$\mathop{\mathbb{E}}_{x \sim \mathbb{D}}[\mathcal{L}_1(w, x, \mu_I)] \leq \frac{1}{m} \sum_{i=1}^m \mathcal{L}_r(w, x^{(i)}, \mu_I^{(i)}) + \frac{8}{m} + 2\sqrt{\frac{d \ln(mBR) + \ln \frac{2}{\delta}}{2m}}. \tag{23}$$

Further, Eq. (23) holds when $\mathcal{L}_r$ is replaced with $\mathcal{L}_h$.

Theorem 2 says that the integrality distance on the training set generalizes to future examples. More precisely, the expected integrality distance on a random instance is upper-bounded by the average integrality ramp (or hinge) loss on the training set, plus two terms that vanish as the number of training examples grows. Thus, the more training data we have, the better we can estimate the expected integrality distance.

Remark 1. There is nothing special about μ_I to Theorem 2. Indeed, we could use any integral assignment as a reference labeling for the loss functions and the proof would be the same. For example, we could replace μ_I with μ_T (a ground truth labeling) and obtain a risk bound for learning with approximate inference, which is a well-studied topic (e.g., Kulesza and Pereira, 2007; London et al., 2016).

6.3. Relationship to Max-Margin Training

In practice, computing the integrality loss is generally infeasible, since it requires exact inference. Therefore, the upper bounds in Theorems 1 and 2 cannot be evaluated. However, the empirical relaxed hinge loss with respect to the ground truth labels *can* be evaluated efficiently. In this section, we show how minimizing this quantity actually minimizes the integrality distance. That is, max-margin training with approximate inference—which is commonly used anyway to learn graphical models—reduces not only the prediction error, but also the inference approximation error.

The key insight that enables this result comes from the following technical lemma.

Lemma 1. *For any w and x, if μ_T is the reference (ground truth) labeling of x and μ_I is the exact MAP state under w, then*

$$\mathcal{L}_h(w, x, \mu_I) \;\leq\; 2\,\mathcal{L}_h(w, x, \mu_T), \tag{24}$$

meaning the integrality hinge loss is at most twice the hinge loss with respect to the true labeling.

Proof First, we decompose the integrality hinge loss as follows:

$$\begin{aligned}
\mathcal{L}_{\mathrm{h}}(w, x, \mu_I) &= \max_{\mu \in \mathcal{M}_L} D_1(\mu_I, \mu) + \theta^\top (\mu - \mu_I) \\
&\leq \max_{\mu \in \mathcal{M}_L} D_1(\mu_I, \mu) + \theta^\top (\mu - \mu_T) \\
&\leq D_1(\mu_I, \mu_T) + \max_{\mu \in \mathcal{M}_L} D_1(\mu_T, \mu) + \theta^\top (\mu - \mu_T) \\
&= D_1(\mu_I, \mu_T) + \mathcal{L}_{\mathrm{h}}(w, x, \mu_T).
\end{aligned} \tag{25}$$

The second term on the right-hand side is the hinge loss of the approximate predictor with respect to the true labeling, which can be evaluated efficiently. The first term on the right-hand side is the Hamming loss of exact inference, which cannot be evaluated efficiently. However, this latter quantity can be upper-bounded as follows:

$$\begin{aligned} D_1(\mu_I, \mu_T) &\leq \max_{\mu \in \mathcal{M}} D_1(\mu, \mu_T) + \theta^\top (\mu - \mu_T) \\ &\leq \max_{\mu \in \mathcal{M}_L} D_1(\mu, \mu_T) + \theta^\top (\mu - \mu_T) \\ &= \mathcal{L}_{\mathrm{h}}(w, x, \mu_T). \end{aligned} \tag{26}$$

Combining Eq. (25) and (26) completes the proof. ■

Note that Lemma 1 also yields an upper bound on the integrality ramp loss, since it is upper-hounded by the integrality hinge loss.

Using Lemma 1, we thus obtain the following corollary of Theorem 2.

Corollary 2. *Let $\mathbb{D}$ denote a distribution over $\mathcal{X} \times \mathcal{Y}$. Let $\phi : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$ denote a feature mapping such that $\sup_{x,y} \|\phi(x,y)\|_2 \leq B < \infty$. Then, for any $\delta \in (0,1)$ and $m \geq 1$, with probability at least $1-\delta$ over draws of $(x^{(1)}, y^{(1)}, \ldots, x^{(m)}, y^{(m)}) \in (\mathcal{X} \times \mathcal{Y})^m$, according to $\mathbb{D}^m$, every weight vector, w, with $\|w\|_2 \leq R < \infty$, satisfies*

$$\mathop{\mathbb{E}}_{x \sim \mathbb{D}}[\mathcal{L}_1(w, x, \mu_I)] \leq \frac{2}{m} \sum_{i=1}^{m} \mathcal{L}_h(w, x^{(i)}, \mu_T^{(i)}) + \frac{8}{m} + 2\sqrt{\frac{d \ln(mBR) + \ln \frac{2}{\delta}}{2m}}, \tag{27}$$

where $\mu_T^{(i)}$ denotes the integral vector corresponding to the ground-truth labeling $y^{(i)}$.

Corollary 2 says that max-margin training with relaxed inference directly minimizes the integrality distance on future examples. Importantly, if the constants B and R are known, then this bound can be efficiently evaluated from training data. It is worth noting that Corollary 2 actually holds for *any* integral assignment, not just the ground truth labels. Nonetheless, we feel the bound is more insightful when stated with respect to the ground truth labels, which are given in the learning setup. In this case $\mathbb{D}$ is defined as a joint distribution over $\mathcal{X}$ and $\mathcal{Y}$, and the bound holds with high probability over draws of both inputs and labels. It is also worth noting that Corollary 2 holds in the presence of global constraints—provided the ground truth (or whichever integral assignments are used) are in the feasible set.

6.4. Decoding a Solution

When the solution to an LP relaxation is fractional, we often round the solution to an integral assignment. Rounding schemes have been studied extensively (e.g., Raghavan and Tompson, 1987; Kleinberg and Tardos, 2002; Chekuri et al., 2004; Ravikumar et al., 2010). Arguably, the simplest method is to select the local assignments $\mu_i(y_i)$ with the highest values. One question that arises is how far the rounding, denoted $\mu_R(x; w)$, is from the exact solution; once this relationship is determined, one can apply our prior generalization analysis to the rounding. It turns out that the distance from μ_R to μ_I can be upper-bounded by a multiple of the integrality distance.

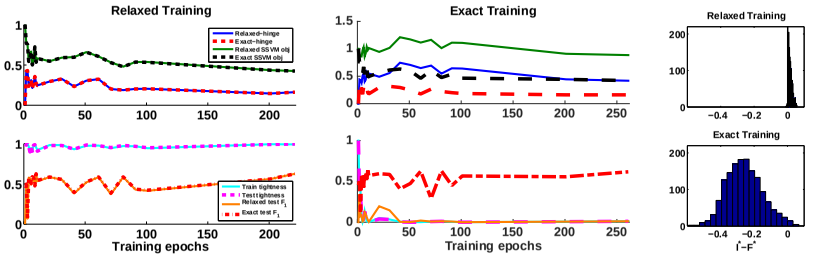

Figure 4: Training with the 'Yeast' multi-label classification dataset. Various quantities of interest are shown as a function of training iterations. (Left) Training with LP relaxation. (Middle) Training with ILP. (Right) Integrality margin (bin widths are scaled differently).

Lemma 2. *Suppose that every output variable has the same domain—i.e., $\mathcal{Y}_1 = \mathcal{Y}_2 = \ldots = \mathcal{Y}_n$—and that each domain has size k. If $\mu_R(x; w)$ is the rounding of the fractional solution, $\mu_L(x; w)$, then*

$$D_1(\mu_R, \mu_I) \;\leq\; k\, D_1(\mu_L, \mu_I). \tag{28}$$

Proof Consider any output variable. If the fractional solution assigns the majority of the local belief to the "correct" label (i.e., the label chosen by exact inference), then the rounding of that variable will be exact. However, if the fractional solution puts most of the local belief on an "incorrect" label, then the rounding of that variable will have D_1 distance 1 from the correct label. Since the incorrect label must have had a fractional value of at least $1/k$, it follows that the fractional solution has D_1 distance at least $1/k$, which is no less than $1/k$ that of the rounding. Applying this logic to every variable completes the proof. ■

Lemma 2 can be combined with Corollary 2 to generate bounds on the expected integrality distance of rounding; the bound simply scales by k.

7. Experiments

In this section we present some numerical results to support our theoretical analysis. We run experiments for a multi-label classification task and an image segmentation task. For training we have implemented the block-coordinate Frank-Wolfe algorithm for structured SVM (Lacoste-Julien et al., 2013), using GLPK as the LP solver. We use a standard L_2 regularizer, chosen via cross-validation.

7.1. Multi-Label Classification

For multi-label classification we adopt the experimental setting of Finley and Joachims (2008). In this setting labels are represented by binary variables, the model consists of

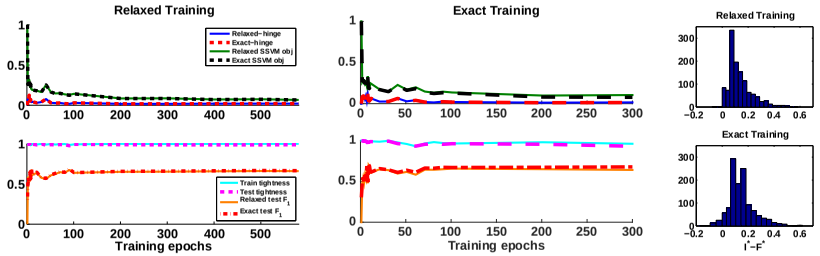

Figure 5: Training with the 'Scene' multi-label classification dataset. Various quantities of interest are shown as a function of training iterations. (Left) Training with LP relaxation. (Middle) Training with ILP. (Right) Integrality margin.

singleton and pairwise factors forming a fully connected graph over the labels, and the task loss is the normalized Hamming distance.

Fig. 4 shows relaxed and exact training iterations for the 'Yeast' dataset (14 labels). We plot the relaxed and exact hinge terms (Eq. (6)), the exact and relaxed SSVM training objectives[12] (Eq. (3) and Eq. (4), respectively), fraction of train and test instances having integral solutions, as well as test accuracy (measured by F_1 score). We use a simple scheme to round fractional solutions found with relaxed inference. First, we note that the relaxed-hinge values are nicely correlated with the relaxed training objective, and likewise the exact-hinge is correlated with the exact objective (left and middle, top). Second, observe that with relaxed training, the relaxed-hinge and the exact-hinge are very close (left, top), so the integrality gap, given by their difference, remains small (almost 0 here). On the other hand, with exact training there is a large integrality gap (middle, top). Indeed, we can see that the percentage of integral solutions is almost 100% for relaxed training (left, bottom), and close to 0% with exact training (middle, bottom). In Fig. 4 (right) we also show histograms of the difference between the optimal integral and fractional values, i.e., the integrality margin $(I^*(w,x) - F^*(w,x))$, under the final learned w for all training instances. It can be seen that with relaxed training this margin is positive (although small), while exact training results in larger negative values. Finally, we note that train and test integrality levels are very close to each other, almost indistinguishable (left and middle, bottom), which provides empirical support to our generalization result from Section 5.

We next train a model using random labels (with similar label counts as the true data). In this setting the learned model obtains 100% tight training instances (not shown), which supports our observation that any integral point can be used in place of the ground-truth, and that accuracy is not important for tightness. Finally, in order to verify that tightness is not coincidental, we test the tightness of the relaxation induced by a random weight vector w. We find that random models are never tight (in 20 trials), which shows that tightness of the relaxation does not come by chance.

12. The displayed objective values are averaged over train instances and exclude regularization.

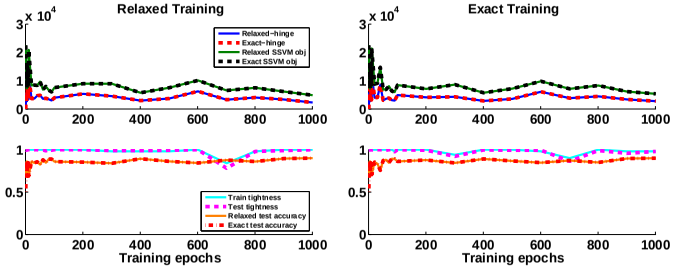

Figure 6: Training for foreground-background segmentation with the Weizmann Horse dataset. Various quantities of interest are shown as a function of training iterations. (Left) Training with LP relaxation. (Right) Training with ILP.

We now proceed to perform experiments on the 'Scene' dataset (6 labels). The results, in Fig. 5, differ from the 'Yeast' results in case of exact training (middle). Specifically, we observe that in this case the relaxed-hinge and exact-hinge are close in value (middle, top), as for relaxed training (left, top). As a consequence, the integrality gap is very small and the relaxation is tight for almost all train (and test) instances. These results illustrate that sometimes optimizing the exact objective can reduce the relaxed objective (and relaxed-hinge) as well. Further, in this setting we observe a larger integrality margin (right), namely the integral optimum is strictly better than the fractional one.

We conjecture that the LP instances are easy in this case due to the dominance of the singleton scores.[13] Specifically, the features provide a strong signal which allows label assignment to be decided mostly based on the local score, with little influence coming from the pairwise terms. To test this conjecture we inject Gaussian noise into the input features, forcing the model to rely more on the pairwise interactions. We find that with the noisy singleton scores the results are indeed more similar to the 'Yeast' dataset, where a large integrality gap is observed and fewer instances are tight (see Appendix C in the supplement).

7.2. Image Segmentation

Finally, we conduct experiments on a foreground-background segmentation problem using the Weizmann Horse dataset (Borenstein et al., 2004). The data consists of 328 images, of which we use the first 50 for training and the rest for testing. Here a binary output variable is assigned to each pixel, and there are $\sim 58K$ variables per image on average. We extract singleton and pairwise features as described in Domke (2013). Fig. 6 shows the same quantities as in the multi-label setting, except for the accuracy measure—here we compute the percentage of correctly classified pixels rather than F_1. We observe a very similar behavior to that of the 'Scene' multi-label dataset (Fig. 5). Specifically, both relaxed and exact training produce a small integrality gap and high percentage of tight instances.

13. With ILP training, the condition in Proposition 2 is satisfied for 65% of all variables, although only 1% of the training instances satisfy it for all their variables.

Unlike the 'Scene' dataset, here only 1.2% of variables satisfy the condition in Proposition 2 (using LP training). In all of our experiments the learned model scores were never balanced (Proposition 1), although for the segmentation problem we believe the models learned are close to balanced, both for relaxed and exact training.

8. Conclusion

In this paper we present a theoretical analysis of the tightness of LP relaxations often observed in structured prediction applications. Our analysis is based on a careful examination of the integrality gap, the integrality distance, and their relation to the training objective. It shows how training with LP relaxations, although designed with accuracy considerations in mind, also induces tightness of the relaxation. Our derivation also suggests that exact training may sometimes have the opposite effect, increasing the integrality gap.

To explain tightness at test time, we show that tightness generalizes in the following two senses: first, if most training predictions are integral, then most test instances will also be integral; secondly, if training predictions are on average "close to" integral, then test predictions will be similarly close to integral in expectation.

Appendix A. γ-Tight LP Relaxations

In this section we provide full derivations for the results in Section 5.1. We make extensive use of the results in Weller et al. (2016), some of which are restated here for completeness. We start by defining a model in minimal representation, which will be convenient for the derivations that follow. Specifically, in the case of binary variables ($y_i \in \{0,1\}$) with pairwise factors, we define a value η_i for each variable, and a value η_{ij} for each pair. The mapping between the over-complete vector μ and the minimal vector η is as follows. For singleton factors, we have:

$$\mu_i = \begin{pmatrix} 1-\eta_i \\ \eta_i \end{pmatrix}$$

Similarly, for the pairwise factors, we have:

$$\mu_{ij} = \begin{pmatrix} 1+\eta_{ij}-\eta_i-\eta_j & \eta_j-\eta_{ij} \\ \eta_i-\eta_{ij} & \eta_{ij} \end{pmatrix},$$

The corresponding mapping to minimal parameters is then:

$$\bar{\theta}_i = \theta_i(1) - \theta_i(0) + \sum_{j \in N_i} (\theta_{ij}(1,0) - \theta_{ij}(0,0))$$
$$\bar{\theta}_{ij} = \theta_{ij}(1,1) + \theta_{ij}(0,0) - \theta_{ij}(0,1) - \theta_{ij}(1,0)$$

In this representation, the LP relaxation is given by (up to constants):

$$\max_{\eta \in \mathbb{L}} f(\eta) := \sum_{i=1}^{n} \bar{\theta}_i \eta_i + \sum_{ij \in \mathcal{E}} \bar{\theta}_{ij} \eta_{ij}$$

where $\mathbb{L}$ is the appropriate transformation of $\mathcal{M}_L$ to the equivalent reduced space of η:

$$\begin{aligned} 0 &\le \eta_i \le 1 && \forall i \\ \max(0, \eta_i + \eta_j - 1) &\le \eta_{ij} \le \min(\eta_i, \eta_j) && \forall ij \in \mathcal{E} \end{aligned}$$

If $\bar{\theta}_{ij} > 0$ ($\bar{\theta}_{ij} < 0$), then the edge is called *attractive* (*repulsive*). If all edges are attractive, then the LP relaxation is known to be tight (Wainwright and Jordan, 2008). When not all edges are attractive, in some cases it is possible to make them attractive by *flipping* a subset of the variables ($y_i \leftarrow 1 - y_i$), which flips the signs of edge potentials for edges with exactly one end in the flipped subset.[14] In such cases the model is called *balanced*.

In the sequel we will make use of the known fact that all vertices of the local polytope are half-integral (take values in $\{0, \frac{1}{2}, 1\}$) (Padberg, 1989). We are now ready to prove the propositions (restated here for convenience).

14. The flip-set, if exists, is easy to find by making a single pass over the graph (see Weller (2015) for more details).

A.1. Proof of Proposition 1

Proposition 1 *A balanced model with a unique optimum is $(\alpha/2)$-tight, where α is the difference between the best and second-best (integral) solutions.*

Proof Weller et al. (2016) define for a given variable i the function $F^i_{\mathbb{L}}(z)$, which returns for every $0 \leq z \leq 1$ the constrained optimum:

$$F^i_{\mathbb{L}}(z) = \max_{\substack{\eta \in \mathbb{L} \\ \eta_i = z}} f(\eta)$$

Given this definition, they show that for a balanced model, $F^i_{\mathbb{L}}(z)$ is a *linear function* (Weller et al., 2016, Theorem 6).

Let m be the optimal score, let η^1 be the unique optimum integral vertex in minimal form so $f(\eta^1) = m$, and by assumption any other integral vertex has value at most $m - \alpha$. Denote the state of η^1 at coordinate i by $z^* = \eta^1_i$, and consider computing the constrained optimum holding η_i to various states. By assumption, any other integral vertex has value at most $m - \alpha$, therefore,

$$F^i_{\mathbb{L}}(z^*) = m$$
$$F^i_{\mathbb{L}}(1 - z^*) \leq m - \alpha$$

(the second line holds with equality if there exists a second-best solution η^2 s.t. $\eta^2_i \neq \eta^1_i$). Since $F^i_{\mathbb{L}}(z)$ is a linear function, we have that:

$$F^i_{\mathbb{L}}(1/2) \leq m - \alpha/2 \tag{29}$$

Next, towards contradiction, suppose that there exists a fractional vertex η^f with value $f(\eta^f) > m - \alpha/2$. Let j be a fractional coordinate, so $\eta^f_j = \frac{1}{2}$ (since vertices are half-integral). Our assumption implies that $F^j_{\mathbb{L}}(1/2) > m - \alpha/2$, but this contradicts Eq. (29). Therefore, we conclude that any fractional solution has value at most $f(\eta^f) \leq m - \alpha/2$. ■

It is possible to check in polynomial time if a model is balanced, if it has a unique optimum, and compute α. This can be done by computing the difference in value to the second-best. In order to find the second-best: one can constrain each variable in turn to differ from the state of the optimal solution, and recompute the MAP solution; finally, take the maximum over all these trials.

A.2. Proof of Proposition 2

Proposition 2 *If all variables satisfy the condition:*

$$\bar{\theta}_i \geq -\sum_{j \in N_i^-} \bar{\theta}_{ij} + \beta, \quad \textit{or} \quad \bar{\theta}_i \leq -\sum_{j \in N_i^+} \bar{\theta}_{ij} - \beta$$

for some $\beta > 0$, then the model is $(\beta/2)$-tight.

Proof For any binary pairwise models, given singleton terms $\{\eta_i\}$, the *optimal* edge terms are given by (for details see Weller et al., 2016):

$$\eta_{ij}(\eta_i, \eta_j) = \begin{cases} \min(\eta_i, \eta_j) & \text{if } \bar{\theta}_{ij} > 0 \\ \max(0, \eta_i + \eta_j - 1) & \text{if } \bar{\theta}_{ij} < 0 \end{cases}$$

Now, consider a variable i and let N_i be the set of its neighbors in the graph. Further, define the sets $N_i^+ = \{j \in N_i | \bar{\theta}_{ij} > 0\}$ and $N_i^- = \{j \in N_i | \bar{\theta}_{ij} < 0\}$, corresponding to attractive and repulsive edges, respectively. We next focus on the parts of the objective affected by the value at η_i (recomputing optimal edge terms); recall that all vertices are half-integral:

$\eta_i = 1$	$\eta_i = 1/2$	$\eta_i = 0$
$\bar{\theta}_i + \sum_{\substack{j \in N_i^+ \\ \eta_j = 1}} \bar{\theta}_{ij} + \frac{1}{2} \sum_{\substack{j \in N_i^+ \\ \eta_j = \frac{1}{2}}} \bar{\theta}_{ij} + \sum_{\substack{j \in N_i^- \\ \eta_j = 1}} \bar{\theta}_{ij} + \frac{1}{2} \sum_{\substack{j \in N_i^- \\ \eta_j = \frac{1}{2}}} \bar{\theta}_{ij}$	$\frac{1}{2}\bar{\theta}_i + \frac{1}{2} \sum_{\substack{j \in N_i^+ \\ \eta_j \in \{\frac{1}{2}, 1\}}} \bar{\theta}_{ij} + \frac{1}{2} \sum_{\substack{j \in N_i^- \\ \eta_j = 1}} \bar{\theta}_{ij}$	0

It is easy to verify that the condition $\bar{\theta}_i \geq -\sum_{j \in N_i^-} \bar{\theta}_{ij} + \beta$ guarantees that $\eta_i = 1$ in the optimal solution. We next bound the difference in objective values resulting from setting $\eta_i = 1/2$.

$$\Delta f = \frac{1}{2} \left(\bar{\theta}_i + \sum_{\substack{j \in N_i^+ \\ \eta_j = 1}} \bar{\theta}_{ij} + \sum_{\substack{j \in N_i^- \\ \eta_j \in \{\frac{1}{2}, 1\}}} \bar{\theta}_{ij} \right) \geq \frac{1}{2} \left(\bar{\theta}_i + \sum_{j \in N_i^-} \bar{\theta}_{ij} \right) \geq \beta/2$$

Similarly, when $\bar{\theta}_i \leq -\sum_{j \in N_i^+} \bar{\theta}_{ij} - \beta$, then $\eta_i = 0$ in any optimal solution. The difference in objective values from setting $\eta_i = 1/2$ in this case is:

$$\Delta f = -\frac{1}{2} \left(\bar{\theta}_i + \sum_{\substack{j \in N_i^+ \\ \eta_j \in \{\frac{1}{2}, 1\}}} \bar{\theta}_{ij} + \sum_{\substack{j \in N_i^- \\ \eta_j = 1}} \bar{\theta}_{ij} \right) \geq -\frac{1}{2} \left(\bar{\theta}_i + \sum_{j \in N_i^+} \bar{\theta}_{ij} \right) \geq \beta/2$$

Notice that for more fractional coordinates the difference in values can only increase, so in any case the fractional solution is worse by at least $\beta/2$. ■

Appendix B. Generalization Bound Proofs

To prove Theorems 1 and 2, we will use the following PAC-Bayes bound. There are other ways of proving generalization bounds for structured predictors (e.g., Weiss and Taskar, 2010), and other PAC-Bayesian analyses of structured prediction (e.g., McAllester, 2007), but we prefer the following for its simplicity. Our analysis is based on London et al.'s (2016), with certain simplifications due to differences in our objective.

Lemma 3. *Let $\mathbb{D}$ denote a distribution over an instance space, $\mathcal{Z}$. Let $\mathcal{H}$ denote a hypothesis class. Let $\mathcal{L} : \mathcal{H} \times \mathcal{Z} \to [0, 1]$ denote a bounded loss function. Let $\mathbb{P}$ denote a fixed prior distribution over $\mathcal{H}$. Then, for any $\delta \in (0, 1)$ and $m \geq 1$, with probability at least $1 - \delta$ over draws of $(Z^{(1)}, \ldots, Z^{(m)}) \in \mathcal{Z}^m$, according to $\mathbb{D}^m$, every posterior distribution, $\mathbb{Q}$, over $\mathcal{H}$, satisfies*

$$\mathop{\mathbb{E}}_{Z \sim \mathbb{D}} \mathop{\mathbb{E}}_{h \sim \mathbb{Q}} [\mathcal{L}(h, Z)] \leq \frac{1}{m} \sum_{i=1}^{m} \mathop{\mathbb{E}}_{h \sim \mathbb{Q}} [\mathcal{L}(h, Z^{(i)})] + 2\sqrt{\frac{D_{\mathrm{KL}}(\mathbb{Q} \| \mathbb{P}) + \ln \frac{2}{\delta}}{2m}} \tag{30}$$

Proof To simplify notation, let

$$\varphi(h, Z^{(i)}) \triangleq \frac{1}{m}\left(\mathop{\mathbb{E}}_{Z\sim\mathbb{D}}[\mathcal{L}(h,Z)] - \mathcal{L}(h, Z^{(i)})\right).$$

For any free parameter, $\epsilon \in \mathbb{R}$, observe that

$$\mathop{\mathbb{E}}_{Z\sim\mathbb{D}}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z)] - \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z^{(i)})] = \frac{1}{\epsilon}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}\left[\sum_{i=1}^{m}\epsilon\,\varphi(h,Z^{(i)})\right]. \tag{31}$$

The next step uses Donsker and Varadhan's (1975) *change of measure* inequality, which states that, if X is a random variable taking values in Ω, then for any two distributions, $\mathbb{P}$ and $\mathbb{Q}$, on Ω,

$$\mathop{\mathbb{E}}_{X\sim\mathbb{Q}}[X] \le D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln \mathop{\mathbb{E}}_{X\sim\mathbb{P}}\left[e^{X}\right].$$

Applying change of measure to the righthand side of Equation 31, we have

$$\frac{1}{\epsilon}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}\left[\sum_{i=1}^{m}\epsilon\,\varphi(h,Z^{(i)})\right] \le \frac{1}{\epsilon}\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln \mathop{\mathbb{E}}_{h\sim\mathbb{P}}\left[\exp\left(\sum_{i=1}^{m}\epsilon\,\varphi(h,Z^{(i)})\right)\right]\right). \tag{32}$$

By Markov's inequality, with probability $1-\delta$ over draws of a training set, $\mathbf{Z} \triangleq (Z^{(1)},\ldots,Z^{(m)})$, according to $\mathbb{D}^m$,

$$\begin{aligned}
\mathop{\mathbb{E}}_{h\sim\mathbb{P}}\left[\exp\left(\sum_{i=1}^{m}\epsilon\,\varphi(h,Z^{(i)})\right)\right] &\le \frac{1}{\delta}\mathop{\mathbb{E}}_{\mathbf{Z}\sim\mathbb{D}^m}\mathop{\mathbb{E}}_{h\sim\mathbb{P}}\left[\exp\left(\sum_{i=1}^{m}\epsilon\,\varphi(h,Z^{(i)})\right)\right] \\
&= \frac{1}{\delta}\mathop{\mathbb{E}}_{h\sim\mathbb{P}}\mathop{\mathbb{E}}_{\mathbf{Z}\sim\mathbb{D}^m}\left[\prod_{i=1}^{m}\exp\left(\epsilon\,\varphi(h,Z^{(i)})\right)\right] \\
&= \frac{1}{\delta}\mathop{\mathbb{E}}_{h\sim\mathbb{P}}\prod_{i=1}^{m}\mathop{\mathbb{E}}_{Z^{(i)}\sim\mathbb{D}}\left[\exp\left(\epsilon\,\varphi(h,Z^{(i)})\right)\right].
\end{aligned} \tag{33}$$

In the last line, we leveraged the fact that the expectation of a product of i.i.d. random variables (in this case, $\varphi(h,Z^{(i)})$) is the product of their expectations. To upper-bound each expectation, we use Hoeffding's inequality, which states that if X is a zero-mean random variable, such that $a \le X \le b$ almost surely, then, for all $\epsilon \in \mathbb{R}$,

$$\mathbb{E}\left[e^{\epsilon X}\right] \le \exp\left(\frac{\epsilon^2(b-a)^2}{8}\right).$$

Since $\varphi(h,Z^{(i)})$ has mean zero, and

$$\mathop{\mathbb{E}}_{Z\sim\mathbb{D}}[\mathcal{L}(h,Z)] - \frac{1}{m} \le \varphi(h,Z^{(i)}) \le \mathop{\mathbb{E}}_{Z\sim\mathbb{D}}[\mathcal{L}(h,Z)] - 0,$$

we have that

$$\mathop{\mathbb{E}}_{Z^{(i)}\sim\mathbb{D}}\left[\exp\left(\epsilon\,\varphi(h,Z^{(i)})\right)\right] \le \exp\left(\frac{\epsilon^2}{8m^2}\right). \tag{34}$$

Combining Equations 31 to 34, we have for any $\epsilon \in \mathbb{R}$, with probability at least $1-\delta$, all $\mathbb{Q}$ satisfy

$$\mathop{\mathbb{E}}_{Z\sim\mathbb{D}}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z)] - \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z^{(i)})] \le \frac{1}{\epsilon}\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{1}{\delta}\right) + \frac{\epsilon}{8m}. \tag{35}$$

The ϵ that minimizes Equation 35 is straightforward: setting the derivative equal to 0 and solving for $\epsilon^\star$, we have $\epsilon^\star = \sqrt{8m(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{1}{\delta})}$. Unfortunately, this optimal value depends on the choice of posterior, $\mathbb{Q}$, which means that the bound would only hold for a single posterior, not *all* posteriors simultaneously. To derive a bound that holds for all posteriors, we employ a covering technique, attributed to Seldin et al. (2012). We first define a countably infinite sequence of ϵ values. For each value, we assign an exponentially decreasing probability that Equation 35 fails to hold, such that with probability at least $1-\delta$ it holds for all values simultaneously. Then, for any posterior, we select an index, $j^\star$, that approximately optimizes Equation 35, and use lower and upper bounds on $\epsilon_{j^\star}$ to simplify the bound.

For $j = 0, 1, 2, \ldots$, let

$$\epsilon_j \triangleq 2^j\sqrt{8m\ln\frac{2}{\delta}}. \tag{36}$$

For each ϵ_j, we assign $\delta_j \triangleq \delta 2^{-(j+1)}$ probability that Equation 35 does not hold, substituting (ϵ_j, δ_j) for (ϵ, δ). Thus, with probability at least $1 - \sum_{j=0}^{\infty}\delta_j = 1 - \delta\sum_{j=0}^{\infty}2^{-(j+1)} = 1-\delta$, all $j = 0, 1, 2, \ldots$ satisfy

$$\mathop{\mathbb{E}}_{Z\sim\mathbb{D}}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z)] - \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z^{(i)})] \le \frac{1}{\epsilon_j}\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{1}{\delta_j}\right) + \frac{\epsilon_j}{8m}$$

For any given posterior, $\mathbb{Q}$, we choose an index, $j^\star$, by taking

$$j^\star \triangleq \left\lfloor \frac{1}{2\ln 2}\ln\left(\frac{D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P})}{\ln(2/\delta)} + 1\right)\right\rfloor,$$

which implies

$$\sqrt{2m\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{2}{\delta}\right)} \le \epsilon_{j^\star} \le \sqrt{8m\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{2}{\delta}\right)}.$$

We further have (from London et al. (2016)) that

$$D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{1}{\delta_{j^\star}} \le \frac{3}{2}\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{2}{\delta}\right).$$

Thus, with probability at least $1-\delta$, all posteriors satisfy

$$\begin{aligned}
&\mathop{\mathbb{E}}_{Z\sim\mathbb{D}}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z)] - \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{h\sim\mathbb{Q}}[\mathcal{L}(h,Z^{(i)})] \\
&\quad\le \frac{1}{\epsilon_{j^\star}}\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{1}{\delta_{j^\star}}\right) + \frac{\epsilon_{j^\star}}{8m} \\
&\quad\le \frac{D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(1/\delta_{j^\star})}{\sqrt{2m(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(2/\delta))}} + \frac{\sqrt{8m(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(2/\delta))}}{8m} \\
&\quad\le \frac{3\left(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(2/\delta)\right)}{2\sqrt{2m(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(2/\delta))}} + \frac{\sqrt{8m(D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(2/\delta))}}{8m} \\
&\quad= 2\sqrt{\frac{D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln(2/\delta)}{2m}},
\end{aligned}$$

which completes the proof. ■

B.1. Proof of Theorem 1

The proof proceeds in three stages: First, we construct prior and posterior distributions. Both are uniform, but the posterior is centered at a learned hypothesis, and its support shrinks as the training data grows. This construction essentially means that we should trust the learned model more as we get more training data. In the second step, we upper-bound the KL divergence term—which is trivial given the uniform constructions. Finally, we show that, under the posterior construction, the loss of a random hypothesis is "close to" the loss of the learned hypothesis; specifically, that the difference between their losses is a small additive term that vanishes as the training set grows.

Let $\mathbb{P}$ denote a uniform prior over $\{w \in \mathbb{R}^d : \|w\|_2 \le R\}$. Given a learned weight vector, w, we construct a posterior, $\mathbb{Q}$, as a uniform distribution over $\{w' \in \mathbb{R}^d : \|w'\|_2 \le R,\ \|w'-w\|_2 \le 2\gamma/(mB)\}$. It can easily be shown (London et al., 2016, Appendix C.3) that

$$D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) \le d\ln(mBR/\gamma). \tag{37}$$

The next part of the proof "derandomizes" the loss functions in Equation 30, replacing the randomized hypothesis, with weights $w' \sim \mathbb{Q}$, with the deterministic predictor based on w. To do so, we will bound the difference $|\mathcal{L}_\gamma(w,x) - \mathcal{L}_\gamma(w',x)|$. We first note that the ramp function is $(1/\gamma)$-Lipschitz; that is, for any γ, x, w and w',

$$\left|\mathcal{L}_\gamma(w,x) - \mathcal{L}_\gamma(w',x)\right| \le \frac{1}{\gamma}\left|D(w,x) - D(w',x)\right|. \tag{38}$$

To upper-bound $|D(w,x) - D(w',x)|$, let

$$\begin{aligned}
\mu_F &\in \mathop{\arg\max}_{\mu\in\mathcal{V}_F} \theta(x;w)^\top\mu \quad\text{and}\quad \mu'_F \in \mathop{\arg\max}_{\mu\in\mathcal{V}_F} \theta(x;w')^\top\mu, \\
\mu_I &\in \mathop{\arg\max}_{\mu\in\mathcal{V}_I} \theta(x;w)^\top\mu \quad\text{and}\quad \mu'_I \in \mathop{\arg\max}_{\mu\in\mathcal{V}_I} \theta(x;w')^\top\mu,
\end{aligned}$$

and observe that

$$\begin{aligned}
\left|D(w,x) - D(w',x)\right| &= \left|\theta(x;w)^\top(\mu_F - \mu_I) - \theta(x;w')^\top(\mu'_F - \mu'_I)\right| \\
&\le \left|\theta(x;w)^\top\mu_F - \theta(x;w')^\top\mu'_F\right| \qquad (39) \\
&\quad + \left|\theta(x;w')^\top\mu'_I - \theta(x;w)^\top\mu_I\right|. \qquad (40)
\end{aligned}$$

We will upper-bound Equations 39 and 40 separately.

Starting with Equation 39, assume that $\theta(x;w)^\top\mu_F \ge \theta(x;w')^\top\mu'_F$. (If the inequality goes in the other direction, we simply swap the left and right terms, which is equivalent inside the absolute value.) We then have that

$$\begin{aligned}
\left|\theta(x;w)^\top\mu_F - \theta(x;w')^\top\mu'_F\right| &= \theta(x;w)^\top\mu_F - \theta(x;w')^\top\mu'_F \\
&\le \theta(x;w)^\top\mu_F - \theta(x;w')^\top\mu_F \\
&= (w-w')^\top\phi(x,\mu_F),
\end{aligned}$$

due to the optimality of μ'_F for $\theta(x;w')$. Then, using Cauchy-Schwarz,

$$(w-w')^\top\phi(x,\mu_F) \le \left\|w-w'\right\|_2 \|\phi(x,\mu_F)\|_2 \le \left\|w-w'\right\|_2 B.$$

An identical analysis of Equation 40 yields

$$\begin{aligned}
\left|\theta(x;w')^\top\mu'_I - \theta(x;w)^\top\mu_I\right| &= \theta(x;w')^\top\mu'_I - \theta(x;w)^\top\mu_I \\
&\le \theta(x;w')^\top\mu'_I - \theta(x;w)^\top\mu'_I \\
&= (w'-w)^\top\phi(x,\mu'_I) \\
&\le \left\|w'-w\right\|_2 \left\|\phi(x,\mu'_I)\right\|_2 \\
&\le \left\|w'-w\right\|_2 B.
\end{aligned}$$

By construction, every $w' \sim \mathbb{Q}$ has distance at most $2\gamma/(mB)$ from w. Therefore, substituting the above inequalities into Equations 39 and 40, we have that

$$\left|D(w,x) - D(w',x)\right| \le \left\|w-w'\right\|_2 B + \left\|w'-w\right\|_2 B \le \frac{2\gamma}{mB}\cdot 2B = \frac{4\gamma}{m};$$

and combining this bound with Equation 38 yields

$$\left|\mathcal{L}_\gamma(w,x) - \mathcal{L}_\gamma(w',x)\right| \le \frac{1}{\gamma}\cdot\frac{4\gamma}{m} = \frac{4}{m}.$$

Thus, the loss of any random weight vector, w', is at most $4/m$ above or below that of the learned weights, w. We can therefore derandomize the randomized loss by bounding its distance to the deterministic loss:

$$\left|\mathcal{L}_\gamma(w,x) - \mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_\gamma(w',x)]\right| \le \mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}\left[\left|\mathcal{L}_\gamma(w,x) - \mathcal{L}_\gamma(w',x)\right|\right] \le \frac{4}{m}.$$

Recalling $\mathcal{L}_0(w,x) \le \mathcal{L}_\gamma(w,x)$, we then have that

$$\mathop{\mathbb{E}}_{x\sim\mathbb{D}}[\mathcal{L}_0(w,x)] \le \mathop{\mathbb{E}}_{x\sim\mathbb{D}}[\mathcal{L}_\gamma(w,x)] \le \mathop{\mathbb{E}}_{x\sim\mathbb{D}}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_\gamma(w',x)] + \frac{4}{m} \tag{41}$$

$$\text{and} \quad \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_\gamma(w',x^{(i)})] \le \frac{1}{m}\sum_{i=1}^{m}\mathcal{L}_\gamma(w,x^{(i)}) + \frac{4}{m}. \tag{42}$$

All that remains is to put the pieces together. Via Lemma 3, with probability at least $1-\delta$ over draws of the training data,

$$\mathop{\mathbb{E}}_{x\sim\mathbb{D}}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_\gamma(w',x)] \le \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_\gamma(w',x^{(i)})] + 2\sqrt{\frac{D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) + \ln\frac{2}{\delta}}{2m}}.$$

To complete the proof, we use Equation 37 to upper-bound the KL divergence, Equation 41 to lower-bound the randomized risk and Equation 42 to upper-bound the empirical randomized risk.

B.2. Proof of Theorem 2

As we did in the previous proof, we define $\mathbb{P}$ as a uniform prior over $\{w \in \mathbb{R}^d : \|w\|_2 \le R\}$. Given w, we construct a posterior, $\mathbb{Q}$, as a uniform distribution over $\{w' \in \mathbb{R}^d : \|w'\|_2 \le R,\ \|w'-w\|_2 \le 2/(mB)\}$ (we omit γ), which yields $D_{\mathrm{KL}}(\mathbb{Q}\|\mathbb{P}) \le d\ln(mBR)$.

In what follows we use the fact that when one of the arguments of $D_1(\mu,\mu')$ (Eq. (18))—say, μ—is integral, $D_1(\mu,\mu')$ can be expressed as $\ell(\mu)^\top\mu'$, where

$$\ell(\mu) \triangleq \frac{1}{n}\begin{bmatrix}\mathbf{1}-\mu_{\mathrm{u}}\\ \mathbf{0}\end{bmatrix}. \tag{43}$$

To derandomize the loss of $w' \sim \mathbb{Q}$, we need to bound the difference $|\mathcal{L}_{\mathrm{r}}(w,x,\mu_I) - \mathcal{L}_{\mathrm{r}}(w',x,\mu_I)|$. Note that w' is being evaluated with respect to the MAP assignment under w, i.e., $\mu_I \in \arg\max_{\mu\in\mathcal{M}}\theta(x;w)^\top\mu$. To simplify notation, we will use the following shorthand:

$$\theta \triangleq \theta(x;w) \quad \text{and} \quad \theta' \triangleq \theta(x;w')\,;$$

$$\mu_L \in \mathop{\arg\max}_{\mu\in\mathcal{M}_L}\ \theta^\top\mu \quad \text{and} \quad \mu'_L \in \mathop{\arg\max}_{\mu\in\mathcal{M}_L}\ (\theta')^\top\mu\,;$$

$$\tilde{\mu}_L \in \mathop{\arg\max}_{\mu\in\mathcal{M}_L}\ (\ell(\mu_I)+\theta)^\top\mu \quad \text{and} \quad \tilde{\mu}'_L \in \mathop{\arg\max}_{\mu\in\mathcal{M}_L}\ (\ell(\mu_I)+\theta')^\top\mu.$$

We then have that the difference of ramp losses decomposes as

$$\begin{aligned}
&\left|\mathcal{L}_{\mathrm{r}}(w,x,\mu_I) - \mathcal{L}_{\mathrm{r}}(w',x,\mu_I)\right| \\
&\quad= \left|\Big((\ell(\mu_I)+\theta)^\top\tilde{\mu}_L - \theta^\top\mu_L\Big) - \Big((\ell(\mu_I)+\theta')^\top\tilde{\mu}'_L - (\theta')^\top\mu'_L\Big)\right| \\
&\quad\le \left|(\ell(\mu_I)+\theta)^\top\tilde{\mu}_L - (\ell(\mu_I)+\theta')^\top\tilde{\mu}'_L\right| &(44)\\
&\qquad+ \left|(\theta')^\top\mu'_L - \theta^\top\mu_L\right|. &(45)
\end{aligned}$$

Just as before, we will upper-bound Equations 44 and 45 separately.

We start with Equation 45, which is slightly simpler. Without loss of generality, assume that $(\theta')^\top\mu'_L \ge \theta^\top\mu_L$. Using the optimality of μ_L with respect to θ, we then have that

$$\begin{aligned}
\left|(\theta')^\top\mu'_L - \theta^\top\mu_L\right| &= (\theta')^\top\mu'_L - \theta^\top\mu_L \\
&\le (\theta')^\top\mu'_L - \theta^\top\mu'_L \\
&= (w'-w)^\top\phi(x,\mu'_L) \\
&\le \left\|w'-w\right\|_2\left\|\phi(x,\mu'_L)\right\|_2 \\
&\le \left\|w'-w\right\|_2 B.
\end{aligned}$$

By construction, every $w' \sim \mathbb{Q}$ has distance at most $2/(mB)$ from w, so

$$\left|(\theta')^\top\mu'_L - \theta^\top\mu_L\right| \le \left\|w'-w\right\|_2 B \le \frac{2}{mB}\cdot B = \frac{2}{m}. \tag{46}$$

Applying the same technique to Equation 44, we assume, without loss of generality, that $(\ell(\mu_I)+\theta)^\top\tilde{\mu}_L \ge (\ell(\mu_I)+\theta')^\top\tilde{\mu}'_L$. Then,

$$\begin{aligned}
\left|(\ell(\mu_I)+\theta)^\top\tilde{\mu}_L - (\ell(\mu_I)+\theta')^\top\tilde{\mu}'_L\right| &= (\ell(\mu_I)+\theta)^\top\tilde{\mu}_L - (\ell(\mu_I)+\theta')^\top\tilde{\mu}'_L \\
&\le (\ell(\mu_I)+\theta)^\top\tilde{\mu}_L - (\ell(\mu_I)+\theta')^\top\tilde{\mu}_L \\
&= (\theta-\theta')^\top\tilde{\mu}_L \\
&= (w-w')^\top\phi(x,\tilde{\mu}_L) \\
&\le \left\|w-w'\right\|_2 B \le \frac{2}{m}.
\end{aligned} \tag{47}$$

Substituting Equation 47 for 44, and Equation 46 for 45, we have that

$$\left|\mathcal{L}_{\mathrm{r}}(w,x,\mu_I) - \mathcal{L}_{\mathrm{r}}(w',x,\mu_I)\right| \le \frac{4}{m}\ ;$$

hence,

$$\left|\mathcal{L}_{\mathrm{r}}(w,x,\mu_I) - \mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_{\mathrm{r}}(w',x,\mu_I)]\right| \le \mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}\left[\left|\mathcal{L}_{\mathrm{r}}(w,x,\mu_I) - \mathcal{L}_{\mathrm{r}}(w',x,\mu_I)\right|\right] \le \frac{4}{m}.$$

Then, using the inequalities in Equation 22, we have that

$$\mathop{\mathbb{E}}_{x\sim\mathbb{D}}[\mathcal{L}_1(w,x,\mu_I)] \le \mathop{\mathbb{E}}_{x\sim\mathbb{D}}[\mathcal{L}_{\mathrm{r}}(w,x,\mu_I)] \le \mathop{\mathbb{E}}_{x\sim\mathbb{D}}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_{\mathrm{r}}(w',x,\mu_I)] + \frac{4}{m}, \tag{48}$$

and

$$\frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_{\mathrm{r}}(w',x^{(i)},\mu_I^{(i)})] \le \frac{1}{m}\sum_{i=1}^{m}\mathcal{L}_{\mathrm{r}}(w,x^{(i)},\mu_I^{(i)}) + \frac{4}{m}. \tag{49}$$

Finally, combining Lemma 3 with Equations 48 and 49 to lower- and upper-bound the randomized losses, we have that, with probability at least $1-\delta$ over draws of the training

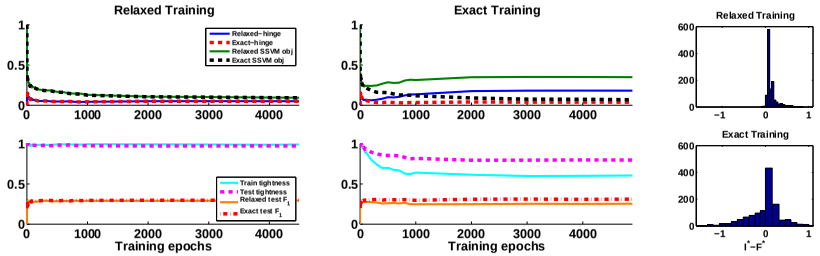

Figure 7: Training with a noisy version of the 'Scene' dataset. Various quantities of interest are shown as a function of training iterations. (Left) Training with LP relaxation. (Middle) Training with ILP. (Right) Integrality margin (bin widths are scaled differently).

set,

$$\begin{aligned}\mathop{\mathbb{E}}_{x\sim\mathbb{D}}[\mathcal{L}_1(w,x,\mu_I)] &\le \mathop{\mathbb{E}}_{x\sim\mathbb{D}}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_{\mathrm{r}}(w',x,\mu_I)] + \frac{4}{m} \\ &\le \frac{1}{m}\sum_{i=1}^{m}\mathop{\mathbb{E}}_{w'\sim\mathbb{Q}}[\mathcal{L}_{\mathrm{r}}(w',x^{(i)},\mu_I^{(i)})] + \frac{4}{m} + 2\sqrt{\frac{d\ln(mBR)+\ln\frac{2}{\delta}}{2m}} \\ &\le \frac{1}{m}\sum_{i=1}^{m}\mathcal{L}_{\mathrm{r}}(w,x^{(i)},\mu_I^{(i)}) + \frac{8}{m} + 2\sqrt{\frac{d\ln(mBR)+\ln\frac{2}{\delta}}{2m}}.\end{aligned}$$

Noting that the hinge loss uniformly upper-bounds the ramp loss completes the proof.

Appendix C. Additional Experimental Results

In this section we present additional experimental results for the 'Scene' dataset. Specifically, we inject random Gaussian noise to the input features in order to reduce the signal in the singleton scores and increase the role of the pairwise interactions. This makes the problem harder since the prediction needs to account for global information.

In Fig. 7 we observe that with exact training the exact loss is minimized, causing the exact-hinge to decrease, since it is upper bounded by the loss (middle, top). On the other hand, the relaxed-hinge (and relaxed loss) *increase* during training, which results in a large integrality gap and fewer tight instances. In contrast, with relaxed training the relaxed loss is minimized, which causes the relaxed-hinge to decrease. Since the exact-hinge is upper bounded by the relaxed-hinge it also decreases, but both hinge terms decrease similarly and remain very close to each other. This results in a small integrality gap and tightness of almost all instances.

Finally, in contrast to other settings, in Fig. 7 we observe that with exact training the test tightness is noticeably higher (about 20%) than the train tightness (Fig. 7, middle, bottom).

This does not contradict our bound from Theorem 1, since in fact the test fractionality is even *lower* than the bound suggests. On the other hand, this result does indicate that train and test tightness may sometimes behave differently, which means that we might need to increase the size of the trainset in order to get a tighter bound.

Abstract

The multi-armed restless bandit problem is studied in the case where the pay-off distributions are stationary φ-mixing. This version of the problem provides a more realistic model for most real-world applications, but cannot be optimally solved in practice, since it is known to be PSPACE-hard. The objective of this paper is to characterize a sub-class of the problem where *good* approximate solutions can be found using tractable approaches. Specifically, it is shown that under some conditions on the φ-mixing coefficients, a modified version of UCB can prove effective. The main challenge is that, unlike in the i.i.d. setting, the distributions of the sampled pay-offs may not have the same characteristics as those of the original bandit arms. In particular, the φ-mixing property does not necessarily carry over. This is overcome by carefully controlling the effect of a sampling policy on the pay-off distributions. Some of the proof techniques developed in this paper can be more generally used in the context of online sampling under dependence. Proposed algorithms are accompanied with corresponding regret analysis.

1. Introduction

As one of the simplest examples of sequential optimization under uncertainty, multi-armed bandit problems arise in various modern real-world applications, such as online advertisement, and Internet routing. These problems are typically studied under the assumption that the pay-offs are independently and identically distributed (i.i.d.), and the arms are independent. However, this assumption does not necessarily hold in many practical situations. Consider, for example, the problem of online advertisement in which the aim is to garner as many clicks as possible from a user. Grouping adverts into categories and associating with each category an arm, this problem turns into a multi-armed bandit. There is dependence over time and across the arms since, for example, we expect a user to be more likely to select adverts that are related to her selections in the recent past.

In this paper, we consider the multi-armed bandit problem in the case where the pay-offs are dependent and each arm evolves over time regardless of whether or not it is played. This is an instance of the so-called *restless* bandit problem (Whittle, 1988; Guha et al., 2010; Ortner et al., 2014). Since in this setting an optimal policy can leverage the inter-dependencies between the samples and switch between the arms at appropriate times, it can obtain an overall pay-off much higher than that given by playing the *best arm*, i.e. the distribution with the highest expected pay-off, see Example 1 in (Ortner et al., 2014). However, finding the best such *switching strategy* is PSPACE-hard, even in the case where the process distributions are Markovian with known dynamics (Papadimitriou and Tsitsiklis, 1999). Therefore, it is useful to consider relaxations of the problem with the aim to devise computationally tractable solutions that effectively approximate the optimal switching strategy. Approximations of the Markovian restless bandit problem *under known dynamics* have been previously considered, see, e.g. (Guha et al., 2010) and references therein. Our focus in this paper is on a more general setting, where the rewards have unknown distributions, exhibit long-range dependencies, and have Markov chains as a special case.

We are interested in a sub-class of the restless bandit problem, where the pay-offs have long-range dependencies. Since the nature of the problem calls for finite-time analysis, we further require that the dependence weakens over time, so as to make use of concentration inequalities in this setting. To this end, a natural approach is to assume that the pay-off distributions are stationary φ-mixing. The so-called φ-mixing coefficients $\varphi_n,\ n \in \mathbb{N}$, of a sequence of random variables $\langle X_t \rangle_{t\in\mathbb{N}}$ measure the amount of dependence between the sub-sequences of $\langle X_t \rangle_{t\in\mathbb{N}}$ separated by n time-steps. A process is said to be φ-mixing if this dependence vanishes with n. This notion is more formally defined in Section 2. In Markov chains φ-mixing coefficients are closely related to mixing times. The mixing time of a Markov chain is a measure of how fast its distribution approaches the stationary distribution. In particular, it is defined to be the time that it takes for the distribution to be within $1/4^{\text{th}}$ of the stationary distribution as measured in total variation distance (Levin et al., 2008)[Sec 4.5]. A classical result by Davydov shows that the decrease in distance of the distribution of the Markov chain to the stationary distribution is controlled (up to a factor of $1/2$) by the φ-mixing coefficients of the Markov chain (Doukhan, 1994)[pp.88]. While φ-mixing coefficients are related to the well-studied mixing properties of Markov chains, φ-mixing processes correspond to a wide variety of stochastic processes of which Markov chains are a special case (Doukhan, 1994).

As discussed earlier, the optimal, yet notoriously infeasible strategy for this version of the problem is to switch between the arms. In this paper, we first address the question of *when* a relaxation obtained by identifying the arm with the highest stationary mean would lead to a viable approximation in this setting. For this purpose, we characterize the approximation error in terms of the amount of dependence between the pay-offs, and show that if φ_1 is small, the optimum of the relaxed problem is close to that given by the optimal switching strategy. Observe that this condition translates directly to the pay-off distributions being weakly dependent. Next, we address the question of *how* an optimistic approach can be devised to identify the best arm. To this end, we propose a UCB-type algorithm and show that it achieves logarithmic regret with respect to the highest stationary mean. Interestingly, the amount of dependence in the form of $\sum_i \varphi_i$ appears in the bound, and in the case where the pay-offs are i.i.d., we recover the regret bound of Auer et al. (2002).

A familiar real-world example for the bandit problem considered in this paper corresponds to recommendation systems where the objective is to present personalized adverts, news-feeds or Massive Open Online Course (MOOC) material to each user. In these cases, depending on the specific application, each bandit arm could correspond to an appropriate subject category, indicating, for example, a genre of products or a class of topics. Once an arm is played, an item of the corresponding category could be selected at random and presented to the user. There are long-range dependencies between the pay-offs as reflected by the users' memory of their past observations. However, the dependence naturally decays over time, while users' short-term memory, which in turn influences the dominant mixing coefficients, can be controlled by capping the maximum frequency at which each specific recommendation is given to users. With minor modifications, this example carries over to a larger class of real-world sequential decision making problems which naturally possess a dependency structure imposed by users' memory.

Note that even this relaxed version of the problem is far from straightforward. The main challenge lies in obtaining confidence intervals around empirical estimates of the stationary means. Since Hoeffding-type concentration bounds exist for φ-mixing processes, it may be tempting to use such inequalities directly with standard UCB algorithms designed for the i.i.d. setting, to find the best arm. However, as we demonstrate in the paper, unlike in the i.i.d. setting, a policy in this framework may introduce strong couplings between past and future pay-offs in such a way that the distribution of the sampled sequence may not even be φ-mixing. This is the reason why a standard UCB algorithm designed for i.i.d. settings is not suitable here, even when equipped with a concentration bound for φ-mixing processes. In fact, this oversight seems to have occurred in previous literature, specifically in the Improved-UCB-based approach of Audiffren and Ralaivola (2015). We refer to Section 4.1 for a more detailed discussion. We circumvent these difficulties by carefully taking *random times*[1] into account and controlling the effect of a policy on the pay-off distributions. Some of our technical results can be more generally used to address the problem of online sampling under dependence.

Finally, while the study of the multi-armed bandit problem with *strongly* dependent pay-offs at its full generality is beyond the scope of this paper, we provide a complementary example for this regime. Specifically, we consider a setting where the bandit arms are governed by stationary Gaussian processes with slowly decaying covariance functions. Such high-dependence scenarios are quite common in practice. For instance, the throughput of radio channels changes slowly over time and the problem of choosing the best channel can be modeled by a bandit problem with strongly dependent pay-offs. The intuitive reason why in this setting it may also be possible to efficiently obtain approximately optimal solutions is that the strong dependencies can allow for the prediction of future rewards even from scarce observations. We give a simple switching strategy for this instance of the problem and show that it significantly outperforms a policy that aims for the best arm. Our regret bound for this algorithm directly reflects the dependence between the pay-offs: the higher the dependence the lower the regret.

A summary of our main contributions is listed below.

i. In an attempt to derive a computationally tractable solution for the restless bandit problem, we first identify a case where the optimal switching strategy can be approximated by playing the arm with the highest stationary mean. To this end, we show that the loss of settling for the highest stationary mean as opposed to finding the best switching strategy is controlled by the amount of inter-dependence as reflected by φ_1. This is shown in Proposition 9.

ii. We provide a detailed example, namely Example 1, where we demonstrate the challenges in the non-i.i.d. bandit problem. In particular, we show that a policy in this framework may introduce strong couplings between past and future pay-offs in such a way that the resulting pay-off sequence may have a completely different dependency structure.

iii. We develop technical machinery to circumvent the difficulties introduced by the inter-dependence between the rewards, and allow us to control the effect of a policy on the pay-off distributions. Some of our derivations concerning sampling under dependence can be of independent interest. We further propose a UCB-type algorithm, namely Algorithm 1 that deploys these tools to identify the arm with the highest stationary mean.

1. These correspond to random variables which determine the time at which an arm is sampled.

iv. We provide an upper bound on the regret of Algorithm 1 (with respect to the highest stationary mean). This is provided in Theorem 12. The regret bound is a function of the amount of inter-dependence as reflected by the φ-mixing coefficients, and in the case where the pay-offs are i.i.d., we recover the regret bound of Auer et al. (2002)[Thm. 1]. This result along with Proposition 9 allow us to argue that in the case where dependence is low Algorithm 1 can be used to approximate the best switching strategy.

The remainder of the paper is organized as follows. In Section 2 we introduce preliminary notation and definitions. We formulate the problem in Section 3 and give our main results in Section 4. We conclude in Section 5 with a discussion of open problems.

2. Preliminaries

We start with some useful notation before discussing basic definitions concerning stochastic processes. Since the bandit problem involves multiple arms (processes), we extend the definition of a φ-mixing process to what we call a jointly φ-mixing process, to be able to model the multi-armed bandit problem. Indeed, in many natural settings, the process is jointly φ-mixing. For example, as we demonstrate in Proposition 5, independent Markov chains are jointly φ-mixing.

Notation. Let $\mathbb{N}_+ := \{1, 2, \ldots\}$ and $\overline{\mathbb{N}} := \mathbb{N} \cup \{\infty\}$ denote the set and extended set of natural numbers respectively. We introduce the abbreviation $\mathbf{a}_{m..n},\ m, n \in \mathbb{N}_+, m \leq n$, for sequences $a_m, a_{m+1}, \ldots, a_n$. Given a finite subset $C \subset \mathbb{N}_+$ and a sequence $\mathbf{a}$, we let $\mathbf{a}_C := \{a_i : i \in C\}$ denote the set of elements of $\mathbf{a}$ indexed by C. If X_C is a sequence of random variables indexed by $C \subset \mathbb{N}_+$, we denote by $\sigma(X_C)$ the smallest σ-algebra generated by X_C.

Notion of φ-dependence. Part of our results concern the so-called φ-dependence between σ-algebras defined as follows, see, e.g. (Doukhan, 1994).

Definition 1 *Consider a probability space $(\Omega, \mathcal{A}, P)$ and let $\mathcal{U}$ and $\mathcal{V}$ denote σ-subalgebras of $\mathcal{A}$ respectively. The φ-dependence between $\mathcal{U}$ and $\mathcal{V}$ is is given by*

$$\varphi(\mathcal{U}, \mathcal{V}) := \sup\{|P(V) - P(V|U)| : U \in \mathcal{U}, P(U) > 0, V \in \mathcal{V}\}.$$

If X and Y are two random variables measurable with respect to $\mathcal{A}$ we simplify notation by letting $\varphi(X, Y) := \varphi(\sigma(X), \sigma(Y))$ denote the φ-dependence between their corresponding σ-algebras; distinction will be clear from the context. Similarly, if X_A and X_B are finite sequences of random variables, with $A, B \subset \mathbb{N}_+$ their φ-dependence can be similarly defined as

$$\varphi(X_A, X_B) := \varphi(\sigma(X_A), \sigma(X_B)).$$

In words, $\varphi(X_A, X_B)$ measures the maximal difference between the probability of an event V and its conditional probability given an event U, where U and V are determined by random variables indexed by A and B respectively. The notion of φ-dependence carries over from probability measures to expectations. In particular, consider a real-valued random variable X defined on some probability space $(\Omega, \mathcal{A}, P)$, and denote by $\mathcal{G}$ some collected information in the form of a σ-subalgebra of $\mathcal{A}$. Let $E(X|\mathcal{G})$ denote Kolmogorov's conditional expectation, i.e. a $\mathcal{G}$-measurable random variable Z such that $\int_B Z = \int_B X$ for all $B \in \mathcal{G}$. As follows from Theorem 2 below, due to Bradley (2007)[vol. 1 pp. 124], the difference between $E(X|\mathcal{G})$ and EX is effectively upper-bounded by $\varphi(\mathcal{G}, \sigma(X))$.

Theorem 2 (Bradley (2007)) *Let $(\Omega, \mathcal{A}, P)$ be a probability space, let X be a real-valued random variable with $\|X\|_1 < \infty$ and let $\mathcal{G}$ be some σ-subalgebra of $\mathcal{A}$. Then*

$$2\varphi(\mathcal{G}, \sigma(X)) = \sup \|E(Y|\mathcal{G}) - E(Y)\|_1 / \|Y\|_1, \tag{1}$$

where the supremum is taken over all $\sigma(X)$-measurable random variables Y with $\|Y\|_1 < \infty$. Furthermore, for any $B \in \mathcal{G}$ it holds that

$$\int_B |E(X|\mathcal{G}) - E(X)|\, dP \leq 2P(B)\|X\|_\infty \varphi(\mathcal{G}, \sigma(X)). \tag{2}$$

Observe that because X is trivially $\sigma(X)$-measurable (1) given in the theorem implies that

$$\|E(X|\mathcal{G}) - E(X)\|_1 \leq 2\|X\|_1 \varphi(\mathcal{G}, \sigma(X)).$$

Stochastic Processes & φ-mixing Properties. Let $(\mathcal{X}, \mathcal{B}_\mathcal{X})$ be a measurable space; we let $\mathcal{X} \subset [0,1]$ [2] and denote by $\mathcal{B}_\mathcal{X}^{(m)}$ the Borel σ-algebra on $\mathcal{X}^m,\ m \in \mathbb{N}_+$. We denote by $\mathcal{X}^\infty$ the set of all $\mathcal{X}$-valued infinite sequences indexed by $\mathbb{N}_+$. A stochastic process can be modeled as a probability measure over the space $(\mathcal{X}^\infty, \mathcal{B})$ where $\mathcal{B}$ denotes the σ-algebra on $\mathcal{X}^\infty$ generated by the cylinder sets. Associated with the stochastic process is a sequence of random variables $X_1, X_2, \ldots$, where $X_t : \mathcal{X}^\infty \to \mathcal{X}$ is the projection onto the t'th element, i.e. $X_t(\omega) = \omega_t$ for $\omega \in \mathcal{X}^\infty$ and $t \in \mathbb{N}_+$. A process ρ is stationary if $\rho(X_{1..m} \in B) = \rho(X_{i+1..i+m} \in B)$ for all Borel sets $B \in \mathcal{B}_\mathcal{X}^{(m)}$, $i, m \in \mathbb{N}_+$. The term *stochastic process* refers to either the process distribution ρ or the associated sequence of random variables $X_t,\ t \in \mathbb{N}_+$; reference will be clear from the context.

Definition 3 (Stationary φ-mixing Process) *Consider a stationary stochastic process $\langle X_i \rangle_{i \in \mathbb{N}_+}$. Its φ-mixing coefficients are given by*

$$\varphi_n := \sup_{u,v \in \mathbb{N}_+} \varphi(X_{1..u}, X_{u+n..u+n+v-1}),\ n \in \mathbb{N}_+$$

and measure the φ-dependence between $\sigma(X_{1..u})$ and $\sigma(X_{u+n..u+n+v-1})$

$$\underbrace{X_1, \ldots, X_u} \ \leftarrow \textit{gap of length } n \rightarrow \ \underbrace{X_{u+n}, \ldots, X_{u+n+v-1}}$$

The process is said to be φ-mixing if $\lim_{n\to\infty} \varphi_n = 0$.

When modeling a bandit problem in this paper, we are concerned with some $k \in \mathbb{N}_+$ stochastic processes with a joint distribution that is stationary φ-mixing. More specifically, for a fixed $k \in \mathbb{N}$, let $(\Omega, \mathcal{A}, P)$ be a probability space where $\Omega := \Omega_1 \times \ldots \times \Omega_k$ with $\Omega_i := \mathcal{X}^\infty,\ i \in 1..k$, P a probability measure and $\mathcal{A}$ obtained via the cylinder sets. Let $\mathcal{B}_\mathcal{X}^{(m,k)}$ denote the Borel σ-algebra on $(\mathcal{X}^m)^k,\ m \in \mathbb{N}_+$. In much the same way as with the single-process described above, associated with the joint process is a sequence of random variables $\langle X_{t,j} \rangle,\ t \in \mathbb{N}_+, j \in 1..k$ where $X_{t,j} : \Omega \to \mathcal{X}$ is the projection on to the t, j-th element, i.e. $X_{t,j}(\omega) = \omega_{t,j}$ for $\omega \in \Omega,\ t \in \mathbb{N}_+, j \in 1..k$. The measure P is stationary if $P(X_{1..m,1..k} \in B) = P(X_{i+1..i+m,1..k} \in B)$ for every $B \in \mathcal{B}_\mathcal{X}^{(m,k)}$ and $i, m \in \mathbb{N}_+$. As above, the term stochastic process is used interchangeably to correspond to the sequence of random variables $\langle X_{t,j} \rangle,\ t \in \mathbb{N}_+, j \in 1..k$ or their corresponding joint measure P.

2. More generally $\mathcal{X}$ can be a finite set or a closed interval $[a, b]$, for $a < b, a, b \in \mathbb{R}$.

Definition 4 (Jointly Stationary φ-mixing Processes) *For a fixed $k \in \mathbb{N}_+$, consider a stationary process $\langle X_{t,j} \rangle,\ t \in \mathbb{N}_+, j \in 1..k$. Its φ-mixing coefficients are given by*

$$\varphi_n := \sup_{u,v \in \mathbb{N}_+} \varphi(X_{1..u,1..k}, X_{u+n..u+n+v-1,1..k}),\ n \in \mathbb{N}_+$$

and measure the φ-dependence between $\sigma(X_{1..u,1..k})$ and $\sigma(X_{u+n..u+n+v-1,1..k})$. The process is said to be jointly φ-mixing if $\lim_{n\to\infty} \varphi_n = 0$.

We use φ_n to denote the φ-mixing coefficient corresponding to a single process or to a joint process given by Definitions 3 and 4 respectively; the notion will be apparent from the context. Under the assumption that the joint process is stationary φ-mixing, there could be dependence between the processes, as the mixing requirement needs only to be fulfilled by the joint process. The assumption that the process is jointly φ-mixing is fulfilled by a variety of well-known models, including independent Markov chains. More generally, as follows from Proposition 5 below, if we have k independent ψ-mixing processes then the joint process is φ-mixing. The ψ-mixing property is defined in the same way as φ-mixing whereby the φ-dependence given by Definition 1 is replaced with

$$\psi(\mathcal{U}, \mathcal{V}) := \sup\{|1 - \rho(U \cap V)/(\rho(V)\rho(U))| : U \in \mathcal{U},\ \rho(U) > 0, V \in \mathcal{V}, \rho(V) > 0\},$$

and the ψ-mixing coefficients are defined in a manner analogous to Definitions 3. A ψ-mixing process is also φ-mixing and the ψ-mixing coefficients upper bound φ-mixing coefficients.

Proposition 5 *Let $(\Omega, \mathcal{A}, P)$ be some probability space with k mutually independent processes defined on it. If each of these processes is ψ-mixing then the joint process is also ψ-mixing and for all $i \in \mathbb{N}$, $1 + \tilde{\psi}_i \leq (1 + \psi_i)^k$, where $\tilde{\psi}_i$ are the mixing coefficients of the joint process and the ψ_i are upper-bounds on the mixing coefficients of the individual processes.*

The proof is provided in Appendix A.2. Using the above result, it can be shown that independent Markov chains are jointly φ-mixing. More specifically, we have the following example.

Corollary 6 (Independent Markov chains are jointly φ-mixing.) *A set of $k \in \mathbb{N}_+$ mutually independent, stationary ergodic, finite-state Markov processes $\rho_i,\ i = 1..k$ give rise to a jointly stationary φ-mixing process.*

Proof By Theorem 3.1 of Bradley (2005) each process $\rho_i,\ i = 1..k$ is ψ-mixing. Moreover, by Proposition 5 above, k mutually independent ψ-mixing processes are jointly φ-mixing. As a result $\rho_i,\ i = 1..k$, are jointly stationary φ-mixing. ■

The significance of the above observation is that jointly φ-mixing processes have mutually independent Markov processes as special case.

3. Problem Formulation: the Jointly φ-mixing Bandit Problem.

We assume in the sequel that a total of $k < \infty$ bandit arms are given, where for each $i \in 1..k$, arm i corresponds to a stationary process that generates a time series of pay-offs $X_{1,i}, X_{2,i}, \ldots$ Furthermore, we assume that the joint process over the k arms is φ-mixing in the sense of Definition 4, and that its sequence of mixing coefficients is summable, i.e. $\|\varphi\| := \sum_{i=1}^\infty \varphi_i < \infty$. Each process has

stationary mean $\mu_i,\ i = 1..k$ and we denote by $\mu^* := \max\{\mu_1, \ldots, \mu_k\}$ the highest stationary mean. We sometimes denote the arm with the highest stationary mean as the *best arm*. At every time-step $t \in \mathbb{N}_+$, a player chooses one of k arms according to a policy π_t and receives a reward X_{t,π_t}. The player's objective is to maximize the sum of the pay-offs received. The policy has access only to the pay-offs gained at earlier stages and to the arms it has chosen. Let $\langle \mathcal{F}_t \rangle_{t\geq 0}$ be a filtration that tracks the pay-offs obtained in the past t rounds, i.e. $\mathcal{F}_0 = \{\emptyset, \Omega\}$, and $\mathcal{F}_t = \sigma(X_{1,\pi_1}, \ldots, X_{t,\pi_t}),\ t \geq 1$. A policy is a sequence of mappings $\pi_t : \Omega \to \{1, \ldots, k\}$, $t \geq 1$, each of which is measurable with respect to $\mathcal{F}_{t-1}$. Note that the assumption that $\pi_t,\ t \geq 1$ is measurable with respect to $\mathcal{F}_{t-1}$ is equivalent to the assumption that the policy can be written as a function of the past pay-offs and chosen arms, see, e.g. (Shiryaev, 1991)[Thm. 3, pp.174]. Let $\Pi = \{\pi := \langle \pi_t \rangle_{t\geq 1} : \pi_t \text{ is } \mathcal{F}_{t-1}\text{-measurable for all } t \geq 1\}$ denote the space of all possible policies. We also let $\mathcal{G}_t$ denote the filtration that keeps track of all the information available up to time t (including unobserved pay-offs). More specifically, let $\langle \mathcal{G}_t \rangle_{t\geq 0}$, $\mathcal{G}_0 = \mathcal{N}$ and $\mathcal{G}_t = \sigma(\bigcup_{i=1}^k \bigcup_{s=1}^t \sigma(X_{s,i}) \cup \mathcal{N})$ for $t \geq 1$, where $\mathcal{N}$ is the family of measurable sets of P-measure zero. We define the maximal value that can be achieved in n rounds as

$$v_n^* = \sup_{\pi\in\Pi} \sum_{t=1}^{n} E X_{t,\pi_t}. \tag{3}$$

The regret that builds up over n rounds for any strategy π is

$$\mathcal{R}_\pi(n) := v_n^* - E(X_{t,\pi_t}). \tag{4}$$

To simplify notation, we may use $\mathcal{R}(n)$ when the policy π is clear from the context.

Remark 7 *Requiring $\|\varphi\| < \infty$, which is standard in the literature on empirical process theory involving mixing processes, does not lead to a strong assumption. This condition is already fulfilled by any stationary ergodic finite-state Markov chain, see, e.g. (Bradley, 2005). In fact, as follows from Theorem 3.4 of Bradley (2005) the φ-mixing coefficient corresponding to any (not necessarily stationary) φ-mixing Markov process has an exponentially fast rate of decay, giving rise to a summable sequence of φ-mixing coefficients. Note that our focus in the sequel is on the more general case of φ-mixing (not necessarily Markov) processes.*

4. Main Results

We consider the restless bandit problem in a setting where the reward distributions are jointly φ-mixing as formulated in Section 3. Recall that, while the optimal strategy in this case is to switch between the arms, obtaining the best switching strategy is PSPACE-hard. We address the question of *when* and *how* a good and computationally tractable approximation of the optimal policy can be obtained in this setting. The former question is answered in Section 4.2 where we characterize (in terms of φ_1) the loss of settling for the highest stationary mean as opposed to following the best switching strategy. We show that for small φ-mixing coefficients, the optimum of this relaxed problem is close to that given by v_n^*. To answer the latter, we devise a UCB-type algorithm in Section 4.3 to identify the arm with the highest stationary mean. The main challenge lies in building confidence intervals around empirical estimates of the stationary means. Indeed, as we demonstrate in Section 4.1, unlike in the i.i.d. setting, a policy in this framework may introduce strong couplings between past and future pay-offs in such a way that the resulting pay-off sequence may not even be φ-mixing. As a result, a standard UCB algorithm designed for an i.i.d. setting is not suitable

here, even when equipped with a Hoeffding-type concentration bound for φ-mixing processes. We circumvent these difficulties in Sections 4.2 and 4.3 by controlling the effect of a policy on the pay-off distributions. Part of the analysis in these two sections relies on some technical results for φ-mixing processes outlined in Appendix A.1, which may be of independent interest. Finally, our results for the weakly dependent reward distributions are complemented in Section 4.4, where we study an example of a class of strongly dependent processes and give a simple switching strategy that significantly outperforms a policy that aims for the best arm.

4.1. Policies, Random Times, and the φ-mixing Property

Recall that a policy $\pi_t,\ t \in \mathbb{N}_+$ is a function which based on the past (observed) data samples one of k bandit arms at time-step t. Therefore, since this decision is based on samples generated by a random process, the times at which bandit arms are played can be naturally modeled via *random times*. More formally, denote by $\tau_{i,j} : \Omega \to \mathbb{N}_+$ a random variable which determines the time at which the j-th arm is sampled for the i-th time, $i \in \mathbb{N}_+$ and $j \in 1..k$, and observe that for any $t \in \mathbb{N}$ the event $\{\tau_{i,j} = t\}$ is in $\mathcal{F}_{t-1}$. We denote by

$$X_{\tau_i,j} := \sum_{t\in\mathbb{N}_+} \chi\{\tau_{i,j} = t\} X_{t,j}$$

the pay-off obtained from sampling arm j at random time $\tau_{i,j}$ for any $i \in \mathbb{N}_+,\ j \in 1..k$, where χ is the indicator function, i.e. $\chi\{\tau_{i,j} = t\}$ is 1 for all $\omega \in \Omega$ such that $\tau_{i,j}(\omega) = t$, and is 0 otherwise.

The main challenge in devising a policy for the φ-mixing bandit problem is that, depending on the policy used, the dependence structure of the pay-off sequence $X_{\tau_1,j},\ X_{\tau_2,j}, \ldots$, for $j \in 1..k$ may be completely different from that of $X_{1,j},\ X_{2,j}, \ldots$. Note that this differs from the simpler i.i.d. setting where the distribution of the j-th arm (with all its characteristics) carries over to that of the sampled sequence. This is illustrated in Example 1 below.

Example 1 *Consider a two-armed bandit problem where the second arm is deterministically set to 0, i.e. $X_{t,2} = 0,\ t \in \mathbb{N}_+$ and the first arm has a process distribution described by a two state Markov chain with the initial distribution and stationary distribution over the states both being $(1/2\ \ 1/2)^\top$ and with the following transition matrix,*

$$T = \begin{pmatrix} 1-\epsilon & \epsilon \\ \epsilon & 1-\epsilon \end{pmatrix}, \quad \text{with some } \epsilon \in (0, 1).$$

Observe that for this process, if ϵ is small, with high probability the Markov chain stays in its current state. Now consider a policy π, and denote by $\tau_1, \tau_2, \ldots$ the sequence of random times at which π samples the first arm according to the following simple rule. Set $\tau_1 = 1$. For subsequent random times, if $X_{\tau_n,1} = X_{1,1}$ for $n \in \mathbb{N}_+$ then $\tau_{n+1} = \tau_n + 1$. Otherwise, τ_{n+1} is set to be significantly larger than τ_n to guarantee that the distribution of $X_{\tau_{n+1},1}$ given $X_{\tau_n,1}$ is close to the stationary distribution of the Markov chain, during which time the first arm is sampled. The sequence $X_{\tau_1,1}, X_{\tau_2,1}, \ldots$ so generated is highly dependent on $X_{1,1}$ and is not φ-mixing. In fact, the expected pay-offs given the first observation, i.e. $E(X_{\tau_n,1}|X_{1,1}),\ n \in \mathbb{N}_+$, are very different from the stationary mean $EX_{1,1}$ if ϵ is small. In particular, $EX_{1,1} = 0.5$ while $E(X_{\tau_n,1}|X_{1,1} = 1)$ is at least $1/(1 + 2\epsilon) - 1/10$ due to Equation (41) on page 28 and, hence, for $\epsilon \leq 0.01$ we have that $E(X_{\tau_n,1}|X_{1,1} = 1) \geq 0.8$.

A more detailed treatment of the above example is given in Appendix A.4.

Indeed, it is a policy's access to the (observed) past data which can lead to strong couplings between past and future pay-offs in this framework. This point has been overlooked in the work of Audiffren and Ralaivola (2015) which relies on Improved-UCB (Auer and Ortner, 2010) to identify the arm with the highest stationary mean, by eliminating potentially sub-optimal arms. The elimination process depends on the data, and the time-steps at which a particular arm is played depend on the remaining arms. Hence, random times and the policy's memory have to be carefully taken into consideration, as the process distribution of the sampled sequence is different from that of the corresponding arm. This notion has not been accounted for in their algorithm, and the confidence intervals involved correspond to the distributions of the arms, and not to those of the sampled sequences, and are therefore invalid in this non-i.i.d. setting.

4.2. Approximation Error

We start by translating φ-mixing properties to those of expectations in order to control the difference between what a switching strategy can achieve as compared to the highest stationary mean. Prior to delving into the bandit problem we consider a single bounded real-valued stationary φ-mixing process $\langle X_t\rangle_{t\in\mathbb{N}_+}$ sampled at random times $\tau_1 < \tau_2 < \ldots$, where $\tau_i,\ i \in \mathbb{N}_+$, is fully defined by the past observations $X_{\tau_1}, \ldots, X_{\tau_{i-1}}$. We control the difference between the mean of the sampled process $\langle X_{\tau_i}\rangle_{i\in\mathbb{N}_+}$ from the stationary mean of the original process. The following proposition shows that the difference in the means is controlled by the φ-mixing coefficients and the increments in the stopping times; the proof is provided in Appendix A.3.

Proposition 8 *Assume that $\langle X_t\rangle_{t\in\mathbb{N}_+}$ is a stationary φ-mixing process with mixing coefficients $\langle\varphi_i\rangle_{i\in\mathbb{N}_+}$ such that $EX_t = \mu,\ t \in \mathbb{N}_+$, and $\sup_{t\in\mathbb{N}_+} |X_t| \leq c$ for some $c \in [0,\infty)$. Furthermore, let $\tau_1, \tau_2, \ldots$ be a sequence of random times such that $\tau_i + \ell \leq \tau_{i+1}$ a.s. for some $\ell \geq 1$ and all $i \in \mathbb{N}_+$, and all τ_{i+1} are $\sigma(X_{\tau_1}, \ldots, X_{\tau_i})$- measurable with $\tau_1 \in \mathbb{N}_+$ being a fixed time. Then for any $n \in \mathbb{N}_+$*

$$\Big|\frac{1}{n}\sum_{i=1}^{n} EX_{\tau_i} - \mu\Big| \leq 2c\varphi_\ell.$$

In other words, when using the sample mean of the sampled process as an estimate of the stationary mean then the bias of the estimator is bounded through the φ_ℓ-mixing coefficient. This result has further implications, in particular, it is telling us something about the leverage a switching policy has. A switching policy selects effectively random times for each arm at which the arm is played and this result is saying that the summed pay-off it can gather cannot be more than $2cn\varphi_\ell$ larger than the stationary mean of the arm. Now, a policy is free to play the arms at any time and we only know that $\tau_{i+1} \geq \tau_i + 1$ for any random time τ_i, i.e. $\ell = 1$. This intuition underlies the following proposition.

Proposition 9 *Consider the jointly stationary φ-mixing bandit problem formulated in Section 3. Let $\mu_1, \ldots, \mu_k$ be the means of the stationary distributions and let $\mu^* := \max\{\mu_1, \ldots, \mu_k\}$. Let φ_1 be the first φ-mixing coefficient as given by Definition 4. For every $n \geq 1$ we have*

$$v_n^* - n\mu^* \leq 2n\varphi_1.$$

Proof Consider an arbitrary policy $\langle\pi_t\rangle_{t\in\mathbb{N}_+}$ and an arbitrary $t \in \mathbb{N}_+$ then

$$EX_{t,\pi_t} = \sum_{j=1}^{k}\sum_{i=1}^{t} EX_{t,j} \times \chi\{\tau_{i,j} = t\}.$$

Recall the definition of $\mathcal{G}_{t-1}$ in Section 3 and observe that $\tau_{i,j}$ is $\mathcal{G}_{t-1}$-measurable. Hence, we have with $B = \{\tau_{i,j} = t\}$ that

$$EX_{t,j} \times \chi\{\tau_{i,j} = t\} = EE(X_{t,j}|\mathcal{G}_{t-1}) \times \chi\{\tau_{i,j} = t\} = \int_B E(X_{t,j}|\mathcal{G}_{t-1}).$$

We can extend the φ-mixing property of the joint process from $\sigma(X_{11}, \ldots, X_{tk})$to $\mathcal{G}_t$ by applying Lemma A.2 and we get

$$\Big|\int_B (E(X_{t,j}|\mathcal{G}_{t-1}) - EX_{1,j})\Big| \leq 2\varphi_1 P(B).$$

Since the different sets $\{\tau_{i,j} = t\}, j \in \{1, \ldots, k\}, i \in \{1, \ldots, t\}$ are disjoint

$$\begin{aligned} EX_{t,\pi_t} - \mu^* &\leq \sum_{j=1}^{k}\sum_{i=1}^{t}(EX_{t,j} \times \chi\{\tau_{i,j} = t\} - P(\tau_{i,j} = t)EX_{1,j}) \\ &\leq 2\varphi_1 \sum_{j=1}^{k}\sum_{i=1}^{t} P(\tau_{i,j} = t) \\ &\leq 2\varphi_1. \end{aligned}$$

■

Observe that this relaxation introduces an inevitable linear component to the regret as shown by Proposition 9. However, we argue that if the reward distributions are weakly dependent in the sense that φ_1 is small, we may settle for the best arm instead of following the best switching strategy.

4.3. An Optimistic Approach

In this section we propose a UCB-type algorithm to identify the arm with the highest stationary mean in a jointly φ-mixing bandit problem. Consider the bandit problem described in Section 3, where we have k arms each with a bounded stationary pay-off sequence such that the joint process is stationary φ-mixing. Suppose that the processes are weakly dependent in the sense that $\varphi_1 \leq \epsilon$ for some small ϵ. As discussed in Section 4.2, in this case a policy to settle for the best arm can serve as a good approximation for the best switching strategy. More specifically, let

$$\overline{\mathcal{R}}_\pi(n) := n\mu^* - \sum_{t=1}^{n} EX_{t,\pi_t}$$

denote the regret of a policy π with respect to the arm with the highest stationary mean. From Proposition 9 we have $\frac{1}{n}(\mathcal{R}_\pi(n) - \overline{\mathcal{R}}_\pi(n)) \leq \epsilon$ and our objective in this section is to minimize $\overline{\mathcal{R}}_\pi$.

Recall that in light of the arguments provided in Section 4.1 it is crucial to take a policy's access to past (observed) data into account when devising a strategy for the bandit problem in this framework.

To address the challenge induced by the inter-dependent reward sequences obtained at random times, our approach relies on the following key observation. Suppose we obtain a sequence of $m \in \mathbb{N}_+$ consecutive samples $X_{\tau,i}, X_{\tau+1,i}, \ldots, X_{\tau+m,i}$ from arm $i \in 1..k$ starting at a random time τ. For a long batch, i.e. large enough m, the average expectations $\frac{1}{m}\sum_{j=0}^{m-1} EX_{\tau+j,i}$ become close to the stationary mean μ_i. More formally we have Lemma 10 below.

Lemma 10 *For a fixed $i \in 1..k$ and $m \in \mathbb{N}_+$, consider the consecutive samples $X_{\tau,i}, X_{\tau+1,i}, \ldots, X_{\tau+m,i}$, where $\tau : \Omega \to \mathbb{N}_+$ is a random time at which the i-th arm is sampled. Let μ_i denote the stationary mean of arm i. We have*

$$\left|\mu_i - \frac{1}{m}\sum_{j=0}^{m-1} EX_{\tau+j,i}\right| \leq \frac{2}{m}\left\|\varphi\right\|.$$

Proof For simplicity of notation we denote $X_{t,i}$ by X_t and $X_{\tau,i}$ by X_τ. Recall that $\mathcal{G}_t$ denotes the filtration that keeps track of all the information available up to time t (including unobserved pay-offs). Observe that $\chi\{\tau = t\}$ is $\mathcal{G}_{t-1}$-measurable so that the event $\{\tau = t\}$ is in $\mathcal{G}_{t-1}$ for all $t \in \mathbb{N}_+$. As a result, for any $t \in \mathbb{N}_+$ and $j \in 0..m-1$ we have

$$E(\chi\{\tau = t\}X_{t+j}|\mathcal{G}_{t-1}) = \chi\{\tau = t\}E(X_{t+j}|\mathcal{G}_{t-1}), \tag{5}$$

see, e.g. (Shiryaev, 1991)[pp.216]. We obtain

$$\begin{aligned}
\left|m\mu_i - \sum_{j=0}^{m-1} EX_{\tau+j,i}\right| &= \left|\sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} E(\chi\{\tau = t\}X_{t+j}) - E\chi\{\tau = t\}EX_t\right| && (6)\\
&= \left|\sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} EE(\chi\{\tau = t\}X_{t+j}|\mathcal{G}_{t-1}) - E\chi\{\tau = t\}EX_t\right| && (7)\\
&= \left|\sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} E(\chi\{\tau = t\}E(X_{t+j}|\mathcal{G}_{t-1})) - E\chi\{\tau = t\}EX_t\right| && (8)\\
&\leq \sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} E\big(\chi\{\tau = t\}|E(X_{t+j}|\mathcal{G}_{t-1}) - EX_t|\big) && (9)\\
&= \sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} E\big(\chi\{\tau = t\}|E(X_{t+j}|\mathcal{G}_{t-1}) - EX_{t+j}|\big) && (10)\\
&= \sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} \int_{\{\tau=t\}} |E(X_{t+j}|\mathcal{G}_{t-1}) - EX_{t+j}|\\
&\leq \sum_{t\in\mathbb{N}_+}\sum_{j=0}^{m-1} 2\varphi(\mathcal{G}_{t-1}, \sigma(X_{t+j}))E\chi\{\tau = t\} && (11)\\
&\leq \sum_{t\in\mathbb{N}_+}\sum_{j=1}^{m} 2\varphi_j E\chi\{\tau = t\} && (12)\\
&\leq 2\left\|\varphi\right\| && (13)
\end{aligned}$$

Algorithm 1 A UCB-type Algorithm for φ-mixing bandits.

Input: Number k of arms; Sum $\|\varphi\| := \sum_{i=1}^{\infty}\varphi_i$ of mixing coefficients[3]

Initialization: Play each arm once and update the empirical mean for each arm

for $i = 1..k$ **do**
  $\overline{X}_i \leftarrow X_i$
  $s_i \leftarrow 1$ ▷ $s_i,\ i = 1..k$ denotes the number of times arm i has been *selected*

Main Loop:

for $t = 1..\infty$ **do**

Arm Selection: Select the arm that maximizes the following UCB

$$j \leftarrow \min\left(\operatorname*{argmax}_{u\in 1..k} \overline{X}_u + \sqrt{\frac{8\xi(\frac{1}{8}+\ln t)}{2^{s_u}}} + \frac{\|\varphi\|}{2^{s_u-1}}\right),\ \text{where } \xi := 1 + 8\left\|\varphi\right\|$$

▷ *The min operator is used to give precedence to the smaller arm-index in the case of a tie.*

Update: Play arm j for 2^{s_j} consecutive iterations and update the empirical mean accordingly.

$$t_j \leftarrow t \qquad t \leftarrow t + 2^{s_j} \qquad \overline{X}_j \leftarrow \frac{1}{2^{s_j}}\sum_{t'=t_j}^{t-1} X_{t',j} \qquad s_j \leftarrow s_j + 1$$

where (6) and (7) are due to stationarity and the law of total expectation respectively, (8) follows from (5), (10) follows from stationarity, (11) follows from Theorem 2, namely Inequality (2), and noting that $\|X\|_\infty = 1$, (12) follows directly from Definition 4, and (13) follows from the definition of $\|\varphi\|$. ■

Inspired by this result, we provide Algorithm 1 which, given the number k of arms and the sum $\|\varphi\|$ of the φ-mixing coefficients, works as follows. First, each arm is sampled once for initialization. Next, from $t = k+1$ on, arms are played in batches of exponentially growing length. Specifically, at each round arm j with the highest upper-confidence on its empirical mean is selected, and played for 2^{s_j} consecutive time-steps, where s_j denotes the number of times that arm j has been selected so far. The upper confidence bound is calculated based on a Hoeffding-type bound for φ-mixing processes given by Corollary 2.1 of Rio (1999). The 2^{s_j} samples obtained by playing the selected arm are used in turn to calculate (from scratch) the arm's empirical mean. The algorithm does not require the values of the individual φ-mixing coefficients, but only their sum $\|\varphi\|$. In fact, any upper-bound $\vartheta \geq \|\varphi\|$ may be used, in which case ϑ would replace $\|\varphi\|$ in the regret bound of Theorem 12.

To analyze the regret of Algorithm 1, first recall that in an i.i.d. setting we trivially have $\overline{\mathcal{R}}(n) = n\mu^* - \mu_j\sum_{j=1}^k ET_j(n) = \sum_{j=1}^k \Delta_j ET_j(n)$ where $T_j(n)$ is the total number of times that arm j is played by the algorithm in n rounds and $\Delta_j := \mu^* - \mu_j,\ j \in 1..k$. In our framework, this equality does not necessarily hold due to the inter-dependencies between the pay-offs. However, as shown in Proposition 11 below, an analogous result *in the form of an upper-bound* holds for our algorithm.

3. Note that only the sum of the coefficients is needed, not the individual coefficients φ_i.

Proposition 11 *Consider the regret $\overline{\mathcal{R}}(n)$ of Algorithm 1 after n rounds of play. We have,*

$$\overline{\mathcal{R}}(n) \leq \sum_{j=1}^{k} \Delta_j E T_j(n) + 2k \left(\sum_{l=0}^{n} \varphi_l \right) \log n$$

Proof Denote by $\tau_{i,j} : \Omega \to \mathbb{N}_+$ the random time at which the j-th arm is sampled for the i-th time. Note that for any $t \in \mathbb{N}$ the event $\{\tau_{i,j} = t\}$ is measurable with respect to the filtration $\mathcal{G}_{t-1}$ that keeps track of all the information available up to time t. First note that

$$\begin{aligned} E(\chi\{\tau_{i,j} = t\} X_{t+l,j}) &= E E(\chi\{\tau_{i,j} = t\} X_{t+l,j} | \mathcal{G}_{t-1}) \\ &= E\left(\chi\{\tau_{i,j} = t\} E\left(X_{t+l,j} | \mathcal{G}_{t-1}\right)\right) \\ &\geq (\mu_j - 2\varphi_l) P\left(\tau_{i,j} = t\right) \end{aligned} \tag{14}$$

where the second equality follows from the fact that the event $\{\tau_{i,j} = t\}$ is $\mathcal{G}_{t-1}$-measurable and (14) follows from Theorem 2. We have,

$$\begin{aligned} \overline{\mathcal{R}}(n) &= n\mu^* - \sum_{t=1}^{n} E X_{t,\pi_t} \\ &= n\mu^* - \sum_{t=1}^{n} \sum_{j=1}^{k} \sum_{m=1}^{\log n} \sum_{l=0}^{\min\{2^m - 1, n-t\}} E\chi\{\tau_{m,j} = t\} X_{t+l,j} \\ &\leq n\mu^* - \sum_{t=1}^{n} \sum_{j=1}^{k} \sum_{m=1}^{\log n} \sum_{l=0}^{\min\{2^m - 1, n-t\}} P\left(\tau_{m,j} = t\right) (\mu_j - 2\varphi_l) \\ &\leq n\mu^* - \sum_{t=1}^{n} \sum_{j=1}^{k} \sum_{m=1}^{\log n} \sum_{l=0}^{\min\{2^m - 1, n-t\}} P\left(\tau_{m,j} = t\right) \mu_j + 2k \left(\sum_{l=0}^{n} \varphi_l \right) \log n \\ &= \sum_{j=1}^{k} \Delta_j E T_j(n) + 2k \left(\sum_{l=0}^{n} \varphi_l \right) \log n \end{aligned}$$

where the last inequality follows from (14).

■

An upper-bound on $\overline{\mathcal{R}}(n)$ is given by Theorem 12 below with proof provided in Appendix B. Recall that $\Delta_i := \mu^* - \mu_i$ is the difference between the highest stationary mean μ^* and the stationary mean μ_i of arm i.

Theorem 12 (Regret Bound.) *For the regret $\overline{\mathcal{R}}(n)$ of Algorithm 1 after n rounds of play. We have,*

$$\overline{\mathcal{R}}(n) \leq \sum_{\substack{i=1 \\ \mu_i \neq \mu^*}}^{k} \frac{32(1 + 8\|\varphi\|)\ln n}{\Delta_i} + (1 + 2\pi^2/3)(\sum_{i=1}^{k} \Delta_i) + \|\varphi\| \log n$$

Remark. Interestingly, $\|\varphi\|$ appears in the bound of Theorem 12. Indeed, in the case where the pay-offs are i.i.d., we recover (up to some constant) the regret bound of Auer et al. (2002)[Thm. 1].

4.4. Strongly Dependent Reward Distributions: a Complementary Example

At the other end of the extreme lie bandit problems with strongly dependent pay-off distributions. Our objective in this section is to give an example where a simple switching strategy can be obtained in this case to leverage the strong inter-dependencies between the samples. This approach gives a much higher overall pay-off than what would be given by settling for the best arm, and is computationally efficient. The intuition is that in many cases strong dependencies may allow for the prediction of future rewards even from scarce observations of a sample path.

We consider a class of stochastic processes for which we can easily control the level of dependency. A natural choice is to use stationary Gaussian processes on $\mathbb{N}_+$. Recall that a Gaussian process is fully specified by its covariance function cov: $\mathbb{N}_+ \times \mathbb{N}_+ \to \mathbb{R}$. Also, for any covariance function Kolmogorov's consistency theorem guarantees the existence of a Gaussian process with this particular covariance function, see, e.g. (Giné and Nickl, 2016). A Gaussian process is stationary if it has constant mean on $\mathbb{N}_+$ and its covariance can be written as $\mathrm{cov}(s) = \mathrm{cov}(t, t+s)$ for all $t \in \mathbb{N}_+, s \in \mathbb{N}$. We measure the degree of dependence of the process by means of Hölder-continuity of the covariance function. In particular, we assume that there exists some $c > 0$ and $\alpha \in (0, 1]$ such that for all $s, t \in \mathbb{N}$, $|\mathrm{cov}(s) - \mathrm{cov}(t)| \leq c|s - t|^\alpha$ and we assume that the covariance function is non-negative. A low c and α correspond to highly dependent processes since the covariance decreases slowly over time. A slowly decreasing covariance also implies large φ-mixing coefficients, since $|\mathrm{cov}(t)|/\mathrm{cov}^2(0) \leq 2(\varphi(X_0, X_t)\varphi(X_t, X_0))^{1/2}$, by Rio (1999)[Thm. 1.4]. Consider a k-armed bandit problem where each arm is distributed according to a stationary Gaussian process with stationary mean μ_i, $i = 1..k$. For simplicity, we assume that the processes are mutually independent with the same, *unknown*, covariance function $\mathrm{cov}(\cdot)$. While $\mathrm{cov}(\cdot)$ is assumed unknown, we have access to an upper-bound on its rate of decay. That is, we are given constants c and α such that $\mathrm{cov}(\cdot)$ is α, c-Hölder continuous. We further assume that an upper bound on the stationary means of the processes is known and that $\mathrm{cov}(0) = 1$. In order to obtain direct control on the regret $\mathcal{R}_\pi(n)$ we would need to make inference about the best possible switching strategy. Instead, we provide guarantees for the regret $\mathcal{R}^+_\pi(n)$ of policy π with respect to the best policy that can choose arms in hindsight, i.e. $\mathcal{R}^+_\pi(n) := \sum_{t=1}^{n} E(\max_{i \leq k}(X_{t,i} - X_{t,\pi_t}))$. Note that $\mathcal{R}^+_\pi(n) \geq \mathcal{R}_\pi(n)$.

We provide a simple algorithm, namely, Algorithm 2, that exploits the dependence between the pay-offs. Starting from an exploration phase, the algorithm alternates between exploration and exploitation, denoted Phase I and Phase II respectively. In Phase I it sweeps through all k arms to observe the corresponding pay-offs. In Phase II it plays the arm with the highest observed pay-off for $m - k$ rounds, where m is a (large) constant given by (1) which reflects the degree of dependence between the samples in the processes. We need not estimate the stationary distributions in this algorithm, as bounds on the differences between the stationary means suffice. Indeed, these differences are of minor relevance unless they are high as compared to the dependence between the individual processes. We have the following regret bound whose proof is given in Appendix C.2.

Proposition 13 *Given Δ such that $\max_{i,j} |\mu_i - \mu_j| \leq \Delta$ and α, c such that $|1 - \mathrm{cov}(t)| \leq ct^\alpha$ for all $t \geq 0$, the regret $\mathcal{R}^+(n)$ of Algorithm 2 after n rounds is at most,*

$$(n + m^\star)k(k-1)\left(\frac{\Delta + \sqrt{2}}{m^\star} + \frac{a_{m^\star} c^{1/2}}{8\pi(1 - b_{m^\star})} \left(2\pi^{1/2} - (1 - \Delta\sqrt{b_{m^\star}/4}) \exp\left(-\frac{\Delta^2 b_{m^\star}}{4} \right) \right) \right),$$

with $a_{m^\star} = 8c(m^\star)^\alpha, b_{m^\star} = c((m^\star - k)^\alpha + k^\alpha)$.

Algorithm 2 An Algorithm for highly dependent arms.

Input: a bound Δ on the difference between the stationary means, $\max_{i,j\leq k}|\mu_i-\mu_j|\leq\Delta$; Hölder coefficients α, c such that $|1-\mathrm{cov}(t)|\leq ct^\alpha$ for all $t\geq 0$.

$$m^\star \leftarrow \left\lceil \left(\frac{\sqrt{\pi}(\Delta+\sqrt{2})}{2\alpha c^{3/2}}\right)^{\frac{1}{1+\alpha}} \right\rceil .$$

if $m^\star \leq k$ **then** $m^\star \leftarrow k+1$

if $\Delta < \sqrt{8(m^*)^\alpha}/(\sqrt{2c}(m^\star-k)^\alpha+k^\alpha))$ **then**

$$m^\star \leftarrow \min \operatorname*{argmax}_{m\in\mathbb{N}}\{m : \Delta \geq \sqrt{8m^\alpha}/(\sqrt{2c}(m-k)^\alpha+k^\alpha))\}.$$

for $l=0\ldots\infty$ **do**

  Phase I: observe pay-offs $X_{lm^\star+1,1}=x_1,\ldots,X_{lm^\star+k,k}=x_k$

$$i^* \leftarrow \min \operatorname*{argmax}_{i\leq k}\{x_1,\ldots,x_k\}$$

  Phase II: play arm i^* for $m^\star-k$ steps.

To interpret the bound consider for simplicity $\alpha=1$ and the case of a highly dependent process and, hence, a very small c. If we choose to play the arm with the highest stationary mean at all rounds, then standard bounds on the normal distribution give us a bound of order $n\exp(-(\Delta^2/4))$ on the regret. In this case, the regret of Algorithm 2 is of order

$$nk^2c^{3/4}$$

because $b_{m^\star}=cm^\star\approx c^{1/4}\pi^{1/4}((\Delta+\sqrt{2})/2)^{1/2}$ is insignificant for small c, $c^{1/2}a_{m^\star}=8c^{3/2}m^\star\approx 8c^{3/4}\pi^{1/4}((\Delta+\sqrt{2})/2)^{1/2}$ and the bracket on the right side is about $2\pi^{1/2}-1$. The gap Δ itself is not of high importance because in Phase I the algorithm selects the arm with highest current pay-off and the value stays stable over a long period as c is small. Both regret bounds are linear in n because the oracle has a significant advantage in this setting: at any given time t the oracle chooses the arm with the highest pay-off in hindsight. However, for a moderate number of arms $k^2c^{3/4}$ is significantly smaller than $\exp(-\Delta^2/4)$ unless Δ is considerably large. The advantage of the switching algorithm vanishes if k is large compared to the smoothness of the process, because eventually the exploration phase (Phase I) will dominate and the smoothness of the arms cannot be exploited by this algorithm. This example demonstrates that large dependence in the stochastic process can be exploited to build switching algorithms that have a significant edge over algorithms that aim to select a single arm and algorithms like Algorithm 1 are outperformed by simple switching algorithms.

5. Outlook

This paper is an initial attempt to characterize special sub-classes of the restless bandit problem where good approximate solutions can be found using simple, computationally tractable approaches. We provide a UCB-type algorithm to approximate the optimal strategy in the case where the pay-offs

are jointly stationary φ-mixing and are only weakly dependent. A natural open problem here is the derivation of a lower-bound. Moreover, while our algorithm only requires knowledge of the sum of the φ-mixing coefficients $\|\varphi\|=\sum_i\varphi_i$ as opposed to that of each individual φ_i, the online estimation of the mixing coefficients can prove useful. Specifically, in light of Proposition 9, if φ_1 is estimated from data, the algorithm can have a real-time estimate of its maximum loss with respect to the best switching strategy after n rounds of play. Further, the results can be strengthened if the algorithm can adaptively estimate $\|\varphi\|$ instead of relying on it as input. Another interesting regime corresponds to strongly dependent pay-off distributions. We provide an example using stationary Gaussian Processes where a simple switching strategy can leverage the dependencies to outperform a best arm policy. An open problem would be to weaken the assumptions on the process distributions and obtain results analogous to the weakly dependent case for the strongly dependent framework.

Acknowledgments.

Appendix A. Proofs for φ-mixing Processes

A.1. Technical Results

The following key lemma allows us to control φ-mixing coefficients corresponding to disjoint events.

Lemma A.1 *Let $(\Omega,\mathcal{A},P)$ be a probability space and let $\mathcal{B},\mathcal{C}$ be two σ-subalgebras of $\mathcal{A}$. If there exists a $\varphi\geq 0$ such that for all $B\in\mathcal{B}$ and $C\in\mathcal{C}$ it holds that $|P(B)P(C)-P(B\cap C)|\leq\varphi P(C)$ then for any disjoint sequence $\langle B_n\rangle_{n\in\mathbb{N}}$, $B_n\in\mathcal{B}$ for all $n\in\mathbb{N}$, and any $C\in\mathcal{C}$, we have*

$$\sum_{n=0}^{\infty}|P(B_n)P(C)-P(B_n\cap C)|\leq 2\varphi P(C).$$

Proof Let $c_n=P(B_n)P(C)-P(B_n\cap C)$, $I_+=\{n\in\mathbb{N}:c_n\geq 0\}$, $I_-=\{n\in\mathbb{N}:c_n<0\}$. Now, since $\bigcup_{n\in I_+}B_n\in\mathcal{B}$ and $\bigcup_{n\in I_-}B_n\in\mathcal{B}$ we have

$$\begin{aligned}P(C)\varphi &\geq P\Big(\bigcup_{n\in I_+}B_n\Big)P(C)-P\Big(\Big(\bigcup_{n\in I_+}B_n\Big)\cap C\Big)\\ &=\sum_{n\in I_+}(P(B_n)P(C)-P(B_n\cap C))=\sum_{n\in I_+}|P(B_n)P(C)-P(B_n\cap C)|\,.\end{aligned}$$

Similarly, $P(C)\varphi\geq\sum_{n\in I_-}|P(B_n)P(C)-P(B_n\cap C)|$. Hence

$$\begin{aligned}2P(C)\varphi &\geq\sum_{n\in I_+}|P(B_n)P(C)-P(B_n\cap C)|+\sum_{n\in I_-}|P(B_n)P(C)-P(B_n\cap C)|\\ &=\sum_{n\in\mathbb{N}}|P(B_n)P(C)-P(B_n\cap C)|\,.\end{aligned}$$

■

The following technical lemma is used in the proof of Proposition 9.

Lemma A.2 *Given some probability space $(\Omega, \mathcal{A}, P)$, three σ-subalgebras $\mathcal{B}, \mathcal{C}, \mathcal{D} \subset \mathcal{A}$ and $\varphi > 0$ such that $|P(U)P(V) - P(U \cap V)| \leq \varphi P(V)$ for all $U \in \mathcal{B}, V \in \mathcal{C}$ and $P(A) = 0$ for all $A \in \mathcal{D}$ then it holds that $|P(U)P(V) - P(U \cap V)| \leq \varphi P(V)$ for all $U \in \mathcal{B}, V \in \sigma(\mathcal{C} \cup \mathcal{D})$.*

Proof **(i)** The set

$$\mathcal{E} := \{A : A \in \mathcal{A}, \text{ there exists a } B \in \mathcal{C} \text{ such that for all } C \in \mathcal{A}, P(A \cap C) = P(B \cap C)\}$$

is a Dynkin system (Fremlin, 2010)[136A]. To see this, note that (1) $\emptyset \in \mathcal{E}$ since $\emptyset \in \mathcal{C}$, (2) for $A \in \mathcal{E}$ take any $B \in \mathcal{C}$ and observe that $P(C \cap (\Omega \backslash A)) = P(C \backslash (C \cap A)) = P(C) - P(C \cap A) = P(C) - P(C \cap B) = P(C \cap (\Omega \backslash B))$ for every $C \in \mathcal{A}$ and $\Omega \backslash B \in \mathcal{C}$, (3) let $\langle A_n \rangle_{n \in \mathbb{N}}$ be a disjoint sequence in $\mathcal{E}$ with corresponding elements $B_n \in \mathcal{C}$ then $P(\bigcup_{n \in \mathbb{N}} A_n) = \sum_{n=0}^{\infty} P(A_n) = \sum_{n=0}^{\infty} P(B_n)$. Let $B'_0 = B_0$ and iteratively let $B'_n = B_n \backslash B'_{n-1}$ then $\langle B'_n \rangle_{n \in \mathbb{N}}$ is a disjoint sequence such that $P(B_n) = P(B'_n)$: for any $m, n \in \mathbb{N}$ we have $P(B_n \cap B_m) = P(A_n \cap B_m) = P(A_n \cap A_m) = 0$ and, hence, $P(B_n \backslash B'_{n-1}) \geq P(B_n) - \sum_{i=0}^{n-1} P(B_n \cap B_i) = P(B_n)$. Therefore, $\sum_{n=0}^{\infty} P(B_n) = \sum_{n=0}^{\infty} P(B'_n) = P(\bigcup_{n \in \mathbb{N}} B'_n) = P(\bigcup_{n \in \mathbb{N}} B_n)$ and $\mathcal{E}$ is a Dynkin system.

(ii) Let $\mathcal{D}' := \{A \cap B : A \in \mathcal{C}, B \in \mathcal{D}\}$. Observe that $\mathcal{C} \cup \mathcal{D} \cup \mathcal{D}'$ is closed under intersection: if $A, B \in \mathcal{C}$ then $A \cap B \in \mathcal{C}$ and similarly for $A, B \in \mathcal{D}$. If $A \in \mathcal{C}$ and $B \in \mathcal{D}$ then $A \cap B$ is in an element of $\mathcal{D}'$. If $A \in \mathcal{C}$ and B is an element of $\mathcal{D}'$ then $B = C \cap D$ for some $C \in \mathcal{C}$, $D \in \mathcal{D}$ and $A \cap B = (A \cap C) \cap D$ which is again an element of $\mathcal{D}'$ (and equivalently for $A \in \mathcal{D}$). Furthermore, $\mathcal{C} \cup \mathcal{D} \cup \{A \cap B : A \in \mathcal{C}, B \in \mathcal{D}\} \subset \mathcal{E}$. Note that $\mathcal{C}$ is a subset of $\mathcal{E}$, and if $B \in \mathcal{D}$ then we obtain $P(\emptyset \cap C) = 0 = P(B \cap C)$ for any $C \in \mathcal{A}$ and $\emptyset \in \mathcal{C}$. Finally, if we have $A \cap B$ where $A \in \mathcal{C}$ and $B \in \mathcal{D}$ then $P(A \cap B \cap C) = 0 = P(\emptyset \cap C)$ for any $C \in \mathcal{A}$. Hence, $\sigma(C \cup D) \subset \mathcal{E}$ by the monotone class theorem (Fremlin, 2010)[136B].

(iii) Now, let us consider a $U \in \mathcal{B}$ and $V \in \sigma(\mathcal{C} \cup \mathcal{D})$. Due to steps (i) and (ii) we can select a $V' \in \mathcal{C}$ such that $P(V \cap C) = P(V' \cap C)$ for all $C \in \mathcal{A}$. Then with this V' we have that $|P(U)P(V) - P(U \cap V)| = |P(U)P(V') - P(U \cap V')| \leq \varphi P(V') = \varphi P(V)$. ■

Another important result in this context concerns the φ-mixing property of a process that starts at a random time. This result is needed to be able to use Hoeffding bounds for batches of observations which occur in our algorithm. To state this result concisely we first define the following two families of events

$$\mathcal{U} := \left\{\{\tau_n < \infty\} \cap (X_{\tau_n,i}, \ldots, X_{\tau_n+u-1,i})^{-1}[B] : B \in \mathcal{B}_{\mathcal{X}}^{(u)}\right\},$$
$$\mathcal{V} := \left\{\{\tau_n < \infty\} \cap (X_{\tau_n+u+l-1,i}, \ldots, X_{\tau_n+u+l+v-2,i})^{-1}[B] : B \in \mathcal{B}_{\mathcal{X}}^{(u)}\right\},$$

where the notation $(X_{\tau_n,i}, \ldots, X_{\tau_n+u-1,i})^{-1}[B]$ denotes the set

$$\{\omega : \omega \in \Omega, (X_{\tau_n(\omega),i}(\omega), \ldots, X_{\tau_n(\omega)+u-1,i}(\omega)) \in B\}$$

and $\mathcal{X}$ is the space in which the random variables $X_{t,i}$ attain values in.

Lemma 14 *In the jointly-stationary φ-mixing bandit problem formulated in Section 3, consider an arm $i \leq k$ and an increasing sequence of starting times $\langle \tau_n \rangle_{n \in \mathbb{N}_+}$ of batches in which arm i is played which are almost surely finite. The following holds for all $n \in \mathbb{N}_+$ and $1 \leq l \leq 2^{n-1} - 1$*

$$\sup\{|P(V) - P(U \cap V)/P(U)| : U \in \mathcal{U}, V \in \mathcal{V}, P(U) > 0, \\ u, v \in \mathbb{N}_+, u + v + l - 1 \leq 2^{n-1}\} \leq 2\varphi_l. \qquad (15)$$

Proof For any U, V as defined in (15) there exist sequences $\langle U_t \rangle_{t \in \mathbb{N}_+}$, and $\langle V_t \rangle_{t \in \mathbb{N}_+}$, where

$$U_t \in \sigma\left(\{(X_{t,i}, \ldots, X_{t+u-1,i})^{-1}[B] \cap \{\tau_n < \infty\} : B \in \mathcal{B}_{\mathcal{X}}^{(u)}\}\right) \text{ and}$$
$$V_t \in \sigma\left(\{(X_{t+u+l-1,i}, \ldots, X_{t+u+l+v-2,i})^{-1}[B] \cap \{\tau_n < \infty\} : B \in \mathcal{B}_{\mathcal{X}}^{(v)}\}\right)$$

such that $U = \bigcup_{t \in \mathbb{N}_+} \{\tau_n = t\} \cap U_t$ and $V = \bigcup_{t \in \mathbb{N}_+} \{\tau_n = t\} \cap V_t$. Observe also that due to stationarity $P(V_t) = P(V_1)$ for all $t \geq 1$. Since, $U_t \cap \{\tau_n = t\} \in \mathcal{G}_t$ the φ-mixing property gives us

$$|P(\{\tau_n = t\} \cap U_t \cap V_t) - P(\{\tau_n = t\} \cap U_t)P(V_t)| \leq \varphi_l P(\{\tau_n = t\} \cap U_t)$$

and since $\tau_n < \infty$ almost surely for each n we have

$$|P(V) - P(V_1)| \leq \sum_{t=1}^{\infty} |P(\{\tau_n = t\} \cap V_t) - P(\tau_n = t)P(V_t)| \leq \varphi_l.$$

Combining these gives the result as

$$\begin{aligned}
&|P(U)P(V) - P(U \cap V)| \\
&\quad = |P(U)P(V) - \sum_{t=1}^{\infty} P(\{\tau_n = t\} \cap U_t \cap V_t)| \\
&\quad \leq |P(U)P(V) - \sum_{t=1}^{\infty} P(\{\tau_n = t\} \cap U_t)P(V_t)| + \sum_{t=1}^{\infty} \varphi_l P(\{\tau_n = t\} \cap U_t) \\
&\quad \leq 2\varphi_l P(U) + |P(U)P(V_1) - \sum_{t=1}^{\infty} P(\{\tau_n = t\} \cap U_t)P(V_1)| = 2\varphi_l P(U).
\end{aligned}$$

■

A.2. Proof of Proposition 5

Let $(\Omega, \mathcal{A}, P)$ be some probability space with k mutually independent processes defined on it. If each of these processes is ψ-mixing then the joint process is also ψ-mixing and for all $i \in \mathbb{N}$, $1 + \tilde{\psi}_i \leq (1 + \psi_i)^k$, where the $\tilde{\psi}_i$ are the mixing coefficients of the joint process and the ψ_i are upper bounds on the mixing coefficients of the individual processes.

Proof Fix some $n, a, u, v > 0$, $a \geq u + n$ and let us denote the individual processes with $\langle X_{n,i} \rangle_{n \in \mathbb{N}_+}$, $i \leq k$. Furthermore, let $A = \{1, \ldots, u\}, B = \{a, \ldots, a + v - 1\}$ and $\mathcal{G} = \sigma(X_{A,1}, \ldots, X_{A,k}), \mathcal{H} = \sigma(X_{B,1}, \ldots, X_{B,k})$. The proof structure is the following: in step (i) we show for "simple" events that the ψ-mixing property carries over to the joint process. In step (ii), we construct a new probability space in which to each of these "simple" events a product of events is associated. The approach is useful since more complex events can be easily approximated by products. In step (iii) we make use of this approximation and we relate arbitrary events to unions of products for each of which the ψ-mixing property derived in (i) applies.

(i) Consider a set $U \in \mathcal{G}$ of the form $U = \bigcap_{i\leq k} U_i$ where $U_i \in \sigma(X_{A,i})$ for all $i \leq k$ and a set $V \in \mathcal{H}$ of the form $V = \bigcap_{i\leq k} V_i$, $V_i \in \sigma(X_{B,i})$, for all $i \leq k$. The mutual independence of the processes implies that

$$
\begin{aligned}
|P(U)P(V) - P(U\cap V)| &= \Big|\prod_{i=1}^{k} P(U_i)P(V_i) - \prod_{i=1}^{k} P(U_i\cap V_i)\Big| \\
&\leq P(U_1)P(V_1)\,\Big|\prod_{i=2}^{k} P(U_i)P(V_i) - \prod_{i=2}^{k} P(U_i\cap V_i)\Big| \\
&\quad + |P(U_1)P(V_1) - P(U_1\cap V_1)|\prod_{i=2}^{k} P(U_i\cap V_i) \\
&\leq \Big(\prod_{i=1}^{2} P(U_i)P(V_i)\Big)\,\Big|\prod_{i=3}^{k} P(U_i)P(V_i) - \prod_{i=3}^{k} P(U_i\cap V_i)\Big| \\
&\quad + P(U_1)P(V_1)\,|P(U_2)P(V_2) - P(U_2\cap V_2)|\prod_{i=3}^{k} P(U_i\cap V_i) \\
&\quad + \psi_n\, P(U_1)P(V_1)\prod_{i=2}^{k} P(U_i\cap V_i) \\
&\leq \psi_n \sum_{i=1}^{k}\Big(\prod_{j=1}^{i} P(U_j)P(V_j)\Big)\Big(\prod_{j=i+1}^{k} P(U_j\cap V_j)\Big) \\
&\leq \psi_n\, P(U)P(V)\sum_{i=1}^{k}\prod_{j=i+1}^{k}\frac{P(U_j\cap V_j)}{P(U_j)P(V_j)} \\
&\leq \psi_n\, P(U)P(V)\sum_{i=0}^{k-1}(1+\psi_n)^{k-i-1} = ((1+\psi_n)^k - 1)\,P(U)P(V).
\end{aligned}
$$

(ii) Next, we demonstrate the ψ-mixing property for $U \in \mathcal{G}$ and $V \in \mathcal{H}$. We use a product measure approach. To make use of this let the index set $C = A \cup B$ and consider the independent σ-algebras $\sigma(X_{C,1}), \ldots, \sigma(X_{C,k})$. Let P_i be the restriction of P to $\sigma(X_{C,i})$ for all $i \leq k$ and define the product space $(\Omega^k, \widehat{\otimes}_{i\leq k}\sigma(X_{C,i}), \mu)$, where μ is the product measure of $P_1, \ldots, P_k$ and $\widehat{\otimes}_{i\leq k}\sigma(X_{C,i})$ denotes the product σ-algebra of $\sigma(X_{C,1}), \ldots, \sigma(X_{C,k})$. The map $\phi : \Omega \to \Omega^k$, $\phi(\omega)(i) = \omega$ for all $i \leq k$, is inverse-measure preserving due to Fremlin (2010)[272J,254Xc]. In particular, $P(\bigcap_{i\leq k} U_i) = P\phi^{-1}[U_1 \times \ldots \times U_k] = \mu(U_1 \times \ldots \times U_k)$ for $U_i \in \sigma(X_{A,i})$. The important property is the following: if $U \in \mathcal{G}$ then there exists an $F \in \widehat{\otimes}_{i\leq k}\sigma(X_{A,i}) \subseteq \widehat{\otimes}_{i\leq k}\sigma(X_{C,i})$ such that $U = \phi^{-1}[F]$. To see this consider the set

$$\mathcal{S} := \{\phi^{-1}[F] : F \in \widehat{\otimes}_{i\leq k}\sigma(X_{A,i})\}.$$

A standard argument shows that $\mathcal{S}$ is a σ-algebra, i.e. $\emptyset \in \mathcal{S}$, if $U \in \mathcal{S}$ then $\Omega\backslash U = \phi^{-1}[\Omega^k\backslash U] \in \mathcal{S}$ and if $\langle U_n\rangle_{n\in\mathbb{N}}$ a sequence in $\mathcal{S}$ then $\bigcup_{n\in\mathbb{N}} U_n = \phi^{-1}[\bigcup_{n\in\mathbb{N}} F_n] \in \mathcal{S}$ for suitable sets F_n. Furthermore, $\mathcal{S} \supseteq \{\bigcap_{i\leq k} U_i : U_i \in \sigma(X_{A,i}), i \leq k\}$ and the latter set is closed under intersection.

Hence, the monotone class theorem tells us that $\mathcal{G} = \sigma\{\bigcap_{i\leq k} U_i : U_i \in \sigma(X_{A,i}), i \leq k\} \subset \mathcal{S}$ and the result follows. Similarly, we can link $V \in \mathcal{G}$ to $\widehat{\otimes}_{i\leq k}\sigma(X_{B,i})$.

(iii) We'd like to demonstrate that the ψ-mixing property carries over to arbitrary elements $U \in \widehat{\otimes}_{i\leq k}\sigma(X_{A,i})$ and $V \in \widehat{\otimes}_{i\leq k}\sigma(X_{B,i})$. First, observe that if $U = U_1 \times \ldots \times U_k$ and $V = V_1 \times \ldots \times V_k$, $U_i \in \sigma(X_{A,i}), V_i \in \sigma(X_{B,i})$, $i \leq k$, then using $(U_1 \times \ldots \times U_k) \cap (V_1 \times \ldots \times V_k) = (U_1 \cap V_1) \times \ldots \times (U_k \cap V_k)$ with the inverse-measure preserving property of ϕ and (i) it follows that

$$
\begin{aligned}
&|\mu(U_1 \times \ldots \times U_k)\mu(V_1 \times \ldots \times V_k) - \mu(U_1 \times \ldots \times U_k \cap V_1 \times \ldots \times V_k)| \\
&= \big|P\big(\textstyle\bigcap_{i\leq k} U_i\big)P\big(\bigcap_{i\leq k} V_i\big) - P\big(\bigcap_{i\leq k} U_i \cap \bigcap_{i\leq k} V_i\big)\big| \\
&\leq ((1+\psi_n)^k - 1)\,P\big(\textstyle\bigcap_{i\leq k} U_i\big)P\big(\bigcap_{i\leq k} V_i\big) \\
&= ((1+\psi_n)^k - 1)\,\mu(U_1 \times \ldots \times U_k)\mu(V_1 \times \ldots \times V_k).
\end{aligned}
$$

The advantage of the product approach is that we can approximate the sets U and V with cylinders of the form $U_1 \times \ldots \times U_k$ and this allows us to carry the ψ-mixing property to $\mathcal{G}$ and $\mathcal{H}$. As follows from Fremlin (2010)[Thm. 251Ie, pp. 200, 251W] for every $\epsilon \in (0, 1]$ there exist sequences $U_{1,1}, \ldots, U_{m_1,1}, \ldots, U_{1,k}, \ldots, U_{m_1,k}$ and $V_{1,1}, \ldots, V_{m_2,1}, \ldots, V_{1,k}, \ldots, V_{m_2,k}$, with $U_{i,j}, V_{i',j} \in \sigma(X_{C,j})$ for all $i \leq m_1, i' \leq m_2, j \leq k$, with the following four properties.

$$\mu\Big(\bigcup_{i\leq m_1} U_{i,1} \times \ldots \times U_{i,k}\Big) \geq \sum_{i\leq m_1} \mu(U_{i,1} \times \ldots \times U_{i,k}) - \epsilon, \tag{16}$$

$$\mu\Big(\bigcup_{i\leq m_2} V_{i,1} \times \ldots \times V_{i,k}\Big) \geq \sum_{i\leq m_2} \mu(V_{i,1} \times \ldots \times V_{i,k}) - \epsilon/m_1, \tag{17}$$

$$\mu\Big(U \triangle \bigcup_{i\leq m_1} U_{i,1} \times \ldots \times U_{i,k}\Big) \leq \epsilon, \text{ and} \tag{18}$$

$$\mu\Big(V \triangle \bigcup_{i\leq m_2} V_{i,1} \times \ldots \times V_{i,k}\Big) \leq \epsilon/m_1, \tag{19}$$

where $\triangle$ denotes the symmetric difference between sets.

From (16) and (17) we obtain $\sum_{i\leq m_1} \mu(U_{i,1} \times \ldots \times U_{i,k}) \leq 1 + \epsilon$ and $\sum_{i\leq m_2} \mu(V_{i,1} \times \ldots \times V_{i,k}) \leq 1 + \epsilon/m_1$ respectively. Moreover, we have

$$\big|\mu(U) - \mu\big(\bigcup_{i\leq m_1} U_{i,1} \times \ldots \times U_{i,k}\big)\big| \leq \mu\big(U \triangle \bigcup_{i\leq m_1} U_{i,1} \times \ldots \times U_{i,k}\big) \leq \epsilon \tag{20}$$

where the second inequality follows from (18). Similarly, from (19) we obtain

$$\big|\mu(V) - \mu\big(\bigcup_{i\leq m_2} V_{i,1} \times \ldots \times V_{i,k}\big)\big| \leq \epsilon/m_1. \tag{21}$$

Furthermore, to obtain a similar result for $U \cap V$,below, we rely on the following elementary set manipulation. Consider sets A_1, A_2, A_3, A_4 then

$$
\begin{aligned}
&(A_1 \cap A_2)\triangle(A_3 \cap A_4) = ((A_1 \cap A_2)\backslash(A_3 \cap A_4)) \cup ((A_3 \cap A_4)\backslash(A_1 \cap A_2)) \\
&= ((A_1 \cap A_2)\backslash A_3) \cup ((A_1 \cap A_2)\backslash A_4) \cup ((A_3 \cap A_4)\backslash A_1) \cup ((A_3 \cap A_4)\backslash A_2) \\
&\subseteq (A_1\backslash A_3) \cup (A_2\backslash A_4) \cup (A_3\backslash A_1) \cup (A_4\backslash A_2) \\
&= (A_1\triangle A_3) \cup (A_2\triangle A_4).
\end{aligned} \tag{22}
$$

We have,

$$
\begin{aligned}
&\big|\mu(U\cap V)-\mu\big(\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)\cap\big(\bigcup_{i\le m_2} V_{i,1}\times\ldots\times V_{i,k}\big)\big)\big| \\
&\le\big|\mu\big((U\cap V)\triangle\big(\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)\cap\big(\bigcup_{i\le m_2} V_{i,1}\times\ldots\times V_{i,k}\big)\big)\big)\big| \\
&\le\mu\big(U\triangle\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)\big)+\mu\big(V\triangle\big(\bigcup_{i\le m_2} V_{i,1}\times\ldots\times V_{i,k}\big)\big) &(23)\\
&\le\epsilon+\epsilon/m_1 &(24)\\
&\le 2\epsilon &(25)
\end{aligned}
$$

where, (23) is due to (22) and (24) follows from (18) and (19). Now, applying (20), (21) and (25) we obtain,

$$
\begin{aligned}
&|\mu(U)\mu(V)-\mu(U\cap V)| \\
&\le|\mu(U)\mu(V)-\mu\big(\bigcup_{i\le m_1}\bigcup_{j\le m_2}(U_{i,1}\times\ldots\times U_{i,k})\cap(V_{j,1}\times\ldots\times V_{j,k})\big)|+2\epsilon \\
&\le 4\epsilon+\big|\mu\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)\mu\big(\bigcup_{i\le m_2} V_{i,1}\times\ldots\times V_{i,k}\big) \\
&\qquad-\mu\big(\bigcup_{i\le m_1}\bigcup_{j\le m_2}(U_{i,1}\times\ldots\times U_{i,k})\cap(V_{j,1}\times\ldots\times V_{j,k})\big)\big|. &(26)
\end{aligned}
$$

Furthermore,

$$
\begin{aligned}
&\big|\sum_{i\le m_1}\sum_{j\le m_2}\mu(U_{i,1}\times\ldots\times U_{i,k})\mu(V_{j,1}\times\ldots\times V_{j,k}) \\
&\qquad\qquad-\mu\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)\mu\big(\bigcup_{i\le m_2} V_{i,1}\times\ldots\times V_{i,k}\big)\big| \\
&\le\Big(\mu\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)+\epsilon\Big)\sum_{j\le m_2}\mu(V_{j,1}\times\ldots\times V_{j,k}) \\
&\qquad\qquad-\mu\big(\bigcup_{i\le m_1} U_{i,1}\times\ldots\times U_{i,k}\big)\mu\big(\bigcup_{i\le m_2} V_{i,1}\times\ldots\times V_{i,k}\big) \\
&\le 2\epsilon+\epsilon^2 \\
&\le 3\epsilon. &(27)
\end{aligned}
$$

Let $U_1,\ldots,U_m$ be such that $\mu(\bigcup_{i\le m}U_i)\ge\sum_{i\le m}\mu(U_i)-\epsilon$. Then $\sum_{i\le m}\mu\big(\bigcup_{j<i}U_j\cap U_i\big)\le\epsilon$. This is because

$$
\begin{aligned}
\mu\big(\bigcup_{i\le m}U_i\big)&=\mu\big(\bigcup_{i\le m}U_i\backslash\big(\bigcup_{j<i}U_j\cap U_i\big)\big)\\
&=\sum_{i\le m}\mu\big(U_i\backslash\big(\bigcup_{j<i}U_j\cap U_i\big)\big)\\
&=\sum_{i\le m}\mu(U_i)-\sum_{i\le m}\mu\big(\bigcup_{j<i}U_j\cap U_i\big)\big).
\end{aligned}
$$

Now, for any measurable set V we have by the same argument that

$$
\begin{aligned}
\mu\big(\bigcup_{i\le m}U_i\cap V\big)&=\mu\big(\bigcup_{i\le m}U_i\cap V\backslash\big(\bigcup_{j<i}U_j\cap U_i\big)\big)\\
&=\sum_{i\le m}\mu\big(U_i\cap V\backslash\big(\bigcup_{j<i}U_j\cap U_i\big)\big)\\
&=\sum_{i\le m}\mu(U_i\cap V)-\sum_{i\le m}\mu\big(\bigcup_{j<i}U_j\cap U_i\big)\big)\\
&\ge\sum_{i\le m}\mu(U_i\cap V)-\epsilon.
\end{aligned}
$$

Hence, using (16) and (17), we can obtain

$$
\begin{aligned}
&\big|\sum_{i\le m_1}\sum_{j\le m_2}\mu\big((U_{i,1}\times\ldots\times U_{i,k})\cap(V_{j,1}\times\ldots\times V_{j,k})\big)\\
&\quad-\mu\big(\bigcup_{i\le m_1}\bigcup_{j\le m_2}(U_{i,1}\times\ldots\times U_{i,k})\cap(V_{j,1}\times\ldots\times V_{j,k})\big)\big|\\
&\le\sum_{i\le m_1}\sum_{j\le m_2}\mu\big((U_{i,1}\times\ldots\times U_{i,k})\cap(V_{j,1}\times\ldots\times V_{j,k})\big)\\
&\quad-\sum_{i\le m_1}\mu\big((U_{i,1}\times\ldots\times U_{i,k})\cap\big(\bigcup_{j\le m_2}(V_{j,1}\times\ldots\times V_{j,k})\big)+\epsilon\\
&\le\epsilon+\sum_{i\le m_1}\epsilon/m_1\\
&=2\epsilon. &(28)
\end{aligned}
$$

We obtain an bound on $|\mu(U)\mu(V)-\mu(U\cap V)|$ by using (26), (27) and (28) together with the result from Step (i), i.e.,

$$
\begin{aligned}
&|\mu(U)\mu(V)-\mu(U\cap V)|\\
&\qquad\le 9\epsilon+\sum_{i\le m_1}\sum_{j\le m_2}|\mu(U_{i,1}\times\ldots\times U_{i,k})\mu(V_{j,1}\times\ldots\times V_{j,k})\\
&\qquad\qquad-\mu\big((U_{i,1}\times\ldots\times U_{i,k})\cap(V_{j,1}\times\ldots\times V_{j,k})\big)|\\
&\qquad\le 9\epsilon+\big((1+\psi_n)^k-1\big)\sum_{i\le m_1}\mu(U_{i,1}\times\ldots\times U_{i,k})\sum_{j\le m_2}\mu(V_{j,1}\times\ldots\times V_{j,k}) &(29)\\
&\qquad\le\big((1+\psi_n)^k-1\big)\,\mu(U)\mu(V)+9\epsilon+5\epsilon\big((1+\psi_n)^k-1\big),
\end{aligned}
$$

where the last inequality follows from the same arguments as used in inequalities (26) and (27). Since ϵ is arbitrary we derive the upper bound for arbitrary elements $U\in\widehat{\otimes}_{i\le k}\sigma(X_{A,i})$ and $V\in\widehat{\otimes}_{i\le k}\sigma(X_{B,i})$.

Note that this last step is the only part of the proof where ψ-mixing is necessary. In particular, we could not derive (29) from the line preceding it by only assuming φ-mixing.

To conclude, if $U \in \mathcal{G}, V \in \mathcal{H}$ then we know from step (ii) that there are elements $E \in \widehat{\otimes}_{i\leq k}\sigma(X_{A,i}), F \in \widehat{\otimes}_{i\leq k}\sigma(X_{B,i})$ such that

$$\begin{aligned}|P(U\cap V) - P(U)P(V)| &= |P\phi^{-1}[E\cap F] - P\phi^{-1}[E]P\phi^{-1}[F]| \\ &= |\mu(E\cap F) - \mu(E)\mu(F)| \\ &\leq ((1+\psi_n)^k - 1)P(U)P(V).\end{aligned}$$

(iv) The joint process is ψ-mixing since $\lim_{n\to\infty}(1-\psi_n)^k - 1 = 0$. ■

A.3. Proof of Proposition 8

In what follows, we denote the probability space by $(\Omega, \mathcal{A}, P)$ and let $\langle \mathcal{E}_t\rangle_{t\geq 1}$ be the filtration $\mathcal{E}_t = \sigma\{\sigma(X_1,\ldots,X_t)\cup\mathcal{N}\}$ where $\mathcal{N}$ is the family of sets of measure zero. The random times are $\tau_i : \Omega \to \mathbb{N}_+$ and they are $\mathcal{A} - \mathcal{P}(\mathbb{N}_+)$ measurable, where $\mathcal{P}(\mathbb{N}_+)$ denotes the power set of $\mathbb{N}_+ = \{1, 2\ldots\}$. Furthermore, let the random variables X_i attain values in $\mathcal{X} \subset \mathbb{R}$ and assume that they are $\mathcal{A} - \mathcal{B}_\mathcal{X}$ measurable, where $\mathcal{B}_\mathcal{X}$ denotes the Borel σ-algebra on $\mathcal{X}$. We define the random times τ_i inductively together with a filtration that tracks the observed information. Let $\mathcal{H}_0 = \{\emptyset, \Omega\}$, let τ_1 be a $\mathcal{H}_0$-measurable random time and let $\mathcal{H}_1 = \sigma(X_{\tau_1})$. Then, for given $\tau_1,\ldots,\tau_i$ and $\mathcal{H}_1,\ldots,\mathcal{H}_i$ let τ_{i+1} be some $\mathcal{H}_i$-measurable random variable such that $\tau_{i+1} > \tau_i$ almost surely and define $\mathcal{H}_{i+1} = \sigma(X_{\tau_1},\ldots,X_{\tau_{i+1}})$. We can observe that $\sigma(X_{\tau_1},\ldots,X_{\tau_i}) = \sigma(X_{\tau_1},\ldots,X_{\tau_t},\tau_1,\ldots,\tau_t)$. To see this, note that τ_1 is $\sigma(X_{\tau_1},\ldots,X_{\tau_t})$-measurable, hence $\sigma(X_{\tau_1},\ldots,X_{\tau_t},\tau_1,\ldots,\tau_t) = \sigma(X_{\tau_1},\ldots,X_{\tau_t},\tau_2,\ldots,\tau_t)$. Moreover, since τ_2 is $\sigma(X_{\tau_1},\tau_1) = \sigma(X_{\tau_1})$-measurable, we have that $\sigma(X_{\tau_1},\ldots,X_{\tau_t},\tau_2,\ldots,\tau_t) = \sigma(X_{\tau_1},\ldots,X_{\tau_t},\tau_3,\ldots,\tau_t)$, and the observation can simply be verified by induction. Recall the statement of Proposition 8 as follows.

Assume that $\langle X_t\rangle_{t\in\mathbb{N}_+}$ is a stationary φ-mixing process with mixing coefficients $\langle\varphi_i\rangle_{i\in\mathbb{N}_+}$ such that $EX_t = \mu,\ t\in\mathbb{N}_+$, and $\sup_{t\in\mathbb{N}_+}|X_t| \leq c$ for some $c\in[0,\infty)$. Furthermore, let $\tau_1,\tau_2,\ldots$ be a sequence of random times such that $\tau_i + \ell \leq \tau_{i+1}$ a.s. for some $\ell \geq 1$ and all $i\in\mathbb{N}_+$, and all τ_{i+1} are $\sigma(X_{\tau_1},\ldots,X_{\tau_i})$- measurable with $\tau_1 \in \mathbb{N}_+$ being a fixed time. Then for any $n\in\mathbb{N}_+$

$$\Big|\frac{1}{n}\sum_{i=1}^n EX_{\tau_i} - \mu\Big| \leq 2c\varphi_\ell.$$

Proof The following technical result is important in this context.

Lemma A.3 *For all $i,t \geq 1$ and $A \in \mathcal{H}_{i-1}$ we have that $A\cap\{\tau_i = t\} \in \mathcal{E}_t$. In particular $\{\tau_i = t\}\in\mathcal{E}_t$.*

Proof For $i = 1$ the result holds trivially since $A\cap\{\tau_i = t\}$ is either Ω or $\emptyset$ and since $\mathcal{E}_t$ is a σ-algebra it contains Ω and $\emptyset$. For any other $i \geq 2$ observe that if the claim holds for all $1\leq j\leq i-1$ then since τ_i is $\mathcal{H}_{i-1}$-measurable and because $\tau_i > \tau_{i-1}$ almost surely implies that $U := \{\tau_i = t\}\cap\{\tau_{i-1}\geq t\} \in \mathcal{N}\subset\mathcal{E}_t$ and we have

$$\{\tau_i = t\} = U \cup \bigcup_{s=1}^{t-1}\{\tau_i = t\}\cap\{\tau_{i-1} = s\} \in \mathcal{E}_t.$$

We can also observe that $\{B\cap\{\tau_i = t\} : B\in\sigma(X_{\tau_i})\}\subset\mathcal{E}_t$ because

$$\{B\cap\{\tau_i = t\} : B\in\sigma(X_{\tau_i})\} = \{X_t^{-1}[B']\cap\{\tau_i = t\} : B'\in\mathcal{B}_\mathcal{X}\}$$

and both $X_t^{-1}[B']$ and $\{\tau_i = t\}$ lie in $\mathcal{E}_t$.

Also, for any $j\in\{1,\ldots,i-1\}$ we have $\{B\cap\{\tau_i = t\} : B\in\sigma(X_{\tau_j})\}\subset\mathcal{E}_t$: let $U = \{\tau_i = t\}\cap\{\tau_j \geq t+1-(i-j)\}$ then $U\in\mathcal{N}$ and

$$\{B\cap\{\tau_i = t\} : B\in\sigma(X_{\tau_j})\} = U\cup\bigcup_{s=1}^{t-(i-j)}\{X_s^{-1}[B']\cap\{\tau_i = t\}\cap\{\tau_j = s\} : B'\in\mathcal{B}_\mathcal{X}\}$$

and $X_s^{-1}[B']\cap\{\tau_j = s\}\in\mathcal{E}_s\subset\mathcal{E}_t$. We have shown that

$$\Big\{\{\tau_i = t\}\cap\bigcap_{j=1}^{i-1}B_j : B_j\in\sigma(X_{\tau_j})\Big\}\subset\mathcal{E}_t.$$

This implies directly that

$$\sigma\Big\{\{\tau_i = t\}\cap\bigcap_{j=1}^{i-1}B_j : B_j\in\sigma(X_{\tau_j})\Big\}\subset\mathcal{E}_t.$$

By induction one can verify that $\{A\cap\{\tau_i = t\} : A\in\sigma(X_{\tau_1},\ldots,X_{\tau_{i-1}})\}$ is included in the left side. ■

We also need the following observation: Let $s,t\in\mathbb{N}_+$, $s < t$ then for any $B\in\mathcal{E}_s$ we have $|\int_B(E(X_t|\mathcal{E}_s) - E(X_t))| \leq 2\varphi_{t-s}cP(B)$. This follows from Lemma A.2 by remembering that $\mathcal{E}_s = \sigma(\sigma(X_1,\ldots,X_s)\cup\mathcal{N})$, i.e. the φ-mixing property implies this upper bound for $\sigma(X_1,\ldots,X_s)$ instead of $\mathcal{E}_s$ and Lemma A.2 allows us to extend this property to $\sigma(\sigma(X_1,\ldots,X_s)\cup\mathcal{N})$ by using in Lemma A.2 the following σ-algebras: $\mathcal{B} = \sigma(X_t), \mathcal{C} = \sigma(X_1,\ldots,X_s)$ and $\mathcal{D} = \mathcal{N}$.

Now, coming to the main proof consider first τ_1. Note that τ_1 is independent of any X_i since for $U\in\sigma(X_i), V\in\sigma(\tau_1) = \{\emptyset,\Omega\}$ we have either $V = \Omega$ and $P(U\cap V) = P(U) = P(U)P(V)$ or $V = \emptyset$ and $P(U\cap V) = 0 = P(U)P(V)$. Independence and stationarity of the process $\langle X_t\rangle_{t\in\mathbb{N}_+}$ give us for any $t\in\mathbb{N}_+$ that

$$E\left(X_t\times\chi\{\tau_1 = t\}\right) = P(\tau_1 = t)E(X_t) = P(\tau_1 = t)E(X_1).$$

Now, since the X_t are bounded and τ_1 attains a value in $\mathbb{N}_+$ we know that

$$\sum_{t=1}^\infty E\left(|X_t|\times\chi\{\tau_1 = t\}\right) = \sum_{t=1}^\infty P(\tau_1 = t)E|X_1|$$

is finite and B. Levi's Theorem (Fremlin, 2010)[123A] tells us that $\sum_{t=1}^\infty|X_t|\times\chi\{\tau_1 = t\}$ is integrable. Also $|\sum_{t=1}^{t'}X_t\times\chi\{\tau_1 = t\}|$ is upper bounded by the integrable function $\sum_{t=1}^\infty|X_t|\times\chi\{\tau_1 = t\}$ for all $t'\in\mathbb{N}_+$ and Lebesgue's Dominated Convergence Theorem (Fremlin, 2010)[123C] gives us

$$E(X_{\tau_1}) = E\big(\sum_{t=1}^\infty X_t\times\chi\{\tau_1 = t\}\big) = \sum_{t=1}^\infty E(X_t\times\chi\{\tau_1 = t\}) = \sum_{t=1}^\infty P(\tau_1 = t)E(X_t) = E(X_1).$$

We perform induction over τ_i, $i \geq 2$. The set $\{\tau_i = t\}$ is an element of $\mathcal{H}_{i-1}$ and for any $s < t$, $s, t \in \mathbb{N}_+$ we have that $B = \{\tau_i = t\} \cap \{\tau_{i-1} = s\} \in \mathcal{H}_{i-1}$. Observe that Lemma A.3 tells us that $B \in \mathcal{E}_s$ and, hence, that

$$\int_B E(X_{\tau_i}|\mathcal{H}_{i-1}) = \int_B X_t = \int_B E(X_t|\mathcal{E}_s).$$

Due to stationarity this implies that

$$\Big|\int_B (E(X_{\tau_i}|\mathcal{H}_{i-1}) - E(X_t))\Big| = \Big|\int_B (E(X_t|\mathcal{E}_s) - E(X_1))\Big| \leq 2c\varphi_{t-s}P(B). \tag{30}$$

Because τ_i is $\mathcal{H}_{i-1}$ measurable we can now write

$$\begin{aligned}
E(X_{\tau_i}) &= EE(X_{\tau_i}|\mathcal{H}_{i-1}) \\
&= EE(\sum_{t=1}^{\infty} X_t \times \chi\{\tau_i = t\}|\mathcal{H}_{i-1}) && (31)\\
&= \sum_{t=1}^{\infty} EE(X_t \times \chi\{\tau_i = t\}|\mathcal{H}_{i-1}) && (32)\\
&= \sum_{t=1}^{\infty} E(E(X_t|\mathcal{H}_{i-1}) \times \chi\{\tau_i = t\}) && (33)\\
&= \sum_{t=1}^{\infty} E(E(X_t|\mathcal{H}_{i-1}) \times \chi\Big(\{\tau_i = t\} \cap \bigcup_{s=1}^{t-\ell}\{\tau_{i-1} = s\}\Big)) \\
&= \sum_{t=1}^{\infty}\sum_{s=1}^{t-\ell} E(E(X_t|\mathcal{H}_{i-1}) \times \chi\Big(\{\tau_i = t\} \cap \{\tau_{i-1} = s\}\Big), && (34)
\end{aligned}$$

where, with the same argument as above, using B. Levi's Theorem and Lebesgue's Dominated Convergence Theorem for the expectation operator and for the conditional expectation operator, the infinite summation in (31) is moved outside to give (32). Moreover, (33) is due to the fact that τ_i is $\mathcal{H}_{i-1}$-measurable. Finally, we obtain,

$$\begin{aligned}
&|E(X_{\tau_i}) - E(X_1)| && (35)\\
&= \left|\sum_{t=1}^{\infty}\sum_{s=1}^{t-\ell}(E(E(X_t|\mathcal{H}_{i-1}) \times \chi\left(\{\tau_i = t\} \cap \{\tau_{i-1} = s\}\right)) - P(\tau_i = t, \tau_{i-1} = s)E(X_1))\right| && (36)\\
&\leq \sum_{t=1}^{\infty}\sum_{s=1}^{t-\ell}\left|(E(E(X_t|\mathcal{H}_{i-1}) \times \chi\left(\{\tau_i = t\} \cap \{\tau_{i-1} = s\}\right)) - P(\tau_i = t, \tau_{i-1} = s)E(X_1))\right| \\
&\leq 2c\sum_{t=1}^{\infty}\sum_{s=1}^{t-\ell}\varphi_{t-s}P(\tau_i = t, \tau_{i-1} = s) && (37)\\
&\leq 2c\varphi_\ell\sum_{t=1}^{\infty}\sum_{s=1}^{t-\ell}P(\tau_i = t, \tau_{i-1} = s) && (38)\\
&= 2c\varphi_\ell,
\end{aligned}$$

where, (36) follows from (34), (37) follows from (30) with $B := \{\tau_i = t\} \cap \{\tau_{i-1} = s\} \in \mathcal{H}_{i-1}$, and (38) is due to the fact that $\langle\varphi_n\rangle_{n\in\mathbb{N}_+}$ is a decreasing sequence, see, e.g. (Bradley, 2007)[vol. 1 pp. 69], and that $t - s \geq \ell$. This proves the statement. ■

A.4. Details of Example 1

We give in this section the details of the construction in Example 1. This example demonstrates that the sequence $\langle X_{\tau_n}\rangle_{n\in\mathbb{N}_+}$ of samples of one of the arms of a two armed bandit problem does not need to be φ-mixing even though the original process is φ-mixing. The argument uses standard results from Markov chains as they can be found in (Levin et al., 2008) and a well known perturbation result for Markov chains. We provide the details of the argument for completeness.

Assume we have a two arm bandit problem where the pay-off for arm two is zero at all time and the pay-off distribution of arm one is described by a Markov chain with two states, transition probabilities $p_{11} = p_{22} = 1 - \epsilon, p_{12} = p_{21} = \epsilon$, for some $\epsilon \in (0, 1)$, and probability $1/2$ to be in state 1 at time $t = 0$. The player gains a pay-off of 1 if the Markov chain is in state 1 and a pay-off of 0 if the Markov chain is in state 2. The Markov chain is irreducible and aperiodic. Furthermore, the Markov chain induces a stationary pay-off distribution. This implies that we are dealing with a jointly stationary φ-mixing process with mixing coefficients φ_k being upper bounded by $\varphi_k \leq (1 - 2\epsilon)^k$: one can derive the particular bound by considering an eigendecomposition of the transition matrix T which yields eigenvalues $\lambda_1 = 1, \lambda_2 = 1 - 2\epsilon$ and eigenvectors $u_1 = \sqrt{2}(1/2 \quad 1/2)^\top, u_2 = \sqrt{2}(1/2 \quad -1/2)^\top$, i.e. with $U = (u_1 \quad u_2)$ and Λ being the diagonal matrix with entries λ_1 and λ_2 we have $T = U\Lambda U^\top$. The stationary distribution over the states is $s = (1/2 \quad 1/2)^\top$ and for any vector $v = (v_1 \quad v_2)^\top, v_1, v_2 \geq 0, v_1 + v_2 = 1$, we have $\Lambda^k U^\top v = (1/\sqrt{2})(1 \quad (1 - 2\epsilon)^k(v_1 - v_2))^\top$. Hence, $T^k v - s = (1/2)(1 - 2\epsilon)^k(v_1 - v_2)(1 \quad -1)^\top$ and $\left\|T^k v - s\right\|_\infty \leq (1/2)(1 - 2\epsilon)^k$. The mixing coefficients can now be bounded in the following way. Let $X_{t,i}, t \geq 1, i \in \{1, 2\}$, be random variables that represent the pay-off of arm i gained at time t. Consider a particular realization where $X_{1,1} = x_1, \ldots, X_{n,1} = x_n$ and $X_{n+k,1} = x_{n+k}, \ldots, X_{n+k+m,1} = x_{n+k+m}$ for some $x_1, \ldots, x_n, x_{n+k+1}, \ldots, x_{n+k+m} \in \{0, 1\}$ then $P(X_{1,1} = x_1, \ldots, X_{n,1} = x_n, X_{n+k,1} = x_{n+k}, \ldots, X_{n+k+m,1} = x_{n+k+m}) = P(X_{1,1} = x_1, \ldots, X_{n,1} = x_n)P(X_{n+k,1} = x_{n+k}, \ldots, X_{n+k+m,1} = x_{n+m+k}|X_{n,1} = x_n)$ and

$$\begin{aligned}
&|P(X_{n+k,1} = x_{n+k}, \ldots, X_{n+k+m,1} = x_{n+m+k}|X_{n,1} = x_n) \\
&\qquad - P(X_{n+k,1} = x_{n+k}, \ldots, X_{n+k+m,1} = x_{n+m+k})| \\
&= P(X_{n+k+1,1} = x_{n+k+1}, \ldots, X_{n+k+m,1} = x_{n+m+k}|X_{n+k,1} = x_{n+k}) \\
&\qquad \times |P(X_{n+k,1} = x_{n+k}) - P(X_{n+k,1} = x_{n+k}|X_{n,1} = x_n)| \\
&\leq (1/2)(1 - 2\epsilon)^k P(X_{n+k+1,1} = x_{n+k+1}, \ldots, X_{n+k+m,1} = x_{n+m+k}|X_{n+k,1} = x_{n+k}) \\
&= (1 - 2\epsilon)^k P(X_{n+k,1} = x_{n+k}, \ldots, X_{n+k+m,1} = x_{n+m+k}). && (39)
\end{aligned}$$

since $P(X_{n+k,1} = x_{n+k}) = 1/2$. Let $A = \{1, \ldots, n\}$, $B = \{n + k, \ldots, n + k + m\}$ and consider $\sigma(X_A), \sigma(X_B)$. The events in these σ-algebras are finite unions of events of the form $\{X_{1,1} = x_1, \ldots, X_{n,1} = x_n\}$ and $\{X_{n+k,1} = x_{n_k}, \ldots, X_{n+k+m,1} = x_{n+k+m}\}$.

For any $U \in \sigma(X_A)$ we know that U consists at most of finitely many such events $U_1, \ldots, U_l$, $U_i \cap U_j = \emptyset$, for all $i, j \leq l$. Similarly for $V \in \sigma(X_B)$ we know that $V = V_1 \cup \ldots \cup V_o$, $V_i \cap V_j = \emptyset$,

for all $i, j \leq o$. The above argument which leads to the bound (39) allows us to conclude that for any $U \in \sigma(X_A)$ and $V \in \sigma(X_B)$

$$|P(U)P(V) - P(U \cap V)| = \sum_{i \leq l} \sum_{j \leq o} |P(U_i)P(V_j) - P(U_i \cap V_j)|$$
$$\leq (1-2\epsilon)^k \sum_{i \leq l} \sum_{j \leq o} P(U_i)P(V_j) \leq (1-2\epsilon)^k.$$

Hence the Markov chain is φ-mixing. The second arm has a constant reward and does not introduce any dependencies in the pay-off over time. Therefore we have a jointly stationary φ-mixing process with the mixing coefficient being equal to the mixing coefficients of the Markov chain.

Now fix some $\delta > 0$ and consider the following policy π^δ. At $t = 1$ the policy plays arm 1 receiving pay-off $X_{1,1}$. Then at any other $t \geq 2$ the arm is selected according to the following rules: if at $t-1$ arm 1 has been played and $X_{t-1,1} = X_{1,1}$ then the policy chooses at t arm 1; if at $t-1$ arm 1 has been played and $X_{t-1,1} \neq X_{1,1}$ then the policy chooses at t arm 2 and plays arm 2 for the next $k := \lceil \log(2\delta)/\log(1-2\epsilon) \rceil$ rounds before switching back to arm 1. We'd like to show that the sequence of pay-offs generated by policy π^δ at arm 1 is not φ-mixing. Let $\tau_1, \tau_2, \ldots$ be the sequence of random times at which arm 1 is played (by construction $\tau_1 = 1$ and $\tau_2 = 2$). The evolution of the process $\langle X_{\tau_n} \rangle_{n \geq 1}$ can also be described by transition matrices. The transition probabilities to move from a state at $t = 1$ to a state at $t = 2$ are just the probabilities summarized in T. For all other t ($t \geq 2$) the transition matrix is either

$$\tilde{T} = \begin{pmatrix} 1-\epsilon & \epsilon \\ (T^k)_{21} & (T^k)_{22} \end{pmatrix} \quad \text{or} \quad \tilde{T} = \begin{pmatrix} (T^k)_{11} & (T^k)_{12} \\ \epsilon & 1-\epsilon \end{pmatrix} \tag{40}$$

depending on X_{τ_1}, i.e. if $X_{\tau_1} = 1$ then the former is describing the evolution and if $X_{\tau_1} = 0$ the latter is the one describing the evolution of the Markov chain. In the following we discuss the case that $X_{\tau_1} = 1$, but the same arguments apply to the case $X_{\tau_1} = 0$. We can observe that $\|v^\top(\tilde{T} - \hat{T})\|_\infty \leq \delta$ for all v with non-negative entries and $v_1 + v_2 = 1$, where

$$\hat{T} = \begin{pmatrix} 1-\epsilon & \epsilon \\ 1/2 & 1/2 \end{pmatrix}$$

in case that $X_{\tau_1} = 1$. The claim can be verified through

$$\left\| v^\top \tilde{T} - v^\top \hat{T} \right\|_\infty = \left\| v^\top \begin{pmatrix} 0 & 0 \\ \tilde{T}_{21} - 1/2 & \tilde{T}_{22} - 1/2 \end{pmatrix} \right\|_\infty$$
$$= v_2 \left\| T^k \begin{pmatrix} 0 \\ 1 \end{pmatrix} - \begin{pmatrix} 1/2 \\ 1/2 \end{pmatrix} \right\|_\infty \leq v_2 \delta \leq \delta.$$

The Markov chains associated to $\tilde{T}$ and $\hat{T}$ are both irreducible and aperiodic. This implies in particular the existence of stationary distributions, with the associated probabilities to be in state one and two summarized in vectors $\tilde{s}, \hat{s} \in [0,1]^2$, and the convergence of $\tilde{T}^l, \hat{T}^l$ to $\tilde{s}, \hat{s}$ in l (measured in $\|\|_\infty$, (Levin et al., 2008)[Thm. 4.9]). In particular, there exist constants $\tilde{c}, \hat{c} > 0$ and $\tilde{\alpha}, \hat{\alpha} \in (0,1)$ such that for all $l \geq 1$ and any vector $v \in [0,1]^2$ with $v_1 + v_2 = 1$

$$\|v^\top \tilde{T}^l - \tilde{s}\|_\infty \leq \tilde{c}\tilde{\alpha}^l \quad \text{and} \quad \|v^\top \hat{T}^l - \hat{s}\|_\infty \leq \hat{c}\hat{\alpha}^l.$$

We can also calculate the stationary distribution of $\hat{T}$ explicitly to get $\hat{s} = (1/(1+2\epsilon) \;\; 2\epsilon/(1+2\epsilon))^\top$.

It is known that Markov chains with slightly perturbed transition matrices have similar stationary distributions. Due to Cho and Meyer (2001) there exists a constant $c > 0$ that is only dependent on $\hat{T}$ (and independent of $\tilde{T}$) such that $\|\tilde{s} - \hat{s}\|_\infty \leq c\|\tilde{T} - \hat{T}\|_{\infty,1} \leq 2\delta c$ where $\|\tilde{T} - \hat{T}\|_{\infty,1} := \max_{i \in \{1,2\}} \sum_{j=1}^2 |\tilde{T}_{i,j} - \hat{T}_{i,j}| \leq 2\delta$. Combining these inequalities yields $\|v^\top \tilde{T}^l - \hat{s}\|_\infty \leq 2\delta c + \tilde{c}\tilde{\alpha}^l$ for any v with non-negative entries and $v_1 + v_2 = 1$.

Consider now the events $U = \{X_{\tau_1,1} = 1\}$ and $V = \{X_{\tau_n,1} = 1\}$ for $n \geq 2$. We have $P(U) = 1/2 = P(V)$ where the second equality follows from

$$2P(X_{\tau_n,1} = 0) = P(X_{\tau_n,1} = 0 | X_{\tau_1,1} = 0) + P(X_{\tau_n,1} = 0 | X_{\tau_1,1} = 1)$$
$$= P(X_{\tau_n,1} = 1 | X_{\tau_1,1} = 1) + P(X_{\tau_n,1} = 1 | X_{\tau_1,1} = 0)$$
$$= 2P(X_{\tau_n,1} = 1).$$

Furthermore, with $\tilde{T}$ being the matrix defined on the left side of (40)

$$\left| \frac{P(U \cap V)}{P(U)} - \frac{1}{1+2\epsilon} \right| = \left| (1-\epsilon \;\; \epsilon) \tilde{T}^{n-1} \begin{pmatrix} 1 \\ 0 \end{pmatrix} - \frac{1}{1+2\epsilon} \right|$$
$$\leq \left\| (1-\epsilon \;\; \epsilon) \tilde{T}^{n-1} - \frac{1}{1+2\epsilon} \begin{pmatrix} 1 \\ 2\epsilon \end{pmatrix} \right\|_\infty$$

and the last term is upper bounded by $2\delta c + \tilde{c}\tilde{\alpha}^{n-1}$. Recalling that c does not depend on $\tilde{T}$ and, hence, not on δ we see that we can make the term $2\delta c$ arbitrary small. Furthermore, by considering a large n we can make the second term arbitrary small. In particular, let $\epsilon = 1/10$ then there exists a π^δ and an $N \in \mathbb{N}$ such that for all $n \geq N$

$$\left| \frac{P(U \cap V)}{P(U)} - \frac{1}{1+2\epsilon} \right| \leq 1/10. \tag{41}$$

Hence, for all $n \geq N$

$$|P(U)P(V) - P(U \cap V)| \geq P(U)\Big(\Big| \frac{1}{2} - \frac{1}{1+2\epsilon} \Big| - 1/10 \Big)$$
$$\geq P(U)/5$$

and the process is not φ-mixing.

Appendix B. Proof of Theorem 12: Regret Bound for φ-mixing Bandits

For the regret $\overline{\mathcal{R}}(n)$ of Algorithm 1 after n rounds of play. We have,

$$\overline{\mathcal{R}}(n) \leq \sum_{\substack{i=1 \\ \mu_i \neq \mu^*}}^k \frac{32(1 + 8\|\varphi\|)\ln n}{\Delta_i} + (1 + 2\pi^2/3)(\sum_{i=1}^k \Delta_i) + \|\varphi\| \log n$$

Proof Thanks to Proposition 11, in order to bound the regret $\overline{\mathcal{R}}(n)$ it suffices to calculate the expected number of times $T_i(n)$ that a suboptimal arm is played in n rounds. For any $s, t \in \mathbb{N}_+$, let $c_{t,s} := \sqrt{(8\zeta((1/8) + \ln t))/2^s} + \|\varphi\|/2^{s-1}$, where $\zeta = 1 + 8\|\varphi\|$. Recall that Algorithm 1

plays its selected arms in batches of exponentially growing length so that if arm j for $j \in 1..k$ is selected at round t, it is played for $2^{s_j(t)}$ consecutive time-steps, where $s_j(t)$ denotes the number of times that arm j has been selected up-to time t. Below, we denote by $\overline{X}_{j,s} := \frac{1}{2^s}\sum_{t'=t}^{t+2^s-1} X_{t',j}$ with $s := s_j(t)$, the Algorithm's estimate of the stationary mean of arm j selected at time t. As usual, a superscript "$*$" refers to the quantities for the arm with the highest stationary mean. Fix some $l \in \mathbb{N}_+$. We have,

$$\begin{aligned}
T_i(n) &= 1 + \sum_{t=k+1}^{n} \chi\{\pi_t = i\} \\
&\le 2^{l+1} + \sum_{t=2^{l+1}+1}^{n} \sum_{m=l+1}^{\log t} 2^m \chi\Big\{ \min_{s=1..\log t} \overline{X}^*_s + c_{t,s} \le \frac{1}{2^{m-1}} \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} + c_{t,m-1} \Big\} \\
&\le 2^{l+1} + \sum_{t=1}^{\infty} \sum_{m=l+1}^{\log t} \sum_{s=1}^{\log t} 2^m \chi\Big\{ \overline{X}^*_s + c_{t,s} \le \frac{1}{2^{m-1}} \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} + c_{t,m-1} \Big\}
\end{aligned}$$

For every $t \in \mathbb{N}$ and every $s \in 1..\log t$ we have that $\overline{X}^*_s + c_{t,s} \le \frac{1}{2^{m-1}}\sum_{u=t}^{t+2^{m-1}-1} X_{u,i} + c_{t,m-1}$ implies that

$$\overline{X}^*_s \le \mu^* - c_{t,s} \tag{42}$$

$$\frac{1}{2^{m-1}} \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} \ge \mu_i + c_{t,m-1} \tag{43}$$

$$\mu^* < \mu_i + 2c_{t,m-1} \tag{44}$$

Now, observe that for a fixed $t \in 1..n$ we have,

$$\begin{aligned}
P(\overline{X}^*_s \le \mu^* - c_{t,s}) &\le P\left(\left| \overline{X}^*_s - \mu^* \right| \ge c_{t,s} \right) \\
&\le P\left(\left| \sum_{j=0}^{2^s-1} X^*_{\tau_s+j} - EX^*_{\tau_s+j} \right| + \left| \sum_{j=0}^{2^s-1} (EX^*_{\tau_s+j} - \mu^*) \right| \ge 2^s c_{t,s} \right) \\
&\le P\left(\left| \sum_{j=0}^{2^s-1} X^*_{\tau_s+j} - EX^*_{\tau_s+j} \right| \ge 2^s c_{t,s} - 2\left\|\varphi\right\| \right) && (45) \\
&\le \sqrt{e} \exp\Big(- \frac{(2^s c_{t,s} - 2\left\|\varphi\right\|)^2}{2^{s+1}\zeta} \Big) && (46) \\
&\le t^{-4}, && (47)
\end{aligned}$$

where, (45) follows from Lemma 10 and (46) follows from a Hoeffding-type bound for φ-mixing processes given by Corollary 2.1 of Rio (1999) which is applicable due to Lemma 14 (pp. 17).

Moreover, noting that $\|\varphi\| \ge 0$ we similarly obtain,

$$\begin{aligned}
P\Big(\frac{1}{2^{m-1}} \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} \ge \mu_i + c_{t,m-1}\Big) &\le P\Big(\frac{1}{2^{m-1}} \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} \ge \mu_i + c_{t,m-1} - \frac{2}{2^{m-1}}\left\|\varphi\right\|\Big) \\
&\le P\Big(\Big| \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} - 2^{m-1}\mu_i \Big| \ge 2^{m-1} c_{t,m-1} - 2\left\|\varphi\right\|\Big) \\
&\le t^{-4}. && (48)
\end{aligned}$$

Let $L := \log \frac{32(1+4\|\varphi\|)\ln n}{\Delta_i^2}$. Since, for $t \ge 2^L+1$ and every $m \ge L+1$ we have $\mu^* - \mu_i - 2c_{t,m-1} \ge 0$, it follows that (44) is false for all $m \ge L+1$. Therefore we have,

$$\begin{aligned}
E(T_i(n)) &\le 2^{L+1} + \sum_{t=1}^{\infty} \sum_{m=L+1}^{\log t} \sum_{s=1}^{\log t} P(\overline{X}^*_s \le \mu^* - c_{t,s}, \frac{1}{2^{m-1}} \sum_{u=t}^{t+2^{m-1}-1} X_{u,i} \ge \mu_i + c_{t,m-1}) \\
&\le 2^{L+1} + \sum_{t=1}^{\infty} \sum_{m=L+1}^{\log t} \sum_{s=1}^{\log t} 2^{m+1} t^{-4} && (49) \\
&\le \frac{32(1+4\left\|\varphi\right\|)\ln n}{\Delta_i^2} + 1 + 2\pi^2/3
\end{aligned}$$

where (49) follows from (47) and (48). ■

Appendix C. Proofs for Strongly Dependent Reward Distributions

C.1. Basic Bounds

Consider two independent and normally distributed random variables X, Y with mean $\mu_X > \mu_Y$ and variance σ_X^2, σ_Y^2. Let $\Delta = \mu_X - \mu_Y > 0$ and $\sigma^2 = \sigma_X^2 + \sigma_Y^2$. We derive in this section the following bounds which are crucial for the derivation of the regret. We use the notation $z^+ = \max\{0, z\}$ and $\phi(x) = (2\pi)^{-1/2}\exp(-x^2/2)$ for the density function of the standard normal distribution.

$$E(Y-X)^+ \le \sigma\phi(\Delta/\sigma), \tag{50}$$

$$E(Y-X)^+ \ge 0, \tag{51}$$

$$E(X-Y)^+ \le \sigma\phi(\Delta/\sigma) + \Delta, \tag{52}$$

$$E(X-Y)^+ \ge \Delta. \tag{53}$$

The derivation is based on basic properties of Gaussian random variables. Recall that $Z = X - Y$ is normally distributed with mean Δ and variance σ^2. Therefore,

$$\begin{aligned}
\sqrt{2\pi}\sigma E(X-Y)^+ &= \int_0^\infty z \exp\left(-\frac{(z-\Delta)^2}{2\sigma^2}\right) \\
&= \int_{-\Delta}^\infty z \exp\left(-\frac{z^2}{2\sigma^2}\right) + \Delta \int_{-\Delta}^\infty \exp\left(-\frac{z^2}{2\sigma^2}\right) \\
&= \sigma^2 \exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma \int_{-\infty}^{\Delta/\sigma} \exp\left(-\frac{z^2}{2}\right)
\end{aligned}$$

Standard bounds on the cdf, as can be found in (Dudley, 2002)[Lem. 12.1.6], lead to (53), i.e.

$$\begin{aligned}\sqrt{2\pi}\sigma E(X-Y)^+ &= \sigma^2 \exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma\sqrt{2\pi}\left(1 - \frac{1}{\sqrt{2\pi}}\int_{\Delta/\sigma}^{\infty}\exp\left(-\frac{z^2}{2}\right)\right)\\ &\geq \sigma^2 \exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma\sqrt{2\pi}\left(1 - \frac{\sigma}{\sqrt{2\pi}\Delta}\exp\left(-\frac{\Delta^2}{2\sigma^2}\right)\right)\\ &= \Delta\sigma\sqrt{2\pi}.\end{aligned}$$

Similarly, if we consider $Z = Y - X$ which has mean $-\Delta$

$$\begin{aligned}\sqrt{2\pi}\sigma E(Y-X)^+ &= \int_0^{\infty} z\exp\left(-\frac{(z+\Delta)^2}{2\sigma^2}\right)\\ &= \sigma^2\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) - \Delta\sigma\int_{\Delta/\sigma}^{\infty}\exp\left(-\frac{z^2}{2}\right).\end{aligned}$$

Applying the result from Dudley (2002)[Lem. 12.1.6] leads here to the trivial lower bound 0 and, hence, inequality (51). We use the following inequalities to obtain upper bounds on $E(Y-X)^+$ and $E(X-Y)^+$. Let Z be a standard normal random variable. Then

$$\Pr(Z \geq c) \geq \begin{cases}\phi(c)/(2c) & \text{if } c \geq 1,\\ \phi(c)(1-c)/2 & \text{if } 0 \leq c < 1.\end{cases}$$

The first bound can be found in (Dudley, 2014). The second bound is a straightforward adaptation of the techniques used to derive the first bound. Applying these bounds we get the following upper bounds on $E(Y-X)^+$. If $\Delta/\sigma \geq 1$ then

$$\begin{aligned}\sqrt{2\pi}\sigma E(Y-X)^+ &\leq \sigma^2\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) - \Delta\sigma\frac{\sigma}{2\Delta}\exp\left(-\frac{\Delta^2}{2\sigma^2}\right)\\ &= \frac{\sigma^2}{2}\exp\left(-\frac{\Delta^2}{2\sigma^2}\right)\end{aligned}$$

and if $0 \leq \Delta/\sigma < 1$

$$\begin{aligned}\sqrt{2\pi}\sigma E(Y-X)^+ &\leq \sigma^2\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) - \Delta\sigma\frac{(1-\Delta/\sigma)}{2}\exp\left(-\frac{\Delta^2}{2\sigma^2}\right)\\ &= (\sigma^2 - \Delta\sigma/2 + \Delta^2/2)\exp\left(-\frac{\Delta^2}{2\sigma^2}\right)\\ &\leq \sigma^2\exp\left(-\frac{\Delta^2}{2\sigma^2}\right)\end{aligned}$$

and the inequality (52) follows. The upper bounds on $E(X-Y)^+$ are derived in the same way. For $\Delta/\sigma \geq 1$ these are

$$\begin{aligned}\sqrt{2\pi}\sigma E(X-Y)^+ &\leq \sigma^2\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) - (\sigma^2/2)\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma\sqrt{2\pi}\\ &= \frac{\sigma^2}{2}\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma\sqrt{2\pi}\end{aligned}$$

and for $0 \leq \Delta/\sigma \leq 1$

$$\begin{aligned}\sqrt{2\pi}\sigma E(X-Y)^+ &\leq \sigma^2\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) - \frac{\Delta\sigma(1-\Delta/\sigma)}{2}\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma\sqrt{2\pi}\\ &= (\sigma^2 - \Delta\sigma/2 + \Delta^2/2)\exp\left(-\frac{\Delta^2}{2\sigma^2}\right) + \Delta\sigma\sqrt{2\pi}\end{aligned}$$

and the inequality (50) follows.

C.2. Proof of Proposition 13

We bound the regret of the two phases individually. Some technical steps are moved further below to streamline the discussion.

Regret of Phase I. We sweep through all k arms at times 1 to k, $m+1$ to $m+k$, etc. During each of these phases we build up regret. This regret can be bounded by

$$\begin{aligned}&\sum_{i=1}^{k} E(\max_{j\neq i} X_{m+i,j} - X_{m+i,i})^+\\ &\qquad\leq \sum_{i=1}^{k}\sum_{j\neq i} E(X_{m+i,j} - X_{m+i,i})^+\\ &\qquad\leq (k-1)\sum_{i=1}^{k}\max_{j\neq i} E(X_{m+i,j} - X_{m+i,i})^+\\ &\qquad\leq (k-1)\sum_{i=1}^{k}\Delta_i + \sqrt{2}(k-1)\sum_{i=1}^{k}\phi(\Delta_i/\sqrt{2})\\ &\qquad\leq (k-1)\sum_{i=1}^{k}(\Delta_i + \sqrt{2}),\end{aligned} \tag{54}$$

where $\Delta_i = \mu^* - \mu_i$ is the difference between the highest stationary mean of the k arms and the stationary mean of arm i. Here, we use Inequality (52) and the assumption that the variance of the individual processes is 1. Therefore, the σ appearing in the bound (52) is $\sqrt{2}$ since σ^2 is the sum of the variances of the two individual processes.

Regret of Phase II. To control the regret building up in the second phase we condition on the observations in a sweep at time lm, $l \in \mathbb{N}$, i.e. on the observed pay-offs $x_1, \ldots, x_k$. Arm i^* is selected such that $x_{i^*} \geq \max_{i\leq k} x_i$ and this arm is played for $m-k$ steps. We need to control $E(\max_{i\leq k}(X_{t',i} - X_{t',\pi_{t'}})^+)$ for all $lm+k+1 \leq t' \leq (l+1)m$. Due to stationarity this is equal to controlling $E(\max_{i\leq k}(X_{t,i} - X_{t,\pi_t})^+)$, for all $k+1 \leq t \leq m$.

We use in the following $P_{x_1,\ldots,x_k}$, P_{x_i,x_u} for the conditional distributions given that $X_{11} = x_1, \ldots, X_{kk} = x_k$ and $X_{ii} = x_i, X_{uu} = x_u$, and we use ν for the marginal measure. In Appendix

C.2.1 below we show that for any $k+1 \leq t \leq m$ it holds that

$$E(\max_{i\leq k}(X_{t,i} - X_{t,\pi_t})^+) \leq \sum_{u=1}^{k}\sum_{i\neq u}\int P_{x_1,\ldots,x_k}(u = i^*) \times \int (X_{t,i} - X_{t,u})^+ dP_{x_i,x_u} d\nu(x_1,\ldots,x_k). \quad (55)$$

The inner integral in (55) can be bounded by using inequality (50)

$$\int (X_{t,i} - X_{t,u})^+ dP_{x_i,x_u} \leq \sigma_{t,i}\phi\left(\frac{\Delta_{t,i}}{\sigma_{t,i}}\right), \quad (56)$$

where $\Delta_{t,i} = E(X_{t,u} - X_{t,i}|X_{i,i} = x_i, X_{u,u} = x_u)$ which equals $E(X_{t,u}|X_{u,u} = x_u) - E(X_{t,i}|X_{i,i} = x_i)$ due to the independence between arm u and i. These are posterior means of Gaussian processes given observations x_u and x_i, respectively. Observe that the posterior mean for $X_{t,u}$ is related to the posterior mean of the zero mean Gaussian process $X_{t,u} - \mu_u$ through $E(X_{t,u}|X_{u,u} = x_u) = \mu_u + E(X_{t,u} - \mu_u|X_{u,u} - \mu_u = x_u - \mu_u)$. The posterior equation for the zero mean Gaussian process $X_{t,u} - \mu_u$ given observation $x_u - \mu_u$ at time u is $\text{cov}(t-u)(x_u - \mu_u)$ since $\text{cov}(0) = 1$. Therefore, $E(X_{t,u}|X_{u,u} = x_u) = \mu_u + \text{cov}(t-u)(x_u - \mu_u)$ and, hence, $E(X_{t,u}|X_{u,u} = x_u) = (1 - \text{cov}(t-u))\mu_u + \text{cov}(t-u)x_u$. Similarly, $E(X_{t,i}|X_{i,i} = x_i) = (1 - \text{cov}(t-i))\mu_i + \text{cov}(t-i)x_i$ By defining $\tilde{\Delta}_i = x_u - x_i$ and by using the Hölder-continuity assumption, we obtain the following lower bound.

$$\begin{aligned}\Delta_{t,i} &= (\mu_u - \mu_i)(1 - \text{cov}(t-k)) + \tilde{\Delta}_i \text{cov}(t-k) + \varepsilon(t)\\ &\geq \tilde{\Delta}_i - |\mu_u - \mu_i||\text{cov}(0) - \text{cov}(t-k)| - \tilde{\Delta}_i|\text{cov}(0) - \text{cov}(t-k)| - |\varepsilon(t)|\\ &\geq \tilde{\Delta}_i - c(t-k)^\alpha(\Delta + \tilde{\Delta}_i) - |\varepsilon(t)| \quad (57)\end{aligned}$$

with $\varepsilon(t)$ being a term which can be bounded by $|\varepsilon(t)| \leq (\Delta + \tilde{\Delta}_i)ck^\alpha$ (see Appendix C.2.2). For the conditional variance,

$$\sigma^2_{t,i} = E(X^2_{t,u}|X_{u,u} = x_u) - E(X_{t,u}|X_{u,u} = x_u)^2 + E(X^2_{t,i}|X_{i,i} = x_i) - E(X_{t,i}|X_{i,i} = x_i)^2,$$

we obtain the following upper-bound

$$\sigma^2_{t,i} = 2 - \text{cov}^2(t-u) - \text{cov}^2(t-i) \leq 2c(t-u)^\alpha + 2c(t-i)^\alpha \leq 4ct^\alpha, \quad (58)$$

where we have used the posterior equation for the covariance, that the covariance is by assumption non-negative, and that, under the Hölder-continuity assumption, for a non-negative covariance $\text{cov}(l) \geq \max\{0, (1 - cl^\alpha)\}$ and, hence,

$$\begin{aligned}\text{cov}^2(l) &\geq \text{cov}(l)\max\{0, 1 - cl^\alpha\}\\ &= \begin{cases}0 & \text{if } cl^\alpha \geq 1,\\ \text{cov}(l)(1 - cl^\alpha) & \text{otherwise,}\end{cases}\\ &\geq \begin{cases}0 & \text{if } cl^\alpha \geq 1,\\ 1 - 2cl^\alpha + c^2l^{2\alpha} & \text{otherwise,}\end{cases}\\ &\geq 1 - 2cl^\alpha.\end{aligned}$$

Combining (56), (57) and (58) we obtain

$$\begin{aligned}&\int (X_{t,i} - X_{t,u})^+ dP_{x_i,x_u}\\ &\leq (2/\pi)^{1/2}c^{1/2}t^{\alpha/2}\exp\left(-\frac{(\tilde{\Delta}_i - c((t-k)^\alpha + k^\alpha)(\tilde{\Delta}_i + \Delta))^2}{8ct^\alpha}\right)\\ &= (2/\pi)^{1/2}c^{1/2}t^{\alpha/2}\exp\left(-\frac{\tilde{\Delta}_i^2}{8ct^\alpha}\Big(1 - c((t-k)^\alpha + k^\alpha)\Big(1 + \frac{\Delta}{\tilde{\Delta}_i}\Big)\Big)^2\right). \quad (59)\end{aligned}$$

The bound is maximized for $t = m$. Substituting this bound back into (55) and after a few manipulations (see Appendix C.2.3) we see that

$$\begin{aligned}&\sum_{t=k+1}^{m} E\Big(\max_{i\leq k}(X_{t,i} - X_{t,\pi_t})^+\Big)\\ &\qquad \leq (m-k)\frac{a_m c^{1/2}k(k-1)}{8\pi(1-b_m)}\left(2\pi^{1/2} - (1 - \Delta\sqrt{b_m/4})\exp\left(-\frac{\Delta^2 b_m}{4}\right)\right) \quad (60)\end{aligned}$$

if $m > k$ and $\Delta < \sqrt{a_m}/(b_m\sqrt{2})$, where $a_m = 8cm^\alpha$ and $b_m = c((m-k)^\alpha + k^\alpha)$.

Combined Regret. Combining (54) with (60) and using $\Delta_i \leq \Delta$ we can observe that the combined regret for any m steps is bounded by

$$k(k-1)\left(\Delta + \sqrt{2} + (m-k)\frac{a_m c^{1/2}}{8\pi(1-b_m)}\left(2\pi^{1/2} - (1 - \Delta\sqrt{b_m/4})\exp\left(-\frac{\Delta^2 b_m}{4}\right)\right)\right)$$

if $m > k$ and $\Delta < \sqrt{a_m}/(b_m\sqrt{2})$. Given a time horizon n we have $\lceil n/m \rceil$ many iterations of Phase I and II and the overall regret is bounded by

$$\begin{aligned}&(n/m+1)k(k-1)\left(\Delta + \sqrt{2} + \frac{a_m c^{1/2}(m-k)}{8\pi(1-b_m)}\left(2\pi^{1/2} - (1 - \Delta\sqrt{b_m/4})\exp\left(-\frac{\Delta^2 b_m}{4}\right)\right)\right)\\ &\leq (n+m)k(k-1)\left(\frac{\Delta + \sqrt{2}}{m} + \frac{a_m c^{1/2}}{8\pi(1-b_m)}\left(2\pi^{1/2} - (1 - \Delta\sqrt{b_m/4})\exp\left(-\frac{\Delta^2 b_m}{4}\right)\right)\right). \quad (61)\end{aligned}$$

This is the regret bound stated in the proposition text.

Instead of trying to find the m that minimizes (61) we optimize m over the considerably simpler expression

$$\frac{\Delta + \sqrt{2}}{m} + \frac{2c^{3/2}m^\alpha}{\sqrt{\pi}}\left(= \frac{\Delta + \sqrt{2}}{m} + \frac{a_m c^{1/2}}{4\sqrt{\pi}}\right). \quad (62)$$

The $(1 - b_m)$ term that we leave out is of minor relevance since b_m is small and the negative term in the bracket that we leave out is not larger than 1. By ignoring this latter term we lose only another constant. Minimizing (62) with respect to m and rounding up yields

$$m^\star = \left\lceil \left(\frac{\sqrt{\pi}(\Delta + \sqrt{2})}{2\alpha c^{3/2}}\right)^{\frac{1}{1+\alpha}} \right\rceil.$$

C.2.1. PROOF OF INEQUALITY (55)

Due to stationarity and since our policy depends only on the observations at the last sweep we have that $E(\max_{i\le k}(X_{t',i}-X_{t',\pi_{t'}})^+)=E(\max_{i\le k}(X_{t,i}-X_{t,\pi_t})^+)$ for any t', $lm+k+1\le t'\le lm$, $l\in\mathbb{N}$, and corresponding $t=t'-lm$. Now, consider any t, $k+1\le t\le m$ and, using i^* for the choice of arm given the observations $X_{1,1},\dots,X_{k,k}$, rewrite the regret in the following way

$$
\begin{aligned}
&E\Big(\max_{i\le k}(X_{t,i}-X_{t,\pi_t})^+\Big)\\
&=\sum_{u=1}^{k}E\Big(\max_{i\le k}\chi\{u=i^*\}\times(X_{t,i}-X_{t,i^*})^+\Big)\\
&=\sum_{u=1}^{k}E\Big(\max_{i\neq u}\chi\{u=i^*\}\times(X_{t,i}-X_{t,u})^+\Big)\\
&\le\sum_{u=1}^{k}\sum_{i\neq u}E\Big(\chi\{u=i^*\}\times(X_{t,i}-X_{t,u})^+\Big)\\
&=\sum_{u=1}^{k}\sum_{i\neq u}\int\int\chi\{u=i^*\}\times(X_{t,i}-X_{t,u})^+dP_{x_1,\dots,x_k}d\nu(x_1,\dots,x_k)\\
&=\sum_{u=1}^{k}\sum_{i\neq u}\int P_{x_1,\dots,x_k}(u=i^*)\times\int(X_{t,i}-X_{t,u})^+dP_{x_1,\dots,x_k}d\nu(x_1,\dots,x_k) \qquad (63)\\
&=\sum_{u=1}^{k}\sum_{i\neq u}\int P_{x_1,\dots,x_k}(u=i^*)\times\int(X_{t,i}-X_{t,u})^+dP_{x_i,x_u}d\nu(x_1,\dots,x_k) \qquad (64)
\end{aligned}
$$

where (63) follows because $\chi\{u=i^*\}$ is independent of $(X_{t,i}-X_{t,u})^+$ given $X_{11}=x_1,\dots,X_{kk}=x_k$ and (64) follows since $(X_{t,i}-X_{t,u})^+$ only depends on $X_{i,i}$ and $X_{u,u}$.

C.2.2. BOUND ON $\varepsilon(t)$.

The term $\varepsilon(t)$ that we introduced is equal to

$$
\begin{aligned}
\varepsilon(t)=&\mu_u(\mathrm{cov}(t-k)-\mathrm{cov}(t-u))-\mu_i(\mathrm{cov}(t-k)-\mathrm{cov}(t-i))\\
&+x_u(\mathrm{cov}(t-u)-\mathrm{cov}(t-k))-x_i(\mathrm{cov}(t-i)-\mathrm{cov}(t-k)).
\end{aligned}
$$

Since, due to our Hölder assumption, $|\mathrm{cov}(t-k)-\mathrm{cov}(t-u)|\le c(k-u)^\alpha\le ck^\alpha$ and $|\mathrm{cov}(t-k)-\mathrm{cov}(t-i)|\le ck^\alpha$, we have the following bound.

$$
|\varepsilon(t)|\le(\Delta+\tilde{\Delta}_i)ck^\alpha.
$$

C.2.3. PROOF OF INEQUALITY (60)

Denote in the following $X_u:=X_{u,u}$ and $X_i=X_{i,i}$ and recall that $\tilde{\Delta}_i=X_u-X_i$ is normally distributed with mean $\mu_u-\mu_i$ and variance 2. Writing

$$
f(X_u,X_i)=(2/\pi)^{1/2}c^{1/2}m^{\alpha/2}\exp\left(-\frac{\tilde{\Delta}_i^2}{8cm^\alpha}\Big(1-c((m-k)^\alpha+k^\alpha)\Big(1+\frac{\Delta}{\tilde{\Delta}_i}\Big)\Big)^2\right)
$$

we have

$$
\begin{aligned}
&\int P_{x_1,\dots,x_k}(u=i^*)\times\int(X_{t,i}-X_{t,u})^+dP_{x_i,x_u}\,d\nu(x_1,\dots,x_k)\\
&\le\int P_{x_1,\dots,x_k}(X_u\ge X_i)\times\int(X_{t,i}-X_{t,u})^+dP_{x_i,x_u}\,d\nu(x_1,\dots,x_k)\\
&\le\int\chi\{x_u\ge x_i\}\times f(x_u,x_i)\,d\nu(x_1,\dots,x_k) \qquad (65)\\
&=\int\chi\{x_u-x_i\ge0\}\times f(x_u,x_i)\,d\nu(x_u,x_i), \qquad (66)
\end{aligned}
$$

where the inequality in (65) follows because $\{X_u\ge X_i\}$ is only dependent on x_u and x_i and by bounding the inner integral with (59). Multiplying the density of $\tilde{\Delta}_i$ by f and using $a=8cm^\alpha$, $b=c((m-k)^\alpha+k^\alpha)$, $d=(ac)^{1/2}/(4\pi)$, in the case where $\Delta<\sqrt{a}/(b\sqrt{2})$, we obtain

$$
\begin{aligned}
&\int\chi\{x_u-x_i\ge0\}\times f(x_u,x_i)\,d\nu(x_u,x_i)\\
&\qquad=d\int_0^\infty\exp\left(-\frac{(\tilde{\Delta}_i(1-b)-\Delta b)^2}{a}-\frac{(\tilde{\Delta}_i-(\mu_u-\mu_i))^2}{4}\right)d\tilde{\Delta}_i\\
&\qquad\le d\int_0^\infty\exp\left(-\frac{(\tilde{\Delta}_i(1-b)-\Delta b)^2}{a}\right)d\tilde{\Delta}_i\\
&\qquad=\frac{d}{1-b}\int_{-\Delta b}^\infty\exp\left(-\frac{\tilde{\Delta}_i^2}{a}\right)d\tilde{\Delta}_i\\
&\qquad=\frac{\sqrt{a}d}{(1-b)\sqrt{2}}\int_{-\infty}^{\frac{\sqrt{2}\Delta b}{\sqrt{a}}}\exp\left(-\frac{\tilde{\Delta}_i^2}{2}\right)d\tilde{\Delta}_i\\
&\qquad=\frac{\sqrt{a}d\sqrt{2\pi}}{(1-b)\sqrt{2}}\left(1-\frac{1}{\sqrt{2\pi}}\int_{\frac{\sqrt{2}\Delta b}{\sqrt{a}}}^\infty\exp\left(-\frac{\tilde{\Delta}_i^2}{2}\right)d\tilde{\Delta}_i\right)\\
&\qquad\le\frac{\sqrt{\pi a}d}{(1-b)}\left(1-\frac{1-\sqrt{2}\Delta b/\sqrt{a}}{2\sqrt{2\pi}}\exp\left(-\frac{\Delta^2b^2}{a}\right)\right)\\
&\qquad=\frac{ac^{1/2}}{4(1-b)\sqrt{\pi}}\left(1-\frac{1-\sqrt{2}\Delta b/\sqrt{a}}{2\sqrt{2\pi}}\exp\left(-\frac{\Delta^2b^2}{a}\right)\right)\\
&\qquad\le\frac{ac^{1/2}}{8\pi(1-b)}\left(2\pi^{1/2}-(1-\Delta b/\sqrt{a})\exp\left(-\frac{\Delta^2b^2}{a}\right)\right)
\end{aligned}
$$

and for $m>k$, since then $a/4\ge b$, this can be further bounded by

$$
\frac{ac^{1/2}}{8\pi(1-b)}\left(2\pi^{1/2}-(1-\Delta\sqrt{b/4})\exp\left(-\frac{\Delta^2b}{4}\right)\right).
$$

Abstract

The automation of posterior inference in Bayesian data analysis has enabled experts and nonexperts alike to use more sophisticated models, engage in faster exploratory modeling and analysis, and ensure experimental reproducibility. However, standard automated posterior inference algorithms are not tractable at the scale of massive modern data sets, and modifications to make them so are typically model-specific, require expert tuning, and can break theoretical guarantees on inferential quality. Building on the Bayesian coresets framework, this work instead takes advantage of data redundancy to shrink the data set itself as a preprocessing step, providing fully-automated, scalable Bayesian inference with theoretical guarantees. We begin with an intuitive reformulation of Bayesian coreset construction as sparse vector sum approximation, and demonstrate that its automation and performance-based shortcomings arise from the use of the supremum norm. To address these shortcomings we develop Hilbert coresets, i.e., Bayesian coresets constructed under a norm induced by an inner-product on the log-likelihood function space. We propose two Hilbert coreset construction algorithms—one based on importance sampling, and one based on the Frank-Wolfe algorithm—along with theoretical guarantees on approximation quality as a function of coreset size. Since the exact computation of the proposed inner-products is model-specific, we automate the construction with a random finite-dimensional projection of the log-likelihood functions. The resulting automated coreset construction algorithm is simple to implement, and experiments on a variety of models with real and synthetic data sets show that it provides high-quality posterior approximations and a significant reduction in the computational cost of inference.

Keywords: Bayesian inference, scalable, automated, coreset, Hilbert, Frank–Wolfe

1. Introduction

Bayesian probabilistic models are a standard tool of choice in modern data analysis. Their rich hierarchies enable intelligent sharing of information across subpopulations, their posterior distributions provide many avenues for principled parameter estimation and uncertainty quantification, and they can incorporate expert knowledge through the prior. In all but the simplest models, however, the posterior distribution is intractable to compute exactly, and we must resort to approximate inference algorithms. Markov chain Monte Carlo (MCMC) (Gelman et al., 2013, Chapters 11, 12) methods are the gold standard, due primarily to their guaranteed asymptotic exactness. Variational Bayes (VB) (Jordan et al., 1999; Wainwright and Jordan, 2008) is also becoming widely used due to its tractability, detectable convergence, and parameter estimation performance in practice.

One of the most important recent developments in the Bayesian paradigm has been the automation of these standard inference algorithms. Rather than having to develop, code, and tune specific instantiations of MCMC or VB for each model, practitioners now have "black-box" implementations that require only a basic specification of the model as inputs. For example, while standard VB requires the specification of model gradients—whose formulae are often onerous to obtain—and an approximating family—whose rigorous selection is an open question—ADVI (Ranganath et al., 2014; Kucukelbir et al., 2015, 2017) applies standard transformations to the model so that a multivariate Gaussian approximation can be used, and computes gradients with automatic differentiation. The user is then left only with the much simpler task of specifying the log-likelihood and prior. Similarly, while Hamiltonian Monte Carlo (Neal, 2011) requires tuning a step size and path length parameter, NUTS (Hoffman and Gelman, 2014) provides a method for automatically determining reasonable values for both. This level of automation has many benefits: it enables experts and nonexperts alike to use more sophisticated models, it facilitates faster exploratory modeling and analysis, and helps ensure experimental reproducibility.

But as modern data sets continue to grow larger over time, it is important for inference to be not only automated, but *scalable* while retaining *theoretical guarantees* on the quality of inferential results. In this regard, the current set of available inference algorithms falls short. Standard MCMC algorithms may be "exact", but they are typically not tractable for large-scale data, as their complexity per posterior sample scales at least linearly in the data set size. Variational methods on the other hand are often scalable, but posterior approximation guarantees continue to elude researchers in all but a few simple cases. Other scalable Bayesian inference algorithms have largely been developed by modifying standard inference algorithms to handle distributed or streaming data processing. Examples include subsampling and streaming methods for variational Bayes (Hoffman et al., 2013; Broderick et al., 2013; Campbell et al., 2015), subsampling methods for MCMC (Welling and Teh, 2011; Ahn et al., 2012; Bardenet et al., 2014; Korattikara et al., 2014; Maclaurin and Adams, 2014; Bardenet et al., 2015), and distributed "consensus" methods for MCMC (Scott et al., 2016; Srivastava et al., 2015; Rabinovich et al., 2015; Entezari et al., 2016). These methods either have no guarantees on the quality of their inferential results, or require expensive iterative access to a constant fraction of the data, but more importantly they tend to be model-specific and require extensive expert tuning. This makes them poor candidates for automation on the large class of models to which standard automated inference algorithms are applicable.

An alternative approach, based on the observation that large data sets often contain redundant data, is to modify the data set itself such that its size is reduced while preserving its original statistical properties. In Bayesian regression, for example, a large data set can be compressed using random linear projection (Geppert et al., 2017; Ahfock et al., 2017; Bardenet and Maillard, 2015). For a wider class of Bayesian models, one can construct a

small weighted subset of the data, known as a *Bayesian coreset*[1] (Huggins et al., 2016), whose weighted log-likelihood approximates the full data log-likelihood. The coreset can then be passed to any standard (automated) inference algorithm, providing posterior inference at a significantly reduced computational cost. Note that since the coresets approach is agnostic to the particular inference algorithm used, its benefits apply to the continuing developments in both MCMC (Robert et al., 2018) and variational (Dieng et al., 2017; Li and Turner, 2016; Liu and Wang, 2016) approaches.

Bayesian coresets, in contrast to other large-scale inference techniques, are simple to implement, computationally inexpensive, and have theoretical guarantees relating coreset size to both computational complexity and the quality of approximation (Huggins et al., 2016). However, their construction cannot be easily automated, as it requires computing the *sensitivity* (Langberg and Schulman, 2010) of each data point, a model-specific task that involves significant technical expertise. This approach also often necessitates a bounded parameter space to ensure bounded sensitivities, precluding many oft-used continuous likelihoods and priors. Further, since Bayesian coreset construction involves i.i.d. random subsampling, it can only reduce approximation error compared to uniform subsampling by a constant, and cannot update its notion of importance based on what points it has already selected.

In this work, we develop a scalable, theoretically-sound Bayesian approximation framework with the same level of automation as ADVI and NUTS, the algorithmic simplicity and low computational burden of Bayesian coresets, and the inferential performance of hand-tuned, model-specific scalable algorithms. We begin with an intuitive reformulation of Bayesian coreset construction as sparse vector sum approximation, in which the data log-likelihood functions are vectors in a vector space, sensitivity is a weighted uniform (i.e. supremum) norm on those vectors, and the construction algorithm is importance sampling. This perspective illuminates the use of the uniform norm as the primary source of the shortcomings of Bayesian coresets. To address these issues we develop Hilbert coresets, i.e., Bayesian coresets using a norm induced by an inner-product on the log-likelihood function space. Our contributions include two candidate norms: one a weighted L^2 norm, and another based on the Fisher information distance (Johnson and Barron, 2004). Given these norms, we provide an importance sampling-based coreset construction algorithm and a more aggressive "direction of improvement"-aware coreset construction based on the Frank–Wolfe algorithm (Frank and Wolfe, 1956; Guélat and Marcotte, 1986; Jaggi, 2013). Our contributions include theoretical guarantees relating the performance of both to coreset size. Since the proposed norms and inner-products cannot in general be computed in closed-form, we automate the construction using a random finite-dimensional projection of the log-likelihood functions inspired by Rahimi and Recht (2007). We test Hilbert coresets empirically on multivariate Gaussian inference, logistic regression, Poisson regression, and von Mises-Fisher mixture modeling with both real and synthetic data; these experiments show that Hilbert coresets provide high quality posterior approximations with a significant reduction in the computational cost of inference compared to standard automated inference algorithms. All proofs are deferred to Appendix A.

1. The concept of a coreset originated in computational geometry and optimization (Agarwal et al., 2005; Feldman and Langberg, 2011; Feldman et al., 2013; Bachem et al., 2015; Lucic et al., 2016; Bachem et al., 2016; Feldman et al., 2011; Han et al., 2016).

2. Background

In the general setting of Bayesian posterior inference, we are given a data set $(y_n)_{n=1}^N$ of N observations, a likelihood $p(y_n|\theta)$ for each observation given the parameter $\theta \in \Theta$, and a prior density $\pi_0(\theta)$ on Θ. We assume throughout that the data are conditionally independent given θ. The Bayesian posterior is given by the density

$$\pi(\theta) := \frac{1}{Z}\exp(\mathcal{L}(\theta))\pi_0(\theta),$$

where the log-likelihood $\mathcal{L}(\theta)$ and marginal likelihood Z are defined by

$$\mathcal{L}_n(\theta) := \log p(y_n \,|\, \theta), \qquad \mathcal{L}(\theta) := \sum_{n=1}^N \mathcal{L}_n(\theta), \qquad Z := \int \exp(\mathcal{L}(\theta))\pi_0(\theta)\,\mathrm{d}\theta.$$

In almost all cases in practice, an exact closed-form expression of π is not available due to the difficulty of computing Z, forcing the use of approximate Bayesian inference algorithms. While Markov chain Monte Carlo (MCMC) algorithms (Gelman et al., 2013, Chapters 11, 12) are often preferred for their theoretical guarantees asymptotic in running time, they are typically computationally intractable for large N. One way to address this is to construct a small, weighted subset of the original data set whose log-likelihood approximates that of the full data set, known as a *Bayesian coreset* (Huggins et al., 2016). This coreset can then be passed to a standard MCMC algorithm. The computational savings from running MCMC on a much smaller data set can allow a much faster inference procedure while retaining the theoretical guarantees of MCMC. In particular, the aim of the Bayesian coresets framework is to find a set of nonnegative weights $w := (w_n)_{n=1}^N$, a small number of which are nonzero, such that the weighted log-likelihood

$$\mathcal{L}(w,\theta) := \sum_{n=1}^N w_n \mathcal{L}_n(\theta) \quad \text{satisfies} \quad |\mathcal{L}(w,\theta) - \mathcal{L}(\theta)| \leq \epsilon\,|\mathcal{L}(\theta)|\,,\ \forall \theta \in \Theta. \tag{2.1}$$

The algorithm proposed by Huggins et al. (2016) to construct a Bayesian coreset is as follows. First, compute the *sensitivity* σ_n of each data point,

$$\sigma_n := \sup_{\theta\in\Theta} \left| \frac{\mathcal{L}_n(\theta)}{\mathcal{L}(\theta)} \right|, \tag{2.2}$$

and then subsample the data set by taking M independent draws with probability proportional to σ_n (resulting in a coreset of size $\leq M$) via

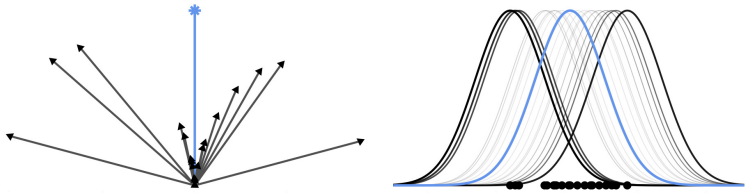
$$\sigma := \sum_{n=1}^N \sigma_n \qquad (M_1, \ldots, M_N) \sim \mathsf{Multi}\left(M, \left(\frac{\sigma_n}{\sigma}\right)_{n=1}^N\right) \qquad W_n = \frac{\sigma}{\sigma_n}\frac{M_n}{M}. \tag{2.3}$$

Since $\mathbb{E}[W_n] = 1$, we have that $\mathbb{E}[\mathcal{L}(W,\theta)] = \mathcal{L}(\theta)$, and we expect that $\mathcal{L}(W,\theta) \to \mathcal{L}(\theta)$ in some sense as M increases. This is indeed the case; Braverman et al. (2016); Feldman and Langberg (2011) showed that with high probability, the coreset likelihood $\mathcal{L}(W,\theta)$ satisfies Eq. (2.1) with $\epsilon^2 = O\left(\frac{1}{M}\right)$, and Huggins et al. (2016) extended this result to the case of Bayesian coresets in the setting of logistic regression. Typically, exact computation of the sensitivities σ_n is not tractable, so upper bounds are used instead (Huggins et al., 2016).

3. Coresets as Sparse Vector Sum Approximation

This section develops an intuitive perspective of Bayesian coresets as sparse vector sum approximation under a uniform norm, and draws on this perspective to uncover the limitations of the framework and avenues for extension. Consider the vector space of functions $g : \Theta \to \mathbb{R}$ with bounded uniform norm weighted by the total log-likelihood $\mathcal{L}(\theta)$,

$$\|g\| := \sup_{\theta \in \Theta} \left| \frac{g(\theta)}{\mathcal{L}(\theta)} \right|. \tag{3.1}$$



In this space, the data log-likelihood functions $\mathcal{L}_n(\theta)$ have vectors $\mathcal{L}_n$ with norm $\sigma_n := \|\mathcal{L}_n\|$ as defined in Eq. (2.2), the total log-likelihood has vector $\mathcal{L} := \sum_{n=1}^N \mathcal{L}_n$, and the coreset guarantee in Eq. (2.1) corresponds to approximation of $\mathcal{L}$ with the vector $\mathcal{L}(w) := \sum_{n=1}^N w_n \mathcal{L}_n$ under the vector norm with error at most ϵ, i.e. $\|\mathcal{L}(w) - \mathcal{L}\| \leq \epsilon$. Given this formulation, we can write the problem of constructing the best coreset of size M as the minimization of approximation error subject to a constraint on the number of nonzero entries in w,

$$\min_{w \in \mathbb{R}^N} \quad \|\mathcal{L}(w) - \mathcal{L}\|^2 \quad \text{s.t.} \quad w \geq 0, \quad \sum_{n=1}^N \mathbb{1}\left[w_n > 0\right] \leq M. \tag{3.2}$$

Eq. (3.2) is a convex optimization with binary constraints, and thus is difficult to solve efficiently in general; we are forced to use approximate methods. The uniform Bayesian coresets framework provides one such approximate method, where $\mathcal{L}/N$ is viewed as the expectation of a uniformly random subsample of $(\mathcal{L}_n)_{n=1}^N$, and importance sampling is used to reduce the expected error of the estimate. Choosing importance probabilities proportional to $\sigma_n = \|\mathcal{L}_n\|$ results in a high-probability bound on approximation error given below in Theorem 3.2. The proof of Theorem 3.2 in Appendix A is much simpler than similar results available in the literature (Feldman and Langberg, 2011; Braverman et al., 2016; Huggins et al., 2016) due to the present vector space formulation. Theorem 3.2 depends on two constants (σ and $\overline{\eta}$) that capture important aspects of the geometry of the optimization problem:

$$\sigma_n := \|\mathcal{L}_n\| \qquad \sigma := \sum_{n=1}^N \sigma_n \qquad \overline{\eta}^2 := \max_{n,m \in [N]} \left\| \frac{\mathcal{L}_n}{\sigma_n} - \frac{\mathcal{L}_m}{\sigma_m} \right\|^2, \tag{3.3}$$

where $[N] := \{1, 2, \ldots, N\}$. The quantity $\sigma \geq 0$ captures the scale of the problem; all error guarantees on $\|\mathcal{L}(w) - \mathcal{L}\|$ should be roughly linearly proportional to σ. The quantity $0 \leq \overline{\eta} \leq 2$ captures how well-aligned the vectors $(\mathcal{L}_n)_{n=1}^N$ are, and thus the inherent difficulty of approximating $\mathcal{L}$ with a sparse weighted subset $\mathcal{L}(w)$. For example, if all vectors are aligned then $\overline{\eta} = 0$, and the problem is trivial since we can achieve 0 error with a single scaled vector $\mathcal{L}_n$. Theorem 3.2 also depends on an approximate notion of the dimension of the span of the log-likelihood vectors $(\mathcal{L}_n)_{n=1}^N$, given by Definition 3.1. Note in particular that the approximate dimension of a set of vectors in $\mathbb{R}^d$ is at most d, corresponding to the usual notion of dimension in this setting.

(a) (b)

Figure 1: (1a): The sparse vector approximation problem, depicting the sum $\mathcal{L}$ in blue and the vectors $\mathcal{L}_n$ in grey. (1b): Uniform Bayesian coresets behavior on the simple exercise of learning a Gaussian mean. Depicted are data likelihoods in black, scaled posterior density in blue, and data as black scatter points. The sensitivity of each datapoint is indicated by the line thickness of the likelihood—a thicker, darker line denotes higher sensitivity, while thinner, lighter lines denote lower sensitivity.

Definition 3.1. The *approximate dimension* $\dim\left(u_n\right)_{n=1}^N$ of N vectors in a normed vector space is the minimum value of $d \in \mathbb{N}$ such that all vectors u_n can be approximated using linear combinations of a set of d unit vectors $(v_j)_{j=1}^d$, $\|v_j\| = 1$:

$$\forall\, n \in [N],\ \exists\, \alpha_n \in [-1,1]^d \text{ s.t. } \left\| \frac{u_n}{\|u_n\|} - \sum_{j=1}^d \alpha_{nj} v_j \right\| \leq \frac{d}{\sqrt{N}}.$$

Theorem 3.2. *Fix any $\delta \in (0,1)$. With probability $\geq 1 - \delta$, the output of the uniform coreset construction algorithm in Eq. (2.3) satisfies*

$$\|\mathcal{L}(W) - \mathcal{L}\| \leq \frac{\sigma}{\sqrt{M}} \left(\frac{3}{2} \dim\left(\mathcal{L}_n\right)_{n=1}^N + \overline{\eta} \sqrt{2 \log \frac{1}{\delta}} \right).$$

The analysis, discussion, and algorithms presented to this point are independent of the particular choice of norm given in Eq. (3.1); one might wonder if the uniform norm used above is the best choice, or if there is another norm more suited to Bayesian inference in some way. For instance, the supremum in Eq. (3.1) can diverge in an unbounded or infinite-dimensional parameter space Θ, requiring an artificial restriction placed on the space (Huggins et al., 2016). This precludes the application to the many common models and priors that have unbounded parameter spaces, even logistic regression with full support $\Theta = \mathbb{R}^d$. The optimization objective function in Eq. (3.1) is also typically nonconvex, and finding (or bounding) the optimum is a model-specific task that is not easily automated.

Perhaps most importantly, the uniform norm lacks a sense of "directionality" as it does not correspond to an inner-product. This implies that the bound in Theorem 3.2 does not scale properly with the alignment of vectors (note how the error does not approach 0 as $\overline{\eta} \to 0$) and that it depends on the approximate dimension (which may be hard to compute). Moreover, the lack of directionality makes the coreset construction algorithm behave counterintuitively and limits its performance in a fundamental way. Fig. 1a provides

a pictorial representation of this limitation. Recall that the goal of coreset construction is to find a *sparse* weighted subset of the vectors $(\mathcal{L}_n)_{n=1}^N$ (grey) that approximates $\mathcal{L}$ (blue). In this example, there are vectors which, when scaled, could individually nearly perfectly replicate $\mathcal{L}$. But the importance sampling algorithm in Eq. (2.3) will instead tend to sample those vectors with large norm that are pointed away from $\mathcal{L}$, requiring a much larger coreset to achieve the same approximation error. This is a consequence of the lack of directionality of the uniform norm; it has no concept of the alignment of certain vectors with $\mathcal{L}$, and is forced to mitigate worst-case error by sampling those vectors with large norm. Fig. 1b shows the result of this behavior in a 1D Gaussian inference problem. In this figure, the likelihood functions of the data are depicted in black, with their uniform norm (or sensitivity) indicated by thickness and opacity. The posterior distribution is displayed in blue, with its log-density scaled by $1/N$ for clarity. The importance sampling algorithm in Eq. (2.3) will tend to sample those data that are *far away* from the posterior mean, with likelihoods that are different than the scaled posterior, despite the fact that there are data close to the mean whose likelihoods are near-perfect approximations of the scaled posterior. Using the intuition from Fig. 1, it is not difficult to construct examples where the expected error of importance sampling is arbitrarily worse than the error of the optimal coreset of size M.

4. Hilbert Coresets

It is clear that a notion of directionality of the vectors $(\mathcal{L}_n)_{n=1}^N$ is key to developing both efficient, intuitive coreset construction algorithms and theory that correctly reflects problem difficulty. Therefore, in this section we develop methods for constructing Bayesian coresets in a Hilbert space (*Hilbert coresets*), i.e., using a norm corresponding to an inner product. The notion of directionality granted by the inner product provides two major advantages over uniform coresets: coreset points can be chosen intelligently based on the residual posterior approximation error vector; and theoretical guarantees on approximation quality can directly incorporate the difficulty of the approximation problem via the alignment of log-likelihood vectors. We provide two coreset construction algorithms which take advantage of these benefits. The first method, developed in Section 4.1, is based on viewing $\mathcal{L}/N$ as the expectation of a uniformly random subsample of $(\mathcal{L}_n)_{n=1}^N$, and then using importance sampling to reduce the expected error of the estimate. The second method, developed in Section 4.2, is based on viewing the cardinality-unconstrained version of Eq. (3.2) as a quadratic optimization over an appropriately-chosen polytope, and then using the Frank–Wolfe algorithm Frank and Wolfe (1956); Guélat and Marcotte (1986); Jaggi (2013) to compute a sparse approximation to the optimum. Theoretical guarantees on posterior approximation error are provided for both. In Section 4.3, we develop streaming/distributed extensions of these methods and provide similar approximation guarantees. Note that this section treats the general case of Bayesian coreset construction with a Hilbert space norm; the selection of a particular norm and its automated computation is left to Section 5.

4.1. Coreset Construction via Importance Sampling

Taking inspiration from the uniform Bayesian coreset construction algorithm, the first Hilbert coreset construction method, Algorithm 1, involves i.i.d. sampling from the vectors $(\mathcal{L}_n)_{n=1}^N$

Algorithm 1 IS: Hilbert coresets via importance sampling

Require: $(\mathcal{L}_n)_{n=1}^N$, M, $\|\cdot\|$
- $\forall n \in [N]$ $\sigma_n \leftarrow \|\mathcal{L}_n\|$, and $\sigma \leftarrow \sum_{n=1}^N \sigma_n$ ▷ compute norms
- $(M_1, \dots, M_N) \leftarrow \mathsf{Multi}\left(M, (\frac{\sigma_n}{\sigma})_{n=1}^N\right)$ ▷ subsample the data
- $W_n \leftarrow \frac{\sigma}{\sigma_n}\frac{M_n}{M}$ for $n \in [N]$ ▷ reweight the subsample
- **return** W

with probabilities $(p_n)_{n=1}^N$ and reweighting the subsample. In contrast to the case of the weighted uniform norm in Eq. (3.1), the choice $p_n \propto \sigma_n$ exactly minimizes the expected squared coreset error under a Hilbert norm (see Eq. (A.2) in Appendix A), yielding

$$\mathbb{E}\left[\|\mathcal{L}(W) - \mathcal{L}\|^2\right] = \frac{\sigma^2\eta^2}{M} \qquad \eta^2 := 1 - \frac{\|\mathcal{L}\|^2}{\sigma^2}, \tag{4.1}$$

where $0 \leq \eta \leq 1$, similar to $\overline{\eta}$, captures how well-aligned the vectors $(\mathcal{L}_n)_{n=1}^N$ are. However, in a Hilbert space η is a tighter constant: $\eta \leq \overline{\eta}/\sqrt{2}$ by Lemma A.4. Theorem 4.1, whose proof in Appendix A relies on standard martingale concentration inequalities, provides a high-probability guarantee on the quality of the output approximation. This result depends on $\overline{\eta}$ from Eq. (3.3) and η from Eq. (4.1).

Theorem 4.1. *Fix any $\delta \in (0,1)$. With probability $\geq 1-\delta$, the output W of Algorithm 1 satisfies*

$$\|\mathcal{L}(W) - \mathcal{L}\| \leq \frac{\sigma}{\sqrt{M}}\left(\eta + \eta_M\sqrt{2\log\frac{1}{\delta}}\right)$$

where

$$\eta_M := \min\left(\overline{\eta}, \eta\sqrt{\frac{2M\eta^2}{\overline{\eta}^2\log\frac{1}{\delta}}}\, H^{-1}\left(\frac{\overline{\eta}^2\log\frac{1}{\delta}}{2M\eta^2}\right)\right)$$
$$H(y) := (1+y)\log(1+y) - y.$$

In contrast to Theorem 3.2, Theorem 4.1 takes advantage of the inner product to incorporate a notion of problem difficulty into the bound. For example, since $H(y) \sim y^2$ as $y \to 0$, we have that $H^{-1}(y) \sim \sqrt{y}$ and so $\lim_{y\to 0}\sqrt{y^{-1}}H^{-1}(y) = 1$. Combined with the fact that $\eta \leq \overline{\eta}$, we have $\lim_{M\to\infty}\eta_M = \eta$, and so the bound in Theorem 4.1 is asymptotically equivalent to $\frac{\sigma\eta}{\sqrt{M}}\left(1+\sqrt{2\log\frac{1}{\delta}}\right)$ as $M \to \infty$. Given that importance sampling can only improve convergence over uniformly random subsampling by a constant, this constant reduction is significant. Note that Theorem 4.1, in conjunction with the fact that $\eta \leq \overline{\eta}$, immediately implies the simpler result in Corollary 4.2.

Corollary 4.2. *Fix any $\delta \in (0,1)$. With probability $\geq 1-\delta$, the output W of Algorithm 1 satisfies*

$$\|\mathcal{L}(W) - \mathcal{L}\| \leq \frac{\sigma\overline{\eta}}{\sqrt{M}}\left(1+\sqrt{2\log\frac{1}{\delta}}\right).$$

4.2. Coreset Construction via Frank–Wolfe

The major advantages of Algorithm 1 are its simplicity and sole requirement of computing the norms $(\|\mathcal{L}_n\|)_{n=1}^N$. Like the original uniform Bayesian coreset algorithm in Eq. (2.3), however, it does not take into account the residual error in the coreset approximation in order to choose new samples intelligently. The second Hilbert coreset construction method, Algorithm 2, takes advantage of the directionality of the Hilbert norm to incrementally build the coreset by selecting vectors aligned with the "direction of greatest improvement."

The development of Algorithm 2 involves two major steps. First, we replace the cardinality constraint on w in Eq. (3.2) with a polytope constraint:

$$\min_{w\in\mathbb{R}^N} \quad (w-1)^T K(w-1) \quad \text{s.t.} \quad w \geq 0, \quad \sum_{n=1}^N \sigma_n w_n = \sigma, \tag{4.2}$$

where $K \in \mathbb{R}^{N\times N}$ is a kernel matrix defined by $K_{ij} := \langle \mathcal{L}_i, \mathcal{L}_j\rangle$, and we take advantage of the Hilbert norm to rewrite $\|\mathcal{L}(w) - \mathcal{L}\|^2 = (w-1)^T K(w-1)$. The polytope is designed to contain the point $w = 1 := [1, 1, \ldots, 1]^T \in \mathbb{R}^N$—which is optimal with cost 0 since $\mathcal{L}(1) = \mathcal{L}$—and have vertices $\frac{\sigma}{\sigma_n} 1_n$ for $n \in [N]$, where 1_n is the n^{th} coordinate unit vector. Next, taking inspiration from the large-scale optimization literature Frank and Wolfe (1956); Guélat and Marcotte (1986); Jaggi (2013); Lacoste-Julien and Jaggi (2015); Clarkson (2010); Reddi et al. (2016); Balasubramanian and Ghadimi (2018); Hazan and Luo (2016), we solve the convex optimization in Eq. (4.2) using the Frank–Wolfe algorithm (Frank and Wolfe, 1956). Frank–Wolfe is an iterative algorithm for solving convex optimization problems of the form $\min_{x\in\mathcal{D}} g(x)$, where each iteration has three steps: 1) given the t^{th} iterate x_t, we first find a search direction $d_t = s_t - x_t$ by solving the linear program $s_t = \arg\min_{s\in\mathcal{D}} \nabla f(x_t)^T s$; 2) we find a step size by solving the 1-dimensional optimization $\gamma_t = \arg\min_{\gamma\in[0,1]} f(x_t + \gamma d_t)$; and 3) we update $x_{t+1} \leftarrow x_t + \gamma_t d_t$. In Eq. (4.2), we are optimizing a convex objective over a polytope, so the linear optimization can be solved by searching over all vertices of the polytope. And since we designed the polytope such that its vertices each have a single nonzero component, the algorithm adds at most a single data point to the coreset at each iteration; after initialization followed by $M-1$ iterations, this produces a coreset of size $\leq M$.

We initialize w_0 to the vertex most aligned with $\mathcal{L}$, i.e.

$$w_0 = \frac{\sigma}{\sigma_{f_0}} 1_{f_0} \quad \text{where} \quad f_0 = \arg\max_{n\in[N]} \left\langle \mathcal{L}, \frac{1}{\sigma_n}\mathcal{L}_n \right\rangle. \tag{4.3}$$

Let w_t be the iterate at step t. The gradient of the cost is $2K(w_t - 1)$, and we are solving a convex optimization on a polytope, so the Frank–Wolfe direction may be computed by searching over its vertices:

$$d_t := \frac{\sigma}{\sigma_{f_t}} 1_{f_t} - w_t \quad \text{where} \quad f_t = \arg\max_{n\in[N]} \left\langle \mathcal{L} - \mathcal{L}(w_t), \frac{1}{\sigma_n}\mathcal{L}_n \right\rangle. \tag{4.4}$$

The Frank–Wolfe algorithm applied to Eq. (4.2) thus corresponds to a simple greedy approach in which we select the vector $\mathcal{L}_{f_t}$ with direction most aligned with the residual error $\mathcal{L} - \mathcal{L}(w_t)$. We perform line search to update $w_{t+1} = w_t + \gamma d_t$ for some $\gamma \in [0, 1]$. Since the objective is

$w \leftarrow \frac{\sigma}{\sigma_f} 1_f$ ▷ initialize w with full weight on f

for $t \in \{1, \ldots, M-1\}$ **do**

$f \leftarrow \arg\max_{n\in[N]} \left\langle \mathcal{L} - \mathcal{L}(w), \frac{1}{\sigma_n}\mathcal{L}_n \right\rangle$ ▷ find the FW vertex index f

$\gamma \leftarrow \frac{\left\langle \frac{\sigma}{\sigma_f}\mathcal{L}_f - \mathcal{L}(w), \mathcal{L} - \mathcal{L}(w) \right\rangle}{\left\langle \frac{\sigma}{\sigma_f}\mathcal{L}_f - \mathcal{L}(w), \frac{\sigma}{\sigma_f}\mathcal{L}_f - \mathcal{L}(w) \right\rangle}$ ▷ closed-form line search for step size γ

$w \leftarrow (1-\gamma)w + \gamma\frac{\sigma}{\sigma_f} 1_f$ ▷ add/reweight data point f in coreset

end for

return w

quadratic, the exact solution for unconstrained line search is available in closed form per Eq. (4.5); Lemma 4.3 shows that this is actually the solution to constrained line search in $\gamma \in [0, 1]$, ensuring that w_{t+1} remains feasible.

$$w_{t+1} = w_t + \gamma_t d_t \quad \text{where} \quad \gamma_t = \frac{\left\langle \frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t), \mathcal{L} - \mathcal{L}(w_t) \right\rangle}{\left\langle \frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t), \frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t) \right\rangle}. \tag{4.5}$$

Lemma 4.3. *For all $t \in \mathbb{N}$, $\gamma_t \in [0, 1]$.*

Theorem 4.4 below provides a guarantee on the quality of the approximation output by Algorithm 2 using the combination of the initialization in Eq. (4.3) and exact line search in Eq. (4.5). This result depends on the constants $\overline{\eta}$ from Eq. (3.3), η from Eq. (4.1), and ν, defined by

$$\nu^2 := 1 - \frac{r^2}{\sigma^2\overline{\eta}^2},$$

where r is the distance from $\mathcal{L}$ to the nearest boundary of the convex hull of $\{\sigma\mathcal{L}_n/\sigma_n\}_{n=1}^N$. Since $\mathcal{L}$ is in the relative interior of this convex hull by Lemma A.5, we are guaranteed that $\nu < 1$. The proof of Theorem 4.4 in Appendix A relies on a technique from Guélat and Marcotte (1986, Theorem 2) and a novel bound on the logistic equation.

Theorem 4.4. *The output w of Algorithm 2 satisfies*

$$\|\mathcal{L}(w) - \mathcal{L}\| \leq \frac{\sigma\eta\overline{\eta}\nu}{\sqrt{\overline{\eta}^2\nu^{-2(M-2)} + \eta^2(M-1)}} \leq \frac{\sigma\overline{\eta}}{\sqrt{M}}.$$

In contrast to previous convergence analyses of Frank–Wolfe optimization, Theorem 4.4 exploits the quadratic objective and exact line search to capture both the logarithmic $1/\sqrt{M}$ convergence rate for small values of M, and the linear ν^M rate for large M. Alternatively,

one can remove the computational cost of computing the exact line search via Eq. (4.5) by simply setting $\gamma_t = \frac{2}{3t+4}$. In this case, Theorem 4.4 is replaced with the weaker result (see the note at the end of the proof of Theorem 4.4 in Appendix A)

$$\|\mathcal{L}(w) - \mathcal{L}\| \leq \frac{2\sigma\overline{\eta}}{\sqrt{3M+1}}.$$

4.3. Distributed Coreset Construction

An advantage of Hilbert coresets—and coresets in general—is that they apply to streaming and distributed data with little modification, and retain their theoretical guarantees. In particular, if the data set $(y_n)_{n=1}^N$ is distributed (not necessarily evenly) among C processors, and either Algorithm 1 or Algorithm 2 are run for M iterations on each processor, the resulting merged coreset of size $\leq MC$ has an error guarantee given by Corollary 4.5 or Corollary 4.6. Note that the weights from each distributed coreset are not modified when merging. These results both follow from Theorems 4.1 and 4.4 with straightforward usage of the triangle inequality, the union bound, and the fact that $\overline{\eta}$ for each subset is bounded above by $\overline{\eta}$ for the full data set.

Corollary 4.5. *Fix any $\delta \in (0,1)$. With probability $\geq 1-\delta$, the coreset constructed by running Algorithm 1 on C nodes and merging the result satisfies*

$$\|\mathcal{L}(w) - \mathcal{L}\| \leq \frac{\sigma\overline{\eta}}{\sqrt{M}}\left(1 + \sqrt{2\log\frac{C}{\delta}}\right).$$

Corollary 4.6. *The coreset constructed by running Algorithm 2 on C nodes and merging the results satisfies*

$$\|\mathcal{L}(w) - \mathcal{L}\| \leq \frac{\sigma\overline{\eta}}{\sqrt{M}}.$$

5. Norms and Random Projection

The algorithms and theory in Section 4 address the scalability and performance of Bayesian coreset construction, but are specified for an arbitrary Hilbert norm; it remains to choose a norm suitable for automated Bayesian posterior approximation. There are two main desiderata for such a norm: it should be a good indicator of posterior discrepancy, and it should be efficiently computable or approximable in such a way that makes Algorithms 1 and 2 efficient for large N, i.e., $O(N)$ time complexity. To address the desideratum that the norm is an indicator of posterior discrepancy, we propose the use of one of two Hilbert norms. It should, however, be noted that these are simply reasonable suggestions, and other Hilbert norms could certainly be used in the algorithms set out in Section 4. The first candidate is the expectation of the squared 2-norm difference between the log-likelihood gradients under a weighting distribution $\hat{\pi}$,

$$\|\mathcal{L}(w) - \mathcal{L}\|_{\hat{\pi},F}^2 := \mathbb{E}_{\hat{\pi}}\left[\|\nabla\mathcal{L}(\theta) - \nabla\mathcal{L}(w,\theta)\|_2^2\right], \tag{5.1}$$

where the weighting distribution $\hat{\pi}$ has the same support as the posterior π. This norm is a weighted version of the Fisher information distance (Johnson and Barron, 2004). The inner product induced by this norm is defined by

$$\langle\mathcal{L}_n, \mathcal{L}_m\rangle_{\hat{\pi},F} := \mathbb{E}_{\hat{\pi}}\left[\nabla\mathcal{L}_n(\theta)^T\nabla\mathcal{L}_m(\theta)\right]. \tag{5.2}$$

Although this norm has a connection to previously known discrepancies between probability distributions, it does require that the likelihoods are differentiable. One could instead employ a simple weighted L^2 norm on the log-likelihoods, given by

$$\|\mathcal{L}(w) - \mathcal{L}\|_{\hat{\pi},2} := \mathbb{E}_{\hat{\pi}}\left[\left(\mathcal{L}(\theta) - \mathcal{L}(w,\theta)\right)^2\right] \tag{5.3}$$

with induced inner product

$$\langle\mathcal{L}_n, \mathcal{L}_m\rangle_{\hat{\pi},2} := \mathbb{E}_{\hat{\pi}}\left[\mathcal{L}_n(\theta)\mathcal{L}_m(\theta)\right]. \tag{5.4}$$

In both cases, the weighting distribution $\hat{\pi}$ would ideally be chosen equal to π to emphasize discrepancies that are in regions of high posterior mass. Though we do not have access to the true posterior without incurring significant computational cost, there are many practical options for setting $\hat{\pi}$, including: the Laplace approximation (Bishop, 2006, Section 4.4), a posterior based on approximate sufficient statistics (Huggins et al., 2017), a discrete distribution based on samples from an MCMC algorithm run on a small random subsample of the data, the prior, independent posterior conditionals (see Eq. (7.1) in Section 7.3), or any other reasonable method for finding a low-cost posterior approximation. This requirement of a low-cost approximation is not unusual, as previous coreset formulations have required similar preprocessing to compute sensitivities, e.g., a k-clustering of the data (Huggins et al., 2016; Lucic et al., 2016; Braverman et al., 2016). We leave the general purpose selection of a weighting function $\hat{\pi}$ for future work.

The two suggested norms $\|\cdot\|_{\hat{\pi},2/F}$ often do not admit exact closed-form evaluation due to the intractable expectations in Eqs. (5.2) and (5.4). Even if closed-form expressions are available, Algorithm 2 is computationally intractable when we only have access to inner products between pairs of individual log-likelihoods $\mathcal{L}_n$, $\mathcal{L}_m$, since obtaining the Frank–Wolfe direction involves the $O(N^2)$ computation $\arg\max_{n\in[N]}\sum_{m=1}^N\langle\mathcal{L}_m, \mathcal{L}_n/\sigma_n\rangle$. Further, the analytic evaluation of expectations is a model- (and $\hat{\pi}$-) specific procedure that cannot be easily automated. To both address these issues and automate Hilbert coreset construction, we use *random features* (Rahimi and Recht, 2007), i.e. a random projection of the vectors $(\mathcal{L}_n)_{n=1}^N$ into a finite-dimensional vector space using samples from $\hat{\pi}$. For the weighted Fisher information inner product in Eq. (5.2), we approximate $\langle\mathcal{L}_n, \mathcal{L}_m\rangle_{\hat{\pi},F}$ with an unbiased estimate given by

$$(d_j)_{j=1}^J \overset{\text{i.i.d.}}{\sim} \mathsf{Unif}(\{1,\ldots,D\}) \quad (\mu_j)_{j=1}^J \overset{\text{i.i.d.}}{\sim} \hat{\pi}$$

$$\langle\mathcal{L}_n, \mathcal{L}_m\rangle_{\hat{\pi},F} \approx \frac{D}{J}\sum_{j=1}^J (\nabla\mathcal{L}_n(\mu_j))_{d_j}(\nabla\mathcal{L}_m(\mu_j))_{d_j},$$

where subscripts indicate the selection of a component of a vector. If we define the J-dimensional vector

$$\hat{\mathcal{L}}_n := \sqrt{\frac{D}{J}}\left[(\nabla\mathcal{L}_n(\mu_1))_{d_1}, (\nabla\mathcal{L}_n(\mu_2))_{d_2}, \ldots, (\nabla\mathcal{L}_n(\mu_J))_{d_J}\right]^T, \tag{5.5}$$

Algorithm 3 Bayesian Hilbert coresets with random projection

Require: $(\mathcal{L}_n)_{n=1}^N$, $\hat{\pi}$, M, J
▷ sample feature points and gradient dimension indices
$(\mu_j)_{j=1}^J \overset{\text{i.i.d.}}{\sim} \hat{\pi}$, $(d_j)_{j=1}^J \overset{\text{i.i.d.}}{\sim} \mathsf{Unif}(\{1,\dots,D\})$
▷ construct the random projection using one of the norms from Eqs. (5.5) and (5.6)
If $\|\cdot\|_{\hat{\pi},F}$: $\forall n \in [N]$, $v_n \leftarrow \sqrt{D/J}\,[(\nabla\mathcal{L}_n(\mu_1))_{d_1},\dots,(\nabla\mathcal{L}_n(\mu_J))_{d_J}]^T$
If $\|\cdot\|_{\hat{\pi},2}$: $\forall n \in [N]$, $v_n \leftarrow \sqrt{1/J}\,[\mathcal{L}_n(\mu_1),\dots,\mathcal{L}_n(\mu_J)]^T$
▷ return the coreset constructed using random feature vectors
return $\mathrm{FW}\left((v_n)_{n=1}^N, M, (\cdot)^T(\cdot)\right)$ or $\mathrm{IS}\left((v_n)_{n=1}^N, M, \|\cdot\|_2\right)$

we have that for all $n, m \in [N]$,

$$\langle \mathcal{L}_n, \mathcal{L}_m \rangle_{\hat{\pi},F} \approx \hat{\mathcal{L}}_n^T \hat{\mathcal{L}}_m.$$

Therefore, for $n \in [N]$, $\hat{\mathcal{L}}_n$ serves as a random finite-dimensional projection of $\mathcal{L}_n$ that can be used in Algorithms 1 and 2. Likewise, for the weighted L^2 inner product in Eq. (5.4), we have

$$(\mu_j)_{j=1}^J \overset{\text{i.i.d.}}{\sim} \hat{\pi} \quad \langle \mathcal{L}_n, \mathcal{L}_m \rangle_{\hat{\pi},2} \approx \frac{1}{J}\sum_{j=1}^J \mathcal{L}_n(\mu_j)\mathcal{L}_m(\mu_j),$$

and so defining

$$\hat{\mathcal{L}}_n := \sqrt{\frac{1}{J}}\,[\mathcal{L}_n(\mu_1), \mathcal{L}_n(\mu_2), \dots, \mathcal{L}_n(\mu_J)]^T, \tag{5.6}$$

we have that for all $n, m \in [N]$,

$$\langle \mathcal{L}_n, \mathcal{L}_m \rangle_{\hat{\pi},2} \approx \hat{\mathcal{L}}_n^T \hat{\mathcal{L}}_m,$$

and once again $\forall n \in [N]$, $\hat{\mathcal{L}}_n$ serves as a finite-dimensional approximation of $\mathcal{L}_n$. The construction of the random projections is both easily automated and enables the efficient computation of inner products with vector sums. For example, to obtain the Frank–Wolfe direction, rather than computing $\arg\max_{n\in[N]} \sum_{m=1}^N \langle \mathcal{L}_m, \mathcal{L}_n/\sigma_n \rangle$, we can simply compute $\hat{\mathcal{L}} = \sum_{n=1}^N \hat{\mathcal{L}}_n$ in $O(NJ)$ time once at the start of the algorithm and then $\arg\max_{n\in[N]} \frac{1}{\sigma_n}\hat{\mathcal{L}}^T\hat{\mathcal{L}}_n$ in $O(NJ)$ time at each iteration. Further, since $\hat{\mathcal{L}}_n^T\hat{\mathcal{L}}_m$ is an unbiased estimate of $\langle \mathcal{L}_n, \mathcal{L}_m \rangle_{\hat{\pi},2/F}$, we expect the error of the approximation to decrease with the random finite projection dimension J. Theorem 5.2 (below), whose proof may be found in Appendix A, shows that under reasonable conditions this is indeed the case: the difference between the true output error and random projection output error shrinks as J increases. Note that Theorem 5.2 is quite loose, due to its reliance on a max-norm quadratic form upper bound.

Definition 5.1. (Boucheron et al., 2013, p. 24) A random variable X is *sub-Gaussian with constant* ξ^2 if

$$\forall \lambda \in \mathbb{R}, \quad \mathbb{E}\left[e^{\lambda X}\right] \le e^{\frac{\lambda^2\xi^2}{2}}.$$

Theorem 5.2. *Let $\mu \sim \hat{\pi}$, $d \sim \mathsf{Unif}(\{1,\dots,D\})$, and suppose $D\nabla\mathcal{L}_n(\mu)_d\nabla\mathcal{L}_m(\mu)_d$ (given $\|\cdot\|_{\hat{\pi},F}$) or $\mathcal{L}_n(\mu)\mathcal{L}_m(\mu)$ (given $\|\cdot\|_{\hat{\pi},2}$) is sub-Gaussian with constant ξ^2. Fix any $\delta \in (0,1)$. With probability $\ge 1-\delta$, the output of Algorithm 3 satisfies*

$$\|\mathcal{L} - \mathcal{L}(w)\|_{\hat{\pi},2/F}^2 \le \|\hat{\mathcal{L}} - \hat{\mathcal{L}}(w)\|_2^2 + \|w-1\|_1^2\sqrt{\frac{2\xi^2}{J}\log\frac{2N^2}{\delta}}.$$

6. Synthetic Evaluation

In this section, we compare Hilbert coresets to uniform coresets and uniformly random subsampling in a synthetic setting where expressions for the exact and coreset posteriors, along with the KL-divergence between them, are available in closed-form. In particular, the methods are used to perform posterior inference for the unknown mean $\mu \sim \mathcal{N}(\mu_0, I)$ of a 2-dimensional multivariate normal distribution with known covariance I from a collection of $N = 1{,}000$ i.i.d. observations $(y_n)_{n=1}^N$:

$$\mu \sim \mathcal{N}(\mu_0, I) \quad (y_n)_{n=1}^N \,|\, \mu \overset{\text{i.i.d.}}{\sim} \mathcal{N}(\mu, I).$$

6.1. Methods

We ran 1000 trials of data generation followed by uniformly random subsampling (`Rand`), uniform coresets (`Unif`), Hilbert importance sampling (`IS`), and Hilbert Frank–Wolfe (`FW`). For the two Hilbert coreset constructions, we used the weighted Fisher information distance in Eq. (5.1). In this simple setting, the exact posterior distribution is a multivariate Gaussian with mean μ_π and covariance Σ_π given by

$$\mu \,|\, (y_n)_{n=1}^N \sim \mathcal{N}(\mu_\pi, \Sigma_\pi) \qquad \Sigma_\pi = \frac{1}{1+N}I \qquad \mu_\pi = \Sigma_\pi\left(\mu_0 + \sum_{n=1}^N y_n\right).$$

For uniform coreset construction, we subsampled the data set as per Eq. (2.3), where the sensitivity of y_n (see Appendix C for the derivation) is given by

$$\sigma_n = \frac{1}{N}\left(1 + \frac{(y_n-\bar{y})^T(y_n-\bar{y})}{\frac{1}{N}\sum_{m=1}^N y_m^T y_m - \bar{y}^T\bar{y}}\right), \quad \bar{y} := \frac{1}{N}\sum_{n=1}^N y_n. \tag{6.1}$$

This resulted in a multivariate Gaussian uniform coreset posterior approximation with mean $\hat{\mu}_\pi$ and covariance $\hat{\Sigma}_\pi$ given by

$$\hat{\Sigma}_\pi = \frac{1}{1+\sum_{n=1}^N W_n}I \qquad \hat{\mu}_\pi = \hat{\Sigma}_\pi\left(\mu_0 + \sum_{n=1}^N W_n y_n\right). \tag{6.2}$$

Generating a uniformly random subsample posterior approximation involved a similar technique, instead using probabilities $\frac{1}{N}$ for all $n \in [N]$. For the Hilbert coreset algorithms, we used the true posterior as the weighting distribution, i.e., $\hat{\pi} = \pi$. This was chosen to illustrate the ideal case in which the true posterior π is well-approximated by the weighting

distribution $\hat{\pi}$. Given this choice, the Fisher information distance inner product is available in closed-form:

$$\langle \mathcal{L}_n, \mathcal{L}_m \rangle_{\pi,F} = \frac{2}{1+N} + (\mu_\pi - y_n)^T (\mu_\pi - y_m). \tag{6.3}$$

Note that the norm $\|\mathcal{L}_n\|_{\pi,F}$ implied by Eq. (6.3) and the uniform sensitivity from Eq. (6.1) are functionally very similar; both scale with the squared distance from y_n to an estimate of μ. Since all the approximate posteriors are multivariate Gaussians of the form Eq. (6.2)—with weights W_n differing depending on the construction algorithm—we were able to evaluate posterior approximation quality exactly using the KL-divergence from the approximate coreset posterior $\tilde{\pi}$ to π, given by

$$\mathrm{D_{KL}}(\pi \| \tilde{\pi}) = \frac{1}{2}\left\{ \mathrm{tr}\left(\Sigma_{\tilde{\pi}}^{-1}\Sigma_\pi\right) + (\mu_{\tilde{\pi}} - \mu_\pi)^T \Sigma_{\tilde{\pi}}^{-1}(\mu_{\tilde{\pi}} - \mu_\pi) - 2 + \log\frac{|\Sigma_{\tilde{\pi}}|}{|\Sigma_\pi|}\right\}.$$

6.2. Results

The results of this test appear in Fig. 2. The visual comparison of the different coreset constructions in Fig. 2a–2d makes the advantages of Hilbert coresets constructed via Frank–Wolfe clear. As more coreset points are added, all approximate posteriors converge to the true posterior; however, the Frank–Wolfe method requires many fewer coreset points to converge on a reliable estimate. While both the Hilbert and uniform coresets subsample the data favoring those points at greater distance from the center, the Frank–Wolfe method first selects a point close to the center (whose scaled likelihood well-approximates the true posterior), and then refines its estimate with points far away from the center. This intuitive behavior results in a higher-quality approximation of the posterior across all coreset sizes. Note that the black coreset points across $M = 5$, 50, and 500 show a single trace of a coreset being constructed, while the green posterior predictive ellipses show the noise in the coreset construction across multiple runs at each fixed value of M. The quantitative results in Figs. 2e and 2f—which plot the KL-divergence between each coreset approximate posterior and the truth as the projection dimension J or the number of coreset iterations M varies—confirm the qualitative evaluations. In addition, Fig. 2e confirms the theoretical result from Theorem 4.4, i.e., that Frank–Wolfe exhibits linear convergence in this setting. Fig. 2f similarly confirms Theorem 5.2, i.e., that the posterior error of the projected Hilbert coreset converges to that of the exact Hilbert coreset as the dimension J of the random projection increases.

7. Experiments

In this section we evaluate the performance of Hilbert coresets compared with uniform coresets and uniformly random subsampling, using MCMC on the full data set as a benchmark. We test the algorithms on logistic regression, Poisson regression, and directional clustering models applied to numerous real and synthetic data sets. Based on the results of the synthetic comparison presented in Section 6, for clarity we focus the tests on comparing uniformly random subsampling to Hilbert coresets constructed using Frank–Wolfe with the weighted Fisher information distance from Eq. (5.1). Additional results on importance sampling, uniform coresets, and the weighted 2-norm from Eq. (5.3) are deferred to Appendix B.

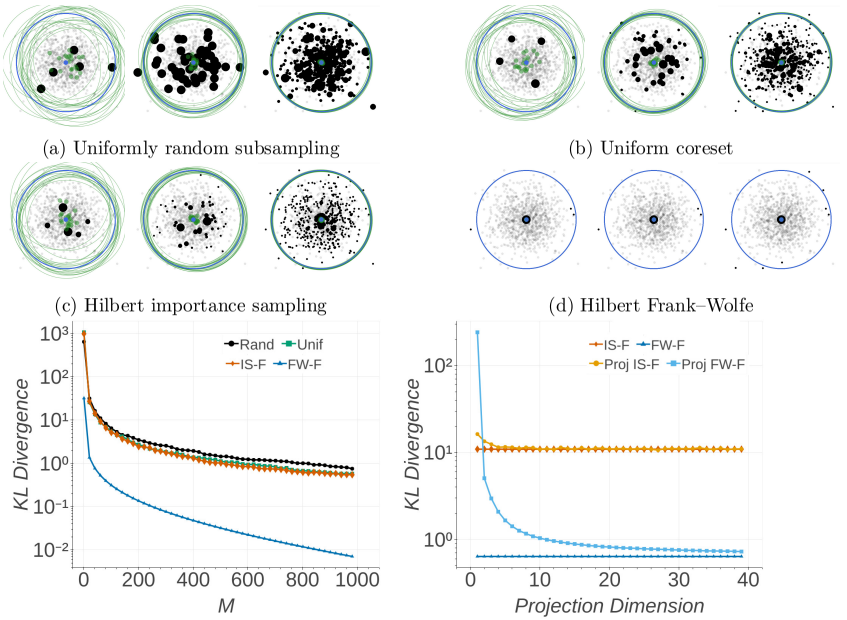

Figure 2: (2a-2d): Comparison of different coreset constructions for Gaussian inference, showing example coreset posterior predictive 3σ ellipses (green), the true data generating distribution 3σ ellipse (blue), and a single trace of coreset construction (black) for $M = 5$, 50, and 500. The radius of each coreset point indicates its weight. (2e): A comparison of approximate posteriors using exact norms versus coreset construction iterations M. (2f): A comparison of exact and projected methods versus projection dimension J, with fixed $M = 50$.

7.1. Models

In the **logistic regression** setting, we are given a set of data points $(x_n, y_n)_{n=1}^N$ each consisting of a feature $x_n \in \mathbb{R}^D$ and a label $y_n \in \{-1, 1\}$, and the goal is to predict the label of a new point given its feature. We thus seek to infer the posterior distribution of the parameter $\theta \in \mathbb{R}^{D+1}$ governing the generation of y_n given x_n via

$$\theta \sim \mathcal{N}(0, I) \qquad y_n \,|\, x_n, \theta \overset{\text{indep}}{\sim} \mathsf{Bern}\left(\frac{1}{1+e^{-z_n^T\theta}}\right) \qquad z_n := [x_n,\, 1]^T.$$

In the **Poisson regression** setting, we are given a set of data points $(x_n, y_n)_{n=1}^N$ each consisting of a feature $x_n \in \mathbb{R}^D$ and a count $y_n \in \mathbb{N}$, and the goal is to learn a relationship

between features x_n and the associated mean count. We thus seek to infer the posterior distribution of the parameter $\theta \in \mathbb{R}^D$ governing the generation of y_n given x_n via

$$\theta \sim \mathcal{N}(0, I) \qquad y_n \,|\, x_n, \theta \overset{\text{indep}}{\sim} \text{Poiss}\left(\log\left(1 + e^{\theta^T z_n}\right)\right) \qquad z_n := [x_n, 1]^T.$$

Finally, in the **directional clustering** setting, we are given a data set of points $(x_n)_{n=1}^N$ on the unit $(D-1)$-sphere, i.e. $x_n \in \mathbb{R}^D$ with $\|x_n\|_2 = 1$, and the goal is to separate them into K clusters. For this purpose we employ a *von Mises-Fisher (vMF) mixture model* (Banerjee et al., 2005). The component likelihood in this model is the von Mises-Fisher distribution $\text{vMF}(\mu, \tau)$ with concentration $\tau \in \mathbb{R}_+$ and mode $\mu \in \mathbb{R}^D$, $\|\mu\|_2 = 1$, having density

$$f_{\text{vMF}}(x; \mu, \tau) = C_D(\tau) e^{\tau x^T \mu} \qquad C_D(\tau) = \frac{\tau^{D/2-1}}{(2\pi)^{D/2} I_{D/2-1}(\tau)}$$

with support on the unit $(D-1)$-sphere $\mathbb{S}^{D-1}$, where I_p denotes the modified Bessel function of the first kind of order p. We place uniform priors on both the component modes and mixture weights, and set $\tau = 50$, resulting in the generative model

$$(\mu_k)_{k=1}^K \overset{\text{i.i.d.}}{\sim} \text{Unif}\left(\mathbb{S}^{D-1}\right) \quad (\omega_k)_{k=1}^K \sim \text{Dir}(1, \ldots, 1)$$
$$(x_n)_{n=1}^N \,|\, (\omega_k, \mu_k)_{k=1}^K \overset{\text{i.i.d.}}{\sim} \sum_{k=1}^K \omega_k \text{vMF}(\mu_k, \tau).$$

7.2. Datasets

We tested the coreset construction methods for each model on a number of data sets. For **logistic regression**, the `Synthetic` data set consisted of $N = 10{,}000$ data points (with 1,000 held out for testing) with covariate $x_n \in \mathbb{R}^2$ sampled i.i.d. from $\mathcal{N}(0, I)$, and label $y_n \in \{-1, 1\}$ generated from the logistic likelihood with parameter $\theta = [3, 3, 0]^T$. The `Phishing`[2] data set consisted of $N = 11{,}055$ data points (with 1,105 held out for testing) each with $D = 68$ features. In this data set, each covariate corresponds to the features of a website, and the goal is to predict whether or not a website is a phishing site. The `ChemReact`[3] data set consisted of $N = 26{,}733$ data points (with 2,673 held out for testing) each with $D = 10$ features. In this data set, each covariate represents the features of a chemical experiment, and the label represents whether a chemical was reactive in that experiment or not.

For **Poisson regression**, the `Synthetic` data set consisted of $N = 10{,}000$ data points (with 1,000 held out for testing) with covariate $x_n \in \mathbb{R}$ sampled i.i.d. from $\mathcal{N}(0, 1)$, and count $y_n \in \mathbb{N}$ generated from the Poisson likelihood with $\theta = [1, 0]^T$. The `BikeTrips`[4] data set consisted of $N = 17{,}386$ data points (with 1,738 held out for testing) each with $D = 8$ features. In this data set, each covariate corresponds to weather and season information for a particular hour during the time between 2011–2012, and the count is the number of bike trips taken during that hour in a bikeshare system in Washington, DC. The `AirportDelays`[5] data set consisted of $N = 7{,}580$ data points (with 758 held out for testing) each with $D = 15$ features. In this data set, each covariate corresponds to the weather information of a day during the time between 1987–2008, and the count is the number of flights leaving Boston Logan airport delayed by more than 15 minutes that day.

Finally, for **directional clustering**, the `Synthetic` data set consisted of $N = 10{,}000$ data points (with 1,000 held out for testing) generated from an equally-weighted vMF mixture with 6 components, one centered at each of the axis poles.

Figure 4: (4a-4c): Comparison of different coreset constructions for Poisson regression on the `Synthetic` data set, showing example coreset posterior Poisson mean curves (green), and a single trace of coreset construction (black) for $M = 10$, 100, and 1,000. The radius of each coreset point indicates its weight. (4d, 4e): A comparison of negative test log-likelihood (4d) and 1-Wasserstein distance (4e) versus computation time for Frank–Wolfe (solid) and uniform random subsampling (dashed) on the Poisson regression model. Both axes are normalized using results from running MCMC on the full data set; see Section 7.3.

7.3. Methods

We ran 50 trials of uniformly random subsampling and Hilbert Frank–Wolfe using the approximate Fisher information distance in Eq. (5.1), varying $M \in \{10, 50, 100, 500, 1{,}000, 5{,}000, 10{,}000\}$. For both **logistic regression** and **Poisson regression**, we used the Laplace approximation (Bishop, 2006, Section 4.4) as the weighting distribution $\hat{\pi}$ in the Hilbert coreset, with the random projection dimension set to $D = 500$. Posterior inference in each of the 50 trials was conducted using random walk Metropolis-Hastings with an isotropic

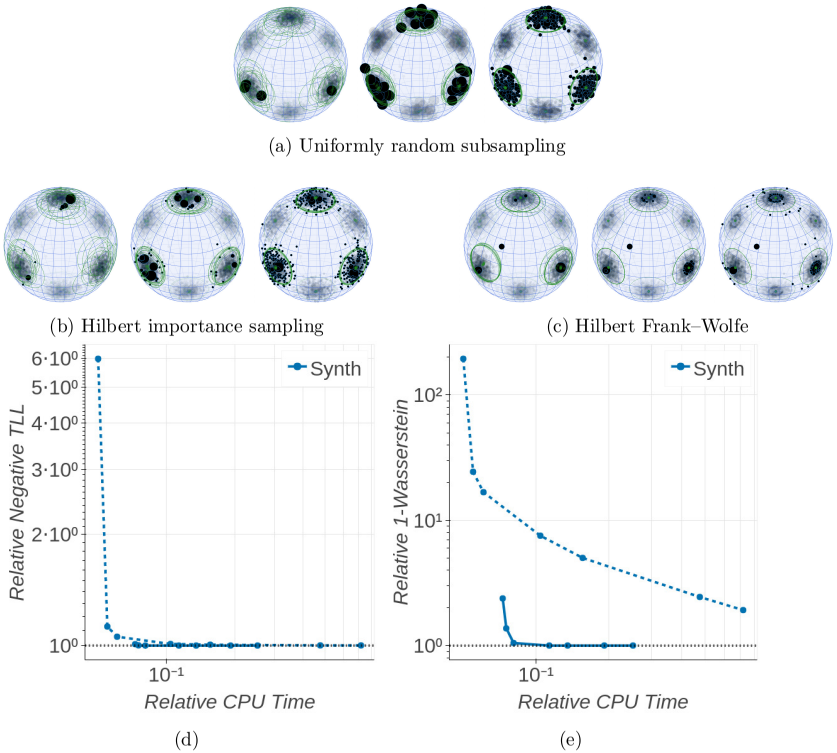
multivariate Gaussian proposal distribution. We simulated a total of 100,000 steps, with 50,000 warmup steps including proposal covariance adaptation with a target acceptance rate of 0.234, and thinning of the latter 50,000 by a factor of 5, yielding 10,000 posterior samples.

For **directional clustering** the weighting distribution $\hat{\pi}$ for the Hilbert coreset was constructed by finding maximum likelihood estimates of the cluster modes $(\hat{\mu}_k)_{k=1}^K$ and weights $\hat{\omega}$ using the EM algorithm, and then setting $\hat{\pi}$ to an independent product of approximate posterior conditionals,

$$\bar{x}_k := \sum_{n=1}^N z_{nk} x_n \qquad \bar{z}_k := \sum_{n=1}^N z_{nk}$$
$$\mu_k \overset{\text{indep}}{\sim} \text{vMF}\left(\frac{\bar{x}_k}{\|\bar{x}_k\|}, \tau\|\bar{x}_k\|\right) \qquad \omega \overset{\text{indep}}{\sim} \text{Dir}\left(1 + \bar{z}_1, \ldots, 1 + \bar{z}_k\right), \tag{7.1}$$

where $(z_n)_{n=1}^N$, $z_n \in \mathbb{R}_+^K$ are the smoothed cluster assignments. The random projection dimension was set to $D = 500$, and the number of clusters K was set to 6. Posterior inference in each of the 50 trials was conducted used Gibbs sampling (introducing auxiliary label variables for the data) with a total of 100,000 steps, with 50,000 warmup steps and thinning of the latter 50,000 by a factor of 5, yielding 10,000 posterior samples. Note that this approach is exact for the full data set; for the coreset constructions with weighted data, we replicate each data point by its ceiled weight, and then rescale the assignment variables to account for the fractional weight. In particular, for coreset weights $(w_n)_{n=1}^N$, we sample labels for points with $w_n > 0$ via

$$\gamma_k \propto \omega_k f_{\text{vMF}}(x_n; \mu_k, \tau) \quad z_n \overset{\text{indep}}{\sim} \text{Multi}(\texttt{ceil}(w_n), \gamma) \quad z_n \leftarrow \frac{w_n}{\texttt{ceil}(w_n)} z_n,$$



and sample the cluster centers and weights via Eq. (7.1).

For all models, we evaluate two metrics of posterior quality: negative log-likelihood on the held-out test set, averaged over posterior MCMC samples; and 1-Wasserstein distance of the posterior samples to samples obtained from running MCMC on the full data set. All negative test log-likelihood results are shifted by the maximum possible test log-likelihood and normalized by the test log-likelihood obtained from the full data set posterior. All 1-Wasserstein distance results are normalized by the median pairwise 1-Wasserstein distance between 10 trials of MCMC on the full data set. All computation times are normalized by the median computation time for MCMC on the full data set across the 10 trials. These normalizations allow the results from multiple data sets to be plotted coherently on the same axes.

We ran the same experiments described above on Hilbert importance sampling for all data sets, and uniform coresets on the logistic regression model with $a = 3$ and $K = 4$ (see Huggins et al. (2016, Sec. 4.2)). We also compared Hilbert coresets with the weighted 2-norm in Eq. (5.3) to the weighted Fisher information distance in Eq. (5.1). The results of these experiments are deferred to Appendix B for clarity.

7.4. Results and discussion

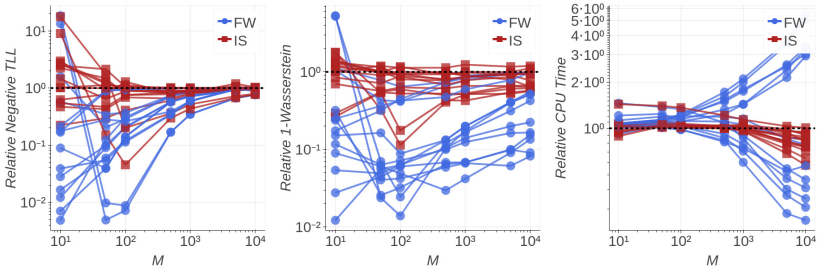
(a) Uniformly random subsampling

(b) Hilbert importance sampling



(c) Hilbert Frank–Wolfe

(d)

(e)

Figure 5: (5a-5c): Comparison of different coreset constructions for directional clustering, showing example coreset posterior mean clusters (green), and a single trace of coreset construction (black) for $M = 10$, 100, and 1,000. The radius of each coreset point indicates its weight. (5d, 5e): A comparison of negative test log-likelihood (5d) and 1-Wasserstein distance (5e) versus computation time for Frank–Wolfe (solid) and uniform random subsampling (dashed) on the directional clustering model. Both axes are normalized using results from running MCMC on the full data set; see Section 7.3.

all models mimic the results of the synthetic evaluation in Fig. 2. For all the algorithms, the approximate posterior converges to the true posterior on the full data set as more coreset points are added; and the Frank–Wolfe Hilbert coreset construction selects the most useful points incrementally, creating intuitive coresets that outperform all the other methods. For example, in the logistic regression model, the uniform coreset construction sensitivities are based on the proximity of the data to the centers of a K-clustering, and do not directly incorporate information about the classification boundary. This construction

(a) (b) (c)

Figure 6: A comparison of (6a) negative test log-likelihood, (6b) 1-Wasserstein posterior distance estimate, and (6c) computation time versus coreset construction iterations M for Frank–Wolfe (blue), importance sampling (red), and uniformly random subsampling (dashed black) across all models and data sets. All metrics are normalized to the median value for uniformly random subsampling; see Section 7.3.

therefore generally favors sampling points on the periphery of the data set and assigns high weight to those near the center. The Hilbert importance sampling algorithm, in contrast, directly considers the logistic regression problem; it favors sampling points lying along the boundary and assigns high weight to points orthogonal to it, thereby fixing the boundary plane more accurately. The Hilbert Frank–Wolfe algorithm selects a single point closely aligned with the classification boundary normal, and then refines its estimate with points near the boundary. This enables it to use far fewer coreset points to achieve a more accurate posterior estimate than the sampling-based methods. Similar statements hold for the two other models: in the Poisson regression model, the Hilbert Frank–Wolfe algorithm chooses a point closest to the true parameter and then refines its estimate using far away points; and in the directional clustering model, the Hilbert Frank–Wolfe algorithm initially selects points near the cluster centers and then refines the estimates with points in each cluster far from its center. The quantitative results demonstrate the strength of the Hilbert Frank–Wolfe coreset construction algorithm: for a given computational time budget, this algorithm provides orders of magnitude reduction in both error metrics over uniformly random subsampling. In addition, the Hilbert Frank–Wolfe coreset achieves the same negative test log-likelihood as the full data set in roughly a tenth of the computation time. These statements hold across all models and data sets considered.

Fig. 6 provides a summary of the performance of Hilbert coresets as a function of construction iterations M across all models and data sets. This demonstrates its power not only as a scalable inference method but also as a data set compression technique. For any value of M and across a wide variety of models and data sets, Hilbert coresets (both importance sampling and Frank–Wolfe-based constructions) provide a significant improvement in posterior approximation quality over uniformly random subsampling, with comparable computation time. This figure also shows a rather surprising result: not only does the Frank–Wolfe-based method provide improved posterior estimates, it also can sometimes

have *reduced overall computational cost* compared to uniformly random subsampling for fixed M. This is due to the fact that M is an upper bound on the coreset size; the Frank–Wolfe algorithm often selects the same point multiple times, leading to coresets of size $\ll M$, whereas subsampling techniques always have coresets of size $\approx M$. Since the cost of posterior inference scales with the coreset size and dominates the cost of setting up either coreset construction algorithm, the Hilbert Frank–Wolfe method has a reduced overall cost. Generally speaking, we expect the Hilbert coreset methods to be slower than random subsampling for small M, where $\hat{\pi}$ setup and random projection dominates the time cost, but the Frank–Wolfe method to sometimes be faster for large M where the smaller coreset provides a significant inferential boost.

Although more detailed results for Hilbert importance sampling, uniform coresets, and the weighted 2-norm from Eq. (5.3) are deferred to Appendix B, we do provide a brief summary here. Fig. 7 shows that Hilbert importance sampling provides comparable performance to both uniform coresets and uniformly random subsampling on all models and data sets. The Hilbert Frank–Wolfe coreset construction algorithm typically outperforms all random subsampling methods. Finally, Figs. 8 and 9 show that the weighted 2-norm and Fisher information norm perform similarly in all cases considered.

8. Conclusion

This paper presented a fully-automated, scalable, and theoretically-sound Bayesian inference framework based on Hilbert coresets. The algorithms proposed in this work are simple to implement, reliably provide high-quality posterior approximation at a fraction of the cost of running inference on the full data set, and enable experts and nonexperts alike to conduct sophisticated modeling and exploratory analysis at scale. There are many avenues for future work, including exploring the application of Hilbert coresets in more complex high-dimensional models, using alternate Hilbert norms, connecting the norms proposed in the present work to more well-known measures of posterior discrepancy, investigating different choices of weighting function, obtaining tighter bounds on the quality of the random projection result, and using variants of the Frank–Wolfe algorithm (e.g. away-step, pairwise, and fully-corrective FW (Lacoste-Julien and Jaggi, 2015)) with stronger convergence guarantees.

Appendix A. Technical results and proofs

In this section we provide proofs of the main results from the paper, along with supporting technical lemmas. Lemma A.1 is the martingale extension of Hoeffding's inequality (Boucheron et al., 2013, Theorem 2.8, p. 34) known as Azuma's inequality. Lemma A.2 is the martingale extension of Bennet's inequality (Boucheron et al., 2013, Theorem 2.9, p. 35).

Lemma A.3 provides bounds on the expectation and martingale differences of the norm of a vector constructed by i.i.d. sampling from a discrete distribution. Finally, Lemma A.5 is a geometric result and Lemma A.6 bounds iterates of the logistic equation, both of which are used in the proof of the Frank-Wolfe error bound. Lemma A.4 provides a relationship between two vector alignment constants in the main text.

Lemma A.1 (Azuma's Inequality). *Suppose $(Y_m)_{m=0}^M$ is a martingale adapted to the filtration $(\mathcal{F}_m)_{m=0}^M$. If there is a constant ξ such that for each $m \in \{1, \dots, M\}$,*

$$|Y_m - Y_{m-1}| \leq \xi \quad a.s.,$$

then for all $\epsilon \geq 0$,

$$\mathbb{P}\left(Y_M - Y_0 > \epsilon\right) \leq e^{-\frac{\epsilon^2}{2M\xi^2}}.$$

Lemma A.2 (Martingale Bennet Inequality). *Suppose $(Y_m)_{m=0}^M$ is a martingale adapted to the filtration $(\mathcal{F}_m)_{m=0}^M$. If there are constants ξ and τ^2 such that for each $m \in \{1, \dots, M\}$,*

$$|Y_m - Y_{m-1}| \leq \xi \qquad \text{and} \qquad \mathbb{E}\left[(Y_m - Y_{m-1})^2 \,|\, \mathcal{F}_{m-1}\right] \leq \tau^2 \quad a.s.,$$

then for all $\epsilon \geq 0$,

$$\mathbb{P}\left(Y_M - Y_0 > \epsilon\right) \leq e^{-\frac{M\tau^2}{\xi^2} H\left(\frac{\epsilon\xi}{M\tau^2}\right)}, \quad H(x) := (1+x)\log(1+x) - x.$$

Lemma A.3. *Suppose U and $\{U_m\}_{m=1}^M$ are i.i.d. random vectors in a normed vector space with discrete support on $(u_n)_{n=1}^N$ with probabilities $(p_n)_{n=1}^N$, and*

$$Y := \left\| \frac{1}{M} \sum_{m=1}^{M} U_m - \mathbb{E}\left[U\right] \right\|.$$

Then we have the following results.

1. *Suppose $\dim\left(u_n\right)_{n=1}^N \leq d$ where $\dim$ is given by Definition 3.1, $\alpha_{n\cdot} \in [-1,1]^d$ are the coefficients used to approximate u_n in Definition 3.1, and A_j is a random variable equal to α_{nj} when $U = u_n$. Then*

$$\mathbb{E}\left[Y\right] \leq \frac{d}{\sqrt{M}} \left(\sum_{n=1}^{N} \|u_n\| \sqrt{\frac{p_n(1-p_n)}{N}} + \sqrt{\mathrm{Var}\left[\|U A_j\|\right]} \right).$$

2. *If the norm is a Hilbert norm,*

$$\mathbb{E}\left[Y\right] \leq \frac{1}{\sqrt{M}} \sqrt{\mathbb{E}\left[\|U\|^2\right] - \|\mathbb{E}\left[U\right]\|^2}.$$

3. *The random variable $Y_m := \mathbb{E}\left[Y \,|\, \mathcal{F}_m\right]$ with $\mathcal{F}_m$ the σ-algebra generated by $U_1, \dots, U_m$ is a martingale that satisfies, for $m \geq 1$, both*

$$|Y_m - Y_{m-1}| \leq \frac{1}{M} \max_{n,\ell} \|u_n - u_\ell\|$$

and

$$\mathbb{E}\left[(Y_m - Y_{m-1})^2 \mid \mathcal{F}_{m-1}\right] \leq \frac{1}{M^2}\mathbb{E}\left[\|U - U_1\|^2\right]$$

almost surely.

Proof. 1. Using the triangle inequality, denoting the number of times vector u_n is sampled as M_n,

$$\begin{aligned}\mathbb{E}[Y] \leq& \frac{1}{M}\sum_{n=1}^{N}\frac{d\,\|u_n\|}{\sqrt{N}}\mathbb{E}\left[|M_n - Mp_n|\right] \\ &+\frac{1}{M}\sum_{j=1}^{d}\mathbb{E}\left[\left|\sum_{n=1}^{N}(M_n - Mp_n)\,\|u_n\|\alpha_{nj}\right|\right].\end{aligned}$$

Bounding $\mathbb{E}[|\cdot|] \leq \sqrt{\mathbb{E}[(\cdot)^2]}$ via Jensen's inequality and evaluating the multinomial variances yields the desired result.

2. This follows from Jensen's inequality to write $\mathbb{E}[Y] \leq \sqrt{\mathbb{E}[Y^2]}$ and the expansion of the squared norm.

3. $(Y_m)_{m=0}^M$ is a standard Doob martingale with $Y_0 = \mathbb{E}[Y]$. Letting $U'_\ell = U_\ell$ for $\ell \neq m$ and U'_m be an independent random variable with $U'_m \overset{d}{=} U_m$, by the triangle inequality we have

$$\begin{aligned}&|Y_m - Y_{m-1}| \\ =&|\mathbb{E}[Y \mid \mathcal{F}_m] - Y_{m-1}| \\ =&\left|\mathbb{E}\left[\left\|\frac{1}{M}\sum_{\ell=1}^{M}U_\ell - \mathbb{E}[U]\right\| \mid \mathcal{F}_m\right] - Y_{m-1}\right| \\ =&\left|\mathbb{E}\left[\left\|\frac{1}{M}\left(U_m - U'_m\right) + \frac{1}{M}\sum_{\ell=1}^{M}U'_\ell - \mathbb{E}[U]\right\| \mid \mathcal{F}_m\right] - Y_{m-1}\right| \\ \leq&\left|\frac{1}{M}\mathbb{E}\left[\left\|U_m - U'_m\right\| \mid \mathcal{F}_m\right] + \mathbb{E}\left[\left\|\frac{1}{M}\sum_{\ell=1}^{M}U'_\ell - \mathbb{E}[U]\right\| \mid \mathcal{F}_m\right] - Y_{m-1}\right| \\ =&\frac{1}{M}\mathbb{E}\left[\left\|U_m - U'_m\right\| \mid \mathcal{F}_m\right] \qquad\qquad (A.1) \\ \leq&\frac{1}{M}\max_{n,\ell}\|u_n - u_\ell\|.\end{aligned}$$

Next, using Eq. (A.1) and Jensen's inequality, we have that

$$\begin{aligned}\mathbb{E}\left[(Y_m - Y_{m-1})^2 \mid \mathcal{F}_{m-1}\right] &\leq \mathbb{E}\left[\mathbb{E}\left[\frac{1}{M}\left\|U_m - U'_m\right\| \mid \mathcal{F}_m\right]^2 \mid \mathcal{F}_{m-1}\right] \\ &\leq \frac{1}{M^2}\mathbb{E}\left[\left\|U_m - U'_m\right\|^2 \mid \mathcal{F}_{m-1}\right] \\ &= \frac{1}{M^2}\mathbb{E}\left[\left\|U_m - U'_m\right\|^2\right].\end{aligned}$$

□

Proof of Theorem 3.2. Set $\delta \in (0,1)$. Rearranging the results of Lemma A.1, we have that with probability $\geq 1-\delta$,

$$Y_M \leq Y_0 + \sqrt{2M\xi^2\log\frac{1}{\delta}}.$$

We now apply the results of Lemma A.3(1) and Lemma A.3(3), noting that $\sum_{n=1}^N\sqrt{p_n(1-p_n)}$ is maximized when $p_n = 1/N$, where the discrete distribution is specified by atoms $u_n = \sigma\mathcal{L}_n/\sigma_n$ with probabilities σ_n/σ for $n \in [N]$. Further, when applying Lemma A.3(1), note that

$$\begin{aligned}\operatorname{Var}\|UA_j\| &= \sigma^2\operatorname{Var}|A_j| \\ &= \sigma^2\operatorname{Var}\left(|A_j| - \frac{1}{2}\right) \leq \sigma^2\mathbb{E}\left[\left(|A_j| - \frac{1}{2}\right)^2\right] \leq \frac{\sigma^2}{4}.\end{aligned}$$

This yields

$$Y_0 \leq \frac{3\sigma d}{2\sqrt{M}} \qquad\qquad \xi = \frac{\sigma\overline{\eta}}{M}.$$

Substituting these results into the above expression,

$$Y_M \leq \frac{\sigma}{\sqrt{M}}\left(\frac{3}{2}\dim\left(\mathcal{L}_n\right)_{n=1}^N + \overline{\eta}\sqrt{2\log\frac{1}{\delta}}\right).$$

□

Proof of Theorem 4.1. Set $\delta \in (0,1)$. Rearranging the results of Lemmas A.1 and A.2, we have that with probability $\geq 1-\delta$,

$$Y_M \leq Y_0 + \min\left(\sqrt{2M\xi^2\log\frac{1}{\delta}}, \frac{M\tau^2}{\xi}H^{-1}\left(\frac{\xi^2}{M\tau^2}\log\frac{1}{\delta}\right)\right).$$

We now apply the results of Lemma A.3(3), where the discrete distribution is specified by atoms $u_n = \mathcal{L}_n/p_n$ with probabilities p_n for $n \in [N]$. Define M_n to be the number of times index n is sampled; then $(M_1, \ldots, M_N) \sim \mathsf{Multi}(M, (p_n)_{n=1}^N)$. Then since our vectors are in a Hilbert space, we use Lemma A.3(2) and Lemma A.3(3) to find that

$$\begin{aligned}Y_M &= \left\|\frac{1}{M}\sum_{m=1}^{M}U_m - \mathbb{E}[U]\right\| = \left\|\sum_{n=1}^{N}\frac{M_n}{Mp_n}\mathcal{L}_n - \mathcal{L}\right\| \\ Y_0 &\leq \sqrt{\frac{1}{M}\left(\sum_{n=1}^{N}\frac{\|\mathcal{L}_n\|^2}{p_n} - \|\mathcal{L}\|^2\right)}\end{aligned}$$

$$\xi = \frac{1}{M}\max_{m,n}\left\|\frac{\mathcal{L}_n}{p_n} - \frac{\mathcal{L}_m}{p_m}\right\|$$
$$\tau^2 = \frac{1}{M^2}\mathbb{E}\left[\left\|U_m - U'_m\right\|^2\right] = \frac{2}{M^2}\left(\sum_{n=1}^N \frac{\|\mathcal{L}_n\|^2}{p_n} - \|\mathcal{L}\|^2\right).$$

Minimizing both τ^2 and Y_0 over $(p_n)_{n=1}^N$ by setting the derivative to 0 yields

$$p_n = \frac{\|\mathcal{L}_n\|}{\sigma} \qquad \sigma := \sum_{n=1}^N \|\mathcal{L}_n\|. \tag{A.2}$$

Finally, we have that

$$Y_0 \leq \sqrt{\frac{1}{M}\sigma^2\eta^2} \qquad \tau^2 = \frac{2\sigma^2}{M^2}\left(1 - \frac{\|\mathcal{L}\|^2}{\sigma^2}\right) = \frac{2\sigma^2\eta^2}{M^2} \qquad \xi = \frac{\sigma}{M}\overline{\eta},$$

and $\frac{M_n}{M}\frac{1}{p_n} = W_n$ from Algorithm 1, so

$$\begin{aligned}\|\mathcal{L}(W) - \mathcal{L}\| &\leq \frac{\sigma\eta}{\sqrt{M}} + \min\left(\sqrt{2\frac{\sigma^2\overline{\eta}^2}{M}\log\frac{1}{\delta}}, \frac{2\sigma\eta^2}{\overline{\eta}}H^{-1}\left(\frac{\overline{\eta}^2}{2M\eta^2}\log\frac{1}{\delta}\right)\right)\\ &= \frac{\sigma}{\sqrt{M}}\left(\eta + \eta_M\sqrt{2\log\frac{1}{\delta}}\right)\\ \eta_M &:= \min\left(\overline{\eta}, \eta\sqrt{\frac{2M\eta^2}{\overline{\eta}^2\log\frac{1}{\delta}}}H^{-1}\left(\frac{\overline{\eta}^2\log\frac{1}{\delta}}{2M\eta^2}\right)\right).\end{aligned}$$

□

Lemma A.4. *Given a Hilbert norm, $\overline{\eta}$ from Eq. (3.3) and η from Eq. (4.1) satisfy*

$$\eta \leq \frac{\overline{\eta}}{\sqrt{2}}.$$

Proof. Noting $\|\mathcal{L}\|^2 = \langle\mathcal{L},\mathcal{L}\rangle$ and expanding the definition from Eq. (4.1),

$$\eta^2 = 1 - \sum_{n,m=1}^N \frac{\sigma_n\sigma_m}{\sigma^2}\left\langle\frac{\mathcal{L}_n}{\sigma_n}, \frac{\mathcal{L}_m}{\sigma_m}\right\rangle \leq 1 - \min_{n,m\in[N]}\left\langle\frac{\mathcal{L}_n}{\sigma_n}, \frac{\mathcal{L}_m}{\sigma_m}\right\rangle = \frac{1}{2}\overline{\eta}^2$$

where the inequality follows from $\sum_{n,m=1}^N \frac{\sigma_n\sigma_m}{\sigma^2} = 1$. □

Lemma A.5. *$\mathcal{L}$ is in the relative interior of the convex hull of $\left\{\frac{\sigma}{\|\mathcal{L}_n\|}\mathcal{L}_n\right\}_{n=1}^N$.*

Proof. First, since K (the kernel matrix of inner products defined in Eq. (4.2)) is a symmetric postive semidefinite $N \times N$ matrix, there exists an $N \times N$ matrix U such that $\|\mathcal{L}(w)\|^2 = w^T K w = w^T U^T U w = \|u(w)\|_2^2$, where $u(w) := \sum_{n=1}^N w_n u_n$, $u := \sum_{n=1}^N u_n$, and $u_n \in \mathbb{R}^N$ are the columns of U. Therefore the mapping $\mathcal{L}(w) \to u(w)$ is a linear isometry from the Hilbert space to $\mathbb{R}^N$, so if u is in the relative interior of the convex hull of $\left\{\frac{\sigma}{\|u_n\|}u_n\right\}_{n=1}^N$, the result follows. Let y be any other point in the convex hull in $\mathbb{R}^N$, with coefficients γ_n. If we set

$$\lambda = \min_{n:\gamma_n > \frac{\|u_n\|}{\sigma}} \frac{\gamma_n}{\gamma_n - \frac{\|u_n\|}{\sigma}}$$

where the minimum of an empty set is defined to be ∞, then $\lambda u + (1-\lambda)y$ is in the convex hull and $\lambda > 1$. Since for any point y we can find such a λ, the result follows from (Rockafeller, 1970, Theorem 6.4, p. 47). □

Lemma A.6. *The logistic recursion,*

$$x_{n+1} \leq \alpha x_n(1 - x_n),$$

for $x_0, \alpha \in [0,1]$ satisfies

$$\forall n \in \mathbb{N}, \quad x_n \leq \frac{x_0}{\alpha^{-n} + x_0 n}.$$

Proof. The proof proceeds by induction. The bound holds at $n = 0$ since

$$x_0 \leq \frac{x_0}{\alpha^0 + 0} = x_0.$$

Since $1 - x \leq 1/(1+x)$, for any $n \geq 0$,

$$x_{n+1} \leq \alpha x_n(1 - x_n) \leq \alpha\frac{x_n}{1 + x_n}.$$

Assuming the bound holds for any $n \geq 0$, and noting $x/(1+x)$ is monotone increasing for $x \geq 0$, we can substitute the bound yielding

$$x_{n+1} \leq \alpha\frac{\frac{x_0}{\alpha^{-n} + nx_0}}{1 + \frac{x_0}{\alpha^{-n} + nx_0}} = \alpha\frac{x_0}{\alpha^{-n} + nx_0 + x_0} = \frac{x_0}{\alpha^{-(n+1)} + \alpha^{-1}(n+1)x_0}.$$

The final result follows since $\alpha^{-1} \geq 1$. □

Proof of Lemma 4.3. Let w_t be the weight vector at iteration t in Algorithm 2, and let f_t and d_t be the Frank-Wolfe vertex index and direction, respectively, from Eq. (4.4). For brevity, denote the cost $J(w) := (w-1)^T K(w-1)$. For any $\gamma \in \mathbb{R}$, if we let $w_{t+1} = w_t + \gamma d_t$ we have that

$$J(w_{t+1}) = J(w_t) + 2\gamma d_t^T K(w_t - 1) + \gamma^2 d_t^T K d_t. \tag{A.3}$$

Minimizing Eq. (A.3) over $\gamma \in \mathbb{R}$ yields Eq. (4.5) (expressed as a quadratic form with gram matrix K),

$$\gamma_t = \frac{d_t^T K(1 - w_t)}{d_t^T K d_t}. \tag{A.4}$$

Suppose $\gamma_t < 0$. Then $d_t^T K(1-w_t) < 0$; but d_t maximizes this product over feasible directions, so

$$0 > d_t^T K(1-w_t) > (1-w_t)^T K(1-w_t) = J(w_t) \geq 0, \tag{A.5}$$

which is a contradiction. Now suppose $\gamma_t > 1$. Then

$$d_t^T K(1-w_t) > d_t^T K d_t,$$

and Eq. (A.5) holds again, so if we were to select $\gamma = 1$ in Eq. (A.3), we would have

$$0 \leq J(w_{t+1}) < J(w_t) + d_t^T K(w_t - 1) \leq 0,$$

which is another contradiction, so $\gamma_t \leq 1$. Therefore $\gamma_t \in [0,1]$ □

Proof of Theorem 4.4. Using the same notation as the proof of Lemma 4.3 above, first note that $J(w_0) \leq \sigma^2\eta^2$ as initialized by Eq. (4.3): for any $\xi \in \mathbb{R}_+^N$ with $\sum_n \xi_n = 1$,

$$\frac{J(w_0)}{\sigma^2} = 1 - 2\left\langle \frac{\mathcal{L}_{f_0}}{\sigma_{f_0}}, \frac{\mathcal{L}}{\sigma} \right\rangle + \frac{\|\mathcal{L}\|^2}{\sigma^2} \leq 1 - 2\sum_{n=1}^N \xi_n \left\langle \frac{\mathcal{L}_n}{\sigma_n}, \frac{\mathcal{L}}{\sigma} \right\rangle + \frac{\|\mathcal{L}\|^2}{\sigma^2}$$

since f_0 maximizes $\langle \mathcal{L}, \mathcal{L}_n/\sigma_n \rangle$ over $n \in [N]$, and picking $\xi_n = \sigma_n/\sigma$ yields

$$\frac{J(w_0)}{\sigma^2} \leq 1 - 2\sum_{n=1}^N \left\langle \frac{\mathcal{L}_n}{\sigma}, \frac{\mathcal{L}}{\sigma} \right\rangle + \frac{\|\mathcal{L}\|^2}{\sigma^2} = 1 - \frac{\|\mathcal{L}\|^2}{\sigma^2} = \eta^2.$$

By Lemma 4.3, we are guaranteed that each Frank-Wolfe iterate using exact line search is feasible, and substituting Eq. (A.4) into Eq. (A.3) yields

$$\begin{aligned} J(w_{t+1}) &= J(w_t) - \frac{\left(d_t^T K(1-w_t)\right)^2}{d_t^T K d_t} \\ &= J(w_t)\left(1 - \left\langle \frac{\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t)}{\|\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t)\|}, \frac{\mathcal{L} - \mathcal{L}(w_t)}{\|\mathcal{L} - \mathcal{L}(w_t)\|} \right\rangle^2\right). \end{aligned} \tag{A.6}$$

We now employ a technique due to Guélat and Marcotte (1986): by Lemma A.5, $\mathcal{L}$ is in the relative interior of the convex hull of the $\left\{\frac{\sigma}{\sigma_n}\mathcal{L}_n\right\}_{n=1}^N$, so there exists an $r > 0$ such that for any feasible w,

$$\mathcal{L}(w) + (\|\mathcal{L} - \mathcal{L}(w)\| + r)\frac{\mathcal{L} - \mathcal{L}(w)}{\|\mathcal{L} - \mathcal{L}(w)\|}$$

is also in the convex hull. Thus, since the Frank-Wolfe vertex $\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t}$ maximizes $\langle \mathcal{L}(w) - \mathcal{L}(w_t), \mathcal{L} - \mathcal{L}(w_t) \rangle$ over feasible w, we have that

$$\left\langle \frac{\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t)}{\|\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t)\|}, \frac{\mathcal{L} - \mathcal{L}(w_t)}{\|\mathcal{L} - \mathcal{L}(w_t)\|} \right\rangle \geq \left\langle \frac{(\|\mathcal{L} - \mathcal{L}(w_t)\| + r)\frac{\mathcal{L} - \mathcal{L}(w_t)}{\|\mathcal{L} - \mathcal{L}(w_t)\|}}{\|\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t)\|}, \frac{\mathcal{L} - \mathcal{L}(w_t)}{\|\mathcal{L} - \mathcal{L}(w_t)\|} \right\rangle$$

$$\begin{aligned} &= \frac{\sqrt{J(w_t)} + r}{\|\frac{\sigma}{\sigma_{f_t}}\mathcal{L}_{f_t} - \mathcal{L}(w_t)\|} \\ &\geq \frac{\sqrt{J(w_t)} + r}{\sigma\overline{\eta}}. \end{aligned}$$

Substituting this into Eq. (A.6) yields

$$J(w_{t+1}) \leq J(w_t)\left(1 - \left(\frac{\sqrt{J(w_t)} + r}{\sigma\overline{\eta}}\right)^2\right) \leq J(w_t)\left(\nu^2 - \frac{J(w_t)}{\sigma^2\overline{\eta}^2}\right),$$

where $\nu := 1 - \frac{r^2}{\sigma^2\overline{\eta}^2}$. Defining $x_t := \frac{J(w_t)}{\sigma^2\overline{\eta}^2\nu^2}$, we have that $0 \leq x_t \leq 1$ and

$$x_{t+1} \leq \nu^2 x_t(1 - x_t),$$

and so Lemma A.6 implies that

$$\frac{J(w_t)}{\sigma^2\overline{\eta}^2\nu^2} \leq \frac{\frac{J(w_0)}{\sigma^2\overline{\eta}^2\nu^2}}{\nu^{-2t} + \frac{J(w_0)}{\sigma^2\overline{\eta}^2\nu^2}t}.$$

Further, since the function $\frac{a}{a+b}$ is monotonically increasing in a for all $a, b \geq 0$, we can use the bound on the initial objective $J(w_0)$, yielding

$$J(w_t) \leq \frac{\sigma^2\eta^2\overline{\eta}^2\nu^2}{\overline{\eta}^2\nu^{2-2t} + \eta^2 t}$$

The proof concludes by noting that we compute $M-1$ iterations after initialization to construct a coreset of size $\leq M$. The second stated bound results from the fact that $\overline{\eta} \geq \eta$ and $\nu \leq 1$.

The weaker bound in the note after the theorem is a result of a technique very similar to that commonly found in past work (Clarkson, 2010; Jaggi, 2013): starting from Eq. (A.3), we bound $d_t^T K d_t \leq \sigma^2\overline{\eta}^2$ and $d_t^T K(w_t - 1) \leq -J(w_t)$, and then use recursion to prove that $J(w_t) \leq \frac{4\sigma^2\overline{\eta}^2}{3t+4}$ given $\gamma_t = \frac{2}{3t+4}$. □

Proof of Theorem 5.2. Suppose $\max_{m,n} \left|\langle \mathcal{L}_n, \mathcal{L}_m \rangle - v_n^T v_m\right| \leq \epsilon$. Then

$$\begin{aligned} &(w-1)^T K(w-1) - (w-1)^T V(w-1) \leq \\ &\qquad \sum_{m,n} |w_n - 1|\,|w_m - 1|\left|\langle \mathcal{L}_n, \mathcal{L}_m \rangle - v_n^T v_m\right| \leq \|w-1\|_1^2\,\epsilon. \end{aligned}$$

We now bound the probability that the above inequality holds, assuming $D\nabla\mathcal{L}_n(\mu)_d\nabla\mathcal{L}_m(\mu)_d$ (when using $\mathcal{D}_{\hat{\pi},F}$) or $\mathcal{L}_n(\mu)\mathcal{L}_m(\mu)$ (when using $\mathcal{D}_{\hat{\pi},2}$) is sub-Gaussian with constant ξ^2. For brevity denote the true vector $\mathcal{L}_n$ as $\mathcal{L}_n$ and its random projection as v_n. Then

$$\mathbb{P}\left(\max_{m,n}\left|\langle \mathcal{L}_n, \mathcal{L}_m \rangle - v_n^T v_m\right| \geq \epsilon\right)$$

$$
\begin{aligned}
&\leq \sum_{m,n} \mathbb{P}\left(\left|\langle \mathcal{L}_n, \mathcal{L}_m\rangle - v_n^T v_m\right| \geq \epsilon\right) \\
&\leq N^2 \max_{m,n} \mathbb{P}\left(\left|\langle \mathcal{L}_n, \mathcal{L}_m\rangle - v_n^T v_m\right| \geq \epsilon\right) \\
&= N^2 \max_{m,n} \mathbb{P}\left(\left|\langle \mathcal{L}_n, \mathcal{L}_m\rangle - \frac{1}{J}\sum_{j=1}^{J} v_{nj} v_{mj}\right| \geq \epsilon\right) \\
&\leq 2N^2 e^{-\frac{J\epsilon^2}{2\xi^2}},
\end{aligned}
$$

using Hoeffding's inequality for sub-Gaussian variables. Thus if we fix $\delta \in (0,1)$, with probability $\geq 1-\delta$,

$$
\sqrt{\frac{2\xi^2}{J}\log\frac{2N^2}{\delta}} \geq \epsilon.
$$

Therefore, with probability $\geq 1-\delta$,

$$
\|\mathcal{L}(w) - \mathcal{L}\|^2 \leq \|v(w) - v\|^2 + \|w-1\|_1^2 \sqrt{\frac{2\xi^2}{J}\log\frac{2N^2}{\delta}}.
$$

□

Appendix B. Additional Results

This section contains supplementary quantitative evaluations. Fig. 7 compares Hilbert importance sampling to uniformly random subsampling and uniform coresets. These results demonstrate that all subsampling techniques perform similarly, with Hilbert coresets often the best choice of the three. The Frank–Wolfe constructions outperform subsampling techniques across all models and data sets considered. Figs. 8 and 9 compare the weighted 2-norm from Eq. (5.3) to the weighted Fisher information norm from Eq. (5.1) in both importance sampling and Frank–Wolfe-based Hilbert coreset constructions. These results show that the 2-norm and F-norm perform similarly in all cases.

Appendix C. Derivation of the Gaussian uniform coreset sensitivity

The sensitivity of observation y_n used in the construction of a Bayesian coreset (Huggins et al., 2016) (ignoring constants) is

$$
N\sigma_n = \sup_{\mu\in\mathbb{R}^d} \frac{N\mathcal{L}_n(\mu)}{\mathcal{L}(\mu)} = \sup_{\mu\in\mathbb{R}^d} \frac{N\left(y_n-\mu\right)^T\left(y_n-\mu\right)}{\sum_{m=1}^{N}\left(y_m-\mu\right)^T\left(y_m-\mu\right)}.
$$

By noting that

$$
\frac{1}{N}\sum_{m=1}^{N}\left(y_m-\mu\right)^T\left(y_m-\mu\right) = \frac{1}{N}\sum_{m=1}^{N} y_m^T y_m - \bar{y}^T\bar{y} + \left(\mu-\bar{y}\right)^T\left(\mu-\bar{y}\right),
$$

where $\bar{y} := \frac{1}{N}\sum_{m=1}^{N} y_m$, we can keep the denominator constant by varying μ on the ball centered at $\bar{y}$ of constant radius. The maximum of the numerator while keeping the

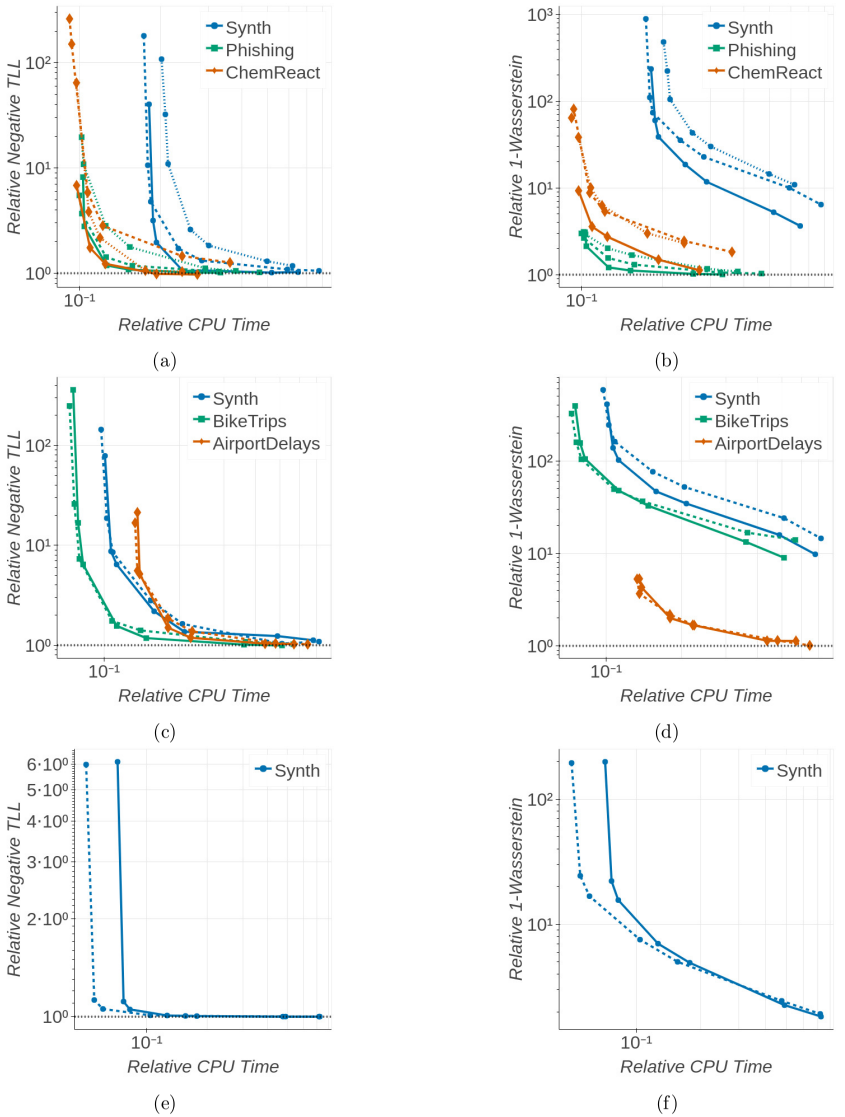

Figure 7: Comparisons for IS-F (solid), uniform coresets (dotted), and uniform random subsampling (dashed) on (7a, 7b) logistic regression, (7c, 7d) Poisson regression, and (7e, 7f) directional clustering. Both axes are normalized; see Section 7.3.

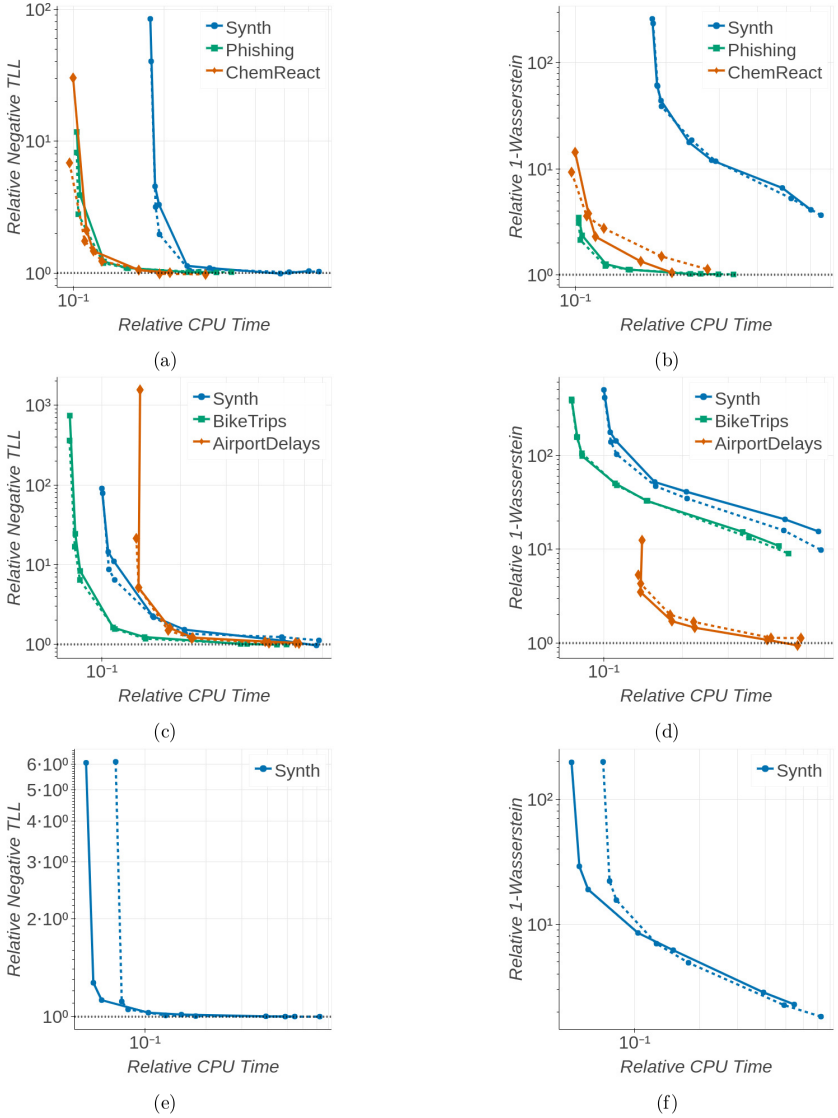

Figure 8: Comparisons for IS-2 (solid) and IS-F (dashed) on (8a, 8b) logistic regression, (8c, 8d) Poisson regression, and (8e, 8f) directional clustering. Both axes are normalized; see Section 7.3.

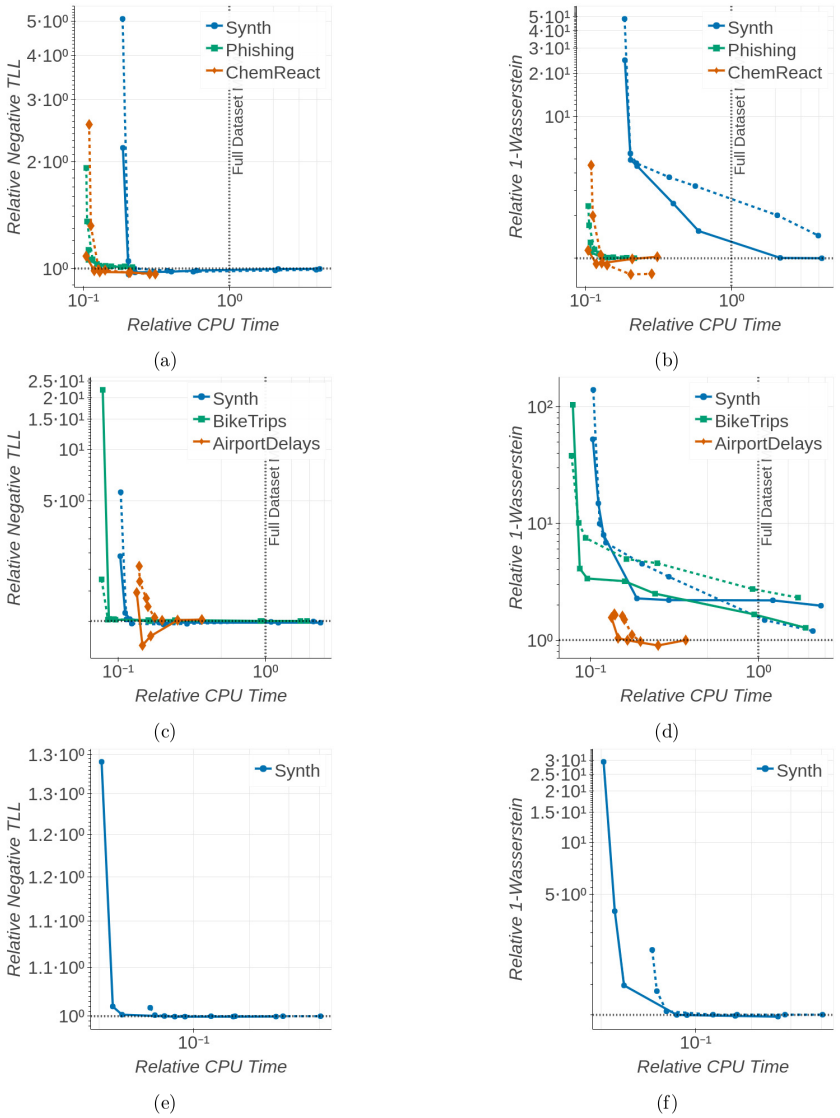

Figure 9: Comparisons for FW-2 (solid) and FW-F (dashed) on (9a, 9b) logistic regression, (9c, 9d) Poisson regression, and (9e, 9f) directional clustering. Both axes are normalized; see Section 7.3.

denominator constant happens when μ lies on the 1d affine space between $\bar{y}$ and y_n; so we can reparametrize $\mu = \lambda\bar{y} + (1-\lambda)y_n$ for $\lambda \in \mathbb{R}$, yielding the optimization

$$\sup_{\mu\in\mathbb{R}^d} \frac{N\mathcal{L}_n(\mu)}{\mathcal{L}(\mu)} = \sup_{\lambda\in\mathbb{R}} \frac{\lambda^2 (y_n-\bar{y})^T (y_n-\bar{y})}{\frac{1}{N}\sum_{m=1}^N y_m^T y_m - \bar{y}^T\bar{y} + (1-\lambda)^2 (y_n-\bar{y})^T (y_n-\bar{y})}$$

for which the optimum occurs at $\lambda^\star = \left(\frac{\frac{1}{N}\sum_{m=1}^N y_m^T y_m - \bar{y}^T\bar{y}}{(y_n-\bar{y})^T(y_n-\bar{y})} + 1\right)$ with value

$$N\sigma_n = \sup_{\mu\in\mathbb{R}^d} \frac{N\mathcal{L}_n(\mu)}{\mathcal{L}(\mu)} = 1 + \frac{(y_n-\bar{y})^T (y_n-\bar{y})}{\frac{1}{N}\sum_{m=1}^N y_m^T y_m - \bar{y}^T\bar{y}}.$$

Abstract

Recommender systems predict users' preferences over a large number of items by pooling similar information from other users and/or items in the presence of sparse observations. One major challenge is how to utilize user-item specific covariates and networks describing user-item interactions in a high-dimensional situation, for accurate personalized prediction. In this article, we propose a smooth neighborhood recommender in the framework of the latent factor models. A similarity kernel is utilized to borrow neighborhood information from continuous covariates over a user-item specific network, such as a user's social network, where the grouping information defined by discrete covariates is also integrated through the network. Consequently, user-item specific information is built into the recommender to battle the 'cold-start" issue in the absence of observations in collaborative and content-based filtering. Moreover, we utilize a "divide-and-conquer" version of the alternating least squares algorithm to achieve scalable computation, and establish asymptotic results for the proposed method, demonstrating that it achieves superior prediction accuracy. Finally, we illustrate that the proposed method improves substantially over its competitors in simulated examples and real benchmark data–*Last.fm* music data.

Keywords: Blockwise coordinate decent, Cold-start, Kernel smoothing, Neighborhood, Personalized prediction, Singular value decomposition, Social networks.

1. Introduction

Recommender systems predict users' preferences over a large number of items by pooling similar information from other users or items when observations are sparse, which are particularly useful in personalized prediction. It has become an essential part of e-commerce, with applications in movie rentals (MovieLens; Miller et al. 2003), restaurant guides (Entree; Burke 2002), book recommendations (Amazon; Linden et al. 2003), and personalized e-news (Daily learner; Billsus and Pazzani 2000).

Two main streams emerge for training recommender systems: collaborative filtering, which predicts users' behaviors based on similar users (Bell and Koren, 2007), and content-based filtering, which builds user and item profiles based on domain knowledge and recommends items with similar profiles (Lang, 1995; Melville et al., 2002). Specifically, collaborative filtering predicts unknown ratings by averaging over similar users' ratings with weights; such as the latent factor approach (Feuerverger et al., 2012), latent Dirichlet allocation (LDA; Blei et al. 2003), probabilistic latent semantic analysis (pLSA; Hofmann 2004), regularized singular value decomposition (regularized SVD; Paterek 2007), and restricted Boltzmann machines (RBM; Salakhutdinov et al. 2007). Among them, the regularized SVD approach has become popular due to its high predictive performance and scalability in real applications. In addition, Koren (2008) further generalizes SVD to model users' implicit feedbacks, and Forbes and Zhu (2011) incorporates content information in the regularized SVD approach through a regression-type of constraint. For content-based filtering, keywords analysis extracts features from items previously rated by a user to develop a profile of the user's interests, and recommendation is made by comparing the user profile and potential items (Lang, 1995). The naive Bayes (Billsus and Pazzani, 2000), decision tree (Pazzani et al., 1996) and kNN (Middleton et al., 2004) formulate this type of recommendation as a classification problem, where each item can be labeled by users as "like" or "dislike". Hybrid recommender systems (Burke, 2002) utilize geo-social correlations to accommodate new users and items through location-based recommendation systems; Bi et al. (2017) proposes a group-specific latent factor model by utilizing missingness-related characteristics to accommodate new users or items without any observed ratings.

To achieve better prediction accuracy, several main challenges remain in training recommender systems. First, smooth structure is contained in the user-item interactions, yet they are not fully utilized in model training. For instances, friends tend to share similar interests and preferences on various items, and relevant items tend to receive comparable ratings from users. Particularly, Figure 1 for the *Last.fm* data indicates that friends behave more similarly than randomly selected user pairs, which can be well characterized by a smoothing pattern of users' preference on items over the user-item specific network. However, such a user-item specific network usually involves a large number of parameters, which imposes great challenges in model building without a sufficient amount of observations. Therefore, how to incorporate the user-item specific network into a recommender system remains one key factor for improving prediction accuracy. Second, covariate information such as demographic and social network information of users, tags and content information of items, can be easily accessible (Nguyen and Zhu, 2013). In the existing literature, a number of methods have been proposed to utilize the side and relational information through Laplacian regularization (Gu et al., 2010), Gaussian generative models (Zhou et al., 2012), probability propagation (Yang et al., 2011), aggregating regression (Demir et al., 2017; Zhao et al., 2016; Zhao and Guo, 2017), Markov logic network (Salakhutdinov and Mnih, 2008; Richardson and Domingos, 2006), and the probabilistic soft logic (Kouki et al., 2015; Bach et al., 2017). Yet, most of the aforementioned methods are rather ad hoc and lack theoretical justification. Mainly, it remains largely unknown how the users' social networks and items' tagging information impact the accuracy of prediction. More importantly, a rating mechanism usu-

ally does not follow a parametric form in terms of covariates, which is commonly assumed in the literature due to the lack of sufficient observations for each user and item. How to employ a nonparametric approach to model the covariate-assisted recommender system in a high-dimensional setting continues to be an open question. Third, missing completely at random (MCAR) is often assumed by existing methods, leading to inaccurate prediction as the MCAR assumption is typically unrealistic for recommender systems. For example, users tend not to rate items that are of little interest to them, as illustrated in Figure 4. Fourth, most methods fail to recommend for new users or items without any observed ratings, which is referred as the "cold-start" problem. Thus, utilizing the covariate information to fully and efficiently solve the "cold-start" problem is attractive in devising recommender systems.

In this paper, we propose a novel approach based on the idea of a similarity-based neighborhood system pooling similar user-item pairs to improve prediction performance. Specifically, for each user-item pair, the proposed approach incorporates similar observed pairs through kernel weighting based on covariates as well as a user-item specific network. The weight function quantifies a smooth rating mechanism in terms of the closeness of continuous covariates within a neighborhood of the connected user-item pairs in the network. One novelty of the proposed approach is that it builds discrete covariates into a user-item specific network with the same discrete covariate values corresponding to connectivity. This enables us to handle high-dimensional covariates while not being burdened by the "curse of dimensionality." Unlike existing methods (Zhu et al., 2016; Bi et al., 2017), our approach is nonparametric, yet it goes beyond the traditional nonparametric framework which focuses primarily on continuous covariates. This provides a flexible framework to handle continuous covariates, discrete covariates and networks all together without specifying a functional relation. Moreover, the proposed approach also tackles the "cold-start" issue as it utilizes observed pairs in the neighborhood of any new user-item pairs in prediction.

The proposed approach takes full advantage of the smoothing pattern of the rating mechanism over covariates, while integrating user-item dependencies through user-item specific networks into a recommender system nonparametrically. This leads to a higher prediction accuracy for a recommender, as demonstrated in the numerical examples in Section 5. Significantly, our approach outperforms the state-of-the-art prediction performance for the *Last.fm* music benchmark dataset by nearly 20%. Additionally, we perform an error analysis, showing that the error rate of the proposed method is governed by the degree of smoothness of a neighborhood system with respect to continuous covariates, given that the grouping information is precisely defined by discrete covariates and networks. Most critically, as suggested by Theorem 1, the method performs well even in a high-dimensional situation in which the overall size of observed ratings is of the same magnitude as the number of unknown parameters.

The rest of the paper is organized as follows. Section 2 briefly introduces the regularized latent factor model, Section 3 presents the proposed recommender system and its implementation via the alternating least squares algorithm. Section 4 establishes the asymptotic results for the proposed method. Section 5 examines the numerical performance of the proposed method in simulation studies and a real application to the *Last.fm* dataset (`http://www.last.fm`). A brief summary is given in Section 6, and the Appendix contains the technical proofs.

2. Regularized latent factors

In this section, we provide the notations in recommender systems, and the framework of a regularized latent factor model. Consider a recommender system of n users' preference scores on m items, where r_{ui} denotes the preference score of user u on item i. Suppose a user-item specific covariate vector $\boldsymbol{x}_{ui} \in \mathcal{X} \subset \mathbb{R}^d$ is observed (e.g., a user's demographics and an item's content information). One key challenge for training a recommender system is that the preference matrix $R = (r_{ui}) \in \mathbb{R}^{n\times m}$ is only partially observed with a high missing percentage. Denote the index set of observed preference scores as Ω, then $|\Omega| \ll nm$.

A recommender system can be formulated in the framework of a latent factor model:

$$r_{ui} = \theta_{ui} + \epsilon_{ui} = \boldsymbol{p}_u^T \boldsymbol{q}_i + \varepsilon_{ui}, \quad 1 \le u \le n, 1 \le i \le m, \tag{1}$$

where $\theta_{ui} = E(r_{ui})$ is the expected preference score of a user-item pair (u, i), and ε_{ui} is independent from $\boldsymbol{x}_{ui}$ with mean zero and finite variance. The latent factor model assumes that θ_{ui} can be represented by user and item latent factors: $\theta_{ui} = \boldsymbol{p}_u^T \boldsymbol{q}_i$, where $\boldsymbol{p}_u$ and $\boldsymbol{q}_i$ are K-dimensional latent vectors representing user u's preference and item i's profile, respectively, and K is the number of latent factors for both users and items, which is also the rank in the latent factor model (Mukherjee et al., 2015).

To estimate these personalized parameters, a regularized SVD method (Paterek, 2007; Zhu et al., 2016) estimates $\boldsymbol{P} = (\boldsymbol{p}_1, \cdots, \boldsymbol{p}_n)^T$ and $\boldsymbol{Q} = (\boldsymbol{q}_1, \cdots, \boldsymbol{q}_m)^T$ by

$$\min_{\boldsymbol{P},\boldsymbol{Q}} \frac{1}{|\Omega|} \sum_{(u,i)\in\Omega} (r_{ui} - \boldsymbol{p}_u^T \boldsymbol{q}_i)^2 + \lambda \Big\{ \sum_{u=1}^{n} J(\boldsymbol{p}_u) + \sum_{i=1}^{m} J(\boldsymbol{q}_i) \Big\}, \tag{2}$$

where λ is a nonnegative tuning parameter, and $J(\cdot)$ can be any penalty function such as the L_q-penalty with $q = 0, 1, 2$ (Zhu et al., 2016) or the alignment penalty (Nguyen and Zhu, 2013). Note that r_{ui} in (2) is often replaced by the residual $r_{ui} - \mu - \boldsymbol{x}_{ui}^T \boldsymbol{\beta}$, where $(\mu, \boldsymbol{\beta})$ is a vector of regression coefficients to be minimized in (2). Alternatively, $\boldsymbol{p}_u = \boldsymbol{s}_u - \boldsymbol{x}_u^T \boldsymbol{\alpha}$ and $\boldsymbol{q}_i = \boldsymbol{t}_i - \boldsymbol{x}_i^T \boldsymbol{\beta}$, where $(\boldsymbol{s}_u, \boldsymbol{t}_i)$ are latent factors, and $(\boldsymbol{\alpha}, \boldsymbol{\beta})$ are regression coefficients to incorporate the covariate effects (Agarwal et al., 2011).

There are a number of major challenges for the regularized SVD model in (2). First, a user-item specific network is often available to capture user-item dependence but is ignored in (2). Here networks consists of information from existing users' social network, or item network, or the network constructed from available discrete covariates of the user-item pair (u, i). It can provide additional information regarding the preference similarity between connected pairs. This is the case for the *Last.fm* data, where a user specific network impacts users' preference on items, indicated by Figure 1. Second, a linear model in (2) may be inadequate to incorporate user and item covariates, especially when the linearity assumption is violated. Third, the objective function (2) assumes implicitly that missing occurs completely at random so that the first loss function in (2) can approximate the loss function for the complete data. When the missing is informative, missing characteristics such as the missing pattern for each user can be utilized for subgrouping (Bi et al., 2017). Fourth, the regularized SVD in (2) suffers from the "cold-start" problem for new users or items in the absence of observed ratings. For instance, if a user u or an item i is completely missing from Ω, the corresponding $\boldsymbol{p}_u$ or $\boldsymbol{q}_i$ is estimated incorrectly as 0 due to the penalty $J(\cdot)$ in (2).

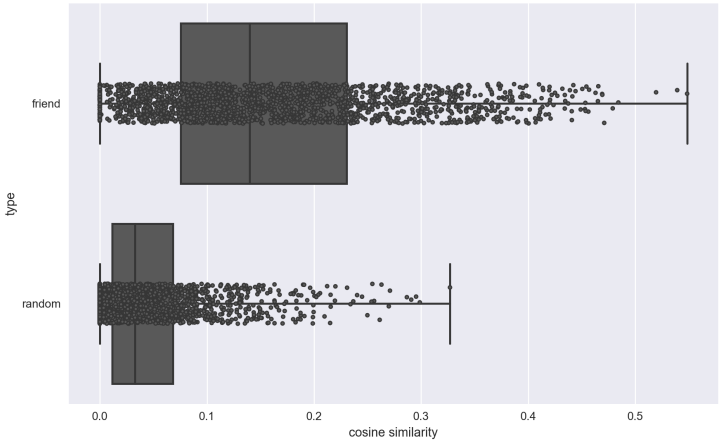

Figure 1: Comparison of the cosine similarity of logarithm of users' listening counts vector between friends and randomly selected users in the *Last.fm* dataset.

3. Methods

This section introduces a smooth recommender system, which incorporates user and/or item specific covariates and the user-item specific network information to improve prediction accuracy. The proposed method utilizes informative observations for each user-item pair for personalized prediction and resolving the "cold-start" problem.

3.1. Proposed method

One key strategy of the proposed method is to pool information across user-item pairs to improve prediction accuracy through increasing effective sample size. In contrast to grouping approaches based on user-item-specific information (Bi et al., 2017; Masthoff, 2011), the proposed recommender system integrates similar observed pairs $(u', i') \in \Omega$ for each (u, i) through a weight function, regardless of whether (u, i) is observed or not. This allows for nonlinear or nonparametric modeling of the relation between user-item preferences and latent factors, which is more flexible than the linear modeling in (2).

The proposed weight function is constructed based on the closeness between continuous covariates in addition to a user-item specific network. To precisely describe the network structure, we define an indicator $S^{ui}_{u'i'} = S^u_{u'} S^i_{i'} = 1$ if there exist edges connecting u and u' in a user-specific social network and i and i' in an item-specific network, and $S^{ui}_{u'i'} = 0$ otherwise. Moreover, we integrate the above user-item specific network with existing user social network, item network, as well as information from discrete covariates. For example,

in the *Last.fm* dataset, r_{ui} is the listening count of a user-artist pair (u, i), and $\boldsymbol{x}_{ui}$ is the pattern of listening counts for user u and artist i. The available network information is given as $S^{ui}_{u'i'} = S^u_{u'} S^i_{i'}$, where $S^u_{u'}$ represents a user's friendship network, and $S^i_{i'}$ is constructed from artists' tag information with $S^i_{i'} = 1$ indicating artists i and i' share the same tags, and $S^i_{i'} = 0$ otherwise.

Using local likelihood via smoothing weights (Tibshirani and Hastie, 1987; Fan and Gijbels, 1996), we propose the following cost function for a smooth neighborhood recommender system:

$$\mathcal{L}(\boldsymbol{P}, \boldsymbol{Q}) = \frac{1}{nm} \sum_{u=1}^{n} \sum_{i=1}^{m} \Big(\sum_{(u',i') \in \Omega} \omega_{ui,u'i'} (r_{u'i'} - \boldsymbol{p}_u^T \boldsymbol{q}_i)^2 \Big) + \lambda_1 \sum_{u=1}^{n} J(\boldsymbol{p}_u) + \lambda_2 \sum_{i=1}^{m} J(\boldsymbol{q}_i), \quad (3)$$

where $J(\cdot)$ is a general penalty, and λ_1 and λ_2 are two nonnegative tuning parameters. It is also assumed that $\sum_{(u',i') \in \Omega} \omega_{ui,u'i'} = 1$. Lemma 1 below gives an equivalent form of (3).

Lemma 1 *The cost function* $\mathcal{L}(\boldsymbol{P}, \boldsymbol{Q})$ *in* (3) *is equivalent to*

$$\frac{1}{nm} \sum_{u=1}^{n} \sum_{i=1}^{m} \Big(\sum_{(u',i') \in \Omega} \omega_{ui,u'i'} r_{u'i'} - \boldsymbol{p}_u^T \boldsymbol{q}_i \Big)^2 + \lambda_1 \sum_{u=1}^{n} J(\boldsymbol{p}_u) + \lambda_2 \sum_{i=1}^{m} J(\boldsymbol{q}_i). \quad (4)$$

The choice of $\omega_{ui,u'i'}$ is critical to properly measure the similarity between (u, i) and (u', i'). We introduce a weight function to define the smooth neighborhood of (u, i):

$$\omega_{ui,u'i'} = \frac{\mathcal{K}_h(\boldsymbol{x}_{ui}, \boldsymbol{x}_{u'i'}) S^{ui}_{u'i'}}{\sum_{(u',i') \in \Omega} \mathcal{K}_h(\boldsymbol{x}_{ui}, \boldsymbol{x}_{u'i'}) S^{ui}_{u'i'}}, \quad (5)$$

where $\omega_{ui,u'i'}$ involves only observed pairs (u', i')'s with $S^{ui}_{u'i'} = 1$. In (5), if $\boldsymbol{x}_{ui}$ or $S^{ui}_{u'i'}$ is absent, $\mathcal{K}_h(\boldsymbol{x}_{ui}, \boldsymbol{x}_{u'i'})$ or $S^{ui}_{u'i'}$ can be set as 1 correspondingly. The kernel function is set as $\mathcal{K}_h(\boldsymbol{x}_{ui}, \boldsymbol{x}_{u'i'}) = \mathcal{K}(h^{-1} \|\boldsymbol{x}_{ui} - \boldsymbol{x}_{u'i'}\|_2)$ measuring the closeness between $\boldsymbol{x}_{ui}$ and $\boldsymbol{x}_{u'i'}$, where the choice of the L_2-norm reduces the dimension of the covariate space and other choices of distance may be also considered. Here $h > 0$ is the window size and $\mathcal{K}(\cdot)$ is a kernel whose degree of smoothness reflects prior knowledge about how the true preference varies in terms of $\|\boldsymbol{x}_{ui} - \boldsymbol{x}_{u'i'}\|_2$. Note that this is different from standard kernel smoothing (Fan and Gijbels, 1996; Delaigle and Hall, 2010), in that the smooth neighborhood is constructed based on continuous and discrete covariates as well as user-item specific networks, whereas standard kernel smoothing focuses primarily on smoothing over continuous covariates.

The proposed framework has the following advantages. First, the user-item specific covariates and network structures are integrated in constructing the neighborhood for (u, i) pairs. Thus the effective sample size for (u, i) increases when pooling information from its neighborhood through $\sum_{(u',i') \in \Omega} \omega_{ui,u'i'} r_{u'i'}$ in (4). Second, it solves the "cold-start" problem and yields more accurate estimators of $\boldsymbol{p}_u$ and $\boldsymbol{q}_i$ for all u's and i's by leveraging dependencies among users and items, expressed in terms of user-specific social networks and items' tagging information. This is evident from (4), since even for an unobserved (u, i), $\sum_{(u',i') \in \Omega} \omega_{ui,u'i'} r_{u'i'}$ is a weighted average of preference scores over its neighborhood. On this ground, a recommendation can be made by estimating $\boldsymbol{p}_u$ and $\boldsymbol{q}_i$ for any new user-item

pair (u,i). Third, the non-ignorable missing can be addressed through a covariate-adjusted neighborhood associated with missingness and users' preferences. For instance, each user's and item's missing percentages and the percentiles of their observed ratings can be modeled nonparametrically as covariates in defining $\omega_{ui,u'i'}$.

3.2. Scalable computation

To solve large-scale optimization in (3), we employ a "divide-and-conquer" type of alternating least squares (ALS) algorithm, with a principle of solving many small penalized regression problems iteratively. This permits parallel and efficient computation. The ALS method has been extensively investigated in the literature (Carroll and Chang, 1970; Friedman and Stuetzle, 1981), and the divide-and-conquer strategy is also employed in (Zhu et al., 2016) for the parallelization of (2).

The computational strategy of ALS is to break large-scale optimization into multiple small subproblems by alternatively fixing either $\boldsymbol{p}_u$ or $\boldsymbol{q}_i$, where each subproblem is a simple penalized least squares regression and can be solved analytically with $J(\cdot) = \|\cdot\|_2^2$. Note that this strategy is applicable as long as $J(\cdot)$ is separable for $\boldsymbol{p}_u$ and $\boldsymbol{q}_i$.

For illustration, consider $J(\cdot) = \|\cdot\|_2^2$. At iteration k, $\widehat{\boldsymbol{Q}}^{(k)}$ is fixed and the latent factor $\boldsymbol{p}_u$ is updated as $\hat{\boldsymbol{p}}_u^{(k+1)} = \text{argmin}_{\boldsymbol{p}_u} \sum_i \Big(\sum_{(u',i')\in\Omega} \omega_{ui,u'i'} (r_{u'i'} - \boldsymbol{p}_u^T \hat{\boldsymbol{q}}_i^{(k)})^2 \Big) + \lambda_1 \|\boldsymbol{p}_u\|_2^2$. Similarly, with fixed $\widehat{\boldsymbol{P}}^{(k+1)}$, $\boldsymbol{q}_i$ is updated as $\hat{\boldsymbol{q}}_i^{(k+1)} = \text{argmin}_{\boldsymbol{q}_i} \sum_u \Big(\sum_{(u',i')\in\Omega} \omega_{ui,u'i'} (r_{u'i'} - (\hat{\boldsymbol{p}}_u^{(k+1)})^T \boldsymbol{q}_i)^2 \Big) + \lambda_2 \|\boldsymbol{q}_i\|_2^2$. Then each subproblem is solved analytically,

$$\hat{\boldsymbol{p}}_u^{(k+1)} = \Big(\sum_i \hat{\boldsymbol{q}}_i^{(k)} (\hat{\boldsymbol{q}}_i^{(k)})^T + \lambda_1 \boldsymbol{I}_K \Big)^{-1} \Big(\sum_i \bar{r}_{ui}^{\Omega} \hat{\boldsymbol{q}}_i^{(k)} \Big), \tag{6}$$

$$\hat{\boldsymbol{q}}_i^{(k+1)} = \Big(\sum_u \hat{\boldsymbol{p}}_u^{(k+1)} (\hat{\boldsymbol{p}}_u^{(k+1)})^T + \lambda_2 \boldsymbol{I}_K \Big)^{-1} \Big(\sum_u \bar{r}_{ui}^{\Omega} \hat{\boldsymbol{p}}_u^{(k+1)} \Big), \tag{7}$$

where $\bar{r}_{ui}^{\Omega} = \sum_{(u',i')\in\Omega} \omega_{ui,u'i'} r_{u'i'}$ is a weighted rating for (u,i) over the neighborhood, and $\boldsymbol{I}_K$ is a $K \times K$ identity matrix. The iterative updating is continued until a termination criterion is reached. Once the solution $\{\hat{\boldsymbol{p}}_u, \hat{\boldsymbol{q}}_i\}_{1\le u\le n; 1\le i\le m}$ is obtained, the final predicted preference is $\hat{r}_{ui} = \hat{\boldsymbol{p}}_u^T \hat{\boldsymbol{q}}_i$.

It follows from Chen et al. (2012) that the algorithm converges to a stationary point $(\bar{\boldsymbol{P}}, \bar{\boldsymbol{Q}})$ of $\mathcal{L}(\boldsymbol{P}, \boldsymbol{Q})$ in (3), where $\bar{\boldsymbol{P}} = \text{argmin}_{\boldsymbol{P}} \mathcal{L}(\boldsymbol{P}, \bar{\boldsymbol{Q}})$, and $\bar{\boldsymbol{Q}} = \text{argmin}_{\boldsymbol{Q}} \mathcal{L}(\bar{\boldsymbol{P}}, \boldsymbol{Q})$. This is due to the nonconvex minimization in addition to having many missing observations. Moreover, each update of $\boldsymbol{p}_u$ and $\boldsymbol{q}_i$ in (6) and (7) can be computed in a parallel fashion. This can substantially speed up the computation, particularly when K is small but m and n are large.

The overall computational complexity of the algorithm is no greater than $O\big((nmK^2 + (n+m)K^3) I_{ALS}\big)$, where I_{ALS} is the number of iterations in the ALS algorithm. In our implementation, the algorithm is coded through PyMP, which is a Python version of OpenMP in C, and can handle a dataset with a size up to the order of 10^8 on a quad-core computer with one 3.40GHz CPU and 8G memory.

4. Theory

This section presents theoretical properties to quantify the asymptotic behavior of the proposed recommender system. Particularly, we show the convergence rate in prediction error of the proposed system.

Let the true and estimated parameters be $\theta_{ui}^0 = \boldsymbol{p}_u^{0\,T} \boldsymbol{q}_i^0$ and $\hat{\theta}_{ui} = \hat{\boldsymbol{p}}_u^T \hat{\boldsymbol{q}}_i$, where $\hat{\boldsymbol{p}}_u$ and $\hat{\boldsymbol{q}}_i$ are estimated latent factors; $u = 1, \cdots, n$; $i = 1, \cdots, m$. Note that the representation is unique with respect to θ_{ui}, although the decomposition of $\boldsymbol{p}_u$ and $\boldsymbol{q}_i$ may not be unique. Let $\hat{\boldsymbol{\theta}} = (\hat{\theta}_{ui}) \in \mathbb{R}^{n\times m}$ and $\boldsymbol{\theta}^0 = (\theta_{ui}^0) \in \mathbb{R}^{n\times m}$, the prediction accuracy of $\hat{\boldsymbol{\theta}}$ is defined by the root mean square error:

$$\text{RMSE}(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) = \Big(\frac{1}{nm} \sum_{u=1}^{n} \sum_{i=1}^{m} \big(\hat{\theta}_{ui} - \theta_{ui}^0\big)^2 \Big)^{1/2}.$$

We require the following technical assumptions.

Assumption A. There exist constants $c_1 > 0$ and $\alpha > 0$ such that for any (u,i) and (u',i') , $\big|\theta_{ui}^0 - \theta_{u'i'}^0\big| \le c_1 \sqrt{K} \max\{\|\boldsymbol{x}_{ui} - \boldsymbol{x}_{u'i'}\|_2^{\alpha}, I(S_{u'i'}^{ui} = 0)\}$, where the corresponding expression in the maximum operator is set as 0 if $\boldsymbol{x}_{ui}$ or $S_{u'i'}^{ui}$ is absent.

Assumption A defines the smoothness of θ_{ui}^0 in terms of the continuous covariate $\boldsymbol{x}_{ui}$ in the presence of connected user-item pairs in the network. As a special case, if $\boldsymbol{x}_{ui}$ is absent, Assumption A degenerates to $\theta_{ui}^0 = \theta_{u'i'}^0$ for pairs with $S_{u'i'}^{ui} = 1$. This assumption is mild when all covariates are available, and is relatively more restrictive when $\boldsymbol{x}_{ui}$ is absent as it pushes the model to be a parametric one with only a finite number of unknown θ's. It is necessary to capture the smooth property of θ over the network structure, and similar assumptions are widely used in nonparametric regression (Vieu, 1991; Wassermann, 2006) and kernel density estimation (Stone, 1984; Marron and Padgett, 1987).

Assumption B. The continuous covariate $\boldsymbol{x}$ has a bounded support $\mathcal{X}$, and the error term ε_{ui} has a sub-Gaussian distribution with variance σ^2.

Assumption B is a regularity condition for the underlying probability distribution, and widely used in literature (Ma and Huang, 2017; Lin et al., 2017). Further, assume that $\{\boldsymbol{x}_{ui}, \Delta_{ui}\}_{1\le u\le n, 1\le i\le m}$ are independent and identically distributed, but the distribution of Δ_{ui} may depend on $\boldsymbol{x}_{ui}$. We denote the parameter space $\boldsymbol{\Gamma}(L)$ to be $\{\boldsymbol{\theta} : \|\boldsymbol{\theta}\|_\infty \le L\}$, where $\|\cdot\|_\infty$ is the uniform norm, and L is chosen so that $\boldsymbol{\theta}^0 \in \boldsymbol{\Gamma}(L)$. To accurately utilize the network information, we set $\omega_{ui,u'i'} = 0$ if $S_{u'i'}^{ui} = 0$. Theorem 1 establishes an upper bound for the estimation error of the proposed recommender system, where the convergence rate is determined by the size of the preference matrix nm, the number of parameters K, the size of the observed ratings $|\Omega|$, the tuning parameters λ_1 and λ_2, and the window size h.

Theorem 1 *Suppose that Assumptions A and B are satisfied. For some constant $c_2 > 0$, let $\kappa_1 = \max_{u,i} \sum_{(u',i')\in\Omega} \omega_{ui,u'i'} \|\boldsymbol{x}_{ui} - \boldsymbol{x}_{u'i'}\|_2^{\alpha}$, and $\kappa_2 = \max_{u,i} \sum_{(u',i')\in\Omega} \omega_{ui,u'i'}^2$, then*

$$P\big(RMSE(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) \ge \eta\big) \le \exp\big\{ -\frac{c_2 \eta^2}{\kappa_2} + \log(nm) \big\},$$

provided that $\eta \ge \max\big\{\sqrt{K}\kappa_1, \sqrt{\kappa_2}\big\} \log(nm)$ and $\lambda_1 \sum_{u=1}^n J(\boldsymbol{p}_u^0) + \lambda_2 \sum_{i=1}^m J(\boldsymbol{q}_i^0) \le \eta^2/4$. The convergence rate then becomes $RMSE(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) = O_p(\max\big\{\sqrt{K}\kappa_1, \kappa_2^{1/2}\big\} \log(nm))$, where κ_1 and κ_2 tend to zero and can be computed for some specific weights.

Theorem 1 provides a general upper bound of RMSE$(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0)$, which may vary by the choice of weights $\omega_{ui,u'i'}$ and the two quantities κ_1 and κ_2. In the following, an explicit convergence rate is given for $\omega_{ui,u'i'}$ defined in (5) under some additional assumptions.

Let $\Delta_{ui} \in \{0, 1\}$ be a binary variable, with $\Delta_{ui} = 1$ indicating that r_{ui} is observed and 0 otherwise. Assume that $\{\boldsymbol{x}_{ui}, \Delta_{ui}\}_{1\le u\le n, 1\le i\le m}$ are independent and identically distributed, but the distribution of Δ_{ui} may depend on $\boldsymbol{x}_{ui}$.

Assumption C. For any (u, i) and (u', i'), $P(S^{ui}_{u'i'} = 1|\Delta_{u'i'} = 1)$ is bounded away from zero, and the conditional density $f_{U^{ui}_{u'i'}|S^{ui}_{u'i'}=1,\Delta_{u'i'}=1}$ is continuous and bounded away from zero, where $U^{ui}_{u'i'} = \|\boldsymbol{x}_{ui} - \boldsymbol{x}_{u'i'}\|_2$.

Assumption C is necessary for tackling the "cold-start" problem, and similar assumptions are also widely used in the local smoothing technique (Chen et al., 2014; Scott, 2015). It ensures that for any pair (u, i), the probability of $\Delta_{ui} = 1$ may depend on covariates $\boldsymbol{x}_{ui}$ and $S^{ui}_{u'i'}$, and that the corresponding neighboring pairs are observed with positive probability. In fact, it suffices to assume that $P(S^{ui}_{u'i'} = 1|\Delta_{u'i'} = 1)$ is bounded away from zero with certain order, and similar results can be obtained with more involved derivation.

Assumption D. There exists a constant c_2 such that the nonnegative kernel $\mathcal{K}(\cdot)$ satisfies

$$\max\Big\{\int_0^\infty \mathcal{K}^2(u)du, \int_0^\infty \mathcal{K}(u)u^\alpha du\Big\} \le c_3.$$

Assumption D is a standard assumption for smoothing kernels. Notably, the choice of kernel should match up the smoothness at an order α of $\boldsymbol{\theta}^0$. Alternatively, to effectively employ the smoothing pattern of θ, the decay rate of the chosen kernel may be larger than α, to filter out more distant user-item pairs and preserve more reliable local neighborhood structure. For example, the Gaussian kernel has an exponential decay rate, and always satisfies the inequality conditions in Assumption D.

Corollary 1 *Suppose that Assumptions A-D are satisfied. For $\omega_{ui,u'i'}$ defined in* (5)*, then the convergence rate of RMSE$(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0)$ becomes RMSE$(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) = O_p\big(|\Omega|^{-\frac{\alpha}{2\alpha+1}} K^{\frac{1}{2(2\alpha+1)}} \log(nm)\big)$.*

Note that this convergence rate is intriguing compared with some existing results. Particularly, when $K = O(1)$, we have RMSE$(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) = O_P\big(|\Omega|^{-\frac{\alpha}{2\alpha+1}} \log(nm)\big)$. For $\alpha > 1/2$, since $|\Omega| \le nm < (n + m)^2$, it leads to a tighter bound than $O_P\Big(\big(\frac{n+m}{|\Omega|}\log(\frac{\sqrt{nm}}{|\Omega|})\big)^{\frac{1}{2}}\Big)$ and $O_P\Big(\big(\frac{n+m}{|\Omega|}\log(m)\log(\frac{|\Omega|}{n+m})\big)^{\frac{1}{2}}\Big)$ established in Bi et al. (2017) and Srebro et al. (2005), respectively. In addition, Theorem 1 still guarantees the convergence of RMSE$(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0)$, if K goes to infinity at a rate slower than $|\Omega|^{2\alpha}(\log(nm))^{-2(2\alpha+1)}$. In practice, the size of Ω is often much less than nm, and only proportional to $(n + m)K$. For example, in the MovieLens 1M dataset with $K = 10$, $nm = 0.2 \times 10^8, |\Omega| = 10^6$, and $(n + m)K = 10^6$; and in the *Last.fm* dataset, $nm = 0.3 \times 10^8, |\Omega| = 10^6$ and $(n + m)K = 0.2 \times 10^6$. In such cases with $K = O(1)$, the theoretical results in Bi et al. (2017) and Srebro et al. (2005) fail to give a reasonable convergence rate. However, Theorem 1 still yields that RMSE$(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) = O_P\big(|\Omega|^{-\frac{\alpha}{2\alpha+1}} \log(nm)\big)$. Interestingly, if the continuous covariates are absent, then Assumption A is satisfied with $\alpha = \infty$, and there is only a finite number of θ's to be estimated for different discrete covariates. In such cases, Theorem 1 implies that the recommender system can be estimated with a rate $\eta \sim O_P\big(|\Omega|^{-1/2} \log(nm)\big)$.

5. Numerical results

This section examines the performance of the proposed method, denoted as sSVD, in simulations and with a real *Last.fm* dataset. We compare sSVD to several strong competitors, including restricted Boltzmann machines (RBM; Salakhutdinov et al. 2007) or a continuous version of restricted Boltzmann machines (CRBM; Chen and Murray 2003); an iterative soft-threshold matrix completion method (SoftImpute; Hastie et al. 2015); the regularized SVD (rSVD; Paterek 2007); the self-recovered side regression (SSR; Zhao et al. (2016)) and a group-specific SVD approach (gSVD; Bi et al. 2017). Note that the Python codes for RBM and CRBM are publicly available (`https://github.com/yusugomori/DeepLearning/tree/master/python`), the code for SoftImpute is available in the Python package "fancyimpute", the Matlab code for SSR is provided by Zhao et al. (2016), and the R code for gSVD is provided by Bi et al. (2017). Note that RBM and CRBM are essentially the same but differ in implementation only for discrete and continuous responses. Although RBM, SoftImpute and rSVD are not designed to incorporate covariates, we include them in comparison to illustrate the importance of utilizing covariates for personalized prediction.

For tuning parameter selection, we set the learning rate, the momentum rate and the number of hidden units for RBM and CRBM as 0.005, 0.9, and 100, respectively. For rSVD, gSVD and sSVD, we set the tuning parameter K to be the true one, and the optimal λ is determined by a grid search over $\{10^{(\nu-31)/10}; \nu = 1, \cdots, 61\}$. For the proposed sSVD, a Gaussian kernel is used with the window size h being the median distance among all user-item pairs. The predictive performance of all methods is measured by the root mean squared error (RMSE).

5.1. Simulated examples

This subsection investigates the "cold-start" problem and the utility of a user-item specific network on prediction performance. We generate the simulation setting as follows. The dimensions of a rating matrix $\{r_{ui}\}_{1\le u\le n; 1\le i\le m}$ are $n = 501$ and $m = 201$. Let $\boldsymbol{p}_u = (1 + 0.002u)\mathbf{1}_K + N(\mathbf{0}_K, \xi\boldsymbol{I}_K)$ and $\boldsymbol{q}_i = (1 + 0.0075i)\mathbf{1}_K + N(\mathbf{0}_K, \xi\boldsymbol{I}_K)$ for $u = 1, \cdots, n$ and $i = 1, \cdots, m$, where $\mathbf{1}_K$ and $\mathbf{0}_K$ being K-dimensional vectors of ones and zeros, respectively. Here we sample observed ratings at random, where π is the missing rate, and the total number of observed ratings is $|\Omega| = (1 - \pi)nm$. For each user-item pair $(u, i) \in \Omega$, we let u and i be uniformly sampled from $1, \cdots, n$ and $1, \cdots, m$, respectively, and r_{ui} be generated from a truncated normal distribution on $[1, 5]$ with mean $\boldsymbol{p}_u^T\boldsymbol{q}_i$ and standard deviation 0.5. Further, r_{ui} is rounded to the closest integer in $\{1, \cdots, 5\}$ to mimic discrete ratings in practice.

To generate a similarity network for each user-item (u, i) pair, we connect (u, i) with its nearest first-order neighbor indices, say $u - 1$ and $u + 1$ for u and $i - 1$ and $i + 1$ for i. This mimics a user's friendship network. In addition, we introduce a "cold-start" rate ρ to examine the prediction accuracy of the proposed method on new users and items. Specifically, we randomly select ρ-proportion of users and items, and retain all of their corresponding ratings in a testing set to resemble the "cold-start" phenomenon. The remaining ratings are randomly split into training, tuning and testing sets with 60%, 15%, and 25% of the observations, respectively. In simulations, we choose $\xi = 0.1$, $K = 3$ or 6, the missing rate $\pi = .8, .9, .95$, and the "cold-start" rate $\rho = 0, 0.1, 0.2$. For the proposed sSVD, the

weight function is set as $\omega_{ui,u'i'} = S^{ui}_{u'i'}$, which is constructed based on the adjacency of each user-item pairs. For gSVD, we use the ranking percentages of each user and item as covariates according to Bi et al. (2017), but the user-item specific network information is not incorporated.

Table 1: *Averaged RMSEs of various methods and their estimated standard deviations in parentheses on the simulated examples over 50 simulations. Here RBM, SoftImput, rSVD, gSVD, sSVD denote: restricted Boltzmann machines (Salakhutdinov et al., 2007), SoftImput method (Hastie et al., 2015), regularized SVD method (Paterek, 2007), group-specific SVD method (Bi et al., 2017) and the proposed method, respectively. The best performer in each setting is bold-faced.*

Table 1 indicates that the proposed sSVD achieves the highest predictive accuracy compared against its competitors in 14 out of 18 different settings, whereas its accuracy is close to the best performer gSVD in the remaining four settings. Note that these four settings correspond to no "cold-start" user-item pairs in a linear situation. This simulation result is anticipated as only sSVD is capable of utilizing user-specific social networks. Interestingly, gSVD, without using the user-specific networks, performs well as it is able to capture user-user dependencies with respect to ranking due to strong dependency from the neighboring user-specific friendship networks. By comparison, SSR has a comparable performance as SoftImput, which is much worse than rSVD, gSVD, and sSVD, partly because it fails to account for non-ignorable missing.

Compared with the methods without using covariates such as rSVD and SoftImpute, sSVD yields superior performance in most scenarios, and the percentages of improvement can be as high as 83.1%. In contrast to RBM, SoftImpute and SSR, the percentages of improvement from the sSVD range from 51.8% to 83.2%. In addition, sSVD is robust

against high missing rates and high "cold-start" rates as measured by the missing rate π and the cold-start rate ρ. As π and ρ increase, the performance of sSVD is stable, whereas the performances of competitors deteriorate rapidly. In other words, the improvement of sSVD over its competitors is more significant when π and ρ are large. For example, the largest amount of improvement of sSVD over the second best performer gSVD is 46.9% when $K = 6$, $\pi = .95$, and $\rho = .2$.

Moreover, we examine the robust aspect of the proposed sSVD with respect to the degree of smoothness of ratings in a neighborhood and the degree of sparseness of a user-specific network. Specifically, given $K = 6$ and $\pi = 0.95$, we contaminate the neighborhood structure by increasing the noise level $\xi = 0.1, 0.2, 0.4, 0.6$, and allow the sparsity ratio $\pi_{network} = 0.0, 0.2, 0.5, 1.0$ for user-item specific networks, where the sparseness ratio is the probability that the edges connecting each pair of users or items are removed from the original network. Thus as $\pi_{network}$ increases, the resultant network becomes sparser, and the proposed sSVD degenerates to rSVD when $\pi_{network} = 1.0$. As suggested by Table 2, the performance of sSVD deteriorates as the contamination level $\pi_{network}$ escalates, yet still outperforming rSVD when $\xi = 0.1, 0.2$. On the other hand, rSVD outperforms the proposed sSVD when $\xi \geq 0.4$, which is anticipated because the proposed sSVD relies on the smoothness structure of the ratings. Moreover, it is evident that the proposed sSVD is less affected by the "cold-start" users and items when $\pi_{network}$ decreases.

Table 2: *Averaged RMSEs and estimated standard deviations over 50 simulations for the proposed method when the error standard deviation is 0.1, 0.2, 0.4, or 0.6, and the "cold-start" rate ρ is 0.0, 0.1, or 0.2, and the network structure missing rate $\pi_{network}$ is 0.0, 0.2, 0.5, or 1.0.*

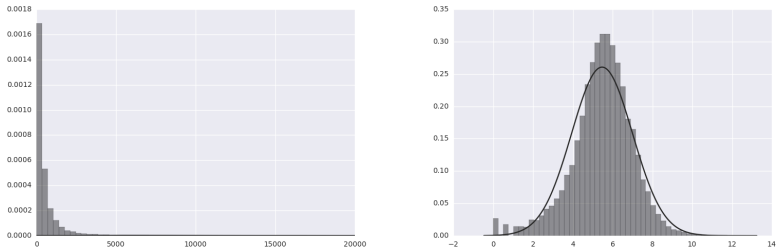
$\rho = 0.1$	0.660(0.004)	0.743(0.007)	1.092(0.008)	1.629(0.011)
$\rho = 0.2$	0.711(0.007)	0.796(0.006)	1.127(0.010)	1.670(0.012)
$\pi_{network} = 1.0$				
$\rho = 0.0$	0.713(0.003)	0.745(0.006)	0.952(0.009)	1.397(0.008)
$\rho = 0.1$	1.015(0.009)	1.046(0.011)	1.289(0.014)	1.686(0.015)
$\rho = 0.2$	1.154(0.006)	1.193(0.009)	1.415(0.013)	1.790(0.020)



In summary, the simulation studies illustrate that integration of user-item specific networks into latent factor modeling can enhance the accuracy of prediction and tackle the "cold-start" issue. In this regard, sSVD is a more effective recommender system than the existing methods in the literature.

5.2. Music data from *Last.fm*

In this section, we analyze a online music dataset from the *Last.fm* (`http://www.last.fm`), which was released in the second International Workshop HetRec 2011 (`http://ir.ii.uam.es/hetrec2011`). This dataset contains user-artist listening counts, social networks among 1,892 users, and tagging information for 17,632 artists. The user-artist listening counts contain 92,834 tuples defined by `[user, artist, listeningCount]`, where each user listens to an average of about 49 artists, and each artist has been listened to by about 5 users on average. Note that the observation rate in this dataset is below 0.28%, leading to a severe "cold-start" problem.

For this application, we focus on utilizing user-item specific covariates and networks to solve the "cold-start" issue. Specifically, in the *Last.fm* dataset, a user-specific social network is available based on 12,717 bi-directional user friendships with an average of about 13 friends per user. Moreover, there are 186,479 tags given by users to artists, with an average of about 99 tags per user, and about 15 tags per artist. A typical tag of an artist gives a short description of the artist, such as "rock", "electronic", "jazz" and "80s". The artist-specific tags are converted to a l-length 0/1 covariate vector to indicate whether music tags are assigned to an artist by users, where l is the total number of different tags.

Figure 2 illustrates the listening pattern, showing that a log-transformation of the listening counts appears to be normally distributed. In addition, Figure 3 indicates that only a small portion of artists are popular and frequently listened to by many users. However, the majority of the artists are categorized in more specialized genres, which make them less popular over all, but still having their own followers. This is illustrated by the horizontal and diagonal stripes in Figure 3 respectively.

(a) Original listening counts (b) log-transformed listening counts

Figure 2: The original and log-transformed listening counts in the *Last.fm* dataset.

Figure 4 shows that popular artists tend to be listened to more by each follower; that is, the number of users listening to each artist is positively related with its averaged listening counts, indicating that missing is non-ignorable and that the missing pattern shall be incorporated in the recommender system.

For comparison, we investigate the performance of five methods: CRBM, SoftImpute, SSR, rSVD, and gSVD, where the residuals of these methods are obtained after adjusting for

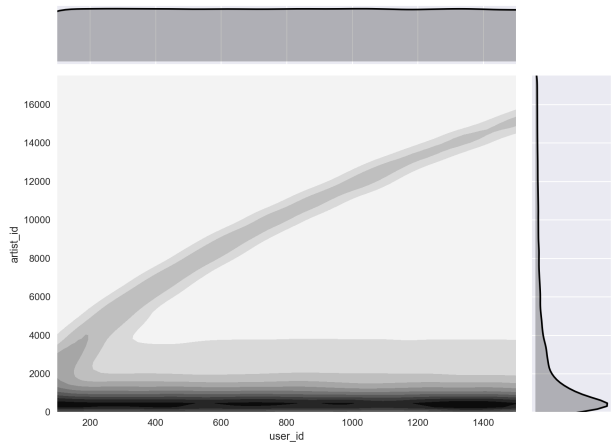


Figure 3: Two-dimensional histogram plot of the joint distribution of the observed user-artist pairs from the *Last.fm* dataset. The grey level represents the concentration, with darker color indicating more densely populated. Together with the joint distribution, the marginal distributions for user and artist are displayed along the horizontal and vertical axes.

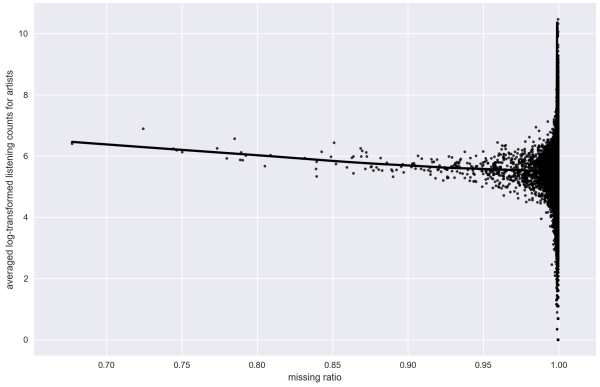

Figure 4: Missing pattern analysis for artists in the *Last.fm* dataset. It is clear that artists attracting fewer users tend to have smaller averaged listening counts.

covariate effects from user-specific social networks and artist-specific tags. Furthermore, to incorporate the non-ignorable missing pattern, the missing percentage is used to generate 12 homogeneous subgroups of users and 10 homogeneous subgroups of artists for gSVD, and covariates $(\boldsymbol{x}_u, \boldsymbol{x}_i)$ for sSVD are obtained from 5%, 25%, 50%, 75%, and 95% quantiles of the log observed listening counts in the training set for each user and artist. Also, we slightly modify the weight $\omega_{ui,u'i'}$ defined in (5) using thresholding. Specifically, $S^{ui}_{u'i'} = S^u_{u'} S^i_{i'}$, where $S^u_{u'} = 0.8$ if user u and u' are adjacent in the user social network, and $S^u_{u'} = 0.5$ otherwise; and $S^i_{i'}$ is computed based on the cosine similarity between the tag information of artists i and i'. For new users or artists, only user social network and artist tags information are available, therefore the weight function for covariate is automatically set as one. Furthermore, we apply a Gaussian kernel with window size h as the median distance among all user-artist pairs. For each user-artist pair (u, i), we compute the weights as in (5), and truncate them to keep only the five most similar user-artist pairs for each (u, i) to facilitate computation.

For evaluation, we apply 5-fold cross-validation over a random partition of the original dataset, and calculate the RMSE as in Koyejo and Ghosh (2011). For SVD-based methods, we set $K = 5$, and select the optimal λ from $\{1, \cdots, 25\}$ through the 5-fold cross-validation. For CRBM, the parameters are set as suggested in Nguyen and Lauw (2016); and for SSR, the parameters are determined through cross-validation as suggested in Zhao et al. (2016).

Table 3: *RMSEs of various methods and their estimated standard deviations in parentheses for observed, cold-start, and entire pairs on the Last.fm dataset. Here RBM, SoftImput, SSR, rSVD, gSVD, sSVD denote: restricted Boltzmann machines (Salakhutdinov et al., 2007), SoftImput method (Hastie et al., 2015), Self-recovered side regression (Zhao et al., 2016), regularized SVD method (Paterek, 2007), group-specific SVD method (Bi et al., 2017) and the proposed method, respectively. The second column indicates what type of covariates are used by each method, where N, T and M denote user-specific social networks, artist tags and non-ignorable missing pattern, respectively. The best performance in each setting is bold-faced.*

	Covariate	Observed pair	"Cold-start" pair	Entire pair
Regression	N, T	1.507(.005)	1.832(.023)	1.552(.005)
CRBM	N, T	1.507(.005)	1.834(.023)	1.552(.004)
SoftImpute	N, T	1.308(.005)	1.832(.023)	1.386(.004)
SSR	N, T	1.436(.006)	1.841(.035)	1.493(.009)
rSVD	N, T	1.124(.006)	1.832(.023)	1.237(.004)
gSVD	M, T	0.997(.013)	1.202(.012)	1.026(.011)
sSVD	N, M, T	**0.880(.004)**	**0.706(.003)**	**0.860(.003)**

Table 3 shows that sSVD significantly outperforms its competitors with a RMSE of 0.860 for the entire dataset, whereas gSVD is the second best performer with a RMSE of 1.020. As a reference, these two RMSEs are both smaller than 1.071 for the weighted interaction method under the same setting, which is reported as the best performer in analyzing the *Last.fm* dataset (Koyejo and Ghosh, 2011). The amounts of improvement of sSVD over gSVD, rSVD, SoftImput, SSR and CRBM are 15.6%, 24.6%, 38.0%, 42.4%, and 44.6%,

respectively. For the "cold-start" pairs, sSVD yields a more than 40% improvement over the second-best competitor gSVD. Note that SoftImput and rSVD do not perform well in handling the "cold-start" problem, as their penalization leads to the same performance as the regression approach.

6. Summary

This article proposes a smooth collaborative recommender system which integrates the network structure of user-item pairs to improve prediction accuracy. The proposed method provides a flexible framework to exploit the covariate information, such as user demographics, item contents, and social network information for users and/or items. The network structure allows us to increase the effective sample size for higher prediction accuracy, in addition to producing a more accurate recommender system for "cold-start" pairs. In addition, we implement a "divide-and-conquer" type of alternating least square algorithm. We also establish the asymptotic properties of the proposed method, which provide the theoretical foundation of its superior performance over other state-of-the-art methods. Although the proposed method is formulated based on the latent factor model, the framework can be extended to other models, such as Koren (2008) and Bi et al. (2017).

Appendix: technical proofs

Proof of Lemma 1. By the definition of $(\hat{\boldsymbol{P}}, \hat{\boldsymbol{Q}})$ as a minimizer of (3), we have

$$
\begin{aligned}
(\hat{\boldsymbol{P}}, \hat{\boldsymbol{Q}}) &= \underset{\boldsymbol{P},\boldsymbol{Q}}{\operatorname{argmin}} \ \frac{1}{nm}\sum_{u=1}^{n}\sum_{i=1}^{m}\Big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}(r_{u'i'}-\boldsymbol{p}_u^T\boldsymbol{q}_i)^2\Big)+\lambda_1\sum_{u=1}^{n}J(\boldsymbol{p}_u)+\lambda_2\sum_{i=1}^{m}J(\boldsymbol{q}_i)\\
&= \underset{\boldsymbol{P},\boldsymbol{Q}}{\operatorname{argmin}} \ \frac{1}{nm}\sum_{u=1}^{n}\sum_{i=1}^{m}\Big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}r_{u'i'}^2-\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}r_{u'i'}\boldsymbol{p}_u^T\boldsymbol{q}_i\\
&\qquad\qquad +\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}(\boldsymbol{p}_u^T\boldsymbol{q}_i)^2\Big)+\lambda_1\sum_{u=1}^{n}J(\boldsymbol{p}_u)+\lambda_2\sum_{i=1}^{m}J(\boldsymbol{q}_i)\\
&= \underset{\boldsymbol{P},\boldsymbol{Q}}{\operatorname{argmin}} \ \frac{1}{nm}\sum_{u=1}^{n}\sum_{i=1}^{m}\Big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}r_{u'i'}^2-\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}r_{u'i'}\boldsymbol{p}_u^T\boldsymbol{q}_i+(\boldsymbol{p}_u^T\boldsymbol{q}_i)^2\\
&\quad -\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}r_{u'i'}^2+\big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}r_{u'i'}\big)^2\Big)+\lambda_1\sum_{u=1}^{n}J(\boldsymbol{p}_u)+\lambda_2\sum_{i=1}^{m}J(\boldsymbol{q}_i)\\
&= \underset{\boldsymbol{P},\boldsymbol{Q}}{\operatorname{argmin}} \ \frac{1}{nm}\sum_{u=1}^{n}\sum_{i=1}^{m}\Big(\big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}r_{u'i'}\big)^2-\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}r_{u'i'}\boldsymbol{p}_u^T\boldsymbol{q}_i+(\boldsymbol{p}_u^T\boldsymbol{q}_i)^2\Big)\\
&\qquad\qquad +\lambda_1\sum_{u=1}^{n}J(\boldsymbol{p}_u)+\lambda_2\sum_{i=1}^{m}J(\boldsymbol{q}_i)\\
&= \underset{\boldsymbol{P},\boldsymbol{Q}}{\operatorname{argmin}} \ \frac{1}{nm}\sum_{u=1}^{n}\sum_{i=1}^{m}\Big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}r_{u'i'}-\boldsymbol{p}_u^T\boldsymbol{q}_i\Big)^2+\lambda_1\sum_{u=1}^{n}J(\boldsymbol{p}_u)+\lambda_2\sum_{i=1}^{m}J(\boldsymbol{q}_i),
\end{aligned}
$$

where the third equality follows that $\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}=1$ and the fact that adding constants to the cost function does not impact minimization. This completes the proof.

Proof of Theorem 1. Our treatment for bounding $P\big(\mathrm{RMSE}(\hat{\boldsymbol{\theta}},\boldsymbol{\theta})\geq\eta\big)$ is to bound empirical processes induced by $\mathrm{RMSE}(\cdot,\cdot)$ by a chaining argument as in (Wong and Shen, 1995; Shen et al., 2003; Liu and Shen, 2006).

Let $\boldsymbol{\Gamma}(L,\eta)=\{\boldsymbol{\theta}\in\boldsymbol{\Gamma}(L):\mathrm{RMSE}(\boldsymbol{\theta},\boldsymbol{\theta}^0)\geq\eta\}$ be a parameter subset of the parameter space $\boldsymbol{\Gamma}(L)$. Let $\lambda J(\boldsymbol{\theta})=\lambda_1\sum_{u=1}^{n}J(\boldsymbol{p}_u)+\lambda_2\sum_{i=1}^{m}J(\boldsymbol{q}_i)$ be the regularizer.

Note that $\hat{\boldsymbol{\theta}}$ is a minimizer of $\mathcal{L}(\boldsymbol{P},\boldsymbol{Q})$ in $\boldsymbol{\Gamma}(L)$, we have that $P\big(\mathrm{RMSE}(\hat{\boldsymbol{\theta}},\boldsymbol{\theta}^0))\geq\eta\big)\leq P^*\Big(\sup_{\boldsymbol{\theta}\in\boldsymbol{\Gamma}(L,\eta)}(\mathcal{L}(\boldsymbol{P}^0,\boldsymbol{Q}^0)-\mathcal{L}(\boldsymbol{P},\boldsymbol{Q}))\geq 0\Big)$, where P^* is the outer probability (Billingsley, 2013). Using the expression of $\mathcal{L}(\boldsymbol{P},\boldsymbol{Q})$, we obtain an upper bound of the latter as follows.

$$
\begin{aligned}
&P^*\Big(\sup_{\boldsymbol{\theta}\in\boldsymbol{\Gamma}(L,\eta)}(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)(2r_{u'i'}-\theta_{ui}^0-\theta_{ui})+\lambda J(\boldsymbol{\theta}^0)-\lambda J(\boldsymbol{\theta})\geq 0\Big)\\
&\leq P^*\Big(\sup_{\boldsymbol{\theta}\in\boldsymbol{\Gamma}(L,\eta)}(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)(2r_{u'i'}-\theta_{ui}^0-\theta_{ui})\geq-\lambda J(\boldsymbol{\theta}^0)\Big),
\end{aligned}
$$

where the fact that $\lambda J(\boldsymbol{\theta})\geq 0$ has been used. Now, let $A_j=\big\{\boldsymbol{\theta}\in\boldsymbol{\Gamma}(L):2^{j-1}\eta\leq\mathrm{RMSE}(\boldsymbol{\theta},\boldsymbol{\theta}^0)\leq 2^j\eta\big\}$; $j=1,\cdots,\infty$ be a partition in that $\boldsymbol{\Gamma}(L,\eta)=\bigcup_{j=1}^{\infty}A_j$. Combining

the above inequalities, we have that $P\big(\mathrm{RMSE}(\hat{\boldsymbol{\theta}},\boldsymbol{\theta}^0)\geq\eta\big)$ is bounded by

$$
\sum_{j=1}^{\infty}P^*\Big(\sup_{A_j}(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)(2r_{u'i'}-\theta_{ui}^0-\theta_{ui})\geq-\lambda J(\boldsymbol{\theta}^0)\Big)\equiv\sum_{j=1}^{\infty}I_j.
$$

Next, we bound each I_j separately. Since $\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}=1$,

$$
\begin{aligned}
&(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)(2r_{u'i'}-\theta_{ui}^0-\theta_{ui})\\
=\ &(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)(\theta_{u'i'}^0-\theta_{ui}^0)\\
&+(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)\epsilon_{u'i'}-(nm)^{-1}\sum_{u,i}(\theta_{ui}-\theta_{ui}^0)^2,
\end{aligned}
$$

which, by Assumption A and the fact that $\omega_{ui,u'i'}=0$ when $S_{u'i'}^{ui}=0$, is upper-bounded by

$$
\begin{aligned}
&c_1\sqrt{K}(nm)^{-1}\sum_{u,i}|\theta_{ui}-\theta_{ui}^0|\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}\|\boldsymbol{x}_{u'i'}-\boldsymbol{x}_{ui}\|_2^{\alpha}\\
&\qquad+(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)\epsilon_{u'i'}-(nm)^{-1}\sum_{u,i}(\theta_{ui}-\theta_{ui}^0)^2.
\end{aligned}
$$

Then for any $\boldsymbol{\theta}\in A_j$, $(2^j\eta)^2\geq(nm)^{-1}\sum_{u,i}(\theta_{ui}-\theta_{ui}^0)^2\geq(2^{j-1}\eta)^2$, by the Cauchy-Schwarz inequality,

$$
\begin{aligned}
&\sup_{A_j}c_1\sqrt{K}(nm)^{-1}\sum_{u,i}|\theta_{ui}-\theta_{ui}^0|\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}\|\boldsymbol{x}_{u'i'}-\boldsymbol{x}_{ui}\|_2^{\alpha}\\
&\leq\sup_{A_j}c_1\sqrt{K}\Big((nm)^{-1}\sum_{u,i}(\theta_{ui}-\theta_{ui}^0)^2\Big)^{1/2}\Big((nm)^{-1}\sum_{u,i}\big(\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}\|\boldsymbol{x}_{u'i'}-\boldsymbol{x}_{ui}\|_2^{\alpha}\big)^2\Big)^{1/2}\\
&\leq 2c_1\sqrt{K}\kappa_1 2^j\eta.
\end{aligned}
$$

Thus, $I_j\leq P^*\Big(\sup_{A_j}(nm)^{-1}\sum_{u,i}\sum_{(u',i')\in\Omega}2\omega_{ui,u'i'}(\theta_{ui}-\theta_{ui}^0)\epsilon_{u'i'}\geq(2^{j-1}\eta)^2-2c_1\sqrt{K}\kappa_1 2^j\eta-\lambda J(\boldsymbol{\theta}^0)\Big)$. Note that $\lambda J(\boldsymbol{\theta}^0)\leq\eta^2/4$ and $\mathrm{RMSE}(\boldsymbol{\theta},\boldsymbol{\theta}^0)=\Big(\sum_{u,i}(\theta_{ui}-\theta_{ui}^0)^2\Big)^{1/2}\geq 2^{j-1}\eta$ for

$\boldsymbol{\theta} \in A_j$. For any $\eta \geq 2^4 c_1\sqrt{K}\kappa_1$, $(2^{j-1}\eta)^2 - 2c_1\sqrt{K}\kappa_1 2^j\eta - \lambda J(\boldsymbol{\theta}^0) \geq 2^{2j-4}\eta^2$, implying that

$$
\begin{aligned}
I_j &\leq P^*\Big(\sup_{A_j}(nm)^{-1}\sum_{u,i}(\theta_{ui}-\theta^0_{ui})\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}\epsilon_{u'i'} \geq 2^{2j-4}\eta^2\Big)\\
&\leq P^*\Big(\sup_{A_j}(nm)^{-1}\Big(\sum_{u,i}(\theta_{ui}-\theta^0_{ui})^2\Big)^{1/2}\Big(\sum_{u,i}\big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}\epsilon_{u'i'}\big)^2\Big)^{1/2} \geq 2^{2j-4}\eta^2\Big)\\
&\leq P^*\Big(\Big((nm)^{-1}\sum_{u,i}\big(\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}\epsilon_{u'i'}\big)^2\Big)^{1/2} \geq 2^{j-4}\eta\Big)\\
&\leq P^*\Big(\max_{u,i}\big|\sum_{(u',i')\in\Omega}\omega_{ui,u'i'}\epsilon_{u'i'}\big| \geq 2^{j-4}\eta\Big)\\
&\leq \sum_{u,i} 2\exp\Big(-\frac{2^{(2j-8)}\eta^2}{2\sigma^2\sum_{(u',i')\in\Omega}\omega^2(\boldsymbol{x}_{ui},\boldsymbol{x}_{u'i'})}\Big) \leq 2nm\exp\Big(-\frac{2^{(2j-8)}\eta^2}{2\sigma^2\kappa_2}\Big),
\end{aligned}
$$

where the second to the last inequalities follow from the Chernoff inequality of a weighted sub-Gaussian distribution (Chung and Lu, 2006) and Assumption B. Hence, there exist some positive constants a_2 and a_3, for $\eta \geq 2^4 c_1\sqrt{K}\kappa_1$ such that

$$
\begin{aligned}
&P\big(\mathrm{RMSE}(\hat{\boldsymbol{\theta}},\boldsymbol{\theta}^0) \geq \eta\big) \leq 4nm\sum_{j=1}^{\infty}\exp\Big\{-\frac{2^{(2j-8)}\eta^2}{2\sigma^2\kappa_2}\Big\}\\
&\leq 4nm\exp\{-a_2\frac{\eta^2}{\sigma^2\kappa_2}\}/(1-\exp\{-a_2\frac{\eta^2}{\sigma^2\kappa_2}\}) \leq a_3\exp\big\{-a_2\frac{\eta^2}{\sigma^2\kappa_2}+\log(nm)\big\}.
\end{aligned}
$$

The desired result then follows immediately. □

Proof of Corollary 1. It suffices to compute κ_1 and κ_2. First, we will show that for any $\boldsymbol{x}_{ui} \in \mathcal{X}$, when $|\Omega|$ is sufficiently large, there exist positive constants a_4–a_7 such that

$$
\begin{aligned}
\sum_{(u',i')\in\Omega}\mathcal{K}_h(\|\boldsymbol{x}_{u'i'}-\boldsymbol{x}_{ui}\|_2)S^{ui}_{u'i'} &\geq \frac{|\Omega|}{2}E\big(\mathcal{K}_h(\|\boldsymbol{x}-\boldsymbol{x}_{ui}\|_2)S^{ui}\big|\Delta=1\big)\\
&= \frac{|\Omega|}{2}P(S^{ui}=1|\Delta=1)E\big(\mathcal{K}_h(\|\boldsymbol{x}-\boldsymbol{x}_{ui}\|_2)\big|S^{ui}=1,\Delta=1\big)\\
&\geq a_4|\Omega|E\big(\mathcal{K}_h(\|\boldsymbol{x}-\boldsymbol{x}_{ui}\|_2)\big|S^{ui}=1,\Delta=1\big)\\
&\geq a_5|\Omega|\int\mathcal{K}_h(u)f_{U^{ui}|S^{ui}=1,\Delta=1}(u)du \geq a_6|\Omega|h\int\mathcal{K}(u)du\\
&\geq a_7|\Omega|h,
\end{aligned}
$$

where the $f_{U^{ui}|S^{ui}=1,\Delta=1}$ is the conditional density for U^{ui}, the first inequality follows from the law of large numbers, and the third inequality and the third to the last inequalities follow from Assumption C. Similarly, for some positive constants a_8 and a_9,

$$
\begin{aligned}
\sum_{(u',i')\in\Omega}\mathcal{K}_h(\|\boldsymbol{x}_{ui}-\boldsymbol{x}_{u'i'}\|_2)\|\boldsymbol{x}_{ui}-\boldsymbol{x}_{u'i'}\|^\alpha S^{ui}_{u'i'} &\leq 2|\Omega|E\big(\mathcal{K}_h(U^{ui})(U^{ui})^\alpha|S^{ui}=1,\Delta=1\big)\\
&= 2|\Omega|\int\mathcal{K}_h(u)u^\alpha f_{U^{ui}|S^{ui}=1,\Delta=1}(u)du \leq a_8|\Omega|h^{\alpha+1},
\end{aligned}
$$

where the last inequality follows from Assumptions C and D, and

$$
\sum_{(u',i')\in\Omega}\mathcal{K}_h^2(\|\boldsymbol{x}_{ui}-\boldsymbol{x}_{u'i'}\|_2)S^{ui}_{u'i'} \leq 2|\Omega|E\big(\mathcal{K}_h^2(U^{ui})|S^{ui}=1,\Delta=1\big) \leq a_9|\Omega|h.
$$

Combing the above inequalities yields that

$$
\sum_{(u',i')\in\Omega}\omega(\boldsymbol{x}_0,\boldsymbol{x}_{u'i'})\|\boldsymbol{x}_0,\boldsymbol{x}_{u'i'}\|_2^\alpha = \frac{\sum_{(u',i')\in\Omega}\mathcal{K}_h(\|\boldsymbol{x}_0-\boldsymbol{x}_{u'i'}\|_2)\|\boldsymbol{x}_0-\boldsymbol{x}_{u'i'}\|_2^\alpha S^{ui}_{u'i'}}{\sum_{(u',i')\in\Omega}\mathcal{K}_h(\|\boldsymbol{x}-\boldsymbol{x}_{u'i'}\|_2)S^{ui}_{u'i'}} \leq a_8h^\alpha.
$$

Furthermore,

$$
\sum_{(u',i')\in\Omega}\omega^2(\boldsymbol{x}_0,\boldsymbol{x}_{u'i'}) \leq \frac{\sum_{(u',i')\in\Omega}\mathcal{K}_h^2(\|\boldsymbol{x}_0-\boldsymbol{x}_{u'i'}\|_2)S^{ui}_{u'i'}}{\big(\sum_{(u',i')\in\Omega}\mathcal{K}_h(\|\boldsymbol{x}-\boldsymbol{x}_{u'i'}\|_2)S^{ui}_{u'i'}\big)^2} \leq \frac{a_9}{a_7^2|\Omega|h}.
$$

Consequently, $\kappa_1 = h^\alpha$ and $\kappa_2 = (|\Omega|h)^{-1}$, then the desired result follows immediately. □

Editor: Network Analysis Special Issue

Abstract

We study networks of communicating learning agents that cooperate to solve a common nonstochastic bandit problem. Agents use an underlying communication network to get messages about actions selected by other agents, and drop messages that took more than d hops to arrive, where d is a delay parameter. We introduce Exp3-Coop, a cooperative version of the Exp3 algorithm and prove that with K actions and N agents the average per-agent regret after T rounds is at most of order $\sqrt{\left(d+1+\frac{K}{N}\alpha_{\leq d}\right)(T\ln K)}$, where $\alpha_{\leq d}$ is the independence number of the d-th power of the communication graph G. We then show that for any connected graph, for $d=\sqrt{K}$ the regret bound is $K^{1/4}\sqrt{T}$, strictly better than the minimax regret $\sqrt{KT}$ for noncooperating agents. More informed choices of d lead to bounds which are arbitrarily close to the full information minimax regret $\sqrt{T\ln K}$ when G is dense. When G has sparse components, we show that a variant of Exp3-Coop, allowing agents to choose their parameters according to their centrality in G, strictly improves the regret. Finally, as a by-product of our analysis, we provide the first characterization of the minimax regret for bandit learning with delay.

Keywords: Multi-armed bandits, distributed learning, cooperative multi-agent systems, regret minimization, LOCAL communication

1. Introduction

Delayed feedback naturally arises in many sequential decision problems. For instance, a recommender system typically learns the utility of a recommendation by detecting the occurrence of certain events (e.g., a user conversion), which may happen with a variable delay after the recommendation was issued. Other examples are the communication delays experienced by interacting learning agents. Concretely, consider a network of geographically distributed ad servers using real-time bidding to sell their inventory. Each server sequentially learns how to set the auction parameters (e.g., reserve price) in order to maximize the network's overall revenue, and shares feedback information with other servers in order to speed up learning. However, the rate at which information is exchanged through the communication network is slower than the typical rate at which ads are served. This causes each learner to acquire feedback information from other servers with a delay that depends on the network's structure.

Motivated by the ad network example, we consider networks of learning agents that cooperate to solve the same nonstochastic bandit problem, and study the impact of delay on the global performance of these agents. We introduce the Exp3-Coop algorithm, a distributed and cooperative version of the Exp3 algorithm of Auer et al. (2002b). Exp3-Coop works within a distributed and synced model where each agent runs an instance of the same bandit algorithm (Exp3). All bandit instances are initialized in the same way irrespective to the agent's location in the network (that is, agents have no preliminary knowledge of the network), and we assume the information about an agent's actions is propagated through the network with a unit delay for each crossed edge. In each round t, each agent selects an action and incurs the corresponding loss (which is the same for all agents that pick that action in round t). Besides observing the loss of the selected action, each agent obtains the information previously broadcast by other agents with a delay equal to the shortest-path distance between the agents. Namely, at time t an agent learns what the agents at shortest-path distance s did at time $t-s$ for each $s=1,\dots,d$, where d is a delay parameter. In this scenario, we aim at controlling the growth of the regret averaged over all agents (the so-called average welfare regret).

In the noncooperative case, when agents ignore the information received from other agents, the average welfare regret grows like $\sqrt{KT}$ (the minimax rate for standard bandit setting), where K is the number of actions and T is the time horizon. We show that, using cooperation, N agents with communication graph G can achieve an average welfare regret of order $\sqrt{\left(d+1+\frac{K}{N}\alpha_{\leq d}\right)(T\ln K)}$. Here $\alpha_{\leq d}$ denotes the independence number of the d-th power of G (i.e., the graph G augmented with all edges between any two pair of nodes at shortest-path distance less than or equal to d). When $d=\sqrt{K}$ this bound is at most $K^{1/4}\sqrt{T\ln K}+\sqrt{K}(\ln T)$ for any connected graph —see Remark 8 in Section 4.1— which is asymptotically better than $\sqrt{KT}$.

Networks of nonstochastic bandits were also investigated by Awerbuch and Kleinberg (2008) in a setting where the distribution over actions is shared among the agents without delay. Awerbuch and Kleinberg (2008) prove a bound on the average welfare regret of order $\sqrt{\left(1+\frac{K}{N}\right)T}$ ignoring polylog factors.[1] We recover the same bound as a special case of our bound when G is a clique and $d=1$. In the clique case our bound is also similar to the bound $\sqrt{\frac{K}{N}(T\ln K)}$ achieved by Seldin et al. (2014) in a single-agent bandit setting where, at each time step, the agent can choose a subset of $N\leq K$ actions and observe their loss. In the case when $N=1$ (single agent), our analysis can be applied to the nonstochastic bandit problem where the player observes the loss of each played action with a delay of d steps. In this case we improve on the previous result of $\sqrt{(d+1)KT}$ by Neu et al. (2010, 2014), and give the first characterization (up to logarithmic factors) of the minimax regret, which is of order $\sqrt{(d+K)\,T}$.

1. The rate proven in (Awerbuch and Kleinberg, 2008, Theorem 2.1) has a worse dependence on T, but we believe this is due to the fact that their setting allows for dishonest agents and agent-specific loss vectors.

In principle, the problem of delays in online learning could be tackled by simple reductions. Yet, these reductions give rise to suboptimal results. In the single agent setting, where the delay is constant and equal to d, one can use the technique of Weinberger and Ordentlich (2002) and run $d+1$ instances of an online algorithm for the nondelayed case, where each instance is used every $d+1$ steps. This delivers a suboptimal regret bound of $\sqrt{(d+1)KT}$. In the case of multiple delays, like in our multi-agent setting, one can repeat the same action for $d+1$ steps while accumulating information from the other agents, and then perform an update on scaled-up losses. The resulting (suboptimal) bound on the average welfare regret would be of the form $\sqrt{(d+1)\big(1+\frac{K}{N}\alpha_{\leq d}\big)(T\ln K)}$.

Rather than using reductions, the analysis of Exp3-Coop rests on quantifying the performance of suitable importance weighted estimates. In fact, in the single-agent setting with delay parameter d, using Exp3-Coop reduces to running the standard Exp3 algorithm performing an update as soon a new loss becomes available. This implies that at any round $t > d$, Exp3 selects an action without knowing the losses incurred during the last d rounds. The resulting regret is bounded by relating the standard analysis of Exp3 to a detailed quantification of the extent to which the distribution maintained by Exp3 can drift in d steps.

In the multi-agent case, the importance weighted estimate of Exp3-Coop is designed in such a way that at each time $t > d$ the instance of the algorithm run by an agent v updates all actions that were played at time $t-d$ by agent v or by other agents not further away than d from v. Compared to the single agent case, here each agent can exploit the information circulated by the other agents. However, in order to compute the importance weighted estimates used locally by each agent, the probabilities maintained by the agents must be propagated together with the observed losses. Here, further concerns may show up, like the amount of communication, and the location of each agent within the network. In particular, when G has sparse components, we show that a variant of Exp3-Coop, allowing agents to choose their parameters according to their centrality within G, strictly improves on the regret of Exp3-Coop.

Finally, we propose a second variant of Exp3-Coop where each agent is able to use loss information as soon as it becomes available. This implies that the updates performed at time t now involve losses with different delays. For this reason, the new variant of Exp3-Coop combines many loss estimators, each defined for a different level of delay, through a fixed distribution D. In the analysis we show how the introduction of combined loss estimators affects the average welfare regret.

A preliminary version of this work appeared as an extended abstract in (Cesa-Bianchi et al., 2016).

2. Additional Related Work

Many important ideas in delayed online learning, including the observation that the effect of delays can be limited by controlling the amount of change in the agent strategy, were introduced by Mesterharm (2005) —see also (Mesterharm, 2007, Chapter 8). A more recent investigation on delayed online learning is due to Neu et al. (2010, 2014), who analyzed exponential weights with delayed feedbacks. Furher progress is made by Joulani et al. (2013), who also study delays in the general partial monitoring setting. Additional works (Joulani

et al., 2016; Quanrud and Khashabi, 2015) prove regret bounds for the full-information case of the form $\sqrt{(D+T)\ln K}$, where D is the total delay experienced over the T rounds. In the stochastic case, bandit learning with delayed feedback was considered by Dudík et al. (2011); Joulani et al. (2013) and in a harder anonymized model by Pike-Burke et al. (2018).

To the best of our knowledge, the first paper about nonstochastic cooperative bandit networks is (Awerbuch and Kleinberg, 2008). More papers analyze the stochastic setting, and the closest one to our work is perhaps (Szorenyi et al., 2013). In that paper, delayed loss estimates in a network of cooperating stochastic bandits are analyzed using a dynamic P2P random networks as communication model. A more recent paper is (Landgren et al., 2015), where the communication network is a fixed graph and a cooperative version of the UCB algorithm is introduced which uses a distributed consensus algorithm to estimate the mean rewards of the arms. The main result is an individual (per-agent) regret bound that depends on the network structure without taking delays into account.

Another interesting paper about cooperating bandits in a stochastic setting is (Kar et al., 2011). Similar to our model, agents sit on the nodes of a communication network. However, only one designated agent observes the rewards of actions he selects, whereas the others remain in the dark. This designated agent broadcasts his sampled actions through the networks to the other agents, who must learn their policies relying only on this indirect feedback. The paper shows that in any connected network this information is sufficient to achieve asymptotically optimal regret. Cooperative bandits with asymmetric feedback are also studied by Barrett and Stone (2011). In their model, an agent must teach the reward distribution to another agent while keeping the discounted regret under control. Tekin and van der Schaar (2015) investigate a stochastic contextual bandit model where each agent can either privately select an action or have another agent select an action on his behalf. In a related paper, Tekin et al. (2014) look at a stochastic bandit model with combinatorial actions in a distributed recommender system setting, and study incentives among agents who can now recommend items taken from other agents' inventories. A more recent paper (Kolla et al., 2016) studies the performance of the UCB algorithm by Auer et al. (2002a) in a multi-agent setting, where at each time step each agent observes also the losses of actions chosen by any agent located in the same neighborhood of the communication network.

A further line of relevant work involves problems of decentralized bandit coordination. For example, Stranders et al. (2012) consider a bandit coordination problem where the reward function is global and can be represented as a factor graph in which each agent controls a subset of the variables.

A parallel thread of research concerns networks of bandits that compete for shared resources. A paradigmatic application domain is that of cognitive radio networks, in which a number of channels are shared among many users and any two or more users interfere whenever they simultaneously try to use the same channel. The resulting bandit problem is one of coordination in a competitive environment, because every time two or more agents select the same action at the same time step they both get a zero reward due to the interference —see (Rosenski et al., 2015) for recent work on stochastic competitive bandits and (Kleinberg et al., 2009) for a study of more general congestion games in a game-theoretic setting.

Finally, there exists an extensive literature on the adaptation of gradient descent and related algorithms to distributed computing settings, where asynchronous processors natu-

rally introduce delays —see, e.g., (Zinkevich et al., 2009; Agarwal and Duchi, 2011; Li et al., 2013; McMahan and Streeter, 2014; Quanrud and Khashabi, 2015; Liu et al., 2015; Duchi et al., 2015). However, none of these works considers bandit settings, which are an essential ingredient for our analysis.

3. Preliminaries

We now establish our notation, along with basic assumptions and preliminary facts related to our algorithms. Notation and setting here both refer to the single agent case. The cooperative setting with multiple agents (and notation thereof) will be introduced in Section 4.

Let $A = \{1, \dots, K\}$ be the action set. A learning agent runs an exponentially-weighted algorithm with weights $w_t(i)$, and learning rate $\eta > 0$. Initially, $w_1(i) = 1$ for all $i \in A$. At each time step $t = 1, 2, \dots$, the agent draws action I_t with probability $\mathbb{P}(I_t = i) = p_t(i) = w_t(i)/W_t$, where $W_t = \sum_{j \in A} w_t(j)$. After observing the loss $\ell_t(I_t) \in [0, 1]$ associated with the chosen action I_t, and possibly some additional information, the agent computes, for each $i \in A$, nonnegative loss estimates $\widehat{\ell}_t(i)$, and performs the exponential update

$$w_{t+1}(i) = p_t(i) \exp\bigl(-\eta\, \widehat{\ell}_t(i)\bigr) \tag{1}$$

to these weights. The following two lemmas are general results that control the evolution of the probability distributions in the exponentially-weighted algorithm. As we said in the introduction, bounding the extent to which the distribution used by our algorithms can drift in d steps is key to controlling regret in a delayed setting. The first result bounds the *additive* change in the probability of any action, and it holds no matter how $\widehat{\ell}_t(i)$ is defined.

Lemma 1 *Under the update rule (1), for all $t \geq 1$ and for all $i \in A$,*

$$-\eta\, p_t(i)\widehat{\ell}_t(i) \leq p_{t+1}(i) - p_t(i) \leq \eta\, p_{t+1}(i) \sum_{j \in A} p_t(j)\widehat{\ell}_t(j)$$

holds deterministically with respect to the agent's randomization.

Proof Directly from the definition of the update (1), $w_{t+1}(i) \leq p_t(i)$ for all $i \in A$, so that $W_{t+1} \leq 1$, which in turn implies $w_{t+1}(i) \leq w_{t+1}(i)/W_{t+1} = p_{t+1}(i)$. Therefore

$$p_{t+1}(i) - p_t(i) \geq w_{t+1}(i) - p_t(i) = p_t(i)\left(e^{-\eta\,\widehat{\ell}_t(i)} - 1\right) \geq -\eta\, p_t(i)\widehat{\ell}_t(i)\ ,$$

the last inequality using $1 - e^{-x} \leq x$, for $x \geq 0$. Similarly,

$$\begin{aligned}
p_{t+1}(i) - p_t(i) &\leq p_{t+1}(i) - w_{t+1}(i) \\
&= p_{t+1}(i) - p_{t+1}(i)W_{t+1} \\
&= p_{t+1}(i) \sum_{j \in A} \bigl(p_t(j) - w_{t+1}(j)\bigr) \\
&= p_{t+1}(i) \sum_{j \in A} p_t(j)\left(1 - e^{-\eta\,\widehat{\ell}_t(j)}\right) \\
&\leq \eta\, p_{t+1}(i) \sum_{j \in A} p_t(j)\widehat{\ell}_t(j)\ ,
\end{aligned}$$

hence concluding the proof. ∎

The second result delivers a *multiplicative* bound on the change in the probability of any action when the loss estimates $\widehat{\ell}_t(i)$ are of the following form:

$$\widehat{\ell}_t(i) = \begin{cases} \dfrac{\ell_{t-d}(i)}{q_{t-d}(i)}\, B_{t-d}(i) & \text{if } t > d, \\ 0 & \text{otherwise}\ , \end{cases} \tag{2}$$

where $d \geq 0$ is a delay parameter, $B_{t-d}(i) \in \{0, 1\}$, for $i \in A$, are indicator functions, and $q_{t-d}(i) \geq p_{t-d}(i)$ for all i and $t > d$. In all later sections, $B_{t-d}(i)$ will be instantiated to the indicator function of the event that action i has been played at time $t - d$ by some agent, and $q_{t-d}(i)$ will be the (conditional) probability of this event.

Lemma 2 *Let $\widehat{\ell}_t(i)$ be of the form (2) for each $t \geq 1$ and $i \in A$. If $\eta \leq \frac{1}{Ke(d+1)}$ in the update rule (1), then*

$$p_{t+1}(i) \leq \left(1 + \frac{1}{d}\right) p_t(i)$$

holds for all $t \geq 1$ and $i \in A$, deterministically with respect to the agent's randomization.

Proof We proceed by induction over t. For all $t \leq d$, $\widehat{\ell}_t(\cdot) = 0$. Hence $p_t(\cdot) = 1/K$, and the lemma trivially holds. For $t > d$ we can write

$$\begin{aligned}
\sum_{i \in A} p_t(i)\widehat{\ell}_t(i) &= \sum_{i \in A} p_t(i) \frac{\ell_{t-d}(i)}{q_{t-d}(i)} B_{t-d}(i) \\
&\leq \sum_{i \in A} \frac{p_t(i)}{q_{t-d}(i)} && \text{(because } B_{t-d}(i)\ell_{t-d}(i) \leq 1\text{)} \\
&\leq \sum_{i \in A} \left(1 + \frac{1}{d}\right)^d \frac{p_{t-d}(i)}{q_{t-d}(i)} && \text{(by the inductive hypothesis)} \\
&\leq \left(1 + \frac{1}{d}\right)^d K && \text{(because } q_{t-d}(i) \geq p_{t-d}(i)\text{)} \\
&\leq Ke\ .
\end{aligned}$$

Hence, using Lemma 1,

$$p_{t+1}(i)\bigl(1 - \eta Ke\bigr) \leq p_{t+1}(i)\left(1 - \eta \sum_{j \in A} p_t(j)\widehat{\ell}_t(j)\right) \leq p_t(i)$$

which implies $p_{t+1}(i) \leq \bigl(1 + \frac{1}{d}\bigr)\, p_t(i)$ whenever $\eta \leq \frac{1}{Ke(d+1)}$. ∎

As we said in Section 1, the idea of controlling the drift of the probabilities in order to bound the effects of delayed feedback is not new. In particular, variants of Lemma 1 were already derived in the work of Neu et al. (2010, 2014). However, Lemma 2 appears to be new, and this is the key result to achieving our improvements.

4. The Cooperative Setting on a Communication Network

In our multi-agent bandit setting, there are N agents sitting on the vertices of a connected and undirected communication graph $G = (V, E)$, with $V = \{1, \dots, N\}$. The agents cooperate to solve the same instance of a nonstochastic bandit problem while limiting the communication among them. Let $N_s(v)$ be the set of nodes $v' \in V$ whose shortest-path distance $\mathrm{dist}_G(v, v')$ from v in G is exactly s. At each time step $t = 1, 2, \dots$, each agent $v \in V$ draws an action $I_t(v)$ from the common action set A. Note that each action $i \in A$ delivers the same loss $\ell_t(i) \in [0, 1]$ to all agents v such that $I_t(v) = i$. At the end of round t, each agent v observes his own loss $\ell_t\big(I_t(v)\big)$, and sends to his neighbors in G the message

$$m_t(v) = \Big\langle t, v, I_t(v), \ell_t\big(I_t(v)\big), \boldsymbol{p}_t(v) \Big\rangle$$

where $\boldsymbol{p}_t(v) = \big(p_t(1, v), \dots, p_t(K, v)\big)$ is the distribution of $I_t(v)$. Moreover, v also receives from his neighbors a variable number of messages $m_{t-s}(v')$. Each message $m_{t-s}(v')$ that v receives from a neighbor is used to update $\boldsymbol{p}_t(v)$ and then forwarded to the other neighbors only if $s < d$, otherwise it is dropped.[2] Here d is the maximum delay, a parameter of the communication protocol. Therefore, at the end of round t, each agent v receives one message $m_{t-s}(v')$ from each agent v' such that $\mathrm{dist}_G(v, v') = s$, where $s \in \{1, \dots, d\}$. Graph G can thus be seen as a synchronous multi-hop communication network where messages are broadcast, each hop causing a delay of one time step. Our learning protocol is summarized in Figure 1, while Figure 2 contains a pictorial example.

Our model is similar to the LOCAL communication model in distributed computing (Linial, 1992; Suomela, 2013), where the output of a node depends only on the inputs of other nodes in a constant-size neighborhood of it, and the goal is to derive algorithms whose running time is independent of the network size. (The main difference is that the task here has no completion time, however, also in our model influence on a node is only through a constant-size neighborhood of it.)

One aspect deserving attention is that, apart from the common delay parameter d, the agents need not share further information. In particular, the agents need not know neither the topology of the graph G nor the total number of agents N. In Section 5, we show that our distributed algorithm can also be analyzed when each agent v uses a personalized delay $d(v)$, thus doing away with the need of a common delay parameter, and guaranteeing a generally better performance.

Further graph notation is needed at this point. Given G as above, let us denote by $G_{\le d}$ the graph $(V, E_{\le d})$ where $(u, v) \in E_{\le d}$ if and only if the shortest-path distance between agents u and v in G is *at most* d (hence $G_{\le 1} = G$). Graph $G_{\le d}$ is sometimes called the d-th power of G. We also use G_0 to denote the graph $(V, \emptyset)$. Recall that an independent set of G is any subset $T \subseteq V$ such that no two $i, j \in T$ are connected by an edge in E. The largest size of an independent set is the *independence number* of G, denoted by $\alpha(G)$. Let d_G be the *diameter* of G (maximal length over all possible shortest paths between all pairs of nodes); then $G_{\le d_G}$ is a clique, and one can easily see that $N = \alpha(G_0) > \alpha(G) \ge \alpha(G_{\le 2}) \ge \cdots \ge \alpha(G_{\le d_G}) = 1$. We show in Section 4.1 that the collective performance of our algorithms depends on $\alpha(G_{\le d})$. If the graph G under consideration is directed (see Section 5), then $\alpha(G)$ is the independence number of the undirected graph obtained from G by disregarding edge orientation.

2. Dropping messages older than d rounds is clearly immaterial with respect to proving bandit regret bounds. We added this feature just to prove a point about the message complexity of the protocol. See Remark 10 in Section 5 for further discussion.

The cooperative bandit protocol
Parameters: Undirected communication graph $G = (V, E)$, hidden loss vectors $\boldsymbol{\ell}_t = \big(\ell_t(1), \dots, \ell_t(K)\big) \in [0, 1]^K$ for $t \ge 1$, delay d.
For $t = 1, 2, \dots$

1. Each agent $v \in V$ plays action $I_t(v) \in A$ drawn according to distribution $\boldsymbol{p}_t(v)$;
2. Each agent $v \in V$ observes loss $\ell_t\big(I_t(v)\big)$, sends to his neighbors the message $m_t(v)$, and receives from his neighbors messages $m_{t-s}(v')$;
3. Each agent $v \in V$ drops any message $m_{t-s}(v')$ received from some neighbor such that $s \ge d$, and forwards to the other neighbors the remaining messages.

Figure 1: The cooperative bandit protocol where all agents share the same delay parameter d.

Figure 2: In this example, G is a line graph with $N = 6$ agents, and delay $d = 2$. At the end of time step t, Agent 4 sends to his neighbors 3 and 5 message $m_t(4)$, receives from Agent 3 messages $m_{t-1}(3)$ and $m_{t-2}(2)$, and from Agent 5 messages $m_{t-1}(5)$ and $m_{t-2}(6)$. Finally, Agent 4 forwards to Agent 5 message $m_{t-1}(3)$ and forwards to Agent 3 message $m_{t-1}(5)$. Any message older than $t - 1$ received by Agent 4 at the end of round t will not be forwarded to his neighbors.

The adversary generating losses is oblivious: loss vectors $\boldsymbol{\ell}_t = \big(\ell_t(1), \dots, \ell_t(K)\big) \in [0, 1]^K$ do not depend on the agents' internal randomization. The agents' goal is to control the *average welfare* regret R_T^{coop}, defined as

$$R_T^{\mathrm{coop}} = \left(\frac{1}{N} \sum_{v \in V} \mathbb{E}\left[\sum_{t=1}^{T} \ell_t\big(I_t(v)\big) \right] - \min_{i \in A} \sum_{t=1}^{T} \ell_t(i) \right) ,$$

the expectation being with respect to the internal randomization of each agent's algorithm. In the sequel, we write $\mathbb{E}_t[\cdot]$ to denote the expectation w.r.t. the product distribution $\prod_{v \in V} \boldsymbol{p}_t(v)$, conditioned on $I_1(v), \dots, I_{t-1}(v)$, $v \in V$.

4.1. The Exp3-Coop algorithm

Our first algorithm, called EXP3-COOP (Cooperative Exp3) is described in Figure 3. The algorithm works in the learning protocol of Figure 1. Each agent $v \in V$ runs the exponentially-weighted algorithm (1), combined with a "delayed" importance-weighted loss estimate

The Exp3-Coop Algorithm
Parameters: Undirected communication graph $G = (V, E)$; delay d; learning rate η.
Init: Each agent $v \in V$ sets weights $w_1(i, v) = 1$ for all $i \in A$.
For $t = 1, 2, \ldots$

1. Each agent $v \in V$ plays action $I_t(v) \in A$ drawn according to distribution $\boldsymbol{p}_t(v) = (p_t(1, v), \ldots, p_t(K, v))$, where
$$p_t(i, v) = \frac{w_t(i, v)}{W_t(v)},\ i = 1, \ldots, K, \qquad \text{and} \qquad W_t(v) = \sum_{j \in A} w_t(j, v)\ ;$$
2. Each agent $v \in V$ observes loss $\ell_t\big(I_t(v)\big)$ and exchanges messages with his neighbors (Steps 2 and 3 of the protocol in Figure 1);
3. Each agent $v \in V$ performs the update $w_{t+1}(i, v) = p_t(i, v)\, \exp\big(-\eta\, \widehat{\ell}_t(i, v)\big)$ for all $i \in A$, where
$$\widehat{\ell}_t(i, v) = \begin{cases} \dfrac{\ell_{t-d}(i)}{q_{d,t-d}(i, v)}\, B_{d,t-d}(i, v) & \text{if } t > d, \\ 0 & \text{otherwise,} \end{cases} \tag{3}$$
and $B_{d,t-d}(i, v) = \mathbb{I}\{\exists v' \in N_{\le d}(v) \,:\, I_{t-d}(v') = i\}$ with
$$q_{d,t-d}(i, v) = 1 - \prod_{v' \in N_{\le d}(v)} \big(1 - p_{t-d}(i, v')\big)\ .$$

Figure 3: The Exp3-Coop algorithm where all agents share the same delay parameter d.

$\widehat{\ell}_t(i, v)$ that incorporates the delayed information sent by the other agents. Specifically, denote by $N_{\le d}(v) = \bigcup_{s \le d} N_s(v)$ the set of nodes in G whose shortest-path distance from v is at most d, and note that, for all v, $\{v\} = N_{\le 0}(v) \subseteq N_{\le 1}(v) \subseteq N_{\le 2}(v) \subseteq \cdots$. If any of the agents in $N_{\le d}(v)$ has played at time $t - d$ action i (that is, $B_{d,t-d}(i, v) = 1$ in (3)), then the corresponding loss $\ell_{t-d}(i)$ is incorporated by v into $\widehat{\ell}_t(i, v)$. The denominator $q_{d,t-d}(i, v)$ is simply, conditioned on the history, the probability of $B_{d,t-d}(i, v) = 1$, i.e., $q_{d,t-d}(i, v) = \mathbb{E}_t[B_{d,t-d}(i, v)]$. Observe that $\{v\} \subseteq N_{\le d}(v)$ for all $d \ge 0$ implies $q_{d,t-d}(i, v) \ge p_{t-d}(i, v)$, as required by (2) so as to make Lemma 2 hold. It is also worth mentioning that, despite this is not strictly needed by our learning protocol, each agent v actually exploits the loss information gathered from playing action $I_t(v)$ only d time steps later. An extension of Exp3-Coop, where each loss is exploited as soon as it is made available to an agent, is analyzed in Section 6. Section 7, instead, studies an important special case of this setting where there is a single bandit agent receiving delayed feedback.

By their very definition, the loss estimates $\widehat{\ell}_t(\cdot, \cdot)$ at time t are determined by the realizations of $I_s(\cdot)$, for $s = 1, \ldots, t - d$. This implies that the numbers $p_t(\cdot, \cdot)$ defining $q_{d,t-d}(\cdot, \cdot)$, are determined by the realizations of $I_s(\cdot)$ for $s = 1, \ldots, t - d - 1$ (because the probabilities $\boldsymbol{p}_t(v)$ at time t are determined by the loss estimates up to time $t - 1$, see (1)). We have, for

all $t > d$, $i \in A$, and $v \in V$,
$$\mathbb{E}_{t-d}\Big[\widehat{\ell}_t(i, v)\Big] = \ell_{t-d}(i)\ . \tag{4}$$

Further, because of what we just said about $p_t(\cdot, \cdot)$ and $q_{d,t-d}(\cdot, \cdot)$ being determined by $I_1(\cdot), \ldots, I_{t-d-1}(\cdot)$, we also have
$$\mathbb{E}_{t-d}\Big[p_t(i, v)\widehat{\ell}_t(i, v)\Big] = p_t(i, v)\ell_{t-d}(i)\ , \quad \mathbb{E}_{t-d}\Big[p_t(i, v)\widehat{\ell}_t(i, v)^2\Big] = p_t(i, v)\frac{\ell_{t-d}(i)^2}{q_{d,t-d}(i, v)}\ . \tag{5}$$

The next lemma relates the variance of the estimates (3) to the structure of the communication graph G. The lemma is stated for a generic undirected communication graph G, but our application of it actually involves graph $G_{\le d}$.

Lemma 3 *Let $G = (V, E)$ be an undirected graph with independence number $\alpha(G)$. For each $v \in V$, let $N_{\le 1}(v)$ be the neighborhood of node v (including v itself), and $\boldsymbol{p}(v) = \big(p(1, v), \ldots, p(K, v)\big)$ be a probability distribution over $A = \{1, \ldots, K\}$. Then, for all $i \in A$,*
$$\sum_{v \in V} \frac{p(i, v)}{q(i, v)} \le \frac{1}{1 - e^{-1}} \left(\alpha(G) + \sum_{v \in V} p(i, v)\right) \quad \textit{where} \quad q(i, v) = 1 - \prod_{v' \in N_{\le 1}(v)} \big(1 - p(i, v')\big)\ .$$

Proof Fix $i \in A$ and set for brevity $P(i, v) = \sum_{v' \in N_{\le 1}(v)} p(i, v')$. We can write
$$\sum_{v \in V} \frac{p(i, v)}{q(i, v)} = \underbrace{\sum_{v \in V \,:\, P(i,v) \ge 1} \frac{p(i, v)}{q(i, v)}}_{\text{(I)}} + \underbrace{\sum_{v \in V \,:\, P(i,v) < 1} \frac{p(i, v)}{q(i, v)}}_{\text{(II)}}\ ,$$
and proceed by upper bounding the two terms (I) and (II) separately. Let $r(v)$ be the cardinality of $N_{\le 1}(v)$. We have, for any given $v \in V$,
$$\min\left\{q(i, v) \,:\, \sum_{v' \in N_{\le 1}(v)} p(i, v') \ge 1\right\} = 1 - \left(1 - \frac{1}{r(v)}\right)^{r(v)} \ge 1 - e^{-1}\ .$$
The equality is due to the fact that the minimum is achieved when $p(i, v') = \frac{1}{r(v)}$ for all $v' \in N_{\le 1}(v)$, and the inequality comes from $r(v) \ge 1$ (for, $v \in N_{\le 1}(v)$). Hence
$$\text{(I)} \le \sum_{v \in V \,:\, P(i,v) \ge 1} \frac{p(i, v)}{1 - e^{-1}} \le \sum_{v \in V} \frac{p(i, v)}{1 - e^{-1}}\ .$$
As for (II), using the inequality $1 - x \le e^{-x}, x \in [0, 1]$, with $x = p(i, v')$, we can write
$$q(i, v) \ge 1 - \exp\left(-\sum_{v' \in N_{\le 1}(v)} p(i, v')\right) = 1 - \exp\left(-P(i, v)\right)\ .$$

In turn, because $P(i,v) < 1$ in terms (II), we can use the inequality $1 - e^{-x} \geq (1 - e^{-1})\, x$, holding when $x \in [0,1]$, with $x = P(i,v)$, thereby concluding that $q(i,v) \geq (1-e^{-1})P(i,v)$. Thus

$$\text{(II)} \leq \sum_{v \in V\,:\, P(i,v)<1} \frac{p(i,v)}{(1-e^{-1})P(i,v)} \leq \frac{1}{1-e^{-1}} \sum_{v \in V} \frac{p(i,v)}{P(i,v)} \leq \frac{\alpha(G)}{1-e^{-1}}$$

where in the last step we used (Alon et al., 2017, Lemma 10). Note that despite the statement of this lemma refers to a directed graph and its maximum acyclic subgraph, in the special case of undirected graphs, the size of the maximum acyclic subgraph coincides with the independence number. Moreover, observe that $p(i,1), \ldots, p(i,N) \geq 0$ need not sum to one in order for this lemma to hold. ■

The following theorem quantifies the behavior of Exp3-Coop in terms of a free parameter γ in the learning rate, the tuning of which will be addressed in the subsequent Theorem 5.

Theorem 4 *The regret of* Exp3-Coop *run over a network $G = (V,E)$ of N agents, each using delay d and learning rate $\eta = \gamma/\big(Ke(d+1)\big)$, for $\gamma \in (0,1]$, satisfies*

$$R_T^{\text{coop}} \leq 2d + \frac{Ke(d+1)\ln K}{\gamma} + \gamma \left(\frac{\alpha(G_{\leq d})}{2(1-e^{-1})(d+1)N} + \frac{3}{Ke} \right) T \ .$$

Proof The standard analysis of the exponentially-weighted algorithm with importance-sampling estimates —see, e.g., the proof of (Alon et al., 2017, Lemma 1)— gives for each agent v and each action k the deterministic bound

$$\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) \leq \sum_{t=1}^{T} \widehat{\ell}_t(k,v) + \frac{\ln K}{\eta} + \frac{\eta}{2} \sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v)^2 \ . \tag{6}$$

We take expectations of the three (double) sums in (6) separately. As for the first sum, note that an iterative application of Lemma 1 gives, for $t > d$,

$$p_t(i,v) \geq p_{t-d}(i,v) - \eta \sum_{s=1}^{d} p_{t-s}(i,v) \widehat{\ell}_{t-s}(i,v) \ ,$$

so that, setting for brevity $A_t(i,v) = \sum_{s=1}^{d} p_{t-s}(i,v) \widehat{\ell}_{t-s}(i,v)$, we have

$$\begin{aligned} \sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) &\geq \sum_{t=2d+1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) \\ &\geq \sum_{t=2d+1}^{T} \sum_{i=1}^{K} p_{t-d}(i,v) \widehat{\ell}_t(i,v) - \eta \sum_{t=2d+1}^{T} \sum_{i=1}^{K} A_t(i,v)\, \widehat{\ell}_t(i,v) \ . \end{aligned}$$

Hence

$$\begin{aligned} &\mathbb{E}\left[\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) \right] \geq \mathbb{E}\left[\sum_{t=2d+1}^{T} \sum_{i=1}^{K} p_{t-d}(i,v) \widehat{\ell}_t(i,v) \right] - \eta\, \mathbb{E}\left[\sum_{t=2d+1}^{T} \sum_{i=1}^{K} A_t(i,v)\, \widehat{\ell}_t(i,v) \right] \\ &= \mathbb{E}\left[\sum_{t=2d+1}^{T} \sum_{i=1}^{K} p_{t-d}(i,v)\, \mathbb{E}_{t-d}\left[\widehat{\ell}_t(i,v) \right] \right] - \eta\, \mathbb{E}\left[\sum_{t=2d+1}^{T} \sum_{i=1}^{K} A_t(i,v)\, \mathbb{E}_{t-d}\left[\widehat{\ell}_t(i,v) \right] \right] \\ &\text{(since } p_t(i,v) \text{ is determined by } I_1(\cdot), \ldots, I_{t-d-1}(\cdot)\text{)} \\ &= \mathbb{E}\left[\sum_{t=2d+1}^{T} \sum_{i=1}^{K} p_{t-d}(i,v)\, \ell_{t-d}(i) \right] - \eta\, \mathbb{E}\left[\sum_{t=2d+1}^{T} \sum_{i=1}^{K} A_t(i,v)\, \ell_{t-d}(i) \right] \qquad \text{(using (4))} \\ &\geq \mathbb{E}\left[\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v)\, \ell_t(i) \right] - 2d - \eta\, T\, d \ . \end{aligned}$$

The last step uses

$$\begin{aligned} \mathbb{E}\left[\sum_{i=1}^{K} A_t(i,v)\, \ell_{t-d}(i) \right] &\leq \mathbb{E}\left[\sum_{i=1}^{K} A_t(i,v) \right] = \mathbb{E}\left[\sum_{i=1}^{K} \sum_{s=1}^{d} p_{t-s}(i,v) \widehat{\ell}_{t-s}(i,v) \right] \\ &= \mathbb{E}\left[\sum_{i=1}^{K} \sum_{s=1}^{d} p_{t-s}(i,v) \ell_{t-s-d}(i) \right] \leq \mathbb{E}\left[\sum_{i=1}^{K} \sum_{s=1}^{d} p_{t-s}(i,v) \right] = d \end{aligned}$$

holding for $t \geq 2d+1$. Similarly, for the second sum in (6), we have

$$\mathbb{E}\left[\sum_{t=1}^{T} \widehat{\ell}_t(k,v) \right] = \sum_{t=d+1}^{T} \ell_{t-d}(k) \leq \sum_{t=1}^{T} \ell_t(k) \ .$$

Finally, for the third sum in (6), an iterative application of Lemma 2 yields, for $t > d$,

$$p_t(i,v) \leq \left(1 + \frac{1}{d}\right)^d p_{t-d}(i,v) \leq e\, p_{t-d}(i,v) \ ,$$

so that we can write

$$\begin{aligned} \mathbb{E}\left[\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v)^2 \right] &= \mathbb{E}\left[\sum_{t=d+1}^{T} \sum_{i=1}^{K} \mathbb{E}_{t-d}\left[p_t(i,v) \widehat{\ell}_t(i,v)^2 \right] \right] \\ &\leq \mathbb{E}\left[\sum_{t=d+1}^{T} \sum_{i=1}^{K} \frac{p_t(i,v)}{q_{d,t-d}(i,v)} \right] \qquad \text{(using (5) and } \ell_t(\cdot) \leq 1\text{)} \\ &\leq e\, \mathbb{E}\left[\sum_{t=d+1}^{T} \sum_{i=1}^{K} \frac{p_{t-d}(i,v)}{q_{d,t-d}(i,v)} \right] \ . \end{aligned}$$

The last inequality comes from an iterative application of Lemma 2, and the observation that $\left(1 + \frac{1}{d}\right)^d \leq e$.

Hence, summing over all agents v, dividing by N, and using Lemma 3 on $G_{\leq d}$ gives

$$\begin{aligned}\frac{1}{N}\,\mathbb{E}\left[\sum_{t=1}^{T}\sum_{i=1}^{K}\sum_{v\in V} p_t(i,v)\widehat{\ell}_t(i,v)^2\right] &\leq \frac{e}{N}\,\mathbb{E}\left[\sum_{t=d+1}^{T}\sum_{i=1}^{K}\sum_{v\in V}\frac{p_{t-d}(i,v)}{q_{d,t-d}(i,v)}\right]\\ &\leq \frac{e}{(1-e^{-1})\,N}\,\mathbb{E}\left[\sum_{t=d+1}^{T}\sum_{i=1}^{K}\left(\alpha(G_{\leq d})+\sum_{v\in V} p_{t-d}(i,v)\right)\right]\\ &\leq \frac{e}{1-e^{-1}}\,T\left(\frac{K}{N}\,\alpha(G_{\leq d})+1\right)\ .\end{aligned}$$

Finally, putting together as in (6), setting $\eta=\gamma/\big(Ke(d+1)\big)$, and overapproximating, we obtain the desired bound. ■

We might be tempted to optimize the bound of Theorem 4 for γ. However, this is not a legal learning rate setting in a distributed scenario, for the optimized value of γ would depend on the global quantities N and $\alpha(G_{\leq d})$. Thus, instead of this global tuning, we let each agent set its own learning rate γ through a "doubling trick" played locally. The doubling trick[3] works as follows. For each $v\in V$, we let $\gamma_r(v)=Ke(d+1)\sqrt{(\ln K)/2^r}$ for each $r=r_0,r_0+1,\ldots$, where $r_0=\big\lceil \log_2\ln K+2\log_2(Ke(d+1))\big\rceil$ is chosen in such a way that $\gamma_r(v)\leq 1$ for all $r\geq r_0$. Let T_r be the random set of consecutive time steps where the same $\gamma_r(v)$ was used. Whenever the local algorithm at v is running with $\gamma_r(v)$ and detects $\sum_{s\in T_r} Q_s(v)>2^r$, where $Q_s(v)$ is the quantity defined in (9) —see the proof of Theorem 5 in the appendix— then we restart this algorithm with $\gamma(v)=\gamma_{r+1}(v)$.

We have the following result (proof in the appendix).

Theorem 5 *The regret of* Exp3-Coop *run over a network $G=(V,E)$ of N agents, each using delay d, and an individual learning rate $\eta(v)=\gamma(v)/\big(Ke(d+1)\big)$, where $\gamma(v)\in(0,1]$ is adaptively selected by each agent through the above doubling trick, satisfies, when T grows large,*[4]

$$R_T^{\mathrm{coop}}=\mathcal{O}\left(\sqrt{(\ln K)\left(d+1+\frac{K}{N}\,\alpha(G_{\leq d})\right)T}+d\,\log T\right)\ .$$

Remark 6 *Theorem 5 shows a natural trade-off between delay and information. To make it clear, suppose $N\approx K$. In this case, the regret bound becomes of order $\sqrt{\big(d+\alpha(G_{\leq d})\big)T\ln K}+d\ln T$. Now, if d is as big as the diameter d_G of G, then $\alpha(G_{\leq d})=1$. This means that at every time step all $N\approx K$ agents observe (with some delay) the losses of each other's actions. This is very much reminiscent of a full information scenario, and in fact our bound becomes of order $\sqrt{(d_G+1)T\ln K}+d_G\ln T$, which is close to the full information minimax rate $\sqrt{(d+1)T\ln K}$ when feedback has a constant delay d (Weinberger and Ordentlich, 2002). When G is sparse (i.e., d_G is likely to be large, say $d_G\approx N$), then agents have no advantage in taking $d=d_G$ since $d_G\approx N\approx K$. In this case, agents may even give up cooperation (choosing $d=0$ in Figure 3), and fall back on the standard bandit bound $\sqrt{TK\ln K}$, which corresponds to running* Exp3-Coop *on the edgeless graph G_0. (No doubling trick is needed in this case, hence no extra $\log T$ term appears.)*

Remark 7 *When $d=d_G$, each neighborhood $N_{\leq d}(v)$ used in the loss estimate (3) is equal to V, hence all agents receive the same feedback. Because they all start off from the same initial weights, the agents end up computing the same updates. This in turn implies that: (1) the individual regret incurred by each agent is the same as the average welfare regret R_T^{coop}; (2) the messages exchanged by the agents (see Figure 1) may be shortened by dropping the distribution part $\boldsymbol{p}_{t-s}(v')$.*

Remark 8 *An interesting question is whether the agents can come up with a reasonable choice for the value of d even when they lack any information whatsoever about the global structure of G. A partial answer to this question follows. It is easy to show that the choice $d=\sqrt{K}$ in Theorem 5 yields a bound on the average welfare regret of the form $K^{1/4}\sqrt{T\ln K}+\sqrt{K}(\ln T)$ for all G (and irrespective to the value of $N=|V|$), provided G is connected. This holds because, for any connected graph G, the independence number $\alpha(G_{\leq d})$ is always bounded by*[5] $\big\lceil 2N/(d+2)\big\rceil$. *To see why this latter statement is true, observe that the neighborhood $N_{\leq d/2}(v)$ of any node v in $G_{\leq d/2}$ contains at least $d/2+1$ nodes (including v), and any pair of nodes $v',v''\in N_{\leq d/2}(v)$ are adjacent in $G_{\leq d}$. Therefore, no independent set of $G_{\leq d}$ can have size bigger than $\big\lceil 2N/(d+2)\big\rceil$. A more detailed bound is contained, e.g., in (Firby and Haviland, 1997).*

Remark 9 *The choice of d minimizing the bound $d+\frac{K}{N}\,\alpha(G_{\leq d})$ requires prior knowledge of the independence numbers $\alpha(G_{\leq d})$ for different values of d. Computing these quantities is NP-hard in general, even when G is fully known.*

5. Extension I: Cooperation with Individual Parameters

In this section, we analyze a modification of Exp3-Coop that allows each agent v in the network to use a delay parameter $d(v)$ different from that of the other agents. We then show how such individual delays may improve the average welfare regret of the agents. In the previous setting, where all agents use the same delay parameter d, messages have an implicit time-to-live equal to d. In this setting, however, agents may not have a detailed knowledge of the delay parameters used by the other agents. For this reason we allow an agent v to generate messages with a time-to-live $ttl(v)$ possibly different from the delay parameter $d(v)$. Note that the role of the two parameters $d(v)$ and $ttl(v)$ is inherently different. Whereas $d(v)$ rules the extent to which v uses the messages received from the other agents, $ttl(v)$ limits the number of times a message from v is forwarded to the other agents, thereby limiting the message complexity of the algorithm. In order to accomodate this additional parameter, we are required to modify the cooperative bandit protocol of

3. There has been some recent work on adaptive learning rate tuning applied to nonstochastic bandit algorithms (Kocák et al., 2014; Neu, 2015). One might wonder whether the same techniques may apply here as well. Unfortunately, the specific form of our update (1) makes this adaptation nontrivial, and this is why we resorted to a more traditional "doubling trick".

4. The big-oh notation here hides additive terms that are independent of T and do depend polynomially on the other parameters.

5. Because it holds for a worst-case (connected) G, this upper bound on $\alpha(G_{\leq d})$ can be made tighter when specific graph topologies are considered.

Figure 1. As in Section 4, we have an undirected communication network $G = (V, E)$ over the agents. However, in this new protocol the message that at the end of round t each agent v sends to his neighbors in G has the format

$$m_t(v) = \Big\langle t, v, ttl(v), I_t(v), \ell_t\big(I_t(v)\big), \boldsymbol{p}_t(v) \Big\rangle$$

where $ttl(v)$ is the time-to-live parameter of agent v. Each message $m_{t-s}(v')$, which v receives from a neighbor, first has its time-to-leave decremented by one. If the resulting value is positive, the message is forwarded to the other neighbors, otherwise it is dropped. Moreover, v uses this message to update $\boldsymbol{p}_t(v)$ only if $s \le d(v)$. Hence, at time t an agent v uses the message sent at time $t - s$ by v' if and only if $\mathrm{dist}_G(v', v) = s$ with $s \le \min\{d(v), ttl(v')\}$, where $\mathrm{dist}_G(v, v')$ is the shortest-path distance from v' to v in G.

Based on the collection $\mathcal{P} = \{d(v), ttl(v)\}_{v \in V}$ of individual parameters, we define the *directed* graph $G_{\mathcal{P}} = (V, E_{\mathcal{P}})$ as follows: arc $(v', v) \in E_{\mathcal{P}}$ if and only if $\mathrm{dist}_G(v, v') \le \min\{d(v), ttl(v')\}$. The in-neighborhood $N^-_{\mathcal{P}}(v)$ of v thus contains the set of all $v' \in V$ whose distance from v is not larger than $\min\{d(v), ttl(v')\}$. Notice that, with this definition, $v \in N^-_{\mathcal{P}}(v)$, so that $(V, E_{\mathcal{P}})$ includes all self-loops (v, v). Figure 4(a) illustrates these concepts through a simple pictorial example.

Remark 10 *It is important to remark that the communication structure encoded by $\mathcal{P}$ is an exogenous parameter of the regret minimization problem, and so our algorithms cannot trade it off against regret. In addition to that, the parameterization $\mathcal{P} = \{d(v), ttl(v)\}_{v \in V}$ defines a simple and static communication graph which makes it relatively easy to express regret as a function of the amount of available communication. This would not be possible if we had each individual node v decide whether to forward a message based, say, on its own local delay parameter $d(v)$. To see why, consider the situation where nodes v and v' are along the route of a message that is reaching v before v'. The decision of v to drop the message may clash with the willingness of v' to receive it, and this may clearly happen when $d(v) < d(v')$. The structure of the communication graph resulting from this individual behavior of the nodes would be rather complicated. On the contrary, the time-to-live-based parametrization, which is commonly used in communication networks to control communication complexity, does not have this issue.*

Figure 5 contains our algorithm (called Exp3-Coop2) for this setting. Exp3-Coop2 is a strict generalization of Exp3-Coop, and so is its analysis. The main difference between the two algorithms is that Exp3-Coop2 deals with directed graphs. This fact prevents us from using the same techniques of Section 4.1 in order to control the regret. Intuitively, adding orientations to the edges reduces the information available to the agents and thus increases the variance of their loss estimates. Thus, in order to control this variance, we need a lower bound[6] on the probabilities $p_t(i, v)$. From Figure 5, one can easily see that

$$1 = \sum_{i \in A} \frac{w_t(i,v)}{W_t(v)} \le \widetilde{P}_t(v) \le \sum_{i \in A} \left(\frac{w_t(i,v)}{W_t(v)} + \frac{\delta}{K} \right) = 1 + \delta \tag{7}$$

6. We find it convenient to derive this lower bound without mixing with the uniform distribution over A —see, e.g., (Auer et al., 2002b)— but in a slightly different manner. This facilitates our delayed feedback analysis.

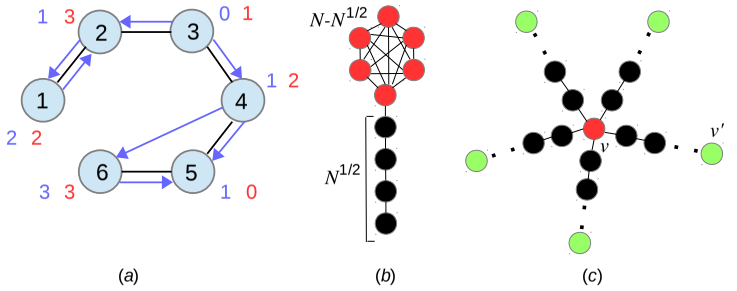

Figure 4: **(a)** In this example, the communication network G is an undirected line graph with $N = 6$ agents, whose edges are depicted in black. Close to each node $v = 1, \ldots, 6$ is the individual delay $d(v)$ (in blue), and the individual time-to-leave $ttl(v)$ (in red). The arcs (a.k.a., directed edges) of the induced directed graph $G_{\mathcal{P}}$ are also depicted in blue. Self-loops are not depicted. For instance, we have $N^-_{\mathcal{P}}(5) = \{4, 5, 6\}$ and $N^-_{\mathcal{P}}(3) = \{3\}$. **(b)** A communication network having a dense (red nodes) and a sparse (black nodes) region. The black region has $N^{1/2}$ agents, the red one has $N - N^{1/2}$ agents. **(c)** A star graph with long rays. The center v (in red) sets a small $d(v)$ and a large $ttl(v)$. The peripheral nodes v' (in green) set a large $d(v')$ and a small $ttl(v')$.

implying the lower bound $p_t(i, v) \ge \frac{\delta}{K(1+\delta)}$, holding for all i, t, and v.

The following theorem (proof in the appendix) is the main result of this section.

Theorem 11 *The regret of* Exp3-Coop2 *run over a network $G = (V, E)$ of N agents, each agent v using individual delay $d(v)$, individual time-to-leave $ttl(v)$, exploration parameter $\delta = 1/T$, and learning rate η such that $\eta \to 0$ as $T \to \infty$ satisfies, when T grows large,*

$$R_T^{\mathrm{coop}} = \mathcal{O}\left(\frac{\ln K}{\eta} + \eta\Big(\bar{d}_V + \frac{K}{N}\, \alpha\left(G_{\mathcal{P}}\right) \ln(TNK) \Big) T \right) \quad , \quad \text{where} \quad \bar{d}_V = \frac{1}{N} \sum_{v \in V} d(v) \ .$$

Using a doubling trick in much the same way we used it to prove Theorem 5, we can state the following result (proof in the appendix).

Corollary 12 *The regret of* Exp3-Coop2 *run over a network $G = (V, E)$ of N agents, each agent v using individual delay $d(v)$, individual time-to-leave $ttl(v)$, exploration parameter $\delta = 1/T$, and individual learning rate $\eta(v)$ adaptively selected by each agent through a doubling trick, satisfies, when T grows large*

$$R_T^{\mathrm{coop}} = \mathcal{O}\left(\sqrt{(\ln K)\left(\bar{d}_V + 1 + \frac{K}{N}\, \alpha(G_{\mathcal{P}}) \ln(TNK) \right) T} + \bar{d}_V \left(\ln T + \ln\ln(TNK) \right) \right) \ .$$

To illustrate the advantage of having individual delays as opposed to sharing the same delay value, it suffices to consider a communication network including regions of different density.

The Exp3-Coop2 Algorithm
Parameters: Undirected graph $G = (V, E)$; learning rate η; exploration parameter $\delta > 0$.
Init: Each $v \in V$ sets weights $w_1(i, v) = 1$, for all $i \in A$, delay $d(v)$, and time-to-live $ttl(v)$.
For $t = 1, 2, \ldots$

1. Each agent $v \in V$ plays action $I_t(v) \in A$ drawn according to distribution $\boldsymbol{p}_t(v) = (p_t(1, v), \ldots, p_t(K, v))$, where

$$p_t(i, v) = \frac{\widetilde{p}_t(i, v)}{\widetilde{P}_t(v)}, \qquad \widetilde{P}_t(v) = \sum_{j \in A} \widetilde{p}_t(j, v),$$

and

$$\widetilde{p}_t(i, v) = \max\left\{ \frac{w_t(i, v)}{W_t(v)}, \frac{\delta}{K} \right\}, \qquad W_t(v) = \sum_{j \in A} w_t(j, v)\,;$$

2. Each agent $v \in V$ observes loss $\ell_t\big(I_t(v)\big)$ and exchanges messages with his neighbors (see main text for an explanation);
3. Each agent $v \in V$ performs the update $w_{t+1}(i, v) = p_t(i, v)\, \exp\big(-\eta\, \widehat{\ell}_t(i, v)\big)$ for all $i \in A$, where

$$\widehat{\ell}_t(i, v) = \begin{cases} \dfrac{\ell_{t-d(v)}(i)}{q_{\mathcal{P}, t-d(v)}(i, v)}\, B_{\mathcal{P}, t-d(v)}(i, v) & \text{if } t > d(v), \\ 0 & \text{otherwise,} \end{cases}$$

and $B_{\mathcal{P}, t-d(v)}(i, v) = \mathbb{I}\{\exists v' \in N^-_{\mathcal{P}}(v) \,:\, I_{t-d(v)}(v') = i\}$, with

$$q_{\mathcal{P}, t-d(v)}(i, v) = 1 - \prod_{v' \in N^-_{\mathcal{P}}(v)} \big(1 - p_{t-d(v)}(i, v')\big)\,.$$

Figure 5: The Exp3-Coop2 algorithm with individual delay and time-to-live parameters.

Concretely, consider the graph in Figure 4(b) with a large densely connected region (red agents) and a small sparsely connected region black agents). In this example, the black agents prefer a large value of their individual delay so as to receive more information from nearby agents, but this comes at the price of a larger bias for their estimators $\widehat{\ell}_t(i, v)$. On the contrary, information from nearby agents is readily available to the red agents, so that they do not gain any regret improvement from a large delay parameter. A similar argument applies here to the individual time-to-live values: red agents v will set a small $ttl(v)$ to reduce communication. Black agents v' may decide to set $ttl(v')$ depending on their intention to reach the red nodes. But because the red agents have set a small $d(v)$, any effort made by v' trying to reach them would be a communication waste. Hence, it is reasonable for a black

agent v' to set a moderately large value for $ttl(v')$, but perhaps not so large as to reach the red agents. One can read this off the bounds in both Theorem 11 and Corollary 12, as explained next. Suppose for simplicity that $K \approx N$ so that, disregarding log factors, these bounds depend on parameters $\mathcal{P}$ only through the quantity $H = \bar{d}_V + \alpha\,(G_{\mathcal{P}})$. Now, in the case of a common delay parameter d (Section 4.1), it is not hard to see that the best setting for d in order to minimize H is of the form $d = N^{1/4}$, resulting in $H = \Theta(N^{1/4})$. On the other hand, the best setting for the individual delays is $d(v) = 1$ when v is red, and $d(v) = \sqrt{N}$ when v is black, resulting in $H = \Theta(1)$.

The time-to-live parameters $ttl(v)$ affect the regret bound only through $\alpha\,(G_{\mathcal{P}})$, but they clearly play the additional role of bounding the message complexity of the algorithm. In our example of Figure 4(b), we essentially have $d(v) \approx ttl(v)$ for all v. A typical scenario where agents may have $d(v) \neq ttl(v)$ is illustrated in Figure 4(c). In this case, we have star-like graph where a central agent is connected through long rays to all others agents. The center v prefers to set a small $d(v)$, since it has a large degree, but also a large $ttl(v)$ in order to reach the green peripheral nodes. The green nodes v' are reasonably doing the opposite: a large $d(v')$ in order to gather information from other nodes, but also a smaller time-to-live than the center, for the information transmitted by v' is comparatively less valuable to the whole network than the one transmitted by the center.

Agents can set their individual parameters in a topology-dependent manner using any algorithm for assessing the centrality of nodes in a distributed fashion —e.g., (Wehmuth and Ziviani, 2013), and references therein. This can be done at the beginning in a number of rounds which only depends on the network topology (but not on T). Hence, this initial phase would affect the regret bound only by an additive constant.

6. Extension II: Cooperation with Mixed Delays

The two algorithms we designed so far do not use the loss information in the most effective way, as they both postpone the update step by d (Figure 3) or $d(v)$ (Figure 5) time steps. The advantage of postponing updates is that loss estimates are simple to design, because the updates at time t all involve losses generated at the same time $t - d$ or $t - d(v)$. In this section, instead, we study generalized versions of Exp3-coop and Exp3-coop2 where all losses $\ell_{t-s}(i)$ sent from agents at distance s to any given agent v are used by v at time t; that is, they are used as soon as they become available to v. Unlike before, the updates performed at time t now involve losses with different delays, and for this reason these generalized algorithms combine many loss estimators, each defined for a different level of delay, through a fixed distribution D (e.g., a distribution emphasizing recent losses). As we show, in the resulting regret bounds both delays and independence numbers end up correspondingly mixed according to the distribution D. In the rest of this section, we present Exp3-Coop-Mix, which generalizes Exp3-Coop to mixed delayed estimators. The learning protocol remains the same (Figure 1). A similar extension exists for Exp3-Coop2, where instead of having individual delays $d(v)$, we have individual distributions over delay values. We decided to omit this further extension from the paper because it does not add any extra value to the overall discussion.

Exp3-Coop-Mix is described in Figure 6, where we simply replaced estimator (3) by its mixed version (8). The next theorem (whose proof is in the appendix) and the subsequent

The Exp3-Coop-Mix Algorithm
Parameters: Undirected communication graph $G = (V, E)$; maximal delay d; delay distribution D over $\{0, 1, \ldots, d-1\}$; learning rate $\eta > 0$.
Init: Each agent $v \in V$ sets weights $w_1(i, v) = 1$ for all $i \in A$.
For $t = 1, 2, \ldots$

1. Each agent $v \in V$ plays action $I_t(v) \in A$ drawn according to distribution $\boldsymbol{p}_t(v) = (p_t(1, v), \ldots, p_t(K, v))$, where

$$p_t(i, v) = \frac{w_t(i, v)}{W_t(v)},\ i = 1, \ldots, K \qquad \text{and} \qquad W_t(v) = \sum_{j \in A} w_t(j, v)\ ;$$

2. Each agent $v \in V$ observes loss $\ell_t\big(I_t(v)\big)$ and exchanges messages with his neighbors (Steps 2 and 3 of the protocol in Figure 1);
3. Each agent $v \in V$ performs the update $w_{t+1}(i, v) = p_t(i, v)\, \exp\big(-\eta\, \widehat{\ell}_t(i, v)\big)$ for all $i \in A$, where

$$\widehat{\ell}_t(i, v) = \begin{cases} \displaystyle\sum_{s=0}^{d-1} D(s)\, \frac{\ell_{t-s}(i)}{q_{s,t-s}(i, v)}\, B_{s,t-s}(i, v) & \text{if } t > d, \\ 0 & \text{otherwise,} \end{cases} \tag{8}$$

and $B_{s,t-s}(i, v) = \mathbb{I}\{\exists v' \in N_{\le s}(v) \,:\, I_{t-s}(v') = i\}$ with

$$q_{s,t-s}(i, v) = 1 - \prod_{v' \in N_{\le s}(v)} \big(1 - p_{t-s}(i, v')\big)\ .$$

Figure 6: The Exp3-Coop-Mix algorithm where all agents share the same delay distribution D.

discussion investigate the impact of using a distribution over delay levels on the average welfare regret bound.

Theorem 13 *The regret of* Exp3-Coop-Mix *run over a network $G = (V, E)$ of N agents, each using the same delay distribution D, and learning rate $\eta \le 1/(Ke(d+1))$, satisfies*

$$R_T^{\text{coop}} \le 3d + \frac{\ln K}{\eta} + \frac{e^2 \eta\, T}{1 - e^{-1}} \left(1 + \mu_D + \frac{2K}{N}\, \bar{\alpha}_D\right)\ ,$$

where $\bar{\alpha}_D = \sum_{s=0}^{d-1} D(s) \alpha(G_{\le s})$ is the expected independence number of G's power as determined by mixture D, and μ_D is the expectation of distribution D.

Through a doubling trick played locally by each agent, which is utterly similar to the one described before the statement of Theorem 5, we can state (proof in the appendix) the following corollary.

Corollary 14 *The regret of* Exp3-Coop-Mix *run over a network $G = (V, E)$ of N agents, each using the same delay distribution D, and individual learning rate $\eta(v)$ adaptively selected by each agent through a doubling trick, satisfies, when T grows large*

$$R_T^{\text{coop}} = \mathcal{O}\left(\sqrt{(\ln K)\left(\mu_D + 1 + \frac{K}{N}\, \bar{\alpha}_D)\right) T} + \mu_D \log T\right)\ .$$

7. Delayed Losses (for a Single Agent)

Exp3-Coop can be specialized to the setting where a single agent is facing a bandit problem in which the loss of the chosen action is observed with a fixed delay d. In this setting, at the end of each round t the agent incurs loss $\ell_t(I_t)$ and observes $\ell_{t-d}(I_{t-d})$, if $t > d$, and nothing otherwise. The regret is defined in the usual way,

$$R_T = \mathbb{E}\left[\sum_{t=1}^{T} \ell_t(I_t)\right] - \min_{i=1,\ldots,K} \sum_{t=1}^{T} \ell_t(i)\ .$$

This problem was studied by Weinberger and Ordentlich (2002) in the full information case, for which they proved that $\sqrt{(d+1)T \ln K}$ is the optimal order for the minimax regret. The result was extended to the bandit case by Neu et al. (2010, 2014) —see also Joulani et al. (2013)— whose techniques can be used to obtain a regret bound of order $\sqrt{(d+1)KT}$. Yet, no matching lower bound was available for the bandit case.

As a matter of fact, the upper bound $\sqrt{(d+1)KT}$ for the bandit case is easily obtained: just run in parallel $d+1$ instances of the minimax optimal bandit algorithm for the standard (no delay) setting, achieving $R_T \le \sqrt{KT}$ (ignoring constant factors). At each time step $t = (d+1)r + s$ (for $r = 0, 1, \ldots$ and $s = 0, \ldots, d$), use instance $s+1$ for the current play. Hence, the no-delay bound applies to every instance and, assuming $d+1$ divides T, we immediately obtain $R_T \le \sum_{s=1}^{d+1} \sqrt{K \frac{T}{d+1}} \le \sqrt{(d+1)KT}$, again, ignoring constant factors.

Next, we show that the machinery we developed in Section 4.1 delivers an improved upper bound on the regret for the bandit problem with delayed losses, and then we complement this result by providing a lower bound matching the upper bound up to log factors, thereby characterizing (up to log factors) the minimax regret for this problem.

Corollary 15 *In the nonstochastic bandit setting with $K \ge 2$ actions and delay $d \ge 0$, where at the end of each round t the predictor has access to the losses $\ell_1(I_1), \ldots, \ell_s(I_s) \in [0, 1]^K$ for $s = \max\{1, t-d\}$, the minimax regret is of order $\sqrt{(K+d)T}$, ignoring logarithmic factors.*

Proof In order to prove the upper bound, we use the exponentially-weighted algorithm with estimate (3) specialized to the case of one agent only, namely $B_{t-d}(i) = \mathbb{I}\{I_{t-d} = i\}$ and $q_{d,t-d}(i) = p_{t-d}(i)$. Notice that this amounts to running the standard Exp3 algorithm performing an update as soon a new loss becomes available. In this case, because $N = \alpha(G_{\le d}) = 1$, the bound of Theorem 4, with a suitable choice of γ (which depends on T, K, and d) reduces to

$$R_T = \mathcal{O}\left(d + \sqrt{(K+d)\, T \ln K}\right)\ .$$

We now prove a lower bound matching our upper bound up to logarithmic factors. The proof hinges on combining the known lower bound $\Omega\big(\sqrt{KT}\big)$ for bandits without delay of Auer et al. (2002b) with the following argument by Weinberger and Ordentlich (2002) that provides a lower bound for the full information case with delay. The proof of the latter bound is by contradiction: we show that a low-regret full information algorithm for delay $d > 0$ can be used to design a low-regret full information algorithm for the $d = 0$ (no delay) setting. We then apply the known lower bound for the minimax regret in the no-delay setting to derive a lower bound for the setting with delay.

Fix $d > 0$ and let $\mathcal{A}$ be a predictor for the full-information online prediction problem with delay d. Let $\boldsymbol{p}_t$ be the probability distribution used by $\mathcal{A}$ at time t. We now apply algorithm $\mathcal{A}$ to design a new algorithm $\mathcal{A}'$ for a full information online prediction problem with arbitrary loss vectors $\boldsymbol{\ell}'_1, \dots, \boldsymbol{\ell}'_B \in [0,1]^K$ and no delay. More specifically, we create a sequence $\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_T \in [0,1]^K$ of loss vectors such that $T = (d+1)B$ and $\boldsymbol{\ell}_t = \boldsymbol{\ell}'_b$ where $b = \big\lceil t/(d+1) \big\rceil$. At each time $b = 1, \dots, B$ algorithm $\mathcal{A}'$ uses the distribution

$$\boldsymbol{p}'_b = \frac{1}{d+1} \sum_{s=1}^{d+1} \boldsymbol{p}_{(d+1)(b-1)+s}$$

where $\boldsymbol{p}_t = \big(\frac{1}{K}, \dots, \frac{1}{K}\big)$ for all $t \le 1$. Note that $\boldsymbol{p}'_b$ is defined using $\boldsymbol{p}_{(d+1)(b-1)+1}, \dots, \boldsymbol{p}_{(d+1)b}$. These are in turn defined using the same loss vectors $\boldsymbol{\ell}'_1, \dots, \boldsymbol{\ell}'_{b-1}$ since, by definition, each $\boldsymbol{p}_{t+1}$ uses $\boldsymbol{\ell}_1, \dots, \boldsymbol{\ell}_{t-d}$, and $\big\lceil (t-d)/(d+1) \big\rceil = b-1$ for all $t = (d+1)(b-1), \dots, (d+1)b-1$. So $\mathcal{A}'$ is a legitimate full-information online algorithm for the problem $\boldsymbol{\ell}'_1, \dots, \boldsymbol{\ell}'_B$ with no delay. As a consequence,

$$\begin{aligned}
\sum_{t=1}^{T} \sum_{i=1}^{K} \ell_t(i) p_t(i) &= \sum_{b=1}^{B} \sum_{s=1}^{d+1} \sum_{i=1}^{K} \ell'_b(i) p_{(d+1)(b-1)+s}(i) \\
&= (d+1) \sum_{b=1}^{B} \sum_{i=1}^{K} \frac{1}{d+1} \sum_{s=1}^{d+1} \ell'_b(i) p_{(d+1)(b-1)+s}(i) \\
&= (d+1) \sum_{b=1}^{B} \sum_{i=1}^{K} \ell'_b(i) p'_b(i) \ .
\end{aligned}$$

Moreover,

$$\min_{k \in A} \sum_{t=1}^{T} \ell_t(k) = (d+1) \min_{k \in A} \sum_{b=1}^{B} \ell'_b(k) \ .$$

Since we know that for any predictor $\mathcal{A}'$ there exists a loss sequence $\boldsymbol{\ell}'_1, \boldsymbol{\ell}'_2, \dots$ such that the regret of $\mathcal{A}'$ is at least $\big(1 - o(1)\big)\sqrt{(T/2)\ln K}$, where $o(1) \to 0$ for $K, B \to \infty$, we have that the regret of $\mathcal{A}$ is at least

$$(d+1) R_{T/(d+1)}(\mathcal{A}') = \big(1 - o(1)\big)(d+1)\sqrt{\frac{T}{2(d+1)} \ln K} = \big(1 - o(1)\big)\sqrt{(d+1)\frac{T}{2} \ln K} \ ,$$

where $R_{T/(d+1)}(\mathcal{A}')$ is the regret of $\mathcal{A}'$ over $T/(d+1)$ time steps. The proof is completed by observing that that the regret of any predictor in the bandit setting with delay d cannot be

smaller than the regret of the predictor in the bandit setting with no delay or smaller than the regret of the predictor in the full information setting with delay d. Hence, the minimax regret in the bandit setting with delay d must be at least of order

$$\max\Big\{\sqrt{KT}, \sqrt{(d+1)T \ln K}\Big\} = \Omega\left(\sqrt{(K+d)\,T}\right) \ ,$$

ignoring log factors. This concludes the proof. ■

Recent results by Joulani et al. (2016)— see also (Quanrud and Khashabi, 2015)— consider a full information setting with variable delays $d_t > 0$. At the end of each round t, the agent simultaneously observes all loss vectors $\boldsymbol{\ell}_s$ such that $s + d_s = t$. For this setting, they prove a regret bound of order $\sqrt{(D+T)\ln K}$, where D is the sum of the delays d_t. The proof is based on a generic algorithm (SOLID) which simply feeds the loss vectors, as soon as they become available, to any deterministic predictor BASE designed to operate in a setting without delays. At the beginning of each round t, SOLID predicts using the current distribution $\boldsymbol{p}_t$ of BASE. A general argument shows that the regret of SOLID is equal to the regret of BASE on the sequence of loss vectors permuted according to the delays, plus a term that accounts for the drift of the distributions $\boldsymbol{p}_t$. For the bandit setting, we conjecture an upper bound on the regret of order $\sqrt{(D+KT)\ln K}$. However, we have not been able to prove this result via a direct application of our techniques.

8. Conclusions and Open Questions

We have investigated a cooperative and nonstochastic bandit scenario where cooperation comes at the price of delayed information. We have proven average welfare regret bounds that exhibit a natural tradeoff between amount cooperation and delay, the tradeoff being ruled by the underlying communication network topology. As a by-product of our analysis, we have also provided the first characterization to date of the regret of learning with (constant) delayed feedback in an adversarial bandit setting. There are a number of possible extensions of this work:

1. Our analysis only delivers average welfare regret bounds. It would be interesting to show simultaneous regret bounds that hold for each agent individually. We conjecture that the individual regret bound of an agent v is of the form

$$\sqrt{(\ln K)\left(d + \frac{K}{|N_{\le d}(v)|}\right) T}$$

   where $|N_{\le d}(v)|$ is the degree of v in $G_{\le d}$ (plus one). Such bound would in fact imply, e.g., the one in Theorem 5. A possible line of attack to solve this problem could be the use of graph sparsity along the lines of (Pan et al., 2015; Duchi et al., 2013; Mania et al., 2015; McMahan and Streeter, 2014).

2. It would be nice to characherize the average welfare regret by complementing our upper bounds with suitable *lower* bounds. For example, is the upper bound of Theorem 5 optimal in the communication model considered here?

3. It is natural to think of ways to adaptively tune our algorithms so as to automatically determine the best local parameters, e.g., the delay parameter d. For instance, disregarding message complexity, is there a way for each agent to adaptively tune d locally so to minimize the bound in Theorem 5?

4. Our messages $m_t(v)$ contain both action/loss information and distribution information. Is it possible to drop the distribution information and still achieve average welfare regret bounds similar to those in Theorems 4, 11, and 13?

5. Besides settling the conjecture advanced at the end of Section 7, we generally think that the study of learning on a communication network with time-varying delays, and its impact on the regret rates, is a topic worth of attention.

Proofs from Section 4.1

Proof of Theorem 5. We start off from first part of the proof of Theorem 4 which, after rearranging terms, gives the following bound for each agent v:

$$\begin{aligned}
&\mathbb{E}\left[\sum_{t=1}^{T}\sum_{i=1}^{K} p_t(i,v)\ell_t(i)\right] - \sum_{t=1}^{T}\ell_t(k) \\
&\le 2d + \mathbb{E}\left[\frac{\ln K}{\eta(v)} + \eta(v)\,d^2 + \eta(v)\sum_{t=d+1}^{T}\left(d + \frac{e}{2}\sum_{i=1}^{K}\frac{p_{t-d}(i,v)}{q_{d,t-d}(i,v)}\right)\right] \\
&\le 3d + \mathbb{E}\left[\frac{Ke(d+1)\ln K}{\gamma(v)} + \frac{\gamma(v)}{Ke(d+1)}\sum_{t=1}^{T}\underbrace{\left(\mathbb{I}\{t>d\}\,d + \frac{e}{2}\left(\sum_{i=1}^{K}\frac{p_{t-d}(i,v)}{q_{d,t-d}(i,v)}\right)\mathbb{I}\{t>d\}\right)}_{Q_t(v)}\right] .
\end{aligned} \tag{9}$$

Note that the optimal tuning of $\gamma(v)$ depends on the random quantity

$$\overline{Q}_T(v) = \sum_{t=1}^{T} Q_t(v) \ .$$

We now apply the doubling trick to each instance of Exp3-Coop. Recall that, for each $v \in V$, we let $\gamma_r(v) = Ke(d+1)\sqrt{(\ln K)/2^r}$ for each $r = r_0, r_0+1, \ldots$, where $r_0 = \left\lceil \log_2 \ln K + 2\log_2(Ke(d+1))\right\rceil$ is chosen in a way that $\gamma_r(v) \le 1$ for all $r \ge r_0$. Let T_r be the random set of consecutive time steps where the same $\gamma_r(v)$ was used. Whenever the algorithm is running with $\gamma_r(v)$ and detects $\sum_{s\in T_r} Q_s(v) > 2^r$, then we restart the algorithm with $\gamma(v) = \gamma_{r+1}(v)$. The largest $r = r(v)$ we need is $\left\lceil \log_2 \overline{Q}_T(v)\right\rceil$ and

$$\sum_{r=r_0}^{\left\lceil \log_2 \overline{Q}_T(v)\right\rceil} 2^{r/2} < 5\sqrt{\overline{Q}_T(v)} \ .$$

Because of (9), the regret agent v suffers when using $\gamma_r(v)$ within T_r is at most $3d + 2\sqrt{(\ln K)2^r}$. Now, since we pay at most regret d at each restart, we have

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=1}^{T}\sum_{i} p_t(i,v)\ell_t(i)\right] - \sum_{t=1}^{T}\ell_t(k) &\le 3d + 4Ke(d+1)\ln K \\
&\quad + \mathbb{E}\left[10\sqrt{(\ln K)\overline{Q}_T(v)} + 3d\left\lceil \log_2 \overline{Q}_T(v)\right\rceil\right] .
\end{aligned}$$

The term $3d + 4Ke(d+1)\ln K$ bounds the regret when the algorithm is never restarted implying that only $\gamma_{r_0}(v)$ is used.

Taking averages with respect to v, using Jensen's inequality multiple times, and applying the deterministic bound

$$\frac{1}{N}\sum_{v\in V}\overline{Q}_T(v) \le \left(d + \frac{e}{2(1-e^{-1})}\,\frac{K\,(\alpha(G_{\le d})+1)}{N}\right) T$$

derived with the aid of Lemma 3 at the end of the proof of Theorem 4, gives

$$\begin{aligned} R_T^{\text{coop}} &\le 3d + 4Ke(d+1)\ln K \\ &\quad + 10\sqrt{(\ln K)\mathbb{E}\left[\frac{1}{N}\sum_{v\in V}\overline{Q}_T(v)\right]} + 3d\log_2\left(\mathbb{E}\left[\frac{1}{N}\sum_{v\in V}\overline{Q}_T(v)\right]\right) \\ &\le 10\sqrt{(\ln K)\left(d + \frac{e}{2(1-e^{-1})}\,\frac{K\left(\alpha(G_{\le d})+1\right)}{N}\right)T} + 3d\log_2 T + C\,, \end{aligned}$$

where C is independent of T and depends polynomially on the other parameters. Hence, as T grows large,

$$R_T^{\text{coop}} = \mathcal{O}\left(\sqrt{(\ln K)\left(d+1+\frac{K}{N}\,\alpha(G_{\le d})\right)T} + d\,\log T\right)$$

as claimed. ■

Proofs from Section 5

We first need to adapt the preliminary Lemmas 1 and 2 to the new update rule of Exp3-Coop2 contained in Figure 5.

Lemma 16 *Under the update rule contained in Figure 5, for all $t \ge 1$, for all $i \in A$, and for all $v \in V$*

$$\begin{aligned} -p_t(i,v)\left(\eta\widehat{\ell}_t(i,v)+\delta\right) &\le p_{t+1}(i,v) - p_t(i,v) \\ &\le p_{t+1}(i,v)\sum_{j=1}^{K} p_t(j,v)\left(1-\mathbb{I}\{\widetilde{p}_{t+1}(i,v)>\delta/K\}\big(1-\eta\,\widehat{\ell}_t(i,v)\big)\right) \end{aligned}$$

holds deterministically with respect to the agents' randomization.

Proof For the lower bound, we have

$$p_{t+1}(i,v) - p_t(i,v) = \frac{\widetilde{p}_{t+1}(i,v)}{\widetilde{P}_{t+1}(v)} - p_t(i,v) \ge \frac{w_{t+1}(i,v)}{W_{t+1}(v)\,\widetilde{P}_{t+1}(v)} - p_t(i,v)\,.$$

Since $W_{t+1}(v) = \sum_{i\in A} p_t(i,v)e^{-\eta\widehat{\ell}_t(i,v)} \le \sum_{i\in A} p_t(i,v) = 1$, and $\widetilde{P}_{t+1}(v) \le 1+\delta$ by (7), we can write

$$\begin{aligned} p_{t+1}(i,v) - p_t(i,v) &\ge \frac{w_{t+1}(i,v)}{1+\delta} - p_t(i,v) \\ &= p_t(i,v)\left(\frac{e^{-\eta\widehat{\ell}_t(i,v)}}{1+\delta} - 1\right) \\ &\ge p_t(i,v)\left(\frac{1-\eta\widehat{\ell}_t(i,v)}{1+\delta} - 1\right) \qquad (\text{using } e^{-x}\ge 1-x) \\ &\ge p_t(i,v)\left(-\delta - \eta\widehat{\ell}_t(i,v)\right) \end{aligned}$$

as claimed. As for the upper bound, we first claim that

$$\frac{w_{t+1}(i,v)}{W_{t+1}(v)} \ge p_{t+1}(i,v)\mathbb{I}\{\widetilde{p}_{t+1}(i,v) > \delta/K\}\,. \tag{10}$$

To prove (10), we recall that $\widetilde{p}_{t+1}(i,v) = \max\left\{\frac{w_{t+1}(i,v)}{W_{t+1}(v)}, \frac{\delta}{K}\right\}$. Then we distinguish two cases:

1. If $\frac{w_{t+1}(i,v)}{W_{t+1}(v)} \le \frac{\delta}{K}$, then $\widetilde{p}_{t+1}(i,v) = \delta/K$, and $w_{t+1}(i,v)/W_{t+1}(v) > 0$ by definition, hence (10) holds;
2. If $\frac{w_{t+1}(i,v)}{W_{t+1}(v)} > \frac{\delta}{K}$ then $\widetilde{p}_{t+1}(i,v) = \frac{w_{t+1}(i,v)}{W_{t+1}(v)}$, so that $p_{t+1}(i,v) \le p_{t+1}(i,v)\,\widetilde{P}_{t+1}(v) = \widetilde{p}_{t+1}(i,v)$ and (10) again holds.

Then, setting for brevity $C = \mathbb{I}\{\widetilde{p}_{t+1}(i,v) > \delta/K\}$, we can write

$$\begin{aligned} p_{t+1}(i,v) - p_t(i,v) &\le p_{t+1}(i,v) - w_{t+1}(i,v) && (\text{from the update (1)}) \\ &\le p_{t+1}(i,v) - W_{t+1}(v)p_{t+1}(i,v)\,C && (\text{using (10)}) \\ &= p_{t+1}(i,v)\big(1 - W_{t+1}(v)\,C\big) \\ &= p_{t+1}(i,v)\left(\sum_{j\in A}\big(p_t(j,v) - C\,w_{t+1}(j,v)\big)\right) \\ &= p_{t+1}(i,v)\sum_{j\in A} p_t(j,v)\left(1 - C\,e^{-\eta\widehat{\ell}_t(j,v)}\right) \\ &\le p_{t+1}(i,v)\sum_{j\in A} p_t(j,v)\left(1 - C(1-\eta\,\widehat{\ell}_t(j,v))\right) \end{aligned}$$

where in the last step we again used $e^{-x} \ge 1-x$. This concludes the proof. ■

Lemma 17 *Under the update rule contained in Figure 5, if $\delta \le 1/d(v)$ and $\eta \le \frac{1}{Ke(d(v)+1)}$, then*

$$p_{t+1}(i,v) \le \left(1 + \frac{1}{d(v)}\right) p_t(i,v) \tag{11}$$

holds for all $t \ge 1$ and $i \in A$, deterministically with respect to the agents' randomization.

Proof If $\widetilde{p}_{t+1}(i,v) = \delta/K$ then, from (7), we have $\delta/K = p_{t+1}(i,v)\widetilde{P}_{t+1}(v) \ge p_{t+1}(i,v)$, and $p_t(i,v) \ge \frac{\delta}{K(1+\delta)}$. Hence, $\frac{p_{t+1}(i,v)}{p_t(i,v)} \le \frac{\delta/K}{\delta/(K(1+\delta))} = 1+\delta$, so the claim follows from $\delta \le \frac{1}{d(v)}$. On the other hand, if $\widetilde{p}_{t+1}(i,v) > \delta/K$, then the proof is exactly the same as the proof of Lemma 2, for the second inequality in the statement of Lemma 16 turns out to be exactly the same as the corresponding inequality in the statement in Lemma 1. ■

Next, we generalize Lemma 3 to the case of directed graphs. This is where we need a lower bound on the probabilities $p_t(i,v)$. If $G = (V,E)$ is a directed graph, then for each $v \in V$ let $N_{\le 1}^{-}(v)$ be the in-neighborhood of node v (i.e., the set of $v' \in V$ such that arc $(v',v) \in E$), including v itself.

Lemma 18 *Let $G = (V, E)$ be a directed graph with independence number $\alpha(G)$. Let $\boldsymbol{p}(v) = \big(p(1,v), \dots, p(K,v)\big)$ be a probability distribution over $A = \{1, \dots, K\}$ such that $p(i,v) \geq \frac{\delta}{K(1+\delta)}$. Then, for all $i \in A$,*

$$\sum_{v \in V} \frac{p(i,v)}{q(i,v)} \leq \frac{1}{1-e^{-1}} \left(6\,\alpha(G) \ln\left(1 + \frac{N^2 K(1+\delta)}{\delta}\right) + \sum_{v \in V} p(i,v) \right) ,$$

where $q(i,v) = 1 - \prod_{v' \in N^-_{\leq 1}(v)} \big(1 - p(i,v')\big)$.

Proof We follow the notation and the proof of Lemma 3, where it is shown that

$$\sum_{v \in V} \frac{p(i,v)}{q(i,v)} \leq \frac{1}{1-e^{-1}} \sum_{v \in V} \left(\frac{p(i,v)}{P(i,v)} + p(i,v) \right) .$$

In order to bound from above the sum $\sum_{v \in V} \frac{p(i,v)}{P(i,v)}$, we combine (Alon et al., 2017, Lemma 14 and 16) and derive the upper bound

$$\sum_{v \in V} \frac{p(i,v)}{P(i,v)} \leq 6\,\alpha(G) \ln\left(1 + \frac{N^2 K(1+\delta)}{\delta}\right)$$

holding when $p(i,v) \geq \frac{\delta}{K(1+\delta)}$. Again, the probabilities $p(i,1), \dots, p(i,N) \geq 0$ need not sum to one in order for this lemma to apply. ■

With the above three lemmas handy, we are ready to prove Theorem 11.

Proof of Theorem 11. This proof is similar to the proof of Theorem 4, hence we only emphasize the differences between the two.

From the update rule in Figure 5, we have, for each $v \in V$,

$$\begin{aligned}
W_{T+1}(v) &= \sum_{i=1}^{K} \frac{\widetilde{p}_T(i)}{\widetilde{P}_T(v)} e^{-\eta \widehat{\ell}_T(i,v)} \\
&\geq \sum_{i=1}^{K} \frac{w_T(i,v)}{W_T(v) \widetilde{P}_T(v)} e^{-\eta \widehat{\ell}_T(i,v)} \qquad \text{(since } \widetilde{p}_T(i) \geq w_T(i,v)/W_T(v)\text{)} \\
&= \sum_{i=1}^{K} \frac{\widetilde{p}_{T-1}(i,v) e^{-\eta \widehat{\ell}_{T-1}(i,v)} e^{-\eta \widehat{\ell}_T(i,v)}}{W_T(v) \widetilde{P}_{T-1}(v) \widetilde{P}_T(v)} \\
&\vdots \\
&\geq \sum_{i=1}^{K} \frac{w_1(i,v)\, e^{-\eta \sum_{t=1}^{T} \widehat{\ell}_t(i,v)}}{W_1(v) \cdots W_T(v) \widetilde{P}_1(v) \cdots \widetilde{P}_T(v)} .
\end{aligned}$$

Now, because $w_1(i,v) = 1$, $W_1(v) = K$, and $\widetilde{P}_t(v) \leq 1 + \delta$ for all t, see (7), the above chain of inequalities implies that, for any fixed action $k \in A$,

$$(1+\delta)^T K \left(\prod_{t=1}^{T} W_{t+1}(v) \right) \geq e^{-\eta \sum_{t=1}^{T} \widehat{\ell}_t(k,v)} . \tag{12}$$

As usual, the quantity $W_{t+1}(v)$ can be upper bounded as

$$\begin{aligned}
W_{t+1}(v) &= \sum_{i=1}^{K} p_t(i,v) e^{-\eta \widehat{\ell}_t(i,v)} \\
&\leq \sum_{i=1}^{K} p_t(i,v) \left(1 - \eta \widehat{\ell}_t(i,v) + \frac{\eta^2}{2} \widehat{\ell}_t(i,v)^2 \right) \\
&\quad \text{(from } e^{-x} \leq 1 - x + x^2/2 \text{ for all } x \geq 0\text{)} \\
&= 1 - \eta \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) + \frac{\eta^2}{2} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v)^2 .
\end{aligned}$$

Substituting into (12) and taking logs of both sides gives

$$\begin{aligned}
&T \ln(1+\delta) + \ln K + \sum_{t=1}^{T} \ln\left(1 - \eta \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) + \frac{\eta^2}{2} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v)^2 \right) \\
&\qquad \geq -\eta \sum_{i=1}^{K} \widehat{\ell}_t(k,v) .
\end{aligned}$$

Finally, using $\ln(1+x) \leq x$, dividing by η, using $\delta = 1/T$, and rearranging yields

$$\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) \leq \frac{1 + \ln K}{\eta} + \sum_{t=1}^{T} \widehat{\ell}_t(k,v) + \frac{\eta}{2} \sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v)^2 , \tag{13}$$

hence arriving at the counterpart of (6). From this point on, we proceed as in the proof of Theorem 4 by taking expectation on the three (double) sums in (13). Note that we do still have, for all $v \in V$, $t > d(v)$, and $i \in A$,

$$\begin{aligned}
\mathbb{E}_{t-d(v)}\Big[\widehat{\ell}_t(i,v)\Big] &= \ell_{t-d(v)}(i) \\
\mathbb{E}_{t-d(v)}\Big[p_t(i,v) \widehat{\ell}_t(i,v)\Big] &= p_t(i,v) \ell_{t-d(v)}(i) \\
\mathbb{E}_{t-d(v)}\Big[p_t(i,v) \widehat{\ell}_t(i,v)^2\Big] &= p_t(i,v) \frac{\ell_{t-d(v)}(i)^2}{q_{\mathcal{P},t-d(v)}(i,v)} .
\end{aligned}$$

We can write

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v) \right] &\geq \mathbb{E}\left[\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v)\, \ell_t(i) \right] - 2d(v) - (\eta + \delta)\, T\, d(v) \\
\mathbb{E}\left[\sum_{t=1}^{T} \widehat{\ell}_t(k,v) \right] &\leq \sum_{t=1}^{T} \ell_t(k)
\end{aligned}$$

and, as in the proof of Theorem 4,

$$\mathbb{E}\left[\sum_{t=1}^{T} \sum_{i=1}^{K} p_t(i,v) \widehat{\ell}_t(i,v)^2 \right] \leq e\, \mathbb{E}\left[\sum_{t=d(v)+1}^{T} \sum_{i=1}^{K} \frac{p_{t-d(v)}(i,v)}{q_{\mathcal{P},t-d(v)}(i,v)} \right] .$$

Summing over all agents v, dividing by N, and applying Lemma 18 to the directed graph $G_{\mathcal{P}}$, the last inequality gives

$$\frac{1}{N}\,\mathbb{E}\left[\sum_{t=1}^{T}\sum_{i=1}^{K}\sum_{v\in V} p_t(i,v)\widehat{\ell}_t(i,v)^2\right] \leq \frac{e}{1-e^{-1}}\,T\left(\frac{6K}{N}\,\alpha\left(G_{\mathcal{P}}\right)\,\ln\left(1+2TN^2K\right)+1\right)\,.$$

Combining as in (13), recalling that $\delta = 1/T$, and setting for brevity $\bar{d}_V = \frac{1}{N}\sum_{v\in V} d(v)$, we have thus obtained that the average welfare regret of Exp3-Coop2 satisfies

$$\begin{aligned} R_T^{\text{coop}} &\leq 3\bar{d}_V + \eta\,T\,\bar{d}_V + \frac{1+\ln K}{\eta} + \frac{e\eta}{2(1-e^{-1})}\,T\left(\frac{6K}{N}\,\alpha\left(G_{\mathcal{P}}\right)\,\ln\left(1+2TN^2K\right)+1\right) \\ &= \mathcal{O}\left(\eta\,T\,\bar{d}_V + \frac{\ln K}{\eta} + \frac{\eta TK}{N}\,\alpha\left(G_{\mathcal{P}}\right)\,\ln\left(TNK\right)\right) \end{aligned}$$

as T grows large. This concludes the proof. ■

Proofs from Section 6

The following are further generalizations of Lemmas 1 and 2 that apply to mixed delay estimators.

Lemma 19 *Let $\widehat{\ell}_t(i,v)$ be of the form (8) for each $t \geq 1$, $i \in A$, and $v \in V$. If $\eta \leq \frac{1}{Ke(d+1)}$ in the update rule $w_{t+1}(i,v) = p_t(i,v)\,\exp\bigl(-\eta\,\widehat{\ell}_t(i,v)\bigr)$ then*

$$p_{t+1}(i,v) \leq \left(1+\frac{1}{d}\right) p_t(i,v)$$

holds for all $t \geq 1$, $i \in A$, and $v \in V$ deterministically with respect to the agent's randomization.

Proof The proof follows a similar inductive argument as in the proof of Lemma 2. We can write, for $t > d$,

$$\begin{aligned} \sum_{i\in A} p_t(i,v)\widehat{\ell}_t(i,v) &= \sum_{i\in A} p_t(i,v)\sum_{s=0}^{d-1} D(s)\,\frac{\ell_{t-s}(i,v)}{q_{s,t-s}(i,v)}B_{s,t-s}(i,v) \\ &\leq \sum_{i\in A} p_t(i,v)\sum_{s=0}^{d-1} D(s)\,\frac{1}{q_{s,t-s}(i,v)} \\ &\leq \sum_{i\in A}\sum_{s=0}^{d-1}\left(1+\frac{1}{d}\right)^s D(s)\,\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)} \\ &\leq \sum_{i\in A}\sum_{s=0}^{d-1}\left(1+\frac{1}{d}\right)^s D(s) \\ &\leq Ke\,. \end{aligned}$$

Combining with Lemma 1 as in the proof of Lemma 2 concludes the proof. ■

Lemma 20 *Under the same assumptions and notation as in Lemma 19, we have that*

$$p_{t+1}(i,v) - p_t(i,v) \geq -e\eta\sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{q_{s,t-s}(i,v)}$$

holds for all $t \geq 1$, $i \in A$, and $v \in V$ deterministically with respect to the agent's randomization.

Proof When $t \leq d$ the statement is trivially verified, hence we continue by assuming $t > d$. From Lemma 1 we have $p_{t+1}(i,v) - p_t(i,v) \geq -\eta\,p_t(i,v)\widehat{\ell}_t(i,v)$. Then, proceeding as in the proof of Lemma 19, we have

$$\begin{aligned} p_t(i,v)\widehat{\ell}_t(i,v) &= p_t(i,v)\sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)} \\ &\leq \sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(i,v)\,p_t(i,v)}{q_{s,t-s}(i,v)} \\ &\leq \sum_{s=0}^{d-1} D(s)\,\left(1+\frac{1}{d}\right)^s\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{q_{s,t-s}(i,v)} \\ &\leq e\sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\,. \end{aligned}$$

Putting together proves the claim. ■

Proof of Theorem 13. As in the proof of Theorem 4, we start off from (6). Using the definition of $\widehat{\ell}_t(i,v)$ in (8) this can be written as

$$\begin{aligned} \sum_{t=d+1}^{T}\sum_{i=1}^{K}\sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(i,v)\,p_t(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)} &\leq \sum_{t=d+1}^{T}\sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(k,v)\,\ell_{t-s}(k)}{q_{s,t-s}(k,v)} \\ &\quad + \frac{\ln K}{\eta} + \frac{\eta}{2}\sum_{t=d+1}^{T}\sum_{i=1}^{K} p_t(i,v)\left(\sum_{s=0}^{d-1} D(s)\,\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}\right)^2\,. \quad (14) \end{aligned}$$

We now bound the first and the third sum in (14) separately. As for the first sum, a repeated application of Lemma 20 for $t \geq 2d+1$ and $s = 1,\ldots,d$ leads to

$$p_t(i,v) \geq p_{t-s}(i,v) - e\eta\sum_{h=1}^{s}\sum_{r=0}^{d-1} D(r)\,\frac{B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)}\,,$$

so that

$$\sum_{t=d+1}^{T}\sum_{i=1}^{K}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,p_t(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)} \geq \sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,p_t(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)} \geq \sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)} - e\eta\sum_{t=2d+1}^{T}\sum_{i=1}^{K} S_t(i,v)\,,$$

where the slack $S_t(i,v)$ satisfies

$$S_t(i,v) = \sum_{s=1}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}\sum_{h=1}^{s}\sum_{r=0}^{d-1} D(r)\frac{B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)}\,. \tag{15}$$

As for the third sum, Jensen's inequality and $\ell_{i,t-s}\in[0,1]$ jointly give

$$\left(\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}\right)^2 \leq \sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)}{q_{s,t-s}(i,v)^2}\,.$$

Moreover, recalling that $s\in\{1,\dots,d\}$, a repeated application of Lemma 19 yields

$$p_t(i,v) \leq \left(1+\frac{1}{d}\right)^s p_{t-s}(i,v) \leq \left(1+\frac{1}{d}\right)^d p_{t-s}(i,v) \leq e\,p_{t-s}(i,v)\;,$$

so that

$$\sum_{t=d+1}^{T}\sum_{i=1}^{K} p_t(i,v)\left(\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}\right)^2 \leq e\sum_{t=d+1}^{T}\sum_{i=1}^{K}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{q_{s,t-s}(i,v)^2}\;.$$

Putting together and summing over $v\in V$ we obtain

$$\underbrace{\sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{v\in V}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}}_{\text{(I)}} \leq \underbrace{\sum_{t=d+1}^{T}\sum_{v\in V}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(k,v)\,\ell_{t-s}(k)}{q_{s,t-s}(k,v)}}_{\text{(II)}} + \frac{N\ln K}{\eta} + e\eta\underbrace{\sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{v\in V} S_t(i,v)}_{\text{(III)}} + \frac{e\eta}{2}\underbrace{\sum_{t=d+1}^{T}\sum_{i=1}^{K}\sum_{v\in V}\sum_{s=0}^{d-1} D(s)\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{q_{s,t-s}(i,v)^2}}_{\text{(IV)}}\,.$$

Similar to before, we have, for any $i\in A$, $v\in V$, $t=1,2,\dots$, and $s=0,\dots,d-1$,

$$\mathbb{E}_{t-s}\left[\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}\right] = \frac{p_{t-s}(i,v)\,\ell_{t-s}(i)}{q_{s,t-s}(i,v)}\,\mathbb{E}_{t-s}\big[B_{s,t-s}(i,v)\big] = p_{t-s}(i,v)\,\ell_{t-s}(i)$$

$$\mathbb{E}_{t-s}\left[\frac{B_{s,t-s}(k,v)\,\ell_{t-s}(k)}{q_{s,t-s}(k,v)}\right] = \frac{\ell_{t-s}(k)}{q_{s,t-s}(k,v)}\,\mathbb{E}_{t-s}\big[B_{s,t-s}(k,v)\big] = \ell_{t-s}(k)$$

$$\mathbb{E}_{t-s}\left[\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{\big(q_{s,t-s}(i,v)\big)^2}\right] = \frac{p_{t-s}(i,v)}{\big(q_{s,t-s}(i,v)\big)^2}\,\mathbb{E}_{t-s}\big[B_{s,t-s}(i,v)\big] = \frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\,.$$

Hence

$$\begin{aligned}\mathbb{E}\left[(\mathrm{I})\right] &= \sum_{i=1}^{K}\sum_{v\in V}\sum_{t=2d+1}^{T}\sum_{s=0}^{d-1} D(s)p_{t-s}(i,v)\,\ell_{t-s}(i)\\ &\geq \sum_{i=1}^{K}\sum_{v\in V}\sum_{t=2d+1}^{T-d+1} p_t(i,v)\,\ell_t(i)\\ &\geq \sum_{i=1}^{K}\sum_{v\in V}\left(\sum_{t=1}^{T} p_t(i,v)\,\ell_t(i) - \sum_{t=1}^{2d} p_t(i,v) - \sum_{t=T-d+2}^{T} p_t(i,v)\right)\\ &\geq \sum_{v\in V}\sum_{t=1}^{T}\sum_{i=1}^{K} p_t(i,v)\,\ell_t(i) - 3dN\end{aligned}$$

and

$$\mathbb{E}\left[(\mathrm{II})\right] = \sum_{v\in V}\sum_{t=2d+1}^{T}\sum_{s=0}^{d-1} D(s)\ell_{t-s}(k) \leq \sum_{v\in V}\sum_{t=1}^{T}\ell_t(k)\,.$$

Moreover, from Lemma 3,

$$\begin{aligned}\mathbb{E}\left[(\mathrm{IV})\right] &= \sum_{i=1}^{K}\sum_{t=d+1}^{T}\sum_{s=0}^{d-1} D(s)\sum_{v\in V}\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\\ &\leq \sum_{i=1}^{K}\sum_{t=d+1}^{T}\sum_{s=0}^{d-1} D(s)\left(\frac{1}{1-e^{-1}}\left(\alpha(G_{\leq s}) + \sum_{v\in V} p_{t-s}(i,v)\right)\right)\\ &= \frac{K}{1-e^{-1}}\sum_{t=d+1}^{T}\sum_{s=0}^{d-1} D(s)\alpha(G_{\leq s}) + \frac{1}{1-e^{-1}}\sum_{t=d+1}^{T}\sum_{s=0}^{d-1} D(s)\sum_{v\in V}\sum_{i=1}^{K} p_{t-s}(i,v)\\ &= \frac{K}{1-e^{-1}}\,(T-d)\,\bar{\alpha}_D + \frac{1}{1-e^{-1}}\,(TN - dN)\\ &< \frac{T}{1-e^{-1}}\,(K\bar{\alpha}_D + N)\;,\end{aligned}$$

where $\bar{\alpha}_D = \sum_{s=0}^{d-1} D(s)\alpha(G_{\leq s})$.

Finally, we are left with upper bounding $\mathbb{E}[(\mathrm{III})]$. Consider each slack term $S_t(i,v)$ in (15) We can then rewrite $S_t(i,v)$ as

$$S_t(i,v) = \sum_{s=1}^{d-1}\sum_{h=1}^{s}\sum_{r=0}^{d-1} D(s)D(r)\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\;.$$

Now, we consider three cases, depending on the value of the indices s,h, and r in the triple sum.

Case 1: $t-s > t-h-r$ (i.e., $s < h+r$). We have

$$\begin{aligned}
&\mathbb{E}\left[\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\right] \\
&= \mathbb{E}\left[\mathbb{E}_{t-s}\left[\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\right]\right] \\
&= \mathbb{E}\left[\frac{\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\mathbb{E}_{t-s}\left[B_{s,t-s}(i,v)\right]\right] \\
&= \mathbb{E}\left[\frac{\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)}\right] \\
&\le \mathbb{E}\left[\frac{p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)}\,E_{t-h-r}[B_{r,t-h-r}(i,v)]\right] \\
&= \mathbb{E}\left[p_{t-h-r}(i,v)\right]\ .
\end{aligned}$$

Case 2: $t-s < t-h-r$ (i.e., $s > h+r$). We can write

$$\begin{aligned}
&\mathbb{E}\left[\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\right] \\
&= \mathbb{E}\left[\mathbb{E}_{t-h-r}\left[\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\right]\right] \\
&= \mathbb{E}\left[\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\mathbb{E}_{t-h-r}\left[B_{r,t-h-r}(i,v)\,\right]\right] \\
&\le \mathbb{E}\left[\frac{B_{s,t-s}(i,v)\,p_{t-h-r}(i,v)}{q_{s,t-s}(i,v)}\right] \\
&\le \left(1+\frac{1}{d}\right)^{s-h-r}\mathbb{E}\left[\frac{B_{s,t-s}(i,v)\,p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\right] \qquad \text{(repeatedly using Lemma 19)} \\
&\le e\,\mathbb{E}\left[\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\,\mathbb{E}_{t-s}\left[B_{s,t-s}(i,v)\right]\right] \\
&= e\,\mathbb{E}\left[p_{t-s}(i,v)\right]\ .
\end{aligned}$$

Case 3: $t-s = t-h-r$ (i.e., $s = h+r$). We have $p_{t-h-r}(i,v) = p_{t-s}(i,v)$. Moreover, since $h \ge 1$ we have $s > r$, so that $B_{s,t-s}(i,v)\,B_{r,t-h-r}(i,v) = B_{r,t-h-r}(i,v)$. We can write

$$\begin{aligned}
&\mathbb{E}\left[\frac{B_{s,t-s}(i,v)\,\ell_{t-s}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\right] \\
&= \mathbb{E}\left[\mathbb{E}_{t-h-r}\left[\frac{\ell_{t-h-r}(i)\,B_{r,t-h-r}(i,v)\,p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\right]\right] \\
&\le \mathbb{E}\left[\frac{p_{t-h-r}(i,v)}{q_{r,t-h-r}(i,v)\,q_{s,t-s}(i,v)}\,\mathbb{E}_{t-h-r}\left[B_{r,t-h-r}(i,v)\right]\right] \\
&= \mathbb{E}\left[\frac{p_{t-h-r}(i,v)}{q_{s,t-s}(i,v)}\right] \\
&= \mathbb{E}\left[\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\right]\ .
\end{aligned}$$

Therefore, piecing together and overapproximating yields

$$\begin{aligned}
\mathbb{E}\left[S_t(i,v)\right] \le e\,\mathbb{E}\Bigg[&\sum_{s,h,r\,:\,s<h+r} D(s)D(r)\,p_{t-h-r}(i,v) + \sum_{s,h,r\,:\,s>h+r} D(s)D(r)\,p_{t-s}(i,v) \\
&+ \sum_{s,h,r\,:\,s=h+r} D(s)D(r)\,\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\Bigg]\ .
\end{aligned}$$

This allows us to write

$$\begin{aligned}
\mathbb{E}[(\mathrm{III})] &\le e\sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{v\in V}\mathbb{E}\Bigg[\sum_{s,h,r\,:\,s<h+r} D(s)D(r)\,p_{t-h-r}(i,v) \\
&\qquad + \sum_{s,h,r\,:\,s>h+r} D(s)D(r)\,p_{t-s}(i,v) + \sum_{s,h,r\,:\,s=h+r} D(s)D(r)\,\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\Bigg] \\
&= e\sum_{t=2d+1}^{T}\sum_{v\in V}\sum_{s,h,r\,:\,s<h+r} D(s)D(r) + e\sum_{t=2d+1}^{T}\sum_{v\in V}\sum_{s,h,r\,:\,s>h+r} D(s)D(r) \\
&\qquad + e\sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{s,h,r\,:\,s=h+r} D(s)D(r)\,\mathbb{E}\left[\sum_{v\in V}\frac{p_{t-s}(i,v)}{q_{s,t-s}(i,v)}\right] \\
&\le e\,T\,N\sum_{s,h,r\,:\,s\neq h+r} D(s)D(r) \\
&\qquad + \frac{e}{1-e^{-1}}\sum_{t=2d+1}^{T}\sum_{i=1}^{K}\sum_{s,h,r\,:\,s=h+r} D(s)D(r)\left(\alpha(G_{\le s}) + \sum_{v\in V} p_{t-s}(i,v)\right) \\
&= e\,T\,N\sum_{s,h,r\,:\,s\neq h+r} D(s)D(r) \\
&\qquad + \frac{T\,e}{1-e^{-1}}\left(K\sum_{s,h,r\,:\,s=h+r} D(s)D(r)\alpha(G_{\le s}) + N\sum_{s,h,r\,:\,s=h+r} D(s)D(r)\right) \\
&< \frac{T\,e}{1-e^{-1}}\left(K\sum_{s,h,r\,:\,s=h+r} D(s)D(r)\alpha(G_{\le s}) + N\sum_{s,h,r} D(s)D(r)\right)
\end{aligned}$$

Now,

$$\sum_{s,h,r} D(s)D(r) = \sum_{s=1}^{d-1} D(s)\sum_{h=1}^{s}\sum_{r=0}^{d-1} D(r) = \sum_{s=1}^{d-1} D(s)\,s = \mu_D$$

and

$$\sum_{s,h,r\,:\,s=h+r} D(s)D(r)\alpha(G_{\le s}) = \sum_{s=1}^{d-1} D(s)\alpha(G_{\le s})\sum_{h=1}^{s} D(s-h) \le \sum_{s=1}^{d-1} D(s)\alpha(G_{\le s}) = \bar{\alpha}_D$$

so that

$$\mathbb{E}[(\mathrm{III})] \leq \frac{T\,e}{1-e^{-1}}\left(N\mu_D + K\bar{\alpha}_D\right).$$

Putting pieces together, dividing by N, and further overapproximating gives

$$R_T^{\mathrm{coop}} \leq 3d + \frac{\ln K}{\eta} + \frac{e^2\eta\,T}{1-e^{-1}}\left(1+\mu_D+\frac{2K}{N}\,\bar{\alpha}_D\right),$$

thereby concluding the proof. ■

Abstract

This paper develops detailed mathematical statistical theory of a new class of cross-validation techniques of local linear kernel hazards and their multiplicative bias corrections. The new class of cross-validation combines principles of local information and recent advances in indirect cross-validation. A few applications of cross-validating multiplicative kernel hazard estimation do exist in the literature. However, detailed mathematical statistical theory and small sample performance are introduced via this paper and further upgraded to our new class of best one-sided cross-validation. Best one-sided cross-validation turns out to have excellent performance in its practical illustrations, in its small sample performance and in its mathematical statistical theoretical performance.

Keywords: Aalen's multiplicative model, multiplicative bias correction, bandwidth, indirect cross-validation

1. Introduction

There is a growing interest in validation techniques. While validation was always a crucial element of mathematical statistics, the use of validation techniques are growing rapidly at the moment under labels such as big data, machine learning or artificial intelligence. Many of these developments seem less patient with laborious mathematical statistical model formulation and estimation theory than what has been the trademark of the field of mathematical statistics. Instead inspiration seems to be taken from neighbouring fields such as engineering, computer science, public health or actuarial science, where specific knowledge is present on the problem at hand, allowing the development of clever and perhaps computationally challenging algorithms often replacing more labour intensive procedures of the past. These algorithms are often defined in such a way that they can change and learn over time via some optimization criteria and an efficient validation procedure. One example of such work relevant to the work of this paper is Muñoz and van der Laan (2012) where an impressive algorithm is developed to solve a complicated survival problem. The introduced

methodology is inspired by machine learning: the validation procedure is called a Super Learner. However, while the Super Learner is optimal in some sense, see van der Laan et al. (2007), then it is not optimal in the more detailed mathematical statistical sense that we consider in this paper. And this is not only because Muñoz and van der Laan (2012) consider piecewise constant hazard models that are less efficient than kernel smoothers. It is also because the validation theory provided by Muñoz and van der Laan (2012) does not provide the mathematical detail promoted in this paper, and therefore crucial insight of noisy second order components is not included in the theory. The approach of Muñoz and van der Laan (2012) is just one among many machine learning inspired survival analyses approaches. This paper considers one dimension only. Multidimensional cross-validation and one-dimensional cross-validation are closely related and mathematical definitions are similar. However, even in the one-dimensional case we face challenging theoretical, as well as practical issues, with cross-validation being too noisy and unstable and to such an extend that we cannot any longer recommend cross-validation in one dimension without some amendment for the noise involved. Our intention is that multidimensional big data type of problems, with further issues with data sparsity and noisy cross-validation, should benefit in the future from the insight on cross-validation analyses as provided in this paper. The mathematical point of view of this paper was perhaps initiated via the early contribution of Hall and Marron (1987) that provided a decision theoretical framework to distinguish between plug-in estimators, aiming at minimizing a mean integrated squared error, and cross-validation aiming at minimizing the infeasible stochastic integrated squared error. They concluded that plug-in did better from an asymptotic perspective even when the aim was the explicit aim of cross-validation: to get as close as possible to the infeasible minimization of the integrated squared error. One could view this as the foundation of a new decision theoretical framework to understand the quality of kernel bandwidth selection; a tractable place to start when understanding the complicated world of model selection. Hall and Johnstone (1992) pointed out that for any bandwidth selector there are two sources of noise for kernel density estimation, one that one can never get rid of and another one that seems to differ for different methods. The second source of noise can theoretically go as low as to zero such that one was left with the first noise component as a lower bound on noise. The plug-in type of methods had considerable lower second-component noise than cross-validation and plug-in was very popular in practice in the nineties, with Sheather and Jones (1991) being the perhaps most popular single method. However, plug-in methods depend on complicated underlying mathematical detail that does not easily generalize to new problems in the same straightforward way as cross-validation does. This is perhaps the single most important reason why cross-validation has regained its importance and is used for a wide variety of complicated problems in mathematical statistics, big data, machine learning and artificial intelligence. Hart and Yi (1998) introduced the concept of indirect cross-validation, formulated in nonparametric kernel regression, which simply meant that cross-validation was performed on an alternative kernel and the bandwidth was scaled back to the original kernel used for estimation. Hart and Yi (1998) suggested to use one-sided kernels as the alternative kernels because of their good practical performance and simple rescaling. In density estimation Savchuk et al. (2010) suggested a combination of a normal-bandwidth kernel and an oversmoothed kernel as alternative kernel to achieve the same mathematical statistical asymptotic performance as the plug-in estimator without the need

of a pilot. However, there was one catch with the elegant approach of Savchuk et al. (2010). Their approach needed to estimate some tuning parameters to decide the relative weight of the oversmoothed kernel that was contributing to the asymptotic noise via some term of lower order. So, even though Savchuk et al. (2010) in principle did pilot free estimation then there was still some tuning going on and some extra terms of just slightly lower order. And that was perhaps exactly the problem of the original plug-in methods as in Sheather and Jones (1991): that something with lower order noise had to be estimated, the pilot, and terms of slightly lower order had to be ignored in the asymptotic results. In this paper we define three dogmas for a modern kernel smoothing estimator:

1. It should be a direct estimation based on principles without complicated mathematical adjustments.

2. Extra terms of slightly lower order are not allowed in the expansions.

3. Further smoothing than those necessary for the original estimator is not allowed to be assumed while analysing the quality of the bandwidth selector.

The original cross-validation estimator and the approach of Hart and Yi (1998) lives up to all three dogma rules while the plug-in type estimators of e.g. Sheather and Jones (1991) and Savchuk et al. (2010) violate all three. We believe this to be the reason why Mammen et al. (2011,2014) concluded that their double one-sided kernel density bandwidth selector, directly inspired by Hart and Yi (1998), worked better in practice than the estimators of Sheather and Jones (1991) and Savchuk et al. (2010). The fundamental principles of this paper are therefore the three dogmas above and the decision theoretical framework of Hall and Marron (1987), and this has let us to explore double one-sided cross-validation and one-sided cross-validation even further because of their apparent practical superiority on the market of current kernel bandwidth selectors. A detailed investigation of both sides of local one-sided bandwidth selection showed us a perhaps surprising fact. While the left-sided and the right-sided cross-validation procedures have the same mathematical statistical behaviour, they do perform very differently in practice. Often one of the two sides breaks down completely. Double one-sided cross-validation works better than one-sided cross-validation in a wide variety of kernel smoothing problems, see for example Mammen et al. (2011,2014), Gámiz et al. (2013a,b, 2016). A closer investigation going through local features of individual simulation samples reveals that behind a good double one-sided cross-validation result often hides an average of a good one-sided estimator and a somehow random result from the other side. The suggestion of this paper is to improve the stability of one-sided cross-validation via a local information principle inspecting at every single local point whether to use the right side or the left side for cross-validation. This approach is stable in its practical performance, it obeys the three above dogmas and it provides the exact same asymptotic performance as the less stable one-sided and double-sided competitors mentioned above. We call the new approach best one-sided cross-validation. This paper furthermore introduces the mathematical statistical approach of Hall and Marron (1987) to multiplicative bias corrected local linear kernel hazard estimators and it introduces asymptotic theory and practical implementation of best one-sided-cross-validation for these multiplicative bias corrected hazard estimators. Multiplicative bias correction is known to improve the practical implementation of kernel hazard estimation, see Nielsen

(1998) and Nielsen and Tanggaard (2001). This parallels insights from the more researched world of kernel density estimation, see for example Jones et al. (1995) and Jones and Signorini (1997). The latter went through a series of small sample studies of kernel density estimation procedures to conclude that multiplicative bias correction seemed to be the best. The contribution of this paper is therefore also to update mathematical statistical theory and practice to the perhaps best practically performing kernel hazard estimator we have: the multiplicative bias corrected local linear kernel hazard estimator.

The rest of the paper is organized as follows. In Section 2 we describe the link between our proposal and methods in machine learning. In Section 3 we formulate the model we assume in the paper and present two hazard estimators, namely the local linear estimator and its multiplicative bias correction. Bandwidth selection for these estimators through cross-validation and the double one-sided cross-validation method of Gámiz et al. (2016) is described in Section 4, and our new best one-sided cross-validation method is suggested. The asymptotic properties of all presented validated bandwidths are analysed in Section 5. Assumptions are deferred to Appendix A and proofs are provided in the Supplementary Material. A further investigation of the theoretical properties of bandwidth selectors is described in Appendix B. Two case studies show the applicability of our proposals, which are described in Section 6. In Section 7 we describe simulation experiments to evaluate the finite sample properties of our proposal. The main findings from the simulations are discussed in Section 8 along with further insights about the asymptotic properties of bandwidth selectors. Final conclusions are drawn in Section 9. All numerical calculations have been performed with `R` and the methods proposed in this paper have been implemented in the `DOvalidation` package (Gámiz et al., 2017).

2. Training and learning versus cross-validation and adjusted cross-validation

To motivate our research beyond a wider crowd than experts in nonparametric hazard estimation, our point of view is formulated below via standard vocabulary from machine learning and artificial intelligence. Let us assume we observe n individuals over some time that could potentially be filtered via truncation and censoring, and let A be a training set and B be a learning set such that the two sets united equals the set $\{1, \ldots, n\}$. Let for the purpose of a discussion the number of elements of A be 80% of n and the number of elements in B be 20% of n. Then a standard approach to validation, see again Muñoz and van der Laan (2012), would be to estimate the hazard on the training set and evaluate it via the learning set. Under some standard independence assumptions this will lead to a decrease in efficiency of estimation itself corresponding to ignoring 20% of the data set and it will decrease the efficiency on the validation approach, compared to cross-validation and the theoretical approach considered in this paper, corresponding to ignoring 80% of the data set. One could of course consider all possible combinations of training and learning sets and average all these validations into one single validation principle or learning principle. This would correspond to a computationally inefficient cross-validation. In conclusion: even if all possible combinations of trainers and learners are calculated, we end up with standard cross-validation with the well known problems of data sparsity and noise. With the help of the theory originally developed by Hall and Marron (1987) in the kernel density context,

we will in this paper, in the kernel hazard context, consider more efficient use of data when estimators are validated or when trainers are learning. It turns out that this is indeed possible via relatively straightforward adjustments of standard cross-validation.

3. The counting process model and kernel hazard estimators

In this section we formulate events via counting processes. Counting processes are well designed when event data are filtered for example via truncation or censoring. An individual zero-one valued exposure process simply keeps tracks on whether an individual is under risk or not at any particular point in time. We assume that individuals are independent and that data filtering is non-informative. Formally, we observe n individuals, $i = 1, \ldots, n$. Let N_i count observed failures for the ith individual in the time interval $[0, T]$, N_i can take values 0 or 1. We assume that N_i is a one-dimensional counting process with respect to an increasing, right continuous, complete filtration $\mathcal{F}_t$, $t \in [0, T]$, i.e., it obeys the usual conditions (Andersen et al., 1993, p. 60). We assume Aalen's multiplicative model (Aalen, 1978) where the random intensity is written as $\lambda_i(t) = \alpha(t)Y_i(t)$, with no restriction on the functional form of the hazard function $\alpha(\cdot)$. Here Y_i is a predictable process taking values 0 or 1, indicating (by the value 1) when the ith individual is at risk and under observation. We assume that $(N_1, Y_1), \ldots, (N_n, Y_n)$ are independent and identically distributed for the n individuals. With these definitions λ_i is predictable and the processes $M_i(t) = N_i(t) - \Lambda_i(t)$, $i = 1, \ldots, n$, with $\Lambda_i(t) = \int_0^t \lambda_i(s)\, ds$, are square integrable local martingales.

As an example we illustrate how the above stochastic processes look like in the case of independent and non-informative left truncation and right censoring, where n tuples (L_i, Z_i, δ_i), $i = 1, \ldots, n$, are observed. Here L_i is the time the ith individual enters the study; Z_i is the time ith individual leaves the study either because an event has happened or because of right censoring; and δ_i is binary and equal to one if an event, for example death or an onset of a disease, is the reason for the ith individual to leave the study, and the value is zero when the reason for the ith individual to leave the study was uninformative right censoring. In this case, the process Y_i above would be $Y_i(t) = I(L_i \leq t < Z_i)$, and $N_i(t) = I(Z_i \leq t)\delta_i$, where $I(\cdot)$ is the indicator function. Hereafter we will work in the convenient and general stochastic process formulation only.

The local linear kernel hazard estimator in our general stochastic process formulation was introduced by Nielsen and Tanggaard (2001) and it is defined as

$$\widehat{\alpha}^{\mathrm{LL}}_{b,K}(t) = \sum_{i=1}^{n} \int_0^T \bar{K}_{t,b}(t-s) dN_i(s), \tag{1}$$

with the stochastic local linear kernel

$$\bar{K}_{t,b}(t-s) = \frac{a_{2,K}(t) - a_{1,K}(t)(t-s)}{a_{0,K}(t)a_{2,K}(t) - \{a_{1,K}(t)\}^2} K_b(t-s), \tag{2}$$

where $K_b(u) = b^{-1}K(u/b)$, $a_{j,K}(t) = \int_0^T K_b(t-s)(t-s)^j Y(s)ds$, for $j = 0, 1, 2$, and $Y(t) = \sum_{i=1}^n Y_i(t)$ is the aggregated risk process. Here K is a kernel function with support $[-1, 1]$ and $b > 0$ is the bandwidth parameter.

The local linear kernel $\bar{K}_{t,b}$ satisfies the properties: $\int_0^T \bar{K}_{t,b}(t-s)Y(s)ds = 1$, $\int_0^T \bar{K}_{t,b}(t-s)(t-s)Y(s)ds = 0$ and $\int_0^T \bar{K}_{t,b}(t-s)(t-s)^2 Y(s)ds > 0$. Thus, $\bar{K}_{t,b}$ can be interpreted as a

second order kernel with respect to the stochastic measure μ, where $d\mu(s) = Y(s)ds$. Defining the aggregated failure process, $N(t) = \sum_{i=1}^n N_i(t)$, we can write $\widehat{\alpha}^{\mathrm{LL}}_{b,K}(t) = \int_0^T \bar{K}_{t,b}(t-s)dN(s)$.

The multiplicative bias corrected estimator constructed from the local linear hazard estimator is defined as

$$\widehat{\alpha}^{\mathrm{MBC}}_{b,K}(t) = \sum_{i=1}^{n} \int \bar{K}^{\mathrm{MBC}}_{t,b}(t-s)\widehat{\alpha}^{\mathrm{LL}}_{b,K}(t)\{\widehat{\alpha}^{\mathrm{LL}}_{b,K}(s)\}^{-1} dN_i(s), \tag{3}$$

where the multiplicative kernel is

$$\bar{K}^{\mathrm{MBC}}_{t,b}(t-s) = \frac{a^{\mathrm{MBC}}_{2,K}(t) - a^{\mathrm{MBC}}_{1,K}(t)(t-s)}{a^{\mathrm{MBC}}_{0,K}(t)a^{\mathrm{MBC}}_{2,K}(t) - \{a^{\mathrm{MBC}}_{1,K}(t)\}^2} \left\{\widehat{\alpha}^{\mathrm{LL}}_{b,K}(s)\right\}^2 K_b(t-s), \tag{4}$$

with $a^{\mathrm{MBC}}_{j,K}(t) = \int_0^T K_b(t-s)(t-s)^j \left\{\widehat{\alpha}^{\mathrm{LL}}_{b,K}(s)\right\}^2 Y(s)ds$, for $j = 0, 1, 2$.

4. Cross-validation and best one-sided cross-validation of our two estimators

The two kernel hazards estimators considered in this paper depend on a bandwidth parameter that determines the smoothness degree of the resulting estimates. Choosing the bandwidth parameter is a crucial problem that starts by defining what the optimal bandwidth would be, so it can be estimated from data.

Let $\widehat{\alpha}_{b,K}$ denote a kernel hazard estimator with bandwidth b and kernel K, which can be any of the two defined in (1) or (3). Ideally we would like a bandwidth parameter b that minimizes the integrated squared error (ISE) defined as

$$\Delta_K(b) = n^{-1} \sum_{i=1}^{n} \int_0^T \{\widehat{\alpha}_{b,K}(s) - \alpha(s)\}^2 Y_i(s)w(s)ds,$$

where $w(\cdot)$ is some weight function. However, the minimizer of the integrated squared error, $\widehat{b}_{\mathrm{ISE},K}$, depends on the unknown hazard function and it is infeasible in practice. In this paper we consider $\widehat{b}_{\mathrm{ISE},K}$ as the optimal bandwidth and in this section we present estimates based on the cross-validation method. We refer the reader to Gámiz et al. (2016) for the history of cross-validation in kernel hazard estimation based on counting processes.

First notice that minimizing $\Delta_K(b)$ is equivalent to minimizing

$$n^{-1}\left[\sum_{i=1}^{n} \int_0^T \{\widehat{\alpha}_{b,K}(s)\}^2 Y_i(s)w(s)ds - 2\sum_{i=1}^{n} \int_0^T \widehat{\alpha}_{b,K}(s)\alpha(s)Y_i(s)w(s)ds\right],$$

and only the second term depends on the unknown hazard. The cross-validation approach estimates this second term from the data replacing $\alpha(s)ds$ by its empirical counterpart $dN_i(s)$. The cross-validated bandwidth, denoted by $\widehat{b}_{\mathrm{CV},K}$, is therefore the minimizer of

$$\widehat{Q}_K(b) = n^{-1}\left[\sum_{i=1}^{n} \int_0^T \{\widehat{\alpha}_{b,K}(s)\}^2 Y_i(s)w(s)ds - 2\sum_{i=1}^{n} \int_0^T \widehat{\alpha}^{[i]}_{b,K}(s)w(s)dN_i(s)\right], \tag{5}$$

where $\widehat{\alpha}^{[i]}_{b,K}(s)$ is the estimator arising when the data set is changed by setting the stochastic process $N_i(s)$ equal to 0 for all $s \in [0,T]$.

A practical and theoretical improvement of cross-validation was given in Gámiz et al. (2016) that developed double one-sided cross-validation (DO-validation), as a simple average of two indirect cross-validated bandwidths. Indirect cross-validation makes use of the fact that, under mild regularity conditions, asymptotically optimal bandwidths for two kernel estimators with different kernels K and L differ by a factor that only depends on the two kernels K and L. In indirect cross-validation one applies cross-validation to a kernel estimator with kernel L, and afterwards one multiplies the cross-validation bandwidth by the factor (depending on K and L) to get a bandwidth for the kernel estimator with kernel K. Such a construction makes sense if cross-validation for a kernel estimator with kernel L works better than cross-validation for a kernel estimator with kernel K. Double one-sided cross-validation averages the two indirect cross-validation bandwidths based on one-sided kernels: the left-sided $K_{\mathrm{L}}(u) = 2K(u)I(u<0)$, or the right-sided $K_{\mathrm{R}}(u) = 2K(u)I(u>0)$. More specifically, two one-sided cross-validation criteria, $\widehat{Q}_{K_{\mathrm{L}}}(b)$ and $\widehat{Q}_{K_{\mathrm{R}}}(b)$, are defined as in (5) but replacing K with K_{L} and K_{R}, respectively. Denoting by $\widehat{b}_{\mathrm{CV},K_{\mathrm{L}}}$ and $\widehat{b}_{\mathrm{CV},K_{\mathrm{R}}}$ their minimizers, the double one-sided cross-validation bandwidth estimate is the (conveniently) weighted average of these

$$\widehat{b}_{\mathrm{DO},K} = \rho \left\{ \frac{\widehat{b}_{\mathrm{CV},K_{\mathrm{L}}} + \widehat{b}_{\mathrm{CV},K_{\mathrm{R}}}}{2} \right\}.$$

For the local linear hazard estimator defined in (1), the factor ρ is

$$\rho^{\mathrm{LL}} = \left\{ \frac{R(K)}{R(\bar{K}^*_{\mathrm{L}})} \frac{\mu_2(\bar{K}^*_{\mathrm{L}})^2}{\mu_2(K)^2} \right\}^{1/5}. \tag{6}$$

Here, for a general kernel L, $\bar{L}^*$ denotes the equivalent local linear kernel defined as

$$\bar{L}^*(u) = \frac{\mu_2(L) - \mu_1(L)u}{\mu_2(L) - \mu_1(L)^2} L(u), \tag{7}$$

where $\mu_l(L) = \int u^l L(u)du$, for $l = 1, 2$, and $R(L) = \int L^2(u)du$. Notice that $\bar{L}^* = L$ if L is symmetric.

For the multiplicative bias corrected estimator, $\widehat{\alpha}^{\mathrm{MBC}}_{b,K}$, defined in (3), the factor ρ becomes

$$\rho^{\mathrm{MBC}} = \left\{ \frac{R(\Gamma_K)}{R(\Gamma_{\bar{K}^*_{\mathrm{L}}})} \frac{\mu_2(\bar{K}^*_{\mathrm{L}})^4}{\mu_2(K)^4} \right\}^{1/9}, \tag{8}$$

where $\Gamma_L(u) = 2L(u) - L(u) * L(u)$ is the kernel obtained by twicing the kernel L. Here $*$ denotes the convolution operator.

The asymptotic theory developed in Gámiz et al. (2016) for the local linear hazard estimator showed that left- and right-sided cross-validation have the same asymptotic properties, but different finite sample performance. There are situations where one of the two one-sided cross-validation methods breaks down so the averaging strategy of double one-sided cross-validation becomes inappropriate. The natural reaction in these cases would be

to take the side which is working fine. One common reason for one of the two one-sided cross-validated bandwidths to break down is the lack of occurrences (or exposures) in one of the two directions. Best one-sided cross-validation (BO-validation), introduced in this paper simply uses the one-sided version that, via local information, is predicted to work best at every single point t. There can therefore be both left-sided and right-sided kernels involved in best one-sided cross-validation. Imagine for example that the estimation interval is $(0,1)$, where two boundaries are present, then one would expect to use different sided kernels for a t close to the left boundary 0 and for a t close to the right boundary 1.

For the local linear hazard estimator we define the kernel estimator needed for best one-sided cross-validation as

$$\widehat{\alpha}^{\mathrm{BO,LL}}_{b,K}(t) = \int_0^T \left[\bar{K}_{t,b;\mathrm{L}}(t-s)\xi_b(t) + \bar{K}_{t,b;\mathrm{R}}(t-s)\left\{1-\xi_b(t)\right\} \right] dN(s), \tag{9}$$

where $\bar{K}_{t,b;\mathrm{L}}$ and $\bar{K}_{t,b;\mathrm{R}}$ are respectively the left and right versions of the local linear kernel $\bar{K}_{t,b}$ in (2), and $\xi_b(t)$ is a stochastic function, depending on the estimation time t and the bandwidth b, which takes the value 1 when the "best" side to consider is the indicated by the kernel K_{L}, and the value 0 otherwise. The combination of one-sided kernels that appears in the integrand of expression (9) is a kernel function which we denote as

$$\bar{K}^{\mathrm{BO,LL}}_{b,K}(t-s) = \bar{K}_{t,b;\mathrm{L}}(t-s)\xi_b(t) + \bar{K}_{t,b;\mathrm{R}}(t-s)\left\{1-\xi_b(t)\right\}. \tag{10}$$

Thus we write the estimator as $\widehat{\alpha}^{\mathrm{BO,LL}}_{b,K}(t) = \int_0^T \bar{K}^{\mathrm{BO,LL}}_{b,K}(t-s)dN(s)$.

For each time t, to designate which side is "best", $\xi_b(t)$ can be defined in terms of the occurrence process by

$$\xi^{\mathrm{O}}_b(t) = I\left(\int_{t-b}^t dN(s) < \int_t^{t+b} dN(s) \right),$$

or the exposure process by

$$\xi^{\mathrm{E}}_b(t) = I\left(\int_{t-b}^t Y(s)ds < \int_t^{t+b} Y(s)ds \right). \tag{11}$$

With any of these ξ^{O}_b or ξ^{E}_b, the best one-sided cross-validation bandwidth estimate is defined as

$$\widehat{b}^{\mathrm{LL}}_{\mathrm{BO},K} = \rho^{\mathrm{LL}} \arg\min_b \widehat{Q}^{\mathrm{BO,LL}}_K(b), \tag{12}$$

where $\widehat{Q}^{\mathrm{BO,LL}}_K$ is the cross-validation score in (5) calculated with the kernel estimator $\widehat{\alpha}^{\mathrm{BO,LL}}_{b,K}(t)$, defined in (9). In a similar way we define the best one-sided cross-validation bandwidth estimate for the multiplicative bias corrected estimator, $\widehat{b}^{MBC}_{\mathrm{BO},K}$, as in (12) but replacing the factor ρ^{LL} with ρ^{MBC}, given in (8), and defining the best one-sided cross-validation score, $\widehat{Q}^{\mathrm{BO,MBC}}_K$, with the hazard estimator

$$\widehat{\alpha}^{\mathrm{BO,MBC}}_{b,K}(t) = \int_0^T \left[\bar{K}^{\mathrm{MBC}}_{t,b;\mathrm{L}}(t-s)\frac{\widehat{\alpha}^{\mathrm{LL}}_{b,K_{\mathrm{L}}}(t)}{\widehat{\alpha}^{\mathrm{LL}}_{b,K_{\mathrm{L}}}(s)}\xi_b(t) + \bar{K}^{\mathrm{MBC}}_{t,b;\mathrm{R}}(t-s)\frac{\widehat{\alpha}^{\mathrm{LL}}_{b,K_{\mathrm{R}}}(t)}{\widehat{\alpha}^{\mathrm{LL}}_{b,K_{\mathrm{R}}}(s)}\left\{1-\xi_b(t)\right\} \right] dN(s). \tag{13}$$

5. Asymptotic theory

In this section we develop theory for the asymptotic behaviour of bandwidth selectors for the local linear hazard estimator in (1), and its multiplicative bias correction in (3). For each estimator we prove the asymptotic normality for bandwidths selectors based on cross-validation, the double one-sided cross-validation of Gámiz et al. (2016) and the new best one-sided cross-validation. Our theoretical results thus extend the results given in Gámiz et al. (2016), by including the new best one-sided cross-validation for local linear hazard estimator and considering its multiplicative bias correction.

Recall that the integrated squared error of a kernel hazard estimator, $\widehat{\alpha}_{b,L}$, with bandwidth b and kernel L, was defined as above as

$$\Delta_L(b) = n^{-1}\int_0^T \left\{\widehat{\alpha}_{b,L}(t)-\alpha(t)\right\}^2 w(t)Y(t)dt, \tag{14}$$

and its minimizer denoted as $\widehat{b}_{\mathrm{ISE},L}$. Hereafter we will make explicit reference to the considered hazard estimator using superscripts (LL for the local linear and MBC for the multiplicative bias correction). Besides a kernel denoted by K is assumed to be symmetric, while we use the notation L for a general kernel that can be asymmetric, as the one-sided kernels involved in double one-sided cross-validation and best one-sided cross-validation (see assumption A1 in Appendix A).

Let consider first the local linear hazard estimator, $\widehat{\alpha}^{\mathrm{LL}}_{b,L}$, given in (1). Following the same arguments described in Nielsen and Tanggaard (2001), the error $\widehat{\alpha}^{\mathrm{LL}}_{b,L}(t)-\alpha(t)$, can be decomposed as, $\widehat{\alpha}^{\mathrm{LL}}_{b,L}(t)-\alpha(t) = V^{\mathrm{LL}}_{b,L}(t)+B^{\mathrm{LL}}_{b,L}(t)$, where $B^{\mathrm{LL}}_{b,L}$ is a stable part converging in probability to zero,

$$B^{\mathrm{LL}}_{b,L} = \int_0^T \bar{L}_{t,b}(t-s)\left\{\alpha(s)-\alpha(t)\right\}Y(s)ds; \tag{15}$$

and $V^{\mathrm{LL}}_{b,L}$ is a variable part converging to a Normal distribution,

$$V^{\mathrm{LL}}_{b,L}(t) = \int_0^T \bar{L}_{t,b}(t-s)dM(s). \tag{16}$$

Using the above decomposition we can expand the integrated squared error for the local linear estimator, using standard martingale theory along with the approach of Mammen and Nielsen (2007). In Lemma 4 in the Supplementary Material we show that, under some regularity assumptions, $\Delta^{\mathrm{LL}}_L(b)$ in (14) is asymptotically equivalent to

$$M^{\mathrm{LL}}_L(b) = b^4\frac{\mu_2(\bar{L}^*)^2}{4}\int\left\{\alpha''(t)\right\}^2\gamma(t)w(t)dt + (nb)^{-1}R\left(\bar{L}^*\right)\int\alpha(t)w(t)dt,$$

where $\gamma(t) = n^{-1}E\left[Y(t)\right]$ is the expected exposure function. From this approximation a deterministic optimal bandwidth for the local linear estimator with kernel L is defined as

$$b^{\mathrm{LL}}_{\mathrm{MISE},L} = C^{\mathrm{LL}}_{0,L}n^{-1/5} \qquad \text{with} \qquad C^{\mathrm{LL}}_{0,L} = \left[\frac{R\left(\bar{L}^*\right)\int\alpha(t)w(t)dt}{\mu_2(\bar{L}^*)^2\int\left\{\alpha''(t)\right\}^2\gamma(t)w(t)dt}\right]^{1/5}. \tag{17}$$

Our main result in this section states the asymptotic normality of the three bandwidth estimates for the local linear hazard estimator, cross-validation, $\widehat{b}^{\mathrm{LL}}_{\mathrm{CV},K}$, double one-sided cross-validation, $\widehat{b}^{\mathrm{LL}}_{\mathrm{DO},K}$, and best one-sided cross-validation, $\widehat{b}^{\mathrm{LL}}_{\mathrm{BO},K}$; as well as the infeasible bandwidth $\widehat{b}^{\mathrm{LL}}_{\mathrm{MISE},K}$. Note that the latter is the optimal bandwidth targeted by plug-in bandwidth selection rules. The proof of the theorem is provided in the Supplementary Material.

Theorem 1 *Under assumptions A1–A3 in Appendix A, the bandwidth selectors, $\widehat{b}^{\mathrm{LL}}_{\mathrm{BO},K}$, $\widehat{b}^{\mathrm{LL}}_{\mathrm{DO},K}$,$\widehat{b}^{\mathrm{LL}}_{\mathrm{CV},K}$, and $\widehat{b}^{\mathrm{LL}}_{\mathrm{MISE},K}$, for the local linear estimator with kernel K satisfy*

$$\begin{aligned}
n^{3/10}\left(\widehat{b}^{\mathrm{LL}}_{\mathrm{BO},K}-\widehat{b}^{\mathrm{LL}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S^{\mathrm{LL}}_2+S^{\mathrm{LL}}_1\Psi^{\mathrm{LL}}_{\mathrm{BO},K}\right)\\
n^{3/10}\left(\widehat{b}^{\mathrm{LL}}_{\mathrm{DO},K}-\widehat{b}^{\mathrm{LL}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S^{\mathrm{LL}}_2+S^{\mathrm{LL}}_1\Psi^{\mathrm{LL}}_{\mathrm{DO},K}\right)\\
n^{3/10}\left(\widehat{b}^{\mathrm{LL}}_{\mathrm{CV},K}-\widehat{b}^{\mathrm{LL}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S^{\mathrm{LL}}_2+S^{\mathrm{LL}}_1\Psi^{\mathrm{LL}}_{\mathrm{CV},K}\right)\\
n^{3/10}\left(\widehat{b}^{\mathrm{LL}}_{\mathrm{MISE},K}-\widehat{b}^{\mathrm{LL}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S^{\mathrm{LL}}_2+S^{\mathrm{LL}}_1\Psi^{\mathrm{LL}}_{\mathrm{MISE},K}\right)
\end{aligned}$$

where

$$S^{\mathrm{LL}}_1 = \frac{1}{25}\frac{R(K)^{-7/5}\int\alpha^2(t)w^2(t)\,dt}{\mu_2(K)^{6/5}\left\{\int\alpha''(t)^2\gamma(t)w(t)\,dt\right\}^{3/5}\left\{\int\alpha(t)w(t)\,dt\right\}^{7/5}},$$

$$S^{\mathrm{LL}}_2 = \frac{4}{25}\frac{R(K)^{-2/5}\int\alpha''(t)^2\gamma(t)w^2(t)\alpha(t)\,dt}{\mu_2(K)^{6/5}\left\{\int\alpha(t)w(t)\,dt\right\}^{2/5}\left\{\int\alpha''(t)^2\gamma(t)w(t)\,dt\right\}^{8/5}},$$

and

$$\begin{aligned}
\Psi^{\mathrm{LL}}_{\mathrm{BO},K} &= \Psi^{\mathrm{LL}}_{\mathrm{DO},K} = \int\left\{\frac{R\left(K\right)}{R\left(\bar{L}^*\right)}\left(H_L-G_L\right)\left(\rho^{\mathrm{LL}}u\right)-H_K(u)\right\}^2 du,\\
\Psi^{\mathrm{LL}}_{\mathrm{CV},K} &= \int\left\{G_K(u)\right\}^2\,du,\\
\Psi^{\mathrm{LL}}_{\mathrm{MISE},K} &= \int\left\{H_K(u)\right\}^2\,du,
\end{aligned}$$

defining the functions $G_L(\cdot)$ and $H_L(\cdot)$ as

$$\begin{aligned}
G_L(w) &= I\left(w\neq 0\right)2\bar{L}^*_1(w),\\
H_L(w) &= I\left(w\neq 0\right)\int\bar{L}^*(u)\left\{\bar{L}^*_1(u+w)+\bar{L}^*_1(u-w)\right\}du,
\end{aligned}$$

where $\bar{L}^*_1(u) = -\bar{L}^*(u)-u\bar{L}^{*'}(u)$, with $L=K$ and $L=K_{\mathrm{L}}$.

Remark 2 *Gámiz et al. (2016) pointed out that all bandwidth estimates have similar asymptotics with the only difference of the factor $\Psi^{\mathrm{LL}}_{\cdot,K}$. These authors considered three*

Table 1: Comparison of asymptotic variances among bandwidth selectors. Factors $\Psi^{\bullet}_{\bullet,K}$ defined in Theorems 1 and 3, are shown for the local linear hazard estimator and its multiplicative bias correction, with three common symmetric kernels K: Epanechnikov, quartic and sextic.

	Local linear estimator			Multiplicative bias correction		
Method	Epanechnikov	Quartic	Sextic	Epanechnikov	Quartic	Sextic
BO-validation	1.09	0.95	1.18	4.41	2.44	2.05
DO-validation	1.09	0.95	1.18	4.41	2.44	2.05
Cross-validation	3.60	2.86	3.49	9.87	6.10	6.50
Plug-in	0.36	0.46	0.59	0.84	0.95	1.31

common choices of the kernel K (Epanechnikov, quartic and sextic kernels) and calculated the numerical value of this factor (multiplied by 2 for convenience in this former paper). It allows the comparison of the asymptotic performance of bandwidth selectors. These numerical values are reported in the first rows of Table 1, where now we have added the new best one-sided cross-validation. Notice that the actual values of S_1^{LL} and S_2^{LL} depend on the unknown hazard function α and its derivatives, but also on the exposure function γ, which are specific to the inference problem. In Appendix B.1 we have calculated the ratio of these two terms for one particular hazard model. The idea is to find out whether the discrepancy in the values of $\Psi^{\mathrm{LL}}_{\bullet,K}$ among bandwidth selectors shown in the table could be misleading in terms of the actual variances. For the considered model the term S_1^{LL} is almost a half of S_2^{LL}, both when exposure time goes zero and infinity. For the multiplicative bias corrected hazard estimator we will discuss in Remark 4 that the corresponding S_1 term can completely dominate the term S_2 in certain situations.

Consider now the multiplicative bias correction of the local linear hazard defined in (3), $\widehat{\alpha}^{\mathrm{MBC}}_{b,L}$, with bandwidth b and kernel L. As for the local linear estimator above, we define the corresponding integrated squared error for its multiplicative bias correction as in (14) and denote it as $\Delta_L^{\mathrm{MBC}}(b)$. We denote its minimizer as $\widehat{b}^{\mathrm{MBC}}_{\mathrm{ISE},L}$.

We consider the decomposition $\widehat{\alpha}^{\mathrm{MBC}}_{b,L}(t)-\alpha(t) = B^{\mathrm{MBC}}_{b,L}(t)+V^{\mathrm{MBC}}_{b,L}(t)$, where $B^{\mathrm{MBC}}_{b,L}(t)$ is a stable term converging in probability to zero, and $V^{\mathrm{MBC}}_{b,L}(t)$ is a variable term converging to a Normal distribution. These two terms are defined as follows:

$$V^{\mathrm{MBC}}_{b,L}(t) = \int f^{\mathrm{MBC}}_{t,b}(s) dM(s)$$

where

$$\begin{aligned} f^{\mathrm{MBC}}_{t,b}(s) &= \bar{L}^{\mathrm{MBC}}_{t,b}(t-s)\frac{\widehat{\alpha}^{\mathrm{LL}}_{b,L}(t)}{\widehat{\alpha}^{\mathrm{LL}}_{b,L}(s)} + \bar{L}_{t,b}(t-s) - \\ &\quad \int_0^T \bar{L}^{\mathrm{MBC}}_{t,b}(t-u)\frac{\widehat{\alpha}^{\mathrm{LL}}_{b,L}(t)}{\widehat{\alpha}^{\mathrm{LL}}_{b,L}(u)}\bar{L}_{u,b}(u-s)Y(u)du \end{aligned}$$

with $\bar{L}^{\mathrm{MBC}}_{t,b}(t-s)$ defined as in (4) for the kernel L,

and

$$\begin{aligned} B^{\mathrm{MBC}}_{b,L}(t) &= B^{\mathrm{LL}}_{b,L}(t) + \int \bar{L}^{\mathrm{MBC}}_{t,b}(t-s)\widehat{\alpha}^{\mathrm{LL}}_{b,L}(t)\left\{\widehat{\alpha}^{\mathrm{LL}}_{b,L}(s)\right\}^{-1} B^{\mathrm{LL}}_{b,L}(s)Y(s)ds \\ &= \int \bar{L}^{\mathrm{MBC}}_{t,b}(t-s)\widehat{\alpha}^{\mathrm{LL}}_{b,L}(t)\left\{\beta_{b,L}(t)-\beta_{b,L}(s)\right\}Y(s)ds, \end{aligned}$$

with $\beta_{b,L}(s) = \{\widehat{\alpha}^{\mathrm{LL}}_{b,L}(s)\}^{-1} B^{\mathrm{LL}}_{b,L}(s)$, where $B^{\mathrm{LL}}_{b,L}$ and $V^{\mathrm{LL}}_{b,L}$ are the stable and variable terms for the local linear estimator given in (15) and (16), respectively.

Using the above decomposition and derivations similar to the local linear case we can expand the integrated squared error of the multiplicative bias corrected estimator. In Lemma 7 in the Supplementary Material we show that, under some regularity assumptions, $\Delta_L^{\mathrm{MBC}}(b)$ is asymptotically equivalent to

$$M_L^{\mathrm{MBC}}(b) = b^8\frac{\mu_2(\bar{L}^*)^4}{16}\int h(t)^2\gamma(t)w(t)dt + (nb)^{-1}R\left(\Gamma_{\bar{L}^*}\right)\int \alpha(t)w(t)dt,$$

with $h(t) = \alpha(t)\left\{\alpha''(t)/\alpha(t)\right\}''$. From this approximation a deterministic optimal bandwidth for the multiplicative bias corrected estimator with kernel L is defined as

$$b^{\mathrm{MBC}}_{\mathrm{MISE,L}} = C^{\mathrm{MBC}}_{0,L}n^{-1/9}; \qquad C^{\mathrm{MBC}}_{0,L} = \left\{\frac{R\left(\Gamma_{\bar{L}^*}\right)\int \alpha(t)w(t)dt}{\frac{\mu_2(\bar{L}^*)^4}{2}\int h(t)^2\gamma(t)w(t)dt}\right\}^{1/9}, \tag{18}$$

where $\Gamma_{\bar{L}^*}(u) = 2\bar{L}^*(u) - \bar{L}^*(u) * \bar{L}^*(u)$ is the kernel obtained by twicing the equivalent kernel, $\bar{L}^*$, given in (7).

The following theorem states the asymptotic normality of the three bandwidth estimates, as well as the minimizer of the mean integrated squared error, for the multiplicative bias corrected hazard estimator with kernel K. The proof is provided in the Supplementary Material.

Theorem 3 *Under assumptions A1, A2' and A3', the bandwidth selectors $\widehat{b}^{\mathrm{MBC}}_{\mathrm{BO},K}$, $\widehat{b}^{\mathrm{MBC}}_{\mathrm{DO},K}$, $\widehat{b}^{\mathrm{MBC}}_{\mathrm{CV},K}$, and $\widehat{b}^{\mathrm{MBC}}_{\mathrm{MISE},K}$ satisfy*

$$\begin{aligned} n^{3/18}\left(\widehat{b}^{\mathrm{MBC}}_{\mathrm{BO},K} - \widehat{b}^{\mathrm{MBC}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S_2^{\mathrm{MBC}} + S_1^{\mathrm{MBC}}\Psi^{\mathrm{MBC}}_{\mathrm{BO},K}\right) \\ n^{3/18}\left(\widehat{b}^{\mathrm{MBC}}_{\mathrm{DO},K} - \widehat{b}^{\mathrm{MBC}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S_2^{\mathrm{MBC}} + S_1^{\mathrm{MBC}}\Psi^{\mathrm{MBC}}_{\mathrm{DO},K}\right) \\ n^{3/18}\left(\widehat{b}^{\mathrm{MBC}}_{\mathrm{CV},K} - \widehat{b}^{\mathrm{MBC}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S_2^{\mathrm{MBC}} + S_1^{\mathrm{MBC}}\Psi^{\mathrm{MBC}}_{\mathrm{CV},K}\right) \\ n^{3/18}\left(\widehat{b}^{\mathrm{MBC}}_{\mathrm{MISE},K} - \widehat{b}^{\mathrm{MBC}}_{\mathrm{ISE},K}\right) &\longrightarrow N\left(0, S_2^{\mathrm{MBC}} + S_1^{\mathrm{MBC}}\Psi^{\mathrm{MBC}}_{\mathrm{MISE},K}\right) \end{aligned}$$

where

$$S_1^{\mathrm{MBC}} = \frac{2^{1/3}}{9^2}\frac{R\left(\Gamma_K\right)^{-5/6}\int \alpha(t)^2w(t)^2\ dt}{\mu_2(K)^{4/3}\left\{\int h(t)^2\gamma(t)w(t)\ dt\right\}^{1/3}\left\{\int \alpha(t)w(t)\ dt\right\}^{5/3}},$$

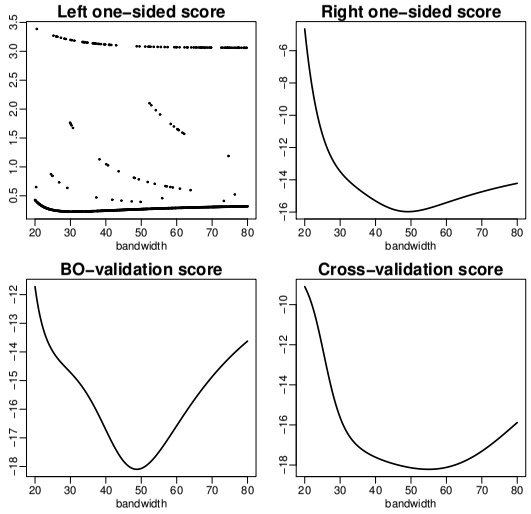
$$S_2^{\mathrm{MBC}} = \frac{2^{10/3}}{9^2}\frac{R\left(\Gamma_K\right)^{-2/3}\int h(t)^2\gamma(t)w(t)^2\alpha(t)\ dt}{\mu_2(K)^{4/3}\left\{\int \alpha(t)w(t)\ dt\right\}^{2/3}\left\{\int h(t)^2\gamma(t)w(t)\ dt\right\}^{4/3}},$$

with

$$\begin{aligned}\Psi^{\mathrm{MBC}}_{\mathrm{BO},K} &= \Psi^{\mathrm{MBC}}_{\mathrm{DO},K} = \int \left\{ \frac{R\left(\Gamma_K\right)}{R\left(\Gamma_{\tilde{L}^*}\right)} \left(H_{\Gamma_{\tilde{L}^*}} - G_{\Gamma_{\tilde{L}^*}}\right)\left(\rho^{\mathrm{MBC}} u\right) - H_{\Gamma_K}(u) \right\}^2 du, \\ \Psi^{\mathrm{MBC}}_{\mathrm{CV},K} &= \int \left\{G_{\Gamma_K}(u)\right\}^2 du, \\ \Psi^{\mathrm{MBC}}_{\mathrm{MISE},K} &= \int \left\{H_{\Gamma_K}(u)\right\}^2 du.\end{aligned}$$

where the functions $G_L(\cdot)$ and $H_L(\cdot)$ are defined as in Theorem 1, with $L = \Gamma_K$ and $L = \Gamma_{\tilde{L}^*}$, defined above.

Remark 4 *The result above shows that all bandwidth selectors have similar asymptotics with the only difference of the factor $\Psi^{\mathrm{MBC}}_{\cdot,K}$. A similar conclusion was derived for the local linear estimator. The three last columns of Table 1 show the value of this factor for three common choices of K. As for the local linear estimator we have calculated the ratio $S_1^{\mathrm{MBC}}/S_2^{\mathrm{MBC}}$ for a particular hazard model, the results are shown in Appendix B.2. In this case the term S_1^{MBC}, relative to the term S_2^{MBC}, is negligible when exposure time goes to zero, but dominates completely (infinite times bigger) when exposure time goes to infinity.*



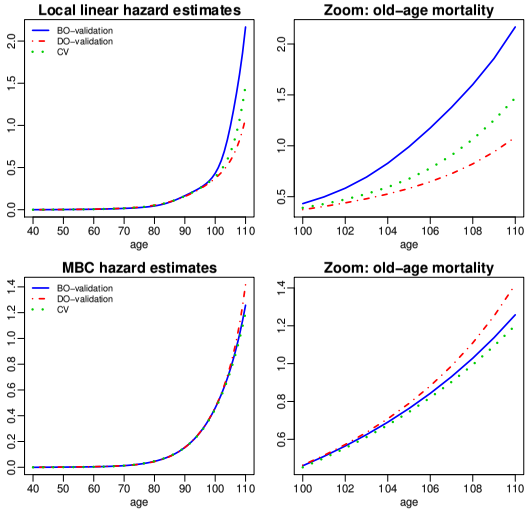
6. Applications

6.1. Old-age mortality

Our first application is on fitting hazard mortality curves for old-age population. We consider mortality data of women in Iceland in the calendar year 2006, with ages from 40 to 110. The same data were considered by Gámiz et al. (2016) and are available in the `DOvalidation` R-package (Gámiz et al., 2017). This package provides also functions implementing the hazard estimators and the bandwidth selection methods described above. The data were obtained from the Human Mortality Database and consist of aggregated yearly occurrences and exposures. Gámiz et al. (2016) showed that estimating the hazard from these data is challenge at the oldest ages. The lack of exposure at the right end and the few observed deaths induce a marked boundary effect precisely in the area of interest, the old ages. For these data we have calculated the two hazard estimators described in this paper, local linear and its multiplicative bias correction, using three bandwidth selectors: cross-validation, double one-sided cross-validation and the new best one-sided cross-validation. The cross-validation scores involved in these methods have been defined using a weighting function such that $w(s)Y(s) \equiv 1$, so all points in the time interval where the hazard function is estimated are evaluated with the same weight. This is different from Gámiz et al. (2016) where the weighting function was chosen so only areas where the exposure is significant contribute to the criteria. Notice that this makes an important difference in this data set where the end of the time interval comprises almost no exposure.

Before looking at the resulting hazard estimates we shall look at the cross-validation scores to be minimized for each bandwidth selection method. Figure 1 shows the cross-validated scores for each method considering the multiplicative bias corrected estimator. The local linear case looks quite similar and can be found in the Supplementary Material. From these plots we can see that the left one-sided score is not well behaved for both

Figure 1: Mortality data: bandwidth selection scores with multiplicative bias corrected hazard estimator.



hazard estimators. Therefore the average DO-validated bandwidth becomes unreliable, even though the obtained values seem to be sensible ($\widehat{b}_{\mathrm{DO}} = 27.3$ for the local linear estimator and $\widehat{b}_{\mathrm{DO}} = 40$ for its multiplicative bias correction). On the other hand the best one-sided cross-validation method shows a clear minimum in both cases and, as expected, it moves close to the one-sided cross-validated bandwidth that is working fine (the right side in this case). Best one-sided cross-validation in this case has been calculated using the exposure process, that is, for each time t we use the function $\xi_b^E(t)$ given in (11). However the results are quite similar using the occurrence process instead. Figure 2 shows the resulting hazard estimates from each method and type of hazard estimate. Note from these plots that the multiplicative bias corrected hazard is more robust to the bandwidth choice than the local linear. Also the new best one-sided cross-validation method seems to provide a reasonable estimate for old-age mortality in both cases.

6.2. Prediction of outstanding liabilities in non-life insurance

We consider now a non-standard forecasting problem that arises in non-life insurance. The goal is to forecast the number of future claims from contracts underwritten in the past, which have not yet been reported. Typically actuaries are responsible of getting these forecasts, which represent perhaps the most important number in the accounts of the company (see

Figure 2: Comparison of hazard estimates from female mortality data in Iceland.

Martínez-Miranda et al. (2013) for a detailed background of this problem). Here we analyse a data set of reported and outstanding claims from a motor business in UK. The same data set was previously considered by Martínez-Miranda et al. (2013) and consists of $n = 1558$ large claims reported between January 1990 and March 2012. From a statistical perspective the data could be described as a sample $\{(X_1, Z_1), \ldots, (X_n, Z_n)\}$, where X_i denotes the underwriting date of the ith claim, and Z_i the corresponding reporting delay, this is, the time between the underwriting date and the reporting date of the claim. The sample is right truncated since it can be observed only those claims for which the underwriting time plus the reporting delay is not greater than the calendar time of data collection. Hence data exist on a triangle with $X_i + Z_i \leq 31$ March 2012, and $X_i + Z_i$ represents the calendar time. The aim is to forecast the mass of the unobserved, future triangle, where $X_i + Z_i > 31$ March 2012, which corresponds to the number of claims underwritten in the past which have not been reported yet. The problem is formulated assuming that the maximum reporting delay is 267 months, in the actuarial literature this assumption is described as the triangle is fully run off. Another challenge of the data set for this problem is that the data are only available in an aggregated way. This is a common feature of this kind of data in the reserving departments of the insurance companies. This means that the available observations are counts living in a triangle of dimension 267×267. Specifically for our data set the triangle has entries $\mathcal{N}_{x,z} = \sum_{i=1}^{n} I(X_i = x,\ Z_i = z)$, with $x, z \in \{1, \ldots, 267\}$, describing the number of claims underwritten in the xth month and reported in the zth month.

Martínez-Miranda et al. (2013) showed that a multiplicative structured density model, $f(x, z) = f_1(x)f_2(z)$, can be used to forecast the claims where the components f_1 and f_2 are the underwriting time density and the reporting time density, respectively. The assumption of a multiplicative density means that the reporting delay does not depend on the underwriting date. Using the counting process formulation considered in this paper, Hiabu et al. (2016) solved the forecasting problem estimating the two density components using a time-reversal approach. Data are transformed to the time reversed scale so the right-truncation problem is replaced by the more tractable left-truncation. Using the same time-reversal approach, we now use the hazard estimation methods presented in the previous sections to estimate the backward hazard functions corresponding to the two components, underwriting (α_1) and reporting delay (α_2). From these hazard estimates the density component estimates can be derived multiplying by respective estimators of the survival functions.

From the above description we solve the forecasting problem considering both local linear hazard estimator and its multiplicative bias correction. For each hazard component, the bandwidth parameters for these estimators have been estimated using cross-validation, double one-sided cross-validation and best one-sided cross-validation. In the three cases we use weighting functions for the involved cross-validation scores that are appropriate for the forecasting problem. Specifically, following the discussion in Hiabu et al. (2016), to estimate α_1 we consider weights $w_1(t) = \widehat{S}_1^2(t)\left\{1 - \widehat{S}_2(t)\right\}^2 / Y_1(t)$, where $\widehat{S}_1$ and $\widehat{S}_2$ are estimators of the survival functions of each component (underwriting time and the reporting time delay) on the reversed time scale; and $Y_1(t)$ is the risk process for the first component. In a similar way we define the weights to estimate α_2. As in the mortality study best one-sided cross-validation has been calculated using the exposure process.

Figure 3 shows the forecasts of the number of claims reported in the future calendar months. Table 2 shows these forecasts aggregated in years. The forecasts are given for each hazard estimator and bandwidth estimate. We have also included the forecasts derived from the chain ladder method, which involves histogram type estimators of the underwriting and reporting density components. The chain ladder method is the classical approach used in the insurance companies (see Martínez-Miranda et al. (2013) for more details about this approach). The plot of the forecasts shows that the classical insurance method chain ladder is overestimating the liabilities, while the kernel hazard methods provide lower forecasts. Previous empirical analyses with these data described in Martínez-Miranda et al. (2013) agree with this result and recommend multiplicative bias corrected local linear estimators for this kind of data. Looking at the results from the kernel estimators we can see that double one-sided cross-validation and best one-sided cross-validation provide similar forecasts when the local linear estimator is considered, but the results are quite different for the multiplicative bias corrected estimator. The predicted total number of claims using double one-sided cross-validated bandwidth is about 299, compared to 313 using best one-sided cross-validation. Our concern is that double one-sided cross-validation might not be behaving properly in this situation. A close inspection to the cross-validation scores that are minimized to derive these bandwidth estimates reveals what is happening. Figures 4 and 5 show these cross-validation scores when the multiplicative bias corrected estimator is considered for both underwriting and reporting delay components. From these plots we can see that the right one-sided score completely breaks down for the underwriting time compo-

Table 2: Forecasts of the number of claims to be reported in the future calendar years.

Year	CLM	LL-CV	LL-DO	LL-BO	MBC-CV	MBC-DO	MBC-BO

nent, exhibiting several local minima. For the reporting delay component the score function continues decreasing as the value of the bandwidth increases, so it reaches the minimum at the upper limit of the search interval of bandwidths. The left one-sided score behaves more reasonably for the underwriting component but again breaks down for the reporting delay component. This means that one shouldn't trust the double one-sided cross-validation bandwidth derived from these two one-sided criteria, even though the derived estimates in this case turned to be reasonable values, $\widehat{b}_{\mathrm{DO}} = 55.8$ for the underwriting time, and $\widehat{b}_{\mathrm{DO}} = 31.6$ for the delay. On the contrary, the new best one-sided cross-validation method provides bandwidth estimates of $\widehat{b}_{\mathrm{BO}} = 43.4$ for the underwriting time and $\widehat{b}_{\mathrm{BO}} = 11.8$ for the delay, exhibiting well-behaved minimization scores as shown in Figure 4. Regarding to the cross-validation method it exhibits a rather flat score in the underwriting component leading to the large bandwidth estimate of $\widehat{b}_{\mathrm{CV}} = 63.5$, and a value of $\widehat{b}_{\mathrm{CV}} = 11.6$ for the delay that is close to the best one-sided cross-validated bandwidth. The impact of the cross-validated bandwidths on the forecasts is moderated, about 309 predicted claims compared to the 313 from best one-sided cross-validation. We have performed the same inspection with the local linear estimators. These plots can be seen in the Supplementary Material. The picture is again quite similar showing a poor performance of double one-sided cross-validation, however the impact on the forecasts in this case is not substantial. The total number predicted from cross-validation is about 293, compared to 295 from double one-sided cross-validation and 298 for best one-sided cross-validation.

7. Finite sample performance

In this section we investigate the finite sample performance of the new best one-sided cross-validation method for the local linear hazard estimator and its multiplicative bias correction. We have considered the same five hazard models described in Gámiz et al. (2016) (see also

Figure 3: Number of outstanding claims forecast using the local linear estimator and its multiplicative bias correction.

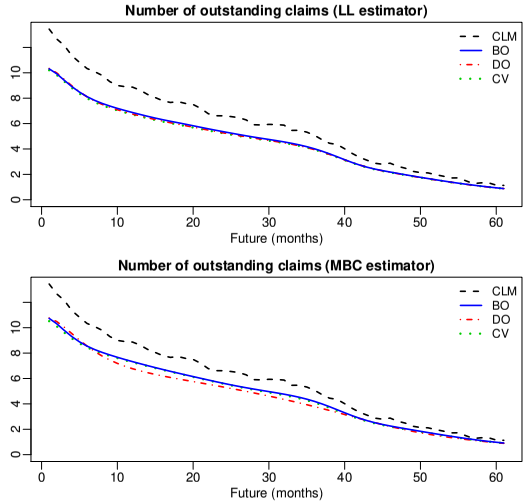

Figure 4: Underwriting component: bandwidth selection scores with multiplicative bias corrected hazard estimator.

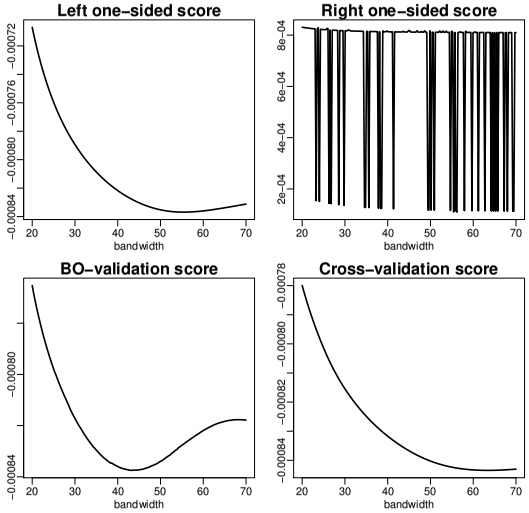

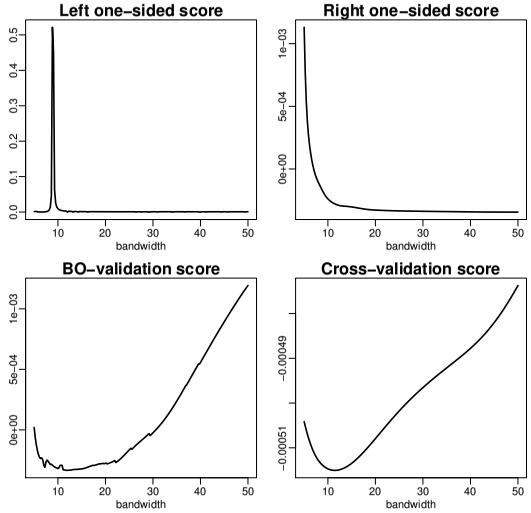

Figure 5: Reporting delay component: bandwidth selection scores with multiplicative bias corrected estimator.

Supplementary Material). The first four models consist of mixtures of Beta densities. Model 5 shows an exponential increase common in hazard mortality rates as those described in the first case study of Section 6. From each model we have simulated samples with three different sample sizes and two sampling schemes, right censoring with and without left truncation. For models 1 to 4 we have considered sample sizes $n = 100, 1000, 10000$, and for model 5, $n = 50000, 75000, 100000$. The number of Monte Carlo replications for each case has been always 500. We use the same mechanism to simulate data as in Gámiz et al. (2016). It generates data in aggregated form (number of occurrences and exposure) for an equally-spaced grid of size R defined on the time interval, and always produces right censored samples. For models 1 to 4 the time interval is $(0, 1)$ and we have defined the grid length with $\delta_R = 1/(R + 1)$. For model 5 time lies in the interval $(40, 110)$ and we have defined the grid length with $\delta_R = 70/(R + 1)$. The grid size has been chosen equal to $R = 500$ in both cases. We shall denote the grid points by t_r $(r = 1, \ldots, R)$. In the case of samples without left truncation, for a sample of n individuals, the number of occurrences at time t_r, denoted as O_r, have been generated from the binomial distribution $Bi\{Y_r, \alpha(t_r)\delta_R\}$, for $r = 1, \ldots, R$. Here Y_r denotes the size of the risk set at the beginning of the rth interval of the grid. The total number of simulated occurrences does not sum to n. Some of the simulated individuals are finally right censored, because they are still at risk at the end of the interval. Therefore our simulated sample are right censored and the censoring rates are around 20–30% for all models. When adding left truncation, independent truncation times are generated from the Uniform distribution.

From the simulated aggregated data we have calculated the local linear hazard estimator and its multiplicative bias correction using the sextic kernel: $K(x) = 3003/2048(1 - x^2)^6 I(-1 < x < 1)$, as in the two data analyses above. For each hazard estimator we have compared the best one-sided cross-validated bandwidth with cross-validation and double one-sided cross-validation. The performance of the bandwidth estimates have been analysed with respect to the (Monte Carlo approximated) mean integrated squared error of the resulting kernel hazard estimator. We shall refer to this performance measure as empirical MISE, denoted as $m_1(\widehat{b})$, for each bandwidth estimate $\widehat{b}$. As benchmarks in our analysis we have considered two infeasible optimal bandwidths: the bandwidth minimizing the integrated squared error criterion, $\widehat{b}_{\text{ISE}}$, and the bandwidth minimizing the empirical MISE. To compute all bandwidth estimates we have considered grids of 100 equally spaced bandwidth values chosen around $\widehat{b}_{\text{ISE}}$, for each model and sample size. All criteria have been defined using a weighting function such that $w(s)Y(s) \equiv 1$, so all points in the time interval where the hazard function is estimated are evaluated with the same weight. As we pointed out in our first case study this is different from Gámiz et al. (2016), and it makes an important difference in models such as Model 5 where the end of the time interval comprises almost no exposure.

Table 3 summarizes the simulation results in the case of samples with right censoring and left truncation. In this table bandwidth estimates are compared according to measure m_1. For convenience we report a relative measure to indicate when best one-sided cross-validation outperforms cross-validation. The relative measure is defined as:

$$Rerr(BO) = \left\{ m_1(\widehat{b}_{\text{CV}}) - m_1(\widehat{b}_{\text{ISE}}) \right\} / \left\{ m_1(\widehat{b}_{\text{BO}}) - m_1(\widehat{b}_{\text{ISE}}) \right\}. \tag{19}$$

With this definition values of $Rerr(BO)$ above 1 indicate that best one-sided cross-validation outperforms cross-validation. An analogous relative measure, $Rerr(DO)$, has been defined for double one-sided cross-validation. Notice that $Rerr(BO)$ greater than $Rerr(DO)$ indicates that best one-sided cross-validation outperforms double one-sided cross-validation. An overall view of the numbers in the table confirms that best one-sided cross-validation for the multiplicative hazard estimator always outperforms cross-validation, exhibiting $Rerr(BO)$ values above 1, and double one-sided cross-validation for all models except for few cases, where double one-sided cross-validation provides slightly lower empirical MISE values. The results for the local linear estimator show that double one-sided cross-validation and best one-sided cross-validation behave quite similarly, both outperforming in general cross-validation. The case of samples without left truncation is shown in Table 4. It brings similar conclusions though in this case best one-sided cross-validation is beaten by double one-sided cross-validation for Model 5. This case deserves a deeper analysis and it is shown in Table 5. In this table we have shown the empirical MISE defined above and denoted by $m_1(\widehat{b})$, for each bandwidth estimate $\widehat{b}$, as well as the average of the bandwidth estimates for all the samples $(avg(\widehat{b}))$, and we have included the left and right one-sided cross-validated bandwidths, from which double one-sided cross-validation is derived. From these results we can clearly see that the left one-sided bandwidth completely breaks down, for all sample sizes and both hazard estimators, while the right side behaves well (notice the large values of the empirical MISE for the left one-sided bandwidth in contrast with those values for the right one-sided bandwidth). The average of the left and right one-sided bandwidths (which double one-sided cross-validation performs) seems to be hiding the problem of the left side, and sometimes it even provides quite reasonable values. Notice that the double one-sided bandwidths are on average closer to the best ISE-optimal bandwidths than the best one-sided cross-validation for the multiplicative bias corrected estimator. However this happens because the double one-sided bandwidth is the average of a small left one-sided bandwidth and a large right one-sided bandwidth. On the other hand best one-sided cross-validation is behaving as the best of the two sides, as we would expect. A similar picture can be seen when analysing the behaviour of double one-sided cross-validation for Model 4 in the case of truncated samples (the full simulation results are provided in the Supplementary Material).

In summary, the simulation results indicate that best-one sided cross-validation and double one-sided cross-validation do better than one-sided cross-validation (that sometimes breaks down) and standard cross-validation. However, it is not always which one is the better of best one-sided cross-validation or double one-sided cross-validation. We suggest to try out both best one-sided and double one-sided cross-validation in any empirical study.

8. Discussion

The overall conclusion of our finite sample section is that double one-sided cross-validation and best one-sided cross-validation are better than standard cross-validation, however, there is no clear winner between double one-sided cross-validation and best one-sided cross-validation. In practice we would suggest to consider both. It is also concluded that the multiplicative bias corrected local linear hazard estimator is more often than not better than the simpler local linear hazard estimator. There is a tendency that double one-sided cross validation is better than best one-sided cross-validation for the simple local linear case,

while the performance is vice versa when using the multiplicative kernel hazard estimation. The exception from this rule seems to be our finite sample study in Table 5 inspired by our real-life mortality data.

In Appendix B we have studied how big the second noise component (the one that is improved by our new bandwidth selectors) is compared to the first noise component in the bandwidth selection (the one that is same across all the bandwidth selectors). Using our real-life mortality data as inspiration, we investigate a simple version of a Gomperz-Makeham shaped hazard and conclude that for the local linear hazard the second variance component is almost a half of the first component, both when exposure time goes zero and infinity. This picture is very different for the multiplicative hazard estimator, where the second variance component is negligible when exposure time goes to zero, but dominates completely (infinite times bigger) when exposure time goes to infinity. One can in other words get all kinds of relationships between the second variance component and first variance component. This calls for more research, but it seems already clear that there will be many situations, where we cannot rely on simple cross-validation (not to mention less efficient training-and-learning algorithms), because cross-validation has a very high second variance component and that second variance component will occasionally dominate completely the smoothing selection problem. We believe our findings to be relevant for machine learning, big data and artificial intelligence in general, where over-reliance of simple training-and-learning or cross-validation might lead to false-discoveries because of the noise involved. Methods such as double one-sided cross-validation, best one-sided cross-validation, or other improved smoothing procedures dampening the second noise component, therefore seem to be a very important element of future research in machine learning and related fields.

9. Conclusion

We have proposed a new bandwidth selection method for local linear hazard estimation and its multiplicative bias correction. Our proposal is called best one-sided cross-validation and consists of an improvement of the double one-sided cross-validation of Gámiz et al. (2016). Best one-sided cross-validation solves the lack of stability of double one-sided cross-validation in practice via a local information principle.

Our empirical studies show that best one-sided cross-validation provides a good strategy for bandwidth selection for both local linear and multiplicative bias corrected hazard estimators. Best one-sided cross-validation inherits the good properties of one-sided cross-validation while avoiding the stability problems that double one-sided cross-validation sometimes faces. The current algorithm is only about optimisation of statistical inference. However, it could be also interesting to consider computational performance, see for example Kapotufe and Verma (2017).

Detailed mathematical theory at the level of Hall and Marron (1987) and Gámiz et al. (2016) is included. This type of theory is completely novel for the multiplicative bias corrected hazard estimators. Theory on best one-sided cross-validation introduced in this paper is of course also new for the local linear hazard estimator.

Appendix A. Assumptions for asymptotic theory

Assumption A1. The kernels K and L are compactly supported (i.e. the support is contained in $[-C_K, C_K]$ for some constants $C_K > 0$). The kernels are continuous on $\mathbb{R}\backslash\{0\}$ and have one-sided derivatives that are Hölder continuous on $\mathbb{R}^- = \{x : x < 0\}$ and $\mathbb{R}^+ = \{x : x > 0\}$, that is there exist constants c and d such that $|\phi(x) - \phi(y)| \leq c|x - y|^d$ for $x, y < 0$ or $x, y > 0$ with ϕ equal to K' or L'. The left- and right-sided derivatives differ at most on a finite set. The kernel K is symmetric.

Assumption A2. For the expected exposure function $\gamma(t) = n^{-1}E\{Y(t)\}$ it holds that $\gamma \in C_2([0,T])$, that it is strictly positive for $t \in [0,T]$, and that

$$\begin{aligned}\sup_{s\in[0,T]} |Y(s)/n - \gamma(s)| &= o_P\left\{(\log n)^{-1}\right\},\\ \sup_{s,t\in[0,T],|t-s|\leq C_K b} |\{Y(t) - Y(s)\}/n - \{\gamma(t) - \gamma(s)\}| &= o_P\left\{(nb\log n)^{-1/2}\right\},\end{aligned}$$

where the constant C_K is defined in assumption A1.

Assumption A2'. Same conditions as in assumption A2 but replacing $o_P\left\{(nb\log n)^{-1/2}\right\}$ with $o_P\left\{(nb)^{-1}\right\}$

Assumption A3. It holds that $\alpha \in C_2([0,T])$, $w \in C_1([0,T])$. The second derivative of α is Hölder continuous with exponent $d > 0$.

Assumption A3'. Same conditions as in assumption A3 but $\alpha \in C_4([0,T])$ and its fourth derivative is Hölder continuous.

Appendix B. Evaluation of the common variance terms

In Section 5 we compare bandwidth selectors by their asymptotic variances which are of the form $S_2 + S_1\Psi$, where Ψ is a factor that differs among bandwidth selectors, while the terms S_1 and S_2 are common for all of them. For both the local linear and the multiplicative biased corrected hazards, the factor Ψ only depends on the chosen kernels so we have evaluated it for some common choices in Table 1. The terms terms S_1 and S_2 however depend on the hazard function α, the exposure function γ and the weighting function w. Here we evaluate the ratio S_1/S_2 for the two hazard estimators, considering a specific choice for these functions. We consider a hazard function of the form $\alpha(t) = \lambda + c\exp(\beta t)$, where λ, c and β are constants. This hazard specification characterizes the Gompertz-Makeham law of mortality, where the empirical magnitudes for the parameters β and c are about 0.085 and 3×10^{31}, respectively. For the weighting function we consider the case $w(t) \equiv 1$, and for the exposure function the case $\gamma(t) = 1_{\{0\leq t\leq T\}}$, for $T > 0$.

B.1. Local linear estimator

For the local linear hazard estimators the terms S_1 and S_2 are given by

$$S_1^{\mathrm{LL}} = \frac{1}{25}\frac{R(K)^{-7/5}\int \alpha^2(t)w^2(t)\,dt}{\mu_2(K)^{6/5}\left\{\int \alpha''(t)^2\gamma(t)w(t)\,dt\right\}^{3/5}\left\{\int \alpha(t)w(t)\,dt\right\}^{7/5}},$$

$$S_2^{\mathrm{LL}} = \frac{4}{25}\frac{R(K)^{-2/5}\int \alpha''(t)^2\gamma(t)w^2(t)\alpha(t)\,dt}{\mu_2(K)^{6/5}\left\{\int \alpha(t)w(t)\,dt\right\}^{2/5}\left\{\int \alpha''(t)^2\gamma(t)w(t)\,dt\right\}^{8/5}},$$

The ratio $R^{\mathrm{LL}} = S_1^{\mathrm{LL}}/S_2^{\mathrm{LL}}$, for $\gamma(t) = 1_{\{0\leq t\leq T\}}$ and $w(t) \equiv 1$, is given by

$$R^{\mathrm{LL}} = \frac{S_1^{\mathrm{LL}}}{S_2^{\mathrm{LL}}} = \frac{1}{4R(K)}\frac{\int_0^T \alpha^2(t)\,dt\int_0^T \alpha''(t)^2\,dt}{\int_0^T \alpha(t)\,dt\int_0^T \alpha''(t)^2\alpha(t)\,dt}$$

For the choice $\alpha(t) = \lambda + c\exp(\beta t)$ the above integrals become

$$\begin{aligned}\int_0^T \alpha(t)\,dt &= \frac{c}{\beta}\left(\exp(\beta T) - 1\right) + \lambda T\\ \int_0^T \alpha(t)^2\,dt &= \frac{c^2}{2\beta}\left(\exp(2\beta T) - 1\right) + \lambda^2 T + \frac{2\lambda c}{\beta}\left(\exp(\beta T) - 1\right)\end{aligned}$$

$$\int_0^T \alpha''(t)^2\ dt = \frac{c^2\beta^3}{2}\left(\exp(2\beta T)-1\right)$$
$$\int_0^T \alpha''(t)^2\alpha(t)\ dt = \frac{c^3\beta^3}{3}\left(\exp(3\beta T)-1\right)+\frac{\lambda c^2\beta^3}{2}\left(\exp(2\beta T)-1\right)$$

We substitute these results in the expression of R^{LL} and take limits for $T\to\infty$. We only look at the leading terms in the numerator and the denominator (that is $\exp(4\beta T)$) and we get that $R_{LL}\to 3/(16R(K))$, as $T\to\infty$. For the Epanechnikov kernels the limit is $5/16$. Notice that the limit at zero is $R_{LL}\to(4R(K))^{-1}$, which takes the value $5/12$ for the Epanechnikov kernel.

B.2. Multiplicative bias corrected estimator

For the multiplicative bias corrected estimator the terms are

$$S_1^{\mathrm{MBC}} = \frac{2^{1/3}}{9^2}\frac{R\left(\Gamma_K\right)^{-5/6}\int\alpha(t)^2w(t)^2\ dt}{\mu_2(K)^{4/3}\left\{\int h(t)^2\gamma(t)w(t)\ dt\right\}^{1/3}\left\{\int\alpha(t)w(t)\ dt\right\}^{5/3}},$$

$$S_2^{\mathrm{MBC}} = \frac{2^{10/3}}{9^2}\frac{R\left(\Gamma_K\right)^{-2/3}\int h(t)^2\gamma(t)w(t)^2\alpha(t)\ dt}{\mu_2(K)^{4/3}\left\{\int\alpha(t)w(t)\ dt\right\}^{2/3}\left\{\int h(t)^2\gamma(t)w(t)\ dt\right\}^{4/3}},$$

where $h(t)=\alpha(t)(\alpha''(t)/\alpha(t))''$.

We compute the ratio $R^{\mathrm{MBC}}=S_1^{\mathrm{MBC}}/S_2^{\mathrm{MBC}}$ for the same choice of γ and w as before. It yields to the following expression

$$R^{\mathrm{MBC}}=\frac{S_1^{\mathrm{MBC}}}{S_2^{\mathrm{MBC}}} = \frac{1}{8R(\Gamma_K)^{1/6}}\frac{\int_0^T\alpha^2(t)\ dt\int_0^T h(t)^2\ dt}{\int_0^T\alpha(t)\ dt\int_0^T h(t)^2\alpha(t)\ dt}$$

For the choice $\alpha(t)=\lambda+c\exp(\beta t)$ the calculations are as follows:

$$\int_0^T\alpha(t)\ dt = \frac{c}{\beta}\left(\exp(\beta T)-1\right)+\lambda T$$
$$\int_0^T\alpha(t)^2\ dt = \frac{c^2}{2\beta}\left(\exp(2\beta T)-1\right)+\lambda^2T+\frac{2\lambda c}{\beta}\left(\exp(\beta T)-1\right)$$

$$\begin{aligned}\int_0^T h^2(t)dt &= \int_{\lambda+c}^{\lambda+c\exp(\beta T)} c\beta^7\lambda^2\frac{e^{\beta t}}{y^4}(2\lambda-y)^2dy=\int_{\lambda+c}^{\lambda+c\exp(\beta T)}\beta^7\lambda\frac{y-\lambda}{y^4}(2\lambda-y)^2dy\\ &= \int_{\lambda+c}^{\lambda+c\exp(\beta T)}\beta^7\lambda^2\left(\frac{8}{y^3}\lambda^2-\frac{4}{y^4}\lambda^3-\frac{5}{y^2}\lambda+\frac{1}{y}\right)dy\\ &= \beta^7\lambda^2\left[\frac{4\lambda^3}{3y^3}-\frac{4\lambda^2}{y^2}+5\frac{\lambda}{y}+\ln y\right]_{y=\lambda+c}^{y=\lambda+c\exp(\beta T)}.\end{aligned}$$

Here

$$h(t) = \alpha(t)\left(\frac{d^2}{dt^2}\left(\alpha''(t)/\alpha(t)\right)\right)=c\beta^4\lambda\frac{e^{t\beta}}{\left(\lambda+ce^{t\beta}\right)^2}\left(\lambda-ce^{t\beta}\right),$$

and we have made the change of variable $y=\alpha(t)$, $dy=c\beta e^{\beta t}dt=\beta(y-\lambda)\ dt$. Similarly

$$\begin{aligned}\int_0^T h^2(t)\alpha(t)\ dt &= \int_{\lambda+c}^{\lambda+c\exp(\beta T)} c\beta^7\lambda^2\frac{e^{\beta t}}{y^3}(2\lambda-y)^2dy=\int_{\lambda+c}^{\lambda+c\exp(\beta T)}\beta^7\lambda\frac{y-\lambda}{y^3}(2\lambda-y)^2dy\\ &= \int_{\lambda+c}^{\lambda+c\exp(\beta T)}\beta^7\lambda^2\left(\frac{8}{y^2}\lambda^2-\frac{4}{y^3}\lambda^3-\frac{5}{y}\lambda+1\right)dy\\ &= \beta^7\lambda^2\left[\frac{2\lambda^3}{y^2}-\frac{8\lambda^2}{y}-5\lambda\ln(y)+y\right]_{y=\lambda+c}^{y=\lambda+c\exp(\beta T)}\end{aligned}$$

We then substitute the above results in the expression of R^{MBC} and take limits for $T\to\infty$. To this goal we only look at the leading terms in the numerator and the denominator and we get that $R_{MBC}\to\infty$ as $T\to\infty$. And the ratio increases to ∞ as $\log(\lambda+c\exp(\beta T))$, this is, at the linear rate βT. The limit for $T\to 0$ is $(8R(\Gamma_K))^{-1/6}$, which for the Epanechnikov kernel is about 0.13.

Abstract

As the data sets increase in size, the process of manually labeling data becomes unfeasible by small groups of experts. Thus, it is common to rely on crowdsourcing platforms which provide inexpensive, but noisy, labels. Although implementations of algorithms to tackle this problem exist, none of them focus on scalability, limiting the area of application to relatively small data sets. In this paper, we present `spark-crowd`, an Apache Spark package for learning from crowdsourced data with scalability in mind.

Keywords: crowdsourcing, crowdsourced data, learning from crowds, big data, multiple noisy labeling, spark

1. Introduction

With the recent appearance of crowdsourcing platforms such as Amazon Mechanical Turk, several researchers have expressed their interest in taking advantage of them to increase the efficiency and scope of their research (Snow et al. 2008). Thanks to these platforms, problems that would be too expensive to tackle using traditional methods have now become easier and, at the same time, tasks which were not feasible become tractable.

However, the use of crowdsourcing in the field of Machine Learning is not without problems. The most important of them is the considerable uncertainty associated with members of the group providing the annotations in the process of data acquisition. Some of them may be better qualified for the task than others; some may give useless information or even try to ruin the results. After this process, the practitioner receives a data set of tuples $(example, annotator, annotation)$. With these, the problem usually consists in estimating the ground truth for each instance using the annotations obtained. As the annotator's quality is unknown, it is also common to want an estimation of the quality of each annotator. Thus, to obtain good results with crowdsourced data, the machine learning process needs to take into account all these difficulties (Zhang et al. 2016).

These problems are exacerbated with large data sets as the cost constraints for the project compels to use as few annotations as possible so that the majority of examples can be labeled. For this reason, the practitioner usually receives a reduced number of annotations per instance, invalidating the use of simple aggregation methods and making the estimation of which annotator to trust crucial. Moreover, as the data increases, some other problems for data practitioners also appear, as processing the data sets in a limited amount of time becomes much more difficult (Ouyang et al. 2016). Recently, platforms such as Apache Hadoop and Apache Spark can tackle these problems, but they are not used in the available implementations of the algorithms capable of learning accurately from crowdsourced data.

In this paper, we present `spark-crowd`[1], an *Apache Spark* package for tackling the problem of learning from crowds in domains where scalability is essential. The following sections will give an overview of the project information and methods, compare it with other packages implementing similar techniques, and comment the future plans of the developers of this package.

2. Project Management

This project makes heavy use of `git` and `Github` to make the collaboration easier, as well as a means for issue tracking, code integration, and idea discussions. To assure the quality of the package, we use a continuous integration system (`CircleCI`) so that the contributions of any developer can be checked automatically to facilitate the integration of new code. Apart from this, we also ensure code quality through a set of unit tests (testing the functionality of all the methods), which provides a coverage of 99% of the package in its version 0.2.1.

The documentation for the project is provided using `sphinx` through Github Pages[2]. This documentation includes installation instructions as well as examples to start using the package. The users can also find a description of the methods as well as a comparison with similar packages. We also offer a Docker Image with the package preinstalled, so that testing the algorithms is as comfortable as possible in the platforms Docker is supported (Windows, Mac and Linux based systems, among others). Moreover, all the dependencies, as well as the package itself, are available under open source licenses so that they can be used in a wide variety of scenarios.

The package is also published in `Maven Central` and `Spark Packages` which makes adding the library as a dependency easier (both as a project dependency or directly in the Spark Shell). It is also published in the `mloss` site, to facilitate dissemination.

3. Implementation Description

This package implements 12 methods for dealing with crowdsourced data, as shown in Table 1. We provide algorithms for both discrete class (binary and multiclass) and continuous target variables. Except for the `MajorityVoting` methods (that includes the mode for discrete classes and the mean for continuous target variables), all of them return an estimation of the annotator's quality. Only the Raykar's algorithms (divided into the methods

1. The package is available in `https://github.com/enriquegrodrigo/spark-crowd`.
2. You can find the documentation of the package at https://enriquegrodrigo.github.io/spark-crowd/.

Table 1: Methods implemented in `spark-crowd`

RaykarBinary, RaykarMulti, and RaykarCont) are able to take advantage of feature vectors while the others just use information about the annotations. For a more detailed description of the implemented algorithms, the reader may refer to the references in Table 1. In addition to the algorithms, the package also provides classes to manage annotation types as well as result objects.

An example of the library usage can be found in Listing 1. Although this code seems simple, it can be executed both locally or in a distributed environment (using the Apache Spark platform) without any modifications. The user may refer to the documentation in order to find more involved examples.

```
import com.enriquegrodrigo.spark.crowd.methods.DawidSkene
import com.enriquegrodrigo.spark.crowd.types._
//Loading file (any spark compatible format)
val data = spark.read.parquet("datafile.parquet").as[MulticlassAnnotation]
//Applying algorithm (data with columns [example, annotator, value])
val mode = DawidSkene(data.as[MulticlassAnnotation])
//Get MulticlassLabel with the class predictions
val pred = mode.getMu().as[MulticlassLabel]
//Annotator precision matrices
val annprec = mode.getAnnotatorPrecision()
```

4. Related Software

The most relevant software packages related to the one presented in this document are `Ceka` (Zhang et al. 2015) and the methods implemented in Zheng et al. 2017 (referred here as `Truth-Inf`). Both of them contain several algorithms for learning from crowdsourced data. The reader can find a full comparison study between these packages in the `spark-crowd` documentation, at the *Comparison with other packages* section. Here, however, we include a comparison for those methods considered in all three packages, i.e. MajorityVoting and DawidSkene[3]. We used the same environment for $\mathbf{t_1}$ (execution using only one core). For

3. The packages also implement GLAD and Raykar's algorithms. However, in `Ceka` these algorithms are implemented using wrappers to other libraries (the library for the GLAD algorithm is not available in our platform as it is given as an EXE Windows file, and the wrapper for Raykar's algorithms does not admit any configuration parameters).
