though it is quite likely that post processing techniques could be used to help reduce length by removing wasteful parts of the plan. This for example has been done effectively in the planning by rewriting framework (Ambite and Knoblock, 2001). In such frameworks, simply finding a sub-optimal solution quickly is a key requirement that our learning approaches help facilitate.

Interestingly, greedy action selection according to both the learned decision list policies and measures of progress is unable to solve any testing problem and very few training problems. This indicates that the learned policies and measures have significant flaws. Yet, when incorporated into our proposed search approach, they are still able to improve planning performance. This shows that even flawed control knowledge can be effectively used in our framework, assuming it provides some amount of useful guidance.

The **DL** system took a significant amount of time to learn in all of the domains, on the order of hours. These domains have more predicates, actions and larger arities for each action than Blocksworld, leading to a bigger policy search space. Still, the benefit of the policy cannot be ignored, since once it is learned, the execution of a policy is much faster than measures of progress or heuristic functions. This is verified by the solution time. **DL** consumes the least planning time among all the learning systems. Finally, we see that for all the domains, the use of the relaxed-plan-based features improved performance as exhibited by the better performance of the systems **DL**, **MoP**, and **H** compared to **DL-noRP**, **MoP-noRP**, and **H-noRP** respectively.

Our approach to incorporating policies into search appears to help speed-up the search process by adding nodes that are far from the current node being expanded, helping to overcome local minima of the heuristic function. To help illustrate this, Figures 10 and 11 show the heuristic value trace during the search in problem 20 of Depot, where **RPL** performed poorly and **DL** solved the problem quickly. The figures plot the heuristic values of each newly expanded node. Figure 10 shows the heuristic trace for best-first search as used by **RPL**. The search stays at heuristic value 40 for more than 10000 node expansion, stuck in some local minima. Rather, Figure 11 shows that **DL**, may have been stuck in a local minima from node expansion 5 to 8, but quickly finds its way out and finds the goal after only 16 node expansions.

In contrast, recall that incorporating our learned policies into search in the Freecell domain hurt performance. To help understand this, we again plotted the heuristic trace during the search in Figures 12 and 13. As is the case with Depots problem 20, the learned policy leads to a heuristic value jump (though small), but the jump did not help and we conjecture that the jump has led the

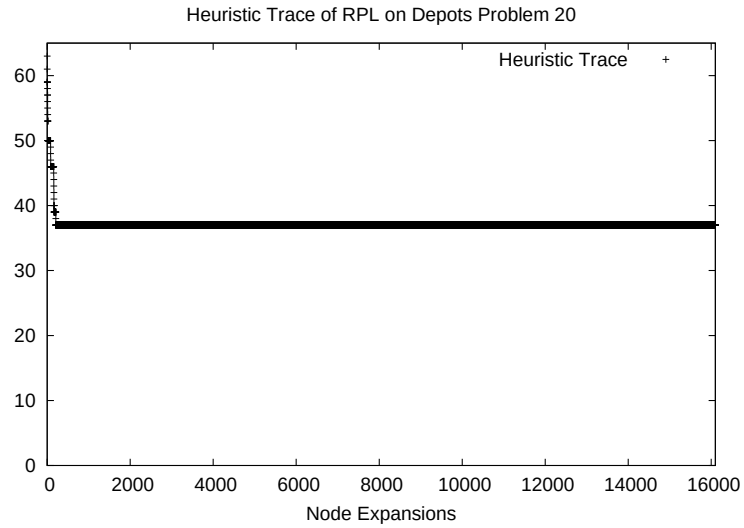

Figure 10: Heuristic trace of RPL on Depots problem 20: The RPL search found some local minimum heuristic around 38 at about 200th node expansion and remain in that region for over 15000 search nodes.

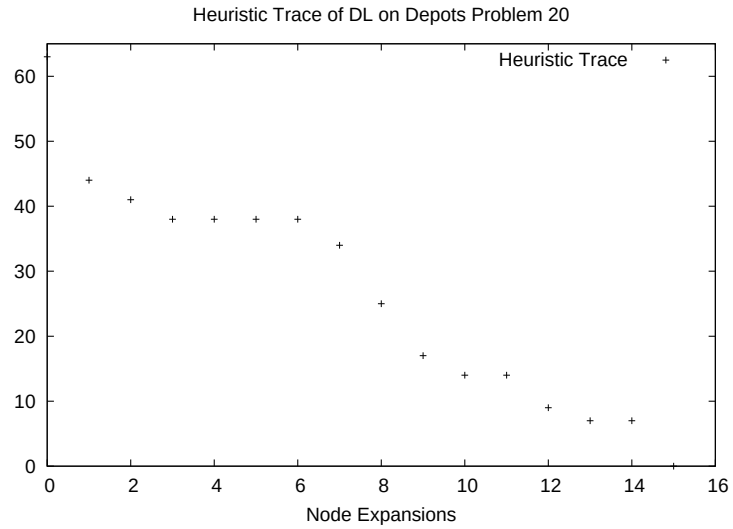

Figure 11: Heuristic trace of DL on Depots problem 20: The DL search hit a local minimum from node expansion 5 to 8, but quickly found a way out of it and reached the goal in just 16 node expansions.

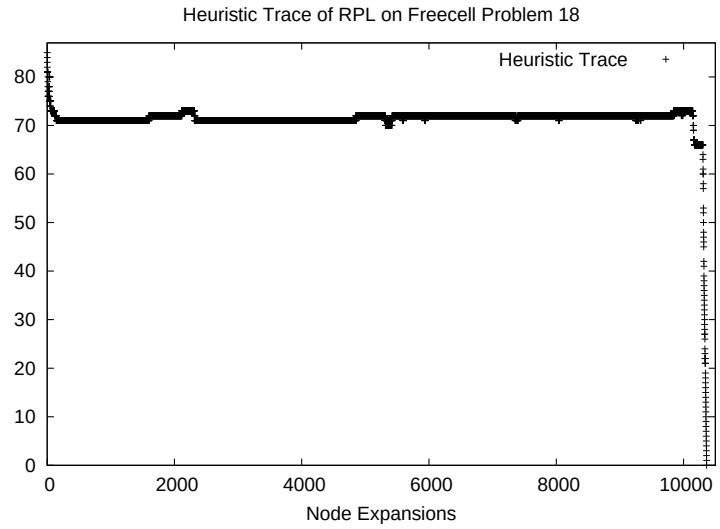

Figure 12: Heuristic trace of RPL on FreeCell problem 18: The RPL search hit a local minimum of around 70 for a long sequence of node expansions, but in the end, the search found a way out after 10000 node expansions.

search to some local minimum for both the heuristic and policy, which would not necessarily be visited with the heuristic alone, causing poor performance here for the policy-based approach.

8.4 IPC4 Results

IPC4 includes seven STRIPS/ADL domains: Airport, Satellite, Pipesworld, Pipesworld-with-Tankage, Philosophers (Promela), Optical Telegraph (Promela), and PSR (middle-compiled). FF's heuristic is very accurate for the first two domains, where for all of the solved problems the solution length and FF's heuristic are almost identical, leaving little room for learning. Thus, we only give results for the latter five domains. Each domain includes either 48 or 50 problems, giving a total of 33 or 35 testing problems, using the 15 lower numbered problems as training examples. Figures 14, 15, 16, 17, 18 present the results.

For the IPC4 results, we show the performance of the competition's best performer in each domain, labeled as **Best**. Note that the best planner varies from domain to domain. The CPU times for the best performer were taken from the official competition results, and thus are not exactly comparable to the CPU times of the other systems which were run on our local machine. In order to provide a rough comparison between the times reported for **Best** from the IPC4 results, and the times on our own machine, we ran Yahsp (Vidal, 2004) on our machine for a number of benchmark problems. In most cases, the times were quite similar. For example, on problems 40 and 45 from Pipesworld with Tankage the IPC4 results reported CPU times of 112.08 and 60.45, while we recorded times of 127.35 and 68.76 on our machine

Overall, as for the IPC4 domains, our learning systems **DL** and **H** solved more problems than FF or **RPL**, showing that the learning and planning approaches are useful. **DL** and **H** solved 127

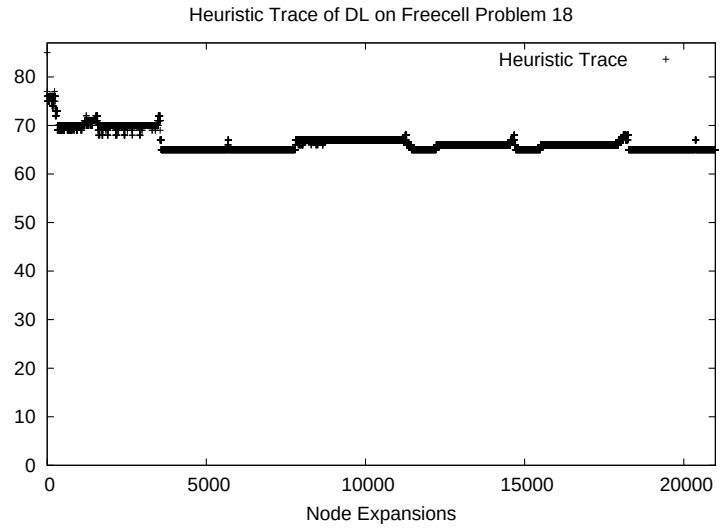

Figure 13: Heuristic trace of DL on FreeCell problem 18: Compared to Figure 12, DL search found lower heuristic states faster but did not find a way out of it. The states may not necessarily been found by RPL search.

problems among 171 testing problems from all of the domains while FF solved 42 and **RPL** solved 41. Quite surprisingly, **DL** and **H** were even able to outperform the collective results of the best performers, which solved a total of 105 problems. The **MoP** system did not perform as well as the other learners. In PSR, **MoP** was unable to learn any monotonic properties, and so was not even run. In Philosophers and Optimal Telegraph, **MoP** did find monotonic properties, but those properties hurt performance. Compared to **DL** and **H**, **DL-noRP** and **H-noRP** significantly underperformed. **DL-noRP** solved 37 and **H-noRP** solved 45 showing the usefulness of the relaxed plan feature space.

Finally, note that for most of these domains, greedy execution of the learned policies does not solve any problems. Again, however, our approach to incorporating the policies into search is still able to exploit them for significant benefits.

9. Discussion and Future Work

This study provided two primary contributions. First, we introduced a novel feature space for representing control knowledge based on extracting features from relaxed plans. Second, we showed how to learn and use control knowledge over this feature space for forward state-space heuristic search planning, a planning framework for which little work has been done in the direction of learning. We have shown that the combined approach is competitive with state-of-the-art planners across a wide range of benchmark problems. To the best of our knowledge, no prior learning-to-plan system has competed this well across such a wide set of benchmarks.

One natural extension to the relaxed-plan feature space introduced in this paper is to consider properties based on the temporal structure of relaxed plans. This could be accomplished by extend-

ing our current feature language to include temporal modalities. Regarding the learning of heuristics, our learning approach reduces the problem to one of standard function approximation. There are a number of ways in which we might further improve the quality of the learned heuristic. One approach would be to use ensemble-learning techniques such as bagging (Breiman, 1996), where we learn and combine multiple heuristic functions. Another more interesting extension would be to develop a learning technique that explicitly considers the search behavior of the heuristic, focusing on parts of the state space that need improvement the most. An initial step in this direction has been considered by Xu et al. (2007).

A key problem in applying learned control knowledge in planning is to robustly deal with imperfect knowledge resulting from the statistical nature of the learning process. Here we have shown one approach to help overcome imperfect policies by incorporating them into a search process. However, there are many other planning settings and forms of control knowledge for which we are interested in developing robust mechanisms for applying control knowledge. For example, stochastic planning domains and planning with richer cost functions are of primary interest. Learning control knowledge for regression-based planners is also of interest—it is not clear how the forms of knowledge

we learn here could be used in a regression based setting. As another example, we are interested in robust methods of incorporating control knowledge into SAT-based planners. Huang et al. (2000) have considered an approach to learning and incorporating constraints into a SAT-based planner. However, the approach has not been widely evaluated and it appears relatively easy for imperfect knowledge to make the planner incomplete by ruling out possible solutions.

Another research direction is to consider extending the relaxed-plan feature space to stochastic planning domains. Here one might determinize the stochastic domain in one or more ways and compute the corresponding relaxed plans. The resulting features could then be used to learn policies or value functions, using an approach such as approximate policy iteration (Fern et al., 2006). It would also be interesting to consider extending our approach for incorporating imperfect policies into search in the context of real-time dynamic programming (Barto et al., 1995).

In summary, we have demonstrated that it is possible to use machine learning to improve the performance of forward state-space search planners across a range of planning domains. However, the results are still far from the performance of human-written control knowledge in most domains, for example, TL-Plan (Bacchus and Kabanza, 2000) and SHOP (Nau et al., 1999). Also the results have still not shown large performance gains over state-of-the-art non-learning systems. Demonstrating this level of performance should be a key goal of future work in learning-based planning systems.

Abstract

Regularized kernel discriminant analysis (RKDA) performs linear discriminant analysis in the feature space via the kernel trick. Its performance depends on the selection of kernels. In this paper, we consider the problem of multiple kernel learning (MKL) for RKDA, in which the optimal kernel matrix is obtained as a linear combination of pre-specified kernel matrices. We show that the kernel learning problem in RKDA can be formulated as convex programs. First, we show that this problem can be formulated as a semidefinite program (SDP). Based on the equivalence relationship between RKDA and least square problems in the binary-class case, we propose a convex quadratically constrained quadratic programming (QCQP) formulation for kernel learning in RKDA. A semi-infinite linear programming (SILP) formulation is derived to further improve the efficiency. We extend these formulations to the multi-class case based on a key result established in this paper. That is, the multi-class RKDA kernel learning problem can be decomposed into a set of binary-class kernel learning problems which are constrained to share a common kernel. Based on this decomposition property, SDP formulations are proposed for the multi-class case. Furthermore, it leads naturally to QCQP and SILP formulations. As the performance of RKDA depends on the regularization parameter, we show that this parameter can also be optimized in a joint framework with the kernel. Extensive experiments have been conducted and analyzed, and connections to other algorithms are discussed.

Keywords: model selection, kernel discriminant analysis, semidefinite programming, quadratically constrained quadratic programming, semi-infinite linear programming

1. Introduction

Formulation of machine learning problems as convex programs has been one of the recent trends in machine learning research. Such formulations offer global solutions and avoid some difficulties encountered by traditional learning algorithms (Lanckriet et al., 2003, 2004b; d'Aspremont et al., 2007). Kernel methods (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004) work by embedding the input data into some high-dimensional feature space, and they are generally formulated as convex optimization problems. The key fact underlying the success of kernel methods is that the embedding into feature space can be determined uniquely by specifying a kernel function that computes the dot product between data points in the feature space. In other words, the kernel

function implicitly defines the nonlinear mapping to the feature space, and expensive computations in the high-dimensional feature space can be avoided by evaluating the kernel function. Thus, one of the central issues in kernel methods is the selection of kernels.

To automate kernel-based learning algorithms, it is desirable to integrate the tuning of kernels into the learning process. This problem has been addressed from different perspectives recently. Lanckriet et al. (2004b) pioneered the work of multiple kernel learning (MKL) in which the optimal kernel matrix is obtained as a linear combination of pre-specified kernel matrices. It was shown (Lanckriet et al., 2004b) that the coefficients in MKL can be determined by solving convex programs in the case of support vector machines (SVM) (Vapnik, 1998; Cristianini and Taylor, 2000). This MKL problem was formulated as support kernel machines (SKM) in Bach et al. (2004), and the sequential minimal optimization (SMO) algorithm (Platt, 1999) was proposed to solve it. Recently, this SKM was reformulated as semi-infinite linear program (SILP) which was shown to be scalable to large data sets and a large number of kernels (Sonnenburg et al., 2006; Rakotomamonjy et al., 2007). Micchelli and Pontil (2005, 2007) studied the problem of finding an optimal kernel from a prescribed convex set of kernels by regularization. To deal with problems with structured output, MKL for joint feature map was proposed in Zien and Ong (2007). While most existing work focuses on learning kernels for SVM, Fung et al. (2004) proposed to learn kernels for discriminant analysis. Based on ideas from MKL, this problem was reformulated as SDP in Kim et al. (2006). In general, approaches based on learning linear combination of kernel matrices offer the additional advantage of facilitating heterogeneous data integration from multiple sources. Such formulations have been applied to combine various biological data, for example, amino acid sequences, hydropathy profiles, and gene expression data, for enhanced biological inference (Lanckriet et al., 2004a).

Ong et al. (2005) showed that the learning of kernels can be accomplished by defining a reproducing kernel Hilbert space on the space of kernels itself, and the resulting optimization problem is an SDP. This formulation was recast into second order cone program (SOCP) (Lobo et al., 1998) in Tsang and Kwok (2006). Hoi et al. (2007) showed that the kernel matrix can be learned in a nonparametric manner by solving SDP. The kernel learning problem in the context of multiple tasks was considered in Jebara (2004). Some recent extensions of kernel learning produced nonstationary combinations (Lewis et al., 2006) and potentially infinite number of kernels (Argyriou et al., 2006).

This paper addresses the issue of kernel learning for regularized kernel discriminant analysis (RKDA) (Mika et al., 1999; Baudat and Anouar, 2000; Mika et al., 2001, 2003). Our proposed methods belong to the MKL framework, and they can thus be used for heterogeneous data integration. We systematically extend the kernel learning problem for RKDA in several directions. First, we extend the formulation in Kim et al. (2006) by proposing a simplified SDP formulation. Based on this simplified form and the equivalence relationship between KRDA and least square problems in the binary-class case, we propose a convex quadratically constrained quadratic programming (QCQP) formulation for this problem. To improve the efficiency of our formulations, we further develop a semi-infinite linear programming (SILP) formulation. While most existing work on kernel learning only deals with binary-class problems, we show that all of our formulations can be extended naturally to the multi-class setting. In particular, we show that the kernel learning problem for multi-class RKDA can be decomposed into a set of binary-class kernel learning problems that are constrained to share a common kernel. It is worth noting that the optimal kernel is the same for the original and the decomposed formulations, though the optimal transformation matrices may not coincide. In other words, the decomposed form is equivalent to the original one for the purpose of kernel learning. We further develop an approximate scheme to reduce the computational cost of

multi-class SDP formulation. Finally, we propose to optimize the regularization parameter along with the kernels in a joint framework. This joint optimization framework is derived from and similar to the work in De Bie et al. (2003); Lanckriet et al. (2004b).

The key contributions of this paper can be highlighted as follows:

- We propose a simplified SDP formulation for the RKDA kernel learning problem in the binary-class case. Based on this simplified form and the equivalence relationship between RKDA and least square problems in the binary-class case, we derive QCQP and SILP formulations for this problem.

- We show that the multi-class RKDA kernel learning problem can be decomposed into k binary-class kernel learning problems where k is the number of classes. This leads to two (exact and approximate) SDP formulations in the multi-class case. Based on this decomposition property, we show that the QCQP and SILP formulations for binary-class problems can be extended naturally to the multi-class case.

- We show that all the proposed formulations can be recast to optimize the regularization parameter simultaneously. This joint learning framework further automates the learning algorithms.

- We conduct extensive experiments using a collection of benchmark data sets to compare several relevant algorithms under a unified experimental setup. To demonstrate the effectiveness of the proposed formulations for heterogeneous data integration, we apply these formulations to combine multiple data sources derived from gene expression pattern images (Tomancak et al., 2002).

The rest of this paper is organized as follows: We derive the SDP, QCQP, and SILP formulations for the binary-class case in Section 2. Section 3 extends these formulations to the multi-class case. The joint optimization of regularization parameter is presented in Section 4. Section 5 presents the experimental evaluation, and this paper concludes with discussion and conclusion in Section 6.

Notation

$x \in \mathbb{R}^n$ denotes an n-dimensional vector. Similarly, $A \in \mathbb{R}^{m \times n}$ denotes a matrix with m rows and n columns. I is used to denote the identity matrix of an appropriate dimension and e_m denotes the vector of all ones of length m. For a square symmetric matrix S, $S \succeq 0$ means it is positive semidefinite. We also use the short-hand $x \geq 0$ to denote that each component of the vector x is non-negative.

2. Convex Formulations for Binary-class Problems

We use $\mathcal{X}$ to denote the input or instance space, which is a subspace of $\mathbb{R}^d$, and $\mathcal{Y} = \{-1, +1\}$ to denote the output or class label set. An input-output pair (x, y), where $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, is called an example. An example is called positive (negative) if its class label is $+1\,(-1)$. We assume that the examples are drawn randomly and independently from a fixed, but unknown, underlying probability distribution over $\mathcal{X} \times \mathcal{Y}$.

A symmetric function $K : \mathcal{X} \times \mathcal{X} \to R$ is called a kernel function (Schölkopf and Smola, 2002) if it satisfies the finitely positive semidefinite property. That is, for any $x_1, \cdots, x_m \in \mathcal{X}$, the *Gram*

matrix $G \in \mathbb{R}^{m\times m}$, defined by $G_{ij} = K(x_i, x_j)$ is positive semidefinite. Any kernel function K implicitly maps the input set $\mathcal{X}$ to a high-dimensional (possibly infinite) Hilbert space $\mathcal{H}_K$ equipped with the inner product $(\cdot,\cdot)_{\mathcal{H}_K}$ through a mapping ϕ_K from $\mathcal{X}$ to $\mathcal{H}_K$:

$$K(x,z) = (\phi_K(x), \phi_K(z))_{\mathcal{H}_K}.$$

In kernel-based classification, the algorithms learn a classifier $f : \mathcal{X} \to \{-1,+1\}$ whose decision boundary between the two classes is affine in the feature space $\mathcal{H}_K$:

$$f(x) = sgn(w^T \phi_K(x) + b),$$

where $w \in \mathcal{H}_K$ is the vector of feature weights, $b \in \mathbb{R}$ is the intercept, and $sgn(u) = +1$, if $u > 0$, and -1 otherwise.

Let $\{x_1^+, \cdots, x_{m_+}^+\}$ and $\{x_1^-, \cdots, x_{m_-}^-\}$ denote the collections of data points from the positive and negative classes, respectively. The total number of data points in the training set is $m = m_+ + m_-$. For a given kernel function K, the basic idea of RKDA in the binary-class case is to find a direction in the feature space $\mathcal{H}_K$ onto which the projections of the two sets $\{\phi_K(x_i^+)\}_{i=1}^{m_+}$ and $\{\phi_K(x_i^-)\}_{i=1}^{m_-}$ are well separated. Define the centroids of the two classes as follows:

$$\mu_K^+ = \frac{1}{m_+}\sum_{i=1}^{m_+}\phi_K(x_i^+),$$
$$\mu_K^- = \frac{1}{m_-}\sum_{i=1}^{m_-}\phi_K(x_i^-),$$

and the two sample class covariance matrices as follows:

$$S_K^+ = \frac{1}{m_+}\sum_{i=1}^{m_+}(\phi_K(x_i^+) - \mu_K^+)(\phi_K(x_i^+) - \mu_K^+)^T,$$
$$S_K^- = \frac{1}{m_-}\sum_{i=1}^{m_-}(\phi_K(x_i^-) - \mu_K^-)(\phi_K(x_i^-) - \mu_K^-)^T.$$

Specifically, in RKDA the separation between the two classes is measured by the ratio of the variance $(w^T(\mu_K^+ - \mu_K^-))^2$ between the classes to the variance $w^T\left(m_+/mS_K^+ + m_-/mS_K^-\right)w$ within the classes. Thus, RKDA maximizes the following objective function:

$$F_1(w,K) = \frac{(w^T(\mu_K^+ - \mu_K^-))^2}{w^T\left(m_+/mS_K^+ + m_-/mS_K^- + \lambda I\right)w}, \tag{1}$$

where $\lambda > 0$ is the regularization parameter. The optimal weight vector

$$w^* \equiv \underset{w}{\operatorname{argmax}}\{F_1(w,K)\}$$

that maximizes the objective function in Equation (1) for a fixed kernel function K and a fixed regularization parameter λ is given by

$$w^* = (m_+/mS_K^+ + m_-/mS_K^- + \lambda I)^{-1}(\mu_K^+ - \mu_K^-).$$

The maximum value

$$F_1^*(K) \equiv \max_w \{F_1(w,K)\}$$

of the objective function in Equation (1) achieved by the optimal weight vector w^* is given by

$$F_1^*(K) = (\mu_K^+ - \mu_K^-)^T \left(m_+/mS_K^+ + m_-/mS_K^- + \lambda I\right)^{-1} (\mu_K^+ - \mu_K^-). \tag{2}$$

It follows from the Representer Theorem (Schölkopf and Smola, 2002) that the optimal weight vector in RKDA is in the span of the images of the training points in the feature space. In other words, there exists a vector

$$\alpha^* = [\alpha_1^+, \cdots, \alpha_{m_+}^+, \alpha_1^-, \cdots, \alpha_{m_-}^-]^T \in \mathbb{R}^m$$

such that

$$w^* = \sum_{i=1}^{m_+} \alpha_i^+ \phi_K(x_i^+) + \sum_{i=1}^{m_-} \alpha_i^- \phi_K(x_i^-) = \phi_K(X)\alpha^*,$$

where $\phi_K(X)$ is the data matrix in the feature space given by

$$\phi_K(X) = \left[\phi_K(x_1^+), \cdots, \phi_K(x_{m_+}^+), \phi_K(x_1^-), \cdots, \phi_K(x_{m_-}^-)\right].$$

The optimal vector α^* is given by Kim et al. (2006) as

$$\alpha^* = \frac{1}{\lambda}(I - J(\lambda I + JGJ)^{-1}JG)a,$$

where I is the identity matrix, a is an m-dimensional vector given by

$$a = [1/m_+, \cdots, 1/m_+, -1/m_-, \cdots, -1/m_-]^T \in \mathbb{R}^m, \tag{3}$$

the matrix J is defined as:

$$J = \begin{pmatrix} \frac{1}{\sqrt{m_+}}(I - \frac{1}{m_+} e_{m_+} e_{m_+}^T) & 0 \\ 0 & \frac{1}{\sqrt{m_-}}(I - \frac{1}{m_-} e_{m_-} e_{m_-}^T) \end{pmatrix},$$

G is restricted to be a linear combination of the p given kernel matrices $G_1, \cdots, G_p$ as

$$G \in \mathcal{G} = \left\{ G = \sum_{i=1}^p \theta_i G_i \;\middle|\; \sum_{i=1}^p \theta_i = 1\,, \quad \theta_i \geq 0 \quad \forall i \right\},$$

and e_{m_+} and e_{m_-} are vectors of all ones of length m^+ and m^-, respectively.

The optimal value $F_1^*(K)$ in Equation (2) is thus given by

$$\begin{aligned} F_1^*(K) &= (\mu_K^+ - \mu_K^-)^T \left(m_+/mS_K^+ + m_-/mS_K^- + \lambda I\right)^{-1} (\mu_K^+ - \mu_K^-) \\ &= (\mu_K^+ - \mu_K^-)^T w^* = (\mu_K^+ - \mu_K^-)^T \phi_K(X)\alpha^* = a^T \phi_K(X)^T \phi_K(X)\alpha^* \\ &= \frac{1}{\lambda} a^T G(I - J(\lambda I + JGJ)^{-1}JG)a. \end{aligned} \tag{4}$$

It was shown in Kim et al. (2006) that the optimal Gram matrix G based on the kernel function K that maximizes $F_1^*(K)$ given in Equation (4) can be obtained by solving a semidefinite program (SDP)

(Vandenberghe and Boyd, 1996; Boyd and Vandenberghe, 2004). General-purpose optimization packages such as SeDuMi (Sturm, 1999) use the interior-point methods (Nesterov and Nemirovskii, 1994) to solve SDP. However, for problems of moderate size in machine learning, this overhead of optimal kernel learning is large, and its computation time can easily exceed that of the learning algorithm itself.

We propose a new SDP formulation for this problem in the next subsection. The proposed SDP formulation has a simplified form. Experimental results presented in Section 5 show that the proposed formulation is comparable to the one in Kim et al. (2006). More importantly, this simplified formulation lays the foundation for the extensions to multi-class problems in Section 3 and the joint optimization of regularization parameter in Section 4.

2.1 Simplified SDP Formulation

In the rest of this paper, we work on the centered version of kernel matrices. This is equivalent to centering the data as preprocessed in linear discriminant analysis (LDA) and principal component analysis (PCA). More precisely, given a set of p kernel matrices $G_1, \cdots, G_p$, the proposed algorithms learn an optimal kernel matrix $\tilde{G} \in \tilde{\mathcal{G}}$, where

$$\tilde{\mathcal{G}} = \left\{ \tilde{G} = \sum_{i=1}^{p} \theta_i \tilde{G}_i \;\middle|\; \sum_{i=1}^{p} \theta_i r_i = 1, \;\; \theta_i \geq 0 \right\},$$

$\tilde{G}_i = PG_iP$, $r_i = \mathrm{trace}(\tilde{G}_i)$, and $P \in \mathbb{R}^{m \times m}$ is the centering matrix defined as

$$P = I - \frac{1}{m} e_m e_m^T, \tag{5}$$

and e_m is the vector of all ones of size m.

Consider the maximization of the following objective function:

$$F_2(w,K) = \frac{(w^T(\mu_K^+ - \mu_K^-))^2}{w^T(\Sigma_K + \lambda I)w}, \tag{6}$$

where Σ_K is defined as follows:

$$\begin{aligned} \Sigma_K &= m_+ S_K^+ + m_- S_K^- + \frac{m_+ m_-}{m} (\mu_K^+ - \mu_K^-)(\mu_K^+ - \mu_K^-)^T \\ &= \sum_{i=1}^{m_+} (\phi_K(x_i^+) - \mu_K)(\phi_K(x_i^+) - \mu_K)^T + \sum_{i=1}^{m_-} (\phi_K(x_i^-) - \mu_K)(\phi_K(x_i^-) - \mu_K)^T \\ &= \phi_K(X) P \phi_K(X)^T, \end{aligned} \tag{7}$$

P is defined in Equation (5), and

$$\mu_K = \frac{1}{m} \left(\sum_{i=1}^{m_+} \phi_K(x_i^+) + \sum_{i=1}^{m_-} \phi_K(x_i^-) \right)$$

is the global centroid of the data in the feature space. Note that the scaling factor $1/m$ has been omitted in the definition of Σ_K in Equation (7). It turns out that for fixed K and λ, Equations (1) and (6) are equivalent in terms of the computation of the optimal weight vector w. We show in the following theorem that optimizing $F_2(w,K)$ in Equation (6) with respect to the kernel function leads to a simplified SDP formulation.

Theorem 2.1 *Given a set of p centered kernel matrices $\tilde{G}_1, \cdots, \tilde{G}_p$, the optimal kernel matrix $\tilde{G} \in \tilde{\mathcal{G}}$ that maximizes the objective function in Equation (6) can be found by solving the following semidefinite programming problem:*

$$\begin{array}{lll} \min\limits_{\theta,t} & t & \\ \textit{subject to} & \begin{pmatrix} I + \frac{1}{\lambda}\sum_{i=1}^{p} \theta_i \tilde{G}_i & a \\ a^T & t \end{pmatrix} \succeq 0, & (8) \\ & \theta \geq 0, & \\ & \theta^T r = 1, & \end{array}$$

where a is defined in Equation (3), $\theta = [\theta_1, \cdots, \theta_p]^T$, *and* $r = \left[trace(\tilde{G}_1), \cdots, trace(\tilde{G}_p)\right]^T$.

Proof The optimal weight vector

$$w^* \equiv \underset{w}{\text{argmax}} \{F_2(w,K)\}$$

is given by

$$w^* = (\Sigma_K + \lambda I)^{-1}(\mu_K^+ - \mu_K^-).$$

The maximum value of the objective function in Equation (6) achieved by w^* is given by

$$F_2^*(K) \equiv F_2(w^*,K) = (\mu_K^+ - \mu_K^-)^T (\Sigma_K + \lambda I)^{-1}(\mu_K^+ - \mu_K^-).$$

It follows from Appendix A that

$$w^* = \frac{1}{\lambda}\phi_K(X)\left(I - P\left(\lambda I + PGP\right)^{-1} PG\right) a,$$

and

$$\begin{aligned} F_2^*(K) &= (\mu_K^+ - \mu_K^-)^T w^* = a^T \phi_K(X)^T w^* \\ &= \frac{1}{\lambda} a^T \left(G - GP\left(\lambda I + PGP\right)^{-1} PG\right) a. \end{aligned}$$

Since the vector a defined in Equation (3) is of zero mean, that is, $Pa = a$, we have

$$\begin{aligned} F_2^*(K) &= \frac{1}{\lambda} a^T P \left(G - GP(\lambda I + PGP)^{-1} PG\right) Pa \\ &= \frac{1}{\lambda} a^T \left(\tilde{G} - \tilde{G}(\lambda I + \tilde{G})^{-1}\tilde{G}\right) a, \end{aligned} \tag{9}$$

where $\tilde{G}$ is derived from G with both rows and columns centered as

$$\tilde{G} = PGP.$$

Since

$$\begin{aligned} \tilde{G} - \tilde{G}(\lambda I + \tilde{G})^{-1}\tilde{G} &= \tilde{G} - \tilde{G}(\lambda I + \tilde{G})^{-1}(\tilde{G} + \lambda I - \lambda I) \\ &= \lambda \tilde{G}(\lambda I + \tilde{G})^{-1} \\ &= \lambda(\tilde{G} + \lambda I - \lambda I)(\lambda I + \tilde{G})^{-1} \\ &= \lambda - \lambda^2(\lambda I + \tilde{G})^{-1}, \end{aligned}$$

the optimal value $F_2^*(K)$ in Equation (9) can be simplified as

$$F_2^*(K) = a^T a - \lambda a^T (\lambda I + \tilde{G})^{-1} a. \tag{10}$$

It follows that the optimal kernel learning problem in RKDA, which maximizes $F_2^*(K)$ in Equation (10) for a fixed regularization parameter λ, is equivalent to minimizing

$$\lambda a^T (\lambda I + \tilde{G})^{-1} a = a^T \left(I + \frac{1}{\lambda} \tilde{G} \right)^{-1} a, \tag{11}$$

subject to the constraint that $\tilde{G} \in \tilde{\mathcal{G}}$.

Mathematically, the optimal kernel learning problem can be formulated as follows:

$$\begin{aligned} \min_{\theta} \quad & a^T \left(I + \frac{1}{\lambda} \sum_{i=1}^{p} \theta_i \tilde{G}_i \right)^{-1} a \\ \text{subject to} \quad & \theta \geq 0, \\ & \theta^T r = 1. \end{aligned}$$

We can write the inequality

$$a^T \left(I + \frac{1}{\lambda} \tilde{G} \right)^{-1} a \leq t$$

equivalently as the linear matrix inequality (LMI) (Boyd and Vandenberghe, 2004)

$$\begin{pmatrix} I + \frac{1}{\lambda} \tilde{G} & a \\ a^T & t \end{pmatrix} \succeq 0,$$

via the Schur complement lemma (Golub and Van Loan, 1996; Lanckriet et al., 2004b). We complete the proof by a simple change of variable. ■

2.2 QCQP Formulation

The optimization problem proposed by Kim et al. (2006) and the one in Theorem 2.1 are both SDP problems, which are computationally very expensive to solve, even with the recent advances in interior point methods. In this subsection, we show that this kernel learning problem can be reformulated equivalently as a quadratically constrained quadratic program (QCQP) (Boyd and Vandenberghe, 2004), which can then be solved more efficiently than SDP.

It is known that discriminant analysis and least square problems are equivalent in the binary-class case (Mika, 2002). Consider the regularized least squares problem, which minimizes the following objective function:

$$F_3(w,K) = ||(\phi_K(X)P)^T w - a||^2 + \lambda ||w||^2. \tag{12}$$

The following lemma relates this problem to the problem of optimal kernel learning.

Lemma 2.1 *The optimal kernel function K solving the optimization problem in Equation (11) is also the minimizer of the objective function in Equation (12).*

Proof The optimal w^* that minimizes the objective function in Equation (12) for a fixed K and λ is given by

$$\begin{aligned} w^* &= \left(\lambda I + \phi_K(X) P \phi_K(X)^T\right)^{-1} \phi_K(X) P a \\ &= \frac{1}{\lambda}\phi_K(X)\left(I - P\left(\lambda I + PGP\right)^{-1} PG\right) a. \end{aligned}$$

The optimal value of the objective function in Equation (12) is therefore given by

$$F_3^*(K) = a^T \left(I + \frac{1}{\lambda}\tilde{G}\right)^{-1} a,$$

where $\tilde{G} = PGP$. This completes the proof of this lemma. ■

Based on this equivalence result, we can formulate the kernel learning problem as a QCQP problem, as summarized in the following theorem.

Theorem 2.2 *Given a set of p centered kernel matrices $\tilde{G}_1, \cdots, \tilde{G}_p$, the optimal kernel matrix, in the form of a convex linear combination of the given p kernel matrices, that minimizes the objective function in Equation (12) can be found by solving the following convex QCQP problem:*

$$\begin{aligned} \max_{\beta, t} \quad & -\frac{1}{4}\beta^T\beta + \beta^T a - \frac{1}{4\lambda}t \\ \textit{subject to} \quad & t \geq \frac{1}{r_i}\beta^T \tilde{G}_i \beta, \ \textit{for } i = 1, \cdots, p, \end{aligned} \tag{13}$$

where $r_i = trace(\tilde{G}_i)$.

Proof We consider the dual formulation of the minimization of $F_3(w,K)$ in terms of w. Denote

$$\eta = (\phi_K(X)P)^T w - a.$$

It follows that

$$F_3(w,K) = ||\eta||^2 + \lambda||w||^2.$$

Define the Lagrangian function of the following optimization problem:

$$\begin{aligned} \min_{w,\eta} \quad & F_3(w,K) = ||\eta||^2 + \lambda||w||^2 \\ \text{subject to} \quad & \eta = (\phi_K(X)P)^T w - a \end{aligned}$$

as follows:

$$L(\eta, w, \beta) = ||\eta||^2 + \lambda||w||^2 - \beta^T((\phi_K(X)P)^T w - a - \eta),$$

where β is the vector of Lagrangian dual variables. Taking the derivatives of $L(\eta, w, \beta)$ with respect to η and w and setting them equal to zero, we get

$$\begin{aligned} \frac{\partial L(\eta, w, \beta)}{\partial \eta} &= 2\eta + \beta = 0, \\ \frac{\partial L(\eta, w, \beta)}{\partial w} &= 2\lambda w - \phi_K(X)P\beta = 0. \end{aligned}$$

It follows that

$$\eta = -\frac{\beta}{2}, \text{ and } w = \frac{\phi_K(X)P\beta}{2\lambda}.$$

Thus, we obtain the following Lagrangian dual function:

$$g(\beta) = \min_{w,\eta} L(\eta, w, \beta) = -\frac{1}{4}\beta^T \left(I + \frac{1}{\lambda} PGP \right) \beta + \beta^T a.$$

The optimal β^* is computed by maximizing $g(\beta)$ as

$$\beta^* = \operatorname*{argmax}_{\beta} g(\beta) = \operatorname*{argmax}_{\beta} \left\{ -\frac{1}{4}\beta^T \left(I + \frac{1}{\lambda} PGP \right) \beta + \beta^T a \right\}.$$

Since strong duality holds, the optimal kernel is given by solving the following optimization problem:

$$\min_{\tilde{G} \in \tilde{\mathcal{G}}} \max_{\beta} \left\{ -\frac{1}{4}\beta^T \left(I + \frac{1}{\lambda} \tilde{G} \right) \beta + \beta^T a \right\}.$$

We can rewrite the above optimization problem as

$$\begin{aligned}
& \min_{\theta:\theta\geq 0, \theta^T r = 1} \max_{\beta} \left\{ -\frac{1}{4}\beta^T \left(I + \frac{1}{\lambda} \sum_{i=1}^{p} \theta_i \tilde{G}_i \right) \beta + \beta^T a \right\} \qquad (14) \\
= & \max_{\beta} \min_{\theta:\theta\geq 0, \theta^T r = 1} \left\{ -\frac{1}{4}\beta^T \left(I + \frac{1}{\lambda} \sum_{i=1}^{p} \theta_i \tilde{G}_i \right) \beta + \beta^T a \right\} \\
= & \max_{\beta} \min_{\theta:\theta\geq 0, \theta^T r = 1} \left\{ -\frac{1}{4\lambda} \sum_{i=1}^{p} \theta_i \beta^T \tilde{G}_i \beta - \frac{1}{4}\beta^T \beta + \beta^T a \right\} \\
= & \max_{\beta} \left\{ -\frac{1}{4}\beta^T \beta + \beta^T a - \frac{1}{4\lambda} \max_{\theta:\theta\geq 0, \theta^T r = 1} \left(\sum_{i=1}^{p} \theta_i \beta^T \tilde{G}_i \beta \right) \right\} \\
= & \max_{\beta} \left\{ -\frac{1}{4}\beta^T \beta + \beta^T a - \frac{1}{4\lambda} \max_{i} \left(\frac{1}{r_i} \beta^T \tilde{G}_i \beta \right) \right\}. \qquad (15)
\end{aligned}$$

The exchange of minimization and maximization in deriving the second equation from the first holds since the objective function is convex in θ and concave in β, the minimization problem is strictly feasible in θ and the maximization problem is strictly feasible in β. Therefore, Slater's condition (Boyd and Vandenberghe, 2004) follows and strong duality holds (Lanckriet et al., 2004b; Boyd and Vandenberghe, 2004). By simply changing the last term in Equation (15) to t and moving it to the constraint, we prove this theorem. ■

Note that general-purpose optimization software packages like SeDuMi (Sturm, 1999) and MOSEK (Andersen and Andersen, 2000) employ the interior point methods, and they solve the primal and dual problems simultaneously. Thus, the coefficients, $\theta_1, \cdots, \theta_p$, can be obtained directly from the dual variables.

The formulation in Equation (13) is a quadratically constrained quadratic program (QCQP), which is a special form of second order cone program (SOCP) (Lobo et al., 1998; Alizadeh and

Goldfarb, 2003) and SDP. Theoretical results on interior point method (Nesterov and Nemirovskii, 1994) show that QCQP can be solved more efficiently than SDP, and it is therefore more scalable to large-scale problems. Similar ideas have been used in Lanckriet et al. (2004b) to learn a non-negative linear combination of kernel matrices.

2.3 SILP Formulation

Semi-infinite programming (SIP) (Hettich and Kortanek, 1993) refers to optimization problems that seek the maximum of the function $F(z)$ subject to a system of constraints on z, expressed as $g(z,t) \leq 0$, for all t in some set B. When both the objective and constraints are linear (and hence convex), it is known as semi-infinite linear programming (SILP). We show in this section that the kernel learning problem for RKDA can be formulated as an SILP problem, as summarized in the following theorem.

Theorem 2.3 *Given a set of p centered kernel matrices $\tilde{G}_1, \cdots, \tilde{G}_p$, the optimal kernel matrix, in the form of a convex linear combination of the given p kernel matrices, that maximizes the objective function in Equation (12) can be found by solving the following SILP problem:*

$$\begin{aligned} \max_{\theta,\gamma} \quad & \gamma && (16) \\ \textit{subject to} \quad & \theta \geq 0, \\ & \theta^T r = 1, \\ & \sum_{i=1}^{p} \theta_i S_i(\beta) \geq \gamma, \quad \textit{for all } \beta, && (17) \end{aligned}$$

where $S_i(\beta)$ is defined as

$$S_i(\beta) = \frac{r_i}{4}\beta^T\beta + \frac{1}{4\lambda}\beta^T\tilde{G}_i\beta - r_i\beta^T a, \quad \textit{for } i = 1, \cdots, p, \tag{18}$$

$r = (r_1, \cdots, r_p)^T$, and $r_i = trace(\tilde{G}_i)$.

Proof It follows from the definition of $S_i(\beta)$ in Equation (18) that the optimization problem in Equation (14) can be expressed equivalently as

$$\begin{aligned} \max_{\theta} \min_{\beta} \quad & \sum_{i=1}^{p} \theta_i S_i(\beta) && (19) \\ \text{subject to} \quad & \theta \geq 0, \\ & \theta^T r = 1. \end{aligned}$$

Assume β^* is the optimal solution to the problem in Equation (19) and define $\gamma^* = \sum_{i=1}^{p} \theta_i S_i(\beta^*)$ as the minimum objective value achieved by β^*. We have

$$\sum_{i=1}^{p} \theta_i S_i(\beta) \geq \gamma^*, \quad \text{for all } \beta.$$

By defining

$$\gamma = \min_{\beta} \sum_{i=1}^{p} \theta_i S_i(\beta)$$

and substituting γ into the objective, we prove this theorem. ■

Note that the optimization problem in Equation (16) is an SILP since both θ and γ are linearly constrained, and there are an infinite number of constraints, one for each possible value of β. As in Sonnenburg et al. (2006), we propose to use the *column generation* technique to solve this SILP problem. In this technique, the optimal θ and γ are computed for a restricted subset of constraints in Equation (17) and this problem is called the *restricted master problem*. Constraints that are not satisfied by current θ and γ are added successively to the restricted master problem until all constraints are satisfied. For fast convergence of the algorithm, it is desirable to add constraint that maximizes the violation for current θ and γ. That is, the β value that solves

$$\beta_\theta = \operatorname*{argmin}_\beta \sum_{i=1}^{p} \theta_i S_i(\beta), \tag{20}$$

is desired. If $\sum_{i=1}^{p} \theta_i S_i(\beta^\theta) \geq \gamma$, then all the constraints are satisfied, and θ and γ reach their optimal values. Otherwise, this constraint is added to the restricted master problem and the iteration continues.

It follows from the definition of $S_i(\beta)$ in Equation (18) that the problem in Equation (20) can be written as

$$\min_\beta \left\{ \frac{1}{4}\beta^T\beta + \frac{1}{4\lambda}\beta^T \left(\sum_{i=1}^{p} \theta_i \tilde{G}_i \right) \beta - \beta^T a \right\}. \tag{21}$$

For a fixed θ, the problem in Equation (21) is an unconstrained convex quadratic program whose solution can be obtained analytically. To avoid computing matrix inverse, we obtain β by solving the following system of linear equations:

$$\left(\frac{1}{2} I + \frac{1}{2\lambda} \sum_{i=1}^{p} \theta_i \tilde{G}_i \right) \beta = a.$$

After β is computed, the corresponding constraint is added to the restricted master problem to obtain the intermediate θ and γ. Note that the restricted master problem is a linear program. Thus, the proposed algorithm for solving the SILP problem proposed in Theorem 2.3 alternates between solving a linear system and a linear program. In contrast, the SILP formulation proposed in Sonnenburg et al. (2006) for SVM kernel learning involves solving a constrained quadratic program (QP) and a linear program. They shown that the constrained QP coincides with a single kernel SVM formulation, and thus existing software for solving SVM can be used directly.

The alternating algorithm for solving the proposed SILP problem belongs to a family of algorithms for solving general SIP problems called the *exchange methods*, in which the constraints are exchanged at each iteration. It follows from Theorem 7.2 in Hettich and Kortanek (1993) that these methods are guaranteed to converge. Similar to the convergence criterion used in Sonnenburg et al. (2006), the algorithm returns when

$$\left| 1 - \frac{\sum_{i=1}^{p} \theta_i^{(t-1)} S_i(\beta^{(t)})}{\gamma^{(t-1)}} \right| \leq \varepsilon, \tag{22}$$

where $\theta_i^{(t-1)}$, for $i = 1, \cdots, p$, and $\gamma^{(t-1)}$ are the optimal solutions to the restricted master problem at the $(t-1)$-th iteration, $\beta^{(t)}$ is the β value that maximizes the constraint violation at the t-th iteration, and ε is a user-specified tolerance parameter. We set $\varepsilon = 5 \times 10^{-4}$ in our experiments.

2.4 Time Complexity Analysis

We analyze the time complexity of the proposed formulations for the binary-class case. It follows from the analysis in Lanckriet et al. (2004b) that the proposed SDP and QCQP formulations have the worst-case time complexity of $O\left((p+n)^2 n^{2.5}\right)$ and $O\left(pn^2+n^3\right)$, respectively, where p is the number of candidate kernels and n is the number of training samples. The algorithm to solve the proposed SILP formulation alternates between solving a linear program (LP) and a linear system of equations. The LP formulation involved has a simple structure and its computation time is small, especially when p is much smaller than n. Note that the number of constraints in the LP depends on the number of iterations. Our experiments show that the algorithm converges within a small number of iterations. Thus, the time complexity of the SILP formulation is dominated by the time in solving the linear system which has a complexity of $O\left(n^3\right)$. Overall, the SILP formulation has a worst-case time complexity of $O\left(n^3 Ite\right)$ where Ite is the number of iterations.

All formulations discussed in Lanckriet et al. (2004b), Kim et al. (2006) and Sonnenburg et al. (2006) are constrained to binary-class problems. We show in the next section that our formulations in this section can be extended naturally to the multi-class case.

3. Convex Formulations for Multi-class Problems

In the multi-class case, we are given a data set that consists of m samples $\{(x_i,y_i)\}_{i=1}^m$, where $x_i \in \mathbb{R}^d$, and $y_i \in \{1,2,\cdots,k\}$ denotes the class label of the i-th sample, and $k>2$. Similar to the binary-class case, let $X=[x_1,\cdots,x_m]$ be the data matrix.

In the multi-class RKDA formulation, the maximization of the following objective function is commonly used (Ye, 2005):

$$F_4(W,K) = \text{trace}\left(\left(W^T\left(\Sigma_K+\lambda I\right)W\right)^{-1} W^T B_K W\right), \tag{23}$$

where W is the transformation matrix, and B_K, the so-called between-class scatter matrix is defined as

$$B_K = \phi_K(X) H H^T \phi_K(X)^T,$$

$H=[h_1,h_2,\cdots,h_k]$, and h_i is a vector whose j-th entry is given by

$$h_i(j) = \begin{cases} \sqrt{\frac{n}{n_j}} - \sqrt{\frac{n_j}{n}} & \text{if the } j\text{-th data point belongs to the } i\text{-th class} \\ -\sqrt{\frac{n_j}{n}} & \text{otherwise.} \end{cases} \tag{24}$$

The optimal W is given by computing the eigenvectors of the following matrix:

$$\left(\Sigma_K+\lambda I\right)^{-1} B_K.$$

Since the weight vectors are in the span of the images of the data points in the feature space, we can express W as $W=\phi_K(X)A$ for some matrix $A \in \mathbb{R}^{m\times\ell}$, where $A=[\alpha_1,\cdots,\alpha_\ell]$. Then

$$F_4(W,K) = \text{trace}\left(\left(A^T\left(GPG+\lambda G\right)A\right)^{-1} A^T GHH^T GA\right).$$

Define two matrices S_t^K and S_b^K as follows:

$$\begin{aligned} S_t^K &= GPG+\lambda G, \\ S_b^K &= GHH^T G. \end{aligned}$$

Since the null space of S_t^K lies in the null space of S_b^K (Ye and Xiong, 2006), there exists a nonsingular matrix Z such that

$$\begin{aligned} Z^T S_t^K Z &= \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix}, \\ Z^T S_b^K Z &= \begin{pmatrix} \Sigma_b & 0 \\ 0 & 0 \end{pmatrix}, \end{aligned}$$

where Σ_b is diagonal with the diagonal entries sorted in non-decreasing order. The optimal A^* is given by

$$A^* = Z_q = [z_1, \cdots, z_q],$$

where Z_q consists of the first q columns of Z, and $q = \text{rank}(S_b^K)$. It follows that the optimal value of $F_4(W,K)$ achieved by the optimal A^* is given by

$$F_4^*(K) = \text{trace}(\Sigma_b) = \text{trace}\left(\left(S_t^K\right)^{-1} S_b^K\right). \tag{25}$$

Here we have assumed that $S_t^K = GPG + \lambda G$ is nonsingular. We could use the pseudo-inverse to deal with the singular case, and all the following arguments still follow.

Thus, in the multi-class case, the optimal kernel function K can be computed by maximizing $F_4^*(K)$ in Equation (25), which is however highly nonlinear and difficult to solve. In the following, we present an equivalent formulation as the one in Equation (25), which is more tractable computationally.

3.1 SDP Formulation

Consider the maximization of the following objective function:

$$F_5(W,K) = \sum_{i=1}^{k} \frac{(w_i^T \phi_K(X) h_i)^2}{w_i^T (\Sigma_K + \lambda I) w_i}, \tag{26}$$

where

$$W = [w_1, \cdots, w_k]$$

is the transformation matrix, and h_i is defined in Equation (24). The following lemma shows that the optimal kernel function K coincides for F_4 and F_5.

Lemma 3.1 *Let F_4 and F_5 be defined as in Equation (23) and Equation (26), respectively. Let W^* and K^* be the optimal solution to the following optimization problem:*

$$\max_K \max_W F_4(W,K), \tag{27}$$

and let $\tilde{W}^*$ and $\tilde{K}^*$ be the optimal solution to the following optimization problem:

$$\max_K \max_W F_5(W,K). \tag{28}$$

Then $K^* = \tilde{K}^*$.

Proof Since $W = \phi_K(X)A$, we have $w_i = \phi_K(X)\alpha_i$ and

$$F_5(W,K) = \sum_{i=1}^{k} \frac{(\alpha_i^T G h_i)^2}{\alpha_i^T (GPG + \lambda G)\alpha_i} = \sum_{i=1}^{k} \frac{(\alpha_i^T G h_i)^2}{\alpha_i^T S_t^K \alpha_i}.$$

The computation of α_i and α_j for $i \neq j$ is independent of each other when the kernel function K and λ are fixed. The optimal α_i^* is given by

$$\alpha_i^* = \left(S_t^K\right)^{-1} G h_i.$$

It follows that the maximum value of $F_5(W,K)$ achieved by the optimal $A^* = [\alpha_1^*, \cdots, \alpha_k^*]$ is given by

$$F_5^*(K) = \sum_{i=1}^{k} (G h_i)^T \left(S_t^K\right)^{-1} G h_i.$$

Based on the properties of matrix trace, we have

$$\begin{aligned}
F_5^*(K) &= \sum_{i=1}^{k} (G h_i)^T \left(S_t^K\right)^{-1} G h_i \\
&= \sum_{i=1}^{k} \text{trace}\left((G h_i)^T \left(S_t^K\right)^{-1} G h_i\right) \\
&= \sum_{i=1}^{k} \text{trace}\left(\left(S_t^K\right)^{-1} G h_i (G h_i)^T\right) \\
&= \text{trace}\left(\left(S_t^K\right)^{-1} \sum_{i=1}^{k} \left(G h_i h_i^T G^T\right)\right) \\
&= \text{trace}\left(\left(S_t^K\right)^{-1} \left(GHH^T G^T\right)\right) \\
&= \text{trace}\left(\left(S_t^K\right)^{-1} S_b^K\right) \\
&= F_4^*(K).
\end{aligned}$$

This completes the proof. ■

It is interesting to note that, in general, the optimal W^* and $\tilde{W}^*$ for the optimization problems in Equations (27) and (28) are different. However, it has been shown recently that, when the value of the regularization parameter is approaching zero, multi-class regularized least squares is equivalent to multi-class discriminant analysis under a mild condition (Ye, 2007). Empirical evidences show that when the value of the regularization parameter is small, which is usually the case in practice, their performance is similar.

The objective function in Equation (26) is closely related to its binary counterpart in Equation (6). Note that a variant of the Fisher discriminant ratio (FDR) (Kim et al., 2006) can be written as:

$$F_2(w,K) = \frac{(w^T \phi_K(X)\, a)^2}{w^T (\Sigma_K + \lambda I) w}.$$

Thus, $F_5(W,K)$ in Equation (26) can be interpreted as the weighted summation of the FDRs between the samples in the i-th class and the rest where $i = 1,\cdots,k$. The weights can be computed from the definition of H in Equation (24) as follows:

$$h_i = \begin{bmatrix} \vdots \\ \sqrt{\frac{n}{n_i}} - \sqrt{\frac{n_i}{n}} \\ \vdots \\ -\sqrt{\frac{n_i}{n}} \\ \vdots \end{bmatrix} = (n-n_i)\sqrt{\frac{n_i}{n}} \begin{bmatrix} \vdots \\ \frac{1}{n_i} \\ \vdots \\ -\frac{1}{n-n_i} \\ \vdots \end{bmatrix} = (n-n_i)\sqrt{\frac{n_i}{n}}\, a^{(i)},$$

where $a^{(i)}$ is obtained from Equation (3) by taking the samples from the i-th class as positive and the rest as negative. It follows that the weight for the i-th binary classification problem is: $(n-n_i)^2 n_i/n$.

Following the results from the last section for the binary-class case, the optimal kernel learning problem for multi-class RKDA can be formulated as follows:

$$\begin{aligned} \min_{t_1,\cdots,t_k,\theta} \quad & \sum_{j=1}^{k} t_j \\ \text{subject to} \quad & \begin{pmatrix} I + \frac{1}{\lambda}\sum_{i=1}^{p} \theta_i \tilde{G}_i & h_j \\ h_j^T & t_j \end{pmatrix} \succeq 0, \text{ for } j = 1,\cdots,k, \\ & \theta \geq 0, \\ & \theta^T r = 1. \end{aligned} \tag{29}$$

Unfortunately, the SDP problem given in Equation (29) is computationally prohibitive due to the presence of positive semidefinite constraints. To alleviate this computational problem, we put all the constraints in a single larger constraint. This imposes stronger constraints than those on the original problem, but the computational cost can be reduced dramatically. It is based on the following lemma.

Lemma 3.2 *Let $M \in \mathbb{R}^{m\times m}$ be any positive definite matrix, $a_1,\cdots,a_k \in \mathbb{R}^m$, $t_1,\cdots,t_k \in \mathbb{R}$. Then*

$$\begin{pmatrix} M & a_1 & a_2 & \cdots & a_k \\ a_1^T & t_1 & 0 & \cdots & 0 \\ a_2^T & 0 & t_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ a_k^T & 0 & 0 & \cdots & t_k \end{pmatrix} \succeq 0 \tag{30}$$

implies

$$\begin{pmatrix} M & a_j \\ a_j^T & t_j \end{pmatrix} \succeq 0, \text{ for all } j. \tag{31}$$

Proof For a symmetric and positive semidefinite matrix, it is known that all of its principal submatrices are also symmetric and positive semidefinite. Matrices in Equation (31) are all principal submatrices of the matrix in Equation (30). This can be seen by removing 2 to j and $j+2$ to $k+1$ rows and columns of the block matrix in Equation (30). This completes the proof of the lemma. ■

We summarize the main result of this section in the following theorem:

Theorem 3.1 *Given a set of p centered kernel matrices $\tilde{G}_1, \cdots, \tilde{G}_p$, the optimal kernel matrix, in the form of linear combination of the given p kernel matrices, that maximizes the objective function in Equation (26) can be found by solving the SDP problem in Equation (29). This problem can be approximated by the following more restricted formulation:*

$$\begin{aligned} \min_{t_1,\cdots,t_k,\theta} \quad & \sum_{j=1}^{k} t_j \\ \textit{subject to} \quad & \begin{pmatrix} I + \frac{1}{\lambda}\sum_{i=1}^{p}\theta_i\tilde{G}_i & h_1 & h_2 & \cdots & h_k \\ h_1^T & t_1 & 0 & \cdots & 0 \\ h_2^T & 0 & t_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ h_k^T & 0 & 0 & \cdots & t_k \end{pmatrix} \succeq 0, \\ & \theta \geq 0, \\ & \theta^T r = 1, \end{aligned} \tag{32}$$

where $r_i = trace(\tilde{G}_i)$. The optimal solution to the formulation in Equation (32) satisfies the constraints in Equation (29).

The formulation in Equation (32) is an approximation to the exact formulation in Equation (29). We use the approximate formulation in our experiments in Section 5, and empirical results show that it achieves comparable performance with other exact formulations.

3.2 QCQP Formulation

Although the approximate SDP formulation in the last section is scalable in terms of the number of classes, interior point algorithms for solving SDP have an inherently large time complexity, and thus it cannot be applied to large-scale problems. In this subsection, we propose a QCQP formulation which is more efficient than its SDP counterpart. The derivations here are similar to those in Section 2.2.

In order to formulate the multi-class RKDA kernel learning problem into a QCQP problem, we first consider the minimization of the following objective function:

$$F_6(W,K) = \sum_{i=1}^{k} \left(||(\phi_K(X)P)^T w_i - h_i||^2 + \lambda ||w_i||^2 \right), \tag{33}$$

where $W = [w_1, \cdots, w_k]$. It is clear that for a fixed K and λ, the computation of w_i and w_j for $i \neq j$ is independent of each other. By extending the results from Lemma 2.1 and Lemma 3.1, it is easy to show that the optimal kernel function K minimizing the objective function in Equation (26) coincides the minimizer of $F_6(W,K)$ in Equation (33). Motivated by this equivalence result, we derive an efficient QCQP formulation for the multi-class RKDA kernel learning problem, as summarized in the following theorem.

Theorem 3.2 *Given a set of p centered kernel matrices $\tilde{G}_1, \cdots, \tilde{G}_p$, the optimal kernel matrix, in the form of a convex linear combination of the given p kernel matrices, that minimizes the objective*

function in Equation (33) can be found by solving the following convex QCQP problem:

$$\begin{aligned} \max_{\beta_1,\cdots,\beta_k,t} \quad & \sum_{j=1}^{k} \beta_j^T h_j - \frac{1}{4}\sum_{j=1}^{k} \beta_j^T \beta_j - \frac{1}{4\lambda} t \\ \textit{subject to} \quad & t \geq \frac{1}{r_i}\sum_{j=1}^{k} \beta_j^T \tilde{G}_i \beta_j,\ i = 1,\cdots,p. \end{aligned} \tag{34}$$

where $r_i = trace(\tilde{G}_i)$.

Proof We first consider the dual formulation of the minimization of $F_6(W,K)$ in terms of W for fixed K and λ. Denote

$$\eta_i = (\phi_K(X)P)^T w_i - h_i.$$

It follows that

$$F_6(w,K) = \sum_{i=1}^{k} ||\eta_i||^2 + \lambda \sum_{i=1}^{k} ||w_i||^2.$$

Define the Lagrangian function of this problem as follows:

$$L(\{\eta_i\}_{i=1}^k, w, \{\beta_i\}_{i=1}^k) = \sum_{i=1}^{k} ||\eta_i||^2 + \lambda \sum_{i=1}^{k} ||w_i||^2 - \sum_{i=1}^{k} \beta_i^T \left((\phi_K(X)P)^T w_i - h_i - \eta_i\right),$$

where the β_i's are the vectors of Lagrangian dual variables. Taking the derivatives of L with respect to η_i and w_i for all i, and setting them equal to zero, we get

$$\begin{aligned} \frac{\partial L}{\partial \eta_i} &= 2\eta_i + \beta_i = 0, \\ \frac{\partial L}{\partial w_i} &= 2\lambda w_i - \phi_K(X)P\beta_i = 0. \end{aligned}$$

Thus, we have

$$\eta_i = -\frac{\beta_i}{2}, \text{ and } w_i = \frac{\phi_K(X)P\beta_i}{2\lambda},$$

and we obtain the following Lagrangian dual function:

$$\begin{aligned} g(\beta_1,\cdots,\beta_k) &= \min_{w_i,\eta_i,i=1,\cdots,k} L(\{\eta_i\}_{i=1}^k, w, \{\beta_i\}_{i=1}^k) \\ &= \sum_{i=1}^{k} \left(-\frac{1}{4}\beta_i^T \left(I + \frac{1}{\lambda} PGP\right)\beta_i + \beta_i^T h_i\right). \end{aligned} \tag{35}$$

The optimal $\beta_1^*,\cdots,\beta_k^*$ can be computed by maximizing $g(\beta_1,\cdots,\beta_k)$ in Equation (35) as

$$(\beta_1^*,\cdots,\beta_k^*) = \operatorname*{argmax}_{\beta_1,\cdots,\beta_k} \left\{ \sum_{i=1}^{k} \left(-\frac{1}{4}\beta_i^T \left(I + \frac{1}{\lambda} PGP\right)\beta_i + \beta_i^T h_i\right)\right\}.$$

Since strong duality holds, the optimal kernel matrix $\tilde{G}$ is given by solving the following optimization problem:

$$\min_{\tilde{G}\in\tilde{\mathcal{G}}} \max_{\beta_1,\cdots,\beta_k} \left\{ \sum_{i=1}^{k} \left(-\frac{1}{4}\beta_i^T \left(I + \frac{1}{\lambda}\tilde{G}\right)\beta_i + \beta_i^T h_i\right)\right\}.$$

Similar to the binary-class case, the above optimization problem can be written as

$$\begin{aligned}
& \min_{\theta:\theta\geq 0,\theta^T r=1} \max_{\beta_1,\cdots,\beta_k} \left\{ \sum_{j=1}^{k} \left(-\frac{1}{4}\beta_j^T \left(I + \frac{1}{\lambda}\sum_{i=1}^{p} \left(\theta_i \tilde{G}_i\right) \right) \beta_j + \beta_j^T h_j \right) \right\} \qquad (36)\\
= & \max_{\beta_1,\cdots,\beta_k} \min_{\theta:\theta\geq 0,\theta^T r=1} \left\{ \sum_{j=1}^{k} \left(-\frac{1}{4}\beta_j^T \left(I + \frac{1}{\lambda}\sum_{i=1}^{p} \theta_i \tilde{G}_i \right) \beta_j + \beta_j^T h_j \right) \right\} \\
= & \max_{\beta_1,\cdots,\beta_k} \min_{\theta:\theta\geq 0,\theta^T r=1} \left\{ -\frac{1}{4}\sum_{j=1}^{k} \beta_j^T \beta_j - \frac{1}{4\lambda}\sum_{i=1}^{p} \theta_i \left(\sum_{j=1}^{k} \beta_j^T \tilde{G}_i \beta_j \right) + \sum_{j=1}^{k} \beta_j^T h_j \right\} \\
= & \max_{\beta_1,\cdots,\beta_k} \left\{ \sum_{j=1}^{k} \beta_j^T h_j - \frac{1}{4}\sum_{j=1}^{k} \beta_j^T \beta_j - \frac{1}{4\lambda} \max_{\theta:\theta\geq 0,\theta^T r=1} \left\{ \sum_{i=1}^{p} \theta_i \left(\sum_{j=1}^{k} \beta_j^T \tilde{G}_i \beta_j \right) \right\} \right\} \\
= & \max_{\beta_1,\cdots,\beta_k} \left\{ \sum_{j=1}^{k} \beta_j^T h_j - \frac{1}{4}\sum_{j=1}^{k} \beta_j^T \beta_j - \frac{1}{4\lambda} \max_i \left(\frac{1}{r_i} \sum_{j=1}^{k} \beta_j^T \tilde{G}_i \beta_j \right) \right\}.
\end{aligned}$$

By constraining

$$\max_i \left(\frac{1}{r_i} \sum_{j=1}^{k} \beta_j^T \tilde{G}_i \beta_j \right) \leq t$$

and putting t in the objective function, we prove the formulation in Equation (34). ■

3.3 SILP Formulation

The QCQP formulation in Theorem 3.2 has a worse-case time complexity of $O(pk^2n^2 + k^3n^3)$, which is cubic in terms of the number of classes and the number of data points. We show in this subsection that the RKDA kernel learning problem in the multi-class case can be formulated as an SILP problem, as summarized in the following theorem.

Theorem 3.3 *Given a set of p centered kernel matrices $\tilde{G}_1, \cdots, \tilde{G}_p$, the optimal kernel matrix, in the form of a convex linear combination of the given p kernel matrices, that minimizes the objective function in Equation (33) can be found by solving the following SILP problem:*

$$\begin{aligned}
\max_{\theta,\gamma} \quad & \gamma \qquad (37)\\
\textit{subject to} \quad & \theta \geq 0, \\
& \theta^T r = 1, \\
& \sum_{i=1}^{p} \theta_i S_i(\beta) \geq \gamma, \quad \textit{for all } \beta,
\end{aligned}$$

where $S_i(\beta)$ is defined as

$$S_i(\beta) = \sum_{j=1}^{k} \left(\frac{r_i}{4}\beta_j^T \beta_j + \frac{1}{4\lambda}\beta_j^T \tilde{G}_i \beta_j - r_i \beta_j^T h_j \right), \quad \textit{for } i = 1, \cdots, p, \qquad (38)$$

$r = (r_1, \cdots, r_p)^T$, and $r_i = trace(\tilde{G}_i)$.

Formulation	SDP	QCQP	SILP
Complexity	$O\left((p+n)^2(k+n)^{2.5}\right)$	$O(pk^2n^2+k^3n^3)$	$O(n^3Ite)$

Table 1: Time complexity of the proposed multi-class RKDA kernel learning formulations: p is the number of candidate kernels, n is the number of training samples, k is the number of classes, and Ite is the number of iterations in SILP.

Proof The proof follows the same procedure as in Theorem 2.3 by starting from Equation (36) and changing the definition of $S_i(\beta)$ from Equation (18) to Equation (38). ■

Note that the only difference between formulations in Theorem 2.3 and Theorem 3.3 lies in the definitions of $S_i(\beta)$. To find the β_j, for $j = 1,\cdots,k$, that maximize the constraint violation in the multi-class case, we need to solve the following k systems of linear equations:

$$\left(\frac{1}{2}I+\frac{1}{2\lambda}\sum_{i=1}^{p}\theta_i\tilde{G}_i\right)\beta_j = h_j, \quad \text{for } j = 1,\cdots,k.$$

Note that the coefficient matrix is the same for all of the k linear systems. Thus the LU decomposition (Golub and Van Loan, 1996) needs to be computed only once, and only the forward/backward substitution needs to be performed k times to obtain the solutions.

3.4 Time Complexity Analysis

In this subsection, we analyze the time complexity of the proposed formulations in the multi-class case. By following similar analysis in the binary-class case, we can show that the proposed (approximate) SDP and QCQP formulations have worse-case time complexity of $O\left((p+n)^2(k+n)^{2.5}\right)$ and $O(pk^2n^2+k^3n^3)$, respectively. For the SILP formulation in the multi-class case, the k linear systems involved in each iterative step share the same coefficient matrix, and they can be solved in $O(n^3)$ time. Thus, the overall complexity is still $O(n^3Ite)$ where Ite is the number of iterations. The complexity of multi-class RKDA kernel learning formulations is summarized in Table 1.

4. Joint Kernel and Regularization Parameter Learning

The formulations presented in the last two sections focus on the estimation of the kernel matrix only, while the regularization parameter λ is pre-specified. In some cases, the performance of RKDA algorithm depends critically on the value of λ. In this section, we show that all the formulations proposed in this paper can be reformulated equivalently, and this new formulation leads naturally to the estimation of the regularization parameter λ in a joint framework. The detailed derivations in this section are similar to those presented in Sections 2 and 3.

4.1 Joint Learning for Binary-class Problems

One key advantage of the kernel learning formulation in Equation (8) in comparison with the one in Kim et al. (2006) is that the regularization parameter λ can also be estimated in a joint optimization

framework. In particular, all the formulations (SDP, QCQP, and SILP) for the binary-class RKDA kernel learning problems, presented in Theorems 2.1–2.3, can be recast to optimize the regularization parameter simultaneously. The next three subsections provide details of these reformulations.

4.1.1 SDP FORMULATION

For the estimation of regularization parameter, we consider a slightly modified version of the regularized least squares formulation, which is equivalent to the standard formulation in Equation (12). The modified version minimizes the following objective function:

$$F_7(w,K,\tau) = \tau||(\phi_K(X)P)^T w - a||^2 + ||w||^2, \tag{39}$$

where $\tau = 1/\lambda$. We will first consider the case when τ is fixed. We will then extend to the general case when τ is optimized jointly.

The optimal w^* that minimizes the objective function in Equation (39) for a fixed K and a fixed τ is given by

$$\begin{aligned} w^* &= \left(\frac{1}{\tau}I + \phi_K(X)P\phi_K(X)^T\right)^{-1}\phi_K(X)Pa \\ &= \tau\phi_K(X)\left(I - P\left(\frac{1}{\tau}I + PGP\right)^{-1}PG\right)a. \end{aligned}$$

The optimal value of the objective function in Equation (39) is given by

$$F_7^*(K,\tau) = a^T\left(\frac{1}{\tau}I + \tilde{G}\right)^{-1}a, \tag{40}$$

where $\tilde{G} = PGP$.

We can observe from Equation (40) that the identity matrix appears in exactly the same form as other kernel matrices. We can thus treat the regularization parameter as one of the coefficients for the kernel matrix and optimize them simultaneously. This leads to the following formulation:

$$\begin{aligned} \min_{t,\tilde{\theta}} \quad & t \\ \text{subject to} \quad & \begin{pmatrix} \sum_{i=0}^p \tilde{\theta}_i\tilde{G}_i & a \\ a^T & t \end{pmatrix} \succeq 0, \\ & \tilde{\theta} \geq 0, \\ & \sum_{i=0}^p \tilde{\theta}_i \text{trace}(\tilde{G}_i) = 1, \end{aligned} \tag{41}$$

where $\tilde{\theta} = [\theta_0, \theta_1, \cdots, \theta_p]^T$, $\theta_0 = \frac{1}{\tau} = \lambda$, and $\tilde{G}_0 = I$.

4.1.2 QCQP FORMULATION

In order to cast the formulation in Theorem 2.2 to optimize the regularization parameter, we again start from the modified least square problem in Equation (39). By following the same procedure as

in Theorem 2.2, the optimization problem in Equation (15) can be expressed as

$$\begin{aligned} & \min_{\theta:\theta\geq 0,\theta^T r=1} \max_{\beta} \left\{ -\frac{1}{4}\beta^T \left(\frac{1}{\tau} I + \sum_{i=1}^{p} \theta_i \tilde{G}_i \right) \beta + \beta^T a \right\} \\ = & \max_{\beta} \min_{\tilde{\theta}:\tilde{\theta}\geq 0,\tilde{\theta}^T r=1} \left\{ -\frac{1}{4}\beta^T \left(\sum_{i=0}^{p} \tilde{\theta}_i \tilde{G}_i \right) \beta + \beta^T a \right\}, \end{aligned} \tag{42}$$

where $\theta_0 = \frac{1}{\tau}$, and $\tilde{G}_0 = I$. This can be formulated to optimize the regularization parameter as one of the coefficients for the kernel matrix as follows:

$$\begin{aligned} \max_{\beta,t} \quad & \beta^T a - \frac{1}{4} t \\ \text{subject to} \quad & t \geq \frac{1}{r_i} \beta^T \tilde{G}_i \beta, \; i = 0, \cdots, p. \end{aligned} \tag{43}$$

This problem is a quadratically constrained linear program.

4.1.3 SILP FORMULATION

The SILP formulation proposed in Theorem 2.3 for the binary-class problem can also be reformulated to optimize λ jointly. It follows from Equation (42) that this joint learning problem can be formulated as follows:

$$\begin{aligned} \max_{\tilde{\theta},\gamma} \quad & \gamma \\ \text{subject to} \quad & \tilde{\theta} \geq 0, \\ & \tilde{\theta}^T r = 1, \\ & \sum_{i=0}^{p} \theta_i S_i(\beta) \geq \gamma, \quad \text{for all } \beta, \end{aligned} \tag{44}$$

where $S_i(\beta)$ is defined as

$$S_i(\beta) = \frac{1}{4}\beta^T \tilde{G}_i \beta - r_i \beta^T a, \quad \text{for } i = 0, \cdots, p,$$

$r = (r_0, \cdots, r_p)^T$, $r_i = \text{trace}(\tilde{G}_i)$, $\tilde{\theta} = [\theta_0, \theta_1, \cdots, \theta_p]^T$, $\theta_0 = \frac{1}{\tau} = \lambda$, and $\tilde{G}_0 = I$.

4.2 Joint Learning for Multi-class Problems

All formulations for the multi-class RKDA kernel learning problems presented in Section 3 can be recast to optimize the regularization parameter jointly. The next three subsections provide details of these reformulations.

4.2.1 SDP FORMULATION

In order to incorporate λ in the optimization problem, we modify the objective function in Equation (26) as follows:

$$F_8(W,K,\tau) = \sum_{i=1}^{k} \frac{(w_i^T \phi_K(X) h_i)^2}{w_i^T (\tau \Sigma_K + I) w_i}.$$

By following the same derivation in Lemma 3.1 and noticing the relationship with the binary-class case, we derive the following SDP formulation for the multi-class RKDA kernel learning problem:

$$\begin{aligned}
\min_{t_1,\cdots,t_k,\tilde{\theta}} \quad & \sum_{j=1}^{k} t_j \\
\text{subject to} \quad & \begin{pmatrix} \sum_{i=0}^{p} \tilde{\theta}_i \tilde{G}_i & h_1 & h_2 & \cdots & h_k \\ h_1^T & t_1 & 0 & \cdots & 0 \\ h_2^T & 0 & t_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ h_k^T & 0 & 0 & \cdots & t_k \end{pmatrix} \succeq 0, \\
& \tilde{\theta} \geq 0, \\
& \tilde{\theta}^T r = 1,
\end{aligned} \tag{45}$$

where $\tilde{\theta} = [\theta_0, \theta_1, \cdots, \theta_p]^T$, $\theta_0 = \frac{1}{\tau} = \lambda$, and $\tilde{G}_0 = I$.

4.2.2 QCQP FORMULATION

Similar to the binary-class case, we modify the least square problem in Equation (33) as follows:

$$F_9(W,K,\tau) = \sum_{i=1}^{k} \left(\tau ||(\phi_K(X)P)^T w_i - h_i||^2 + ||w_i||^2 \right),$$

where $\tau = 1/\lambda$. By following the same derivation as in Theorem 3.2, we obtain the following joint optimization problem:

$$\begin{aligned}
\max_{\beta_1,\cdots,\beta_k,t} \quad & \sum_{j=1}^{k} \beta_j^T h_j - \frac{1}{4} t \\
\text{subject to} \quad & t \geq \frac{1}{r_i} \sum_{j=1}^{k} \beta_j^T \tilde{G}_i \beta_j, \; i = 0, \cdots, p.
\end{aligned} \tag{46}$$

This is a quadratically constrained linear program.

4.2.3 SILP FORMULATION

Similar to the reformulation in the binary-class case, the SILP formulation for multi-class problems can also be formulated to optimize λ simultaneously as follows:

$$\begin{aligned} \max_{\tilde{\theta},\gamma} \quad & \gamma \\ \text{subject to} \quad & \tilde{\theta} \geq 0, \\ & \tilde{\theta}^T r = 1, \\ & \sum_{i=0}^{p} \theta_i S_i(\beta) \geq \gamma, \quad \text{for all } \beta, \end{aligned} \tag{47}$$

where

$$S_i(\beta) = \sum_{j=1}^{k} \left(\frac{1}{4} \beta_j^T \tilde{G}_i \beta_j - r_i \beta_j^T h_j \right), \quad \text{for } i = 0, \cdots, p,$$

$r = (r_0, \cdots, r_p)^T$, $r_i = \text{trace}(\tilde{G}_i)$, $\tilde{\theta} = [\theta_0, \theta_1, \cdots, \theta_p]^T$, $\theta_0 = \frac{1}{\tau} = \lambda$, and $\tilde{G}_0 = I$.

The reformulations to optimize λ simultaneously proposed in this section are motivated from Lanckriet et al. (2004b) and De Bie et al. (2003). As has been show in Lanckriet et al. (2004b), this joint optimization of λ works well in most cases in comparison with the simple approach of pre-specifying λ, but improved performance is not guaranteed.

5. Experimental Study

We conduct extensive experiments in this section to compare various aspects of relevant algorithms. The first part of the experiments focuses on combining kernel matrices derived from a single source of data. We demonstrate the effectiveness of the proposed MKL formulations for heterogeneous data integration in the second part of the experiments. The SDP formulations in Equations (8), (32), (41), and (45) are solved using the optimization package SeDuMi (Sturm, 1999). The QCQP formulations in Equations (13), (34), (43), and (46) are solved using the MOSEK package (Andersen and Andersen, 2000). The linear programs involved in the SILP formulations in Equations (16), (37), (44), and (47) are solved using the MATLAB[1] build-in function *linprog*. The tolerance parameter ε, defined in Equation (22), is set to 5×10^{-4}. The source codes of the proposed formulations for the experiments are available online.[2]

We first evaluate the proposed formulations for binary-class problems in Section 5.1. The experimental results and analysis for the multi-class formulations are presented in Section 5.2. We demonstrate the effectiveness of the proposed formulations for heterogeneous data integration in Section 5.3. In Section 5.4, we analyze the relationship between RKDA and SVM, and Section 5.5 studies the effect of regularization parameter on classification performance.

5.1 Experiments on Binary-class Problems

In the binary-class case, we compare our formulations with the 1-norm soft margin SVM, 2-norm soft margin SVM with and without the regularization parameter C optimized jointly as proposed in

Table 2: Comparison of twelve methods on the *sonar* data set. The twelve methods, listed from top to bottom are: SDP formulation with λ fixed as proposed in Theorem 2.1, SDP formulation with λ optimized jointly as proposed in Equation (41), QCQP formulation with λ fixed as proposed in Theorem 2.2, QCQP formulation with λ optimized jointly as proposed in Equation (43), SILP formulation with λ fixed as proposed in Theorem 2.3, SILP formulation with λ optimized jointly as proposed in Equation (44), SDP formulation proposed in Kim et al. (2006), 1-norm soft margin SVM, 2-norm soft margin SVM without and with C optimized as proposed in Lanckriet et al. (2004b), RKDA and SVM with the kernels and regularization parameters selected by double cross-validation. Generally, subscripts of names in the first column are used to denote quantities that are optimized. The ten pre-specified kernels are all RBF kernels and the σ values used are 0.10, 0.22, 0.46, 1.00, 2.15, 4.46, 10.00, 21.54, 46.42, 100.00, as in Kim et al. (2006). The table is partitioned into three sections row-wise. In the first section, the columns headed with θ_i are the coefficients learned from the corresponding methods. The coefficients for the proposed six formulations are normalized to sum to one while those for other compared approaches are reported as obtained from their formulations. The column headed with λ/C provides the values of the regularization parameters, whether fixed or learned, and the test set accuracies and standard deviations are given in the last column. The second section includes RKDA and SVM with kernel and regularization parameter chosen by double cross-validation. We also report the number of times that a particular kernel is selected by cross-validation. The third section shows the accuracies of RKDA and SVM when the kernel is fixed and the regularization parameters chosen by cross-validation. Dashes are used to denote non-applicable items.

Lanckriet et al. (2004b), and the SDP formulation proposed in Kim et al. (2006). Also, we use double cross-validation to choose kernels and regularization parameters for SVM and RKDA. The 1-norm SVM classifier used is the LIBSVM package (Chang and Lin, 2001) and the 2-norm SVM code was obtained by adapting Anton Schwaighofer's implementation.[7]

Four data sets are used in the binary-class case. The *sonar, ionosphere*, and *cancer* data were retrieved from the UCI Machine Learning Repository (Newman et al., 1998). The *heart* data were

3. The number of times that a kernel is chosen by doubly cross-validated RKDA over 30 randomizations.
4. The number of times that a kernel is chosen by doubly cross-validated SVM over 30 randomizations.
5. Accuracy of RKDA when the kernel is fixed to each of the ten candidate kernels and λ is chosen by cross-validation.
6. Accuracy of SVM when the kernel is fixed to each of the ten candidate kernels and C is chosen by cross-validation.
7. The URL is `http://ida.first.fraunhofer.de/~anton/software.html`.

obtained from the STATLOG project.[8] All data are normalized. For each data set, we randomly partition the entire data set into training and test sets using the ratio 8:2. Ten RBF kernels are constructed from the training set data with different choices of the parameter σ as in Kim et al. (2006). Then the ten kernels are fed into the optimization software packages to obtain the corresponding coefficients for each kernel. Finally, the kernels are combined and used to compute the accuracy. For formulations SDP_θ, QCQP_θ, and SILP_θ, the λ value is fixed to 5.0×10^{-4}. For SDP_{Kim}, this value is fixed to 10^{-8}, as used in Kim et al. (2006). Following Lanckriet et al. (2004b), we fix C to 1 for SM1 and SM2.

Tables 2–5 present the experimental results on *sonar, heart, ionosphere*, and *cancer* data sets, respectively. In terms of performance, formulations that optimize λ jointly achieve similar accuracies to the ones with λ fixed. Note that for our experiments, all the data are normalized and the λ value is tuned manually for formulations with λ fixed. In practice, the optimal λ value is data-dependent. Thus, formulations that optimize λ jointly are expected to work better in such situations. In cases where no numerical problems have been reported, all the twelve compared methods achieve similar performance. However, for the first ten methods, there is no need for cross-validation, and they can be used for heterogeneous data integration from various sources.

For MKL formulations in Tables 2–5, we present the coefficients learned for each kernel. For doubly cross-validated methods, that is, $\text{RKDA}_{K,\lambda}$ and $\text{SVM}_{K,C}$, we record the number of times that a particular kernel has been selected in cross-validation. To understand the relative importance of each kernel when they are used individually, we fix the kernel to each of the ten pre-specified kernels and tune the regularization parameter using cross-validation and the accuracy of each kernel is recorded. We expect these quantities to have some relationship with the coefficients learned by solving convex programs. For the *sonar* data, RKDA_λ achieves the best performance on kernels corresponding to θ_6 and θ_7 while SVM_C achieves the highest accuracy on θ_6, θ_7 and θ_8. On the other hand, methods using linear combination of kernels favor kernels corresponding to θ_5 and θ_6. For the *heart* data, cross-validated SVM favors kernels corresponding to θ_9 and θ_{10} (they were chosen 9 and 17 times out of 30, respectively) while cross-validated RKDA uses kernels corresponding to θ_7, θ_8, and θ_9 most frequently. Our six formulations all give kernels corresponding to θ_1 and θ_{10} large weights, especially to θ_1, while SVM-based MKL formulations all set θ_{10} to zero. This may be due to the fact that RKDA and SVM optimize different criteria and thus favor different kernels. Another interesting observation is that all the ten MKL formulations give the first kernel a large weight while it is the worst kernel when used individually. This implies that the best individual kernel may not lead to a large weight when used in combination with others and poorly-performed individual kernel may contain complementary information that is useful when combined with other kernels. Such complementary information can not be incorporated when cross-validation is used to choose a single best kernel. For the *ionosphere* data, the best three individual kernels chosen by cross-validation are kernels corresponding to θ_5, θ_6 and θ_7. Interestingly, the kernel corresponding to θ_5 is assigned a zero weight by nine out of the ten MKL-based methods. For the *cancer* data, all kernels achieve similar performance when used separately while MKL-based formulations tend to assign a large weight to the kernel corresponds to θ_2.

To compare the efficiency of the proposed formulations with methods based on cross-validation, we record the computation time of the proposed QCQP and SILP formulations along with that of methods based on double cross-validation. Figure 1 plots the computation time of these six methods.

8. The URL is `http://www.liacc.up.pt/ML/old/statlog/datasets.html`.

Note that methods based on SDP have a much larger computation time than these six methods and their results are thus omitted. It can be seen that the proposed SILP formulations are more efficient than cross-validation based methods. Note that the convergence rate of the algorithm for solving the QCQP formulation depends on the data and parameter setting. Thus, it may take a relatively long time to converge in some cases, as shown by QCQP_θ on the *cancer* data in Figure 1.

5.2 Experiments on Multi-class Problems

In the multi-class experiments, we compare our formulations with KRDA and SVM with kernels and regularization parameters tuned using double cross-validation. The methods proposed in Lanckriet et al. (2004b) and Kim et al. (2006) are only applicable to binary-class problems. Five data sets with different numbers of classes are used for this experiment. The *USPS* handwritten digits database was described in Hull (1994). We choose the first $3, 6$, and 8 classes with 100 data points in each class for the experiment. The *wine* data set was obtained from UCI Machine Learning Repository and the *satimage* and *segment* were obtained from the STATLOG project. We use the first $3, 5$, and 6 classes for the *satimage* data and the first 3 and 4 classes for the *segment* data. The *waveform*

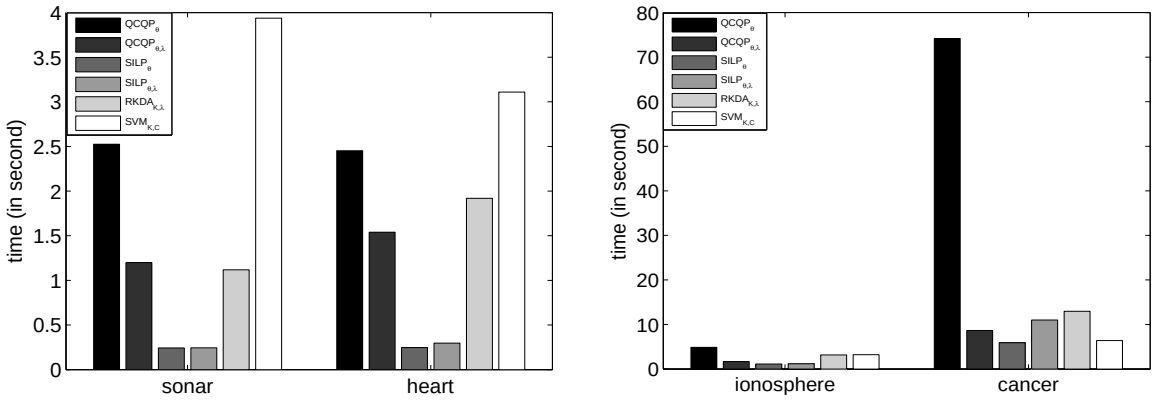

Figure 1: Computation time (in seconds) of the six methods on four binary-class data sets.

data set was described in Breiman et al. (1984) and are also available from UCI Machine Learning Repository. For each data set, we randomly partition the entire set into two subsets with 60% of the samples in the training set and 40% in the test set. Ten RBF kernels, with σ assigned the same values as in the binary-class case, are constructed from the training set.

Tables 6–15 present the experimental results on the ten data sets. In general, all the six proposed formulations achieve similar performance on the ten data sets. Compared to the QCQP and SILP formulations which are exact, our approximate SDP formulation for the multi-class problems work well in most cases. This implies that the approximate formulation is close to the exact one while the computational cost is lower. Furthermore, methods based on MKL and cross-validation achieve similar performance on all of the data sets.

In order to gain insights into the relative importance of each kernel when used in combination or separately, we use a similar experimental setup to the binary-class case. We found that for the *USPS*(3),[9] *USPS*(6), and *USPS*(8) data, all eight compared approaches favor the kernels corresponding to θ_9 and θ_{10}. Similar behavior has been observed for the *waveform*(3) data where only the last two kernels are selected by cross-validation and they are given large weights by all six MKL-based

9. The number in the parentheses denotes the number of classes used in the experiment.

Table 6: Comparison of eight methods on the *USPS* data set when the first three classes are used. The eight methods, listed from top to bottom, are the SDP formulation with λ fixed as proposed in Theorem 3.1, the SDP formulation with λ optimized jointly as proposed in Equation (45), the QCQP formulation with λ fixed as proposed in Theorem 3.2, the QCQP formulation with λ optimized jointly as proposed in Equation (46), the SILP formulation with λ fixed as proposed in Theorem 3.3, the SILP formulation with λ optimized jointly as proposed in Equation (47), RKDA and SVM with kernels and regularization parameters chosen by double cross-validation. Generally, subscripts of names in the first column are used to denote quantities that are optimized. Ten RBF kernels are pre-specified and the values for σ are the same as those used in the binary-class case (see caption of Table 2). This table is partitioned into two sections row-wise. In the first section, the columns headed with θ_i present the coefficients learned from each method. Note that all coefficients are normalized to sum to one. This is followed by the values for the λ, whether fixed or learned. The test set accuracies are given in the last column. In the second section, we report the number of times that each kernel has been selected by double cross-validation and the accuracies. Dashes are used to denote non-applicable items.

approaches. Thus for these data sets, the kernels selected by cross-validation and multiple kernel learning (MKL) agree. In contrast, for the *satimage*(3), *satimage*(5), and *satimage*(6) data sets, the proposed MKL-based approaches assign large weights to the first five kernels. In particular, θ_2, θ_3, and θ_5 are given large values for the *satimage*(3) data; θ_2, θ_4, and θ_5 are given large values for the *satimage*(5) data; θ_1, θ_2, and θ_4 are given large values for the *satimage*(6) data. On the other hand,

10. The number in parenthesis denotes the number of classes used in the experiments.
11. RKDA with kernel and λ chosen by double cross-validation. The first ten columns show the number of times that a kernel is chosen by doubly cross-validated RKDA over 30 randomizations.
12. SVM with kernel and λ chosen by double cross-validation. The first ten columns show the number of times that a kernel is chosen by doubly cross-validated SVM over 30 randomizations.

the two methods based on cross-validation tend to use the last five kernels more frequently than the first five kernels. This demonstrates that the best kernels used in combination and separately differ significantly for the *satimage* data set. We expect that complementary information exists among kernels for this data set such that a subset of kernels can be combined to obtain the optimal performance though none of them is the best kernel when used individually. Similar phenomenon can be observed from the *segment*(3) and *segment*(4) data sets in which the first kernel is assigned the largest weight by MKL-based formulations while it is never selected by cross-validation. This analysis shows that the information used by methods based on MKL and cross-validation may coincide or differ depending on the data.

To compare the efficiency of various methods, we report the computation time of the eight methods on the ten data sets in Table 16. It can be seen that the SDP formulations are much slower than methods based on cross-validation due to its inherent large complexity. The QCQP formulations are relatively efficient for data sets with a small number of classes. When the number of classes increases, their computation time increases rapidly. This is consistent with the theoretical

analysis in Section 3.4. In contrast, the proposed SILP formulations are more efficient than methods based on cross-validation on all of the ten data sets.

5.3 Gene Expression Pattern Image Classification

In this experiment, we demonstrate the effectiveness of the proposed multiple kernel learning (MKL) formulations for data (feature) integration. Gene expression pattern images of *Drosophila melanogaster* embryo at a given developmental stage (time) capture the spatial and temporal distribution of gene expression patterns (Tomancak et al., 2002). The identification of genes showing spatial overlaps in their expression patterns is fundamentally important to formulating and testing gene interaction hypotheses (Kumar et al., 2002; Peng and Myers, 2004). Estimation of pattern overlap is most biologically meaningful when images from a similar time point (developmental stage) are compared. Thus, one of the central issues in gene expression pattern image analysis is the classification of images into different developmental stage ranges (Ye et al., 2006).

Table 16: Comparison of computation time (in seconds) of various methods. The reported time is averaged over 30 random partitions.

We collect 2705 gene expression pattern images in the first three stage ranges (1-3, 4-6, and 7-8) from the FlyExpress[13] database. The raw gene expression pattern images are of size 128×320. It has been observed (Gargesha et al., 2005) that across various developmental stages, a distinguishing feature is the image textural properties at sub-block level, because image texture at the sub-block level changes as embryonic development progresses. Gabor filters (Daugman, 1988) have been shown to be effective in detecting local texture features and are well suited for extracting textural features for gene expression pattern images.

We apply Log Gabor Filters to extract the texture features (Daugman, 1988). Gabor filters are the product of a complex sinusoidal function and a Gaussian-shaped function. We use Log Gabor filters with 4 different wavelet scales and 6 different filter orientations to extract the texture information. Hence, 24 Gabor images were obtained from the filtering operation. Note that all 24 Gabor images have the same size (i.e., 128×320) as the original one. Figure 2 plots the 24 Gabor im-

13. The URL is `http://www.flyexpress.net`.

ages extracted from a sample image. These images contain different but potentially complementary information for stage classification. Two RBF kernels are built from each of the 24 Gabor images with σ values assigned as 50 and 100, respectively. We thus obtain a total of 48 kernel matrices. To exploit the complementary information in kernels constructed from different Gabor images, we apply the proposed SILP formulation to learn a linear combination of the 48 kernel matrices.

The 2705 images are randomly partitioned into training and test sets using the ratio 1:9. Our experimental results show that SILP_θ achieves a classification accuracy of about 88.28%. To see how each of the 48 kernel matrices works when used individually, we fix the kernel matrix and tune the λ value using cross-validation. The maximum, minimum, and average accuracies achieved across the 48 kernel matrices are 72.03%, 54.37%, and 61.88%, respectively. We also assign a uniform weight of 1 to each of the 48 kernel matrices and the combined kernel matrix achieves an accuracy of about 72.65%. These results demonstrate that different Gabor images contain complementary information, which is critical for stage classification, and the proposed MKL formulations are effective in exploiting this information by combining different kernel matrices.

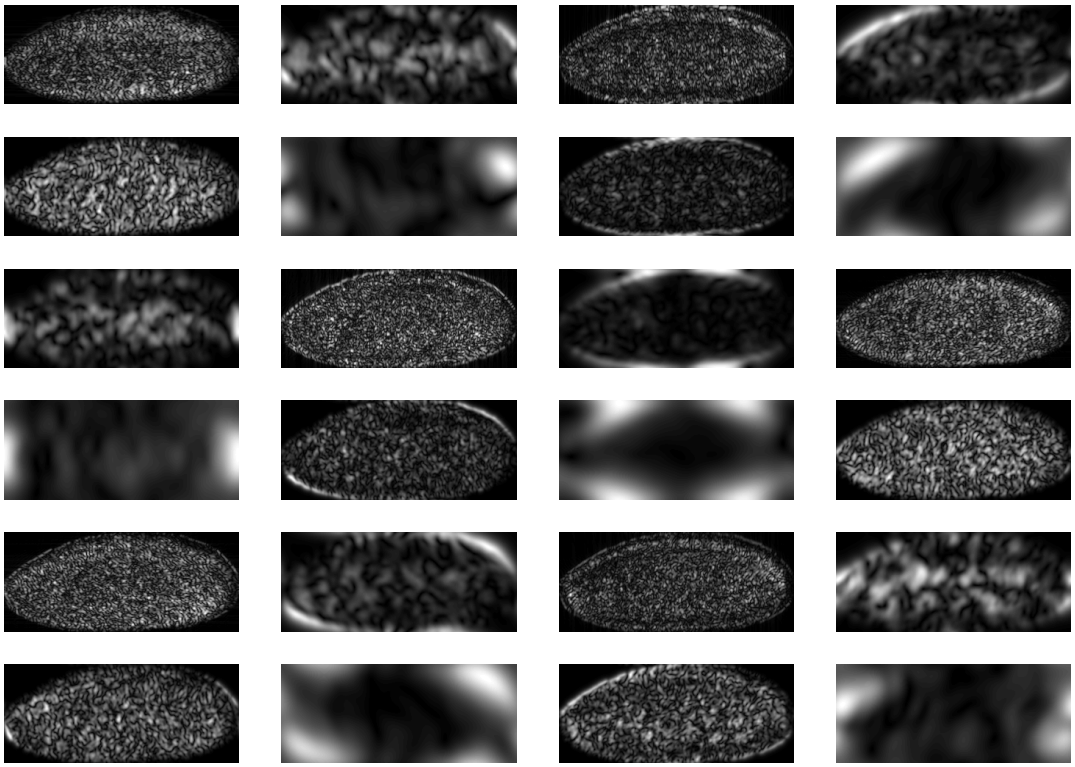

Figure 2: The 24 Gabor images extracted from a single sample image with 4 different wavelet scales and 6 different filter orientations.

		SM1			SM2			$SM2_C$

Table 17: The numbers of support vectors ("SVs") obtained from the 1-norm soft margin SVM, 2-norm soft margin SVM without and with C learned jointly that were proposed in Lanckriet et al. (2004b). These numbers are averaged over 30 random partitions. The total number of data points in the training set and the C values are also shown. The columns with title "PCT" show the percentage of support vectors over the training set.

5.4 SVM versus RKDA

It was shown (Shashua, 1999) that hard margin linear SVM is equivalent to linear discriminant analysis (LDA) when all the training points are support vectors. Through experiments, we found that the C values chosen by the 2-norm soft margin SVM proposed in Lanckriet et al. (2004b) are very large. Under such circumstances, soft margin SVM is approaching hard margin SVM. It has already been observed that SVM and kernel discriminant analysis usually have similar performance (Mika, 2002) and this has been confirmed by our experiments in the last two subsections. Thus it is interesting to report the number of support vectors for SVM. We record the average number of support vectors for 1-norm soft margin SVM, 2-norm soft margin SVM without and with C optimized jointly over the 30 random partitions reported in Section 5.1. As proposed in Lanckriet et al. (2004b), C is fixed to 1 for 1-norm and 2-norm soft margin SVM without C optimized. Table 17 reports the average C values obtained by the joint optimization 2-norm soft margin SVM and the average number of support vectors. For ease of comparison, we also report the size of training set and the averaged percentage of support vectors over 30 randomizations. It can be seen that for three out of four data sets, the percentages of support vectors are very high. This implies that SVM is similar to RKDA and explains why they have similar performance, as reported in the last two subsections.

5.5 The Effect of Regularization Parameter

In order to investigate the effect of regularization parameter in RKDA, we sampled 30 λ values between 10^{-10} and 10^2 uniformly over logarithmic scale and the accuracies of SDP_θ and QCQP_θ are plotted for two binary-class data sets (Figure 3) and two multi-class data sets (Figure 4). The results for SILP formulations are omitted since their performance is similar to their QCQP counterparts. It can be observed that as λ value changes, the accuracies oscillate in all cases. It can also be observed from the four figures that QCQP_θ tends to be less sensitive to the change of λ value than SDP_θ. This may be attributable to the fact that SDP is more computationally intensive and numerical problems may cause the poor performance. Indeed, we observed several reports of numerical problems from SeDuMi while conducting SDP experiments. The low accuracies of SDP_θ for some choices of λ in Figures 3 and 4 were caused by numerical problems and should be interpreted with caution.

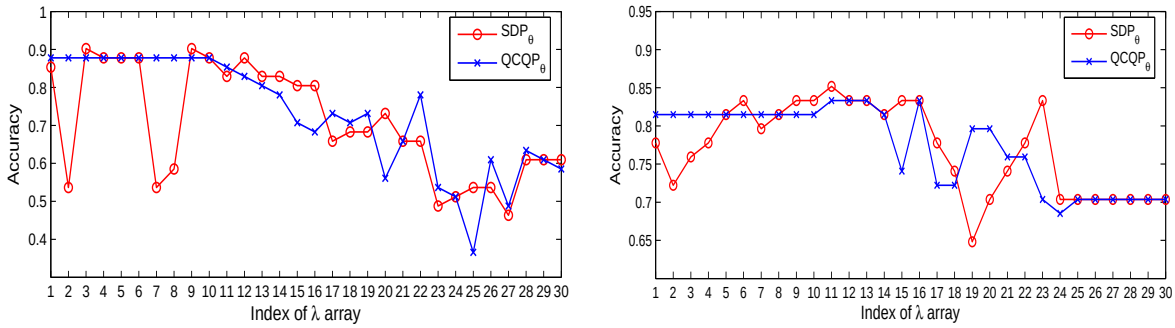

Figure 3: The change of accuracies for SDP_θ and QCQP_θ when λ varies from 10^{-10} to 10^2 for the *sonar* (left) and *heart* (right) data. The horizontal axis represents the indexes of the 30 λ values.

6. Discussion and Conclusion

We address the issue of learning appropriate kernels for RKDA in this paper. This problem is formulated as convex programs and thus globally optimal solutions are guaranteed. Practically, some convex optimization problems are computationally expensive and we propose approaches that are scalable and efficient to solve. While most existing work on kernel learning only deal with binary-class problems, we show that our binary-class formulations can be extended naturally to multi-class setting. Furthermore, we consider the problem of optimizing the kernel and regularization parameter in a joint framework, thus approaching the desirable goal of automated learning.

We have conducted extensive experiments to evaluate the proposed algorithms. When combining kernels from a single source of data, the proposed formulations have similar performance with approaches based on double cross-validation. When the candidate kernels contain complementary information, we show that the proposed formulations are effective to exploit such information. In terms of computation time, the SILP formulations are more efficient than approaches based on cross-validation. When evaluating the relative importance of each kernel (either used separately or in linear combination), we found that the best individual kernel sometimes coincides with the highly-weighted kernels in linear combination and sometimes disagrees considerably.

There are some directions for future work. Our experimental results have shown that the proposed approximate SDP formulation works well in most cases while it has a much lower computational cost in comparison with the exact formulation. We plan to compare the approximate formulation to the exact one in terms of complexity and performance. The derivation of multi-class formulations is based on an alternative criterion defined in Equation (23). This results in the same optimal transformation matrix as the original criterion in Equation (26) when a common (fixed) kernel matrix is used. However, they may differ when the kernel matrix is also optimized. We plan to investigate their differences further in the future. Most existing formulations for learning SVM kernels are restricted to the binary-class case. The idea from this paper may be useful for kernel learning in multi-class SVM. A more general problem is learning kernels for multi-label data in which each data point can be assigned to multiple classes. Such data are common in automatic image annotation problems (Lavrenko et al., 2004). We plan to explore these in the future.

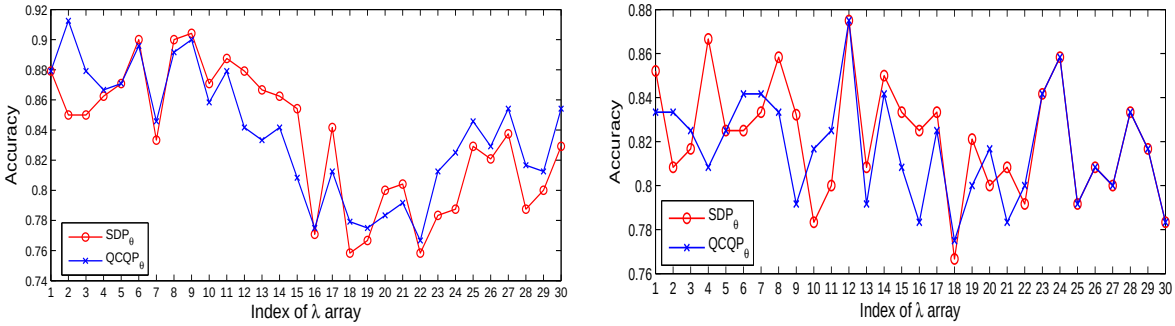

Figure 4: The change of accuracies for SDP_θ and QCQP_θ when λ varies from 10^{-10} to 10^2 for the *satimage*(6) (left) and *waveform*(3) (right) data. The horizontal axis represents the indexes of the 30 λ values.

Acknowledgments

The extensive experimental study in this paper was made possible with help from several researchers. Special thanks to Dr. Seung Jean Kim for helping in replicating their experiments. Dr. Johan Löfberg answered many questions about SeDuMi and his YALMIP through the online forum and E-mails. Dr. Anton Schwaighofer helped the authors to modify his SVM toolbox. The implementation of the proposed QCQP formulations is based on code for SVM kernel learning provided by Dr. Gert Lanckriet. This research is sponsored in part by funds from the Arizona State University and the National Science Foundation under Grant No. IIS-0612069.

Appendix A.

One of the basic tools used in our proof is the Sherman-Woodbury-Morrison formula (Golub and Van Loan, 1996): Let $S \in \mathbb{R}^{d\times d}$, and $Q, R \in \mathbb{R}^{d\times n}$. Assuming that both the matrices S and $(I + R^T S^{-1} Q)$ are nonsingular, we have

$$(S+QR^T)^{-1} = S^{-1} - S^{-1}Q(I+R^T S^{-1}Q)^{-1}R^T S^{-1}.$$

Since $P = PP$ and $P = P^T$, where P is the centering matrix defined in Equation (5), it follows that

$$\begin{aligned}
w^* &= (\Sigma_K + \lambda I)^{-1}(\mu_K^+ - \mu_K^-) \\
&= \left(\phi_K(X) P \phi_K(X)^T + \lambda I\right)^{-1} \phi_K(X) a \\
&= \left(\phi_K(X) PP \phi_K(X)^T + \lambda I\right)^{-1} \phi_K(X) a \\
&= \left((\phi_K(X)P)(\phi_K(X)P)^T + \lambda I\right)^{-1} \phi_K(X) a \\
&= \left(\frac{1}{\lambda} I - \frac{1}{\lambda^2}\phi_K(X) P \left(I + \frac{1}{\lambda} P\phi_K(X)^T \phi_K(X) P\right)^{-1} P \phi_K(X)^T\right) \phi_K(X) a \\
&= \frac{1}{\lambda}\phi_K(X)\left(I - P\left(\lambda I + PGP\right)^{-1} PG\right) a.
\end{aligned}$$

Bayesian Inference and Optimal Design for the Sparse Linear Model

Matthias W. Seeger SEEGER@TUEBINGEN.MPG.DE
Max Planck Institute for Biological Cybernetics
Spemannstr. 38, Tübingen, Germany

Editor: Martin Wainwright

Abstract

The linear model with sparsity-favouring prior on the coefficients has important applications in many different domains. In machine learning, most methods to date search for maximum a posteriori sparse solutions and neglect to represent posterior uncertainties. In this paper, we address problems of Bayesian optimal design (or experiment planning), for which accurate estimates of uncertainty are essential. To this end, we employ expectation propagation approximate inference for the linear model with Laplace prior, giving new insight into numerical stability properties and proposing a robust algorithm. We also show how to estimate model hyperparameters by empirical Bayesian maximisation of the marginal likelihood, and propose ideas in order to scale up the method to very large underdetermined problems.

We demonstrate the versatility of our framework on the application of gene regulatory network identification from micro-array expression data, where both the Laplace prior and the active experimental design approach are shown to result in significant improvements. We also address the problem of sparse coding of natural images, and show how our framework can be used for compressive sensing tasks.

Part of this work appeared in Seeger et al. (2007b). The gene network identification application appears in Steinke et al. (2007).

Keywords: sparse linear model, Laplace prior, expectation propagation, approximate inference, optimal design, Bayesian statistics, gene network recovery, image coding, compressive sensing

1. Introduction

In many settings favoured in current machine learning work, the model and data set are given in advance, and predictions with low error are sought. Many methods from different paradigms have successfully been applied to these problems. While Bayesian approaches, such as the one we describe here, enjoy some benefits in this regime, they can be more difficult to implement, less algorithmically robust, and often require more computation time than, for example, penalised estimation methods, whose computation often reduces to a standard optimisation problem. In our opinion, the real practical power of the Bayesian way is revealed better in higher-level tasks such as making optimally cost-efficient decisions or *experimental design*. In the latter, aspects of the model and measurement experiments are adapted based on growing knowledge about the current situation, and data is sampled in a sequential and actively controlled manner, with the aim of obtaining answers as quickly as possible. Our main motivation in the present work is to demonstrate how Bayesian experimental design can be implemented in a computationally efficient and robust way, and how a range of challenging applications can benefit from selectively sampling data where it is most needed.

A number of characteristics of the framework we propose here, are especially useful, if not essential, to drive efficient experimental design for the applications we consider. The latter, at least in the sequential variant discussed here, proceeds through a significant number of individual decisions (say, where to sample data next). In order to make each decision, our current uncertainty in variables of interest needs to be estimated quantitatively, and for a large number of candidates we have to consider how, and by how much, each of them would reduce this uncertainty estimate. As will become clear in the sequel, the uncertainty estimate is given by the posterior distribution, an approximation to which can be obtained robustly and efficiently by our method. The estimate is given as a Gaussian distribution, whose change after one more experiment can robustly and very efficiently be quantified. These points motivate our insistence on robustness[1] and efficiency below. Another key aspect of the models treated here is sparsity. This regularisation principle allows us to start from an overparameterised model, forcing parameters close to zero if they are not required. In our experiments, we demonstrate that the interplay between sparsity regularisation and experimental design seems to be particularly successful. In sequential design, most of the decisions have to be done early, without a lot of data available, and the focus (under a sparsity prior) on a few relevant effects only seems particularly useful in that respect.[2] In contrast, if the models of interest here are used with Gaussian priors, as is usually done, then sequential design is not different from optimising X beforehand. Although observations become available along the way, these are not used at all. We come back to this important point below.

In this work, we consider the *linear model*

$$u = Xa + \varepsilon, \quad \varepsilon \sim N(0, \sigma^2 I), \tag{1}$$

where $X \in \mathbb{R}^{m,n}$ is the design matrix, and $a \in \mathbb{R}^n$ is the vector of unknown parameters (or weights). σ^2 is the variance of the Gaussian noise. The model can be thought of as representing a noisy linear system. It is called *underdetermined* if $m \leq n$, and *overdetermined* otherwise. In the underdetermined case, there are in general many solutions, even if we did not allow for noise, and additional desired qualities of a need to be formalised. In a Bayesian framework, this is done by placing a *prior distribution* on a, concentrating its mass on parameters fulfilling the requirements.

In the applications we consider, sparsity of a is a key prior assumption: elements of a should be set to very small values whenever they are not required to describe the data well. On the other hand, few elements should be allowed to be large if necessary. Among different solutions, the ones with the largest number of very small components should be preferred *a priori*. Enforcing sparsity is a fundamental statistical regularisation principle and lies behind many well known ideas such as *selective shrinkage* or *feature selection*. It is discussed in more detail in Section 2.1. Many sparsity-favouring priors have been suggested in statistics. In this paper, we concentrate on independent *Laplace* (or *double exponential*) distribution priors of the form

$$P(a) = \prod_i P(a_i), \quad P(a_i) = \frac{\tilde{\tau}}{2} e^{-\tilde{\tau}|a_i|}, \quad \tilde{\tau} = \tau/\sigma. \tag{2}$$

1. Robustness is an issue which is often overlooked when comparing machine learning methods, yet it is quite essential in experimental design, where many decisions have to be done based on small posterior changes, and where non-robust methods often lead to undesired, erratic high-variance behaviour. In experimental design, robustness can be more important than high posterior approximation accuracy.
2. We report empirical observations here at the moment. We are not aware of strong theoretical results about this aspect.

A key advantage of this choice over others is log-concavity, which implies important computational advantages (see Section 2.1, Section 3.5). We refer to the linear model with Laplace prior as *sparse linear model*.[3]

It is important to note that our method here is different from most of the classical treatments of experimental design for the linear model, which entirely focus on Gaussian prior distributions. The difference to these approaches lies in our use of non-Gaussian sparsity priors. Bayesian inference for the linear model with Gaussian prior is analytically tractable (see O'Hagan, 1994, Chapter 9), and most of the algorithmic complications we address in the following, do not arise there. On the other hand, comparative results in some of our experiments show very significant benefits of using experimental design with sparsity priors rather than Gaussian ones. Our findings point out the need to theoretically analyse and understand experimental design with non-Gaussian priors, although in the absence of analytically tractable formulae for inference, such studies would have to be done conditioned on particular inference approximations.

Once the linear model is endowed with sparsity priors which are not Gaussian, Bayesian inference in general is not analytically tractable anymore and has to be approximated. In this paper, we employ the expectation propagation (EP) algorithm (Minka, 2001b; Opper and Winther, 2000) for approximate Bayesian inference in the sparse linear model. Our motivation runs contrary to most machine learning applications of the sparse linear model considered so far (where maximally sparse solutions for a given fixed problem are estimated and good uncertainty representations seem unimportant), mainly because Bayesian experimental design is fundamentally driven by such uncertainty representations. While Bayesian inference can also be performed using Markov chain Monte Carlo (MCMC) (Park and Casella, 2005), our approach is much more efficient, especially in the context of sequential design, and can be applied to large-scale problems of interest in machine learning. Moreover, experimental design requires the robust estimation in posterior changes across many candidates, starting from a well-defined current distribution, which seems difficult to do with MCMC. The application of EP to the sparse linear model is numerically challenging, and some novel techniques are introduced here in order to obtain a robust algorithm. In this context, the role of log-concavity for numerical stability of EP is clarified. Moreover, a variant known as fractional EP (or Power EP) (Minka, 2004) is shown to essentially overcome stability problems in the context of underdetermined models, while standard EP seems inherently unworkable in these cases. This observation about fractional EP is novel to our knowledge.

We apply our method to the problem of identifying gene regulatory networks from data obtained through active experiments, disturbing the system in a controlled manner. Since such experiments are expensive and time-consuming, a sequentially designed approach is clearly beneficial. Indeed, our experiments on synthetic data, simulated using realistic setups, show clear advantages in using Bayesian experimental design and sparsity priors over traditional approaches.

We also address the problem of sparse linear coding of natural images, optimising the codebook by empirical Bayesian marginal likelihood maximisation. Since current hypotheses about the development of early visual neurons in the brain are equivalent to a Bayesian sparse linear model setup (Lewicki and Olshausen, 1999), our method is useful to test and further refine these.

There has been a lot of recent interest in signal processing in the problem of compressive sensing (Candès et al., 2006; Donoho, 2006; Ji and Carin, 2007). We show how our framework directly

3. The reader may be puzzled about the parameterisation in terms of $\tilde{\tau} = \tau/\sigma$. One reason for this is that it renders τ scale-free: it does not depend on the scale of the response u. A more important reason is given in Section 3.5.

addresses the key issues there, which are in fact optimal design problems, and we motivate applications.

The structure of this paper is as follows. In Section 2, the statistical notion of sparsity is explained and contrasted with notions currently dominant in machine learning. Furthermore, some key applications of the sparse linear model are described. In Section 3, we show how to do approximate inference using the expectation propagation method. Optimal design is discussed in Section 4, and an approximation to the marginal likelihood is given in Section 5. We show how to address large-scale problems in Section 6. Experimental results are presented in Section 7. Our framework is directly related to other approximate inference techniques in Section 8. The paper closes with a discussion in Section 9.

Efficient and extendible code for the sparse linear model will be put into the public domain, as part of the LHOTSE toolbox for adaptive statistical models.[4]

2. The Role of Sparsity. Applications

In this section, we clarify the statistical role of sparsity and motivate the Laplace prior (2) towards this end. We also introduce the applications of interest in our work here: identification of gene networks, and sparse coding of natural images, and we give remarks about applications to compressive sensing, which are subject to work in progress (Seeger and Nickisch, 2008). The importance of optimal design and hyperparameter estimation are motivated using these examples.

2.1 The Role of Sparsity Priors

In order to obtain flexible inference methods, it often makes sense in statistics to employ models with many more degrees of freedom than could uniquely be adapted given finite data. The resulting under-determinedness (sometimes referred to as "ill-posedness", "curse", or other equally negative terms) is broken by making additional assumptions, leading to the fact that some solutions are preferred over others, although both fit the data equally well. The mechanics of this comes in different variants, such as adding a penalty term (or regulariser) to a data-fit functional, or placing a prior distribution over hypotheses. The underlying principles are, however, the same.

A fundamental regularisation idea is *sparsity*. For example, suppose a prediction function is a linear combination of features. If knowledge of good (or optimal) features for a task is vague, it makes sense to allow for a large number of candidates, then let the data decide which are relevant. A sparsity prior (or regulariser) on the coefficients, for example in the sparse linear model (1) with Laplace prior (2), leads to just that. It is important to contrast this with the different, frequently used idea of forcing components to be uniformly small in size, so that the final predictor is a sum of many (or all) features, with each giving a small but non-zero contribution. An example of the latter is the linear model (1) with a *Gaussian* prior $P(a)$, which due to conjugacy allows for a simple analytical treatment (see O'Hagan, 1994, Chapter 9). Such a prior does not encode sparsity. The Laplace distribution puts much more weight close to zero than the Gaussian, while still having higher probabilities for large values. The implications are depicted in Figure 1, see also Tipping (2001).

A sparsity prior embodies the bi-separation characteristic: such parameters a with many very small components at the expense of few large ones are favoured over a whose components are

4. See www.kyb.tuebingen.mpg.de/bs/people/seeger/lhotse/.

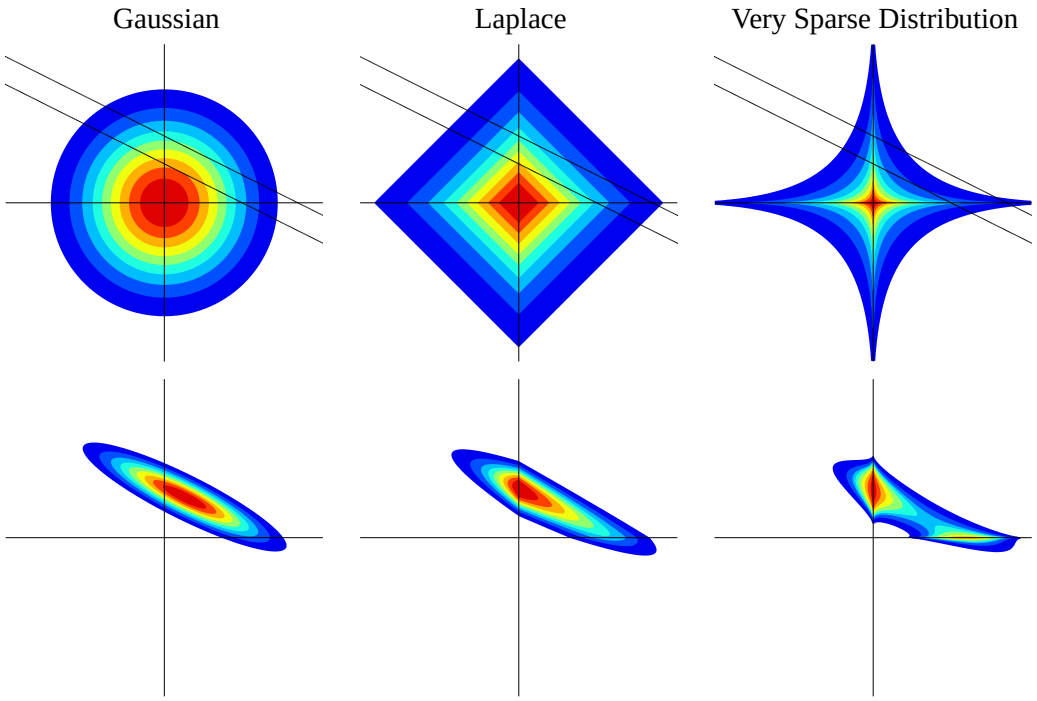

Figure 1: The entries of the parameter a can be given different prior distributions. Shown above are three candidates, plotted jointly over the values of two entries: a Gaussian, a Laplace, and a "very sparse" distribution ($P(a_i) \propto \exp(-\tau|a_i|^{0.4})$). We show contour plots of density functions, where areas of a specific color contain the same probability mass for each of the distributions. The upper row shows prior distributions of unit variance, together with the likelihood for a single measurement (a single linear constraint with Gaussian uncertainty). The lower row shows the corresponding posterior distributions. Whereas the Gaussian prior is spherically distributed, the other two shift probability mass towards the axes, so that more mass is given to sparse tuples (with one entry close to zero). This effect is clearly visible in the posterior distributions, being the normalised product of prior and likelihood. For the Gaussian prior, the areas close to the axes have rather low mass. In comparison, the posterior for the Laplace prior is skewed, so that more mass is concentrated close to the vertical axis. Both posteriors are log-concave and unimodal. The posterior for the "very sparse" prior shows shrinkage towards the axes even more strongly, and in terms of enforcing sparsity, this prior is preferable to the Laplacian. However, the posterior is bimodal now, suggesting two different interpretations for the single observation. The number of posterior modes can increase exponentially with the number of dimensions, so that sampling from or even representing this distribution has combinatorial complexity in general. *Figure by Florian Steinke*.

uniformly small throughout, but sizes are distributed regularly over this "range of smallness". Under the prior, most mass concentrates close to zero, but the tails are also comparatively heavy, allowing for occasional large values. In fact, heavy tails are an essential feature of a sparsity prior, since suppressing many components while still maintaining a flexible range of hypotheses is possible only if some components are allowed to take dominant values. The opposite is true for traditional Gaussian priors. Ishwaran and Rao (2005) call this bi-separation effect *selective shrinkage*, in that

parameters are shrunk towards zero selectively, while a Gaussian prior leads to a more uniform shrinkage. This characteristic is embodied even more strongly in sparsity priors other than the Laplace, such as "spike-and-slab" (mixture of narrow and very wide Gaussian), Student's t, or distributions $\propto \exp(-|\cdot|^\alpha)$, $\alpha < 1$, see also Figure 1. Among these, only the Laplace distribution is *log-concave*, leading to a posterior whose log density is a concave function, thus has a single local maximum. This simplifies and robustifies accurate inference computations significantly (see Section 3.5). For a non-log-concave prior, posteriors tend to be multi-modal, spreading their mass among many bumps, and accurate approximate inference can be a very hard problem. Furthermore, existing variational inference methods are more prone to non-robust unstable behaviour if applied to such models, and convergence or approximation errors can be hard to assess. Since we aim our method to be robust and easy to use by non-experts, we concentrate on log-concave Laplace sparsity priors in the sequel. The importance of log-concavity has been recognised in statistics and Markov chain sampling (Pratt, 1981; Gilks and Wild, 1992; Park and Casella, 2005; Lovász and Vempala, 2003; Paninski, 2005), but has not received much attention so far in work on variational approximate inference.

Our decision to prefer the Laplace sparsity prior over the conventional Gaussian choice, at the expense of having to approximate inference and of introducing significant complications, is ultimately validated by our experimental findings, where the Laplace prior yields large improvements over the Gaussian setting (see Section 7.1). However, apart from failing to encode a sparsity bi-separation, the Gaussian prior leads to other serious artifacts in the context of experimental design with the linear model. For example, suppose we are interested in sequentially designing covariates x for which responses u are queried (this is related to, but not the same setting we use here, see Section 4), say by choosing a "location" t in a feature map $x(t)$. It is well known and easily established that the Bayesian optimal design is *independent* of the response measurements we obtain along the way, it can in fact be computed beforehand. This fact seems absurd for many design problems, including ours here, pointing out a shortcoming of the model-prior combination. In the gene network identification problem (see Section 2.2 for notation), if we were to use a Gaussian prior, the posterior covariances would be identical for all rows of A. This means that no matter what disturbance experiments are done, the uncertainty in how gene i is influenced directly by the others, is the same for all i! Since design decisions mainly hinge on these uncertainty estimates, such artifacts due to a bad prior choice can lead to very suboptimal outcomes (see Section 7.1).

It is important to contrast our approach, and more generally the Bayesian statistical notion of sparsity, with what some *maximum a posteriori* (MAP) treatments of the sparse linear model are aiming to do. In the latter approach, which is very prominent in machine learning (Tibshirani, 1996; Chen et al., 1999; Peeters and Westra, 2004), the mode $\hat{a}$ of the posterior $P(a|X,u)$ is found through convex optimisation (recall that the log posterior is concave), and $\hat{a}$ is treated as posterior estimate of a. $\hat{a}$ has the property that many components are exactly zero:[5] the vector is sparse as such. This is useful for applications which aim for such exact sparsity, say for reasons of algorithmic efficiency. In contrast, in the Bayesian case, the posterior mass of all exactly sparse a (at least one component exactly zero) is zero, because the posterior has a density w.r.t. Lebesgue measure.[6] Not even commonly used Bayesian estimates of a, such as posterior mean or median, are exactly sparse in general. From a Bayesian viewpoint this makes sense, since in the presence of finite data,

5. One can easily show that as $\sigma^2 \to 0$, no more than m components of $\hat{a}$ can be non-zero.
6. Spike-and-slab sparsity priors have been used which place point masses on zero. However, approximate inference for such a setting is very challenging. Such priors are certainly not log-concave distributions.

one should always have some remaining uncertainty in exact values of parameters. The role of a sparsity prior in our situation is not to force many parameter values exactly to zero, but rather to enforce a clear partition into a large set of parameters which are close to zero with high (posterior) probability, and a small set which have significant mass on large values. Interestingly, following this probabilistic notion of sparsity sometimes allows to uncover sparsity in parameters of higher order that are of real interest, which is missed by MAP approaches. Our findings in Section 7.2 are a nice example of this effect.

2.2 Gene Network Identification

Measuring m-RNA expression levels for many genes in parallel is affordable and widely done today using DNA micro-arrays (DeRisi et al., 1997). One goal of such efforts is to recover regulatory networks. For example, some genes may code for transcription factor proteins, which up-/down-regulate the expression of other genes. In an *active* approach to network recovery, the evolution of expression levels of n genes is modeled by a system of ordinary differential equations, which is linearised at its steady state:

$$\dot{x}(t) = Ax(t) - u(t) + \varepsilon(t), \tag{3}$$

where $x(t)$ is the deviation in expression from steady state, and $\varepsilon(t)$ is white noise. A is the system matrix, whose non-zero entries represent the edges of the network. $u(t)$ is an external control, allowing the active user to probe the unknown A. It is generally assumed that $u(t)$ is small enough not to drive the system out of its linearity region. Due to the noisy environment, it is typical to restrict controls to be constant, $u(t) \equiv u$, and to measure the new steady state $\lim_{t\to\infty} x(t)$ (Tegnér et al., 2003). Such disturbances may be implemented biologically using gene switches (Gardner et al., 2000), which puts further restrictions on allowable u.

The linear model of (1) captures this setup as follows. Suppose that m observations $D = \{x_i, u_i\}$ have been made, where u_i is an external control, and x_i is the corresponding difference between steady state expression levels of the perturbed and the unperturbed system. We write $U = (u_i)^T \in \mathbb{R}^{m,n}$, $X = (x_i)^T \in \mathbb{R}^{m,n}$. We have that $u_i \sim N(Ax_i, \sigma^2 I)$. If a_i is the transpose of the i-th row of A, this Gaussian likelihood decomposes into n factors, one for each a_i. If the coefficients of A are assumed to be independent Laplacian *a priori*, the posterior factorises accordingly:

$$P(A|D) = \prod_j P(a_j|D), \quad P(a_j|D) \propto N(U_{\cdot,j}|Xa_j, \sigma^2 I) \prod_i P(a_{j,i}).$$

Thus, we have n independent sparse linear models, on which inference is done separately.

Since biological experiments involving gene switches are expensive and time-consuming, a key requirement is to perform with as few data as possible, which is possible if biological prior knowledge is encoded in $P(A)$. Importantly, regulatory networks are observed to be sparsely connected, that is, plausible A are sparse, a property which is directly represented in the sparse linear model. A principled way of saving on the number of expensive experiments is *optimal design*, which in a special case of interest here boils down to the question: given the current posterior belief and a set of candidate controls u_*, which of these experiments renders most new information about A? Thus, a "value of information" is sought which can be computed for each candidate u_* *without* doing the corresponding experiment. Optimal design is well developed in classical and Bayesian statistics (Fedorov, 1972; Chaloner and Verdinelli, 1995; MacKay, 1991), and access to this methodology is a key motivation for developing a good inference approximation here.

2.3 Coding of Natural Images

A second application of the sparse linear model is concerned with linear coding of natural images (Olshausen and Field, 1997; Lewicki and Olshausen, 1999), with the aim of understanding properties of visual neurons in the brain. Before we describe the setup, it is important to point out what our motivation is here, since it deviates significantly from what is usually done in machine learning. One approach in theoretical neuroscience is to formulate principles which can be described reasonably simply in mathematical terms, so that certain phenomena observed in experiments emerge if *only these principles are followed*. Once such principles are established, one can think about neural mechanisms implementing them. Also, if different principles lead to the same observed phenomena, one can plan experiments to further discriminate between them. In machine learning, the problems are known, and methods are compared with the aim of finding the best one, using an evaluation score and methodology independent of the set of methods to ensure a fair comparison. If results are not much different across methods, the most efficient one is usually preferred. In theoretical neuroscience,[7] the outcomes are known, and simple "universal" principles to explain them are sought. Once a principle is suggested, the aim is to devise a method following that principle as closely as possible. If such a method can then successfully reproduce observed phenomena, the principle can be established. In the context here, we are interested in testing a hypothesis put forward by Lewicki and Olshausen (1999), which is formulated in Bayesian terms. We are not interested here in coding images in the best possible way, and certainly not in how to do this with the highest computational efficiency.

An image $u \in \mathbb{R}^m$ is modeled as $u = Xa + \varepsilon$, where the columns of X are codebook vectors, $a \in \mathbb{R}^n$ are basis coefficients, and $\varepsilon \sim N(0, \sigma^2 I)$ independently. Note that codebook vectors are also referred to as filters, or basis functions. A central assumption on a is sparsity, which is especially important in the underdetermined (or overcomplete) regime: $m < n$. The Bayesian approach via the sparse linear model (1) has been suggested by Lewicki and Olshausen (1999), where the average coding cost of images under the model is put forward as criterion for ranking different code matrices X. Their work aims to give a probabilistic interpretation to the findings of Olshausen and Field (1997). In a Bayesian nomenclature, the average coding cost is the negative log marginal likelihood $-\log P(D)$, where $P(D) = \prod_j P(u_j)$, $P(u_j) = \int P(u_j|a_j)P(a_j)\,da_j$, and differences of these for different X are log Bayes factors. In Section 5, we show how to obtain a good approximation to $-\log P(D)$ through EP, which can be minimised w.r.t. the code matrix X in a gradient-based way. This general idea is proposed by Lewicki and Olshausen (1999) as well, but they use a second-order (Laplace) approximation to $-\log P(D)$, which is not suitable in case of a Laplace prior.[8] In the earlier approach of Olshausen and Field (1997), the learning of X is driven by point estimates (or maximum a posteriori decoding), and a criterion different from the average coding cost is optimised. This ignores posterior uncertainty in the decodings, and requires additional renormalisation heuristics in order to learn a good code. Our approximation here implements the probabilistic hypothesis of Lewicki and Olshausen (1999) fairly accurately, and can therefore be used to analyse more closely which of the features found by Olshausen and Field (1997) are due to the minimisation of average coding cost, versus which may rather be caused by particular characteristics of their learning method. Note that maximisation of the marginal likelihood is an important empirical

7. Or, in fact, in most natural sciences, with the exception of Engineering and Computer Science.
8. The problem is that $\log P(a_j)$ is not differentiable at the posterior mode $\hat{a}_j$, so that the matrix B in Lewicki and Olshausen (1999) is not well-defined. See comments in Section 3.

Bayesian way of estimating free hyperparameters, and Bayes factors are routinely used to compare model setups, so our approximation will be useful in other applications of the sparse linear model as well.

One of the key questions in natural image modelling is: under which conditions do basis vectors emerge which are spatially oriented and localised, thus show properties which have been established for the receptive fields of certain visual neurons? Given that the hypothesis of Lewicki and Olshausen (1999) is taken for granted, the sparsity hypothesis can be tested using the sparse linear model. Interestingly, other conditions brought forward (such as non-negativity) can also be dealt with in principle using the linear model, with different priors on a. Technically, non-negativity can be implemented by "cutting off" (and renormalising) a given prior density, which amounts to replacing $P(a_i)$ by $2P(a_i)\mathrm{I}_{\{a_i \geq 0\}}$. Importantly, if $P(a_i)$ is log-concave, so is this modification, because $\log \mathrm{I}_{\{a_i \geq 0\}}$ is (generalised) concave. For example, "cutting off" the Laplace distribution results in the exponential distribution,[9] which has been used in the context of image modelling by Hojen-Sorensen et al. (2002). While exponential priors encode non-negativity and sparsity at the same time, a cut-off Gaussian $P(a_i) = 2N(a_i|0, \tilde{\tau}^{-2})\mathrm{I}_{\{a_i \geq 0\}}$ could be used to represent non-negativity alone.

2.4 Bayesian Compressive Sensing

There has been a lot of recent interest in signal processing in the problem of compressive sensing (Candès et al., 2006; Donoho, 2006). The idea is appealingly simple. Suppose a signal is measured and then transferred over some channel or stored on some media. The second step almost always includes lossy compression in practice, especially with signals such as images or sound, where the loss may not be perceivable. Many of today's codes are *sparse*: the signal is transformed one-to-one, after which many coefficients are close to zero. These coefficients are then set to zero, and are not transmitted or stored. The first sensing (or sampling) step is traditionally done in a way which does not lead to loss of information, say by relying on the Nyquist/Shannon sampling theorem. The question of compressive sensing is whether one can sample a signal in a more efficient, but lossy way, so that the loss is part of that one encountered through subsequent compression anyway. The main attractiveness is that if a lossy compression is used, compressive sensing does not add further losses.

Although maybe not phrased in that way by much of the existing work, this is a classical problem of experimental design. An approximate Bayesian variant of compressive sensing has been proposed by Ji and Carin (2007), using sparse Bayesian learning (Tipping, 2001) to approximate the inference. Most practical codes today are linear, in that $y = \Phi a$, where y is the signal (say, an image), Φ is the code matrix (say, a Wavelet transform), and a are the coding coefficients. The code is designed such that a is approximately sparse, in much the same sense as elaborated in Section 2.1. Typically, Φ is one-to-one, even unitary. We then measure the signal linearly, that is, obtain $u = Py + \varepsilon$, where P is a measurement matrix, u are the responses, and ε is noise due to measurement errors. Here, $P \in \mathbb{R}^{m,n}$ with $m < n$ (the savings promised by compressive sensing). If $X = P\Phi$, this is exactly the setup of the linear model (1). Furthermore, the sparsity of a is encoded via a Laplace prior, motivating the sparse linear model for compressive sensing.

The measurement matrix P can be designed at will, where we are possibly limited to certain parametric families, due to constraints from the measurement architecture or (for very large n)

9. For this reason, the Laplace distribution is sometimes called double exponential distribution.

computational tractability (see Section 6). Anyway, we can design P row by row through an instance of standard sequential experimental design described in Section 4. This has been proposed in Ji and Carin (2007). Moreover, we can try to optimise P *a priori* over a large database of signals from the domain of the application, in what turns out to be an interesting variant of the image coding problem of Section 2.3. Here, the image code Φ is fixed, but P is to be learned.

Another point in which our approach differs from much of the existing work on compressive sensing, has to do with the sparsity prior we employ. Namely, many theoretical results have been obtained under the assumption that the signal y can be *exactly* sparsely coded, in that most coefficients in the corresponding a are exactly zero. However, in many real-world applications, this may be too strict an assumption. For example, the Wavelet transform of an image is virtually never exactly sparse, but rather features the bi-separation characteristic discussed in Section 2.1: many coefficients are very close to zero, and a subsequent quantisation leads to an image visually indistinguishable from y. Our sparsity prior concentrates on the bi-separation characteristic, without enforcing exact sparseness, thus may be better suited to many compressive sensing applications than the requirement of exact sparsity.

Results from experiments with different variants of compressive sensing are in preparation (joint work with Hannes Nickisch) and will be presented in a later paper (Seeger and Nickisch, 2008).

3. Expectation Propagation for the Linear Model

Exact Bayesian inference is not analytically tractable for the sparse linear model. In this section, we show how to apply the recently proposed *expectation propagation* (EP) method (Minka, 2001b; Opper and Winther, 2000) to this problem, circumventing some caveats we have not seen being addressed before. We begin with a high-level description, filling in the details further below. In the case of EP for the sparse linear model, it turns out that some details concerning robustness are essential for obtaining a practically useful method.

In EP, we compute a Gaussian approximation $Q(a)$ to the posterior

$$P(a|D) \propto N(u|Xa, \sigma^2 I) P(a).$$

Here, the likelihood $N(u|Xa, \sigma^2 I)$ is Gaussian, and it is the non-Gaussian prior $P(a)$ which forces us to approximate Bayesian inference. Our restriction to Gaussian $Q(a)$ is primarily done for pragmatic reasons, since Bayesian computations such as marginalisation and conditioning can be done analytically in this family, using standard matrix operations which can be computed robustly and efficiently. However, in our case, the Gaussian approximation can be argued for more strongly than in many others. Namely, recall that $\log P(a)$ is concave (2). Since the likelihood is a Gaussian function of a, the true log posterior $\log P(a|D)$ is concave as well, thus has a single mode only.

If $P^{(0)}(a) := N(u|Xa, \sigma^2 I)$ is the Gaussian likelihood (1), the true posterior is

$$P(a|D) \propto P^{(0)}(a) \prod_i t_i(a_i), \quad t_i(a_i) = \frac{\tilde{\tau}}{2} e^{-\tilde{\tau}|a_i|}.$$

We refer to the t_i as *sites*, and to $P^{(0)}$ as *base measure*. Note that the latter is not in general normalisable.

In order to motivate EP, note that an optimal Gaussian posterior approximation $Q(a)$ (at least in our context here) would be obtained by setting its mean and covariance to the true posterior

statistics. However, this would require a n-dimensional non-Gaussian integration, which cannot at present be done tractably. However, we are able to compute *one-dimensional* integrals involving a single non-Gaussian site $t_i(a_i)$. EP makes use of this capability in an iterative fashion, in order to approximate the desired joint posterior moments. The EP posterior approximation has the form

$$Q(a) \propto P^{(0)}(a) \prod_i \tilde{t}_i(a_i),$$

where $\tilde{t}_i(a_i|b_i,\pi_i)$ are Gaussian factors. Formally, one gets from the intractable $P(a|D)$ to its Gaussian approximation $Q(a)$ by replacing each non-Gaussian $t_i(a_i)$ by a Gaussian counterpart $\tilde{t}_i(a_i)$. This formal replacement introduces *site parameters* $b, \pi \in \mathbb{R}^n$, and the EP algorithm is an iterative method for adjusting these in turn.

In a single EP update, b_i, π_i are adjusted, while leaving all other site parameters the same. Starting from the current Gaussian approximation Q, we compute the Gaussian *cavity distribution* $Q^{\backslash i} \propto Q\tilde{t}_i^{-1}$ by dividing out the *site approximation* $\tilde{t}_i(a_i)$, then the non-Gaussian *tilted distribution* $\hat{P}_i \propto Q^{\backslash i} t_i$ by multiplying in the true site $t_i(a_i)$ instead, finally we update b_i, π_i such that the new Q' has the same mean and covariance as $\hat{P}_i$. These single updates are iterated in some random ordering over the sites until convergence.[10] Thus, EP is inherently based on the idea of *moment matching*. In other words, Q' is chosen by minimising the relative entropy $\mathrm{D}[\hat{P}_i \,\|\, \cdot]$ over all Gaussians.

From an algorithmic viewpoint, several questions have to be addressed. First, how can we *represent* the Gaussian $Q(a)$, so that single EP updates are served well in terms of efficiency and robustness? We will see that a good representation has to allow for the rapid "random-access" extraction of marginals $Q(a_i)$, and we have to be able to efficiently and robustly update it after a change of b_i, π_i. Second, how can the mean and variance of the non-Gaussian $\hat{P}_i(a_i)$ be computed accurately? To address these questions, we need to introduce some notation and details.

Denote the family of unnormalised Gaussian measures by

$$N^U(z|b,P) := \exp\left(-\frac{1}{2} z^T P z + b^T z\right),$$

P being positive semidefinite. Then, $P^{(0)}(a) = N^U(a|\sigma^{-2}b^{(0)}, \sigma^{-2}\Pi^{(0)})$ with $\Pi^{(0)} = X^T X$, $b^{(0)} = X^T u$. The site approximations are $\tilde{t}_i(a_i) = N^U(a_i|\sigma^{-2}b_i, \sigma^{-2}\pi_i)$, so that Q is a Gaussian. In general applications of EP, the π_i can become negative, but this does not happen in the cases discussed in this paper. We will show in Section 3.5 that for *log-concave sites* t_i, all π_i remain nonnegative throughout the course of the EP algorithm.

Moreover, the reader may wonder why we restrict ourselves to $\tilde{t}_i(a_i)$, instead of allowing for general site approximations $\tilde{t}_i(a)$. Also, a careful reader may have noted that we are only concerned about marginal distributions $Q(a_i)$ and $\hat{P}_i(a_i)$ during an EP update at t_i. Importantly, all this does not come with a loss of generality, as is shown in Section 3.1.

We initialise the algorithm with $b = 0$ and $\pi = \varepsilon 1$, $\varepsilon > 0$. A useful heuristic is $\varepsilon = \tau^2/2$, making sure that $t_i(a_i)$ and $\tilde{t}_i(a_i)$ have the same variance initially. In the case of the sparse linear model, the implementation of EP is complicated in a fundamental way. If $m < n$ (underdetermined case), the base measure $P^{(0)}(a)$ is not normalisable, because $\Pi^{(0)} = X^T X$ is singular. It is easily seen that

10. To our knowledge, little is known in general about convergence properties of EP, even with log-concave sites. Empirically, we have never observed failure of convergence in the log-concave case, except for reasons of numerical instability (see Section 3.3.1). Obtaining a formal convergence proof in this case remains a very important point for future research.

if any of the $\pi_i = 0$, the resulting $Q(a)$ is (in general) not a proper Gaussian either, so we have to ensure that $\pi_i > 0$ at all times. If $m \ll n$, we would like to represent the posterior Q in a way which scales with m rather than n. We address these issues below in this section.

It is important to note that EP is not merely a local approximation, in that $\tilde{t}_i$ is somehow fitted to t_i locally. This would not be useful at all,[11] because posterior mean and covariance are shaped *jointly* by the non-Gaussian t_i and the coupled Gaussian base measure. Loosely speaking, the likelihood couples coefficients a_i, so that the intentions of the prior factors $t_i(a_i)$, namely to force their respective arguments towards zero, have to be weighted against each other in a very non-local procedure.[12] After each EP update, although only a single site approximation is modified, its influence propagates to all other sites, because they are coupled through the base measure. In fact, non-locality is a central aspect of Bayesian inference which makes it so hard to compute, and inference is particularly hard to do in models where strong long-range posterior dependencies are present which cannot easily be predicted from local interactions only.

Finally, would it not be much simpler and more efficient to locate the true posterior mode through convex optimisation (recall that the posterior is log-concave), then do a Laplace approximation there, which amounts to expanding the log posterior density to second order around the mode? Indeed, finding the mode can be done efficiently by solving a quadratic program (Tibshirani, 1996). General problems with this approach include that the curvature around the mode may not be characteristic of the target density, and that the mode may not be a good place to center a Gaussian approximation at. In the case of the sparse linear model, the Laplace approximation is not even a valid option, since it is not well-defined in the presence of a Laplace prior.[13] Namely, $\log P(a_i)$ does not have a curvature at $a_i = 0$. The posterior mode is guaranteed to contain at least some zero components, so the curvature there is not defined. EP does not require $P(a_i)$ or $\log P(a_i)$ to be differentiable. On models where both methods can be applied, EP tends to improve upon a Laplace approximation significantly, but is also typically more expensive (Minka, 2001a; Kuss and Rasmussen, 2005).

3.1 Overview of Algorithm

In this section, we provide a schematic overview of the EP algorithm, filling in details in the sections to come. Recall that EP iterates site updates at $i \in \{1,\ldots,n\}$, computing $Q^{\backslash i} \propto Q\tilde{t}_i^{-1}$ and $\hat{P}_i \propto Q^{\backslash i} t_i$, then adjusting $Q \to Q'$ such that Q' has the same mean and covariance as $\hat{P}_i$. Since t_i depends on a_i only, $\hat{P}_i(a_{\backslash i}|a_i) = Q^{\backslash i}(a_{\backslash i}|a_i)$, where $a_{\backslash i} := (a_j)_{j\neq i}$, thus $Q'(a_{\backslash i}|a_i) = Q^{\backslash i}(a_{\backslash i}|a_i)$. Therefore, an EP update automatically results in the site approximation $\tilde{t}_i$ being a (Gaussian) function of a_i only. It also implies that in order to drive the EP update, all we need is the *marginal* distribution $Q(a_i)$. Just as most other variational "message-passing" approximate inference methods, EP can be seen as an iterative algorithm, improving estimates of the marginals $Q(a_i)$, $i = 1,\ldots,n$ until convergence. An EP update is *local*, in that its input is a marginal $Q(a_i)$ and it affects single site parameters b_i, π_i only. However, this *globally* affects all other marginals, which have to be updated through Gaussian propagation.

In common variational algorithms applied to discrete structured graphical models, such corrections of marginal estimates are performed by passing messages along the graph. In our case, the

11. Our experiments comparing Laplace and Gaussian priors in Section 7.1 illustrate this fact very nicely.
12. Our arguments about locality assume that a neighborhood structure can be imposed on a, say neighboring pixels in an image.
13. It is not known whether P. S. Laplace thought about this problem or even fixed it.

Algorithm 1 Expectation propagation algorithm for sparse linear model.

fully coupled Gaussian factor $P^{(0)}$ plays the role of the graph, and the messages are replaced by a *posterior representation* of $Q(a) = N(a|h, \sigma^2\Sigma)$. Just as with messages, the purpose of a representation is twofold: first, it needs to deliver mean and variance of an arbitrary marginal $Q(a_i)$ rapidly. Second, we need to be able to update it efficiently after each EP update. Our representations are given in Section 3.2, together with efficient update rules. Numerical errors can accumulate after many updates, so the representation is *refreshed* (i.e., recomputed from scratch) after each $O(n)$ EP updates. An iteration of EP updates over all (or most of the) sites is referred to as *sweep*. The structure of the EP approximate inference algorithm is given in Algorithm 1.

We close this section by remarking on the stopping rule we use in our EP implementation. One could stop once the site parameters do not change significantly anymore. However, we are really interested in the marginal means and variances, which in some cases are only weakly dependent on certain site parameters. For example, a large π_i means in general that the corresponding marginal mean is nailed down with a small variance, and increasing π_i further may have no large effect on the marginal distribution. Let $d(a,b) := |a-b| / \max\{|a|, |b|, 10^{-3}\}$ and $\Delta_i = \max\{d(h_i', h_i), \sigma d(\sqrt{\rho_i'}, \sqrt{\rho_i})\}$, where $Q(u_i) = N(h_i, \sigma^2\rho_i)$ and $Q'(u_i) = N(h_i', \sigma^2\rho_i')$ are the posterior marginals before and after an update at site i. We stop once $\max_i \Delta_i$ for a sweep over all sites is below some threshold.

3.2 Posterior Representation

In this section, we develop a representation of the posterior approximation $Q(a) = N(h, \sigma^2\Sigma)$ which allows efficient access to entries of h, $\operatorname{diag}\Sigma$ (marginal moments), and which can be updated robustly and efficiently for single site parameter changes (after EP updates). In fact, we propose two different representations: a degenerate and a non-degenerate one. The former is only useful in the underdetermined case ($m < n$), its updates are less numerically stable and more complicated, but it scales as $O(m^2)$, while the non-degenerate one scales as $O(n^2)$. If $m \ll n$, the degenerate representation leads to large computational savings.

We begin with the simpler non-degenerate representation:

$$\Sigma^{-1} = X^T X + \Pi = LL^T, \quad \gamma := L^{-1}(b^{(0)} + b),$$

where $\Pi := \operatorname{diag}\pi$ here and elsewhere. $L \in \mathbb{R}^{n,n}$ is the lower-triangular Cholesky factor (Horn and Johnson, 1985). Recall that $b^{(0)} = X^T u$. Note that $h = L^{-T}\gamma$. The marginal $Q(a_i) = N(h_i, \sigma^2\rho_i)$

is determined as $h_i = v^T\gamma$, $\rho_i = \|v\|^2$, where $v = L^{-1}\delta_i$. Here, δ_i is the Dirac unit vector with 1 at position i, and 0 elsewhere. This costs $O(n^2)$ (single back-substitution). After an EP update $b_i \to b_i'$, $\pi_i \to \pi_i'$, we have that

$$L'(L')^T = LL^T + (\pi_i' - \pi_i)\delta_i\delta_i^T, \quad L'\gamma' = L\gamma + (b_i' - b_i)\delta_i.$$

L', γ' are computed from L, γ using a Cholesky rank one update (downdate) for positive (negative) $\pi_i' - \pi_i$. This can be done in $O(n^2)$, we use a modification of the `LINPACK` routines `dchud`, `dchdd` (Dongarra et al., 1979), see Seeger (2004) for details. The update (downdate) is not done if $|\pi_i' - \pi_i|$ is too small. The reader may wonder why we do not represent and update Σ directly, using the Woodbury formula (see below). However, this would be numerically less stable than the Cholesky representation suggested here, and the operation count is the about the same.

In the underdetermined case $m < n$, another *degenerate* representation can be used, which leads to large savings if $m \ll n$. We noted in Section 3 above that Q is well-defined only if all $\pi_i > 0$. For numerical stability (with the degenerate representation), we require that $\pi_i \geq \kappa$ at all times, where $\kappa > 0$ is a small constant (we use $\kappa = 10^{-8}$ presently). This constraint is enforced in all EP updates. We can use the Woodbury formula (Henderson and Searle, 1981) in order to write

$$\begin{aligned}\Sigma &= \left(X^T X + \Pi\right)^{-1} \\ &= \Pi^{-1} - \Pi^{-1}X^T\left(I + X\Pi^{-1}X^T\right)^{-1}X\Pi^{-1}.\end{aligned}$$

We represent this via the lower-triangular Cholesky factor L in

$$LL^T = I + X\Pi^{-1}X^T.$$

Furthermore, let $\gamma := L^{-1}X\Pi^{-1}(b^{(0)} + b)$, whence

$$h = \Sigma(b^{(0)} + b) = \Pi^{-1}\left(b^{(0)} + b - X^T L^{-T}\gamma\right),$$

thus both h and Σ are represented by L, γ. For not too small κ, this representation is numerically stable. The marginal $Q(a_i)$ is obtained as $\rho_i = \pi_i^{-1}(1 - \pi_i^{-1}\|v\|^2)$, $h_i = \pi_i^{-1}(b_i^{(0)} + b_i - v^T\gamma)$, where $v := L^{-1}x$ with $x = X_{\cdot,i}$. After an EP update $b_i \to b_i'$, $\pi_i \to \pi_i'$, the representation is modified as follows. Let $\Delta_1 := (b_i^{(0)} + b_i')/\pi_i' - (b_i^{(0)} + b_i)/\pi_i$, $\Delta_2 := (\pi_i')^{-1} - \pi_i^{-1}$. We have that

$$L'(L')^T = LL^T + \Delta_2 xx^T, \quad L'\gamma' = L\gamma + \Delta_1 x.$$

Just as above, L', γ' can be computed from L, γ as a Cholesky rank one update/downdate, at the cost of $O(m^2)$. We do not modify π_i and the representation if $|\Delta_2|$ falls below some small threshold.

All in all, we can use a representation of Q whose size, as well as cost of a single site update, is quadratic in the smaller of n and m. Beware that L, γ have different definitions in the two cases. Note that we can also use the non-degenerate representation in the case $m < n$. In general, the non-degenerate representation leads to more numerically stable computations (supposedly because the Woodbury formula is not used), which are in fact more efficient in practice once $m \approx n/2$. We recommend to use the degenerate representation only if significant computational savings are observed in practice.

In some experimental design applications, such as gene network identification considered here, $m \ll n$ initially, but m grows up to $n/2$ eventually. In such cases, one could be tempted to use the degenerate representation initially, then switch to the non-degenerate one. In general, this does not make sense, since the majority of the computational effort is spent in the later stages anyway, and the non-degenerate representation should be used throughout.

3.3 The EP Update

An EP update works by matching moments between a tilted and the new posterior distribution. For an update at site i, we require the marginal $Q(a_i) = N(h_i, \sigma^2\rho_i)$ only, which is obtained from the Q representation. The moment matching requires the computation of Gaussian expectations with $t_i(a_i)$, a univariate quadrature which in general is not an analytical computation.

If $Q^{\backslash i}(a_i) = N(h_{\backslash i}, \sigma^2\rho_{\backslash i})$, we have that

$$\rho_{\backslash i} = \frac{\rho_i}{1-\rho_i\pi_i}, \quad h_{\backslash i} = \frac{h_i - \rho_i b_i}{1-\rho_i\pi_i}.$$

If the degenerate representation is used, it is more stable to compute the cavity marginal directly. Namely, if $v := L^{-1}X_{\cdot,i}$, then $\rho_{\backslash i} = \|v\|^{-2} - \pi_i^{-1}$ and $h_{\backslash i} = (b_i^{(0)} - v^T\gamma)/\|v\|^2 + b_i/\pi_i$.

Next, we need to compute mean and variance of $\hat{P}_i(a_i) = Z_i^{-1}Q^{\backslash i}(a_i)t_i(a_i)$, which we do as described in Seeger (2003), Appendix C.1.3. Note that $Z_i = \mathrm{E}_{Q^{\backslash i}}[t_i(a_i)]$, and define $\beta_i := (d\log Z_i)/(dh_{\backslash i})$, $\nu_i := -(d^2\log Z_i)/(dh_{\backslash i}^2)$. The concrete computation of β_i, ν_i (or equivalently, of the first and second moment of $\hat{P}_i(a_i)$) can be done analytically for Laplace sites, but is not straightforward due to issues of numerical stability, it is described in Appendix A. Then, the new site parameters are given by

$$\pi_i' = \frac{\sigma^2\nu_i}{1-\sigma^2\nu_i\rho_{\backslash i}}, \quad b_i' = \frac{\sigma^2(\beta_i + h_{\backslash i}\nu_i)}{1-\sigma^2\nu_i\rho_{\backslash i}}.$$

We show in Section 3.5 that $\nu_i \geq 0$, thus $\pi_i' \geq 0$, due to the log-concavity of t_i. If $\pi_i' < \kappa$ and the degenerate representation is used, we set $\pi_i' = \kappa$.

The numerical difficulties with the EP update for Laplace sites are remarkable, given that no such problems occur in several other EP applications, for example Gaussian process classification (GPC) with probit or logit noise (Minka, 2001b; Opper and Winther, 2000; Lawrence et al., 2003), where less careful implementations still work fine, and even approximate Gaussian quadrature can be used. Several early attempts of ours led to complete failure of the algorithm on realistic data (in the underdetermined case), motivating the fairly elaborate solution in Appendix A. While we cannot offer a firm explanation for this yet, our intuition is that the effect of Laplace prior sites on the posterior is much stronger, trying to emulate the essentially discrete feature selection process in a "unimodal" manner. Our findings also shed some sceptical light on proposals to implement a generic toolbox for EP, applying Gaussian quadrature[14] to do EP updates for general sites (Zoeter and Heskes, 2005). In the gene network identification application, we ran into problems of numerical instability coming from the combination of Laplace sites with very underdetermined coupling factors $P^{(0)}$. We suspect these problems are inherent, and in our case could be handled only by considering a modification of EP, as discussed just below.

3.3.1 FRACTIONAL EP UPDATES

We just mentioned the numerical difficulty of doing EP updates with Laplace sites in the strongly underdetermined case $m < n$. A frequent cause of numerical problems with EP is sloppiness in

14. Gaussian quadrature would fail completely for sites like the Laplace, which are not smooth functions. A central assumption with virtually all quadrature methods today is that the integrand up to a predefined weight function can be closely approximated by a low-order polynomial. Note that Monte Carlo integration is usually not considered useful for (low-dimensional) quadrature, due to its poor relative accuracy.

the implementation. For example, representation updates based on the Woodbury formula are a frequent source of accumulation of round-off and cancellation errors (see Section 3.2). The EP update with Laplace sites is quite difficult to do in a stable way (see Appendix A).[15] However, even using all these careful measures did not allow us to run standard EP on many of the gene network identification problems of Section 7.1 or on a fraction of the image coding problems of Section 7.2. We think that these stability problems of EP are inherent for some tasks, giving some motivation below. Fortunately, EP can be modified to use fractional updates, which in fact counter exactly the numerical problems we face. While fractional EP has been suggested as alternative to standard EP (Minka, 2004), its role for circumventing stability problems has not been noted so far to our knowledge.

Recall from Section 3 that if we set all or most of the $\pi_i = 0$ in the underdetermined case, the variance of most marginals $Q(a_i)$ is infinite. We face this problem by ensuring that $\pi_i \geq \kappa$ at all times. Still, at least for some updates, the cavity marginal variance of $Q^{\setminus i}(a_i)$ is huge. This is because we divide through the site approximation $\tilde{t}_i(a_i)$, whose $\pi_i \geq \kappa$ keeps the variance small. The variance is not infinite due to the effect of the other $\pi_j \geq \kappa$ and the coupling through $P^{(0)}$, but in many underdetermined situations, this coupling is weak. We then try to do an EP update based on a very wide cavity distribution $Q^{\setminus i}(a_i)$ and a quite narrow site $t_i(a_i)$ (enforcing a strong sparsity constraint requires a rather large τ). This is inherently difficult to do.

It would be better to make $Q^{\setminus i}(a_i)$ narrower and $t_i(a_i)$ wider, which is exactly what happens in *fractional EP updates*. Here, we obtain $Q^{\setminus i}(a_i)$ by dividing out only a fraction of $\tilde{t}_i(a_i)$, and $\hat{P}_i(a_i)$ by multiplying with only a fraction of $t_i(a_i)$. This idea is fairly natural, simply imagine the sites being replicated q times, then taken to the power of $\eta = 1/q$ to obtain the original setup. The only difference to standard EP is that we tie the parameters of the corresponding fractional site approximation replicas. Of course, the idea is not limited to rational fractions. Some extensions and theory of this method are discussed by Minka (2004). Another view on fractional EP is that projections from standard EP's $\hat{P}_i$ to Q' are done based not on the relative entropy (see Section 3), but on an α-divergence depending on the fraction.

For the fraction parameter $\eta \in (0,1]$, let $Q^{\setminus i} \propto Q\tilde{t}_i^{-\eta}$ and $\hat{P}_i \propto Q^{\setminus i} t_i^{\eta}$. We choose the new site parameters b_i', π_i' such that the moments of $\hat{P}_i$ and Q' match. This can be incorporated into the derivations above by setting $\tilde{b}_i = \eta b_i$, $\tilde{\pi}_i = \eta\pi_i$, and $\tilde{\tau} = \eta\tau$. The cavity moments are computed as

$$\rho_{\setminus i} = \frac{\rho_i}{1 - \rho_i \eta \pi_i}, \quad h_{\setminus i} = \frac{h_i - \rho_i \eta b_i}{1 - \rho_i \eta \pi_i}.$$

For the degenerate representation, a direct computation may be more stable:

$$\rho_{\setminus i} = \pi_i^{-1} \frac{R}{1 - \eta R}, \quad h_{\setminus i} = \pi_i^{-1} \left(\frac{b_i^{(0)} - v^T \gamma}{1 - \eta R} + b_i \right), \quad R = 1 - \pi_i^{-1} \|v\|^2.$$

We then compute $\tilde{b}_i', \tilde{\pi}_i'$ as above, using $\tilde{\tau} = \eta\tau$ instead of τ in the Laplace site, so that $\hat{P}_i$ and $\propto Q^{\setminus i}\tilde{t}_i(\cdot|\tilde{b}_i', \tilde{\pi}_i')$ have the same moments. Fractional updates are easily implemented for sites $t_i(a_i|\tau)$ with some hyperparameter τ, such that $t_i(a_i|\tau)^{\eta} = t_i(a_i|\eta\tau)$. The Laplace site is of this kind, if the normalisation constant of $\tau/(2\sigma)$ is dropped (it does not affect mean or variance of $\hat{P}_i$). Note that in

15. It is even harder to do for certain non-log-concave sites. For example, the sparse linear model with Student's t prior would be very hard to address with standard EP (Malte Kuss, pers. comm.).

general, t_i^η is log-concave if t_i is. Finally, the site parameters are updated as

$$b_i' = (1-\eta)b_i + \tilde{b}_i', \quad \pi_i' = (1-\eta)\pi_i + \tilde{\pi}_i',$$

upon which $\hat{P}_i$ and the new Q' have the same moments.

Another idea of making EP run smoother on hard problems is *damping* (Minka, 2001a). There, the full standard EP update is computed, but the site parameters are updated to a convex combination of old and proposed new values. This addresses a quite contrary problem to ours here. Damping is useful if EP update computations are stable, but lead to an improper new posterior, or the propagation of the updated information fails. If EP is viewed as finding a saddle point of a free energy approximation (Opper and Winther, 2005), damping can be understood as a step-size rule within this process. It slows down convergence in general in situations where EP without damping works fine, but the fixed points are not altered. Our problem is not solved by damping, since proposed new values for the site parameters cannot even be computed.

Finally, the reader may wonder whether the problems with standard EP are due to a bad initialisation of the site parameters. While we have not analysed it in all details, we think the problem is inherent. For example, we tried to run fractional EP to convergence, then start standard EP (with $\eta = 1$) from the fractional fixed point. On critical cases, this fails about as fast as if started in the usual way, often in the first sweep of standard EP.

3.4 Inclusion of a New Point

Suppose we would like to operate inference in the sparse linear model in a sequential manner, in that new data points (x_*, u_*) become available over time. This is the case in sequential design applications, since single experiments result in new measurements. In this section, we show how the EP posterior representation is updated once a new point (x_*, u_*) is added to the current data set D. The inclusion of (x_*, u_*) works in two stages. First, the Gaussian base measure is modified in order to incorporate the new point. Second, EP updates are done until convergence. The mechanics of the latter have been described above, so we can concentrate on the first stage here.

For the non-degenerate representation, let $v := L^{-1}x_*$. The change of $b^{(0)}$ results in $\tilde{\gamma} = \gamma + u_* v$. Since $L'(L')^T = LL^T + x_* x_*^T$, L', γ' is obtained from $L, \tilde{\gamma}$ by a rank one Cholesky update (see Section 3.2). The cost is $O(n^2)$.

For the degenerate representation, let $X' = (X^T, x_*)^T \in \mathbb{R}^{m+1,n}$ and $u' = (u^T, u_*)^T \in \mathbb{R}^{m+1}$. Since $b^{(0)} = X^T u$, we have that $b^{(0)\prime} = b^{(0)} + u_* x_*$. Let $l := L^{-1} X \Pi^{-1} x_*$. Then, $\tilde{\gamma} = \gamma + u_* l$ incorporates the update of $b^{(0)}$. Next, LL^T grows by a row/column $((Ll)^T, 1 + x_*^T \Pi^{-1} x_*)^T$. Therefore, L', γ' are obtained from $L, \tilde{\gamma}$ by a Cholesky extension, as described in Seeger (2004). The cost of the inclusion is $O(m^2)$.

3.5 Some Consequences of Log-concavity

A nonnegative function $f(x)$ is *log-concave* if

$$f(\lambda x_1 + (1-\lambda)x_2) \geq f(x_1)^\lambda f(x_2)^{1-\lambda}$$

for all x_1, x_2, and $\lambda \in [0,1]$. $f(x)$ is log-concave iff $\log f(x)$ is concave as a generalised function, which can take on the value $-\infty$, see Boyd and Vandenberghe (2002), Sect. 3.5. We call a distribution log-concave, if its density exists and is log-concave. In this section, we show some implications of log-concave sites for the numerical stability of EP.

Gaussians are clearly log-concave, so models of the sort considered here are log-concave if the sites are (products of log-concave functions are log-concave). For example, Laplace sites $t_i(a_i)$ are log-concave, while Student's t sites are not. A direct consequence is that for log-concave sites, the posterior is log-concave, so its unique mode can be found by convex optimisation. Log-concavity is stronger than unimodality though. For example, all upper level sets (areas enclosed by contours) of the posterior are convex sets. Intuitively, log-concave distributions are "simple", although strong consequences of this fact for variational approximate inference methods are not known to our knowledge.[16] Our main result is the following theorem.

Theorem 1 *Let EP be applied to a model with true posterior of the form*

$$P(a|D) \propto P^{(0)}(a) \prod_i t_i(a_i),$$

where $P^{(0)}(a)$ is a joint unnormalised Gaussian factor, and the sites $t_i(a_i)$ are log-concave. Suppose the site parameters π_i are initialised to non-negative values. Then, all EP updates are computable (in exact arithmetic), and all π_i remain non-negative throughout.

The proof is given in Appendix A.1. The theorem holds just as well for general sites $t_i(a)$ with corresponding site approximations $\tilde{t}_i(a) = N^U(\sigma^{-2}b_i, \sigma^{-2}\Pi_i)$, if "$\pi_i \geq 0$" is replaced by "$\Pi_i$ positive semidefinite". It hinges on a fundamental marginalisation theorem for log-concave functions due to Prékopa, see Bogachev (1998). Namely, suppose that $f(x,y)$ is jointly log-concave in (x,y), $x \in \mathbb{R}^p$, $y \in \mathbb{R}^q$. Then $\int f(x,y)\,dy$ is log-concave in x. Theorem 1 implies that EP can be implemented in a numerically stable way. Namely, the non-negativity of all π_i ensures that the representations introduced in Section 3.2 can be updated in a stable manner. The situation for some applications with non-log-concave sites is much less satisfactory. It is usually not possible to keep all π_i positive anymore, without making significant approximation errors (Minka, 2001a). Full EP updates lead to erratic behaviour or cannot even be done, and damping has to be used, leading to slower convergence. Negative entries π_i can lead to very ill-conditioned Cholesky factors in the representations, resulting in large errors at each update.

Our theorem also implies that for applications where EP is started with $\pi = 0$, for example Gaussian process classification, we have that the entropy $\mathrm{H}[Q]$ of the posterior decreases monotonically during the first sweep. Namely, the entropy is $\log|\Sigma|$ up to constants, which is decreasing in every single π_i. Minka (2001a) notes that the first sweep of EP is equivalent to a method called *assumed density filtering* (Kushner and Budhiraja, 2000), so our theorem has implications for this method as well.[17]

Another interesting consequence of log-concavity holds for the sparse linear model, independent of whether EP is used for approximate inference or not. It serves to motivate the parameterisation of the Laplace sites (2) in terms of $\tilde{\tau} = \tau/\sigma$. Up to additive constants, $\log P(u,a)$ has the form

$$(2m+n)\log\sigma^{-1} - \frac{1}{2}\|u/\sigma - Xa/\sigma\|^2 - \tau\sum_i |a_i/\sigma|,$$

16. In contrast, MCMC sampling from log-concave distributions has been proven to be computationally efficient (Lovász and Vempala, 2003).

17. The entropy $\mathrm{H}[Q]$ can increase in later sweeps of EP (this happens regularly, not only in special cases). This is why we need to consider Cholesky *downdates* in Section 3.2, and shows that $\mathrm{H}[Q]$ alone cannot be used to prove convergence of EP.

which is jointly concave in (ϕ, σ^{-1}), where $\phi := a/\sigma$. This fact has been noted in Park and Casella (2005). In fact, even $P(u,a)\sigma$ is log-concave in (ϕ, σ^{-1}), since $2m+n \geq 1$. The marginal likelihood $P(u)$ is a crucial criterion when it comes to hyperparameter optimisation or Bayesian tests (see Section 5). Now,

$$P(u) = \int P(u,a)\, da = \int P(u,a)\sigma\, d\phi,$$

and by the marginalisation theorem, $P(u)$ is log-concave in σ^{-1}. This implies that if all other hyperparameters are fixed, the empirical Bayesian maximisation of $\log P(u)$ w.r.t. the noise variance σ^2 is in fact a convex problem with a unique solution. Unfortunately, this property does not extend to other hyperparameters such as τ or X. On a practitioner's level, it is interesting to relate this fact to a scheme mapping out the entire regularisation path of Lasso (or, equivalently, an SVM) (Hastie et al., 2004). In either case, adjusting one hyperparameter trading off prior and likelihood given all others is shown to be simple. Here, as there, this gives some reassurance if σ^2 is adapted along with other parameters (see Section 7.2).

We close this section by some technical side comments for readers interested in details, all others may skip this paragraph. We require results from Section 5. We just showed that the exact $\log P(u)$ is concave in σ^{-1}, but how about the EP approximation of this quantity, called L in Section 5? To answer this question, we first have to establish that L is well-defined and continuous as a function of σ^2 in the first place. Now, L is defined in terms of the site parameters at convergence, and the EP algorithm has not been proven to always converge uniquely. Opper and Winther (2005) show that L is a proper approximate free energy as function of b, π, but the site parameters at convergence are only a saddle point thereof. Using tools such as the implicit function theorem, one can argue that $L(\sigma^2)$ is well-defined across some range, but does this hold globally across all σ^2? If the dependence of the site parameters on σ^2 is ignored locally, then L is log-concave in σ^{-1}, following similar arguments as above. We know from Section 5 that for computing the first derivative w.r.t. σ^2, the site parameters can be assumed constant, but this is not true in general for the second derivative (which would characterise concavity). Clearly, there is more work needed to gain a better understanding of such properties of the implicitly defined EP approximate free energy L.

4. Sequential Optimal Design

The role of sequential optimal design[18] for saving on expensive experiments has already been motivated in Section 2. The topic is well-researched in classical and Bayesian statistics (Fedorov, 1972; Chaloner and Verdinelli, 1995). A variant is known in machine learning as *active learning*[19] (Seung et al., 1992). We follow MacKay (1991) here, whose setting is closest to ours.

In the sparse linear model, a typical design problem can be formulated as follows. Given a set of candidate points x_*, at which of these should a corresponding target value u_* be sampled in order to obtain as much new information about the unknown a as possible? Assuming (for the moment) that u_* is known for a x_*, natural scores quantify the decrease in posterior uncertainty or gain in

18. *Optimal design* is a fixed term in statistics for a methodology, in which designs are optimised. We have no intention of claiming that any of the methods presented here solve problems in an optimal way, in fact they usually do not. In the context of this paper, *optimal design* and *experimental design* mean the same thing.
19. Confusingly, *active learning* is also used for the related, but not identical setup, where data comes in sequentially, and the method has to decide which cases to incorporate versus which to ignore. We are not interested here in this latter setting.

information from the current posterior Q to the novel Q' which is obtained by including (x_*, u_*) into the data set D. In this paper, we concentrate on the information gain $\mathrm{D}[Q' \,\|\, Q] = \mathrm{E}_{Q'}[\log Q' - \log Q]$. A large information gain means that Q' is different from Q, thus much novel information is gained from (x_*, u_*). Now, u_* is *not* known for the candidates x_*. Bayesian methodology dictates that u_* is averaged over its current posterior $Q(u_*|x_*, D) = \int P(u_*|x_*, a) Q(a|D)\, da$. Since $Q(a|D)$ is Gaussian for our approximation, the posterior over u_* is Gaussian as well. A natural score for x_* is the expected information gain $\mathrm{E}_{Q(u_*|x_*,D)}[\mathrm{D}[Q' \,\|\, Q]]$. This one-dimensional integral can easily be approximated using Gaussian quadrature.

However, optimal design for the gene network application of Section 2 does not fall into this standard category and requires some additional thoughts. The goal is to score the utility of inclusion of candidate controls u_*, given current data D (and posterior Q). Among a list of candidates, the highest-scoring u_* is then subjected to a new experiment in order to obtain x_*, whence (u_*, x_*) are included to form $D' = D \cup \{(u_*, x_*)\}$ and a new posterior Q'. Here, the posterior is a product of independent factors for the rows of A, so that for given (x_*, u_*), the information gain is the sum of $\mathrm{D}[Q' \,\|\, Q]$ over the posterior factors, where $(x_*, u_{*,j})$ is appended to D for the j-th factor.

More importantly, it is x_* which is unknown, rather than u_* in the standard setup. While $Q(u_*|x_*, D)$ is a Gaussian in our setup, $Q(x_*|u_*, D) = \int P(x_*|u_*, A) Q(A|D)\, dA$ is not a simple distribution. However, we can easily sample from it by first drawing $A \sim Q(A|D)$, then[20] $x_* = A^{-1}(u_* - \varepsilon)$, $\varepsilon \sim N(0, \sigma^2 I)$. Sampling from $Q(A|D)$ is discussed in Appendix B.2. Our *information gain* score in the gene network application is

$$S(u_*; D) = \mathrm{E}_{Q(x_*|u_*,D)} \left[\mathrm{D}[Q' \,\|\, Q] \right],$$

where the expectation is approximated by using a number of independent samples x_*.

Going back to the standard setup, for fixed (u_*, x_*), Q' is obtained from the current Q by first modifying the base measure $P^{(0)}$ corresponding to the inclusion, then updating the site parameters b, π. The problem with this is that the EP updates are expensive, so only few candidates could be scored for each inclusion.[21] A simpler and much cheaper alternative is to *approximate* the information gain by modifying $P^{(0)}$ only, but keeping the old site parameters, when defining Q' in $\mathrm{D}[Q' \,\|\, Q]$. In other words, for the purpose of scoring, we treat the model as purely linear-Gaussian, with Q as "effective Gaussian prior". This simple score can be computed very efficiently and reliably, so many candidates can be scored. Details are given in Section 4.1. Recall that the score for the gene network setup is the sum of information gains for the posteriors of each row of A.

Once a candidate is chosen for inclusion, a true experiment is done in order to obtain a complete new data point. In the standard setup, this means drawing u_*, given x_*, but in the gene network setting, we determine x_* for given control u_*. The new information is then included by a posterior update, as described in Section 3.4, and the site parameters are driven to new convergence by the EP algorithm.

Note that the fact that we approximate the true posterior $P(a|D)$ by a Gaussian $Q(a)$, as well as use Q' with the same site parameters as Q, means that we merely approximate the information gain, and at present we cannot give useful approximation guarantees, beyond our empirical demonstrations that good designs are usually found. However, our use of Gaussian Q and a simple update

20. We use a LU decomposition of A. The cost of $O(n^3)$ may be prohibitive for large n (although the same A sample can be used to score *all* candidates), in which case we would recommend sparsifying A and using a sparse matrix solver.
21. One idea would be to update few sites only after each inclusion. The extension described in Section 6.3 could be used to implement this, which is however not done here.

$Q \to Q'$ means that our information gain approximation can be computed robustly, which, as noted in Section 1, is often as important for experimental design as is high approximation accuracy.

4.1 Simple Information Gain

The simple information gain score is $\mathrm{D}[Q' \,\|\, Q]$, where Q is the current posterior, and Q' is obtained from Q by including (x_*, u_*) into the base measure $P^{(0)}$ as discussed in Section 3.4, but leaving the site parameters b, π at their old value. The relative entropy between Gaussians is well known:

$$\begin{aligned}\mathrm{D}[N(h', \sigma^2\Sigma') \,\|\, N(h, \sigma^2\Sigma)] = &\frac{1}{2}\log|M| + \frac{1}{2}\mathrm{tr}\left(M^{-1} - I\right) \\ &+ \frac{1}{2}\sigma^{-2}(h'-h)^T\Sigma^{-1}(h'-h), \quad M := (\Sigma')^{-1}\Sigma.\end{aligned} \tag{4}$$

Importantly, in our case we have that $(\Sigma')^{-1} = \Sigma^{-1} + x_* x_*^T$, so that $M = I + x_* x_*^T\Sigma$ has a simple form. This allows us to compute the simple information gain very efficiently. Details are given in Appendix B.1.

4.2 Marginal Criteria

The simple information gain scored discussed in the previous section measures the distance between the *joint* distributions Q and Q' (before and after inclusion). However, inference schemes such as expectation propagation (and other variational ones) are designed to approximate the posterior marginals well. EP applied to models with Gaussian base distribution results in a full joint posterior approximation Q, which can of course be used to make decisions or to compute information scores, but very little is known about the quality of Q beyond its marginals. A careful approach would therefore base experimental design scores on the marginals of Q only. On the other hand, criteria based on the full joint posterior can be more powerful in order to distinguish between many candidates.

For such marginal scores, we need to know how the marginals change after an update of $P^{(0)}$. Let $h, \mathrm{diag}\,\Sigma$ be the current marginal moments. We need to compute $h', \mathrm{diag}\,\Sigma'$ after inclusion of (x_*, u_*) (we only deal with the "simple" variant here, where no EP updates are done after the inclusion). Let $\alpha = x_*^T\Sigma x_*$, $z_* = \Sigma x_*$. By the Woodbury formula, we have that

$$\Sigma' = \Sigma - (1+\alpha)^{-1} z_* z_*^T.$$

The new h' is given in Appendix B.1, where we also show how to compute z_*, α efficiently. The marginal moments $h, \mathrm{diag}\,\Sigma$ have to be computed from the representation before each scoring round, although another idea is developed in Section 6.

Interestingly, in initial gene network identification experiments, employing the sum of marginal information gains worked less well than using the simple joint information gain of Section 4.1. In this case, the latter seems to carry more useful information about the candidates. In other words, the posterior correlations estimated by EP seem good enough to be useful here. Results with marginal scores are not reported in this paper.

5. The Marginal Likelihood

Bayesian methodology requires that unobserved variables are marginalised over in order to do predictions or to make optimal decisions. However, in many situations this is not practically feasible

for some variables. In the case of the sparse linear model, we can approximately integrate out the parameters a using EP, but likelihood and prior depend on other *hyperparameters* still, namely σ^2, τ, and (parameters of) X. A surrogate widely accepted amongst Bayesian practitioners is to *estimate* good values for the hyperparameters by maximising the *marginal likelihood* of the observed data.[22]

An approximation to the marginal likelihood may be obtained from EP. Details about this approximation can be found in Seeger (2005). As shown there, it is the same as the approximate free energy proposed in Opper and Winther (2005). We give the derivation for fractional EP in general (see Section 3.3.1), $\eta \in (0,1]$. Standard EP is obtained for $\eta = 1$. We have that

$$P(D) = P(u) = \int \prod_{i=1}^{n} t_i(a_i) P^{(0)}(a)\, da. \tag{5}$$

Recall that in EP, the sites t_i are replaced by approximations $\tilde{t}_i$ of Gaussian form. Earlier on, we did not bother with the normalisation constants of these approximations, but now we have to make them explicit: $t_i(a_i) \to C_i \tilde{t}_i(a_i)$, $\tilde{t}_i(a_i) = N^U(a_i|\sigma^{-2}b_i, \sigma^{-2}\pi_i)$. Roughly speaking, EP works by making the first and second order moments of the posterior marginals $Q(a_i)$ and the tilted distributions $\hat{P}_i(a_i)$ equal for all i. In this line, we fix the C_i such that the normalisation constants are the same as well:

$$\log C_i = \eta^{-1}(\log Z_i - \log \tilde{Z}_i), \quad Z_i = \mathrm{E}_{Q^{\setminus i}}\left[t_i(a_i)^\eta\right],\ \tilde{Z}_i = \mathrm{E}_{Q^{\setminus i}}\left[\tilde{t}_i(a_i)^\eta\right].$$

Here, $Q^{\setminus i} \propto Q\tilde{t}_i(a_i)^{-\eta}$. The EP approximation $L \approx \log P(u)$ is then obtained by replacing t_i by $C_i\tilde{t}_i$ in (5). This results in

$$L = \sum_{i=1}^{n} \log C_i + \frac{1}{2}\left(\log|\Sigma| + \sigma^{-2}h^T(b^{(0)} + b) - \sigma^{-2}\|u\|^2 + (n-m)\log(2\pi\sigma^2)\right). \tag{6}$$

In order to maximise L, we require its gradient w.r.t. hyperparameters, which can be computed exactly if EP is run to convergence, such that the moments of all $Q(a_i)$ and $\hat{P}_i(a_i)$ coincide. In Seeger (2005), the following is shown:

$$\nabla_{\theta^{(0)}} L = \mathrm{E}_Q[\nabla_{\theta^{(0)}} \log P^{(0)}(a)], \tag{7}$$

where $\theta^{(0)}$ are the natural parameters of $P^{(0)}$. Furthermore, if α is a parameter of the site t_i independent of $P^{(0)}$, then

$$\frac{\partial L}{\partial \alpha} = \frac{\partial \log Z_i}{\partial \alpha} = \mathrm{E}_{\hat{P}_i}\left[\frac{\partial}{\partial \alpha}\log t_i(a_i)\right]. \tag{8}$$

Note that this holds for fractional EP in general, if $\eta \in (0,1]$. The specialisations to our case are given in Appendix C.

Note that the EP approximation L of $\log P(u)$ has an important consistency property. It is well known that $\nabla_{\theta^{(0)}} \log P(u) = \mathrm{E}_{P(a|D)}[\nabla_{\theta^{(0)}} \log P^{(0)}(a)]$, from which (7) is obtained by replacing the true posterior by the EP approximation $Q(a)$: the true gradient of the approximate criterion is the approximate gradient of the true criterion. Another way to view this is to note that L depends on hyperparameters directly as well as through the EP site parameters b, π, thus the gradient has direct as well as indirect contributions. Importantly, the stationary conditions of EP at convergence

22. In work in progress, we show how the noise variance σ^2 can be integrated out along with a using EP. This, however, leads to a significantly more complicated and somewhat less robust algorithm. Details will be given in a later paper.

imply that the latter contributions do vanish. In Seeger (2005), it is shown that $(\partial L)/(\partial \sigma^{-2} b_i) = (\partial L)/(\partial \sigma^{-2} \pi_i) = 0$ at EP stationary points, which directly implies the simple formulae (7), (8). This fact becomes clear if L is seen as approximate free energy (Opper and Winther, 2005) (although only the case $\eta = 1$ is discussed there).

Note that the fraction η is a parameter of the approximation method, not a statistical variable or hyperparameter. It is natural to ask for which η one would obtain the best approximation of $\log P(u)$. Since L is not a bound on $\log P(u)$, we cannot directly optimise η. Useful theoretical insights about fractional EP variational free energies for different η are not known to us. We will address this point as part of an empirical comparative study, which is subject to future work. However, note that EP cannot be run at all in a stable way for certain setups if η is (very close to) one (see Section 7.1).

6. Large-Scale Applications

A naive implementation of the EP algorithm for the sparse linear model requires $O(n^3)$ time for each sweep and $O(n^2)$ memory, if the non-degenerate representation is used. While this is acceptable for moderate sizes of n, like in the gene network identification application, it is certainly not feasible for large n. In this section, we propose some ideas in order to apply our framework in such situations.

The dominant computation within our framework, both for experimental design and marginal likelihood maximisation, is spent performing a sweep of EP updates. Naively, this is a loop over all n sites (in random ordering). For each site i, the marginal $Q(a_i)$ has to be determined, and the representation for doing so has to be updated afterwards. Time can be saved by doing less than n updates per sweep, and by speeding up the marginal extraction or representation update. In a sequential context such as experimental design, it is sensible to assume that many EP updates will not lead to much change in Q, especially during later stages. A key problem is how to efficiently detect the sites whose update would change the current posterior the most.

Furthermore, a large-scale application will normally not be generic, but comes with a lot of structure already. For example, the design matrix $X \in \mathbb{R}^{m,n}$ is often given implicitly, since its storage alone would be too costly, and matrix-vector multiplications (MVMs) with X are often much more efficient than $O(nm)$. A key step in the direction of a large-scale implementation is to make sure that such special structure is used optimally.

A motivating example for a large-scale application comes from compressive sensing (see Section 2.4). Recall that $X = P\Phi$, where Φ is a fixed coding matrix, and P is a measurement matrix we can design. If the task deals with full images, n can be a million, and neither Φ nor P can be stored as dense matrices, but have to be defined implicitly as linear mappings. For example, Φ could be an orthonormal Wavelet code, and P could consist of m selected rows from the discrete cosine transform (DCT) matrix. An MVM with Φ costs $O(n)$, an MVM with P is $O(n\,log\,n)$, both much faster than a naive $O(nm)$ MVM for large m. Experiments with this setup are in preparation.

6.1 Matrix-free Updates

We already noted that storing X explicitly should not be necessary, if we have an efficient method to compute MVMs with X and X^T. For example, X could be of special structure, or it could be sparse (most entries exactly zero). Suppose that $m \ll n$ with very large n. In this case, the degenerate representation of $Q(a)$ is used, requiring $O(m^2)$ storage. Each EP update requires $O(m^2)$ and the extraction of a column of X, in other words $X\delta_i$, a single MVM (see Section 3.3). It is necessary to refresh the representation now and then, which requires the computation of $X\Pi^{-1}X^T$ for arbitrary

positive π_i. This can be reduced to computing $X\Pi^{-1}X^T\delta_i$, $i = 1,\ldots,m$, corresponding to m MVMs with X and X^T each.

6.2 No Representation At All

It is in general not feasible to compute all required marginals on demand, just storing π, b, and the data. A representation is used in order to do this feasibly, using the fact that each update leads to a rank one modification only. Time is traded for memory, as explained in Section 3.2.

However, suppose that MVMs with X and X^T can be done very efficiently. For an update at site i, we require $Q(a_i) = N(h_i, \sigma^2\rho_i)$. Recall that $\Sigma^{-1} = X^TX + \Pi$ and $h = \Sigma(b^{(0)} + b)$. The quadratic criterion

$$q(v) := \delta_i^T v - (1/2)v^T(X^TX + \Pi)v$$

can be minimised using the linear conjugate gradients (LCG) algorithm (Saad, 1996), requiring a MVM with $X^TX + \Pi$ per iteration, thus MVMs with X, X^T, and $O(n)$. At the minimum, we have $v_* = \Sigma\delta_i$ and $q(v_*) = \rho_i/2$, whence $h_i = v_*^T(b^{(0)} + b)$.

We can also start from the degenerate representation and formulate the marginal computation as quadratic minimisation over vectors of size m, where the system matrix is $I + X\Pi^{-1}X^T$. However, both variants have the same cost of two MVMs per iteration, and their convergence behaviour should be similar.

This method has the advantage of not requiring any representation at all. Apart from the architecture for computing X and X^T MVMs, we need $O(n)$ memory only. However, it is useful only if LCG converges to satisfying accuracy rapidly (after many fewer than n iterations), and if single MVMs can be done much faster than $O(nm)$. Another drawback is that the marginal computations are approximate only, and the error may well depend on the current π. Therefore, it is maybe most sensible to combine it with a way of reducing the number of EP updates required, as is discussed just below.

6.3 Keeping Marginal Moments Up-to-date

The suggestions so far try to speed up single EP update computations. However, if n is very large, a major problem is that we cannot update all n sites in a sweep. For example, in the context of experimental design, it is not affordable to update each site after each new data point inclusion. Updates have to be done selectively on a subset. In this section, we indicate how this can be done. See Seeger and Nickisch (2008) for a demonstration in practice.

Given the marginal $Q(a_i)$, an EP update at i is $O(1)$, so its effect on $Q(a_i)$ can be measured cheaply. The costly part (in the formulation used so far) is to extract the marginal from the representation, and to update the latter. It is reasonable to assume that a small impact of an EP update on the marginal $Q(a_i)$ implies that the whole posterior Q changes little, so site i need not be updated at the moment.

In order to direct EP updates towards sites with maximum marginal impact, it is necessary to keep *all* marginals $Q(a_i)$ up-to-date at all times. In other words, $Q(a_i)$ must be computable in $O(1)$ from the representation, for any i. With the representations of Section 3.2, this costs $O((\min\{n,m\})^2)$. We concentrate on the degenerate representation, which is more important in the large-scale context (the non-degenerate case is also simpler). Let $V := X^TL^{-T}$, and define

$e_1 = \mathrm{diag} VV^T$, $e_2 = V\gamma$. Given the latter vectors, each marginal can be computed in $O(1)$:

$$\rho = \Pi^{-1}(1 - \Pi^{-1} e_1), \quad h = \Pi^{-1}(b^{(0)} + b - e_2).$$

We show how e_1, e_2 can be updated along with the representation. Recall Section 3.2, $x = X_{\cdot,i}$. We can compute Δ_1, Δ_2 and $Q'(a_i)$ in $O(1)$, without knowing $v = L^{-1}x = (V_{i,\cdot})^T$. If $|\Delta_2|$ or $\mathrm{D}[Q'(a_i) \,\|\, Q(a_i)]$ is too small, the update is rejected. Otherwise, we compute v and $w := L^{-T}v$, $r := X^T w$. First, $\tilde{\gamma} = \gamma + \Delta_1 v$. The Woodbury formula gives

$$\left(L'(L')^T\right)^{-1} = \left(LL^T\right)^{-1} - (\Delta_2^{-1} + e_{1,i})^{-1} ww^T,$$

so that $e_1' = e_1 - (\Delta_2^{-1} + e_{1,i})^{-1} r \circ r$, and

$$e_2' = V'(L')^{-1}(L\tilde{\gamma}) = e_2 + (\Delta_1 - (\Delta_2^{-1} + e_{1,i})^{-1} v^T \tilde{\gamma}) r.$$

Now, $v^T\tilde{\gamma} = e_{2,i} + \Delta_1 \|v\|^2 = e_{2,i} + \Delta_1 e_{1,i}$, so that

$$e_2' = e_2 + \frac{\Delta_1 - \Delta_2 e_{2,i}}{1 + \Delta_2 e_{1,i}} r.$$

Finally, L', γ' are obtained from $L, \tilde{\gamma}$ by a rank one Cholesky update as before. The cost is increased by the computation of w and r, the latter requires a single MVM with X^T.

The representation has to be recomputed now and then. Here, the computation of e_1 is most challenging, but can be reduced to doing m MVMs with X^T (with the columns of L^{-T}, obtained by back-substitutions).

In an experimental design context, the representation has to be updated once new data points (x_*, u_*) are included, as discussed in Section 3.4. Using the notation there, V is transformed to V' by appending the column $v := l_*^{-1}(x_* - X^T L^{-T} l)$, where (l^T, l_*) is the new row of L'. Therefore, $e_1' = e_1 + v \circ v$. Moreover, $\gamma' = ((\gamma + u_* l)^T, g_*)^T$ for a scalar g_*, so that

$$e_2' = V(\gamma + u_* l) + g_* v = e_2 + u_* x_* + (g_* - u_* l_*) v.$$

The computation of v requires one MVM with X^T.

Once every marginal is available in $O(1)$ at all times, we can actively select which one to update next. For a set of candidates i, we compute score values S_i, selecting site $\mathrm{argmax}_i S_i$ for the next update. A possible score is $S_i = \mathrm{D}[Q'(a_i) \,\|\, Q(a_i)]$. Scoring all sites for each update is $O(n)$, thus prohibitive, so a set of scoring candidates J should be maintained and evolved. A simple rule, which has been used in the context of sparse Gaussian process methods (Lawrence et al., 2003), works as follows. Before each update, all sites in J are scored. The winner is chosen for the update, and is removed from J, along with a fraction (say, $1/2$) of the worst-scored ones. J is then filled up again by drawing at random from $\{1, \ldots, n\} \setminus J$.

Finally, we note that it is possible in principle to maintain e_1, e_2, therefore the marginal moments, without storing a representation of size $O(m^2)$ at all. For example, the update after a change of π_i, b_i is in terms of $r = X^T L^{-T} v = VV^T \delta_i$. Since $VV^T = \Pi - \Pi\Sigma\Pi$, we have that $r = \pi_i(\delta_i - \Pi\Sigma\delta_i)$. We have shown above how to approximate $\Sigma\delta_i$ by the LCG algorithm. Equivalently, $VV^T = X^T(I + X\Pi^{-1}X^T)^{-1}X$, so we can also compute r by LCG on a system of size m. In principle, such a representation-free method can be used to address problems with large m. However, when working without a representation, we have no efficient possibility anymore to "refresh"

e_1, e_2 now and then. Moreover, using LCG is an additional source of approximation errors. The danger is that (e_1, e_2) and (π, b) drift away from the relation that binds them with exact computations. Experiments assessing the usefulness of such a representation-free treatment in comparison to a $O(m^2)$ representation are in preparation.

7. Experiments

In this section, we present experiments for gene regulatory network identification, for sparse coding of natural images, and for compressive sensing.

7.1 Regulatory Network Identification

Our application of experimental design to gene network identification, using the sparse linear model, has been described in Section 2.2. The material presented here is extracted from Steinke et al. (2007), where all details omitted here can be found. The experiments were done by Florian Steinke. Note that `Matlab` code is available[23] for scientific use. The results given here can be reproduced with this code.

In order to evaluate our method, we simulate the whole network identification process. First, we generate a biologically inspired ground-truth network together with parameters for a numerical simulator of nonlinear dynamics, respecting the network. We feed our method with a number of candidate perturbations $\{u_*\}$, among which it can choose the experiments to be done. If (say) u_* is chosen, a corresponding x_* is drawn from the simulator, and (u_*, x_*) is included into the posterior $Q(A)$ as new observation. We score the predictions from the current posterior against the true network after each inclusion.

Our generator samples networks with a scale-free edge distribution, using $n = 50$ nodes with in-degrees (excluding self-edges) in $\{0, \ldots, 6\}$. An edge is activating with probability $1/2$, inhibitory otherwise. For a given network structure, we sample plausible interaction dynamics, using noisy Hill-type kinetics inspired by the model of Kholodenko et al. (2002). Here, systems without a stable fixed point are rejected.

The disturbance candidates u_* were restricted to have a small number r of non-zero entries, since a tightly controlled excitation or inhibition for many genes at the same time is unreasonably expensive in practice. All non-zero elements have the same size, but a random sign, so that all u_* have the same norm. We use a pool of 200 randomly generated candidates in general.

All results are averaged over 100 runs with independently drawn networks and systems. In the comparative plots presented below, the different methods all run on the same data.

Our evaluation score measures the quality of the ranking of candidate edges, computed from the posterior according to the probabilities $Q(\{|a_{ij}| > 0.1\})$. We modify a standard ROC curve (true positive rate (TPR) as function of false positive rate (FPR)) by computing the area under the ROC curve (AUC) only up to a number of false positives equal to the number of edges in the true network. Namely, since true networks are sparse, there are many more non-edges than edges, and only very small FPRs are acceptable at all. We denote our score as *iAUC*, it is normalised to lie in $[0, 1]$. For $n = 50$, the trivial method which outputs a random permutation as ranking, has expected iAUC of 0.02. Furthermore, on average about 25% of the true edges are "undetectable"

23. See `www.kyb.tuebingen.mpg.de/sparselinearmodel/`. The code is joint work with Florian Steinke and Koji Tsuda. If you use it as part of a scientific publication, please cite Steinke et al. (2007) (details are on the web site).

after linearisation: their entries a_{ij} are very close to zero, so they do not contribute to the dynamics within the linearisation region. Such edges were excluded from the computation of iAUC.

Our method comes with two hyperparameters: the noise variance σ^2, and the scale τ of the Laplace prior. Given sufficient data, they could be estimated by the method described in Section 5, but this is hard to do in an experimental design setting, where we start with very few observations.[24] It is reasonable to assume that a good value for σ^2 does not change too much between networks with similar biological attributes, so that we can transfer it from a system whose dynamics are known, or for which sufficiently many observations are already available. This transfer was simulated in our experiments by generating 50 networks with data as mentioned above, then estimating σ^2 from the size of the ε residuals. The prior parameter τ was set by a simple heuristic described in Steinke et al. (2007).

We used fractional EP with $\eta = 1/2$. Standard EP (i.e., $\eta = 1$) does not converge for the majority of the inference tasks required. This problem is discussed in Section 3.3.1.

In Figure 2, we present reconstruction curves for our method versus competing techniques, which lack novelties of our approach (experimental design, Laplace prior). Very clearly, experimental; design helps to save on costly experiments. The effect is more pronounced for the Laplace than for the Gaussian prior. The former is a better prior for the task, and it is usually observed that improvements of designed over random experiments scale with the appropriateness of the model. In this case, the iAUC level 0.9 is attained after 36 experiments with designed disturbances, yet only after 50 measurements with randomly chosen ones, thus saving 30% of the experiments. In fact, our results indicate that experimental design only realises its full potential together with the non-Gaussian sparsity prior (see also Section 2.1).

In general, the model with Laplace prior does significantly better than with a Gaussian one. Of course, τ for the Laplace and the variance for the Gaussian prior were selected independently, specific to the prior. The difference is most pronounced at times when significantly less than n experiments have been done and the linear system (3) is strongly underdetermined. This confirms our arguments in favour of the Laplace prior (see Section 2.1).

The under-performance of the most direct variant LD of our method, up to about $n/2$ observations, is not yet completely understood. However, it has been repeatedly observed that aggressive experimental design based on very little knowledge can perform worse than random data sampling, if the model does not perfectly reflect the truth. On the other hand, it is important to note that LD recovers completely from the initial under-performance, and from $m = 25$ onwards significantly outperforms the random variant LR, so the initial design choices are not just plain wrong. We also tested a hybrid strategy LM of starting with random, then switching to designed experiments. In this particular application, starting from no knowledge about the network, an initial random exploration seems to lead to most useful results early on, while not hurting a subsequent sequential design.

7.2 Sparse Coding of Natural Images

The application of the sparse linear model to image coding (Olshausen and Field, 1997; Lewicki and Olshausen, 1999) is motivated in Section 2.3. Here, we present results of a study along the lines of work reported by Olshausen and Field (1997).[25] As is argued at length in Section 2.3, our goal here

24. One may be able to correct initial estimates of σ^2, as more observations are made, and a method for doing so is subject to future work.

25. Data and code used there was obtained from `http://redwood.berkeley.edu/bruno/sparsenet/`.

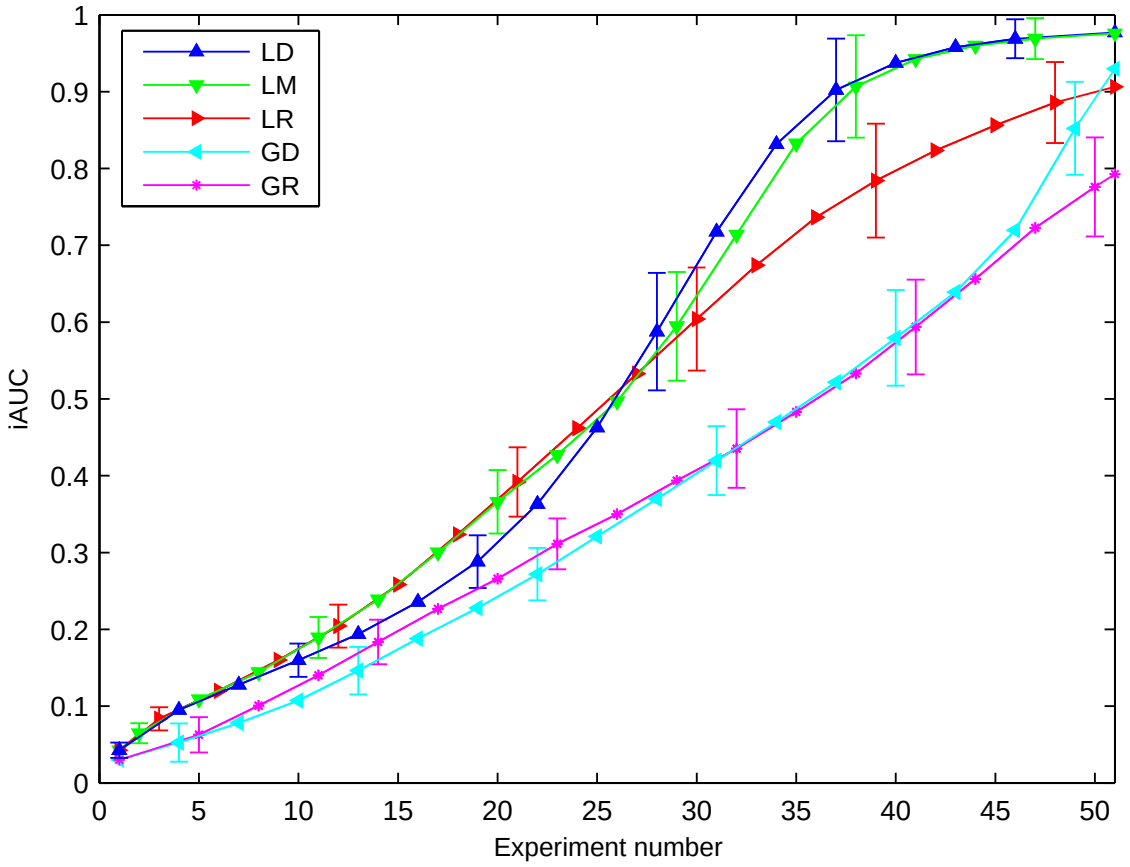

Figure 2: Reconstruction curves for experiments (gene expression changes of 1%, SNR 100, $r = 3$ non-zeros per u). **LD**: Laplace prior, experimental design. **LR**: Laplace prior, random experiments. **GD**: Gaussian prior, experimental design. **GR**: Gaussian prior, random experiments. **LM**: Laplace prior, mixed selections (first 20 random, then designed). Error bars show one standard deviation over runs. All visually discernible differences in mean curves of different methods are significant under the t-test at level 1%.

is not to compare a range of models to find out which can code images better or learn codes more efficiently, but rather to test the hypothesis put forward in Lewicki and Olshausen (1999), which does not call for such a comparison. We extracted two data sets of $r = 50000$ image patches of size 12×12 by subsampling the 10 whitened natural scenes, using their Matlab code. One is for training, the other for evaluation.[26] We allow for a twice overcomplete basis, therefore $m = 144$, $n = 288$. We also drew a random subsample of size 1000 from the test set, which was used in order to produce curves over many codes. Recall that a code in our model is given by the matrix X, whose columns are referred to as codebook vectors or filters.

26. The sets are not guaranteed to be completely distinct, although the extraction of the same patch during the different sampling runs is unlikely.

Before we describe the results, we should stress that the main aim at this point is to demonstrate the efficiency and usefulness of our method on a learning problem of large scale. 41473 hyperparameters are learned here on a set of 50000 cases. Each update step requires approximate inference on 100 models, each of which comes with 288 latent parameters. A more careful study will explore the implications of our findings to neuroscience (early vision) and image coding. This will entail a more refined learning schedule for our method, while our choices here are ad hoc and did not receive much tuning. Moreover, we base our evaluation entirely on the EP marginal likelihood approximation on a test set. An independent MCMC evaluation of this criterion, using for example annealed importance sampling together with hybrid Monte Carlo (which seems commonly accepted, but is very expensive to run), is clearly needed in order to draw any scientific conclusions (which we refrain from doing here). Such a study is subject to future work, and is not in the scope of this paper.

As noted above, the approach of Olshausen and Field (1997) is to approximate inference by maximum a posteriori (MAP): $P(a_j|u_j,X) \approx \delta_{\hat{a}_j}(a_j)$, where $\hat{a}_j$ is the posterior mode. Since the log posterior is concave, this mode is unique and can be found efficiently. In order to learn the code X, they propose to impute their estimates in order to obtain a complete data set $\{(u_j,\hat{a}_j)\}$, then to do maximum likelihood training. Since the estimate $\hat{a}_j$ depends on the current X, this is an iterative process. Their method will be called OF in the sequel. In contrast to this, we follow the hypothesis of Lewicki and Olshausen (1999) and learn X by maximising the EP approximation to the log marginal likelihood $\log P(D|X)$ (see Section 5). While Lewicki and Olshausen (1999) argue that the method of Olshausen and Field (1997) can be seen as optimising a (different) surrogate to $\log P(D|X)$ as well, ours is a much better approximation in general.[27]. Our method will be called EP here.

We had to modify their code in a minimal way, in order for it to run automatically on a given fixed training set. Our changes are detailed in Appendix E. Just as with our own method, we did not attempt to refine parameters for their code here.

The code of Olshausen and Field (1997) performs stochastic gradient descent on batches of size $|B| = 100$. We use a similar approach, which works as follows. The criterion $-\log P(D|X)$ is a sum of independent parts, one for each image. Let $\phi := -\sum_{j\in B} L_j$ be the EP approximation to this criterion, evaluated over a batch of size $|B|$ (here, L_j is the EP log marginal likelihood approximation on image j). The update rule for X is

$$X' = X - D', \quad D' = 0.85D + \xi X X^T \nabla_X \phi,$$

where $\xi > 0$ is the learning rate. The pre-multiplication of the gradient by XX^T is advantageous for this application, as has been argued in the context of "natural gradient" learning. As opposed to Olshausen and Field (1997) and Lewicki and Olshausen (1999), we adjust the noise variance σ^2 in the same way by minimising ϕ. If $l := \log\sigma^2$, a simple update rule is

$$l' = l - d', \quad d' = 0.85d + \xi_l \nabla_l \phi,$$

where $\xi_l > 0$ is a learning rate different from ξ. The learning rates are decreased in a reasonably slow way,

$$\xi(t) = \frac{A}{B+t}, \quad \xi_l(t) = \frac{A_l}{B_l+t},$$

27. MCMC experiments to strengthen this claim are subject to future work.

where t is the number of updates so far, and A, B, A_l, and B_l are free parameters (Bottou, 1998).

We can compare our update rule of X with the one used in Olshausen and Field (1997). It is easy to see that the gradient of the exact log marginal likelihood is

$$\nabla_X \log P(u_j|X) = \sigma^{-2} \mathrm{E}_{P(a_j|u_j,X)}[e_j a_j^T] = \sigma^{-2} \left((u - X\,\mathrm{E}[a_j])\mathrm{E}[a_j]^T - X\,\mathrm{Cov}[a_j] \right),$$

where $e_j := u_j - X a_j$. If OF is seen as optimising an approximation thereof, then the expectation over $P(a_j|u_j,X)$ is replaced by plugging in the mode $\hat{a}_j$ (which is what we mean by "imputation" above). In other words, the posterior mean $\mathrm{E}[a_j]$ is replaced with the mode, and the second term depending on the posterior covariance $\mathrm{Cov}[a_j]$ is neglected altogether. Since the Laplace sparsity prior leads to a posterior which is significantly skewed (towards coordinate axes, see Figure 1), mean and mode tend to be quite different.[28] In EP, the posterior expectations are replaced by $\mathrm{E}_Q[\cdot]$, where $Q = N(h, \sigma^2\Sigma)$ is the EP posterior approximation (see Appendix C). In fact, running OF precisely with the learning rule just stated does not work well in practice, and the neglectance of posterior uncertainty in the learning rule is put forward as a reason for this in Lewicki and Olshausen (1999). Olshausen and Field (1997) propose a heuristic renormalisation of the columns of X towards some "desired variance" as remedy, and this seems an important feature in their code. This heuristic comes with a number of parameters, which are fixed in their code to some values presumably optimised for their data by hand. In contrast, EP comes with τ, σ^2 only, and the latter can be adjusted automatically as well,[29] as is demonstrated here. Note that Lewicki and Olshausen (1999) suggest to approximate $\mathrm{Cov}[a_j]$ by the Laplace method in order to improve on the OF learning rule. However, as noted in Section 3, this method is not well-defined in case of the sparse linear model. Code implementing the proposal of Lewicki and Olshausen (1999) is not publicly available.

We can draw an analogy between the difference of learning X in OF and EP to current practices in speech recognition (Rabiner and Juang, 2003). Given a trained system, the recognition (or decoding) is done by searching for the most likely sequence, in what is called Viterbi decoding. However, training the system should be done by expectation Maximisation (EM), where the latent sequence is integrated out using inference. This is about what EP does here, with the difference that inference in hidden Markov models used for speech is analytically tractable, but has to be approximated here (by EP). However, since EM training is still computationally demanding, most speech recognition systems use Viterbi training today, where just as in OF the most likely (MAP) sequence is imputed instead of doing inference. While EM training is known to produce better recognisers on the same data, MAP training is still preferred for reasons of computational efficiency.

Our setup is as follows. We ran all methods on the same training data set, starting from the same initial code (drawn at random). For OF, learning rate and renormalisation heuristic parameters were left unchanged in their code. We used the values $0.1, 0.2, 0.4, 0.6962$ for τ, and $0.006, 0.01$ for σ^2. The values $\tau = 0.6962$, $\sigma^2 = 0.01$ come from the OF code, while $\sigma^2 = 0.006$ is closer to values ultimately preferred by the EP runs. All methods were run for 10000 batch updates, thus 20 sweeps over all images (in random ordering, different for each sweep). OF was run[30] separately for each of the eight (τ, σ^2) variants. On the other hand, for the EP runs, σ^2 was adjusted along with X as described above, and only τ was provided (the initial value for σ^2 was 0.002). The following

28. As discussed in Section 2.1, the mode $\hat{a}_j$ has many components which are exactly zero, which does not hold for the mean.
29. We could adjust τ in the same way with EP, but this is not done here. As noted in Section 3.5, the optimisation of σ^2 should behave better.
30. We also ran OF with $\tau = 0.05$, which gave bad results not reported here.

	$\tau = 0.1$		$\tau = 0.2$		$\tau = 0.4$		$\tau = 0.69$	
σ^2	OF	EP	OF	EP	OF	EP	OF	EP
0.006	-27.09	-80.04	-68.17	-80.04	-35.91	-80.05	92.73	-80.04
0.01	-2.329	-63.37	-53.53	-63.47	-43.69	-63.63	60.44	-63.80

Table 1: EP negative log marginal likelihood (EP average coding cost) per image, evaluated on the full test set (50000 cases), for different methods after 10000 batch updates of learning X. OF: Olshausen/Field; EP: our method.

learning rate schedule parameters[31] were used: $A = 0.79$, $B = 0.79 \cdot 10^3$, $A_l = 0.79 \cdot 10^{-5}$, $B_l = B$. This means that ξ decreases from 10^{-3} to $7.32 \cdot 10^{-5}$, and ξ_l from 10^{-8} to $7.32 \cdot 10^{-10}$.

We compare methods in general by evaluating the EP negative log marginal likelihood approximation on the test set, normalised by the number of images. This is equivalent to the EP approximation of the average coding cost per image (Lewicki and Olshausen, 1999) (smaller is better). For all but the final codes (after 10000 updates), we do this evaluation on the subset of size 1000. In order to evaluate test scores or to learn X (EP variants only), we need to perform EP inference on each image separately. To this end, we intended to use standard EP initially ($\eta = 1$, see Section 3.3.1), but ran into severe numerical problems on a significant number of images,[32] as described in Section 3.3.1. This led us to use fractional EP with $\eta = 0.9$ instead, which is the basis for all learning and test score evaluation results presented in this section.

learning curves along 10000 batch updates are shown in Figure 3 (using the test subset), and final EP negative log marginal likelihoods per image on the full test are given in Table 1. To recapitulate, the figures show average coding costs per image under the codes learned by the different methods, where τ and σ^2 are fixed for the evaluation. While OF was provided with τ, σ^2, EP only received τ during learning and had to adjust σ^2 alongside the code matrix X. We see from Figure 3 (upper left) that for the learning rate schedule used here, EP grows σ^2 smoothly from 0.002 to about 0.005.

Note that in the Bayesian viewpoint of image coding, all hyperparameters of a model work together in order to represent a data distribution (of image patches u) well, that is the code X, but also τ and the noise variance σ^2. In other words, code and noise variance are dependent. The EP runs settle at around $\sigma^2 = 0.005$, so the codes X found by them do better at $\sigma^2 = 0.006$ than at $\sigma^2 = 0.01$. The results for EP seem to not much depend on τ, but the situation is quite different for OF. At $\tau = 0.2$, the OF codes do well in comparison to the EP ones, and the lower $\sigma^2 = 0.006$ is preferred as well. For $\tau = 0.1$ or $\tau = 0.4$, they do significantly worse, and the preferred value is

31. These values were chosen after few initial runs, but not optimised over. Only for $\xi_l(0)$ did we compare runs, looking at learning curves on the training set. For $\xi_l(0) = 10^{-9}$, σ^2 hardly changed at all, while for $\xi_l(0) = 10^{-7}$, σ^2 increased sharply to above 0.02, then descended slowly towards 0.01.

32. None of these problems happened with fractional EP, $\eta = 0.9$. However, there is a pattern to these failures, indicating that further analysis would be valuable. In general, during learning X, EP convergence was harder to attain when the code was already optimised, with structural features emerging in the filters. While X could still be learned with $\tau = 1$, the test set log marginal likelihood evaluations for these codes could not be computed for many patches (using EP with $\eta = 1$). We evaluated these scores using EP with $\eta = 0.9$, finding very similar results (not shown here) than with the codes learned using $\eta = 0.9$. The reason for not simply abandoning standard EP for more robust fractional variants in general is based on arguments concerning alpha-divergences (Minka, 2004) (no hard theory is available to settle this issue, to our knowledge), apart from the somewhat more appealing motivation that can be given for standard EP (Opper and Winther, 2000).

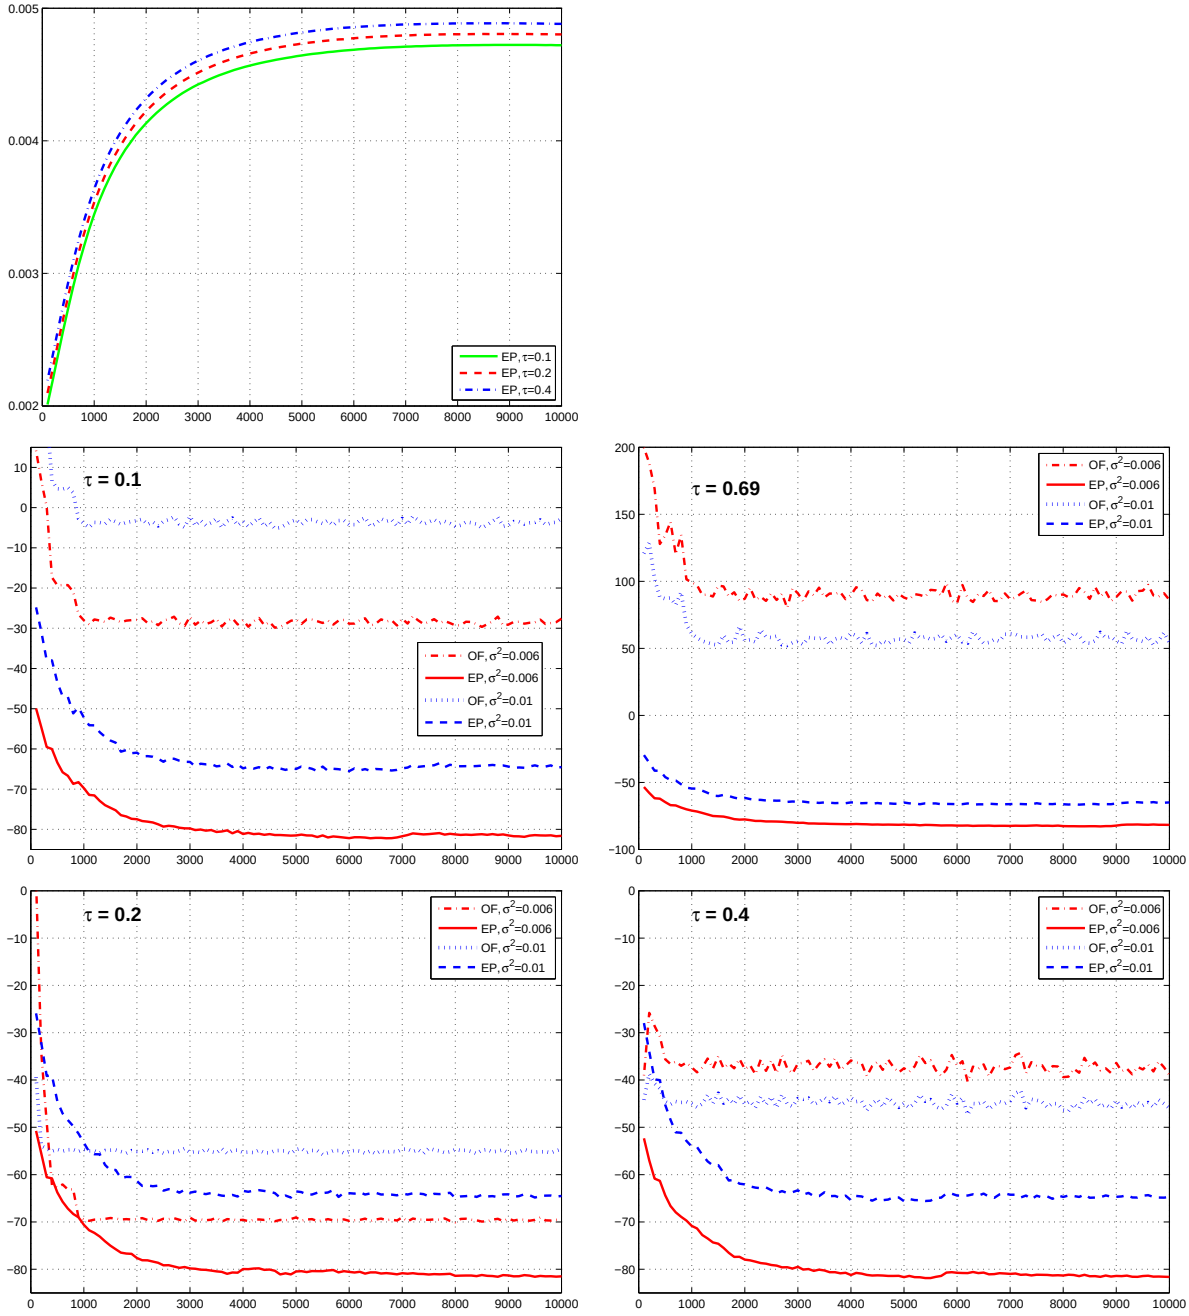

Figure 3: learning curves along 10000 batch updates. Upper left: Noise variance σ^2 for EP (different prior scales τ). Others: EP $-\log P(D)/r$ on test subset ($r = 1000$); $\tau = 0.1$ (middle left), $\tau = 0.6962$ (middle right), $\tau = 0.2$ (lower left), $\tau = 0.4$ (lower right).

$\sigma^2 = 0.01$ for $\tau = 0.4$. Finally, poor results[33] are obtained by OF with $\tau = 0.6962$, as well as with

33. We re-ran this case several times, in the way described in Appendix E, always obtaining the same poor results.

$\tau = 0.05$ (not shown here). The learning curve behaviour of the EP runs is much smoother than for OF, suggesting that the former optimisation problem is better behaved.

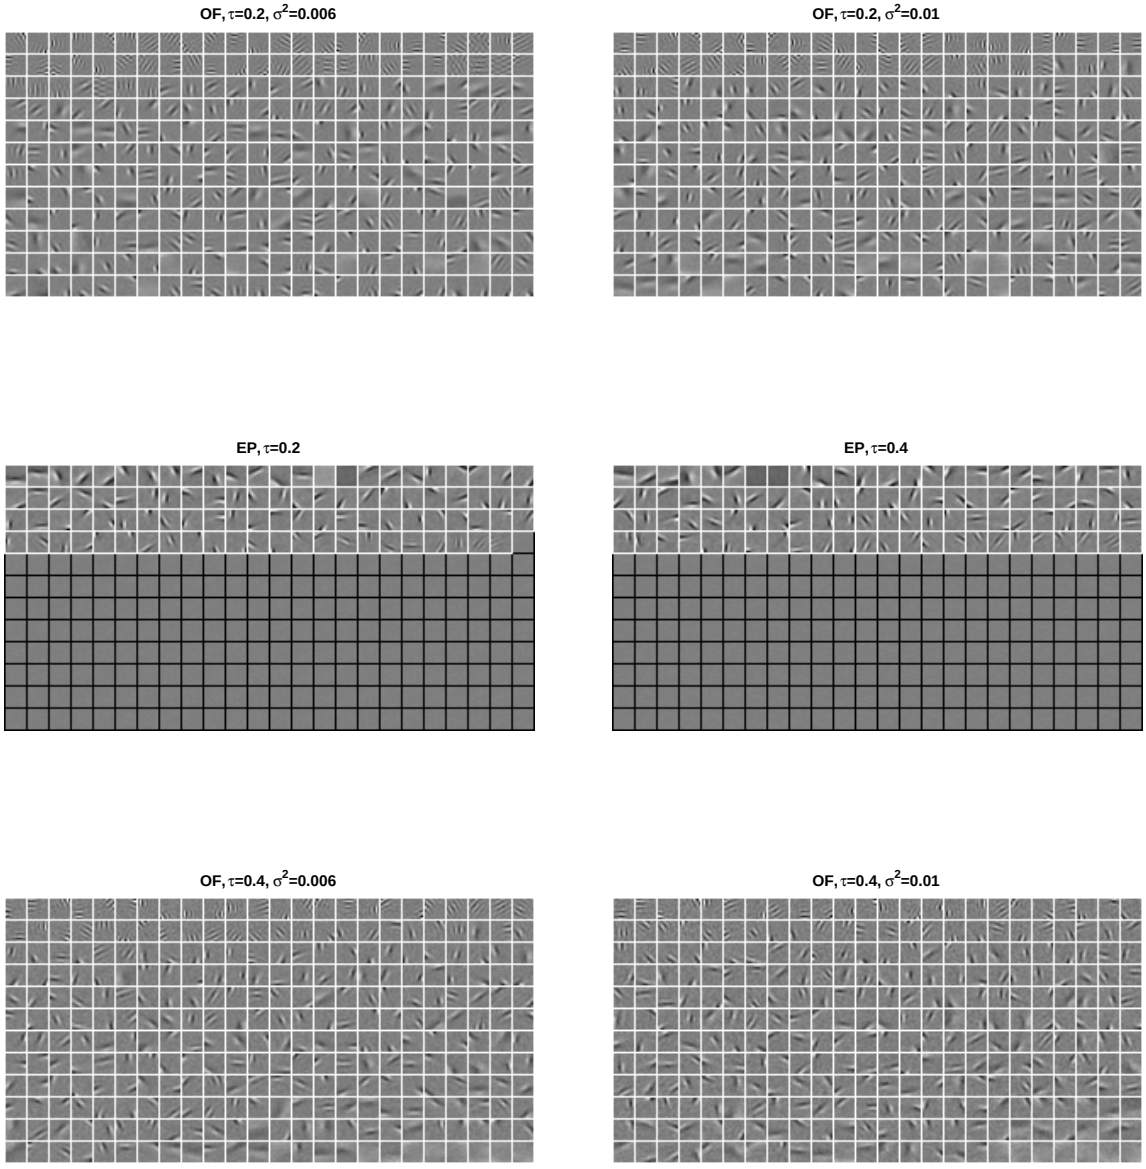

Figure 4: Final codes (after 10000 batch updates). Filters are ordered by descending $\|X_{\cdot,i}\|$, row-major ordering. Filters with $\|X_{\cdot,i}\| > (3\%) \max_j \|X_{\cdot,j}\|$ have white frame, black otherwise.

	$\tau = 0.1$		$\tau = 0.2$		$\tau = 0.4$		$\tau = 0.69$	
σ^2	EP[96]	EP[288]	EP[95]	EP[288]	EP[96]	EP[288]	EP[94]	EP[288]
0.006	-81.41	-80.04	-81.41	-80.04	-81.41	-80.05	-81.41	-80.04
0.01	-64.74	-63.37	-64.84	-63.47	-65.18	-63.63	-65.18	-63.80

Table 2: EP negative log marginal likelihood (EP average coding cost) per image, evaluated on the full test set (50000 cases), where X has been learned by EP. EP[288]: All X columns (copied from Table 1); EP[94–96]: Only X columns of significant size.

The final codes for different setups are given in Figure 4. The most distinctive difference between EP and OF codes is that for the latter, the filters do not differ much in size,[34] while there is a clear size signature in the codes found by EP: about 96 filters have significant sizes, while the remaining ones are about two orders of magnitude smaller. In the panels of Figure 4, filters with $\|X_{\cdot,i}\|$ larger than three percent of the maximum value are surrounded by white frames. For EP, these are 94–96 of 288 columns of X. In Table 2, we show EP average coding costs for the full test set, given that only the filters of significant size are used. These are even slightly lower than for the respective models using all columns of X.

We see that for the given task, codes attaining the lowest average cost are in fact *undercomplete*. A Bayesian method (such as EP here) removes unnecessary dimensions by default, through what has been called automatic relevance determination (see also Section 8.1). This does not happen for the OF method, which is not Bayesian and ignores covariances when learning X. We also note that in the codes found by OF, the filters of largest size are non-localised gratings, while all filters of significant size found by EP are localised and oriented. Both the smaller number of filters required and the strict localisation properties can be explained by noting that each image patch is explained probabilistically in EP, following Lewicki and Olshausen (1999), while in OF, this has to be done using a deterministic sparse encoding. In an update of X, each image only affects a small number of filters. It is then not too surprising that additional non-localised filters emerge in OF. If the hypothesis of Lewicki and Olshausen (1999) is taken for granted, these filters should be interpreted as artifacts of its improper implementation.

Note that the OF method runs much faster than EP. Finding $\hat{a}_j$ is a quadratic program (Tibshirani, 1996), which can be solved efficiently. Our EP code for the experiments here is "naive", in that all sites are visited in random ordering, no further efforts (such as the ones described in Section 6.3) are done. However, the arguments in Olshausen and Field (1997) and Lewicki and Olshausen (1999) do not call for a method which can be run very efficiently on a digital computer. A model is suggested which, in simple terms such as independence, linearity, and sparsity, could account for the formation of early visual neuron's receptive fields. The hypothesis of Lewicki and Olshausen (1999) is equivalent to a Bayesian perspective, where inference is a core requirement for improving the code, in much the same way as in EM for speech recognition, or graphical model learning in general. For both OF and EP, filters of significant size are localised, oriented gratings. However, our EP method more accurately implements the hypothesis of Lewicki and Olshausen (1999) than the algorithm of Olshausen and Field (1997), and leads to *qualitatively different* find-

34. Their renormalisation heuristic keeps them at similar, yet not at equal sizes.

ings: the data calls for a significantly undercomplete, therefore rather compact code, a fact that is not picked up by the OF method at all (Berkes et al., 2008, report similar findings with an approximate Bayesian method). Moreover, OF uses a significant number of non-localised filters, which are not present among the vectors of significant size found by EP. A more careful study based on our framework will shed light on what relevant properties in the codes can be explained by the probabilistic hypothesis of Lewicki and Olshausen (1999), versus which findings should rather be attributed to their particular computational method (maximum a posteriori, winner-takes-all X updates, variance renormalisation heuristic, etc.).

Apart from learning codes with EP, we can also use the log marginal likelihood approximation of EP in order to compare codes obtained by other methods. In Bayesian terms, such a comparison is done by computing Bayes factors, which is comparable to hypothesis testing. Moreover, for a fixed code X and data $\{u_j\}$, the noise variance σ^2 can be optimised by EP, in what is suggested to be a robust process in Section 3.5.

7.3 Compressive Sensing

In this section, we present results for a compressive sensing toy example. The motivation behind this application was given in Section 2.4. Results from a larger set of experiments, including some large-scale applications (see Section 6), are given in a later paper (Seeger and Nickisch, 2008). The experiments have been done by Hannes Nickisch.

In our toy experiment, the signal $y \in \mathbb{R}^n$ is sparse itself, so the coding matrix Φ is the identity. We have $n = 512$. Measurements are taken as $u = Py + \varepsilon$, where P (or X here) is the measurement matrix, and ε is Gaussian noise with standard deviation $\sigma = 0.005$. We compare methods where the measurement projections P are optimised in a sequential row-by-row manner, with methods where P is drawn uniformly at random on the unit hypersphere. In any case, the projections (i.e., rows of P) are constrained to have unit norm. The signal y is created by drawing $k = 20$ non-zero positions at random. The non-zero y_i are drawn at random from $\{-1,+1\}$ (uniform spikes), or according to a density[35] with support $\mathbb{R} \setminus (-0.21, 0.21)$ (non-uniform spikes). Examples for such signals are shown in Figure 5.

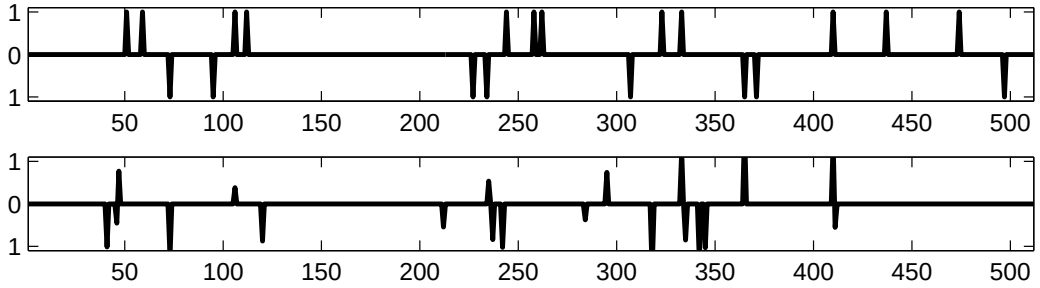

Figure 5: Examples for signal y. Top: uniform spikes. Bottom: non-uniform spikes.

The sequential experimental design of rows of P is a special case of the standard design setup of Section 4. Namely, among all p_j of unit norm, select the one which leads to minimum expected entropy $\mathrm{E}[\mathrm{H}[Q']]$, where Q' is the posterior after inclusion of p_j, and the expectation is w.r.t. $Q(u_j)$,

35. Namely, $y_i = \alpha(r + 0.25\,\mathrm{sgn}\, r)$, $r \sim N(0,1)$, where $\alpha = (5/4 + \sqrt{2/\pi} - 2/\pi)^{-1/2} \approx 0.84$, so that $\mathrm{Var}[y_i] = 1$.

u_j being the new measurement. Note that $\mathrm{H}[Q']$ is in fact independent of u_j, since Q' is Gaussian. Moreover, one can show that this criterion is equivalent to the expected information gain in this case (MacKay, 1991). A simple argument shows that the eigenvector for the largest eigenvalue of Σ solves this problem, where $Q = N(h, \sigma^2\Sigma)$ is the current posterior. This eigenvector can be found by the power method.

We compare the following methods. Our design approach based on EP is called *EP opt*. The method suggested by Ji and Carin (2007) is called *RVM opt* (P designed) or *RVM rand* (P random). They select P in the same way as we do, but making use of their approximate posterior, which they obtain as a variant of sparse Bayesian learning (SBL) (Tipping, 2001) (RVM refers to the most commonly used variant of SBL). The method most frequently used in compressive sensing applications so far is basis pursuit (Chen et al., 1999), where y is estimated by minimising $\|y\|_1 = \sum_i |y_i|$, subject to $Xy = u$. Note that this corresponds to MAP estimation in the sparse linear model if $\sigma^2 \to 0$ (noiseless case). This can be formulated as a linear program. *L1* and *BP* here use two different implementations.[36] For all methods, the first 40 rows of P are drawn at random. If $\hat{y}$ denotes the best prediction of y from the measurements u (the mean of Q for our method and the RVM variants), the error is measured as $\|\hat{y} - y\|/\|y\|$, where $\|\cdot\|$ is the Euclidean norm. Results are shown in Figure 6.

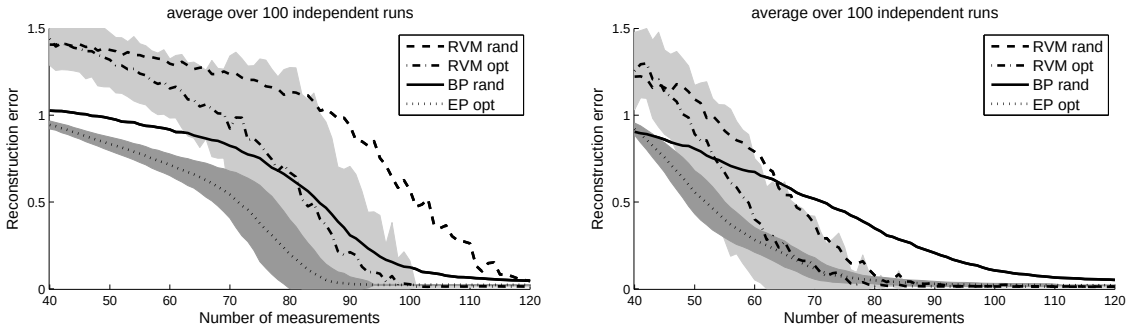

Figure 6: Results for compressive sensing toy example comparison. Left: uniform spikes. Right: non-uniform spikes. Averaged over 100 runs, shown are means and standard deviations (latter only for EP and RVM). See text for details.

Further experiments are required in order to draw definite conclusions, such are in preparation. We note that our EP method outperforms all others, and that random methods in general perform worse than the ones using experimental design. Moreover, our method clearly performs much better than the method of Ji and Carin (2007), while theirs is somewhat faster. Notably, our method also performs more robustly across runs than theirs. Moreover, the methods trying to approximate Bayesian inference in general perform better than basis pursuit on this task. The latter is certainly significantly faster than any of the other methods here, but its suboptimal performance on the same fixed data, and more importantly the lack of an experimental design framework, clearly motivates considering approximate Bayesian inference for compressive sensing as well.

36. *L1* is `l1-magic` from `www.acm.caltech.edu/l1magic/`, and *BP* is from SparseLab `sparselab.stanford.edu/`.

8. Related Approximate Inference Methods

In this section, we put EP for the sparse linear model into perspective by directly comparing it to other proposed methods of approximate inference. We rely on Palmer et al. (2006), who provide a somewhat more general discussion, but EP is not mentioned there. Before we start, we remind the reader that by "approximate inference" method, we mean a technique which delivers a useful approximation of marginal (or even joint) posteriors, and ideally can also be used in order to approximate the marginal likelihood. This is important in the context of the sparse linear model, where many methods rather try to find a maximally sparse solution of the noisy system (1), without addressing the former points. A study, comparing the methods discussed here in terms of approximation quality of marginals and of the marginal likelihood, is subject to future work. Note that none of these methods has been applied to the experimental design problem we address here (to our knowledge), with the exception of SBL (Ji and Carin, 2007).

8.1 Sparse Bayesian Learning

The idea of automatic relevance determination (ARD) has been proposed by Neal (1996). It is a variant of empirical Bayesian marginal likelihood maximisation (see Section 5). In the context of the sparse linear model, only a few components of a are typically relevant for describing the data, all others could be set to zero. ARD works by placing a prior $N(a_i|0,\sigma^2\pi_i^{-1})$ on a_i, where π_i is a scale parameter, then maximising the marginal likelihood $P(u,\pi)$ w.r.t. π. Here, π_i can be given a heavy-tailed hyperprior. The Occam's razor effect embedded in empirical Bayes (MacKay, 1992) leads to π_i becoming large for irrelevant components a_i: a model with few relevant components is simpler than one with many, and if both describe the data well, the former is preferred under ARD.

ARD has been applied to the sparse linear model by Tipping (2001), where the method was called *sparse Bayesian learning* (SBL). The derivation there makes use of *scale mixture* decompositions (Gneiting, 1997; Palmer et al., 2006) for the non-Gaussian prior sites. Namely, many univariate symmetric distributions can be represented in the form $P(a_i) = \mathrm{E}[N(a_i|0,\sigma^2\pi_i^{-1})]$, with some distribution over π_i. Tipping uses Student's t sparsity priors $P(a_i)$, for which π_i has a Gamma distribution. However, a direct comparison with the sparse linear model used here requires Laplace priors.

The Laplace density has the following scale mixture decomposition (Park and Casella, 2005; Gneiting, 1997):

$$\frac{\tilde{\tau}}{2}e^{-\tilde{\tau}|a_i|} = \mathrm{E}[N(a_i|0,\sigma^2\pi_i^{-1})], \quad \pi_i \sim \lambda\pi_i^{-2}e^{-\lambda/\pi_i}\mathrm{I}_{\{\pi_i>0\}} = \mathrm{IG}(1,\lambda),\ \lambda = \frac{\tau^2}{2}. \tag{9}$$

Note that the scale distribution of π_i does not have mean or variance. With $\Pi = \mathrm{diag}\,\pi$, we have

$$P(u,\pi) = \int P^{(0)}(a)N(a|0,\sigma^2\Pi^{-1})\,da|\Pi|^{-2}\lambda^n e^{-\lambda 1^T(\pi^{-1})},$$

which has the same form as in our framework. Here, $b_i = 0$, and the π_i have a different interpretation as scale hyperparameters. The marginal likelihood $P(u)$ is obtained by integrating out π, which cannot be done tractably. Instead, a *maximum a posteriori* (MAP) approximation is done in SBL: we find a maximiser $\hat{\pi}$ of $P(u,\pi)$, then approximate $P(u) \approx P(u,\hat{\pi})$. This is a joint non-convex optimisation problem, so all we can hope for is a local maximum. Faul and Tipping (2002) propose

the simple sequential technique of maximising $P(u,\pi)$ one π_i at a time. This results in the following update rule, as is shown in Appendix D.1:

$$\pi_i' = \frac{\sqrt{9+4\tau^2\beta}-3}{2\beta}, \quad \beta = \rho_i + \sigma^{-2}h_i^2 = \sigma^{-2}\mathrm{E}_Q[a_i^2]. \tag{10}$$

Confusingly, this is in fact not the method used in the experiments of Tipping (2001). This point is clarified at the end of this section.

Comparing SBL to our EP method, we note that the former does not require quadrature, but merely simple analytical updates. The π_i remain positive, and the method is numerically stable. SBL can be implemented using the same representation as ours. While $b = 0$ here, this does not lead to simplifications in representations or updates. In fact, both methods can share much of the same code, they differ only in how $\pi_i \to \pi_i'$ is computed for each site i. The marginal likelihood approximation resulting from SBL is $P(u,\hat{\pi})$. Just as for EP, this is not a bound on $P(u)$ (see Section 5).

Note that a variant of SBL with the Laplace prior has been proposed by Figueiredo (2003). However, they were interested in the MAP solution $\mathrm{argmax}_a P(a|D)$ rather than in an approximation to the posterior, which allowed them to integrate out the π_i by EM. Note also that SBL for the linear model with Student's t prior has been applied to gene network identification by Rogers and Girolami (2005), although they did not consider experimental design.

While a direct comparison is subject to future work, we note that SBL is certainly simpler to implement for the sparse linear model. Some safeguards required to make EP run in a numerically robust way, are not needed with SBL. On the other hand, EP is of course more general, since SBL is limited to non-Gaussian sites with a scale mixture decomposition. For example, non-symmetrical distributions such as classification likelihoods cannot be used.

There is at least the following worrying fact about SBL as approximation to Bayesian inference. We have used the scale mixture decomposition of the Laplace density (9) in terms of π_i, but we could just as well have chosen the one based on $s_i = \pi_i^{-1}$, with an exponential distribution on s_i. Doing so, we obtain an entirely different method, which did much worse than the variant derived here in initial experiments and in fact fails badly as approximation to Bayesian inference, since predictive variances are orders of magnitude too small. Furthermore, this "variant" of SBL converges exceedingly slowly in the s_i, while the method given here runs quite fast. Nevertheless, *both* variants are motivated in the same way: scale mixture decomposition, followed by a MAP approximation. The problem is that the latter, much in contrast to exact Bayesian inference (or, in fact, to expectation propagation), is not invariant to reparameterisations. The one chosen by Tipping (2001) certainly works well, at least in terms of delivering sparse solutions, but with others, SBL can fail badly. This important ambiguity has been noted by Wipf et al. (2004).

Finally, we note that there is some confusion about what exactly constitutes SBL, started in part by somewhat unclear formulations in Tipping (2001). In the paper, a method for finding maximally sparse solutions to the noisy linear system (1) is proposed. While the motivation is clearly Bayesian, the fact that a Student's t sparsity prior is used, is mentioned only in order to explain the favourable results. In fact, the "prior" actually used for π_i is $\propto 1/\pi_i$, resulting in $P(a_i) \propto 1/|a_i|$. Both are not normalisable as distributions. Our interest is in approximate Bayesian inference, with an eye towards experimental design, so we cannot consider such uninformative priors. We take the freedom here to interpret SBL as introducing scale mixture parameters π_i, followed by a MAP approximation w.r.t. π, at the expense of actually not covering the algorithm used in the experiments of Tipping

(2001). Wipf et al. (2004) show that the latter algorithm can in fact be interpreted as an instance of direct site bounding (see Section 8.2), which at first sight has little to do with scale mixtures, but see Palmer et al. (2006).

We would not stress this point if there was little difference in practice between (what we refer to as) SBL and direct site bounding (or other variants of the theme). However, initial comparative experiments with the sparse linear model show very significant differences in approximation quality. All these techniques find local maxima of $P(u|\pi)f(\pi)$. Contrary to what seems to be widely believed among practitioners, the form of f really matters. From our experience, the quality of approximate inference as well as the speed of convergence of sequential optimisation depend strongly on f. Wipf et al. (2007) show that the capability of the method estimating the correct relevant subset also hinges dominantly on the choice of f. Beyond that, the dependence on f of the quality of the covariance estimate, centrally important for experimental design, has not been analysed at all to our knowledge.

8.2 Direct Site Bounding. Variational Mean Field Bayes

A direct approach for obtaining an easily computable lower bound on the log marginal likelihood $\log P(u)$ works by lower-bounding the sites $t_i(a_i)$ by terms of Gaussian form. A powerful way of obtaining global lower bounds of simple form is exploiting convexity (Jaakkola, 1997). We can apply this approach to the sparse linear model with Laplace prior, which results in a method proposed by Girolami (2001). The general idea in the context of non-Gaussian linear models is noted in Palmer et al. (2006).

For the Laplace (2), we have that $\log t_i(a_i) = -\tilde{\tau}\sqrt{a_i^2} + \log(\tilde{\tau}/2)$, which is convex in a_i^2. A global tight lower bound is obtained using Legendre-Fenchel duality (Boyd and Vandenberghe, 2002), resulting in

$$e^{-\tilde{\tau}|a_i|} = \sup_{\pi_i>0} N^U(a_i|0,\sigma^{-2}\pi_i)e^{-(\tau^2/2)\pi_i^{-1}}.$$

We can plug in the r.h.s. for $t_i(a_i)$, then integrate out a in order to obtain a lower bound on $\log P(u)$. The outcome is quite similar to SBL, where t_i is replaced by the same term times $(2\pi)^{-1/2}\tau\pi_i^{-3/2}$. Since the ratio does not depend on a, we have that

$$P(u) \geq P_{Giro}(u;\pi) = (2\pi)^{-n/2}\tau^n|\Pi|^{-3/2}P_{SBL}(u,\pi),$$

Following Appendix D.1, it is clear that the update of π_i, keeping all others fixed, results in a quadratic equation with the positive solution

$$\pi_i' = \frac{\tau}{\sqrt{\beta}}, \quad \beta = \rho_i + \sigma^{-2}h_i^2 = \sigma^{-2}\mathrm{E}_Q[a_i^2].$$

While SBL does not render a bound on $\log P(u)$, Girolami's method does so by construction. Note that SBL and direct site bounding lead to quite similar replacements for t_i, if applied to the linear model with Laplace prior. The same is true if a Student's t prior is used, as has been observed by Wipf et al. (2004). Somewhat ironically, the modification in the latter case is precisely the result of the "uninformative limit" taken in Tipping (2001), which also seems to work best in practice. This point is discussed at the end of Section 8.1. Palmer et al. (2006) give the precise relationship between SBL and direct site bounding (called "integral case" and "convex case" there), showing that if t_i admits a scale mixture decomposition, it can also be bounded via Legendre duality.

Note that for the same (β, τ), π'_i is smaller for the SBL update than for the direct site bounding one. Namely,

$$\pi'_{SBL,i} = \pi'_{Giro,i} \times \left(\sqrt{1+\alpha} - \sqrt{\alpha}\right), \quad \alpha = 9/(4\tau^2\beta).$$

The ratio is smallest for small β, so Girolami's method chooses much larger π_i for the components which are "switched off", in that $\mathrm{E}_Q[a_i^2/\sigma^2] \approx 0$. It is thus more aggressively aiming for sparse solutions. In initial comparative experiments, Girolami's method outperformed SBL on the sparse linear model significantly in terms of the quality of inference approximation. Especially, the SBL marginal likelihood approximation turned out to be poor. A larger comparative study, from which conclusions can be drawn, is subject to future work.

A comparison between approximate inference techniques would be incomplete without including *variational mean field Bayes* (VMFB) (Attias, 2000; Ghahramani and Beal, 2001), maybe the most well known variational technique in the moment. It is also simply known as "variational Bayes" (see `www.variational-bayes.org`), although we understand this term as encompassing other variational methods for Bayesian inference as well, such as EP, SBL, direct site bounding, and others more. The distinctive feature of VMFB, previously known as "structured mean field", is the use of the generic mean field lower bound, as reviewed in Appendix D.2. VMFB for the sparse linear model is equivalent to direct site bounding, as has been shown in Palmer et al. (2006), and as is discussed in more detail in Appendix D.2. This equivalence holds as well for linear models with many other symmetric priors, for example Student's t.

8.3 Markov Chain Monte Carlo

While variational approximations are fairly established in machine learning, the dominant methods for approximating Bayesian inference in statistics are Markov chain Monte Carlo (MCMC) simulations (Neal, 1993; Gilks et al., 1996). In these techniques, a Markov chain over latent variables of interest (and possibly additional auxiliary ones) is simulated, whose stationary distribution is the desired posterior.

A simple MCMC method for the sparse linear model with Laplace prior has been proposed by Park and Casella (2005). They employ the scale mixture representation (9), introducing the scale parameters π as auxiliary variables alongside a. Their method is an instance of block Gibbs sampling, in that a is resampled given π, and vice versa. For simplicity, we denote the true posterior $P(\ldots|D)$ by Q in this section only. Now, the full conditional distribution $Q(a|\pi)$ is simply $N(a|h, \sigma^2\Sigma)$, with h, Σ defined as usual in terms of π (as in SBL above, $b = 0$ here), a Gaussian we can sample from easily (see Appendix B.2).

Next, the π_i are independent under $Q(\pi|a)$, with

$$Q(\pi_i|a) \propto \pi_i^{-3/2} \exp\left(\frac{-a_i^2\sigma^{-2}(\sqrt{2\lambda\sigma^2}/|a_i| - \pi_i)^2}{2\pi_i}\right) \propto \pi_i^{-3/2} \exp\left(\frac{-\tilde{\lambda}(\pi_i - \tilde{\mu})^2}{2\tilde{\mu}^2\pi_i}\right),$$

with $\tilde{\mu} = \sqrt{2\lambda\sigma^2}/|a_i|$, $\tilde{\lambda} = 2\lambda = \tau^2$. This density is the inverse Gaussian, which can be sampled from easily (see Chhikara and Folks, 1989, Section 4.5). The normalisation constant is $(\lambda/\pi)^{1/2}$.

Note that, just as with SBL and direct site bounding, we can use our existing EP code in order to implement this method as well. The π_i are resampled, instead of being updated deterministically. While they could be updated sequentially, Park and Casella (2005) consider joint updates which

tend to have better mixing properties. The representation, now maintaining the true $Q(a|\pi)$, has to be recomputed from scratch after each π update, so that each step costs $O(n \min\{m,n\}^2)$.

This sampler is certainly very simple to implement, especially with our representation code in place. Park and Casella (2005) give some arguments about the favourable role of log-concavity of $Q(a)$ for the sampler.[37] These are empirical, and even if good theoretical properties of MCMC samplers for log-concave posteriors have been established (Lovász and Vempala, 2003), these are different from the method considered here. Initial experiments with the sampler gave good results, although some erratic jumps in π components can be observed. The main cause of failure of block Gibbs samplers is the presence of strong dependencies between a and π. A more definite statement would require a comparison between this method and another sampler not based on scale variables.

The main advantage of MCMC over variational approximations is that it has no approximation bias in principle, if the chain is run for an unbounded amount of steps. In contrast, variational methods such as EP do have such a bias, which cannot be diminished by simply running them for longer.[38] It is also the case that simple variants of MCMC are typically fairly easy to implement, for example there are hardly ever problems with numerical stability. A main drawback of MCMC applied to problems of the sort considered here is that significantly more running time is required in order to obtain solutions of similar accuracy. Another major disadvantage is that a lot of expertise is required in order to run MCMC in a proper way. There are no convergence diagnostics which are easy to use or, in fact, are generally widely accepted. Most machine learning applications, such as the ones considered here, require methods which can be run robustly by users without extensive training in diagnosing Markov chain convergence. This problem becomes severe in the context of experiment design, where new decisions have to be done continuously, and even an expert would be hard pressed trying to diagnose proper convergence for all MCMC runs in between. Another drawback of MCMC is that while samples of the posterior are obtained, these cannot be used in a simple way in order to obtain a good estimate of the log marginal likelihood $\log P(u)$ (see Section 5). While the method of Chib (1995) proposes just that, it failed catastrophically in toy experiments of rather small scale with the sampler considered here, even if an excessive number of steps was used. This failure is interesting, given that the posterior is a log-concave (unimodal) distribution.

9. Discussion

We have shown how to perform accurate approximate Bayesian inference in the linear model with Laplace prior efficiently, by means of expectation propagation, and how this can be used to address tasks such as optimal design and hyperparameter estimation. The importance of numerical stability is raised for EP, and several means of improving robustness are proposed. Some implications of log-concavity for EP, and for approximate inference in general, have been shown.

The optimal design capability has been demonstrated for the application of gene regulatory network identification, where the sparsity prior was found to be essential in order to realise very significant gains. It is also motivated by preliminary experiments in the area of compressive sensing. Marginal likelihood optimisation has been used in order to optimise sparse codes for natural images,

37. They sample jointly over (a,σ^2), noting that $Q(a,\sigma^2)$ is log-concave in the transformation of (a,σ^2) described in Section 3.5.

38. Many variational methods allow for the choice of approximation families of varying complexity. For example, EP can be run with exponential families beyond the Gaussian, and even the case of Gaussian Q can potentially be improved by considering joint updates of blocks of sites. This requires the computation of multivariate non-Gaussian integrals, which is hard to do accurately, and is not done here.

in what constitutes an application of approximate inference on a large scale. Our experiments have been driven by a robust, efficient, and general implementation, which will be made available for scientific use.

9.1 Related Work

The sparse linear model (1) is of high practical relevance in statistics and machine learning, and has received a lot of attention. Some approximate inference techniques related to ours have been reviewed in Section 8. It is noted there that the computational representations and their robust update rules developed here, are required for these just as well.

The idea of L_1 regularisation of least squares has been used in very many contexts. The maximum a posteriori (MAP) treatment of the sparse linear model has been proposed as *Lasso* (Tibshirani, 1996) and as *basis pursuit* (Chen et al., 1999) (the latter for $\sigma^2 \to 0$). While the Lasso results in a quadratic program, basis pursuit is a linear programming problem. The prime advantage of an MAP treatment is that fitting to fixed data can be done very efficiently, in fact significantly faster than running EP until convergence. Very recently, several strong properties of the Lasso, basis pursuit, or other convex programming formulations of sparse estimation have been established, showing that in certain regimes they perfectly reconstruct very sparse signals in a minimax sense (Donoho and Elad, 2003; Candès et al., 2006; Wainwright, 2006). On the other hand, MAP as an approximation to Bayesian inference is fairly poor in this case. As noted in Section 3, a direct Laplace approximation is not well-defined for the sparse linear model. Even if this obvious problem was not present, the fact that there are many more variables than observations, renders the usual justification for Laplace's method obsolete. We have demonstrated a few advantages of going the full Bayesian way properly in this paper, such as optimal design based on uncertainty estimates, or marginal likelihood hyperparameter estimation. The MAP approximation for the sparse linear model has been applied to the gene network identification problem by Peeters and Westra (2004), but they did not address the problem of optimal design.

A general framework for EP on a class of hybrid models has been proposed by Zoeter and Heskes (2005). EP updates are done generically using Gaussian quadrature. Based on our findings here, EP for the sparse linear model with Laplace prior is very sensitive to the accuracy of EP updates, and the Gauss-Hermite rule would not lead to a working solution here. The generic proposal of converting between natural and moment parameterisation stated there is known to be unstable even in purely Gaussian models such as the Kalman filter, while our representation updates are essentially stable for log-concave sites. Also, the generality is quite restricted, in that they assume a fully factorised distribution family $\mathcal{F}$, which would not include joint Gaussians Q we consider here. Thus, while the prospect of a generic EP implementation is intriguing, important special cases such as Laplace or other sparsity prior sites, or joint Gaussian factors, would have to be treated as special cases. It remains to be seen whether the techniques to improve EP's numerical properties proposed here, are useful in this more general context as well.

Technically, our framework is quite related to the Independent Component Analysis method of Hojen-Sorensen et al. (2002), using Adaptive TAP (Opper and Winther, 2000) in order to estimate mean and covariance of the sources.[39] In fact, EP can be seen as particularly efficient way of searching for an ADATAP fixed point. They address the sparse image coding problem with the sparse linear model, but do not consider optimal design applications. Our approach is different to

39. What is meant is the *posterior* covariance of the sources, since in ICA, they are assumed to be independent *a priori*.

theirs in several important points. Their paper approaches a larger range of problems. On the other hand, they do not employ the natural EP marginal likelihood approximation we use here, but rather a variational bound. The study of Kuss and Rasmussen (2005) has indicated the superior quality of the EP approximation in a different, but related situation. Second, their image coding experiments are fairly small in scale, and they do not report any of the numerical problems we encountered, or in fact propose special measures to deal with such. Their paper treats numerically benign cases such as classification with logistic or probit likelihood alongside challenging (Laplace) or (in our opinion) highly problematic ones (Student's t; exponential power with exponent < 1), essentially recommending the same generic computations (which do not work, to the best of our knowledge and experience, in the situations we were interested in here).

9.2 Future Work

We have commented in Section 2.3 on the application of our method to the problem of learning and analysing image codes (Olshausen and Field, 1997; Lewicki and Olshausen, 1999), with the aim of understanding properties of visual neurons in the brain. In this context, the sparse linear model has been proposed as a useful setup, in which codes can be learned by maximising the marginal likelihood. The marginal likelihood approximation of Section 5 is more accurate than the one used by Lewicki and Olshausen (1999), and it will be interesting to test their hypothesis using our framework. A study with similar aims is given in Berkes et al. (2008), using variational mean field Bayes to approximate inference.

Other interesting applications lie in the area of compressive sensing. Some potential ones have been motivated in Section 2.4, and results will be reported in a later paper (Seeger and Nickisch, 2008). In this context, the large scale techniques motivated in Section 6 will be explored. Our preliminary findings in Section 7.3 indicate that approximate Bayesian inference and experimental design hold significant promises for compressive sensing, where so far approaches based on L_1-penalised estimation and random designs seem to predominate.

As detailed in Section 8, our EP framework is closely related to several other established methods of approximate inference. We plan to do a large, comparative study on several different tasks and data sets, where ground truth computations will be done via computationally intensive MCMC. We are not aware of existing comparative studies encompassing several approximate inference techniques for the sparse linear model.

Our experiences with the sparse linear model on the image coding problem (or with very underdetermined gene network identification settings) suggest that in some relevant cases, numerical stability issues seem to be inherently present in EP (i.e., are not just due to a bad implementation). These need to be understood much better, before we can seriously talk about generic EP solutions (Zoeter and Heskes, 2005), comparable to BUGS (Spiegelhalter et al., 1995) for Gibbs sampling or VIBES (Bishop and Winn, 2003) for variational mean field Bayes, both of which do not pose big problems of numerical stability. The sparse linear model seems a good test bed for such studies, different to the Gaussian process classification problem, which is numerically rather harmless. Since log-concavity helps in the important special case of fully Gaussian posterior approximations, its role needs to be understood better. Again, the Laplace prior of the sparse linear model will be important there, being "just about log-concave". Also, "cut-off" sites enforcing non-negativity, or more generally linear constraints (see Section 2.3), will play an important role there, not even being supported on all of $\mathbb{R}$.

In the MCMC approach of Park and Casella (2005), the noise variance σ^2 is integrated out along with the parameters a. This is possible (approximately) with EP as well, by choosing Q from an exponential family over (a, σ^2), which is not purely Gaussian. We have already done initial experiments with this extension, which will be reported in a later paper. In comparison to the method given here, the extension treats σ^2 as nuisance variable in a proper Bayesian fashion. It does not have to be chosen by other means, such as marginal likelihood maximisation. Much of the treatment of a, such as the representation of $Q(a|\sigma^2)$, or the analytical EP update w.r.t. a_i, is inherited from the framework given here. As an extension of EP beyond the case of fully Gaussian approximations, the extension is important as test bed for theoretical analyses. On the other hand, the extension is somewhat more complicated to implement, furthermore some of the numerical robustness of our method here is lost. For example, Theorem 1 does not hold for non-Gaussian Q. Moreover, the integration over σ^2 required by the EP updates cannot be done analytically, and approximate Gauss-Laguerre quadrature has to be used.

The Bayesian sparse linear model may have many other applications, given that its MAP variants (Lasso, basis pursuit) are very widely used. EP has also been applied to approximate inference in generalised linear models, where the likelihood is not Gaussian anymore, but comes from another exponential family. An application of this sparse generalised linear model to analysing neuronal spiking data is given in Seeger et al. (2007a) and Gerwinn et al. (2008), see also Qi et al. (2004). In this context, efficient online optimisation of experimental stimuli is an important task as well (Lewi et al., 2007).

The recent empirical success of EP in many different applications renders it important to gain a firm understanding of this technique. Some of the many relevant open questions are: For which models does the (single loop) EP algorithm provably converge? For which models is there no more than a single fixed point? How good is an EP approximation in terms of the marginals, and beyond that in terms of the covariance estimate? Numerical stability is an important issue for EP, which does not arise with most other approximate inference techniques. For which models can we expect numerical difficulties, and why? The step towards fractional EP may improve numerical properties of the method in general, but how do fractional EP approximations compare to the standard EP fixed points? Finally, how can EP fixed points be found for very large n, when the current practice of visiting each site in turn becomes unpractical?

Acknowledgments

The gene network identification application has been done in joint work with Florian Steinke and Koji Tsuda. The preliminary experiments with compressive sensing have been done in joint work with Hannes Nickisch. For the image coding application, we would like to acknowledge discussions with Matthias Bethge. We would like to thank Manfred Opper for interesting discussions about EP, and the anonymous referees for helpful comments. Supported in part by the IST Programme of the European Community, under the PASCAL Network of Excellence, IST-2002-506778.

Appendix A. Details for the EP Update

In this section, we collect details concerning the EP update described in Section 3.3.

The Laplace site is $t_i(a) = \exp(-\tilde{\tau}|a|)$, $\tilde{\tau} = \tau/\sigma > 0$. Note that elsewhere, a prefactor of $\tilde{\tau}/2$ is used, which means that the value for Z_i to be computed here has to be multiplied post hoc.[40] We need to compute moments $I_k = \mathrm{E}_{N(h,\rho)}[a^k t_i(a)]$, $k = 0,1,2$, where we write $a = a_i$, $h = h_{\setminus i}$, $\rho = \rho_{\setminus i}$ for simplicity. W.l.o.g., we can assume that $\tilde{\tau} = 1$. Then, $I_0 = \tilde{I}_0(h) + \tilde{I}_0(-h)$, where some algebra gives

$$\tilde{I}_0(h) := \mathrm{E}\left[\mathrm{I}_{\{a\geq 0\}} e^{-a}\right] = \exp(\rho/2 - h)(1 - \Phi(\rho^{1/2} - h\rho^{-1/2})),$$

where Φ denotes the cumulative distribution function of $N(0,1)$. Now, from the definition of $\tilde{I}_0$, it is easy to see that $\tilde{I}_0(|h|) \geq \tilde{I}_0(-|h|)$, so that

$$\log I_0 = \log \tilde{I}_0(|h|) + \log\left(1 + \frac{\tilde{I}_0(-|h|)}{\tilde{I}_0(|h|)}\right)$$

can be computed in a stable manner. In the following, we make use of the well known asymptotic expansion

$$1 - \Phi(x) \sim N(x)x^{-1}\left(1 - 1x^{-2}\left(1 - 3x^{-2}\left(1 - 5x^{-2}\left(1 - 7x^{-2}(\ldots)\right)\right)\right)\right).$$

If $F(x) := \log(1 - \Phi(x))$, we use the asymptotic expansion up to $1 - 7x^{-2}$ for $x > 5$, while computing $F(x)$ exactly otherwise.[41] It is interesting to note that the simpler approximation $1 - \Phi(x) \approx N(x)/x$ is insufficient and leads to complete failure of EP on most tasks.

With this in mind, we have that $\log \tilde{I}_0(|h|) = \rho/2 - |h| + F(\rho^{1/2} - |h|\rho^{-1/2})$, and

$$R := \frac{\tilde{I}_0(-|h|)}{\tilde{I}_0(|h|)} = \exp\left(2|h| + F(\rho^{1/2} + |h|\rho^{-1/2}) - F(\rho^{1/2} - |h|\rho^{-1/2})\right).$$

For example, if $\rho^{1/2} - |h|\rho^{-1/2} > 5$, we use the tail approximation for both F terms. Namely, if the approximation is $1 - \Phi(x) \approx N(x)x^{-1}g(x)$, we end up with

$$R = \frac{(\rho - |h|)g(\rho^{1/2} + |h|\rho^{-1/2})}{(\rho + |h|)g(\rho^{1/2} - |h|\rho^{-1/2})}.$$

Note that in general, $R \in (0,1]$.

Next, $I_1 = \tilde{I}_1(h) - \tilde{I}_1(-h)$, with

$$\tilde{I}_1(h) := \mathrm{E}\left[\mathrm{I}_{\{a\geq 0\}} a e^{-a}\right] = (h - \rho)\tilde{I}_0(h) + \rho^{1/2}\exp(\rho/2 - h)\mathrm{E}\left[\mathrm{I}_{\{s\geq \rho^{1/2} - h\rho^{-1/2}\}} s\right],$$

where $s \sim N(0,1)$. Using $(dN(s))/ds = -sN(s)$, we have that $\mathrm{E}[\mathrm{I}_{\{s\geq s_0\}} s] = N(s_0)$. Furthermore,

$$\exp(\rho/2 \pm h)N(\rho^{1/2} \pm h\rho^{-1/2}) = N(h\rho^{-1/2}),$$

which does not depend on $\operatorname{sgn} h$. Therefore, the mean of $\hat{P}_i(a)$ is

$$\begin{aligned}\hat{h} = \frac{I_1}{I_0} &= \frac{(h - \rho)\tilde{I}_0(h) - (-h - \rho)\tilde{I}_0(-h)}{I_0} = h + \rho\frac{\tilde{I}_0(-h) - \tilde{I}_0(h)}{I_0} \\ &= h + \rho(\operatorname{sgn} h)\left(1 - 2(1 + R)^{-1}\right).\end{aligned}$$

40. The reason for dropping this prefactor is that we want to deal with the case of fractional sites (see Section 3.3.1) t_i^η by simply replacing τ by $\eta\tau$.

41. The C math library provides `log1p`$(x) = \log(1 + x)$, which is accurate for small $|x|$.

Since $I_1/I_0 = h + \rho\beta_i$, we have that

$$\beta_i = (\mathrm{sgn}\, h)\left(1 - 2(1+R)^{-1}\right). \tag{11}$$

Next, $I_2 = \tilde{I}_2(h) + \tilde{I}_2(-h)$, where some algebra gives

$$\begin{aligned}
\tilde{I}_2(h) &:= \mathrm{E}\left[\mathrm{I}_{\{a\geq 0\}} a^2 e^{-a}\right] \\
&= (\rho^2 - h^2)\tilde{I}_0(h) + 2h\tilde{I}_1(h) - 2\rho^{3/2} N(h\rho^{-1/2}) + \rho\exp(\rho/2 - h)\mathrm{E}\left[\mathrm{I}_{\{s\geq \rho^{1/2} - h\rho^{-1/2}\}} s^2\right] \\
&= (h-\rho)^2\tilde{I}_0(h) + 2\rho^{1/2} N(h\rho^{-1/2})(h-\rho) + \rho\exp(\rho/2 - h)\mathrm{E}\left[\mathrm{I}_{\{s\geq \rho^{1/2} - h\rho^{-1/2}\}} s^2\right].
\end{aligned}$$

Using $s^2 N(s) = N(s) - (dsN(s))/ds$, we see that

$$\rho\exp(\rho/2 - h)\mathrm{E}\left[\mathrm{I}_{\{s\geq \rho^{1/2} - h\rho^{-1/2}\}} s^2\right] = \rho\tilde{I}_0(h) + \rho(\rho^{1/2} - h\rho^{-1/2}) N(h\rho^{-1/2}).$$

Together, we have

$$\tilde{I}_2(h) = (h^2 + \rho^2 + \rho - 2h\rho)\tilde{I}_0(h) + \rho^{1/2} N(h\rho^{-1/2})(h-\rho),$$

thus

$$I_2 = (h^2 + \rho^2 + \rho) I_0 - 2\rho h(\tilde{I}_0(h) - \tilde{I}_0(-h)) - 2\rho^{3/2} N(h\rho^{-1/2}).$$

Using that $\beta_i = (\tilde{I}_0(-h) - \tilde{I}_0(h))/I_0$ and $\hat{h} = h + \rho\beta_i$, some algebra gives that

$$\frac{I_2}{I_0} = \rho + \rho^2 + h^2 + 2h(\hat{h} - h) - 2\rho^{3/2} N(h\rho^{-1/2}) I_0^{-1}.$$

Therefore, the variance of $\hat{P}_i(a)$ is

$$\begin{aligned}
\hat{\rho} &= \frac{I_2}{I_0} - \hat{h}^2 = -h^2 + (2h - \hat{h})\hat{h} + \rho + \rho^2 - 2\rho^{3/2} N(h\rho^{-1/2}) I_0^{-1} \\
&= \rho + \rho^2(1 - \beta_i^2) - 2\rho^{3/2} N(h\rho^{-1/2}) I_0^{-1},
\end{aligned}$$

since $(2h - \hat{h})\hat{h} = h^2 - (\rho\beta_i)^2$. Since $\hat{\rho} = \rho(1 - \rho\nu_i)$, we have that

$$\nu_i = \beta_i^2 - 1 + (\pi\rho/2)^{-1/2} \exp\left(-\frac{h^2}{2\rho} - \log I_0\right).$$

Finally, in order to incorporate $\tilde{\tau} \neq 1$, we note that this simply means plugging in $h = \tilde{\tau} h_{\setminus i}$, $\rho = \tilde{\tau}^2 \rho_{\setminus i}$ above, and multiplying β_i by $\tilde{\tau}$, ν_i by $\tilde{\tau}^2$. Note that $Z_i = I_0 = \mathrm{E}_{Q^{\setminus i}}[t_i(a_i)]$ is not required for the EP update itself, but has to be evaluated if an approximation to the marginal likelihood $P(D)$ is sought (see Section 5; recall that Z_i as computed here has to be multiplied with the prefactor $\tilde{\tau}/2$ of t_i which we omitted).

A.1 The Role of Log-concavity

In this section, we give the proof of Theorem 1. Recall the definition of log-concavity and the marginalisation theorem of Prékopa from Section 3.5. For an update at site i, we can assume that $Q^{\setminus i}(a_i)$ is a proper Gaussian. We begin by showing that $Z_i = \mathrm{E}_{Q^{\setminus i}}[t_i(a_i)]$ is log-concave in $h_{\setminus i}$. Namely, $\log Q^{\setminus i}$ is jointly concave in $(a_i, h_{\setminus i})$ (being a negative quadratic in $a_i - h_{\setminus i}$), so that $t_i(a_i)Q^{\setminus i}(a_i|h_{\setminus i})$ is log-concave in $(a_i, h_{\setminus i})$. Then, $Z_i(h_{\setminus i})$ is log-concave by the marginalisation theorem. Therefore, $\nu_i = -(\partial^2 \log Z_i)/(\partial h_{\setminus i}^2) \geq 0$ (see Section 3.3). The variance of $\hat{P}_i$ is $\sigma^2\rho_i'$, where $\rho_i' = \rho_{\setminus i}(1 - \sigma^2\nu_i\rho_{\setminus i})$. Since t_i is bounded with support of positive measure, this variance exists and is positive, implying that $1 - \sigma^2\nu_i\rho_{\setminus i} \in (0, 1]$. But $\pi_i' = \sigma^2\nu_i/(1 - \sigma^2\nu_i\rho_{\setminus i}) \geq \sigma^2\nu_i \geq 0$, so π_i' remains nonnegative throughout.

Appendix B. Details for Sequential Design

In this section, we collect details for the sequential design application of the sparse linear model.

B.1 The Simple Information Gain Score

The simple information gain is introduced in Section 4.1. Recall the Gaussian relative entropy from (4), and the fact that $M = I + x_* x_*^T \Sigma$. Thus, if $\alpha := 1 + x_*^T \Sigma x_*$, then $\log|M| = \log\alpha$, using the relation $|I + VW^T| = |I + W^T V|$. Furthermore, the Woodbury formula (Henderson and Searle, 1981) gives $M^{-1} = I - \alpha^{-1} x_* x_*^T \Sigma$, so that $\mathrm{tr}(M^{-1} - I) = \alpha^{-1} - 1$.

Finally, $\tilde{b}' = \tilde{b} + u_* x_*$, where $\tilde{b} = b^{(0)} + b$ (see Section 3.4), so that

$$h' = \left(\Sigma - \alpha^{-1}\Sigma x_* x_*^T \Sigma\right)\left(\tilde{b} + u_* x_*\right) = h + \alpha^{-1}(u_* - x_*^T h)\Sigma x_*,$$

and

$$(h' - h)^T \Sigma^{-1}(h' - h) = (\alpha - 1)\alpha^{-2}(u_* - x_*^T h)^2.$$

Altogether, the simple information gain score is

$$S(x_*, u_*) = \frac{1}{2}\left(\log\alpha + \frac{\alpha - 1}{\alpha}\left(-1 + \alpha^{-1}\left(\frac{u_* - x_*^T h}{\sigma}\right)^2\right)\right).$$

We need to compute α and $x_*^T h$. In the degenerate case, let $v = L^{-1} X \Pi^{-1} x_*$, then $\alpha = 1 + x_*^T \Pi^{-1} x_* - \|v\|^2$, and $x_*^T h = x_*^T \Pi^{-1}(b^{(0)} + b) - v^T\gamma$. In the non-degenerate case, let $v = L^{-1} x_*$, then $\alpha = 1 + \|v\|^2$, and $x_*^T h = v^T\gamma$.

The marginal criteria of Section 4.2 require the computation of $z_* = \Sigma x_*$. In the non-degenerate case, $z_* = L^{-T} v$. In the degenerate case, $z_* = \Pi^{-1}(x_* - X^T L^{-T} v)$.

B.2 Sampling A

We need to sample from $Q(A|D)$ in order to approximate the expected information gain, as noted in Section 4. Let $Q(a)$ be the posterior over a row of A, based on the representation given in Section 3.2, and let $n \sim N(0, I)$. In the non-degenerate case, $a = L^{-T}(\sigma n + \gamma)$ is distributed according to $N(h, \sigma^2\Sigma)$.

Sampling is more difficult in the degenerate case. Let

$$I + X\Pi^{-1}X^T = UDU^T$$

be the spectral decomposition, where D is diagonal and nonnegative, and $U \in \mathbb{R}^{m,m}$ is orthonormal. We make the ansatz

$$c = \left(I - \Pi^{-1} X^T U R U^T X\right) \Pi^{-1/2} n$$

with diagonal R. $\mathrm{E}[cc^T] = \Sigma$ gives $(D-I)R^2 - 2R + D^{-1} = 0$, which is solved by $R = \mathrm{diag}(1/(\sqrt{d_i}(\sqrt{d_i}+1)))_i$. Finally, $a = \sigma c + h$.

Appendix C. The Marginal Likelihood

In this section, we derive the EP marginal likelihood approximation and its gradient w.r.t. model parameters. Recall the discussion of Section 5, the definition of L is given in (6). First, $\log C_i = \eta^{-1}(\log Z_i - \log \tilde{Z}_i)$. The computation of $\log Z_i$ is discussed in Appendix A. Some algebra (Seeger, 2005) gives

$$\log \tilde{Z}_i = \frac{1}{2}\left(\log(1-\eta\pi_i\rho_i) - \frac{\eta\pi_i h_i^2 - 2h_i\eta b_i + \rho_i(\eta b_i)^2}{\sigma^2(1-\eta\pi_i\rho_i)}\right),$$

where $Q(a_i) = N(a_i|h_i, \sigma^2\rho_i)$.

We begin with $\nabla_X L$ and $\partial L/\partial\sigma^{-2}$ (both parameters of $P^{(0)}$), using (7). Since σ^2 also features explicitly in the sites t_i, the derivative is the sum of two parts, and we deal with the second part below.

$$d\log P^{(0)}(a) = \mathrm{tr}\left(\sigma^{-2} e a^T\right)^T (dX) + \frac{1}{2}\left(m\sigma^2 - \|e\|^2\right)(d\sigma^{-2}), \quad e := u - Xa.$$

If $Q(a) = N(h, \sigma^2\Sigma)$, then

$$\mathrm{E}_Q\left[d\log P^{(0)}(a)\right] = \mathrm{tr}\left(\sigma^{-2} f h^T - X\Sigma\right)^T (dX) - \frac{1}{2}\left(\|f\|^2 + \sigma^2\,\mathrm{tr}\, X\Sigma X^T - m\sigma^2\right)(d\sigma^{-2}),$$
$$f := \mathrm{E}_Q[e] = u - Xh.$$

Now, $\mathrm{tr}\, X\Sigma X^T = \mathrm{tr}(I - \Sigma\Pi) = n - (\mathrm{diag}\,\Sigma)^T\pi$, so that

$$dL = \mathrm{tr}\left(\sigma^{-2} f h^T - X\Sigma\right)^T (dX) - \frac{1}{2}\left(\|f\|^2 - \sigma^2(\mathrm{diag}\,\Sigma)^T\pi + (n-m)\sigma^2\right)(d\sigma^{-2}).$$

The derivative w.r.t. $\tilde{\tau} = \tau/\sigma$ is computed using (8). We have that $(d/d\tilde{\tau})\log t_i(a_i) = -|a_i| + 1/\tilde{\tau}$, so we need to compute

$$\mathrm{E}_{\hat{P}_i}[-|a_i|] = -Z_i^{-1}\mathrm{E}_{Q^{\setminus i}}[|a_i| t_i(a_i)],$$

which is of similar from to I_1 in Appendix A. In the notation used there, if $\hat{I}_1 = \tilde{I}_1(h) + \tilde{I}_1(-h)$, then $\hat{I}_1/I_0 = -\rho - \beta_i h + 2\rho^{1/2} N(h\rho^{-1/2}) I_0^{-1}$. Plugging in $h = \tilde{\tau} h_{\setminus i}$, $\rho = \tilde{\tau}^2\rho_{\setminus i}$, and dividing by $\tilde{\tau}$, we have that

$$-Z_i^{-1}\mathrm{E}_{Q^{\setminus i}}[|a_i| t_i(a_i)] = \tilde{\tau}\rho_{\setminus i} + \beta_i h_{\setminus i} - 2\rho_{\setminus i}^{1/2} N(h_{\setminus i}\rho_{\setminus i}^{-1/2}) I_0^{-1},$$

where β_i is given by (11) (it is not multiplied by $\tilde{\tau}$). Finally, $d\tilde{\tau} = \sigma^{-1}(d\tau) + \frac{1}{2}\tau\sigma(d\sigma^{-2})$, whereby we can complete the derivative w.r.t. σ^{-2} as well.

As an aside, there is a subtle issue concerning the derivative w.r.t. σ^2. Seeger (2005) shows that indirect dependencies on hyperparameters through the site parameters do not have to be taken into account when computing the gradient. But if the derivative of (6) w.r.t. σ^2 is computed, keeping

b_i, π_i constant, the result is different from ours here. This is explained by our non-standard parameterisation of site parameters in the present paper. Namely, what is referred to as site parameters in Seeger (2005), are in fact the $\sigma^{-2}b_i, \sigma^{-2}\pi_i$ here, *not* b_i, π_i. If the former are kept constant, a direct differentiation of (6) renders our result here.

Appendix D. Related Approximate Inference Techniques

In this section, we give details on the approximate inference techniques discussed in Section 8.

D.1 Sparse Bayesian Learning

Recall Section 8.1. In order to compute the marginal likelihood $P(u,\pi)$, we note that

$$P^{(0)}(a)N(a|0,\sigma^2\Pi^{-1}) = (2\pi\sigma^2)^{-m/2}e^{-(\sigma^{-2}/2)\|u\|^2}(2\pi\sigma^2)^{-n/2}|\Pi|^{1/2} N^U(a|\sigma^{-2}b^{(0)},\sigma^{-2}(X^TX+\Pi)),$$

so that with $h = \Sigma b^{(0)}$, $\Sigma^{-1} = X^TX + \Pi$, some algebra gives

$$2\log P(u,\pi) = \sigma^{-2}h^Tb^{(0)} + \log|\Sigma| - \tau^2 1^T(\pi^{-1}) + C,$$

where $C = -3\log|\Pi| - m\log(2\pi\sigma^2) - \sigma^{-2}\|u\|^2 + 2n\log(\tau^2/2)$.

We need to maximise $\log P(u,\pi)$ w.r.t. π_i, keeping all other π_j fixed. Then, $d\Pi = (d\pi_i)\delta_i\delta_i^T$, and let $\log P(u,\pi) = (1/2)\psi + C$. Furthermore, $Q(a_i) = N(a_i|h_i,\sigma^2\rho_i)$, that is, $\rho_i = \Sigma_{i,i}$. Now, $d\log|\Pi + X^TX| = \rho_i(d\pi_i)$, and $d\sigma^{-2}h^Tb^{(0)} = -\sigma^{-2}h_i^2(d\pi_i)$, so that

$$d\psi = \left(-\sigma^{-2}h_i^2 - 3\pi_i^{-1} - \rho_i + \frac{\tau^2}{\pi_i^2}\right)d\pi_i.$$

Equating this to zero results in a quadratic equation for π_i, whose nonnegative solution is given by (10).

D.2 Variational Mean Field Bayes

The *variational mean field Bayesian* (VMFB) framework is a fairly generic approach to variational inference. It starts from the classical variational characterisation of inference (Wainwright and Jordan, 2003):

$$\log P(u) = \sup_Q \mathrm{E}_Q\left[\log P(u,a,\sigma^2,\pi) - \log Q(a,\sigma^2,\pi)\right], \tag{12}$$

then relaxes the problem by imposing factorisation constraints on allowable Q (the optimal unconstrained choice for Q is the true posterior).[42] The variational characterisation is also known as mean field lower bound, because it is the defining feature of (structured) mean field approximations (Jordan et al., 1997).

Once appropriate factorisation assumptions are placed on Q, the feasible set can be written analytically in terms of factors from these families, and the right hand side of (12) and its gradient

42. Here, we introduce the scale parameters π_i by employing the scale mixture representation (9). VMFB works for models which can be represented exclusively in terms of exponential family distributions, which is often possible by introducing latent variables. One could possibly choose another representation of the Laplace sites, whence the equivalence of VMFB and direct site bounding would not hold, but this is not done here.

can be computed easily. Furthermore, this expression now lower bounds $\log P(u)$, because the maximisation is over the subset of factorising Q. On the other hand, the optimisation over factorising Q is not convex in general, and usually only a local optimum is found. Moreover, even the global maximum is the minimiser of $\mathrm{D}[Q \,\|\, P(\cdot|D)]$ over factorising Q (this is also the slack in the lower bound), so that Q does not in general have the same marginal moments as $P(\cdot|D)$. The latter would be obtained by minimising $\mathrm{D}[P(\cdot|D) \,\|\, Q]$ over factorising Q, but not even local minima of the latter can be found by any tractable method currently known.

For fixed σ^2, it has been shown in Palmer et al. (2006) that VMFB is strongly equivalent to Girolami's method of Section 8.2, in that the variational parameters, their updates, and the $\log P(u)$ lower bound are the same. We make the factorisation assumption $Q(a,\pi) = Q(a)Q(\pi)$. The resulting lower bound on $\log P(u)$ is optimised by updating the factors in turn, fixing the corresponding other one. If we fix $Q(\pi)$, the maximiser is $Q(a) = N(h, \sigma^2\Sigma)$, where h, Σ are defined as usual, but plugging in $\mathrm{E}_Q[\pi]$ for π. If $Q(a)$ is kept fixed, then the maximiser is

$$Q(\pi) \propto e^{\mathrm{E}_{Q(a,\sigma^2)}[\log P(\pi|a,\sigma^2,u)]} \propto P(\pi) e^{\mathrm{E}_{Q(a,\sigma^2)}[\log P(a|\sigma^2,\pi)]},$$

which decomposes w.r.t. the π_i. The form is given in Section 8.3, namely $\log Q(\pi_i) = C + \log \pi_i^{-3/2} - (\pi_i^2 \mathrm{E}[a_i^2\sigma^{-2}] + 2\lambda)/(2\pi_i)$, which is inverse Gaussian with mean $\tilde{\mu} = \tau/\sqrt{\mathrm{E}[a_i^2\sigma^{-2}]}$ and $\tilde{\lambda} = \tau^2$. A sequential VMFB variant iterates over the sites, updating $\pi_i' = \tau/\sqrt{\mathrm{E}[a_i^2\sigma^{-2}]}$. This is algorithmically equivalent the direct site bounding method of Section 8.2.

Appendix E. Modifications of Olshausen/Field Code

We compare our method against the one proposed by Olshausen and Field (1997), using their code which can be obtained at `http://redwood.berkeley.edu/bruno/sparsenet/`. Since the code is written for interactive use, we had to modify it in order to work for our study, which compares fully automatic methods.

First, our modification accepts a fixed training set of $r = 50000$ image patches, while the original code extracts patches on the fly.[43] A sweep over the whole set consists of 500 batch updates, where batches are drawn at random without replacement. 20 sweeps are done in total.

The code comes with several parameters. A study of the code reveals that `noise_var` is our σ^2, `beta` is our $\tilde{\tau} = \tau/\sigma$, and `sigma` is set to one. There is a learning rate parameter `eta`, which the documentation recommends to set by hand, starting with $\eta = 5$, reducing it towards $\eta = 1$ (the default value in the code). We chose the following schedule: $\eta = 5, 4, 3$ for 100, $\eta = 2$ for 500, then $\eta = 1$ for the remaining 9200 updates.

Abstract

In this paper we develop a theoretical analysis of the performance of sampling-based fitted value iteration (FVI) to solve infinite state-space, discounted-reward Markovian decision processes (MDPs) under the assumption that a generative model of the environment is available. Our main results come in the form of finite-time bounds on the performance of two versions of sampling-based FVI. The convergence rate results obtained allow us to show that both versions of FVI are well behaving in the sense that by using a sufficiently large number of samples for a large class of MDPs, arbitrary good performance can be achieved with high probability. An important feature of our proof technique is that it permits the study of weighted L^p-norm performance bounds. As a result, our technique applies to a large class of function-approximation methods (e.g., neural networks, adaptive regression trees, kernel machines, locally weighted learning), and our bounds scale well with the effective horizon of the MDP. The bounds show a dependence on the stochastic stability properties of the MDP: they scale with the discounted-average concentrability of the future-state distributions. They also depend on a new measure of the approximation power of the function space, the inherent Bellman residual, which reflects how well the function space is "aligned" with the dynamics and rewards of the MDP. The conditions of the main result, as well as the concepts introduced in the analysis, are extensively discussed and compared to previous theoretical results. Numerical experiments are used to substantiate the theoretical findings.

Keywords: fitted value iteration, discounted Markovian decision processes, generative model, reinforcement learning, supervised learning, regression, Pollard's inequality, statistical learning theory, optimal control

1. Introduction

During the last decade, reinforcement learning (RL) algorithms have been successfully applied to a number of difficult control problems, such as job-shop scheduling (Zhang and Dietterich, 1995), backgammon (Tesauro, 1995), elevator control (Crites and Barto, 1997), machine maintenance (Mahadevan et al., 1997), dynamic channel allocation (Singh and Bertsekas, 1997), or airline seat allocation (Gosavi, 2004). The set of possible states in these problems is very large, and so only

∗. Most of this work was done while the author was with the Computer and Automation Research Inst. of the Hungarian Academy of Sciences, Kende u. 13-17, Budapest 1111, Hungary.

algorithms that can successfully generalize to unseen states are expected to achieve non-trivial performance. The approach in the above mentioned works is to learn an approximation to the optimal value function that assigns to each state the best possible expected long-term cumulative reward resulting from starting the control from the selected state. The knowledge of the optimal value function is sufficient to achieve optimal control (Bertsekas and Tsitsiklis, 1996), and in many cases an approximation to the optimal value function is already sufficient to achieve a good control performance. In large state-space problems, a function approximation method is used to represent the learnt value function. In all the above successful applications this is the approach used. Yet, the interaction of RL algorithms and function approximation methods is still not very well understood.

Our goal in this paper is to improve this situation by studying one of the simplest ways to combine RL and function approximation, namely, using function approximation in value iteration. The advantage of studying such a simple combination is that some technical difficulties are avoided, yet, as we will see, the problem studied is challenging enough to make its study worthwhile.

Value iteration is a dynamic programming algorithm which uses 'value backups' to generate a sequence of value functions (i.e., functions defined over the state space) in a recursive manner. After a sufficiently large number of iterations the obtained function can be used to compute a good policy. Exact computations of the value backups require computing parametric integrals over the state space. Except in a few special cases, neither such exact computations, nor the exact representation of the resulting functions is possible. The idea underlying *sampling-based fitted value iteration* (FVI) is to calculate the back-ups approximately using Monte-Carlo integration at a finite number of points and then find a best fit within a user-chosen set of functions to the computed values. The hope is that if the function set is rich enough then the fitted value function will be a good approximation to the next iterate, ultimately leading to a good policy. A large number of successful experimental works concerned algorithms that share many similarities with FVI (e.g., Wang and Dietterich, 1999; Dietterich and Wang, 2002; Lagoudakis and Parr, 2003; Jung and Uthmann, 2004; Ernst et al., 2005; Riedmiller, 2005). Hence, in this paper we concentrate on the theoretical analysis of FVI, as we believe that such an analysis can yield to useful insights into why and when sampling-based approximate dynamic programming (ADP) can be expected to perform well. The relative simplicity of the setup allows a simplified analysis, yet it already shares many of the difficulties that one has to overcome in other, more involved scenarios. (In our followup work we studied other variants of sampling-based ADP. The reader interested in such extensions should consult the papers Antos et al. (2006, 2007, 2008).)

Despite the appealing simplicity of the idea and the successful demonstrations of various sampling-based ADP algorithms, without any further considerations it is still unclear whether sampling-based ADP, and in particular sampling-based FVI is indeed a "good" algorithm. In particular, Baird (1995) and Tsitsiklis and Van Roy (1996) gave simple counterexamples showing that FVI can be unstable. These counterexamples are deceptively simple: the MDP is finite, exact backups can be and are computed, the approximate value function is calculated using a linear combination of a number of fixed basis functions and the optimal value function can be represented exactly by such a linear combination. Hence, the function set seems sufficiently rich. Despite this, the iterates diverge. Since value iteration without projection is well behaved, we must conclude that the instable behavior is the result of the errors introduced when the iterates are projected onto the function space. Our aim in this paper is to develop a better understanding of why, despite the conceivable difficulties, practitioners often find that sampling-based FVI is well behaving and, in particular, we want to develop a theory explaining when to expect good performance.

The setting studied in this paper is as follows: We assume that the state space is a compact subset of a Euclidean space and that the MDP has a finite number of actions. The problem is to find a policy (or controller) that maximizes the expectation of the infinite-horizon, discounted sum of rewards. We shall assume that the solver can sample any transition from any state, that is, that a *generative model* (or simulator) of the environment is available. This model has been used in a number of previous works (e.g., Kearns et al., 1999; Ng and Jordan, 2000; Kakade and Langford, 2002; Kakade, 2003). An extension of the present work to the case when only a single trajectory is available for learning is published elsewhere (Antos et al., 2006).

We investigate two versions of the basic algorithm: In the *multi-sample variant* a fresh sample set is generated in each iteration, while in the *single-sample variant* the same sample set is used throughout all the iterations. Interestingly, we find that no serious degradation of performance results from reusing the samples. In fact, we find that when the discount factor is close to one then the single-sample variant can be expected to be more efficient in the sense of yielding smaller errors using fewer samples. The motivation of this comparison is to get prepared for the case when the samples are given or when they are expensive to generate for some reason.

Our results come in the form of high-probability bounds on the performance as a function of the number of samples generated, some properties of the MDP and the function class used for approximating the value functions. We will compare our bounds to those available in supervised learning (regression), where alike bounds have two terms: one bounding the *bias* of the algorithm, while the other bounding the *variance*, or *estimation error*. The term bounding the bias decreases when the *approximation power* of the function class is increased (hence this term is occasionally called the approximation error term). The term bounding the *variance* decreases as the number of samples is increased, but increases when the richness of the function class is increased.

Although our bounds are similar to bounds of supervised learning, there are some notable differences. In regression estimation, the approximation power of the function set is usually measured w.r.t. (with respect to) some fixed reference class $\mathcal{G}$:

$$d(\mathcal{G},\mathcal{F}) = \sup_{g\in\mathcal{G}} \inf_{f\in\mathcal{F}} \|f-g\|.$$

The reference class $\mathcal{G}$ is typically a classical smoothness class, such as a Lipschitz space. This measure is inadequate for our purposes since in the counterexamples of Baird (1995) and Tsitsiklis and Van Roy (1996) the target function (whatever function space it belongs to) can be approximated with zero error, but FVI still exhibits unbounded errors. In fact, our bounds use a different characterization of the approximation power of the function class $\mathcal{F}$, which we call the *inherent Bellman error* of $\mathcal{F}$:

$$d(T\mathcal{F},\mathcal{F}) = \sup_{g\in\mathcal{F}} \inf_{f\in\mathcal{F}} \|f-Tg\|.$$

Here T is the Bellman operator underlying the MDP (capturing the essential properties of the MDP's dynamics) and $\|\cdot\|$ is an appropriate weighted p-norm that is chosen by the user (the exact definitions will be given in Section 2). Observe that no external reference class is used in the definition of $d(T\mathcal{F},\mathcal{F})$: the inherent Bellman error reflects how well the function space $\mathcal{F}$ is 'aligned' to the Bellman operator, that is, the dynamics of the MDP. In the above-mentioned counterexamples the inherent Bellman error of the chosen function space is infinite and so the bound (correctly) indicates the possibility of divergence.

The bounds on the variance are closer to their regression counterparts: Just like in regression our variance bounds depend on the capacity of the function space used and decay polynomially

with the number of samples. However, the rate of decay is slightly worse than the corresponding rate of (optimal) regression procedures. The difference comes from the bias of approximating the maximum of expected values by the maximum of sample averages. Nevertheless the bounds still indicate that the maximal error of the procedure in the limit when the number of samples grows to infinity converges to a finite positive number. This in turn is controlled by the inherent Bellman error of the function space.

As it was already hinted above, our bounds display the usual *bias-variance tradeoff*: In order to keep both the approximation and estimation errors small, the number of samples and the power of the function class has to be increased simultaneously. When this is done in a principled way, the resulting algorithm becomes *consistent*: It's error in the limit disappears for a large class of MDPs. Consistency is an important property of any MDP algorithm. If an algorithm fails to prove to be consistent, we would be suspicious about its use.

Our bounds apply only to those MDPs whose so-called *discounted-average concentrability of future-state distributions* is finite. The precise meaning of this will be given in Section 5, here we note in passing that this condition holds trivially in every finite MDP, and also, more generally, if the MDP's transition kernel possesses a bounded density. This latter class of MDPs has been considered in many previous theoretical works (e.g., Chow and Tsitsiklis, 1989, 1991; Rust, 1996b; Szepesvári, 2001). In fact, this class of MDPs is quite large in the sense that they contain hard instances. This is discussed in some detail in Section 8. As far as practical examples are concerned, let us mention that resource allocation problems will typically have this property. We will also show a connection between our concentrability factor and Lyapunov exponents, well known from the stability analysis of dynamical systems.

Our proofs build on a recent technique proposed by Munos (2003) that allows the propagation of weighted p-norm losses in approximate value iteration. In contrast, most previous analysis of FVI relied on propagating errors w.r.t. the maximum norm (Gordon, 1995; Tsitsiklis and Van Roy, 1996). The advantage of using p-norm loss bounds is that it allows the analysis of algorithms that use p-norm fitting (in particular, 2-norm fitting). Unlike Munos (2003) and the follow-up work (Munos, 2005), we explicitly deal with infinite state spaces, the effects of using a finite random sample, that is, the bias-variance dilemma and the consistency of sampling-based FVI.

The paper is organized as follows: In the next section we introduce the concepts and notation used in the rest of the paper. The problem is formally defined and the algorithms are given in Section 3. Next, we develop finite-sample bounds for the error committed in a single iteration (Section 4). This bound is used in proving our main results in Section 5. We extend these results to the problem of obtaining a good policy in Section 6, followed by a construction that allows one to achieve asymptotic consistency when the unknown MDP is smooth with an unknown smoothness factor (Section 7). Relationship to previous works is discussed in details in Section 8. An experiment in a simulated environment, highlighting the main points of the analysis is given in Section 9. The proofs of the statements are given in the Appendix.

2. Markovian Decision Processes

A discounted *Markovian Decision Process* (discounted MDP) is a 5-tuple $(\mathcal{X}, \mathcal{A}, P, S, \gamma)$, where $\mathcal{X}$ is the *state space*, $\mathcal{A}$ is the *action space*, P is the *transition probability kernel*, S is *the reward kernel* and $0 < \gamma < 1$ is the *discount factor* (Bertsekas and Shreve, 1978; Puterman, 1994). In this paper we consider continuous state space, finite action MDPs (i.e., $|\mathcal{A}| < +\infty$). For the sake of

simplicity we assume that $\mathcal{X}$ is a bounded, closed subset of a Euclidean space, $\mathbb{R}^d$. The system of Borel-measurable sets of $\mathcal{X}$ shall be denoted by $\mathcal{B}(\mathcal{X})$.

The interpretation of an MDP as a control problem is as follows: Each initial state X_0 and action sequence $a_0, a_1, \ldots$ gives rise to a sequence of states $X_1, X_2, \ldots$ and rewards $R_1, R_2, \ldots$ satisfying, for any B and C Borel-measurable sets the equalities

$$\mathbb{P}(X_{t+1} \in B | X_t = x, a_t = a) = P(B|x,a),$$

and

$$\mathbb{P}(R_t \in C | X_t = x, a_t = a) = S(C|x,a).$$

Equivalently, we write $X_{t+1} \sim P(\cdot|X_t, a)$, $R_t \sim S(\cdot|X_t, a)$. In words, we say that when action a_t is executed from state $X_t = x$ the process makes a transition from x to the next state X_{t+1} and a reward, R_t, is incurred. The history of the process up to time t is $H_t = (X_0, a_0, R_0, \ldots, X_{t-1}, a_{t-1}, R_{t-1}, X_t)$. We assume that the random rewards $\{R_t\}$ are bounded by some positive number $\hat{R}_{\max}$, w.p. 1 (with probability one).[1]

A *policy* is a sequence of functions that maps possible histories to probability distributions over the space of actions. Hence if the space of histories at time step t is denoted by $\mathcal{H}_t$ then a policy π is a sequence $\pi_0, \pi_1, \ldots$, where π_t maps $\mathcal{H}_t$ to $M(\mathcal{A})$, the space of all probability distributions over $\mathcal{A}$.[2] 'Following a policy' means that for any time step t given the history $x_0, a_0, \ldots, x_t$ the probability of selecting an action a equals $\pi_t(x_0, a_0, \ldots, x_t)(a)$. A policy is called *stationary* if π_t depends only on the last state visited. Equivalently, a policy $\pi = (\pi_0, \pi_1, \ldots)$ is called stationary if $\pi_t(x_0, a_0, \ldots, x_t) = \pi_0(x_t)$ holds for all $t \geq 0$. A policy is called *deterministic* if for any history $x_0, a_0, \ldots, x_t$ there exists some action a such that $\pi_t(x_0, a_0, \ldots, x_t)$ is concentrated on this action. Hence, any deterministic stationary policy can be identified by some mapping from the state space to the action space and so in the following, at the price of abusing the notation and the terminology slightly, we will call such mappings policies, too.

The goal is to find a policy π that maximizes the expected total discounted reward given any initial state. Under this criterion the value of a policy π and a state $x \in \mathcal{X}$ is given by

$$V^\pi(x) = \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R_t^\pi | X_0 = x\right],$$

where R_t^π is the reward incurred at time t when executing policy π. The optimal expected total discounted reward when the process is started from state x shall be denoted by $V^*(x)$; V^* is called the *optimal value function* and is defined by $V^*(x) = \sup_\pi V^\pi(x)$. A policy π is called *optimal* if it attains the optimal values for *any* state $x \in \mathcal{X}$, that is if $V^\pi(x) = V^*(x)$ for all $x \in \mathcal{X}$. We also let $Q^*(x,a)$ denote the long-term total expected discounted reward when the process is started from state x, the first executed action is a and it is assumed that after the first step an optimal policy is followed. Since by assumption the action space is finite, the rewards are bounded, and we assume discounting, the existence of deterministic stationary optimal policies is guaranteed (Bertsekas and Shreve, 1978).

1. This condition could be replaced by a standard moment condition on the random rewards (Györfi et al., 2002) without changing the results.
2. In fact, π_t must be a measurable mapping so that we are allowed to talk about the probability of executing an action. Measurability issues by now are well understood and hence we shall not deal with them here. For a complete treatment the interested reader is referred to Bertsekas and Shreve (1978).

Let us now introduce a few function spaces and operators that will be needed in the rest of the paper. Let us denote the space of bounded measurable functions with domain $\mathcal{X}$ by $B(\mathcal{X})$. Further, the space of measurable functions bounded by $0 < V_{\max} < +\infty$ shall be denoted by $B(\mathcal{X}; V_{\max})$. A deterministic stationary policy $\pi : \mathcal{X} \to \mathcal{A}$ defines the transition probability kernel P^π according to $P^\pi(dy|x) = P(dy|x, \pi(x))$. From this kernel two related operators are derived: a right-linear operator, $P^\pi \cdot : B(\mathcal{X}) \to B(\mathcal{X})$, defined by

$$(P^\pi V)(x) = \int V(y) P^\pi(dy|x),$$

and a left-linear operator, $\cdot P^\pi : M(\mathcal{X}) \to M(\mathcal{X})$, defined by

$$(\mu P^\pi)(dy) = \int P^\pi(dy|x) \mu(dx).$$

Here $\mu \in M(\mathcal{X})$ and $M(\mathcal{X})$ is the space of all probability distributions over $\mathcal{X}$.

In words, $(P^\pi V)(x)$ is the expected value of V after following π for a single time-step when starting from x, and μP^π is the distribution of states if the system is started from $X_0 \sim \mu$ and policy π is followed for a single time-step. The product of two kernels P^{π_1} and P^{π_2} is defined in the natural way:

$$(P^{\pi_1} P^{\pi_2})(dz|x) = \int P^{\pi_1}(dy|x) P^{\pi_2}(dz|y).$$

Hence, $\mu P^{\pi_1} P^{\pi_2}$ is the distribution of states if the system is started from $X_0 \sim \mu$, policy π_1 is followed for the first step and then policy π_2 is followed for the second step. The interpretation of $(P^{\pi_1} P^{\pi_2} V)(x)$ is similar.

We say that a (deterministic stationary) policy π is *greedy* w.r.t. a function $V \in B(\mathcal{X})$ if, for all $x \in \mathcal{X}$,

$$\pi(x) \in \arg\max_{a \in \mathcal{A}} \left\{ r(x,a) + \gamma \int V(y) P(dy|x,a) \right\},$$

where $r(x,a) = \int z S(dz|x,a)$ is the expected reward of executing action a in state x. We assume that r is a bounded, measurable function. Actions maximizing $r(x,a) + \gamma \int V(y) P(dy|x,a)$ are said to be *greedy* w.r.t. V. Since $\mathcal{A}$ is finite the set of greedy actions is non-empty for any function V.

Define operator $T : B(\mathcal{X}) \to B(\mathcal{X})$ by

$$(TV)(x) = \max_{a \in \mathcal{A}} \left\{ r(x,a) + \gamma \int V(y) P(dy|x,a) \right\}, \quad V \in B(\mathcal{X}).$$

Operator T is called the *Bellman operator* underlying the MDP. Similarly, to any stationary deterministic policy π there corresponds an operator $T^\pi : B(\mathcal{X}) \to B(\mathcal{X})$ defined by

$$(T^\pi V)(x) = r(x, \pi(x)) + (P^\pi V)(x).$$

It is well known that T is a contraction mapping in supremum norm with contraction coefficient γ: $\|TV - TV'\|_\infty \le \gamma \|V - V'\|_\infty$. Hence, by Banach's fixed-point theorem, T possesses a unique fixed point. Moreover, this fixed point turns out to be equal to the optimal value function, V^*. Then a simple contraction argument shows that the so-called *value-iteration algorithm*,

$$V_{k+1} = TV_k,$$

with arbitrary $V_0 \in B(\mathcal{X})$ yields a sequence of iterates, V_k, that converge to V^* at a geometric rate. The contraction arguments also show that if $|r(x,a)|$ is bounded by $R_{\max} > 0$ then V^* is bounded by $R_{\max}/(1-\gamma)$ and if $V_0 \in B(\mathcal{X}; R_{\max}/(1-\gamma))$ then the same holds for V_k, too. Proofs of these statements can be found in many textbooks such as in that of Bertsekas and Shreve (1978).

Our initial set of assumptions on the class of MDPs considered is summarized as follows:

Assumption A0 [MDP Regularity] The MDP $(\mathcal{X}, \mathcal{A}, P, S, \gamma)$ satisfies the following conditions: $\mathcal{X}$ is a bounded, closed subset of some Euclidean space, $\mathcal{A}$ is finite and the discount factor γ satisfies $0 < \gamma < 1$. The reward kernel S is such that the immediate reward function r is a bounded measurable function with bound $R_{\max}$. Further, the support of $S(\cdot|x,a)$ is included in $[-\hat{R}_{\max}, \hat{R}_{\max}]$ independently of $(x,a) \in \mathcal{X} \times \mathcal{A}$.

Let μ be a distribution over $\mathcal{X}$. For a real-valued measurable function g defined over $\mathcal{X}$, $\|g\|_{p,\mu}$ is defined by $\|g\|_{p,\mu}^p = \int |g(x)|^p \mu(dx)$. The space of functions with bounded $\|\cdot\|_{p,\mu}$-norm shall be denoted by $L^p(\mathcal{X}; \mu)$.

3. Sampling-based Fitted Value Iteration

The parameters of sampling-based FVI are a distribution, $\mu \in M(\mathcal{X})$, a function set $\mathcal{F} \subset B(\mathcal{X})$, an initial value function, $V_0 \in \mathcal{F}$, and the integers N, M and K. The algorithm works by computing a series of functions, $V_1, V_2, \ldots \in \mathcal{F}$ in a recursive manner. The $(k+1)$th iterate is obtained from the kth function as follows: First a Monte-Carlo estimate of TV_k is computed at a number of random states $(X_i)_{1 \le i \le N}$:

$$\hat{V}(X_i) = \max_{a \in \mathcal{A}} \frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i,a} + \gamma V_k(Y_j^{X_i,a}) \right], \quad i = 1, 2, \ldots, N.$$

Here the *basepoints*, $X_1, \ldots, X_N$, are sampled from the distribution μ, independently of each other. For each of these basepoints and for each possible action $a \in \mathcal{A}$ the next states, $Y_j^{X_i,a} \in \mathcal{X}$, and rewards, $R_j^{X_i,a} \in \mathbb{R}$, are drawn via the help of the generative model of the MDP:

$$\begin{aligned} Y_j^{X_i,a} &\sim P(\cdot|X_i,a), \\ R_j^{X_i,a} &\sim S(\cdot|X_i,a), \end{aligned}$$

$(j = 1, 2, \ldots, M,\ i = 1, \ldots, N)$. By assumption, $(Y_j^{X_i,a}, R_j^{X_i,a})$ and $(Y_{j'}^{X_{i'},a'}, R_{j'}^{X_{i'},a'})$ are independent of each other whenever $(i,j,a) \neq (i',j',a')$. The next iterate V_{k+1} is obtained as the best fit in $\mathcal{F}$ to the data $(X_i, \hat{V}(X_i))_{i=1,2,\ldots,N}$ w.r.t. the p-norm based empirical loss

$$V_{k+1} = \operatorname*{argmin}_{f \in \mathcal{F}} \sum_{i=1}^{N} |f(X_i) - \hat{V}(X_i)|^p. \tag{1}$$

These steps are iterated $K > 0$ times, yielding the sequence $V_1, \ldots, V_K$.

We study two variants of this algorithm: When a fresh sample is generated in each iteration, we call the algorithm the *multi-sample variant*. The *total number* of samples used by the multi-sample algorithm is thus $K \times N \times M$. Since in a single iteration only a fraction of these samples is used, one may wonder if it were more sample efficient to use *all the samples* in all the iterations.[3] We shall call

3. Sample-efficiency becomes an issue when the sample generation process is not controlled (the samples are given) or when it is expensive to generate the samples due to the high cost of simulation.

the version of the algorithm the *single-sample variant* (details will be given in Section 5). A possible counterargument against the single-sample variant is that since the samples used in subsequent iterations are correlated, the bias due to sampling errors may get amplified. One of our interesting theoretical findings is that the bias-amplification effect is not too severe and, in fact, the single-sample variant of the algorithm is well behaving and can be expected to outperform the multi-sample variant. In the experiments we will see such a case.

Let us now discuss the choice of the function space $\mathcal{F}$. Generally, $\mathcal{F}$ is selected to be a finitely parameterized class of functions:

$$\mathcal{F} = \{ f_\theta \in B(\mathcal{X}) \,|\, \theta \in \Theta \}, \quad \dim(\Theta) < +\infty.$$

Our results apply to both linear ($f_\theta(x) = \theta^T \phi(x)$) and non-linear ($f_\theta(x) = f(x;\theta)$) parameterizations, such as wavelet based approximations, multi-layer neural networks or kernel-based regression techniques. Another possibility is to use the kernel mapping idea underlying many recent state-of-the-art supervised-learning methods, such as support-vector machines, support-vector regression or Gaussian processes (Cristianini and Shawe-Taylor, 2000). Given a (positive definite) kernel function $\mathcal{K}$, $\mathcal{F}$ can be chosen as a closed convex subset of the reproducing-kernel Hilbert-space (RKHS) associated to $\mathcal{K}$. In this case the optimization problem (1) still admits a finite, closed-form solution despite that the function space $\mathcal{F}$ cannot be written in the above form for any finite dimensional parameters space (Kimeldorf and Wahba, 1971; Schölkopf and Smola, 2002).

4. Approximating the Bellman Operator

The purpose of this section is to bound the error introduced in a single iteration of the algorithm. There are two components of this error: The approximation error caused by projecting the iterates into the function space $\mathcal{F}$ and the estimation error caused by using a finite, random sample.

The approximation error can be best explained by introducing the metric projection operator: Fix the sampling distribution $\mu \in M(\mathcal{X})$ and let $p \geq 1$. The *metric projection* of TV onto $\mathcal{F}$ w.r.t. the μ-weighted p-norm is defined by

$$\Pi_{\mathcal{F}} TV = \operatorname*{argmin}_{f \in \mathcal{F}} \| f - TV \|_{p,\mu}.$$

Here $\Pi_{\mathcal{F}} : L^p(\mathcal{X};\mu) \to \mathcal{F}$ for $g \in L^p(\mathcal{X};\mu)$ gives the *best approximation* to g in $\mathcal{F}$.[4] The *approximation error* in the kth step for $V = V_k$ is $d_{p,\mu}(TV, \mathcal{F}) = \| \Pi_{\mathcal{F}} TV - TV \|_{p,\mu}$. More generally, we let

$$d_{p,\mu}(TV, \mathcal{F}) = \inf_{f \in \mathcal{F}} \| f - TV \|_{p,\mu}.$$

Hence, the approximation error can be made small by selecting $\mathcal{F}$ to be large enough. We shall discuss how this can be accomplished for a large class of MDPs in Section 7.

4. The existence and uniqueness of best approximations is one of the fundamental problems of approximation theory. Existence can be guaranteed under fairly mild conditions, such as the compactness of $\mathcal{F}$ w.r.t. $\|\cdot\|_{p,\mu}$, or if $\mathcal{F}$ is finite dimensional (Cheney, 1966). Since the metric projection operator is needed for discussion purposes only, here we simply assume that $\Pi_{\mathcal{F}}$ is well-defined.

Let us now turn to the discussion of the estimation error. In the kth iteration, given $V = V_k$, the function $V' = V_{k+1}$ is computed as follows:

$$\hat{V}(X_i) = \max_{a \in \mathcal{A}} \frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i,a} + \gamma V(Y_j^{X_i,a}) \right], \quad i = 1, 2, \ldots, N, \tag{2}$$

$$V' = \operatorname*{argmin}_{f \in \mathcal{F}} \sum_{i=1}^{N} \left| f(X_i) - \hat{V}(X_i) \right|^p, \tag{3}$$

where the random samples satisfy the conditions of the previous section and, for the sake of simplicity, we assume that the minimizer in Equation (3) exists.

Clearly, for a fixed X_i, $\max_a 1/M \sum_{j=1}^{M} (R_j^{X_i,a} + \gamma V(Y_j^{X_i,a})) \to (TV)(X_i)$ as $M \to \infty$ w.p.1. Hence, for large enough M, $\hat{V}(X_i)$ is a good approximation to $(TV)(X_i)$. On the other hand, if N is big then for any $(f,g) \in \mathcal{F} \times \mathcal{F}$, the *empirical p-norm loss*, $1/N \sum_{i=1}^{N} (f(X_i) - g(X_i))^p$, is a good approximation to the *true loss* $\|f - g\|_{p,\mu}^p$. Hence, we expect to find the minimizer of (3) to be close to the minimizer of $\|f - TV\|_{p,\mu}^p$. Since the function x^p is strictly increasing for $x > 0$, $p > 0$, the minimizer of $\|f - TV\|_{p,\mu}^p$ over $\mathcal{F}$ is just the metric projection of TV on $\mathcal{F}$, hence for N, M big, V' can be expected to be close to $\Pi_{\mathcal{F}} TV$.

Note that Equation (3) looks like an ordinary p-norm function fitting. One difference though is that in regression the target function equals the regressor $g(x) = E[\hat{V}(X_i) | X_i = x]$, whilst in our case the target function is TV and $TV \neq g$. This is because

$$\mathbb{E}\left[\max_{a \in \mathcal{A}} \frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i,a} + \gamma V(Y_j^{X_i,a}) \right] \,\middle|\, X_i \right] \geq \max_{a \in \mathcal{A}} \mathbb{E}\left[\frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i,a} + \gamma V(Y_j^{X_i,a}) \right] \,\middle|\, X_i \right].$$

In fact, if we had an equality here then we would have no reason to set $M > 1$: in a pure regression setting it is always better to have a completely fresh pair of samples than to have a pair where the covariate is set to be equal to some previous sample. Due to $M > 1$ the rate of convergence with the sample size of sampling-based FVI will be slightly worse than the rates available for regression.

Above we argued that for N large enough and for a fixed pair $(f,g) \in \mathcal{F} \times \mathcal{F}$, the empirical loss will approximate the true loss, that is, the estimation error will be small. However, we need this property to hold for V'. Since V' is the minimizer of the empirical loss, it depends on the random samples and hence it is a random object by itself and so the argument that the estimation error is small for any *fixed*, deterministic pair of functions cannot be used with V'. This is, however, the situation in supervised learning problems, too. A simple idea developed there is to bound the estimation error of V' by the worst-case estimation error over $\mathcal{F}$:

$$\left| \frac{1}{N} \sum_{i=1}^{N} |V'(X_i) - g(X_i)|^p - \|V' - g\|_{p,\mu}^p \right| \leq \sup_{f \in \mathcal{F}} \left| \frac{1}{N} \sum_{i=1}^{N} |f(X_i) - g(X_i)|^p - \|f - g\|_{p,\mu}^p \right|.$$

This inequality holds w.p. 1 since for any random event ω, $V' = V'(\omega)$ is an element of $\mathcal{F}$. The right-hand side here is the maximal deviation of a large number of empirical averages from their respective means. The behavior of this quantity is the main focus of empirical process theory and we shall use the tools developed there, in particular Pollard's tail inequality (cf., Theorem 5 in Appendix A).

When bounding the size of maximal deviations, the size of the function set becomes a major factor. When the function set has a finite number of elements, a bound follows by exponential tail

inequalities and a union bounding argument. When $\mathcal{F}$ is infinite, the 'capacity' of $\mathcal{F}$ measured by the (empirical) *covering number* of $\mathcal{F}$ can be used to derive an appropriate bound: Let $\varepsilon > 0$, $q \geq 1$, $x^{1:N} \stackrel{\text{def}}{=} (x_1, \ldots, x_N) \in \mathcal{X}^N$ be fixed. The (ε, q)-*covering number of the set* $\mathcal{F}(x^{1:N}) = \{(f(x_1), \ldots, f(x_N)) \,|\, f \in \mathcal{F}\}$ is the smallest integer m such that $\mathcal{F}(x^{1:N})$ can be covered by m balls of the normed-space $(\mathbb{R}^N, \|\cdot\|_q)$ with centers in $\mathcal{F}(x^{1:N})$ and radius $N^{1/q}\varepsilon$. The (ε, q)-covering number of $\mathcal{F}(x^{1:N})$ is denoted by $\mathcal{N}_q(\varepsilon, \mathcal{F}(x^{1:N}))$. When $q = 1$, we use $\mathcal{N}$ instead of $\mathcal{N}_1$. When $X^{1:N}$ are i.i.d. with common underlying distribution μ then $\mathbb{E}\left[\mathcal{N}_q(\varepsilon, \mathcal{F}(X^{1:N}))\right]$ shall be denoted by $\mathcal{N}_q(\varepsilon, \mathcal{F}, N, \mu)$. By Jensen's inequality $\mathcal{N}_p \leq \mathcal{N}_q$ for $p \leq q$. The logarithm of $\mathcal{N}_q$ is called the *q-norm metric entropy* of $\mathcal{F}$. For $q = 1$, we shall call $\log \mathcal{N}_1$ the *metric entropy* of $\mathcal{F}$ (without any qualifiers).

The idea underlying covering numbers is that what really matters when bounding maximal deviations is how much the functions in the function space vary *at the actual samples*. Of course, without imposing any conditions on the function space, covering numbers can grow as a function of the sample size.

For specific choices of $\mathcal{F}$, however, it is possible to bound the covering numbers of $\mathcal{F}$ *independently* of the number of samples. In fact, according to a well-known result due to Haussler (1995), covering numbers can be bounded as a function of the so-called *pseudo-dimension* of the function class. The pseudo-dimension, or VC-subgraph dimension $V_{\mathcal{F}^+}$ of $\mathcal{F}$ is defined as the VC-dimension of the subgraphs of functions in $\mathcal{F}$.[5] The following statement gives the bound that does not depend on the number of sample points:

Proposition 1 (Haussler (1995), Corollary 3) *For any set $\mathcal{X}$, any points $x^{1:N} \in \mathcal{X}^N$, any class $\mathcal{F}$ of functions on $\mathcal{X}$ taking values in $[0, L]$ with pseudo-dimension $V_{\mathcal{F}^+} < \infty$, and any $\varepsilon > 0$,*

$$\mathcal{N}(\varepsilon, \mathcal{F}(x^{1:N})) \leq e(V_{\mathcal{F}^+} + 1)\left(\frac{2eL}{\varepsilon}\right)^{V_{\mathcal{F}^+}}.$$

For a given set of functions $\mathcal{F}$ let $a + \mathcal{F}$ denote the set of functions shifted by the constant a: $a + \mathcal{F} = \{f + a \,|\, f \in \mathcal{F}\}$. Clearly, neither the pseudo-dimension nor covering numbers are changed by shifts. This allows one to extend Proposition 1 to function sets with functions taking values in $[-L, +L]$.

Bounds on the pseudo-dimension are known for many popular function classes including linearly parameterized function classes, multi-layer perceptrons, radial basis function networks, several non-and semi-parametric function classes (cf., Niyogi and Girosi, 1999; Anthony and Bartlett, 1999; Györfi et al., 2002; Zhang, 2002, and the references therein). If q is the dimensionality of the function space, these bounds take the form $O(\log(q))$, $O(q)$ or $O(q \log q)$.[6]

Another route to get a useful bound on the number of samples is to derive an upper bound on the metric entropy that grows with the number of samples at a *sublinear* rate. As an example consider the following class of bounded-weight, linearly parameterized functions:

$$\mathcal{F}_A = \{f_\theta : \mathcal{X} \to \mathbb{R} \,|\, f_\theta(x) = \theta^T \phi(x), \|\theta\|_q \leq A\}.$$

5. The VC-dimension of a set system is defined as follows (Sauer, 1972; Vapnik and Chervonenkis, 1971): Given a set system $\mathcal{C}$ with base set $\mathcal{U}$ we say that $\mathcal{C}$ shatters the points of $A \subset \mathcal{U}$ if all possible $2^{|A|}$ subsets of A can be obtained by intersecting A with elements of $\mathcal{C}$. The VC-dimension of $\mathcal{C}$ is the cardinality of the largest subset $A \subset \mathcal{U}$ that can be shattered.

6. Again, similar bounds are known to hold for the supremum-norm metric entropy.

It is known that for finite-dimensional smooth parametric classes their metric entropy scales with $\dim(\phi) < +\infty$. If ϕ is the feature map associated with some positive definite kernel function $\mathcal{K}$ then ϕ can be infinite dimensional (this class arises if one 'kernelizes' FVI). In this case the bounds due to Zhang (2002) can be used. These bound the metric entropy by $\lceil A^2B^2/\varepsilon^2 \rceil \log(2N+1)$, where B is an upper bound on $\sup_{x\in\mathcal{X}} \|\phi(x)\|_p$ with $p = 1/(1-1/q)$.[7]

4.1 Finite-sample Bounds

The following lemma shows that with high probability, V' is a good approximation to TV when some element of $\mathcal{F}$ is close to TV and if the number of samples is high enough:

Lemma 1 *Consider an MDP satisfying Assumption A0. Let $V_{\max} = R_{\max}/(1-\gamma)$, fix a real number $p \geq 1$, integers $N, M \geq 1$, $\mu \in M(\mathcal{X})$ and $\mathcal{F} \subset B(\mathcal{X}; V_{\max})$. Pick any $V \in B(\mathcal{X}; V_{\max})$ and let $V' = V'(V, N, M, \mu, \mathcal{F})$ be defined by Equation (3). Let $\mathcal{N}_0(N) = \mathcal{N}\left(\frac{1}{8}\left(\frac{\varepsilon}{4}\right)^p, \mathcal{F}, N, \mu\right)$. Then for any $\varepsilon, \delta > 0$,*

$$\left\|V' - TV\right\|_{p,\mu} \leq d_{p,\mu}(TV, \mathcal{F}) + \varepsilon$$

holds w.p. at least $1-\delta$ provided that

$$N > 128 \left(\frac{8V_{\max}}{\varepsilon}\right)^{2p} \left(\log(1/\delta) + \log(32\mathcal{N}_0(N))\right) \tag{4}$$

and

$$M > \frac{8\left(\hat{R}_{\max} + \gamma V_{\max}\right)^2}{\varepsilon^2} \left(\log(1/\delta) + \log(8N|\mathcal{A}|)\right). \tag{5}$$

As we have seen before, for a large number of choices of $\mathcal{F}$, the metric entropy of $\mathcal{F}$ is independent of N. In such cases Equation (4) gives an explicit bound on N and M. In the resulting bound, the total number of samples per iteration, $N \times M$, scales with $\varepsilon^{-(2p+2)}$ (apart from logarithmic terms). The comparable bound for the pure regression setting is ε^{-2p}. The additional quadratic factor is the price to pay because of the biasedness of the values $\hat{V}(X_i)$.

The main ideas of the proof are illustrated using Figure 1 (the proof of the Lemma can be found in Appendix A). The left-hand side of this figure depicts the space of bounded functions over $\mathcal{X}$, while the right-hand side figure shows a corresponding vector space. The spaces are connected by the mapping $f \mapsto \tilde{f} \stackrel{\text{def}}{=} (f(X_1), \ldots, f(X_N))^T$. In particular, this mapping sends the set $\mathcal{F}$ into the set $\tilde{F} = \{\tilde{f} \mid f \in \mathcal{F}\}$.

The proof goes by upper bounding the distance between V' and TV in terms of the distance between f^* and TV. Here $f^* = \Pi_{\mathcal{F}} TV$ is the best fit to TV in $\mathcal{F}$. The choice of f^* is motivated by the fact that V' is the best fit in $\mathcal{F}$ to the data $(X_i, \hat{V}(X_i))_{i=1,\ldots,N}$ w.r.t. the p-norm $\|\cdot\|_p$. The bound is developed by relating a series of distances to each other: In particular, if N is large then $\|V' - TV\|_{p,\mu}^p$ and $\|\widetilde{V'} - \widetilde{TV}\|_p^p$ are expected to be close to each other. On the other hand, if M is large then $\hat{V}$ and $\widetilde{TV}$ are expected to be close to each other. Hence, $\|\widetilde{V'} - \widetilde{TV}\|_p^p$ and $\|\widetilde{V'} - \hat{V}\|_p^p$ are expected to be close to each other. Now, since $\widetilde{V'}$ is the best fit to $\hat{V}$ in $\widetilde{\mathcal{F}}$, the distance between $\widetilde{V'}$ and $\hat{V}$ is not larger than the distance between the image $\widetilde{f}$ of an arbitrary function $f \in \mathcal{F}$ and $\hat{V}$. Choosing $f = f^*$ we conclude that the distance between $\widetilde{f^*}$ and $\hat{V}$ is not smaller than $\|\widetilde{V'} - \hat{V}\|_p^p$.

7. Similar bounds exist for the supremum-norm metric entropy.

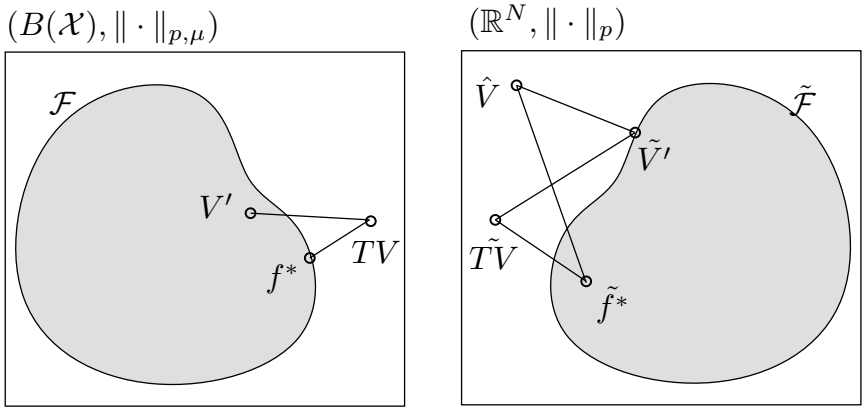

Figure 1: Illustration of the proof of Lemma 1 for bounding the distance of V' and TV in terms of the distance of f^* and TV, where f^* is the best fit to TV in $\mathcal{F}$ (cf., Equations 2, 3). For a function $f \in B(\mathcal{X})$, $\widetilde{f} = (f(X_1), \ldots, f(X_N))^T \in \mathbb{R}^N$. The set $\widetilde{\mathcal{F}}$ is defined by $\{\widetilde{f} \,|\, f \in \mathcal{F}\}$. Segments on the figure connect objects whose distances are compared in the proof.

Exploiting again that M is large, we see that the distance between $\widetilde{f^*}$ and $\hat{V}$ must be close to that of between $\widetilde{f^*}$ and $\widetilde{TV}$, which in turn must be close to the $L^p(\mathcal{X};\mu)$ distance of f^* and TV if N is big enough. Hence, if $\|f^* - TV\|_{p,\mu}^p$ is small then so is $\|V' - TV\|_{p,\mu}^p$.

4.2 Bounds for the Single-Sample Variant

When analyzing the error of sampling-based FVI, we would like to use Lemma 1 for bounding the error committed when approximating TV_k starting from V_k based on a new sample. When doing so, however, we have to take into account that V_k is random. Yet Lemma 1 requires that V, the function whose Bellman image is approximated, is some fixed (non-random) function. The problem is easily resolved in the multi-sample variant of the algorithm by noting that the samples used in calculating V_{k+1} are independent of the samples used to calculate V_k. A formal argument is presented in Appendix B.3. The same argument, however, does not work for the single-sample variant of the algorithm when V_{k+1} and V_k are *both* computed using the *same set of random variables*. The purpose of this section is to extend Lemma 1 to cover this case.

In formulating this result we will need the following definition: For $\mathcal{F} \subset B(\mathcal{X})$ let us define

$$\mathcal{F}_{T-} = \{\, f - Tg \,|\, f \in \mathcal{F}, g \in \mathcal{F} \,\}.$$

The following result holds:

Lemma 2 *Denote by Ω the sample-space underlying the random variables $\{X_i\}$, $\{Y_j^{X_i,a}\}$, $\{R_j^{X_i,a}\}$, $i = 1,\ldots,N, j = 1,\ldots,M, a \in \mathcal{A}$. Then the result of Lemma 1 continues to hold if V is a random function satisfying $V(\omega) \in \mathcal{F}$, $\omega \in \Omega$ provided that*

$$N = O(V_{\max}^2 (1/\varepsilon)^{2p} \log(\mathcal{N}(c\varepsilon, \mathcal{F}_{T-}, N, \mu)/\delta))$$

and

$$M = O((\hat{R}_{\max} + \gamma V_{\max})^2/\varepsilon^2 \log(N|\mathcal{A}|\mathcal{N}(c'\varepsilon, \mathcal{F}, M, \mu)/\delta)),$$

where $c, c' > 0$ are constants independent of the parameters of the MDP and the function space $\mathcal{F}$.

The proof can be found in Appendix A.1. Note that the sample-size bounds in this lemma are similar to those of Lemma 1, except that N now depends on the metric entropy of $\mathcal{F}_{T-}$ and M depends on the metric entropy of $\mathcal{F}$. Let us now give two examples when explicit bounds on the covering number of $\mathcal{F}_{T-}$ can be given using simple means:

For the first example note that if $g : (\mathbb{R}\times\mathbb{R}, \|\cdot\|_1) \to \mathbb{R}$ is Lipschitz[8] with Lipschitz constant G then the ε-covering number of the space of functions of the form $h(x) = g(f_1(x), f_2(x))$, $f_1 \in \mathcal{F}_1$, $f_2 \in \mathcal{F}_2$ can be bounded by $\mathcal{N}(\varepsilon/(2G), \mathcal{F}_1, n, \mu)\mathcal{N}(\varepsilon/(2G), \mathcal{F}_2, n, \mu)$ (this follows directly from the definition of covering numbers). Since $g(x,y) = x - y$ is Lipschitz with $G = 1$, $\mathcal{N}(\varepsilon, \mathcal{F}_{T-}, n, \mu) \le \mathcal{N}(\varepsilon/2, \mathcal{F}, n, \mu)\mathcal{N}(\varepsilon/2, \mathcal{F}_T, n, \mu)$. Hence it suffices to bound the covering numbers of the space $\mathcal{F}_T = \{Tf | f \in \mathcal{F}\}$. One possibility to do this is as follows: Assume that $\mathcal{X}$ is compact, $\mathcal{F} = \{f_\theta | \theta \in \Theta\}$, Θ is compact and the mapping $H : (\Theta, \|\cdot\|) \to (B(\mathcal{X}), L^\infty)$ defined by $H(\theta) = f_\theta$ is Lipschitz with coefficient L. Fix $x^{1:n}$ and consider $\mathcal{N}(\varepsilon, \mathcal{F}_T(x^{1:n}))$. Let θ_1, θ_2 be arbitrary. Then $|Tf_{\theta_1}(x) - Tf_{\theta_2}(x)| \le \|Tf_{\theta_1} - Tf_{\theta_2}\|_\infty \le \gamma \|f_{\theta_1} - f_{\theta_2}\|_\infty \le \gamma L \|\theta_1 - \theta_2\|$. Now assume that $C = \{\theta_1, \dots, \theta_m\}$ is an $\varepsilon/(L\gamma)$-cover of the space Θ and consider any $n \ge 1$, $(x_1, \dots, x_n) \in \mathcal{X}^n$, $\theta \in \Theta$. Let θ_i be the nearest neighbor of θ in C. Then, $\left\|(Tf_\theta)(x^{1:n}) - (Tf_{\theta_i})(x^{1:n})\right\|_1 \le n\|Tf_\theta - Tf_{\theta_i}\|_\infty \le n\varepsilon$. Hence, $\mathcal{N}(\varepsilon, \mathcal{F}_T(x^{1:n})) \le \mathcal{N}(\varepsilon/(L\gamma), \Theta)$.

Note that the mapping H can be shown to be Lipschitzian for many function spaces of interest. As an example let us consider the space of linearly parameterized functions taking the form $f_\theta = \theta^T\phi$ with a suitable basis function $\phi : \mathcal{X} \to \mathbb{R}^{d_\phi}$. By the Cauchy-Schwarz inequality, $\left\|\theta_1^T\phi - \theta_2^T\phi\right\|_\infty = \sup_{x\in\mathcal{X}} |\langle\theta_1 - \theta_2, \phi(x)\rangle| \le \|\theta_1 - \theta_2\|_2 \sup_{x\in\mathcal{X}} \|\phi(x)\|_2$. Hence, by choosing the ℓ^2 norm in the space Θ, we get that $\theta \mapsto \theta^T\phi$ is Lipschitz with coefficient $\|\|\phi(\cdot)\|_2\|_\infty$ (this gives a bound on the metric entropy that is linear in d_ϕ).

5. Main Results

For the sake of specificity, let us reiterate the algorithms. Let $V_0 \in \mathcal{F}$. The *single-sample variant* of sampling-based FVI produces a sequence of function $\{V_k\}_{0\le k\le K} \subset \mathcal{F}$ satisfying

$$V_{k+1} = \operatorname*{argmin}_{f\in\mathcal{F}} \sum_{i=1}^{N} \left| f(X_i) - \max_{a\in\mathcal{A}} \frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i,a} + \gamma V_k(Y_j^{X_i,a}) \right] \right|^p. \tag{6}$$

The *multi-sample variant* is obtained by using a fresh set of samples in each iteration:

$$V_{k+1} = \operatorname*{argmin}_{f\in\mathcal{F}} \sum_{i=1}^{N} \left| f(X_i^k) - \max_{a\in\mathcal{A}} \frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i^k,a,k} + \gamma V_k(Y_j^{X_i^k,a,k}) \right] \right|^p. \tag{7}$$

Let π_k be a greedy policy w.r.t. V_k. We are interested in bounding the loss due to using policy π_k instead of an optimal one, where the loss is measured by a weighted p-norm:

$$L_k = \|V^* - V^{\pi_k}\|_{p,\rho}.$$

Here ρ is a distribution whose role is to put more weight on those parts of the state space where performance matters more. A particularly sensible choice is to set ρ to be the distribution over the

8. A mapping g between normed function spaces $(B_1, \|\cdot\|)$ and $(B_2, \|\cdot\|)$ is Lipschitz with factor $C > 0$ if $\forall x, y \in B_1$, $\|g(x) - g(y)\| \le \|x - y\|$.

states from which we start to use π_k. In this case if $p = 1$ then L_k measures the expected loss. For $p > 1$ the loss does not have a similarly simple interpretation, except that with $p \to \infty$ we recover the supremum-norm loss. Hence increasing p generally means that the evaluation becomes more pessimistic.

Let us now discuss how we arrive at a bound on the expected p-norm loss. By the results of the previous section we have a bound on the error introduced in any given iteration. Hence, all we need to show is that the errors do not blow up as they are propagated through the algorithm. Since the previous section's bounds are given in terms of weighted p-norms, it is natural to develop weighted p-norm bounds for the whole algorithm. Let us concentrate on the case when in all iterations the error committed is bounded. Since we use weighted p-norm bounds, the usual supremum-norm analysis does not work. However, a similar argument can be used.

The sketch of this argument is as follows: Since we are interested in developing a bound on the performance of the greedy policy w.r.t. the final estimate of V^*, we first develop a pointwise analogue of supremum-norm Bellman-error bounds:

$$(I - \gamma P^{\pi})(V^* - V^{\pi}) \leq \gamma (P^{\pi^*} - P^{\pi})(V^* - V).$$

Here V plays the role of the final value function estimate, π is a greedy policy w.r.t. V, and V^{π} is its value-function. Hence, we see that it suffices to develop upper and lower bounds on $V^* - V$ with $V = V_K$. For the upper estimate, we use that $V^* - TV_k = TV^* - TV_k = T^{\pi^*}V^* - T^{\pi_k}V_k \leq T^{\pi^*}V^* - T^{\pi^*}V_k = \gamma P^{\pi^*}(V^* - V_k)$. Hence, if $V_{k+1} = TV_k - \varepsilon_k$ then $V^* - V_{k+1} \leq \gamma P^{\pi^*}(V^* - V_k) + \varepsilon_k$. An analogous reasoning results in the lower bound $V^* - V_{k+1} \geq \gamma P^{\pi_k}(V^* - V_k) + \varepsilon_k$. Here π_k is a policy greedy w.r.t. V_k. Now, exploiting that the operator P^{π} is linear for any π, iterating these bounds yields upper and lower bounds on $V^* - V_K$ as a function of $\{\varepsilon_k\}_k$. A crucial step of the argument is to replace T, the non-linear Bellman operator by linear operators (P^{π}, for suitable π) since propagating errors through linear operators is easy, while in general, it is impossible to do the same with non-linear operators. Actually, as we propagate the errors, it is not hard to foresee that operator products of the form $P^{\pi_K}P^{\pi_{K-1}}\dots P^{\pi_k}$ enter our bounds and that the error amplification caused by these product operators is the major source of the possible increase of the error.

Note that if a supremum-norm analysis were followed ($p = \infty$), we would immediately find that the maximum amplification by these product operators is bounded by one: Since, as it is well known, for any policy π, $|\int V(y)P(dy|x,\pi(x))| \leq \int |V(y)|P(dy|x,\pi(x)) \leq \|V\|_\infty \int P(dy|x,\pi(x)) = \|V\|_\infty$, that is, $\|P^{\pi}\|_\infty \leq 1$. Hence

$$\|P^{\pi_K}\dots P^{\pi_k}\|_\infty \leq \|P^{\pi_K}\|_\infty \dots \|P^{\pi_k}\|_\infty \leq 1,$$

and starting from the pointwise bounds, one recovers the well-known supremum-norm bounds by just taking the supremum of the bounds' two sides. Hence, the pointwise bounding technique yields as tight bounds as the previous supremum-norm bounding technique. However, since in the algorithm only the weighted p-norm errors are controlled, instead of taking the pointwise supremum, we integrate the pointwise bounds w.r.t. the measure ρ to derive the desired p-norm bounds provided that the induced operator-norm of these operator products w.r.t. weighted p-norms can be bounded. One simple assumption that allows this is as follows:

Assumption A1 [Uniformly stochastic transitions] For all $x \in \mathcal{X}$ and $a \in \mathcal{A}$, assume that $P(\cdot|x,a)$ is absolutely continuous w.r.t. μ and the Radon-Nikodym derivative of P w.r.t. μ is bounded uniformly

with bound C_μ:

$$C_\mu \stackrel{\text{def}}{=} \sup_{x\in\mathcal{X},a\in\mathcal{A}} \left\| \frac{dP(\cdot|x,a)}{d\mu} \right\|_\infty < +\infty.$$

Assumption A1 can be written in the form $P(\cdot|x,a) \le C_\mu \mu(\cdot)$, an assumption that was introduced by Munos (2003) in a finite MDP context for the analysis of approximate policy iteration. Clearly, if Assumption A1 holds then for $p \ge 1$, by Jensen's inequality, $|\int V(y)P(dy|x,\pi(x))|^p \le \int |V(y)|^p P(dy|x,\pi(x)) \le \int C_\mu |V(y)|^p d\mu(dy)$, hence $\|P^\pi V\|_{p,\rho} \le C_\mu^{1/p} \|V\|_{p,\mu}$ and thus $\|P^\pi\|_{p,\rho} \le C_\mu^{1/p}$. Note that when μ is the Lebesgue-measure over $\mathcal{X}$ then Assumption A1 becomes equivalent to assuming that the transition probability kernel $P(dy|x,a)$ admits a uniformly bounded density. The noisier the dynamics, the smaller the constant C_μ. Although $C_\mu < +\infty$ looks like a strong restriction, the class of MDPs that admit this restriction is still quite large in the sense that there are hard instances in it (this is discussed in detail in Section 8). However, the above assumption certainly excludes completely or partially deterministic MDPs, which might be important, for example, in financial applications.

Let us now consider another assumption that allows for such systems, too. The idea is that for the analysis we only need to reason about the operator norms of weighted sums of the product of arbitrary stochastic kernels. This motivates the following assumption:

Assumption A2 [Discounted-average concentrability of future-state distributions] Given ρ, μ, $m \ge 1$ and an arbitrary sequence of stationary policies $\{\pi_m\}_{m\ge 1}$, assume that the future-state distribution $\rho P^{\pi_1} P^{\pi_2} \dots P^{\pi_m}$ is absolutely continuous w.r.t. μ. Assume that

$$c(m) \stackrel{\text{def}}{=} \sup_{\pi_1,\dots,\pi_m} \left\| \frac{d(\rho P^{\pi_1} P^{\pi_2} \dots P^{\pi_m})}{d\mu} \right\|_\infty \tag{8}$$

satisfies

$$C_{\rho,\mu} \stackrel{\text{def}}{=} (1-\gamma)^2 \sum_{m\ge 1} m\gamma^{m-1} c(m) < +\infty.$$

We shall call $c(m)$ the m-step concentrability of a future-state distribution, while we call $C_{\rho,\mu}$ the *discounted-average concentrability coefficient* of the future-state distributions.
The number $c(m)$ measures how much ρ can get amplified in m steps as compared to the reference distribution μ. Hence, in general we expect $c(m)$ to grow with m. In fact, the condition that $C_{\rho,\mu}$ is finite is a growth rate condition on $c(m)$. Thanks to discounting, $C_{\rho,\mu}$ is finite for a reasonably large class of systems: In fact, we will now argue that Assumption A2 is weaker than Assumption A1 and that $C_{\rho,\mu}$ is finite when the top-Lyapunov exponent of the MDP is finite.

To show the first statement it suffices to see that $c(m) \le C_\mu$ holds for any m. This holds since by definition for any distribution ν and policy π, $\nu P^\pi \le C_\mu \mu$. Then take $\nu = \rho P^{\pi_1} \dots P^{\pi_{m-1}}$ and $\pi = \pi_m$ to conclude that $\rho P^{\pi_1} \dots P^{\pi_{m-1}} P^{\pi_m} \le C_\mu \mu$ and so $c(m) \le C_\mu$.

Let us now turn to the comparison with the top-Lyapunov exponent of the MDP. As our starting point we take the definition of top-Lyapunov exponent associated with sequences of finite dimensional matrices: If $\{P_t\}_t$ is sequence of square matrices with non-negative entries and $\{y_t\}_t$ is a sequence of vectors that satisfy $y_{t+1} = P_t y_t$ then, by definition, the top-Lyapunov exponent is $\hat{\gamma}_{\text{top}} = \limsup_{t\to\infty} (1/t) \log^+(\|y_t\|_\infty)$. If the top-Lyapunov exponent is positive then the associated system is sensitive to its initial conditions (unstable). A negative top-Lyapunov exponent, on the other hand, indicates that the system is stable; in case of certain stochastic systems the existence

of strictly stationary non-anticipating realizations is equivalent to a negative Lyapunov exponent (Bougerol and Picard, 1992).[9]

Now, one may think of y_t as a probability distribution over the state space and the matrices as the transition kernels. One way to generalize the above definition to controlled systems and infinite state spaces is to identify y_t with the future state distribution when the policies are selected to maximize the growth rate of $\|y_t\|_\infty$. This gives rise to $\hat{\gamma}_{\text{top}} = \limsup_{m\to\infty} \frac{1}{m} \log c(m)$, where $c(m)$ is defined by (8).[10] Then, by elementary arguments, we get that if $\hat{\gamma}_{\text{top}} < \log(1/\gamma)$ then $\sum_{m\geq 0} m^p \gamma^m c(m) < \infty$. In fact, if $\hat{\gamma}_{\text{top}} \leq 0$ then $C(\rho,\nu) < \infty$. Hence, we interpret $C(\rho,\nu) < +\infty$ as a weak stability condition.

Since Assumption A1 is stronger than Assumption A2 in the proofs we will proceed by first developing a proof under Assumption A2. The reason Assumption A1 is still considered is that it will allow us to derive supremum-norm performance bounds even though in the algorithm we control only the weighted p-norm bounds.

As a final preparatory step before the presentation of our main results, let us define the *inherent Bellman error* associated with the function space $\mathcal{F}$ (as in the introduction) by

$$d_{p,\mu}(T\mathcal{F},\mathcal{F}) = \sup_{f\in\mathcal{F}} d_{p,\mu}(Tf,\mathcal{F}).$$

Note that $d_{p,\mu}(T\mathcal{F},\mathcal{F})$ generalizes the notion of Bellman errors to function spaces in a natural way: As we have seen the error in iteration k depends on $d_{p,\mu}(T\hat{V}_k,\mathcal{F})$. Since $\hat{V}_k \in \mathcal{F}$, the inherent Bellman error gives a uniform bound on the errors of the individual iterations.[11]

The next theorem is the main result of the paper. It states that with high probability the final performance of the policy found by the algorithm can be made as close to a constant times the inherent Bellman error of the function space $\mathcal{F}$ as desired by selecting a sufficiently high number of samples. Hence, sampling-based FVI can be used to find near-optimal policies if $\mathcal{F}$ is sufficiently rich:

Theorem 2 *Consider an MDP satisfying Assumption A0 and A2. Fix $p \geq 1$, $\mu \in M(\mathcal{X})$ and let $V_0 \in \mathcal{F} \subset B(\mathcal{X};V_{\max})$. Then for any $\varepsilon,\delta > 0$, there exist integers K,M and N such that K is linear in $\log(1/\varepsilon)$, $\log V_{\max}$ and $\log(1/(1-\gamma))$, N, M are polynomial in $1/\varepsilon$, $\log(1/\delta)$, $\log(1/(1-\gamma))$, $V_{\max}$, $\hat{R}_{\max}$, $\log(|\mathcal{A}|)$, $\log(\mathcal{N}(c\varepsilon(1-\gamma)^2/(C_{\rho,\mu}^{1/p}\gamma),\mathcal{F},N,\mu))$ for some constant $c > 0$, such that if the multi-sample variant of sampling-based FVI is run with parameters $(N,M,\mu,\mathcal{F})$ and π_K is a policy greedy w.r.t. the Kth iterate then w.p. at least $1-\delta$,*

$$\|V^* - V^{\pi_K}\|_{p,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p}\, d_{p,\mu}(T\mathcal{F},\mathcal{F}) + \varepsilon.$$

If, instead of Assumption A2, Assumption A1 holds then w.p. at least $1-\delta$,

$$\|V^* - V^{\pi_K}\|_{\infty} \leq \frac{2\gamma}{(1-\gamma)^2} C_{\mu}^{1/p}\, d_{p,\mu}(T\mathcal{F},\mathcal{F}) + \varepsilon.$$

Further, the results continue to hold for the single-sample variant of sampling-based FVI with the exception that N depends on $\log(\mathcal{N}(c\varepsilon,\mathcal{F}_{T-},N,\mu))$ and M depends on $\log(\mathcal{N}(c'\varepsilon,\mathcal{F},M,\mu))$ for appropriate $c,c' > 0$.

9. The lack of existence of such solutions would probably preclude any sample-based estimation of the system.
10. Here we allow the sequence of policies to be changed with each m. It is an open question is a single sequence of policies would give the same result.
11. More generally, $d_{p,\mu}(\mathcal{G},\mathcal{F}) \stackrel{\text{def}}{=} \sup_{g\in\mathcal{G}} d_{p,\mu}(g,\mathcal{F}) \stackrel{\text{def}}{=} \sup_{g\in\mathcal{G}} \inf_{f\in\mathcal{F}} \|g-f\|_{p,\mu}$.

The proof is given in Appendix B. Assuming that the pseudo-dimension of the function-space $\mathcal{F}$ is finite as in Proposition 1, a close examination of the proof gives the following high-probability bound for the multi-sample variant:

$$\|V^* - V^{\pi_K}\|_{p,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} \, d_{p,\mu}(T\mathcal{F}, \mathcal{F}) + O(\gamma^K V_{\max})$$
$$+ \quad O\left\{ \left(\frac{V_{\mathcal{F}^+}}{N} (\log(N) + \log(K/\delta)) \right)^{1/2p} + \left(\frac{1}{M} (\log(N|\mathcal{A}|) + \log(K/\delta)) \right)^{1/2} \right\}. \qquad (9)$$

Here N, M, K are arbitrary integers and the bound holds w.p. $1-\delta$. The first term bounds the approximation error, the second arises due to the finite number of iterations, while the last two terms bound the estimation error.

This form of the bound allows us to reason about the likely best choice of N and M given a fixed budget of $n = K \times N \times M$ samples (or $\hat{n} = N \times M$ samples per iteration). Indeed, optimizing the bound yields that the best choice of N and M (apart from constants) is given by $N = (V_{\mathcal{F}^+})^{1/(p+1)} \hat{n}^{p/(p+1)}$, $M = (\hat{n}/V_{\mathcal{F}^+})^{1/(p+1)}$, resulting in the bound $(n/(KV_{\mathcal{F}^+}))^{-1/(2p+2)}$ for the estimation error, disregarding logarithmic terms. Note that the choice of N, M does not influence the other error terms.

Now, let us consider the single-sample variant of FVI. A careful inspection of the proof results in an inequality identical to (9) just with the pseudo-dimension of $\mathcal{F}$ replaced by the pseudo-dimension of $\mathcal{F}^-$ and $1/M$ replaced by $V_{\mathcal{F}^+}/M$. We may again ask the question of how to choose N, M, given a fixed-size budget of $n = N \times M$ samples. The formulae are similar to the previous ones. The resulting optimized bound on the estimation error is $(n/(V_{\mathcal{F}^-} V_{\mathcal{F}^+}))^{-1/(2p+2)}$. It follows that given a fixed budget of n samples provided that $K > V_{\mathcal{F}^-}$ the bound for the single-sample variant is better than the one for the multi-sample variant. In both cases a logical choice is to set K to minimize the respective bounds. In fact, the optimal choice turns out to be $K \sim 1/\log(1/\gamma) \approxeq 1/(1-\gamma)$ in both cases. Hence as γ approaches one, the single-sample variant of FVI can be expected to become more efficient, provided that everything else is kept the same. It is interesting to note that as γ becomes larger the number of times the samples are reused increases, too. That the single-sample variant becomes more efficient is because the variance reduction effect of sample reuse is stronger than the increase of the bias. Our computer simulations (Section 9) confirm this experimentally.

Another way to use the above bound is to make comparisons with the rates available in non-parametric regression: First, notice that the approximation error of $\mathcal{F}$ is defined as the inherent Bellman error of $\mathcal{F}$ instead of using an external reference class. This seems reasonable since we are trying to find an approximate fixed point of T within $\mathcal{F}$. The estimation error, for a sample size of n, can be seen to be bounded by $O(n^{-1/(2(p+1))})$, which for $p = 2$ gives $O(n^{-1/6})$. In regression, the comparable error (when using a bounding technique similar to ours) is bounded by $n^{-1/4}$ (Györfi et al., 2002). With considerably more work, using the techniques of Lee et al. (1996) (see also Chapter 11 of Györfi et al., 2002) in regression it is possible to get a rate of $n^{-1/2}$, at the price of multiplying the approximation error by a constant larger than one. It seems possible to use these techniques to improve the exponent of N from $-1/2p$ to $-1/p$ in Equation (9) (at the price of increasing the influence of the approximation error). Then the new rate would become $n^{-1/4}$. This is still worse than the best possible rate for non-parametric regression. The additional factor comes from the need to use the samples to control the bias of the target values (i.e., that we need $M \to \infty$). Thus, in the case of FVI, the inferior rate as compared with regression seems unavoidable. By

switching from state value functions to action-value functions it seems quite possible to eliminate this inefficiency. In this case the capacity of the function space would increase (in particular, in Equation (9) $V_{\mathcal{F}^+}$ would be replaced by $|\mathcal{A}|V_{\mathcal{F}^+}$).

6. Randomized Policies

The previous result shows that by making the inherent Bellman error of the function space small enough, we can ensure a close-to-optimal performance if one uses a policy greedy w.r.t. the last value-function estimate, V_K. However, the computation of such a greedy policy requires the evaluation of some expectations, whose exact values are however often difficult to compute. In this section we show that by computations analogous to that used in obtaining the iterates we can compute a randomized near-optimal policy based on V_K.

Let us call an action a α-*greedy* w.r.t. the function V and state x, if

$$r(x,a)+\gamma\int V(y)P(dy|x,a)\geq (TV)(x)-\alpha.$$

Given V_K and a state $x\in\mathcal{X}$ we can use sampling to draw an α-greedy action w.p. at least $1-\lambda$ by executing the following procedure: Let $R_j^{x,a}\sim S(\cdot,x,a)$, $Y_j^{x,a}\sim P(\cdot|x,a)$, $j=1,2,\ldots,M'$ with $M'=M'(\alpha,\lambda)$ and compute the approximate value of a at state x using

$$Q_{M'}(x,a)=\frac{1}{M'}\sum_{j=1}^{M'}\left[R_j^{x,a}+\gamma V_K(Y_j^{x,a})\right].$$

Let the policy $\pi_{\alpha,\lambda}^K:\mathcal{X}\to\mathcal{A}$ be defined by

$$\pi_{\alpha,\lambda}^K(x)=\arg\max_{a\in\mathcal{A}}Q_{M'}(x,a).$$

The following result holds:

Theorem 3 *Consider an MDP satisfying Assumptions A0 and A2. Fix $p\geq 1$, $\mu\in M(\mathcal{X})$ and let $V_0\in\mathcal{F}\subset B(\mathcal{X};V_{\max})$. Select $\alpha=(1-\gamma)\varepsilon/8$, $\lambda=\frac{\varepsilon}{8}\frac{(1-\gamma)}{V_{\max}}$ and let $M'=O(|\mathcal{A}|\hat{R}_{\max}^2\log(|\mathcal{A}|/\lambda)/\alpha^2)$. Then, for any $\varepsilon,\delta>0$, there exist integers K,M and N such that K is linear in $\log(1/\varepsilon)$, $\log V_{\max}$ and $\log(1/(1-\gamma))$, N,M are polynomial in $1/\varepsilon$, $\log(1/\delta)$, $1/(1-\gamma)$, $V_{\max}$, $\hat{R}_{\max}$, $\log(|\mathcal{A}|)$, $\log(\mathcal{N}(c\varepsilon(1-\gamma)^2/C_{\rho,\mu}^{1/p}),\mathcal{F},\mu)))$ for some $c>0$, such that if $\{V_k\}_{k=1}^K$ are the iterates generated by multi-sample FVI with parameters $(N,M,K,\mu,\mathcal{F})$ then for the policy $\pi_{\alpha,\lambda}^K$ as defined above, w.p. at least $1-\delta$, we have*

$$\left\|V^*-V^{\pi_{\alpha,\lambda}^K}\right\|_{p,\mu}\leq\frac{4\gamma}{(1-\gamma)^2}C_{\rho,\mu}^{1/p}d_{p,\mu}(T\mathcal{F},\mathcal{F})+\varepsilon.$$

An analogous result holds for the supremum-norm loss under Assumptions A0 and A1 with $C_{\rho,\mu}$ replaced by C_μ.

The proof can be found in Appendix C.

A similar result holds for the single-sample variant of FVI. We note that in place of the above uniform sampling model one could also use the Median Elimination Algorithm of Even-Dar et al. (2002), resulting in a reduction of M' by a factor of $\log(|\mathcal{A}|)$. However, for the sake of compactness we do not explore this option here.

7. Asymptotic Consistency

A highly desirable property of any learning algorithm is that as the number of samples grows to infinity, the error of the algorithm should converge to zero; in other words, the algorithm should be *consistent*. Sampling based FVI with a *fixed* function space $\mathcal{F}$ is not consistent: Our previous results show that in such a case the loss converges to $\frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} d_{p,\mu}(T\mathcal{F},\mathcal{F})$. A simple idea to remedy this situation is to let the function space grow with the number of samples. In regression the corresponding method was proposed by Grendander (1981) and is called the *method of sieves*. The purpose of this section is to show that FVI combined with this method gives a consistent algorithm for a large class of MDPs, namely for those that have Lipschitzian rewards and transitions. It is important to emphasize that although the results in this section assume these smoothness conditions, the method itself does not require the knowledge of the smoothness factors. It is left for future work to determine whether similar results hold for larger classes of MDPs.

The smoothness of the transition probabilities and rewards is defined w.r.t. changes in the initial state: $\forall (x,x',a) \in \mathcal{X}\times\mathcal{X}\times\mathcal{A}$,

$$\begin{aligned} \|P(\cdot|x,a) - P(\cdot|x',a)\| &\leq L_P \left\|x - x'\right\|^{\alpha}, \\ |r(x,a) - r(x',a)| &\leq L_r \left\|x - x'\right\|^{\alpha}. \end{aligned}$$

Here $\alpha, L_P, L_r > 0$ are the unknown smoothness parameters of the MDP and $\|P(\cdot|x,a) - P(\cdot|x',a)\|$ denotes the total variation norm of the signed measure $P(\cdot|x,a) - P(\cdot|x',a)$.[12]

The method is built on the following observation: If the MDP is smooth in the above sense and if $V \in B(\mathcal{X})$ is uniformly bounded by $V_{\max}$ then TV is $L = (L_r + \gamma V_{\max} L_P)$-Lipschitzian (with exponent $0 < \alpha \leq 1$):

$$|(TV)(x) - (TV)(x')| \leq (L_r + \gamma V_{\max} L_P)\|x - x'\|^{\alpha}, \quad \forall x, x' \in \mathcal{X}.$$

Hence, if $\mathcal{F}_n$ is restricted to $V_{\max}$-bounded functions then $T\mathcal{F}_n \stackrel{\text{def}}{=} \{TV \,|\, V \in \mathcal{F}_n\}$ contains L-Lipschitz $V_{\max}$-bounded functions only:

$$T\mathcal{F}_n \subset \mathrm{Lip}(\alpha; L, V_{\max}) \stackrel{\text{def}}{=} \{ f \in B(\mathcal{X}) \,|\, \quad \|f\|_\infty \leq V_{\max}, |f(x) - f(y)| \leq L\|x - y\|^{\alpha} \}.$$

By the definition of $d_{p,\mu}$,

$$d_{p,\mu}(T\mathcal{F}_n, \mathcal{F}_n) \leq d_{p,\mu}(\mathrm{Lip}(\alpha; L, V_{\max}), \mathcal{F}_n).$$

Hence if we make the right-hand side converge to zero as $n \to \infty$ then so will do $d_{p,\mu}(T\mathcal{F}_n, \mathcal{F}_n)$. The quantity, $d_{p,\mu}(\mathrm{Lip}(\alpha; L, V_{\max}), \mathcal{F}_n)$ is nothing but the approximation error of functions in the Lipschitz class $\mathrm{Lip}(\alpha; L, V_{\max})$ by elements of $\mathcal{F}_n$. Now, $d_{p,\mu}(\mathrm{Lip}(\alpha; L, V_{\max}), \mathcal{F}_n) \leq d_{p,\mu}(\mathrm{Lip}(\alpha; L), \mathcal{F}_n)$, where $\mathrm{Lip}(\alpha; L)$ is the set of Lipschitz-functions with Lipschitz constant L and we exploited that $\mathrm{Lip}(\alpha, L) = \cup_{V_{\max}>0} \mathrm{Lip}(\alpha; L, V_{\max})$. In approximation theory an approximation class $\{\mathcal{F}_n\}$ is said to be *universal* if for any $\alpha, L > 0$,

$$\lim_{n\to\infty} d_{p,\mu}(\mathrm{Lip}(\alpha; L), \mathcal{F}_n) = 0.$$

12. Let μ be a signed measure over $\mathcal{X}$. Then the total variation measure, $|\mu|$ of μ is defined by $|\mu|(B) = \sup \sum_{i=1}^{\infty} |\mu(B_i)|$, where the supremum is taken over all at most countable partitions of B into pairwise disjoint parts from the Borel sets over $\mathcal{X}$. The total variation norm $\|\mu\|$ of μ is $\|\mu\| = |\mu|(\mathcal{X})$.

For a large variety of approximation classes (e.g., approximation by polynomials, Fourier basis, wavelets, function dictionaries) not only universality is established, but variants of Jackson's theorem give us rates of convergence of the approximation error: $d_{p,\mu}(\mathrm{Lip}(\alpha;L),\mathcal{F}_n) = O(Ln^{-\alpha})$ (e.g., DeVore, 1997).

One remaining issue is that classical approximation spaces are not uniformly bounded (i.e., the functions in them do not assume a uniform bound), while our previous argument showing that the image space $T\mathcal{F}_n$ is a subset of Lipschitz functions critically relies on that $\mathcal{F}_n$ is uniformly bounded. One solution is to use truncations: Let $\mathcal{T}_{V_{\max}}$ be the truncation operator,

$$\mathcal{T}_{V_{\max}} r = \begin{cases} \mathrm{sign}(r) V_{\max}, & \text{if } |r| > V_{\max}, \\ r, & \text{otherwise.} \end{cases}$$

Now, a simple calculation shows that

$$d_{p,\mu}(\mathrm{Lip}(\alpha;L) \cap B(\mathcal{X};V_{\max}), \mathcal{T}_{V_{\max}}\mathcal{F}_n) \le d_{p,\mu}(\mathrm{Lip}(\alpha;L),\mathcal{F}_n),$$

where $\mathcal{T}_{V_{\max}}\mathcal{F}_n = \{\mathcal{T}_{V_{\max}} f \mid f \in \mathcal{F}_n\}$. This, together with Theorem 2 gives rise to the following result:

Corollary 4 *Consider an MDP satisfying Assumptions A0 and A2 and assume that both its immediate reward function and transition kernel are Lipschitzian. Fix $p \ge 1$, $\mu \in M(\mathcal{X})$ and let $\{\mathcal{F}_n\}$, be a universal approximation class such that the pseudo-dimension of $\mathcal{T}_{V_{\max}}\mathcal{F}_n$ grows sublinearly in n. Then, for each $\varepsilon,\delta > 0$ there exist an index n_0 such that for any $n \ge n_0$ there exist integers K,N,M that are polynomial in $1/\varepsilon$,$\log(1/\delta)$, $1/(1-\gamma)$, $V_{\max}$, $\hat{R}_{\max}$, $\log(|\mathcal{A}|)$, and $V_{(\mathcal{T}_{V_{\max}}\mathcal{F}_n)^+}$ such that if V_K is the output of multi-sample FVI when it uses the function set $\mathcal{T}_{V_{\max}}\mathcal{F}_n$ and $X_i \sim \mu$ then $\|V^* - V^{\pi_K}\|_{p,\rho} \le \varepsilon$ holds w.p. at least $1-\delta$. An identical result holds for $\|V^* - V^{\pi_K}\|_\infty$ when Assumption A2 is replaced by Assumption A1.*

The result extends to single-sample FVI as before.

One aspect in which this corollary is not satisfactory is that solving the optimization problem defined by Equation (1) over $\mathcal{T}_{V_{\max}}\mathcal{F}_n$ is computationally challenging even when $\mathcal{F}_n$ is a class of linearly parameterized functions and $p = 2$. One idea is to do the optimization first over $\mathcal{F}_n$ and then truncate the obtained functions. The resulting procedure can be shown to be consistent (cf., Chapter 10 of Györfi et al., 2002, for an alike result in a regression setting).

It is important to emphasize that the construction used in this section is just one example of how our main result may lead to consistent algorithms. An immediate extension of the present work would be to target the best possible convergence rates for a given MDP by using penalized estimation. We leave the study of such methods for future work.

8. Discussion of Related Work

Sampling based FVI has roots that date back to the early days of dynamic programming. One of the first examples of using value-function approximation methods is the work of Samuel who used both linear and non-linear methods to approximate value functions in his programs that learned to play the game of checkers (Samuel, 1959, 1967). At the same time, Bellman and Dreyfus (1959) explored the use of polynomials for accelerating dynamic programming. Both in these works and also in most later works (e.g., Reetz, 1977; Morin, 1978) FVI with representative states was considered.

Of these authors, only Reetz (1977) presents theoretical results who, on the other hand, considered only one-dimensional feature spaces.

FVI is a special case of *approximate value iteration* (AVI) which encompasses any algorithm of the form $V_{t+1} = TV_t + \varepsilon_t$, where the errors ε_t are controlled in some way. If the error terms, ε_t, are bounded in supremum norm, then a straightforward analysis shows that asymptotically, the worst-case performance-loss for the policy greedy w.r.t. the most recent iterates can be bounded by $\frac{2\gamma}{(1-\gamma)^2} \sup_{t\geq 1} \|\varepsilon_t\|_\infty$ (e.g., Bertsekas and Tsitsiklis, 1996). When V_{t+1} is the best approximation of TV_t in $\mathcal{F}$ then $\sup_{t\geq 1} \|\varepsilon_t\|_\infty$ can be upper bounded by the inherent Bellman error $d_\infty(T\mathcal{F}, \mathcal{F}) = \sup_{f\in\mathcal{F}} \inf_{g\in\mathcal{F}} \|g - Tf\|_\infty$ and we get the loss-bound $\frac{2\gamma}{(1-\gamma)^2} d_\infty(T\mathcal{F}, \mathcal{F})$. Apart from the smoothness factors ($C_{\rho,\mu}$, C_μ) and the estimation error term, our loss-bounds have the same form (cf., Equation 9). In particular, if μ is absolutely continuous w.r.t. the Lebesgue measure then letting $p \to \infty$ allows us to recover these previous bounds (since then $C_\mu^{1/p} d_{p,\mu}(T\mathcal{F}, \mathcal{F}) \to d_\infty(T\mathcal{F}, \mathcal{F})$). Further, we expect that the p-norm bounds would be tighter since the supremum norm is sensitive to outliers.

A different analysis, originally proposed by Gordon (1995) and Tsitsiklis and Van Roy (1996), goes by assuming that the iterates satisfy $V_{t+1} = \Pi TV_t$, where Π is an operator that maps bounded functions to the function space $\mathcal{F}$. While Gordon (1995) and Tsitsiklis and Van Roy (1996) considered the planning scenario with known dynamics and making use of a set of representative states, subsequent results by Singh et al. (1995), Ormoneit and Sen (2002) and Szepesvári and Smart (2004) considered less restricted problem settings, though none of these authors presented finite-sample bounds. The main idea in these analyses is that the above iterates must converge to some limit V_∞ if the composite operator ΠT is a supremum-norm contraction. Since T is a contraction, this holds whenever Π is a supremum-norm non-expansion. In this case, the loss of using the policy greedy w.r.t. V_∞ can be bounded by $\frac{4\gamma}{(1-\gamma)^2}\varepsilon_\Pi$, where ε_Π is the best approximation to V^* by fixed points of Π: $\varepsilon_\Pi = \inf_{f\in\mathcal{F}:\Pi f=f} \|f - V^*\|_\infty$ (e.g., Tsitsiklis and Van Roy, 1996, Theorem 2).

In practice a special class of approximation methods called *averagers* are used (Gordon, 1995). For these methods Π is guaranteed to be a non-expansion. Kernel regression methods, such as k-nearest neighbors smoothing with fixed centers, tree based smoothing (Ernst et al., 2005), or linear interpolation with a fixed set of basis functions such as spline interpolation with fixed knots all belong to this class. In all these examples Π is a linear operator and takes the form $\Pi f = \alpha + \sum_{i=1}^n (L_i f)\phi_i$ with some function α, appropriate basis functions, ϕ_i, and linear functionals L_i ($i = 1, 2, \ldots, n$). One particularly interesting case is when $L_i f = f(x_i)$ for some points $\{x_i\}$, $\phi_0 \geq 0$, $\sum_i \phi_i \equiv 1$, $\alpha \equiv 0$, $(\Pi f)(x_i) = f(x_i)$ and $(\phi_i(x_j))_{ij}$ has full rank. In this case all members of the space spanned by the basis functions $\{\phi_i\}$ are fixed points of Π. Hence $\varepsilon_\Pi = d_\infty(\mathrm{span}(\phi_1, \ldots, \phi_n), V^*)$ and so the loss of the procedure is directly controlled by the size of $\mathcal{F}_n = \mathrm{span}(\phi_1, \ldots, \phi_n)$.

Let us now discuss the choice of the function spaces in averagers and sampling-based FVI. In the case of averagers, the class is restricted, but the approximation requirement, making ε_Π small, seems to be easier to satisfy than the corresponding requirement which asks for making the inherent Bellman residual of the function space $\mathcal{F}_n$ small. We think that in the lack of knowledge of V^* this advantage might be minor and can be offset by the larger freedom to choose $\mathcal{F}_n$ (i.e., nonlinear, or kernel-based methods are allowed). In fact, when V^* is unknown one must resort to the generic properties of the class of MDPs considered (e.g., smoothness) in order to find the appropriate function space. Since the optimal policy is unknown, too, it is not quite immediate that the fact that only a single function (that depends on an unknown MDP) must be well approximated should be an advantage. Still, one may argue that the self-referential nature of the inherent Bellman-

error makes the design for sampling-based FVI harder. As we have shown in Section 7, provided that the MDPs are smooth, designing these spaces is not necessarily harder than designing a function approximator for some regression task.

Let us now discuss some other related works where the authors consider the error resulting from some Monte-Carlo procedure. One set of results closely related to the ones presented here is due to Tsitsiklis and Roy (2001). These authors studied sampling-based fitted value iteration with linear function approximators. However, they considered a different class of MDPs: finite horizon, optimal stopping with discounted total rewards. In this setting the next-state distribution under the condition of not stopping is uncontrolled—the state of the market evolves independently of the decision maker. Tsitsiklis and Roy (2001) argue that in this case it is better to sample full trajectories than to generate samples in some other, arbitrary way. Their algorithm implements approximate backward propagation of the values (by L^2 fitting with linear function approximators), exploiting that the problem has a fixed, finite horizon. Their main result shows that the estimation error converges to zero w.p. 1 as the number of samples grows to infinity. Further, a bound on the asymptotic performance is given. Due to the special structure of the problem, this bound depends only on how well the optimal value function is approximated by the chosen function space. Certainly, because of the known counterexamples (Baird, 1995; Tsitsiklis and Van Roy, 1996), we cannot hope such a bound to hold in the general case.

The work presented here builds on our previous work. For finite state-space MDPs, Munos (2003, 2005) considered planning scenarios with known dynamics analyzing the stability of both approximate policy iteration and value iteration with weighted L^2 (resp., L^p) norms. Preliminary versions of the results presented here were published in Szepesvári and Munos (2005). Using techniques similar to those developed here, recently we have proved results for the learning scenario when only a single trajectory of some fixed behavior policy is known (Antos et al., 2006). We know of no other work that would have considered the weighted p-norm error analysis of sampling-based FVI for continuous state-space MDPs and in a discounted, infinite-horizon settings.

One work where the author studies fitted value iteration and which comes with a finite-sample analysis is by Murphy (2005), who, just like Tsitsiklis and Roy (2001), studied finite horizon problems with no discounting.[13] Because of the finite-horizon setting, the analysis is considerable simpler (the algorithm works backwards). The samples come from a number of independent trajectories just like in the case of Tsitsiklis and Roy (2001). The error bounds come in the form of performance differences between a pair of greedy policies: One of the policies from the pair is greedy w.r.t. the value function returned by the algorithm, while the other is greedy w.r.t. to some arbitrary 'test' function from the function set considered in the algorithm. The derived bound shows that the number of samples needed is exponential in the horizon of the problem and is proportional to ε^{-4}, where ε is the desired estimation error. The approximation error of the procedure, however, is not considered: Murphy suggests that the optimal action-value function could be added at virtually no cost to the function sets used by the algorithm. Accordingly, her bounds scale only with the complexity of the function class and do not scale directly with the dimensionality of the state space (just through

13. We learnt of the results of Murphy (2005) after submitting our paper. One interesting aspect of this paper is that the results are presented for partially observable problems. However, since all value-function approximation methods introduce state aliasing anyway, results worked out for the fully observable case carry through to the limited feedback case without any change except that the approximation power of the function approximation method is further limited by the information that is fed into the approximator. Based on this observation one may wonder if it is possible to get consistent algorithms that avoid an explicit 'state estimation' component. However, this remains the subject of future work.

the complexity of the function class). One interpretation of this is that if we are lucky to choose a function approximator so that the optimal value function (at all stages) can be represented exactly with it then the rate of convergence can be fast. In the unlucky case, no bound is given. We will come back to the discussion of worst-case sample complexity after discussing the work by Kakade and Langford (Kakade and Langford, 2002; Kakade, 2003).

The algorithm considered by Kakade and Langford is called conservative policy iteration (CPI). The algorithm is designed for discounted infinite horizon problems. The general version searches in a fixed policy space, Π, in each step an optimizer picking a policy that maximizes the average of the empirical advantages of the previous policy at a number of states (basepoints) sampled from some distribution. These advantages could be estimated by sampling sufficiently long trajectories from the basepoints. The policy picked this way is mixed into the previous policy to prevent performance drops due to drastic changes, hence the name of the algorithm.

Theorems 7.3.1 and 7.3.3 Kakade (2003) give bounds on the loss of using the policy returned by this procedure relative to using some other policy π (e.g., a near-optimal policy) as a function of the total variation distance between ν, the distribution used to sample the basepoints (this distribution is provided by the user), and the discounted future-state distribution underlying π when π is started from a random state sampled from ν ($d_{\pi,\nu}$). Thus, unlike in the present paper the error of the procedure can only be controlled by finding a distribution that minimizes the distance to $d_{\pi,\gamma}$, where π is a near-optimal policy. This might be as difficult as the problem of finding a good policy. Theorem 6.2 in Kakade and Langford (2002) bounds the expected performance loss under ν as a function of the imprecision of the optimizer and the Radon-Nykodim derivative of $d_{\pi^*,\nu}$ and $d_{\pi_0,\nu}$, where π_0 is the policy returned by the algorithm. However this result applies only to the case when the policy set is unrestricted, and hence the result is limited to finite MDPs.

Now let us discuss the worst-case sample complexity of solving MDPs. A very simple observation is that it should be impossible to get bounds that scale polynomially with the dimension of the state-space unless special conditions are made on the problem. This is because the problem of estimating the value function of a policy in a trivial finite-horizon problem with a single time step is equivalent to regression. Hence known lower bounds for regression must apply to RL, as well (see Stone, 1980, 1982 and Chapter 3 of Györfi, Kohler, Krzyżak, and Walk, 2002 for such bounds). In particular, from these bounds it follows that the minimax sample complexity of RL is exponential in the dimensionality of the state space provided the class of MDPs is large enough. Hence, it is not surprising that unless very special conditions are imposed on the class of MDPs considered, FVI and its variants are subject to the curse-of-dimensionality. One way to help with this exponential scaling is when the algorithm is capable of taking advantage of the possible advantageous properties of the MDP to be solved. In our opinion, one major open problem in RL is to design such methods (or to show that some existing method possesses this property).

The curse-of-dimensionality is not specific to FVI variants. In fact, a result of Chow and Tsitsiklis (1989) states the following: Consider a class of MDPs with $\mathcal{X} = [0,1]^d$. Assume that for any MDP in the class, the transition probability kernel underlying the MDP has a density w.r.t. the Lebesgue measure and these densities have a common upper bound. Further, the MDPs within the class are assumed to be uniformly smooth: for any MDP in the class the Lipschitz constant of the reward function of the MDP is bounded by an appropriate constant and the same holds for the Lipschitz constant of the density function. Fix a desired precision, ε. Then, any algorithm that is guaranteed to return an ε-optimal approximation to the optimal value function must query (sample) the reward function and the transition probabilities at least $\Omega(1/\varepsilon^d)$-times, for some MDP within the

class considered. Hence, even classes of smooth MDPs with uniformly bounded transition densities have very hard instances.

The situation changes dramatically if one is allowed to interleave computations and control. In this case, building on the *random-discretization method* of Rust (1996b), it is possible to achieve near-optimal behavior by using a number of samples per step that scales polynomially in the important quantities (Szepesvári, 2001). In particular, this result shows that it suffices to let the number of samples scale linearly in the dimensionality of the state space. Interestingly, this result holds for a class of MDPs that subsumes the one considered by Chow and Tsitsiklis (1989). The random-discretization method requires that the MDPs in the class satisfy Assumption A1 with a common constant and also the knowledge of the density underlying the transition probability kernel. When the density does not exist or is not known, it could be estimated. However, estimating conditional density functions itself is also subject to the curse of dimensionality, hence, the advantage of the random-discretization method melts away in such situations, making sampling-based FVI a viable alternative. This is the case indeed, since the results presented here require weaker assumptions on the transition probability kernel (Assumption A2) and thus apply to a broader class of problems.

Another method that interleaves computations and control is the sparse trajectory-tree method of Kearns et al. (1999). The sparse trajectory-tree method builds a random lookahead tree to compute sample based approximation to the values of each of the actions available at the current state. This method does not require the knowledge of the density underlying the transition probability kernel, nor does it require any assumptions on the MDP. Unfortunately, the computational cost of this method scales exponentially in the 'ε-horizon', $\log_\gamma(R_{\max}/(\varepsilon(1-\gamma)))$. This puts severe limits on the utility of this method when the discount factor is close to one and the number of actions is moderate. Kearns et al. (1999) argue that without imposing additional assumptions (i.e., smoothness) on the MDP the exponential dependency on the effective horizon time is unavoidable (a similar dependence on the horizon shows up in the bounds of Murphy, 2005 and Kakade, 2003).

9. Simulation Study

The purpose of this section is to illustrate the tradeoffs involved in using FVI. Since identical or very similar algorithms have been used successfully in many prior empirical studies (e.g., Longstaff and Shwartz, 2001; Haugh, 2003; Jung and Uthmann, 2004), we do not attempt a thorough empirical evaluation of the algorithm.

9.1 An Optimal Replacement Problem

The problem used as a testbed is a simple one-dimensional optimal replacement problem, described for example by Rust (1996a). The system has a one-dimensional state. The state variable, $x_t \in \mathbb{R}_+$, measures the accumulated utilization of a product, such as the odometer reading on a car. By convention, we let $x_t = 0$ denote a brand new product. At each time step, t, there are two possible decisions: either keep ($a_t = \mathbf{K}$) or replace ($a_t = \mathbf{R}$) the product. This latter action implies an additional cost C of selling the existing product and replacing it by a new one. The transition to

a new state occurs with the following exponential densities:

$$p(y|x,\mathbf{K}) = \begin{cases} \beta e^{-\beta(y-x)}, & \text{if } y \geq x; \\ 0, & \text{if } y < x, \end{cases}$$
$$p(y|x,\mathbf{R}) = \begin{cases} \beta e^{-\beta y}, & \text{if } y \geq 0; \\ 0, & \text{if } y < 0. \end{cases}$$

The reward function is $r(x,\mathbf{K}) = -c(x)$, where $c(x)$ represents the cost of maintaining the product. By assumptions, c is monotonically increasing. The reward associated with the replacement of the product is independent of the state and is given by $r(x,\mathbf{R}) = -C - c(0)$.

The optimal value function solves the Bellman optimality equation:

$$V^*(x) = \max\Big[-c(x) + \gamma \int_x^\infty p(y|x,\mathbf{K})V^*(y)dy, -C - c(0) + \gamma \int_0^\infty p(y|x,\mathbf{R})V^*(y)dy\Big].$$

Here the first argument of max represents the total future reward given that the product is not replaced, while the second argument gives the total future reward provided that the product is replaced. This equation has a closed form solution:

$$V^*(x) = \begin{cases} \int_x^{\bar{x}} \frac{c'(y)}{1-\gamma}(1-\gamma e^{-\beta(1-\gamma)(y-x)})dy - \frac{c(\bar{x})}{1-\gamma}, & \text{if} \quad x \leq \bar{x}; \\ \frac{-c(\bar{x})}{1-\gamma}, & \text{if} \quad x > \bar{x}, \end{cases}$$

Here $\bar{x}$ is the unique solution to

$$C = \int_0^{\bar{x}} \frac{c'(y)}{1-\gamma}(1-\gamma e^{-\beta(1-\gamma)y})dy.$$

The optimal policy is $\pi^*(x) = \mathbf{K}$ if $x \in [0,\bar{x}]$, and $\pi^*(x) = \mathbf{R}$ if $x > \bar{x}$.

9.2 Results

We chose the numerical values $\gamma = 0.6$, $\beta = 0.5$, $C = 30$, $c(x) = 4x$. This gives $\bar{x} \simeq 4.8665$ and the optimal value function, plotted in Figure 2, is

$$V^*(x) = \begin{cases} -10x + 30(e^{0.2(x-\bar{x})} - 1), & \text{if} \quad x \leq \bar{x}; \\ -10\bar{x}, & \text{if} \quad x > \bar{x}. \end{cases}$$

We consider approximation of the value function using polynomials of degree l. As suggested in Section 7, we used truncation. In order to make the state space bounded, we actually consider a problem that closely approximates the original one. For this we fix an upper bound for the states, $x_{\max} = 10 \gg \bar{x}$, and modify the problem definition such that if the next state y happens to be outside of the domain $[0, x_{\max}]$ then the product is replaced immediately, and a new state is drawn as if action $\mathbf{R}$ were chosen in the previous time step. By the choice of $x_{\max}$, $\int_{x_{\max}}^\infty p(dy|x,\mathbf{R})$ is negligible and hence the optimal value function of the altered problem closely matches that of the original problem when it is restricted to $[0, x_{\max}]$.

We chose the distribution μ to be uniform over the state space $[0, x_{\max}]$. The transition density functions $p(\cdot|x,a)$ are bounded by β, thus Assumption A1 holds with $C_\mu = \beta x_{\max} = 5$.

Figure 2 illustrates two iterates ($k = 2$ and $k = K = 20$) of the multi-sample version of sampling-based FVI: the dots represents the points $\{(X_n, \hat{V}_{M,k+1}(X_n))\}_{1 \leq n \leq N}$ for $N = 100$, where X_i is drawn

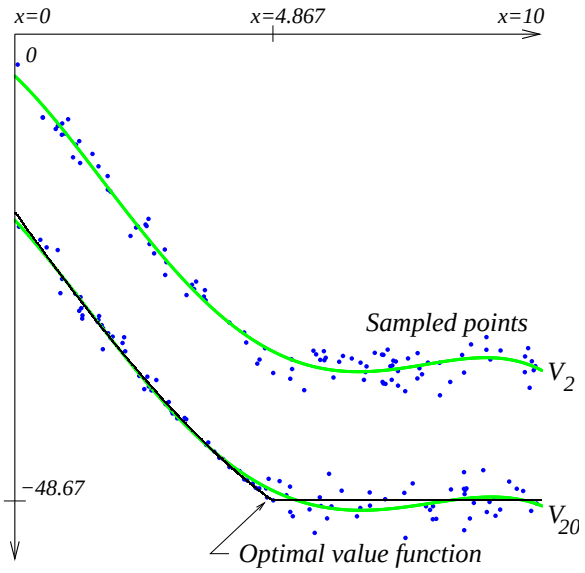

Figure 2: Illustration of two iteration steps of Sampling based FVI (up: $k = 2$, down: $k = 20$). The dots represent the pairs $(X_i, \hat{V}_{M,k}(X_i))$, $i = 1,\ldots,N$ based on $M = 10$ sampled transitions per basepoint and $N = 100$ basepoints. The grey curve is the best fit among polynomials of degree $l = 4$. The thin black curve is the optimal value function.

from μ and $\{\hat{V}_{M,k+1}(X_n)\}_{1\le n\le N}$ is computed using (2) with $V = V_k$ and $M = 10$ samples. The grey curve is the best fit (minimizing the least square error to the data, that is, $p = 2$) in $\mathcal{F}$ (for $l = 4$) and the thin black curve is the optimal value function.

Figure 3 shows the L_∞ approximation errors $||V^* - V_K||_\infty$ for different values of the degree l of the polynomial regression, and different values of the number of basepoints N and the number of sampled next states M. The number of iterations was set to $K = 20$. The reason that the figure shows the error of approximating V^* by V_K (i.e., $\varepsilon_K = \|V^* - V_K\|_\infty$) instead of $\|V^* - V^{\pi_K}\|_\infty$ is that in this problem this latter error converges very fast and thus is less interesting. (The technique developed in the paper can be readily used to derive a bound on the estimation error of V^*.) Of course, the performance loss is always upper bounded (in L_∞-norm) by the approximation error, thanks to the well-known bound (e.g., Bertsekas and Tsitsiklis, 1996): $||V^* - V^{\pi_K}||_\infty \le 2/(1-\gamma)||V^* - V_K||_\infty$.

From Figure 3 we observe when the degree l of the polynomials increases, the error decreases first because of the decrease of the inherent approximation error, but eventually increases because of overfitting. This graph thus illustrates the different components of the bound (9) where the approximation error term $d_{p,\mu}(T\mathcal{F}, \mathcal{F})$ decreases with l (as discussed in Section 7) whereas the estimation error bound, being a function of the pseudo-dimension of $\mathcal{F}$, increases with l (in such a linear approximation architecture $V_{\mathcal{F}^+}$ equals the number of basis function plus one, that is, $V_{\mathcal{F}^+} = l + 2$) with rate $O\big(\big(\frac{l+2}{N}\big)^{1/2p}\big) + O(1/M^{1/2})$, disregarding logarithmic factors. According to this bound, the estimation error decreases when the number of samples increases, which is corroborated by the experiments that show that overfitting decreases when the number of samples N, M increases. Note that truncation never happens except when the degree of the polynomial is very large compared with the number of samples.

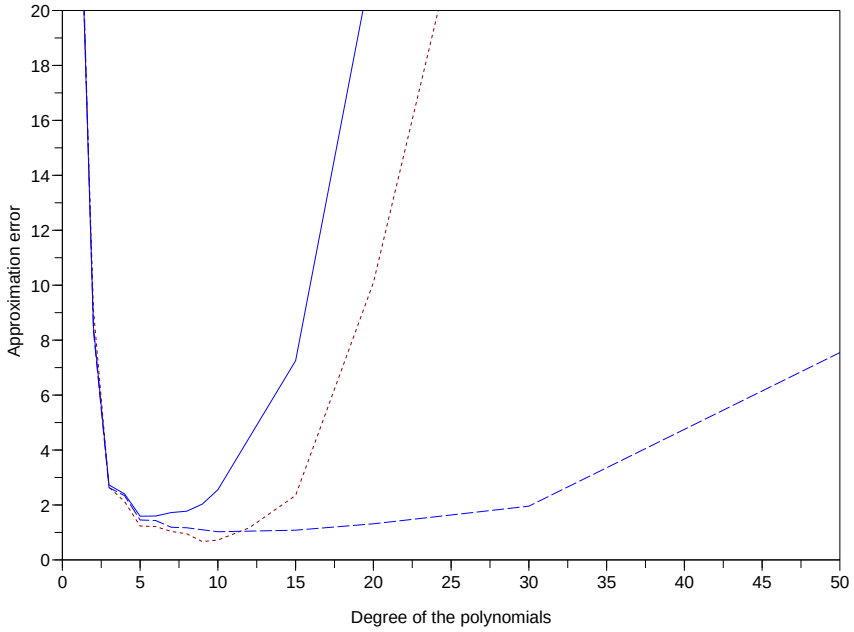

Figure 3: Approximation errors $||V^* - V_K||_\infty$ of the function V_K returned by sampling-based FVI after $K = 20$ iterations, for different values of the polynomials degree l, for $N = 100$, $M = 10$ (plain curve), $N = 100$, $M = 100$ (dot curve), and $N = 1000$, $M = 10$ (dash curve) samples. The plotted values are the average over 100 independent runs.

In our second set of experiments we investigated whether in this problem the single-sample or the multi-sample variant of the algorithm is more advantageous provided that sample collection is expensive or limited in some way.

Figure 4 shows the distributional character of $V_K - V^*$ as a function of the state. The order of the fitted polynomials is 5. The solid (black) curve shows the mean error (representing the bias) for 50 independent runs, the dashed (blue) curves show the upper and lower confidence intervals at 1.5-times the observed standard deviation, while the dash-dotted (red) curves show the minimum/maximum approximation errors. Note the peak at $\bar{x}$: The value function at this point is non-smooth, introducing a bias that converges to zero rather slowly (the same effect in Fourier analysis is known as the Gibbs phenomenon). It is also evident from the figure that the approximation error near the edges of the state space is larger. In polynomial interpolation for the uniform arrangements of the basepoints, the error actually blows up at the end of the intervals as the order of interpolation is increased (Runge's phenomenon). A general suggestion to avoid this is to increase the denseness of points near the edges or to introduce more flexible methods (e.g., splines). In FVI the edge effect is ultimately washed out, but it may still cause a considerable slow down of the procedure when the behavior of the value-function near the boundaries is critical.

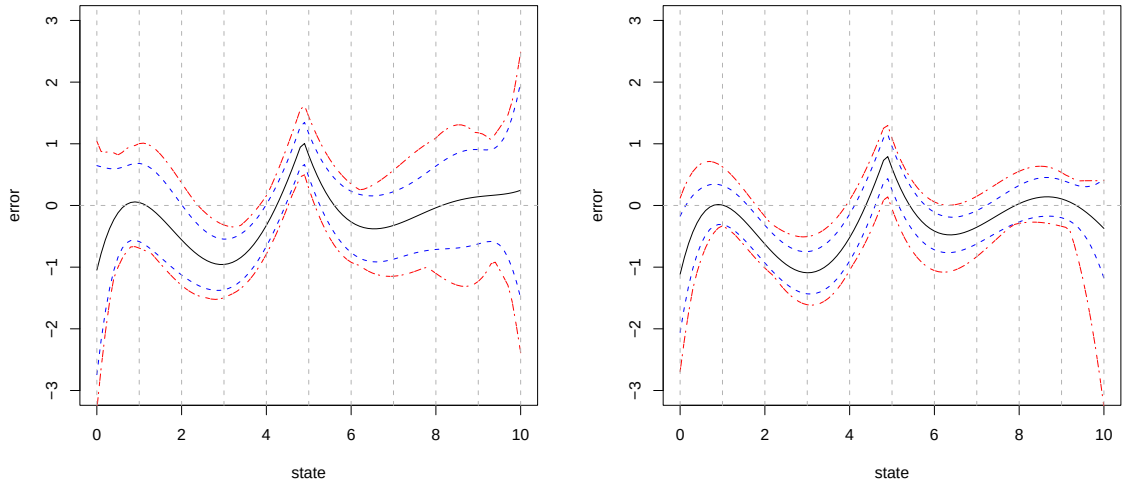

Figure 4: Approximation errors for the multi-sample (left figure) and the single-sample (right) variants of sampling based FVI. The figures show the distribution of errors for approximating the optimal value function as a function of the state, as measured using 50 independent runs. For both version, $N = 100$, $K = 10$. However, for the multi-sample variant $M = 10$, while for the single-sample variant $M = 100$, making the total number of samples used equal in the two cases.

Now, as to the comparison of the single- and multi-sample algorithms, it should be apparent from this figure that for this specific setup, the single-sample variant is actually preferable: The bias does not seem to increase much due to the reuse of samples, while the variance of the estimates decreases significantly.

10. Conclusions

We considered sampling-based FVI for discounted, large (possibly infinite) state space, finite-action Markovian Decision Processes when only a generative model of the environment is available. In each iteration, the image of the previous iterate under the Bellman operator is approximated at a finite number of points using a simple Monte-Carlo technique. A regression method is used then to fit a function to the data obtained. The main contributions of the paper are performance bounds for this procedure that holds with high probability. The bounds scale with the inherent Bellman error of the function space used in the regression step, and the stochastic stability properties of the MDP. It is an open question if the finiteness of the inherent Bellman error is necessary for the stability of FVI, but the counterexamples discussed in the introduction suggest that the inherent Bellman residual of the function space should indeed play a crucial role in the final performance of FVI. Even less is known about whether the stochastic stability conditions are necessary or if they can be relaxed.

We argued that by increasing the number of samples and the richness of the function space at the same time, the resulting algorithm can be shown to be consistent for a wide class of MDPs. The

derived rates show that, in line with our expectations, FVI would typically suffer from the curse-of-dimensionality except when some specific conditions (extreme smoothness, only a few state variables are relevant, sparsity, etc.) are met. Since these conditions could be difficult to verify a priori for any practical problem, adaptive methods are needed. We believe that the techniques developed in this paper may serve as a solid foundations for developing and studying such algorithms.

One immediate possibility along this line would be to extend our results to penalized empirical risk minimization when a penalty term penalizing the roughness of the candidate functions is added to the empirical risk. The advantage of this approach is that without any a priori knowledge of the smoothness class, the method allows one to achieve the optimal rate of convergence (see Györfi et al., 2002, Section 21.2).

Another problem left for future work is to improve the scaling of our bounds. An important open question is to establish tight lower bounds for the rate of convergence for value-function based RL methods.

There are other ways to improve the performance of our algorithm that are more directly related to specifics of RL. Both Tsitsiklis and Roy (2001) and Kakade (2003) argued that μ, the distribution used to sample the states should be selected to match the future state distribution of a (near-)optimal policy. Since the only way to learn about the optimal policy is by running the algorithm, one idea is to change the sampling distribution by moving it closer to the future-state distribution of the most recent policy. The improvement presumably manifests itself by decreasing the term including $C_{\rho,\mu}$. Another possibility is to adaptively choose M, the number of sampled next states based on the available local information like in active learning, hoping that this way the sample-efficiency of the algorithm could be further improved.

We would like to thank Barnabás Póczos and the anonymous reviewers for helpful comments, suggestions and discussions.

Appendix A. Proof of Lemma 1

In order to prove Lemma 1 we use the following inequality due to Pollard:

Theorem 5 (Pollard, 1984) *Let $\mathcal{F}$ be a set of measurable functions $f : \mathcal{X} \to [0,K]$ and let $\varepsilon > 0$, N be arbitrary. If X_i, $i = 1,\dots,N$ is an i.i.d. sequence taking values in the space $\mathcal{X}$ then*

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}}\left|\frac{1}{N}\sum_{i=1}^{N} f(X_i) - \mathbb{E}\left[f(X_1)\right]\right| > \varepsilon\right) \le 8\mathbb{E}\left[\mathcal{N}(\varepsilon/8, \mathcal{F}(X^{1:N}))\right] e^{-\frac{N\varepsilon^2}{128K^2}}.$$

Here one should perhaps work with outer expectations because, in general, the supremum of an uncountably many random variables cannot be guaranteed to be measurable. However, since for specific examples of function space $\mathcal{F}$, measurability can typically be established by routine separability arguments, we will altogether ignore these measurability issues in this paper.

Now, let us prove Lemma 1 that stated the finite-sample bound for a single iterate.

Proof Let Ω denote the sample space underlying the random variables. Let $\varepsilon'' > 0$ be arbitrary and let f^* be such that $\|f^* - TV\|_{p,\mu} \le \inf_{f\in\mathcal{F}} \|f - TV\|_{p,\mu} + \varepsilon''$. Define $\|\cdot\|_{p,\hat{\mu}}$ by

$$\|f\|_{p,\hat{\mu}}^p = \frac{1}{N}\sum_{i=1}^N |f(X_i)|^p.$$

We will prove the lemma by showing that the following sequence of inequalities hold simultaneously on a set of events of measure not smaller than $1-\delta$:

$$\begin{aligned}
\left\|V' - TV\right\|_{p,\mu} &\le \left\|V' - TV\right\|_{p,\hat{\mu}} + \varepsilon' && (10)\\
&\le \left\|V' - \hat{V}\right\|_{p,\hat{\mu}} + 2\varepsilon' && (11)\\
&\le \left\|f^* - \hat{V}\right\|_{p,\hat{\mu}} + 2\varepsilon' && (12)\\
&\le \|f^* - TV\|_{p,\hat{\mu}} + 3\varepsilon' && (13)\\
&\le \|f^* - TV\|_{p,\mu} + 4\varepsilon' && (14)\\
&= d_{p,\mu}(TV,\mathcal{F}) + 4\varepsilon' + \varepsilon''.
\end{aligned}$$

It follows then that $\|V' - TV\|_{p,\mu} \le \inf_{f\in\mathcal{F}} \|f - TV\|_{p,\mu} + 4\varepsilon' + \varepsilon''$ w.p. at least $1-\delta$. Since $\varepsilon'' > 0$ was arbitrary, it also follows that $\|V' - TV\|_{p,\mu} \le \inf_{f\in\mathcal{F}} \|f - TV\|_{p,\mu} + 4\varepsilon'$ w.p. at least $1-\delta$. Now, the Lemma follows by choosing $\varepsilon' = \varepsilon/4$.

Let us now turn to the proof of (10)–(14). First, observe that (12) holds due to the choice of V' since $\left\|V' - \hat{V}\right\|_{p,\hat{\mu}} \le \left\|f - \hat{V}\right\|_{p,\hat{\mu}}$ holds for all functions f from $\mathcal{F}$ and thus the same inequality holds for $f^* \in \mathcal{F}$, too.

Thus, (10)–(14) will be established if we prove that (10), (11), (13) and (14) all hold w.p. at least $1-\delta'$ with $\delta' = \delta/4$. Let

$$Q = \max\left(\left|\left\|V' - TV\right\|_{p,\mu} - \left\|V' - TV\right\|_{p,\hat{\mu}}\right|, \left|\|f^* - TV\|_{p,\mu} - \|f^* - TV\|_{p,\hat{\mu}}\right|\right).$$

We claim that

$$\mathbb{P}\left(Q > \varepsilon'\right) \le \delta', \tag{15}$$

where $\delta' = \delta/4$. From this, (10) and (14) will follow.

In order to prove (15) note that for all $\omega \in \Omega$, $V' = V'(\omega) \in \mathcal{F}$. Hence,

$$\sup_{f\in\mathcal{F}} \left|\|f - TV\|_{p,\mu} - \|f - TV\|_{p,\hat{\mu}}\right| \ge \left|\left\|V' - TV\right\|_{p,\mu} - \left\|V' - TV\right\|_{p,\hat{\mu}}\right|$$

holds pointwise in Ω. Therefore the inequality

$$\sup_{f\in\mathcal{F}} \left|\|f - TV\|_{p,\mu} - \|f - TV\|_{p,\hat{\mu}}\right| > Q \tag{16}$$

holds pointwise in Ω, too and hence

$$\mathbb{P}\left(Q > \varepsilon'\right) \le \mathbb{P}\left(\sup_{f\in\mathcal{F}} \left|\|f - TV\|_{p,\mu} - \|f - TV\|_{p,\hat{\mu}}\right| > \varepsilon'\right).$$

We claim that

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}}\left|\|f-TV\|_{p,\mu}-\|f-TV\|_{p,\hat{\mu}}\right|>\varepsilon'\right)\leq\mathbb{P}\left(\sup_{f\in\mathcal{F}}\left|\|f-TV\|_{p,\mu}^{p}-\|f-TV\|_{p,\hat{\mu}}^{p}\right|>(\varepsilon')^{p}\right). \tag{17}$$

Consider any event ω such that

$$\sup_{f\in\mathcal{F}}\left|\|f-TV\|_{p,\mu}-\|f-TV\|_{p,\hat{\mu}}\right|>\varepsilon'.$$

For any such event, ω, there exist a function $f'\in\mathcal{F}$ such that

$$\left|\|f'-TV\|_{p,\mu}-\|f'-TV\|_{p,\hat{\mu}}\right|>\varepsilon'.$$

Pick such a function. Assume first that $\|f'-TV\|_{p,\hat{\mu}}\leq\|f'-TV\|_{p,\mu}$. Hence, $\|f'-TV\|_{p,\hat{\mu}}+\varepsilon'<\|f'-TV\|_{p,\mu}$. Since $p\geq 1$, the elementary inequality $x^p+y^p\leq(x+y)^p$ holds for any non-negative numbers x,y. Hence we get $\|f'-TV\|_{p,\hat{\mu}}^{p}+\varepsilon^p\leq(\|f'-TV\|_{p,\hat{\mu}}+\varepsilon)^p<\|f'-TV\|_{p,\mu}^{p}$ and thus

$$\left|\|f'-TV\|_{p,\hat{\mu}}^{p}-\|f'-TV\|_{p,\mu}^{p}\right|>\varepsilon^p.$$

This inequality can be shown to hold by an analogous reasoning when $\|f'-TV\|_{p,\hat{\mu}}>\|f'-TV\|_{p,\mu}$.

Inequality (17) now follows since

$$\sup_{f\in\mathcal{F}}\left|\|f-TV\|_{p,\mu}^{p}-\|f-TV\|_{p,\hat{\mu}}^{p}\right|\geq\left|\|f'-TV\|_{p,\mu}^{p}-\|f'-TV\|_{p,\hat{\mu}}^{p}\right|.$$

Now, observe that $\|f-TV\|_{p,\mu}^{p}=\mathbb{E}\left[|(f(X_1)-(TV)(X_1))|^p\right]$, and $\|f-TV\|_{p,\hat{\mu}}^{p}$ is thus just the sample average approximation of $\|f-TV\|_{p,\mu}^{p}$. Hence, by noting that the covering number associated with $\{f-TV|f\in\mathcal{F}\}$ is the same as the covering number of $\mathcal{F}$, calling for Theorem 5 results in

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}}\left|\|f-TV\|_{p,\mu}^{p}-\|f-TV\|_{p,\hat{\mu}}^{p}\right|>(\varepsilon')^{p}\right)\leq 8\mathbb{E}\left[\mathcal{N}(\tfrac{(\varepsilon')^p}{8},\mathcal{F}(X^{1:N}))\right]e^{-\frac{N}{2}\left(\frac{1}{8}\left(\frac{\varepsilon'}{2V_{\max}}\right)^p\right)^2}.$$

By making the right-hand side upper bounded by $\delta'=\delta/4$ we find a lower bound on N, displayed in turn in (4). This finishes the proof of (15).

Now, let us prove inequalities (11) and (13). Let f denote an arbitrary random function such that $f=f(x;\omega)$ is measurable for each $x\in X$ and assume that f is uniformly bounded by $V_{\max}$. Making use of the triangle inequality

$$\left|\|f-g\|_{p,\hat{\mu}}-\|f-h\|_{p,\hat{\mu}}\right|\leq\|g-h\|_{p,\hat{\mu}},$$

we get that

$$\left|\|f-TV\|_{p,\hat{\mu}}-\|f-\hat{V}\|_{p,\hat{\mu}}\right|\leq\|TV-\hat{V}\|_{p,\hat{\mu}}. \tag{18}$$

Hence, it suffices to show that $\|TV-\hat{V}\|_{p,\hat{\mu}}\leq\varepsilon'$ holds w.p $1-\delta'$.

For this purpose we shall use Hoeffding's inequality (Hoeffding, 1963) and union bound arguments. Fix any index i ($1 \le i \le N$). Let $K_1 = \hat{R}_{\max} + \gamma V_{\max}$. Then, by assumption $R_j^{X_i,a} + \gamma V(Y_j^{X_i,a}) \in [-K_1, K_1]$ holds w.p. 1 and thus by Hoeffding's inequality,

$$\mathbb{P}\left(\left| \mathbb{E}\left[R_1^{X_i,a} + \gamma V(Y_1^{X_i,a}) \,|\, X^{1:N} \right] - \frac{1}{M} \sum_{j=1}^{M} R_j^{X_i,a} + \gamma V(Y_j^{X_i,a}) \right| > \varepsilon' \,|\, X^{1:N} \right) \le 2 e^{-\frac{2M(\varepsilon')^2}{K_1^2}}, \qquad (19)$$

where $X^{1:N} = (X_1, \ldots, X_N)$. Making the right-hand side upper bounded by $\delta'/(N|\mathcal{A}|)$ we find a lower bound on M (cf., Equation 5). Since

$$\left| (TV)(X_i) - \hat{V}(X_i) \right| \le \max_{a \in A} \left| \mathbb{E}\left[R_1^{X_i,a} + \gamma V(Y_1^{X_i,a}) \,|\, X^{1:N} \right] - \frac{1}{M} \sum_{j=1}^{M} \left[R_j^{X_i,a} + \gamma V(Y_j^{X_i,a}) \right] \right|$$

it follows by a union bounding argument that

$$\mathbb{P}\left(\left| (TV)(X_i) - \hat{V}(X_i) \right| > \varepsilon' \,|\, X^{1:N} \right) \le \delta'/N,$$

and hence another union bounding argument yields

$$\mathbb{P}\left(\max_{i=1,\ldots,N} \left| (TV)(X_i) - \hat{V}(X_i) \right|^p > (\varepsilon')^p \,|\, X^{1:N} \right) \le \delta'.$$

Taking the expectation of both sides of this inequality gives

$$\mathbb{P}\left(\max_{i=1,\ldots,N} \left| (TV)(X_i) - \hat{V}(X_i) \right|^p > (\varepsilon')^p \right) \le \delta'.$$

Hence also

$$\mathbb{P}\left(\frac{1}{N} \sum_{i=1}^{N} \left| (TV)(X_i) - \hat{V}(X_i) \right|^p > (\varepsilon')^p \right) \le \delta'$$

and therefore by (18),

$$\mathbb{P}\left(\left| \|f - TV\|_{p,\hat{\mu}} - \left\|f - \hat{V}\right\|_{p,\hat{\mu}} \right| > \varepsilon' \right) \le \delta'$$

Using this with $f = V'$ and $f = f^*$ shows that inequalities (11) and (13) each hold w.p. at least $1 - \delta'$. This finishes the proof of the lemma. ■

Now, let us turn to the proof of Lemma 2, which stated a finite-sample bound for the single-sample variant of the algorithm.

A.1 Proof of Lemma 2

Proof The proof is analogous to that of Lemma 1, hence we only give the differences. Up to (16) the two proofs proceed in an identical way, however, from (16) we continue by concluding that

$$\sup_{g \in \mathcal{F}} \sup_{f \in \mathcal{F}} \left| \|f - Tg\|_{p,\mu} - \|f - Tg\|_{p,\hat{\mu}} \right| > Q$$

holds pointwise in Ω. From this point onward, $\sup_{f\in\mathcal{F}}$ is replaced by $\sup_{g,f\in\mathcal{F}}$ throughout the proof of (15): The proof goes through as before until the point where Pollard's inequality is used. At this point, since we have two suprema, we need to consider covering numbers corresponding to the function set $\mathcal{F}_{T-} = \{ f - Tg \,|\, f \in \mathcal{F}, g \in \mathcal{F} \}$.

In the second part of the proof we must also use Pollard's inequality in place of Hoeffding's. In particular, (19) is replaced with

$$\mathbb{P}\left(\sup_{g\in\mathcal{F}} \left| \mathbb{E}\left[R_1^{X_i,a} + \gamma g(Y_1^{X_i,a}) \,|\, X^{1:N} \right] - \frac{1}{M}\sum_{j=1}^{M} R_j^{X_i,a} + \gamma g(Y_j^{X_i,a}) \right| > \varepsilon' \,\middle|\, X^{1:N} \right)$$
$$\leq \quad 8\mathbb{E}\left[\mathcal{N}(\varepsilon'/8, \mathcal{F}_+(Z_{i,a}^{1:M})) \right] e^{-\frac{M(\varepsilon')^2}{128K_1^2}},$$

where $Z_{i,a}^j = (R_j^{X_i,a}, Y_j^{X_i,a})$. Here $\mathcal{F}_+ = \{ h : \mathbb{R}\times\mathcal{X} \to \mathbb{R} \,|\, h(s,x) = s\mathbb{I}_{\{|s|\leq V_{\max}\}} + f(x) \text{ for some } f \in \mathcal{F} \}$. The proof is concluded by noting that the covering numbers of $\mathcal{F}_+$ can be bounded in terms of the covering numbers of $\mathcal{F}$ using the arguments presented after the Lemma at the end of Section 4. ■

Appendix B. Proof of Theorem 2

The theorem states PAC-bounds on the sample size of sampling-based FVI. The idea of the proof is to show that *(i)* if the errors in each iteration are small then the final error will be small when K, the number of iterations is high enough and *(ii)* the previous results (Lemma 1 and 2) show that the errors stay small with high probability in each iteration provided that M, N is high enough. Putting these results together gives the main result. Hence, we need to show *(i)*.

First, note that iteration (7) or (6) may be written

$$V_{k+1} = TV_k - \varepsilon_k$$

where ε_k, defined by $\varepsilon_k = TV_k - V_{k+1}$, is the approximation error of the Bellman operator applied to V_k due to sampling. The proof is done in two steps: we first prove a statement that gives pointwise bounds (i.e., the bounds hold for any state $x \in \mathcal{X}$) which is then used to prove the necessary L^p bounds. Parts *(i)* and *(ii)* are connected in Sections B.3, B.4.

B.1 Pointwise Error Bounds

Lemma 3 *We have*

$$V^* - V^{\pi_K} \leq \quad (I - \gamma P^{\pi_K})^{-1} \Big\{ \textstyle\sum_{k=0}^{K-1} \gamma^{K-k} \left[(P^{\pi^*})^{K-k} + P^{\pi_K} P^{\pi_{K-1}} \dots P^{\pi_{k+1}} \right] |\varepsilon_k| \qquad (20)$$
$$+ \gamma^{K+1} \left[(P^{\pi^*})^{K+1} + (P^{\pi_K} P^{\pi_{K-1}} \dots P^{\pi_0}) \right] |V^* - V_0| \Big\}.$$

Proof Since $TV_k \geq T^{\pi^*} V_k$, we have

$$V^* - V_{k+1} = T^{\pi^*} V^* - T^{\pi^*} V_k + T^{\pi^*} V_k - TV_k + \varepsilon_k \leq \gamma P^{\pi^*}(V^* - V_k) + \varepsilon_k,$$

from which we deduce by induction

$$V^* - V_K \leq \sum_{k=0}^{K-1} \gamma^{K-k-1} (P^{\pi^*})^{K-k-1} \varepsilon_k + \gamma^K (P^{\pi^*})^K (V^* - V_0). \qquad (21)$$

Similarly, from the definition of π_k and since $TV^* \geq T^{\pi_k}V^*$, we have

$$V^* - V_{k+1} = TV^* - T^{\pi_k}V^* + T^{\pi_k}V^* - TV_k + \varepsilon_k \geq \gamma P^{\pi_k}(V^* - V_k) + \varepsilon_k.$$

Thus, by induction,

$$V^* - V_K \geq \sum_{k=0}^{K-1} \gamma^{K-k-1}(P^{\pi_{K-1}}P^{\pi_{K-2}}\dots P^{\pi_{k+1}})\varepsilon_k + \gamma^K(P^{\pi_{K-1}}P^{\pi_{K-2}}\dots P^{\pi_0})(V^* - V_0). \qquad (22)$$

Now, from the definition of π_K, $T^{\pi_K}V_K = TV_K \geq T^{\pi^*}V_K$, and we have

$$\begin{aligned} V^* - V^{\pi_K} &= T^{\pi^*}V^* - T^{\pi^*}V_K + T^{\pi^*}V_K - TV_K + T^{\pi_K}V_K - T^{\pi_K}V^{\pi_K} \\ &\leq \gamma P^{\pi^*}(V^* - V_K) + \gamma P^{\pi_K}(V_K - V^* + V^* - V^{\pi_K}) \\ (I - \gamma P^{\pi_K})(V^* - V^{\pi_K}) &\leq \gamma(P^{\pi^*} - P^{\pi_K})(V^* - V_K), \end{aligned}$$

and since $(I - \gamma P^{\pi_K})$ is invertible and its inverse is a monotonic operator[14] (we may write $(I - \gamma P^{\pi_K})^{-1} = \sum_{m\geq 0}\gamma^m(P^{\pi_K})^m$), we deduce

$$V^* - V^{\pi_K} \leq \gamma(I - \gamma P^{\pi_K})^{-1}(P^{\pi^*} - P^{\pi_K})(V^* - V_K)$$

Now, using (21) and (22),

$$\begin{aligned} V^* - V^{\pi_K} \leq \quad & (I - \gamma P^{\pi_K})^{-1}\Big\{ \textstyle\sum_{k=0}^{K-1}\gamma^{K-k}\big[(P^{\pi^*})^{K-k} - P^{\pi_K}P^{\pi_{K-1}}\dots P^{\pi_{k+1}}\big]\varepsilon_k \\ & + \gamma^{K+1}\big[(P^{\pi^*})^{K+1} - (P^{\pi_K}P^{\pi_{K-1}}\dots P^{\pi_0})\big](V^* - V_0)\Big\} \end{aligned}$$

from which (20) follows by taking the absolute value of both sides. ■

B.2 L^p Error Bounds

We have the following approximation results.

Lemma 4 *For any $\eta > 0$, there exists K that is linear in $\log(1/\eta)$ (and $\log V_{\max}$) such that, if the $L^p(\mu)$ norm of the approximation errors is bounded by some ε ($\|\varepsilon_k\|_{p,\mu} \leq \varepsilon$ for all $0 \leq k < K$) then*

- *Given Assumption A1 we have*

$$\|V^* - V^{\pi_K}\|_\infty \leq \frac{2\gamma}{(1-\gamma)^2}C_\mu^{1/p}\varepsilon + \eta. \qquad (23)$$

- *Given Assumption A2 we have*

$$\|V^* - V^{\pi_K}\|_{p,\rho} \leq \frac{2\gamma}{(1-\gamma)^2}C_{\rho,\mu}^{1/p}\varepsilon + \eta. \qquad (24)$$

14. An operator T is monotonic if for any $x \leq y$, $Tx \leq Ty$.

Note that if $\|\varepsilon_k\|_\infty \leq \varepsilon$ then letting $p \to \infty$ we get back the well-known, unimprovable supremum-norm error bounds

$$\limsup_{K\to\infty} \|V^* - V^{\pi_K}\|_\infty \leq \frac{2\gamma}{(1-\gamma)^2}\varepsilon$$

for approximate value iteration (Bertsekas and Tsitsiklis, 1996). (In fact, by inspecting the proof below it turns out that for this the weaker condition, $\limsup_{k\to\infty} \|\varepsilon_k\|_\infty \leq \varepsilon$ suffices, too.)

Proof We have seen that if A1 holds then A2 also holds, and for any distribution ρ, $C_{\rho,\mu} \leq C_\mu$. Thus, if the bound (24) holds for any ρ then choosing ρ to be a Dirac at each state proves (23). Thus we only need to prove (24).

We may rewrite (20) as

$$V^* - V^{\pi_K} \leq \frac{2\gamma(1-\gamma^{K+1})}{(1-\gamma)^2}\left[\sum_{k=0}^{K-1} \alpha_k A_k |\varepsilon_k| + \alpha_K A_K |V^* - V_0|\right],$$

with the positive coefficients

$$\alpha_k = \frac{(1-\gamma)\gamma^{K-k-1}}{1-\gamma^{K+1}}, \text{ for } 0 \leq k < K, \text{ and } \alpha_K = \frac{(1-\gamma)\gamma^K}{1-\gamma^{K+1}},$$

(defined such that they sum to 1) and the probability kernels:

$$\begin{aligned} A_k &= \frac{1-\gamma}{2}(I - \gamma P^{\pi_K})^{-1}\left[(P^{\pi^*})^{K-k} + P^{\pi_K} P^{\pi_{K-1}} \ldots P^{\pi_{k+1}}\right], \text{ for } 0 \leq k < K, \\ A_K &= \frac{1-\gamma}{2}(I - \gamma P^{\pi_K})^{-1}\left[(P^{\pi^*})^{K+1} + P^{\pi_K} P^{\pi_{K-1}} \ldots P^{\pi_0}\right]. \end{aligned}$$

We have:

$$\begin{aligned} \|V^* - V^{\pi_K}\|_{p,\rho}^p &= \int \rho(dx)|V^*(x) - V^{\pi_K}(x)|^p \\ &\leq \left[\frac{2\gamma(1-\gamma^{K+1})}{(1-\gamma)^2}\right]^p \int \rho(dx)\left[\sum_{k=0}^{K-1} \alpha_k A_k |\varepsilon_k| + \alpha_K A_K |V^* - V_0|\right]^p (x) \\ &\leq \left[\frac{2\gamma(1-\gamma^{K+1})}{(1-\gamma)^2}\right]^p \int \rho(dx)\left[\sum_{k=0}^{K-1} \alpha_k A_k |\varepsilon_k|^p + \alpha_K A_K |V^* - V_0|^p\right](x), \end{aligned}$$

by using two times Jensen's inequality (since the sum of the coefficients α_k, for $k \in [0,K]$, is 1, and the A_k are positive linear operators with $A_k 1 = 1$) (i.e., convexity of $x \to |x|^p$).

The term $|V^* - V_0|$ may be bounded by $2V_{\max}$. Now, under Assumption A2, $\rho A_k \leq (1-\gamma)\sum_{m\geq 0}\gamma^m c(m+K-k)\mu$ and we deduce

$$\|V^* - V^{\pi_K}\|_{p,\rho}^p \leq \left[\frac{2\gamma(1-\gamma^{K+1})}{(1-\gamma)^2}\right]^p \left[\sum_{k=0}^{K-1} \alpha_k (1-\gamma) \sum_{m\geq 0} \gamma^m c(m+K-k) \|\varepsilon_k\|_{p,\mu}^p + \alpha_K (2V_{\max})^p\right].$$

Replace α_k by their values, and from the definition of $C_{\rho,\mu}$, and since $\|\varepsilon_k\|_{p,\mu} \le \varepsilon$, we have:

$$\begin{aligned}\|V^* - V^{\pi_K}\|_{p,\rho}^p &\le \left[\frac{2\gamma(1-\gamma^{K+1})}{(1-\gamma)^2}\right]^p \left[\frac{(1-\gamma)^2}{1-\gamma^{K+1}} \right. \\ &\qquad \left. \sum_{m\ge 0}\sum_{k=0}^{K-1} \gamma^{m+K-k-1} c(m+K-k)\varepsilon^p + \frac{(1-\gamma)\gamma^K}{1-\gamma^{K+1}}(2V_{\max})^p\right] \\ &\le \left[\frac{2\gamma(1-\gamma^{K+1})}{(1-\gamma)^2}\right]^p \left[\frac{1}{1-\gamma^{K+1}} C_{\rho,\mu}\varepsilon^p + \frac{(1-\gamma)\gamma^K}{1-\gamma^{K+1}}(2V_{\max})^p\right]\end{aligned}$$

Thus there is K linear in $\log(1/\eta)$ and $\log V_{\max}$ such that

$$\gamma^K < \left[\frac{(1-\gamma)^2}{4\gamma V_{\max}}\eta\right]^p$$

such that the second term is bounded by η^p, thus,

$$\|V^* - V^{\pi_K}\|_{p,\rho}^p \le \left[\frac{2\gamma}{(1-\gamma)^2}\right]^p C_{\rho,\mu}\varepsilon^p + \eta^p$$

thus

$$\|V^* - V^{\pi_K}\|_{p,\rho} \le \frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p}\varepsilon + \eta$$

■

B.3 From Pointwise Expectations to Conditional Expectations

We will need the following lemma in the proof of the theorem:

Lemma 5 *Assume that X, Y are independent random variables taking values in the respective measurable spaces, $\mathcal{X}$ and $\mathcal{Y}$. Let $f : \mathcal{X}\times\mathcal{Y} \to \mathbb{R}$ be a Borel-measurable function such that $\mathbb{E}[f(X,Y)]$ exists. Assume that for all $y \in \mathcal{Y}$, $\mathbb{E}[f(X,y)] \ge 0$. Then $\mathbb{E}[f(X,Y)|Y] \ge 0$ holds, too, w.p.1.*

This lemma is an immediate consequence of the following result, whose proof is given for the sake of completeness:

Lemma 6 *Assume that X, Y are independent random variables taking values in the respective measurable spaces, $\mathcal{X}$ and $\mathcal{Y}$. Let $f : \mathcal{X}\times\mathcal{Y} \to \mathbb{R}$ be a Borel-measurable function and assume that $\mathbb{E}[f(X,Y)]$ exists. Let $g(y) = \mathbb{E}[f(X,y)]$. Then $\mathbb{E}[f(X,Y)|Y] = g(Y)$ holds w.p.1.*

Proof Let us first consider the case when f has the form $f(x,y) = \mathbb{I}_{\{x\in A\}}\mathbb{I}_{\{y\in B\}}$, where $A \subset \mathcal{X}$, $B \subset \mathcal{Y}$ are measurable sets. Write $r(x) = \mathbb{I}_{\{x\in A\}}$ and $s(y) = \mathbb{I}_{\{y\in B\}}$. Then $\mathbb{E}[f(X,Y)|Y] = \mathbb{E}[r(X)s(Y)|Y] = r(Y)\mathbb{E}[s(X)|Y]$ since $s(Y)$ is Y-measurable. Since X and Y are independent, so are $s(X)$ and Y and thus $\mathbb{E}[s(X)|Y] = \mathbb{E}[s(X)]$. On the other hand, $g(y) = \mathbb{E}[r(X)s(y)] = s(y)\mathbb{E}[r(X)]$, and thus it indeed holds that $\mathbb{E}[f(X,Y)|Y] = g(Y)$ w.p.1. Now, by the additivity of expectations the same relation holds for sums of functions of the above form and hence, ultimately, for all simple functions. If f is nonnegative valued then we can find a sequence of increasing simple functions f_n with limit f.

By Lebesgue's monotone convergence theorem, $g_n(y) \stackrel{\text{def}}{=} \mathbb{E}[f_n(X,y)] \to \mathbb{E}[f(X,y)] (= g(y))$. Further, since Lebesgue's monotone convergence theorem also holds for conditional expectations, we also have $\mathbb{E}[f_n(X,Y)|Y] \to \mathbb{E}[f(X,Y)|Y]$. Since $g_n(Y) = \mathbb{E}[f_n(X,Y)|Y] \to \mathbb{E}[f(X,Y)|Y]$ w.p.1., and $g_n(Y) \to g(Y)$ w.p.1., we get that $g(Y) = \mathbb{E}[f(X,Y)|Y]$ w.p.1. Extension to an arbitrary function follows by decomposing the function into its positive and negative parts. ■

B.4 Proof of Theorem 2

Proof Let us consider first the multi-sample variant of the algorithm under Assumption A2. Fix $\varepsilon, \delta > 0$. Let the iterates produced by the algorithm be $V_1, \ldots, V_K$. Our aim is to show that by selecting the number of iterates, K and the number of samples, N, M large enough, the bound

$$\|V^* - V^{\pi_K}\|_{p,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} \, d_{p,\mu}(T\mathcal{F}, \mathcal{F}) + \varepsilon \tag{25}$$

holds w.p. at least $1-\delta$. First, note that by construction the iterates V_k remain bounded by $V_{\max}$. By Lemma 4, under Assumption A2, for all those events, where the error $\varepsilon_k = TV_k - V_{k+1}$ of the kth iterate is below (in $L^p(\mu)$-norm) some level ε_0, we have

$$\|V^* - V^{\pi_K}\|_{p,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} \varepsilon_0 + \eta, \tag{26}$$

provided that $K = \Omega(\log(1/\eta))$. Now, choose $\varepsilon' = (\varepsilon/2)(1-\gamma)^2/(2\gamma C_{\rho,\mu}^{1/p})$ and $\eta = \varepsilon/2$. Let $f(\varepsilon, \delta)$ denote the function that gives lower bounds on N, M in Lemma 1 based on the value of the desired estimation error ε and confidence δ. Let $(N, M) \geq f(\varepsilon', \delta/K)$. One difficulty is that V_k, the kth iterate is random itself, hence Lemma 1 (stated for deterministic functions) cannot be applied directly. However, thanks to the independence of samples between iterates, this is easy to fix via the application of Lemma 5.

To show this let us denote the collection of random variables used in the kth step by S_k. Hence, S_k consists of the N basepoints, as well as $|\mathcal{A}| \times N \times M$ next states and rewards. Further, introduce the notation $V'(V, S_k)$ to denote the result of solving the optimization problem (2)–(3) based on the sample S_k and starting from the value function $V \in B(\mathcal{X})$. By Lemma 1,

$$\mathbb{P}\left(\left\| V'(V, S_k) - TV \right\|_{p,\mu} \leq d_{p,\mu}(TV, \mathcal{F}) + \varepsilon' \right) \geq 1 - \delta/K.$$

Now let us apply Lemma 5 with $X := S_k$, $Y := V_k$ and $f(S, V) = \mathbb{I}_{\{\|V'(V,S) - TV\|_{p,\mu} \leq d_{p,\mu}(TV, \mathcal{F}) + \varepsilon'\}} - (1 - \delta/K)$. Since S_k is independent of V_k the lemma can indeed be applied. Hence,

$$\mathbb{P}\left(\left\| V'(V_k, S_k) - TV_k \right\|_{p,\mu} \leq d_{p,\mu}(TV_k, \mathcal{F}) + \varepsilon' | V_k \right) \geq 1 - \delta/K.$$

Taking the expectation of both sides gives $\mathbb{P}\left(\|V'(V_k, S_k) - TV_k\|_{p,\mu} \leq d_{p,\mu}(TV_k, \mathcal{F}) + \varepsilon' \right) \geq 1 - \delta/K$. Since $V'(V_k, S_k) = V_{k+1}$, $\varepsilon_k = TV_k - V_{k+1}$, we thus have that

$$\|\varepsilon_k\|_{p,\mu} \leq d_{p,\mu}(TV, \mathcal{F}) + \varepsilon' \tag{27}$$

holds except for a set of bad events B_k of measure at most δ/K.

Hence, inequality (27) holds simultaneously for $k = 1, \ldots, K$, except for the events in $B = \cup_k B_k$. Note that $\mathbb{P}(B) \le \sum_{k=1}^K \mathbb{P}(B_k) \le \delta$. Now pick any event in the complementer of B. Thus, for such an event (26) holds with $\varepsilon_0 = d_{p,\mu}(TV, \mathcal{F}) + \varepsilon'$. Plugging in the definitions of ε' and η we obtain (25).

Now assume that the MDP satisfies Assumption A1. As before, we conclude that (27) holds except for the events in B_k and with the same choice of N and M, we still have $\mathbb{P}(B) = \mathbb{P}(\cup_k B_K) \le \delta$. Now, using (23) we conclude that except on the set B, $\|V^* - V^{\pi_K}\|_\infty \le \frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} d_{p,\mu}(T\mathcal{F}, \mathcal{F}) + \varepsilon$, concluding the first part of the proof.

For single-sample FVI the proof proceeds identically, except that now one uses Lemma 2 in place of Lemma 1. ■

Appendix C. Proof of Theorem 3

Proof We would like to prove that the policy defined in Section 6 gives close to optimal performance. Let us prove first the statement under Assumption A2.

By the choice of M', it follows using Hoeffding's inequality (see also Even-Dar et al., 2002, Theorem 1) that $\pi_{\alpha,\lambda}^K$ selects α-greedy actions w.p. at least $1-\lambda$.

Let π_α^K be a policy that selects α-greedy actions. A straightforward adaptation of the proof of Lemma 5.17 of Szepesvári (2001) yields that for all state $x \in \mathcal{X}$,

$$|V^{\pi_{\alpha,\lambda}^K}(x) - V^{\pi_\alpha^K}(x)| \le \frac{2V_{\max}\lambda}{1-\gamma}. \tag{28}$$

Now, use the triangle inequality to get

$$\left\|V^* - V^{\pi_{\alpha,\lambda}^K}\right\|_{p,\rho} \le \left\|V^* - V^{\pi_\alpha^K}\right\|_{p,\rho} + \left\|V^{\pi_\alpha^K} - V^{\pi_{\alpha,\lambda}^K}\right\|_{p,\rho}.$$

By (28), the second term can be bounded by $\frac{2V_{\max}\lambda}{1-\gamma}$, so let us consider the first term.

A modification of Lemmas 3 and 4 yields the following result, the proof of which will be given at the end of this section:

Lemma 7 *The following bound*

$$\left\|V^* - V^{\pi_\alpha^K}\right\|_{p,\rho} \le 2^{1-1/p}\left[\frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} \max_{0\le k<K} \|\varepsilon_k\|_{p,\mu} + \eta + \frac{\alpha}{1-\gamma}\right] \tag{29}$$

holds for K such that $\gamma^K < \left[\frac{(1-\gamma)^2}{4\gamma V_{\max}}\eta\right]^p$.

Again, let $f(\varepsilon,\delta)$ be the function that gives the bounds on N, M in Lemma 1 for given ε and δ and set $(N,M) \ge f(\varepsilon',\delta/K)$ for ε' to be chosen later. Using the same argument as in the proof of Theorem 2 and Lemma 1 we may conclude that $\|\varepsilon_k\|_{p,\mu} \le d_{p,\mu}(TV_k, \mathcal{F}) + \varepsilon' \le d_{p,\mu}(T\mathcal{F}, \mathcal{F}) + \varepsilon'$ holds except for a set B_k with $\mathbb{P}(B_k) \le \delta/K$.

Thus, except on the set $B = \cup_k B_k$ of measure not more than δ,

$$\begin{aligned}\left\|V^* - V^{\pi_{\alpha,\lambda}^K}\right\|_{p,\rho} &\le 2^{1-1/p}\left[\frac{2\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p}\left(d_{p,\mu}(T\mathcal{F}, \mathcal{F}) + \varepsilon'\right) + \eta + \frac{\alpha}{1-\gamma}\right] + \frac{2V_{\max}\lambda}{1-\gamma} \\ &\le \left[\frac{4\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} d_{p,\mu}(T\mathcal{F}, \mathcal{F}) + \frac{4\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p}\varepsilon' + 2\eta + \frac{2\alpha}{1-\gamma}\right] + \frac{2V_{\max}\lambda}{1-\gamma}.\end{aligned}$$

Now define $\alpha = \varepsilon(1-\gamma)/8$, $\eta = \varepsilon/8$, $\varepsilon' = \frac{\varepsilon}{4}\frac{(1-\gamma)^2}{4\gamma}C_{\rho,\mu}^{-1/p}$ and $\lambda = \frac{\varepsilon}{4}\frac{(1-\gamma)}{2V_{\max}}$ to conclude that

$$\left\|V^* - V^{\pi^K_{\alpha,\lambda}}\right\|_{p,\rho} \leq \frac{4\gamma}{(1-\gamma)^2} C_{\rho,\mu}^{1/p} d_{p,\mu}(T\mathcal{F},\mathcal{F}) + \varepsilon$$

holds everywhere except on B. Also, just like in the proof of Theorem 2, we get that under Assumption A1 the statement for the supremum norm holds, as well.

It thus remained to prove Lemma 7:

Proof [Lemma 7] Write $\mathbf{1}$ for the constant function that equals to 1. Since π^K_α is α-greedy w.r.t. V_K, we have $TV_K \geq T^{\pi^K_\alpha}V_K \geq TV_K - \alpha\mathbf{1}$. Thus, similarly to the proof of Lemma 3, we have

$$\begin{aligned}
V^* - V^{\pi^K_\alpha} &= T^{\pi^*}V^* - T^{\pi^*}V_K + T^{\pi^*}V_K - TV_K + TV_K - T^{\pi^K_\alpha}V_K + T^{\pi^K_\alpha}V_K - T^{\pi^K_\alpha}V^{\pi^K_\alpha} \\
&\leq \gamma P^{\pi^*}(V^* - V_K) + \gamma P^{\pi^K_\alpha}(V_K - V^* + V^* - V^{\pi^K_\alpha}) + \alpha\mathbf{1} \\
&\leq (I - \gamma P^{\pi^K_\alpha})^{-1}\left[\gamma(P^{\pi^*} - P^{\pi^K_\alpha})(V^* - V_K)\right] + \frac{\alpha\mathbf{1}}{1-\gamma},
\end{aligned}$$

and by using (21) and (22), we deduce

$$\begin{aligned}
V^* - V^{\pi^K_\alpha} \leq\ & (I - \gamma P^{\pi^K_\alpha})^{-1}\Big\{\textstyle\sum_{k=0}^{K-1}\gamma^{K-k}\left[(P^{\pi^*})^{K-k} + P^{\pi^K_\alpha}P^{\pi_{K-1}}\dots P^{\pi_{k+1}}\right]|\varepsilon_k| \\
& + \gamma^{K+1}\left[(P^{\pi^*})^{K+1} + (P^{\pi^K_\alpha}P^{\pi_K}P^{\pi_{K-1}}\dots P^{\pi_1})\right]|V^* - V_0|\Big\} + \tfrac{\alpha\mathbf{1}}{1-\gamma}.
\end{aligned}$$

Now, from the inequality $|a+b|^p \leq 2^{p-1}(|a|^p + |b|^p)$, we deduce, by following the same lines as in the proof of Lemma 4, that

$$\left\|V^* - V^{\pi^K_\alpha}\right\|_{p,\rho}^p \leq 2^{p-1}\left\{\left[\frac{2\gamma}{(1-\gamma)^2}\right]^p C_{\rho,\mu}(\max_{0\leq k<K}\|\varepsilon_k\|_{p,\mu})^p + \eta^p + \left[\frac{\alpha}{1-\gamma}\right]^p\right\},$$

and Lemma 7 follows. ■

Abstract

This paper introduces a new PAC transductive error bound for classification. The method uses information from the training examples and inputs of working examples to develop a set of likely assignments to outputs of the working examples. A likely assignment with maximum error determines the bound. The method is very effective for small data sets.

Keywords: error bound, transduction, nearest neighbor, dynamic programming

1. Introduction

An error bound based on VC dimension (Vapnik and Chervonenkis, 1971; Vapnik, 1998) uses uniform bounds over the largest number of assignments possible from a class of classifiers, based on worst-case arrangements of training and working examples. However, as the number of training examples grows, the probability that training error is a good approximation of working error is so great that the VC error bound succeeds in spite of using uniform bounds based on worst-case assumptions about examples. Also, it is easy to compute VC bounds for any number of examples, assuming the VC dimension for the class is known. This makes VC bounds useful and convenient for large data sets, that is, data sets having thousands of examples. However, VC error bounds have some drawbacks: they are ineffective for smaller data sets, and they do not apply to some classifiers, such as nearest neighbor classifiers.

Transductive inference (Vapnik, 1998) is a training method that uses information provided by inputs of working examples in addition to information provided by training examples. The idea is to develop the best classifier for the inputs of the specific working examples at hand rather than develop a classifier that is good for general inputs and then apply it to the working examples. Transductive inference improves on general VC bounds by using the actual working example inputs, instead of a worst-case arrangement of inputs, to find the number of different assignments that classifiers in each training class can produce. The bounds are then used to select among classes, mediating a tradeoff between small classes that are more likely to have good generalization and large classes that are more likely to capture the dynamics of the training data.

The error bound presented here is designed to provide error bounds for data sets so small that other bounds are ineffective. Like transductive inference, the error bound presented here uses information provided by the inputs of the working examples in addition to information provided by the

training examples. But it also uses information provided by the training procedure rather than just the class of all classifiers that can be produced by the training procedure. However, it requires more computation than VC bounds. In fact, the required computation grows so quickly with data set size that the bound is practical only for small data sets. (Nearest neighbor classifiers are an exception to this limitation; this paper contains an efficient method to compute bounds for them.)

Normally, algorithm designers are concerned about how computation grows as problem size increases, focusing on asymptotic behavior as problem size goes to infinity. This paper does not focus on what happens as data set size goes to infinity—there are already many effective bounds for large data sets. This paper focuses on how much information we can wring out of small data sets. Small data sets do occur in practice, for example in early stage drug tests in medicine and in setting prices and making markets for ad-matching systems that have to deal with tiny markets out in the long tail of information domains. In short, there is "plenty of room at the bottom" for improved error bounds.

The error bound in this paper is based on the fact that if the training and working examples are generated independently and identically distributed (i.i.d.), then each partition of the complete set of training and working examples into a training set and a working set is equally likely. Several error bounds for machine learning are based on this principle. Examples include VC error bounds (Vapnik and Chervonenkis, 1971; Cristianini and Shawe-Taylor, 2000, Section 4.2, p. 55), error bounds for support vector machines (Vapnik, 1998, Chapter 8, pp. 339-343), compression-based error bounds (Littlestone and Warmuth, 1986), and uniform error bounds based on constraints imposed by patterns of agreement and disagreement among classifiers over the working inputs (Bax, 1999). For some other ways of developing and using this idea, refer to Audibert (2004), Blum and Langford (2003), Catoni (2003), Catoni (2004), Derbeko et al. (2003), and El-Yaniv and Gerzon (2005).

This paper is organized as follows. Section 2 introduces concepts and notation for the error bound. Section 3 presents the error bound. Section 4 introduces sampled filters, which reduce computation required for the bound. Section 5 analyzes speed and storage requirements for filters based on all partitions and for sampled filters. Section 6 introduces filters based on virtual partitioning, which do not require explicit computation over multiple partitions of the data into different training and working sets. Section 7 gives an efficient algorithm to compute an error bound for a 1-nearest neighbor classifier. Section 8 presents test results comparing bounds produced by different filters on a set of problems. Section 9 is a discussion of possible directions for future research.

2. Concepts and Notation

This paper concerns validation of classifiers learned from examples. Each example $Z = (X, Y)$ includes an input X and a class label $Y \in \{0,1\}$. We observe

$$(X_1, Y_1), ..., (X_t, Y_t), X_{t+1}, ..., X_{t+w}$$

that is, inputs and outputs of *t training examples* and just the inputs of *w working examples*. (We will use T to denote the set of training examples and W to denote the set of working examples.) A classifier g, which is a mapping from the input space for X to $\{0,1\}$, is developed using the observed data. Then classifier g is used to predict the working example outputs $Y_{t+1}, \ldots, Y_{t+w}$ associated with $X_{t+1}, \ldots, X_{t+w}$.

For any sequence of examples

$$c = (x_1, y_1), ...(x_{t+w}, y_{t+w}) \tag{1}$$

from the joint space of inputs and labels, define the *error* to be

$$E_c = \frac{1}{w} \sum_{i=t+1}^{t+w} I(g(x_i) \neq y_i),$$

where I is the indicator function—one if the argument is true and zero otherwise. Let

$$C = Z_1, ..., Z_{t+w}.$$

Examples in this *complete sequence* $Z_1 = (X_1, Y_1)$, ..., $Z_{t+w} = (X_{t+w}, Y_{t+w})$ are assumed to be drawn i.i.d. from an unknown joint distribution of inputs and labels.

The goal is to produce a PAC (probably approximately correct) bound on E_C, the error on complete sequence C.

The bounds in this paper consider different possible assignments to the unknown labels of the working set examples and use permutations of the complete sequence. So we introduce some notation around assignments and permutations. For any *assignment* $a \in \{0,1\}^w$ and any permutation σ of $\{1, \ldots, t+w\}$, let *C(a, σ)* be the sequence that results from assigning labels to the working examples in C:

$$\forall i \in \{1, ..., w\} : Y_{t+i} = a_i,$$

then permuting the sequence according to σ. Let *T(a, σ)* be the set consisting of the first t examples in *C(a, σ)*. Let *W(a, σ)* be the set consisting of the last w examples in *C(a, σ)*. Let *g(a, σ)* be the classifier produced by applying the training procedure with *T(a, σ)* as the training set and *W(a, σ)* as the working set. Let *E(a, σ)* be the error of *g(a, σ)* over *W(a, σ)*; in other words, let *E(a, σ)* be the error E as defined in Equation (1) that would result from using *C(a, σ)* as the complete sequence.

Let a^* be the actual (unknown) labels of the working examples. Let *Id* be the identity permutation. Then

$$E_C = E(a^*, Id).$$

3. First Error Bound and Algorithm

Section 3.1 presents the error bound. Section 3.2 shows how to compute the bound over partitions instead of permutations. Section 3.3 presents the algorithm for computing the bound.

3.1 Bound

Let *Id* be the identity permutation. Define a *likely set*

$$L = \{a \in \{0,1\}^w | P[E(a, \sigma) \geq E(a, Id)] > \delta\},$$

where the probability is over the uniform distribution of permutations σ of $\{1, \ldots, t+w\}$. The bound is

$$\max_{a \in L} E(a, Id). \tag{2}$$

Theorem 3.1

With probability at least $1 - \delta$,

$$E(a^*, Id) \leq \max_{a \in L} E(a, Id), \tag{3}$$

where the probability is over random complete sequences drawn i.i.d. from a joint input-label distribution.

Proof of Theorem 3.1

If $a^* \in L$, then Equation (3) holds. So it suffices to show that

$$P_C(a^* \notin L) \leq \delta,$$

where subscript C denotes probability over the distribution of complete sequences C. By the definition of L, the LHS is

$$= P_C[P_\sigma[E(a^*, \sigma) \geq E(a^*, Id)] \leq \delta | C],$$

where subscript σ denotes probability over the uniform distribution of permutations σ of $\{1, \ldots, t+w\}$. Convert the probability over the distribution of complete sequences to an integral over complete sequences:

$$\int_C I(P_\sigma[E(a^*, \sigma) \geq E(a^*, Id)] \leq \delta | C) p(C) dC,$$

where *p(C)* is the pdf of C. Since each permutation of a complete sequence is equally likely, we can replace the integral over complete sequences by an integral over sequences Q of $t+w$ examples followed by an average over permutations σ' of Q to form complete sets:

$$= \int_Q \frac{1}{(t+w)!} \sum_{\sigma'} I(P_\sigma[E(a*, \sigma) \geq E(a^*, \sigma')] \leq \delta | C = \sigma' Q) p(Q) dQ. \tag{4}$$

For each set Q, only δ $(t+w)!$ or fewer permutations σ' can rank in the top δ $(t+w)!$ of all $(t+w)!$ permutations for any statistic, including the statistic *E(a*, σ)*. So,

$$\forall Q : \sum_{\sigma'} I(P_\sigma[E(a^*, \sigma) \geq E(a^*, \sigma')] \leq \delta | Q) \leq \delta (t+w)!.$$

Substitute this inequality into Equation (4), to show it is

$$\leq \int_Q \frac{1}{(t+w)!} \delta (t+w)! p(Q) dQ.$$

Cancel terms $(t+w)!$ and integrate to get δ, completing the proof.

3.2 From Permutations to Partitions

For each assignment $a \in \{0,1\}^w$ and each size-t subset S of $\{1, \ldots, t+w\}$, let *T(a, S)* be the set (or multi-set) of examples in *C(a, Id)* indexed by entries of S, and let *W(a, S)* be the remaining examples in *C(a, Id)*. Refer to the pair *T(a, S)* and *W(a, S)* as the partition induced by S. Let *g(a, S)* be the classifier that results from training with *T(a, S)* as the training set and *W(a, S)* as the working set. Let *E(a, S)* be the error of *g(a, S)* over *W(a, S)*.

For each permutation σ of $\{1, \ldots, t+w\}$, let σ_i be the position in *C(a, Id)* of the example in position i in *C(a, σ)*. Note that

$$\{\sigma_1, ..., \sigma_t\} = S \Rightarrow (T(a,\sigma), W(a,\sigma)) = (T(a,S), W(a,S)).$$

For each S, there is the same number, $t!w!$, of permutations σ with $\{\sigma_1, \ldots, \sigma_t\} = S$, because there are $t!$ ways to order the elements of S in $\sigma_1, \ldots, \sigma_t$ and $w!$ ways to order the remaining elements of $\{1, \ldots, t+w\}$ in $\sigma_{t+1}, \ldots, \sigma_{t+w}$. Since there is this $t!w!$-to-one mapping from permutations σ to subsets S with *E(a, σ) = E(a, S)*, the probability over permutations in the definition of L can be replaced by the following probability over partitions induced by subsets S :

$$L = \{a \in \{0,1\}^w | P_S[E(a,S) \geq E(a,S^*)] > \delta\},$$

where the probability is uniform over size-t subsets S of $\{1, \ldots, t+w\}$, and $S^* = \{1, \ldots, t\}$. Hence, we can compute errors *E(a, S)* over size-t subsets S rather than over all permutations in order to compute bound in Equation (2).

3.3 Algorithm

Given an array C of t training examples followed by w working examples and a bound failure probability ceiling δ, Algorithm 3.3.1 returns a valid error bound with probability at least $1 - \delta$. The procedure *E(a, S, C)*, which is not shown, computes *E(a, S)* by assigning a to the labels of the last w entries in C, training a classifier using the entries of C indicated by S as the training set and the remaining entries as the working set, and returning the error of that classifier over that working set.

Algorithm 3.3.1

```
procedure bound(C, delta)
  // Variable bound stores the running max of errors for likely assignments.
  bound := 0;

  // Try all assignments.
  for (a in {0,1}^w)
    // Check if error is high enough to be a new max.
    if (E(a, {1, ..., t}, C) > bound)
      // Variable f[i] stores the frequency of E(a, S) = i/w.
      f[0 ... w] = 0;
      // Find error frequencies.
      for (S subset of {1, ..., t+w} with |S|=t) f[E(a, S, C)]++;
      // Variable tail stores the frequency of error
```

```
      //   greater than for S={1, ..., t}.
      tail := 0;
      // Sum the tail.
      for (i=E(a, {1, ..., t}, C) to w) tail += f[i];
      // If assignment is likely, increase bound.
      if (tail > delta) bound := E(a, {1, ..., t}, C);
    end if
  end for

  return bound;
end procedure
```

4. Sampled Filters and Ranking with Random Tie Breaking

The goal is to reject from L as many false assignments a as possible among those that have $E(a, Id) > E(a^*, Id)$, while only rejecting a^* in a fraction δ or fewer of cases. The bound process in the previous section rejects assignments a for which $E(a, S^*)$ is abnormally high among errors $E(a, S)$ over subsets S of $\{1, \ldots, t+w\}$, that is, among partitions of the complete sequence into training and working sets. For each assignment a, the process is equivalent to ranking all subsets S in order of $E(a, S)$, finding the fraction of subsets that outrank S^*, even with S^* losing all ties, and rejecting a if the fraction is δ or less. Call this filter the *complete filter*, because it compares S^* to all subsets S. This section introduces alternative filters that do not require computation over all subsets and a random tie breaking process that ranks S^* fairly among subsets S having the same error instead of having S^* lose all ties.

4.1 Sampled Filters

The complete filter is expensive to compute. To motivate thinking about alternative filters, note that any filter that accepts a* into L with probability at least 1-δ produces a valid bound. For example, a filter that simply makes a random determination for each assignment, accepting it into L with probability 1-δ, independent of any data about the problem at hand, still produces a valid error bound. Of course, this *random filter* is unlikely to produce a strong bound, because it does not preferentially reject assignments a that have high error $E(a, S^*)$.

The following *sampled filter*, based on errors $E(a, S)$ over a random sample of subsets S, rejects assignments with high error $E(a, S^*)$, and it is less expensive to compute than the complete filter. For each assignment a, generate a sample of n size-t subsets S of $\{1, \ldots, t+w\}$. Generate the sample by drawing subsets i.i.d. with replacement based on a uniform distribution over subsets, or generate the sample by drawing subsets i.i.d. without replacement based on a distribution that is uniform over subsets other than S^* and has zero probability for S^*. After drawing the sample by either method, add S^* to the sample. Then use the sample in place of the set of all subsets S in the algorithm, that is, accept assignment a if the fraction of subsets S in the sample with $E(a, S)$ at least $E(a, S^*)$ is greater than δ . Like the complete filter, this sampled filter has probability at most δ of rejecting the true assignment. Here is the proof for sampling with replacement. The proof for sampling without replacement is similar, and it is outlined after the proof for sampling with replacement.

Theorem 4.1.1

Let R be the set of all size-t subsets of $\{1, \ldots, t+w\}$. Let M be a set (or multi-set) of entries from R, drawn i.i.d. with replacement based on a uniform distribution over R. Let

$$L_M = \left\{a \in \{0,1\}^w | P_{S \in M \cup \{S^*\}}[E(a,S) \geq E(a,S^*)] > \delta\right\}$$

where the probability is uniform over all sets S in M. Then, with probability at least $1-\delta$,

$$E(a^*,S^*) \leq \max_{a \in L_M} E(a,S^*), \tag{5}$$

where the probability is over random complete sequences C drawn i.i.d. from a joint input-label distribution and over random subset samples M.

Proof of Theorem 4.1.1

If $a^* \in L_M$, then Equation (5) holds. So we will show

$$P_{C,M}(a^* \notin L_M) \leq \delta, \tag{6}$$

where the probability is over the joint distribution of complete sequences C and subset samples M. By the definition of L_M, the LHS is

$$= P_{C,M}[P_{S \in M \cup \{S^*\}}[E(a^*,S) \geq E(a^*,S^*)] \leq \delta | C].$$

Convert the probability over C into an integral over sequences Q of $t+w$ examples, followed by a probability over permutations σ' of Q to form complete sets:

$$\int_Q P_{\sigma',M}[P_{S \in M \cup \{S^*\}}[E(a^*,S) \geq E(a^*,S^*)] \leq \delta | C = \sigma' Q] p(Q) dQ, \tag{7}$$

where the first probability is over a joint distribution of σ' and M, with σ' drawn uniformly at random from permutations of $t+w$ elements and independently of M. For any fixed sequence Q, consider the expression from within Equation (7):

$$P_{\sigma',M}[P_{S \in M \cup \{S^*\}}[E(a^*,S) \geq E(a^*,S^*)] \leq \delta | C = \sigma' Q]. \tag{8}$$

Define multi-set

$$H(Q) = \{E(a^*,S) | S \in M \cup \{S^*\}\}.$$

Random draws of σ' and M make $H(Q)$ a multi-set of random values drawn i.i.d. from a uniform distribution over the set

$$U(Q) = \{E(a^*,S) | S \subseteq \{1,...,t+w\} \wedge |S| = t\}.$$

Since the elements of $H(Q)$ are drawn i.i.d., the probability that $E(a^*, S^*)$ ranks in the top $\delta |H(Q)|$ of the positions in a ranking of entries in $H(Q)$ is at most δ. Note that Equation (8) is this probability. So

$$\forall Q : P_{\sigma',M}[P_{S \in M \cup \{S^*\}}[E(a^*,S) \geq E(a^*,S^*)] \leq \delta | C = \sigma' Q] \leq \delta.$$

Substitute this inequality into Equation (7), showing that the LHS of Equation (6) is

$$\leq \int_Q \delta p(Q) dQ.$$

Integrate to get δ, completing the proof.

Now consider the case of sampling subsets without replacement:

Theorem 4.1.2

Let R' be the set of all size-t subsets of $\{1, \ldots, t+w\}$, except for S^*. Let M' be a set of entries from R', drawn i.i.d. without replacement based on a uniform distribution over R'. Let

$$L_{M'} = \left\{ a \in \{0,1\}^w | P_{S \in M' \cup \{S^*\}} [E(a,S) \geq E(a,S^*)] > \delta \right\},$$

where the probability is uniform over all sets S in M'. Then, with probability at least $1 - \delta$,

$$E(a^*, S^*) \leq \max_{a \in L_{M'}} E(a, S^*),$$

where the probability is over random complete sequences C drawn i.i.d. from a joint input-label distribution and over random subset samples M.

Proof of Theorem 4.1.2

The proof is almost the same as the proof of Theorem 4.1.1, substituting M' for M. The set *H(Q)* becomes a set of random variables drawn i.i.d. from *U(Q)* without replacement, rather than with replacement. But with or without replacement, the probability that *E(a*, S*)* ranks in the top δ $|H(Q)|$of the positions in a ranking of entries in *H(Q)* is at most δ. Otherwise, the proof is the same.

4.2 Random Tie Breaking

Both the complete filter and the sampled filter accept an assignment if the fraction of a set of subsets S with *E(a, S)* at least *E(a, S*)* is greater than δ. In essence, if other subsets S have the same error as S^*, then this rule errs on the side of safety by treating those subsets S as having greater error than S^*. This ensures that the bound is valid, but it makes the bound weaker than necessary. To close the gap, use random tie breaking to rank S^* at random among the subsets S that have *E(a, S) = E(a, S*)*. Let k be the number of subsets S with the same error as S^*, including S^* itself. Generate an integer uniformly at random in [1,k] to be the number of subsets S with the same error that rank at or above S^* after random tie breaking. If that number plus the number of subsets S with error greater than for S^* is a larger fraction of the partitions than δ, then accept the assignment.

5. Speed and Storage Requirements for Complete and Sampled Filters

Consider the storage requirements for the bound process. Since the maximum error *E(a, S)* over assignments in L is obtained by maintaining a running maximum as assignments are added to L, there is no need to store L explicitly. So the storage requirements are mild, including space for a data set, for two classifiers, and for training a classifier.

Using the complete filter to produce a bound requires time to train

$$O(2^w \begin{pmatrix} t+w \\ t \end{pmatrix})$$

classifiers. Using the sampled filter instead requires time to train

$$O(2^w n)$$

classifiers, where n is the number of sample partitions per assignment. Both types of filters can be computed in parallel, using different machines to filter different sets of assignments, each keeping a running maximum of *E(a, S*)* over accepted assignments, and then finishing by fanning in the maximum over the machines.

To reduce computation, evaluate assignments a for membership in L in decreasing order of *E(a, S*)*. When the first assignment a is accepted into L, return *E(a, S*)* as the error bound, and stop. To order assignments by *E(a, S*)*, train a classifier g, and apply it to each input in W to form the assignment with zero error. Invert that assignment to form the assignment with maximum error. Invert single elements of that assignment to produce assignments with the next greatest error rates. Then invert pairs of elements, then triples, etc. (This technique reduces computation only by a small fraction when the bound is effective; the reduction is only about half for an error bound of 0.5 and even less for smaller error bounds. On the other hand, it does contribute to "fast failure" when the bound is not effective.)

6. Virtual Partitions

Section 6.1 introduces the virtual partition filter. Section 6.2 describes the leave-one-out filter. Section 6.3 presents scoring functions. Section 6.4 suggests a scoring function for support vector machines.

6.1 Virtual Partition Filter

Define a *general likely set* L_h, based on some function h:

$$L_h = \{a \in \{0,1\}^w | P_S[h(a,S) \geq h(a,S^*)] > \delta\},$$

where the probability is over subsets S of $\{1, \ldots, t+w\}$. Define a *general error bound*

$$E_h(a,S) = \max_{a \in L_h} E(a,S^*).$$

If the filter

$$P_S[h(a,S) \geq h(a,S^*)] > \delta$$

can be computed for each assignment a without explicitly computing *h(a, S)* over some subsets S, then we call it a *virtual partition filter*.

6.2 Leave-One-Out Filter

For example, let *h(a, S)* be the number of leave-one-out errors in *W(a, S)*. (A leave-one-out error is an example in *C(a)* that has a different label than the closest other example in *C(a)*, with distance based on some metric over the input domain.) A filter based on leave-one-out errors excludes assignments *a* that cause an improbably large fraction of the leave-one-out errors in *C(a)* to be in the working set. Frequencies of leave-one-out errors in *W(a, S)* over subsets *S* can be computed without explicitly iterating over the subsets. The frequencies have a hypergeometric distribution—if there are *m* leave-one-out errors in *C(a)*, then

$$P_S[h(a,S) = j] = \frac{\left(\begin{array}{c} m \\ j \end{array} \right) \left(\begin{array}{c} t+w-m \\ w-j \end{array} \right)}{\left(\begin{array}{c} t+w \\ w \end{array} \right)},$$

where the probability is uniform over size-t subsets S of $\{1, \ldots, t+w\}$.

Compute the filter for each assignment as follows. Set the labels of $Z_{t+1}, \ldots, Z_{t+w}$ according to *a*. Then compute the number of leave-one-out errors in *C(a)*; call it *m*. Next, compute frequencies:

$$\forall j \in \{\max(0, m-t), ..., \min(w, m)\} : f_j = \left(\begin{array}{c} m \\ j \end{array} \right) \left(\begin{array}{c} t+w-m \\ w-j \end{array} \right).$$

Let *j*=h(a,S*)*, that is, the number of leave-one-out errors in *W(a, S*)*. Let

$$v = \sum_{j=j^*}^{\min(w,m)} f_j.$$

For random tie breaking, subtract from v a number drawn uniformly at random from $[0, f_{j*} - 1]$.Then divide by the number of partitions:

$$\left(\begin{array}{c} t+w \\ w \end{array} \right).$$

If the result is δ or less, then reject assignment *a*.

6.3 Scoring Functions

In general, let *s* be a *scoring function* on examples in *C(a)* that returns an integer. Let

$$h(a,S) = \sum_{Z \in W(a,S)} s(Z).$$

Let *n(Z)* be the nearest neighbor to Z in $T \cup W - \{Z\}$. For example, when counting leave-one-out errors,

$$s(Z) = \begin{cases} 1 & if\ n(Z).y \neq Z.y \\ 0 & otherwise \end{cases}$$

where *.y* after an example denotes the output, *Y*, for the example.

Another useful scoring function counts leave-one-out errors caused by example Z:

$$s(Z) = |\{Q \in T \cup W | n(Q) = Z \text{ and } Q.y \neq Z.y\}|.$$

For scoring functions, such as this one, that have a range other than {0,1}, the hypergeometric distribution does not apply. However, dynamic programming allows efficient computation of the frequencies, as follows. Let

$$c_{ijk} \equiv \left| \left\{ A \subseteq \{1,...,i\} \,|\, |A| = j \text{ and } \sum_{b \in A} s(Z_b) = k \right\} \right|,$$

that is, the number of size-*j* subsets of the first *i* examples in C(a) that have sum of scores *k*. The base cases are

$$\forall (j,k) : c_{0jk} = 0$$

except

$$c_{000} = 1,$$

and

$$\forall k < 0 : c_{ijk} = 0.$$

The recurrence is

$$c_{ijk} = c_{i-1,j,k} + c_{i-1,j-1,k-s(i)},$$

where *s(i)* is the score of example *i*. The frequencies are:

$$P_S[h(a,S) = k] = c_{t+w,w,k}.$$

Computing an error bound using virtual partitions requires $O(2^w poly(t+w))$ time because the scoring function is computed for each of the 2^w assignments. (This assumes O(poly(t+w)) time to compute the filter for each assignment.) The computation requires O(poly(t+w)) space since each assignment can be filtered without reference to others, and the maximum error of a likely assignment can be maintained using a single variable.

6.4 Scoring Functions for SVMs

Now consider filters with virtual partitions for support vector machines (SVMs). A leave-one-out filter can require much computation—for each assignment, training separate SVMs with each example held out in order to compute the number of leave-one-out errors. Joachims discovered a method to bound the number of leave-one-out errors based on the results of training a single SVM on all examples. The method is called εα-estimation (Joachims, 2002, Ch. 5). Computing the εα-estimator involves producing a set of examples that are potential leave-one-out errors. The set can be used as the basis for a filter that is binary-valued—each example in the set scores one and each other example scores zero. The εα-estimation procedure can also be used as the basis of a more complex filter, because it computes scores for examples before using a threshold to determine which ones are in the set. So the scores (or discretized scores) can be used directly as the scoring function for a filter.

7. Efficient Computation of Error Bounds for 1-Nearest Neighbor Classifiers

When using virtual partitions based on leave-one-out errors to produce an error bound for a 1-nearest neighbor classifier, there is a way to avoid iterating over all assignments to compute the bound. Avoiding this iteration leads to an efficient method to compute an error bound for a 1-nearest neighbor classifier, that is, a method that requires time polynomial in the size of the problem. This section begins with some preliminary concepts before presenting the recurrences and dynamic programming algorithm. Next there is a small example to illustrate the algorithm. Then there are details on how to compute the recurrences efficiently. This section ends with a note on how to extend the algorithm to improve the bounds by allowing random tie breaking for ranking.

7.1 Preliminaries and Concepts

To begin, ensure that each example has a unique nearest neighbor by randomly perturbing the inputs of examples that tie to be nearest neighbors to any example. Perturb by so little that no new nearest neighbor can be introduced. Repeat until each example has a unique minimum distance to another example.

Lemma 7.1.1

This form of random tie breaking makes it impossible for a cycle of three or more examples to have each example in the cycle the nearest neighbor of the next.

The proof is by contradiction. Let $n(Z)$ be the nearest neighbor of example Z in $T \cup W - \{Z\}$. Suppose there is a cycle of examples $Z_1, \ldots, Z_m, Z_1$ with $m > 2$ and each example the nearest neighbor of the next, that is,

$$\forall i \in \{1,...,m\} : Z_i = n(Z_{i+1}),$$

and

$$Z_m = n(Z_1)$$

Let d be the distance metric over example inputs. Then

$$d(Z_1,Z_2) \leq ... \leq d(Z_m,Z_1) \leq d(Z_1,Z_2).$$

For cycles greater than length two, the tie breaking makes equality impossible. So we have

$$d(Z_1,Z_2) < ... < d(Z_m,Z_1) < d(Z_1,Z_2).$$

Having the same distance on the left and right implies that the distance from the first example to the second is greater than itself, which is impossible, completing the proof.

Let G be a directed graph with each example in $Z_1, \ldots, Z_{t+w}$ a node and with edges

$$\{(n(Z_1),Z_1),...,(n(Z_{t+w}),Z_{t+w})\},$$

that is, an edge to each example from its nearest neighbor. By Lemma 7.1.1, G has no cycles of length greater than two. So G is a directed tree or forest, plus some directed edges that complete length two cycles by going back along tree edges. Let F be a directed forest created by removing from G one edge from each two-cycle. The algorithm to efficiently compute an error bound uses dynamic programming, starting at the leaves of F and working up to the root or roots.

7.2 Recurrences and Algorithm

Let *F(k)* be the subtree of F rooted at example Z_k, that is, Z_k and all nodes that can be reached by following directed sequences of edges from Z_k. Let *A(i,j,k)* be the subset of assignments in $\{0,1\}^w$ that have i leave-one-out errors among the training examples in *F(k)* and j leave-one-out errors among the working examples of *F(k)*. Let *n(Z,T)* be the nearest neighbor of example Z among the training examples. Define

$$e_{ijky} = \max_{a \in A(i,j,k)} |\{Z \in F(k) \cap W | Z.y = y \text{ and } Z.y \neq n(Z,T).y\}|,$$

that is, it is the maximum number of working examples in the subtree of F rooted at example Z_k that are misclassified by their nearest training examples, with the maximum being over assignments that have i leave-one-out errors on the training examples in the subtree, j leave-one-out errors on the working examples in the subtree, and label y on example Z_k. If there are no such assignments, then define

$$e_{ijky} = -1,$$

to signify that the value is "undefined."

The base cases are leaves of F. For a leaf example Z_k that is in T and has label y,

$$e_{00ky} = 0,$$

and, for all other combinations of i, j, and y,

$$e_{ijky} = -1.$$

For a leaf example Z_k that is in W and has label y,

$$e_{00ky} = 0,$$

$$e_{0,0,k,1-y} = 1,$$

and, for all other combinations of i, j, and y,

$$e_{ijky} = -1.$$

Before defining the general recurrence, we first define some terms that express how interactions between examples and their parent examples in F influence the numbers of leave-one-errors in T and W and the error. Let Z_i be an example, Let $y_i = Z_i.y$, let Z_k be the parent of Z_i in F, and let $y_k = Z_k.y$. Define

$$c_T(i,y_i,k,y_k) = \begin{cases} 1 & Z_i \in T \text{ and } y_i \neq y_k \\ 0 & \text{otherwise} \end{cases}, \tag{9}$$

to count whether Z_k having label y_k causes example Z_i to be a leave-one-out error in T. Define

$$d_T(i,y_i,k,y_k) = \begin{cases} 1 & Z_k \in T, y_i \neq y_k, \text{ and } Z_i = n(Z_k) \\ 0 & \text{otherwise} \end{cases}, \tag{10}$$

to count whether example Z_k having label y_k causes example Z_k to be a leave-one-out error in T. Define

$$c_W(i,y_i,k,y_k) = \begin{cases} 1 & Z_i \in W \text{ and } y_i \neq y_k \\ 0 & \text{otherwise} \end{cases}, \tag{11}$$

to count whether example Z_k having label y_k causes example Z_i to be a leave-one-out error in W if it has label y_i. Define

$$d_W(i,y_i,k,y_k) = \begin{cases} 1 & Z_k \in W, y_i \neq y_k, \text{ and } Z_i = n(Z_k) \\ 0 & \text{otherwise} \end{cases}, \tag{12}$$

to count whether example Z_i having label y_i causes example Z_k to be a leave-one-out error in W if it has label y_k. Define $n_T(Z)$ to be the nearest neighbor of example Z in T. Define

$$h(k,y_k) = \begin{cases} 1 & Z_k \in W \text{ and } y_k \neq n_T(Z_k).y \\ 0 & \text{otherwise} \end{cases},$$

to count whether example Z_k having label y_k causes example Z_k to be misclassified by its nearest training example.

Let *r(Z)* be the parent of example Z in F. Define

$$B(k) \equiv \{b | r(Z_b) = Z_k\},$$

that is, *B(k)* is the set of positions in C of the children of Z_k in F. Let $y_b = Z_b.y$. Then

$$e_{ijky} = \max_{\substack{\{(i_b,j_b,b,y_b) : b \in B(k), e_{i_b j_b b y_b} \neq -1\} \text{ s.t.} \\ \sum_{b \in B(k)} [i_b + c_T(b,y_b,k,y) + d_T(b,y_b,k,y)] = i, \text{ and} \\ \sum_{b \in B(k)} [j_b + c_W(b,y_b,k,y) + d_W(b,y_b,k,y)] = j}} h(k,y_k) + \sum_{b \in B(k)} e_{i_b j_b b y_b}. \tag{13}$$

Let *A(i,j)* be the subset of assignments in $\{0,1\}^w$ that have *i* leave-one-out errors on training examples and *j* leave-one-out errors on working examples. Define

$$v_{ij} \equiv \max_{a \in A(i,j)} |\{Z \in W | Z.y \neq n(Z,T).y\}|,$$

that is, the maximum error over assignments that have *i* leave-one-out errors on training examples and *j* leave-one-out errors on working examples. If there are no such assignments, then let

$$v_{ij} = 0.$$

Define

$$B \equiv \{b | Z_b \text{ is a root of } F\}.$$

Then

$$v_{ij} = \max_{\substack{\{(i_b,j_b,b,y_b) : b \in B, e_{i_b j_b b y_b} \neq -1\} \text{ s.t.} \\ \sum_{b \in B} i_b = i, \text{and} \\ \sum_{b \in B} j_b = j}} \sum_{b \in B} e_{i_b j_b b y_b}.$$

Let u_{ij} be the probability that j or more leave-one-out errors are in $W(S)$ for a random size-t subset S of $\{1, \ldots, t+w\}$, given that there are $i+j$ leave-one-out errors in $T \cup W$. Then

$$u_{ij} = \sum_{z=j}^{\min(w,i+j)} \frac{\binom{i+j}{z}\binom{t+w-i-j}{w-z}}{\binom{t+w}{w}}. \tag{14}$$

For a given δ, the value

$$\max_{u_{ij} \geq \delta} v_{ij} \tag{15}$$

bounds the number of working examples misclassified by their training examples, with probability at least 1-δ.

Note that the recurrence for each term e_{ijky} depends on terms e_{ijby} for all $b \in B(k)$. So produce an ordering σ_k on examples in C that places all children before their parents in F. Compute terms e_{ijky} in that order, to ensure that each term is computed prior to computing any term that depends on it. Next compute terms v_{ij} based on terms e_{ijby} for all $b \in B$. Then compute values u_{ij} using Equation (14), and compute the bound according to Equation (15).

7.3 Example of Computing Values e_{ijky}

Consider a small example to demonstrate the recurrence for e_{ijky}. Use the following examples:

example	input	output	set
0	11.1	0	T
1	12.3	1	T
2	15.6	?	W

The graph G of nearest neighbors has edges (0,1), (1,0), and (1,2). Removing the first edge produces a tree F, with node 1 as root and the other nodes as leaves. An ordering that places children before parents in F is (0, 2, 1). So compute terms e_{ijky} for $k = 0$, then $k = 2$, then $k = 1$.

For $k = 0$, node 0 is a leaf in F. Since example 0 is in T and has output $y_0 = 0$,

$$e_{0000} = 0,$$

meaning that, in the single-node subtree consisting of node 0, there are no leave-one-out errors in T or in W, and there are no examples in W misclassified by nearest neighbors in T. For all other i, j, and y

$$e_{ij0y} = -1.$$

For $k = 2$, node 2 is a leaf in F. Since example 2 is in W, it may have output $y_2 = 0$ or $y_2 = 1$. If $y_2 = 0$, then example 2 is misclassified by its nearest neighbor in T, which is example 1. So

$$e_{0020} = 1.$$

If $y_2 = 1$, then example 2 is properly classified by example 1, so

$$e_{0021} = 0.$$

For k = 1, example 1 is in T, and y_1 = 1. Node 1 has two children in G—nodes 0 and 2. For child node 0, only the term e_{000} is defined. For child node 2, terms e_{0020} and e_{0021} are defined. Each pair of terms with one from each child node can produce a term for node 1.

Begin with the pair e_{000} and e_{0020}. Relationships between node 1 and each child node contribute to the term. For the relationship between node 1 and node 0, the values are n = 0, y_n = 0, k = 1, and y_k = 1. With these arguments:

1. c_T(0,0,1,1) = 1 because example 1 (the parent) misclassifies example 0 (the child), causing a leave-one-out error in T.
2. d_T(0,0,1,1) = 1 because example 0 (the child) misclassifies example 1 (the parent), causing a leave-one-out error in T.
3. c_W(0,0,1,1) = 0 and d_W(0,0,1,1) = 0 because neither example is in W.

For the relationship between node 1 and node 2, the values are n = 2, y_n = 0, k = 1, and y_k = 1. With these arguments:

1. c_T(2,0,1,1) = 0 because example 2 (the child) is not in T.
2. d_T(2,0,1,1) = 0 because example 2 (the child) does not classify example 1 (the parent).
3. c_W(2,0,1,1) = 1 because example 1 (the parent) misclassifies example 2 (the child), causing a leave-one-out error in W.
4. d_W(2,0,1,1) = 0 because example 1 (the parent) is not in W.

The resulting term has

$$\begin{aligned} i &= [i_0 + c_T(0,0,1,1) + d_T(0,0,1,1)] + [i_2 + c_T(2,0,1,1) + d_T(2,0,1,1)] \\ &= [0+1+1] + [0+0+0] = 2 \end{aligned}$$

and

$$\begin{aligned} j &= [j_0 + c_W(0,0,1,1) + d_W(0,0,1,1)] + [j_2 + c_W(2,0,1,1) + d_W(2,0,1,1)] \\ &= [0+0+0] + [0+1+0] = 1. \end{aligned}$$

So the term is e_{2111}. The value is

$$e_{2111} = h(1,1) + e_{0000} + e_{0020} = 0 + 0 + 1 = 1.$$

(The value of h(1,1) is zero since example 1 is not in W.) The value e_{2111} = 1 means that, in the subtree of F rooted at node 1, that is, in F, it is possible to have two leave-one-out errors in T, one leave-one-out error in W, and one example in W misclassified by its nearest neighbor in T.

Now consider the other pair of terms from children, e_{0000} and e_{0021}. The relationship between node 1 and node 0 is the same as for the previous pair. The relationship between node 1 and node 2 changes because now y_2 = 1, so n = 2, y_n = 1, k = 1, and y_k = 1. With these arguments:

1. $c_T(2,1,1,1) = 0$ because example 2 (the child) is not in T.
2. $d_T(2,1,1,1) = 0$ because example 2 (the child) does not classify example 1 (the parent).
3. $c_W(2,1,1,1) = 0$ because example 1 (the parent) properly classifies example 2 (the child), causing no leave-one-out error in W.
4. $d_W(2,1,1,1) = 0$ because example 1 (the parent) is not in W.

The resulting term has

$$\begin{aligned} i &= [i_0 + c_T(0,0,1,1) + d_T(0,0,1,1)] + [i_2 + c_T(2,1,1,1) + d_T(2,1,1,1)] \\ &= [0+1+1] + [0+0+0] = 2 \end{aligned}$$

and

$$\begin{aligned} j &= [j_0 + c_W(0,0,1,1) + d_W(0,0,1,1)] + [j_2 + c_W(2,1,1,1) + d_W(2,1,1,1)] \\ &= [0+0+0] + [0+0+0] = 0. \end{aligned}$$

So the term is e_{2011}. The value is

$$e_{2011} = h(1,1) + e_{0000} + e_{0021} = 0+0+0 = 0,$$

which means that it is possible to have two leave-one-out errors in T, zero leave-one-out errors in W, and zero examples in W misclassified by nearest neighbors in T. Other than e_{2111} and e_{2011}, for all other i, j, and y

$$e_{ij1y} = -1.$$

This completes the computation of e_{ijky} values for this problem.

7.4 Efficient Computation

The bound can be computed using storage and time O(poly(t+w)). Computing values e_{ijky} and v_{ij} directly from the recurrences is inefficient. First consider values e_{ijky}. Recurrence (13) handles terms for all children of example Z_k at the same time. To improve efficiency, accumulate terms from one child at a time, as follows. Define $e_{\bullet\bullet ky}$ to be the "slice" of values with the specified k and y and all values of i and j. To compute each slice, iterate through children Z_b of Z_k, using a slice-sized array *prev* to store the accumulation over terms from children before Z_b and a slice-sized array *next* to store the accumulation of terms from children up to and including Z_b. In other words, when the iteration begins for child Z_{b^*}, $prev_{ij}$ is the value that e_{ijky} would have if the subtree in F rooted at k had children

$$\bigcup_{\{b \in B(k) | b < b^*\}} Z_b.$$

And when the iteration ends for child Z_{b^*}, $next_{ij}$ is the value that e_{ijky} would have if the subtree in F rooted at k had children

$$\bigcup_{\{b \in B(k) | b \leq b^*\}} Z_b.$$

Compute the iteration for child Z_{b^*} according to the recurrence:

$$next_{ij} = \max_{\substack{(i_a, j_a, i_{b^*}, j_{b^*}, y_{b^*}) : prev_{i_a j_a} \neq -1, e_{i_{b^*} j_{b^*} b^* y_{b^*}} \neq -1, \\ i_a + i_{b^*} + c_T(b^*, y_{b^*}, k, y) + d_T(b^*, y_{b^*}, k, y) = i, and \\ j_a + j_{b^*} + c_W(b^*, y_{b^*}, k, y) + d_W(b^*, y_{b^*}, k, y) = j.}} prev_{i_a j_a} + e_{i_{b^*} j_{b^*} b^* y_{b^*}}.$$

The base cases for this recurrence are the definitions for values of *prev* for the first child. By the definition of *prev*, these values should treat Z_k as a leaf in F. So use the base case values given previously for terms e_{ijky} for leaves in F to initialize *prev*.

Algorithm 7.4.1 computes an error bound efficiently. The inputs are:

1. Z – An array of examples, ordered such that children in F come before their parents. (The variables Z[k].x and Z[k].y store (X_k, Y_k), the input and output for example k.)
2. B – An array of arrays B, with B[k] the array of indices b such that Z[b] is a child of Z[k] in F.
3. R – An array of indices b such that Z[b] is a root in F.
4. u – An array with u[i][j] = u_{ij} as defined in Equation (14).
5. delta – The acceptable probability of the bound being invalid, δ.

The algorithm uses subprocedures:

1. cT, dT, cW, and dW – As defined in Equations (9) to (12).
2. nT – Returns the nearest neighbor to an example among examples in T, that is, $n_T(Z)$.

Algorithm 7.4.1

```
procedure bound(Z, B, R, u, delta)
  e[0...t][0...w][0...t+w][0...1] := -1;
    // Initialize all e[][][][] values to 1.

  // Compute slices, one for each example and assignment to the
  //   label of the example.
  for ((k, yk) in {0,...,t+w} x {0,1})
    if (Z[k] in T and yk != Z[k].y) continue;
      // Impossible assignment, so skip it.

    prev[0...t][0...w] := -1;
    next[0...t][0...w] := -1;

    // Initialize prev[0][0].
```

```
  if (Z[k] in T) prev[0][0] :=  0;
  if (Z[k] in W)
    Z[k].y = yk;
    if (nT(Z[k]) != Z[k].y) prev[0][0] := 1; else prev[0][0] := 0;
  end if

  // Compute the contribution for each child b of k in F.
  for ((b, yb) in B[k] x {0,1})
    if (Z[b] in T and yb != Z[b].y) continue;
      // impossible assignment, so skip it.
    if (Z[b] in W) Z[b].y := yb;
    di := cT(b,k) + dT(b,k);
    dj := cW(b,k) + dW(b,k);

    for ((i, j) in {0,...,t} x {0,...,w} such that e[i][j][b][yb] != -1)
      for ((ii, jj) in {0,...,t} x {0,...,w} such that prev[ii][jj] != -1)
        next[ii + i + di][jj + j + dj] = max(next[ii + i + di][jj + j + dj],
                                             prev[ii][jj] + e[i][j][b][yb]);
      end for (ii, jj)
    end for (i, j)

    // Prepare to compute contribution for next child b of k in F.
    prev := next;
    next[0...t][0...w] := -1;
  end for (b, yb)

  // Copy the slice into e[][][][].
  for ((i, j) in {0,...,t}x{0,...,w}) e[i][j][k][yk] = prev[i][j];
end for (k, yk)

// Combine roots: treat each root as a child of a virtual super-root.
prev[0...t][0...w] := -1;
next[0...t][0...w] := -1;

prev[0][0] := 0; // The virtual super-root introduces no errors.

// Accumulate terms over roots b in R.
for ((b, i, j) in R x {0,...,t} x {0,,w})
  m := max(e[i][j][b][0], e[i][j][b][1]);

  if (m!=-1)
    for ((ii, jj) in {0,...,t} x {0,...,w} such that prev[ii][jj]!=-1)
      next[ii + i][jj + j] := max(next[ii + i][jj + j], prev[ii][jj] + m);
    end for (ii, jj)
  end if
```

```
    prev = next;
    next[0...t][0...w] := -1;
  end for (b, i, j)

  // Maximize v over feasible u to produce a bound on error count.
  v = prev;

  mx := 0;

  for ((i, j) in {0,...,t}x{0,...,w})
    if (u[i][j] >= delta) mx = max(mx, v[i][j])
  end for (i, j)

  return mx;
end procedure
```

Appendix A contains Java code to compute error bounds by this procedure. The code uses $O(t^2w^2(t+w))$ time and O($tw(t+w)$) storage. Appendix A also contains a note on how to use less storage.

7.5 Random Tie Breaking for Ranking

Random tie breaking for ranking, as defined in Section 4 and applied to virtual partitions in Section 6, cannot be applied to the bound returned by the algorithm above. The error count that is the bound corresponds to an assignment that maximizes the error of using training examples to classify working examples, subject to the constraints that there are i leave-one-out errors on training examples, there are j leave-one-out errors on working examples, and the counts i and j make the assignment likely even without random tie breaking. It is valid to apply random tie breaking to the assignment behind the error count that is a candidate for the bound, as explained in Section 6. However, if random tie breaking declares the assignment unlikely, then we are left without a next candidate for the bound.

To use random tie breaking, the algorithm needs to store all candidates rather than just the maximum error count candidate in each variable e_{ijky} and v_{ij}. So instead of storing a single maximum value in each variable, store a vector indexed by error counts, with values indicating how many partial assignments (for variables e_{ijky}) or assignments (for variables v_{ij}) produce each error count. Follow the structure of the maximization algorithm, but replace maximization by accumulating candidates. Compute values u_{ij} as in the maximization algorithm above, and use those values to determine which vectors v_{ij} count potentially likely candidates for the bound. (Only the combinations of i and j that are likely without random tie breaking are potentially likely with random tie breaking.) . Then iterate through possible error counts, in descending order. For each error count, for each candidate counted by a vector of potentially likely candidates, apply random tie breaking to the candidate. If the candidate is likely, then return it as the bound.

8. Tests

This section presents results of tests for bounding methods developed in this paper. First there are tests comparing different bounding methods. Next, there are tests to examine the joint frequencies of errors and error bounds. Then there are tests to explore the effect of working set size on error bounds.

8.1 Comparing Bounding Methods

Here are results of tests to compare different bounding methods on 1-nearest neighbor classification for different types of data. The different bounding methods are:

1. Complete – Use the complete filter.
2. 100 – Use a sample filter with 100 sample partitions.
3. 1000 – Use a sample filter with 1000 sample partitions.
4. 10,000 – Use a sample filter with 10,000 sample partitions.
5. LOO – Use virtual partitioning, with a filter that scores one for each leave-one-out error.
6. Double – Use virtual partitioning, with a filter that scores one for each example that is misclassified by both of its two nearest neighbors in $T \cup W$.

All bounding methods use ranking with random tie breaking, as explained in Sections 4 and 6. The sample filters draw partitions without replacement.

For each type of data, there is a table of results. Each row holds results for a different value of the bound certainty parameter δ. The first column of each table shows errors from using training data as a 1-nearest neighbor classifier on working data. The other columns show differences between the bounds on error and actual error for different bounding methods.

Each cell shows a mean and standard deviation over 1000 trials. The cells in the "Error" column show mean and standard deviation of errors. The cells in subsequent columns show mean and standard deviation of difference between bound and error. For example, suppose the error has mean 0.3 and standard deviation 0.4, and a bounding method has mean 0.1 and standard deviation 0.0. This indicates that the error averages 0.3 over the 1000 trials, and the error varies quite a bit, but the bound is always exactly 0.1 greater than the actual error.

Note that the standard deviations displayed in cells are standard deviations of the values over 1000 trials. They are not standard deviations of the estimates of the means of values over 1000 trials, that is, their large sizes do not indicate uncertainty about the accuracy of the means. Since there are 1000 trials, those standard deviations are about 1/33 of the ones shown, indicating that most differences in means for different bounding methods in the tests below are statistically significant.

Each row of each table is based on the same 1000 trials, but different rows are based on different sets of trials. For each trial, a size $t+w$ subset of examples is selected at random from a data set. A size-t subset is selected at random to form the training set T, and the remaining w examples form the working set W. The error is computed, and each bounding method is applied to (T,W) to compute an error bound. The error is subtracted from each bound, and the differences are accumulated into the statistics for the bounding methods. In each row, we show the least mean among bounding methods in bold print.

δ	Error	Complete	100	1000	10,000	LOO	Double
0.1	0.0±0.0	0.21±0.096	0.23±0.10	0.21±0.097	0.21±0.10	0.25±0.18	$\mathbf{0.11 \pm 0.24}$

Table 1: Bound Methods Compared on Iris Data

All tests ran on an Apple Macintosh, with dual 1.42 GHz PowerPC processors and 512 MB of RAM. The longest-running tests were for the data set involving diabetes among Pima Indians, with t = 200 training examples and w = 15 working examples. The tests for δ = 0.1, δ = 0.2, and δ = 0.3 ran concurrently, taking about a day and a half for the 3000 trials, or about a minute per trial.

8.1.1 IRIS DATA

Table 1 has results for a data set involving iris classification. The data set is from the repository of data sets for machine learning maintained by the University of California at Irvine, which is available online. The data set contains examples for three types of iris; we use only the examples for the first two types in order to have binary classification problems. This leaves 100 examples, with 50 from each class. Each example has four input dimensions. We use t = 40 training examples and w = 4 working examples for each trial. The iris data are easy to classify, as indicated by the fact that the errors are always zero.

For δ = 0.1, the best method is virtual partitioning with a filter based on whether the two nearest neighbors to an example both misclassify the example. To understand why this filter is effective for data sets that are easy to classify, imagine a lone working example in the midst of many training examples that all have the same label. Suppose an assignment gives the opposite label to the working example. The two nearest neighbors are both training examples with the other label, so the filter recognizes the working example. On the other hand, even if the working example is the nearest neighbor of several training examples, the filter ignores the fact that the working example misclassifies those examples, because their next-nearest neighbors are other training examples with the same label. Contrast this with a filter based on leave-one-out errors. This filter would recognize the incorrectly labeled working example, but it would also recognize any nearby training examples that had the working example as nearest neighbor.

The best method for δ = 0.2 uses a complete filter. The best method for δ = 0.3 uses a sample size of 1000. For all values of δ, methods using sampled filters based on 1000 and 10,000 partitions perform about as well as the method using a complete filter—the differences between them are not statistically significant. The method using a sampled filter based on 100 partitions performs slightly worse, indicating that using fewer samples for ranking allows into the likely set some assignments with high error on the working set that would be rejected by using more samples. In general, more samples give stronger bounds, but at the cost of added computation.

8.1.2 DIABETES DATA

Table 2 has results for data involving diabetes in Pima Indians. This data set is also from the UC Irvine repository. The inputs have different scales, so we normalize the data, translating and scaling each input dimension to make each input dimension have mean zero and standard deviation one. There are 768 examples, with 500 from one class and 268 from another. There are eight input

δ	Error	100	1000	LOO

Table 3: Bound Methods Compared on Data with a Linear Class Boundary

δ	Error	100	1000	LOO	Double
0.1	0.18 ± 0.13	0.27 ± 0.15	$\mathbf{0.24 \pm 0.14}$	0.31 ± 0.17	0.39 ± 0.12
0.2	0.18 ± 0.12	0.17 ± 0.14	$\mathbf{0.16 \pm 0.14}$	0.22 ± 0.17	0.32 ± 0.18
0.3	0.16 ± 0.11	0.12 ± 0.13	$\mathbf{0.11 \pm 0.13}$	0.18 ± 0.17	0.28 ± 0.18

Table 4: Bound Methods Compared on Data with a Nonlinear Class Boundary

dimensions. We use $t = 200$ training examples and $w = 15$ working examples for each trial. We use 1-nearest neighbor classification.

The error indicates that this is a challenging data set for 1-nearest neighbor classification; even a classifier that always returns the label of the class with 500 examples of the 768 in the data would have average error about 0.35. The bounding method that uses 1000 partitions in a sampled filter performs best for all three values of δ. On average, that method adds error rate margins of 20% for $\delta = 0.1$, about 15% for $\delta = 0.2$, and about 11% for $\delta = 0.3$.

8.1.3 DATA WITH A LINEAR CLASS BOUNDARY

Table 3 has results for randomly generated data. The data consist of 1100 examples drawn uniformly at random from a three-dimensional input cube with length one on each side. The class label is zero if the input is from the left half of the cube and one if the input is from the right half of the cube. For these tests, there are $t = 100$ training examples and $w = 10$ working examples, using 1-nearest neighbor classification. Once again, the method that uses a sample filter with 1000 partitions in the sample outperforms the other methods in the test. On average, the method adds error rate margins of 20% for $\delta = 0.1$, about 12% for $\delta = 0.2$, and about 7.5% for $\delta = 0.3$.

8.1.4 DATA WITH A NONLINEAR CLASS BOUNDARY

Table 4 shows results for randomly generated data with a nonlinear class boundary. The data have the same characteristics as in the previous test, except that each class label is determined by the XOR of whether the input is in the left half of the cube, the bottom half of the cube, and the front half of the cube. In other words, the cube is cut into eight sub-cubes, and each sub-cube has a different class than the three sub-cubes with which it shares a side. This class scheme adds some

	Bound										
Error	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0

0.8											
0.9											
1.0											

Table 5: Bounds vs. Errors for $\delta = 0.1$

error. As in the previous test, the method that uses a sample filter with 1000 partitions in the sample outperforms the other methods in the test. The method adds error rate margins that are higher than for the previous test, that is, about 24% for $\delta = 0.1$, about 16% for $\delta = 0.2$, and about 11% for $\delta = 0.3$.

8.1.5 COMPARISON TO BOUNDS BASED ON VC DIMENSION

The test results in tables 1 to 4 show that error bounds based on worst likely assignments can be effective for small data sets. Compare these bounds to error bounds based on VC dimension (Vapnik and Chervonenkis, 1971), as follows. Suppose that we train linear classifiers on the training sets for our tests. To simplify our analysis, assume that all trained classifiers are consistent, that is, they have zero error on their training data. This consistency assumption produces stronger VC bounds, allowing us to use the bound formula (Cristianini and Shawe-Taylor, 2000, p. 56):

$$\frac{2}{t}\left(d\log\frac{2et}{d}+\log\frac{2}{\delta}\right),$$

where t is the number of training examples, d is the VC dimension, which is one more than the number of input dimensions for linear classifiers, and δ is the allowed probability of bound failure. Let $\delta = 0.3$. For the iris problem, $t = 40$ and $d = 5$, producing bound 1.5. For the diabetes problem, $t = 200$, $d = 9$, and the bound is 0.65. For the problems with randomly generated data, $t = 100$, $d = 4$, and the bound is 0.62. Compare these bounds to those for $\delta = 0.3$ in tables 1 to 4.

8.2 Joint Frequencies of Errors and Error Bounds

Tables 5, 6, and 7 show bound versus error for 1000 trials using the same XOR-based random data generator used in the previous test and the same classification method, 1-nearest neighbor. These results are for a sampled filter with 1000 sample partitions. Errors are listed down the left column, and error bounds are listed across the top. The value in each cell is the number of trials that have the error indicated by the row and the bound indicated by the column. Cells with value zero are left blank.

	Bound

9	$\mathbf{0.31 \pm 0.076}$	0.47 ± 0.18	0.40 ± 0.22
10	$\mathbf{0.33 \pm 0.074}$	0.52 ± 0.17	0.45 ± 0.22

Table 9: Bounds vs. Number of Working Examples for $\delta = 0.1$

Table 8 summarizes the frequencies of bound margins, that is, of differences between bound and error. A bound margin less than zero means the bounding method fails, supplying an invalid error bound. From the failure column in Table 8, observe that the actual frequency of bound failure is significantly less than δ, the allowed rate of failure. The subsequent columns indicate differences between bound and actual error: exact match, over by 0.1, and over by 0.2.

Suppose we define bound failure as a negative margin and bound success as a valid bound within 0.2 of actual error. Then for $\delta = 0.1$, we have about 3% failure and about 46% success. For $\delta = 0.2$, we have about 6% failure and about 66% success. For $\delta = 0.3$, we have 11% failure and about 74% success.

8.3 Working Set Sizes and Bounds

The next results are from tests to explore how working set sizes affect error bounds. In general, since the bounding methods rely on training examples to constrain the set of likely assignments and hence to constrain the error bound, having more training examples and fewer working examples produces stronger bounds. These tests illustrate this effect and compare it over some bounding methods.

These tests use the iris classification data. The bounding methods are a sampled filter with 1000 sample partitions (1000), virtual partitioning with a leave-one-out filter (LOO), and virtual partitioning with a filter that scores one for each example misclassified by both of its two nearest neighbors (Double). For $\delta = 0.1$, $\delta = 0.2$, and $\delta = 0.3$, the number of training examples is held constant at $t = 40$ while the number of working examples w varies from three to 10.

Table 9 shows results for $\delta = 0.1$, with the lowest mean score for a bounding method in each row in bold. Note that the double-error method is better than the other two methods for small working sets, but not for larger ones. Recall that the double-error method is most effective when each working example has as nearest neighbors training examples that agree with one another. As working set sizes increase, it becomes more likely that working examples become nearest neighbors of other working examples, weakening the double-error filter.

Table 10 shows results for $\delta = 0.2$, with the lowest mean score for a bounding method in each row in bold. A variety of methods perform well for small working sets, but the sampled filter method works best for larger working sets.

Table 11 shows results for $\delta = 0.3$, with the lowest mean score for a bounding method in each row in bold. For these tests, the sampled filter method performed best for all working set sizes. Compare values in this table to values in the previous two tables. Notice that the performance of

w	1000	LOO	Double

the sampled filter method improves noticeably as δ increases. In contrast, the performance of the double-error filter does not change much with δ, especially for small working sets.

9. Discussion

This paper introduces a new method to compute an error bound for applying a classifier based on training examples to a set of working examples with known inputs. The method uses information from the training examples and inputs of working examples to develop a set of likely assignments to outputs of the working examples. A likely assignment with maximum error determines the bound. The method is very effective for small data sets.

In the bounds, filters translate training examples and inputs of working examples into constraints on the assignments to outputs of the working examples. Several filters are introduced in this paper. The complete filter is simple and direct; it evaluates each assignment by comparing the error caused by the training/working partition at hand to the errors caused by all other training/working partitions, rejecting the assignment as unlikely if the error for the partition at hand is especially large. The complete filter is effective because it optimizes directly over the error on the partition at hand, which is the basis for the bound. The sampled filter is an easier-to-compute variant that uses only a subset of training/working partitions rather than computing error for all of them. With a sufficient number of samples, the sampled filter performs about as well as the complete filter.

Filters based on virtual partitions reduce computation by not computing errors over partitions for each assignment. The tradeoff is that filters for virtual partitions rely on indirect measures of

whether assignments are likely. This paper introduces a filter based on leave-one-out error and presents an algorithm based on that filter to efficiently compute an error bound for 1-nearest neighbor classification. This paper also introduces a filter based on whether the two nearest neighbors both misclassify an example. Tests show that this filter can be more effective than the complete filter for problems with little classification error and small numbers of working examples.

Directions for future research include:

1. Develop and analyze new filters for use with virtual partitions, to compete with the leave-one-out and double-error filters presented here.

2. Analyze how training set size, working set size, and properties of the data influence the bounds, with the goal of developing new filters that target different types of problems.

3. Develop efficient algorithms for nearest neighbor classifiers using virtual partitioning with filters beyond the leave-one-out filter.

4. Develop efficient algorithms to compute error bounds using virtual partitioning for classifiers other than nearest neighbor classifiers, such as condensed and edited nearest neighbors classifiers (Devroye et al., 1996) and support vector machines (Vapnik, 1998).

5. Explore how to use efficient bounds for nearest neighbor classifiers to indirectly produce bounds for other types of classifiers. For example, for support vector machines, first bound nearest neighbor error. Then use the bound to constrain assignments, and bound the support vector machine error by the maximum error over the constrained set of assignments.

6. Consider using alternatives to the set of sister partitions in the complete and sampled filters. For example, with 100 training examples and 10 working examples, partition the training examples into blocks of 10 examples each. Treating the working examples as another block, there are 11 blocks. Each partition that has one block as the working examples and the remaining blocks as the training examples is equally likely. So these partitions can be used in place of the sister partitions. As another example, with 10 training examples and 10 working examples, pair off each working example with a different training example. Each partition that has one of each pair in the working examples and the other in the training examples is equally likely. So these partitions can be used in place of the sister partitions.

Acknowledgments

We thank Joel Franklin for encouraging this research through his example and his teaching. We also thank two anonymous referees for very helpful suggestions on notation and presentation.

Appendix A. Java Code to Compute Error Bounds for 1-Nearest Neighbor Classifiers

The excerpt of Java code below uses the approach described in Section 7.4 to efficiently compute all e_{ijky} in methods computePossibilities and computeSlice. (Array a in the code plays the role of array *prev* in Section 7.4, and array b plays the role of array *next*.) The same technique is used to compute all *v*ij in method combineRoots. Each root is treated as a child of a virtual "super-root". The method named bound is included to give an overview of the computation.

```
public class VirtualPartitionBounder
{
  Problem p; // Handles examples, labels, neighbors, memberships in T and W.
  int[][][][] e; // e[i][j][k][y]'s.
  int[][] a; // a[i][j]'s to accumulate a slice over children.
  int[][] b; // b[i][j]'s to accumulate a slice over children.
  int[] order; // Ordering of examples with children in F before parents
  int[][] children; // children[k][] is a list of children of k in F
  int[] roots; // Examples that are roots in F

  /**
   * Constructor.
   **/
  public VirtualPartitionBounder(Problem p)
  {
    this.p = p;
    this.e = new int[p.sizeT()+1][p.sizeW()+1][p.sizeTuW()][2];
    this.a = new int[p.sizeT()+1][p.sizeW()+1];
    this.b = new int[p.sizeT()+1][p.sizeW()+1];
  }

  /**
   * Returns a bound on the number of errors on W by T, with probability
   * of bound failure at most delta.
   **/

              for (int jj=0; jj<a[ii].length; jj++)
                if (a[ii][jj]!=-1)
                {
                  b[ii+i+di][jj+j+dj] = max(b[ii+i+di][jj+j+dj],
                      a[ii][jj] + e[i][j][n][yn]);
                }
          }
    }

    copyBToA(); // Copy b to a before handling the next child.
    clearB(); // Set all b[i][j] to -1.
  }

  insertAIntoE(k, yk);
}

/**
 * Combine roots to compute v-values. Treat each root as a child
 * of a virtual super-root.
 **/
private void combineRoots()
{
  clearA(); // Set all a[i][j] to -1.
  clearB(); // Set all b[i][j] to -1.

  a[0][0] = 0; // The super-root introduces no errors.

  // Accumulate terms over roots.
  for (int look=0; look<roots.length; look++)
  {
```

```
      int n = roots[look]; // Get root.

      for (int i=0; i<e.length; i++)
        for (int j=0; j<e[i].length; j++)
        {
          int v = max(e[i][j][n][0], e[i][j][n][1]);

          if (v!=-1)
            for (int ii=0; ii<a.length; ii++)
              for (int jj=0; jj<a[ii].length; jj++)
                if (a[ii][jj]!=-1)
                  b[ii+i][jj+j] = max(b[ii+i][jj+j],
                      a[ii][jj] + v);
        }

      copyBToA(); // Copy b to a before handling the next root.
    }
  }
}
```

Now consider the storage and time requirements for this technique. The storage is dominated by the array *e*, which has size O(*tw(t+w)*). The time is dominated by the nested loops in methods computePossibilities, computeSlice, and combineRoots. Examine the nested loops in computeSlice that run for each child and possible *y*-value for the child. The nesting is four deep, with two loops of size *t*+1 and two of size *w*+1. So, for each child-parent relationship, the time is $O(t^2w^2)$. Note that the loops for each root in combineRoots are similar to those for each child in computeSlice. Since each of the t+w examples is a child of one example in *F* or a root in *F*, and there are at most two possible *y*-values for each example, the total time is $O(t^2w^2(t+w))$.

To reduce storage, discard the slice for each example after using it to compute the slice for the parent of the example in *F*. To reduce storage and time in most cases, store a list of nonnegative values for each slice rather than storing the slice in array form with all the -1's included. Then iterate over those lists rather than all pairs (*i*,*j*) and (*ii*,*jj*) in methods computeSlice and combineRoots.

Abstract

In graphical modelling, a bi-directed graph encodes marginal independences among random variables that are identified with the vertices of the graph. We show how to transform a bi-directed graph into a maximal ancestral graph that (i) represents the same independence structure as the original bi-directed graph, and (ii) minimizes the number of arrowheads among all ancestral graphs satisfying (i). Here the number of arrowheads of an ancestral graph is the number of directed edges plus twice the number of bi-directed edges. In Gaussian models, this construction can be used for more efficient iterative maximization of the likelihood function and to determine when maximum likelihood estimates are equal to empirical counterparts.

Keywords: ancestral graph, covariance graph, graphical model, marginal independence, maximum likelihood estimation, multivariate normal distribution

1. Introduction

In graphical modelling, bi-directed graphs encode marginal independences among random variables that are identified with the vertices of the graph (Pearl and Wermuth, 1994; Kauermann, 1996; Richardson, 2003). In particular, if two vertices are not joined by an edge, then the two associated random variables are assumed to be marginally independent. For example, the graph G in Figure 1, whose vertices are to be identified with a random vector (X_1, X_2, X_3, X_4), represents the pairwise marginal independences $X_1 \perp\!\!\!\perp X_3$, $X_1 \perp\!\!\!\perp X_4$, and $X_2 \perp\!\!\!\perp X_4$. While other authors (Cox and Wermuth, 1993, 1996; Edwards, 2000) have used dashed edges to represent marginal independences, the bi-directed graphs we employ here make explicit the connection to path diagrams (Wright, 1934; Koster, 1999).

Gaussian graphical models for marginal independence, also known as covariance graph models, impose zero patterns in the covariance matrix, which are linear hypotheses on the covariance matrix (Anderson, 1973). The graph in Figure 1, for example, imposes $\sigma_{13} = \sigma_{14} = \sigma_{24} = 0$. An estimation procedure designed for covariance graph models is described in Drton and Richardson (2003); see

Figure 1: A bi-directed graph G with (unique) minimally oriented graph $G^{\min}$.

also Chaudhuri et al. (2007). Other recent work involving these models includes Mao et al. (2004) and Wermuth et al. (2006).

In this paper we employ the connection between bi-directed graphs and the more general ancestral graphs with undirected, directed, and bi-directed edges (Section 2). For the statistical motivation of ancestral graphs see Richardson and Spirtes (2002); for causal interpretation see Richardson and Spirtes (2003). We show how to construct a maximal ancestral graph $G^{\min}$, which we call a minimally oriented graph, that is Markov equivalent to a given bi-directed graph G and such that the number of arrowheads is minimal (Sections 3–4). Two ancestral graphs are Markov equivalent if the independence models associated with the two graphs coincide; see for example Roverato (2005) for some recent results on Markov equivalence of different types of graphs. The number of arrowheads is the number of directed edges plus twice the number of bi-directed edges. Minimally oriented graphs provide useful nonparametric information about Markov equivalence of bi-directed, undirected and directed acyclic graphs. For example, the graph G in Figure 1 is not Markov equivalent to an undirected graph because $G^{\min}$ is not an undirected graph, and G is not Markov equivalent to a DAG because $G^{\min}$ contains a bi-directed edge. The graph G in Figure 1 has a unique minimally oriented graph but in general, minimally oriented graphs are not unique. Our construction procedure (Algorithm 14) involves a choice of a total order among the vertices. Varying the order one may obtain all minimally oriented graphs (Theorem 17).

For covariance graph models, minimally oriented graphs allow one to determine when the maximum likelihood estimate of a variance or covariance is available explicitly as its empirical counterpart (Section 5). For example, since no arrowheads appear at the vertices 1 and 4 in the graph $G^{\min}$ in Figure 1, the maximum likelihood estimates of σ_{11} and σ_{44} must be equal to the empirical variances of X_1 and X_4, respectively. The likelihood function for covariance graph models may be multi-modal, though simulations suggest this only occurs at small sample sizes, or under misspecification (Drton and Richardson, 2004a). However, when a minimally oriented graph reveals that a parameter estimate is equal to an empirical quantity (such as σ_{11} and σ_{44} in the above example) then even if the likelihood function is multi-modal this parameter will take the same value at every mode. Perhaps most importantly, minimally oriented graphs allow for computationally more efficient maximum likelihood fitting; see Remark 24 and the example in Section 5.3.

2. Ancestral Graphs and Their Global Markov Property

This paper deals with *simple mixed graphs*, which feature undirected ($v - w$), directed ($v \to w$) and bi-directed edges ($v \leftrightarrow w$) under the constraint that there is at most one edge between two vertices. In this section we give a formal definition of these graphs and discuss their Markov interpretation.

2.1 Simple Mixed Graphs

Let $\mathcal{E} = \{\emptyset, -, \leftarrow, \rightarrow, \leftrightarrow\}$ be the set of possible edges between an ordered pair of vertices; $\emptyset$ denoting that there is no edge. A *simple mixed graph* $G = (V, E)$ is a pair of a finite *vertex set* V and an *edge map* $E : V \times V \to \mathcal{E}$. The edge map E has to satisfy that for all $v, w \in V$,

(i) $E(v,v) = \emptyset$, that is, there is no edge between a vertex and itself,

(ii) $E(v,w) = E(w,v)$ if $E(v,w) \in \{-, \leftrightarrow\}$,

(iii) $E(v,w) = \rightarrow \iff E(w,v) = \leftarrow$.

In the sequel, we write $v - w \in G$, $v \to w \in G$, $v \leftarrow w \in G$ or $v \leftrightarrow w \in G$ if $E(v,w)$ equals $-$, $\rightarrow$, $\leftarrow$ or $\leftrightarrow$, respectively. If $E(v,w) \neq \emptyset$, then v and w are *adjacent*. If there is an edge $v \leftarrow w \in G$ or $v \leftrightarrow w \in G$ then there is an *arrowhead at* v on this edge. If there is an edge $v \to w \in G$ or $v - w \in G$ then there is a *tail at* v on this edge. A vertex w is in the *boundary* of v, denoted by $\mathrm{bd}(v)$, if v and w are adjacent. The boundary of vertex set $A \subseteq V$ is the set $\mathrm{bd}(A) = [\cup_{v \in A} \mathrm{bd}(v)] \setminus A$. We write $\mathrm{Bd}(v) = \mathrm{bd}(v) \cup \{v\}$ and $\mathrm{Bd}(A) = \mathrm{bd}(A) \cup A$. An induced subgraph of G over a vertex set A is the mixed graph $G_A = (A, E_A)$ where E_A is the restriction of the edge map E on $A \times A$. The *skeleton* of a simple mixed graph is obtained by making all edges undirected.

In a simple mixed graph a sequence of adjacent vertices $(v_1, \ldots, v_k)$ uniquely determines the sequence of edges joining consecutive vertices v_i and v_{i+1}, $1 \leq i \leq k-1$. Hence, we can define a *path* π between two vertices v and w as a sequence of distinct vertices $\pi = (v, v_1, \ldots, v_k, w)$ such that each vertex in the sequence is adjacent to its predecessor and its successor. A path $v \to \cdots \to w$ with all edges of the form $\rightarrow$ and pointing toward w is a directed path from v to w. If there is such a directed path from v to $w \neq v$, or if $v = w$, then v is an *ancestor* of w. We denote the set of all ancestors of a vertex v by $\mathrm{An}(v)$ and for a vertex set $A \subseteq V$ we define $\mathrm{An}(A) = \cup_{v \in A} \mathrm{An}(v)$. Finally, a directed path from v to w together with an edge $w \to v \in G$ is called a *directed cycle*.

Important subclasses of simple mixed graphs are illustrated in Figure 2. *Bi-directed*, *undirected* and *directed graphs* contain only one type of edge. *Directed acyclic graphs* (DAGs) are directed graphs without directed cycles. These three types of graph are special cases of *ancestral graphs* (Richardson and Spirtes, 2002).

Definition 1 *A simple mixed graph G is an* ancestral graph *if it holds that*

(i) G does not contain any directed cycles;

(ii) if $v - w \in G$, then there does not exist u such that $u \to v \in G$ or $u \leftrightarrow v \in G$;

(iii) if $v \leftrightarrow w \in G$, then v is not an ancestor of w.

2.2 Global Markov Property for Ancestral Graphs

Ancestral graphs can be given an independence interpretation, known as the global Markov property, by a graphical separation criterion called *m*-separation (Richardson and Spirtes, 2002, §3.4). An extension of Pearl's (1988) *d*-separation for DAGs, *m*-separation uses the notion of *colliders*. A non-endpoint vertex v_i on a path is a *collider on the path* if the edges preceding and succeeding v_i on the path both have an arrowhead at v_i, that is, $v_{i-1} \to v_i \leftarrow v_{i+1}$, $v_{i-1} \to v_i \leftrightarrow v_{i+1}$, $v_{i-1} \leftrightarrow v_i \leftarrow v_{i+1}$ or $v_{i-1} \leftrightarrow v_i \leftrightarrow v_{i+1}$ is part of the path. A non-endpoint vertex that is not a collider is a *non-collider on the path*.

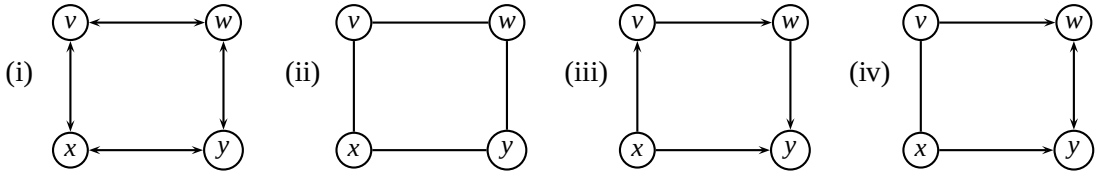

Figure 2: Simple mixed graphs. (i) A bi-directed graph, (ii) an undirected graph, (iii) a DAG, (iv) an ancestral graph.

Definition 2 *A path π between vertices v and w in a simple mixed graph G is m-*connecting *given a possibly empty set $C \subseteq V \setminus \{v,w\}$ if (i) every non-collider on π is not in C, and (ii) every collider on π is in* $\mathrm{An}(C)$. *If no path m-connects v and w given C, then v and w are m-*separated *given C. Two non-empty and disjoint sets A and B are m-separated given $C \subseteq V \setminus (A \cup B)$, if any two vertices $v \in A$ and $w \in B$ are m-separated given C.*

Let $G = (V,E)$ be an ancestral graph whose vertices index a random vector $(X_v \mid v \in V)$. For $A \subseteq V$, let X_A be the subvector $(X_v \mid v \in A)$. The *global Markov property* for G states that X_A is conditionally independent of X_B given X_C whenever A, B and C are pairwise disjoint subsets such that A and B are m-separated given C in G. Subsequently, we denote such conditional independence using the shorthand $A \perp\!\!\!\perp B \mid C$ that avoids making the probabilistic context explicit. The global Markov property, when applied to each of the graphs in Figure 2 in turn, implies (among other independences) that:

(i) $v \perp\!\!\!\perp y$ and $w \perp\!\!\!\perp x$;

(ii) $v \perp\!\!\!\perp y \mid \{w,x\}$ and $w \perp\!\!\!\perp x \mid \{v,y\}$;

(iii) $v \perp\!\!\!\perp y \mid \{w,x\}$ and $w \perp\!\!\!\perp x \mid v$;

(iv) $v \perp\!\!\!\perp y \mid x$ and $w \perp\!\!\!\perp x \mid v$.

If G is a bi-directed graph, then the global Markov property states the marginal independence $v \perp\!\!\!\perp w$ if v and w are not adjacent. In a multivariate normal distribution such pairwise marginal independences hold iff all independences stated by the global Markov property for G hold (Kauermann, 1996). Without any distributional assumption, Richardson (2003, §4) shows that the independences stated by the global Markov property of a bi-directed graph hold iff certain (not only pairwise) marginal independences hold; see also Matúš (1994). Two ancestral graphs G_1 and G_2 are *Markov equivalent* if they have the same vertex set and the global Markov property states the same independences for G_1 as for G_2.

The graphs in Figure 2 have the property that for every pair of non-adjacent vertices v and w there exists some subset C such that the global Markov property states that $v \perp\!\!\!\perp w \mid C$. Ancestral graphs with this property are called *maximal*. If an ancestral graph G is not maximal, then there exists a unique Markov equivalent maximal ancestral graph $\overline{G}$ that contains all the edges present in G. Moreover, any edge in $\overline{G}$ that is not present in G is bi-directed (Richardson and Spirtes, 2002, §3.7).

The following facts are easily established; see also Richardson and Spirtes (2002).

Lemma 3 *(i) Markov equivalent maximal ancestral graphs have the same skeleton.*

(ii) If $\bar{G}$ is an ancestral graph that is Markov equivalent to a maximal ancestral graph G and has the same skeleton as G, then $\bar{G}$ is also a maximal ancestral graph.

(iii) Bi-directed, undirected and directed acyclic graphs are maximal ancestral graphs.

2.3 Boundary Containment

In the subsequent Sections 3 and 4 we will construct maximal ancestral graphs that are Markov equivalent to a given bi-directed graph. Via Theorem 5 below, the following property plays a crucial role in these constructions.

Definition 4 *A simple mixed graph G has the* boundary containment property *if for all distinct vertices $v, w \in V$ the presence of an edge $v - w$ implies that* $\mathrm{Bd}(v) = \mathrm{Bd}(w)$ *and the presence of an edge $v \to w$ in G implies that* $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$.

In the Appendix we present lemmas on the structure of m-connecting paths in graphs with the boundary containment property. These lemmas yield the following key result.

Theorem 5 *If $\bar{G}$ is an ancestral graph that has the same skeleton as a bi-directed graph G, then G and $\bar{G}$ are Markov equivalent iff $\bar{G}$ has the boundary containment property.*

Proof Two vertices are adjacent in G iff they are adjacent in $\bar{G}$. Therefore, G and $\bar{G}$ are Markov equivalent iff it holds that two non-adjacent vertices v and w are m-connected given $C \subseteq V$ in G iff they are m-connected given C in $\bar{G}$.

($\Longrightarrow$:) Suppose $\bar{G}$ does not have the boundary containment property, that is, there exists an edge $v - w \in \bar{G}$ or an edge $v \to w \in \bar{G}$ such that $\mathrm{Bd}(v) \not\subseteq \mathrm{Bd}(w)$. Choose $u \in \mathrm{Bd}(v) \setminus \mathrm{Bd}(w)$. Since u and w are not adjacent, they are m-separated given $C = \emptyset$ in G. In $\bar{G}$, however, the path (u, v, w) m-connects u and w given $C = \emptyset$. Hence, G and $\bar{G}$ are not Markov equivalent.

($\Longleftarrow$:) First, let v and w be non-adjacent vertices that are m-connected given $C \subseteq V$ in $\bar{G}$. By Lemma 29, there is a path $\bar{\pi} = (v, v_1, \ldots, v_k, w)$ that m-connects v and w given C in $\bar{G}$ and is such that $v_1, \ldots, v_k$ are colliders with $\{v_1 \ldots, v_k\} \subseteq C$. Since G is a bi-directed graph, the corresponding path $\pi = (v, v_1, \ldots, v_k, w)$ in G also m-connects v and w given C.

Conversely, let v and w be non-adjacent vertices that are m-connected given $C \subseteq V$ in G. Let $\pi = (v_0, v_1, \ldots, v_k, v_{k+1})$ m-connect $v = v_0$ and $w = v_{k+1}$ given C in G such that no shorter path m-connects v and w given C. Then $v_1, \ldots, v_k$ are colliders, $\{v_1 \ldots, v_k\} \subseteq C$, and v_{i-1} and v_{i+1}, $i = 1, \ldots, k$, are not adjacent in G. (This is a special case of Lemmas 27 and 29 because a bi-directed graph trivially satisfies the boundary containment property.) It follows that, for all $i = 1, \ldots, k-1$, $v_{i-1} \in \mathrm{Bd}(v_i)$ but $v_{i-1} \notin \mathrm{Bd}(v_{i+1})$, and similarly $v_{i+2} \notin \mathrm{Bd}(v_i)$ but $v_{i+2} \in \mathrm{Bd}(v_{i+1})$. This implies that $\mathrm{Bd}(v_i) \not\subseteq \mathrm{Bd}(v_{i+1})$ and $\mathrm{Bd}(v_i) \not\supseteq \mathrm{Bd}(v_{i+1})$ for all $i = 1, \ldots, k-1$. Since $\bar{G}$ has the boundary containment property, it must hold that $v_i \leftrightarrow v_{i+1} \in \bar{G}$ for all $i = 1, \ldots, k-1$. Therefore, $v_2, \ldots, v_{k-1}$ are colliders on the path $\bar{\pi} = (v, v_1, \ldots, v_k, w)$ in $\bar{G}$. Similarly, it follows that $v_2 \in \mathrm{Bd}(v_1) \setminus \mathrm{Bd}(v)$, which entails $\mathrm{Bd}(v_1) \not\subseteq \mathrm{Bd}(v)$. Thus, v_1 is a collider on $\bar{\pi}$. Analogously, we can show that v_k is a collider on $\bar{\pi}$, which yields that $\bar{\pi}$ is a path in $\bar{G}$ that m-connects v and w given C. ■

3. Simplicial Graphs

In this section we show how simplicial vertex sets of a bi-directed graph can be used to construct a Markov equivalent maximal ancestral graph by removing arrowheads from certain bi-directed edges. Simplicial sets are also important in other contexts such as collapsibility (Madigan and Mosurski, 1990; Kauermann, 1996; Lauritzen, 1996, §2.1.3, p.121 and 219) and triangulation of graphs (Jensen, 2001, §5.3).

Definition 6 *A vertex $v \in V$ is* simplicial, *if* $\mathrm{Bd}(v)$ *is complete, that is, every pair of vertices in* $\mathrm{Bd}(v)$ *are adjacent. Similarly, a set $A \subseteq V$ is* simplicial, *if* $\mathrm{Bd}(A)$ *is complete.*

Simplicial vertices can be characterized in terms of boundary containment as follows.

Proposition 7 *A vertex $v \in V$ is simplicial iff* $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$ *for all* $w \in \mathrm{Bd}(v)$.

If an edge between v and w has an arrowhead at v, then we say that we *drop the arrowhead at v* when either $v \leftarrow w$ is replaced by $v - w$ or $v \leftrightarrow w$ is replaced by $v \rightarrow w$.

Definition 8 *Let G be a bi-directed graph. The* simplicial graph G^s *is the simple mixed graph obtained by dropping all the arrowheads at simplicial vertices of G.*

For the graph from Figure 1, G^s is equal to the depicted graph $G^{\min}$; additional examples are given in Figure 3. Parts (i) and (ii) of the next lemma show that simplicial graphs have the boundary containment property.

Lemma 9 *Let v and w be adjacent vertices in a simplicial graph G^s. Then*

(i) if $v - w \in G^s$, then $\mathrm{Bd}(v) = \mathrm{Bd}(w)$*;*

(ii) if $v \rightarrow w \in G^s$, then $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w)$*;*

(iii) if $v \leftrightarrow w \in G^s$, then each of $\mathrm{Bd}(v) = \mathrm{Bd}(w)$, $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w)$, *and* $\mathrm{Bd}(v) \not\subseteq \mathrm{Bd}(w) \not\subseteq \mathrm{Bd}(v)$ *might be the case.*

Proof (i) and (ii) follow from Proposition 7. For (iii) see, respectively, the graphs G^s_1, G^s_2 in Figure 3, and $G^s = G^{\min}$ in Figure 1. ■

Theorem 10 *The simplicial graph G^s of a bi-directed graph G is a maximal ancestral graph that is Markov equivalent to G.*

Proof By Lemma 3, Theorem 5 and Lemma 9, it suffices to show that G^s is an ancestral graph. This, however, follows from Lemma 11 below. ■

Lemma 11 *If G is an ancestral graph that has the boundary containment property, then dropping all arrowheads at simplicial vertices of G yields an ancestral graph.*

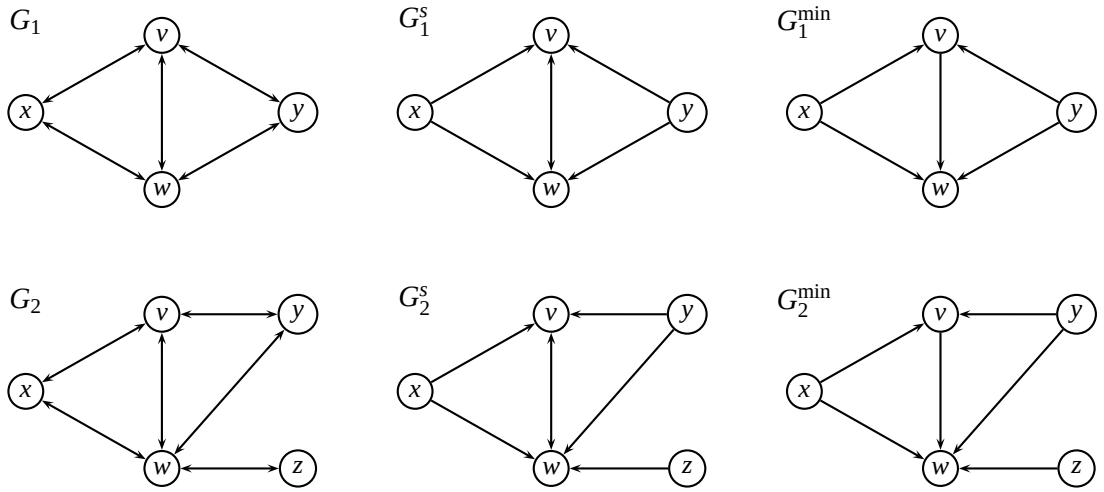

Figure 3: Bi-directed graphs with simplicial and minimally oriented graphs.

Proof Let $\bar{G}$ be the graph obtained by dropping the arrowheads at simplicial vertices. First, suppose $v \to w \in \bar{G}$ or $v \leftrightarrow w \in \bar{G}$ but that there is a path π from w to v that is a directed path in $\bar{G}$. Since there are no arrowheads at simplicial vertices in $\bar{G}$, no vertex on π including the endpoints v and w can be simplicial. This implies that π is a directed path from w to v in G. However, since $v \to w \in G$ or $v \leftrightarrow w \in G$, this is a contradiction to G being ancestral. We conclude that $\bar{G}$ satisfies conditions (i) and (iii) of Definition 1.

Next, suppose $v - w \in \bar{G}$ but that there exists another vertex u such that $u \to v \in \bar{G}$ or $u \leftrightarrow v \in \bar{G}$. It follows that v is not simplicial. Since G is ancestral, this implies that $v \to w \in G$ which in turn implies that $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$ because G has the boundary containment property. The set $\mathrm{Bd}(v)$ is not complete because v is not simplicial. Thus $\mathrm{Bd}(w)$ is not complete, that is, w is not a simplicial vertex. However, this is a contradiction to the fact that $v \to w \in G$ but $v - w \in \bar{G}$. Thus, $\bar{G}$ is indeed an ancestral graph. ■

Proposition 12 *A bi-directed graph G is Markov equivalent to an undirected graph iff the simplicial graph G^s induced by G is an undirected graph iff G is a disjoint union of complete (bi-directed) graphs.*

Proof If G^s is an undirected graph, then by Theorem 10, G is Markov equivalent to an undirected graph, namely G^s. Conversely, assume that there exists an undirected graph U that is Markov equivalent to G. Necessarily, G and U have the same skeleton (recall Lemma 3). By Theorem 5, U has the boundary containment property, which implies that every vertex is simplicial and thus that G^s is an undirected graph (and equal to U).

The simplicial graph G^s is an undirected graph iff the vertex set of the inducing bi-directed graph G can be partitioned into pairwise disjoint sets $A_1, \ldots, A_q$ such that (a) if $v \in A_i$, $1 \leq i \leq q$, and $w \in A_j$, $1 \leq j \leq q$, are adjacent, then $i = j$, and (b) all the induced subgraphs G_{A_i}, $i = 1, \ldots, q$ are complete graphs (Kauermann, 1996). ■

Under multivariate normality, a bi-directed graph that is Markov equivalent to an undirected graph represents a hypothesis that is linear in the covariance matrix as well as in its inverse. The general structure of such models is studied in Jensen (1988).

4. Minimally Oriented Graphs

The simplicial graph G^s sometimes may be a DAG. For example, the graph $u \leftrightarrow v \leftrightarrow w$ has the simplicial graph $u \rightarrow v \leftarrow w$. However, there exist bi-directed graphs that are Markov equivalent to a DAG and yet the simplicial graph contains bi-directed edges. For example, the graph G_1 in Figure 3 is Markov equivalent to the DAG $G_1^{\min}$ in the same Figure. Hence, some arrowheads may be dropped from bi-directed edges in a simplicial graph while preserving Markov equivalence. In this section we construct maximal ancestral graphs from which no arrowheads may be dropped without destroying Markov equivalence.

4.1 Definition and Construction

The following definition introduces the key object of this section.

Definition 13 *Let G be a bi-directed graph. A* minimally oriented graph *of G is a graph $G^{\min}$ that satisfies the following three properties:*

(i) *$G^{\min}$ is a maximal ancestral graph;*

(ii) *G and $G^{\min}$ are Markov equivalent;*

(iii) *$G^{\min}$ has the minimum number of arrowheads of all maximal ancestral graphs that are Markov equivalent to G. Here the number of arrowheads of an ancestral graph G with d directed and b bi-directed edges is defined as* $\mathrm{arr}(G) = d + 2b$.

By Lemma 3, a minimally oriented graph $G^{\min}$ has the same skeleton as the underlying bi-directed graph G. According to Theorem 5, $G^{\min}$ has the boundary containment property. Examples of minimally oriented graphs are shown in Figure 3. Given the small number of vertices of these graphs the claim that these graphs are indeed minimally oriented graphs can be verified directly. The example of graph G_1 in Figure 3 also illustrates that minimally oriented graphs are not unique. By symmetry, reversing the direction of the edge $v \rightarrow w$ in the depicted $G_1^{\min}$ yields a second minimally oriented graph for G_1.

We now turn to the problem of how to construct a minimally oriented graph. Define a relation on the vertex set V of the given bi-directed graph G by letting $v \preccurlyeq_B w$ if $v = w$ or if $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w)$ in G. The relation $\preccurlyeq_B$ is a partial order and can thus be extended to a total order $\leq$ on V such that the strict boundary containment $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w)$ implies that $v < w$. In general, the choice of such an extension to a total order is not unique.

Algorithm 14 *Let G be a bi-directed graph, and $\leq$ a total order on V that extends the partial order $\preccurlyeq_B$ obtained from strict boundary containment. Create a new graph $G_<^{\min}$ as follows:*

(a) *find the simplicial graph G^s of G;*

(b) set $G^{\min}_{<} = G^s$*;*

(c) replace every bi-directed edge $v \leftrightarrow w \in G^{\min}_{<}$ *with* $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$ *and* $v < w$ *by the directed edge* $v \rightarrow w$*.*

The notation $G^{\min}_{<}$ indicates the dependence of this graph on *both* the bi-directed graph G and the total order $\leq$. Clearly, by Theorem 5, in order for $G^{\min}_{<}$ to be a minimally oriented graph it is necessary that it satisfies the boundary containment property. The next lemma shows that this is true.

Lemma 15 *Let G be a bi-directed graph and $G^{\min}_{<}$ the graph constructed in Algorithm 14. It then holds that*

(i) if $v - w$ *is an undirected edge in* $G^{\min}_{<}$*, then* $\mathrm{Bd}(v) = \mathrm{Bd}(w)$*;*

(ii) if $v \rightarrow w$ *is a directed edge in* $G^{\min}_{<}$*, then* $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$*;*

(iii) $v \leftrightarrow w$ *is a bi-directed edge in* $G^{\min}_{<}$ *iff* $\mathrm{Bd}(v) \not\subseteq \mathrm{Bd}(w) \not\subseteq \mathrm{Bd}(v)$*.*

Proof (i) follows directly from Lemma 9(i) because it follows from Algorithm 14 that $G^{\min}_{<}$ and G^s contain the same undirected edges.

(ii) If the edge $v \rightarrow w$ is already present in G^s, then $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w)$ according to Lemma 9(ii). If $v \rightarrow w$ is not already present in G^s, then $v < w$ and $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$.

(iii) Suppose v and w are two adjacent vertices such that $\mathrm{Bd}(v) \not\subseteq \mathrm{Bd}(w) \not\subseteq \mathrm{Bd}(v)$. Then $v \leftrightarrow w$ in G^s and this edge cannot be replaced by a directed edge in step (c) of Algorithm 14. For the converse, consider two adjacent vertices v and w such that $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$. (The other case is symmetric.) If $v < w$, then according to the definition of the simplicial graph and step (c) of Algorithm 14 the edge between v and w in $G^{\min}_{<}$ cannot have an arrowhead at v and thus cannot be bi-directed. If $v > w$, then $\mathrm{Bd}(v) = \mathrm{Bd}(w)$ because $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w)$ would imply $v < w$. It follows that the edge between v and w in $G^{\min}_{<}$ cannot be bi-directed as the arrowhead at w would be removed in step (c). ■

By Lemma 15(iii), $v \leftrightarrow w \in G^{\min}_{<}$ iff there exist vertices $x \in \mathrm{bd}(v) \setminus \{w\}$ and $y \in \mathrm{bd}(w) \setminus \{v\}$ such that the induced subgraph $G_{\{x,y,v,w\}}$ equals one of the two graphs shown in Figure 4. Graphs that do not contain the four-cycle from Figure 4(ii) as an induced subgraph are known as chordal or decomposable and play an important role in graphical modelling (Lauritzen, 1996). Graphs not containing the path from Figure 4(i) as an induced subgraph are called cographs and have favorable computational properties (Brandstädt et al., 1999). For instance, cographs can be recognized in linear time (Corneil et al., 1985).

Theorem 16 *The graph $G^{\min}_{<}$ constructed in Algorithm 14 is a minimally oriented graph for the bi-directed graph G.*

Proof We verify the conditions (i) and (iii) of Definition 13. This is sufficient because $G^{\min}_{<}$ has the boundary containment property (Lemma 15) and thus condition (i) implies condition (ii) by Theorem 5.

(i) $G^{\min}_{<}$ is a maximal ancestral graph:
By Lemma 3 it suffices to show that $G^{\min}_{<}$ is an ancestral graph. Let v and w be adjacent vertices

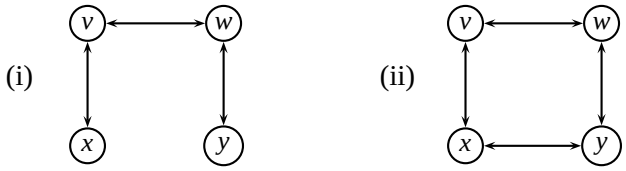

Figure 4: Induced subgraphs for which no arrowhead can be dropped from edge $v \leftrightarrow w$.

such that $v - w \in G^{\min}_{<}$. This is equivalent to $v - w \in G^s$, and it follows that there does not exist an arrowhead at v or w; compare the proof of Theorem 10. Furthermore, $G^{\min}_{<}$ does not contain any directed cycles because Algorithm 14 ensures that the presence of a directed edge $v \to w \in G^{\min}_{<}$ implies $v < w$ in the total order. Finally, assume that there exists $v \leftrightarrow w \in G^{\min}_{<}$. Then there cannot be a directed path from v to w, since by Lemma 15(ii) this would imply $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$, contradicting Lemma 15(iii).

(iii) $G^{\min}_{<}$ has the minimal number of arrowheads:
Let $\bar{G}$ be a maximal ancestral graph that is Markov equivalent to the (bi-directed) graph G, which requires that $\bar{G}$ and G, and thus also $G^{\min}_{<}$ have the same skeleton. Assume that $\mathrm{arr}(\bar{G}) < \mathrm{arr}(G^{\min}_{<})$. Then either (a) there exists $v \to w \in G^{\min}_{<}$ such that $v - w \in \bar{G}$ or (b) there exists $v \leftrightarrow w \in G^{\min}_{<}$ such that $v \to w \in \bar{G}$ or $v - w \in \bar{G}$.

Case (a): If $v \to w \in G^{\min}_{<}$, then w cannot be simplicial. Hence, there exist two vertices $x, y \in \mathrm{bd}(w)$ that are not adjacent in $G^{\min}_{<}$, and thus not adjacent in G; ($v = x$ is possible). The global Markov property of G states that $x \perp\!\!\!\perp y$. Since $\bar{G}$ is an ancestral graph and $v - w \in \bar{G}$, however, there may not be any arrowheads at w on the edges between x and w, and y and w in $\bar{G}$. Therefore, x and y are m-connected given $\emptyset$ in $\bar{G}$, which yields that the global Markov property of $\bar{G}$ does not imply $x \perp\!\!\!\perp y$; a contradiction.

Case (b): Suppose $v \leftrightarrow w \in G^{\min}_{<}$ but there is no arrowhead at v on the edge between v and w in $\bar{G}$. By Lemma 15(iii) there exists $x \in \mathrm{bd}(v) \setminus \mathrm{Bd}(w)$ such that x and w are not adjacent in $G^{\min}_{<}$. Thus x and w are not adjacent in G and $x \perp\!\!\!\perp w$ is stated by the global Markov property for G. In $\bar{G}$, however, v is a non-collider on the path (x, v, w) and thus this path m-connects x and w given $\emptyset$, which yields that the global Markov property of $\bar{G}$ does not imply $x \perp\!\!\!\perp w$; a contradiction. ■

The next result shows that our construction of minimally oriented graphs is complete in the sense that every minimally oriented graph can be obtained as the output of Algorithm 14 by appropriate choice of a total order on the vertex set.

Theorem 17 *If $G^{\min}$ is a minimally oriented graph for a bi-directed graph G, then there exists a total order $\leq$ on the vertex set such that $G^{\min} = G^{\min}_{<}$.*

Proof The graph $G^{\min}$ is an ancestral graph and thus contains no directed cycles. Hence, the directed edges in $G^{\min}$ yield a partial order $\preccurlyeq_D$ on the vertex set V in which $v \preccurlyeq_D w$ if $v = w$ or if there is a directed path from v to w. Define the relation $\preccurlyeq_{BD}$ by letting $v \preccurlyeq_{BD} w$ if $v \preccurlyeq_B w$ or $v \preccurlyeq_D w$. Clearly, $v \preccurlyeq_{BD} v$, that is, the relation is reflexive. We claim that the relation is in fact a partial order.

By Theorem 5, $G^{\min}$ has the boundary containment property such that $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$ if $v \preccurlyeq_D w$. Consequently, if $v \neq w$ then $v \preccurlyeq_D w$ implies $w \not\preccurlyeq_B v$ and $v \preccurlyeq_B w$ implies $w \not\preccurlyeq_D v$. This implies that

$\preccurlyeq_{BD}$ is anti-symmetric. In order to verify transitivity, it suffices to consider three distinct vertices satisfying $v \preccurlyeq_D w \preccurlyeq_B u$ or $v \preccurlyeq_B w \preccurlyeq_D u$. In the former case $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w) \subsetneq \mathrm{Bd}(u)$, and in the latter case $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(w) \subseteq \mathrm{Bd}(u)$. In both cases $\mathrm{Bd}(v) \subsetneq \mathrm{Bd}(u)$ such that $v \preccurlyeq_B u$, which implies the required conclusion $v \preccurlyeq_{BD} u$.

We can now choose a total order $\leq$ on V that extends the partial order $\preccurlyeq_{BD}$ and thus extends both $\preccurlyeq_B$ and $\preccurlyeq_D$. Let $G^{\min}_{<}$ be the output of Algorithm 14 when the bi-directed graph G and the chosen total order $\leq$ are given as the input. We claim that $G^{\min} = G^{\min}_{<}$.

First note that if v is a simplicial vertex of G, then there are no arrowheads at v in $G^{\min}$. Otherwise, we could drop all arrowheads at simplicial vertices in $G^{\min}$ to obtain an ancestral graph (Lemma 11) with fewer arrowheads. The new graph would have the boundary containment property and thus be Markov equivalent to G (by Theorem 5). This would contradict the assumed minimality of $G^{\min}$.

The observation about simplicial vertices implies that an undirected edge in the simplicial graph G^s is also an undirected edge in $G^{\min}$. Conversely, if $v - w \in G^{\min}$ then there may not be an arrowhead at v on any other edge, and likewise for w, because $G^{\min}$ is ancestral. Since $G^{\min}$ has the boundary containment property, it follows from Proposition 7 that both v and w are simplicial vertices. This implies that $v - w \in G^s$ and we conclude that $G^{\min}$ and G^s have the same undirected edges. By construction, the same holds for $G^{\min}_{<}$ and G^s. Hence, $G^{\min}$ and $G^{\min}_{<}$ have the same undirected edges.

Suppose $v \to w \in G^{\min}$. Then $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$ because $G^{\min}$ has the boundary containment property. Moreover, $v < w$ because the total order $\leq$ extends $\preccurlyeq_D$. It follows that $v \to w \in G^{\min}_{<}$. In other words, every directed edge in $G^{\min}$ is also in $G^{\min}_{<}$. This together with the fact that $G^{\min}$ and $G^{\min}_{<}$ have the same skeleton and the same number of arrowheads, $\mathrm{arr}(G^{\min}) = \mathrm{arr}(G^{\min}_{<})$, implies that $G^{\min} = G^{\min}_{<}$. ■

4.2 Markov Equivalence Results

The following corollary is an immediate consequence of Proposition 12 because a minimally oriented graph $G^{\min}$ is an undirected graph iff G^s is an undirected graph.

Corollary 18 *Let $G^{\min}$ be a minimally oriented graph for a bi-directed graph G. If G is Markov equivalent to an undirected graph U, then $G^{\min} = U$ is the unique minimally oriented graph of G.*

A minimally oriented graph also reveals whether the original bi-directed graph is Markov equivalent to a DAG.

Theorem 19 *Let $G^{\min}$ be a minimally oriented graph for a bi-directed graph G. Then G is Markov equivalent to a DAG iff $G^{\min}$ contains no bi-directed edges.*

Proof Let G be a bi-directed graph such that $G^{\min}$ contains no bi-directed edges. If $A \subseteq V$ is a simplicial set, then the induced subgraph $(G^{\min})_A$ is undirected and complete (this follows directly from Theorem 17 and Algorithm 14). Let $A_1, \ldots, A_q$ be the inclusion-maximal simplicial sets of G. Let D be a directed graph obtained by replacing each induced subgraph $(G^{\min})_{A_i}$, $i = 1, \ldots, q$, by a complete DAG. Then D itself is acyclic, which can be seen as follows: First, since $G^{\min}$ does not contain any directed cycles, a directed cycle π in D must involve a vertex $v \in \cup_{i=1}^{q} A_i$. Let $v \in A_j$.

Since the induced subgraphs D_{A_i}, $i = 1,\dots,q$, are all acyclic, π must also involve a vertex not in A_j. Therefore, there exists an edge $x \to w$ on π such that $w \in A_j$ and $x \notin A_j$. Since the sets A_i are inclusion-maximal simplicial sets, no vertex in A_i, $i \neq j$, is adjacent to any vertex in A_j. Hence, $x \notin \cup_{i=1}^{q} A_i$, which implies that the edge $x \to w$ is also present in $G^{\min}$. This is a contradiction to w being a simplicial vertex.

Two vertices are adjacent in $G^{\min}$ iff they are adjacent in D. Moreover, D has the boundary containment property because $G^{\min}$ has this property, and if $u \to \bar{u}$ in D then either $u \to \bar{u}$ in $G^{\min}$ or $u - \bar{u}$ in $G^{\min}$. It thus follows from Theorem 5 that D is Markov equivalent to $G^{\min}$ and G.

Conversely, suppose that $v \leftrightarrow w \in G^{\min}$ and for a contradiction, that G is Markov equivalent to a DAG D. Note that D must have the same skeleton as G (and $G^{\min}$). By Lemma 15(iii), there exist two different vertices $x \in \mathrm{bd}(v) \setminus \{w\}$ and $y \in \mathrm{bd}(w) \setminus \{v\}$ such that, by the Markov property of G, $x \perp\!\!\!\perp w$ and $v \perp\!\!\!\perp y$. Hence, v and w must be colliders on the paths (x,v,w) and (v,w,y) in D, respectively. This is impossible in the DAG D. ■

Theorem 19 can be shown to be equivalent to a Markov equivalence result stated without proof in Theorem 1 in Pearl and Wermuth (1994). This latter theorem requires 'no chordless four-chain', which must be read as excluding graphs with induced subgraphs that are either of the graphs in Figure 4. Under this condition, Pearl and Wermuth (1994) also state that a Markov equivalent DAG can be constructed from the (undirected) skeleton of G by introducing directed and bi-directed edges in an operation they term 'sink orientation', and turning remaining undirected edges into directed ones. The sink orientation of the graph G_1 in Figure 3 has the directed edges of G_1^s but an undirected edge $v - w$. Thus sink orientation need not yield an ancestral graph. The bi-directed graphical models considered in Theorem 19 also appear in the construction of generalized Wishart distributions (Letac and Massam, 2007, Theorem 2.2). In that context the models are called *homogeneous* and characterized in terms of Hasse diagrams.

As the next result reveals, bi-directed graphs that are Markov equivalent to DAGs exhibit a structure that corresponds to a multivariate regression model. The graphs can also be termed chordal cographs; compare the paragraph before Theorem 16.

Proposition 20 *Let $G^{\min}$ be a minimally oriented graph for a connected bi-directed graph G. If $G^{\min}$ contains no bi-directed edges, then the set A of all simplicial vertices is non-empty, the induced subgraph $(G^{\min})_A$ is a disjoint union of complete undirected graphs, the induced subgraph $(G^{\min})_{V\setminus A}$ is a complete DAG, and an edge $v \to w$ joins any two vertices $v \in A$ and $w \notin A$ in $G^{\min}$.*

Proof For two adjacent vertices v and w in $G^{\min}$, Lemma 15(i)-(ii) implies that $\mathrm{Bd}(v) \subseteq \mathrm{Bd}(w)$ or $\mathrm{Bd}(w) \subseteq \mathrm{Bd}(v)$. Hence, we can list the vertex set as $V = \{v_1,\dots,v_p\}$ such that $\mathrm{Bd}(v_i) \subseteq \mathrm{Bd}(v_j)$ if v_i and v_j are adjacent and $i \leq j$. It follows that $v_1 \in A$ and thus $A \neq \emptyset$. Let $A_1,\dots,A_q$ be the inclusion-maximal simplicial sets of G. Then $(G^{\min})_A$ equals the union of the disjoint complete undirected graphs $(G^{\min})_{A_1},\dots,(G^{\min})_{A_q}$. Since $G^{\min}$ is an ancestral graph, $(G^{\min})_{V\setminus A}$ is a DAG.

We prove the remaining claims by induction on $|V \setminus A|$. If $|V \setminus A| = 0$, then the connected graph $G^{\min}$ is a complete undirected graph and there is nothing to show. Let $|V \setminus A| \geq 1$. It follows that $v_p \in V \setminus A$. If the shortest path between some vertex v_{i_1} and v_p in G is of the form $v_{i_1} \leftrightarrow \dots \leftrightarrow v_{i_k} \leftrightarrow v_p$, then $i_1 < \dots < i_k < p$ and $\mathrm{Bd}(v_{i_1}) \subseteq \dots \subseteq \mathrm{Bd}(v_{i_k}) \subseteq \mathrm{Bd}(v_p)$, which is easily shown by induction on k. However, since $v_{i_1} \in \mathrm{Bd}(v_{i_1})$ it must in fact hold that v_{i_1} and v_p are adjacent. Hence, there is an edge between every vertex $v \in V \setminus \{v_p\}$ and v_p, which for $v \in A$ is of

the form $v \to v_p$ because clearly $v_p \notin A$. The proof is finished by combining what we learned about v_p with the induction assumption applied to the induced subgraph G_W with $W = \{v_1, \ldots, v_{p-1}\}$. Note that for $v, w \in W$, the inclusion $\mathrm{Bd}_G(v) \subseteq \mathrm{Bd}_G(w)$ implies that $\mathrm{Bd}_{G_W}(v) \subseteq \mathrm{Bd}_{G_W}(w)$. Thus by Lemma 15 and Theorem 16, $(G_W)^{\min}$ does not contain any bi-directed edges. ■

5. Maximum Likelihood Estimation in Gaussian Models

In this section we consider the Gaussian covariance models associated with bi-directed graphs and demonstrate that the graphical constructions from Sections 3 and 4 can be employed for more efficient computation of maximum likelihood estimates.

5.1 Covariance Graphs and Gaussian Ancestral Graph Models

Let G be a bi-directed graph, and

$$\mathbf{P}(G) = \left\{ \Sigma \in \mathbb{R}^{V \times V} \mid \Sigma = (\sigma_{vw}) \text{ sym. pos. def., } \sigma_{vw} = 0 \; \forall (v,w) : v \leftrightarrow w \notin G \right\}$$

be the cone of symmetric positive definite matrices with zero pattern induced by G. The *covariance graph model* associated with G is the family of multivariate normal distributions $\mathbf{N}(G) = \big(\mathcal{N}(0,\Sigma) \mid \Sigma \in \mathbf{P}(G)\big)$. It can be shown that every distribution in $\mathbf{N}(G)$ satisfies all conditional independences stated by the global Markov property for the bi-directed graph G (Kauermann, 1996, Prop. 2.2). Conversely, if a distribution $\mathcal{N}(0,\Sigma)$ satisfies the global Markov property for G, then $\Sigma \in \mathbf{P}(G)$.

Let $S \in \mathbb{R}^{V \times V}$ be the empirical covariance matrix computed from an i.i.d. sample drawn from some unknown distribution $\mathcal{N}(0,\Sigma) \in \mathbf{N}(G)$, that is, the (v,w)-th entry in S is the dot-product of the vectors of observations for the v-th and w-th variables divided by the sample size n. The log-likelihood function $\ell_{S,n} : \mathbf{P}(G) \to \mathbb{R}$ of $\mathbf{N}(G)$ can be written as

$$\ell_{S,n}(\Sigma) = -\frac{n|V|}{2}\log(2\pi) - \frac{n}{2}\log|\Sigma| - \frac{n}{2}\mathrm{tr}\left(\Sigma^{-1}S\right).$$

If S is positive definite then the global maximum of $\ell_{S,n}$ over $\mathbf{P}(G)$ exists. The likelihood equations obtained by setting to zero the partial derivatives of $\ell_{S,n}$ with respect to the non-restricted entries in Σ take on the form

$$(\Sigma^{-1})_{vw} = (\Sigma^{-1}S\Sigma^{-1})_{vw} \quad \forall v,w \in V : \; v = w \;\text{ or }\; v \leftrightarrow w \in G; \tag{1}$$

compare Anderson and Olkin (1985, §2.1.1). A matrix $\hat{\Sigma}(S) \in \mathbf{P}(G)$ that solves (1) is *a solution to the likelihood equations* of $\mathbf{N}(G)$. Since subsequent theorems on the structure of the likelihood equations are obtained via Gaussian ancestral graph models, we briefly review the parametrization of these models.

Let G be an ancestral graph and $\mathrm{un}_G \subseteq V$ the set of vertices v that are such that any edge with endpoint v has a tail at v. By Definition 1(i), $v - w \in G$ implies $v, w \in \mathrm{un}_G$, and $v \leftrightarrow w \in G$ implies that $v, w \notin \mathrm{un}_G$. Let Λ be a symmetric positive definite $\mathrm{un}_G \times \mathrm{un}_G$ matrix such that $\Lambda_{vw} \neq 0$ only if $v = w$ or $v - w \in G$. Let Ω be a symmetric positive definite $(V \setminus \mathrm{un}_G) \times (V \setminus \mathrm{un}_G)$ matrix such that $\Omega_{vw} \neq 0$ only if $v = w$ or $v \leftrightarrow w \in G$. Finally, let B be a $V \times V$ matrix such that $B_{vw} \neq 0$ only if

$w \to v \in G$. Define the symmetric positive definite matrix

$$\Sigma(\Lambda, B, \Omega) = (I - B)^{-1} \begin{pmatrix} \Lambda^{-1} & 0 \\ 0 & \Omega \end{pmatrix} (I - B)^{-\mathrm{T}}, \tag{2}$$

where I is the identity matrix.

Let $\mathbf{N}(G)$ be the Gaussian ancestral graph model associated with G, that is, the family of all centered normal distributions that are globally Markov with respect to G. As shown in Richardson and Spirtes (2002, §8), the normal distribution $\mathcal{N}(0, \Sigma)$ with $\Sigma = \Sigma(\Lambda, B, \Omega)$ defined in (2) is in $\mathbf{N}(G)$. Conversely, if G is *maximal*, then for any $\mathcal{N}(0, \Sigma) \in \mathbf{N}(G)$ there exist unique Λ, Ω, B of the above type such that $\Sigma = \Sigma(\Lambda, B, \Omega)$. (Note that Richardson and Spirtes, 2002, use B for what is here denoted by $I - B$).

Since a bi-directed graph G and a minimally oriented graph $G^{\min}$ are Markov equivalent and maximal, the parametrization map for $G^{\min}$, $(\Lambda, B, \Omega) \mapsto \Sigma(\Lambda, B, \Omega)$, has image equal to $\mathbf{P}(G)$. By Richardson and Spirtes (2002, Theorem 8.14, Lemma 8.22), we obtain the following Lemma.

Lemma 21 *Let G be a bi-directed graph. The covariance matrix $\Sigma(\Lambda, B, \Omega)$ solves the likelihood equations of $\mathbf{N}(G)$ iff (Λ, B, Ω) solves the likelihood equations of $\mathbf{N}(G^{\min})$.*

5.2 Empirical Maximum Likelihood Estimates

Using the graphical results established earlier, we can show that over simplicial sets a solution to the likelihood equations (1) agrees with its empirical counterpart in S.

Theorem 22 *Let G be a bi-directed graph with associated covariance graph model $\mathbf{N}(G)$. If $A \subseteq V$ is simplicial, S is a symmetric positive definite matrix, and $\hat{\Sigma}(S) \in \mathbf{P}(G)$ is a solution to the likelihood equations (1), then $\hat{\Sigma}(S)_{A \times A} = S_{A \times A}$.*

Proof By Theorem 10, the covariance graph model $\mathbf{N}(G)$ and the Gaussian ancestral graph model $\mathbf{N}(G^s)$ based on the simplicial graph G^s are equal. Let $\mathbf{N}(G^s)$ be parametrized by the precision matrix Λ, the matrix of regression coefficients B and the covariance matrix Ω as described in §5.1. In particular, it follows from Richardson and Spirtes (2002, Lemma 8.4) that if $\Sigma = \Sigma(\Lambda, B, \Omega)$, then $(\Lambda^{-1})_{A \times A} = \Sigma_{A \times A}$.

The inclusion-maximal simplicial sets $A_1, \ldots, A_q$ of G form a partition of un_{G^s}. The induced subgraphs $G^s_{A_i}$, $i = 1, \ldots, q$, are complete undirected graphs. It follows that Λ is a block-diagonal matrix such that $\Lambda_{vw} = 0$ if there does not exist an inclusion-maximal simplicial set A_i such that $v, w \in A_i$. Now the discussion in Richardson and Spirtes (2002, §8.5) and Lemma 21 imply that every solution to the likelihood equations for Λ, B, Ω in the Gaussian ancestral graph model $\mathbf{N}(G^s)$ satisfies that $(\hat{\Lambda}^{-1})_{A_i \times A_i} = S_{A_i \times A_i}$ for all $i = 1, \ldots, q$. Since $A \subseteq A_j$ for some j, it holds that $\hat{\Sigma}_{A \times A} = (\hat{\Lambda}^{-1})_{A \times A} = S_{A \times A}$. ■

Our graphical constructions also provide information on when maximum likelihood estimates of conditional parameters are equal to their empirical counterparts. The conditional parameters we consider are the regression coefficients and conditional variance for the conditional distribution of variable v given its *parents* $\mathrm{pa}(v) = \{w \in V \mid w \to v \in G^{\min}\}$ in a minimally oriented graph $G^{\min}$. If $\mathrm{pa}(v) = \emptyset$, then conditioning variable v on $\mathrm{pa}(v)$ is understood to yield the marginal distribution of v.

Theorem 23 *Let $G^{\min}$ be a minimally oriented graph for a bi-directed graph G, S a symmetric positive definite matrix, and $\hat{\Sigma}(S) \in \mathbf{P}(G)$ a solution to the likelihood equations (1). If v is a vertex such that there is no vertex w with $v \leftrightarrow w \in G^{\min}$, then the regression coefficients for v given $\mathrm{pa}(v)$ are*

$$\hat{\Sigma}(S)_{v\times \mathrm{pa}(v)} \left[\hat{\Sigma}(S)_{\mathrm{pa}(v)\times \mathrm{pa}(v)}\right]^{-1} = S_{v\times \mathrm{pa}(v)} \left(S_{\mathrm{pa}(v)\times \mathrm{pa}(v)}\right)^{-1}, \tag{3}$$

and that the conditional variance for v given $\mathrm{pa}(v)$ is

$$\hat{\Sigma}(S)_{vv} - \hat{\Sigma}(S)_{v\times \mathrm{pa}(v)} \left[\hat{\Sigma}(S)_{\mathrm{pa}(v)\times \mathrm{pa}(v)}\right]^{-1} \hat{\Sigma}(S)_{\mathrm{pa}(v)\times v} = S_{vv} - S_{v\times \mathrm{pa}(v)} \left(S_{\mathrm{pa}(v)\times \mathrm{pa}(v)}\right)^{-1} S_{\mathrm{pa}(v)\times v}. \tag{4}$$

Proof If $\mathrm{pa}(v) = \emptyset$, then v is a simplicial vertex, and the claim reduces to $\hat{\Sigma}(S)_{vv} = S_{vv}$, which follows from Theorem 22. Otherwise, using the parametrization of $\mathbf{N}(G^{\min})$, it follows from Richardson and Spirtes (2002, Theorem 8.7) that if $\Sigma = \Sigma(\Lambda, B, \Omega)$, then

$$\Sigma_{v\times \mathrm{pa}(v)} \left[\Sigma_{\mathrm{pa}(v)\times \mathrm{pa}(v)}\right]^{-1} = B_{v\times \mathrm{pa}(v)}$$

and

$$\Sigma_{vv} - \Sigma_{v\times \mathrm{pa}(v)} \left[\Sigma_{\mathrm{pa}(v)\times \mathrm{pa}(v)}\right]^{-1} \Sigma_{\mathrm{pa}(v)\times v} = \Omega_{vv}.$$

If $\hat{\Lambda}$, $\hat{B}$, $\hat{\Omega}$ solve the likelihood equations for $\mathbf{N}(G^{\min})$, then $\hat{B}_{v\times \mathrm{pa}(v)}$ and $\hat{\Omega}_{vv}$ solve the likelihood equations of the model in which all parameters in Λ, B, Ω except for $B_{v\times \mathrm{pa}(v)}$ and Ω_{vv} are held fixed. It follows from Drton and Richardson (2004b, §§5.1-2) that $\hat{B}_{v\times \mathrm{pa}(v)}$ and $\hat{\Omega}_{vv}$ are equal to the empirical expressions on the right hand side of (3) and (4), respectively. Applying Lemma 21 yields the claim. ■

Remark 24 *Iterative Conditional Fitting* is a special purpose algorithm for maximum likelihood estimation in covariance graph models (Drton and Richardson, 2003; Chaudhuri et al., 2007). However, it does not exploit the results of Theorems 22 and 23. On the other hand, if one runs the ancestral graph extension of iterative conditional fitting described in Drton and Richardson (2004b) on a minimally oriented graph, then unnecessary computations are avoided by implicitly exploiting Theorems 22 and 23. This is illustrated in the example in Section 5.3.

If a bi-directed graph G has a minimally oriented graph $G^{\min}$ without bi-directed edges then G is Markov equivalent to a DAG (Theorem 19) and the likelihood equations have a unique solution that is a rational function of the empirical covariance matrix S. However, this is no longer true if there is a bi-directed edge in $G^{\min}$. In this case, G contains one of the two graphs in Figure 4 as a subgraph; compare Lemma 15(iii). Solving the likelihood equations for the bi-directed four-chain in Figure 4(i) is equivalent to computing the roots of a quintic polynomial. There exist data for which this quintic has exactly three real roots (Drton and Richardson, 2004a). Galois theory (Stewart, 1989, Lemma 14.7) implies that for these data the quintic is unsolvable by radicals, that is, the roots of the quintic and thus the solutions to the likelihood equations cannot be computed from the data in finitely many steps involving addition, subtraction, multiplication, division, or taking r-th roots. (Geiger et al., 2006, obtain similar results in the context of undirected graphs). Similarly, solving the likelihood equations of the bi-directed four-cycle in Figure 4(ii) corresponds to solving

a polynomial equation system of degree 17. This can be verified in computer algebra systems such as `Singular` (Greuel et al., 2005); see also Drton and Sullivant (2007, §5). It is natural to conjecture that there exist data for which this system is also unsolvable by radicals.

5.3 Example: Gene Expression Measurements

The application of covariance graph models to gene expression data has been promoted in Butte et al. (2000). For illustration, we select data from microarray experiments with yeast strands (Gasch et al., 2000). We focus on eight genes involved in galactose utilization. Expression measurements for all eight genes are available in $n = 134$ experiments, for which the empirical correlation matrix is shown in the upper-diagonal part of Table 1.

For these data, the covariance graph model induced by the graph G in Figure 5(i) has a deviance of 8.87 over 8 degrees of freedom, which indicates a good model fit; the p-value computed using a chi-square distribution is 0.35. Figure 5(ii) shows the unique minimally oriented graph $G^{\min}$. The maximum likelihood estimate obtained by fitting the model to the correlation matrix is shown in the lower-diagonal part of Table 1; note that this estimate is not a correlation matrix (not all the italicized diagonal entries are equal to one). As predicted by Theorem 22, the submatrix over GAL1, GAL7, and GAL10 equals the respective submatrix in the empirical correlation matrix. The regression coefficients for the regression of GAL2 on all remaining variables are identical when computed from the maximum likelihood versus the empirical estimate (Theorem 23).

The use of a minimally oriented graph $G^{\min}$ leads to a considerable gain in computational efficiency in the iterative calculation of the maximum likelihood estimate $\hat{\Sigma}$. With the identity matrix as starting value, iterative conditional fitting (Remark 24) on the original bi-directed graph G performs eight multiple regressions per iteration and converges after 103 iterations. Using the same starting value and termination criterion, iterative conditional fitting on $G^{\min}$ converges after only 5 iterations and requires only five multiple regressions per iteration (for the genes GAL2, GAL3, GAL4, GAL11, and GAL80), of which the one for GAL2 has to be executed only in the first iteration.

As in any application of covariance graph models, one might question the assumption of Gaussianity. Indeed there are 10 experiments in which the measurements for the genes GAL1, GAL7, GAL10 and GAL80 come out to be large negative values, and one in which GAL7 alone takes such

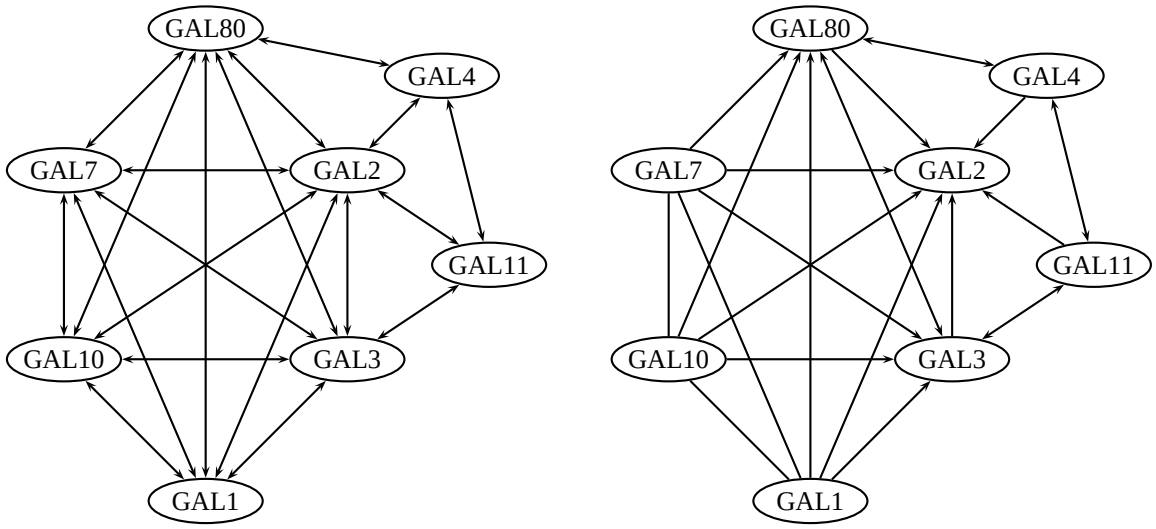

Figure 5: (i) Bi-directed graph G for gene expression measurements, (ii) the unique minimally oriented graph $G^{\min}$.

a value. These appear to be outliers (standardized values between -3 and -5), possibly produced by thresholding, as some values are identical. However, the measurements for the other genes are well within the range of the observations for the remaining 123 experiments. Thus it is unclear whether removing these 11 experiments from consideration is appropriate. If the 11 experiments are removed, then the correlations among GAL1, GAL7 and GAL10 decrease to values between 0.38 and 0.60, the latter value is the maximum of all correlations. Nevertheless the deviance for G only changes slightly to 10.09 (p-value 0.26). The iterative conditional fitting algorithm based on G now converges after only 20 iterations rather than 103. However, this is still four times as many iterations as required in iterative conditional fitting based on the minimally oriented graph $G^{\min}$; recall that in addition each iteration is also simpler.

The original correlation matrix in Table 1 exhibits an apparent similarity of the rows for GAL1, GAL7 and GAL10; this is also reflected in the graph G in which these variables form a complete set and have the same spouses. Such symmetry could be investigated further via a group symmetry model (Andersson and Madsen, 1998).

6. Conclusion

We showed how to remove a maximal number of arrowheads from the edges of a bi-directed graph G such that one obtains a maximal ancestral graph $G^{\min}$ that is Markov equivalent to G. The graph $G^{\min}$, called a minimally oriented graph, reveals whether G is Markov equivalent to an undirected graph, and also whether G is Markov equivalent to a DAG.

For the (Gaussian) covariance graph model associated with G, a minimally oriented graph $G^{\min}$ yields an alternative parametrization that provides insight into likelihood inference. The structure of the arrowheads in $G^{\min}$ allowed us to identify parts of the covariance matrix for which the maximum

likelihood estimates are equal to their empirical counterparts (this applies to all solutions to the likelihood equations if, as occasionally happens, there is more than one solution). This makes it possible to avoid or speed up iterative estimation of the full covariance matrix. We also saw that the maximum likelihood estimator of the covariance matrix in a covariance graph model is a rational function of empirical covariance matrix if $G^{\min}$ contains no bi-directed edge. This is similar to the results that identify decomposable models as the sub-class of all log-linear and all covariance selection models (Dempster, 1972) for which the maximum likelihood estimator is available in closed form.

Drton and Richardson (2008) formulate binary models based on the Markov property of bi-directed graphs. For these models, the maximum likelihood estimator is available in closed form if the model-inducing graph is Markov equivalent to a DAG. Moreover, we verified that in the example of the graph G in Figure 1, the maximum likelihood estimates of the marginal distributions of X_1 and X_4 are equal to the corresponding empirical proportions. We thus believe that analogs to the Gaussian results established here will hold in discrete models, but a general parametrization of discrete ancestral graph models is required to fully access the potential of the results obtained in this paper.

Appendix A. Connecting Paths and Boundary Containment

In this appendix we prove results about graphs that satisfy the *boundary containment property* from Definition 4. These results are used in the proof of Theorem 5.

Let v and w be two fixed distinct vertices that are m-connected given $C \subseteq V \setminus \{v,w\}$ in a simple mixed graph G. Define $\Pi_G(v,w|C)$ to be the set of paths that m-connect v and w given C in G, and let $\Pi_G^{\min}(v,w|C)$ be the set of paths that are of minimal length among the paths in $\Pi_G(v,w|C)$.

Lemma 25 *If a simple mixed graph G satisfies the boundary containment property, v_{i-1}, v_i and v_{i+1} are three consecutive vertices on a path π in G, and v_i is a non-collider on π, then v_{i-1} and v_{i+1} are adjacent.*

Proof If v_i is a non-collider, then the edge between v_i and v_{i-1} or the edge between v_i and v_{i+1} must have a tail at v_i. Suppose, without loss of generality, that the latter is the case. Then $\mathrm{Bd}(v_i) \subseteq \mathrm{Bd}(v_{i+1})$ and thus $v_{i-1} \in \mathrm{Bd}(v_{i+1})$, which is the claim. ■

Lemma 26 *Let G be a simple mixed graph, and $\pi = (v, v_1, \ldots, v_k, w) \in \Pi_G(v,w|C)$. Let $v_0 = v$ and $v_{k+1} = w$. If v_i is a non-endpoint vertex on π and there is an arrowhead at v_i on the edge between v_{i-1} and v_i, then either (i) $v_i \in \mathrm{An}(C)$ or (ii) the path $(v_i, v_{i+1}, \ldots, v_k, w)$ is a directed path from v_i to w.*

Proof Suppose the result is false. Let v_j be the vertex closest to w satisfying the antecedent of the Lemma, but not the conclusion. If v_j is a collider, then by definition of m-connection, $v_j \in \mathrm{An}(C)$, which is a contradiction. If v_j is a non-collider then $v_j \to v_{j+1}$ on π. If $v_{j+1} = w$, if $v_{j+1} \in \mathrm{An}(C)$, or if $(v_{j+1}, \ldots, v_k, w)$ is a directed path from v_{j+1} to w, then clearly v_j satisfies the conclusion of the Lemma, which is a contradiction. But if $v_{j+1} \notin \mathrm{An}(C)$ and $(v_{j+1}, \ldots, v_k, w)$ is not a directed path from v_{j+1} to w then v_{j+1} satisfies the conditions on v_j, but is closer to w, again a contradiction. ■

Lemma 27 *If G is an ancestral graph that satisfies the boundary containment property and $\pi = (v, v_1, \ldots, v_k, w) \in \Pi_G^{\min}(v, w|C)$ then no non-consecutive vertices on π are adjacent.*

Proof Let $v_0 = v$ and $v_{k+1} = w$, and suppose for a contradiction that there are non-consecutive vertices on the path π which are adjacent. Let (v_p, v_q), $p < q$, be a pair of adjacent vertices which are furthest apart on the path, that is, (p, q) maximizes the distance $|r - s|$ among pairs of indices of adjacent vertices v_r and v_s on the path. Since π is of minimal length, either $v \neq v_p$ or $w \neq v_q$.

Suppose that $v \neq v_p$. By definition of (p, q), v_{p-1} is not adjacent to v_q. Consequently, by Lemma 25, v_p is a collider on (v_{p-1}, v_p, v_q), and thus the edge between v_{p-1} and v_p has an arrowhead at v_p. It then follows by Lemma 26 that either $v_p \in \mathrm{An}(C)$ or $(v_p, v_{p+1}, \ldots, v_k, w)$ is a directed path from v_p to w. In the latter case $v_p \in \mathrm{An}(v_q)$, but there is an arrowhead at v_p on the edge between v_p and v_q, which contradicts that G is ancestral. Hence $v_p \in \mathrm{An}(C)$. If $v_q = w$ then the path $(v, v_1, \ldots, v_p, v_q = w)$ is m-connecting given C and shorter than π. Hence $v_q \neq w$. It then follows by the same argument that v_q is a collider on (v_p, v_q, v_{q+1}) and in $\mathrm{An}(C)$. However, this also leads to a contradiction since then the path $(v, v_1, \ldots, v_p, v_q, v_{q+1}, \ldots, v_k, w)$ is both m-connecting given C and shorter than π.

The case where $w \neq v_q$ may be argued symmetrically. ■

Corollary 28 *If G is an ancestral graph that satisfies the boundary containment property and $\pi = (v = v_0, v_1, \ldots, v_k, v_{k+1} = w) \in \Pi_G^{\min}(v, w|C)$, then all the non-endpoint vertices $v_1, \ldots, v_k$ are colliders on π.*

Proof This follows directly from Lemma 27 and Lemma 25. ■

Even though all non-endpoints on a path of the type described in Corollary 28 in $\Pi_G^{\min}(v, w|C)$ are colliders, not all non-endpoints must be in the set C. For example, in the graph $G_2^{\min}$ from Figure 3, the path (x, v, y) m-connects x and y given $\{w\}$ since the collider v is an ancestor of w. However, as the next Lemma shows, there will always exist a path in $\Pi_G^{\min}(v, w|C)$ such that all non-endpoints are colliders in C. In $G_2^{\min}$ from Figure 3, the path (x, w, y) m-connects x and y given $\{w\}$.

Lemma 29 *If G is an ancestral graph that satisfies the boundary containment property, and $\pi = (v = v_0, v_1, \ldots, v_k, v_{k+1} = w) \in \Pi_G^{\min}(v, w|C)$ is such that no other path in $\Pi_G^{\min}(v, w|C)$ has more non-endpoint vertices in C than π, then all non-endpoint vertices $v_1, \ldots, v_k$ on π are colliders that are in C.*

Proof By Corollary 28, all non-endpoints $v_1, \ldots, v_k$ are colliders. Assume that there exists $v_i \notin C$, $1 \leq i \leq k$. Since $\pi \in \Pi_G(v, w|C)$, and thus $v_i \in \mathrm{An}(C)$, there exists $c \in C$ such that $v_i \to \cdots \to c \in G$.

In particular, $c \neq v_{i-1}$ and $c \neq v_{i+1}$ because v_i is ancestral neither to v_{i-1} nor to v_{i+1}. The boundary containment property and the fact that G does not contain directed cycles imply that $v_i \to c \in G$. By Lemma 25, G contains edges between c and both v_{i-1} and v_{i+1}. Since the edge between v_{i-1} and v_i has an arrowhead at v_i and $v_i \to c \in G$, the edge between v_{i-1} and c must have an arrowhead at c because otherwise the fact that G is an ancestral graph would be contradicted. Similarly, the edge between v_{i+1} and c must have an arrowhead at c. If $v_{i-1} \to c$, then $v_i \neq v$, v_{i-2} is adjacent to c and by the same argument as above there must be an arrowhead at c on the edge between v_{i-2} and c. Repeating this argument yields that there exists a vertex v_ℓ, $\ell \leq i-1$, such that either $v_\ell \leftrightarrow c \in G$, or $v_\ell = v$ and $v \to c$. The same arguments also imply that there exists a vertex v_j, $j \geq i+1$, such that either $v_j \leftrightarrow c \in G$, or $v_j = w$ and $w \to c$. Therefore, the path $(v, v_1, \ldots, v_\ell, c, v_j, \ldots, v_k, w)$ is in $\Pi_G(v, w|C)$ and is either shorter than π or of equal length but with more non-endpoint vertices in C. This contradicts the choice of π and therefore the assumption of a non-endpoint on π that is not in C must be false. ■

Abstract

We investigate robustness properties for a broad class of support vector machines with non-smooth loss functions. These kernel methods are inspired by convex risk minimization in infinite dimensional Hilbert spaces. Leading examples are the support vector machine based on the ε-insensitive loss function, and kernel based quantile regression based on the pinball loss function. Firstly, we propose with the Bouligand influence function (BIF) a modification of F.R. Hampel's influence function. The BIF has the advantage of being positive homogeneous which is in general not true for Hampel's influence function. Secondly, we show that many support vector machines based on a Lipschitz continuous loss function and a bounded kernel have a bounded BIF and are thus robust in the sense of robust statistics based on influence functions.

Keywords: Bouligand derivatives, empirical risk minimization, influence function, robustness, support vector machines

1. Introduction

The goal in non-parametric regression is to estimate a functional relationship between an $\mathbb{R}^d$-valued input random variable X and an $\mathbb{R}$-valued output random variable Y, under the assumption that the joint distribution P of (X,Y) is (almost) completely unknown. In order to model this relationship one typically assumes that one has a training data set $D_{train} = \big((x_1,y_1),\ldots,(x_n,y_n)\big)$ from independent and identically distributed (i.i.d.) random variables (X_i,Y_i), $i = 1,\ldots,n$, which all have the distribution P. Informally, the aim is to build a predictor $f : \mathbb{R}^d \to \mathbb{R}$ based on these observations such that $f(X)$ is a good approximation of Y. To formalize this aim one uses a continuous *loss function* $L : Y \times \mathbb{R} \to [0,\infty)$ that assesses the quality of a prediction $f(x)$ for an observed output y by $L(y,f(x))$. We follow the convention that the smaller $L(y,f(x))$ is, the better the prediction is. The quality of a predictor f is measured by the *L-risk* $\mathcal{R}_{L,\mathrm{P}}(f) := \mathbb{E}_{\mathrm{P}} L(Y,f(X))$ which of course is unknown, because P is unknown. One tries to find a predictor whose risk is close to the minimal risk, that is to the Bayes risk $\mathcal{R}^*_{L,\mathrm{P}} := \inf\{\mathcal{R}_{L,\mathrm{P}}(f);\, f : \mathbb{R}^d \to \mathbb{R} \text{ measurable}\}$. One way to build a non-parametric predictor f is to use a support vector machine (SVM) which finds a minimizer $f_{\mathrm{P},\lambda}$

of the regularized risk

$$\mathcal{R}^{reg}_{L,P,\lambda}(f) := \mathbb{E}_P L(Y, f(X)) + \lambda \|f\|^2_{\mathcal{H}}, \tag{1}$$

where $\lambda > 0$ is a regularization parameter to reduce the danger of overfitting, $\mathcal{H}$ is a reproducing kernel Hilbert space (RKHS) of a measurable kernel $k : X \times X \to \mathbb{R}$, and L is a measurable, *convex* loss function in the sense that $L(y,\cdot) : \mathbb{R} \to [0,\infty)$ is convex for all $y \in Y$, see Vapnik (1998) and Schölkopf and Smola (2002). Since (1) is strictly convex in f, the minimizer $f_{P,\lambda}$ is unique if it exists. We denote the canonical feature map by $\Phi : \mathcal{H} \to \mathcal{H}$, $\Phi(x) := k(\cdot,x)$. The reproducing property gives $f(x) = \langle f, \Phi(x)\rangle_{\mathcal{H}}$ for all $f \in \mathcal{H}$ and $x \in X$. A kernel k is bounded, if $\|k\|_\infty := \sup\{\sqrt{k(x,x)} : x \in X\} < \infty$. Using the reproducing property and $\|\Phi(x)\|_{\mathcal{H}} = \sqrt{k(x,x)}$, one obtains the well-known inequalities

$$\|f\|_\infty \le \|k\|_\infty \|f\|_{\mathcal{H}} \quad \text{and} \quad \|\Phi(x)\|_\infty \le \|k\|_\infty \|\Phi(x)\|_{\mathcal{H}} \le \|k\|^2_\infty \tag{2}$$

for $f \in \mathcal{H}$ and $x \in X$. The Gaussian radial basis function kernel defined by $k_{RBF}(x,x') = \exp(-\|x - x'\|^2/\gamma^2)$, $\gamma > 0$, is bounded and universal on every compact subset of $\mathbb{R}^d$ (Steinwart, 2001) which partially explains its popularity. The corresponding RKHS of this kernel has infinite dimension. Of course, $\mathcal{R}^{reg}_{L,P,\lambda}(f)$ is not computable, because P is unknown. However, the empirical distribution $D = \frac{1}{n}\sum_{i=1}^n \delta_{(x_i,y_i)}$ corresponding to the training data set D_{train} can be used as an estimator of P. Here $\delta_{(x_i,y_i)}$ denotes the Dirac distribution in (x_i,y_i). If we replace P by D in (1), we obtain the regularized empirical risk

$$\mathcal{R}^{reg}_{L,D,\lambda}(f) := \mathbb{E}_D L\big(Y, f(X)\big) + \lambda \|f\|^2_{\mathcal{H}}.$$

An empirical SVM f_{D,λ_n} with $\lambda_n > 0$ and $\lambda_n \to 0$ if $n \to \infty$, is called L-risk consistent if $\mathcal{R}_{L,P}(f_{D,\lambda_n}) \to \mathcal{R}^*_{L,P}$ in probability for $n \to \infty$.

Traditionally, research in nonparametric regression is often based on the least squares loss $L_{LS}(y,t) := (y-t)^2$. The least squares loss function is convex in t, is useful to estimate the conditional mean function, and is advantageous from a numerical point of view, but L_{LS} is not Lipschitz continuous. From a practical point of view there are situations in which a different loss function is more appropriate. (i) In some situations one is actually not interested in modeling the conditional mean, but in fitting a conditional quantile function instead. For this purpose the convex pinball loss function $L_{\tau-pin}(y,t) := (\tau-1)(y-t)$, if $y - t < 0$, and $L_{\tau-pin}(y,t) := \tau(y-t)$, if $y - t \ge 0$, is used, where $\tau \in (0,1)$ specifies the desired conditional quantile, see Koenker and Bassett (1978) and Koenker (2005) for parametric quantile regression and Takeuchi et al. (2006) for nonparametric quantile regression. (ii) If the goal is to estimate the conditional median function, then the ε-insensitive loss given by $L_\varepsilon(y,t) := \max\{|y-t| - \varepsilon, 0\}$, $\varepsilon \in (0,\infty)$, promises algorithmic advantages in terms of sparseness compared to the L1-loss function $L_{L1}(y,t) = |y-t|$, see Vapnik (1998) and Schölkopf and Smola (2002). (iii) If the regular conditional distribution of Y given $X = x$ is known to be symmetric, basically all invariant loss functions of the form $L(y,t) = \psi(r)$ with $r = y - t$, where $\psi : \mathbb{R} \to [0,\infty)$ is convex, symmetric and has its only minimum at 0, can be used to estimate the conditional mean, see Steinwart (2007). In this case a less steep loss function such as the Lipschitz continuous Huber loss function given by $L_{c-Huber}(y,t) := \psi(r) = r^2/2$, if $|r| \le c$, and $\psi(r) = c|r| - c^2/2$, if $|r| > c$ for some $c \in (0,\infty)$, may be more suitable if one fears outliers in y-direction, see Huber (1964) and Christmann and Steinwart (2007).

The deeper reason to consider Lipschitz continuous loss functions is the following. One strong argument in favor of SVMs is that they are L-risk consistent under weak assumptions, that is SVMs

are able to "learn", but it is also important to investigate the robustness properties for such statistical learning methods. In almost all cases statistical models are only approximations to the true random process which generated a given data set. Hence the natural question arises what impact such deviations may have on the results. J.W. Tukey, one of the pioneers of robust statistics, mentioned already in 1960 (Hampel et al., 1986, p. 21): *"A tacit hope in ignoring deviations from ideal models was that they would not matter; that statistical procedures which were optimal under the strict model would still be approximately optimal under the approximate model. Unfortunately, it turned out that this hope was often drastically wrong; even mild deviations often have much larger effects than were anticipated by most statisticians."*

Let us consider $T(\mathrm{P}) := \mathcal{R}^{reg}_{L,\mathrm{P},\lambda}(f)$, with P a probability measure, as a mapping $T : \mathrm{P} \mapsto \mathcal{R}^{reg}_{L,\mathrm{P},\lambda}(f)$. In robust statistics we are interested in smooth and bounded functions T, because this will give stable regularized risks within small neighborhoods of P. If an appropriate derivative $\nabla T(\mathrm{P})$ of $T(\mathrm{P})$ is bounded, then the function $T(\mathrm{P})$ cannot increase or decrease unlimited in small neighborhoods of P. Several notions of differentiability have been used for this purpose.

Let us therefore take a look at the following results from Averbukh and Smolyanov (1967, 1968), Fernholz (1983) and Rieder (1994) on various notions of differentiation to clarify the connections between these notions. For every pair of normed real vector spaces (X,Y) let a subset $\mathcal{S}(X,Y)$ of the functions from X to Y be given. The following conditions are imposed on this system $\mathcal{S}$, which will provide the (Landau) o remainder of the first-order Taylor approximation of an $\mathcal{S}$-differentiation: (i) $\rho(0) = 0$, $\rho \in \mathcal{S}(X,Y)$, (ii) $\mathcal{S}(X,Y)$ is a real vector subspace of all functions from X to Y, (iii) $\mathcal{S}(X,Y) \cap \mathcal{L}(X,Y) = \{0\}$ where $\mathcal{L}(X,Y)$ is the space of continuous linear mappings from X to Y, and 0 stands for the zero operator and (iv) moreover, in case $X = \mathbb{R}$, it is required that $\mathcal{S}(\mathbb{R},Y) = \{\rho : \mathbb{R} \to Y | \lim_{t\to 0} \rho(t)/t = 0\}$. If $\mathcal{S}$ fulfills (i) to (iv), then some mapping $T : X \to Y$ is called *$\mathcal{S}$-differentiable* at x if there exists some $A \in \mathcal{L}(X,Y)$ and $\rho \in \mathcal{S}(X,Y)$ such that for all $h \in X$, $T(x+h) = T(x) + Ah + \rho(h)$. The continuous linear mapping $\nabla^{\mathcal{S}} T(x) = A$ is called *$\mathcal{S}$-derivative* of T at x. The set of all functions $T : X \to Y$ which are $\mathcal{S}$-differentiable at x is denoted by $\mathcal{D}_{\mathcal{S}}(X,Y;x)$. From conditions (ii) and (iii) it is seen that the $\mathcal{S}$-derivative $\nabla^{\mathcal{S}} T(x)$ is uniquely defined. Condition (iv) ensures that $\mathcal{S}$-differentiability in case $X = \mathbb{R}$ coincides with the usual notion of differentiability. The function $T \mapsto \nabla^{\mathcal{S}} T(x)$ is a linear mapping from $\mathcal{D}_{\mathcal{S}}(X,Y;x)$ to $\mathcal{L}(X,Y)$.

$\mathcal{S}$-differentiations may be constructed in a special way by means of coverings $\mathcal{C}$, whose elements are naturally assumed to be bounded sets C (so that $th \to 0$ uniformly for $h \in C$ as $t \to 0$). For every normed real vector space X let a covering $\mathcal{C}_X$ of X be given which consists of bounded subsets of X. If Y is another normed real vector space, define $\mathcal{S}_C(X,Y) = \{\rho : X \to Y | \lim_{t\to 0} \sup_{h\in C} \frac{\|\rho(th)\|}{t} = \rho(0) = 0 \; \forall C \in \mathcal{C}_X\}$. Then the class $\mathcal{S}_C$ satisfies the conditions (i) to (iv). With X ranging through all normed real vector spaces, we can then define the following concepts of differentiation by varying the covering $\mathcal{C}_X$. *Gâteaux*-differentiation is defined by the choices $\mathcal{C}_{GX} = \{C \subset X | C \text{ finite}\}$. For *Hadamard*-differentiation, $\mathcal{C}_{HX} = \{C \subset X | C \text{ compact}\}$ and *Fréchet*-differentiation uses the covering $\mathcal{C}_{FX} = \{C \subset X | C \text{ bounded}\}$. The three differentiations will be indicated by the corresponding authors' initials. From these definitions it is clear that ∇^F implies ∇^H which implies ∇^G. It can be shown that ∇^H is actually the weakest $\mathcal{S}$-derivative which fulfills the chain rule.

One general approach to robustness (Hampel, 1968, 1974) is the one based on influence functions which are related to Gâteaux-derivatives. Let $\mathcal{M}_1$ be the set of probability distributions on some measurable space $(Z, \mathcal{B}(Z))$ and let $\mathcal{H}$ be a reproducing kernel Hilbert space. The influence

function (IF) of $T : \mathcal{M}_1 \to \mathcal{H}$ at a point $z \in Z$ for a distribution P is defined as

$$\mathrm{IF}(z;T,\mathrm{P}) = \lim_{\varepsilon \downarrow 0} \frac{T((1-\varepsilon)\mathrm{P} + \varepsilon\delta_z) - T(\mathrm{P})}{\varepsilon}, \tag{3}$$

if the limit exists. Within this approach robust estimators are those which have a bounded influence function.[1] The influence function is neither supposed to be linear nor continuous. If the influence functions exists for all points $z \in Z$ and if it is continuous and linear, then the IF is a special Gâteaux-derivative.

Christmann and Steinwart (2004, 2007) and Steinwart and Christmann (2008b) showed that SVMs have a bounded influence function in binary classification and in regression problems provided that the kernel is bounded and continuous, L is twice Fréchet-differentiable w.r.t. the second argument, and the first and second F-derivative of L is bounded. Hence Lipschitz continuous loss functions are of special interest from a robustness point of view. An example of a loss function with these properties is the logistic loss given by $L_{log}(y,t) := -\log\big(4\Lambda(y-t)(1-\Lambda(y-t))\big)$, $y,t \in \mathbb{R}$, where $\Lambda(y-t) = 1/\big(1+e^{-(y-t)}\big)$. However the important special cases $L_{\underline{\varepsilon}}$, $L_{\tau-pin}$, and $L_{c-Huber}$ are excluded in these results, because these loss functions are not everywhere Fréchet-differentiable.

The present paper tries to fill this gap: we will propose in Definition 1 an alternative to the influence function. This alternative is based on Bouligand-derivatives whereas Hampel's influence function was defined having Gâteaux-derivatives in mind. The second goal of this paper is to use this new notion of robustness to show that SVMs for regression are robust in this sense even if the loss function has no Fréchet-derivative.

Let us now recall some facts on Bouligand-derivatives and strong approximation of functions. For the rest of the introduction let X, Y, W, and Z be normed linear spaces, and we consider neighborhoods $\mathcal{N}(x_0)$ of x_0 in X, $\mathcal{N}(y_0)$ of y_0 in Y, and $\mathcal{N}(w_0)$ of w_0 in W. Let F and G be functions from $\mathcal{N}(x_0) \times \mathcal{N}(y_0)$ to Z, h_1 and h_2 functions from $\mathcal{N}(w_0)$ to Z, f a function from $\mathcal{N}(x_0)$ to Z and g a function from $\mathcal{N}(y_0)$ to Z. A function f *approximates* F in x at (x_0,y_0), written as $f \sim_x F$ at (x_0,y_0), if $F(x,y_0) - f(x) = o(x-x_0)$. Similarly, $g \sim_y F$ at (x_0,y_0) if $F(x_0,y) - g(y) = o(y-y_0)$. A function h_1 *strongly approximates* h_2 at w_0, written as $h_1 \approx h_2$ at w_0, if for each $\varepsilon > 0$ there exists a neighborhood $\mathcal{N}(w_0)$ of w_0 such that whenever w and w' belong to $\mathcal{N}(w_0)$, $\big\|\big(h_1(w) - h_2(w)\big) - \big(h_1(w') - h_2(w')\big)\big\| \le \varepsilon \|w - w'\|$. A function f *strongly approximates* F in x at (x_0,y_0), written as $f \approx_x F$ at (x_0,y_0), if for each $\varepsilon > 0$ there exist neighborhoods $\mathcal{N}(x_0)$ of x_0 and $\mathcal{N}(y_0)$ of y_0 such that whenever x and x' belong to $\mathcal{N}(x_0)$ and y belongs to $\mathcal{N}(y_0)$ we have $\big\|\big(F(x,y) - f(x)\big) - \big(F(x',y) - f(x')\big)\big\| \le \varepsilon \|x - x'\|$. Strong approximation amounts to requiring $h_1 - h_2$ to have a strong Fréchet-derivative of 0 at w_0, though neither h_1 nor h_2 is assumed to be differentiable in any sense. A similar definition is made for strong approximation in y. We define strong approximation for functions of several groups of variables, for example $G \approx_{(x,y)} F$ at (x_0,y_0), by replacing W by $X \times Y$ and making the obvious substitutions. Note that one has both $f \approx_x F$ and $g \approx_y F$ at (x_0,y_0) exactly if $f(x) + g(y) \approx_{(x,y)} F$ at (x_0,y_0).

Recall that a function $f : X \to Z$ is called *positive homogeneous* if

$$f(\alpha x) = \alpha f(x) \quad \forall \alpha \ge 0, \forall x \in X.$$

Following Robinson (1987) we can now define the *Bouligand-derivative*. Given a function f from an open subset $\mathcal{X}$ of a normed linear space X into another normed linear space Z, we say that

1. In the following we use the term "robust" in this sense, unless otherwise stated.

f is *Bouligand-differentiable* at a point $x_0 \in \mathcal{X}$, if there exists a positive homogeneous function $\nabla^B f(x_0) : \mathcal{X} \to Z$ such that

$$f(x_0+h) = f(x_0) + \nabla^B f(x_0)(h) + o(h). \tag{4}$$

We can write (4) also as

$$\lim_{h\to 0} \left\| f(x_0+h) - f(x_0) - \nabla^B f(x_0)(h) \right\|_Z / \|h\|_X = 0. \tag{5}$$

Let $F : X \times Y \to Z$, and suppose that F has a partial B-derivative[2] $\nabla_1^B F(x_0,y_0)$ with respect to x at (x_0,y_0). We say $\nabla_1^B F(x_0,y_0)$ is *strong* if $F(x_0,y_0) + \nabla_1^B F(x_0,y_0)(x-x_0) \approx_x F$ at (x_0,y_0). Robinson (1987) showed that the chain rule holds for Bouligand-derivatives. Let f be a Lipschitzian function from an open set $\Omega \subset \mathbb{R}^m$ to $\mathbb{R}^k$, $x_0 \in \Omega$, and f B-differentiable at x_0. Let g be a Lipschitzian function from an open set $\Gamma \subset \mathbb{R}^k$, with $f(x_0) \in \Gamma$, to $\mathbb{R}^l$ be B-differentiable at $f(x_0)$. Then $g \circ f$ is B-differentiable at x_0 and $\nabla^B(g \circ f)(x_0) = \nabla^B g\big(f(x_0)\big) \circ \nabla^B f(x_0)$. The fact that B-derivatives, just as F- and H-derivatives, fulfill the chain rule is no contradiction to the before mentioned fact that H-differentiability is the *weakest $\mathcal{S}$-differentiation* which fulfills the chain rule (Rieder, 1994, p. 4) because the B-derivative is not necessarily a continuous linear function.

In general Gâteaux- and Bouligand-differentiability are not directly comparable, because B-derivatives are by definition positive homogeneous, but not necessarily linear. We will show that the existence of the BIF implies the existence of the IF and that in that case BIF=IF. Please note that this in general does not imply that the IF is a Gâteaux-derivative.

In this paper, we will prove that many SVMs based on Lipschitz continuous loss functions have a bounded Bouligand influence function. To formulate our results we will use Bouligand-derivatives in the sense of Robinson (1991) as defined above. These directional derivatives were to our best knowledge not used in robust statistics so far, but are successfully applied in approximation theory for non-smooth functions. Section 2 covers our definition of the Bouligand influence function (BIF) and contains the main result which gives the BIF for support vector machines based on a bounded kernel and a B-differentiable Lipschitz continuous convex loss function. In Section 3 it is shown that this result covers the loss functions $L_{\underline{\varepsilon}}$, $L_{\tau-pin}$, $L_{c-Huber}$, and L_{log} as special cases. Section 4 contains the conclusions. All proofs are given in the Appendix.

2. Main Result

This section contains our two main results: the definition of the Bouligand influence function and a theorem which shows that a broad class of support vector machines based on a Lipschitz continuous, but not necessarily Fréchet-differentiable loss function have a bounded Bouligand influence function. We denote the set of all probability distributions on some measurable space $(Z, \mathcal{B}(Z))$ by $\mathcal{M}_1$ and let $\mathcal{H}$ be a Hilbert space.

Definition 1 *The **Bouligand influence function (BIF)** of the function $T : \mathcal{M}_1 \to \mathcal{H}$ for a distribution* P *in the direction of a distribution* $\mathrm{Q} \neq \mathrm{P}$ *is the special Bouligand-derivative (if it exists)*

$$\lim_{\varepsilon \downarrow 0} \frac{\left\| T\big((1-\varepsilon)\mathrm{P} + \varepsilon \mathrm{Q}\big) - T(\mathrm{P}) - \mathrm{BIF}(\mathrm{Q}; T, \mathrm{P}) \right\|_{\mathcal{H}}}{\varepsilon} = 0. \tag{6}$$

2. Throughout the paper we will denote partial B-derivatives of f by $\nabla_1^B f$, $\nabla_2^B f$, $\nabla_{2,2}^B f := \nabla_2^B(\nabla_2^B f)$ etc.

The BIF has the interpretation that it measures the impact of an infinitesimal small amount of contamination of the original distribution P in the direction of Q on the quantity of interest $T(\mathrm{P})$. It is thus desirable that the function T has a *bounded* BIF.

Note that (6) is indeed a special B-derivative, because we consider the directions $h = \varepsilon(\mathrm{Q}-\mathrm{P})$ and $x_0 = \mathrm{P}$. If Q equals the Dirac distribution δ_z in a point $z \in Z$, that is $\delta_z(\{z\}) = 1$, we write $\mathrm{BIF}(z;T,\mathrm{P})$. The choice of the metric on $\mathcal{M}_1$ is not important for the definition of the BIF, because $\|\varepsilon(\mathrm{Q}-\mathrm{P})\| = \varepsilon\,\|\mathrm{Q}-\mathrm{P}\|$ and $\|\mathrm{Q}-\mathrm{P}\|$ is a positive constant. For the norm of total variation we obtain for example,

$$\lim_{\varepsilon(\mathrm{Q}-\mathrm{P})\downarrow 0} \frac{\big\|T\big(\mathrm{P}+\varepsilon(\mathrm{Q}-\mathrm{P})\big) - T(\mathrm{P}) - \mathrm{BIF}(\mathrm{Q};T,\mathrm{P})\big\|_{\mathcal{H}}}{\|\varepsilon(\mathrm{Q}-\mathrm{P})\|_{\mathrm{tv}}} = 0,$$

(cf., Equation 5). Since $\varepsilon(\mathrm{Q}-\mathrm{P}) \to 0$ iff $\varepsilon \to 0$ and by assumption $\mathrm{Q} \neq \mathrm{P}$ we obtain (6).

The Bouligand influence function is a modification of the influence function given by (3). Recall that the Gâteaux-derivative of some mapping f at a point x_0 equals $\nabla^G f(x_0)(h) = \lim_{\varepsilon\downarrow 0}\big(f(x_0+\varepsilon h) - f(x_0)\big)/\varepsilon$ if it exists for every $h \in X$. Hence the influence function is the special Gâteaux-derivative with $\mathrm{Q} = \delta_z$ and $h = \delta_z - \mathrm{P}$, if the IF is continuous and linear. However, the BIF is always positive homogeneous because it is a Bouligand-derivative, which is in general not true for the influence function. As will be shown in (13), this property leads to the result that for $\alpha \geq 0$ and $h := \varepsilon(\mathrm{Q}-\mathrm{P})$ the asymptotic bias $T((1-\alpha\varepsilon)\mathrm{P}+\alpha\varepsilon\mathrm{Q}) - T(\mathrm{P})$ equals $\alpha\,\mathrm{BIF}(\mathrm{Q};T,\mathrm{P}) + o(h)$.

The following simple calculations clarify the connection between the BIF and the IF. In general we have for B-derivatives with $h = \varepsilon\tilde{h}$, where $\varepsilon \in (0,\infty)$ and $\tilde{h} \in X$ with $0 < \|\tilde{h}\| \leq 2$,

$$\begin{aligned}
0 &= \lim_{h\to 0} \frac{\|f(x_0+h) - f(x_0) - \nabla^B f(x_0)(h)\|}{\|h\|} \\
&= \lim_{\varepsilon\downarrow 0} \frac{\|f(x_0+\varepsilon\tilde{h}) - f(x_0) - \varepsilon\nabla^B f(x_0)(\tilde{h})\|}{\varepsilon\|\tilde{h}\|} \\
&= \lim_{\varepsilon\downarrow 0} \Big\| \frac{f(x_0+\varepsilon\tilde{h}) - f(x_0)}{\varepsilon} - \nabla^B f(x_0)(\tilde{h}) \Big\|.
\end{aligned}$$

Hence $\lim_{\varepsilon\downarrow 0}\big(f(x_0+\varepsilon\tilde{h}) - f(x_0)\big)/\varepsilon = \nabla^B f(x_0)(\tilde{h})$. In particular we obtain for $\mathrm{Q} \neq \mathrm{P}$ and taking $0 < \|\mathrm{Q}-\mathrm{P}\| \leq 2$ into account that, if $\mathrm{BIF}(\mathrm{Q};T,\mathrm{P})$ exists, then $\mathrm{BIF}(\mathrm{Q};T,\mathrm{P}) = \lim_{\varepsilon\downarrow 0}\big(T((1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}) - T(P)\big)/\varepsilon$, which is the definition of the IF, if we choose $\mathrm{Q} = \delta_z$.

We can now give a general result on the BIF of the support vector machine $T(\mathrm{P}) := f_{\mathrm{P},\lambda}$. We restrict attention to Lipschitz continuous loss functions, because the growth behavior of L plays an important role to obtain consistency and robustness results as was shown by Christmann and Steinwart (2007). For notational convenience we shall often write $\nabla_2^B L(Y, f(X))$ instead of $\nabla_2^B L(Y,\cdot)(f(X))$, because $f(X) \in \mathbb{R}$. We will sometimes explicitly write "$\cdot$" for multiplication to avoid misunderstandings.

Theorem 2 *Let $X \subset \mathbb{R}^d$ and $Y \subset \mathbb{R}$ be closed sets, $\mathcal{H}$ be a RKHS with a bounded, continuous kernel k, $f_{\mathrm{P},\lambda} \in \mathcal{H}$, and $L : Y \times \mathbb{R} \to [0,\infty)$ be a convex loss function which is Lipschitz continuous w.r.t. the second argument with uniform Lipschitz constant $|L|_1 := \sup_{y\in Y} |L(y,\cdot)|_1 \in (0,\infty)$. Further, assume that L has measurable partial B-derivatives w.r.t. to the second argument with*

$$\kappa_1 := \sup_{y\in Y} \big\|\nabla_2^B L(y,\cdot)\big\|_\infty \in (0,\infty)\ ,\ \kappa_2 := \sup_{y\in Y} \big\|\nabla_{2,2}^B L(y,\cdot)\big\|_\infty < \infty. \tag{7}$$

Let $\delta_1 > 0$, $\delta_2 > 0$, $\mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda}) := \{f \in \mathcal{H}; \|f - f_{\mathrm{P},\lambda}\|_{\mathcal{H}} < \delta_1\}$, $\lambda > \frac{1}{2}\kappa_2 \|k\|_\infty^3$, *and* P, Q *be probability measures*[3] *on* $\big(X \times Y, \mathcal{B}(X \times Y)\big)$ *with* $\mathbb{E}_\mathrm{P}|Y| < \infty$ *and* $\mathbb{E}_\mathrm{Q}|Y| < \infty$. *Define* $G : (-\delta_2, \delta_2) \times \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda}) \to \mathcal{H}$,

$$G(\varepsilon, f) := 2\lambda f + \mathbb{E}_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X), \tag{8}$$

and assume that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ *is strong. Then the Bouligand influence function of* $T(\mathrm{P}) := f_{\mathrm{P},\lambda}$ *in the direction of* $\mathrm{Q} \neq \mathrm{P}$ *exists,*

$$\begin{aligned} \mathrm{BIF}(\mathrm{Q}; T, \mathrm{P}) &= S^{-1}\big(\mathbb{E}_\mathrm{P} \nabla_2^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \Phi(X)\big) && (9) \\ &\quad - S^{-1}\big(\mathbb{E}_\mathrm{Q} \nabla_2^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \Phi(X)\big), && (10) \end{aligned}$$

where $S : \mathcal{H} \to \mathcal{H}$ *with*

$$S(\cdot) := \nabla_2^B G(0, f_{\mathrm{P},\lambda})(\cdot) = 2\lambda \,\mathrm{id}_{\mathcal{H}}(\cdot) + \mathbb{E}_\mathrm{P} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \langle \Phi(X), \cdot \rangle_{\mathcal{H}} \Phi(X),$$

and $\mathrm{BIF}(\mathrm{Q}; T, \mathrm{P})$ *is bounded.*

Remark 3 *We additionally show that under the assumptions of Theorem 2 we have:*

1. *For some* χ *and each* $f \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$, $G(\cdot, f)$ *is Lipschitz continuous on* $(-\delta_2, \delta_2)$ *with Lipschitz constant* χ.

2. G *has partial B-derivatives with respect to* ε *and* f *at* $(0, f_{\mathrm{P},\lambda})$.

3. $\nabla_2^B G(0, f_{\mathrm{P},\lambda})(h - f_{\mathrm{P},\lambda})$ *lies in a neighborhood of* $0 \in \mathcal{H}$, $\forall h \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$.

4. $d_0 := \inf_{h_1, h_2 \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda}) - f_{\mathrm{P},\lambda}; h_1 \neq h_2} \frac{\|\nabla_2^B G(0, f_{\mathrm{P},\lambda})(h_1) - \nabla_2^B G(0, f_{\mathrm{P},\lambda})(h_2)\|_{\mathcal{H}}}{\|h_1 - h_2\|_{\mathcal{H}}} > 0$.

5. *For each* $\xi > d_0^{-1}\chi$ *there exist constants* $\delta_3, \delta_4 > 0$, *a neighborhood* $\mathcal{N}_{\delta_3}(f_{\mathrm{P},\lambda}) := \{f \in \mathcal{H}; \|f - f_{\mathrm{P},\lambda}\|_{\mathcal{H}} < \delta_3\}$, *and a function* $f^* : (-\delta_4, \delta_4) \to \mathcal{N}_{\delta_3}(f_{\mathrm{P},\lambda})$ *satisfying*

   v.1) $f^*(0) = f_{\mathrm{P},\lambda}$.

   v.2) f^* *is Lipschitz continuous on* $(-\delta_4, \delta_4)$ *with Lipschitz constant* $|f^*|_1 = \xi$.

   v.3) For each $\varepsilon \in (-\delta_4, \delta_4)$ *is* $f^*(\varepsilon)$ *the unique solution of* $G(\varepsilon, f) = 0$ *in* $\mathcal{N}_{\delta_3}(f_{\mathrm{P},\lambda})$.

   v.4) $\nabla^B f^*(0)(u) = \big(\nabla_2^B G(0, f_{\mathrm{P},\lambda})\big)^{-1}\big(-\nabla_1^B G(0, f_{\mathrm{P},\lambda})(u)\big)$, $u \in (-\delta_4, \delta_4)$.

   The function f^* *is the same as in the implicit function theorem by Robinson (1991), see Theorem 7.*

Remark 4 *It will be shown that* $\kappa_2 = 0$ *for* $L = L_{\underline{\varepsilon}}$ *and* $L = L_{\tau-pin}$ *and thus the regularization condition only states that* $\lambda > \frac{1}{2}\kappa_2 \|k\|_\infty^3 = 0$.

3. Because X and Y are assumed to be closed, P can be split up into the marginal distribution P_X and the regular conditional probability $\mathrm{P}(\cdot|x)$, $x \in X$, on Y. Same for Q.

Note that S can be interpreted as the (Bouligand-)Hessian of the regularized risk, see (14) and (17). Further the formula in (9) and (10) is similar to the one obtained by Christmann and Steinwart (2007) for the IF of $T(\mathrm{P}) = f_{\mathrm{P},\lambda}$. The difference is that we used B-derivatives instead of F-derivatives, because we allow non-smooth L.

Note that the first summand of the BIF given in (9) does *not* depend on the contaminating distribution Q. In contrast to that, the second summand of the BIF given in (10) depends on Q and consists of two factors. The first factor depends on the partial B-derivative of the loss function, and is hence bounded due to (7). For many loss functions this factor depends only on the residual term $y - f_{\mathrm{P},\lambda}(x)$. The second factor is the feature map $\Phi(x)$ which is bounded, because k is bounded. For the Gaussian RBF kernel we expect that the second factor is not only bounded, but that the impact of $\mathrm{Q} \neq \mathrm{P}$ on the BIF is approximately local, because $k(x,x')$ converges exponentially fast to zero if $||x-x'||_2$ is large.

3. Examples

In this section we show that our main theorem covers some SVMs widely used in practice. The following result treats SVMs based on the ε-insensitive loss function or Huber's loss function for regression, and SVMs based on the pinball loss function for nonparametric quantile regression. These loss functions have uniformly bounded first and second partial B-derivatives w.r.t. the second argument, see the Appendix.

Corollary 5 *Let $X \subset \mathbb{R}^d$ and $Y \subset \mathbb{R}$ be closed, and P, Q be distributions on $X \times Y$ with $\mathbb{E}_{\mathrm{P}}|Y| < \infty$ and $\mathbb{E}_{\mathrm{Q}}|Y| < \infty$.*

1. *For $L \in \{L_{\tau-pin}, L_{\varepsilon}\}$, assume that for all $\delta > 0$ there exist positive constants ξ_{P}, ξ_{Q}, c_{P}, and c_{Q} such that for all $t \in \mathbb{R}$ with $|t - f_{\mathrm{P},\lambda}(x)| \leq \delta \|k\|_\infty$ the following inequalities hold for all $a \in [0, 2\delta\|k\|_\infty]$ and $x \in X$:*

$$\mathrm{P}\big(Y \in [t, t+a] \,\big|\, x\big) \leq c_{\mathrm{P}} a^{1+\xi_{\mathrm{P}}} \text{ and } \mathrm{Q}\big(Y \in [t, t+a] \,\big|\, x\big) \leq c_{\mathrm{Q}} a^{1+\xi_{\mathrm{Q}}}. \tag{11}$$

2. *For $L = L_{c-Huber}$, assume for $x \in X$:*

$$\mathrm{P}\big(Y \in \big\{ f_{\mathrm{P},\lambda}(x) - c, f_{\mathrm{P},\lambda}(x) + c \big\} \,\big|\, x\big) = \mathrm{Q}\big(Y \in \big\{ f_{\mathrm{P},\lambda}(x) - c, f_{\mathrm{P},\lambda}(x) + c \big\} \,\big|\, x\big) = 0. \tag{12}$$

Then the assumptions of Theorem 2 are valid: $\mathrm{BIF}(\mathrm{Q}; T, \mathrm{P})$ *of $T(\mathrm{P}) := f_{\mathrm{P},\lambda}$ exists, is given by (9) to (10), and is bounded.*

For the somewhat smoother Huber loss function we only need to exclude by (12) that the conditional probabilities of Y given X with respect to P and Q have no point probabilities at the two points $f_{\mathrm{P},\lambda}(x) - c$ and $f_{\mathrm{P},\lambda}(x) + c$. Therefore, for this loss function Q can be a Dirac distribution and in this case we have BIF = IF.

For the pinball loss function some calculations give

$$\begin{aligned} \mathrm{BIF}(\mathrm{Q}; T, \mathrm{P}) \;&=\; \frac{1}{2\lambda} \int_X \big(\mathrm{P}\big(Y \leq f_{\mathrm{P},\lambda}(x) \,\big|\, x\big) - \tau\big) \Phi(x) \, d\mathrm{P}_X(x) \\ &\quad - \frac{1}{2\lambda} \int_X \big(\mathrm{Q}\big(Y \leq f_{\mathrm{P},\lambda}(x) \,\big|\, x\big) - \tau\big) \Phi(x) \, d\mathrm{Q}_X(x), \end{aligned}$$

if the BIF exists. We expect the first integral to be small, because $f_{\mathrm{P},\lambda}(x)$ approximates the τ-quantile of $\mathrm{P}(\cdot\,|x)$ and even rates of convergence are known (Steinwart and Christmann, 2008a,b). As will become clear from the proof, (11) and (12) guarantee that the regular conditional probabilities $\mathrm{P}(\cdot\,|x)$ and $\mathrm{Q}(\cdot\,|x)$ do not have large point masses at those points where the Lipschitz continuous loss function L is *not* F-differentiable or in small neighborhoods around these points. Even for the case of parametric quantile regression, that is for $L = L_{\tau-pin}$, $\lambda = 0$ and the unbounded linear kernel $k(x,x') := \langle x,x'\rangle$, some assumptions on the distribution P seem to be necessary for the existence of the IF, see Koenker (2005, p. 44). He assumes that P has a continuous density which is strictly positive where needed.

Nevertheless, the question arises whether Theorem 2 and Corollary 5 can be shown without any assumption on the distributions P and Q. This is—at least with the techniques we used—not possible for non-smooth loss functions as the following counterexample shows. Let us consider kernel based quantile regression based on the Gaussian RBF kernel, that is $L = L_{\tau-pin}$, $k = k_{RBF}$, and $\lambda > 0$. Hence the set $\mathfrak{D}$ of discontinuity points of $\nabla_2^B L$ is $\mathfrak{D} = \{0\}$. Fix $x \in X$ and $y, y^* \in Y$ with $y \neq y^*$. Define $\mathrm{P} = \delta_{(x,y)}$ and $\mathrm{Q} = \delta_{(x,y^*)}$. Consider $f_1, f_2 \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$ with $f_1(x) \neq f_2(x)$, $y - f_1(x) > 0$, $y - f_2(x) < 0$, $y^* - f_1(x) > 0$, and $y^* - f_2(x) < 0$. Hence, $\nabla_2^B L(y, f_1(x)) = \nabla_2^B L(y^*, f_1(x)) = -\tau$ and $\nabla_2^B L(y, f_2(x)) = \nabla_2^B L(y^*, f_2(x)) = 1-\tau$. Note that $\nabla_{2,2}^B L(y,t) = 0$ for all $y,t \in \mathbb{R}$. We thus obtain for the $\mathcal{H}$-norm in (19) that $\big\|\mathbb{E}_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}}\big(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X))\big)\cdot\Phi(X)\big\|_{\mathcal{H}} = \|\Phi(x)\|_{\mathcal{H}} > 0$. Hence $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ is not strong in this special case, because $\|\Phi(x)\|_{\mathcal{H}}$ is in general greater than $\varepsilon^*\,\|f_1 - f_2\|_{\mathcal{H}}$ for arbitrarily small values of ε^*.

Now we shall show for L_{log} that the assumptions (11) or (12) are not needed to obtain a bounded BIF. It is easy to see that L_{log} is strictly convex w.r.t. the second argument and Fréchet-differentiable with $\nabla_2^F L_{log}(y,t) = 1 - 2\Lambda(y-t)$, $\nabla_{2,2}^F L_{log}(y,t) = 2\Lambda(y-t)[1-\Lambda(y-t)]$, and $\nabla_{2,2,2}^F L_{log}(y,t) = -2\Lambda(y-t)[1-\Lambda(y-t)][1-2\Lambda(y-t)]$. Obviously, these partial derivatives are bounded for all $y,t \in \mathbb{R}$. Furthermore, $\kappa_1 = \sup_{y\in\mathbb{R}} |\nabla_2^F L_{log}(y,\cdot)|_1 = 1/2$ and $\kappa_2 = \sup_{y\in\mathbb{R}} |\nabla_{2,2}^F L_{log}(y,\cdot)|_1 \leq 1/2$, because an everywhere F-differentiable function g is Lipschitz continuous with $|g|_1 = ||\nabla^F g||_\infty$ if $\nabla^F g$ is bounded.

Corollary 6 *Let $X \subset \mathbb{R}^d$ and $Y \subset \mathbb{R}$ be closed, $L = L_{log}$, and P, Q be distributions on $X \times Y$ with $\mathbb{E}_{\mathrm{P}}|Y| < \infty$ and $\mathbb{E}_{\mathrm{Q}}|Y| < \infty$. Then the assumptions of Theorem 2 are valid, and $\mathrm{BIF}(\mathrm{Q}; T, \mathrm{P})$ of $T(\mathrm{P}) := f_{\mathrm{P},\lambda}$ exists, is given by (9) to (10), and $\mathrm{BIF}(\mathrm{Q}; T, \mathrm{P})$ is bounded.*

Corollary 6 is of course also valid for empirical distributions D_n and Q_m consisting of n and m data points, because no specific assumptions on P and Q are made.

The influence function of $T(\mathrm{P}) = f_{\mathrm{P},\lambda}$ based on L_{log} and error bounds of the type

$$\big\|T\big((1-\varepsilon)\mathrm{P} + \varepsilon\delta_{(x,y)} - T(\mathrm{P})\big)\big\|_{\mathcal{H}} \leq c^*\,\varepsilon$$

where the constant c^* is known and depends only on P, $\mathrm{Q} := \delta_{(x,y)}$, and λ, were recently derived by Christmann and Steinwart (2007). We like to mention that Corollary 6 shows that this influence function is even a Bouligand-derivative, hence *positive homogeneous* in $h = \varepsilon(\mathrm{Q} - \mathrm{P})$. Therefore, we immediately obtain from the existence of the BIF that the asymptotic bias of SVMs has the form

$$\begin{aligned} f_{(1-\alpha\varepsilon)\mathrm{P}+\alpha\varepsilon\mathrm{Q},\lambda} - f_{\mathrm{P},\lambda} &= T(\mathrm{P} + \alpha h) - T(\mathrm{P}) \\ &= \alpha\,\mathrm{BIF}(\mathrm{Q}; T, \mathrm{P}) + o(\alpha h) \\ &= \alpha\big(T(\mathrm{P}+h) - T(\mathrm{P}) + o(h)\big) + o(\alpha h) \\ &= \alpha\big(f_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q},\lambda} - f_{\mathrm{P},\lambda}\big) + o(\alpha\varepsilon(\mathrm{Q}-\mathrm{P})), \quad \alpha \geq 0. \end{aligned} \tag{13}$$

This equation nicely describes the behavior of the asymptotic bias term $f_{(1-\varepsilon)P+\varepsilon Q,\lambda} - f_{P,\lambda}$ if we consider the amount $\alpha\varepsilon$ of contamination instead of ε.

4. Discussion

Bouligand-derivatives and strong Bouligand-derivatives were successfully used in approximation theory, see for example Clarke (1983), Robinson (1987, 1991), Ip and Kyparisis (1992), and the references cited therein. To our best knowledge however, these concepts were not used so far to investigate robustness properties of statistical operators.

Therefore, we defined the Bouligand influence function (BIF) as a modification of the influence function (IF), the latter being related to Gâteaux-derivatives and a cornerstone of robust statistics, see Hampel (1974), Hampel et al. (1986), and Maronna et al. (2006). If the BIF exists, then it is identical to the IF. The BIF is a positive homogeneous function by definition. This is in general not true for the IF. We used the BIF to show that support vector machines for regression, which play an important role in modern statistical learning theory, are robust in the sense of influence functions, if a bounded continuous kernel is used and if the convex loss function is Lipschitz continuous and twice Bouligand-differentiable, but not necessarily twice Fréchet-differentiable. The result covers the important special cases of SVMs based on the ε-insensitive, Huber or logistic loss function for regression, and kernel based quantile regression based on the pinball loss function. The IF of SVMs based on the logistic loss was recently derived by Christmann and Steinwart (2007) and Steinwart and Christmann (2008b).

From our point of view, the Bouligand-derivative is a promising concept for robust statistics for the following reason. Many robust estimators proposed in the literature are implicitly defined as solutions of minimization problems where the objective function or loss function is continuous or Lipschitz continuous, but not necessarily twice Fréchet-differentiable. Examples are not only SVMs treated in this paper, but also M-estimators of Huber-type and certain maximum likelihood estimators under non-standard conditions. Bouligand-differentiation nicely fills the gap between Fréchet-differentiation, which is too strong for many robust estimators, and Gâteaux-differentiation which is the basis for the robustness approach based on influence functions. Bouligand-derivatives fulfill a chain rule and a theorem of implicit functions which is in general not true for Gâteaux-derivatives.

Acknowledgments

We thank S.M. Robinson for drawing our attention to his paper from 1987. We also thank the editor and three anonymous referees.

Appendix A. Proofs

This appendix contains all the proofs of the previous sections.

A.1 Proofs for the Results in Section 2

For the proof of Theorem 2 we shall use the following implicit function theorem for B-derivatives, see Robinson (1991, Cor. 3.4). For a function f from a metric space (X, d_X) to another metric space

(Y, d_Y), we define

$$\delta(f, X) = \inf\{d_Y\big(f(x_1), f(x_2)\big) / d_X(x_1, x_2) \mid x_1 \neq x_2; x_1, x_2 \in X\}.$$

Theorem 7 *Let Y be a Banach space and X and Z be normed linear spaces. Let x_0 and y_0 be points of X and Y, respectively, and let $\mathcal{N}(x_0)$ be a neighborhood of x_0 and $\mathcal{N}(y_0)$ be a neighborhood of y_0. Suppose that G is a function from $\mathcal{N}(x_0) \times \mathcal{N}(y_0)$ to Z with $G(x_0, y_0) = 0$. In particular, for some ϕ and each $y \in \mathcal{N}(y_0)$, $G(\cdot, y)$ is assumed to be Lipschitz continuous on $\mathcal{N}(x_0)$ with modulus ϕ. Assume that G has partial B-derivatives with respect to x and y at (x_0, y_0), and that: (i) $\nabla_2^B G(x_0, y_0)(\cdot)$ is strong. (ii) $\nabla_2^B G(x_0, y_0)(y - y_0)$ lies in a neighborhood of $0 \in Z$, $\forall y \in \mathcal{N}(y_0)$. (iii) $\delta(\nabla_2^B G(x_0, y_0), \mathcal{N}(y_0) - y_0) =: d_0 > 0$. Then for each $\xi > d_0^{-1}\phi$ there are neighborhoods U of x_0 and V of y_0, and a function $f^* : U \to V$ satisfying (a) $f^*(x_0) = y_0$. (b) f^* is Lipschitz continuous on $\mathcal{N}(x_0)$ with modulus ξ. (c) For each $x \in U$, $f^*(x)$ is the unique solution in V of $G(x, y) = 0$. (d) The function f^* is B-differentiable at x_0 with $\nabla^B f^*(x_0)(u) = \big(\nabla_2^B G(x_0, y_0)\big)^{-1}\big(-\nabla_1^B G(x_0, y_0)(u)\big)$.*

We will also need the following consequence of the open mapping theorem, see Lax (2002, p. 170).

Theorem 8 *Let X and Y be Banach spaces, $A : X \to Y$ be a bounded, linear, and bijective function. Then the inverse $A^{-1} : Y \to X$ is a bounded linear function.*

The key ingredient of our proof of Theorem 2 is of course the map $G : \mathbb{R} \times \mathcal{H} \to \mathcal{H}$ defined by (8). If $\varepsilon < 0$ the integration is w.r.t. a signed measure. The $\mathcal{H}$-valued expectation used in the definition of G is well-defined for all $\varepsilon \in (\delta_2, \delta_2)$ and all $f \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$, because $\kappa_1 \in (0, \infty)$ by (7) and $\|\Phi(x)\|_\infty \leq \|k\|_\infty^2 < \infty$ by (2). For F- and B-derivatives holds a chain rule and F-differentiable functions are also B-differentiable. For $\varepsilon \in [0, 1]$ we thus obtain

$$G(\varepsilon, f) = \frac{\partial \mathcal{R}^{reg}_{L,(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q},\lambda}}{\partial \mathcal{H}}(f) = \nabla_2^B \mathcal{R}^{reg}_{L,(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q},\lambda}(f). \tag{14}$$

Since $f \mapsto \mathcal{R}^{reg}_{L,(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q},\lambda}(f)$ is convex and continuous for all $\varepsilon \in [0, 1]$ equation (14) shows that we have $G(\varepsilon, f) = 0$ if and only if $f = f_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q},\lambda}$ for such ε. Hence

$$G(0, f_{\mathrm{P},\lambda}) = 0. \tag{15}$$

We shall show that Theorem 7 is applicable for G and that there exists a B-differentiable function $\varepsilon \mapsto f_\varepsilon$ defined on a small interval $(-\delta_2, \delta_2)$ for some $\delta_2 > 0$ satisfying $G(\varepsilon, f_\varepsilon) = 0$ for all $\varepsilon \in (-\delta_2, \delta_2)$. From the existence of this function we shall obtain $\mathrm{BIF}(\mathrm{Q}; T, \mathrm{P}) = \nabla^B f_\varepsilon(0)$.

Proof of Theorem 2. The existence of $f_{\mathrm{P},\lambda}$ follows from the convexity of L and the penalizing term, see also Christmann and Steinwart (2007, Prop. 8). The assumption that $G(0, f_{\mathrm{P},\lambda}) = 0$ is valid by (15). Let us now prove the results of Remark 3 parts 1 to 5.

Remark 3 part 1. For $f \in \mathcal{H}$ fixed let $\varepsilon_1, \varepsilon_2 \in (-\delta_2, \delta_2)$. Using $\|k\|_\infty < \infty$ and (15) we obtain

$$\begin{aligned}
& \left|\mathbb{E}_{(1-\varepsilon_1)\mathrm{P}+\varepsilon_1\mathrm{Q}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) - \mathbb{E}_{(1-\varepsilon_2)\mathrm{P}+\varepsilon_2\mathrm{Q}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X)\right| \\
= & \left|(\varepsilon_1 - \varepsilon_2) \mathbb{E}_{\mathrm{Q}-\mathrm{P}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X)\right| \\
\leq & |\varepsilon_1 - \varepsilon_2| \int \left|\nabla_2^B L(y, f(x)) \cdot \Phi(x)\right| d|\mathrm{Q}-\mathrm{P}|(x,y) \\
\leq & |\varepsilon_1 - \varepsilon_2| \int \sup_{y \in Y} |\nabla_2^B L(y, f(x))| \sup_{x \in X} |\Phi(x)| \, d|\mathrm{Q}-\mathrm{P}|(x,y) \\
\leq & |\varepsilon_1 - \varepsilon_2| \, \|\Phi(x)\|_\infty \sup_{y \in Y} \left\|\nabla_2^B L(y, \cdot)\right\|_\infty \int d|\mathrm{Q}-\mathrm{P}|(x,y) \\
\leq & 2 \, \|k\|_\infty^2 \sup_{y \in Y} \left\|\nabla_2^B L(y, \cdot)\right\|_\infty |\varepsilon_1 - \varepsilon_2| \\
= & 2 \, \|k\|_\infty^2 \, \kappa_1 \, |\varepsilon_1 - \varepsilon_2| < \infty .
\end{aligned}$$

Remark 3 part 2. We have

$$\begin{aligned}
\nabla_1^B G(\varepsilon, f) &= \nabla_1^B \Big(\mathbb{E}_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) \Big) \\
&= \nabla_1^B \Big(\mathbb{E}_{\mathrm{P}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) + \varepsilon \mathbb{E}_{\mathrm{Q}-\mathrm{P}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) \Big) \\
&= \mathbb{E}_{\mathrm{Q}-\mathrm{P}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) \\
&= \mathbb{E}_{\mathrm{Q}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) - \mathbb{E}_{\mathrm{P}} \nabla_2^B L(Y, f(X)) \cdot \Phi(X) . \qquad (16)
\end{aligned}$$

This expectation exists due to (2) and (7). Furthermore, we obtain

$$\begin{aligned}
& \nabla_2^B G(0, f_{\mathrm{P},\lambda})(h) + o(h) \\
= & G(0, f_{\mathrm{P},\lambda} + h) - G(0, f_{\mathrm{P},\lambda}) \\
= & 2\lambda h + \mathbb{E}_{\mathrm{P}} \nabla_2^B L(Y, (f_{\mathrm{P},\lambda}(X) + h(X))) \cdot \Phi(X) - \mathbb{E}_{\mathrm{P}} \nabla_2^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \Phi(X) \\
= & 2\lambda h + \mathbb{E}_{\mathrm{P}} \Big(\nabla_2^B L\big(Y, (f_{\mathrm{P},\lambda}(X) + h(X))\big) - \nabla_2^B L\big(Y, f_{\mathrm{P},\lambda}(X)\big) \Big) \cdot \Phi(X) .
\end{aligned}$$

This expectation exists, as the term $\nabla_2^B L\big(Y, (f_{\mathrm{P},\lambda}(X) + h(X))\big) - \nabla_2^B L\big(Y, f_{\mathrm{P},\lambda}(X)\big)$ is bounded due to (2), (7), and $\|k\|_\infty < \infty$. Using $\langle \Phi(X), \cdot \rangle_{\mathcal{H}} \in \mathcal{H}$, we get

$$\nabla_2^B G(0, f_{\mathrm{P},\lambda})(\cdot) = 2\lambda \mathrm{id}_{\mathcal{H}}(\cdot) + \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \langle \Phi(X), \cdot \rangle_{\mathcal{H}} \Phi(X) . \qquad (17)$$

Note that $\mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L\big(Y, f(X)\big) = \nabla_2^B \mathbb{E}_{\mathrm{P}} \nabla_2^B L\big(Y, f(X)\big)$, because

$$\begin{aligned}
& \nabla_2^B \mathbb{E}_{\mathrm{P}} \nabla_2^B L\big(Y, f(X)\big) - \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L\big(Y, f(X)\big) \\
= & \mathbb{E}_{\mathrm{P}} \big(\nabla_2^B L(Y, (f(X) + h(X))) - \nabla_2^B L(Y, f(X)) \big) - \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f(X)) + o(h) \\
= & \mathbb{E}_{\mathrm{P}} \big(\nabla_2^B L(Y, (f(X) + h(X))) - \nabla_2^B L(Y, f(X)) - \nabla_{2,2}^B L(Y, f(X)) \big) + o(h) = o(h)
\end{aligned}$$

by definition of the B-derivative.

Remark 3 part 3. Let $\mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$ be a δ_1-neighborhood of $f_{\mathrm{P},\lambda}$. Because $\mathcal{H}$ is a RKHS and hence a vector space it follows for all $h \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$ that $\left\| f_{\mathrm{P},\lambda} - h - 0 \right\|_{\mathcal{H}} \leq \delta_1$ and hence $h - f_{\mathrm{P},\lambda} \in \mathcal{N}_{\delta_1}(0) \subset$

$\mathcal{H}$. Note that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})(\cdot)$ computed by (17) is a mapping from $\mathcal{H}$ to $\mathcal{H}$. For $\xi := h - f_{\mathrm{P},\lambda}$ we have $\|\xi\|_{\mathcal{H}} \le \delta_1$ and the reproducing property yields

$$\nabla_2^B G(0, f_{\mathrm{P},\lambda})(\xi) = 2\lambda\xi + \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \xi\Phi(X).$$

Using (2) and (7) we obtain

$$\begin{aligned}
& \left\| 2\lambda\xi + \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \xi\Phi(X) - 0 \right\|_{\mathcal{H}} \\
\le\ & 2\lambda \|\xi\|_{\mathcal{H}} + \left\| \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \xi\Phi(X) \right\|_{\mathcal{H}} \\
\le\ & 2\lambda \|\xi\|_{\mathcal{H}} + \sup_{y \in Y} \left\| \nabla_{2,2}^B L(y, \cdot) \right\|_\infty \|\xi\|_\infty \|\Phi(x)\|_\infty \\
\le\ & 2\lambda \|\xi\|_{\mathcal{H}} + \kappa_2 \|\xi\|_{\mathcal{H}} \|k\|_\infty^3 \\
\le\ & \left(2\lambda + \kappa_2 \|k\|_\infty^3\right) \delta_1 ,
\end{aligned}$$

which shows that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})(h - f_{\mathrm{P},\lambda})$ lies in a neighborhood of $0 \in \mathcal{H}$, for all $h \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$.

Remark 3 part 4. Due to (17) we have to prove that

$$d_0 := \inf_{f_1 \ne f_2} \frac{\left\| 2\lambda(f_1 - f_2) + \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L\big(Y, f_{\mathrm{P},\lambda}(X)\big) \cdot (f_1 - f_2)\Phi(X) \right\|_{\mathcal{H}}}{\|f_1 - f_2\|_{\mathcal{H}}} > 0 .$$

If $f_1 \ne f_2$, then (2), (7), and $\lambda > \frac{1}{2}\kappa_2 \|k\|_\infty^3$ yield that

$$\begin{aligned}
& \left\| 2\lambda(f_1 - f_2) + \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L\big(Y, f_{\mathrm{P},\lambda}(X)\big) \cdot (f_1 - f_2)\Phi(X) \right\|_{\mathcal{H}} / \|f_1 - f_2\|_{\mathcal{H}} \\
\ge\ & \left(\|2\lambda(f_1 - f_2)\|_{\mathcal{H}} - \left\| \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1 - f_2)\Phi(X) \right\|_{\mathcal{H}} \right) / \|f_1 - f_2\|_{\mathcal{H}} \\
\ge\ & 2\lambda - \kappa_2 \|k\|_\infty^3 > 0
\end{aligned}$$

by our assumption, which gives the assertion.

Remark 3 part 5. The assumptions of Robinson's implicit function theorem, see Theorem 7, are valid for G due to the results of Remark 3 parts 1 to 4 and the assumption that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ is strong. This gives part 5.

The result of Theorem 2 now follows from inserting (16) and (17) into Remark 3 part 5(v.4). Using (7) we see that S is bounded. The linearity of S follows from its definition and the inverse of S does exist by Theorem 7. If necessary we can restrict the range of S to $S(\mathcal{H})$ to obtain a bijective function $S_* : \mathcal{H} \to S(\mathcal{H})$ with $S_*(f) = S(f)$ for all $f \in \mathcal{H}$. Hence S^{-1} is also bounded and linear by Theorem 8. This gives the existence of a bounded BIF specified by (9) and (10). ■

A.2 Calculations for the Results in Section 3

For the proof of Corollary 5 we need the partial B-derivatives for the three loss functions and also have to check that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ is strong. We shall compute the partial B-derivatives for these loss functions in advance.

A.2.1 $\underline{\varepsilon}$-INSENSITIVE LOSS

We shall show for the $\underline{\varepsilon}$-insensitive loss $L = L_{\underline{\varepsilon}}$ that

$$\nabla_2^B L(y,t)(h) = \begin{cases} -h & \text{if} \quad \{t < y - \underline{\varepsilon}\} \text{ or } \{y - t = \underline{\varepsilon}, h < 0\} \\ 0 & \text{if} \quad \{y - \underline{\varepsilon} < t < y + \underline{\varepsilon}\} \text{ or } \{y - t = \underline{\varepsilon}, h \geq 0\} \\ & \quad \text{or } \{y - t = -\underline{\varepsilon}, h < 0\} \\ h & \text{if} \quad \{t > y + \underline{\varepsilon}\} \text{ or } \{y - t = -\underline{\varepsilon}, h \geq 0\} \end{cases}$$

and $\nabla_{2,2}^B L(y,t)(h) = 0$.

For the derivation of $\nabla_2^B L(y,t)$ we need to consider 5 cases.

1. If $t > y + \underline{\varepsilon}$, we have $t + h > y + \underline{\varepsilon}$ as long as h is small enough. Therefore,

$$\nabla_2^B L(y,t)(h) + o(h) = L(y,t+h) - L(y,t) = t + h - y - \underline{\varepsilon} - (t - y - \underline{\varepsilon}) = h.$$

2. If $t < y - \underline{\varepsilon}$, we have $t + h < y + \underline{\varepsilon}$ if h is sufficiently small. Thus

$$\nabla_2^B L(y,t)(h) + o(h) = y - t - h - \underline{\varepsilon} - (y - t - \underline{\varepsilon}) = -h.$$

3. If $y - t \in (-\underline{\varepsilon}, \underline{\varepsilon})$ we have $y - t - h \in (-\underline{\varepsilon}, \underline{\varepsilon})$ for $h \to 0$. This yields $\nabla_2^B L(y,t)(h) + o(h) = 0 - 0 = 0$.

4. If $y - t = \underline{\varepsilon}$ we have to consider 2 cases. If $h \geq 0$ and small, then $-\underline{\varepsilon} < y - t - h < \underline{\varepsilon}$ and hence $\nabla_2^B L(y,t)(h) + o(h) = 0 - 0 = 0$.
   If $h < 0$, we have $y - t - h > \underline{\varepsilon}$ and thus

$$\nabla_2^B L(y,t)(h) + o(h) = y - t - h - \underline{\varepsilon} - 0 = -h.$$

5. If $y - t = -\underline{\varepsilon}$ we have again to consider 2 cases. If $h \geq 0$, we have $y - t - h < -\underline{\varepsilon}$. Hence

$$\nabla_2^B L(y,t)(h) + o(h) = t + h - y - \underline{\varepsilon} - 0 = h.$$

   If $h < 0$, we get $-\underline{\varepsilon} < y - t - h < \underline{\varepsilon}$ which gives $\nabla_2^B L(y,t)(h) + o(h) = 0 - 0 = 0$.

This gives the assertion for the first partial B-derivative. Using the same reasoning we obtain $\nabla_{2,2}^B L(y,t)(h) = 0$.

A.2.2 PINBALL-LOSS

It will be shown that for the pinball loss $L = L_{\tau-pin}$ we get

$$\nabla_2^B L(y,t)(h) = \begin{cases} (1-\tau)h & \text{if} \quad \{y - t < 0\} \text{ or } \{y - t = 0, h \geq 0\} \\ -\tau h & \text{if} \quad \{y - t > 0\} \text{ or } \{y - t = 0, h < 0\} \end{cases}$$

and $\nabla_{2,2}^B L(y,t)(h) = 0$.

For the calculation of $\nabla_2^B L(y,t)$ we consider 3 cases.

1. If $y-t<0$ we have $y-t-h<0$ for sufficiently small values of $|h|$. Hence

$$\begin{aligned}\nabla_2^B L(y,t)(h)+o(h) &= L(y,t+h)-L(y,t)\\ &= (\tau-1)(y-t-h)-(\tau-1)(y-t)=(1-\tau)h.\end{aligned}$$

2. If $y-t>0$ we have $y-t-h>0$ for sufficiently small values of $|h|$ which yields

$$\nabla_2^B L(y,t)(h)+o(h)=\tau(y-t-h)-\tau(y-t)=-\tau h.$$

3. Assume $y-t=0$. If $y-t-h<0$ we have

$$\nabla_2^B L(y,t)(h)+o(h)=(1-\tau)h.$$

If $y-t-h>0$ it follows

$$\nabla_2^B L(y,t)(h)+o(h)=\tau(y-t-h)-\tau(y-t)=-\tau h.$$

Together this gives the assertion for $\nabla_2^B L(y,t)(h)$. In the same way we get $\nabla_{2,2}^B L(y,t)(h)=0$.

A.2.3 HUBER LOSS

It will be shown that for the Huber loss $L=L_{c-Huber}$ we have

$$\nabla_2^B L(y,t)(h)=\begin{cases}-c\,\mathrm{sign}(y-t)h & \text{if} \quad |y-t|>c\\ -(y-t)h & \text{if} \quad |y-t|\le c\end{cases}$$

and

$$\nabla_{2,2}^B L(y,t)(h) = \begin{cases} h & \text{if} \quad \{y-t=c, h\ge 0\} \text{ or } \{y-t=-c, h<0\} \\ & \quad \text{or } \{|y-t|<c\} \\ 0 & \text{if} \quad \text{else}. \end{cases}$$

For the derivation of $\nabla_2^B L(y,t)$ we consider the following 5 cases.

1. Let $y-t=c$. If $h\ge 0$ or $y-t-h\le c$ then

$$\begin{aligned}\nabla_2^B L(y,t)(h)+o(h) &= L(y,t+h)-L(y,t)\\ &= \frac{1}{2}(y-t-h)^2-\frac{1}{2}(y-t)^2=-(y-t)h+\frac{h^2}{2}.\end{aligned}$$

If $h<0$ or $y-t-h>c>0$ we have

$$\begin{aligned}\nabla_2^B L(y,t)(h)+o(h) &= c|y-t-h|-\frac{c^2}{2}-\frac{1}{2}(y-t)^2\\ &= c(y-t-h)-\frac{c^2}{2}-\frac{c^2}{2}\\ &= c(c-h)-c^2=-(y-t)h.\end{aligned}$$

2. Now we consider the case $y-t=-c$. If $h \geq 0$ or $y-t-h \leq -c < 0$ we obtain

$$\begin{aligned} \nabla_2^B L(y,t)(h)+o(h) &= c|y-t-h| - \frac{c^2}{2} - \frac{1}{2}(y-t)^2 \\ &= c(c+h) - \frac{c^2}{2} - \frac{c^2}{2} = -(y-t)h. \end{aligned}$$

If $h < 0$ or $y-t-h > -c$ we get

$$\nabla_2^B L(y,t)(h)+o(h) = \frac{1}{2}(y-t-h)^2 - \frac{1}{2}(y-t)^2 = -(y-t)h + \frac{h^2}{2}.$$

3. If $y-t > c$, we have $y-t-h > c$ and thus

$$\begin{aligned} \nabla_2^B L(y,t)(h)+o(h) &= c|y-t-h| - \frac{c^2}{2} - c|y-t| + \frac{c^2}{2} \\ &= c(y-t-h) - c(y-t) = -ch = -c\,\mathrm{sign}(y-t)h. \end{aligned}$$

4. If $y-t < -c$, we have $y-t-h < -c$ and obtain analogously to (iii) that

$$\begin{aligned} \nabla_2^B L(y,t)(h)+o(h) &= c|y-t-h| - \frac{c^2}{2} - c|y-t| + \frac{c^2}{2} \\ &= c(-y+t+h) - c(-y+t) = ch = -c\,\mathrm{sign}(y-t)h. \end{aligned}$$

5. If $-c < y-t < c$, then $-c < y-t-h < c$ and

$$\nabla_2^B L(y,t)(h)+o(h) = \frac{1}{2}(y-t-h)^2 - \frac{1}{2}(y-t)^2 = -(y-t)h + \frac{h^2}{2}.$$

This gives the assertion for $\nabla_2^B L(y,t)(h)$. Only the first two cases, where $y-t=\pm c$, were necessary to compute, since in the other 3 parts the function is already F-differentiable, and thus also B-differentiable. For the second partial B-derivative we consider 3 cases.

1. Assume $y-t=c$. If $y-t-h < c$ then

$$\nabla_{2,2}^B L(y,t)(h)+o(h) = \nabla_2^B L(y,t+h) - \nabla_2^B L(y,t) = -(y-t-h) - (-(y-t)) = h.$$

If $y-t-h > c$ then $\nabla_{2,2}^B L(y,t)(h)+o(h) = -c - (-(y-t)) = 0$.

2. Assume $y-t=-c$. If $y-t-h < -c$ we obtain $\nabla_{2,2}^B L(y,t)(h)+o(h) = c - (-(y-t)) = 0$. If $y-t-h > -c$ then

$$\nabla_{2,2}^B L(y,t)(h)+o(h) = -(y-t-h) - (-(y-t)) = h.$$

3. Assume that $|y-t| \neq c$. Then $\nabla_2^B L(y,t+h) = \nabla_2^B L(y,t)$. The difference, and consequently $\nabla_{2,2}^B L(y,t)(h) = 0$.

This gives the assertion for Huber's loss function.

Proof of Corollary 5. Now that we have shown that these loss functions have bounded first and second partial B-derivatives, we are ready to check if $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ is strong in these cases. Recall that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ is strong, if for all $\varepsilon^* > 0$ there exist a neighborhood $\mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$ and an interval $(-\delta_2, \delta_2)$ with $\delta_1, \delta_2 > 0$ such that for all $f_1, f_2 \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$ and for all $\varepsilon \in (-\delta_2, \delta_2)$ we have

$$\big\| \big(G(\varepsilon, f_1) - g(f_1)\big) - \big(G(\varepsilon, f_2) - g(f_2)\big) \big\|_{\mathcal{H}} \leq \varepsilon^* \, \| f_1 - f_2 \|_{\mathcal{H}} \,, \tag{18}$$

where

$$\begin{aligned} g(f) \;=\; & 2\lambda f_{\mathrm{P},\lambda}(X) + \mathbb{E}_{\mathrm{P}} \nabla_2^B L\big(Y, f_{\mathrm{P},\lambda}(X)\big) \cdot \Phi(X) + 2\lambda \, \mathrm{id}_{\mathcal{H}}(f(X) - f_{\mathrm{P},\lambda}(X)) \\ & + \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L\big(Y, f_{\mathrm{P},\lambda}(X)\big) \cdot \langle (f(X) - f_{\mathrm{P},\lambda}(X)), \Phi(X) \rangle_{\mathcal{H}} \Phi(X) \,, \;\; f \in \mathcal{H}. \end{aligned}$$

Fix $\varepsilon^* > 0$. Obviously, (18) is valid for $f_1 = f_2$. For the rest of the proof we therefore fix arbitrary functions $f_1, f_2 \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$ with $f_1 \neq f_2$. We obtain for the term on the left hand side of (18) that

$$\begin{aligned} & \Big\| \Big(2\lambda f_1(X) + \mathbb{E}_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}} \nabla_2^B L(Y, f_1(X)) \cdot \Phi(X) \\ & \quad - 2\lambda f_{\mathrm{P},\lambda}(X) - \mathbb{E}_{\mathrm{P}} \nabla_2^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \Phi(X) \\ & \quad - 2\lambda (f_1(X) - f_{\mathrm{P},\lambda}(X)) - \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_{\mathrm{P},\lambda}(X)) \Phi(X) \Big) \\ & \quad - \Big(2\lambda f_2(X) + \mathbb{E}_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}} \nabla_2^B L(Y, f_2(X)) \cdot \Phi(X) \\ & \quad\quad - 2\lambda f_{\mathrm{P},\lambda}(X) - \mathbb{E}_{\mathrm{P}} \nabla_2^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot \Phi(X) \\ & \quad\quad - 2\lambda (f_2(X) - f_{\mathrm{P},\lambda}(X)) - \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_2(X) - f_{\mathrm{P},\lambda}(X)) \Phi(X) \Big) \Big\|_{\mathcal{H}} \\ = \;\; & \Big\| \mathbb{E}_{(1-\varepsilon)\mathrm{P}+\varepsilon\mathrm{Q}} \Big(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X)) \Big) \cdot \Phi(X) \\ & \quad - \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_2(X)) \Phi(X) \Big\|_{\mathcal{H}} \qquad (19) \\ \leq \;\; & |1-\varepsilon| \, \Big\| \mathbb{E}_{\mathrm{P}} \Big(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X)) \\ & \quad\quad - \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_2(X)) \Big) \Phi(X) \Big\|_{\mathcal{H}} \\ & + |\varepsilon| \, \Big\| \mathbb{E}_{\mathrm{Q}} \Big(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X)) \Big) \cdot \Phi(X) \Big\|_{\mathcal{H}} \\ & + |\varepsilon| \, \Big\| \mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_2(X)) \Phi(X) \Big\|_{\mathcal{H}} \\ =: \;\; & |1-\varepsilon| A + |\varepsilon| B + |\varepsilon| C \,. \qquad (20) \end{aligned}$$

We shall show that (20) is bounded from above by $\varepsilon^* \| f_1 - f_2 \|_{\mathcal{H}}$. When we look at the first partial B-derivatives of our loss functions, we see that we can separate them in 2 cases: for $L_{\underline{\varepsilon}}$ and $L_{\tau-pin}$ there are one or more discontinuities in $\nabla_2^B L$, whereas $\nabla_2^B L$ is continuous for $L_{c-Huber}$. Recall that the set $\mathfrak{D}$ of points where Lipschitz continuous functions are *not* Fréchet-differentiable, has Lebesgue measure zero by Rademacher's theorem (Rademacher, 1919). Define the function $h\big(y, f_1(x), f_2(x)\big) := \nabla_2^B L\big(y, f_1(x)\big) - \nabla_2^B L\big(y, f_2(x)\big)$. For $L \in \{L_{\underline{\varepsilon}}, L_{\tau-pin}\}$, denote the set of discontinuity points of $\nabla_2^B L$ by $\mathfrak{D}$. Take $f_1,\ f_2 \in \mathcal{N}_{\delta_1}(f_{\mathrm{P},\lambda})$. For $\nabla_2^B L(Y, f_{\mathrm{P},\lambda}(x)) \notin \mathfrak{D}$ we obtain $\nabla_2^B L(Y, f_1(x)) = \nabla_2^B L(Y, f_2(x))$ for sufficiently small δ_1 and hence $h(y, f_1(x), f_2(x)) = 0$. If, on the other hand, $\nabla_2^B L(Y, f_{\mathrm{P},\lambda}(x)) \in \mathfrak{D}$ and $f_1(x) < f_{\mathrm{P},\lambda}(x) < f_2(x)$ or $f_2(x) < f_{\mathrm{P},\lambda}(x) < f_1(x)$, then $\nabla_2^B L(Y, f_1(x)) \neq \nabla_2^B L(Y, f_2(x))$ and hence $h(y, f_1(x), f_2(x)) \neq 0$. Define $m = 2|\mathfrak{D}|$.

A.2.4 PINBALL LOSS

Using the first part of this proof we see that for the pinball loss $L = L_{\tau-pin}$ we obtain $|h(y, f_1(x), f_2(x))| \le c_1$, with $c_1 = 1$, $\mathfrak{D} = \{0\}$, $m = 2$, and $\nabla^B_{2,2} L(y,t) = 0$, for all $t \in \mathbb{R}$. For all $f \in \mathcal{N}_{\delta_1}(f_{P,\lambda})$ we get

$$|f(x) - f_{P,\lambda}(x)| \le \left\| f - f_{P,\lambda} \right\|_\infty \le \|k\|_\infty \left\| f - f_{P,\lambda} \right\|_{\mathcal{H}} \le \|k\|_\infty \delta_1 . \tag{21}$$

Further

$$|f_1(x) - f_2(x)| \le \|f_1 - f_2\|_\infty \le \|k\|_\infty \|f_1 - f_2\|_{\mathcal{H}} \le 2\|k\|_\infty \delta_1 . \tag{22}$$

Using (21), (22), and (11) we obtain

$$\begin{aligned}
A &= \left\| \mathbb{E}_P(\nabla^B_2 L(Y, f_1(X)) - \nabla^B_2 L(Y, f_2(X))) \cdot \Phi(X) \right\|_{\mathcal{H}} \\
&\le \mathbb{E}_P |h(Y, f_1(X), f_2(X))| \, |\Phi(X)| \\
&\le \|k\|^2_\infty \, \mathbb{E}_P |h(Y, f_1(X), f_2(X))| \mathbf{1}_{\{h \neq 0\}} \\
&\le \|k\|^2_\infty c_1 P\big(\nabla^B_2 L(Y, f_1(X)) \neq \nabla^B_2 L(Y, f_2(X))\big) \\
&= \|k\|^2_\infty \Big(P\big(\{Y - f_1(X) < 0\} \wedge \{Y - f_2(X) > 0\}\big) \\
&\qquad + P\big(\{Y - f_2(X) < 0\} \wedge \{Y - f_1(X) > 0\}\big) \Big) \\
&= \|k\|^2_\infty \int_X P\big(Y \in (f_2(x), f_1(x)) \,|x\big) + P\big(Y \in (f_1(x), f_2(x)) \,|x\big) dP_X(x) \\
&= \|k\|^2_\infty \int_X P\big(Y \in (f_2(x), f_2(x) + [f_1(x) - f_2(x)]) \,|x\big) \\
&\qquad + P\big(Y \in (f_1(x), f_1(x) + [f_2(x) - f_1(x)]) \,|x\big) dP_X(x) \\
&\le m \|k\|^2_\infty \int_X c_P |f_1(x) - f_2(x)|^{1+\xi_P} dP_X(x) \\
&\le m \|k\|^2_\infty c_P \|f_1 - f_2\|^{1+\xi_P}_\infty \\
&\le m c_P \|k\|^{3+\xi_P}_\infty \|f_1 - f_2\|^{1+\xi_P}_{\mathcal{H}} ,
\end{aligned}$$

where P_X denotes the marginal distribution of X. Similar calculations give that $B \le m c_Q \|k\|^{3+\xi_Q}_\infty \|f_1 - f_2\|^{1+\xi_Q}_{\mathcal{H}}$. We obtain $C = 0$, because $\nabla^B_{2,2} L(Y, f_{P,\lambda}(X)) = 0$. Hence, the term in (20) is less than or equal to

$$\begin{aligned}
& |1 - \varepsilon| m c_P \|k\|^{3+\xi_P}_\infty \|f_1 - f_2\|^{1+\xi_P}_{\mathcal{H}} + |\varepsilon| m c_Q \|k\|^{3+\xi_Q}_\infty \|f_1 - f_2\|^{1+\xi_Q}_{\mathcal{H}} \\
= \; & \big(|1 - \varepsilon| c_P \|k\|^{\xi_P}_\infty \|f_1 - f_2\|^{\xi_P}_{\mathcal{H}} + |\varepsilon| c_Q \|k\|^{\xi_Q}_\infty \|f_1 - f_2\|^{\xi_Q}_{\mathcal{H}} \big) m \|k\|^3_\infty \|f_1 - f_2\|_{\mathcal{H}} \\
\le \; & \varepsilon^* \|f_1 - f_2\|_{\mathcal{H}} ,
\end{aligned}$$

where $\varepsilon^* = (|1 - \varepsilon| c_P \|k\|^{\xi_P}_\infty 2^{\xi_P} \delta_1^{\xi_P} + |\varepsilon| c_Q \|k\|^{\xi_Q}_\infty 2^{\xi_Q} \delta_1^{\xi_Q}) m \|k\|^3_\infty$.

A.2.5 $\underline{\varepsilon}$-INSENSITIVE LOSS

The proof for the $\underline{\varepsilon}$-insensitive loss $L = L_{\underline{\varepsilon}}$ is analogous to the proof for $L_{\tau-pin}$, but with $c_1 = 2$, $\mathfrak{D} = \{-\underline{\varepsilon}, +\underline{\varepsilon}\}$, $m = 4$ and thus we must consider 4 cases instead of 2 where $h(y, f_1(x), f_2(x)) \neq 0$.

A.2.6 HUBER LOSS

For Huber's loss function $L = L_{c-Huber}$ we have $|\nabla^B_{2,2}L(y,t)| \leq 1 := c_2$ and $h(y, f_1(x), f_2(x))$ is bounded by $c_1 = 2c$. Let us define

$$\begin{aligned} h^*(y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) &:= \nabla^B_2 L(y, f_1(x)) - \nabla^B_2 L(y, f_2(x)) \\ &\quad -\nabla^B_{2,2} L(y, f_{\mathrm{P},\lambda}(x)) \cdot (f_1(x) - f_2(x)). \end{aligned}$$

Somewhat tedious calculations show that there are 8 cases where $h^*(y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) \neq 0$ and 6 cases where $h^*(y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) = 0$. In each of the 8 cases, $y - f_{\mathrm{P},\lambda}(x) \in \{-c, c\}$ and $|h^*(y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x))| \leq |f_1(x) - f_2(x)|$. Due to symmetry of the Huber loss function, the calculations are quite similar, therefore we only consider here some cases.

If $-c < Y - f_{\mathrm{P},\lambda}(x) < c$, then $\nabla^B_{2,2}L(Y, f_{\mathrm{P},\lambda}(x)) \cdot (f_1(x) - f_2(x)) = f_1(x) - f_2(x)$ and for sufficiently small δ_1, $\nabla^B_2 L(Y, f_1(x)) = -(Y - f_1(x))$ and $\nabla^B_2 L(Y, f_2(x)) = -(Y - f_2(x))$. A small calculation shows that $h^*(Y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) = 0$.

By straightforward calculations we also obtain that $h^*(Y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) = 0$ for the following 5 cases:

1. $Y - f_{\mathrm{P},\lambda}(x) < -c$ or $Y - f_{\mathrm{P},\lambda}(x) > c$,
2. $Y - f_{\mathrm{P},\lambda}(x) = -c$ and $f_{\mathrm{P},\lambda}(x) > f_2(x) > f_1(x)$,
3. $Y - f_{\mathrm{P},\lambda}(x) = -c$ and $f_1(x) > f_2(x) > f_{\mathrm{P},\lambda}(x)$,
4. $Y - f_{\mathrm{P},\lambda}(x) = c$ and $f_{\mathrm{P},\lambda}(x) > f_2(x) > f_1(x)$,
5. $Y - f_{\mathrm{P},\lambda}(x) = c$ and $f_1(x) > f_2(x) > f_{\mathrm{P},\lambda}(x)$.

If $Y - f_{\mathrm{P},\lambda}(x) = -c$ and $f_1(x) > f_{\mathrm{P},\lambda}(x) > f_2(x)$, we get $\nabla^B_2 L(Y, f_1(X)) = c$, $\nabla^B_2 L(Y, f_2(x)) = -(Y - f_2(x))$ and $\nabla^B_{2,2}L(Y, f_{\mathrm{P},\lambda}(x)) \cdot (f_1(x) - f_2(x)) = 0$. Hence,

$$h^*(Y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) = c + Y - f_2(x) = f_{\mathrm{P},\lambda}(x) - f_2(x) \neq 0,$$

since $f_2(x) < f_{\mathrm{P},\lambda}(x)$.

Analogously, some calculations show that $h^*(Y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x)) \neq 0$ for the following 7 cases:

1. $Y - f_{\mathrm{P},\lambda}(x) = -c$ and $f_2(x) > f_{\mathrm{P},\lambda}(x) > f_1(x)$,
2. $Y - f_{\mathrm{P},\lambda}(x) = -c$ and $f_{\mathrm{P},\lambda}(x) > f_1(x) > f_2(x)$,
3. $Y - f_{\mathrm{P},\lambda}(x) = -c$ and $f_2(x) > f_1(x) > f_{\mathrm{P},\lambda}(x)$,
4. $Y - f_{\mathrm{P},\lambda}(x) = c$ and $f_1(x) > f_{\mathrm{P},\lambda}(x) > f_2(x)$,
5. $Y - f_{\mathrm{P},\lambda}(x) = c$ and $f_2(x) > f_{\mathrm{P},\lambda}(x) > f_1(x)$,
6. $Y - f_{\mathrm{P},\lambda}(x) = c$ and $f_{\mathrm{P},\lambda}(x) > f_1(x) > f_2(x)$,
7. $Y - f_{\mathrm{P},\lambda}(x) = c$ and $f_2(x) > f_1(x) > f_{\mathrm{P},\lambda}(x)$.

Using (12) in (20) we get for the term A in (20) that

$$\begin{aligned} A &= \left\|\mathbb{E}_{\mathrm{P}} h^*(Y, f_{\mathrm{P},\lambda}(X), f_1(X), f_2(X))\Phi(X)\right\|_{\mathcal{H}} \\ &\leq \|k\|_\infty^2 \int |h^*(y, f_{\mathrm{P},\lambda}(x), f_1(x), f_2(x))| \mathbf{1}_{\{h^*\neq 0\}} d\mathrm{P}(x,y) \\ &\leq \|k\|_\infty^2 \int |f_1(x) - f_2(x)| \mathrm{P}\big(Y \in \{-c + f_{\mathrm{P},\lambda}(x), c + f_{\mathrm{P},\lambda}(x)\} \big| x\big) d\mathrm{P}_X(x) = 0. \end{aligned}$$

Also $C = \left\|\mathbb{E}_{\mathrm{P}} \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_2(X))\Phi(X)\right\|_{\mathcal{H}} \leq \kappa_2 \|k\|_\infty^3 \|f_1 - f_2\|_{\mathcal{H}}$. One can compute the analogous terms to A and C, say $A(\mathrm{Q})$ and $C(\mathrm{Q})$, respectively, where the integration is with respect to Q instead of P. Combining these expressions we obtain

$$\begin{aligned} B &= \left\|\mathbb{E}_{\mathrm{Q}}(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X))) \cdot \Phi(X)\right\|_{\mathcal{H}} \\ &\leq \mathbb{E}_{\mathrm{Q}} \big|\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X)) - \\ &\qquad \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_2(X))\big| |\Phi(X)| \\ &\quad + \mathbb{E}_{\mathrm{Q}} \big|\nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}(X)) \cdot (f_1(X) - f_2(X))\big| |\Phi(X)| \\ &= A(\mathrm{Q}) + C(\mathrm{Q}) \leq \kappa_2 \|k\|_\infty^3 \|f_1 - f_2\|_{\mathcal{H}}. \end{aligned}$$

Hence, the term in (20) is less than or equal to $\varepsilon^* \|f_1 - f_2\|_{\mathcal{H}}$ where $\varepsilon^* = 2|\varepsilon|\kappa_2 \|k\|_\infty^3$. This gives the assertion, because $|\varepsilon|$ can be chosen arbitrarily small. ■

Proof of Corollary 6. Both partial F-derivatives $\nabla_2^F L_{log}(y,t) = 1 - 2\Lambda(y-t)$ and $\nabla_{2,2}^F L_{log}(y,t) = 2\Lambda(y-t)[1-\Lambda(y-t)]$ are clearly bounded, because $\Lambda(z) \in (0,1)$, $z \in \mathbb{R}$. We only have to show that $\nabla_2^B G(0, f_{\mathrm{P},\lambda})$ is strong for $L = L_{log}$, that is that the term in (19) is bounded by $\varepsilon^* \|f_1 - f_2\|_{\mathcal{H}}$ for arbitrary chosen $\varepsilon^* > 0$. A Taylor expansion gives for arbitrary $y, t_1, t_2 \in \mathbb{R}$ that

$$\Lambda(y - t_2) = \Lambda(y - t_1) + (t_1 - t_2)\Lambda(y - t_1)\big(1 - \Lambda(y - t_1)\big) + O((t_1 - t_2)^2). \tag{23}$$

Combining (2), (21), (22), and (23) we obtain

$$\begin{aligned} &\big|\mathbb{E}_{\mathrm{P}}\big(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X)) - \nabla_{2,2}^B L(Y, f_{\mathrm{P},\lambda}) \cdot (f_1(X) - f_2(X))\big)\Phi(X)\big| \\ \leq\ & 2\|k\|_\infty^2 \mathbb{E}_{\mathrm{P}} \big|\Lambda(Y - f_2(X)) - \Lambda(Y - f_1(X)) \\ &\qquad -\Lambda(Y - f_{\mathrm{P},\lambda}(X))(1 - \Lambda(Y - f_{\mathrm{P},\lambda}(X))\big(f_1(X) - f_2(X)\big)\big| \\ \leq\ & 2\|k\|_\infty^2 \mathbb{E}_{\mathrm{P}} \big|\big(f_1(X) - f_2(X)\big)\big[\Lambda(Y - f_1(X))(1 - \Lambda(Y - f_1(X))) \\ &\qquad -\Lambda(Y - f_{\mathrm{P},\lambda}(X))(1 - \Lambda(Y - f_{\mathrm{P},\lambda}(X)))\big] + O((f_1(X) - f_2(X))^2)\big| \\ \leq\ & 2\|k\|_\infty^2 \mathbb{E}_{\mathrm{P}} \big(\|f_1 - f_2\|_\infty \big|\Lambda(Y - f_1(X))(1 - \Lambda(Y - f_1(X))) \\ &\qquad -\Lambda(Y - f_{\mathrm{P},\lambda}(X))(1 - \Lambda(Y - f_{\mathrm{P},\lambda}(X)))\big| + c_3 \|f_1 - f_2\|_\infty^2\big). \end{aligned} \tag{24}$$

A Taylor expansion around $f_{\mathrm{P},\lambda}(x)$ shows that $\Lambda(y - f_1(x))(1 - \Lambda(y - f_1(x)))$ equals

$$\begin{aligned} &\Lambda(y - f_{\mathrm{P},\lambda}(x))(1 - \Lambda(y - f_{\mathrm{P},\lambda}(x))) \\ +\ &\big(f_{\mathrm{P},\lambda}(x) - f_1(x)\big)\Lambda(y - f_{\mathrm{P},\lambda}(x))(1 - \Lambda(y - f_{\mathrm{P},\lambda}(x)))(1 - 2\Lambda(y - f_{\mathrm{P},\lambda}(x))) \\ +\ &O((f_1(x) - f_{\mathrm{P},\lambda}(x))^2). \end{aligned}$$

Using this expansion and (2), (21), and (22) it follows that the term in (24) is bounded by

$$\begin{aligned} & 2\|k\|_\infty^2 \mathbb{E}_P\big(\|f_1 - f_2\|_\infty \big(\big\|f_1 - f_{P,\lambda}\big\|_\infty/4 + c_4\delta_1^2\|k\|_\infty^2\big) + c_3\|f_1 - f_2\|_\infty^2\big) \\ \leq \quad & \|k\|_\infty^4\big(\delta_1/2 + 2c_4\delta_1^2\|k\|_\infty + 4c_3\delta_1\big)\|f_1 - f_2\|_{\mathcal{H}}\,. \end{aligned} \tag{25}$$

Using the Lipschitz continuity of $\nabla_2^B L(y,\cdot)$, (2), and (23) we obtain

$$\begin{aligned} & |\varepsilon|\,\mathbb{E}_{Q-P}\big|\big(\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X))\big)\cdot\Phi(X)\big| \\ \leq \quad & |\varepsilon|\,\|k\|_\infty^2\,\mathbb{E}_{|Q-P|}\big|\nabla_2^B L(Y, f_1(X)) - \nabla_2^B L(Y, f_2(X))\big| \\ \leq \quad & |\varepsilon|\,\|k\|_\infty^3\,\|f_1 - f_2\|_{\mathcal{H}}\,. \end{aligned} \tag{26}$$

Combining (25) and (26) shows that the term in (19) is bounded by $\varepsilon^*\|f_1 - f_2\|_{\mathcal{H}}$ with the positive constant $\varepsilon^* = \|k\|_\infty^3\big(\delta_1\|k\|_\infty/2 + 2c_4\delta_1^2\|k\|_\infty^2 + 4c_3\delta_1\|k\|_\infty + |\varepsilon|\big)$, where $\delta_1 > 0$ and $\varepsilon > 0$ can be chosen as small as necessary. ■

Abstract

Many complex control problems require sophisticated solutions that are not amenable to traditional controller design. Not only is it difficult to model real world systems, but often it is unclear what kind of behavior is required to solve the task. Reinforcement learning (RL) approaches have made progress by using direct interaction with the task environment, but have so far not scaled well to large state spaces and environments that are not fully observable. In recent years, neuroevolution, the artificial evolution of neural networks, has had remarkable success in tasks that exhibit these two properties. In this paper, we compare a neuroevolution method called Cooperative Synapse Neuroevolution (CoSyNE), that uses cooperative coevolution at the level of individual synaptic weights, to a broad range of reinforcement learning algorithms on very difficult versions of the pole balancing problem that involve large (continuous) state spaces and hidden state. CoSyNE is shown to be significantly more efficient and powerful than the other methods on these tasks.

Keywords: coevolution, recurrent neural networks, non-linear control, genetic algorithms, experimental comparison

1. Introduction

In many decision making processes such as manufacturing, aircraft control, and robotics researchers are faced with the problem of controlling systems that are highly complex and unstable. A controller or *agent* must be built that observes the state of the system, or *environment*, and outputs a control signal that affects future states of the environment in some desirable way.

The problem with designing or programming such controllers by direct engineering methods is twofold: (1) The environment is often non-linear and noisy so that it is impossible to obtain the kind of accurate and tractable mathematical model required by these methods. (2) The task is complex enough that there is very little *a priori* knowledge of what constitutes a reasonable, much less optimal, control strategy.

These two problems have compelled researchers to explore methods based on Dynamic Programming, for example Reinforcement Learning (RL; Sutton and Barto, 1998). Instead of trying to pre-program a response to every likely situation, an agent *learns* the utility of being in each state

∗. Also at Technische Universität München Boltzmannstr. 3, 85748 Garching, München, Germany.

(i.e., a value-function) from a reward signal it receives while interacting directly with the environment. In principle, RL methods can solve these problems: they do not require a mathematical model (i.e., the state transition probabilities) of the environment and can solve many problems where examples of correct behavior are not available. However, in practice, they have not scaled well to large state spaces or tasks where the state of the environment is not fully observable to the agent. This is a serious problem because the real world is continuous (i.e., there are an infinite number of states) and artificial agents, like natural organisms, are necessarily constrained in their ability to fully perceive their environment.

More recently, methods for evolving artificial neural networks or *neuroevolution* have shown promising results on continuous, partially observable tasks (Gomez, 2003; Nolfi and Parisi, 1995; Yamauchi and Beer, 1994). Our previous method, Enforced SubPopulations, is a particularly effective neuroevolution algorithm that has been a applied successfully to many domains (Perez-Bergquist, 2001; Lubberts and Miikkulainen, 2001; Greer et al., 2002; Whiteson et al., 2003; Bryant and Miikkulainen, 2003; Gomez et al., 2001; Grasemann and Miikkulainen, 2005), including the real world reinforcement learning task of finless rocket control (Gomez and Miikkulainen, 2003). The goal of this paper is to present a new algorithm that builds on ESP called Cooperative Synapse Neuroevolution (CoSyNE), and compare it to a wide range of other learning systems in a setting that is both challenging and practical. To this end, we have chosen a set of pole balancing tasks ranging from the trivial to versions that are extremely difficult for some of todays most advanced methods.

The paper is organized as follows: in Section 2, we discuss the general neuroevolution paradigm. In Section 3, the underlying approach used by CoSyNE, cooperative coevolution is described. In Section 4, the CoSyNE algorithm is presented. Section 5 presents our experiments comparing CoSyNE with value function, policy search, and other evolutionary methods. Sections 6 and 7 provide some discussion of our overall results, and conclusions.

2. Neuroevolution

The basic idea of Neuroevolution (NE; Yao, 1999) is to search the space of neural network policies directly using a genetic algorithm. In contrast to *ontogenetic* learning involving a single agent that learns incrementally (i.e., value-based RL), NE uses a population of solutions. The individual solutions are not modified during evaluation; instead, adaptation arises through repeatedly recombining the population's most fit individuals in a kind of collective or *phylogenetic* learning. The population gradually improves as a whole until a sufficiently fit individual is found.

In NE, neural network specifications are encoded in string representations or *chromosomes* (see Figure 1). A chromosome can encode any relevant network parameter including synaptic weight values, number of processing units, connectivity (topology), learning rate, etc. These network *genotypes* are then evolved in a sequence of generations. Each generation each genotype is mapped to its network phenotype (i.e., the actual network), and then evaluated in the problem environment and awarded a fitness score that quantifies its performance in some desirable way. After this evaluation phase, genotypes are selected from the population according to fitness through a variety of possible schemes (e.g., fitness proportional, linear ranking, tournament selection, etc.), and then mated through crossover and possibly mutated to form new genotypes that usually replace the least fit members of the population. This cycle repeats until a sufficiently fit network is found, or some other stopping criteria is met.

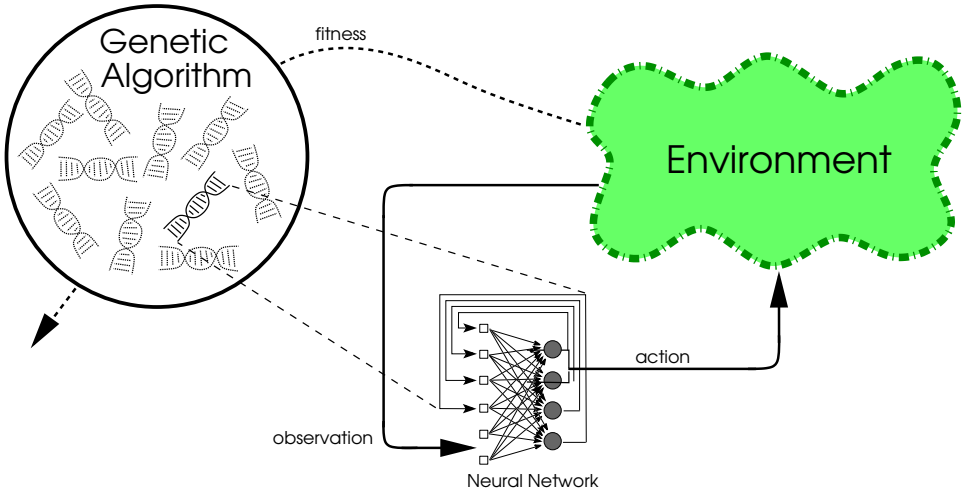

Figure 1: **Neuroevolution.** Each chromosome is transformed into a neural network phenotype and evaluated on the task. The agent receives input from the environment (observation) and propagates it through its neural network to compute an output signal (action) that affects the environment. At the end of the evaluation, the network is assigned a fitness according to its performance. The networks that perform well on the task are mated to generate new networks.

NE approaches differ primarily in how they encode neural network specifications into genetic strings. Direct encoding schemes represent the parameters explicitly on the chromosome as binary or real numbers that are mapped directly to the phenotype (Belew et al., 1991; Jefferson et al., 1991; Moriarty, 1997; Gomez, 2003; Stanley and Miikkulainen, 2002). Indirect encodings operate at a higher level of abstraction. Some simply provide a coarse description such as delineating a neuron's receptive field (Mandischer, 1993) or connective density (Harp et al., 1989), while others are more algorithmic, providing growth rules in the form of graph generating grammars (Kitano, 1990; Voigt et al., 1993; Gruau et al., 1996b). These schemes have the advantage that very large networks can be represented without requiring large chromosomes. Our CoSyNE method is a direct encoding method that does not evolve topology.

By searching the space of policies directly, NE can be applied to reinforcement learning problems without using a value function—neural network controllers map observations from the environment directly to actions. This mapping is potentially powerful: neural networks are universal function approximators that can generalize and tolerate noise. Networks with feedback connections (i.e., recurrent networks) can maintain internal state extracted from a history of inputs, allowing them to solve partially observable tasks. By evolving these networks instead of training them, NE avoids the problem of vanishing error gradients that affect recurrent network learning algorithms (Hochreiter et al., 2001). For NE to work, the environment need not satisfy any particular constraints—it can be continuous and partially observable. All that concerns a NE system is that the network representations be large enough to solve the task and that there is an effective way to evaluate the relative quality of candidate solutions.

Algorithm 1: Cooperative Coevolution (n, m)

```
1  Initialize {P_1, ..., P_n}
2  repeat
3      repeat
4          for j = 1 to n do     // construct complete solution
5              x_ij = Select(P_j)
6              x ⇐ x_ij          // add subgenotype to complete solution
7          end
8          Evaluate(x)
9      until enough solutions evaluated
10     for i = 1 to n do         // each subpopulation reproduces independently
11         Recombine(P_i)
12     end
13 until solution is found
```

3. Cooperative Coevolution

In natural ecosystems, organisms of one species compete and/or cooperate with many other different species in their struggle for resources and survival. The fitness of each individual changes over time because it is coupled to that of other individuals inhabiting the environment. As species evolve they specialize and co-adapt their survival strategies to those of other species. This phenomenon of *coevolution* has been used to encourage complex behaviors in GAs.

Most coevolutionary problem solving systems have concentrated on competition between species (Darwen, 1996; Pollack et al., 1996; Paredis, 1994; Miller and Cliff, 1994; Rosin, 1997). These methods rely on establishing an "arms race" where each species produces stronger and stronger strategies for the others to defeat. This is a natural approach for problems such as game-playing where often an optimal opponent is not available.

A very different kind of coevolutionary model emphasizes cooperation. Cooperative coevolution is motivated, in part, by the recognition that the complexity of difficult problems can be reduced through modularization (e.g., the human brain; Grady, 1993). In cooperative coevolutionary algorithms the species represent solution components. Each individual forms a part of a complete solution but need not represent anything meaningful on its own. The components are evolved by measuring their contribution to complete solutions and recombining those that are most beneficial to solving the task.

Algorithm 1 outlines the basic operation of a generic cooperative coevolutionary algorithm. The first parameter n specifies the number of species (components) that will be coevolved. Each species has its own subpopulation $P_i, i = 1..n$, containing m *subgenotypes*, $x_{ij} \in P_i, j = 1..m$ which are initialized with random values (line 1). Assuming complete solutions of fixed size, n determines the granularity at which the coevolutionary search is conducted.

Next, some number of complete solutions are constructed and evaluated (lines 3-9). A complete solution $\mathbf{x}$ is formed by combining one subgenotype, selected according to some policy, from each of the subpopulations. Usually, the string representations of each subgenotype are simply concatenated in a predefined order to form a single chromosome. Each $\mathbf{x}$ is evaluated in the problem environment and a fitness score is assigned to each constituent subgenotype. Since the number of evaluations per

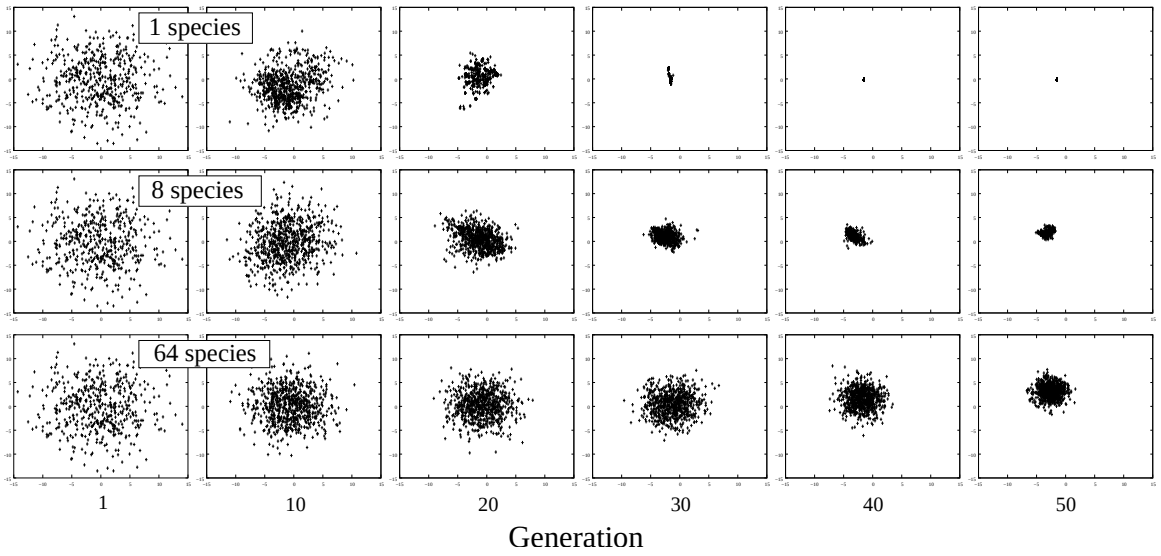

Figure 2: **Convergence speed for varying numbers of species.** Each row shows a PCA projection of 128-dimensional chromosomes at different generations during an evolutionary run optimizing a very simple multi-modal test function. All three runs start with the same set of complete solution (see first column). In row 1, the solutions are not coevolved because each genotype is a complete solution. In row 2, 8 species are coevolved (i.e., have to be combined to form a the complete solutions shown in the plots), and in row 3, 64 species are coevolved. The more species there are to cooperate, the longer it takes for the evolution to converge.

generation can exceed m, subgenotypes can participate in more that one evaluation per generation. Therefore, the fitness score of each x_{ij} at the end of a generation is some function of the raw fitness scores accumulated over multiple evaluations, and is considered a *subjective measure* because it is coupled with that of its *collaborators*, in contrast to an objective measure that only depends on the individual itself (Wiegand, 2003). The exact number of evaluations per subgenotype depends on the collaboration scheme employed by a particular algorithm. One common approach, for example, is simply to evaluate each subgenotype in n trials, and then take the average or best fitness.

Once enough evaluations have been performed, each subpopulation is recombined to form new subgenotypes, as in a normal GA.

Early work in this area was done by Holland and Reitman (1978) in Classifier Systems. A population of rules was evolved by assigning a fitness to each rule based on how well it interacted with other rules. This approach has been used in learning neural network classifiers, in coevolution of cascade correlation networks, and in coevolution of radial basis functions (Eriksson and Olsson, 1997; Horn et al., 1994; Paredis, 1995; Whitehead and Choate, 1995). More recently, Husbands and Mill (1991) and Potter and De Jong (1995) developed a method called Cooperative Coevolutionary GA (CCGA) in which each of the species is evolved independently in its own population. As in Classifier Systems, individuals in CCGA are rewarded for making favorable contributions to complete solutions, but members of different populations (species) are not allowed to mate. A

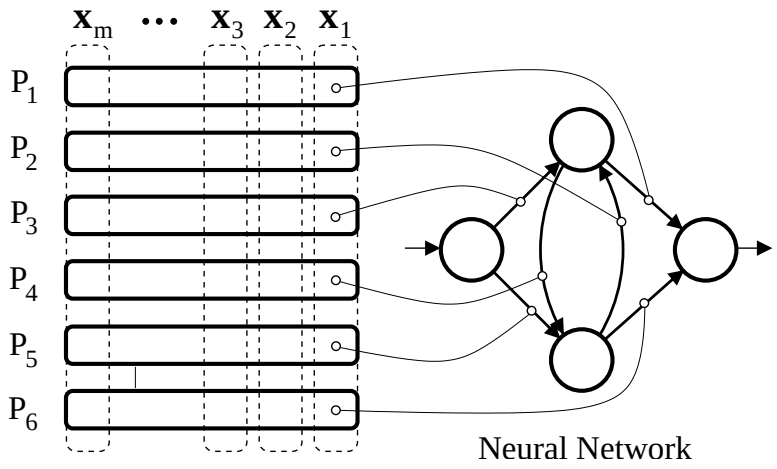

Figure 3: **The CoSyNE method for neuroevolution.** On the left, the figure shows and example population consisting of six subpopulations, $P_1..P_6$, each containing m weight values. To create a network, first the weights at a given index in each subpopulation are collected into a chromosome $\mathbf{x}$, then the weights are mapped to their corresponding synapses in a predefined network architecture with six connections, shown at right.

particularly powerful idea is to combine cooperative coevolution with neuroevolution so that the benefits of evolving neural networks can be enhanced further through improved search efficiency.

Much of the motivation for using the cooperative coevolutionary approach is based on the intuition that many problems may be decomposable into weakly coupled low-dimensional subspaces that can be searched semi-independently by separate species (Wiegand et al., 2001; Jansen and Wiegand, 2003, 2004; Panait et al., 2006). Our experience shows that there may be another, complementary, explanation as to why cooperative coevolution in many cases outperforms single-population algorithms. Figure 2 compares the convergence behavior of the same initial population of complete solutions using different number of species: 1, 8, and 64. Each point represents a 128-dimensional chromosome projected onto 2-D using Principal Component Analysis. The chromosomes are coevolved to optimize a continuous multi-modal test function[1] with 128 randomly distributed maxima that represent valid solutions. As the number of species increases, the selection of subgenotypes for reproduction becomes less greedy, causing the search points that are evaluated each generation to converge more slowly, providing more paths toward better solutions (not shown). In a normal evolutionary algorithm, a subgenotype suffers the fate of the complete solution to which it is attached. If the complete solution performs with high fitness, the subgenotype is retained in the population, even if it is not ultimately beneficial to the search; if it is less fit then this potentially useful component (if combined with other subgenotypes in the population) is lost. This diversity sustaining mechanism is exploited fully in the CoSyNE algorithm, introduced next.

9          Sort(P_i)
10         for k = 1 to l do     // replace least fit weights with
11             x_i,m−k ⇐ o_ik     // weights from offspring nets
12         end
13         for j = 1 to m do
14             prob(x_ij) ⇐ F(P, i, j)     // assign probability to each weight
15             if rand() < prob(x_ij) then
16                 mark(x_ij)     // mark weight for permutation probabilistically
17             end
18         end
19         PermuteMarked(P_i)     // see Figure 4
20     end
21 until solution is found
```

4. Cooperative Synapse Neuroevolution (CoSyNE)

Previous Cooperative Coevolution NE methods decomposed networks at the neuron level (Moriarty, 1997; Potter and De Jong, 1995; Gomez, 2003). This is a natural approach dictated by phenotypic structure: networks consist of multiple processing units that function in parallel. In contrast, CoSyNE evolves at the lowest possible level of granularity, the level of the individual synaptic weight. For each network connection, there is a separate subpopulation consisting of real valued weights. Like neuron-level methods such as ESP, networks are constructed by selecting one member from each subpopulation and plugging them into a predefined network topology.

Algorithm 2 describes the CoSyNE algorithm in pseudocode. First (line 1), a population $\mathcal{P}$ consisting of n subpopulations $P_i, i = 1..n$, is created, where n is the number of synaptic weights in the networks to be evolved, determined by a user-specified network architecture Ψ. Each subpopulation is initialized to contain m real numbers, $x_{ij} = \mathcal{P}_{ij} \in P_i, j = 1..m$, chosen from a uniform probability distribution in the interval $[-\alpha, \alpha]$. The population is thereby represented by an $n \times m$ matrix.

CoSyNE then loops through a sequence of *generations* until a sufficiently good network is found (lines 2-21). Each generation starts by constructing a complete network chromosome $\mathbf{x}_j = (x_{1j}, x_{2j}, \ldots, x_{nj})$ from each row in $\mathcal{P}$. The m resulting chromosomes are transformed into networks by assigning their weights to their corresponding synapses, in Ψ (line 4; see Figure 3).

After all of the networks have been evaluated (line 5) and assigned a fitness, the top quarter with the highest fitness (i.e., the parents) are recombined (line 7) using crossover and mutation. Recombination produces a pool of offspring O consisting of l new network chromosomes $\mathbf{o}_k$, where

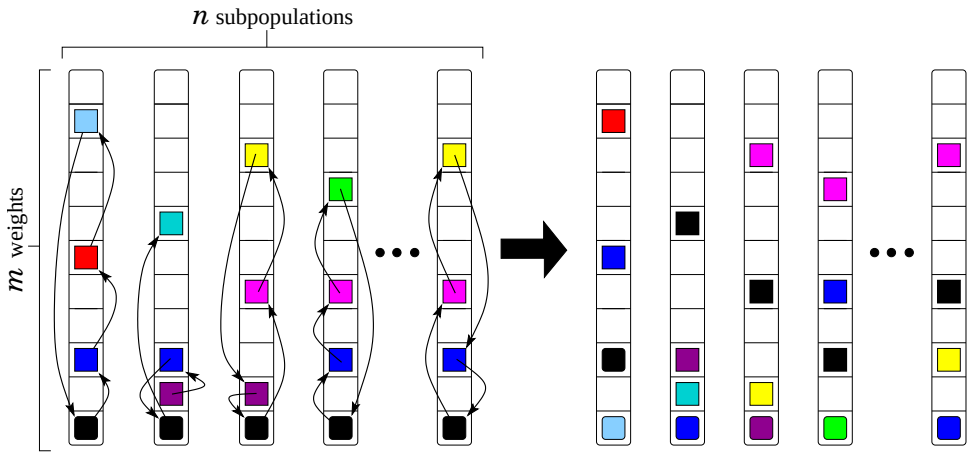

Figure 4: **Probabilistic permutations.** On the left is the set of subpopulations before permutation. The colored boxes are denote those genotypes that have been marked for permutation based on Equation 1. As the individuals are sorted by fitness within each subpopulation, notice that the less fit individuals have a higher probability of being permuted. On the right, the marked individuals have been permuted among themselves with each subpopulation. All unmarked genotypes remain part of the same complete solution.

$o_{ik} = O_{ik} \in O_i, i = 1..n, k = 1..l$, and O_i is the offspring subpopulation corresponding to P_i. The subpopulations are then sorted by fitness (line 9), and the weights from the new networks are added to $\mathcal{P}$ by replacing the least fit weights in their corresponding subpopulation (i.e., the P with the same index i; lines 10-11).

At this point the algorithm functions as a conventional neuroevolution system that evolves complete network chromosomes. In order to *coevolve* the synaptic weights, the subpopulations are permuted so that each weight forms part of a potentially different network in the next generation. Permutation is performed probabilistically. First, weights are marked randomly according to probabilities assigned by a user-defined function $F()$ (lines 14-17). Then the marked weights are permuted amongst themselves (see Figure 4). The function $F()$ can be anything from as simple as $\text{prob}(x_{ij}) = 1.0, \forall i, j$, in which case all weights are permuted, or more sophisticated:

$$\text{prob}(x_{ij}) = 1 - \sqrt[n]{\frac{f(x_{ij}) - f_i^{min}}{f_i^{max} - f_i^{min}}} \tag{1}$$

where $f(x_{ij})$ is the fitness of subgenotype (weight) x_{ij}, and f_j^{min} and f_j^{max} are, respectively, the fitness of the least and most fit individuals in subpopulation i. In this case, the probability of disrupting the network $\mathbf{x}_j$ is inversely proportional to its relative fitness, so that weight combinations that receive high fitness are more likely to be preserved, while those with low fitness are more likely to be disrupted and their constituents used to search for new complete solutions. In the experiments below, the simpler function that permutes all weights, except for the newly inserted offspring weights, was found to work well.

The basic CoSyNE framework does not specify how the weights are grouped in the complete solution chromosomes (i.e., which entry in the chromosome corresponds to which synapse) or which

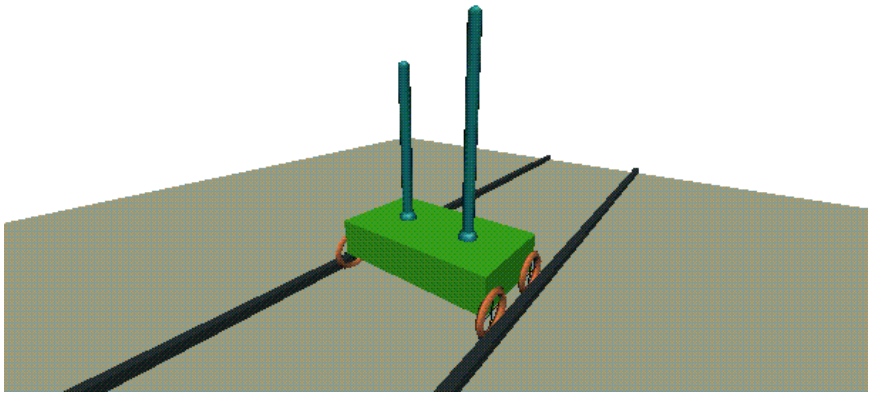

Figure 5: **The double pole balancing system.** Both poles must be balanced simultaneously by applying a continuous force to the cart. The system becomes more difficult to control as the poles assume similar lengths and if the velocities are not provided to the controller. The figure is a snapshot of a 3D real-time simulation.

genetic operators are used. In the implementation used in this paper, the weights of each neuron are grouped together (i.e., form a substring) and are separated into adjacent input, output, and recurrent weight segments, and the neuron substrings are concatenated together in a fixed order. For the genetic operators, we use multi-point crossover where 1-point crossover is applied to each neuron segment of the chromosome to generate two offspring, and mutation where each weight in $\mathcal{P}$ has a probability of being perturbed by Cauchy distributed noise with zero mean $\alpha = 0.3$.

5. Experiments

We compared CoSyNE to a broad range of learning algorithms on a sequence of increasingly difficult versions of the pole balancing task. This scheme allows us to compare methods at different levels of task complexity, exposing the strengths and limitations of each method with respect to specific challenges introduced by each succeeding task.

5.1 The Pole Balancing Problem

The basic pole balancing or inverted pendulum system consists of a pole hinged to a wheeled cart on a finite stretch of track. The objective is to apply a force to the cart at regular intervals such that the pole is balanced indefinitely and the cart stays within the track boundaries. This task has been a popular artificial learning testbed for over 30 years (Michie and Chambers, 1968; Anderson, 1989; Jang, 1992; Lin and Mitchell, 1992; Whitley et al., 1993) because it requires solving the temporal credit assignment problem, and is a good surrogate for a more general class of unstable control problems such as bipedal robot walking, and rocket guidance.

This long history notwithstanding, it turns out that the basic pole balancing problem can be solved easily by random search. To make it challenging for artificial learners, a variety of extensions to the basic pole-balancing task have been suggested. (Wieland, 1991) presented several variations that can be grouped into two categories: (1) modifications to the mechanical system itself, such as

adding a second pole either next to or on top of the other, and (2) restricting the amount of state information that is given to the controller; for example, only providing the cart position and the pole angle. The first category makes the task more difficult by introducing non-linear interactions between the poles. The second makes the task non-Markov, requiring the controller to employ short term memory to disambiguate underlying process states. Together, these extensions represent a family of tasks that can effectively test algorithms designed to learn control policies.

The sequence of comparisons presented below begins with a single pole version and then moves on to progressively more challenging variations culminating in a version where two separate poles of different length must be balanced simultaneously without the benefit of velocity information (see Appendix A for the equations of motion).

5.2 Other Methods

CoSyNE was compared to eight *ontogenetic* methods and seven *phylogenetic* methods in the pole balancing domain:

5.2.1 ONTOGENETIC METHODS

Random Weight Guessing (RWG) where the network weights are chosen at random (i.i.d.) from a uniform distribution. This approach is used to give an idea of how difficult each task is to solve by simply guessing a good set of weights.

Policy Gradient RL (PGRL; Sutton et al., 2000) where sampled Q-values are used to differentiate the performance of a given policy with respect to its parameters. The policy was implemented using a feed-forward neural network with one hidden layer.

Recurrent Policy Gradients (RPG; Wierstra et al., 2007) where a stochastic policy is represented by a Long Short-Term Memory network (LSTM; Hochreiter and Schmidhuber, 1997) trained with BackPropagation Through Time (Werbos, 1990). The gradient of the expected future reward over all possible state trajectories with respect to the policy parameters is calculated by Monte Carlo approximation. To reduce variance in the approximation, a *baseline* representing the expected average reward is used.

Value and Policy Search (VAPS; Meuleau et al., 1999) extends the work of Baird and Moore (1999) to policies that can make use of memory. The algorithm uses stochastic gradient descent to search the space of finite policy graph parameters. A policy graph is a state automaton that consists of nodes labeled with actions that are connected by arcs labeled with observations. When the system is in a particular node, the action associated with that node is taken and the underlying Markov environment transitions to the next observation that determines which arc is followed to the next action node.

Q-learning with MLP (Q-MLP): This method is the basic Q-learning algorithm (Watkins and Dayan, 1992) that uses a Multi-Layer Perceptron (i.e., a feed-forward artificial neural network) to map state-action pairs to values $Q(s,a)$. The input layer of the network has one unit per state variable and one unit per action variable. The output layer consists of a single unit indicating the Q-value. Values are learned through gradient descent on the prediction error using the backpropagation algorithm. This kind of approach has been studied widely with

success in tasks such as pole-balancing (Lin and Mitchell, 1992), pursuit-evasion games (Lin, 1992), and backgammon (Tesauro, 1992).

Sarsa(λ) with Case-Based function approximator (SARSA-CABA; Santamaria et al., 1998): This method consists of the Sarsa on-policy Temporal Difference control algorithm with eligibility traces that uses a case-based memory to approximate the *Q*-function. The memory explicitly records state-action pairs (i.e., cases) that have been experienced by the controller. The value of a new state-action pair not in the memory is calculated by combining the values of the *k*-nearest neighbors. A new case is added to the memory whenever the current query point is further than a specified *density threshold*, t_d away from all cases already in the memory. The case-based memory provides a locally-linear model of the Q-function that concentrates its resources on the regions of the state space that are most relevant to the task and expands its coverage dynamically according to t_d.

Sarsa(λ) with CMAC function approximator (SARSA-CMAC; Santamaria et al., 1998): This is the same as SARSA-CABA except that it uses a Cerebellar Model Articulation Controller (CMAC; Albus, 1975; Sutton, 1996) instead of a case-based memory to represent the Q-function. The CMAC partitions the state-action space with a set of overlapping tilings. Each tiling divides the space into a set of discrete *features* which maintain a value. When a query is made for a particular state-action pair, its *Q*-value is returned as the sum of the value in each tiling corresponding to the feature containing the query point. SARSA-CABA and SARSA-CMAC have both been applied to the pendulum swing-up task and the double-integrator task.

Adaptive Heuristic Critic (AHC; Anderson, 1987): uses a learning agent composed of two components: an *actor* (policy) and a *critic* (value-function), both of which are implemented using a feed-forward neural network trained with a variant of backpropagation.

The three value-function based methods (SARSA-CABA, SARSA-CMAC, and Q-MLP) each use a different kind of function approximator to represent a *Q*-function that can generalize across the continuous space of state-action pairs. Although these approximators can compute a value for any state-action pair, they do not implement true continuous control since the policy is not explicitly stored. Instead, continuous control is approximated by discretizing the action space at a resolution that is adequate for the problem. In order to select the optimal action *a* for a given state *s*, a *one-step* search in the action space is performed. The control agent selects actions according to an ε-*greedy* policy: with probability $1-\varepsilon$, $0 \leq \varepsilon < 1$, the action with the highest value is selected, and with probability ε, the action is random. This policy allows some exploration so that information can be gathered for all actions. In all simulations the controller was tested every 20 trials with ε=0 and learning turned off to determine whether a solution had been found.

5.2.2 PHYLOGENETIC METHODS

Symbiotic, Adaptive Neuro-Evolution (SANE; Moriarty, 1997) is a cooperative coevolutionary method that evolves two different populations simultaneously: a population of neurons and a population of *network blueprints* that specify how the neurons are combined to form complete networks. Each generation of networks is formed both using the blueprints and at random. Neurons that combine to form good networks receive high fitness, and are recombined in a

single population. Blueprints that result in favorable neuron combinations are also recombined to search for even better combinations.

Conventional Neuroevolution (CNE) is our implementation of single-population Neuroevolution similar to the algorithm used in Wieland (1991). In this approach, each chromosome in the population represents a complete neural network. CNE differs from Wieland's algorithm in that (1) the network weights are encoded with real instead of binary numbers, (2) it uses rank selection, and (3) it uses burst mutation. CNE is like ESP except that it evolves at the network level instead of the neuron level, and therefore provides a way to isolate the performance advantage of cooperative coevolution (ESP) over a single population approach (CNE).

Evolutionary Programming (EP; Saravanan and Fogel, 1995) is a general mutation-based evolutionary method that can be used to search the space of neural networks. Individuals are represented by two n-dimensional vectors (where n is the number of weights in the network): $\vec{x}$ contains the synaptic weight values for the network, and $\vec{\delta}$ is a vector of standard deviation values of $\vec{x}$. A network is constructed using the weights in $\vec{x}$, and offspring are produced by applying Gaussian noise to each element $\vec{x}(i)$ with standard deviation $\vec{\delta}(i), i \in \{1..n\}$.

Cellular Encoding (CE; Gruau et al., 1996a,b) uses Genetic Programming (GP; Koza, 1991) to evolve graph-rewriting programs. The programs control how neural networks are constructed out of "cells." A cell represents a neural network processing unit (neuron) with its input and output connections and a set of registers that contain synaptic weight values. A network is built through a sequence of operations that either copy cells or modify the contents of their registers. CE uses the standard GP crossover and mutation to recombine the programs allowing evolution to automatically determine an appropriate architecture for the task and relieve the investigator from this often trial-and-error undertaking.

Covariance Matrix Adaptation Evolutionary Strategies (CMA-ES; Hansen and Ostermeier 2001) evolves the covariance matrix of the mutation operator in evolutionary strategies. The results in the pole-balancing domain were obtained from Igel (2003).

NeuroEvolution of Augmenting Topologies (NEAT; Stanley and Miikkulainen, 2002; Stanley 2004) is another NE method that evolves topology as well as synaptic weights, but unlike CE it uses a direct encoding. NEAT starts with a population of minimal networks (i.e., no hidden units) that can increase in complexity by adding either new connections or units through mutation. Every time a new gene appears, a *global innovation number* is incremented and assigned to that gene. Innovation numbers allow NEAT to keep track of the historical origin of every gene in the population so that (1) crossover can be performed between networks with different topologies, and (2) the networks can be grouped into "species" based on topological similarity.

Whenever two networks are recombined, the genes in both chromosomes with the same innovation numbers are lined up. Those genes that do not match are either *disjoint* or *excess*, depending on whether they occur within or outside the range of the other parent's innovation numbers, and are inherited from the more fit parent.

The number of disjoint and excess genes is used to measure the distance between genomes. Using this distance, the population is divided into species so that individuals compete primarily within their own species instead of with the population at large. This way, topological

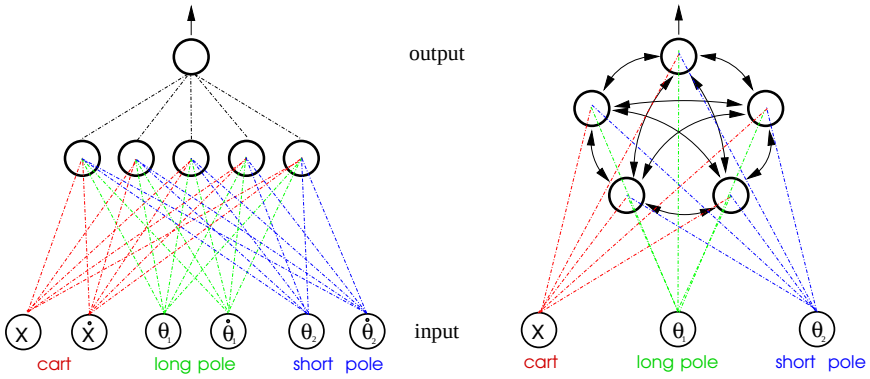

Figure 6: **Neural network control of the pole balancing system.** At each time step the network receives the current state of the cart-pole system $(x, \dot{x}, \theta_1, \dot{\theta_1}, \theta_2, \dot{\theta_2})$ through its input layer. For the feed-forward networks (a) used in the Markov tasks (1a and 2a), the input layer activation is propagated forward through the hidden layer of neurons to the output unit which indicates force to be applied to the cart. For the recurrent networks (b) used in the non-Markov tasks (1b and 2b), the neurons do not receive the velocities $(\dot{x}, \dot{\theta_1}, \dot{\theta_2})$, instead they must use their feedback connections to determine which direction the poles are moving. For the single pole version the network only has inputs for the cart and long pole.

innovations are protected and have time to optimize their structure before they have to compete with other species in the population.

Enforced SubPopulations (ESP; Gomez and Miikkulainen, 1997) is similar to SANE in that it uses cooperative coevolution at the neuron level, but, instead of using blueprints, the neuron population is split into disjoint subpopulations, one for each hidden unit in the network architecture being evolved. Instead of selecting neurons from a single population, as in SANE, to form networks, networks consist of one neuron from each subpopulation. During reproduction, neuron genotypes are only mated with members of their own subpopulation, and offspring remain in their parents' subpopulation.

For Q-MLP, SANE, CNE, ESP, and CoSyNE, experiments were run using our own code. For PGRL, AHC, SARSA, publicly available code from Grudic (2000), Anderson (1987), and Santamaria et al. (1998), was used respectively, modified for the pole-balancing domain. The parameter settings for each of these methods are listed in Appendix B. For VAPS, EP, CMA-ES, NEAT, and CE, the results were taken from the papers cited above. Data was not available for all methods on all tasks: however, in all such cases the method is shown to be significantly weaker already in a previous, easier task.

5.3 Task Setup

The pole balancing environment was implemented using a realistic physical model with friction, and fourth-order Runge-Kutta integration with a step size of 0.01s (see Appendix A for the equations of motion and parameters used). The state variables for the system are the following:

x : position of the cart.
$\dot{x}$: velocity of the cart.
θ_i : angle of the *i*-th pole $(i = 1, 2)$.
$\dot{\theta}_i$: angular velocity of the *i*-th pole.

Figure 6 shows how the network controllers interact with the pole balancing environment. At each time-step (0.02 seconds of simulated time) the network receives the state variable values scaled to [-1.0, 1.0]. This input activation is propagated through the network to produce a signal from the output unit that represents the amount of force used to push the cart. The force is then applied and the system transitions to the next state which becomes the new input to the controller. This cycle is repeated until a pole falls or the cart goes off the end of the track. In keeping with the setup in prior work (e.g., Wieland, 1991; Gruau et al., 1996b) we restrict the force to be no less than $\pm 1/256 \times 10$ Newtons so that the controllers cannot maintain the system in unstable equilibrium by outputting a force of zero when the poles are vertical.

The following four task configurations of increasing difficulty were used:

1. One Pole
   (a) Complete state information
   (b) Incomplete state information
2. Two Poles
   (a) Complete state information
   (b) Incomplete state information

Task 1a is the classic one-pole configuration. In 1b, the controller only has access to two of the four state variables: it does not receive the velocities $(\dot{x}, \dot{\theta})$. In 2a, the system now has a second pole next to the first, making the state-space 6-dimensional. Task 2b, like 1b, is non-Markov with the controller only seeing x, θ_1, and θ_2. Fitness was determined by the number of time steps a network could keep both poles within a specified failure angle from vertical and the cart between the ends of the track. The failure angle was 12° and 36° for the one and two pole tasks, respectively. For the one-pole tasks, the initial pole angle was set to 4.0° from vertical. For the two-pole tasks, the initial angle of the long pole was 4.0°, and the short pole was vertical. A task was considered solved if a network could do this for 100,000 time steps, which is equal to over 30 minutes in simulated time. CoSyNE evolved networks with one hidden unit, 20 weights per subpopulation for the 1-pole tasks, and 30 weights for the 2-pole tasks. Mutation was set to 0.3 for all experiments, which means that each weight in a new network have a 30% chance of being perturbed with Cauchy distributed noise. The initial weight range was $[-10, 10]$. All simulations were run on a 1.5GHz Intel Xeon.

5.4 Results: Balancing One Pole

Balancing one pole is a relatively easy problem that gives us a performance baseline before moving on to the much harder two-pole task. It has also been solved with many other methods and therefore serves to put the results in perspective with prior literature.

5.4.1 COMPLETE STATE INFORMATION

Table 1 shows the results for the single pole balancing task with complete state information. The results show that simply choosing weights at random (RWG) is sufficient to solve this task efficiently. CoSyNE was the only method that solved the task in fewer evaluations.

Table 1: **One pole with complete state information.** Comparison of various learning methods on the basic pole balancing problem with continuous control. Results for all methods are averages of 50 runs.

With the exception of RWG, there is a clear divide between the performance of the ontogenetic and phylogenetic methods, especially in terms of CPU time. For the value-based, ontogenetic methods, evaluating and updating values can be computationally expensive. The value-function approximator must be evaluated $O(|A|)$ times per state transition to determine the best action-value estimate, where A is a finite set of actions. Q-MLP and AHC have a notable CPU time advantage over SARSA because their value functions are represented compactly by neural networks which can be evaluated quickly, while the CMAC and case-based memory are coarse-codings have memory requirements and evaluation cost grow exponentially with the dimensionality of the state space.

In contrast, evolutionary methods do not update any agent parameters during interaction with the environment and only need to evaluate a function approximator once per state transition since the policy is represented explicitly.

PGRL is also quite slow as each update to the policy requires sampling $O(|A|T)$ trajectories, where T is the number of state transitions in the initial trajectory of each update. RPG performed best of the ontogenetic methods, but it must be noted that the criteria for success in the referenced work (Wierstra et al., 2007) was 10K steps instead of the 100K steps used with all the other methods (hence the parentheses in all tables for this method).

This task poses very little difficulty for the NE methods. However, NEAT required more than twice as many evaluations as CNE, SANE, and ESP because it explores different topologies that initially behave poorly and require time to develop. For this task the speciation process is an overkill—the task can be solved more efficiently by devoting resources to searching for weights only. All observed performance differences are statistically significant ($p < 0.01$) except between CNE, SANE and ESP.

CoSyNE	127	2

Table 2: **One pole with incomplete state information.** The table shows the number of evaluations, CPU time, and success rate of the various methods. Results are the average of 50 simulations, and all differences are statistically significant ($p < 0.01$). The results for VAPS are in parenthesis since only a single unsuccessful run according to our criteria was reported by Meuleau et al. (1999).

5.4.2 INCOMPLETE STATE INFORMATION

This task is identical to the first task except the controller only senses the cart position x and pole angle θ. Therefore, the underlying states $\{x, \dot{x}, \theta, \dot{\theta}\}$ are hidden and the networks need to be recurrent so that the velocities can be computed internally using feedback connections. This makes the task significantly harder since it is more difficult to control the system when the concomitant problem of velocity calculation must also be solved. We were unable to solve this task with AHC and PGRL.

To allow Q-MLP and the SARSA methods to solve this task, we extended their inputs to include the immediately previous cart position, pole angle, and action $(x_{t-1}, \theta_{t-1}, a_{t-1})$ in addition to x_t, θ_t, and a_t. This *delay window* of depth 1 is sufficient to disambiguate process states (Lin and Mitchell, 1992). For VAPS, the state-space was partitioned into unequal intervals, 8 for x and 6 for θ, with the smaller intervals being near the center of the value ranges (Meuleau et al., 1999).

Table 2 compares the various methods in this task. The table shows the number of evaluations and average CPU time for the successful runs.

The results for VAPS are in parenthesis in the table because only a single run was reported by Meuleau et al. (1999). It is clear, however, that VAPS is the slowest method in this comparison, only being able to balance the pole for around 1 minute of simulated time after several days of computation (Meuleau et al., 1999). The evaluations and CPU time for the SARSA methods are the average of the successful runs only (out 29 of 50 for SARSA-CMAC and 35 out of 50 for SARSA-CABA). Of the value-function methods, Q-MLP fared the best, reliably solving the task and doing so much more rapidly than SARSA. Since both the CMAC and the cased-based memory are local function approximators, they require a dense sampling of the state space to obtain good value estimate. The MLP, being a global function approximator, is able to learn values for a whole set of states every time a state is updated. This property has been considered undesirable in some domains because updates at one state can disrupt or unlearn values at distant states. Because the

relatively simple form of the optimal value function for this task, the MLP accelerates learning by providing "useful" information about more of the state space on each update which is especially useful to bootstrap learning at the beginning when there is virtually no information about the value of most states. For more complicated value functions, the potential for instability in the MLP could give local representations the advantage (Boyan and Moore, 1995).

The performance of the five evolutionary methods degrades only slightly compared to the previous task. CoSyNE, CNE, and ESP were two orders of magnitude faster than VAPS and SARSA, one order of magnitude faster than Q-MLP, and approximately twice as fast as SANE and NEAT. CoSyNE was able to balance the pole for over 30 minutes of simulated time usually within 2 seconds of learning CPU time, and do so reliably.

The results on these first two tasks show that the single pole environment is not very challenging. A large part of the search space represents successful solutions, so that simply choosing points at random (i.e., RWG) can compete favorably with other ontogenetic approaches that start at one point and then must make relatively small incremental changes to reach a solution, without not getting stuck in a local minimum.

5.5 Results: Balancing Two Poles

The double pole problem is a better test environment for these methods, representing a significant jump in difficulty. Here the controller must balance two poles of different lengths (1m and 0.1m) simultaneously. The second pole adds two more dimensions to the state-space $(\theta_2, \dot{\theta}_2)$ and non-linear interactions between the poles.

5.5.1 COMPLETE STATE INFORMATION

For this task, CoSyNE was compared with Q-MLP, CNE, SANE, ESP, NEAT, and the published results of RPG, EP, and CMA-ES. Despite extensive experimentation with many different parameter settings, we were unable to get the SARSA methods to solve this task within 12 hours of computation.

Table 3 shows the results for the two-pole configuration with complete state information. Q-MLP compares very well to the NE methods with respect to evaluations, in fact, better than on task 1b, but again lags behind SANE, ESP and NEAT by nearly an order of magnitude in CPU time. ESP and NEAT are statistically even in terms of evaluations, requiring roughly three times fewer evaluations than SANE. In terms of CPU time, ESP has a slight but statistically significant ($p < 0.01$) advantage over NEAT. This is an interesting result because the two methods take such different approaches to evolving neural networks. NEAT is based on searching for an optimal topology, whereas ESP, like CoSyNE, optimizes a single, general topology (i.e., fully recurrent networks). At least in the difficult versions of the pole balancing task, the performance of these two approaches is very similar.

CMA-ES required the fewest number of evaluations, 59 less than CoSyNE on average, although we do not have the CMA-ES run data to test for statistical significance.

5.5.2 INCOMPLETE STATE INFORMATION

Although the previous task is difficult, the controller has the benefit of complete state information. In this task, as in task 1b, the controller does not have access to the velocities, that is, it does not know how fast or in which direction the poles are moving.

Method	Evaluations	CPU time
RWG	474,329	70
EP	307,200	—
CNE	22,100	73
SANE	12,600	37
Q-MLP	10,582	153
RPG	(4,981)	—
NEAT	3,600	31
ESP	3,800	22
CoSyNE	954	4
CMA-ES	895	—

Table 3: **Two poles with complete state information.** The table shows the number of pole balancing attempts (evaluations) and CPU time required by each method to solve the task. Evolutionary Programming data is taken from Saravanan and Fogel (1995), CMA-ES from Igel (2003). Q-MLP, CNE, SANE, NEAT, ESP, CoSyNE data are the average of 50 simulations, and all differences are statistically significant ($p < 0.01$) except the number of evaluations for NEAT and ESP.

Gruau et al. (1996b) were the first to tackle the two-pole problem without velocity information. Although they report the performance for only one simulation, we include their results to put the performance of the other methods in greater perspective. None of the value-function methods we tested made noticeable progress on the task after approximately 12 hours of computation. Therefore, in this task, only the evolutionary methods are compared.

To accommodate a comparison with CE, controllers were evolved using both the standard fitness function used in the previous tasks and also the "damping" fitness function used by Gruau et al. (1996b). The damping fitness is the weighted sum of two separate fitness measurements ($0.1 f_1 + 0.9 f_2$) taken over a simulation of 1000 time steps:

$$f_1 = t/1000,$$

$$f_2 = \begin{cases} 0 & \text{if } t < 100 \\ \left(\dfrac{0.75}{\sum_{i=t-100}^{t} (|x^i| + |\dot{x}^i| + |\theta_1^i| + |\dot{\theta}_1^i|)} \right) & \text{otherwise,} \end{cases}$$

where t is the number of time steps the poles were balanced out of the first 1000 steps. This complex fitness is intended to force the network to compute the pole velocities, and avoid solutions that balance the poles by merely swinging them back and forth (i.e., without calculating the velocities).

Table 4 compares the "surviving" methods for both fitness functions. To determine when the task was solved for the damping fitness function, the best controller from each generation was tested using the standard fitness to see if it could balance the poles for 100K time steps. The results for CE are in parenthesis in the table because only a single run was reported by Gruau et al. (1996b).

Using the damping fitness, CMA-ES, ESP, CNE, NEAT, and CoSyNE required two orders of magnitude fewer evaluations than CE. ESP was three times faster than CNE using either fitness

Method	Evaluations	
	Standard fitness	Damping fitness
RWG	415,209	1,232,296
CE	—	(840,000)
SANE	262,700	451,612
CNE	76,906	87,623
ESP	7,374	26,342
NEAT	—	6,929
RPG	(5,649)	—
CMA-ES	3,521	6,061
CoSyNE	1,249	3,416

Table 4: **Two poles with incomplete state information.** The table shows the number of evaluations for CNE, NEAT, and ESP using the standard fitness function (middle column), and using the damping fitness function (right column). Results are the average of 50 simulations for all methods except CE which is from a single run. All results are statistically significant ($p < 0.01$) .

function, with CNE failing to solve the task about 40% of the time, and NEAT, using small populations of size 16 (Stanley, 2004) performed nearly as well as CMA-ES (damping function). RPG was the only ontogenetic method to make significant progress in this task, again, however, only up to 10K time-steps of balancing.

On this most difficult task CoSyNE outperformed the next best method, CMA-ES, by a factor of two on both fitness functions.

6. Discussion

The results of the comparisons show that the phylogenetic methods (i.e., neuroevolution) are more efficient on this set of tasks than the ontogenetic methods. In the single pole tasks, the value-based ontogenetic methods were outperformed by random search. Our hope is that these results will help put an end to the use of this task for evaluating artificial learning systems. On the more difficult two-pole tasks, only Q-MLP was able to solve the completely observable version (task 2a), and none of the ontogenetic methods could solve the partially observable one (task 2b). In contrast, all of the neuroevolution methods scaled up to the most difficult tasks, with CMA-ES and CoSyNE leading the pack.

The most challenging of the tasks exhibit many of the dimensions of difficulty found in real world control problems: (1) continuous state and action spaces, (2) partial observability, and (3) non-linearity. The first two are problematic for value-based reinforcement learning methods because they either complicate the representation of the value function or the access to it. Neuroevolution deals with them by evolving recurrent networks; the networks can compactly represent arbitrary temporal, non-linear mappings. The success of CoSyNE on tasks of this complexity suggests that it can be applied to the control of real systems that manifest similar properties—specifically, non-linear, continuous systems such as aircraft control, satellite detumbling, and robot bipedal walking.

Other types of environments that are discrete or discontinuous, such as game-playing, job-shop scheduling, and resource allocation may be better served by other learning or optimization strategies.

The CoSyNE implementation used in this paper permuted all members of a subpopulation each generation. This means that it is possible for the networks evaluated in a given generation to not contain any combinations of weights found in the networks of the previous generation. While this maximizes the amount of exploration performed by sampling new networks, good weight combinations may be lost that could lead to a solution more efficiently. This aggressive exploration could become a problem for large networks, such as those that use very high-dimensional vision inputs. Future work will begin by investigating schemes for assigning permutation probabilities to weights (e.g., fitness proportional) in order to retain potential useful building blocks in the system and facilitate search in larger network spaces.

7. Conclusion

Reinforcement learning can in principle be used to control real world systems, but conventional methods scale poorly to large state-spaces and non-Markov environments. In this paper, we have shown that for a set of benchmark tasks that exhibit many of the key dimensions of difficulty found in real world control problems, neuroevolution in general, and CoSyNE in particular, can solve these problems much more reliably and efficiently than non-evolutionary reinforcement learning approaches.

Appendix A. Pole-balancing Equations

The equations of motion for N unjointed poles balanced on a single cart are

$$\ddot{x} = \frac{F - \mu_c sgn(\dot{x}) + \sum_{i=1}^{N} \tilde{F}_i}{M + \sum_{i=1}^{N} \tilde{m}_i},$$

$$\ddot{\theta}_i = -\frac{3}{4l_i}(\ddot{x}\cos\theta_i + g\sin\theta_i + \frac{\mu_{pi}\dot{\theta}_i}{m_i l_i}),$$

where $\tilde{F}_i$ is the effective force from the ith pole on the cart,

$$\tilde{F}_i = m_i l_i \dot{\theta}_i^2 \sin\theta_i + \frac{3}{4} m_i \cos\theta_i (\frac{\mu_{pi}\dot{\theta}_i}{m_i l_i} + g\sin\theta_i),$$

and $\tilde{m}_i$ is the effective mass of the ith pole,

$$\tilde{m}_i = m_i(1 - \frac{3}{4}\cos^2\theta_i).$$

Parameters used for the single pole problem:

Sym.	Description	Value
x	Position of cart on track	[-2.4,2.4] m
θ	Angle of pole from vertical	[-12,12] deg.
F	Force applied to cart	-10,10 N
l	Half length of pole	0.5m
M	Mass of cart	1.0 kg
m	Mass of pole	0.1 kg

Parameters for the double pole problem.

Sym.	Description	Value
x	Position of cart on track	[-2.4,2.4] m
θ	Angle of pole from vertical	[-36,36] deg.
F	Force applied to cart	[-10,10] N
l_i	Half length of ith pole	l_1 = 0.5m l_2 = 0.05m
M	Mass of cart	1.0 kg
m_i	Mass of ith pole	m_1 = 0.1 kg m_2 = 0.01 kg
μ_c	Coefficient of friction of cart on track	0.0005
μ_p	Coefficient of friction if ith pole's hinge	0.000002

Appendix B. Parameter Settings Used in Pole Balancing Comparisons

Below are the parameters used to obtain the results for Q-MLP, SARSA-CABA, SARSA-CMAC, CNE, SANE, ESP, and NEAT. The parameters for VAPS (Meuleau et al., 1999), RPG (Wierstra et al., 2007), CMA-ES (Igel, 2003), EP (Saravanan and Fogel, 1995), and CE2 (Gruau et al., 1996b) along with a detailed description of each method can be found in the cited papers.

Table 5 describes the parameters common to all of the value function methods.

Parameter	Description
ε	greediness of policy
α	learning rate
γ	discount rate
λ	eligibility

Table 5: All parameters have a range of (0,1).

Q-MLP

Parameter	Task		
	1a	1b	2a
ε	0.1	0.1	0.05
α	0.4	0.4	0.2
γ	0.9	0.9	0.9
λ	0	0	0

For all Q-MLP experiments the Q-function network had 10 hidden units and the action space was quantized into 26 possible actions: $\pm 0.1, 0.25, 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10$.

SARSA-MLP

Parameter	Task		
	1a	1b	2a
ε	0.1	0.1	0.05
α	0.4	0.4	0.1
γ	0.9	0.9	0.9
λ	0	0	0.3

For all Q-MLP experiments the Q-function network had 10 hidden units and the action space was quantized into 26 possible actions: $\pm 0.1, 0.25, 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10$.

SARSA-CABA

Parameter	Task	
	1a	1b
τ_d	0.03	0.03
τ_k^x	0.05	0.05
τ_k^u	0.1	0.1
ε	0.05	0.05
α	0.4	0.1
γ	0.99	0.99
λ	0.4	0.4

τ_d is the density threshold, τ_k^x and τ_k^u are the smoothing parameters for the input and output spaces, respectively. See Santamaria et al. (1998) for a more detailed description of the Case-Based Memory architecture.

SARSA-CMAC

Parameter	Task	
	1a	1b
ε	0.05	0.05
α	0.4	0.1
γ	0.9	0.9
λ	0.5	0.3
No. of tilings	45: 10 based on $x, \dot{x}, \theta_1$ 5 based on x, θ 5 based on $x, \dot{\theta}$ 5 based on $\dot{x}, \dot{\theta}$ 5 based on x 5 based on $\dot{x}$ 5 based on θ 5 based on $\dot{\theta}$	50 : 10 based on x_t, x_{t-1}, θ_t 10 based on $x, \theta_t, \theta_{t-1}$ 5 based on x_t, θ_t 5 based on x_{t-1}, θ_{t-1} 5 based on x_t 5 based on x_{t-1} 5 based on θ_t 5 based on θ_{t-1}

where x_t and θ_t are the cart position and pole angle at time t. Each variable was divided in to 10 intervals in each tiling. For a more complete explanation of the CMAC architecture see Santamaria et al. (1998).

SANE

Parameter	Task	
	1(a,b)	2(a,b)
no. of neurons	100	200
no. of blueprints	50	100
evals per generation	200	400
size of networks	5	7

The mutation rate for all runs was set to 10%.

CNE

Parameter	Task			
	1a	1b	2a	2b
no. of networks	200	200	400	1000
size of networks	5	5	5	rand [1..9]
burst threshold	10	10	10	15

The mutation rate for all runs was set to 40%. Burst threshold is the number of generations after which burst mutation is activated if the best network found so far is not improved upon. CNE evaluates each of the networks in its population once per generation.

ESP

Parameter	Task			
	1a	1b	2a	2b
network type	FF	FR	FF	FR
initial no. of subpops	5	5	5	5
size of subpopulations	20	20	40	100
evals per generation	200	200	400	1000
burst threshold	10	10	10	5

The mutation rate for all runs was set to 40%. Burst threshold is the number of generations after which burst mutation is activated if the best network found so far is not improved upon. FF denotes a feed-forward network, whereas FR denotes a fully recurrent network.

Abstract

Pointwise consistent, feasible procedures for estimating contemporaneous linear causal structure from time series data have been developed using multiple conditional independence tests, but no such procedures are available for non-linear systems. We describe a feasible procedure for learning a class of non-linear time series structures, which we call additive non-linear time series. We show that for data generated from stationary models of this type, two classes of conditional independence relations among time series variables and their lags can be tested efficiently and consistently using tests based on additive model regression. Combining results of statistical tests for these two classes of conditional independence relations and the temporal structure of time series data, a new consistent model specification procedure is able to extract relatively detailed causal information. We investigate the finite sample behavior of the procedure through simulation, and illustrate the application of this method through analysis of the possible causal connections among four ocean indices. Several variants of the procedure are also discussed.

Keywords: conditional independence test, contemporaneous causation, additive model regression, Granger causality, ocean indices

1. Introduction

For stationary time series of four or more dimensions, Swanson and Granger (1997) proposed to determine contemporaneous causation—causal influences occurring more rapidly than the sampling interval of the time series data—by regressing each time series variable on all lags of all variables considered and using the residuals to test for vanishing partial correlations. Using search procedures for directed acyclic graphical linear models, in particular, the PC algorithm (Spirtes et al., 2000), Bessler et al. (2002), Demiralp and Hoover (2003), and Hoover (2005) generalized Swanson and Granger's procedure to allow specification searches for contemporaneous linear systems among all partial orderings of the dependencies among the variables. Moneta (2003) derived the correction needed for the fact that the correlations are obtained from residuals of a regression, and applied it to a set of cointegrated variables.

All these methods are designed for linear systems with joint Normal distributions, and allow neither unrecorded (latent) common causes nor feedbacks. One source of these limitations is the

search algorithm used by all of these procedures, PC, which is known to be consistent only in the absence of feedback relations and latent common causes. In principle, some of these difficulties can be met by replacing PC with related algorithms: the FCI algorithm (Spirtes et al., 2000), which allows latent variables, or an algorithm due to Richardson and Spirtes (1999) that allows linear feedback relations, though no algorithm is available that is consistent for search for linear causal models when both latent variables *and* feedback may be present.

More fundamentally, PC and related algorithms require conditional independence information about the random variables as input, and are therefore limited to distribution families for which conditional independence tests of arbitrary order are available, such as Multinomial and Normal distributions. (Another group of causal inference algorithms that are based on model scores, such as Bayesian posteriors, are unable to handle either latent variables *or* feedbacks, except under extra constraints (Silva et al., 2006; Drton et al., 2006). For *non-Gaussian* linear models with latent variables, independent component analysis based algorithms (Hoyer et al., 2006) could be more informative than PC and FCI.) Extending the PC and related algorithms based on conditional independence constraints to a larger class of systems that includes nonlinear continuous models requires more general conditional independence tests. We begin by considering some of the difficulties involved with finding such tests.

In theory, using nonparametric density estimation, we can test conditional independence for any set of random variables which have a joint density with respect to the Lebesgue measure. For example, let the joint density of $\{X,Y,Z\}$ be $f_{XYZ}(x,y,z)$, the joint density of $\{X,Z\}$ be $f_{XZ}(x,z)$, the joint density of $\{Y,Z\}$ be $f_{YZ}(y,z)$, and the marginal density of Z be $f_Z(z)$. We could test if X and Y are independent given Z by testing if the Hellinger distance between $f_{XYZ}(x,y,z)f_Z(z)$ and $f_{XZ}(x,z)f_{YZ}(y,z)$ is 0. For example, Su and White (2007) propose a conditional independence test for stationary time series satisfying certain conditions, based on a weighted Hellinger distance between $f_{X|YZ}(x;y,z)$ and $f_{X|Z}(x;z)$, where $f_{X|YZ}(x;y,z)$ and $f_{X|Z}(x;z)$ are densities of the conditional distributions of X given $\{Y,Z\}$ and Z respectively. However, this approach requires nonparametric density estimation of multivariate distributions, which is subject to the curse of dimensionality: as the number of variables increases, the data points become sparse rapidly in the space spanned by the variables.

Baek and Brock (1992) and Hiemstra and Jones (1994) proposed a nonparametric method intended for Granger causality testing of nonlinear time series. Consider a bivariate time series $\{X_t,Y_t\}$, $t = 1,\cdots$, let $\boldsymbol{X}_t^m = (X_t,\cdots,X_{t+m-1})$ for some m, they proposed to test if $\boldsymbol{X}_t^m$ and $\boldsymbol{Y}_{t-b}^b$ are independent given $\boldsymbol{X}_{t-a}^a$ by testing the following null hypothesis:

$$P\left(\|\boldsymbol{X}_t^m - \boldsymbol{X}_s^m\|_\infty < e \mid \|\boldsymbol{X}_{t-a}^a - \boldsymbol{X}_{s-a}^a\|_\infty < e, \|\boldsymbol{Y}_{t-b}^b - \boldsymbol{Y}_{s-b}^b\|_\infty < e\right)$$
$$= P\left(\|\boldsymbol{X}_t^m - \boldsymbol{X}_s^m\|_\infty < e \mid \|\boldsymbol{X}_{t-a}^a - \boldsymbol{X}_{s-a}^a\|_\infty < e\right).$$

Unfortunately, only under some specific conditions is the above null hypothesis equivalent to the hypothesis that $\boldsymbol{X}_t^m$ is independent of $\boldsymbol{Y}_{t-b}^b$ given $\boldsymbol{X}_{t-a}^a$ (Diks and Panchenko, 2006).

Bell et al. (1996) considered additive model regression (Hastie and Tibshirani, 1990) for conditional independence tests in their study of nonlinear Granger causality. An additive model assumes that the response variable Y is a linear combination of univariate smooth functions of predictors $\boldsymbol{X} = \{X_1,\cdots,X_p\}$ plus an independent error term. That is:

$$Y = \sum_{i=1}^{p} f_i(X_i) + \varepsilon \tag{1}$$

where it is possible that $f_i(X_i) = 0$ for some $i \in \{1, \cdots, p\}$. Assuming Equation (1), additive model regression could be used to test if the response variable Y and some predictors $\boldsymbol{X}_a \subseteq \boldsymbol{X}$ are independent conditional on the other predictors $\boldsymbol{X}_b = \boldsymbol{X} \setminus \boldsymbol{X}_a$, because Y is independent of $\boldsymbol{X}_a$ given $\boldsymbol{X}_b$ if and only if $\mathrm{E}[Y|\boldsymbol{X}]$ is constant in $\boldsymbol{X}_a$}.

Additive regression works well as a conditional independence test in the study of Granger causality when no contemporaneous causation is allowed among time series, because the only type of conditional independence relations to be tested is the one described above. For example, in Bell et al. (1996), two additive models were fitted: one model for estimating the conditional expectation of a variable X_{T+1} given its T lags $\{X_1, X_2, \cdots, X_T\}$, another for conditional expectation of X_{T+1} given $\{X_1, X_2, \cdots, X_T\}$ and $\{Y_1, Y_2, \cdots, Y_T\}$. The F test was used to compare these two regression models: if the test failed to reject the first model, X_{T+1} was judged independent of $\{Y_1, Y_2, \cdots, Y_T\}$ given $\{X_1, X_2, \cdots, X_T\}$.

However, the use of additive model regression as a general purpose nonlinear conditional independence test is problematic, even for variables that are known to be related via additive models. Generally speaking, it is not always valid to use additive model regression to test conditional independence relations other than those between the response variable and some predictors given the other predictors. First, in some cases, additive model regression may miss some conditional dependencies. Consider a causal system with two exogenous variables X_1 and X_2, and an endogenous variable Y such that $Y = X_1^2 + X_2^2 + \varepsilon_Y$, where X_1, X_2 and ε_Y are independent Gaussian variables. Although the predictors X_1 and X_2 are dependent given the response variable Y, the conditional expectation of X_1 given Y and X_2 estimated using additive model regression will be constant in X_2. Second, even worse, in some cases additive model regression may miss some conditional independencies. Consider a system with two exogenous variables X_1 and X_2, and five endogenous variables $W = X_1 + X_2 + \varepsilon_W$, $Y = W^2 + \varepsilon_Y$, $U = \log(X_1) + \varepsilon_U$, $V = \log(X_2) + \varepsilon_V$, and $Z = U + V + \varepsilon_Z$. Although the two response variables Y and Z are independent conditional on the predictors X_1 and X_2, Z will be present in the conditional expectation of Y given $\{X_1, X_2, Z\}$ estimated by additive model regression. (Note that Y contains a term $2X_1X_2$, and $e^Z = e^{\varepsilon_U + \varepsilon_V + \varepsilon_Z} X_1 X_2$.)

Nevertheless, additive model regression has some very attractive features. First, and probably most importantly, it is not subject to the curse of dimensionality. In fact, Stone (1985) shows that the rate of convergence for an additive model regression is the same as that for a univariate smoother, which is much faster than a general multidimensional nonparametric regression method. The second major advantage of additive model regression is that it is possible to identify the contribution of each predictor to the response variable, thus allowing an intuitive interpretation of the fitted models.

In the following sections, we define a additive non-linear time series model by imposing linear constraints only among contemporaneous variables. We show that two families of conditional independence relations can be tested consistently among variables in a additive non-linear time series model using additive model regression. That is, asymptotically, additive model regression will neither miss any conditional independence relations nor report any spurious conditional independence relations when applied to data generated from a additive non-linear time series model to test those two families of conditional independence relations. We propose an inference procedure for nonlinear time series data that requires only information about these two families of conditional independence relations.

2. Additive Non-linear Time Series Models

Below we present the definition of a family of nonlinear time series models for which additive model regression based conditional independence test is possible. Here $\boldsymbol{X}_t$ is a p dimensional observed time series, $\boldsymbol{U}_t$ a q dimensional unobserved time series, and $\boldsymbol{\varepsilon}_t$ a p dimensional white noise.
Definition: A p dimensional time series $\{\boldsymbol{X}\}_t = \{\cdots, \boldsymbol{X}_1, \cdots, \boldsymbol{X}_T, \cdots\}$, where $\boldsymbol{X}_t = \{X_{t,1}, \cdots, X_{t,p}\}$, is generated from a *lag T additive non-linear model* if it satisfies the following conditions:

C1 For $i = 1, \cdots, p$,

$$X_{t,i} = \sum_{1 \le j \le p, j \ne i} c_{j,i} X_{t,j} + \sum_{1 \le k \le p, 1 \le l \le T} f_{k,i,l}(X_{t-l,k}) + \sum_{m=1}^{q} b_{m,i} U_{t,m} + \varepsilon_{t,i} \tag{2}$$

where $b_{m,i}$'s and $c_{j,i}$'s are constants, and $f_{k,i,l}$'s are smooth univariate functions

C2 $\cdots, \varepsilon_{1,1}, \cdots, \varepsilon_{1,p}, \varepsilon_{2,1}, \cdots, \varepsilon_{t,i}, \cdots$ and $\cdots, U_{1,1}, \cdots, U_{1,q}, U_{2,1}, \cdots, U_{t,j}, \cdots$ are jointly independent, with $\varepsilon_{t,i} \sim N(0, \sigma^2_{1,i})$ and $U_{t,j} \sim N(0, \sigma^2_{2,j})$.

C3 There is a k and an i such that $f_{k,i,T}(\cdot) \ne 0$

C4 There is no sequence of indices $\{j_1, j_2, \cdots, j_m\}$ such that c_{j_1,j_2}, c_{j_2,j_3}, $\cdots$, c_{j_{m-1},j_m}, c_{j_m,j_1} are all nonzero.

The model is additive because Equation (2) includes both linear terms and arbitrary smooth terms. It is also recursive in the sense that given an initialization of $\boldsymbol{X}_{t-T}, \cdots, \boldsymbol{X}_{t-1}$, all the later points in the time series, starting from $\boldsymbol{X}_t$, can be generated inductively.

A additive non-linear model can be causally interpreted in the following way:

- $X_{t,j}$ is a direct cause of $X_{t,i}$ if and only if $c_{j,i} \ne 0$ in Equation (2), (for the definition of *direct cause*, see Spirtes et al., 2000; Pearl, 2000);
- $X_{t-l,j}$ is a direct cause of $X_{t,i}$ if and only if $f_{j,i,l}(\cdot) \ne 0$ in Equation (2);
- Latent common causes are allowed only for variables in the same time tier, and $X_{t,i}$ and $X_{t,j}$ have a latent common cause $U_{t,m}$ if and only if there is an m such that $b_{m,i} b_{m,j} \ne 0$.

  Note that both $\boldsymbol{U}_t$ and $\boldsymbol{\varepsilon}_t$ are multi-dimensional Gaussian white noise and both are unobserved. However, for $i = 1, \cdots, p$, $\varepsilon_{t,i}$ can only be a direct cause of $X_{t,i}$, where for $m = 1, \cdots, q$, $U_{t,m}$ can be a direct cause of several variables in $\boldsymbol{X}_t$.
- Condition C4 means that no contemporaneous feedback is allowed. If condition C4 is violated, X_{t,j_m} would be a direct cause of X_{t,j_1}, while at the same time X_{t,j_1} would be a (possibly indirect) cause of X_{t,j_m}.

  Note that using results of Richardson and Spirtes (1999) the method described in Section 3 can be modified to allow contemporaneous feedback.

A additive non-linear model can be represented by a directed graph consisting of nodes for $X_{T+1,1}, \cdots, X_{T+1,p}$ and their direct causes, and directed edges between nodes for the direct influences between the corresponding variables. We call this graph a *unit causal graph* for the corresponding

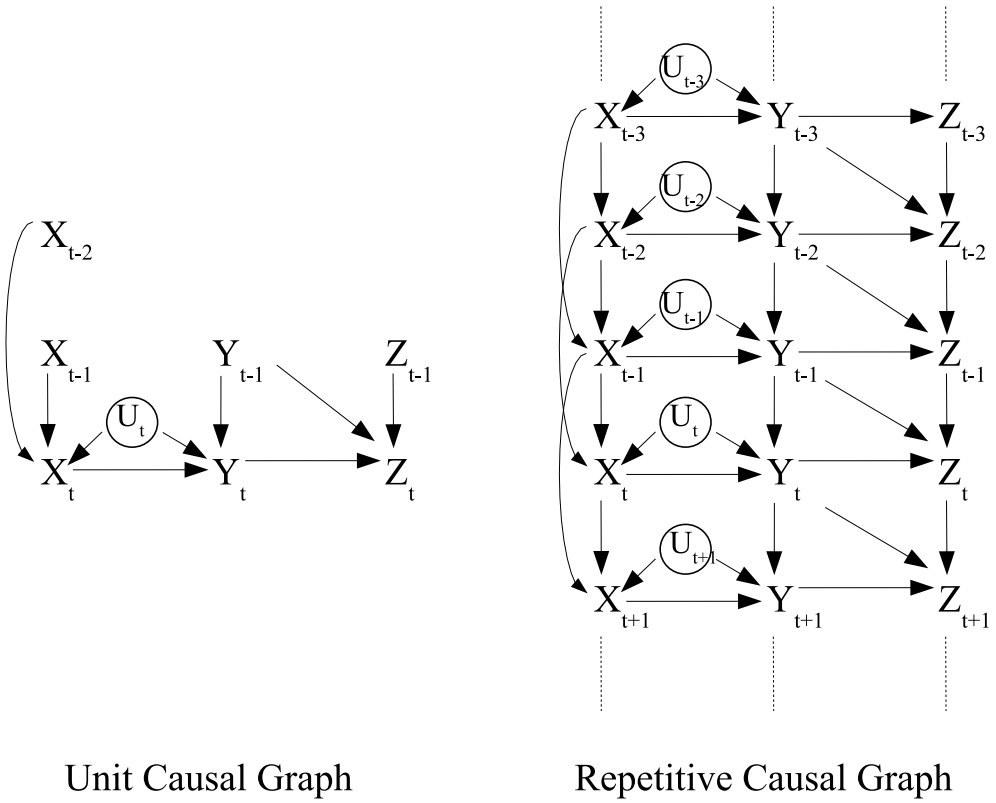

Figure 1: Unit causal graph and repetitive causal graph

time series. A unit causal graph can be extended to a *repetitive causal graph* by including all the variables in $\boldsymbol{X}_1, \cdots, \boldsymbol{X}_{T+1}$. Moreover, if there is an edge between $X_{T+1,i}$ and $X_{t,j}$, where $1 \leq t \leq T+1$, then similar edges will be added between $X_{T+1-l,j}$ and $X_{t-l,i}$ for $1 \leq l \leq t-1$. Figure 1 shows a unit causal graph and a segment of the corresponding repetitive graph. (The circled variables are latent variables.) In the remaining part of this paper, all time series causal models are represented by unit causal graphs.

Additive non-linear time series models make it possible to use the additive regression method, which is not subject to the curse of dimensionality, to test conditional independence for nonlinear time series. For a time series $\{\boldsymbol{X}\}_t$ generated from a lag T additive non-linear model, the following holds:

Proposition 1: Let X_t^1 and X_t^2 be any two distinct entries of random vector $\boldsymbol{X}_t$, $\boldsymbol{X}_t^c$ any subset, possibly empty, of $\boldsymbol{X}_t \setminus \{X_t^1, X_t^2\}$, and $\boldsymbol{X}_t^d$ any subset, possibly empty, of $\boldsymbol{X}_t \setminus \{X_t^1\}$. Let $\boldsymbol{X}^l = \{\boldsymbol{X}_{t-T}, \cdots, \boldsymbol{X}_{t-1}\}$, and $\boldsymbol{X}^e = \boldsymbol{X}^l \setminus \{X_{t-i,j}\}$ for some $X_{t-i,j} \in \boldsymbol{X}^l$.

- For any $\boldsymbol{x}_t^d$ and $\boldsymbol{x}^l$, conditional on $\boldsymbol{X}_t^d = \boldsymbol{x}_t^d$ and $\boldsymbol{X}^l = \boldsymbol{x}^l$, X_t^1 has a normal distribution $N(\mu_{1|a}, \sigma_{1|a}^2)$ such that $\mu_{1|a}$ is a linear combination of $\boldsymbol{x}_t^d$ and smooth univariate functions of entries of $\boldsymbol{x}^l$, and $\sigma_{1|a}$ is independent of t, $\boldsymbol{x}^l$ and $\boldsymbol{x}_t^d$. Thus, X_t^1 is independent of $X_{t-i,j}$ conditional on $\boldsymbol{X}^e$ and $\boldsymbol{X}_t^d$ if and only if $\mu_{1|a}$, the conditional expectation of X_t^1 given $\boldsymbol{X}_t^d = \boldsymbol{x}_t^d$ and $\boldsymbol{X}^l = \boldsymbol{x}^l$, is constant in $x_{l,j}$.

- For any x_t^2, $\boldsymbol{x}_t^c$ and $\boldsymbol{x}^l$, conditional on $X_t^2 = x_t^2$, $\boldsymbol{X}_t^c = \boldsymbol{x}_t^c$, and $\boldsymbol{X}^l = \boldsymbol{x}^l$, X_t^1 has a normal distribution $N(\mu_{1|b}, \sigma_{1|b}^2)$ such that $\mu_{1|b}$ is a linear combination of x_t^2, $\boldsymbol{x}_t^c$, and smooth univariate functions of entries of $\boldsymbol{x}^l$, and $\sigma_{1|b}$ is constant in t, x_t^2, $\boldsymbol{x}_t^c$, and $\boldsymbol{x}^l$. Thus, X_t^1 is independent of X_t^2 conditional on $\boldsymbol{X}_t^c$ and $\boldsymbol{X}^l$ if and only if, $\mu_{1|b}$, the conditional expectation of X_t^1 given $X_t^2 = x_t^2$, $\boldsymbol{X}_t^c = \boldsymbol{x}_t^c$, and $\boldsymbol{X}^l = \boldsymbol{x}^l$, is constant in x_t^2.

Proposition 1 implies that it is possible to use additive model regression to test the following two types of conditional independence relations among variables in a additive non-linear model. First, we can test if X_t^1 and X_t^2 are independent conditional on $\boldsymbol{X}_t^c$ and $\boldsymbol{X}^l$ by estimating the conditional expectation of X_t^1 given $\{X_t^2\} \cup \boldsymbol{X}_t^c \cup \boldsymbol{X}^l$ using additive model regression, and check if X_t^2 is a significant predictor for X_t^1 using statistical tests such as the F test (Bell et al., 1996) or the BIC scores (Huang and Yang, 2004). Similarly, if $X_{t-i,j}$ is not a significant predictor for X_t^1 in the additive model regression of X_t^1 against $\boldsymbol{X}^l$ and $\boldsymbol{X}_t^d$, we would say X_t^1 and $X_{t-i,j}$ are independent conditional on $\boldsymbol{X}_t^d$ and $\boldsymbol{X}^e$.

To make the above tests valid, we also need the assumption that additive model regression is an (asymptotically) consistent estimator of conditional expectations such as $\mathrm{E}[X_t^1|\boldsymbol{X}_t^d, \boldsymbol{X}^l]$ and $\mathrm{E}[X_t^1|X_t^2, \boldsymbol{X}_t^c, \boldsymbol{X}^l]$. Fortunately, it has been shown that, given a stationary nonlinear time series $\{\boldsymbol{X}\}_t$, nonparametric estimation of the conditional mean $\mathrm{E}[X_t|\boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T}]$ is asymptotically consistent and/or asymptotically normal, provided certain conditions are satisfied (Robinson, 1983; Truong and Stone, 1992; Chen and Tsay, 1993; Tjøstheim and Auestad, 1994; Härdle et al., 1997; Cai and Masry, 2000; Huang and Yang, 2004). Generally speaking, besides some regularity conditions on the density of $\boldsymbol{X}_t \cup \boldsymbol{X}^l$ and smoothness condition on $\mathrm{E}[X_t|\boldsymbol{X}^l]$, $\{\boldsymbol{X}\}_t$ should satisfy some form of α mixing condition. $\{\boldsymbol{X}\}_t$ is α mixing if for some $\alpha(n) \to 0$,

$$\sup\{|P(A \cap B) - P(A)P(B)| : A \in \mathcal{F}_t, B \in \mathcal{G}_{n+t}\} \leq \alpha(n)$$

where $\mathcal{F}_t$ is the σ-field generated by $\boldsymbol{X}_t, \boldsymbol{X}_{t-1}, \cdots$, and $\mathcal{G}_{n+t}$ the σ-field generated by $\boldsymbol{X}_{t+n}, \boldsymbol{X}_{t+n+1}, \cdots$.

A concept closely related to α mixing is geometric ergodicity. A stationary time series $\{\boldsymbol{X}\}_t$ is geometrically ergodic if there is a function $M(x) < \infty$ and a constant $\rho < 1$ such that for all x:

$$\sup_A |P(X_n \in A|X_0 = x) - \pi(A)| \leq M(x)\rho^n$$

where π is the stationary distribution of $\{\boldsymbol{X}\}_t$. For stationary time series, geometric ergodicity implies α mixing for an $\alpha(n)$ of exponential rate (Davydov, 1973). Sufficient conditions for a nonlinear time series to be geometrically ergodic can be found in Chan and Tong (1994), An and Huang (1996), and Cline and Pu (1999). In particular, Xia and An (1999) provides a set of sufficient conditions for the geometric ergodicity of time series generated by projection pursuit models, of which our additive non-linear model is a special case.

3. A Causal Inference Algorithm

Consider a time series $\{\boldsymbol{X}\}_t = \{\boldsymbol{X}_1, \cdots, \boldsymbol{X}_t, \cdots\}$ are generated from a lag T additive non-linear model. Let $\boldsymbol{X}^l = \{\boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T}\}$, X_t^1 and X_t^2 be any two entries of $\boldsymbol{X}_t$, $\boldsymbol{X}_t^b$ be any subset, possibly empty, of $\boldsymbol{X}_t \setminus \{X_t^1\}$, $\boldsymbol{X}_t^c$ be any subset, possibly empty, of $\boldsymbol{X}_t \setminus \{X_t^1, X_t^2\}$, $X_{t-i,j}$ any variable in $\boldsymbol{X}^l$, and $\boldsymbol{X}^e = \boldsymbol{X}^l \setminus \{X_{t-i,j}\}$. Using additive model regression, we can test two types of conditional independence relations: 1), if X_t^1 and X_t^2 are independent given $\boldsymbol{X}_t^c$ and $\boldsymbol{X}^l$, and 2), if X_t^1 and $X_{t-i,j}$ are independent given $\boldsymbol{X}_t^b$ and $\boldsymbol{X}^e$. These pieces of information are not generally sufficient for currently available causal inference algorithms, such as the PC and FCI, to be informative: these procedures require (in the worst case) complete conditional independence information. However, starting from the same principle behind the PC and FCI algorithms, we describe a procedure that requires only these two types of conditional independence information. The procedure, which is capable of producing very informative causal structures, takes advantage of the constraints on possible causal relations among the random variables imposed by additive non-linear models, for example, $X_{t_2,k}$ cannot be a cause of $X_{t_1,j}$ if $t_1 < t_2$, no latent common cause exists for $X_{t_2,k}$ and $X_{t_1,j}$ if $t_1 \neq t_2$, etc.

The following propositions are needed to justify our procedure. We assume familiarity with notions from the graphical modeling literature, including the notion of d-separation (Pearl, 2000), and faithfulness (Spirtes et al., 2000). In summary:

Formally a causal graph G is defined as an ordered pair $\langle \boldsymbol{V}, \boldsymbol{E} \rangle$, where $\boldsymbol{V}$ is the set of variables in G, and $\boldsymbol{E}$ the set of edges in G. An edge e in $\boldsymbol{E}$ is again defined as an ordered pair $\langle V_i, V_j \rangle$, where V_i and V_j are two variables in $\boldsymbol{V}$. Given an edge $e = \langle V_i, V_j \rangle$ in graph G, we say that V_i is a direct cause of V_j in G. The *subgraph G_m induced by $\boldsymbol{V}_m$*, where $\boldsymbol{V}_m$ is a subset of $\boldsymbol{V}$, is defined as an ordered pair $\langle \boldsymbol{V}_m, \boldsymbol{E}_n \rangle$ such that an edge $e = \langle V_i, V_j \rangle$ is in $\boldsymbol{E}_n$ if and only if e is in $\boldsymbol{E}$ and the two variables $\{V_i, V_j\}$ are both in $\boldsymbol{V}_m$. A vertex is a collider on an undirected path in a directed acyclic graph (DAG) if and only if it is the second member of both of two edges on the path, that is, two edges on the path are directed into it. Two vertices X, Y (representing random variables) are d-separated with respect to a set $\boldsymbol{Z}$ of vertices if and only if every undirected path between the variables contains a collider having no directed path into a member of $\boldsymbol{Z}$ or contains a non-collider that is a member of $\boldsymbol{Z}$. A joint distribution on the variables (vertices) of a DAG is faithful if and only if all conditional independence relations follow from the d-separation property applied to the DAG.

In the three propositions below, $\{\boldsymbol{X}_1, \cdots, \boldsymbol{X}_t, \cdots\}$ form a time series generated from a lag T additive non-linear model, $\boldsymbol{X}^l = \{\boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T}\}$, X_t^1 and X_t^2 are any two entries of $\boldsymbol{X}_t$, and $\boldsymbol{X}^e = \boldsymbol{X}^l \setminus \{X_{t-i,j}\}$ for some $X_{t-i,j} \in \boldsymbol{X}^l$

Proposition 2: The d-separation relations among the variables in $\boldsymbol{X}_t$ conditional on $\boldsymbol{X}^l$ in a repetitive causal graph G_c are the same as the d-separation relations among the variables in $\boldsymbol{X}_t$ in the subgraph of G_c induced by $\boldsymbol{X}_t$.

Proof: See Moneta (2003), proposition 4. □

Proposition 3: Consider a time series $\{\boldsymbol{X}\}_t = \{\boldsymbol{X}_1, \cdots, \boldsymbol{X}_t, \cdots\}$ generated from a lag T additive non-linear model. Let $\boldsymbol{X}^l = \{\boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T}\}$, X_t^1 and X_t^2 be any two entries of $\boldsymbol{X}_t$. Assuming faithfulness, if there is a variable $X_{t-i,j} \in \boldsymbol{X}^l$ such that X_t^2 and $X_{t-i,j}$ are independent conditional on $\boldsymbol{X}^e = \boldsymbol{X}^l \setminus \{X_{t-i,j}\}$, but $X_{t-i,j}$ and X_t^1 are not independent conditional on $\boldsymbol{X}^e$, then X_t^1 is not a cause of X_t^2.

Proof: Suppose X_t^1 is a cause of X_t^2, then there must be a directed path P' from X_t^1 to X_t^2 such that each vertex on P' is in $\boldsymbol{X}_t$. If $X_{t-i,j}$ and X_t^1 are dependent given $\boldsymbol{X}^e$, there must be a path P d-connecting $X_{t-i,j}$ and X_t^1 given $\boldsymbol{X}^e$. Thus, no variable in $\boldsymbol{X}^e$ is a non-collider on path P, and all the colliders on path P must be observed ancestors of $\boldsymbol{X}^e$, hence must be in $\boldsymbol{X}^e$. (Note that the set of observed ancestors of $\boldsymbol{X}^e$ is either $\boldsymbol{X}^e$ or $\boldsymbol{X}^e \cup \{X_{t-i,j}\}$). This implies that P must be into X_t^1, because otherwise either P would be a direct path from X_t^1 to $X_{t-i,j}$, which is not allowed, or there must be a collider on P that is both a descendant of X_t^1 and an element of $\boldsymbol{X}^e$, which also is impossible. By appending the direct path P' to P, we get a path d-connecting $X_{t-i,j}$ and X_t^2 given $\boldsymbol{X}^e$, which is a contradiction. □

Proposition 4: Consider a time series $\{\boldsymbol{X}\}_t = \{\boldsymbol{X}_1, \cdots, \boldsymbol{X}_t, \cdots\}$ generated from a lag T additive non-linear model. Let $\boldsymbol{X}^l = \{\boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T}\}$, X_t^1 be any entry of $\boldsymbol{X}_t$, $X_{t-i,j}$ be any variable in $\boldsymbol{X}^l$, $\boldsymbol{X}_t^d$ be the set of all observed contemporary direct causes of X_t^1, and $\boldsymbol{X}^e = \boldsymbol{X}^l \setminus \{X_{t-i,j}\}$. Assuming faithfulness, $X_{t-i,j}$ and X_t^1 are dependent conditional on $\boldsymbol{X}_t^d$ and $\boldsymbol{X}^e$ if and only if:

- either $X_{t-i,j}$ is a direct cause of X_t^1,
- or there is a path P between X_t^1 and $X_{t-i,j}$, with $\langle W_1, \cdots, W_m \rangle$ being the set of observed variables on P between X_t^1 and $X_{t-i,j}$ and ordered along the direction from X_t^1 to $X_{t-i,j}$, such that:
  1. $W_i \in \boldsymbol{X}_t$ for $i = 1, \cdots, m$;
  2. X_t^1 and W_1 have a latent common cause;
  3. if $W_i \in \boldsymbol{X}_t^d$ then W_i is a collider on P;
  4. W_i is a (possibly indirect) cause of X_t^1 for $i = 1, \cdots, m$;
  5. $X_{t-i,j}$ is a direct cause of W_m.

Proof: The *if* part of the proposition is trivial, here we only prove the *only if* part.

Suppose $X_{t-i,j}$ is not a direct cause of X_t^1, then there is a path P d-connecting $X_{t-i,j}$ and X_t^1 conditional on $\boldsymbol{X}_t^d$ and $\boldsymbol{X}^e$. Let $\boldsymbol{W} = \langle W_1, \cdots, W_m \rangle$ be the set of observed variables on P between X_t^1 and $X_{t-i,j}$, ordered along the direction from X_t^1 to $X_{t-i,j}$.

To show that $W_i \in \boldsymbol{X}_t$ for $i = 1, \cdots, m$, we note that if W_j is the first element in $\boldsymbol{W}$ such that $W_j \notin \boldsymbol{X}_t$, it must belong to $\boldsymbol{X}^e$, where W_{j-1} is in $\boldsymbol{X}_t$. Because there is no observed variable between W_{j-1} and W_j on P, by the definition of additive non-linear models, there must be a direct edge from W_j to W_{j-1} on P (let $X_t^1 = W_0$ when $j = 1$). This means that W_j is not a collider on P, hence P cannot d-connect X_t^1 and $X_{t-i,j}$ conditional on $\boldsymbol{X}^e$ and $\boldsymbol{X}_t^d$, which contradicts our assumption. Using the same argument, given that $W_m \in \boldsymbol{X}_t$, it is easy to see that $X_{t-i,j}$ must be a direct cause of W_m.

Next we show that W_1 and X_t^1 must have a latent common cause. Assume that there is no latent common cause for W_1 and X_t^1. Because there is no observed variable between W_1 and X_t^1 on P, they must be adjacent on P, hence there must be a direct causal relation between X_t^1 and W_1. Consider the two alternative cases:

- First, suppose that W_1 is a direct cause of X_t^1. Then $W_1 \in \boldsymbol{X}_t^d$, and is a non-collider on P, hence P cannot d-connecting $X_{t-i,j}$ and X_t^1 conditional on $\boldsymbol{X}_t^d$ and $\boldsymbol{X}^e$.

- Second, suppose X_t^1 is a direct cause of W_1. Then there must be a variable W_i for some $i \geq 1$ such that the subpath $\{X_t^1, W_1, \cdots, W_i\}$ of P is a directed path from X_t^1 to W_i, and W_i is a collider on P. This would imply that W_i has to be a cause of X_t^1, for otherwise neither W_i nor any of its descendants belong to $\boldsymbol{X}_t^d$, which means that P cannot d-connect X_t^1 and $X_{t-i,j}$ conditional on $\boldsymbol{X}^e$ and $\boldsymbol{X}_t^d$. But allowing W_i to be a cause of X_t^1 would make the path $X_t^1, W_1, \cdots, W_i, X_t^1$ a directed cycle, which is impossible.

It is obvious that if $W_i \in \boldsymbol{X}_t^d$, then it must be a collider on P. To show that W_i is a cause of X_t^1, we note that if W_j is a collider on P, it must be a cause of X_t^1, for otherwise neither W_j nor any of its descendants belongs to $\boldsymbol{X}_t^d$, hence P cannot d-connect X_t^1 and $X_{t-i,j}$ conditional on $\boldsymbol{X}^e$ and $\boldsymbol{X}_t^d$. Therefore W_i must be a cause of X_t^1, because it is either a collider on P, or a cause of a collider on P. □

Given propositions 2, 3, and 4, we propose a three-step procedure for inference to unit causal graphs from time series data generated by additive non-linear models. The output of this causal inference procedure is a Partial Ancestral Graph (PAG). Roughly speaking, a PAG is a graph consisting of a list of vertices representing observed random variables, and 3 types of end points, $-$, $\circ$, and $>$, which are combined to form the following 4 types of edges representing causal relations between random variables.

- $X \to Y$ means that X is a (possibly indirect) cause of Y.
- $X \leftrightarrow Y$ means that there is a latent variable Z that is a (possibly indirect) cause of both X and Y.
- $X \circ\!\!\to Y$ means either $X \to Y$ or $X \leftrightarrow Y$.
- $X \circ\!\!-\!\!\circ Y$ means either $X \to Y$, or $Y \circ\!\!\to X$. In other words, $X \circ\!\!-\!\!\circ Y$ means that X and Y cannot be d-separated by any other observed variables.

For detailed explanation of PAGs, see Spirtes et al. (2000). Following Spirtes et al. (2000), we also use * as a meta symbol to represent any of the three end points.

Below is a constraint based additive non-linear time series causal inference procedure for non-linear time series with latent common causes. The conditional independence information required by the procedure can be obtained using additive model regression based conditional independence tests mentioned in the previous section. Here we assume that the time series data satisfies various conditions for the asymptotic consistency and normality of the additive model estimator, and that an upper bound T_{max} on the unknown true lag number T of the additive non-linear model has been set, either using the procedures in Tjøstheim and Auestad (1994) or Huang and Yang (2004), or based on background knowledge. So long as T_{max} is no less than T, the following procedure asymptotically obtains a correct PAG. Of course, choosing a T_{max} much higher than T will reduce the efficiency of the procedure.

The symbols in the following procedure are defined in the same way as in the beginning of this section, except that $\boldsymbol{X}^l$ is redefined as $\boldsymbol{X}^l = \{\boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T_{max}}\}$.

1. Identify contemporary causal relations

   (a) For all choices of X_t^1, X_t^2, and $\boldsymbol{X}_t^c$, determine if X_t^1 is independent of X_t^2 conditional on $\boldsymbol{X}_t^c$ and $\boldsymbol{X}^l$.

(b) Treat the above conditional independence relations as if they were conditional independence relations between X_t^1 and X_t^2 given $\boldsymbol{X}_t^c$.

- Feed these conditional independencies to a causal inference algorithm allowing presence of latent common causes, such as the FCI algorithm. Derive the PAG for the contemporary causal structure among variables in $\boldsymbol{X}_t$. Call this PAG π_t.
- For all choices of X_t^1, identify the set of *possible contemporaneous direct causes* of X_t^1, where X_t^2 is a possible contemporaneous direct cause of X_t^1 if in π_t either $X_t^2 \circ\!\!-\!\!\circ X_t^1$, or $X_t^2 \circ\!\!\rightarrow X_t^1$, or $X_t^2 \rightarrow X_t^1$. Denote by $\mathrm{PCDC}(X_t^1)$ the set of possible contemporaneous direct causes of X_t^1.

2. Identify lagged causal relations.

(a) Create a new graph π_f such that the vertices in π_f are $\{\boldsymbol{X}_t, \boldsymbol{X}_{t-1}, \cdots, \boldsymbol{X}_{t-T}\}$, and the edges in π_f are exactly the same as the edges in π_t.

(b) For all choices of X_t^1, $X_{t-i,j}$, and $\boldsymbol{X}_t^b$, determine if X_t^1 and $X_{t-i,j}$ are independent given $\boldsymbol{X}^e$ and $\boldsymbol{X}_t^b$

- For all choices of X_t^1, identify the set of *possible lagged direct causes* of X_t^1, where a lagged variable $X_{t-i,j}$ is a possible lagged direct cause of X_t^1 if for all $\boldsymbol{X}_t^d \subseteq \mathrm{PCDC}(X_t^1)$, $X_{t-i,j}$ and X_t^1 are dependent given $\boldsymbol{X}_t^d$ and $\boldsymbol{X}^e$. Denote by $\mathrm{PLDC}(X_t^1)$ the set of possible lagged direct causes of X_t^1
- For all choices of X_t^1, identify the set of *permanent lagged predictors* of X_t^1, where $X_{t-i,j}$ is a permanent lagged predictor of X_t^1 if for all $\boldsymbol{X}_t^b \subseteq (\boldsymbol{X}_t \setminus \{X_t^1\})$, $X_{t-i,j}$ and X_t^1 are dependent given $\boldsymbol{X}_t^b$ and $\boldsymbol{X}^e$. Denote by $\mathrm{PLP}(X_t^1)$ the set of permanent lagged predictors of X_t^1

(c) Add edges representing the lagged causes of each variable in $\boldsymbol{X}_t$ to π_f:

i. For all choices of X_t^1, add an edge $X_{t-i,j} \rightarrow X_t^1$ to π_f if $X_{t-i,j} \in \mathrm{PLP}(X_t^1)$.

ii. For all choices of X_t^1, add an edge $X_{t-i,j} \rightarrow X_t^1$ to π_f if $X_{t-i,j} \in \mathrm{PLDC}(X_t^1)$, and $X_{t-i,j}$ is not adjacent to any other variable in π_f.

3. Orient the contemporary PAG according to the following rule:

(a) Repeat the following procedure until no more changes can be made to π_f.

i. If $X_{t-i,j} \rightarrow X_t^1 \circ\!\!-\!\!* X_t^2$ is in π_f, and $X_{t-i,j}$ and X_t^2 are not adjacent, then:
If $X_{t-i,j}$ and X_t^2 are independent given $\boldsymbol{X}^e$, but dependent given X_t^1 and $\boldsymbol{X}^e$, then orient the edge between X_t^1 and X_t^2 as $X_t^1 \leftarrow\!\!* X_t^2$

ii. If $X_{t-i,j} \rightarrow X_t^1 \circ\!\!-\!\!* X_t^2$ is in π_f, and $X_{t-i,j}$ and X_t^2 are not adjacent, then:
If $X_{t-i,j}$ and X_t^2 are dependent conditional on $\boldsymbol{X}^e$, but independent conditional on X_t^1 and $\boldsymbol{X}^e$, then orient the edge between X_t^1 and X_t^2 as $X_t^1 \rightarrow X_t^2$

(b) Apply the orientation step of FCI algorithm to further orient the contemporary PAG π_f.

Proposition 2 provides justification for the first step in this procedure, proposition 3 the third step. Proposition 4 is needed for the second step, as we can see that the set of contemporaneous direct causes of a variable X_t^1 is a subset of $\mathrm{PCDC}(X_t^1)$, thus by proposition 4 we have:

$$\text{Lagged direct causes of } X_t^1 \subseteq \text{PLP}(X_t^1) \subseteq \text{PLDC}(X_t^1) \subseteq \text{Lagged causes of } X_t^1$$

Note that step 2(c) is designed to make the procedure more robust.

The complexity of the above procedure is primarily determined by step 1(a), where $k2^{k-1}$ additive model regressions are performed to test the conditional independence relations required by the later steps.

We want to emphasize that the above procedure can be modified in various ways to accommodate changes in the assumptions about the time series data generating models. In the last section (Section 6) of this paper, we discuss in details about different extensions of the above procedure.

4. Simulation Study

In this section, we conduct a simple simulation study to evaluate the performance of the additive non-linear causal inference algorithm presented in Section 3. In particular, we would like to see if the additive non-linear algorithm can provide a viable solution to the problem of nonlinear time series causal inference. For comparison, we also apply a causal inference procedure designed for linear time series to the simulated data. Because there is no currently available efficient *automated* causal inference algorithm for linear time series with contemporaneous causal relations, the linear procedure used for comparison actually is an extension of our additive non-linear causal inference procedure under the assumption that the time series data are generated from linear models. (Bessler et al. 2002, Demiralp and Hoover 2003, Moneta 2003 and Hoover 2005 discussed efficient ways of identifying the contemporaneous causal pattern, that is, the Markov equivalence classes (MEC) of the causal graphs for contemporaneous variables assuming causal sufficiency. However, their procedures are not complete because, when the MEC consists of multiple contemporaneous causal graphs, these procedures all require further background information to uniquely identify the contemporaneous causal graph before proceeding to derive the causal pattern for both contemporaneous and lagged variables. Oxley et al. (2004) provides a less efficient algorithm for linear time series that treats a k-dimensional lag p structural vector autoregressive model (SVAR(p)) as a linear causal model with $k(p+1)$ variables.) The linear procedure differs from the additive non-linear algorithm only in step 1: unlike the original algorithm which uses additive regression to test conditional independence, the linear procedure uses linear regression instead.

We use the Mersenne Twister algorithm implemented in java package RngPack (version 1.1a) for random number generation, and the `gam` function in the R package gam (version 0.97) for additive model regression.

The simulated data are generated from the four causal structures shown in Figure 2. Note that in this simulation study the true PAGs happen to have no circles, and can be represented by the same graphs in Figure 2. The chain-like contemporaneous causal structure is chosen to evaluate the ability of our algorithm to identify the direction of those contemporaneous causal relations that could not be detected using previous algorithms (Bessler et al., 2002; Demiralp and Hoover, 2003; Moneta, 2003; Hoover, 2005). For each causal structure, we consider the following four types of models, characterized by the type of functional relations between an effect variable and its direct causes:

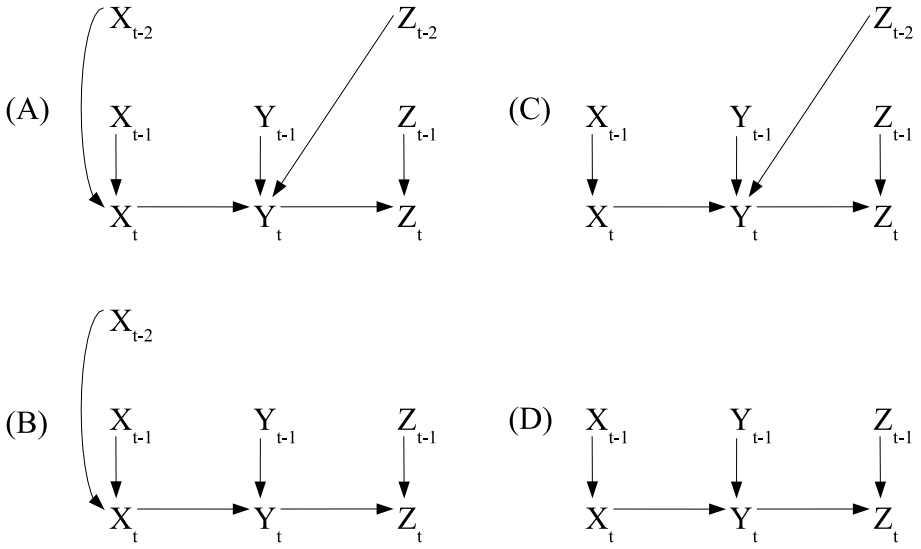

Figure 2: Causal graphs and true PAGs of simulation data

- Trigonometric lag models: Each contemporaneous variable is a linear combination of other contemporaneous variables and univariate trigonometric functions of lagged variables. For example, in one model, we have:

$$Y_t = 0.5X_t + \sin(2Y_{t-1}) - \cos(10Z_{t-2}) + \varepsilon_Y.$$

- Polynomial lag models: Each contemporaneous variable is a linear combination of other contemporaneous variables and univariate polynomial functions of lagged variables. For example, in one model, we have:

$$Y_t = 0.5X_t + 0.3Y_{t-1}^2 - 0.1Z_{t-2}^3 + \varepsilon_Y.$$

- Linear lag models: Each contemporaneous variable is a linear combination of other contemporaneous variables and lagged variables. For example, in one model, we have:

$$Y_t = 0.5X_t + 0.3Y_{t-1} - 0.1Z_{t-2} + \varepsilon_Y.$$

- Trigonometric contemporaneous models: Each contemporaneous variable is a linear combination of univariate trigonometric functions of other contemporaneous variables and lagged variables. For example, in one model, we have:

$$Y_t = \cos(X_t) + \sin(2Y_{t-1}) - \cos(10Z_{t-2}) + \varepsilon_Y.$$

Note that these models do not belong to the family of additive non-linear time series models, for they violate the assumption C1.

In total we have 16 data generating models, with 12 of them being additive non-linear time series models (including 4 linear time series models). For each of the 16 models, we generate 4 random time series data sets of length 200, 500, 1000, and 2000 respectively. For each data set, we run both the additive non-linear procedure and the linear procedure. The upper bound T_{max} of the true lag number T is set to 3 for all simulations, (T is equal to 2 for 12 of the data generating models based on casual structure (A), (B), and (C) in Figure 2, and 1 for the other 4 models based on casual structure (D)). The learned PAGs are compared with the true PAGs, which are also represented by the graphs in Figure 2.

The additive non-linear procedure presented in Section 3 requires, for each contemporaneous variable, say X_t, the following two types of conditional independence information: (1) if X_t is independent of another contemporaneous variable, say Y_t, given all the lagged variables $\boldsymbol{L} = \{X_{t-2}, X_{t-1}, Y_{t-2}, Y_{t-1}, Z_{t-2}, Z_{t-1}\}$ and a subset of the remaining contemporaneous variables, say, $\{Z_t\}$; and (2), if X_t is independent of a lagged variable, say X_{t-1}, given all the other lagged variables and a subset of contemporaneous variables, say, $\{Z_t\}$. These conditional independence relations are tested by checking if $\mathrm{E}[X_t|\boldsymbol{L}, Z_t]$ is constant in Y_t or X_{t-1} respectively. For example, to test if X_{t-1} is present in $\mathrm{E}[X_t|\boldsymbol{L}, Z_t]$, we follow Huang and Yang (2004) by starting from a model A, where X_t is regressed against $\boldsymbol{L}$ and Z_t, and searching for a submodel of A with the lowest BIC score. If X_{t-1} is present in this submodel with lowest BIC score, it is present in $\mathrm{E}[X_t|\boldsymbol{L}, Z_t]$. Otherwise, it is not.

The simulation results are summarized in Figure 3. Each of the four panes in Figure 3 summarizes the results of 16 simulated time series data sets generated from the same type of models. We use the average error rates to evaluate the performance of the two algorithms. The definitions of the various error rates are similar to those in Spirtes and Meek (1995). Consider a p dimensional time series data. An edge omission error occurs when two variables are adjacent in the true PAG but not in the learned PAG. An edge commission error occurs when two variables are adjacent in the learned PAG but absent in the true PAG.

The edge omission error rate is defined as:

$$E_o = \frac{\text{Number of edge omission errors}}{\text{Number of edges in the true PAG}}.$$

The edge commission error rate is defined as:

$$E_c = \frac{\text{Number of edge commission errors}}{\text{Maximum number of possible edge commission errors}}.$$

When inferring causal structure from a p dimensional time series data set, if the upper bound of the true lag number is set to T_{max}, the maximum number of possible edge commission errors is equal to:

$$p^2 T_{max} + \frac{p(p-1)}{2} - \text{Number of edges in the true PAG}$$

where $p^2 T_{max} + p(p-1)/2$ is the maximum number of edges can be found in the unit causal graph for any p-dimension lag T_{max} time series model.

The solid lines in each pane of Figure 3 represent the average omission error rates for different time series lengths; the dotted lines represent the average commission error rates. Blue lines with

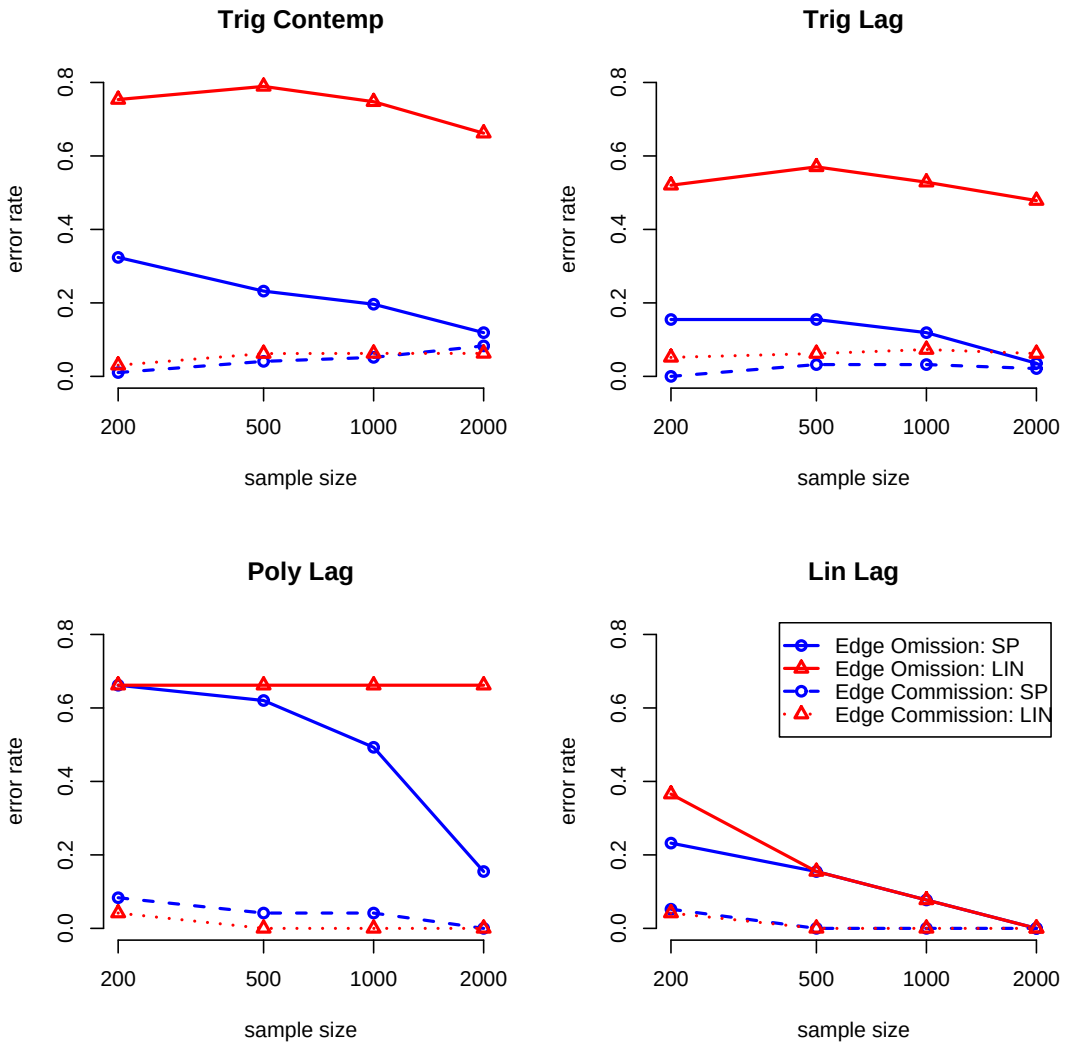

Figure 3: Error rate for edge discovery

circles represent results obtained by the additive non-linear algorithm, red lines with triangles the results by the linear procedure.

The pane with label "Trig Contemp" gives the results for data generated from the *trigonometric contemporaneous models*. We choose these models in the simulation study precisely because they lie outside of the family of additive non-linear time series models, for they violate the functional assumption (C1) in the definition of additive non-linear time series models. The simulation results suggest that, when the assumption C1 is violated, the additive non-linear algorithm can still discover most of the edges. However, as the length of time series increases, the average number of extra edges also increases, apparently because the data generating models are not additive non-linear time series models. The linear procedure is not satisfactory, missing most of the edges in the true models.

The panes labeled with "Trig Lag" and "Poly Lag" show the results for *trigonometric lag models* and *polynomial lag models*, both of which are genuine additive non-linear time series models. The additive non-linear algorithm performs very well for the trigonometric lag models, but less than satisfactory for polynomial lag models. Its performance for polynomial lag models, however, does improve as the length of time series increases. The linear procedure performs poorly in both cases, missing at least half of the edges.

The pane with label "Lin Lag" provides the results for *linear lag models*. Given that a linear lag model is simply a linear time series model, which is a special case of additive non-linear time series model, we expect that both algorithms should perform very well, as they do. This, on the one hand, suggests that the linear procedure is a good choice for linear time series causal inference, on the other hand, implies that the additive non-linear algorithm does not suffer from overfitting.

We also compare the average error rates for orientation of the edges among contemporaneous variables by the additive non-linear algorithm and the linear procedure. Suppose X_t and Y_t are adjacent in both the learned PAG and the true PAG, an arrowhead omission error occurs if the edge is oriented as $X_t *\!\!\rightarrow Y_t$ in the true PAG, but as $X_t *\!\!-\!\!* Y_t$ or $X_t *\!\!-\!\!\circ Y_t$ in the learned PAG. Similarly, an arrowhead commission error occurs if the edge is oriented as $X_t -\!\!* Y_t$ or $X_t \circ\!\!-\!\!* Y_t$ in the true PAG, but as $X_t \leftarrow\!\!* Y_t$ in the learned PAG. Let E be the set of edges among contemporaneous variables in the true PAG such that the pairs of variables connected by these edges are also adjacent in the learned PAG. The arrowhead omission error rate is defined as:

$$A_o = \frac{\text{Number of arrowhead omission errors}}{\sum_{e \in E} \text{Number of arrowheads in } e}.$$

The arrowhead commission error rate is defined as:

$$A_c = \frac{\text{Number of arrowhead commission errors}}{\sum_{e \in E} \text{Number of non-arrowheads in } e}.$$

In Figure 4, the solid lines in each pane represent the average *arrowhead omission error rates*; the dotted lines represent the average *arrowhead commission error rates*. As in Figure 3, blue lines with circles represent results obtained by the additive non-linear algorithm, red lines with triangles the results by the linear procedure. (Note that in the top two panels labeled respectively with "Trig Contemp" and "Trig Lag", the lines representing omission error and commission error for the additive non-linear algorithm overlap. In the bottom two panels labeled respectively with "Poly Lag" and "Lin Lag", the lines representing commission error for the additive non-linear algorithm and the linear algorithm overlap.)

There are two more scores to measure how close a learned PAG is to the true PAG, that is, the tail omission error rate and the tail commission error rate. Suppose X_t and Y_t are adjacent in both the learned PAG and the true PAG, a tail omission error occurs if the edge is oriented as $X_t \rightarrow Y_t$ in the true PAG, but as $X_t \circ\!\!-\!\!* Y_t$ in the learned PAG. A tail commission error occurs if the edge is oriented as $X_t \circ\!\!-\!\!* Y_t$ in the true PAG, but as $X_t \rightarrow Y_t$ in the learned PAG. Note that these definitions are stated so that an arrowhead commission/omission error will not be counted again as a tail omission/commission error. Because there is no circle in the true PAGs in this simulation study, we can only compute the tail omission errors for the learn PAGs, shown in Figure 5. The tail omission error rate is defined as:

$$T_o = \frac{\text{Number of tail omission errors}}{\sum_{e \in E} \text{Number of tails in } e}.$$

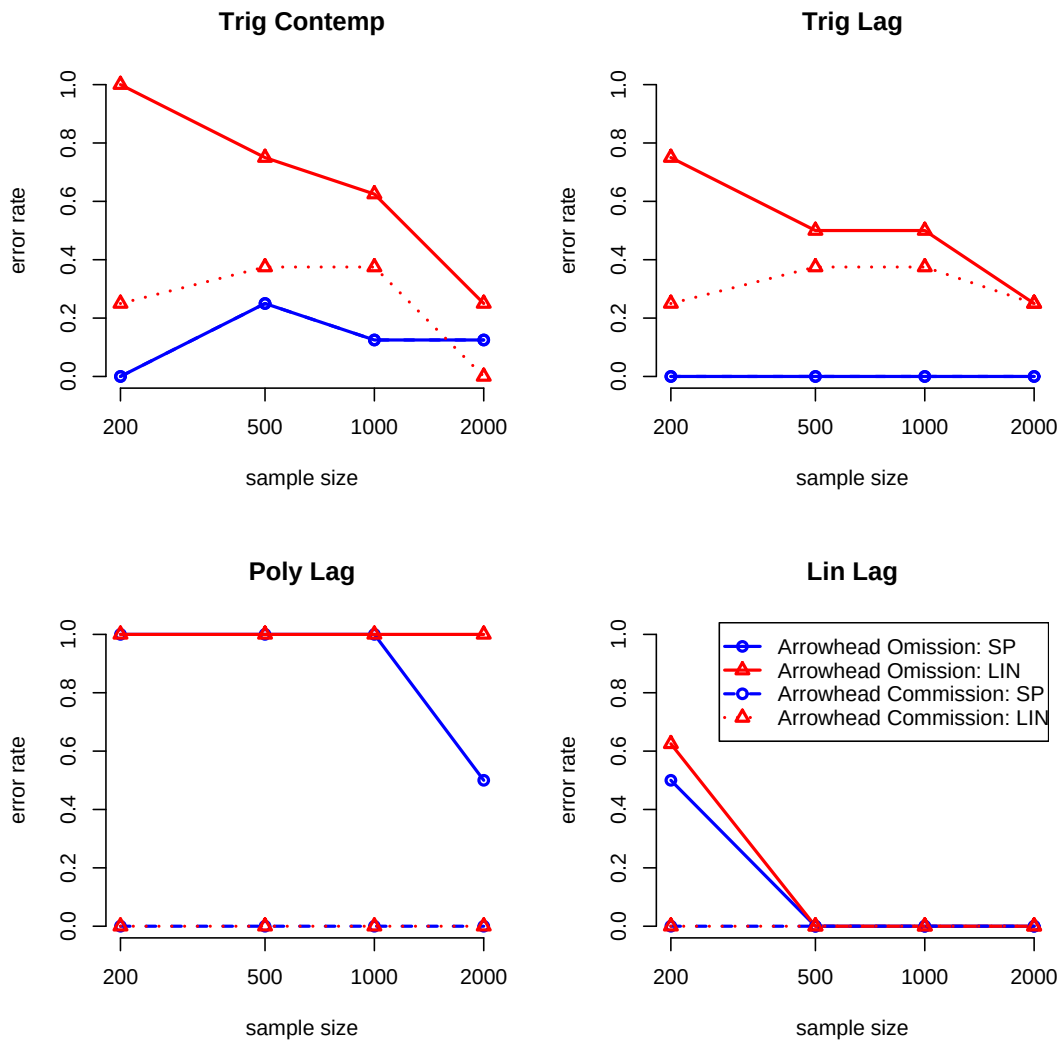

Figure 4: Error rate for edge orientation: Arrowhead

The additive non-linear algorithm gives excellent results. For example, for the data sets generated from additive non-linear models, that is, the trigonometric lag models, the polynomial lag models, and linear lag models, the additive non-linear algorithm makes no arrowhead commission errors. The linear procedure performs quite well for polynomial lag models and linear lag models.

Although the scope of this simulation study is very limited, we can get some general idea about the performance of our additive non-linear casual inference algorithm. If we count the number of variables in a p dimensional lag T additive non-linear time series model as $p(T+1)$, then roughly speaking, for longer time series, (80 or more observations per variable), the additive non-linear algorithm outperforms the linear procedure in all situations, including cases where the true model is more complex than the additive non-linear model and cases where the true model is a linear model.

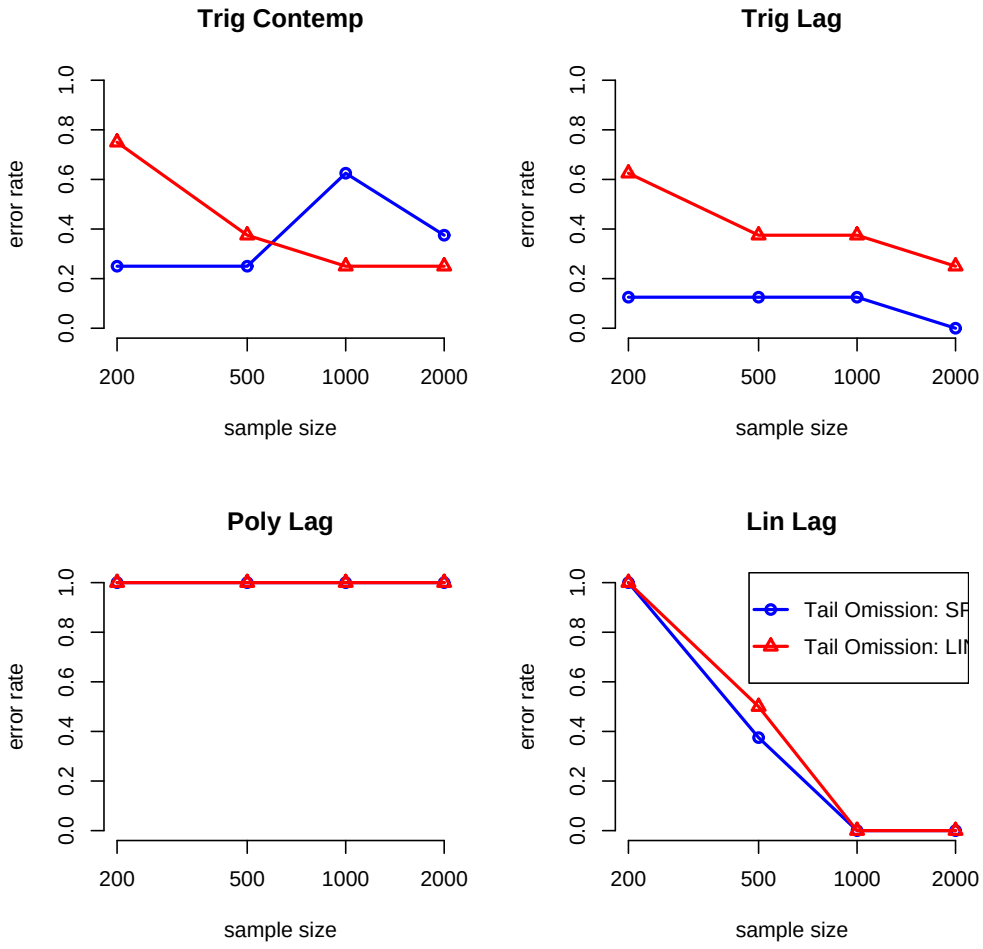

Figure 5: Error rates for edge orientation: Tail

For shorter time series, (less than 40 observations per variable), the additive non-linear model is still better in general, but may be not as good as the linear procedure in some cases. Our suggestion is that, for longer time series always choose the additive non-linear algorithm. For shorter time series, if computational cost is critical, the linear procedure is a reasonable choice; otherwise we still recommend the additive non-linear algorithm, or better yet, try both of them.

5. Case Study: Ocean Climate Indices

To illustrate the application of the additive non-linear causal inference algorithm for nonlinear time series, we use it to study the causal relations among some ocean climate indices.

Climate teleconnections are associations of geospatially remote climate phenomena produced by atmospheric and oceanic processes. The most famous, and first established teleconnection, is the association of the El Nino/Southern Oscillation (ENSO) with the failure of monsoons in India. A variety of associations have been documented among sea surface temperatures (SST), atmospheric pressure at sea level (SLP), land surface temperatures (LST) and precipitation over land areas. Since the 1970s data from a sequence of satellites have provided monthly (and now daily) measurements of such variables, at resolutions as small as 1 square kilometer. Measurements in particular spatial regions have been clustered into time indexed indices for the regions, usually by principal components analysis, but also by other methods. Climate research has established that some of these phenomena are exogenous drivers of others, and has sought physical mechanisms for the teleconnections. We consider here whether constraints on such mechanisms can be obtained by data-driven model selection from time series of ocean indices.

Our data set consists of the following 4 ocean climate indices, recorded monthly from 1958 to 1999, each forming a time series of 504 time steps:

SOI Southern Oscillation Index: Sea Level Pressure (SLP) anomalies between Darwin and Tahiti

WP Western Pacific: Low frequency temporal function of the 'zonal dipole' SLP spatial pattern over the North Pacific.

AO Arctic Oscillation: First principal component of SLP poleward of 20° N

NAO North Atlantic Oscillation: Normalized SLP differences between Ponta Delgada, Azores and Stykkisholmur, Iceland

To check stationarity, we conduct the augmented Dickey-Fuller (ADF) test. ADF tests for all 4 time series reject the null hypothesis that the tested series has a unit root against the alternative that the series is stationary, with p values of the tests smaller than 0.01. As a complementary to ADF tests, we also conduct the Kwiatkowski-Phillips-Schmidt-Shin (KPSS) test. For all 4 time series, KPSS tests with lag truncation parameter set to 12 fail to reject the null hypothesis that the tested series is (trend) stationary against the unit root alternative, with p values of the tests higher than 0.1. We also plot the autocorrelations for the 4 time series to check if the data satisfies the strong mixing condition (Figure 6). The idea is that, if a time series satisfies the strong mixing condition, its autocorrelation should decrease rapidly as the lag increases. From the plot, the auto correlations of SOI do not decrease as quickly as for other indices, but they become insignificant when the lag is above 12 months.

We assume that the 4 indices are generated from a lag 12 additive non-linear model. The choice of 12 is partly based on the fact that the ocean indices are monthly data. Another concern is that with a length of 504, the data would be too sparse for a model with a much longer lag. As in the simulation study, the R package gam (version 0.97) is used in this analysis. We first remove any linear trend from the data, then, following the causal inference procedure presented in Section 3, derive a causal structure represented by a PAG for the 4 ocean climate indices. Figure 7 gives the learned causal structure.

Because of the relative shorter length of the ocean indices data (10 observations per variable for a lag 12 model), it is worth conducting another inference on the 4 ocean indices using the linear procedure. The resulting causal structure is given in Figure 8.

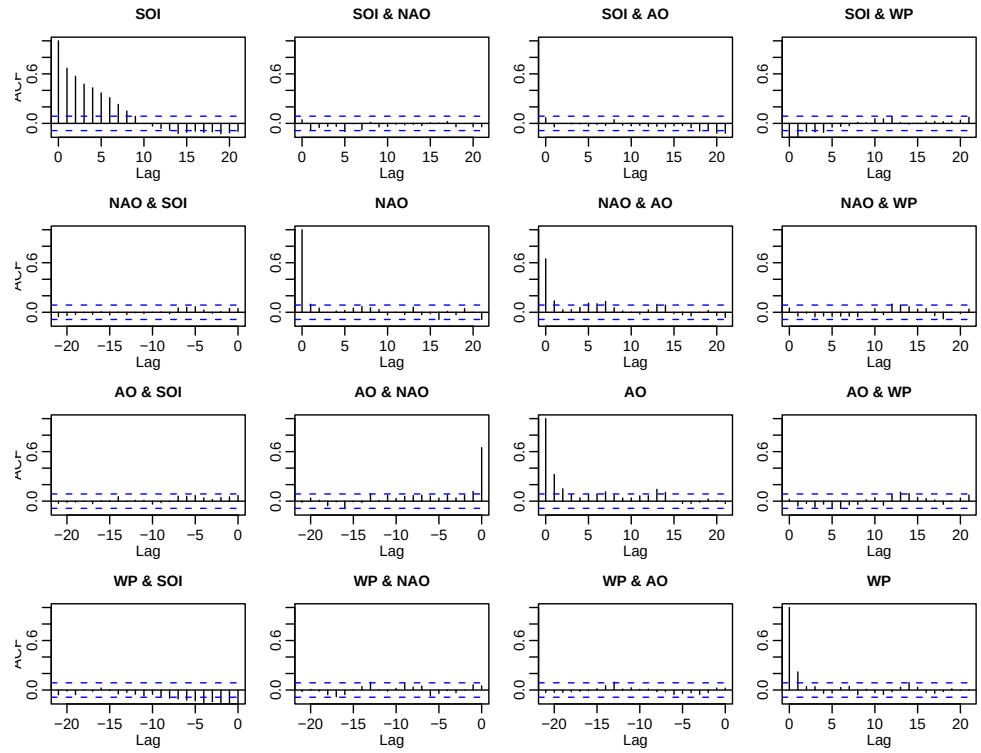

Figure 6: Autocorrelation plot for 4 times series

Without a gold standard, it is hard to say which method gives the more accurate information in this case. But the graph obtained using the linear procedure is likely to miss some nonlinear dependencies. For example, an arrow from SOI_{t-1} to AO_t is present in Figure 7, but absent from Figure 8. It turns out, when regressing AO_t against SOI_{t-1}, AO_{t-1} and NAO_{t-1} using additive model regression, the estimated influence of SOI_{t-1} on AO_t is clearly nonlinear (see Figure 9, where the contribution of SOI_{t-1} to AO_t is plotted as a smooth univariate function of SOI_{t-1}). This is not surprising given the complexity of the processes represented by the ocean climate indices, and illustrates the need of causal inference procedures that can be applied to data generated from nonlinear models.

6. Discussion

Methods of causal inference, first developed in the machine learning literature, have been successfully applied to many diverse fields, including biology, medicine, and sociology (Pearl, 2000; Spirtes et al., 2000). An essential and distinct feature of these methods is that they require comparatively less domain knowledge about the system to be studied.

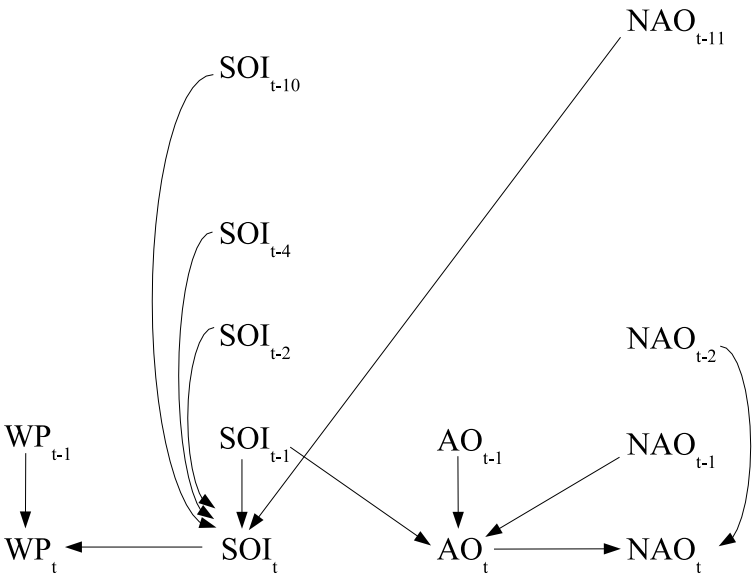

Figure 7: Causal connections among 4 ocean climate indices, using the additive non-linear algorithm

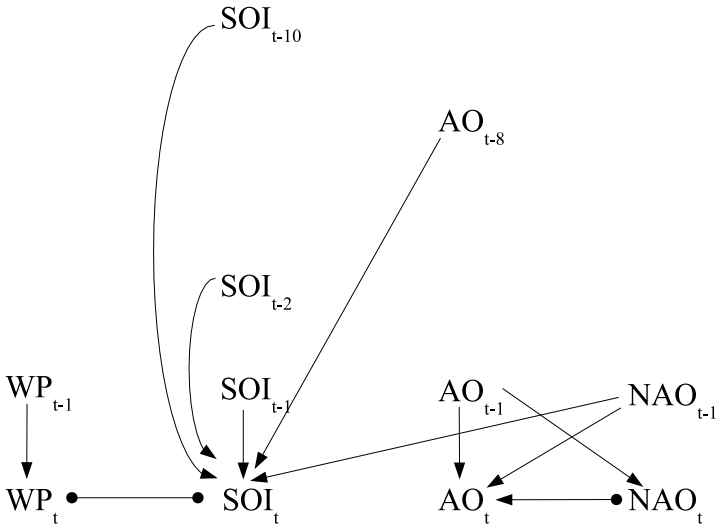

Figure 8: Causal connections among 4 ocean climate indices, using the linear procedure

This study extends the application of causal inference to nonlinear time series data. We present a new procedure that combines semi-automated model search for causal structure with additive

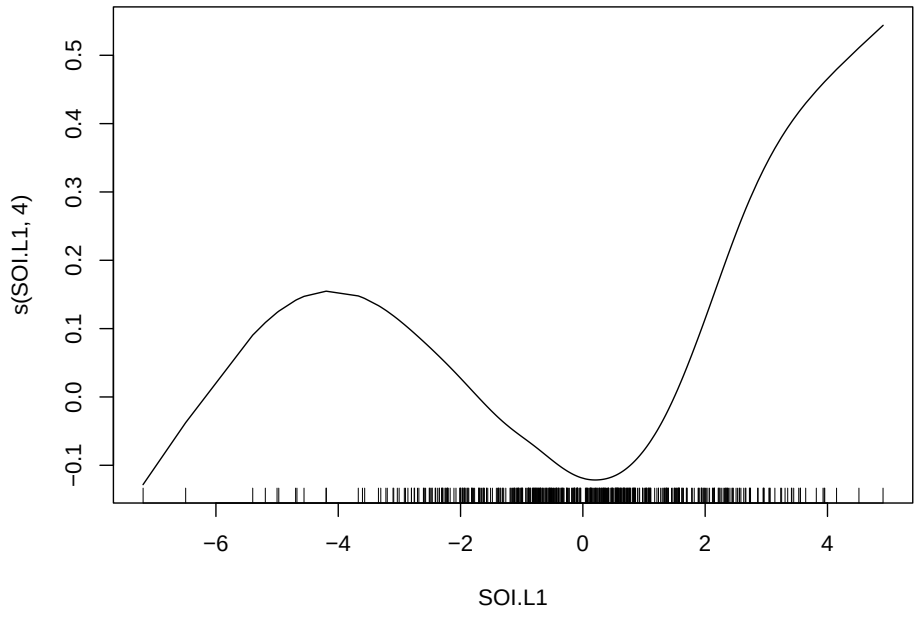

Figure 9: Nonlinear relation between SOI_{t-1} and AO_t

model regression methods. The particular example is to ocean climate indices, but the component procedures have been individually applied to econometric data with some success, suggesting that the criteria for successful application of the joint procedures are statistical and causal rather than domain specific.

Our approach is modular, and its two main components, that is, conditional independence testing and causal model search, could be replaced by other comparable methods. Thus, with appropriate data generated from appropriate mechanisms, related analyses could be conducted under weaker or alternative assumptions. Below we briefly discuss several possible extensions of our method:

6.1 Nonstationary Nonlinear Time Series

In most of this paper we assume that the nonlinear time series are stationary, only because it has been shown that for stationary nonlinear time series data satisfying certain conditions, nonparametric regression is asymptotically consistent. The algorithm and propositions proposed in this paper do not require stationarity. However, to apply our algorithm to nonstationary nonlinear time series data, we must find an efficient regression method to estimate the conditional expectations and conduct conditional independence tests. Cointegration analysis is not suitable for this purpose, because it is mainly designed for and applicable to cointegrated linear time series (Engle and Granger, 1987; Johansen, 1991). However, recent studies on applying nonparametric regression methods to nonstationary time series data (Phillips and Park, 1998; Karlsen and Tjøstheim, 2001; Bandi and Phillips, 2003; Karlsen et al., 2005) seem promising. Not surprisingly, the convergence rate of nonparametric regression for nonstationary time series data may be slower than that of stationary data.

6.2 Feedback Models

The original definition of additive non-linear models in Section 2 does not allow any feedback among contemporaneous variables (see condition C4). To represent mutual influences among contemporary variables, we can remove condition C4 from the original definition. We also have to drop the U terms in Equation 2 because the currently available algorithm capable of handling feedbacks (Richardson and Spirtes, 1999) does not work in the presence of latent common causes. The resulting definition defines a *additive non-linear feedback model*, which, compared to the additive non-linear model, allows feedback, but not latent common causes. Propositions 1, 2, and 3 still hold for the new model, proposition 4 needs some modification:

Proposition 4': Let $\boldsymbol{X}_t^b$ be the set of all contemporary direct causes of X_t^1. Assuming there is no latent common cause, $X_{t-i,j}$ and X_t^1 are dependent conditional on $\boldsymbol{X}_t^b$ and $\boldsymbol{X}^e$ if and only if either $X_{t-i,j}$ is either a direct cause of X_t^1, or a direct cause of a contemporaneous cause of X_t^1.

The only change needed in the causal inference procedure to handle data generated from additive non-linear feedback models is, in step 1(b), that the FCI algorithm should be replaced by a consistent causal inference algorithm capable of outputting cyclic graphs, such as the one proposed in Richardson and Spirtes (1999).

6.3 Score Based Search Procedure

The causal inference procedure presented in Section 3 is constraint based. That is, the procedure requires explicit conditional independence information as input, (although each conditional independence constraint is obtained using a BIC score based model selection procedure). As we mentioned in Section 3, the main advantage of this procedure and its modified version is that they can handle the presence of latent common causes or feedbacks in the contemporaneous causal structure. (Drton et al. 2006 provides a maximum likelihood estimation algorithm that allows the computation of BIC scores for certain types of linear models with correlated error terms, though not for the contemporaneous causal structure of a additive non-linear model.) If we are willing to exclude feedbacks and latent common causes, a simple two-step score based procedure can be used to infer causal information from data generated by additive non-linear models. In the first step, a score based algorithm, such as the GES algorithm (Meek, 1996; Chickering, 2002a,b), is applied to the residuals of additive model regression of contemporaneous variables against all lags to obtain a causal pattern representing a Markov equivalence class π_t of directed acyclic graphs for the contemporaneous variables. In the second step, for each directed acyclic graph G belonging to the Markov equivalence class π_t, we generate a time series causal model M and compute its BIC score in the following way:

- Each contemporaneous variable X_t^i is regressed against its parents in G and all the lagged variables $\boldsymbol{X}^l$. The BIC score method proposed in Huang and Yang (2004) is used to identify the best submodel (with the lowest BIC score s_i). The significant predictors of X_t^i in that best submodel are direct causes of X_t^i in causal model M.

- The BIC score of causal model M is $\sum_i s_i$.

The causal model with the best (lowest) BIC score then is returned as the result of the score based casual inference algorithm.

Acknowledgments

The authors thank the anonymous referees for their helpful comments to improve this paper. Abstract

SHARK is an object-oriented library for the design of adaptive systems. It comprises methods for single- and multi-objective optimization (e.g., evolutionary and gradient-based algorithms) as well as kernel-based methods, neural networks, and other machine learning techniques.

Keywords: machine learning software, neural networks, kernel-methods, evolutionary algorithms, optimization, multi-objective-optimization

1. Overview

SHARK is a modular C++ library for the design and optimization of adaptive systems. It serves as a toolbox for real world applications and basic research in computational intelligence and machine learning. The library provides methods for single- and multi-objective optimization, in particular evolutionary and gradient-based algorithms, kernel-based learning methods, neural networks, and many other machine learning techniques. Its main design criteria are flexibility and speed. Here we restrict the description of SHARK to its core components, albeit the library contains plenty of additional functionality. Further information can be obtained from the HTML documentation and tutorials. More than 60 illustrative example programs serve as starting points for using SHARK.

2. Basic Tools—Rng, Array, and LinAlg

The library provides general auxiliary functions and data structures for the development of machine learning algorithms. The Rng module generates reproducible and platform independent sequences of pseudo random numbers, which can be drawn from 14 predefined discrete and continuous parametric distributions. The Array class provides dynamical array templates of arbitrary type and dimension as well as basic operations acting on these templates. LinAlg implements linear algebra algorithms such as matrix inversion and singular value decomposition.

3. ReClaM—Regression and Classification Methods

The goal of the ReClaM module is to provide machine learning algorithms for supervised classification and regression in a unified, modular framework. It is built like a construction kit, where the main building blocks are adaptive data processing models, error functions, and optimization

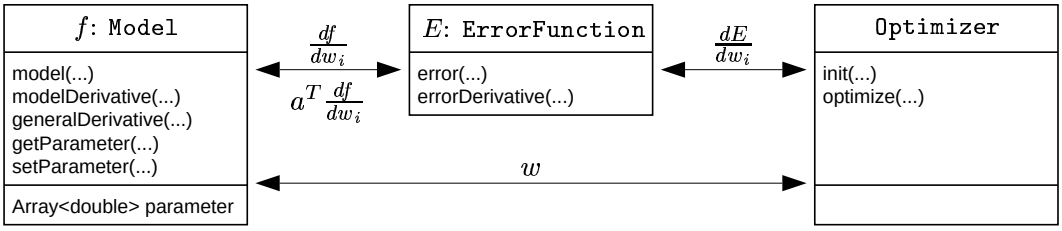

Figure 1: Almost all ReClaM objects are inherited from one of the three base classes `Model`, `ErrorFunction`, and `Optimizer`. The optimizer has access to the parameter vector w of the model $f : \mathbb{R}^n \times \mathbb{R}^p \to \mathbb{R}^m$, $(x, w) \mapsto f_w(x)$, to minimize a scalar error function E. For gradient-based optimization, the error function provides the derivative dE/dw based on df/dw. In many cases we can speed up the computation of dE/dw by a factor of m by using $a^T df/dw$, where a is a vector of coefficients dependent on the error function.

algorithms (see Figure 1). The superclasses representing these components communicate through fixed interfaces. Problem definition and solution are clearly separated. A problem is defined by a model defining a parametric family of candidate hypotheses, and a possibly regularized error function to minimize (and, of course, sample data). It is usually solved with an (iterative) optimization algorithm, which adapts the model parameters in order to minimize the error function evaluated on the given data set. Additional error functions and data sets can then be used to test the resulting performance. This clear structure makes ReClaM easy to use and extend.

ReClaM focuses on kernel methods and neural networks. It offers a variety of predefined network models including feed-forward and recurrent multi-layer perceptron networks, radial basis function networks, and CMACs. Several gradient-based optimization algorithms are available for network training and general purpose optimization including the conjugate gradient method, the BFGS algorithm, and improved Rprop (Igel and Hüsken, 2003).

In the remainder of this section we present the realization of kernel-based learning in more detail. The library offers kernelized versions of several learning machines from nearest neighbor classifiers and simple Gaussian processes to different flavors of support vector machines. These algorithms operate on general kernel objects and users can supply new kernel functions easily. At the time of writing, ReClaM provides the fastest support vector machine (SVM) implementation for dense large-scale learning problems. The SVM training automatically switches between the most efficient SMO-like algorithms available depending on the current problem size (Fan et al., 2005; Glasmachers and Igel, 2006).

On top of these models, ReClaM defines meta-models for model selection of kernel and regularization parameters. It offers more objective functions and optimization methods for model selection than any other library. Objective functions include leave-one-out and cross validation errors, radius-margin quotient, kernel-target alignment, and the span bound (Chapelle et al., 2002; Glasmachers and Igel, 2005; Igel et al., 2007a). For optimization, nested grid-search and evolutionary kernel learning are supported, and efficient gradient-based optimization is available whenever possible. For both model training and model selection, we make use of ReClaM's superclass architecture to describe and solve the optimization problems. For example, a gradient-based optimization algorithm

may decrease a radius-margin quotient in order to adapt the hyperparameters of an SVM, where in each iteration an SVM model is trained by a special quadratic program optimizer to determine the margin.

To reduce the complexity of SVMs and Gaussian processes after training, algorithms for approximating the solutions in feature space are implemented (Romdhani et al., 2004; Suttorp and Igel, 2007).

4. EALib and MOO-EALib—Evolutionary Single- and Multi-objective Optimization

The evolutionary algorithms module (EALib) implements classes for stochastic direct optimization using evolutionary computing, in particular genetic algorithms and evolution strategies (ESs). Evolutionary algorithms (EAs) maintain populations (i.e., multi-sets) of candidate solutions. In the EALib structure, instances of the class `Population` contain instances of `Individual` consisting of one or more `Chromosome`s, which can have different types. Numerous variation (i.e., mutation and recombination) operators for different types of chromosomes, for example real-valued or binary vectors, are available. The user has the choice between many different deterministic and stochastic selection mechanisms operating on population level.

The MOO-EALib extends the EALib to evolutionary multi-objective (i.e., vector valued) optimization (EMO). The goal of EMO is usually to approximate the set of Pareto-optimal solutions, where a solution is Pareto-optimal if it cannot be improved in one objective without getting worse in another one. To our knowledge, the MOO-EALib module makes SHARK one of the most comprehensive libraries for EMO. The efficient implementation of measures for quantifying the quality of sets of candidate solutions is a strong argument for the MOO-EALib.

In SHARK we put an emphasis on variable-metric ESs for real-valued optimization. Thus, the most recent implementation of the covariance matrix adaptation ES (CMA-ES; Hansen et al., 2003) and its EMO counterpart (Igel et al., 2007b) are included. We do not know any C++ toolbox for EAs that comes close to the EALib in terms of flexibility and quality of algorithms for continuous optimization.

5. Availability and Requirements

The C++ source code is available from `http://shark-project.sourceforge.net` under GNU Public License and compiles under MS Windows, Linux, Solaris, and MacOS X. No third-party libraries are required, except Qt and Qwt for graphical examples.

Acknowledgments

The authors of this paper comprise the team responsible for a major revision and the maintenance of the SHARK library at the time of writing the article. The SHARK project was started by M. Kreutz, who wrote the basic components such as LinAlg, Array, and Rng as well as the EALib. Then B. Sendhoff joined the project, which was fused with C. Igel's ReClaM library. Afterwards, many people contributed to the package, in particular (in alphabetic order) R. Alberts, T. Bücher, A. W. Dietrich, who invented the name Shark, T. Glasmachers, who extended the ReClaM library, M. Hüsken, T. Okabe, who wrote the MOO-EALib, S. Roth, P. Stagge, T. Suttorp, M. Toussaint, and T. Voß. The SHARK project is supported by the Honda Research Institute Europe.

Hit Miss Networks with Applications to Instance Selection

Elena Marchiori ELENAM@CS.RU.NL
Department of Computer Science
Radboud University
Nijmegen, The Netherlands

Editor: Leon Bottou

Abstract

In supervised learning, a training set consisting of labeled instances is used by a learning algorithm for generating a model (classifier) that is subsequently employed for deciding the class label of new instances (for generalization). Characteristics of the training set, such as presence of noisy instances and size, influence the learning algorithm and affect generalization performance. This paper introduces a new network-based representation of a training set, called hit miss network (HMN), which provides a compact description of the nearest neighbor relation over pairs of instances from each pair of classes. We show that structural properties of HMN's correspond to properties of training points related to the one nearest neighbor (1-NN) decision rule, such as being border or central point. This motivates us to use HMN's for improving the performance of a 1-NN classifier by removing instances from the training set (instance selection). We introduce three new HMN-based algorithms for instance selection. HMN-C, which removes instances without affecting accuracy of 1-NN on the original training set, HMN-E, based on a more aggressive storage reduction, and HMN-EI, which applies iteratively HMN-E. Their performance is assessed on 22 data sets with different characteristics, such as input dimension, cardinality, class balance, number of classes, noise content, and presence of redundant variables. Results of experiments on these data sets show that accuracy of 1-NN classifier increases significantly when HMN-EI is applied. Comparison with state-of-the-art editing algorithms for instance selection on these data sets indicates best generalization performance of HMN-EI and no significant difference in storage requirements. In general, these results indicate that HMN's provide a powerful graph-based representation of a training set, which can be successfully applied for performing noise and redundance reduction in instance-based learning.

Keywords: graph-based training set representation, nearest neighbor, instance selection for instance-based learning

1. Introduction

In supervised learning, a machine learning algorithm is given a training set, consisting of training examples called labeled *instances* (here called also *points*). Each instance consists of an input vector of values, one for each *variable* of the learning task, and has assigned a class label. A machine learning algorithm uses the training set to generate a so-called *model* that is subsequently used for deciding the class label of (*classify*) new instances. In particular, the 1-NN rule classifies an unknown point into the class of the nearest of the training set points. This rule does not rely on knowledge of the underlying data distribution (non-parametric classification). Moreover, for all distributions, its probability of error is bounded above by twice the Bayes' probability of error (Cover and Hart, 1967).

A central issue in 1-NN classification, and more generally in instance-based learning, concerns storage requirements. The basic 1-NN rule stores all training instances, hence can be slow when classifying new instances. Moreover, when the training set contains noisy instances, generalization accuracy can be negatively affected if these instances are stored as well (see Wilson and Martinez, 2000). Instance selection algorithms tackle these issues by selecting a subset of the training set in order to reduce storage and possibly also enhance accuracy of the 1-NN rule on new instances (generalization performance).

In this paper we introduce a new graph-based representation of a training set, called Hit Miss Network. In an HMN, nodes are instances of the considered training set. Edges are defined as follows: for each node x and for each class, there is a directed edge from x to its nearest neighbor among training set instances belonging to that class. Thus HMN represents a 'more specific' nearest neighbor relation, namely between points from *each* pair of classes. Exact computation of HMN has quadratic time complexity. This bound can be reduced by using metric trees or other spatial data structures (Grother et al., 1997).

We show that structural properties of HMN's correspond to properties of training instances related to the decision boundary of the 1-NN rule, such as being border or central point. These observations motivate the use of HMN for performing instance selection for the 1-NN rule. We introduce three new instance selection algorithms. The first algorithm, called HMN-C, discards instances corresponding to nodes of the HMN with no incoming edges (zero in-degree nodes). We prove that instance selection by means of this algorithm does not change the 1-NN classification of instances in the original training set. The second algorithm, called HMN-E, employs a more aggressive deletion strategy, removing a larger number of training instances, including those with zero in-degree. The last algorithm, called HMN-EI, applies iteratively HMN-E. These algorithms have the desirable properties of being order-independent and of having quadratic time complexity, which can be reduced using metric trees or other spatial data structures.

We assess effectiveness of the proposed algorithms with respect to generalization performance of the 1-NN rule and storage requirements, using 22 data sets with different characteristics, such as input dimension, cardinality, class balance, number of classes, noise content, and presence of redundant variables. Results of experiments show that HMN-EI improves significantly average accuracy of the 1-NN rule, and achieves significantly better performance than HMN-C and HMN-E. Experiments on the same data sets are conducted with the following three algorithms, which have been analyzed in Brighton and Mellish's paper on advances in instance selection (Brighton and Mellish, 2002). Edited Nearest Neighbor (E-NN), designed for noise reduction (Wilson, 1972), and two state-of-the-art editing algorithms: Iterative Case Filtering (ICF) (Brighton and Mellish, 1999) and the best of the Decremental Reduction Optimization algorithms introduced in Wilson and Martinez (1997) (DROP3). Comparison of the results shows that HMN-EI achieves best accuracy, with storage requirements similar to those of ICF and DROP3.

These results indicate that HMN's provide a powerful graph-based representation of training sets, with local structural graph properties useful for analyzing and enhancing 1-NN-based classification.

1.1 Related Work

Graphs have been successfully used for representing relations between points of a given data set, such as functional interaction between proteins (protein-protein interaction networks) or proximity (nearest neighbor graphs) (Dorogovtsev and Mendes, 2003). Graph representations in the context of

1-NN instance-based learning mainly use proximity graphs. Proximity graphs are defined as graphs in which points close to each other by some definition of closeness are connected (Barnett, 1976). The nearest neighbor graph (NNG) is a typical example of proximity graph, where each vertex is a data point that is joined by an edge to its nearest neighbor. The minimum spanning tree (MST) is also a proximity graph. Graph-based applications to instance-based learning algorithms mainly use the Gabriel graph (GG). Exact computation of the Gabriel graph is cubic in the number of nodes. Both the NNG and MST are subgraphs of the GG. The GG is a subgraph of the Delaunay Triangulation (DT), the dual of the Voronoi diagram. The Voronoi diagram and correspondingly the DT of a point set capture all the proximity information about the point set because they represent the original 1-NN rule decision boundary.

There are two main differences between the above proximity graphs and HMN's. First, HMN's explicitly use the class label of points in the definition of edges. As a consequence, while the above proximity graphs can be applied to any data set, HMN's are specifically defined for labeled data. Second, HMN's are directed graphs, while the above proximity graphs are not.

A class of directed proximity graphs, called class cover catch digraphs (CCCD's) has been introduced in Marchette et al. (2003), which provide a graph-based representation of one (target) class versus a different (non-target) class. In a CCCD of two such classes, nodes are the target instances and the maximal covering balls centered on each target instance, where a maximal covering ball of a target point is the ball centered in that point with maximum radius, which does not contain any non-target point. Each maximal covering ball is connected to its center by a directed edge.

CCCD's have been used for translating the so-called 'constrained class cover problem' (CCCP) to a problem on directed graphs. The CCCP amounts to find a minimum cardinality set of open covering balls with centers in target class points whose union covers the target class and does not contain any point of the non-target class.

The problem of finding an optimal solution to an instance of the CCCP has been shown to be equivalent to the one of finding a minimum cardinality dominating set in a general digraph. For CCCD's with points on Euclidean L_2 metric space, the problem can be solved in $O(n^m)$ time, with n and m equal to the number of target and non-target points, respectively. Further information about analysis of CCCD's and their application to classification can be found in DeVinney and Priebe (2005), DeVinney and Priebe (2006) and D.J. Marchette and Priebe (2005).

While both HMN's and CCCD are directed graphs, they describe different relations: HMN's describe the nearest neighbor relation between points of each pair of classes, while CCCD's describe the relation between maximal covering balls and target instances of one class.

Representations of a data set based on proximity graphs have been used to define algorithms for reducing the size of the training set (for instance, Bhattacharya, 1982), for removing noisy instances (for instance, Sánchez et al., 1997), and for detecting critical instances close to the decision boundary (for instance, Bhattacharya and Kaller, 1998), in order to improve storage and accuracy of 1-NN.

In particular, in Toussaint et al. (1984) a so-called Voronoi condensed data set is introduced, obtained by discarding all those points whose Voronoi cell shares a face with those cells that contain points of the same class. The 1-NN decision boundary is then characterized by the union of the common faces of the Voronoi diagram between Voronoi cell neighbors of different classes. The resulting instance selection algorithm produces a decision-boundary consistent set. Voronoi condensing does not reduce the number of points to a great extent and its computational complexity in higher dimensions is exponential in the number of dimensions (Toussaint et al., 1984).

Faster algorithms for instance selection based on the GG and the Reduced Neighborhood graph (Jaromczyk and Toussaint, 1992) have been proposed, for instance in Bhattacharya and Kaller (1998), Bhattacharya et al. (2005), Bhattacharya (1982), Mukherjee (2004) and Sánchez et al. (1997). In particular, in Bhattacharya et al. (2005) a specific data-structure for efficient computation of approximate Gabriel neighbor is proposed. Moreover, three instance selection algorithms are considered: Gabriel-Graph algorithm, ICF, and a so-called Hybrid. Hybrid incorporates E-NN, ICF, and the Gabriel graph rule. Specifically, it consists of the sequential application of a modified version of E-NN based on approximate Gabriel neighbor, a condensing step using Gabriel graph rule, and a filtering step of ICF. The authors provide a rather short discussion of results, and do not test the difference in quality of the average results of the algorithms.

For a thorough survey of graph-based methods for nearest neighbor classification, the reader is referred to Toussaint (2002).

The rest of the paper is organized as follows. After introducing the terminology used throughout the paper, the next section defines HMN's and discusses their properties. Section 3 presents a brief review of instance selection methods. Section 4 introduces HMN-C, HMN-E and HMN-EI. Section 5 describes experiments. Finally, in Section 6, we conclude and point to future work.

1.2 Terminology

The following notions and terms will be used in the sequel.
- X: a training set,
- $L = 1,\ldots,c$: class labels of X
- x: an element of X,
- $|X|$: the number of elements (cardinality) of X,
- X_i: the set of points of X with label i,
- $label(x)$: the class label of x,
- 1-NN(x,l): the nearest neighbor of x among those points (different from x) with label l,
- G: a directed graph with nodes representing elements of X,
- $e = (x,y)$: an edge of G, with x the vertex from which e is directed and y the vertex to which e is directed,
- $d(x)$: the number of edges where x occurs (the degree of x),
- $d(G)$: the total number of edges of G (the degree of G),
- *in-degree* of x: the number of edges pointing to x,

2. Hit Miss Networks

Suppose X consists of points from c different classes. In an HMN of X, a directed edge from point x to y is defined if y is the nearest neighbor of x in the class of y. Thus each point x has c outgoing edges, one for each class. When the classes of x and y are the same, we call x a *hit of* y, otherwise a *miss of* y . The name hit miss network is derived from these terms.

Definition 2.1 (Hit Miss Network) *The Hit Miss Network of* X, HMN(X), *is a directed graph* $G = (V,E)$ *with*

- $V = X$ *and*

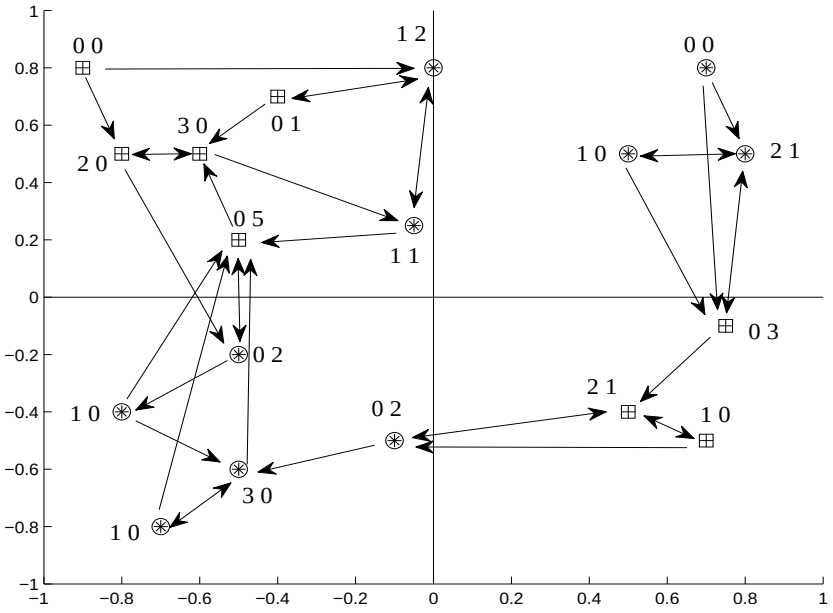

Figure 1: HMN graph of the training set for an artificial classification problem. Hit- and miss-degree of each node is written on the left and right side of the node, respectively.

- $E = \{(x, \texttt{1-NN}(x,l)) \textit{ for each } x \in X \textit{ and } l \in L\}$.

Definition 2.2 (Hit, Miss Points) *Let $G = \texttt{HMN}(X)$. A hit of x (respectively, miss of x) is any point y such that $e = (y,x)$ is an edge of G and $label(y) = label(x)$ (respectively, $label(y) \neq label(x)$).*

We call *hit-degree* (respectively *miss-degree*) of x the number of hit (respectively miss) nodes of x. $Hit(x)$ (respectively $Miss(x)$) denotes the set of hit (respectively miss) nodes of x.

Figure 1 shows the HMN of the training set for a toy binary classification task. Observe that the two points with zero in-degree are relatively isolated and far from points of the opposite class, while points with high miss-degree are closer to points of the opposite class and to the 1-NN decision boundary.

Computing HMN requires quadratic time complexity in the number of points. Nevertheless, by using metric trees or other spatial data structures this bound can be reduced. For instance, using *kd* trees, whose construction takes time proportional to $n\log(n)$, nearest neighbor search exhibits approximately $O(n^{1/2})$ behavior (Grother et al., 1997). A recent fast all nearest neighbor algorithm for applications involving large point-clouds is introduced in Sankaranarayanan et al. (2007).

By construction, the degree of G, and the degree $d(x)$ of a node $x \in V$ satisfy the following properties:

$$d(G) = c \cdot |X|$$

and

$$c \leq d(x) \leq |X| + c - 1.$$

HMN's describe the nearest neighbor relation over pairs of points from *each pair of classes* of the training set. Formally, it is easy to check that

$$\mathtt{HMN}(X) = \cup_{i,j,i\neq j,i,j\in[1,c]} \mathtt{HMN}(X_i \cup X_j).$$

Therefore, the HMN's of pairs of classes can be constructed independently, supporting parallel execution. Moreover, if a new class is added, one does not need to reconstruct the entire HMN, but the HMN, between the new class and each of the other ones.

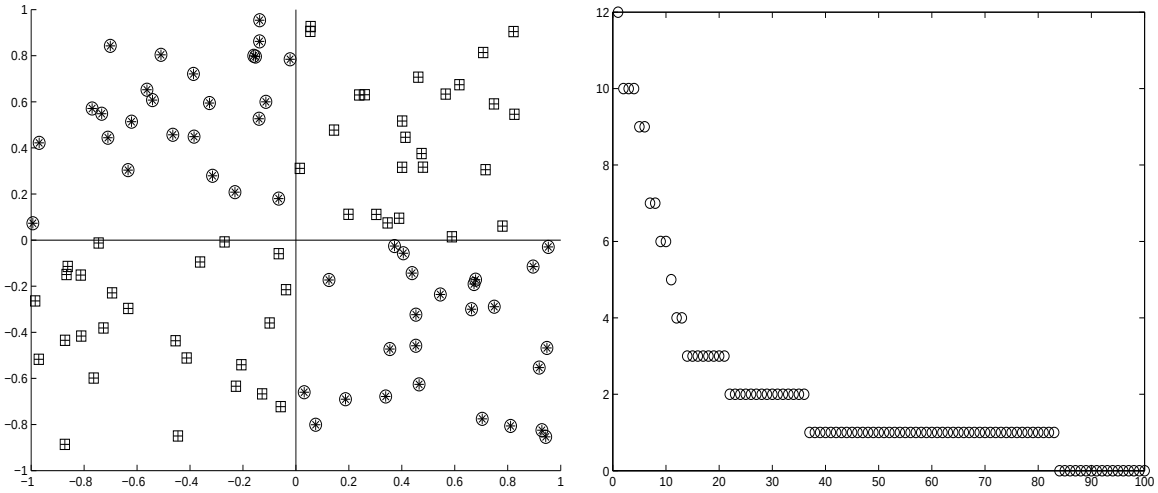

Figure 2: A XOR problem data set (left) and plot of sorted in-degrees (y-axis) of nodes (x-axis), in decreasing order, of the corresponding HMN graph (right).

Figure 2 shows a training set for a XOR classification task, and the sorted in-degrees of its HMN graph. The in-degree distribution seems to follow a Power law, where very few nodes have high in-degree. If we randomly permute the class labels of the training set then the degree distribution changes, with lower in-degree values and more nodes having small in-degree (cf., Figure 3).

These observations indicate that the local structure of HMN provides information about properties of the training points, and motivate us to use HMN's for defining a new instance selection technique. Before that, in the next section we review briefly instance selection algorithms.

3. Instance Selection Algorithms

In instance-based learning, the training set is stored, and the machine learning algorithm computes a distance between the new instance and the stored ones in order to classify new instances. In particular, in the one nearest neighbor algorithm (1-NN) the class label of a new instance is the one of the stored instance with minimum distance.

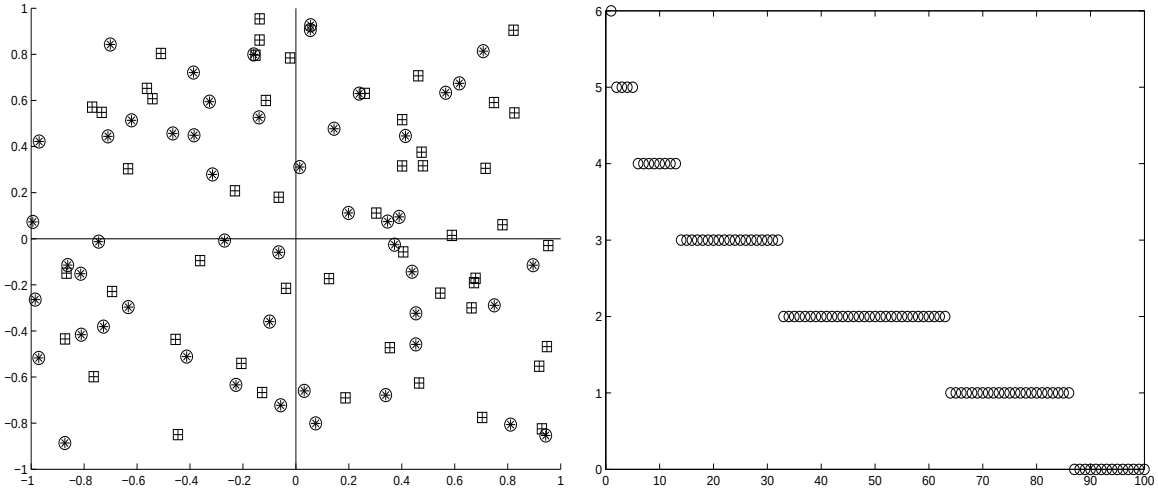

Figure 3: Training points of a XOR problem data set with labels randomly permuted (left figure) and plot of in-degrees, sorted in decreasing order, obtained by applying `HMN` (right figure).

Instance selection techniques, here also called *editing* techniques, select a subset of the training set in order to improve the storage and possibly the generalization performance of an instance-based learning algorithm. In this paper we focus on the `1-NN` classifier.

Research on instance selection started with the seminal work of Hart (1968). Subsequent research focussed mainly on three types of training set condensation techniques (Brighton and Mellish, 2002): competence preservation, competence enhancement, and hybrid approaches.

- *Competence preservation* algorithms compute a *training set consistent subset* by removing irrelevant points that do not affect the classification accuracy of the training set (see for instance Angiulli, 2007; Dasarathy, 1994).
- *Competence enhancement* methods remove noisy points in order to increase classifier accuracy. Noise reduction techniques can remove exception instances or border instances which cannot be distinguished from true noise by the technique, hence can possibly affect negatively the generalization performance of the classifier that uses only the selected instances (see for instance Vezhnevets and Barinova, 2007; Wilson, 1972).
- *Hybrid* methods aim at finding a subset of the training set that is both noise free and does not contain irrelevant points (for instance, Brighton and Mellish, 2002; Wilson and Martinez, 1997). Alternative methods use prototypes instead of instances of the training set (see for instance Pekalska et al., 2006).

In Wilson and Martinez (2000), Wilson and Martinez present a comprehensive survey of concepts and issues related to reduction techniques for instance-based learning algorithms, including a thorough experimental comparison of algorithms. Other, more recent surveys of instance selection techniques are Brighton and Mellish (2002), Jankowski and Grochowski (2004a) and Jankowski and Grochowski (2004b).

In particular, in Brighton and Mellish (2002) the authors compare experimentally Edited Nearest Neighbor (E-NN) and the state-of-the-art editing algorithms Iterative Case Filtering (ICF) and Decremental Reduction Optimization Procedure 3 (DROP3). E-NN is an algorithm generally considered in comparative experimental analysis of editing methods mainly because it provides useful information on the amount of 'noisy' instances contained in the considered data sets, and on the improvement of accuracy obtained by their removal. Iterative Case Filtering uses E-NN as pre-processing noise reduction step, followed by an iterative procedure for deleting 'superfluous points'. Also DROP3 begins with the application of a simple noise reduction step, followed by another simple type of heuristic for discarding 'superfluous points'.

Results of an extensive comparative experimental analysis performed in Wilson and Martinez (2000) and in Brighton and Mellish (2002) indicate that ICF and DROP3 are cutting-edge instance selection algorithms, achieving best K-NN accuracy and storage reduction on a large number of learning tasks over many other editing methods. These algorithms, together with E-NN, are described in more detail below and used to assess comparatively the performance of the HMN-based editing algorithms we propose.

3.1 Edited Nearest Neighbor

Wilson (1972) introduced the *Edited Nearest Neighbor* (E-NN), where each point x is removed from X if it does not agree with the majority of its K nearest neighbors. This editing rule removes noisy points as well as points close to the decision boundary, yielding to smoother decision boundaries.

3.2 Iterative Case Filtering

In Brighton and Mellish (1999) the *Iterative Case Filtering* algorithm (ICF) was proposed, which first applies E-NN iteratively until it cannot remove any point, and next iteratively removes other points as follows. At each iteration, all points for which the so-called *reachability* set is smaller than the *coverage* one are deleted. The reachability of a point x consists of the points inside the largest hyper-sphere containing only points of the same class as x. The *coverage* of x is defined as the set of points that contain x in their reachability set.

3.3 Decremental Reduction Optimization

The family of Decremental Reduction Optimization (DROP) algorithms was first introduced by Wilson and Martinez (1997), and further extended and analyzed in Wilson and Martinez (2000). It consists of five algorithms DROP1-5. DROP1 is the basic removal rule, which removes a point x from X if the accuracy of the K-NN rule on the set of its associates does not decrease. Each point has a list of K nearest neighbors and a list of associates, which are updated each time a point is removed from X. A point y is an *associate* of x if x belongs to the set of K nearest neighbors of y. If x is removed then the list of K nearest neighbors of each of its associates y is updated by adding a new neighbor point z, and y is added to the list of associates of z. Moreover, for each of the K nearest neighbors y of x, x is removed from the list of associates of y.

DROP2 is obtained from DROP1 by discarding the last update step, hence it considers all associates in the entire training set when testing accuracy performance in the removal rule. Moreover, the removal rule is applied to the points sorted in decreasing order of distance from their nearest

neighbor from the other classes (nearest enemy). In this way, points furthest from their nearest enemy are selected first.

DROP3 applies a pre-processing step which discards points of X misclassified by their K nearest neighbors, and then applies DROP2.

DROP4 uses a stronger pre-processing step which discards points of X misclassified by their K nearest neighbors if their removal does not hurt the classification of other instances.

Finally DROP5 modifies DROP2 by considering the reverse order of selection of points, in such a way that instances are considered for removal beginning with instances that are nearest to their nearest enemy.

DROP3 achieves the best mix of storage reduction and generalization accuracy of the DROP methods (see Wilson and Martinez, 2000). Moreover, results of experiments conducted in Wilson and Martinez (1997, 2000) show that DROP3 achieves higher accuracy and smaller storage requirements than several other methods, such as CNN (Hart, 1968), SNN (Ritter et al., 1975), E-NN (Wilson, 1972), the All k-NN method (Tomek, 1976), IB2, IB3 (Aha et al., 1991), and the Explore method (Cameron-Jones, 1995). Therefore we use DROP3 and ICF as representatives of the state-of-the-art, in order to assess the performance of the HMN-based editing algorithms introduced in the following section.

4. Instance Selection with Hit Miss Networks

Zero in-degree nodes of HMN(X) include relatively isolated points, and points not too close to the decision boundary. This is illustrated in the HMN-C sub-plot of Figure 5, where zero in-degree nodes of the HMN for a XOR data set are highlighted in bold.

Zero in-degree nodes can be safely removed from X without affecting 1-NN classification of the original training. Formally, we have the following result.

Proposition 4.1 *Let S be obtained by removing from X all points with zero in-degree. Then S is a decision-boundary consistent subset.*

Proof

Suppose there exists $x \in X$ s.t. 1-NN$(x,X) = y$, 1-NN$(x,S) = y_1$ and $l(y) \neq l(y_1)$. Then $y \neq y_1$ and y has been removed. So y has in-degree equal to 0.

From 1-NN$(x,X) = y$ it follows that x is in $Hit(y)$ or in $Miss(y)$, hence the in-degree of y is at least 1, which yields a contradiction.

Then $l(y) \neq l(y_1)$ was false. Hence S is a training set consistent subset.

We call HMN-C (HMN for training set Consistent instance selection) the algorithm that removes from the training set all instances with zero in-degree.

HMN-C does not remove noisy instances, which are in general close to the class decision boundary. Therefore, a more aggressive removal strategy is adopted in the following instance selection heuristic algorithm, called HMN-E (HMN for Editing), which compares the hit- and miss-degree of each node for deciding whether to remove it.

Pseudo-code of this algorithm is given in Figure 1. HMN-E is based on four if-then rules, described below.

(1) **compute** HMN(X)
(2) **for** x in X
(3) **if** $w_{l(x)} * |Miss(x)| + \varepsilon > (1 - w_{l(x)}) * |Hit(x)|$
(4) **flag** x for removal (rule R1)
(5) **end if**
(6) **end for**
(7) $X_{R1,remove} = \{x \in X$ with **flag** for removal$\}$
(8) **for** l in $1 \ldots c$
(9) $Left_l = \{x \notin X_{R1,remove} \mid l(x) = l\}$
(10) **if** $|Left_l| < 4$
(11) **unflag** $\{z \in X_{R1,remove} \mid l(z) = l,$ *in-degree*$(z) > 0\}$ (rule R2)
(12) **end if**
(13) **end for**
(14) **for** x in $X_{R1,remove}$
(15) **if** $c > 3$ and $|Miss(x)| < c/2$ and *in-degree*$(x) > 0$
(16) **unflag** x (rule R3)
(17) **end if**
(18) **if** $|Hit(x)| \geq |X_{l(x)}|/4$
(19) **unflag** x (rule R4)
(20) **end if**
(21) **end for**
(22) **remove** from X all x with **flag** for removal

Figure 4: Pseudo-code of HMN-E algorithm. Input: training set X. Output: subset of X.

1. The first rule removes x if its miss-degree is greater or equal than its hit-degree, that is $|Miss(x)| \geq |Hit(x)|$. This amounts to discard a point when it is isolated (that is, has zero in-degree), as well as when it has more 'miss' than 'hit' points.

   In order to deal with unbalanced data sets, the terms of the inequality are weighted by the fraction of points of the same and other classes, respectively, resulting in rule R1 (lines 3-5 in Figure 1) which removes a point x from X if

   $$w_{l(x)} * |Miss(x)| + \varepsilon > (1 - w_{l(x)}) * |Hit(x)|, \tag{1}$$

   where $w_{l(x)} = |\{z \mid l(z) = l(x)\}|/|X|$ and $\varepsilon < 1$ ($\varepsilon = 0.1$ is used in our experiments).

2. On small data sets, application of R1 could remove too many points of one class. Rule R2 (lines 10-12 in Figure 1) handles this case. It checks if the size of a class becomes too small after application of R1. In such a case all points of that class having positive in-degree are added. The threshold used in the rule is set in such a way that the minimum size of a condensed class becomes equal to 4. We consider this to be a reasonable class storage lower bound for the condensed 1-NN rule.

3. Suppose for simplicity each class has equal size ($|X|/c$). Then $|Miss(x)| \leq \frac{(c-1)^2|X|}{c}$, and $|Hit(x)| \leq |X|/c - 1$. This $|Miss(x)|$'s upper bound grows linearly with the number c of

classes, while the $|Hit(x)|$'s upper bound depends on c in an inversely linear way. Therefore $|Miss(x)|$ is more likely to grow faster than $|Hit(x)|$ in the presence of many classes. This justifies the introduction of the heuristic Rule R3 (lines 15-17 in Figure 1), which deals with data sets having more than three classes. For more than three classes, a point x with in-degree greater than 0 is added if it has a low number of 'miss' points, low with respect to c. Here we use as threshold half of the total number of classes.

4. Points with many 'hits' are closer to the 'centroid' of the class, hence are considered to be relevant for discriminating the classes, even when they are close to points of other classes. This case is implemented in rule R4 (lines 18-20 in Figure 1) which adds x if it is the 'hit' of at least 25% of the points of its class.

Rules R2 - R4 are 'rules of thumb'. The threshold in each of these rules has been fixed to a value considered reasonable, and has not been tuned on each specific data set. These rules could be improved by means of parameter tuning or domain knowledge on the specific data distribution of the learning task.

In order to remove more "redundant" points, HMN-E can be applied iteratively as follows: repeat the application of HMN-E until the generalization accuracy of 1-NN on the original training set with the reduced set decreases. We call this algorithm HMN-E *Iterated* (HMN-EI).

Observe that the three HMN-based editing algorithms are order independent, that is, their output does not depend on the order in which training points are processed. Moreover, by construction, points removed by HMN-C are also removed by HMN-E, and points removed by HMN-E are also removed by HMN-EI.

4.1 Comparison of the Methods on the XOR Problem

Figure 5 shows application of the considered editing algorithms to the training set of a XOR classification task. Points removed by an algorithm are shown in bold. As expected, points removed by E-NN are close to the decision boundary. ICF and DROP3 delete also 'safe' points far from the decision boundary (in order to enhance storage requirements). HMN-C removed points 'locally' isolated, while HMN-E removes also 'safe' points as well as points close to the decision boundary. Its iterated version HMN-EI selects very few points far from the decision boundary. The figures do not show any other apparent set-theoretic relationship between the subsets of points removed by the methods.

Figure 6 plots the sorted in-degrees of the considered XOR training set, where in-degree of points removed by a method are marked with triangles. As expected, points removed by ICF and not already deleted by E-NN have low in-degree. The majority of points removed by E-NN have high in-degree, showing the tendency of 'noisy' points to have high in-degree. HMN-E removes more points with high in-degree than E-NN, and it selects points with low, but not zero, degree. While HMN-EI selects only points with in-degree 1 and 2, ICF and DROP3 select also points of higher degree. On this example, HMN-EI achieves best storage reduction.

5. Experiments

The following seven algorithms are considered: 1-NN (no instance selection), HMN-C, HMN-E, HMN-EI, E-NN, ICF, and DROP3. In order to assess their comparative performance, we implemented the above

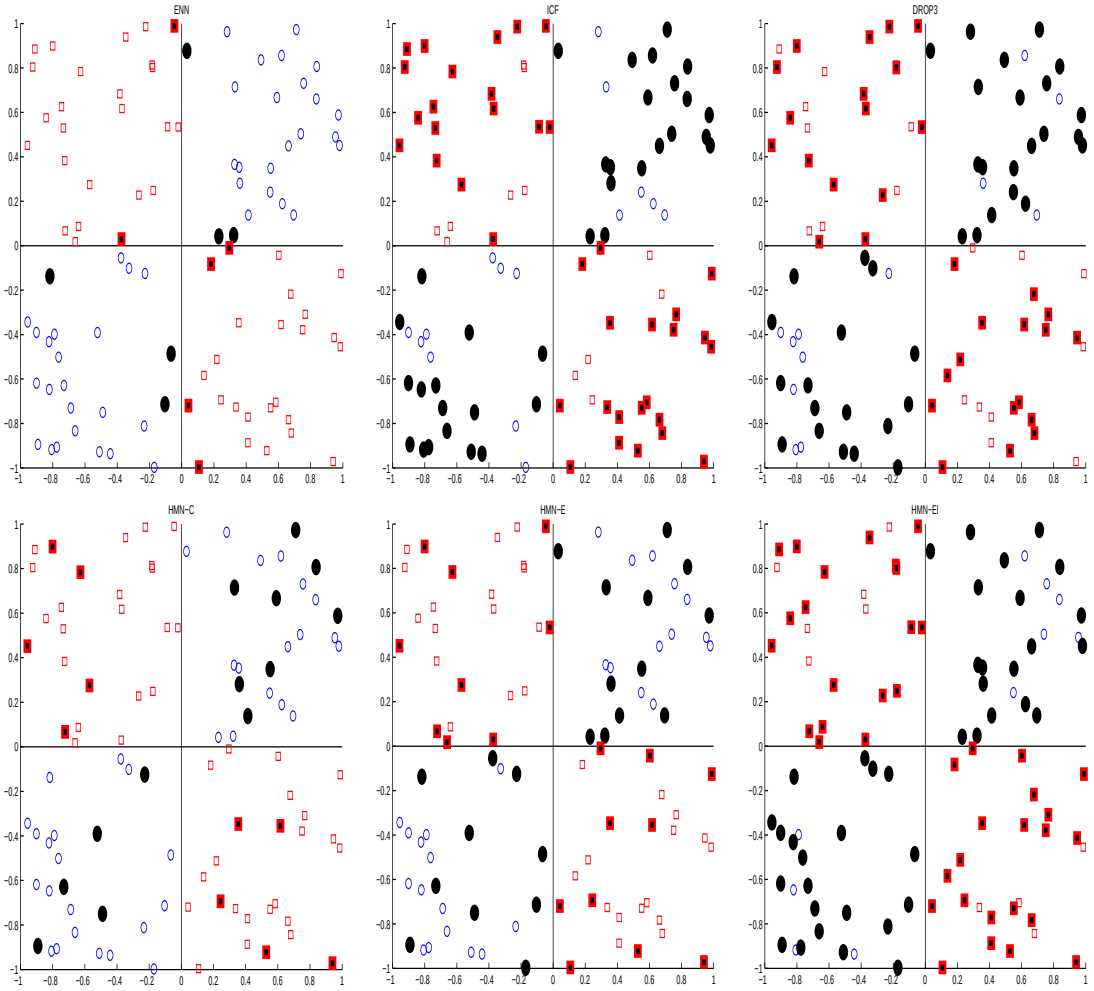

Figure 5: Effect of the algorithms on a XOR problem training set: removed points are shown with filled markers. Top row, from left to right: `E-NN`, `ICF`, `DROP3`. Bottom row, from left to right: `HMN-C`, `HMN-E` and `HMN-EI`.

algorithms and conducted extensive experiments on 22 Machine Learning benchmark data sets. All algorithms are tested using one neighbor.

The performance measures here used are (average) test accuracy of the classifier and (average) percentage of the training set removed by the method.

5.1 Data Sets

The following 22 publicly available benchmark data sets used in previous studies on model selection for (semi)supervised learning, are considered.

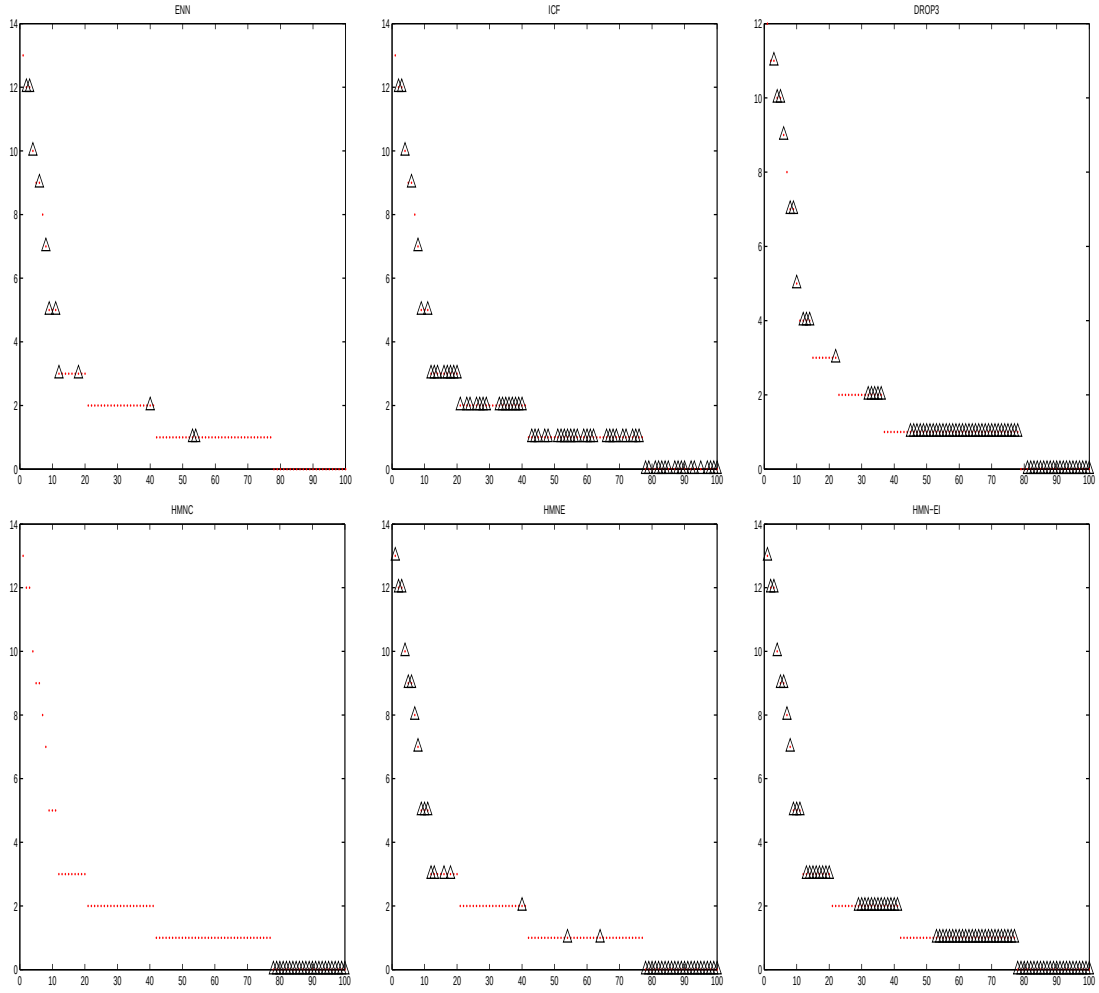

Figure 6: In-degree of nodes of the HMN built on the considered XOR training set, sorted in decreasing order. The in-degree of points removed by an algorithm are marked with triangles. Top row, from left to right: E-NN, ICF, DROP3. Bottom row, from left to right: HMN-C, HMN-E and HMN-EI.

1. Raetsch's binary classification benchmark data sets have been used in Rätsch et al. (2001): they consists of 1 artificial and 12 real-life data sets from the UCI, DELVE and STATLOG benchmark repositories.

   For each experiment, the 100 (20 for Splice and Image) partitions of each data set into training and test set available in the repository are here used.

2. Chapelle's benchmark data sets used in Chapelle and Zien (2005) are from two artificial binary classification and three real-life multi-class classification problems. Specifically, g50c and g10n are generated from two standard normal multi-variate Gaussians. In g50c, the labels correspond to the Gaussians, and the means are located in 50-dimensional space such that the

Bayes' error is 5%. In contrast, g10n is a deterministic problem in 10 dimensions, where the decision function traverses the centers of the Gaussians, and depends on only two of the input dimensions.

The three real world data sets are Coil20, consisting of gray-scale images of 20 different objects taken from different angles, in steps of 5 degrees, Uspst, the test data part of the USPS data on handwritten digit recognition, and Text consisting of the classes 'mac' and 'mswindows' of the Newsgroup20 data set.

For each experiment, the 10 partitions of each data set into training and test set available in the repository are used.

3. Finally, we consider four standard benchmark data sets from the UCI Machine Learning repository: Iris, Bupa, Pima, and Breast-W.

   For each experiment, 100 partitions of each data set into training and test set are used. Each partition randomly divides the data set into training and test set, equal to 80% and 20% of the data, respectively.

Thus the benchmark data consists of 3 artificial data sets (Banana, g50c, g10n) and 19 real-life ones, with different characteristics as shown in Table 1. In particular, Chapelle's data sets are balanced, that is, all classes are represented by similar number of points, while some of Raetsch's data sets are rather unbalanced.

5.2 Results

Cross validation is applied to each data set. For each partition of the data set, each editing algorithm is applied to the training set X from which a subset S is returned. The one nearest neighbor classifier that uses only points of S is applied to the test set. The average accuracy on the test set over the given partitions is reported for each algorithm (cf., Table 2, Table 3). The average percentage of instances that are excluded from S is also reported under the column with label R. Average and median accuracy and training set reduction percentage for each algorithm over all the 22 data sets is reported near the bottom of the Table.

We compare statistically HMN-EI with each of the other algorithms as follows.

- First a paired t-test on the cross validation results on each data set is applied, to assess whether the average accuracy for HMN-EI is significantly different than each of the other algorithms. In Tables 2, 3 a '+' indicates that HMN-EI's average accuracy is significantly higher than the other algorithm at a 0.05 significance level. Similarly, a '-' indicates that HMN-EI's average accuracy is significantly lower than the other algorithm at a 0.05 significance level. The row labeled 'Sig.acc.+/-' reports the number of times HMN-EI's average accuracy is significantly better and worse than each of the other algorithms at a 0.05 significance level. A paired t-test is also applied to assess significance of differences in storage reduction percentages for each experiment.

- Second, in order to assess whether differences in accuracy and storage reduction on all runs of the entire group of data sets are significant, a non-parametric paired test, the Wilcoxon Signed Ranks test[1] is applied to compare HMN-EI with each of the other algorithms. A '+'

1. We used 'wilcoxon' Matlab routine by G. Cardillo.

Table 1: Data Sets used in the experiments. Raetsch's benchmark repository available at `http://ida.first.fraunhofer.de/projects/bench/benchmarks.htm`. Chapelle's one at `http://www.kyb.tuebingen.mpg.de/bs/people/chapelle/lds/`. Four popular benchmark data sets from UCI Machine Learning repository available at `http://mlearn.ics.uci.edu/MLRepository.html`. CL = number of classes, TR = training set, TE = test set, VA = number of variables, Cl.Inst. = number of instances in each class.

(respectively '-') in the row labeled 'Wilcoxon' indicates that `HMN-EI` is significantly better (respectively worse) than the other algorithm.

Results of Table 2 show that `HMN-EI` achieves best generalization accuracy, significantly better than the one of `1-NN` and of `HMN-C`. Moreover, `HMN-EI` outperforms significantly `HMN-E` with respect to storage requirements and achieves similar generalization performance. For these reasons, `HMN-EI` is chosen for further comparison with state-of-the-art editing algorithms.

5.3 Comparison with Other Algorithms

From the results of the experiments reported in Table 3 we derive the following observations.

Data Set	1-NN	HMN-C	R	HMN-E	R	HMN-EI	R
Banana	86.4 +	85.6 +	19.7 +	88.2 +	38.5 +	**88.6**	57.9

Table 2: Results of experiments on ML benchmark data sets. Each column labeled with the name of an algorithm reports its average test set accuracy on each data set. R = percentage of training points removed. Best results are shown in bold. Average (Median) = average (median) results over data sets. Sig.+/- = number of times HMN-EI average accuracy (storage reduction) is significantly better (+) or significantly worse (-) than the other algorithm, according to a paired t-test at 0.05 significance level. Wilcoxon = a '+' indicates HMN-EI significantly better than the other algorithm at a 0.01 significance level according to a Wilcoxon test for paired samples, $\sim$ indicates no significant difference.

- On the g50c data set, HMN-EI achieves highest average accuracy, significantly better than that of all other methods. With an average error of about 13%, close to twice the Bayes probability of error, HMN-EI performs almost optimally, and discards about 88% of the training data. This shows effectiveness and robustness of this method with respect to the presence of noise (on this type of classification task).

Table 3: Results of experiments on ML benchmark data sets of HMN-EI, ICF, Wilson's editing, and DROP3.

- On the g10n data set, HMN-EI achieves significantly better performance than that of the other methods, indicating robustness to the presence of irrelevant variables (on this type of classification task).
- On data sets with more than three classes, HMN-EI has worse storage requirements than the other algorithms, but also generally higher accuracy, due to the more conservative editing strategy (Rule 3) HMN-EI uses on data sets with many classes.
- Results of a paired t-test at a 0.05 significance level shows better accuracy performance of HMN-EI over ICF, E-NN and DROP3 (cf., row Sig.+/-) on 15, 12, and 17 of the data sets, and worse accuracy on 2, 5, and 4 data sets, respectively. Storage reduction of HMN-EI is 7, 22, and 11 times better, and 15, 0, and 8 worse, indicating better storage performance of

ICF, according to this test. As shown, for instance, in Demsar (2006), comparison of the performance of two algorithms based on the t-test is only indicative because the assumptions of the test are not satisfied, and the Wilcoxon test is shown to provide more reliable estimates.

- Results of the non parametric Wilcoxon test for paired samples at a 0.01 significance level indicate that the performance of HMN-EI on the entire set of classification tasks is significantly better than each one of the other algorithms with respect to accuracy, and that there is no significant difference in storage reduction between HMN-EI and state-of-the-art editing algorithms (cf., last row of the table).

- The three best performing instance selection algorithms, DROP3, ICF and HMN-EI have quadratic computational complexity in the number of instances (which can be reduced by using ad-hoc data structures such as kd-trees). ICF and HMN-EI are in principle slower than the other algorithms, due to their multiple passes over (selected) instances. Nevertheless, in our experiments these algorithms require a small number of iterations (about 7 for ICF and 3 for HMN-EI). Thus their computational complexity is not significantly worse than that of DROP3.

In summary, results of these experiments indicate effectiveness of HMN-based instance selection and robustness of HMN-EI with respect to the presence of high number of variables, training examples, multiple classes, noise and irrelevant variables. Comparison with results obtained by E-NN, ICF and DROP3 shows improved average accuracy and similar storage requirement of HMN-EI, ICF and DROP3 on these data sets.

6. Conclusions and Future Work

This paper proposed a new graph-based representation of a training set and showed how local structural properties of nodes provide information about the closeness of the corresponding points to the decision boundary of the 1-NN rule. We formalized these properties by means of the notions of *Hit* and *Miss* set, and used such notions for defining three algorithms for 1-NN's instance selection. We proved that HMN-C removes instances without affecting the accuracy of the 1-NN rule on the original training set (it computes a decision-boundary consistent subset). We showed that HMN-E and HMN-EI remove more points than HMN-C, including those close to the decision boundary. Results of extensive experiments indicated that HMN-EI significantly improves the generalization accuracy of 1-NN and reduces significantly its storage requirements.

We compared experimentally HMN-EI with a popular noise reduction algorithm (E-NN), and two state-of-the-art editing algorithms (ICF and DROP3). Results of extensive experiments on 19 real-life data sets and 3 artificial ones showed that HMN-EI achieved best average accuracy, and storage reduction similar to that of ICF and DROP3. This indicates that simple local topological properties of the proposed graph-based data set representation provide an effective tool for 1-NN's instance selection.

The design of condensing algorithms could also be based on an extension of HMN for describing the K-nearest neighbor relation between each pair of classes. We conducted preliminary experiments to investigate whether using more than one neighbor to classify new points affects the accuracy performance of the condensing algorithms here considered. Results of experiments on seven UCI ML data setdata sets, using 3 and 5 neighbors for classifying new points, showed that HMN-EI still achieves best average accuracy. In general, the generalization performance increased (of about 1%, 2%) when 3 and 5 neighbors were used.

In this paper we use only the degree of nodes as mean for analyzing a training set in order to improving 1-NN's performance. It would be interesting to investigate whether other graph-theoretical properties of HMN's, such as information on path distance, clustering coefficient and diameter, provide useful information for studying and improving the 1-NN's performance.

Other future work includes the use of HMN's to tackle the following interesting problems: measuring the difficulty of a learning task with respect to a given training set (see for instance Zighed et al., 2002); enhancing classification techniques based on a notion of margin, such as Support Vector Machines (see for instance Shin and Cho, 2007); improving Boosting algorithms by means of editing techniques (see for instance Vezhnevets and Barinova, 2007), and, more generally, tackling over-fitting in supervised learning.

Abstract

Regularization by the sum of singular values, also referred to as the *trace norm*, is a popular technique for estimating low rank rectangular matrices. In this paper, we extend some of the consistency results of the Lasso to provide necessary and sufficient conditions for rank consistency of trace norm minimization with the square loss. We also provide an adaptive version that is rank consistent even when the necessary condition for the non adaptive version is not fulfilled.

Keywords: convex optimization, singular value decomposition, trace norm, consistency

1. Introduction

In recent years, regularization by various non Euclidean norms has seen considerable interest. In particular, in the context of linear supervised learning, norms such as the ℓ_1-norm may induce sparse loading vectors, that is, loading vectors with low cardinality or ℓ_0-norm. Such regularization schemes, also known as the Lasso (Tibshirani, 1994) for least-square regression, come with efficient path following algorithms (Efron et al., 2004). Moreover, recent work has studied conditions under which such procedures consistently estimate the sparsity pattern of the loading vector (Yuan and Lin, 2007; Zhao and Yu, 2006; Zou, 2006).

When learning on rectangular matrices, the rank is a natural extension of the cardinality, and the sum of singular values, also known as the trace norm or the nuclear norm, is the natural extension of the ℓ_1-norm; indeed, as the ℓ_1-norm is the convex envelope of the ℓ_0-norm on the unit ball (i.e., the largest lower bounding convex function) (Boyd and Vandenberghe, 2003), the trace norm is the convex envelope of the rank over the unit ball of the spectral norm (Fazel et al., 2001). In practice, it leads to low rank solutions (Fazel et al., 2001; Srebro et al., 2005) and has seen recent increased interest in the context of collaborative filtering (Srebro et al., 2005), multi-task learning (Abernethy et al., 2006; Argyriou et al., 2007; Abernethy et al., 2008) or classification with multiple classes (Amit et al., 2007).

In this paper, we consider the rank consistency of trace norm regularization with the square loss, that is, if the data were actually generated by a low-rank matrix, will the matrix and its rank be consistently estimated? In Section 4, we provide necessary and sufficient conditions for the rank consistency that are extensions of corresponding results for the Lasso (Yuan and Lin, 2007; Zhao and Yu, 2006; Zou, 2006) and the group Lasso (Bach, 2008). We do so under two sets of sampling

assumptions detailed in Section 3.2: a full i.i.d assumption and a non i.i.d assumption which is natural in the context of collaborative filtering.

As for the Lasso and the group Lasso, the necessary condition implies that such procedures do not always estimate the rank correctly; similar to the adaptive version of the Lasso and group Lasso (Zou, 2006), we design an adaptive version to achieve $n^{-1/2}$-consistency and rank consistency, with no consistency conditions. Following Zou (2006), the adaptive version is based on a unregularized least-squares estimates which is used to design appropriate reweighted matrices. Finally, in Section 6, we present a smoothing approach to convex optimization with the trace norm, while in Section 6.3, we show simulations on toy examples to illustrate the consistency results.

2. Notation

In this paper we consider various norms on vectors and matrices. On vectors x in $\mathbb{R}^d$, we always consider the Euclidean norm, that is, $\|x\| = (x^\top x)^{1/2}$. On rectangular matrices in $\mathbb{R}^{p\times q}$, however, we consider several norms, based on singular values (Stewart and Sun, 1990): the *spectral norm* $\|M\|_2$ is the largest singular value (defined as $\|M\|_2 = \sup_{x\in\mathbb{R}^q} \frac{\|Mx\|}{\|x\|}$), the *trace norm* (or *nuclear norm*) $\|M\|_*$ is the sum of singular values, and the *Frobenius norm* $\|M\|_F$ is the ℓ_2-norm of singular values—also defined as $\|M\|_F = (\mathrm{tr} M^\top M)^{1/2}$. In Appendix A and B, we review and derive relevant tools and results regarding perturbation of singular values as well as the trace norm.

Given a matrix $M \in \mathbb{R}^{p\times q}$, $\mathrm{vec}(M)$ denotes the vector in $\mathbb{R}^{pq}$ obtained by stacking its columns into a single vector; and $A \otimes B$ denotes the Kronecker product between matrices $A \in \mathbb{R}^{p_1\times q_1}$ and $B \in \mathbb{R}^{p_2\times q_2}$, defined as the matrix in $\mathbb{R}^{p_1 p_2 \times q_1 q_2}$, defined by blocks of sizes $p_2 \times q_2$ equal to $a_{ij}B$. We make constant use of the following identities: $(B^\top \otimes A)\,\mathrm{vec}(X) = \mathrm{vec}(AXB)$ and $\mathrm{vec}(uv^\top) = v \otimes u$. For more details and properties, see Golub and Loan (1996) and Magnus and Neudecker (1998). We also use the notation ΣW for $\Sigma \in \mathbb{R}^{pq\times pq}$ and $W \in \mathbb{R}^{p\times q}$ to design the matrix in $\mathbb{R}^{p\times q}$ such that $\mathrm{vec}(\Sigma W) = \Sigma\,\mathrm{vec}(W)$ (note the potential confusion with ΣW when Σ is a matrix with p columns).

We use the following standard asymptotic notations: a random variable Z_n is said to be of order $O_p(a_n)$ if for any $\eta > 0$, there exists $M > 0$ such that $\sup_n P(|Z_n| > Ma_n) < \eta$. Moreover, Z_n is said to be of order $o_p(a_n)$ if Z_n/a_n converges to zero in probability, that is, if for any $\eta > 0$, $P(|Z_n| \geqslant \eta a_n)$ converges to zero. See Van der Vaart (1998) and Shao (2003) for further definitions and properties of asymptotics in probability.

Finally, we use the following two conventions: lowercase for vectors and uppercase for matrices, while bold fonts are reserved for population quantities.

3. Trace Norm Minimization

We consider the problem of predicting a real random variable z as a linear function of a matrix $M \in \mathbb{R}^{p\times q}$, where p and q are two fixed strictly positive integers. Throughout this paper, we assume that we are given n observations (M_i, z_i), $i = 1,\dots,n$, and we consider the following optimization problem with the square loss:

$$\min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2n}\sum_{i=1}^n (z_i - \mathrm{tr} W^\top M_i)^2 + \lambda_n \|W\|_*, \tag{1}$$

where $\|W\|_*$ denotes the *trace norm* of W.

3.1 Special Cases

Regularization by the trace norm has numerous applications (see, e.g., Recht et al., 2007, for a review); in this paper, we are particularly interested in the following two situations:

Lasso and group Lasso When $x_i \in \mathbb{R}^m$, we can define $M_i = \mathrm{Diag}(x_i) \in \mathbb{R}^{m \times m}$ as the diagonal matrix with x_i on the diagonal. In this situation, the minimization of problem in Eq. (1) must lead to diagonal solutions (indeed the minimum trace norm matrix with fixed diagonal is the corresponding diagonal matrix, which is a consequence of Lemma 20 and Proposition 21) and for a diagonal matrix the trace norm is simply the ℓ_1 norm of the diagonal. Once we have derived our consistency conditions, we check in Section 4.5 that they actually lead to the known ones for the Lasso (Yuan and Lin, 2007; Zhao and Yu, 2006; Zou, 2006).

We can also see the group Lasso as a special case; indeed, if $x_{ij} \in \mathbb{R}^{d_j}$ for $j = 1, \ldots, m$, $i = 1, \ldots, n$, then we define $M_i \in \mathbb{R}^{(\sum_{j=1}^m d_j) \times m}$ as the block diagonal matrix (with non square blocks) with diagonal blocks x_{ji}, $j = 1, \ldots, m$. Similarly, the optimal $\hat{W}$ must share the same block-diagonal form, and its singular values are exactly the norms of each block, that is, the trace norm is indeed the sum of the norms of each group. We also get back results from Bach (2008) in Section 4.5.

Note that the Lasso and group Lasso can be seen as special cases where the singular vectors are fixed. However, the main difficulty in analyzing trace norm regularization, as well as the main reason for it use, is that singular vectors are not fixed and those can often be seen as implicit features learned by the estimation procedure (Srebro et al., 2005). In this paper we derive consistency results about the value and numbers of such features.

Collaborative filtering and low-rank completion Another natural application is collaborative filtering where two types of attributes x and y are observed and we consider bilinear forms in x and y, which can be written as a linear form in $M = xy^\top$ (thus it corresponds to situations where all matrices M_i have rank one). In this setting, the matrices M_i are not usually i.i.d. but exhibit a statistical dependence structure outlined in Section 3.2. A special case here is when then no attributes are observed and we simply wish to complete a partially observed matrix (Srebro et al., 2005; Abernethy et al., 2006). The results presented in this paper do not immediately apply because the dimension of the estimated matrix may grow with the number of observed entries and this situation is out of the scope of this paper.

Multivariate linear supervised learning When predicting multiple variables, in the context of multivariate linear regression (Yuan et al., 2007) or in the multiple category classification (Amit et al., 2007), the trace norm allows to perform feature selection.

3.2 Assumptions

We make the following assumptions on the sampling distributions of $M \in \mathbb{R}^{p \times q}$ for the problem in Eq. (1). We let denote: $\hat{\Sigma}_{mm} = \frac{1}{n} \sum_{i=1}^n \mathrm{vec}(M_i)\,\mathrm{vec}(M_i)^\top \in \mathbb{R}^{pq \times pq}$, and we consider the following assumptions:

(**A1**) Given M_i, $i = 1, \ldots, n$, the n values z_i are i.i.d. and there exists $\mathbf{W} \in \mathbb{R}^{p \times q}$ such that for all i, $\mathbb{E}(z_i | M_1, \ldots, M_n) = \mathrm{tr}\mathbf{W}^\top M_i$ and $\mathrm{var}(z_i | M_1, \ldots, M_n)$ is a strictly positive constant σ^2. $\mathbf{W}$ is not equal to zero and does not have full rank.

(**A2**) There exists an *invertible* matrix $\Sigma_{mm} \in \mathbb{R}^{pq \times pq}$ such that $\mathbb{E}\|\hat{\Sigma}_{mm} - \Sigma_{mm}\|_F^2 = O(\zeta_n^2)$ for a certain sequence ζ_n that tends to zero.

(**A3**) The random variable $n^{-1/2}\sum_{i=1}^n \varepsilon_i \operatorname{vec}(M_i)$ is converging in distribution to a normal distribution with mean zero and covariance matrix $\sigma^2\Sigma_{mm}$.

Assumption (**A1**) states that given the input matrices M_i, $i = 1,\dots,n$ we have a linear prediction model, where the loading matrix $\mathbf{W}$ is non trivial and rank-deficient, the goal being to estimate this rank (as well as the matrix itself). We let denote $\mathbf{W} = \mathbf{U}\operatorname{Diag}(\mathbf{s})\mathbf{V}^\top$ its singular value decomposition, with $\mathbf{U} \in \mathbb{R}^{p\times \mathbf{r}}$, $\mathbf{V} \in \mathbb{R}^{q\times \mathbf{r}}$, and $\mathbf{r} \in (0, \min\{p,q\})$ denotes the rank of $\mathbf{W}$. We also let denote $\mathbf{U}_\perp \in \mathbb{R}^{p\times(p-\mathbf{r})}$ and $\mathbf{V}_\perp \in \mathbb{R}^{q\times(q-\mathbf{r})}$ any orthogonal complements of $\mathbf{U}$ and $\mathbf{V}$.

We let denote $\varepsilon_i = z_i - \operatorname{tr}\mathbf{W}^\top M_i$ and $\hat{\Sigma}_{Mz} = \frac{1}{n}\sum_{i=1}^n z_i M_i \in \mathbb{R}^{p\times q}$, $\hat{\Sigma}_{M\varepsilon} = \frac{1}{n}\sum_{i=1}^n \varepsilon_i M_i = \hat{\Sigma}_{Mz} - \hat{\Sigma}_{mm}\mathbf{W} \in \mathbb{R}^{p\times q}$. We may then rewrite Eq. (1) as

$$\min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2}\operatorname{vec}(W)^\top \hat{\Sigma}_{mm}\operatorname{vec}(W) - \operatorname{tr}W^\top \hat{\Sigma}_{Mz} + \lambda_n \|W\|_*,$$

or, equivalently,

$$\min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2}\operatorname{vec}(W-\mathbf{W})^\top \hat{\Sigma}_{mm}\operatorname{vec}(W-\mathbf{W}) - \operatorname{tr}W^\top \hat{\Sigma}_{M\varepsilon} + \lambda_n \|W\|_*.$$

The sampling assumptions (**A2**) and (**A3**) may seem restrictive, but they are satisfied in the following two natural situations. The first situation corresponds to a classical full i.i.d problem, where the pairs (z_i, M_i) are sampled i.i.d:

Lemma 1 *Assume (**A1**). If the matrices M_i are sampled i.i.d., z and M have finite fourth order moments, and $\mathbb{E}\left\{\operatorname{vec}(M)\operatorname{vec}(M)^\top\right\}$ is invertible, then (**A2**) and (**A3**) are satisfied with $\zeta_n = n^{-1/2}$.*

Note the further refinement when for each i, $M_i = x_i y_i^\top$ and x_i and y_i are independent, which implies that Σ_{mm} is factorized as a Kronecker product, of the form $\Sigma_{yy} \otimes \Sigma_{xx}$ where Σ_{xx} and Σ_{yy} are the (invertible) second order moment matrices of x and y.

The second situation corresponds to a collaborative filtering situation where two types of attributes are observed, for example, x and y, and for every pair (x,y) we wish to predict z as a bilinear form in x and y: we first sample n_x values for x, and n_y values for y, and we select uniformly at random a subset of $n \leqslant n_x n_y$ observations from the $n_x n_y$ possible pairs. The following lemma, proved in Appendix C.1, shows that this set-up satisfies our assumptions:

Lemma 2 *Assume (**A1**). Assume moreover that n_x values $\tilde{x}_1,\dots,\tilde{x}_{n_x}$ are sampled i.i.d and n_y values $\tilde{y}_1,\dots,\tilde{y}_{n_y}$ are also sampled i.i.d. from distributions with finite fourth order moments and invertible second order moment matrices Σ_{xx} and Σ_{yy}. Assume also that a random subset of size n of pairs (i_k, j_k) in $\{1,\dots,n_x\}\times\{1,\dots,n_y\}$ is sampled uniformly, then if n_x, n_y and n tend to infinity, then (**A2**) and (**A3**) are satisfied with $\Sigma_{mm} = \Sigma_{yy}\otimes\Sigma_{xx}$ and $\zeta_n = n^{-1/2} + n_x^{-1/2} + n_y^{-1/2}$.*

3.3 Optimality Conditions

From the expression of the subdifferential of the trace norm in Proposition 21 (Appendix B), we can identify the optimality condition for problem in Eq. (1), that we will constantly use in the paper:

Proposition 3 *The matrix W with singular value decomposition $W = U\,\mathrm{Diag}(s)V^\top$ (with strictly positive singular values s) is optimal for the problem in Eq. (1) if and only if*

$$\hat{\Sigma}_{mm}W - \hat{\Sigma}_{Mz} + \lambda_n UV^\top + N = 0,$$

with $U^\top N = 0$, $NV = 0$ and $\|N\|_2 \leqslant \lambda_n$.

This implies notably that W and $\hat{\Sigma}_{mm}W - \hat{\Sigma}_{Mz}$ have *simultaneous* singular value decompositions, and the largest singular values are less than λ_n, and exactly equal to λ_n for the corresponding strictly positive singular values of W. Note that when all matrices are diagonal (the Lasso case), we obtain the usual optimality conditions (see also Recht et al., 2007, for further discussions).

4. Consistency Results

We consider two types of consistency; first, the *regular consistency*, that is, we want the probability $\mathbb{P}(\|\hat{W} - \mathbf{W}\| \geqslant \varepsilon)$ to tend to zero as n tends to infinity, for all $\varepsilon > 0$. We also consider the *rank consistency*, that is, we want that $\mathbb{P}(\mathrm{rank}(\hat{W}) \neq \mathrm{rank}(\mathbf{W}))$ tends to zero as n tends to infinity. Following the similar properties for the Lasso, the consistency depends on the decay of the regularization parameter. Essentially, we obtain the following results:

a) if λ_n does not tend to zero, then the trace norm estimate $\hat{W}$ is not consistent;

b) if λ_n tends to zero faster than $n^{-1/2}$, then the estimate is consistent and its error is $O_p(n^{-1/2})$ while it is not rank-consistent with probability tending to one (see Section 4.1);

c) if λ_n tends to zero exactly at rate $n^{-1/2}$, then the estimator is consistent with error $O_p(n^{-1/2})$ but the probability of estimating the correct rank is converging to a limit in $(0,1)$ (see Section 4.2);

d) if λ_n tends to zero more slowly than $n^{-1/2}$, then the estimate is consistent with error $O_p(\lambda_n)$ and its rank consistency depends on specific *consistency conditions* detailed in Section 4.3.

The following sections will look at each of these cases, and state precise theorems. We then consider some special cases, that is, factored second-order moments and implications for the special cases of the Lasso and group Lasso.

The first proposition (proved in Appendix C.2) considers the case where the regularization parameter λ_n is converging to a certain limit λ_0. When this limit is zero, we obtain regular consistency (Corollary 5 below), while if $\lambda_0 > 0$, then $\hat{W}$ tends in probability to a limit which is always different from $\mathbf{W}$:

Proposition 4 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If λ_n tends to a limit $\lambda_0 \geqslant 0$, then $\hat{W}$ converges in probability to the unique global minimizer of*

$$\min_{W \in \mathbb{R}^{p\times q}} \frac{1}{2}\,\mathrm{vec}(W - \mathbf{W})^\top \Sigma_{mm}\,\mathrm{vec}(W - \mathbf{W}) + \lambda_0 \|W\|_*.$$

Corollary 5 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If λ_n tends to zero, then $\hat{W}$ converges in probability to $\mathbf{W}$.*

We now consider finer results when λ_n tends to zero at certain rates, slower or faster than $n^{-1/2}$, or exactly at rate $n^{-1/2}$.

4.1 Fast Decay of Regularization Parameter

The following proposition—which is a consequence of standard results in M-estimation (Shao, 2003; Van der Vaart, 1998)—considers the case where $n^{1/2}\lambda_n$ is tending to zero, where we obtain that $\hat{W}$ is asymptotically normal with mean $\mathbf{W}$ and covariance matrix $n^{-1}\sigma^2\Sigma_{mm}^{-1}$, that is, for fast decays, the first order expansion is the same as the one with no regularization parameter:

Proposition 6 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If $n^{1/2}\lambda_n$ tends to zero, $n^{1/2}(\hat{W}-\mathbf{W})$ is asymptotically normal with mean $\mathbf{W}$ and covariance matrix $\sigma^2\Sigma_{mm}^{-1}$.*

We now consider the corresponding rank consistency results, when λ_n goes to zero faster than $n^{-1/2}$. The following proposition (proved in Appendix C.3) states that for such regularization parameter, the solution has rank strictly greater than $\mathbf{r}$ with probability tending to one and can thus not be rank consistent:

Proposition 7 *Assume (**A1-3**). If $n^{1/2}\lambda_n$ tends to zero, then $\mathbb{P}(\mathrm{rank}(\hat{W}) > \mathrm{rank}(\mathbf{W}))$ tends to one.*

4.2 $n^{-1/2}$-decay of the Regularization Parameter

We first consider regular consistency through the following proposition (proved in Appendix C.4), then rank consistency (proposition proved in Appendix C.5):

Proposition 8 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If $n^{1/2}\lambda_n$ tends to a limit $\lambda_0 > 0$, then $n^{1/2}(\hat{W}-\mathbf{W})$ converges in distribution to the unique global minimizer of*

$$\min_{\Delta\in\mathbb{R}^{p\times q}} \frac{1}{2}\mathrm{vec}(\Delta)^\top\Sigma_{mm}\mathrm{vec}(\Delta) - \mathrm{tr}\Delta^\top A + \lambda_0\left[\mathrm{tr}\mathbf{U}^\top\Delta\mathbf{V} + \|\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp\|_*\right],$$

where $\mathrm{vec}(A)\in\mathbb{R}^{pq}$ is normally distributed with mean zero and covariance matrix $\sigma^2\Sigma_{mm}$.

Proposition 9 *Assume (**A1-3**). If $n^{1/2}\lambda_n$ tends to a limit $\lambda_0 > 0$, then the probability that the rank of $\hat{W}$ is different from the rank of $\mathbf{W}$ is converging to $\mathbb{P}(\|\Lambda - \lambda_0^{-1}\Theta\|_2 \leqslant 1) \in (0,1)$ where $\Lambda \in \mathbb{R}^{(p-\mathbf{r})\times(q-\mathbf{r})}$ is defined in Eq. (3) (Section 4.3) and $\Theta\in\mathbb{R}^{(p-\mathbf{r})\times(q-\mathbf{r})}$ has a normal distribution with mean zero and covariance matrix*

$$\sigma^2\left((\mathbf{V}_\perp\otimes\mathbf{U}_\perp)^\top\Sigma_{mm}^{-1}(\mathbf{V}_\perp\otimes\mathbf{U}_\perp)\right)^{-1}.$$

The previous proposition ensures that the estimate $\hat{W}$ cannot be rank consistent with this decay of the regularization parameter. Note that when we take λ_0 small (i.e., we get closer to fast decays), the probability $\mathbb{P}(\|\Lambda-\lambda_0^{-1}\Theta\|_2\leqslant 1)$ tends to zero, while when we take λ_0 large (i.e., we get closer to slow decays), the same probability tends to zero or one depending on the sign of $\|\Lambda\|_2 - 1$. This heuristic argument is made more precise in the following section.

4.3 Slow Decay of Regularization Parameter

When λ_n tends to zero more slowly than $n^{-1/2}$, the first order expansion is deterministic, as the following proposition shows (proof in Appendix C.6):

Proposition 10 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If $n^{1/2}\lambda_n$ tends to $+\infty$ and λ_n tends to zero, then $\lambda_n^{-1}(\hat{W}-\mathbf{W})$ converges in probability to the unique global minimizer Δ of*

$$\min_{\Delta\in\mathbb{R}^{p\times q}} \frac{1}{2}\operatorname{vec}(\Delta)^\top \Sigma_{mm}\operatorname{vec}(\Delta) + \operatorname{tr}\mathbf{U}^\top\Delta\mathbf{V} + \|\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp\|_*. \tag{2}$$

Moreover, we have $\hat{W} = \mathbf{W} + \lambda_n\Delta + O_p(\lambda_n + \zeta_n + \lambda_n^{-1}n^{-1/2})$.

The last proposition gives a first order expansion of $\hat{W}$ around $\mathbf{W}$. From Proposition 18 (Appendix B), we obtain immediately that if $\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp$ is different from zero, then the rank of $\hat{W}$ is ultimately strictly larger than $\mathbf{r}$. The condition $\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp = 0$ is thus necessary for rank consistency when $\lambda_n n^{1/2}$ tends to infinity while λ_n tends to zero. The next lemma (proved in Appendix 11), gives a necessary and sufficient condition for $\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp = 0$.

Lemma 11 *Assume Σ_{mm} is invertible, and $\mathbf{W} = \mathbf{U}\operatorname{Diag}(\mathbf{s})\mathbf{V}^\top$ is the singular value decomposition of $\mathbf{W}$. Then the unique global minimizer of*

$$\operatorname{vec}(\Delta)^\top \Sigma_{mm}\operatorname{vec}(\Delta) + \operatorname{tr}\mathbf{U}^\top\Delta\mathbf{V} + \|\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp\|_*$$

satisfies $\mathbf{U}_\perp^\top\Delta\mathbf{V}_\perp = 0$ if and only if

$$\left\| \left((\mathbf{V}_\perp\otimes\mathbf{U}_\perp)^\top\Sigma_{mm}^{-1}(\mathbf{V}_\perp\otimes\mathbf{U}_\perp)\right)^{-1}\left((\mathbf{V}_\perp\otimes\mathbf{U}_\perp)^\top\Sigma_{mm}^{-1}(\mathbf{V}\otimes\mathbf{U})\operatorname{vec}(\mathbf{I})\right)\right\|_2 \leqslant 1.$$

This leads to consider the matrix $\Lambda\in\mathbb{R}^{(p-\mathbf{r})\times(q-\mathbf{r})}$ defined as

$$\operatorname{vec}(\Lambda) = \left((\mathbf{V}_\perp\otimes\mathbf{U}_\perp)^\top\Sigma_{mm}^{-1}(\mathbf{V}_\perp\otimes\mathbf{U}_\perp)\right)^{-1}\left((\mathbf{V}_\perp\otimes\mathbf{U}_\perp)^\top\Sigma_{mm}^{-1}(\mathbf{V}\otimes\mathbf{U})\operatorname{vec}(\mathbf{I})\right), \tag{3}$$

and the two weak and strict *consistency conditions*:

$$\|\Lambda\|_2 \leqslant 1, \tag{4}$$

$$\|\Lambda\|_2 < 1. \tag{5}$$

Note that if Σ_{mm} is proportional to identity, they are always satisfied because then $\Lambda = 0$. We can now prove that the condition in Eq. (5) is sufficient for rank consistency when $n^{1/2}\lambda_n$ tends to infinity, while the condition Eq. (4) is necessary for the existence of a sequence λ_n such that the estimate is both consistent and rank consistent (which is a stronger result than restricting λ_n to be tending to zero slower than $n^{-1/2}$). The following two theorems are proved in Appendix C.8 and C.9:

Theorem 12 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If the condition in Eq. (5) is satisfied, and if $n^{1/2}\lambda_n$ tends to $+\infty$ and λ_n tends to zero, then the estimate $\hat{W}$ is consistent and rank-consistent.*

Theorem 13 *Assume (**A1-3**). Let $\hat{W}$ be a global minimizer of Eq. (1). If the estimate $\hat{W}$ is consistent and rank-consistent, then the condition in Eq. (4) is satisfied.*

As opposed to the Lasso, where Eq. (4) is a necessary and sufficient condition for rank consistency (Yuan and Lin, 2007), this is not even true in general for the group Lasso (Bach, 2008). Looking at the limiting case $\|\Lambda\|_2 = 1$ would similarly lead to additional but more complex sufficient and necessary conditions, and is left out for future research.

Moreover, it may seem surprising that even when the sufficient condition Eq. (5) is fulfilled, that the first order expansion of $\hat{W}$, that is, $\hat{W} = \mathbf{W} + \lambda_n \Delta + o_p(\lambda_n)$ is such that $\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp = 0$, but nothing is said about $\mathbf{U}_\perp^\top \Delta \mathbf{V}$ and $\mathbf{U}^\top \Delta \mathbf{V}_\perp$, which are not equal to zero in general. This is due to the fact that the first $\mathbf{r}$ singular vectors U and V of $\mathbf{W} + \lambda_n \Delta$ are not fixed; indeed, the $\mathbf{r}$ first singular vectors (i.e., the implicit features) do rotate but with no contribution on $\mathbf{U}_\perp \mathbf{V}_\perp^\top$. This is to be contrasted with the adaptive version where asymptotically the first order expansion has constant singular vectors (see Section 5).

Finally, in this paper, we have only proved whether the probability of correct rank selection tends to zero or one. Proposition 9 suggests that when $\lambda_n n^{1/2}$ tends to infinity slowly, then this probability is close to $\mathbb{P}(\|\Lambda - \lambda_n^{-1} n^{1/2} \Theta\|_2 \leqslant 1)$, where Θ has a normal distribution with known covariance matrix, which converges to one exponentially fast when $\|\Lambda\|_2 < 1$. We are currently investigating additional assumptions under which such results are true and thus estimate the convergence rates of the probability of good rank selection as done by Zhao and Yu (2006) for the Lasso.

4.4 Factored Second Order Moment

Note that in the situation where n_x points in $\mathbb{R}^p$ and n_y points in $\mathbb{R}^q$ are sampled i.i.d and a random subset of n points in selected, then, we can refine the condition as follows (because $\Sigma_{mm} = \Sigma_{yy} \otimes \Sigma_{xx}$):

$$\Lambda = (\mathbf{U}_\perp^\top \Sigma_{xx}^{-1} \mathbf{U}_\perp)^{-1} \mathbf{U}_\perp^\top \Sigma_{xx}^{-1} \mathbf{U} \mathbf{V}^\top \Sigma_{yy}^{-1} \mathbf{V}_\perp (\mathbf{V}_\perp^\top \Sigma_{yy}^{-1} \mathbf{V}_\perp)^{-1},$$

which is equal to (by the expression of inverses of partitioned matrices):

$$\Lambda = (\mathbf{U}_\perp^\top \Sigma_{xx} \mathbf{U})(\mathbf{U}^\top \Sigma_{xx} \mathbf{U})^{-1} (\mathbf{V}^\top \Sigma_{yy} \mathbf{V})^{-1} (\mathbf{V}^\top \Sigma_{yy} \mathbf{V}_\perp).$$

This also happens when $M_i = x_i y_i^\top$ and x_i and y_i independent for all i.

4.5 Corollaries for the Lasso and Group Lasso

For the Lasso or the group Lasso, all proposed results in Section 4.3 should hold with the additional conditions that W and Δ are diagonal (block-diagonal for the group Lasso). In this situation, the singular values of the diagonal matrix $W = \mathrm{Diag}(w)$ are the norms of the diagonal blocks, while the left singular vectors are equal to the normalized versions of the block (the signs for the Lasso). However, the results developed in Section 4.3 do not immediately apply since the assumptions regarding the invertibility of the second order moment matrix is not satisfied. For those problems, all matrices M that are ever considered belong to a strict subspace of $\mathbb{R}^{p \times q}$ and we need to satisfy invertibility on that subspace.

More precisely, we assume that all matrices M are such that $\mathrm{vec}(M) = Hx$ where H is a given *design matrix* in $\mathbb{R}^{pq \times s}$ where s is the number of implicit parameter and $x \in \mathbb{R}^s$. If we replace the invertibility of Σ_{mm} by the invertibility of $H^\top \Sigma_{mm} H$, then all results presented in Section 4.3 are

valid, in particular, the matrix Λ may be written as

$$\mathrm{vec}(\Lambda) = \left((\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top H (H^\top \Sigma_{mm} H)^{-1} H^\top (\mathbf{V}_\perp \otimes \mathbf{U}_\perp)\right)^\dagger \times \left((\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top H (H^\top \Sigma_{mm} H)^{-1} H^\top (\mathbf{V} \otimes \mathbf{U}) \mathrm{vec}(\mathbf{I})\right), \quad (6)$$

where $A^\dagger$ denotes the pseudo-inverse of A (Golub and Loan, 1996).

We now apply Eq. (6) to the case of the group Lasso (which includes the Lasso as a special case). In this situation, we have $M = \mathrm{Diag}(x_1, \ldots, x_m)$ and each $x_j \in \mathbb{R}^{d_j}$, $j = 1, \ldots, m$; we consider w as being defined by blocks $w_1, \ldots, w_m$, where each $w_j \in \mathbb{R}^{d_j}$. The design matrix H is such that $Hw = \mathrm{vec}(\mathrm{Diag}(w))$ and the matrix $H^\top \Sigma_{mm} H$ is exactly equal to the joint covariance matrix Σ_{xx} of $x = (x_1, \ldots, x_m)$. Without loss of generality, we assume that the generating sparsity pattern corresponds to the first $\mathbf{r}$ blocks. We can then compute the singular value decomposition in closed form as $\mathbf{U} = \binom{(\mathrm{Diag}(\mathbf{w}_i / \|\mathbf{w}_i\|)_{i \leqslant \mathbf{r}})}{0}$, $\mathbf{V} = \binom{\mathbf{I}}{0}$ and $\mathbf{s} = (\|\mathbf{w}_j\|)_{j \leqslant \mathbf{r}}$. If we let denote, for each j, $\mathbf{O}_j$ a basis of the subspace orthogonal to $\mathbf{w}_j$, we have: $\mathbf{U}_\perp = \begin{pmatrix} \mathrm{Diag}(\mathbf{O}_i)_{i \leqslant \mathbf{r}} & 0 \\ 0 & \mathbf{I} \end{pmatrix}$ and $\mathbf{V}_\perp = \binom{0}{\mathbf{I}}$. We can put these singular vectors into Eq. (6) and get $(H^\top \Sigma_{mm} H)^{-1} H^\top (\mathbf{V} \otimes \mathbf{U}) \mathrm{vec}(\mathbf{I}) = (\Sigma_{xx}^{-1})_{\mathbf{J} \cup \mathbf{J}^c, \mathbf{J}} \eta_{\mathbf{J}}$, where $\mathbf{J} = \{1, \ldots, \mathbf{r}\}$ and $\eta_{\mathbf{J}}$ is the vector of normalized $\mathbf{w}_j$, $j \in \mathbf{J}$. Thus, for the group Lasso, we finally obtain:

$$\begin{aligned} \|\Lambda\|_2 &= \left\|\mathrm{Diag}\left[((\Sigma_{xx}^{-1})_{\mathbf{J}^c \mathbf{J}^c})^{-1} (\Sigma_{xx}^{-1})_{\mathbf{J}^c, \mathbf{J}} \eta_{\mathbf{J}}\right]\right\|_2 \\ &= \left\|\mathrm{Diag}\left[(\Sigma_{xx})_{\mathbf{J}^c \mathbf{J}} (\Sigma_{xx})_{\mathbf{J},\mathbf{J}}^{-1} \eta_{\mathbf{J}}\right]\right\|_2 \text{ by the partitioned matrices inversion lemma,} \\ &= \max_{i \in \mathbf{J}^c} \left\|\Sigma_{x_i x_{\mathbf{J}}} \Sigma_{x_{\mathbf{J}} x_{\mathbf{J}}}^{-1} \eta_{\mathbf{J}}\right\|. \end{aligned}$$

The condition on the invertibility of $H^\top \Sigma_{mm} H$ is exactly the invertibility of the full joint covariance matrix of $x = (x_1, \ldots, x_m)$ and is a standard assumption for the Lasso or the group Lasso (Yuan and Lin, 2007; Zhao and Yu, 2006; Zou, 2006; Bach, 2008). Moreover the condition $\|\Lambda\|_2 \leqslant 1$ is exactly the one for the group Lasso (Bach, 2008), where the pattern consistency is replaced by the consistency for the number of non zero groups.

Note that we only obtain a result in terms of numbers of selected groups of variables and not in terms of the identities of the groups themselves. However, because of regular consistency, we know that at least the $\mathbf{r}$ true groups will be selected, and then correct model size is asymptotically equivalent to the correct groups being selected.

5. Adaptive Version

We can follow the adaptive version of the Lasso to provide a consistent algorithm with no consistency conditions such as Eq. (4) or Eq. (5). More precisely, we consider the least-square estimate $\mathrm{vec}(\hat{W}_{LS}) = \hat{\Sigma}_{mm}^{-1} \mathrm{vec}(\hat{\Sigma}_{Mz})$. We have the following well known result for least-square regression:

Lemma 14 *Assume (**A1-3**). Then $n^{1/2}(\hat{\Sigma}_{mm}^{-1} \mathrm{vec}(\hat{\Sigma}_{Mz}) - \mathrm{vec}(\mathbf{W}))$ is converging in distribution to a normal distribution with zero mean and covariance matrix $\sigma^2 \Sigma_{mm}^{-1}$.*

We consider the singular value decomposition of $\hat{W}_{LS} = U_{LS} \mathrm{Diag}(s_{LS}) V_{LS}^\top$, where $s_{LS} \geqslant 0$. With probability tending to one, $\min\{p, q\}$ singular values are strictly positive (i.e., the rank of $\hat{W}_{LS}$ is

full). We consider the *full* decomposition where U_{LS} and V_{LS} are orthogonal *square* matrices and the matrix $\mathrm{Diag}(s_{LS})$ is rectangular. We complete the singular values $s_{LS} \in \mathbb{R}^{\min\{p,q\}}$ by $n^{-1/2}$ to reach dimensions p and q (we keep the same notation for both dimensions for simplicity).

For $\gamma \in (0,1]$, we let denote

$$A = U_{LS}\,\mathrm{Diag}(s_{LS})^{-\gamma} U_{LS}^\top \in \mathbb{R}^{p\times p} \text{ and } B = V_{LS}\,\mathrm{Diag}(s_{LS})^{-\gamma} V_{LS}^\top \in \mathbb{R}^{q\times q},$$

two positive definite symmetric matrices, and, following the adaptive Lasso of Zou (2006), we consider replacing $\|W\|_*$ by $\|AWB\|_*$—note that in the Lasso special case, this exactly corresponds to the adaptive Lasso of Zou (2006). We obtain the following consistency theorem (proved in Appendix C.10):

Theorem 15 *Assume (**A1-3**). If $\gamma \in (0,1]$, $n^{1/2}\lambda_n$ tends to 0 and $\lambda_n n^{1/2+\gamma/2}$ tends to infinity, then any global minimizer $\hat{W}_A$ of*

$$\frac{1}{2n}\sum_{i=1}^n (z_i - \mathrm{tr} W^\top M_i)^2 + \lambda_n \|AWB\|_*$$

is consistent and rank consistent. Moreover, $n^{1/2}\,\mathrm{vec}(\hat{W}_A - \mathbf{W})$ is converging in distribution to a normal distribution with mean zero and covariance matrix

$$\sigma^2 (\mathbf{V}\otimes\mathbf{U}) \Big[(\mathbf{V}\otimes\mathbf{U})^\top \Sigma_{mm} (\mathbf{V}\otimes\mathbf{U}) \Big]^{-1} (\mathbf{V}\otimes\mathbf{U})^\top.$$

Note the restriction $\gamma \leqslant 1$ which is due to the fact that the least-square estimate $\hat{W}_{LS}$ only estimates the singular subspaces at rate $O_p(n^{-1/2})$. In Section 6.3, we illustrate the previous theorem on synthetic examples. In particular, we exhibit some singular behavior for the limiting case $\gamma = 1$.

6. Algorithms and Simulations

In this section we provide a simple algorithm to solve problems of the form

$$\min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2}\mathrm{vec}(W)^\top \Sigma\, \mathrm{vec}(W) - \mathrm{tr} W^\top Q + \lambda \|W\|_*, \tag{7}$$

where $\Sigma \in \mathbb{R}^{pq\times pq}$ is a positive definite matrix (note that we do not restrict Σ to be of the form $\Sigma = A\otimes B$ where A and B are positive semidefinite matrices of size $p\times p$ and $q\times q$). We assume that $\mathrm{vec}(Q)$ is in the column space of Σ, so that the optimization problem is bounded from below (and thus the dual is feasible). In our setting, we have $\Sigma = \hat{\Sigma}_{mm}$ and $Q = \hat{\Sigma}_{Mz}$.

We focus on problems where p and q are not too large so that we can apply Newton's method to obtain convergence up to machine precision, which is required for the fine analysis of rank consistency in Section 6.3. For more efficient algorithms with larger p and q, see Srebro et al. (2005); Rennie and Srebro (2005) and Abernethy et al. (2006); Lu et al. (2008).

Because the dual norm of the trace norm is the spectral norm (see Appendix B), the dual is easily obtained as

$$\max_{V\in\mathbb{R}^{p\times q}, \|V\|_2\leqslant 1} -\frac{1}{2}\mathrm{vec}(Q-\lambda V)^\top \Sigma^{-1}\,\mathrm{vec}(Q-\lambda V). \tag{8}$$

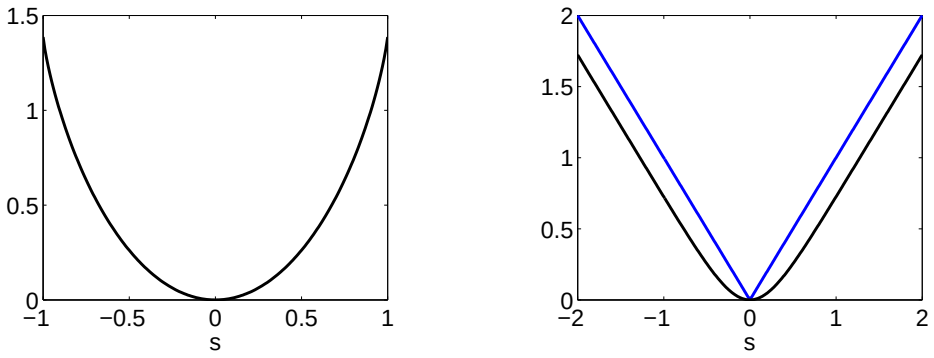

Figure 1: Spectral barrier functions: (left) primal function $b(s)$ and (right) dual functions $b^*(s)$.

Indeed, we have:

$$\begin{aligned}
& \min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2}\mathrm{vec}(W)^\top \Sigma \mathrm{vec}(W) - \mathrm{tr}W^\top Q + \lambda\|W\|_* \\
= & \min_{W\in\mathbb{R}^{p\times q}} \max_{V\in\mathbb{R}^{p\times q},\|V\|_2\leqslant 1} \frac{1}{2}\mathrm{vec}(W)^\top \Sigma \mathrm{vec}(W) - \mathrm{tr}W^\top Q + \lambda \mathrm{tr}V^\top W \\
= & \max_{V\in\mathbb{R}^{p\times q},\|V\|_2\leqslant 1} \min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2}\mathrm{vec}(W)^\top \Sigma \mathrm{vec}(W) - \mathrm{tr}W^\top Q + \lambda \mathrm{tr}V^\top W \\
= & \max_{V\in\mathbb{R}^{p\times q},\|V\|_2\leqslant 1} -\frac{1}{2}\mathrm{vec}(Q-\lambda V)^\top \Sigma^{-1}\mathrm{vec}(Q-\lambda V),
\end{aligned}$$

where strong duality holds because both the primal and dual problems are convex and strictly feasible (Boyd and Vandenberghe, 2003).

6.1 Smoothing

The problem in Eq. (7) is convex but non differentiable; in this paper we consider adding a strictly convex function to its dual in Eq. (8) in order to make it differentiable, while controlling the increase of duality gap yielded by the added function (Bonnans et al., 2003).

We thus consider the following smoothing of the trace norm, namely we define

$$F_\varepsilon(W) = \max_{V\in\mathbb{R}^{p\times q},\|V\|_2\leqslant 1} \mathrm{tr}V^\top W - \varepsilon B(V),$$

where $B(V)$ is a spectral function (i.e., that depends only on singular values of V, equal to $B(V) = \sum_{i=1}^{\min\{p,q\}} b(s_i(V))$ where $b(s) = (1+s)\log(1+s) + (1-s)\log(1-s)$ if $|s| \leqslant 1$ and $+\infty$ otherwise ($s_i(V)$ denotes the i-th largest singular values of V). This function F_ε may be computed in closed form as:

$$F_\varepsilon(W) = \sum_{i=1}^{\min\{p,q\}} b^*(s_i(W)),$$

where $b^*(s) = \varepsilon\log(1+e^{s/\varepsilon}) + \varepsilon\log(1+e^{-s/\varepsilon}) - 2\varepsilon\log 2$. These functions are plotted in Figure 1; note that $|b^*(s) - |s||$ is uniformly bounded by $2\log 2$.

We finally get the following pairs of primal/dual optimization problems:

$$\min_{W\in\mathbb{R}^{p\times q}} \frac{1}{2}\operatorname{vec}(W)^\top \Sigma \operatorname{vec}(W) - \operatorname{tr} W^\top Q + \lambda F_{\varepsilon/\lambda}(W),$$

$$\max_{V\in\mathbb{R}^{p\times q}, \|V\|_2\leqslant 1} -\frac{1}{2}\operatorname{vec}(Q-\lambda V)^\top \Sigma^{-1}\operatorname{vec}(Q-\lambda V) - \varepsilon B(V).$$

We can now optimize directly in the primal formulation which is infinitely differentiable, using Newton's method. Note that the stopping criterion should be an $\varepsilon \times \min\{p,q\}$ duality gap, as the controlled smoothing also leads to a small additional gap on the solution of the original non smoothed problem. More precisely, a duality gap of $\varepsilon \times \min\{p,q\}$ on the smoothed problem, leads to a gap of at most $(1+2\log 2)\varepsilon \times \min\{p,q\}$ for the original problem.

6.2 Implementation Details

In this section, we provide details about the implementation of the estimation algorithm presented earlier.

Derivatives of spectral functions Note that derivatives of spectral functions of the form $B(W) = \sum_{i=1}^{\min\{p,q\}} b(s_i(W))$, where b is an even twice differentiable function such that $b(0) = b'(0) = 0$, are easily calculated as follows; Let $U\operatorname{Diag}(s)V^\top$ be the singular value decomposition of W. We then have the following Taylor expansion (Lewis and Sendov, 2002):

$$B(W+\Delta) = B(W) + \operatorname{tr}\Delta^\top U \operatorname{Diag}(b'(s_i))V^\top + \frac{1}{2}\sum_{i=1}^{p}\sum_{j=1}^{q}\frac{b'(s_i)-b'(s_j)}{s_i-s_j}(u_i^\top \Delta v_j)^2,$$

where the vector of singular values is completed by zeros, and $\frac{b'(s_i)-b'(s_j)}{s_i-s_j}$ is defined as $b''(s_i)$ when $s_i = s_j$.

Choice of ε and computational complexity Following the common practice in barrier methods we decrease the parameter geometrically after each iteration of Newton's method (Boyd and Vandenberghe, 2003). Each of these Newton iterations has complexity $O(p^3q^3)$. Empirically, the number of iterations does not exceed a few hundreds for solving one problem up to machine precision. We are currently investigating theoretical bounds on the number of iterations through self concordance theory (Boyd and Vandenberghe, 2003).

Start and end of the path In order to avoid to consider useless values of the regularization parameter and thus use a well adapted grid for trying several λ's, we can consider a specific interval for λ. When λ is large, the solution is exactly zero, while when λ is small, the solution tends to $\operatorname{vec}(W) = \Sigma^{-1}\operatorname{vec}(Q)$.

More precisely, if λ is larger than $\|Q\|_2$, then the solution is exactly zero (because in this situation 0 is in the subdifferential). On the other side, we consider for which λ, $\Sigma^{-1}\operatorname{vec}(Q)$ leads to a duality gap which is less than $\varepsilon\operatorname{vec}(Q)^\top\Sigma^{-1}\operatorname{vec}(Q)$, where ε is small. A looser condition is to take $V=0$, and the condition becomes $\lambda\|\Sigma^{-1}\operatorname{vec}(Q)\|_* \leqslant \varepsilon\operatorname{vec}(Q)^\top\Sigma^{-1}\operatorname{vec}(Q)$. Note that this is in the correct order (i.e., lower bound smaller than upper bound), because

$$\operatorname{vec}(Q)^\top\Sigma^{-1}\operatorname{vec}(Q) = \langle \operatorname{vec}(Q), \Sigma^{-1}\operatorname{vec}(Q)\rangle \leqslant \|\Sigma^{-1}\operatorname{vec}(Q)\|_*\|\operatorname{vec}(Q)\|_2.$$

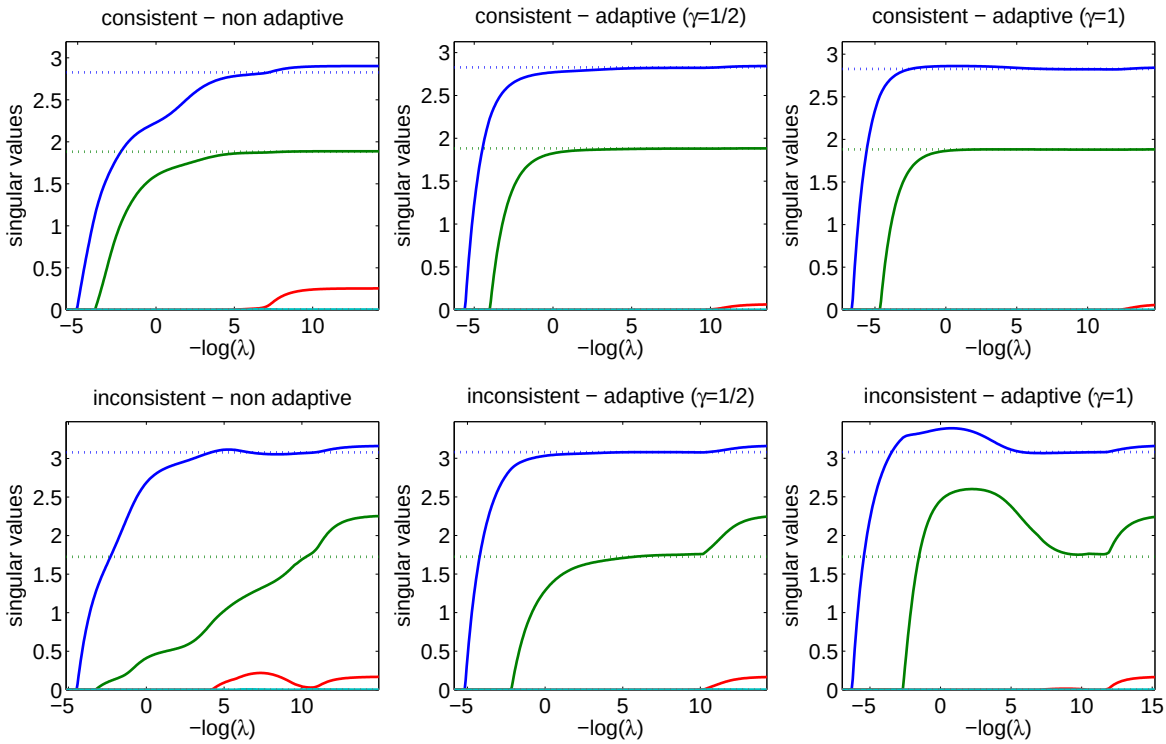

Figure 2: Examples of paths of singular values for $\|\Lambda\|_2 = 0.49 < 1$ (consistent, top) and $\|\Lambda\|_2 = 4.78 > 1$ (inconsistent, bottom) rank selection: regular trace norm penalization (left) and adaptive penalization with $\gamma = 1/2$ (center) and $\gamma = 1$ (right). Estimated singular values are plotted in plain, while population singular values are dotted.

This allows to design a good interval for searching for a good value of λ or for computing the regularization path by uniform grid sampling (in log scale), or for numerical path following with predictor-corrector methods such as used by Bach et al. (2004).

6.3 Simulations

In this section, we perform simulations on toy examples to illustrate our consistency results. We generate random i.i.d. data $\tilde{X}$ and $\tilde{Y}$ with Gaussian distributions and we select a low rank matrix $\mathbf{W}$ at random and generate $Z = \mathrm{diag}(\tilde{X}^\top \mathbf{W} \tilde{Y}) + \varepsilon$ where ε has i.i.d components with normal distributions with zero mean and known variance. In this section, we always use $\mathbf{r} = 2$, $p = q = 4$, while we consider several numbers of samples n, and several distributions for which the consistency conditions Eq. (4) and Eq. (5) may or may not be satisfied.[1]

In Figure 2, we plot regularization paths for $n = 10^3$, by showing the singular values of $\hat{W}$ compared to the singular values of $\mathbf{W}$, in two particular situations (Eq. (4) and Eq. (5) satisfied and not satisfied), for the regular trace norm regularization and the adaptive versions, with $\gamma = 1/2$ and $\gamma = 1$. Note that in the consistent case (top), the singular values and their cardinalities are well jointly estimated, both for the non adaptive version (as predicted by Theorem 12) and the adaptive

1. Simulations may be reproduced with MATLAB code available from `http://www.di.ens.fr/~fbach/tracenorm/`.

versions (Theorem 15), while the range of correct rank selection increases compared to the adaptive versions. However in the inconsistent case, the non adaptive regularizations scheme (bottom left) cannot achieve regular consistency together with rank consistency (Theorem 13), while the adaptive schemes can. Note the particular behavior of the limiting case $\gamma = 1$, which still achieves both consistencies but with a singular behavior for large λ.

In Figure 3, we select the distribution used for the rank-consistent case of Figure 2, and compute the paths from 200 replications for $n = 10^2$, 10^3, 10^3 and 10^5. For each λ, we plot the proportion of estimates with correct rank on the left plots (i.e., we get an estimation of $\mathbb{P}(\operatorname{rank}(\hat{W}) = \operatorname{rank}(\mathbf{W}))$, while we plot the logarithm of the average root mean squared estimation error $\|\hat{W} - \mathbf{W}\|$ on the right plot. For the three regularization schemes, the range of values with high probability of correct rank selection increases as n increases, and, most importantly achieves good mean squared error (right plot); in particular, for the non adaptive schemes (top plots), this corroborates the results from Proposition 9, which states that for $\lambda_n = \lambda_0 n^{-1/2}$ the probability tends to a limit in $(0,1)$: indeed, when n increases, the value λ_n which achieves a particular limit grows as $n^{-1/2}$, and considering the log-scale for λ_n in Figure 3 and the uniform sampling for n in log-scale as well, the regular spacing between the decaying parts observed in Figure 3 is coherent with our results.

In Figure 4, we perform the same operations but with the inconsistent case of Figure 2. For the non adaptive case (top plot), the range of values of λ that achieve high probability of correct rank selection does not increase when n increases and stays bounded, in places where the estimation error is not tending to zero: in the inconsistent case, the trace norm regularization does not manage to solve the trade-off between rank consistency and regular consistency. However, for the adaptive versions, it does, still with a somewhat singular behavior of the limiting case $\gamma = 1$.

Finally, in Figure 5, we consider 400 different distributions with various values of $\|\Lambda\|_2$ smaller or greater than one, and computed the regularization paths with $n = 10^3$ samples. From the paths, we consider the estimate $\hat{W}$ with correct rank and best distance to $\mathbf{W}$ and plot the best error versus $\log_{10}(\|\Lambda\|_2)$. For positive values of $\log_{10}(\|\Lambda\|_2)$, the best error is far from zero, and the error grows with the distance to zero; while for negative values, we get low errors with lower errors for small $\log_{10}(\|\Lambda\|_2)$, corroborating the influence of $\|\Lambda\|_2$ described in Proposition 9.

7. Conclusion

We have presented an analysis of the rank consistency for the penalization by the trace norm, and derived general necessary and sufficient conditions. This work can be extended in several interesting ways: first, by going from the square loss to more general losses, in particular for other types of supervised learning problems such as classification; or by looking at the collaborative filtering setting where only some of the attributes are observed (Abernethy et al., 2006) and dimensions p and q are allowed to grow. Moreover, we are currently pursuing non asymptotic extensions of the current work, making links with the recent work of Recht et al. (2007) and of Meinshausen and Yu (2006).

Appendix A. Tools for Analysis of Singular Value Decomposition

In this appendix, we review and derive precise results regarding singular value decompositions. We consider $W \in \mathbb{R}^{p \times q}$ and we let denote $W = U \operatorname{Diag}(s) V^\top$ its singular value decomposition with $U \in \mathbb{R}^{p \times r}$, $V \in \mathbb{R}^{q \times r}$ with orthonormal columns, and $s \in \mathbb{R}^r$ with strictly positive values (r is the rank

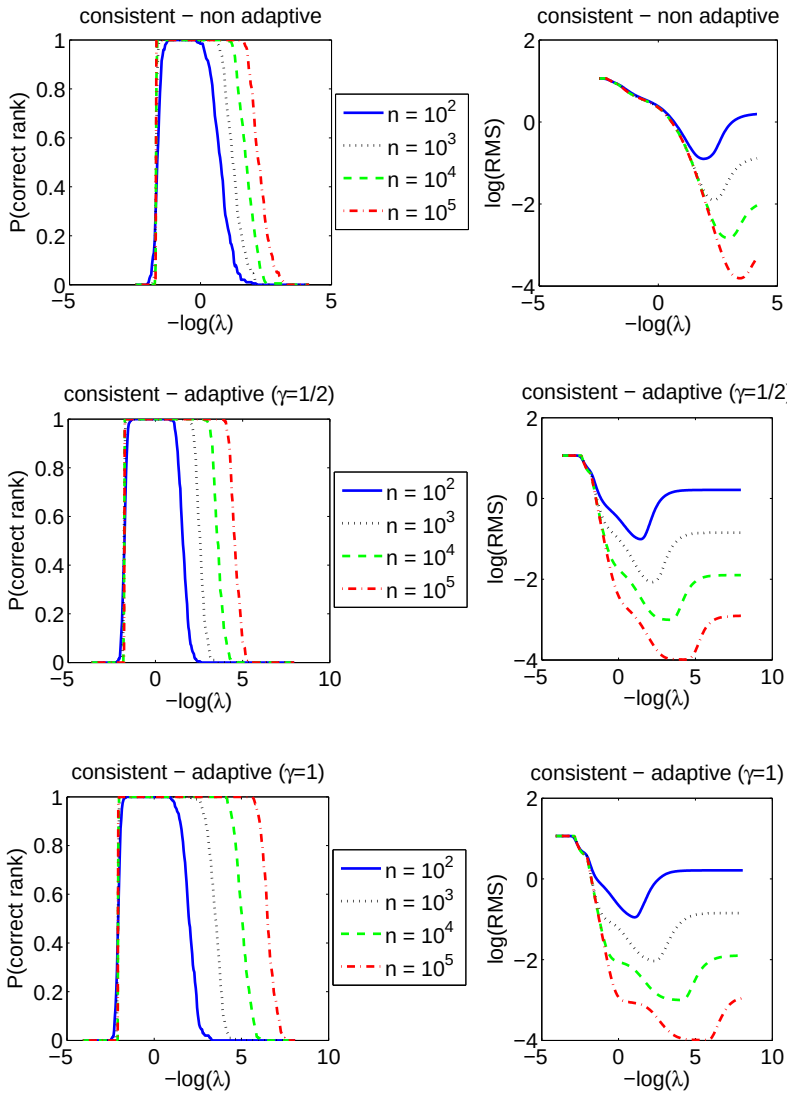

Figure 3: Synthetic example where consistency condition in Eq. (5) is satisfied: probability of correct rank selection (left) and logarithm of the expected mean squared estimation error (right), for several number of samples as a function of the regularization parameter, for regular regularization (top), adaptive regularization with $\gamma = 1/2$ (center) and $\gamma = 1$ (bottom).

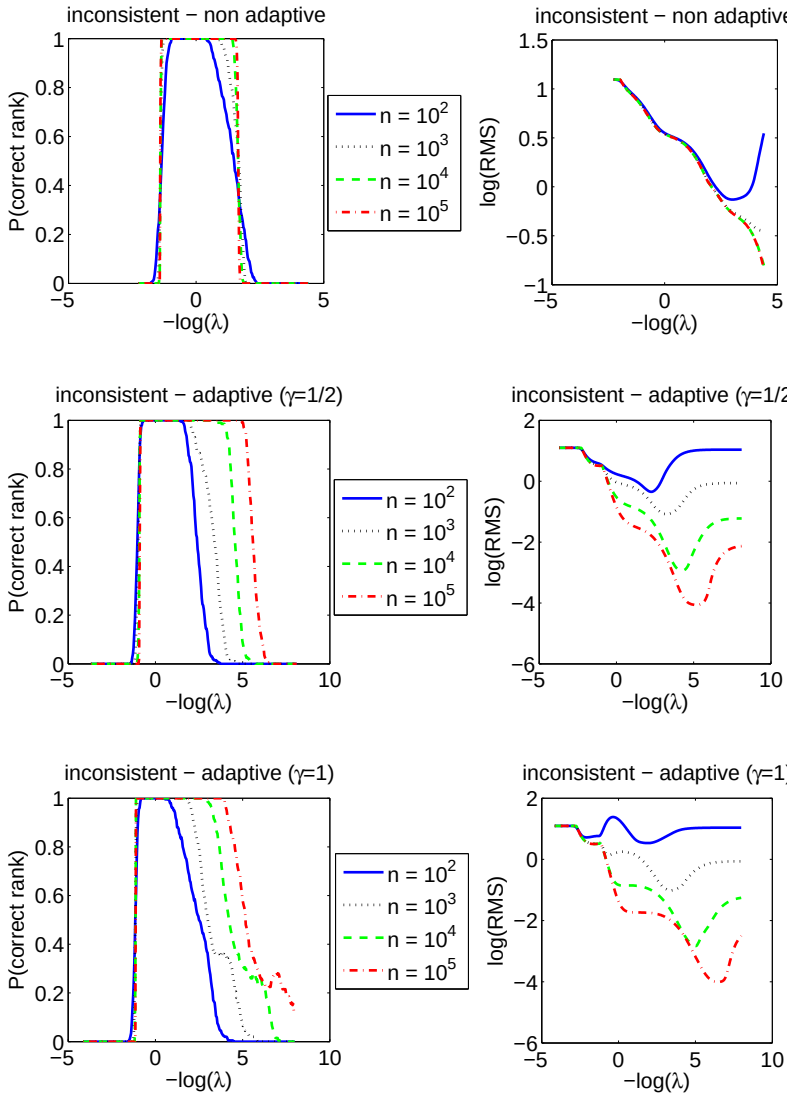

Figure 4: Synthetic example where consistency condition in Eq. (4) is not satisfied: probability of correct rank selection (left) and logarithm of the expected mean squared estimation error (right), for several number of samples as a function of the regularization parameter, for regular regularization (top), adaptive regularization with $\gamma = 1/2$ (center) and $\gamma = 1$ (bottom).

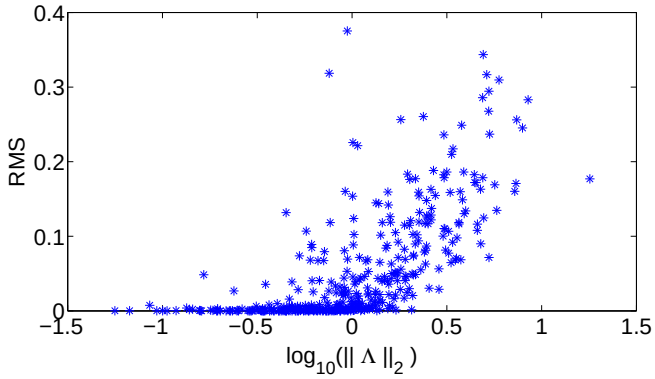

Figure 5: Scatter plots of $\log_{10}(\|\Lambda\|_2)$ versus the squared error of the best estimate with correct rank (i.e., such that $\mathrm{rank}(\hat{W}) = \mathbf{r}$ and $\|\hat{W} - \mathbf{W}\|$ as small as possible). See text for details.

of W). Note that when a singular value s_i is simple, that is, does not coalesce with any other singular values, then the vectors u_i and v_i are uniquely defined up to simultaneous sign flips, that is, only the matrix $u_i v_i^\top$ is unique. However, when some singular values coalesce, then the corresponding singular vectors are defined up to a rotation, and thus in general care must be taken and considering isolated singular vectors should be avoided (Stewart and Sun, 1990). All tools presented in this appendix are robust to the particular choice of the singular vectors.

A.1 Jordan-Wielandt Matrix

We use the fact that singular values of W can be obtained from the eigenvalues of the Jordan-Wielandt matrix $\bar{W} = \begin{pmatrix} 0 & W \\ W^\top & 0 \end{pmatrix} \in \mathbb{R}^{(p+q)\times(p+q)}$ (Stewart and Sun, 1990). Indeed this matrix has eigenvalues s_i and $-s_i$, $i = 1,\ldots,r$, where s_i are the (strictly positive) singular values of W, with eigenvectors $\frac{1}{\sqrt{2}}\begin{pmatrix} u_i \\ v_i \end{pmatrix}$ and $\frac{1}{\sqrt{2}}\begin{pmatrix} u_i \\ -v_i \end{pmatrix}$ where u_i, v_i are the left and right associated singular vectors. Also, the remaining eigenvalues are all equal to zero, with eigensubspace (of dimension $p+q-2r$) composed of all $\begin{pmatrix} u \\ v \end{pmatrix}$ such that for all $i \in \{1,\ldots,r\}$, $u^\top u_i = v^\top v_i = 0$. We let denote $\bar{U}$ the eigenvectors of $\bar{W}$ corresponding to non zero eigenvalues in $\bar{S}$. We have $\bar{U} = \frac{1}{\sqrt{2}}\begin{pmatrix} U & U \\ V & -V \end{pmatrix}$ and $\bar{S} = \frac{1}{\sqrt{2}}\begin{pmatrix} \mathrm{Diag}(s) & 0 \\ 0 & -\mathrm{Diag}(s) \end{pmatrix}$ and $\bar{W} = \bar{U}\bar{S}\bar{U}^\top$, $\bar{U}\bar{U}^\top = \begin{pmatrix} UU^\top & 0 \\ 0 & VV^\top \end{pmatrix}$, and $\bar{U}\mathrm{sign}(\bar{S})\bar{U}^\top = \begin{pmatrix} 0 & UV^\top \\ VU^\top & 0 \end{pmatrix}$.

A.2 Cauchy Residue Formula and Eigenvalues

Given the matrix $\bar{W}$, and a simple closed curve $\mathcal{C}$ in the complex plane that does not go through any of the eigenvalues of $\bar{W}$, then

$$\Pi_{\mathcal{C}}(\bar{W}) = \frac{1}{2i\pi}\oint_{\mathcal{C}} \frac{d\lambda}{\lambda\mathbf{I} - \bar{W}}$$

is equal to the orthogonal projection onto the orthogonal sum of all eigensubspaces of $\bar{W}$ associated with eigenvalues in the interior of $\mathcal{C}$ (Kato, 1966). This is easily seen by writing down the eigenvalue decomposition and the Cauchy residue formula ($\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda-\lambda_i}=1$ if λ_i is in the interior $\text{int}(\mathcal{C})$ of $\mathcal{C}$ and 0 otherwise), and:

$$\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda\mathbf{I}-\bar{W}}=\sum_{i=1}^{2r}\bar{u}_i\bar{u}_i^\top\times\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda-\bar{s}_i}=\sum_{i,\,\bar{s}_i\in\text{int}(\mathcal{C})}u_iu_i^\top.$$

See Rudin (1987) for an introduction to complex analysis and Cauchy residue formula. Moreover, we can obtain the restriction of $\bar{W}$ onto a specific eigensubspace as:

$$\bar{W}\Pi_{\mathcal{C}}(\bar{W})=\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{\bar{W}d\lambda}{\lambda\mathbf{I}-\bar{W}}=-\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{\lambda d\lambda}{\lambda\mathbf{I}-\bar{W}}.$$

We let denote s_1 and s_r the largest and smallest strictly positive singular values of W; if $\|\Delta\|_2<s_r/2$, then $W+\Delta$ has r singular values strictly greater than $s_r/2$ and the remaining ones are strictly less than $s_r/2$ (Stewart and Sun, 1990). Thus, if we denote $\mathcal{C}$ the oriented circle of radius $s_r/2$, $\Pi_{\mathcal{C}}(\bar{W})$ is the projector on the $p+q-2r$-dimensional null space of $\bar{W}$, and for any Δ such that $\|\Delta\|_2<s_r/2$, $\Pi_{\mathcal{C}}(\bar{W}+\bar{\Delta})$ is also the projector on the $p+q-2r$-dimensional invariant subspace of $\bar{W}+\bar{\Delta}$, which corresponds to the smallest eigenvalues. We let denote $\Pi_o(\bar{W}+\bar{\Delta})$ that projector and $\Pi_r(\bar{W}+\bar{\Delta})=\mathbf{I}-\Pi_o(\bar{W}+\bar{\Delta})$ the orthogonal projector (which is the projection onto the $2r$-th principal subspace).

We can now find expansions around $\Delta=0$ as follows:

$$\begin{aligned}\Pi_o(\bar{W}+\bar{\Delta})-\Pi_o(\bar{W}) &= \frac{1}{2i\pi}\oint_{\mathcal{C}}(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W}-\bar{\Delta})^{-1}d\lambda\\ &= \frac{1}{2i\pi}\oint_{\mathcal{C}}(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W})^{-1}d\lambda\\ &\quad+\frac{1}{2i\pi}\oint_{\mathcal{C}}(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W}-\bar{\Delta})^{-1}d\lambda,\end{aligned}$$

and

$$\begin{aligned}(\bar{W}+\bar{\Delta})\Pi_o(\bar{W}+\bar{\Delta})-\bar{W}\Pi_o(\bar{W}) &= -\frac{1}{2i\pi}\oint_{\mathcal{C}}\lambda(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W}-\bar{\Delta})^{-1}d\lambda\\ &= -\frac{1}{2i\pi}\oint_{\mathcal{C}}\lambda(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W})^{-1}d\lambda\\ &\quad-\frac{1}{2i\pi}\oint_{\mathcal{C}}\lambda(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W})^{-1}\bar{\Delta}(\lambda\mathbf{I}-\bar{W}-\bar{\Delta})^{-1}d\lambda,\end{aligned}$$

which lead to the following two propositions:

Proposition 16 *Assume W has rank r and $\|\Delta\|_2<s_r/4$ where s_r is the smallest positive singular value of W. Then the projection $\Pi_r(\bar{W})$ on the first r eigenvectors of $\bar{W}$ is such that*

$$\|\Pi_o(\bar{W}+\bar{\Delta})-\Pi_o(\bar{W})\|_2\leqslant\frac{4}{s_r}\|\Delta\|_2$$

and

$$\|\Pi_o(\bar{W}+\bar{\Delta})-\Pi_o(\bar{W})-(\mathbf{I}-\bar{U}\bar{U}^\top)\bar{\Delta}\bar{U}\bar{S}^{-1}\bar{U}^\top-\bar{U}\bar{S}^{-1}\bar{U}^\top\bar{\Delta}(\mathbf{I}-\bar{U}\bar{U}^\top)\|_2\leqslant\frac{8}{s_r^2}\|\bar{\Delta}\|_2^2.$$

Proof For $\lambda \in \mathcal{C}$ we have: $\|(\lambda \mathbf{I} - \bar{W})^{-1}\|_2 \geqslant 2/s_r$ and $\|(\lambda \mathbf{I} - \bar{W} - \bar{\Delta})^{-1}\|_2 \geqslant 4/s_r$, which implies

$$\begin{aligned}\|\Pi_r(\bar{W}+\bar{\Delta}) - \Pi_r(\bar{W})\|_2 &\leqslant \frac{1}{2\pi}\oint_{\mathcal{C}} \|(\lambda \mathbf{I} - \bar{W})^{-1}\|_2 \|\Delta\|_2 \|(\lambda \mathbf{I} - \bar{W} - \bar{\Delta})^{-1}\|_2 \\ &\leqslant \left(\frac{1}{2\pi} 2\pi \frac{s_r}{2}\right) \|\Delta\|_2 \frac{2}{s_r}\frac{4}{s_r}.\end{aligned}$$

In order to prove the other result, we simply need to compute:

$$\begin{aligned}\frac{1}{2i\pi}\oint_{\mathcal{C}} (\lambda \mathbf{I} - \bar{W})^{-1}\bar{\Delta}(\lambda \mathbf{I} - \bar{W})^{-1} d\lambda &= \sum_{i,j} \bar{u}_i \bar{u}_i^\top \Delta \bar{v}_j \bar{v}_j^\top \frac{1}{2i\pi}\oint_{\mathcal{C}} \frac{1}{(\lambda - \bar{s}_i)(\lambda - \bar{s}_j)} d\lambda \\ &= \sum_{i,j} \bar{u}_i \bar{u}_i^\top \Delta \bar{v}_j \bar{v}_j^\top \left(\frac{1_{i \notin \mathrm{int}(\mathcal{C})} 1_{j \in \mathrm{int}(\mathcal{C})}}{\bar{s}_i} + \frac{1_{j \notin \mathrm{int}(\mathcal{C})} 1_{i \in \mathrm{int}(\mathcal{C})}}{\bar{s}_j}\right) \\ &= (\mathbf{I} - \bar{U}\bar{U}^\top)\bar{\Delta}\bar{U}\bar{S}^{-1}\bar{U}^\top + \bar{U}\bar{S}^{-1}\bar{U}^\top\bar{\Delta}(\mathbf{I} - \bar{U}\bar{U}^\top).\end{aligned}$$

■

Proposition 17 *Assume W has rank r and $\|\Delta\|_2 < s_r/4$ where s_r is the smallest positive singular value of W. Then the projection $\Pi_r(\bar{W})$ on the first r eigenvectors of $\bar{W}$ is such that*

$$\|\Pi_o(\bar{W}+\bar{\Delta})(\bar{W}+\bar{\Delta}) - \Pi_o(\bar{W})\bar{W}\|_2 \leqslant 2\|\Delta\|_2$$

and

$$\|\Pi_o(\bar{W}+\bar{\Delta})(\bar{W}+\bar{\Delta}) - \Pi_o(\bar{W})\bar{W} + (\mathbf{I} - \bar{U}\bar{U}^\top)\bar{\Delta}(\mathbf{I} - \bar{U}\bar{U}^\top)\|_2 \leqslant \frac{4}{s_r}\|\bar{\Delta}\|_2^2.$$

Proof For $\lambda \in \mathcal{C}$ we have: $\|(\lambda \mathbf{I} - \bar{W})^{-1}\|_2 \geqslant 2/s_r$ and $\|(\lambda \mathbf{I} - \bar{W} - \bar{\Delta})^{-1}\|_2 \geqslant 4/s_r$, which implies

$$\begin{aligned}\|\Pi_r(\bar{W}+\bar{\Delta}) - \Pi_r(\bar{W})\|_2 &\leqslant \frac{1}{2\pi}\oint_{\mathcal{C}} |\lambda| \|(\lambda \mathbf{I} - \bar{W})^{-1}\|_2 \|\Delta\|_2 \|(\lambda \mathbf{I} - \bar{W} - \bar{\Delta})^{-1}\|_2 \\ &\leqslant \left(\frac{1}{2\pi} 2\pi \frac{s_r}{2}\right) \frac{s_r}{2}\|\Delta\|_2 \frac{2}{s_r}\frac{4}{s_r}.\end{aligned}$$

In order to prove the other result, we simply need to compute:

$$\begin{aligned}-\frac{1}{2i\pi}\oint_{\mathcal{C}} \lambda(\lambda \mathbf{I} - \bar{W})^{-1}\bar{\Delta}(\lambda \mathbf{I} - \bar{W})^{-1} d\lambda &= -\sum_{i,j} \bar{u}_i \bar{u}_i^\top \Delta \bar{v}_j \bar{v}_j^\top \frac{1}{2i\pi}\oint_{\mathcal{C}} \frac{\lambda}{(\lambda - \bar{s}_i)(\lambda - \bar{s}_j)} d\lambda \\ &= -\sum_{i,j} \bar{u}_i \bar{u}_i^\top \Delta \bar{v}_j \bar{v}_j^\top \left(1_{i \in \mathrm{int}(\mathcal{C})} 1_{j \in \mathrm{int}(\mathcal{C})}\right) \\ &= -(\mathbf{I} - \bar{U}\bar{U}^\top)\bar{\Delta}(\mathbf{I} - \bar{U}\bar{U}^\top).\end{aligned}$$

■

The variations of $\Pi(\bar{W})$ translates immediately into variations of the singular projections $UU^\top$ and $VV^\top$. Indeed we get that the first order variation of $UU^\top$ is $-(\mathbf{I} - UU^\top)\Delta V S^{-1}U^\top$ and the variation of V is equal to $-(\mathbf{I} - VV^\top)\Delta^\top U S^{-1}V^\top$, with errors bounded in spectral norm by $\frac{8}{s_r^2}\|\Delta\|_2^2$. Similarly, when restricted to the small singular values, the first order expansion is $(\mathbf{I} - UU^\top)\Delta(\mathbf{I} - VV^\top)$, with error term bounded in spectral norm by $\frac{4}{s_r}\|\Delta\|_2^2$. Those results lead to the following proposition that gives a local sufficient condition for $\mathrm{rank}(W+\Delta) > \mathrm{rank}(W)$:

Proposition 18 *Assume W has rank $r < \min\{p,q\}$ with ordered singular value decomposition $W = U\,\mathrm{Diag}(s)V^\top$. If $\frac{4}{s_r}\|\Delta\|_2^2 < \|(\mathbf{I}-UU^\top)\Delta(\mathbf{I}-VV^\top)\|_2$, then $\mathrm{rank}(W+\Delta) > r$.*

Appendix B. Some Facts about the Trace Norm

In this appendix, we review known properties of the trace norm that we use in this paper. Most of the results are extensions of similar results for the ℓ_1-norm on vectors. First, we have the following result:

Lemma 19 (Dual norm, Fazel et al., 2001) *The trace norm $\|\cdot\|_*$ is a norm and its dual norm is the operator norm $\|\cdot\|$.*

Note that the dual norm $N(W)$ is defined as Boyd and Vandenberghe (2003):

$$N(W) = \sup_{\|V\|_* \leqslant 1} \mathrm{tr} W^\top V.$$

This immediately implies the following result:

Lemma 20 (Fenchel conjugate) *We have: $\max_{W \in \mathbb{R}^{p\times q}} \mathrm{tr} W^\top V - \|W\|_* = 0$ if $\|V\| \leqslant 1$ and $+\infty$ otherwise.*

In this paper, we need to compute the subdifferential and directional derivatives of the trace norm. We have from Recht et al. (2007) or Borwein and Lewis (2000):

Proposition 21 (Subdifferential) *If $W = U\,\mathrm{Diag}(s)V^\top$ with $U \in \mathbb{R}^{p\times m}$ and $V \in \mathbb{R}^{q\times m}$ having orthonormal columns, and $s \in \mathbb{R}^m$ is strictly positive, is the singular value decomposition of W, then $\|W\|_* = \sum_{i=1}^m s_i$ and the subdifferential of $\|\cdot\|_*$ is equal to*

$$\partial\|\cdot\|_*(W) = \left\{UV^\top + M, \text{ such that } \|M\|_2 \leqslant 1,\ U^\top M = 0 \text{ and } MV = 0\right\}.$$

This result can be extended to compute directional derivatives:

Proposition 22 (Directional derivative) *The directional derivative at $W = USV^\top$ is equal to:*

$$\lim_{\varepsilon \to 0^+} \frac{\|W+\varepsilon\Delta\|_* - \|W\|_*}{\varepsilon} = \mathrm{tr} U^\top \Delta V + \|U_\perp^\top \Delta V_\perp\|_*,$$

where $U_\perp \in \mathbb{R}^{p\times(p-m)}$ and $V_\perp \in \mathbb{R}^{q\times(q-m)}$ are any orthonormal complements of U and V.

Proof From the subdifferential, we get the directional derivative (Borwein and Lewis, 2000) as

$$\lim_{\varepsilon \to 0^+} \frac{\|W+\varepsilon\Delta\|_* - \|W\|_*}{\varepsilon} = \max_{V \in \partial\|\cdot\|_*(W)} \mathrm{tr}\Delta^\top V$$

which exactly leads to the desired result. ■

The final result that we use is a bit finer as it gives an upper bound on the error in the previous limit:

Proposition 23 *Let $W = U\,\mathrm{Diag}(s)V^\top$ the ordered singular value decomposition, where* $\mathrm{rank}(W) = r$, $s > 0$ *and $U_\perp$ and $V_\perp$ be orthogonal complement of U and V; then, if $\|\Delta\|_2 \leqslant s_r/4$:*

$$\left| \|W+\Delta\|_* - \|W\|_* - \mathrm{tr} U^\top \Delta V - \|U_\perp^\top \Delta V_\perp\|_* \right| \leqslant 16 \min\{p,q\} \frac{s_1^2}{s_r^3} \|\Delta\|_2^2.$$

Proof The trace norm of $\|W+\Delta\|_*$ may be divided into the sum of the r largest and the sum of the remaining singular values. The sums of the remaining ones are given through Proposition 17 by $\|U_\perp^\top \Delta V_\perp\|_*$ with an error bounded by $\min\{p,q\}\frac{4}{s_r}\|\Delta\|_2^2$. For the first r singular values, we need to upperbound the second derivative of the sum of the r largest eigenvalues of $\bar{W}+\bar{\Delta}$ with strictly positive eigengap, which leads to the given bound by using the same Cauchy residue technique described in Appendix A. ■

Appendix C. Proofs

In this appendix, we give the proofs of the results presented in the paper.

C.1 Proof of Lemma 2

We let denote $S \in \{0,1\}^{n_x \times n_y}$ the sampling matrix; that is, $S_{ij} = 1$ if the pair (i,j) is observed and zero otherwise. We let denote $\tilde{X}$ and $\tilde{Y}$ the data matrices. We can write $M_k = \tilde{X}^\top \delta_{i_k} \delta_{j_k}^\top \tilde{Y}$ and:

$$\begin{aligned}
\frac{1}{n}\sum_{k=1}^n \mathrm{vec}(M_k)\mathrm{vec}(M_k)^\top &= \frac{1}{n}\sum_{k=1}^n (\tilde{Y}\otimes\tilde{X})^\top \mathrm{vec}(\delta_{i_k}\delta_{j_k}^\top)\mathrm{vec}(\delta_{i_k}\delta_{j_k}^\top)^\top (\tilde{Y}\otimes\tilde{X}) \\
&= \frac{1}{n}(\tilde{Y}\otimes\tilde{X})^\top \mathrm{Diag}(\mathrm{vec}(S))(\tilde{Y}\otimes\tilde{X}),
\end{aligned}$$

which leads to (denoting $\hat{\Sigma}_{xx} = n_x^{-1}\tilde{X}^\top\tilde{X}$ and $\hat{\Sigma}_{yy} = n_x^{-1}\tilde{Y}^\top\tilde{Y}$):

$$\left(\frac{1}{n}\sum_{k=1}^n \mathrm{vec}(M_k)\mathrm{vec}(M_k)^\top - \hat{\Sigma}_{yy}\otimes\hat{\Sigma}_{xx}\right) = \frac{1}{n}(\tilde{Y}\otimes\tilde{X})^\top \mathrm{Diag}(\mathrm{vec}(S - n/n_x n_y))(\tilde{Y}\otimes\tilde{X}).$$

We can thus compute the squared Frobenius norm:

$$\begin{aligned}
&\left\| \frac{1}{n}\sum_{k=1}^n \mathrm{vec}(M_k)\mathrm{vec}(M_k)^\top - \hat{\Sigma}_{yy}\otimes\hat{\Sigma}_{xx} \right\|_F^2 \\
= \;& \frac{1}{n^2}\mathrm{tr}\,\mathrm{Diag}(\mathrm{vec}(S-n/n_xn_y))(\tilde{Y}\tilde{Y}^\top\otimes\tilde{X}\tilde{X}^\top)\,\mathrm{Diag}(\mathrm{vec}(S-n/n_xn_y))(\tilde{Y}\tilde{Y}^\top\otimes\tilde{X}\tilde{X}^\top) \\
= \;& \frac{1}{n^2}\sum_{i,j,i',j'} (S_{ij}-n/n_xn_y)(\tilde{Y}\tilde{Y}^\top\otimes\tilde{X}\tilde{X}^\top)_{ij,i'j'}(S_{i'j'}-n/n_xn_y)(\tilde{Y}\tilde{Y}^\top\otimes\tilde{X}\tilde{X}^\top)_{ij,i'j'}.
\end{aligned}$$

We have, by properties of sampling without replacement (Hoeffding, 1963):

$$\begin{aligned}
\mathbb{E}(S_{ij}-n/n_xn_y)(S_{i'j'}-n/n_xn_y) &= n/n_xn_y(1-n/n_xn_y) \text{ if } (i,j)=(i',j'), \\
\mathbb{E}(S_{ij}-n/n_xn_y)(S_{i'j'}-n/n_xn_y) &= -n/n_xn_y(1-n/n_xn_y)\frac{1}{n_xn_y-1} \text{ if } (i,j)\neq(i',j').
\end{aligned}$$

This implies

$$\begin{aligned}\mathbb{E}(\|\frac{1}{n}\sum_{k=1}^n \operatorname{vec}(M_k)\operatorname{vec}(M_k)^\top - \hat\Sigma_{yy}\otimes\hat\Sigma_{xx}\|_F^2|\tilde X,\tilde Y)&\\ = \frac{1}{n_x n_y n}\sum_{i,j}(\tilde Y\tilde Y^\top\otimes\tilde X\tilde X^\top)^2_{ij,ij} - \frac{1}{(n_xn_y-1)n_xn_yn}\sum_{(i,j)\neq(i',j')}(\tilde Y\tilde Y^\top\otimes\tilde X\tilde X^\top)^2_{ij,i'j'}&\\ \leqslant \frac{2}{n_xn_yn}\sum_{i,j}\|\tilde y_j\|^4\|\tilde x_i\|^4.&\end{aligned}$$

This finally implies that

$$\begin{aligned}&\mathbb{E}\left\|\frac{1}{n}\sum_{k=1}^n \operatorname{vec}(M_k)\operatorname{vec}(M_k)^\top - \Sigma_{yy}\otimes\Sigma_{xx}\right\|_F^2\\ \leqslant\ & \frac{4}{n}\sum_{i,j}\mathbb{E}\|x\|^4\mathbb{E}\|y\|^4 + 2\mathbb{E}\|\hat\Sigma_{xx}-\Sigma_{xx}\|_F^2\mathbb{E}\|\hat\Sigma_{yy}\|_F^2 + 2\mathbb{E}\|\hat\Sigma_{yy}-\Sigma_{yy}\|_F^2\|\Sigma_{xx}\|_F^2\\ \leqslant\ & C\mathbb{E}\|x\|^4\mathbb{E}\|y\|^4\times(\frac{1}{n}+\frac{1}{n_y}+\frac{1}{n_x}),\end{aligned}$$

for some constant $C>0$. This implies (**A2**). To prove the asymptotic normality in (**A3**), we use the martingale central limit theorem (Hall and Heyde, 1980) with sequence of σ-fields $\mathcal{F}_{n,k} = \sigma(\tilde X,\tilde Y,\varepsilon_1,\dots,\varepsilon_k,(i_1,j_1),\dots,(i_k,j_k))$ for $k\leqslant n$. We consider $\Delta_{n,k} = n^{-1/2}\varepsilon_{i_kj_k}y_{j_k}\otimes x_{i_k}\in\mathbb{R}^{pq}$ as the martingale difference. We have $\mathbb{E}(\Delta_{n,k}|\mathcal{F}_{n,k-1})=0$ and

$$\mathbb{E}(\Delta_{n,k}\Delta_{n,k}^\top|\mathcal{F}_{n,k-1}) = n^{-1}\sigma^2 y_{j_k}y_{j_k}^\top\otimes x_{i_k}x_{i_k}^\top,$$

with $\mathbb{E}(\|\Delta_{n,k})\|^4) = O(n^{-2})$ because of the finite fourth order moments. Moreover,

$$\sum_{k=1}^n \mathbb{E}(\Delta_{n,k}\Delta_{n,k}^\top|\mathcal{F}_{n,k-1}) = \sigma^2\hat\Sigma_{mm},$$

and thus tends in probability to $\sigma^2\Sigma_{yy}\otimes\Sigma_{xx}$ because of (**A2**). The assumptions of the martingale central limit theorem are met, we have that $\sum_{k=1}^n\operatorname{vec}(\Delta_{n,k})$ is asymptotically normal with mean zero and covariance matrix $\sigma^2\Sigma_{yy}\otimes\Sigma_{xx}$, which concludes the proof.

C.2 Proof of Proposition 4

We may first restrict minimization over the ball $\{W,\ \|W\|_*\leqslant\|\hat\Sigma_{mm}^{-1}\hat\Sigma_{Mz}\|_*\}$ because the optimum value is less than the value for $W=\hat\Sigma_{mm}^{-1}\hat\Sigma_{Mz}$. Since this random variable is bounded in probability, we can reduce the problem to a compact set. The sequence of continuous random functions $W\mapsto\frac{1}{2}\operatorname{vec}(W-\mathbf{W})^\top\hat\Sigma_{mm}\operatorname{vec}(W-\mathbf{W}) - \operatorname{tr}W^\top\hat\Sigma_{M\varepsilon}+\lambda_n\|W\|_*$ converges pointwise in probability to $W\mapsto\frac{1}{2}\operatorname{vec}(W-\mathbf{W})^\top\Sigma_{mm}\operatorname{vec}(W-\mathbf{W})+\lambda_0\|W\|_*$ with a unique global minimum (because Σ_{mm} is assumed invertible). We can thus apply standard result of consistency in M-estimation (Van der Vaart, 1998; Shao, 2003).

C.3 Proof of Proposition 7

We consider the result of Proposition 6: $\hat{\Delta} = n^{1/2}(\hat{W} - \mathbf{W})$ is asymptotically normal with mean zero and covariance $\sigma^2 \Sigma_{mm}^{-1}$. By Proposition 18 in Appendix B, if $\frac{4n^{-1/2}}{s_r}\|\hat{\Delta}\|_2^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2$, then $\mathrm{rank}(\hat{W}) > \mathbf{r}$. For a random variable Θ with normal distribution with mean zero and covariance matrix $\sigma^2 \Sigma_{mm}^{-1}$, we let denote $f(C) = \mathbb{P}(\frac{4C^{-1/2}}{s_r}\|\Theta\|_2^2 < \|\mathbf{U}_\perp^\top \Theta \mathbf{V}_\perp\|_2)$. By the dominated convergence theorem, $f(C)$ converges to one when $C \to \infty$. Let $\varepsilon > 0$, thus there exists $C_0 > 0$ such that $f(C_0) > 1 - \varepsilon/2$. By the asymptotic normality result, $\mathbb{P}(\frac{4C_0^{-1/2}}{s_r}\|\hat{\Delta}\|_2^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2)$ converges to $f(C_0)$ thus $\exists n_0 > 0$ such that $\forall n > n_0$, $\mathbb{P}(\frac{4C_0^{-1/2}}{s_r}\|\hat{\Delta}\|_2^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2) > f(C_0) - \varepsilon/2 > 1 - \varepsilon$, which concludes the proof, because $\mathbb{P}(\frac{4n^{-1/2}}{s_r}\|\hat{\Delta}\|_2^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2) \geqslant \mathbb{P}(\frac{4C_0^{-1/2}}{s_r}\|\hat{\Delta}\|_2^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2)$ as soon as $n > C_0$.

C.4 Proof of Proposition 8

This is the same result as Fu and Knight (2000), but extended to the trace norm minimization, simply using the directional derivative result of Proposition 22 and the epiconvergence theorem from Geyer (1994, 1996). Indeed, if we denote $V_n(\Delta) = \mathrm{vec}(\Delta)^\top \hat{\Sigma}_{mm} \mathrm{vec}(\Delta) - \mathrm{tr}\Delta^\top n^{1/2} \hat{\Sigma}_{M\varepsilon} + \lambda_0 n^{1/2}(\|\mathbf{W} + n^{-1/2}\Delta\|_* - \|\mathbf{W}\|_*)$ and $V(\Delta) = \mathrm{vec}(\Delta)^\top \Sigma_{mm} \mathrm{vec}(\Delta) - \mathrm{tr}\Delta^\top A + \lambda_0 \left[\mathrm{tr}\mathbf{U}^\top \Delta \mathbf{V} + \|\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp\|_*\right]$, then for each Δ, $V_n(\Delta)$ converges in probability to $V(\Delta)$, and V is strictly convex, which implies that it has an unique global minimum; thus the epi-convergence theorem can be applied, which concludes the proof.

Note that a simpler analysis using regular tools in M-estimation leads to $\hat{W} = \mathbf{W} + n^{-1/2}\hat{\Delta} + o_p(n^{-1/2})$, where $\hat{\Delta}$ is the unique global minimizer of

$$\min_{\Delta \in \mathbb{R}^{p \times q}} \frac{1}{2} \mathrm{vec}(\Delta)^\top \Sigma_{mm} \mathrm{vec}(\Delta) - \mathrm{tr}\Delta^\top (n^{1/2} \hat{\Sigma}_{M\varepsilon}) + \lambda_0 \left[\mathrm{tr}\mathbf{U}^\top \Delta \mathbf{V} + \|\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp\|_*\right],$$

that is, we can actually take $A = n^{1/2} \hat{\Sigma}_{M\varepsilon}$ (which is asymptotically normal with correct moments).

C.5 Proof of Proposition 9

We let denote $\hat{\Delta} = n^{1/2}(\hat{W} - \mathbf{W})$. We first show that $\limsup_{n \to \infty} \mathbb{P}(\mathrm{rank}(\hat{W}) = \mathbf{r})$ is smaller than the proposed limit a. We consider the following events:

$$\begin{aligned} E_0 &= \{\mathrm{rank}(\hat{W}) = \mathbf{r}\} \\ E_1 &= \{\|n^{-1/2}\hat{\Delta}\|_2 < \mathbf{s}_r/2\} \\ E_2 &= \left\{ \frac{4n^{-1/2}}{s_r}\|\hat{\Delta}\|_2^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2 \right\}. \end{aligned}$$

By Proposition 18 in Appendix B, we have $E_1 \cap E_2 \subset E_0^c$, and thus it suffices to show that $\mathbb{P}(E_1)$ tends to one, while $\limsup_{n \to \infty} \mathbb{P}(E_2^c) \leqslant a$. The first assertion is a simple consequence of Proposition 8.

Moreover, by Proposition 8, $\hat{\Delta}$ converges in distribution to the unique global optimum $\Delta(A)$ of an optimization problem parameterized by a vector A with normal distribution. For a given $\eta > 0$, we consider the probability $\mathbb{P}(\|\mathbf{U}_\perp^\top \Delta(A) \mathbf{V}_\perp\|_2 \leqslant \eta)$. For any A, when η tends to zero, the indicator function $1_{\|\mathbf{U}_\perp^\top \Delta(A) \mathbf{V}_\perp\|_2 \leqslant \eta}$ converges to $1_{\|\mathbf{U}_\perp^\top \Delta(A) \mathbf{V}_\perp\|_2 = 0}$, which is equal to $1_{\|\Lambda(A)\|_2 \leqslant \lambda_0}$, where

$$\mathrm{vec}(\Lambda(A)) = \Big((\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top \Sigma_{mm}^{-1} (\mathbf{V}_\perp \otimes \mathbf{U}_\perp)\Big)^{-1} \Big((\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top \Sigma_{mm}^{-1} ((\mathbf{V} \otimes \mathbf{U}) \mathrm{vec}(\mathbf{I}) - \mathrm{vec}(A))\Big).$$

By the dominated convergence theorem, $\mathbb{P}(\|\mathbf{U}_\perp^\top \Delta(A)\mathbf{V}_\perp\|_2 \leqslant \eta)$ converges to

$$a = \mathbb{P}(\|\Lambda(A)\|_2 \leqslant \lambda_0),$$

which is the proposed limit. This limit is in $(0,1)$ because of the normal distribution has an invertible covariance matrix and the set $\{\|\Lambda\|_2 \leqslant 1\}$ and its complement have non empty interiors.

Since $\hat{\Delta} = O_p(1)$, we can instead consider $E_3 = \{\frac{4n^{-1/2}}{s_r} M^2 < \|\mathbf{U}_\perp^\top \hat{\Delta} \mathbf{V}_\perp\|_2\}$ for a particular M, instead of E_2. Then following the same line or arguments than in Appendix C.3, we conclude that $\limsup_{n\to\infty} \mathbb{P}(E_3^c) \leqslant a$, which concludes the first part of the proof.

We now show that $\liminf_{n\to\infty} \mathbb{P}(\operatorname{rank}(\hat{W}) = \mathbf{r}) \geqslant a$. A sufficient condition for rank consistency is the following: we let denote $\hat{W} = USV^\top$ the singular value decomposition of $\hat{W}$ and we let denote U_o and V_o the singular vectors corresponding to all but the $\mathbf{r}$ largest singular values. Since we have simultaneous singular value decompositions, a sufficient condition is that $\operatorname{rank}(\hat{W}) \geqslant \mathbf{r}$ and $\left\|U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon}\right) V_o\right\|_2 < \lambda_n(1-\eta)$. If $\|\Lambda(n^{1/2}\hat{\Sigma}_{M\varepsilon})\| \leqslant \lambda_0(1-\eta)$, then, by Lemma 11, $\mathbf{U}_\perp^\top \Delta(n^{1/2}\hat{\Sigma}_{M\varepsilon})\mathbf{V}_\perp = 0$, and we get, using the proof of Proposition 8 and the notation $\hat{A} = n^{1/2}\hat{\Sigma}_{M\varepsilon}$:

$$U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon}\right) V_o \;=\; U_o^\top n^{-1/2} \left(\hat{\Sigma}_{mm}\Delta(\hat{A}) - \hat{A}\right) V_o + o_p(n^{-1/2}).$$

Moreover, because of regular consistency and a positive eigengap for $\mathbf{W}$, the projection onto the first $\mathbf{r}$ singular vectors of $\hat{W}$ converges to the projection onto the first $\mathbf{r}$ singular vectors of $\mathbf{W}$ (see Appendix A), which implies that the projection onto the orthogonal is also consistent, that is, $U_o U_o^\top$ converges in probability to $\mathbf{U}_\perp \mathbf{U}_\perp^\top$ and $V_o V_o^\top$ converges in probability to $\mathbf{V}_\perp \mathbf{V}_\perp^\top$. Thus:

$$\begin{aligned}
\left\|U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon}\right) V_o\right\|_2 &= \left\|U_o U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon}\right) V_o V_o^\top\right\|_2 \\
&= n^{-1/2}\|\mathbf{U}_\perp \mathbf{U}_\perp^\top (\hat{\Sigma}_{mm}\Delta(\hat{A}) - \hat{A})\mathbf{V}_\perp \mathbf{V}_\perp^\top\|_2 + o_p(n^{-1/2}) \\
&= n^{-1/2}\|\Lambda(A)\|_2 + o_p(n^{-1/2}).
\end{aligned}$$

This implies that

$$\liminf_{n\to\infty} \left\|U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon}\right) V_o\right\|_2 < \lambda_n(1-\eta) \geqslant \liminf_{n\to\infty} \mathbb{P}(\|\Lambda(\hat{A})\|_2 \leqslant \lambda_0(1-\eta))$$

which converges to a when η tends to zero, which concludes the proof.

C.6 Proof of Proposition 10

This is the same result as Fu and Knight (2000), but extended to the trace norm minimization, simply using the directional derivative result of Proposition 22. If we write $\hat{W} = \mathbf{W} + \lambda_n \hat{\Delta}$, then $\hat{\Delta}$ is defined as the global minimum of

$$\begin{aligned}
V_n(\Delta) &= \frac{1}{2}\operatorname{vec}(\Delta)^\top \hat{\Sigma}_{mm} \operatorname{vec}(\Delta) - \lambda_n^{-1} \operatorname{tr}\Delta^\top \hat{\Sigma}_{M\varepsilon} + \lambda_n^{-1}(\|\mathbf{W} + \lambda_n \Delta\|_* - \|\mathbf{W}\|_*) \\
&= \frac{1}{2}\operatorname{vec}(\Delta)^\top \Sigma_{mm} \operatorname{vec}(\Delta) + O_p(\zeta_n \|\Delta\|_2^2) + O_p(\lambda_n^{-1} n^{-1/2}) + \operatorname{tr}\Delta^\top \hat{\Sigma}_{M\varepsilon} \\
&\quad + \operatorname{tr}\mathbf{U}^\top \Delta \mathbf{V} + \|\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp\|_* + O_p(\lambda_n \|\Delta\|_2^2) \\
&= V(\Delta) + O_p(\zeta_n \|\Delta\|_2^2) + O_p(\lambda_n^{-1} n^{-1/2}) + O_p(\lambda_n \|\Delta\|_2^2).
\end{aligned}$$

More precisely, if $M\lambda_n < \mathbf{s}_r/2$,

$$\begin{aligned}\mathbb{E}\sup_{\|\Delta\|_2 \leqslant M} |V_n(\Delta) - V(\Delta)| &= \text{cst} \times \left(M^2 \mathbb{E}\|\hat{\Sigma}_{mm} - \Sigma_{mm}\|_F + M\lambda_n^{-1}\mathbb{E}(\|\hat{\Sigma}_{M\varepsilon}\|^2)^{1/2} + \lambda_n M^2 \right) \\ &= O(M^2\zeta_n + M\lambda_n^{-1}n^{-1/2} + \lambda_n M^2).\end{aligned}$$

Moreover, $V(\Delta)$ achieves its minimum at a bounded point $\Delta_0 \neq 0$. Thus, by Markov inequality the minimum of $V_n(\Delta)$ over the ball $\|\Delta\|_2 < 2\|\Delta_0\|_2$ is with probability tending to one strictly inside and is thus also the unconstrained minimum, which leads to the proposition.

C.7 Proof of Proposition 11

The optimal $\Delta \in \mathbb{R}^{p\times q}$ should be such that $\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp$ has low rank, where $\mathbf{U}_\perp \in \mathbb{R}^{p\times(p-\mathbf{r})}$ and $\mathbf{V}_\perp \in \mathbb{R}^{q\times(q-\mathbf{r})}$ are orthogonal complements of the singular vectors $\mathbf{U}$ and $\mathbf{V}$. We now derive the condition under which the optimal Δ is such that $\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp$ is actually equal to zero: we consider the minimum of $\frac{1}{2}\operatorname{vec}(\Delta)^\top \Sigma_{mm} \operatorname{vec}(\Delta) + \operatorname{vec}(\Delta)^\top \operatorname{vec}(\mathbf{U}\mathbf{V}^\top)$ with respect to Δ such that $\operatorname{vec}(\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp) = (\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top \operatorname{vec}(\Delta) = 0$. The solution of that constrained optimization problem is obtained through the following linear system (Boyd and Vandenberghe, 2003):

$$\begin{pmatrix} \Sigma_{mm} & (\mathbf{V}_\perp \otimes \mathbf{U}_\perp) \\ (\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top & 0 \end{pmatrix} \begin{pmatrix} \operatorname{vec}(\Delta) \\ \operatorname{vec}(\Lambda) \end{pmatrix} = \begin{pmatrix} -\operatorname{vec}(\mathbf{U}\mathbf{V}^\top) \\ 0 \end{pmatrix},$$

where $\Lambda \in \mathbb{R}^{(p-\mathbf{r})\times(q-\mathbf{r})}$ is the Lagrange multiplier for the equality constraint. We can solve explicitly for Δ and Λ which leads to

$$\operatorname{vec}(\Lambda) = \left((\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top \Sigma_{mm}^{-1} (\mathbf{V}_\perp \otimes \mathbf{U}_\perp) \right)^{-1} \left((\mathbf{V}_\perp \otimes \mathbf{U}_\perp)^\top \Sigma_{mm}^{-1} (\mathbf{V} \otimes \mathbf{U}) \operatorname{vec}(\mathbf{I}) \right),$$

and

$$\operatorname{vec}(\Delta) = -\Sigma_{mm}^{-1} \operatorname{vec}(\mathbf{U}\mathbf{V}^\top - \mathbf{U}_\perp \Lambda \mathbf{V}_\perp^\top).$$

Then the minimum of the function $F(\Delta)$ in Eq. (2) is such that $\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp = 0$ (and thus equal to Δ defined above) if and only if for all $\Theta \in \mathbb{R}^{p\times q}$, the directional derivative of F at Δ in the direction Θ is nonnegative, that is:

$$\lim_{\varepsilon \to 0^+} \frac{F(\Delta + \varepsilon\Theta) - F(\Delta)}{\varepsilon} \geqslant 0.$$

By Proposition 22, this directional derivative is equal to

$$\begin{aligned}\operatorname{tr}\Theta^\top(\Sigma_{mm}\Delta + \mathbf{U}\mathbf{V}^\top) + \|\mathbf{U}_\perp^\top \Theta \mathbf{V}_\perp\|_* &= \operatorname{tr}\Theta^\top \mathbf{U}_\perp \Lambda \mathbf{V}_\perp + \|\mathbf{U}_\perp^\top \Theta \mathbf{V}_\perp\|_* \\ &= \operatorname{tr}\Lambda^\top \mathbf{U}_\perp^\top \Theta \mathbf{V}_\perp + \|\mathbf{U}_\perp^\top \Theta \mathbf{V}_\perp\|_*.\end{aligned}$$

Thus the directional derivative is always non negative if for all $\Theta' \in \mathbb{R}^{(p-\mathbf{r})\times(q-\mathbf{r})}$, $\operatorname{tr}\Lambda^\top \Theta' + \|\Theta'\|_* \geqslant 0$, that is, if and only if $\|\Lambda\|_2 \leqslant 1$, which concludes the proof.

C.8 Proof of Theorem 12

Regular consistency is obtained by Corollary 5. We consider the problem in Eq. (2) of Proposition 10, where $\lambda_n n^{1/2} \to \infty$ and $\lambda_n \to 0$. Since Eq. (5) is satisfied, the solution Δ indeed satisfies $\mathbf{U}_\perp^\top \Delta \mathbf{V}_\perp = 0$ by Lemma 11.

We have $\hat{W} = \mathbf{W} + \lambda_n \Delta + o_p(\lambda_n)$ and we now show that the optimality conditions are satisfied with rank $\mathbf{r}$. From the regular consistency, the rank of $\hat{W}$ is, with probability tending to one, larger than $\mathbf{r}$ (because the rank is lower semi-continuous function). We now need to show that it is actually equal to $\mathbf{r}$. We let denote $\hat{W} = USV^\top$ the singular value decomposition of $\hat{W}$ and we let denote U_o and V_o the singular vectors corresponding to all but the $\mathbf{r}$ largest singular values. Since we have simultaneous singular value decompositions, we simply need to show that, $\left\| U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon} \right) V_o \right\|_2 < \lambda_n$ with probability tending to one. We have:

$$\begin{aligned} U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon} \right) V_o &= U_o^\top \left(\lambda_n \hat{\Sigma}_{mm} \Delta + o_p(\lambda_n) - O_p(n^{-1/2}) \right) V_o \\ &= \lambda_n U_o^\top (\Sigma_{mm} \Delta) V_o + o_p(\lambda_n). \end{aligned}$$

Moreover, because of regular consistency and a positive eigengap for $\mathbf{W}$, the projection onto the first $\mathbf{r}$ singular vectors of $\hat{W}$ converges to the projection onto the first $\mathbf{r}$ singular vectors of $\mathbf{W}$ (see Appendix A), which implies that the projection onto the orthogonal is also consistent, that is, $U_o U_o^\top$ converges in probability to $\mathbf{U}_\perp \mathbf{U}_\perp^\top$ and $V_o V_o^\top$ converges in probability to $\mathbf{V}_\perp \mathbf{V}_\perp^\top$. Thus:

$$\begin{aligned} \left\| U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon} \right) V_o \right\|_2 &= \left\| U_o U_o^\top \left(\hat{\Sigma}_{mm}(\hat{W} - \mathbf{W}) - \hat{\Sigma}_{M\varepsilon} \right) V_o V_o^\top \right\|_2 \\ &= \lambda_n \| \mathbf{U}_\perp \mathbf{U}_\perp^\top (\Sigma_{mm} \Delta) \mathbf{V}_\perp \mathbf{V}_\perp^\top \|_2 + o_p(\lambda_n) \\ &= \lambda_n \| \Lambda \|_2 + o_p(\lambda_n). \end{aligned}$$

This implies that that the last expression is asymptotically of magnitude strictly less than one, which concludes the proof.

C.9 Proof of Theorem 13

We have seen earlier that if $n^{1/2}\lambda_n$ tends to zero and λ_n tends to zero, then Eq. (4) is necessary for rank-consistency. We just have to show that there is a subsequence that does satisfy this. If $\liminf \lambda_n > 0$, then we cannot have consistency (by Proposition 6), thus if we consider a subsequence, we can always assume that λ_n tends to zero.

We now consider the sequence $n^{1/2}\lambda_n$, and its accumulation points. If zero or $+\infty$ is one of them, then by Propositions 7 and 9, we cannot have rank consistency. Thus, for all accumulation points (which are finite and strictly positive), by considering a subsequence, we are in the situation where $n^{1/2}\lambda_n$ tends to $+\infty$ and λ_n tends to zero, which implies Eq. (4), by definition of Λ in Eq. (3) and Lemma 11.

C.10 Proof of Theorem 15

We let denote $U_{LS}^{\mathbf{r}}$ and $V_{LS}^{\mathbf{r}}$ the first $\mathbf{r}$ columns of U_{LS} and V_{LS} and U_{LS}^o and V_{LS}^o the remaining columns; we also denote $s_{LS}^{\mathbf{r}}$ the corresponding first $\mathbf{r}$ singular values and s_{LS}^o the remaining singular values. From Lemma 14 and results in the appendix, we get that $\|s_{LS}^{\mathbf{r}} - \mathbf{s}\|_2 = O_p(n^{-1/2})$ and $\|s_{LS}^o\|_2 = O_p(n^{-1/2})$ and $\|U_{LS}^{\mathbf{r}}(U_{LS}^{\mathbf{r}})^\top - \mathbf{U}\mathbf{U}^\top\|_2 = O_p(n^{-1/2})$ and $\|V_{LS}^{\mathbf{r}}(V_{LS}^{\mathbf{r}})^\top - \mathbf{V}\mathbf{V}^\top\|_2 = O_p(n^{-1/2})$. By writing $\hat{W}_A = \mathbf{W} + n^{-1/2}\hat{\Delta}_A$, $\hat{\Delta}_A$ is defined as the minimum of

$$\frac{1}{2} \operatorname{vec}(\Delta)^\top \hat{\Sigma}_{mm} \operatorname{vec}(\Delta) - n^{1/2} \operatorname{tr} \Delta^\top \hat{\Sigma}_{M\varepsilon} + n\lambda_n \left(\|A\mathbf{W}B + n^{-1/2} A\Delta B\|_* - \|A\mathbf{W}B\|_* \right).$$

We have:

$$\begin{aligned} A\mathbf{U} &= U_{LS}\,\mathrm{Diag}(s_{LS})^{-\gamma}U_{LS}^{\top}\mathbf{U} \\ &= U_{LS}^{\mathbf{r}}\,\mathrm{Diag}(s_{LS}^{\mathbf{r}})^{-\gamma}(U_{LS}^{\mathbf{r}})^{\top}\mathbf{U} + U_{LS}^{o}\,\mathrm{Diag}(s_{LS}^{o})^{-\gamma}(U_{LS}^{o})^{\top}\mathbf{U} \\ &= \mathbf{U}\,\mathrm{Diag}(\mathbf{s})^{-\gamma} + O_p(n^{-1/2}) + O_p(n^{-1/2}n^{\gamma/2}) \\ &= \mathbf{U}\,\mathrm{Diag}(\mathbf{s})^{-\gamma} + O_p(n^{-1/2}n^{\gamma/2}), \end{aligned}$$

and

$$\begin{aligned} A\mathbf{U}_{\perp} &= U_{LS}\,\mathrm{Diag}(s_{LS})^{-\gamma}U_{LS}^{\top}\mathbf{U}_{\perp} \\ &= U_{LS}^{\mathbf{r}}\,\mathrm{Diag}(s_{LS}^{\mathbf{r}})^{-\gamma}(U_{LS}^{\mathbf{r}})^{\top}\mathbf{U}_{\perp} + U_{LS}^{o}\,\mathrm{Diag}(s_{LS}^{o})^{-\gamma}(U_{LS}^{o})^{\top}\mathbf{U}_{\perp} \\ &= \mathbf{U}_{\perp}\,\mathrm{Diag}(s_{LS}^{o})^{-\gamma} + O_p(n^{\gamma/2-1/2}) \\ &= O_p(n^{\gamma/2}). \end{aligned}$$

Similarly we have: $B\mathbf{V} = \mathbf{V}\,\mathrm{Diag}(\mathbf{s})^{-\gamma} + O_p(n^{-1/2}n^{\gamma/2})$ and $B\mathbf{V} = O_p(n^{\gamma/2})$. We can decompose any $\Delta \in \mathbb{R}^{p\times q}$ as $\Delta = (\mathbf{U}\ \mathbf{U}_{\perp})\begin{pmatrix} \Delta_{\mathbf{rr}} & \Delta_{\mathbf{r}o} \\ \Delta_{o\mathbf{r}} & \Delta_{oo} \end{pmatrix}(\mathbf{V}\ \mathbf{V}_{\perp})^{\top}$. We have assumed that $\lambda_n n^{1/2}n^{\gamma/2}$ tends to infinity. Thus,

- if $\mathbf{U}_{\perp}^{\top}\Delta = 0$ and $\Delta\mathbf{V}_{\perp} = 0$ (i.e., if Δ is of the form $\mathbf{U}\Delta_{\mathbf{rr}}\mathbf{V}^{\top}$),

$$\begin{aligned} n\lambda_n\|A\mathbf{W}B + n^{-1/2}A\Delta B\|_* - \|A\mathbf{W}B\|_* &\leqslant \lambda_n n^{1/2}\|A\Delta B\|_* \\ &= \lambda_n n^{1/2}\|\,\mathrm{Diag}(\mathbf{s})^{-\gamma}\Delta_{\mathbf{rr}}\,\mathrm{Diag}(\mathbf{s})^{-\gamma}\|_* \\ &\qquad + O_p(\lambda_n n^{\gamma/2}) \\ &= O_p(\lambda_n n^{1/2}) \end{aligned}$$

  tends to zero.

- Otherwise, $n\lambda_n\|A\mathbf{W}B + n^{-1/2}A\Delta B\|_* - \|A\mathbf{W}B\|_*$ is larger than $\lambda_n n^{1/2}\|A\Delta B\|_* - 2\|A\mathbf{W}B\|_*$. The term $\|A\mathbf{W}B\|_*$ is bounded in probability because we can write $A\mathbf{W}B = \mathbf{U}\,\mathrm{Diag}(\mathbf{s})^{1-2\gamma}\mathbf{V}^{\top} + O_p(n^{-1/2+\gamma/2})$ and $\gamma \leqslant 1$. Besides, $\lambda_n n^{1/2}\|A\Delta B\|_*$ is tending to infinity as soons as any of $\Delta_{o\mathbf{r}}$, $\Delta_{\mathbf{r}o}$ or $\Delta_{\mathbf{rr}}$ are different from zero. Indeed, by equivalence of finite dimensional norms $\lambda_n n^{1/2}\|A\Delta B\|_*$ is larger than a constant times $\lambda_n n^{1/2}\|A\Delta B\|_F$, which can be decomposed in four pieces along $(\mathbf{U}, \mathbf{U}_{\perp})$ and $(\mathbf{V}, \mathbf{V}_{\perp})$, corresponding asymptotically to Δ_{oo}, $\Delta_{o\mathbf{r}}$, $\Delta_{\mathbf{r}o}$ or $\Delta_{\mathbf{rr}}$. The smallest of those terms grows faster than $\lambda_n n^{1/2+\gamma/2}$, and thus tends to infinity.

Thus, since Σ_{mm} is invertible, by the epi-convergence theorem of Geyer (1994, 1996), $\hat{\Delta}_A$ converges in distribution to the minimum of

$$\frac{1}{2}\,\mathrm{vec}(\Delta)^{\top}\Sigma_{mm}\,\mathrm{vec}(\Delta) - n^{1/2}\mathrm{tr}\Delta^{\top}\hat{\Sigma}_{M\varepsilon},$$

such that $\mathbf{U}_{\perp}^{\top}\Delta = 0$ and $\Delta\mathbf{V}_{\perp} = 0$. This minimum has a simple asymptotic distribution, namely $\Delta = \mathbf{U}\Theta\mathbf{V}^{\top}$ and Θ is asymptotically normal with mean zero and covariance matrix $\sigma^2\left[(\mathbf{V}\otimes\mathbf{U})^{\top}\Sigma_{mm}(\mathbf{V}\otimes\mathbf{U})\right]^{-1}$, which leads to the consistency and the asymptotic normality.

In order to finish the proof, we consider the optimality conditions which can be written as $A\Delta B$ and

$$A^{-1}\left(\hat{\Sigma}_{mm}\hat{\Delta}_A - n^{1/2}\hat{\Sigma}_{M\varepsilon}\right)B^{-1}$$

having simultaneous singular value decompositions with proper decays of singular values, that is, such that the first $\mathbf{r}$ are equal to $\lambda_n n^{1/2}$ and the remaining ones are less than $\lambda_n n^{1/2}$.

From the asymptotic normality we get that $\hat{\Sigma}_{mm}\hat{\Delta}_A - n^{1/2}\hat{\Sigma}_{M\varepsilon}$ is $O_p(1)$, we can thus consider matrices of the form $A^{-1}\Theta B^{-1}$ where Θ is bounded, the same way we considered matrices of the form $A\Delta B$.

We have:

$$\begin{aligned} A^{-1}\mathbf{U} &= U_{LS}\,\mathrm{Diag}(s_{LS})^{\gamma}U_{LS}^{\top}\mathbf{U} \\ &= U_{LS}^{\mathbf{r}}\,\mathrm{Diag}(s_{LS}^{\mathbf{r}})^{\gamma}(U_{LS}^{\mathbf{r}})^{\top}\mathbf{U} + U_{LS}^{o}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}(U_{LS}^{o})^{\top}\mathbf{U} \\ &= \mathbf{U}\,\mathrm{Diag}(\mathbf{s})^{\gamma} + O_p(n^{-1/2}), \end{aligned}$$

and

$$\begin{aligned} A^{-1}\mathbf{U}_{\perp} &= U_{LS}\,\mathrm{Diag}(s_{LS})^{\gamma}U_{LS}^{\top}\mathbf{U}_{\perp} \\ &= U_{LS}^{\mathbf{r}}\,\mathrm{Diag}(s_{LS}^{\mathbf{r}})^{\gamma}(U_{LS}^{\mathbf{r}})^{\top}\mathbf{U}_{\perp} + U_{LS}^{o}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}(U_{LS}^{o})^{\top}\mathbf{U}_{\perp} \\ &= O_p(n^{-1/2}) + \mathbf{U}_{\perp}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}, \end{aligned}$$

with similar expansions for $B^{-1}\mathbf{V}$ and $B^{-1}\mathbf{V}_{\perp}$. We obtain the first order expansion:

$$\begin{aligned} A^{-1}\Theta B^{-1} = \mathbf{U}\,\mathrm{Diag}(\mathbf{s})^{\gamma}\Theta_{\mathbf{rr}}\,\mathrm{Diag}(\mathbf{s})^{\gamma}\mathbf{V}^{\top} + \mathbf{U}_{\perp}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}\Theta_{o\mathbf{r}}\,\mathrm{Diag}(\mathbf{s})^{\gamma}\mathbf{V}^{\top} \\ + \mathbf{U}\,\mathrm{Diag}(\mathbf{s})^{\gamma}\Theta_{\mathbf{r}o}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}\mathbf{V}_{\perp}^{\top} + \mathbf{U}_{\perp}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}\Theta_{oo}\,\mathrm{Diag}(s_{LS}^{o})^{\gamma}\mathbf{V}_{\perp}^{\top} \end{aligned}$$

Because of the regular consistency, the first term is of the order of $\lambda_n n^{1/2}$ (so that the first $\mathbf{r}$ singular values of $\hat{W}$ are strictly positive), while the three other terms have norms less than $O_p(n^{-\gamma/2})$ which is less than $O_p(n^{1/2}\lambda_n)$ by assumption. This concludes the proof.

Learning Similarity with Operator-valued Large-margin Classifiers

Andreas Maurer ANDREASMAURER@COMPUSERVE.COM
Adalbertstr. 55

Germany

Editor: Peter Bartlett

Abstract

A method is introduced to learn and represent similarity with linear operators in kernel induced Hilbert spaces. Transferring error bounds for vector valued large-margin classifiers to the setting of Hilbert-Schmidt operators leads to dimension free bounds on a risk functional for linear representations and motivates a regularized objective functional. Minimization of this objective is effected by a simple technique of stochastic gradient descent. The resulting representations are tested on transfer problems in image processing, involving plane and spatial geometric invariants, handwritten characters and face recognition.

Keywords: learning similarity, similarity, transfer learning

1. Introduction

Similarity seems fundamental to perception and reasoning. The precise meaning of the word "similarity" however is elusive and a corresponding Google search reveals a plethora of definitions ranging from "the property of being similar" to the analyses of Wittgenstein, Russel or Carnap. This is not surprising: Pairs of triangles may or may not be similar, two poems may induce similar or radically different moods in similar people, pairs of wines, bird-calls, weather patterns, approaches to cognitive science, movies and definitions of similarity themselves may each be similar or not similar or similar to a varying degree. It is the very universality of the concept which explains the lack of a universal definition, beyond the structural feature that similarity is a property possessed by pairs of objects and the vague feeling that it is somehow related to geometric proximity.

What cannot be defined may still be learned. Even if we cannot explain the meaning of a concept, as long as it has observable manifestations we can hope to infer models to predict future observations. These models will generally be domain-dependent and not in the form of definitions, but rather vectors of synaptic efficacies, transformation coefficients or other constructions which often defy verbalization, they are more akin to feeling than to rationality and they will be judged by their predictive power rather than by logical clarity and comprehensibility.

This paper introduces a technique to learn and to represent similarity, an analysis of generalization performance, an algorithmic realization and some experimental results.

1.1 A General Framework

Assumption 1: There is a measurable space $\mathcal{X}$ and a probability measure ρ on $\mathcal{X}^2 \times \{-1,1\}$, the *pair oracle*.

The interpretation is as follows: $\mathcal{X}$ is the input space containing the objects in question. Whenever we call the oracle it will return the triplet $(x,x',r) \in \mathcal{X}^2 \times \{-1,1\}$ with probability $\rho(x,x',r)$. If the oracle returns $(x,x',1)$ it asserts that x and x' are *similar*, if it returns $(x,x',-1)$ it asserts that x and x' are *dissimilar*. The assumption that similarity is a binary property, which can only have the values of true or false, is a simplification which can in principle be removed (see Section 4.1 below). Beyond this restriction arbitrary definitions of similarity can be substituted, we do not require "obvious properties" such as $\rho(x,x',r) = \rho(x',x,r)$ or $\rho(x,x,-1) = 0$. We will however use an intuitive property of similarity, a kinship to closeness or geometric proximity, in the choice of our hypothesis spaces below.

Assumption 2: $\mathcal{X} \subset H$, where H is a real separable finite- or infinite-dimensional Hilbert space, and $diam(\mathcal{X}) \leq 1$.

Either the inputs are already members of some Euclidean space (vectors of neural activations, pixel vectors or vectors of feature-values), or we identify them with their images under some feature map, which may be realized by some fixed pre-processor such as a fixed weight neural network or by a positive definite kernel on $\mathcal{X}$. In the more detailed description of the proposed algorithm and experimental results we will be more explicit about these feature maps. The bound on the diameter of the input space is a convenience for the statement of our theoretical results.

Assumption 3: There is a training sample

$$S = \left(\left(x_1,x_1',r_1\right),...,\left(x_m,x_m',r_m\right)\right) \in \left(\mathcal{X}^2 \times \{-1,1\}\right)^m,$$

generated in m independent, identical trials of ρ, that is, $S \sim \rho^m$.

The assumptions of independence and stationarity are crucial and very strong: The oracle is without memory of our previous calls and not affected by the passage of time. It will not deliberately help nor mislead the learner. The training sample contains all the information available to the learner who wants to find a rule to predict the oracles behavior.

Definition 1: A pair hypothesis is a function $f : \mathcal{X}^2 \to \{-1,0,1\}$. Its risk is

$$R(f) = \Pr_{(x,x',r)\sim\rho}\left\{f\left(x,x'\right) \neq r\right\}.$$

The pair hypothesis attempts to predict the similarity value of a pair (x,x') and its risk is its error probability as measured by the pair oracle. We allowed the value 0 to account for the possibility that f may refuse to make a decision. Any such refusal is counted as an error by the risk functional.

1.2 Risk Bounds and Regularized Objectives

So far we have only used the structural condition that similarity is a property possessed by pairs of objects. In the choice of the hypothesis space we will follow the intuition that similarity is related to closeness or geometrical proximity. We will consider hypotheses from the set

$$\mathcal{H} = \left\{f_T : \left(x,x'\right) \mapsto sgn\left(1 - \left\|Tx - Tx'\right\|\right) : T \in \mathcal{L}_0(H)\right\},$$

where $\mathcal{L}_0(H)$ is the set of linear operators of finite rank on H. A transformation $T \in \mathcal{L}_0(H)$ thus defines a hypothesis f_T which regards a pair of inputs as similar if the distance between their respective images under T is smaller than one, and as dissimilar if this distance is larger than one. Fixing the threshold to one causes no loss of generality, because any other positive threshold could be absorbed as a factor of the transformation.

This choice of the hypothesis space combines the geometric connotation of similarity with the simplicity of linear representations. The transformations which parametrize our hypothesis space are in some ways more interesting and useful than the hypotheses themselves. A choice of $T \in \mathcal{L}_0(H)$ also implies a choice of the Mahalanobis distance $d^2(x,x') = \langle T^*T(x-x'), x-x' \rangle$ and the positive semidefinite kernel $\kappa(x,x') = \langle T^*Tx, x' \rangle$.

The risk of the hypothesis f_T induces a risk functional on $\mathcal{L}_0(H)$

$$R(T) = R(f_T) = \Pr_{(x,x',r)\sim\rho} \left\{ r\left(1 - \left\|Tx - Tx'\right\|^2\right) \leq 0 \right\}.$$

Since we can write $\|Tx - Tx'\|^2 = \langle T^*T(x-x'), x-x' \rangle = \langle T^*T, Q_{x-x'} \rangle_2$, where $Q_{x-x'}$ and $\langle .,. \rangle_2$ are respectively the outer product operator and the Hilbert-Schmidt inner product (see Section 2.1), the last expression is reminiscent of the risk of a classifier defined by a linear function thresholded at 1. This provides the intuition underlying the proposed technique: We will look for a linear large-margin classifier whose weight vector is the positive operator T^*T.

Let $\psi : \mathbb{R} \to \mathbb{R}$, $\psi \geq 1_{(-\infty,0]}$ with Lipschitz constant L. Given our training sample $S = ((x_1, x_1', r_1), \ldots, (x_m, x_m', r_m))$ we define the empirical risk estimate

$$\hat{R}_\psi(T,S) = \frac{1}{m} \sum_{i=1}^{m} \psi\left(r_i\left(1 - \left\|T\left(x_i - x_i'\right)\right\|^2\right)\right). \tag{1}$$

We then have the following theorem, a proof of which will be given in Section 3.

Theorem 1 *$\forall \delta > 0$, with probability greater $1-\delta$ in a sample $S \sim \rho^m$*
$\forall T \in \mathcal{L}_0(H)$ with $\|T^*T\|_2 \geq 1$

$$R(T) \leq \hat{R}_\psi(T,S) + \frac{4L\ \|T^*T\|_2 + \sqrt{(1/2)\ln(2\|T^*T\|_2/\delta)}}{\sqrt{m}}.$$

where $\|A\|_2 = Tr(A^*A)^{1/2}$ is the Hilbert-Schmidt- or Frobenius- norm of A.

The theorem gives a high-probability-bound on the true risk valid for all transformations in terms of the empirical risk estimate and a complexity term. Because of the uniform nature of the bound, a principled approach could search for $T \in \mathcal{L}_0(H)$ to minimize the right side of the bound. This is just what we propose to do, with two practical modifications:

- The term $\sqrt{(1/2)\ln(2\|T^*T\|_2/\delta)}$ is neglected, the one linear in $\|T^*T\|_2$ being regarded as the dominant contribution.
- The factor $4L$ is replaced by an adjustable regularization parameter $\lambda > 0$. This allows to compensate the fact that the difficult estimates in such generalization bounds overestimate the estimation error.

As a Lipschitz function ψ we use h_γ, the hinge-loss with margin γ, which has the value $1 - t/\gamma$ for $t < \gamma$, and the value 0 otherwise. This leads to the regularized objective function

$$\Lambda_{h_\gamma,\lambda}(T) := \frac{1}{m} \sum_{i=1}^{m} h_\gamma\left(r_i\left(1 - \left\|T\left(x_i - x_i'\right)\right\|^2\right)\right) + \frac{\lambda\|T^*T\|_2}{\sqrt{m}},$$

which is convex in T^*T. Details related to the minimization of $\Lambda_{\gamma,\lambda}$ are given in Section 3.3. It follows from the nature of the objective function that the minimizing operator will have rank $\leq m$.

1.3 The Multi-category Problem and Learning-to-learn

In many classification problems occurring in a complex environment a learner cannot hope to obtain examples for all potential categories. An example is furnished by the recognition of human faces, since nobody can be expected to ever see all the faces which possibly need to be distinguished in the future and the total number of categories is itself uncertain.

Human learning appears to cope with these empirically deficient problems: In addition to the recognition of the already known categories human learners develop meta-techniques to improve the learning and recognition of future categories. As a child learns to recognize parents, family, friends, neighbors, classmates and teachers it learns to memorize, recognize and distinguish faces in general, an ability which leads to a reliable recall often already on the basis of a single training image. The earlier learning process leading to an improvement of future learning performance is often referred to as *learning-to-learn* or *meta-learning*.

The practical utility of such mechanisms for machine-learning is obvious, and theoretically well founded models of learning-to-learn may also be interesting from the point of view of cognitive science or psychology (see Robins, 1998; Thrun, 1998; Baxter, 1998 for surveys, theoretical and experimental contributions).

Here we exploit the fact that partial empirical knowledge of some of the categories of a domain implies partial empirical knowledge of an underlying principle of similarity. By a very crude operational definition similarity is a property of two phenomena which makes them belong to the same category of some domain, and dissimilarity is the negation of similarity. Following this idea we can define a pair oracle which regards pairs of inputs as similar if and only if they come with the same label, use this oracle to generate a large number of examples and train our algorithm to obtain a similarity rule, together with a representing operator T.

Subsequently, once a novel category is represented by a first example, any new phenomenon can be classified as belonging to the given category if and only if it is similar to the representing example. Let us call this decision rule the *elementary verifier* generated from the example. It follows from our analysis, that we can be confident that a single randomly chosen example for a future (possibly previously unseen) category will give an elementary verifier with expected error bounded by the bound in Theorem 1. These constructions and some related questions will be discussed in Section 5.

A related concept is *transfer*, where a representation trained from the data-set of a training-task is applied to facilitate the learning of another, presumably related, target-task. Corresponding experiments were carried out on a number of problems in image recognition, such as the recognition of handwritten characters, rotation and scale invariant character recognition and the recognition of human faces. In all these cases the representations generated from the training-tasks yielded a considerable performance improvement for single-sample nearest neighbor classifiers on the target-tasks.

This paper is organized as follows: Section 2 gives notation and theoretical background, Section 3 introduces operator valued large-margin classifiers and a corresponding algorithm to train representations, Section 4 derives an alternative algorithm related to PCA, Section 5 discusses the application of our method to meta-learning and transfer, Section 6 describes experimental results and Section 7 gives a brief review of some related approaches in the literature.

A precursor of this paper appeared in the NIPS'06 workshop on "Learning to Compare Examples" (Maurer, 2006c).

2. Notation, Definitions and Preliminary Results

In this section we introduce some notation and necessary theoretical background. For the readers convenience there is also an appendix with a tabular summary of most of the notation used in this paper.

2.1 Hilbert Space and Hilbert Schmidt Operators

The letter H denotes a finite- or infinite-dimensional real, separable Hilbert space, with inner product $\langle .,. \rangle$ and norm $\|.\|$. Inner products and norms on other spaces will be identified with subscripts. If $\left(\mathcal{S}, \|.\|_{\mathcal{S}}\right)$ is a generic normed space and $E \subseteq \mathcal{S}$, we will use the notation

$$\|E\|_{\mathcal{S}} = \sup_{x \in E} \|x\|_{\mathcal{S}}.$$

If H' is another Hilbert space, with inner product $\langle .,. \rangle'$ and norm $\|.\|'$, then $\mathcal{L}_\infty(H,H')$ denotes the Banach space of linear transformations $T : H \to H'$ such that

$$\|T\|_\infty = \sup_{x \in H, \|x\| \leq 1} \|Tx\|' < \infty.$$

For $T \in \mathcal{L}_\infty(H,H')$, $Ker(T)$ is the subspace $\{x : Tx = 0\}$ and T^* is the unique member of $\mathcal{L}_\infty(H',H)$ satisfying $\langle Tx, y \rangle' = \langle x, T^* y \rangle$, $\forall x \in H, y \in H'$. If $S \subset H$ then $S^\perp$ is the subspace $\{x : \langle x, y \rangle = 0, \forall y \in S\}$. A transformation $U \in \mathcal{L}_\infty(H,H')$ is called a partial isometry if $\|Ux\| = \|x\|$, $\forall x \in Ker(U)^\perp$.

We write $\mathcal{L}_\infty(H) = \mathcal{L}_\infty(H,H)$. An operator $T \in \mathcal{L}_\infty(H)$ is called symmetric if $T = T^*$ and positive if it is symmetric and $\langle Tx, x \rangle \geq 0$, $\forall x \in H$. We use $\mathcal{L}_\infty^*(H)$ and $\mathcal{L}_\infty^+(H)$ to denote the sets of symmetric and positive members of $\mathcal{L}_\infty(H)$ respectively. For every $T \in \mathcal{L}_\infty^+(H)$ there is some unique $T^{1/2} \in \mathcal{L}_\infty^+(H)$ with $T = T^{1/2} T^{1/2}$. Evidently for every $T \in \mathcal{L}_\infty(H,H')$ we have $T^*T \in \mathcal{L}_\infty^+(H)$ and we denote with $|T|$ the positive operator $(T^*T)^{1/2}$. For every $T \in \mathcal{L}_\infty(H,H')$ there is a polar decomposition $T = U|T|$ for a unique partial isometry $U \in \mathcal{L}_\infty(H,H')$.

For $\mathcal{V} \subseteq \mathcal{L}_\infty(H)$ we use the notation $\mathcal{V}^*\mathcal{V} = \left\{T^*T : T \in \mathcal{V}\right\}$. The set of finite rank operators on H is denoted by $\mathcal{L}_0(H)$. Any orthonormal basis establishes a one-to-one correspondence between $\mathcal{L}_0(H)$ and $\bigcup_{n=1}^\infty \{T : H \to \mathbb{R}^n : T \text{ linear}\}$.

With $\mathcal{L}_2(H)$ we denote the real vector space of operators $T \in \mathcal{L}_\infty(H)$ satisfying $\sum_{i=1}^\infty \|Te_i\|^2 \leq \infty$ for every orthonormal basis $(e_i)_{i=1}^\infty$ of H. The members of $\mathcal{L}_2(H)$ are compact and called *Hilbert Schmidt operators*. For $S, T \in \mathcal{L}_2(H)$ and an orthonormal basis (e_i) the series $\sum_i \langle Se_i, Te_i \rangle$ is absolutely summable and independent of the chosen basis. The number

$$\langle S, T \rangle_2 = \sum_i \langle Se_i, Te_i \rangle$$

defines an inner product on $\mathcal{L}_2(H)$, making it a Hilbert space. We denote the corresponding norm with $\|.\|_2$ (see Reed and Simon, 1980 for background on functional analysis). $\mathcal{L}_2^*(H)$ and $\mathcal{L}_2^+(H)$ denote the sets of symmetric and positive members of $\mathcal{L}_2(H)$ respectively. For every member of $\mathcal{L}_2^*(H)$ there is a complete orthonormal basis of eigenvectors, and for $T \in \mathcal{L}_2^*(H)$ the norm $\|T\|_2$ is just the ℓ_2-norm of its sequence of eigenvalues. In the finite dimensional case the norm $\|T\|_2$ is the Frobenius norm of the matrix of T in an orthonormal representation.

The set of d-dimensional, orthogonal projections in H is denoted with $\mathcal{P}_d$. It is easy to verify that $\mathcal{P}_d \subset \mathcal{L}_2^+(H)$ and if $P \in \mathcal{P}_d$ then $\|P\|_2 = \sqrt{d}$ and $P^2 = P$.

Definition 2 *For $x \in H$ define an operator Q_x on H by $Q_x z = \langle z, x \rangle x$, $\forall z \in H$.*

The map $x \to Q_x$ is an embedding of H in $\mathcal{L}_2^+(H)$ which is homogeneous of degree two (i.e., $Q_{\lambda x} = \lambda^2 Q_x$, $\lambda \in \mathbb{R}$, $x \in H$). In matrix terminology Q_x is the 'outer product' of x with itself. The following simple lemma is crucial for our proofs (see also Maurer, 2006b).

Lemma 3 *Let $x, y \in H$ and $T \in \mathcal{L}_2(H)$. Then*
(i) $Q_x \in \mathcal{L}_2^+(H)$ and $\|Q_x\|_2 = \|x\|^2$.
(ii) $\langle Q_x, Q_y \rangle_2 = \langle x, y \rangle^2$.
(iii) $\langle T, Q_x \rangle_2 = \langle Tx, x \rangle$.
(iv) $\langle T^* T, Q_x \rangle_2 = \|Tx\|^2$.
(v) For $\alpha \in \mathbb{R}$, $Q_{\alpha x} = \alpha^2 Q_x$.
(vi) For $P \in \mathcal{P}_d$ we have $\|PTP\|_2 \leq \|T\|_2$.

Proof For $x = 0$ all assertions are trivial. Otherwise extend $x/\|x\|$ to an orthonormal basis of H and use this basis in the definition of $\langle T, Q_x \rangle_2$ to obtain $\langle T, Q_x \rangle_2 = \langle Tx/\|x\|, Q_x x/\|x\| \rangle = \|x\|^{-2} \langle Tx, \langle x, x \rangle x \rangle = \langle Tx, x \rangle$, which is (iii). (ii),(iv) and the second half of (i) follow immediately, the first part of (i) then follows from (iii) with $T = Q_x$. (v) is trivial. To prove (vi) complete a basis $\{e_i\}_{i=1,..,d}$ for the range of P to a basis e_i for H to get $\|PTP\|_2^2 = \sum_{ij} \langle PTPe_i, e_j \rangle^2 = \sum_{i,j \leq d} \langle Te_i, e_j \rangle^2 \leq \sum_{ij} \langle Te_i, e_j \rangle^2 = \|T\|_2^2$. ■

2.2 Rademacher Complexities

To derive the uniform laws of large numbers we need for Theorem 1 we will use Rademacher averages as complexity measures for function classes:

Definition 4 *Let $\mathcal{F}$ be a real-valued function class on a space $\mathcal{X}$. Let $\{\sigma_i : i \in \{1, ..., m\}\}$ be a collection of independent random variables, distributed uniformly in $\{-1, 1\}$. The empirical Rademacher complexity of $\mathcal{F}$ is the function $\hat{\mathcal{R}}_m(\mathcal{F})$ defined on $\mathcal{X}^m$ by*

$$\hat{\mathcal{R}}_m(\mathcal{F})(\mathbf{x}) = \mathbb{E}_\sigma \left[\sup_{\mathbf{f} \in \mathcal{F}} \frac{2}{m} \sum_{i=1}^m \sigma_i f(x_i) \right].$$

If $\mathbf{X} = (X_i)_{i=1}^m$ is a vector of $\mathcal{X}$-valued independent random variables then the expected Rademacher complexity of $\mathcal{F}$ is

$$\mathcal{R}_m(\mathcal{F}) = \mathbb{E}_{\mathbf{X}} \left[\hat{\mathcal{R}}_m(\mathcal{F})(\mathbf{X}) \right].$$

Theorem 5 *Let $\mathcal{F}$ be a $[0,1]$-valued function class on a space $\mathcal{X}$, and $\mathbf{X} = (X_i)_{i=1}^m$ a vector of $\mathcal{X}$-valued independent, identically distributed random variables. Fix $\delta > 0$.*

With probability greater than $1 - \delta$ we have for all $f \in \mathcal{F}$

$$E[f(X_1)] \leq \frac{1}{m} \sum_{i=1}^m f(X_i) + \mathcal{R}_m(\mathcal{F}) + \sqrt{\frac{\ln(1/\delta)}{2m}}.$$

We also have with probability greater than $1-\delta$ *for all* $f \in \mathcal{F}$*, that*

$$E\left[f\left(X_1\right)\right] \leq \frac{1}{m}\sum_{i=1}^{m} f\left(X_i\right) + \hat{\mathcal{R}}_m\left(\mathcal{F}\right)\left(\mathbf{X}\right) + \sqrt{\frac{9\ln\left(2/\delta\right)}{2m}}.$$

For a proof see Bartlett and Mendelson (2002) or Maurer (2006b). We will also use the following result from Bartlett et al. (2005):

Theorem 6 *Let* $\mathcal{F}$ *be a class of real-valued functions on a space* $\mathcal{X}$ *and suppose that* $\psi : \mathbb{R} \to \mathbb{R}$ *has Lipschitz constant* L*. Let* $\psi \circ \mathcal{F} = \{\psi \circ f : f \in \mathcal{F}\}$*. Then* $\hat{\mathcal{R}}_m\left(\psi \circ \mathcal{F}\right) \leq L\,\hat{\mathcal{R}}_m\left(\mathcal{F}\right)$*.*

2.3 Bounds for Vector-valued Processes

In this section we review some bounds for vector valued processes and linear classifiers. The bounds are not at all original (they are taken from Koltchinskii and Panchenko, 2002; Bartlett and Mendelson, 2002; Shawe-Taylor and Christianini, 2003), nor are they necessarily the tightest possible, because they are uniformly valid on the chosen function classes (compare with Bartlett et al., 2005). Because the proofs are easy we provide them for the readers convenience.

Using Lemma 3 all these results can be easily transferred from the Hilbert space H to the Hilbert space $\mathcal{L}_2\left(H\right)$. This simple step, together the geometrical interpretation implied by Lemma 3 (iv), is the principal theoretical contribution of this paper.

Lemma 7 *Let* $V \subset H$ *and* $\mathcal{F} = \{x \in H \mapsto \langle x, v\rangle : v \in V\}$*. Then for any* $\mathbf{x} = (x_1, ..., x_m) \in H^m$

$$\hat{\mathcal{R}}_m\left(\mathcal{F}\right)\left(\mathbf{x}\right) \leq \frac{2\left\|V\right\|}{m}\left(\sum_{i=1}^{m}\left\|x_i\right\|^2\right)^{1/2}.$$

Proof From Schwartz' and Jensen's inequality and linearity we obtain

$$\begin{aligned}\hat{\mathcal{R}}_m\left(\mathcal{F}\right)\left(\mathbf{x}\right) &= \mathbb{E}_\sigma\left[\sup_{v\in V}\frac{2}{m}\sum_{i=1}^{m}\sigma_i\left\langle x_i, v\right\rangle\right] = \mathbb{E}_\sigma\left[\sup_{v\in V}\frac{2}{m}\left\langle\sum_{i=1}^{m}\sigma_i x_i, v\right\rangle\right] \\ &\leq \frac{2\left\|V\right\|}{m}\mathbb{E}_\sigma\left[\left\|\sum_{i=1}^{m}\sigma_i x_i\right\|\right] \leq \frac{2\left\|V\right\|}{m}\left(\mathbb{E}_\sigma\left[\left\|\sum_{i=1}^{m}\sigma_i x_i\right\|^2\right]\right)^{1/2},\end{aligned}$$

but by the properties of the σ_i we have $\mathbb{E}_\sigma\left[\sigma_i\sigma_j\right] = \delta_{ij}$, so we get

$$\mathbb{E}_\sigma\left[\left\|\sum_{i=1}^{m}\sigma_i x_i\right\|^2\right] = \sum_{i=1}^{m}\sum_{j=1}^{m}\mathbb{E}_\sigma\left[\sigma_i\sigma_j\right]\left\langle x_i, x_j\right\rangle = \sum_{i=1}^{m}\left\|x_i\right\|^2.$$

■

Theorem 8 *Let (X,r) be a random variable with values in $H\times\{-1,1\}$ and let $(\mathbf{X},\mathbf{r})=((X_1,r_1),\ldots,(X_m,r_m))$ be a vector of m iid copies of (X,r). Let $\psi:\mathbb{R}\to\mathbb{R}$, $\psi\geq 1_{(-\infty,0]}$ with Lipschitz constant L and $V\subset H$. For $v\in V$ denote $err(v)=\Pr\{sign(1-\langle X,v\rangle)\neq r\}$ and*

$$\hat{err}_\psi(v,(\mathbf{X},\mathbf{r}))=\frac{1}{m}\sum_{i=1}^m\psi(r_i(1-\langle X_i,v\rangle)).$$

Let $\delta>0$. Then with probability greater than $1-\delta$ we have for all $v\in V$

$$err(v)\leq\hat{err}_\psi(v,(\mathbf{X},\mathbf{r}))+\frac{2L\,\|V\|}{m}\left(\sum_{i=1}^m\|X_i\|^2\right)^{1/2}+\sqrt{\frac{9\ln(2/\delta)}{2m}}.$$

If $\|X\|\leq 1$ a.s. then with probability greater than $1-\delta$ we have for all $v\in V$ that

$$err(v)\leq\hat{err}_\psi(v,(\mathbf{X},\mathbf{r}))+\frac{2L\,\|V\|}{\sqrt{m}}+\sqrt{\frac{\ln(1/\delta)}{2m}}.$$

Proof If we can prove the Theorem for $\psi:\mathbb{R}\to[0,1]$, then it will follow for general ψ, because it will also be true for $\min\{\psi,1\}$ which has Lipschitz constant bounded by L and $\hat{\text{er}}_{\min\{\psi,1\}}(v,(\mathbf{X},\mathbf{r}))\leq\hat{\text{er}}_\psi(v,(\mathbf{X},\mathbf{r}))$. We can thus assume $\psi:\mathbb{R}\to[0,1]$ and since $\psi\geq 1_{(-\infty,0]}$ we have $R(v)=\mathbb{E}\left[1_{(-\infty,0]}(r(1-\langle X,v\rangle))\right]\leq\mathbb{E}[\psi(r(1-\langle X,v\rangle))]$. In view of Theorem 5 it therefore suffices to prove that

$$\hat{\mathcal{R}}_m(\psi\circ\mathcal{F})(\mathbf{X})\leq\frac{2L\,\|V\|}{m}\left(\sum_{i=1}^m\|X_i\|^2\right)^{1/2},\tag{2}$$

where $\mathcal{F}$ is the function class

$$\mathcal{F}=\{(x,r)\in H\times\{-1,1\}\mapsto r(1-\langle x,v\rangle):v\in V\}.$$

By Theorem 6 we have $\hat{\mathcal{R}}_m(\psi\circ\mathcal{F})\leq L\,\hat{\mathcal{R}}_m(\mathcal{F})$ and one verifies easily that $\hat{\mathcal{R}}_m(\mathcal{F})=\hat{\mathcal{R}}_m(x\mapsto\langle x,v\rangle:v\in V)$, so (2) follows from Lemma 7. ■

To derive our bounds for hyperbolic PCA in Section 4 we need the following lemma. A similar statement can be found in Shawe-Taylor and Christianini (2003).

Lemma 9 *Let $V,W\subset H$ be and suppose that $X_1,\ldots,X_m$ are independent, identically distributed, zero-mean random variables with values in W. Then for ε and m such that $\|W\|\,\|V\|<\sqrt{m}\varepsilon$ we have*

$$\Pr\left\{\sup_{v\in V}\left|\frac{1}{m}\sum_{i=1}^m\langle v,X_i\rangle\right|>\varepsilon\right\}\leq\exp\left(\frac{-\left(\sqrt{m}\varepsilon-\|V\|\,\|W\|\right)^2}{2\left|\langle V,W\rangle\right|^2}\right).$$

Proof Consider the average $\bar{\mathbf{X}}=(1/m)\sum_1^m X_i$. With Jensen's inequality and using independence we obtain

$$\left(\mathbb{E}\left[\left\|\bar{\mathbf{X}}\right\|\right]\right)^2\leq\mathbb{E}\left[\left\|\bar{\mathbf{X}}\right\|^2\right]=\frac{1}{m^2}\sum_{i=1}^m\mathbb{E}\left[\|X_i\|^2\right]\leq\|W\|^2/m.$$

Now let $f : W^m \to \mathbb{R}$ be defined by $f(\mathbf{x}) = \sup_{v \in V} |(1/m) \sum_1^m \langle v, x_i \rangle|$. We have to bound the probability that $f > \varepsilon$. By Schwartz' inequality and the above bound we have

$$\mathbb{E}[f(\mathbf{X})] = \mathbb{E}\left[\sup_{v \in V} \left|\left\langle v, \bar{\mathbf{X}} \right\rangle\right|\right] \leq \|V\| \, \mathbb{E}\left[\left\|\bar{\mathbf{X}}\right\|\right] \leq \left(1/\sqrt{m}\right) \|V\| \, \|W\|. \tag{3}$$

Let $\mathbf{x} \in W^m$ be arbitrary and $\mathbf{x}' \in W^m$ be obtained by modifying a coordinate x_k of $\mathbf{x}$ to be an arbitrary $x'_k \in W$. Then

$$\left|f(\mathbf{x}) - f\left(\mathbf{x}'\right)\right| \leq \frac{1}{m} \sup_{v \in V} \left|\langle v, x_k \rangle - \left\langle v, x'_k \right\rangle\right| \leq \frac{2}{m} \left|\langle V, W \rangle\right|.$$

By (3) and the bounded-difference inequality (see McDiarmid, 1998) we obtain for $t > 0$

$$\Pr\left\{ f(\mathbf{X}) > \frac{\|V\| \, \|W\|}{\sqrt{m}} + t \right\} \leq \Pr\{ f(\mathbf{X}) - \mathbb{E}[f(\mathbf{X})] > t \} \leq \exp\left(\frac{-mt^2}{2\left|\langle V, W \rangle\right|^2} \right).$$

The conclusion follows from setting $t = \varepsilon - (1/\sqrt{m}) \|V\| \, \|W\|$ ■

We will also use the following model-selection lemma taken from (Anthony and Bartlett, 1999, Lemma 15.5):

Lemma 10 *Suppose*

$$\{F(\alpha_1, \alpha_2, \delta) : 0 < \alpha_1, \alpha_2, \delta \leq 1\}$$

is a set of events such that:

(i) For all $0 < \alpha \leq 1$ *and* $0 < \delta \leq 1$,

$$\Pr\{F(\alpha, \alpha, \delta)\} \leq \delta.$$

(ii) For all $0 < \alpha_1 \leq \alpha \leq \alpha_2 \leq 1$ *and* $0 < \delta_1 \leq \delta \leq 1$,

$$F(\alpha_1, \alpha_2, \delta_1) \subseteq F(\alpha, \alpha, \delta).$$

Then for $0 < a, \delta < 1$,

$$\Pr\left(\bigcup_{\alpha \in (0,1]} F(\alpha a, \alpha, \delta\alpha(1-a)) \right) \leq \delta.$$

3. Operator Valued Large Margin Classifiers

In this section we derive our algorithm. We give a proof of Theorem 1, then discuss the derivation of an objective functional and finally some issues related to its minimization.

3.1 Generalization Bounds

We first give a version of Theorem 1 for a fixed hypothesis space given by Hilbert-Schmidt operators of uniformly bounded norm and then derive from it a regularized version applying to all Hilbert-Schmidt operators.

Recall that the pair oracle is a probability measure ρ on $\mathcal{X}^2 \times \{-1,1\}$, the set of labeled pairs (sometimes also called equivalence constraints; Bar-Hillel et al., 2005), and that we assumed the input space $\mathcal{X}$ to be embedded in the Hilbert space H such that $diam(\mathcal{X}) \leq 1$. We will apply Theorem 8 to the Hilbert space $\mathcal{L}_2(H)$ instead of H and replace the random variable (X,r) of Theorem 8 by the random variable $(Q_{x-x'},r)$ with values in $\mathcal{L}_2(H) \times \{-1,1\}$, where (x,x',r) are distributed according to the pair oracle ρ. The training sample $S = ((x_1,x_1',r_1),...,(x_m,x_m',r_m))$ corresponds to m independent realizations $\left(\left(Q_{x_1-x_1'},r_1\right),...,\left(Q_{x_m-x_m'},r_m\right)\right)$ of this random variable. Since $diam(\mathcal{X}) \leq 1$ we have $\|Q_{x-x'}\|_2 = \|x-x'\|^2 \leq 1$ a.s. by virtue of Lemma 3 (i).

Recall the definition of the risk associated with a transformation T. Using Lemma 3 (iv) we have

$$\begin{aligned} R(T) &= \Pr\left\{r\left(1-\left\|Tx-Tx'\right\|^2\right) \leq 0\right\} = \Pr\left\{r\left(1-\langle Q_{x-x'}, T^*T\rangle_2\right) \leq 0\right\} \\ &= \operatorname{err}(T^*T). \end{aligned}$$

Here $\operatorname{err}(T^*T)$ (see Theorem 8) is the expected error of the linear classifier defined by the vector T^*T in $\mathcal{L}_2(H)$ thresholded at the value 1 and applied to a random labeled data point $(Q_{x-x'},r) \in \mathcal{L}_2(H) \times \{-1,1\}$. Also note that the empirical estimator (1) can be rewritten

$$\hat{R}_\psi(T,S) = \frac{1}{m}\sum_{i=1}^m \psi\left(r_i\left(1-\left\langle Q_{x_i-x_i'}, T^*T\right\rangle_2\right)\right).$$

With corresponding substitutions Theorem 8 becomes

Theorem 11 *Let $\psi : \mathbb{R} \to \mathbb{R}$, $\psi \geq 1_{(-\infty,0]}$ with Lipschitz constant L and $\mathcal{V} \subset \mathcal{L}_2(H)$. Let $\delta > 0$.*

(i) With probability greater than $1-\delta$ we have for all $T \in \mathcal{L}_\infty(H)$ such that $T^*T \in \mathcal{V}$

$$R(T) \leq \hat{R}_\psi(T,S) + \frac{2L\ \left\|\mathcal{V}\right\|_2}{m}\left(\sum_{i=1}^m \left\|X_i - X_i'\right\|^4\right)^{1/2} + \sqrt{\frac{9\ln(2/\delta)}{2m}}.$$

(ii) With probability greater than $1-\delta$ we have for all $T \in \mathcal{L}_\infty(H)$ such that $T^*T \in \mathcal{V}$

$$R(T) \leq \hat{R}_\psi(T,S) + \frac{2L\ \left\|\mathcal{V}\right\|_2}{\sqrt{m}} + \sqrt{\frac{\ln(1/\delta)}{2m}}.$$

Typically $\mathcal{V}$ would be a ball of some fixed radius, say c, about the origin in $\mathcal{L}_2(H)$, so that $\left\|\mathcal{V}\right\|_2 = c$. Our application of the vector valued generalization Theorem 8 introduced a certain looseness: Theorem 8 gives bounds on $\operatorname{err}(A)$ for all $A \in \mathcal{V}$, while we only require the bounds for those $A \in \mathcal{V}$ which are of the form $A = T^*T$, that is we are only using the linear functionals in $\mathcal{V} \cap \mathcal{L}_2^+(H)$. This raises the question if we might not get much better bounds for $\mathcal{V} \cap \mathcal{L}_2^+(H)$ than for $\mathcal{V}$. The following proposition shows that this will not work using Rademacher averages.

Proposition 12 *Let $\mathcal{F}$ and $\mathcal{F}^+$ be the function classes on $\mathcal{L}_2(H)$ given by*

$$\begin{aligned}\mathcal{F} &= \{B \in \mathcal{L}_2(H) \mapsto \langle B,A\rangle_2 : \|A\|_2 \le 1\},\\ \mathcal{F}^+ &= \left\{B \in \mathcal{L}_2(H) \mapsto \langle B,A\rangle_2 : \|A\|_2 \le 1,\ A \in \mathcal{L}_2^+(H)\right\}.\end{aligned}$$

Then $\hat{\mathcal{R}}_m(\mathcal{F}^+) \le \hat{\mathcal{R}}_m(\mathcal{F}) \le 4\hat{\mathcal{R}}_m(\mathcal{F}^+)$.

Proof The first inequality is obvious since $\mathcal{F}^+ \subset \mathcal{F}$ (see Theorem 12 in Bartlett and Mendelson, 2002). Suppose $\|A\|_2 \le 1$. With $A_1 = (A+A^*)/2$ and $A_2 = (A+A^*)/2$ we can write $A = A_1 + A_2$ with A_i symmetric and $\|A_i\|_2 \le 1$. By symmetry of the A_i and the spectral theorem we can write $A_i = A_{i1} - A_{i2}$ with $A_{ij} \in \mathcal{L}_2^+(H)$ and $\|A_{ij}\|_2 \le 1$. So any $f \in \mathcal{F}$ can be written in the form $f = f_{11} - f_{12} + f_{21} - f_{22}$ with $f_{ij} \in \mathcal{F}^+$, or $\mathcal{F} = \mathcal{F}^+ - \mathcal{F}^+ + \mathcal{F}^+ - \mathcal{F}^+$, whence the second inequality also follows from Theorem 12 in Bartlett and Mendelson (2002), or from an application of the triangle inequality. ■

By stratification over balls in $\mathcal{L}_2(H)$ we arrive at a generalization bound valid for *all* bounded operators. If specialized to $\mathcal{L}_0(H)$, the second conclusion below becomes Theorem 1 in the introduction.

Theorem 13 *Let $\psi : \mathbb{R} \to \mathbb{R}$, $\psi \ge 1_{(-\infty,0]}$ with Lipschitz constant L and $\delta > 0$.*

1. With probability greater than $1-\delta$ we have for all $T \in \mathcal{L}_\infty(H)$

$$R(T) \le \hat{R}_\psi(T,S) + \frac{4L\ \|T^*T\|_2}{m}\left(\sum_{i=1}^m \left\|X_i - X_i'\right\|^4\right)^{1/2} + \sqrt{\frac{9\ln(4\|T^*T\|_2/\delta)}{2m}}.$$

2. With probability greater than $1-\delta$ we have for all $T \in \mathcal{L}_\infty(H)$

$$R(T) \le \hat{R}_\psi(T,S) + \frac{4L\ \|T^*T\|_2}{\sqrt{m}} + \sqrt{\frac{\ln(2\|T^*T\|_2/\delta)}{2m}}.$$

Proof We will use Lemma 10. For $\alpha \in (0,1]$ let $\mathcal{V}(\alpha) = \{T \in \mathcal{L}_\infty(H) : \|T^*T\|_2 \le 1/\alpha\}$ and consider the events

$$F(\alpha_1,\alpha_2,\delta) = \Big\{\exists T \in \mathcal{V}(\alpha_2) \text{ such that } R(T) > \hat{R}(T,S) + \frac{2L}{\alpha_1 m}\left(\sum_{i=1}^m \left\|Q_{X_i - X_i'}\right\|^2\right)^{1/2} + \sqrt{\frac{9\ln(2/\delta)}{2m}}\Big\}.$$

By the first conclusion of Theorem 11 the events $F(\alpha_1,\alpha_2,\delta)$ satisfy hypothesis (i) of Lemma 10, and it is easy to see that (ii) also holds. If we set $a = 1/2$ and replace α by $1/\|T^*T\|_2$, then the conclusion of Lemma 10 becomes the first conclusion above. The second conclusion is proved similarly. ■

3.2 The Objective Functional

Because of the complicated estimates involved, risk bounds such as Theorem 13 have a tendency to be somewhat loose, so that a learning algorithm relying on naive minimization of the bounds may end up with suboptimal hypotheses. On the other hand in the absence of other helpful information such a bound provides a valuable guiding principle, as long as it is transformed to an objective functional which can be minimized in practice and allows for a flexible parametrization of the slack suspected in the bound.

Departing from the simpler of the two conclusions of Theorem 13, a naive approach would look for some $T \in \mathcal{L}_0(H)$ to minimize the objective functional

$$\hat{R}_\psi(T,S) + \frac{4L\ \|T^*T\|_2}{\sqrt{m}} + \sqrt{\frac{\ln\left(2\|T^*T\|_2/\delta\right)}{2m}}.$$

Our first modification is to discard the last term on the grounds that it will be dominated by second one. This is only justified if we exclude extremely small values of the confidence parameter δ and work with operators of reasonably large norm, so that $\|T^*T\|_2$ is substantially greater than $\sqrt{\ln\|T^*T\|_2/\delta}$. The new objective functional reads

$$\hat{R}_\psi(T,S) + \frac{4L\ \|T^*T\|_2}{\sqrt{m}}.$$

Our second modification is to replace the factor $4L$ in the second term by an adjustable regularization parameter $\lambda > 0$. On the one hand this just absorbs the Lipschitz constant L of the function ψ (which is yet to be fixed), on the other hand it expresses the belief that $\|T^*T\|_2/\sqrt{m}$ gives the right order of the true estimation error. We will stick to this belief, even though it can be successfully argued that it is naive, because the estimation error may decay much more rapidly than $m^{-1/2}$ as shown by Bartlett et al. (2005) and several other works. There were in fact experimental indications, that in our case the decay is not much better than $m^{-1/2}$, because the same value of λ appeared to work very well for different applications with rather different values of m (see Section 6.1).

The objective functional now depends on ψ and λ and has the form

$$\Lambda_{\psi,\lambda}(T,S) = \hat{R}_\psi(T,S) + \frac{\lambda\|T^*T\|_2}{\sqrt{m}}. \tag{4}$$

We still have to fix the Lipschitz function ψ, satisfying $\psi \geq 1_{(-\infty,0]}$. We want it to be as small as possible to reduce slack, but it should be convex for practical reasons. It is easy to show that any convex function ψ with $\psi \geq 1_{(-\infty,0]}$ and Lipschitz constant L satisfies $\psi \geq h_{L^{-1}}$, where h_γ is the hinge loss with margin $\gamma > 0$, defined by

$$h_\gamma(t) = \begin{cases} 1 - t/\gamma & \text{if} \quad t \leq \gamma \\ 0 & \text{if} \quad t > \gamma \end{cases}.$$

We settle for the hinge loss, not only because it is optimal with respect to convexity, the Lipschitz condition and the lower bound constraint, but because of its simplicity. Our final objective function thus depends on the two parameters λ and γ and reads

$$\Lambda_{h_\gamma,\lambda}(T,S) = \frac{1}{m}\sum_{i=1}^{m} h_\gamma\left(r_i\left(1 - \left\|Tx_i - Tx_i'\right\|^2\right)\right) + \frac{\lambda\|T^*T\|_2}{\sqrt{m}},$$

for a sample $S = ((x_1, x_1', r_1), ..., (x_m, x_m', r_m))$ generated in m independent, identical trials of the pair oracle ρ. The proposed algorithm searches for $T \in \mathcal{L}_\infty(H)$ to minimize $\Lambda_{h_\gamma,\lambda}(T,S)$.

While the hinge loss is used in most of our experiments, there are other choices. It is inherent to the problem of similarity learning that one is led to consider an asymmetric response to similar and dissimilar examples (see, for example, the approaches of Bar-Hillel et al., 2005 and Xing et al., 2002). This is implemented by making the Lipschitz function ψ dependent on the parameter r which indicates similarity or dissimilarity. We thus consider two functions $\psi_1, \psi_{-1} : \mathbb{R} \to \mathbb{R}$, $\psi_i \geq 1_{(-\infty,0]}$ and the objective functional

$$\Lambda_{\psi_1,\psi_{-1},\lambda}(T,S) = \frac{1}{m}\sum_{i=1}^{m} \psi_{r_i}\left(r_i\left(1 - \left\|T\left(x_i - x_i'\right)\right\|^2\right)\right) + \frac{\lambda\|T^*T\|_2}{\sqrt{m}}.$$

Note that our generalization bounds remain valid for the empirical risk estimate using ψ_1 and ψ_{-1} as long as we use for L the Lipschitz constant of $\min\{\psi_1, \psi_{-1}\}$. Using $\psi_i = h_{\gamma_i}$ we are effectively considering an *inside margin* γ_1, which applies to similar pairs, and an *outside margin* γ_{-1}, which applies to dissimilar pairs.

The use of different margins, or more generally different functions ψ_i in response to similar and dissimilar examples is nonsensical from the point of view of our bounds, which would always assume a smaller value if we used $\min\{\psi_1, \psi_{-1}\}$ to begin with. These bounds however were imported from the inherently symmetric vector valued case to a situation which is inherently asymmetric, because $\langle Q_{X-X'}, T^*T\rangle_2 = \|TX - TX'\|^2 \geq 0$ for all possible solutions T. The asymmetric margins may therefore have their merit and an instance of asymmetric margins is described in Section 4.

Even with symmetric margins the response will be asymmetrical: If we use $\gamma = 1$ (as in fact we did in our experiments) every similar pair (x_i, x_i') will make a contribution to the objective function unless $Tx_i = Tx_i'$, whereas dissimilar pairs will only contribute if $\|Tx_i - Tx_i'\|^2 < 2$, which can exclude many examples of dissimilarity, in particular if the regularization parameter λ is small.

Why not use the trace-norm $\|T^*T\|_1 = \|T\|_2^2$ as a regularizer? Since $\|T^*T\|_2 \leq \|T^*T\|_1$ the trace-norm could be substituted in our bounds and the regularization part of the algorithm in Table 1 below would simplify considerably if we used $\|T\|_2^2$ instead of $\|T^*T\|_2$. Regularization with the trace-norm is also believed to enforce sparsity in the sense of a low rank of T.

The trace-norm was not used for three reasons:

1. The bounds become looser upon substitution of $\|T^*T\|_1$. While this is obvious, one could argue, that there may be other bounds which work well with $\|T^*T\|_1$. Besides, the idea of minimizing bounds has to be approached with caution, so this argument is not decisive.

2. The trace-norm does not work as well in practice. In all experiments the trace norm was tried and performance found to be slightly inferior (while still comparable) to the use of the Hilbert-Schmidt norm $\|T^*T\|_2$ (see Section 6).

3. Regularization with the trace norm can cause too much sparsity and instability of the learning algorithm. This can be seen by simplifying the empirical part of the objective to be linear in $V = T^*T$ (that this is a valid approximation is shown in Proposition 15 below). Then there is an empirical operator A (made explicit in Section 4.2) such that an objective functional can be written as
$$-\langle V, A\rangle_2 + \lambda\|T^*T\|_p^p,$$

to be minimized with positive operators V. In this case the minimizers can be given explicitly in terms of A. For $p=2$ (the Hilbert-Schmidt case) one finds that the minimizer is a multiple of the positive part A_+ of the empirical operator A (the source of the sparsity observed in our experiments), and stable under small perturbations of the eigenvalues of A. For $p=1$ however the minimizer V will be a multiple of the projection to the subspace spanned by the eigenvectors corresponding to the largest positive eigenvalue of A. This space will be generically one-dimensional, making it useless for many data-representations. If it is more than one-dimensional then it will be unstable under perturbations of the eigenvalues of A.

3.3 Minimization of the Objective Functional

Throughout this section fix a sample $S=((x_1,x_1',r_1),...,(x_m,x_m',r_m))$ and assume that $\psi:\mathbb{R}\to\mathbb{R}$ is convex, satisfying $\psi\geq 1_{(-\infty,0]}$. For $\lambda>0$ consider the functional $\Omega_{\psi,\lambda}:\mathcal{L}_2^+(H)\to\mathbb{R}$

$$\Omega_{\psi,\lambda}(A)=\frac{1}{m}\sum_{i=1}^m\psi\left(r_i\left(1-\left\langle Q_{x_i-x_i'},A\right\rangle_2\right)\right)+\frac{\lambda\|A\|_2}{\sqrt{m}}. \tag{5}$$

Comparison with (4) reveals that $\Lambda_{\psi,\lambda}(T)=\Omega_{\psi,\lambda}(T^*T)$, so that any operator T is a minimizer of $\Lambda_{\psi,\lambda}$ if and only if T^*T is a minimizer of $\Omega_{\psi,\lambda}$ in $\mathcal{L}_2^+(H)$, a simple fact which has several important consequences. Note that $\Omega_{\psi,\lambda}$ is convex if ψ is convex, and since $\mathcal{L}_2^+(H)$ is a convex set we obtain a convex optimization problem. The situation somewhat resembles that of an SVM (in particular if ψ is the hinge loss), but solutions cannot be sought in all of $\mathcal{L}_2(H)$ but must lie in the cone $\mathcal{L}_2^+(H)$, a positivity constraint which makes the optimization problem quite different.

Denote with M the linear span of $\{x_i-x_i':i=1,...,m\}$ in H and define a map from M^m to $\mathcal{L}_2^+(H)$ by

$$A_{\mathbf{v}}=\sum_{i=1}^m Q_{v_i}\text{ where }\mathbf{v}=(v_1,...,v_m)\in M^m.$$

That $A_{\mathbf{v}}\in\mathcal{L}_2^+(H)$ follows from Lemma 3. We also define a linear transformation $T_{\mathbf{v}}:H\to\mathbb{R}^m$ by setting

$$(T_{\mathbf{v}}z)_k=\langle z,v_k\rangle\text{ for }k=1,...,m\text{ and }z\in H. \tag{6}$$

Then we have $T_{\mathbf{v}}^*T_{\mathbf{v}}=A_{\mathbf{v}}$. Also note that $\mathbf{v}\leftrightarrow T_{\mathbf{v}}$ establishes a continuous bijection between M^m and the set of all linear transformations $T:H\to\mathbb{R}^m$ with $M^\perp\subseteq Ker(T)$.

Suppose we can find some $\mathbf{v}\in M^m$ such that $\Omega_{\psi,\lambda}(A_{\mathbf{v}})\leq\Omega_{\psi,\lambda}(A)$ for all $A\in\mathcal{L}_2^+(H)$. Then $\Lambda_{\psi,\lambda}(T_{\mathbf{v}})=\Omega_{\psi,\lambda}(T_{\mathbf{v}}^*T_{\mathbf{v}})=\Omega_{\psi,\lambda}(A_{\mathbf{v}})$ is also optimal, so $T_{\mathbf{v}}$ will be an optimal pre-processor and we are done. To find such an optimal $\mathbf{v}\in M^m$ we plan to do gradient descent of $\Omega_{\psi,\lambda}(A_{\mathbf{v}})$ in the parameter $\mathbf{v}$ which automatically ensures the positivity constraint and keeps us comfortable in an at most m-dimensional environment. Since $\Omega_{\psi,\lambda}(A_{\mathbf{v}})$ is not generally convex in $\mathbf{v}$, even if $\Omega_{\psi,\lambda}$ is convex, one might worry about the existence of local minima.[1] The following theorem excludes this possibility:

Theorem 14 *Assume that ψ is convex. For $\mathbf{v}\in M^m$ define $\Phi(\mathbf{v})=\Omega_{\psi,\lambda}(A_{\mathbf{v}})$. If Φ has a stable local minimum at $\mathbf{v}\in M^m$ then $A_{\mathbf{v}}$ is a global minimizer of $\Omega_{\psi,\lambda}$ in $\mathcal{L}_2^+(H)$.*

1. Recall that a real function f on a topological space $\mathcal{X}$ has a local minimum at $x\in\mathcal{X}$ if there is an open set $O\ni x$ such that $f(x)\leq f(y)\ \ \forall y\in O$

Proof Abbreviate $\Omega_{\psi,\lambda}$ to Ω and use P to denote the orthogonal projection onto M. We first claim that

$$\forall A \in \mathcal{L}_2^+(H) \text{ we have } \Omega(PAP) \leq \Omega(A). \tag{7}$$

This follows from $\left\langle Q_{x_i-x_i'}, PAP \right\rangle_2 = \left\langle Q_{x_i-x_i'}, A \right\rangle_2$ and Lemma 3 (vi) by inspection of (5). Next consider the identity

$$\{A_{\mathbf{v}} : \mathbf{v} \in M^m\} = \left\{PAP : A \in \mathcal{L}_2^+(H)\right\}. \tag{8}$$

First note that the inclusion from left to right follows from $A_{\mathbf{v}} = PA_{\mathbf{v}}P$ for $\mathbf{v} \in M^m$. On the other hand for any $A \in \mathcal{L}_2^+(H)$ all the eigenvectors of PAP with nonzero eigenvalues have to lie in M, and enumerating the eigenvectors e_i of PAP beginning with those in M (of which there can be at most m) we have

$$PAPz = \sum_{i=1}^{m} \lambda_i \langle z, e_i \rangle e_i = \sum_{i=1}^{m} \left\langle z, \lambda_i^{1/2} e_i \right\rangle \lambda_i^{1/2} e_i = \sum_{i=1}^{m} Q_{\left(\lambda_i^{1/2} e_i\right)} z = A_{\mathbf{v}} z$$

for all $z \in H$, so that $PAP \in \{A_{\mathbf{v}} : \mathbf{v} \in M^m\}$ which proves (8).

To prove the theorem let Φ attain a local minimum at $\mathbf{v} \in M^m$. We will assume that Ω does not attain a global minimum at $A_{\mathbf{v}}$ and derive a contradiction. We can write $A_{\mathbf{v}} = T_{\mathbf{v}}^* T_{\mathbf{v}}$, using (6). Since Ω is convex it cannot even attain a local minimum at $A_{\mathbf{v}}$, so there is a sequence $A_n \in \mathcal{L}_2^+(H)$ such that $A_n \to A_{\mathbf{v}}$ and $\Omega(A_n) < \Omega(A_{\mathbf{v}})$. By continuity of multiplication also $PA_nP \to PA_{\mathbf{v}}P = A_{\mathbf{v}}$, by (7) $\Omega(PA_nP) \leq \Omega(A_n) < \Omega(A_{\mathbf{v}})$ and by (8) there exists $\mathbf{v}_n \in M^m$ such that $A_{\mathbf{v}_n} = PA_nP$. We thus have $A_{\mathbf{v}_n} \to A_{\mathbf{v}}$ (this does not imply that $\mathbf{v}_n \to \mathbf{v}$!) and $\Omega(A_{\mathbf{v}_n}) < \Omega(A_{\mathbf{v}})$. By continuity of the square-root $A_{\mathbf{v}_n}^{1/2} \to A_{\mathbf{v}}^{1/2} = |T_{\mathbf{v}}|$. By polar decomposition we can write $T_{\mathbf{v}} = U|T_{\mathbf{v}}|$, where U is a partial isometry, and define $T_n : M \to \mathbb{R}^m$ by $T_n = UA_n^{1/2}$. Then $T_n \to U_{\mathbf{v}}|T_{\mathbf{v}}| = T_{\mathbf{v}}$, so if $\mathbf{w}_n$ is chosen such that $T_n = T_{\mathbf{w}_n}$ we have $\mathbf{w}_n \to \mathbf{v}$, but also $\Phi(\mathbf{w}_n) = \Omega(T_n^* T_n) = \Omega\left(A_n^{1/2} U^* U A_n^{1/2}\right) = \Omega(A_n) < \Omega(A_{\mathbf{v}}) = \Phi(\mathbf{v})$, so Φ cannot attain a local minimum at $\mathbf{v}$. ■

Observe that this result justifies the gradient descent method in the presence of positivity constraints also for other convex loss functions besides the hinge loss. Nevertheless, it does not exclude the existence of points with vanishing gradients away from the global minimum. While the probability of arriving at these points during gradient descent is vanishing, the algorithm can still be slowed down considerably in their neighborhood, a possibility which we have to be prepared for (although it doesn't seem to happen in practice). The theorem therefore only proves that the gradient descent works, but not that it is efficient.

There is an alternative technique (see Xing et al., 2002) of iterative projections which avoids the problem of vanishing gradients and stays more closely to the original convex optimization problem. Briefly, one extends the functional Ω to all of $\mathcal{L}_2(H)$, so that the problem becomes equivalent to an SVM, and then alternates between gradient descent in Ω, which is convex, and projections onto $\mathcal{L}_2^+(H)$. The projection of an operator $A \in \mathcal{L}_2(H)$ to $\mathcal{L}_2^+(H)$ is effected by an eigen-decomposition and reconstruction with all the negative eigenvalues set to zero, so that only the positive part of A is retained. This method would also work for our objective functional, in fact for any convex objective constrained to positive operators. Here this technique was not chosen, because it appeared that the effort of the repeated eigen-decomposition might cancel the advantages of the method. Also the proposed gradient descent, which is easily converted to an online algorithm, appeared more elegant

Given sample S, regularization parameter λ, margin γ, learning rate θ
set $\lambda' = \lambda/\sqrt{|S|}$ and $d = m$
randomly initialize $v = (v_1, ..., v_d)$
repeat
  Compute $\|A_v\|_2 = \left(\sum_{ij} \langle v_i, v_j \rangle^2\right)^{1/2}$
  For $i = 1, ..., d$ compute $w_i = 2\|A_v\|_2^{-1} \sum_j \langle v_i, v_j \rangle v_i$
  Fetch (x, x', r) randomly from sample S
  For $i = 1, ..., d$ compute $a_i \leftarrow \langle v_i, x - x' \rangle$
  Compute $b \leftarrow \sum_{i=1}^d a_i^2$
  If $r(1-b) < \gamma$
    then for $i := 1, ..., d$ do $v_i \leftarrow v_i - \theta\left(\frac{r}{\gamma} a_i (x - x') + \lambda' w_i\right)$
    else for $i := 1, ..., d$ do $v_i \leftarrow v_i - \theta\lambda' w_i$
until convergence

Table 1: Learning algorithm

in its implicit adherence to the positivity constraint. The ultimate reason to stay with the proposed technique was of course its practical success.

So our algorithm will randomly initialize the vector $\mathbf{v} \in M^m$ and then follow the negative gradient of Φ, either for a specified number of steps or until some heuristic convergence criterion on the value of Φ is met. Straightforward differentiation gives for the k-th component of the gradient of Φ at $\mathbf{v} \in M^m$ the expression

$$\begin{aligned}(\nabla\Phi)_k(\mathbf{v}) &= \frac{-2}{m}\sum_{i=1}^m \psi'\left(r_i\left(1 - \sum_{j=1}^m a_{ij}^2\right)\right) r_i a_{ik}\left(x_i - x_i'\right) \\ &\quad + \frac{2\lambda}{\|A_{\mathbf{v}}\|_2 \sqrt{m}} \sum_{j=1}^m \langle v_k, v_j \rangle v_j,\end{aligned}$$

where $a_{ik} = \langle x_i - x_i', v_k \rangle$ and $\|A_{\mathbf{v}}\|_2 = \left(\sum_{i,j} \langle v_i, v_j \rangle^2\right)^{1/2}$. In Table 1 we give a corresponding algorithm of stochastic gradient descent for the case that ψ is the hinge-loss with margin γ.

In a simplified view, which disregards the regularization term (or if $\lambda = 0$), the algorithm will modify T in an attempt to bring Tx_i and Tx_i' closer if x_i and x_i' are similar (i.e., $r_i = 1$) and their distance exceeds $1 - \gamma$, it will attempt to move Tx_i and Tx_i' further apart if x_i and x_i' are dissimilar (i.e., $r_i = -1$) and their distance is less than $1 + \gamma$, and it will be indifferent to all other cases. This procedure can also be interpreted in terms of the effect which the individual gradient steps have on the level ellipsoid of the quadratic form induced by T^*T. Figure 1 tries to shows the simple geometrical intuition behind this construction.

There are two heuristic approximations to accelerate this algorithm. A simple time-saver is the observation that the contribution of the regularization term to the gradient changes only very little with small updates $\mathbf{v}$. It therefore doesn't need to be recomputed on every iteration, but it suffices to compute it intermittently.

Also in the experiments reported below a singular value decomposition of the optimal operator revealed that it was dimensionally sparse, in the sense that very few (generally less than 50) singular

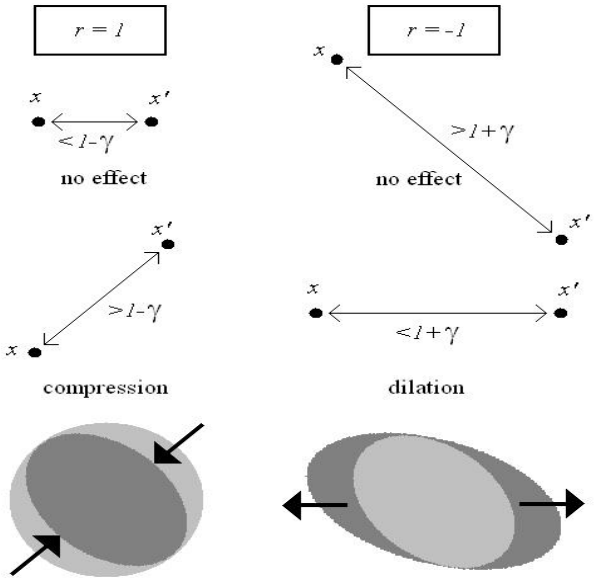

Figure 1: The effect of similar and dissimilar pairs on the level ellipsoid of the quadratic form induced by T^*T in the case of hinge loss with margin γ. If $\|Tx - Tx'\| \leq 1-\gamma$ for similar or $\|Tx - Tx'\| \geq 1+\gamma$ for dissimilar pairs there is no effect. If $\|Tx - Tx'\| < 1+\gamma$ for similar pairs, the ellipsoid is compressed in a direction parallel to the line between x and x'. If $\|Tx - Tx'\| > 1-\gamma$ for dissimilar pairs, the ellipsoid is dilated. Regularization corresponds to a shrinking of the ellipsoid.

values were significantly different from zero. This implies that $A_{\mathbf{v}}$ can be well approximated by some $A_{\mathbf{w}}$ where $\mathbf{w} \in M^d$ with $d \ll m$, and shows that the proposed algorithm effects a dimensional reduction. It also suggests that one might try gradient descent in M^d instead of M^m for $d < m$, which causes a considerable acceleration if $d \approx 10^2$ and $m \geq 10^3$. Of course the argument in Theorem 14 is then no longer valid, because finite dimensional constraints are not convex, so that local minima might become a problem. In practice this never happened for $d \approx 10^2$ and was observed only for $d \leq 5$. The heuristic is implemented by accordingly modifying the initialization $d = m$ in Table 1. In our experiments we used $d = 100$.

There is a simple practical use to an eigen-decomposition of the optimal $A_{\mathbf{v}}$ returned by the algorithm. The v_i will in general not be orthogonal, the algorithm does not enforce this in any way). If the decomposition reveals that only few eigenvalues of $A_{\mathbf{v}}$ are significantly different from zero, we can restrict ourselves to the span of the corresponding eigenvalues. This yields a representation operator T with very low dimensional range, which is easier to compute and facilitates subsequent processing.

By virtue of our dimension free bounds the algorithm is well suited for kernel implementations. Note that the search space consists of vectors $\mathbf{v} = (v_1, ..., v_d) \in M^d$ which admit a linear representation

$$v_i = \sum_{j=1}^{m} \alpha_j^i \left(x_j - x_j'\right)$$

in terms of the training sample. To add two such $\mathbf{v}$ we just add the corresponding matrices α_j^i, to compute inner products we just use the kernel function on the input space. Substituting these rules one finds that there is no problem in kernelization of the algorithm.

4. Similarity Regression and Hyperbolic PCA

In this section we consider some alternatives. The first is rather obvious and extends the method described above to continuous similarity values. The other method is derived from the risk functional R and has already been described in Maurer (2006a).

4.1 Similarity Regression

The bounds in Section 3.1 have straightforward extensions to the case, when the oracle measure is not supported on $\mathcal{X}^2 \times \{-1,1\}$ but on $\mathcal{X}^2 \times [0,1]$, corresponding to a continuum of similarity values, and $\ell : [0,1] \times \mathbb{R} \to \mathbb{R}$ is a loss function such that $\ell(y,.)$ has Lipschitz constant at most L for all $y \in [0,1]$. The corresponding risk functional to be minimized would be

$$R'(T) = \mathbb{E}_{(x,x',r)\sim\rho}\left[\ell\left(r, \left\|Tx - Tx'\right\|^2\right)\right].$$

If ℓ has the appropriate convexity properties, then an obvious modification of the proposed algorithm can be used. With a least-squares loss function the square of the norm (an unavoidable feature of our method) will lead to an overemphasis of large distances, probably an undesirable feature which can be partially compensated by a redefinition of the loss function at the expense of a large Lipschitz constant (e.g., with $\ell(y,t) = (y-t)^2/(y-y_0)^2$ for some $y_0 > 0$).

The possibilities of this type of similarity regression (or learning of metrics) remain to be explored.

4.2 Risk Bounds with Affine Loss Functions and Hyperbolic PCA

Consider again the case of a binary oracle (similar/dissimilar) and the task of selecting an operator from some set $\mathcal{V} \subset \mathcal{L}_2(H)$.

Proposition 15 *Suppose* $1 < \left\|\mathcal{V}\right\|_\infty = c < \infty$ *and set* $\eta_1 = -1$ *and* $\eta_{-1} = 1/\left(c^2-1\right)$. *Then for all* $T \in \mathcal{V}$

$$R(T) \leq 1 + \mathbb{E}_{(x,x',r)\sim\rho}\left[\eta_r\right] - \left\langle T^*T, \mathbb{E}_{(x,x',r)\sim\rho}\left[\eta_r Q_{x-x'}\right]\right\rangle_2.$$

For a balanced oracle this becomes

$$R(T) \leq \frac{c^2}{2\left(c^2-1\right)} - \left\langle T^*T, \mathbb{E}_{(x,x',r)\sim\rho}\left[\eta_r Q_{x-x'}\right]\right\rangle_2.$$

Proof Define real functions ψ_1, ψ_{-1} by $\psi_1(t) = 1-t$ and $\psi_{-1}(t) = 1 - t/\left(c^2-1\right)$. Since $\|x-x'\| \leq 1$ a.s. and by the definition of c we have for $T \in \mathcal{V}$

$$1_{(-\infty,0]}\left(r\left(1 - \left\|TX - TX'\right\|^2\right)\right) \leq \psi_r\left(r\left(1 - \left\|TX - TX'\right\|^2\right)\right) \text{ a.s.}$$

We also have for $r \in \{-1,1\}$ that $\psi_r(t) = 1 + r\eta_r t$, whence

$$\begin{aligned} R(T) &= \mathbb{E}_{(x,x',r)\sim\rho}\left[1_{(-\infty,0]}\left(r\left(1-\left\|TX-TX'\right\|^2\right)\right)\right] \\ &\leq \mathbb{E}_{(x,x',r)\sim\rho}\left[\psi_r\left(r\left(1-\left\|TX-TX'\right\|^2\right)\right)\right] \\ &= \mathbb{E}_{(x,x',r)\sim\rho}\left[1+\eta_r\left(1-\left\|TX-TX'\right\|^2\right)\right] \\ &= 1+\mathbb{E}_{(x,x',r)\sim\rho}\left[\eta_r\right] - \left\langle T^*T, \mathbb{E}_{(x,x',r)\sim\rho}\left[\eta_r Q_{x-x'}\right]\right\rangle_2. \end{aligned}$$

Since for a balanced oracle $1+\mathbb{E}_{(x,x',r)\sim\rho}[\eta_r] = c^2/\left(2\left(c^2-1\right)\right)$, the second conclusion is immediate. ■

Of course we can use the risk bounds of the previous section for an empirical estimator constructed from the Lipschitz functions ψ_1, ψ_{-1} used in the proof above, corresponding to an inner margin of 1 and an outer margin of c^2-1 (see Section 3.1 and 3.2). The affine nature of these functions however allows a different, more direct analysis and a different algorithmic implementation.

The operator

$$A := \mathbb{E}_{(x,x',r)\sim\rho}\left[\eta_r Q_{x-x'}\right]$$

is the expectation of the operator-valued random variable $(x,x',r) \mapsto \eta_r Q_{x-x'}$. Minimizing the bounds in Proposition 15 is equivalent to maximizing $\langle T^*T, A\rangle_2$, which is the only term depending on the operator T. Given the sample $S = ((x_1,x_1',r_1),\ldots,(x_m,x_m',r_m))$ the obvious way to try this is by maximizing the empirical counterpart $\left\langle T^*T, \hat{A}\right\rangle_2$ where $\hat{A}$ is the *empirical operator*

$$\hat{A}(S) = \frac{1}{m}\sum_{i=1}^{m} \eta_{r_i} Q_{x_i - x_i'}. \tag{9}$$

The next result addresses the issue of estimation. The result is similar to Theorem 13 but can be obtained without the use of Rademacher averages.

Theorem 16 *Under the above assumptions and if $c \geq 2$ we have for $\delta > 0$ with probability greater $1-\delta$ in the sample S that for all $T \in \mathcal{V}$*

$$\left|\left\langle T^*T, \hat{A}\right\rangle_2 - \langle T^*T, A\rangle_2\right| \leq \frac{2}{\sqrt{m}}\left(\sup_{T\in\mathcal{V}} \|T^*T\|_2 + c^2\sqrt{2\ln(1/\delta)}\right).$$

Proof Apply Lemma 9 to the $\mathcal{L}_2(H)$-valued random variable $\eta_r Q_{x-x'} - \mathbb{E}[\eta_r Q_{x-x'}]$. The corresponding substitutions give

$$\Pr\left\{\left|\left\langle T^*T, \hat{A}\right\rangle_2 - \langle T^*T, A\rangle_2\right| > \varepsilon\right\} \leq \exp\left(\frac{-\left(\sqrt{m}\varepsilon - 2\sup_{T\in\mathcal{V}}\|T^*T\|_2\right)^2}{8c^4}\right),$$

and the result follows from equating the right side to δ. ■

Of course an analogous result could have been obtained from Theorem 11.

We now specialize the space of candidate operators to $\mathcal{V} = c\mathcal{P}_d$ where $\mathcal{P}_d$ is the set of d-dimensional orthogonal projections. Then $\sup_{T\in\mathcal{V}} \|T^*T\|_2 = c^2\sqrt{d}$ in the bound above. The optimization problem now is to maximize $\left\langle P,\hat{A}\right\rangle_2$ for $P \in \mathcal{P}_d$ which is done by projecting onto a maximal eigenspace of $\hat{A}$, as shown by the following proposition.

Proposition 17 *Suppose $A \in \mathcal{L}_2(H)$ is symmetric with eigenvectors e_i and corresponding eigenvalues λ_i. Suppose that $d \in \mathbb{N}$ and that the sum in the eigen-expansion of A can be ordered in such a manner that $\lambda_i \geq \lambda_j$ for all $i \leq d < j$. Then*

$$\max_{P\in\mathcal{P}_d} \langle A,P\rangle_2 = \sum_{i=1}^{d} \lambda_i,$$

the maximum being attained by the projection onto the span of $(e_i)_{i=1}^d$.

Proof let $P \in \mathcal{P}_d$ with $v_1,...,v_d$ being an orthonormal basis for the range of P. Then

$$\begin{aligned}
\langle A,P\rangle_2 &= \sum_{j=1}^{d}\sum_{i=1}^{d} \lambda_i \left\langle v_j,e_i\right\rangle^2 + \sum_{j=1}^{d}\sum_{i=d+1}^{\infty} \lambda_i \left\langle v_j,e_i\right\rangle^2 \\
&\leq \sum_{i=1}^{d}\lambda_i \sum_{j=1}^{d} \left\langle v_j,e_i\right\rangle^2 + \lambda_d \sum_{j=1}^{d}\left(\sum_{i=d+1}^{\infty} \left\langle v_j,e_i\right\rangle^2\right) \\
&= \sum_{i=1}^{d}\lambda_i \sum_{j=1}^{d} \left\langle v_j,e_i\right\rangle^2 + \lambda_d \sum_{i=1}^{d}\left(1-\sum_{j=1}^{d} \left\langle v_j,e_i\right\rangle^2\right) \\
&\leq \sum_{i=1}^{d}\lambda_i \sum_{j=1}^{d} \left\langle v_j,e_i\right\rangle^2 + \sum_{i=1}^{d}\lambda_i\left(1-\sum_{j=1}^{d} \left\langle v_j,e_i\right\rangle^2\right) = \sum_{i=1}^{d}\lambda_i,
\end{aligned}$$

which proves $\sup_{P\in\mathcal{P}_d} \langle A,P\rangle_2 \leq \sum_{i=1}^{d}\lambda_i$ (this also follows directly from Horn's theorem; Simon, 1979, Theorem 1.15). If P is the projection onto the span of $(e_i)_{i=1}^d$ we can set $v_j = e_j$ above and obtain an equality. ■

This gives an alternative algorithm to the one described in Section 3: Fix a quantity $c > 2$ and construct a matrix representation of the empirical operator $\hat{A}$ given in (9). For some fixed target-dimension d find the projection onto a d-dimensional dominant eigenspace of $\hat{A}$. We omit the rather straightforward technical details concerning to the representation of $\hat{A}$ and the implementation of a kernel. Some of these issues are discussed in Maurer (2006a) where corresponding experiments are reported.

There is an intuitive interpretation to this algorithm, which could be called hyperbolic PCA: The empirical objective functional is proportional to

$$\begin{aligned}
m\left\langle P,\hat{A}\right\rangle_2 &= \sum_{i=1}^{m} \eta_{r_i} \left\|Px_i - Px_i'\right\|^2 \\
&= \frac{1}{c^2-1}\sum_{i:x_i,x_i' \text{ dissimilar}} \left\|Px_i - Px_i'\right\|^2 - \sum_{i:x_i,x_i' \text{ similar}} \left\|Px_i - Px_i'\right\|^2.
\end{aligned}$$

When similarity and dissimilarity are defined by class memberships, then maximizing this expression corresponds to maximizing inter-class- and minimizing intra-class variance, where the parameters $1/\left(c^2-1\right)$ and the proportions of similar and dissimilar pairs control the trade-off between these potentially conflicting goals. A similar proposal can be found in Thrun (1998). Typically we have $c \gg 1$ so that $1/\left(c^2-1\right) \ll 1$, so that dissimilar pairs ('negative equivalence constraints') receive a much smaller weight than similar pairs, corresponding to the intuitive counting argument given ba Bar-Hillel et al. (2005).

The method is similar to principal component analysis insofar as it projects to a principal eigenspace of a symmetric operator. In contrast to PCA, where the operator in question is the empirical covariance operator, which is always nonnegative, we will project to an eigenspace of an empirical operator which is a linear combination of empirical covariances and generally not positive. While the quadratic form associated with the covariance has elliptic level sets, the empirical operator induces hyperbolic level sets.

5. Applications to Multi-category Problems and Learning to Learn

In this section we apply similarity learning to problems where the nature of the application task is partially or completely unknown, so that the available data is used for a preparatory learning process, to facilitate future learning.

5.1 Classification Problems Involving a Large Number of Categories

A multi-category task τ with input space $\mathcal{X}$ is a pair $\tau = (\mathcal{Y}, \mu)$ where $\mathcal{Y}$ is a finite or countable alphabet of labels and μ a probability measure on $\mathcal{X} \times \mathcal{Y}$. We interpret $\mu(x,y)$ as the probability to encounter the pattern x with label y. As usual we assume $\mathcal{X}$ to be embedded in the Hilbert space H.

Let $\tau = (\mathcal{Y}, \mu)$ be such a task, $T \in \mathcal{L}_0(H)$ and suppose that we are given a *single* labeled example $(x,y) \in \mathcal{X} \times \mathcal{Y}$. Any classifier trained on this example alone and applied to another pattern $x' \in \mathcal{X}$ can sensibly only make the decisions "x' *is of type* y" or "x' *is not of type* y" or no decision at all. Face verification is a case where such classifiers can be quite important in practice: Anyone having to verify the identity of a person on the basis of a single photograph has to learn and generalize on the basis of a single example image. A simple classifier using only the pseudo-metric induced by T is the *elementary verifier* $\varepsilon_T(x,y)$ which decides

$$\begin{array}{cc} x' \textit{ is of type } y & \text{if} \quad \|T(x-x')\| < 1 \\ \textit{undecided} & \text{if} \quad \|T(x-x')\| = 1 \\ x' \textit{ is not of type } y & \text{if} \quad \|T(x-x')\| > 1 \end{array} .$$

Relative to the task $\tau = (\mathcal{Y}, \mu)$ it has the error probability (counting 'undecided' as an error)

$$\mathrm{err}_\tau(\varepsilon_T(x,y)) = \Pr_{(x',y') \sim \mu} \left\{ r\left(y,y'\right)\left(1 - \left\|T\left(x-x'\right)\right\|\right) \leq 0 \right\},$$

where the function $r : \mathcal{Y} \times \mathcal{Y} \to \{-1,1\}$ quantifies equality and inequality: $r(y,y') = 1$ if $y = y'$ and $r(y,y') = -1$ if $y \neq y'$.

There is a canonical pair oracle derived from the task τ. It is the probability measure ρ_τ on $\mathcal{X}^2 \times \{-1,1\}$ given by

$$\rho_\tau(A) = \Pr_{((x,y),(x',y')) \sim \mu^2} \left\{ \left(x, x', r\left(y,y'\right)\right) \in A \right\} \text{ for } A \subseteq \mathcal{X}^2 \times \{-1,1\}. \tag{10}$$

To generate a draw (x,x',r) from ρ_τ make two independent draws of (x,y) and (x',y') from μ and then return $(x,x',1)$ if $y=y'$ and $(x,x',-1)$ if $y\neq y'$. Then

$$\mathbb{E}_{(x,y)\sim\mu}\left[\mathrm{err}_\tau\left(\varepsilon_T\left(x,y\right)\right)\right]=R_{\rho_\tau}\left(T\right), \tag{11}$$

so we can use the risk bounds in Sections 3.1 or 4.2 to bound the expected error of the elementary verifier $\varepsilon_T\left(x,y\right)$ under a random draw of the training example (x,y).

If there are many labels appearing approximately equally likely, then dissimilar pairs will be sampled much more frequently than similar ones, resulting in a negative bias of elementary classifiers. Similar unwanted effects have been noted by Xing et al. (2002) and Bar-Hillel et al. (2005). This does not mean that our bounds are paradoxical, because the biased sampling corresponds to an equally biased error measure: Under these circumstances the non-verifier which always asserts "x' *is not of type* y" would already have a small error.

This problem can be avoided by a simple balancing technique: In the computation of the error of the elementary classifier $\varepsilon_d\left(x,y\right)$ we assign different weights to the cases of false rejection and false acceptance. Define a balanced error

$$\begin{aligned}\overline{\mathrm{err}}_\tau\left(\varepsilon_d\left(x,y\right)\right) &= \frac{1}{2C_1}\Pr_{(x',y')\sim\mu}\left\{\left\|T\left(x-x'\right)\right\|\geq 1 \text{ and } y'=y\right\}\\ &\quad+\frac{1}{2C_{-1}}\Pr_{(x',y')\sim\mu}\left\{\left\|T\left(x-x'\right)\right\|\leq 1 \text{ and } y'\neq y\right\},\end{aligned}$$

where $C_1=\mu^2\left\{\left(\left(x,y\right),\left(x',y'\right)\right):y'=y\right\}$ and $C_{-1}=\mu^2\left\{\left(\left(x,y\right),\left(x',y'\right)\right):y'=y\right\}$ are the probabilities to obtain examples with equal and unequal labels respectively in two independent draws of μ. If we define a balanced pair oracle $\overline{\rho}$ by

$$\overline{\rho}_\tau\left(A\right)=\frac{\rho_\tau\left(A\cap\mathcal{X}^2\times\{1\}\right)}{2\rho_\tau\left(\mathcal{X}^2\times\{1\}\right)}+\frac{\rho_\tau\left(A\cap\mathcal{X}^2\times\{-1\}\right)}{2\rho_\tau\left(\mathcal{X}^2\times\{-1\}\right)},$$

where ρ_τ is defined in (10) then one again verifies that

$$\mathbb{E}_{(x,y)\sim\mu}\left[\overline{\mathrm{err}}_\tau\left(\varepsilon_d\left(x,y\right)\right)\right]=R_{\overline{\rho}_\tau}\left(T\right) \tag{12}$$

and that $\overline{\rho}_\tau$ returns similar and dissimilar pairs with equal probability. To generate a draw of (x,x',r) from $\overline{\rho}_\tau$ first draw (x,y) from μ and then flip a fair coin. On heads draw x' from the class conditional distribution of y and return $(x,x',1)$, on tails draw x' from the conditional distribution for $\mathcal{Y}\setminus\{y\}$ (or continue to draw $(x',y')\sim\mu$ until $y'\neq y$) and return $(x,x',-1)$.

Whichever of the two oracles we use: If we make m independent draws from it to obtain a sample $S=\left(\left(x_1,x_1',r_1\right),\ldots,\left(x_m,x_m',r_m\right)\right)$ from which we generate the operator T according to the algorithm derived in Section 3, then we are essentially minimizing a bound on the expected error of elementary verifiers trained on future examples. In this way the proposed algorithm can be considered an algorithm of learning to learn.

This is particularly interesting if $m<|\mathcal{Y}|$, because we obtain performance guarantees for categories which we haven't seen before. Consider for example the case where $\mathcal{Y}$ stands for a large population of human individuals, and the inputs correspond to facial images. From a sample $S=\left(\left(x_1,x_1',r_1\right),\ldots,\left(x_m,x_m',r_m\right)\right)$ we train an operator T and then use the elementary verifiers ε_T for face-verification on the entire population. With methods similar to the balancing technique described above the oracle can be also modified to achieve different desired penalties for false rejection and false acceptance.

5.2 Similarity as a Vehicle for Transfer

The face-verification system proposed above is somewhat naive from an economical point of view, because the example-pairs have to be obtained independently, which means that we will need images of approximately $3m/2$ individuals (with balancing), all of which will probably have to be paid to cooperate. It would be preferable to collect the data independently but conditional to a smaller subpopulation $\mathcal{Y}' \subset \mathcal{Y}$ with $|\mathcal{Y}'| < m$, so that multiple images can be gathered from each individual. This effectively replaces the original task $\tau = (\mathcal{Y}, \mu)$ with a subtask $\tau' = (\mathcal{Y}', \mu')$, where

$$\mu'(A) = \frac{\mu(A)}{\mu(\mathcal{X} \times \mathcal{Y}')} \text{ for } A \subseteq \mathcal{X} \times \mathcal{Y}'.$$

Of course events which are independent w.r.t. μ are not independent w.r.t. μ' and vice versa, so if we sample independently from μ' our generalization guarantees will only work for the task τ'. The operator T generated from the sample drawn from μ' may nonetheless work for the original task τ corresponding to the entire population.

This points to a different method to apply the proposed algorithm: Use one task $\tau = (\mathcal{Y}, \mu)$, the training task, to draw the training sample and train the representation T, and apply T to the data of the application task $\tau' = (\mathcal{Y}', \mu')$.

As the application task is unknown at the time of training T, this transfer mechanism may of course fail. Deciding between success or failure however does not have the sample complexity of learning, which is affected by a complexity penalty of the function class, but only the sample complexity of validation, which can be determined from Hoeffdings inequality. If T has been trained from τ and is subsequently tested on $\tau' = (\mathcal{Y}', \mu')$ then with probability greater $1 - \delta$ in an i.i.d. sample S' of size m drawn from μ' we have

$$R_{\rho_{\tau'}}(T) \leq \hat{R}_{1_{(-\infty,0]}}(T, S') + \sqrt{\frac{\ln(1/\delta)}{2m}},$$

which is of course much better than the bounds in Theorem 11 (here $\hat{R}_{1_{(-\infty,0]}}(T, S')$ is the empirical risk of T on S').

Of course this type of transfer can be attempted between any two binary classification tasks, but its success normally requires a similarity of the pattern classes themselves. A classifier trained to distinguish images of the characters "a" and "b" will be successfully applied to two classes of images if these pattern classes have some resemblance of "a" and "b". A representation of similarity however can be successfully transferred if there is a similar notion of similarity applicable to both problems. It is this higher conceptual level of similarity concepts that allows them to transcend task-boundaries. This kind of 'meta-similarity" is for example present, when there is a common process of data generation, as is the case when the tasks share an invariance property.

Suppose now that the learner has trained operators $T_1, ..., T_K$ from the samples $S_1, ..., S_K$ gathered in past experience, with each S_k drawn iid from a corresponding multi-category task τ_k, and that the learner is currently confronted with a new task τ', for which a new sample S' is available. A simple union bound yields from Hoeffdings inequality the following standard result: $\forall \delta > 0$ with probability greater $1 - \delta$ in S' we have that for every $k \in \{1, ..., K\}$

$$R_{\rho_{\tau'}}(T_k) \leq \hat{R}_{1_{(-\infty,0]}}(T_k, S') + \sqrt{\frac{\ln K + \ln(1/\delta)}{2m}}.$$

Let us assume that K is not too large. Minimizing $\hat{R}_{1_{(-\infty,0]}}(T_k, S')$ over k is a simple algorithm which does two things:

1. It finds the operator T_{k^*} which optimally represents the data of τ' for the purpose of recognition on the basis of single training examples.

2. It classifies the new task τ into one of the K meta-categories defined by the old tasks $\tau_1, ..., \tau_K$. The classification is essentially carried out on the basis of compatibility of underlying notions of similarity.

The more obvious practical aspect is the first, because T_{k^*} can be put to use right away. There are however interesting strategies for "life long learning" (Thrun, 1998) where the mechanism of task classification is also useful. If the optimal empirical risk $\hat{R}_{1_{(-\infty,0]}}(T_k, S')$ is too large one could use S' to train T' which is appended to $(T_1, ..., T_K)$ to reflect the fact that a new type of task has been discovered. If $\hat{R}_{1_{(-\infty,0]}}(T_k, S')$ is small on the other hand, one could merge the data S' of the new task with the data S_{k^*} of the most closely matching task and retrain on $S' \cup S_{k^*}$ to obtain an operator T'' to replace T_{k^*} for better generalization due to the larger sample size, and keep the number K constant.

In this context it should be noted, that "multi-task learning", the idea of pooling the data from various tasks to achieve a smaller estimation error (see Caruana 1998; Baxter, 2000; Evgeniou et al., 2004; Maurer 2006b), is easily implemented in the case of similarity learning by just concatenating the samples $S_1 \cup ... \cup S_K$ and training. The concatenated sample corresponds to a draw from the mixed pair oracle $\rho = \sum c_k \rho_k$ with $c_k = |S_k| / \sum_i |S_i|$.

The proposed method has been derived from the objective of minimizing the risk functional R which is connected to classification through the identities (11) and (12). It is therefore a principled technique to train representations for future learning on the basis of a *single example*. While the representation T can be used to preprocess data for other algorithms operating on larger future training examples, there is reason to believe that it will be no longer optimal if there are more examples. It is a challenging problem to define risk functionals giving optimality for algorithms operating on other future sample sizes. While the algorithm proposed in Argyriou et al. (2006) appears to have such properties, corresponding risk bounds are lacking and the relationship to the current work remains to be explored.

6. Experiments

All the experiments reported concern transfer in machine vision where a representation trained on one task is applied to another one. The experiments involved the recognition of randomly rotated-, randomly scaled-, randomly rotated and scaled-, and handwritten characters, spatially rotated objects and face recognition. Below we briefly describe the parametrization of the training algorithm, the various tasks tried and the parameters recorded in testing. An executable to reproduce most of the experiments will be made available at the web-site www.andreas-maurer.eu.

6.1 Parametrization and Experimental Setup

All the experiments with character recognition used gray-scale images of 28×28 pixels, corresponding to 784-dimensional vectors. The images of the COIL100 database had 64×64, the images of the ATT face database had 92×112 pixels. Pixel vectors were normalized to unity, otherwise

there was no preprocessing. The embedding in the Hilbert space H was effected by the Gaussian RBF-kernel

$$\langle x,y\rangle = \kappa(x,y) = (1/2)\exp\left(-4\left|\frac{x}{|x|}-\frac{y}{|y|}\right|^2\right),$$

where x and y are two images, $|.|$ is the euclidean norm on pixel vectors and $\langle .,.\rangle$ is the inner product of the embedded vectors in the RKHS H (see, for example, Christianini and Shawe-Taylor, 2000, for kernel techniques).

For all tasks involved in the experiments corresponding data-sets were generated and processed in this kernel-representation.

In every transfer experiment there was a training task and an application- or test task, represented by corresponding labeled data-sets. On the data-set of the training task the algorithm given in Table 1 was used, together with the accelerating heuristics in Section 3.3, to generate a representation T. All the experiments reported below were carried out with margin $\gamma = 1$ and the regularization parameter either $\lambda = 0.005$ (for the Hilbert-Schmidt norm $\|T^*T\|_2$) or $\lambda = 0.001$ (for $\|T^*T\|_1 = \|T\|_2^2$). These values were determined by cross validation for problem of handwritten character recognition below and reused in all the other experiments. Separately optimizing parameters for each experiment using cross validation would only lead to an improvement of the results.

The gradient descent was carried out for 10^6 steps with a constant learning rate $\theta = 0.01$. For the training task we report the final values of the objective function Λ and the empirical risk $\hat{R}(T) = \hat{R}_{1_{(-\infty,0]}}(T)$. Another interesting property of T is its 'essential rank' as the number of singular values appreciably larger than 0. In the results below this is referred to as 'sparsity' and given as the number of singular values larger than 2% of the spectral norm.

The representation T is applied to the data-set of the application task, with pixel vectors equi-dimensional to those in the training data-set. Application and training data-sets had no overlapping categories.

On the application task we measured three properties related to the quality of the representation:

1. The empirical risk $\hat{R}(T) = \hat{R}_{1_{(-\infty,0]}}(T)$ as an estimator for the true risk $R(T)$. This relates to the theory above and to the performance of elementary verifiers.

2. The area under the ROC-curve (ROC area T) for the distance as a detector of class-equality. This can be regarded as an estimator for the probability that a pattern pair with equal labels is represented at a closer distance than an independently chosen pair with different labels.

3. The error (error T) of nearest neighbor classifiers when each category of the application task is represented by a *single* example, averaged over 100 runs with randomly chosen examples.

Both of the latter two quantities were also measured for the unrepresented but normalized input pixel vectors (ROC area input, error input). The values obtained using the trace-norm regularization are given in parentheses.

It has been pointed out by a referee that the theory is not exactly applicable to the experiments, because training sets and the test sets are not chosen iid from the same distribution. The experiments were carried out in the present form to illustrate the utility of similarity for transfer. Separating the same data-sets into sets of training- and test pairs would certainly have produced even better results.

6.2 Training and Application Tasks

In some of the transfer experiments the training and application tasks shared a definitive class of invariants, so that similarity of two pattern corresponds the existence of a transformation in the class of invariants, which (roughly) maps one pattern to the other.

Rotation invariant character recognition. Randomly rotated images of printed alpha characters were used for the training set and randomly rotated images of printed digits were used for the test set, the digit 9 being omitted for obvious reasons.

Scale invariant character recognition. Randomly scaled images of printed alpha characters for the training, randomly scaled images of printed digits were used for the test set. Scaling ranged over a factor of 2.

Rotation and scale invariant character recognition. Randomly rotated and scaled characters for training, randomly rotated and scaled images of printed digits were used for the test set, the digit 9 being omitted for obvious reasons. Scaling ranged over a factor of 2, the digit 9 is omitted in the test set.

Spatially rotation invariant object recognition. The COIL100 database contains images of objects rotated about an axis at an angle 60° to the optical axis. Here the invariance transformations which relate similar patterns cannot be explicitly computed from the images. The first 80 objects of the database were taken for training, the remaining 20 for testing.

In the remaining experiments the underlying notion of similarity cannot be explicitly specified and corresponds to a Gestalt-property of the domain in question.

Handwritten character recognition. The images of handwritten alpha characters from the NIST database were used for training, the handwritten digits from the MNIST database for testing.

Face recognition. The first 35 images of the ATT database for training, the last 5 for testing. Unfortunately the ATT database is at the same time very small and very clean and easy, so that the results are not very conclusive. Attempts to obtain the potentially more interesting Purdue database failed.

The images for the first three experiments are available on the web-site www.andreas-maurer.eu, the others are publicly available.

6.3 Results for Transfer

The results are summarized in Tables 2 and 3. The various row headings will be explained in the sequel.

In all experiments the representation T brings an improvement in recognition rates. This improvement is moderate (54% error downto 33% in the case of handwritten characters) to spectacular (72% downto $< 1\%$ for plane rotations). The results on the COIL and ATT databases slightly improve on the corresponding results in Fleuret and Blanchard, (2005) and Chopra et al. (2005), but the margin is so small, that this may well be a statistical artifact. What is more remarkable is that our results are at all comparable, because our method makes no assumption on the specific properties of image data, such as high correlations for neighboring pixels: In contrast to the approaches described in Chopra et al. (2005) and Fleuret and Blanchard (2005), our method would yield the same results if the images were subjected to any fixed but unknown permutation of pixel indices.

6.4 One Experiment in Detail

To illustrate these experiments and results we will consider the example of combined rotation and scale-invariance, corresponding to the last column in Table 2. Figure 2 shows some typical training examples, of which there are 200 representing each of the 20 categories, making a total number of 4000.

The oracle presents the learner with pairs of these images together with a similarity value $r \in \{-1,1\}$. Similar pairs are chosen from the same category (the same column in Fig. 2) dis-

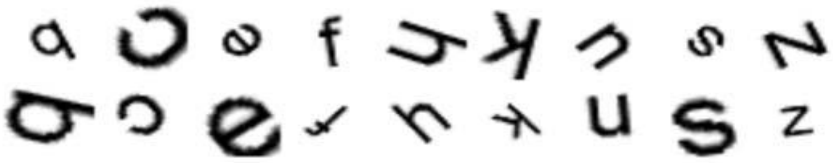

Figure 2: Randomly rotated and scaled alpha-characters

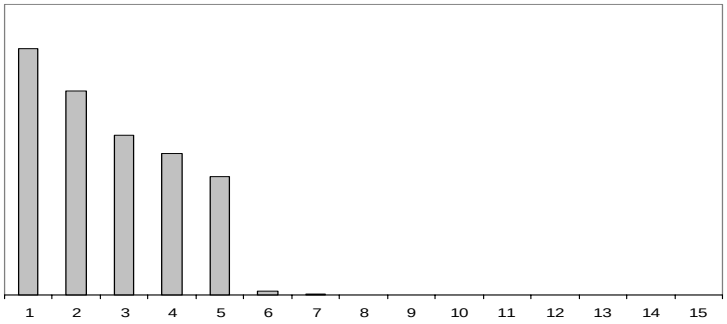

Figure 3: The 15 largest eigenvalues of T^*T in proportion

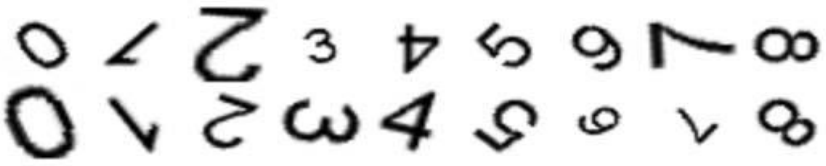

Figure 4: Randomly rotated and scaled digits

similar ones from different categories (different columns). The pairs are chosen at random under the constraint that similar pairs appear with equal frequency as dissimilar ones. These pairs are fed as input to the stochastic gradient descent algorithm in Table 1. While there are $O\left(10^6\right)$ pairs potentially generated, only about 2000 of these can be statistically independent in terms of the generation of the original sample.

The spectrum of T^*T (Fig. 3) of the resulting operator T shows a marked decrease of singular values, allowing the conclusion that the data characterizing rotation and scale invariant character categories in the chosen Gaussian kernel representation is essentially only 5-dimensional. This observed sparsity is not a consequence of the regularization with the Hilbert-Schmidt norm, because an increase in the regularization parameter λ increases the essential rank of T (a different behavior would be expected with a 1-norm regularizer), but an intrinsic property of the data which the algorithm discovers.

The representation T is then applied to the recognition of digits. Fig. 4 exemplifies the test data.

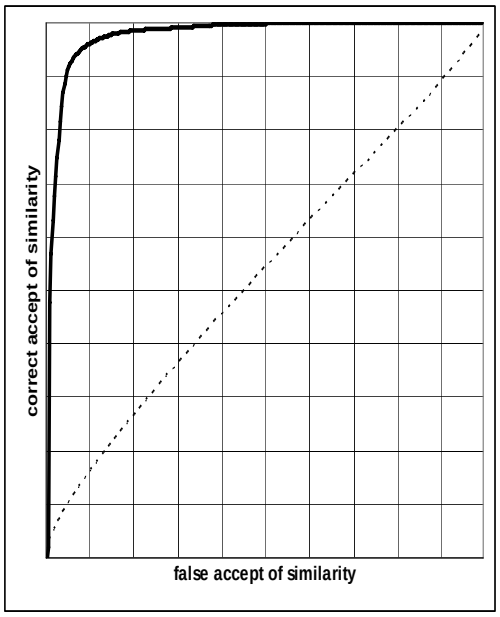

Figure 5: ROC curve for the metric as a feature for similarity. Transformed data solid, input data dotted.

To measure the empirical risk $\hat{R}(T) = \hat{R}_{1_{(-\infty,0]}}(T)$ we generate a random sequence of pairs as we did with the training task above and average the relative rates of dissimilar pairs with $\|Tx - Tx'\|_H \leq 1$ and the rate of similar pairs with $\|Tx - Tx'\|_H \geq 1$. Here the subscript H refers to the distance in the RKHS. This gives the entry 0.128 in the row labeled by 'Risk T', so the representation T organizes the data of rotation and scale invariant character categories into balls of diameter 1, up to an error of about 13%.

To parametrize a potential verification system an ROC curve for the utility of the metric as a feature for class equality is useful. Fig 5 shows these curves dotted for the metric $\|x - x'\|_{28\times 28}$ (where the distance is measured on the raw normalized pixel vectors in $\mathbb{R}^{28\times 28}$) in red and solid for $\|Tx - Tx'\|_H$. The areas under these curves correspond to the rows labeled 'ROC area input' and 'ROC area T' respectively. The values in parentheses correspond to regularization with $\|T\|_2^2$, which givel slightly inferior results.

Finally we measure the performance of a single-nearest neighbor classifier. A prototype is selected randomly from each category. The images in either one of the rows in Fig. 4 could represent such a 'training sample'. We then measure the performance of the corresponding 1-NN classifier on the test set with the training data omitted. The error rates are averaged over 100 random selections of the prototype set. These computations are carried out (with equal prototypes) for the metric $\|x - x'\|_{28\times 28}$ and the metric $\|Tx - Tx'\|_H$ and give the entries in the rows 'error input' and 'error T' respectively. Again the values in parentheses correspond to regularization with $\|T\|_2^2$.

6.5 Classification of Tasks

We report some simple results concerning the recognition of task-families on the basis of the similarity of underlying similarity concepts, as proposed in Section 5.2. In Table 4 we consider task-

families with 28×28 pixel data. These families share the properties of rotation invariance, scale invariance, combined rotation and scale invariance and the property of being handwritten respectively. The columns correspond to alpha-characters used to train representation, the rows to digits used for testing. Each entry is the empirical risk $\hat{R}(T)$ of the operator T trained from the alpha-task heading the column, measured on the digit-task heading the row. The minimum in each row occurs

	rotation	scaling	rot.+scaling	handwritten
rotation	0.055	0.38	0.089	0.374
scaling	0.36	0.061	0.11	0.304
rot.+scaling	0.375	0.39	0.128	0.434
handwritten	0.4	0.336	0.35	0.18

Table 4:

on the diagonal, which shows that the underlying similarity property or invariance of a data-set is reliably recognized. The margin of this minimum is weakened only for separate rotation and scale invariances, because the representation for combined rotation and scale invariance also performs reasonably well on these data-sets, although not as well as the specialized representations. Scale invariant representations perform better on handwritten data than rotation invariant ones, probably because scale invariance is more related to the latent invariance properties of handwritten characters than full rotation invariance.

Given the nature of the algorithm, these results are perhaps not surprising, but they seem to point in interesting new directions for the design of more autonomous systems of pattern recognition.

7. Related Work

A lot of work has been done to develop learning algorithms for data-representations with optimal metric properties. Typically a heuristically derived objective function is optimized, and often there is no discussion of generalization performance for high dimensional input data.

The classical method seems to be *Linear Discriminant Analysis* (LDA, Fukunaga, 1990) which projects onto a dominant subspace of the matrix quotient of the inter-class and intra-class empirical covariances. This can only work if the intra-class covariance operator is non-singular, and it will work poorly even if it is non-singular, but has very small eigenvalues (a generic situation in high dimensions), whence there have been several efforts to remedy the situation by optimization within the null-space of the intra-class covariance operator (NLDA) or by simultaneous diagonalisation of the intra- and inter-class covariances (OLDA). The stability problem inherent to the quotient approach is approached by a heuristic regularization prescription (ROLDA). These various extensions to LDA are presented by Ye and Xiong (2006) and have been tested in an experimental situation where the trained representation is combined with K-NN classification on the same task where the representation was trained. The performance appears to be comparable to SVM.

LDA and its extensions can be best compared to the algorithm of hyperbolic PCA presented in Section 4. In contrast to LDA hyperbolic PCA projects onto a dominant eigenspace of a weighted difference and not the quotient of the inter- and intra-class covariances. For this reason hyperbolic PCA is free of the stability problems of LDA and generalization guarantees are easily obtained.

An interesting technique has been proposed by Goldberger et al (2004). The desired representation is chosen to optimize the performance of a stochastic variant of K-NN classification on the

represented data. The method, called *Neighborhood Component Analysis* (NCA) appears to admit a regularized version, with essentially the same regularizer as in this work, and it seems possible to obtain dimension-free generalization guarantees for the regularized version. Unfortunately the optimization problem underlying NCA is not convex.

There is a certain kinship of NCA to the technique presented in this work, because both approaches depart from an objective defined by performance requirements of algorithms operating on the represented data. The stochastic K-NN classifiers of NCA correspond to the elementary verifiers (see Section 5) in our approach.

The problem of similarity learning from pair oracles similar to this paper has been considered by several authors.

In the work of Bar-Hillel et al. (2005) the triplets (x,x',r) generated by the oracle are called equivalence constraints, positive if $r=1$ and negative if $r=-1$. Their algorithm, called RCA for *Relevant Component Analysis*, does not use negative equivalence constraints on the grounds that these are less informative than positive ones, a claim supported by a simple counting argument. The objective of RCA is essentially entropy maximization under the constraint that "chunklets" of data points belonging to the same class, as inferred from the positive equivalence constraints, remain confined to balls of a fixed diameter. Under Gaussian assumptions there is a bound on the variance of the RCA-estimator, but in general it is unclear if a representation optimizing the objective for one data-set will also be nearly optimal for another one drawn from the same distribution.

Xing et al. (2002) use both positive and negative equivalence constraints and pose the following optimization problem (in our notation) for a sample $((x_1,x'_1,r_1),...,(x_m,x'_m,r_m))$

$$\min_T \sum_{i:r_i=1} \left\|Tx_i - Tx'_i\right\|^2 \text{ such that } \sum_{i:r_i=-1} \left\|Tx_i - Tx'_i\right\| \geq 1.$$

To solve this problem they propose an algorithm which enforces the positivity constraint for T^*T by alternating gradient descent and projection to the cone of positive operators by eigenvalue decompositions, a method which seems generally applicable when a convex objective is to be optimized under a positivity constraint.

It is surprising that both in Bar-Hillel et al. (2005) and Xing et al. (2002) the existence of a pair oracle to generate a sample of labeled pairs (or equivalence constraints) is implicitly assumed, without attempting to directly predict this oracles behavior. If there is a process which generates labeled examples (and this is what the equivalence constraints are) it seems natural to learn to predict the labels.

This idea has already been proposed by Thrun and Mitchell (1995) (see also Thrun, 1998), where also the obvious connection to transfer and meta-learning is mentioned. This work combines this with the idea of representation learning, as also proposed by Thrun (1998).

Some authors (Chopra et al., 2005; Fleuret and Blanchard 2005) have considered the utility of representation learning for the purpose of multi-category and multi-task pattern recognition on the basis of single training examples. In contrast to the more general method introduced above, these approaches are tailored to the special domain of image processing.

8. Conclusion

This work presented a technique to represent pattern similarity on the basis of data generated by a domain dependent oracle. The method works well in multi-task and multi-category environments

as a preparation for future learning with minimal training sets, such as a single training example or a single training example per category.

A major theoretical problem is to explain the good performance of the method in the context of transfer, a phenomenon which doesn't seem to be completely understood.

Another important development would be a learning algorithm of optimal representations for larger future sample sizes. It is conceivable that, in the context of learning-to-learn, the learner can choose from a catalogue of previously trained representations on the basis of the size of the available training sample. The representations trained by the proposed algorithm would then constitute only one extreme entry in this catalogue, corresponding to a minimal sample size of one.

Appendix A. Notation Table

Notation	Short Description	Section
$\mathcal{X}$	input space, $\mathcal{X} \subset H, diam(\mathcal{X}) \leq 1$	1.1
ρ	pair oracle. P-measure on $\mathcal{X}^2 \times \{-1,1\}$	1.1
(x,x',r)	generic triplet $(x,x',r) \in \mathcal{X}^2 \times \{-1,1\}$	1.1
S	training sample $S \in \left(\mathcal{X}^2 \times \{-1,1\}\right)^m, S \sim \rho^m$	1.1
$R(T)$	risk of operator $= \Pr\left\{r\left(1-\|Tx-Tx'\|^2\right) \leq 0\right\}$	1.2
$\hat{R}_\psi(T,S)$	empirical risk estimate for $\psi \geq 1_{(-\infty,0]}$ $= \frac{1}{m}\sum_{i=1}^m \psi\left(r_i\left(1-\|T(x_i-x_i')\|^2\right)\right)$	1.2
$\hat{R}(T,S)$	empirical risk, $\hat{R}(T,S) = \hat{R}_{1_{(-\infty,0]}}(T,S)$	6.1
h_γ	hinge-loss with margin γ	1.2
λ	regularization parameter	3.2
$\Lambda_{\psi,\lambda}(T,S)$	objective functional $\Lambda_{\psi,\lambda}(T,S) = \hat{R}_\psi(T,S) + m^{-1/2}\lambda\|T^*T\|_2$	3.2
Ω	convex objective, $\Omega(T^*T) = \Lambda(T)$	3.3
H	real, separable Hilbert space	2.1
$\langle .,. \rangle$ and $\|.\|$	inner product and norm on H	2.1
$\|T\|_\infty$	operator norm $\|T\|_\infty = \sup_{x\in H, \|x\|\leq 1}\|Tx\|$	2.1
T^*	adjoint of the operator T	2.1
$\mathcal{L}_\infty(H)$	set of operators on H with $\|T\|_\infty < \infty$	2.1
$\mathcal{L}_\infty^*(H)$	$\{T \in \mathcal{L}_\infty(H) : T^* = T\}$	2.1
$\mathcal{L}_\infty^+(H)$	$\{T \in \mathcal{L}_\infty^*(H) : \langle Tx,x\rangle \geq 0, \forall x \in H\}$	2.1
$\mathcal{L}_0(H)$	set of finite-rank operators on H	2.1
$\|T\|_2$	Hilbert-Schmidt norm	2.1
$\mathcal{L}_2(H)$	set of operators on H with $\|T\|_2 < \infty$	2.1
$\langle T,S\rangle_2$	inner product in $\mathcal{L}_2(H)$	2.1
$\mathcal{L}_2^*(H)$, $\mathcal{L}_2^+(H)$	$\mathcal{L}_\infty^*(H) \cap \mathcal{L}_2(H)$ and $\mathcal{L}_\infty^+(H) \cap \mathcal{L}_2(H)$ resp.	2.1
$\mathcal{P}_d$	d-dimensional orthogonal projections in H	2.1
Q_x, for $x \in H$	the operator $Q_x(z) = \langle z,x\rangle x$	2.1
$\|E\|_{\mathcal{S}}, E \subseteq \mathcal{S}$	maximal norm in E, that is, $\sup_{x\in E}\|x\|_{\mathcal{S}}$	2.1
$\hat{\mathcal{R}}_m(\mathcal{F})$	empirical Rademacher complexity of $\mathcal{F}$	2.2
σ_i	Rademacher variables, uniform on $\{-1,1\}$	2.2

Abstract

Feature ranking is a fundamental machine learning task with various applications, including feature selection and decision tree learning. We describe and analyze a new feature ranking method that supports categorical features with a large number of possible values. We show that existing ranking criteria rank a feature according to the *training* error of a predictor based on the feature. This approach can fail when ranking categorical features with many values. We propose the Ginger ranking criterion, that estimates the *generalization* error of the predictor associated with the Gini index. We show that for almost all training sets, the Ginger criterion produces an accurate estimation of the true generalization error, regardless of the number of values in a categorical feature. We also address the question of finding the optimal predictor that is based on a single categorical feature. It is shown that the predictor associated with the misclassification error criterion has the minimal expected generalization error. We bound the bias of this predictor with respect to the generalization error of the Bayes optimal predictor, and analyze its concentration properties. We demonstrate the efficiency of our approach for feature selection and for learning decision trees in a series of experiments with synthetic and natural data sets.

Keywords: feature ranking, categorical features, generalization bounds, Gini index, decision trees

1. Introduction

In this paper we address the problem of supervised feature ranking in the presence of categorical features. Feature ranking mechanisms have various applications; For instance, they can be used to define a filter for feature selection or as a splitting criterion for growing decision trees. In the feature ranking task we order a given set of features according to their relevance for predicting a target label. As in other supervised learning tasks, the ranking of the features is generated based on an input training set. Examples of widely used feature ranking criteria are the Gini index, the misclassification error, and Information Gain, also termed 'cross-entropy' (Hastie et al., 2001). The focus of this paper is feature ranking in the presence of *categorical* features. We show that a direct application of existing ranking criteria might lead to poor results in the presence of categorical

*. A preliminary version of this paper appeared at the 20th Annual Conference on Learning Theory under the title "Prediction by Categorical Features: Generalization Properties and Application to Feature Ranking"

features that can take many values. We propose an adaptation of existing ranking criteria that copes with these difficulties.

Many feature ranking methods are equivalent to the following two-phase process: First, each individual feature is used to construct a predictor of the label. Then, the features are ranked based on the errors of these predictors. Most current approaches use the same training set both for constructing the predictor and for evaluating its error. When dealing with binary features, the training error is likely to be close to the generalization error, and therefore the ranking generated by current methods works rather well. However, this is not the case when dealing with categorical features that can take a large number of values. To illustrate this fact, consider the problem of predicting whether someone is unemployed, based on their social security number (SSN). A predictor constructed using any finite training set would have zero error on the training set but a large generalization error. Therefore, a ranking criterion that supports categorical features should employ a more robust estimation of the generalization error.

The first contribution of this paper is an estimator for the generalization error of the predictor associated with the Gini index. This estimator can be calculated from the training set and we propose to use it instead of the original Gini index criterion in the presence of categorical features. We prove that regardless of the underlying distribution, our estimation is close to the true value of the generalization error for almost all training sets.

Based on our perspective of ranking criteria as estimators of the generalization error of a certain predictor, a natural question that arises is which predictor to use. Among all predictors that are based on a single feature, we ultimately would like to use the one whose generalization error is minimal. We prove that the best predictor in this sense is the predictor associated with the misclassification error criterion. We analyze the difference between the expected generalization error of this predictor and the error of the Bayes optimal hypothesis. Finally, we show a concentration result for the generalization error of this predictor.

Feature ranking criteria have been extensively studied in the context of decision trees (Mingers, 1989; Kearns and Mansour, 1996; Quinlan, 1993). The failure of existing feature ranking criteria in the presence of categorical features with a large number of possible values has been previously discussed in Quinlan (1993) and Mitchell (1997). Quinlan suggested the Information Gain Ratio as a correction to the Information Gain criterion. In a broader context, information-theoretic measures are commonly used for feature ranking (see for example Torkkola, 2006, and the references therein). One justification for their use is the existence of bounds on the Bayes optimal error that are based on these measures (Torkkola, 2006). However, obtaining estimators for the entropy or mutual information seems to be difficult in the general case (Antos and Kontoyiannis, 2001). Another ranking criterion designed to address the above difficulty is a distance-based measure introduced by de Mantaras (1991).

The problem we address shares some similarities with the problem of estimating the missing mass of a sample, typically encountered in language modeling (Good, 1953; McAllester and Schapire, 2000; Drukh and Mansour, 2005). The missing mass of a sample is the total probability mass of the values not occurring in the sample. Indeed, in the aforementioned example of the SSN feature, the value of the missing mass will be close to one. In some of our proofs we borrow ideas from McAllester and Schapire (2000) and Drukh and Mansour (2005). However, our problem is more involved, as even for a value that we do observe in the sample, if it appears only a small number of times then the training error is likely to diverge from the generalization error. Finally, we would like to note that classical VC theory for bounding the difference between the training error

and the generalization error is not applicable here. This is because the VC dimension grows with the number of values a categorical feature may take, and in our framework this number is unbounded.

This paper is organized as follows. In Sec. 2 we formally describe our problem setting. We introduce our main results in Sec. 3 and prove them in Sec. 4. We present experimental results in Sec. 5 and concluding remarks are given in Sec. 6.

2. Problem Setting

In this section we establish the notation used throughout the paper and formally describe our problem setting. In the supervised feature ranking setting we are provided with k categorical features and with a label. Each categorical feature is a random variable that takes values from a finite set. We denote a feature by X and the set of values X can take by V. We make no assumptions on the identity of V for each X nor on its size. The label is a binary random variable, denoted Y, that takes values from $\{0,1\}$.

Generally speaking, the goal of supervised feature ranking is to rank the features based on their merit in constructing an accurate classification rule. The features are ranked according to their "relevance" to the label. Different criteria exist for assessing the relevance of a feature to the label. Since relevance is assessed for each feature separately, let us ignore the fact that we have k features and from now on focus on defining a relevance measure for a single feature X. We denote by V the set of values that X can take. To simplify our notation we denote

$$p_v \stackrel{\Delta}{=} \Pr[X = v] \quad \text{and} \quad q_v \stackrel{\Delta}{=} \Pr[Y = 1 | X = v].$$

In practice, the probabilities $\{p_v\}$ and $\{q_v\}$ are unknown. Instead, it is assumed that we have a training set $S = \{(x_i, y_i)\}_{i=1}^m$, which is sampled i.i.d. according to the joint probability distribution $\Pr[X,Y]$. Based on S, the probabilities $\{p_v\}$ and $\{q_v\}$ are usually estimated as follows. Let $c_v = |\{i : x_i = v\}|$ be the number of examples in S for which the feature takes the value v and let $c_v^+ = |\{i : x_i = v \wedge y_i = 1\}|$ be the number of examples in which the value of the feature is v and the label is 1. Then $\{p_v\}$ and $\{q_v\}$ are estimated as follows:

$$\hat{p}_v \stackrel{\Delta}{=} \frac{c_v}{m} \quad \text{and} \quad \hat{q}_v \stackrel{\Delta}{=} \begin{cases} \frac{c_v^+}{c_v} & c_v > 0 \\ \frac{1}{2} & c_v = 0. \end{cases}$$

Note that $\hat{p}_v$ and $\hat{q}_v$ are implicit functions of the training set S.

Two popular relevance criteria (Hastie et al., 2001) are the misclassification error

$$\sum_{v \in V} \hat{p}_v \min\{\hat{q}_v, (1 - \hat{q}_v)\} , \tag{1}$$

and the Gini index

$$2 \sum_{v \in V} \hat{p}_v \hat{q}_v (1 - \hat{q}_v) . \tag{2}$$

In these criteria, smaller values indicate more relevant features.

Both the misclassification error and the Gini index were found to work rather well in practice when $|V|$ is small. However, for categorical features with a large number of possible values, we might end up with a poor feature ranking criterion. As an example (see Mitchell, 1997), suppose that Y indicates whether a person is unemployed and we have two features: X_1 is the person's SSN

and X_2 is 1 if the person has a mortgage and 0 otherwise. For the first feature, V is the set of all the SSNs. Because the SSN alone determines the target label, we have that $\hat{q}_v$ is either 0 or 1 for any v such that $\hat{p}_v > 0$. Thus, both the misclassification error and the Gini index are zero for this feature. For the second feature, it can be shown that with high probability over the choice of the training set, the two criteria mentioned above take positive values. Therefore, both criteria prefer the first feature over the second. In contrast, for our purposes X_2 is much better than X_1. This is because X_2 can be used later for learning a reasonable classification rule based on a finite training set, while X_1 will suffer from over-fitting.

It would have been natural to attribute the failure of the relevance criteria to the fact that we use estimated probabilities instead of the true (unknown) probabilities. However, note that in the above example, the same problem would arise even if we used $\{p_v\}$ and $\{q_v\}$ in Eq. (1) and Eq. (2). The aforementioned problem was previously underscored in the context of the Information Gain criterion (Quinlan, 1993; de Mantaras, 1991; Mitchell, 1997). In that context, Quinlan (1993) suggested an adaptation of the Information Gain, called Information Gain Ratio, which was found rather effective in practice.

In this paper we take a different approach, and propose to interpret a feature ranking criterion as the generalization error of a classification rule that can be inferred from the training set. To do so, let us first introduce some additional notation. A probabilistic hypothesis is a function $h : V \to [0,1]$, where $h(v)$ is the probability to predict the label 1 given the value v. The generalization error of h is the probability to incorrectly predict the label,

$$\ell(h) \stackrel{\Delta}{=} \sum_{v \in V} p_v \left(q_v \left(1 - h(v)\right) + \left(1 - q_v\right) h(v) \right) \quad . \tag{3}$$

We now define two hypotheses based on the training set S. The first one is

$$h_S^{\text{Gini}}(v) = \hat{q}_v \quad . \tag{4}$$

As its name indicates, h_S^{Gini} is closely related to the Gini index filter given in Eq. (2). To see this, we note that the generalization error of h_S^{Gini} is

$$\ell(h_S^{\text{Gini}}) = \sum_{v \in V} p_v \left(q_v \left(1 - \hat{q}_v\right) + \left(1 - q_v\right) \hat{q}_v \right) \quad .$$

If the estimated probabilities $\{\hat{p}_v\}$ and $\{\hat{q}_v\}$ coincide with the true probabilities $\{p_v\}$ and $\{q_v\}$, then $\ell(h_S^{\text{Gini}})$ is identical to the Gini index defined in Eq. (2). This will be approximately true, for example, when $m \gg |V|$. In other words, the Gini index is the training error of h_S^{Gini}. When the training set is small, using $\ell(h_S^{\text{Gini}})$ is preferable to using the Gini index given in Eq. (2), because $\ell(h_S^{\text{Gini}})$ takes into account the fact that the estimated probabilities might be skewed.

The second hypothesis we define is

$$h_S^{\text{Bayes}}(v) \;=\; \begin{cases} 1 & \hat{q}_v > \frac{1}{2} \\ 0 & \hat{q}_v < \frac{1}{2} \\ \frac{1}{2} & \hat{q}_v = \frac{1}{2} \end{cases} \quad . \tag{5}$$

Note that if $\{\hat{q}_v\}$ coincide with $\{q_v\}$ then h_S^{Bayes} is the Bayes optimal classifier, which we denote by h_∞^{Bayes}. If in addition $\{\hat{p}_v\}$ and $\{p_v\}$ are the same, then $\ell(h_S^{\text{Bayes}})$ is identical to the misclassification

error defined in Eq. (1). Here again, the misclassification error might differ from $\ell(h_S^{\text{Bayes}})$ for small training sets.

To illustrate the advantage of $\ell(h_S^{\text{Gini}})$ and $\ell(h_S^{\text{Bayes}})$ over their counterparts given in Eq. (2) and Eq. (1), we return to the example mentioned above. For X_1, the SSN feature we have $\ell(h_S^{\text{Gini}}) = \ell(h_S^{\text{Bayes}}) = \frac{1}{2}M_0$, where $M_0 \stackrel{\Delta}{=} \sum_{v:c_v=0} p_v$. In general, we denote

$$M_k \stackrel{\Delta}{=} \sum_{v:c_v=k} p_v \ . \tag{6}$$

The quantity M_0 is known as the missing mass (Good, 1953; McAllester and Schapire, 2000) and for the SSN feature, $M_0 \geq (|V|-m)/|V|$. Therefore, the generalization error of both h_S^{Gini} and h_S^{Bayes} would be close to 1 for a reasonable m. On the other hand, for X_2, the feature of having a mortgage, it can be verified that both $\ell(h_S^{\text{Bayes}})$ and $\ell(h_S^{\text{Gini}})$ are likely to be small. Therefore, using $\ell(h_S^{\text{Gini}})$ or $\ell(h_S^{\text{Bayes}})$ yields a correct ranking for this naive example.

We have proposed a modification of the Gini index and the misclassification error that uses the generalization error and therefore is suitable even when m is smaller than $|V|$. In practice, however, we cannot directly use the generalization error criterion since it depends on the unknown probabilities $\{p_v\}$ and $\{q_v\}$. To overcome this obstacle, we must derive estimators for the generalization error that can be calculated from the training set. In the next section we discuss the problem of estimating $\ell(h_S^{\text{Gini}})$ and $\ell(h_S^{\text{Bayes}})$ based on the training set. Additionally, we analyze the difference between $\ell(h_S^{\text{Bayes}})$ and the error of the Bayes optimal hypothesis.

3. Main Results

We start this section with a derivation of an estimator for $\ell(h_S^{\text{Gini}})$, which can serve as a new feature ranking criterion. We show that for most training sets, this estimator will be close to the true value of $\ell(h_S^{\text{Gini}})$. We then shift our attention to $\ell(h_S^{\text{Bayes}})$. First, we prove that among all predictors with no prior knowledge on the distribution $\Pr[X,Y]$, the generalization error of h_S^{Bayes} is smallest in expectation. Next, we bound the difference between the generalization error of h_S^{Bayes} and the error of the Bayes optimal hypothesis. Finally, we prove a concentration bound for $\ell(h_S^{\text{Bayes}})$. Regretfully, we could not find a good estimator for $\ell(h_S^{\text{Bayes}})$. Nevertheless, we believe that our concentration results can be used for finding such an estimator. This task is left for future research.

We propose the following estimator for the generalization error of h_S^{Gini}:

$$\hat{\ell} \stackrel{\Delta}{=} \frac{|\{v : c_v = 1\}|}{2m} + \sum_{v:c_v>1} \frac{2c_v}{c_v - 1} \hat{p}_v \hat{q}_v (1 - \hat{q}_v) \ . \tag{7}$$

This estimator can be derived using a leave-one-out technique (see for instance Wasserman, 2004). In the next section we show a different derivation, based on a conditional cross-validation technique. We suggest to use the estimation of $\ell(h_S^{\text{Gini}})$ given in Eq. (7) rather than the original Gini index given in Eq. (2) as a feature ranking criterion. Let us compare these two criteria: First, for values v that appear many times in the training set we have that $\frac{c_v}{c_v-1} \approx 1$. If for all $v \in V$ we have that the size of the training set is much larger than $1/p_v$, then all values in V are likely to appear many times in the training set and thus the definitions in Eq. (7) and Eq. (2) consolidate. The two definitions differ when there are values that appear rarely in the training set. For such values, the correction term is larger than 1. Special consideration is given to values that appear exactly once in the training

set. For such values we estimate the generalization error to be $\frac{1}{2}$, which is the highest possible error. Intuitively, since one example provides us with no information as to the variance of the label Y given $X = v$, we cannot have a more accurate estimation for the contribution of this value to the total generalization error. Furthermore, the fraction of values that appear exactly once in the training set is an estimator for the probability mass of those values that do not appear at all in the training set (see also Good, 1953; McAllester and Schapire, 2000).

We now turn to analyze the quality of the proposed estimator. We first show in Thm. 1 that the bias of this estimator is small. Then, in Thm. 2, we prove a concentration bound for the estimator, which holds for any joint distribution of $\Pr[X,Y]$ and does not depend on the size of V. Specifically, we show that for any $\delta \in (0,1)$, in a fraction of at least $1-\delta$ of the training sets the error of the estimator is $O(\frac{\ln(m/\delta)}{\sqrt{m}})$.

Theorem 1 *Let S be a set of m examples sampled i.i.d. according to the probability measure $\Pr[X,Y]$. Let h_S^{Gini} be the Gini hypothesis given in Eq. (4) and let $\ell(h_S^{Gini})$ be the generalization error of h_S^{Gini}, where ℓ is as defined in Eq. (3). Let $\hat{\ell}$ be the estimation of $\ell(h_S^{Gini})$ as given in Eq. (7). Then, $\left|\mathbb{E}[\ell(h_S^{Gini})] - \mathbb{E}[\hat{\ell}]\right| \leq \frac{1}{2m}$, where expectation is taken over all samples S of m examples.*

The next theorem shows that for most training sets, our estimator is close to the true generalization error of h_S^{Gini}.

Theorem 2 *Under the same assumptions as in Thm. 1, let δ be an arbitrary scalar in $(0,1)$. Then, with probability of at least $1-\delta$ over the choice of S, we have*

$$\left|\ell(h_S^{Gini}) - \hat{\ell}\right| \leq O\left(\frac{\ln(m/\delta)\sqrt{\ln(1/\delta)}}{\sqrt{m}}\right) \ .$$

Based on the above theorem, $\hat{\ell}$ can be used as a ranking criterion. The convergence rate shown can be used to establish confidence intervals on the true Gini generalization error. The proofs of Thm. 1 and Thm. 2 are given in the next section.

So far we have derived an estimator for the generalization error of the Gini hypothesis and shown that it is close to the true Gini error. The Gini hypothesis has the advantage of being highly concentrated around its mean. This is important especially when the sample size is fairly small. However, the Gini hypothesis does not produce the lowest generalization error in expectation. We now turn to show that the hypothesis h_S^{Bayes} defined in Eq. (5) is optimal in this respect, but that its concentration might be weaker. These two facts are characteristic of the well known bias-variance tradeoff commonly found in estimation and prediction tasks.

Had we known the underlying distribution of our data, we could have used the Bayes optimal hypothesis, h_∞^{Bayes}, that achieves the smallest possible generalization error. When the underlying distribution is unknown, the training set is used to construct the hypothesis. Thm. 3 below shows that among all hypotheses that can be learned from a finite training set, h_S^{Bayes} achieves the smallest generalization error in expectation. More precisely, h_S^{Bayes} is optimal among all the hypotheses that are symmetric with respect to both $|V|$ and the label values. Clearly, symmetric hypotheses cannot exploit prior knowledge on the underlying distribution $\Pr[X,Y]$. Formally, let $\mathcal{F}$ be the set of all symmetric functions over $\mathbb{N}\times\mathbb{N}$, that is,

$$\mathcal{F} \ = \ \{\, f : \mathbb{N}\times\mathbb{N} \to [0,1] \mid \forall n_1, n_2 \in \mathbb{N},\ f(n_1,n_2) = 1 - f(n_1, n_1 - n_2) \,\}$$

and let H be the following set of mappings from samples of size m to hypotheses:

$$H = \left\{ h : (V \times \{0,1\})^m \to V^{[0,1]} \;\middle|\; \exists f \in \mathcal{F} \text{ s.t. } \forall S \in (V \times \{0,1\})^m, \forall v \in V, \quad h[S](v) = f(c_v(S), c_v^+(S)) \right\} . \tag{8}$$

That is, H is the set of mappings that given a sample, generate a hypothesis based solely on the sample. Thus, hypotheses that rely on any prior knowledge on $\Pr[X,Y]$ are excluded.

The following theorem establishes the optimality of h_S^{Bayes} and bounds the difference between the Bayes optimal error and the error achieved by h_S^{Bayes}.

Theorem 3 *Let S be a set of m examples sampled i.i.d. according to the probability measure $\Pr[X,Y]$. For any hypothesis h, let $\ell(h)$ be the generalization error of h, as defined in Eq. (3). Let h_S^{Bayes} be the hypothesis given in Eq. (5), let h_∞^{Bayes} be the Bayes optimal hypothesis, and let H be the set of hypothesis mappings defined in Eq. (8). Then*

$$\mathbb{E}[\ell(h_S^{Bayes})] = \min_{h \in H} \mathbb{E}[\ell(h[S])], \tag{9}$$

and

$$\mathbb{E}[\ell(h_S^{Bayes})] - \ell(h_\infty^{Bayes}) \leq \frac{1}{2}\mathbb{E}[M_0] + \frac{1}{8}\mathbb{E}[M_1] + \frac{1}{8}\mathbb{E}[M_2] + \sum_{k=3}^{m} \frac{1}{\sqrt{ek}}\mathbb{E}[M_k], \tag{10}$$

where M_k is as defined in Eq. (6). Furthermore,

$$\lim_{m\to\infty} \left(\frac{1}{2}\mathbb{E}[M_0] + \frac{1}{8}\mathbb{E}[M_1] + \frac{1}{8}\mathbb{E}[M_2] + \sum_{k=3}^{m} \frac{1}{\sqrt{ek}}\mathbb{E}[M_k] \right) = 0. \tag{11}$$

Note that the first term in the difference between $\mathbb{E}[\ell(h_S^{\text{Bayes}})]$ and $\ell(h_\infty^{\text{Bayes}})$ is exactly half the expectation of the missing mass. This is expected, because we cannot improve our prediction over the baseline error of $\frac{1}{2}$ for values not seen in the training set, as exemplified in the SSN example described in the previous section. Subsequent terms in the bound can be attributed to the fact that even for values observed in the training set, a wrong prediction might be generated if there is a small number of examples.

We have shown that h_S^{Bayes} has the smallest generalization error in expectation, but this does not guarantee a small generalization error on a given sample. Thm. 4 below bounds the concentration of $\ell(h_S^{\text{Bayes}})$. This concentration along with Thm. 3 provides us with a bound on the difference between h_S^{Bayes} and the Bayes optimal error that is true for most samples.

Theorem 4 *Under the same assumptions of Thm. 3, assume that $m \geq 8$ and let δ be an arbitrary scalar in $(0,1)$. Then, with probability of at least $1-\delta$ over the choice of S, we have*

$$|\ell(h_S^{Bayes}) - \mathbb{E}[\ell(h_S^{Bayes})]| \leq O\left(\frac{\ln(m/\delta)\sqrt{\ln(1/\delta)}}{m^{1/6}} \right).$$

The concentration bound for $\ell(h_S^{\text{Bayes}})$ is weaker than the concentration bound for $\ell(h_S^{\text{Gini}})$, suggesting that indeed the choice between h_S^{Gini} and h_S^{Bayes} is not trivial. To use $\ell(h_S^{\text{Bayes}})$ as a ranking criterion, an estimator for this quantity is needed. However, at this point we cannot provide such an estimator. We conjecture that based on Thm. 4 an estimator with a small bias but a weak concentration can be constructed. We leave this task to further work. Finally, we would like to note that Antos et al. (1999) have shown that the Bayes optimal error cannot be estimated based on a finite training set. Finding an estimator for $\ell(h_S^{\text{Bayes}})$ would allow us to approximate the Bayes optimal error up to the bias term quantified in Thm. 3.

4. Proofs of Main Results

In this section we provide the full proofs of the theorems presented above.

4.1 Proof of Thm. 1

In the previous section, an estimator for the generalization error of the Gini hypothesis was presented. We stated that for most training sets this estimation is reliable. In this section, we first derive the estimator $\hat{\ell}$ given in Eq. (7) using a conditional cross-validation technique, and then use this interpretation of $\hat{\ell}$ to prove Thm. 1 and Thm. 2.

To derive the estimator given in Eq. (7), let us first rewrite $\ell(h_S^{\text{Gini}})$ as the sum $\sum_v \ell_v(h_S^{\text{Gini}})$, where $\ell_v(h_S^{\text{Gini}})$ is the amount of error due to value v and is formally defined as

$$\ell_v(h) \stackrel{\Delta}{=} \Pr[X=v]\Pr[h(X)\neq Y \mid X=v] = p_v\left(q_v(1-h(v))+(1-q_v)h(v)\right) .$$

We now estimate the two factors $\Pr[X=v]$ and $\Pr[h_S^{\text{Gini}}(X)\neq Y \mid X=v]$ independently. Later on we multiply the two estimations. The resulting local estimator of $\ell_v(h)$ is denoted $\hat{\ell}_v$ and our global estimator is $\hat{\ell} \stackrel{\Delta}{=} \sum_v \hat{\ell}_v$.

To estimate $\Pr[X=v]$, we use the straightforward estimator $\hat{p}_v$. Turning to the estimation of $\Pr[h_S^{\text{Gini}}(X)\neq Y \mid X=v]$, recall that h_S^{Gini}, defined in Eq. (4), is a probabilistic hypothesis where $\hat{q}_v$ is the probability to return the label 1 given that the value of X is v. Equivalently, we can think of the label that $h_S^{\text{Gini}}(v)$ returns as being generated based on the following process: Let $S(v)$ be the set of those indices in the training set in which the feature takes the value v, namely, $S(v)=\{i : x_i = v\}$. Then, to set the label $h_S^{\text{Gini}}(v)$ we randomly choose an index $i \in S(v)$ and return the label y_i. Based on this interpretation, a natural path for estimating $\Pr[h_S^{\text{Gini}}(X)\neq Y \mid X=v]$ is through cross-validation: Select an $i \in S(v)$ to determine $h_S^{\text{Gini}}(v)$, and estimate the generalization error to be the fraction of the examples whose label is different from the label of the selected example. That is, the estimation is $\frac{1}{c_v-1}\sum_{j\in S(v):j\neq i}\mathbf{1}_{y_i\neq y_j}$. Obviously, this procedure cannot be used if $c_v=1$. We handle this case separately later on. To reduce the variance of this estimation, this process can be repeated, selecting each single example from $S(v)$ in turn and validating each time using the rest of the examples in $S(v)$. It is then possible to average over all the choices of the examples. The resulting estimation therefore becomes

$$\sum_{i\in S(v)}\frac{1}{c_v}\left(\frac{1}{c_v-1}\sum_{j\in S(v):j\neq i}\mathbf{1}_{y_i\neq y_j}\right) = \frac{1}{c_v(c_v-1)}\sum_{i,j\in S(v):i\neq j}\mathbf{1}_{y_i\neq y_j} .$$

Thus, we estimate $\Pr[h_S^{\text{Gini}}(X)\neq Y \mid X=v]$ based on the fraction of differently-labeled pairs of examples in $S(v)$. Multiplying this estimator by $\hat{p}_v$ we obtain the following estimator for $\ell_v(h_S^{\text{Gini}})$,

$$\begin{aligned}\hat{\ell}_v &= \hat{p}_v\frac{1}{c_v(c_v-1)}\sum_{i,j\in S(v),i\neq j}\mathbf{1}_{y_i\neq y_j} \\ &= \hat{p}_v\frac{2c_v^+(c_v-c_v^+)}{c_v(c_v-1)} = \hat{p}_v\frac{2c_v^2\hat{q}_v(1-\hat{q}_v)}{c_v(c_v-1)} = \hat{p}_v\cdot\frac{2c_v}{c_v-1}\hat{q}_v(1-\hat{q}_v).\end{aligned} \tag{12}$$

Finally, for values v that appear only once in the training set, the above cross-validation procedure cannot be applied, and we therefore estimate their generalization error to be $\frac{1}{2}$, the highest possible

error. The full definition of $\hat{\ell}_v$ is thus:

$$\hat{\ell}_v = \begin{cases} \hat{p}_v \cdot \frac{1}{2} & c_v \leq 1 \\ \hat{p}_v \cdot \frac{2c_v}{c_v - 1} \hat{q}_v (1 - \hat{q}_v) & c_v \geq 2. \end{cases} \tag{13}$$

The resulting estimator $\hat{\ell}$ defined in Eq. (7) is exactly the sum $\sum_v \hat{\ell}_v$.

Based on the above derivation of $\hat{\ell}_v$, we now turn to prove Thm. 1, in which it is shown that the expectations of our estimator and of the true generalization error of the Gini hypothesis are close. To do so, we first inspect each of these expectations separately, starting with $\mathbb{E}[\hat{\ell}_v]$. The following lemma calculates the expectation of $\hat{\ell}_v$ over those training sets with exactly k appearances of the value v.

Lemma 5 *For k such that $1 < k \leq m$, $\mathbb{E}[\hat{\ell}_v \mid c_v(S) = k] = \frac{k}{m} \cdot 2q_v(1 - q_v)$.*

Proof If $c_v = k$, then $\hat{p}_v = \frac{k}{m}$. Therefore, based on Eq. (12), we have

$$\mathbb{E}[\hat{\ell}_v \mid c_v(S) = k] = \frac{k}{m} \frac{1}{k(k-1)} \mathbb{E}\left[\sum_{i,j \in S(v), i \neq j} \mathbf{1}_{y_i \neq y_j} \mid c_v(S) = k \right] . \tag{14}$$

Let $Z_1, \ldots, Z_k$ be independent binary random variables with $\Pr[Z_i = 1] = q_v$ for all $i \in [k]$. The conditional expectation on the right-hand side of Eq. (14) equals to

$$\mathbb{E}[\sum_{i \neq j} \mathbf{1}_{Z_i \neq Z_j}] \;=\; \sum_{i \neq j} \mathbb{E}[\mathbf{1}_{Z_i \neq Z_j}] \;=\; \sum_{i \neq j} 2\,q_v\,(1 - q_v) \;=\; k(k-1) \cdot 2\,q_v\,(1 - q_v) \;.$$

Combining the above with Eq. (14) concludes the proof. ■

Based on the above lemma, we are now ready to calculate $\mathbb{E}[\hat{\ell}_v]$. We have

$$\mathbb{E}[\hat{\ell}_v] = \sum_S \Pr[S]\, \mathbb{E}[\hat{\ell}_v] = \sum_{k=0}^{m} \sum_{S : c_v(S) = k} \Pr[S] \cdot \mathbb{E}[\hat{\ell}_v \mid c_v(S) = k]. \tag{15}$$

From the definition of $\hat{\ell}$, we have $\mathbb{E}[\hat{\ell}_v \mid c_v(S) = 1] = \frac{1}{2m}$ and $\mathbb{E}[\hat{\ell}_v \mid c_v(S) = 0] = 0$. Combining this with Lemma 5 and Eq. (15), we get

$$\begin{aligned} E[\hat{\ell}_v] &= \Pr[c_v = 1] \cdot \frac{1}{2m} + \sum_{k=2}^{m} \Pr[c_v = k] \cdot \frac{k}{m} \cdot 2q_v(1 - q_v) \\ &= \frac{1}{m} \left(\frac{1}{2} - 2q_v(1 - q_v)\right) \Pr[c_v = 1] + 2q_v(1 - q_v) \sum_{k=0}^{m} \Pr[c_v = k] \cdot \frac{k}{m} \\ &= \frac{1}{m} \left(\frac{1}{2} - 2q_v(1 - q_v)\right) \Pr[c_v = 1] + p_v \cdot 2q_v(1 - q_v) \;, \end{aligned} \tag{16}$$

where the last equality follows from the fact that $\sum_{k=0}^{m} \Pr[c_v = k] \frac{k}{m} = \mathbb{E}[\hat{p}_v] = p_v$. Having calculated the expectation of $\hat{\ell}_v$ we now calculate the expectation of $\ell_v(h_S^{\text{Gini}})$.

Lemma 6 $\mathbb{E}[\ell_v(h_S^{Gini})] = p_v(\frac{1}{2} - 2q_v(1 - q_v)) \Pr[c_v = 0] + p_v \cdot 2q_v(1 - q_v)$.

Proof From the definition of $\ell_v(h_S^{\text{Gini}})$, we have that

$$\begin{aligned}\mathbb{E}[\ell_v(h_S^{\text{Gini}})] &= \mathbb{E}[p_v\,(q_v(1-h_S^{\text{Gini}}(v))+(1-q_v)h_S^{\text{Gini}}(v))] \\ &= p_v\,(q_v(1-\mathbb{E}[h_S^{\text{Gini}}(v)])+(1-q_v)\,\mathbb{E}[h_S^{\text{Gini}}(v)]) \\ &= p_v\,(q_v+(1-2\,q_v)\,\mathbb{E}[h_S^{\text{Gini}}(v)]))\ . \end{aligned} \tag{17}$$

Next, we calculate $\mathbb{E}[h_S^{\text{Gini}}(v)]$ as follows

$$\begin{aligned}\mathbb{E}[h_S^{\text{Gini}}(v)] &= \sum_S \Pr[S] h_S^{\text{Gini}}(v) \\ &= \Pr[c_v(S)=0]\cdot\frac{1}{2} \;+\; \sum_{k=1}^{m}\sum_{i=0}^{k}\Pr[c_v(S)=k \text{ and } c_v^+(S)=i]\,\frac{i}{k} \\ &= \Pr[c_v(S)=0]\cdot\frac{1}{2} \;+\; \sum_{k=1}^{m}\Pr[c_v(S)=k]\sum_{i=0}^{k}\Pr[c_v^+(S)=i \mid c_v(S)=k]\,\frac{i}{k} \\ &= \Pr[c_v(S)=0]\cdot\frac{1}{2}+\sum_{k=1}^{m}\Pr[c_v(S)=k]\cdot q_v \\ &= \Pr[c_v(S)=0]\cdot\frac{1}{2}+\Pr[c_v(S)>0]\cdot q_v \\ &= q_v+\frac{1}{2}(1-2\,q_v)\Pr[c_v(S)=0]\ . \end{aligned} \tag{18}$$

Plugging Eq. (18) into Eq. (17) and rearranging terms we conclude our proof. ■

Equipped with the expectation of $\hat{\ell}_v$ given in Eq. (16) and the expectation of $\ell_v(h_S^{\text{Gini}})$ given in Lemma 6, we are now ready to prove Thm. 1.

Proof [of Thm. 1] Using the definitions of $\ell(h_S^{\text{Gini}})$ and $\hat{\ell}$ we have that

$$\mathbb{E}[\hat{\ell}]-\mathbb{E}[\ell(h_S^{\text{Gini}})] \;=\; \mathbb{E}[\sum_v \hat{\ell}_v]-\mathbb{E}[\sum_v \ell_v(h_S^{\text{Gini}})] \;=\; \sum_v(\mathbb{E}[\hat{\ell}_v]-\mathbb{E}[\ell_v(h_S^{\text{Gini}})])\ . \tag{19}$$

Fix some $v\in V$. From Eq. (16) and Lemma 6 we have

$$\mathbb{E}[\hat{\ell}_v]-\mathbb{E}[\ell_v(h_S^{\text{Gini}})] = (\frac{1}{2}-2q_v(1-q_v))(\frac{1}{m}\Pr[c_v=1]-p_v\Pr[c_v=0])\ . \tag{20}$$

Also, it is easy to see that

$$\begin{aligned}\frac{1}{m}\Pr[c_v=1]-p_v\Pr[c_v=0] &= p_v(1-p_v)^{m-1}-p_v(1-p_v)^m \\ &= p_v^2(1-p_v)^{m-1}=\frac{p_v}{m}\Pr[c_v=1]\ . \end{aligned}$$

Plugging this into Eq. (20) we obtain:

$$\mathbb{E}[\hat{\ell}_v]-\mathbb{E}[\ell_v(h_S^{\text{Gini}})] = (\frac{1}{2}-2q_v(1-q_v))\frac{1}{m}p_v\Pr[c_v=1].$$

For any q_v we have that $0\le 2q_v(1-q_v)\le\frac{1}{2}$, which implies the following inequality:

$$0\le\mathbb{E}[\hat{\ell}_v]-\mathbb{E}[\ell_v(h_S^{\text{Gini}})]\le\frac{1}{2m}\,p_v\Pr[c_v=1]\le\frac{p_v}{2m}.$$

Summing this over v and using Eq. (19) we conclude that

$$0 \;\leq\; \mathbb{E}[\hat{\ell}] - \mathbb{E}[\ell(h_S^{\text{Gini}})] \;\leq\; \sum_v \frac{p_v}{2m} \;=\; \frac{1}{2m} \;.$$

■

4.2 Proof of Thm. 2

We now turn to prove Thm. 2 in which we argue that with high confidence on the choice of S, the value of our estimator is close to the actual generalization error of h_S^{Gini}. To do this, we show that both our estimator and the true generalization error of h_S^{Gini} are concentrated around their mean. The proof of Thm. 2 will then follow from Thm. 1.

We start by showing that our estimator $\hat{\ell}$ is concentrated around its expectation. The concentration of $\hat{\ell}$ follows relatively easily by application of McDiarmid's Theorem (McDiarmid, 1989):

Theorem 7 (McDiarmid) *Let $X_1,\ldots,X_m$ be independent random variables taking values in a set V and let $f : V^m \to \mathbb{R}$ be such that for every $1 \leq i \leq m$*

$$\sup |f(x_1,\ldots,x_m) - f(x_1,\ldots,x_{i-1},x_i',x_{i+1},\ldots,x_m)| \leq c_i$$

where the supremum is taken over all $x_1,\ldots,x_m,x_i' \in V$. Then with probability at least $1-\delta$

$$f(X_1,\ldots,X_m) \leq \mathbb{E}[f(X_1,\ldots,X_m)] + \sqrt{\frac{1}{2}\ln(\frac{1}{\delta})\sum_{i=1}^m c_i}$$

and with probability at least $1-\delta$

$$f(X_1,\ldots,X_m) \geq \mathbb{E}[f(X_1,\ldots,X_m)] - \sqrt{\frac{1}{2}\ln(\frac{1}{\delta})\sum_{i=1}^m c_i} \;.$$

To simplify our notation, we will henceforth use the shorthand $\forall^\delta S \quad \pi[S,\delta]$ to indicate that the predicate $\pi[S,\delta]$ holds with probability of at least $1-\delta$ over the choice of S.

Lemma 8 *Let $\delta \in (0,1)$. Then, $\forall^\delta S \quad \left|\hat{\ell} - \mathbb{E}[\hat{\ell}]\right| \leq 12\sqrt{\frac{\ln(\frac{2}{\delta})}{2m}}$.*

Proof We prove the lemma using McDiardmid's theorem. To do so, we need to show that $\hat{\ell}$ has the bounded differences property; namely, we shall find an upper bound for the effect of any change of a single example in S on $\hat{\ell}$. Changing example (x_i,y_i) in S to (x_i',y_i') is tantamount to first removing (x_i,y_i) and then adding (x_i',y_i'). Since the effect of adding is simply the opposite of the effect of removing, it is sufficient to find an upper bound for the effect a single removal of example can have. Then the effect of a change on the sample would be no larger than twice the effect of the removal.

Let $S^{\setminus i}$ denote the set $S \setminus \{(x_i,y_i)\}$. We therefore need to bound $|\hat{\ell}(S) - \hat{\ell}(S^{\setminus i})|$. Assume, without loss of generality, that $x_i = v$ and $y_i = 0$. Then, using the definition of $\hat{\ell}_v$ we have that

$$|\hat{\ell}(S) - \hat{\ell}(S^{\setminus i})| = |\hat{\ell}_v(S) - \hat{\ell}_v(S^{\setminus i})| \;.$$

Based on the definitions of $\hat{p}_v = c_v/m$ and $\hat{q}_v = c_v^+/c_v$, we can rewrite Eq. (13) as

$$\hat{\ell}_v(S) = \begin{cases} \frac{1}{2m} & c_v = 1 \\ \frac{2c_v^+(c_v - c_v^+)}{m(c_v-1)} & c_v \geq 2. \end{cases}$$

Therefore, if $c_v \geq 3$,

$$\begin{aligned} |\hat{\ell}_v(S) - \hat{\ell}_v(S^{\setminus i})| &= \frac{2c_v^+}{m}\left(\frac{c_v - c_v^+}{c_v - 1} - \frac{c_v - c_v^+ - 1}{c_v - 2}\right) = \frac{2c_v^+(c_v^+ - 1)}{m(c_v-1)(c_v-2)} \\ &\leq \frac{2c_v(c_v-1)}{m(c_v-1)(c_v-2)} = \frac{2c_v}{m(c_v-2)} \leq \frac{6}{m} \ , \end{aligned}$$

while if $c_v = 2$ then

$$|\hat{\ell}_v(S) - \hat{\ell}_v(S^{\setminus i})| = \frac{2c_v^+(2-c_v^+)}{m} - \frac{1}{2m} \leq \frac{2}{m} \ .$$

Lastly, if $c_v = 1$ then $|\hat{\ell}_v(S) - \hat{\ell}_v(S^{\setminus i})| = \frac{1}{2m}$. Therefore for any sample S

$$|\hat{\ell}_v(S) - \hat{\ell}_v(S^{\setminus i})| \leq \frac{6}{m} \ ,$$

and thus the effect of a single change in S is no larger than $\frac{12}{m}$. We can now apply McDiarmid's theorem to get that with probability of at least $1-\delta$:

$$|\hat{\ell} - \mathbb{E}[\hat{\ell}]| \leq \sqrt{\frac{1}{2}\ln\left(\frac{2}{\delta}\right) m(\frac{12}{m})^2} = 12\sqrt{\frac{\ln\left(\frac{2}{\delta}\right)}{2m}}.$$

■

We now turn to show a concentration bound on the true generalization error $\ell(h_S^{\text{Gini}})$. Here we cannot directly use McDiarmid's Theorem since the bounded differences property does not hold for $\ell(h_S^{\text{Gini}})$. To see this, suppose that $V = \{0,1\}$, $p_0 = p_1 = \frac{1}{2}$, $q_0 = 0.99$ and $q_1 = 1$. Assume in addition that $|S(0)| = 1$; namely, there is only a single example in S for which the feature takes the value 0, an unlikely but possible scenario. In this case, if the single example in $S(0)$ is labeled 1, then $\ell(h_S^{\text{Gini}}) = 0.01$, but if this example is labeled 0, then $\ell(h_S^{\text{Gini}}) = 0.99$. That is, a change of a single example might have a dramatic effect on $\ell(h_S^{\text{Gini}})$. This problem can intuitively be attributed to the fact that S is an atypical sample of the underlying distribution $\{p_v\}$. To circumvent this obstacle, we use the following lemma. Note that a similar result can be derived from the results in Kutin (2002), albeit with much larger constants. The lemma below provides tighter bounds for a more restricted case.

Lemma 9 *Let S be a sample with m examples drawn i.i.d from the distribution $\Pr[X,Y]$. Let δ be a confidence parameter. For two samples S_1 and S_2 with m examples, we say that $d(S_1,S_2) \leq 1$ if there is at most one example that is different between the two samples. Let f be a real function of the sample. If there exists a function of the sample g and real numbers c, b such that the following*

conditions hold:

$$\forall S_1, S_2 \text{ s.t. } d(S_1,S_2) \leq 1 \quad |g(S_1) - g(S_2)| \leq \frac{c}{m} \tag{21}$$

$$\forall^{\delta} S \quad f(S) = g(S) \tag{22}$$

$$|\mathbb{E}[f(S)] - \mathbb{E}[g(S)]| \leq \frac{b}{\sqrt{m}} \ , \tag{23}$$

then

$$\forall^{2\delta} S \quad |f(S) - \mathbb{E}[f(S)]| \leq \frac{c\sqrt{\ln(\frac{2}{\delta})} + b\sqrt{2}}{\sqrt{2m}} \ .$$

Proof From Eq. (21) and McDiarmid's theorem we have

$$\forall^{\delta} S \quad |g(S) - \mathbb{E}[g(S)]| \leq \frac{c\sqrt{\ln(\frac{2}{\delta})}}{\sqrt{2m}}.$$

In addition,

$$|f(S) - \mathbb{E}[f(S)]| \leq |f(S) - g(S)| + |g(S) - \mathbb{E}[g(S)]| + |\mathbb{E}[f(S)] - \mathbb{E}[g(S)]| \ .$$

Therefore, using Eq. (22) and Eq. (23) and applying a union bound, we have

$$\forall^{2\delta} S \, |f(S) - \mathbb{E}[f(S)]| \leq 0 + \frac{c\sqrt{\ln(\frac{2}{\delta})}}{\sqrt{2m}} + \frac{b}{\sqrt{m}} = \frac{c\sqrt{\ln(\frac{2}{\delta})} + b\sqrt{2}}{\sqrt{2m}}.$$

■

To use Lemma 9 we define a new hypothesis h_S^{δ} that depends both on the sample S and on the desired confidence parameter δ. This hypothesis would 'compensate' for atypical samples. We let $f \triangleq \ell(h_S^{\text{Gini}})$ and $g \triangleq \ell(h_S^{\delta})$, and show that the conditions of the lemma hold.

We construct a hypothesis h_S^{δ} such that g satisfies the three requirements given in Eqs. (21-23) based on Lemma 10 below. This lemma states that except for values with small probabilities, we can assure that with high confidence, $c_v(S)$ grows with p_v. This means that as long as p_v is not too small, a change of a single example in $c_v(S)$ does not change $h_S^{\delta}(v)$ too much. On the other hand, if p_v is small then the value v has little effect on the error to begin with. Therefore, regardless of the probability p_v, the error $\ell(h_S^{\delta})$ cannot be changed too much by a single change of example in S. This would allow us to prove a concentration bound on $\ell(h_S^{\delta})$ using McDiardmid's theorem. Let us first introduce a new notation. Given a confidence parameter $\delta > 0$, a probability $p \in [0,1]$, and a sample size m, we define

$$\rho(\delta, p, m) \ \triangleq \ mp - \sqrt{mp \cdot 3\ln(2/\delta)}.$$

Lemma 10 below states that $c_v(S)$ is likely to be at least $\rho(\delta/m, p_v, m)$ for all values with non-negligible probabilities.

Lemma 10 *Let $\delta \in (0,1)$ be a confidence parameter. Then,*

$$\forall^{\delta} S \quad \forall v \in V: \ p_v \geq \frac{6\ln(\frac{2m}{\delta})}{m} \quad \Rightarrow \quad c_v(S) \geq \rho(\delta/m, p_v, m) > 1.$$

Proof The proof is based on lemma 44 from Drukh and Mansour (2005). This lemma states that for all $v \in V$ such that $p_v \geq \frac{3\ln(\frac{2}{\delta})}{m}$ we have that

$$\forall^{\delta} S \quad |p_v - \hat{p}_v| \leq \sqrt{\frac{p_v \cdot 3\ln(\frac{2}{\delta})}{m}}. \tag{24}$$

Based on this lemma, we immediately get that for all v such that $p_v \geq 3\ln(\frac{2}{\delta})/m$,

$$\forall^{\delta} S \quad c_v \geq \rho(\delta, p_v, m).$$

Note, however, that this bound is trivial for $p_v = 3\ln(\frac{2}{\delta})/m$, because in this case $\rho(\delta, p_v, m) = 0$. We therefore use the bound for values in which $p_v \geq 6\ln(\frac{2}{\delta})/m$. For these values it is easy to show that $\rho(\delta, p_v, m) > 1$ for any $\delta \in (0,1)$. Trivially, there are at most m values v for which $p_v \geq \frac{6\ln(2/\delta)}{m}$. Therefore, by substituting δ/m for δ and applying a union bound, the proof is concluded. ■

Based on the bound given in the above lemma, we define h_S^{δ} to be

$$h_S^{\delta}(v) \triangleq \begin{cases} h_S^{\text{Gini}}(v) & p_v < \frac{6\ln(\frac{2m}{\delta})}{m} \text{ or } c_v \geq \rho(\frac{\delta}{m}, p_v, m) \\ \frac{c_v^+ + q_v(\lceil \rho(\frac{\delta}{m}, p_v, m) \rceil - c_v)}{\lceil \rho(\frac{\delta}{m}, p_v, m) \rceil} & \text{otherwise.} \end{cases}$$

That is, $h_S^{\delta}(v)$ is equal to $h_S^{\text{Gini}}(v)$ if either p_v is negligible or if there are enough representatives of v in the sample. If this is not the case, then S is not a typical sample and thus we "force" it to be typical by adding $\lceil \rho(\frac{\delta}{m}, p_v, m) \rceil - c_v$ 'pseudo-examples' to S with the value v and with labels that are distributed according to q_v. Therefore, except for values with negligible probability p_v, the hypothesis $h_S^{\delta}(v)$ is determined by at least $\lceil \rho(\frac{\delta}{m}, p_v, m) \rceil$ 'examples'. As a direct result of this construction we obtain that a single example from S has a small effect on the value of $\ell(h_S^{\delta})$.

We can now show that each of the properties in (21-23) hold. From the definition of h_S^{δ} and Lemma 10 it is clear that Eq. (22) holds. Let us now show that Eq. (23) holds, with b.

Lemma 11 $\left|\mathbb{E}[\ell(h_S^{Gini})] - \mathbb{E}[\ell(h_S^{\delta})]\right| \leq \frac{1}{m}$.

Proof We have

$$\mathbb{E}[\ell(h_S^{\text{Gini}})] - \mathbb{E}[\ell(h_S^{\delta})] = \sum_v \left(\mathbb{E}[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta})] \right). \tag{25}$$

We bound $\mathbb{E}[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta})]$ as follows. First, for values v such that $p_v < 6\ln(\frac{2m}{\delta})/m$, we have that $h_S^{\text{Gini}}(v) = h_S^{\delta}(v)$. Thus $\mathbb{E}[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta})] = 0$. For the rest of the values, $p_v \geq 6\ln(\frac{2m}{\delta})/m$ and thus the definition of $\ell_v(h_S^{\delta})$ implies

$$\begin{aligned} &\mathbb{E}[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta})] = \\ &\quad \Pr[c_v < \rho(\delta/m, p_v, m)] \cdot \mathbb{E}\left[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta}) \mid c_v < \rho(\delta/m, p_v, m) \right] . \end{aligned} \tag{26}$$

Using Eq. (24) again, we obtain that $\Pr[c_v < \rho(\delta/m, p_v, m)] \leq \delta/m$. In addition, since both $\ell_v(h_S^{\text{Gini}})$ and $\ell_v(h_S^{\delta})$ are in $[0, p_v]$ we have that

$$\left| \mathbb{E}\left[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta}) \mid c_v < \rho(\delta/m, p_v, m) \right] \right| \leq p_v.$$

Combining the above two facts with Eq. (26) we get

$$\left|\mathbb{E}[\ell_v(h_S^{\text{Gini}}) - \ell_v(h_S^{\delta})]\right| \leq \frac{p_v \delta}{m} \leq \frac{p_v}{m}.$$

Summing the above over v and using Eq. (25) we conclude that,

$$\left|\mathbb{E}[\ell(h_S^{\text{Gini}}) - \ell(h_S^{\delta})]\right| \leq \sum_v \frac{p_v}{m} = \frac{1}{m}.$$

■

Finally, the following lemma shows that Eq. (21) also holds.

Lemma 12 *For any $\delta > 0$, and for any two samples S_1 and S_2 with m examples such that $d(S_1, S_2) \leq 1$ with d defined as in Lemma 9,*

$$\left|\ell(h_{S_1}^{\delta}) - \ell(h_{S_2}^{\delta})\right| \leq \frac{12 \ln(\frac{2m}{\delta})}{m}.$$

The proof of this lemma is deferred to the appendix.

We have shown that the functions $g \stackrel{\Delta}{=} \ell(h_S^{\delta})$ and $f \stackrel{\Delta}{=} \ell(h_S^{\text{Gini}})$ satisfy the three requirements given in Eqs. (21-23) and therefore Lemma 9 can be used to show that $\ell(h^{\text{Gini}})$ is concentrated.

Lemma 13 $\forall \delta > 0 \quad \forall^{\delta} S \quad \left|\ell(h_S^{Gini}) - \mathbb{E}[\ell(h_S^{Gini})]\right| \leq \frac{12 \ln(\frac{4m}{\delta}) \sqrt{\ln(\frac{4}{\delta})}}{\sqrt{2m}} + \frac{1}{m}$.

Proof In Lemma 9, let $f \stackrel{\Delta}{=} \ell(h_S^{\text{Gini}})$ and let $g \stackrel{\Delta}{=} \ell(h_S^{\delta})$. Let $c \stackrel{\Delta}{=} 12 \ln(\frac{2m}{\delta})$, and let $b \stackrel{\Delta}{=} \frac{1}{\sqrt{m}}$. By Lemma 10, Eq. (22) holds. By Lemma 12, Eq. (21) holds, and by Lemma 11, Eq. (23) holds. Therefore, from Lemma 9 we have

$$\forall \delta > 0 \quad \forall^{2\delta} S \quad |f(S) - \mathbb{E}[f(S)]| \leq \frac{12 \ln(\frac{2m}{\delta}) \sqrt{\ln(\frac{2}{\delta})}}{\sqrt{2m}} + \frac{1}{m} \ .$$

The proof is concluded by substituting $\frac{\delta}{2}$ for δ. ■

Thm. 2 states that with high confidence, the estimator $\hat{\ell}$ is close to the true generalization error of the Gini hypothesis, $\ell(h_S^{\text{Gini}})$. We conclude the analysis of the Gini estimator by proving this theorem.

Proof [of Thm. 2] Substituting $\frac{\delta}{2}$ for δ and applying a union bound, we have that all three properties stated in Lemma 13, Thm. 1 and Lemma 8 hold with probability of at least $1 - \delta$. We therefore conclude that with probability of at least $1 - \delta$,

$$\begin{aligned}\left|\ell(h_S^{\text{Gini}}) - \hat{\ell}\right| &\leq |\ell(h_S^{\text{Gini}}) - \mathbb{E}[\ell(h_S^{\text{Gini}})]| + \left|\mathbb{E}[\ell(h_S^{\text{Gini}})] - \mathbb{E}[\hat{\ell}]\right| + \left|\mathbb{E}[\hat{\ell}] - \hat{\ell}\right| \\ &\leq \frac{2}{m} + \frac{12 \ln\left(\frac{8m}{\delta}\right) \sqrt{\ln\left(\frac{8}{\delta}\right)}}{\sqrt{2m}} + 12\sqrt{\frac{\ln(\frac{4}{\delta})}{2m}} \ = \ O\left(\frac{\ln(\frac{m}{\delta}) \sqrt{\ln(\frac{1}{\delta})}}{\sqrt{m}}\right) \ .\end{aligned}$$

■

4.3 Proof of Thm. 3

Throughout this section we use the notation $S^{(m)}$ to denote a random training set of m examples. Before proving Thm. 3, we provide the following lemma, that shows that the expectation of M_k converges to 0 for any k.

Lemma 14 *For any natural k and a countable V,*

$$\lim_{m\to\infty} \mathbb{E}[M_k(S^{(m)})] = 0$$

Proof Following McAllester and Schapire (2000) we have that for any m

$$\mathbb{E}[M_k(S^{(m)})] = \sum_{v\in V} p_v \Pr[|S_v^{(m)}| = k] \ .$$

Since V is a countable set we can rewrite it as $V \stackrel{\Delta}{=} \{v_1, v_2, v_3, \ldots\}$. Let $\varepsilon > 0$, and let N be a positive integer such that $\sum_{i=1}^{N} p_{v_i} > 1 - \frac{\varepsilon}{2}$. Since $\lim_{m\to\infty} \left(\Pr[|S_v^{(m)}| = k]\right) = 0$ for any natural k, there exists an m' such that for any $m > m'$, $\sum_{i=1}^{N} p_{v_i} \Pr[|S_{v_i}^{(m)}| = k] < \frac{\varepsilon}{2}$. In addition, $\sum_{i=N+1}^{|V|} p_{v_i} < \frac{\varepsilon}{2}$. Hence, for every $m > m'$,

$$\mathbb{E}[M_k(S^{(m)})] = \sum_{i=1}^{N} p_{v_i} \Pr[|S_{v_i}^{(m)}| = k] + \sum_{i=N+1}^{|V|} p_{v_i} \Pr[|S_{v_i}^{(m)}| = k] < \varepsilon.$$

■

Proof [of Thm. 3] To prove Eq. (9), we calculate the expectation of the generalization error $\mathbb{E}[\ell(h_S)]$ of an arbitrary hypothesis mapping $h \in H$ and show that this error is minimized when $h[S] = h_S^{\text{Bayes}}$. Let $f_h : \mathbb{N}\times\mathbb{N} \to [0,1]$ be a function such that $f_h(n_1,n_2) = 1 - f_h(n_1, n_1 - n_2)$ and let h be a hypothesis mapping such that for all $v \in V$, $h[S](v) = f_h(c_v(S), c_v^+(S))$. Then,

$$\begin{aligned}\mathbb{E}[\ell(h[S])] &= \sum_v p_v \mathbb{E}[q_v(1 - f_h(c_v(S), c_v^+(S))) + (1-q_v) f_h(c_v(S), c_v^+(S))] \\ &= \sum_v p_v (q_v + (1-2q_v))\, \mathbb{E}[f_h(c_v(S), c_v^+(S))].\end{aligned}$$

From the above expression it is clear that if $q_v < \frac{1}{2}$ then $\mathbb{E}[\ell(h[S])]$ is minimal when $\mathbb{E}[f_h(c_v(S), c_v^+(S))]$ is minimal, and if $q_v > \frac{1}{2}$ then $\mathbb{E}[\ell(h[S])]$ is minimal when $\mathbb{E}[f_h(c_v(S), c_v^+(S))]$ is maximal. If $q_v = \frac{1}{2}$ the expectation equals $\frac{1}{2}$ regardless of the choice of f_h. We have

$$\begin{aligned}\mathbb{E}[f_h(c_v(S), c_v^+(S))] &= \sum_S \Pr[S]\, f_h(c_v(S), c_v^+(S)) \\ &= \sum_{k=0}^{m} \Pr[c_v(S) = k] \sum_{i=0}^{k} \Pr[c_v^+(S) = i \mid c_v(S) = k]\, f_h(k,i)\end{aligned}$$

Consider the summation on i for a single k from the above sum. If k is odd, then

$$\begin{aligned}
&\sum_{i=0}^{k} \Pr[c_v^+ = i \mid c_v = k] f_h(k,i) \\
&= \sum_{i=0}^{\frac{k-1}{2}} \Pr[c_v^+ = i \mid c_v = k] f_h(k,i) + \sum_{i=\frac{k+1}{2}}^{k} P[c_v^+ = i \mid c_v = k](1 - f_h(k,k-i)) \\
&= \sum_{i=0}^{\frac{k-1}{2}} \Pr[c_v^+ = i \mid c_v = k] f_h(k,i) + \sum_{i=0}^{\frac{k-1}{2}} \Pr[c_v^+ = k-i \mid c_v = k](1 - f_h(k,i)) \\
&= C + \sum_{i=0}^{\frac{k-1}{2}} \left(\Pr[c_v^+ = i \mid c_v = k] - \Pr[c_v^+ = k-i \mid c_v = k] \right) f_h(k,i)
\end{aligned}$$

where C is a constant that does not depend on f_h. In the above expression, note that if $q_v < \frac{1}{2}$ then for each $i \leq \frac{k-1}{2}$, $\Pr[c_v^+ = i \mid c_v = k] - \Pr[c_v^+ = k-i \mid c_v = k]$ is positive, and that if $q_v > \frac{1}{2}$ then this expression is negative. This means that in both cases, to minimize $\mathbb{E}[\ell(h_S)]$, we need to maximize $f_h(k,i)$ for $i \leq \frac{k-1}{2}$. For an even k the analysis is similar, except that we have the special case of $i = \frac{k}{2}$ that does not pair with another summand. However, from the symmetry constraint on f_h it follows that $f_h(k, \frac{k}{2}) = \frac{1}{2}$. Therefore no maximization or minimization is allowed for this value of i. Based on the above analysis, the function f_h that minimizes $\mathbb{E}[\ell(h_S)]$ is:

$$f_h(n_1,n_2) = \begin{cases} 1 & n_2 \leq \frac{n_1-1}{2} \\ 0 & n_2 \geq \frac{n_1+1}{2} \\ \frac{1}{2} & n_2 = \frac{n_1}{2} \end{cases}$$

Setting $h_S(v) = f_h(c_v(S), c_v^+(S))$ we have that $h_S(v) = h_S^{\text{Bayes}}(v)$ for all values v in V.

To prove Eq. (10), we first calculate the difference between $\ell_v(h_\infty^{\text{Bayes}})$ and the expectation of $\ell_v(h_S^{\text{Bayes}})$. Assume without loss of generality that $q_v > \frac{1}{2}$. Then $\ell_v(h_\infty^{\text{Bayes}}) = p_v(1-q_v)$, and

$$\mathbb{E}[\ell_v(h_S^{\text{Bayes}})] = p_v(q_v \Pr[\hat{q}_v < \frac{1}{2}] + (1-q_v)(1 - \Pr[\hat{q}_v < \frac{1}{2}]) + \frac{1}{2}\Pr[\hat{q}_v = \frac{1}{2}]).$$

Subtracting, we have

$$\begin{aligned}
\mathbb{E}[\ell_v(h_S^{\text{Bayes}})] - \ell_v(h_\infty^{\text{Bayes}}) &= p_v(2q_v - 1)(\Pr[\hat{q}_v < \frac{1}{2}] + \frac{1}{2}\Pr[\hat{q}_v = \frac{1}{2}]) \\
&\leq p_v(2q_v-1)\Pr[c_v = 0] \cdot \frac{1}{2} + p_v \sum_{k=1}^{m} \Pr[c_v = k](2q_v - 1)\Pr[\hat{q}_v \leq \frac{1}{2} | c_v = k].
\end{aligned}$$

We use Lemma 17 below to bound $(2q_v - 1)\Pr[\hat{q}_v \leq \frac{1}{2} | c_v = k]$ for $k \geq 3$. For $k = 0, 1, 2$ we maximize this term individually for each k. This leads us to the following bound:

$$\begin{aligned}
&\mathbb{E}[\ell_v(h_S^{\text{Bayes}})] - \ell_v(h_\infty^{\text{Bayes}}) \\
&\leq \frac{1}{2} p_v \Pr[c_v = 0] + \frac{1}{8} p_v \Pr[c_v = 1] + \frac{1}{8} p_v \Pr[c_v = 2] + \sum_{k=3}^{m} \frac{1}{\sqrt{ek}} p_v \Pr[c_v = k].
\end{aligned}$$

Recall that M_k is the probability mass of the values seen k times in the sample. Following McAllester and Schapire (2000) we have that for $k \geq 0$, $\mathbb{E}[M_k] = \sum_v p_v \Pr[c_v = k]$. Hence, summing over all the values v, we have

$$\begin{aligned}\mathbb{E}[\ell(h_S^{\text{Bayes}})] - \ell(h_\infty^{\text{Bayes}}) &= \sum_v (\mathbb{E}[\ell_v(h_S^{\text{Bayes}})] - \ell_v(h_\infty^{\text{Bayes}})) \\ &\leq \frac{1}{2}\mathbb{E}[M_0] + \frac{1}{8}\mathbb{E}[M_1] + \frac{1}{8}\mathbb{E}[M_2] + \sum_{k=3}^{m} \frac{1}{\sqrt{ek}}\mathbb{E}[M_k].\end{aligned}$$

To prove Eq. (11), denote by $S^{(m)}$ a sample of m examples. Let $\varepsilon > 0$ be a scalar. Then there exists an integer t such that $\frac{1}{\sqrt{et}} < \frac{\varepsilon}{2}$. Since $\sum_{k=1}^{m} \mathbb{E}[M_k(S^{(m)})] = 1$, we have

$$\sum_{k=t}^{m} \frac{1}{\sqrt{ek}}\mathbb{E}[M_k(S^{(m)})] < \frac{\varepsilon}{2}. \tag{27}$$

Now, by Lemma 14, for every $k < t$, $\lim_{m\to\infty} \mathbb{E}[M_k(S^{(m)})] = 0$. Hence, there exists an m' such that for every $m > m'$,

$$\frac{1}{2}\mathbb{E}[M_0(S^{(m)})] + \frac{1}{8}\mathbb{E}[M_1(S^{(m)})] + \frac{1}{8}\mathbb{E}[M_2(S^{(m)})] + \sum_{k=3}^{t} \frac{1}{\sqrt{ek}}\mathbb{E}[M_k(S^{(m)})] < \frac{\varepsilon}{2}. \tag{28}$$

Combining Eq. (27) and Eq. (28), we have that for every $m > m'$,

$$\frac{1}{2}\mathbb{E}[M_0] + \frac{1}{8}\mathbb{E}[M_1] + \frac{1}{8}\mathbb{E}[M_2] + \sum_{k=3}^{m} \frac{1}{\sqrt{ek}}\mathbb{E}[M_k] < \varepsilon.$$

Hence the limit of this expression when $m \to \infty$ is 0. ■

4.4 Proof of Thm. 4

To prove Thm. 4, we first introduce some additional notation. Let $\delta \in (0,1)$ be a confidence parameter. Let V_1^δ, V_2^δ, and V_3^δ be three sets that partition V according to the values of the probabilities p_v:

$$\begin{aligned}V_1^\delta &= \{v \mid p_v \leq 6\ln\left(\frac{2m}{\delta}\right) m^{-\frac{2}{3}}\} \\ V_2^\delta &= \{v \mid 6\ln\left(\frac{2m}{\delta}\right) m^{-\frac{2}{3}} < p_v \leq 6\ln\left(\frac{2m}{\delta}\right) m^{-\frac{1}{2}}\} \\ V_3^\delta &= \{v \mid 6\ln\left(\frac{2m}{\delta}\right) m^{-\frac{1}{2}} < p_v\}\end{aligned}$$

We denote the contribution of each set to $\ell(h_S^{\text{Bayes}})$ by $\ell_i^\delta(S) \stackrel{\Delta}{=} \sum_{v\in V_i^\delta} \ell_v(h_S^{\text{Bayes}})$. Additionally, given two samples S and S', let $\kappa(S,S')$ be the predicate that gets the value "true" if for all $v \in V$ we have $c_v(S) = c_v(S')$.

Using the above definitions and the triangle inequality, we can bound $|\ell(h_S^{\text{Bayes}}) - \mathbb{E}[\ell(h_S^{\text{Bayes}})]|$ as follows:

$$\begin{aligned}
|\ell(h_S^{\text{Bayes}}) - \mathbb{E}[\ell(h_S^{\text{Bayes}})]| &= \left|\sum_{i=1}^{3}\left(\ell_i^\delta(S) - \mathbb{E}[\ell_i^\delta]\right)\right| \\
&\leq \left|\,\ell_1^\delta(S) - \mathbb{E}[\ell_1^\delta]\,\right| + \left|\,\ell_2^\delta(S) - \mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')]\,\right| + \\
&\quad \left|\,\ell_3^\delta(S) - \mathbb{E}[\ell_3^\delta(S') \mid \kappa(S,S')]\,\right| + \left|\,\mathbb{E}[\ell_2^\delta(S') + \ell_3^\delta(S') \mid \kappa(S,S')] - \mathbb{E}[\ell_2^\delta + \ell_3^\delta]\,\right|.
\end{aligned}$$

To prove Thm. 4 we bound each of the above terms as follows: First, to bound $\left|\,\ell_1^\delta(S) - \mathbb{E}[\ell_1^\delta]\,\right|$ (Lemma 15 below), we use the fact that for each $v \in V_1^\delta$ the probability p_v is small. Thus, a single change of an example in S has a moderate effect on the error and we can use McDiarmid's theorem. To bound $\left|\,\ell_2^\delta(S) - \mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')]\,\right|$ (Lemma 16 below) we note that the expectation is taken with respect to those samples S' in which $c_v(S') = c_v(S)$ for all v. Therefore, the variables $\ell_v(h_S^{\text{Bayes}})$ are independent. We show in addition that each of these variables is bounded in $[0, p_v]$ and thus we can apply Hoeffding's bound. Next, to bound $\left|\,\ell_3^\delta(S) - \mathbb{E}[\ell_3^\delta(S') \mid \kappa(S,S')]\,\right|$ (Lemma 19 below), we use the fact that in a typical sample, $c_v(S)$ is large for all $v \in V_3^\delta$. Thus, we bound the difference between $\ell_v(h_S^{\text{Bayes}})$ and $\mathbb{E}[\ell_v(S') \mid \kappa(S,S')]$ for each value in V_3^δ separately. Then, we apply a union bound to show that for all of these values the above difference is small. Finally, we use the same technique to bound $\left|\,\mathbb{E}[\ell_2^\delta(S') + \ell_3^\delta(S') \mid \kappa(S,S')] - \mathbb{E}[\ell_2^\delta + \ell_3^\delta]\,\right|$ (Lemma 20 below). The proof of the first lemma, stated below, is omitted.

Lemma 15 $\forall \delta > 0 \quad \forall^\delta S \quad |\ell_1^\delta(S) - \mathbb{E}[\ell_1^\delta]| \leq \frac{12\ln\left(\frac{2m}{\delta}\right)}{m^{1/6}}\sqrt{\frac{1}{2}\ln\left(\frac{2}{\delta}\right)}$.

Proof We prove the lemma using McDiarmid's theorem. To do so, we examine the effect a removal of a single example (x_i, y_i) from S can have on $\ell_1^\delta(h_S^{\text{Bayes}})$. The largest effect occurs if $x_i \in V_1^\delta$ and the removal of y_i changes the value of $h^{\text{Bayes}}(x_i)$. In this case,

$$|\ell_1^\delta(S) - \ell_1^\delta(S^{\setminus i})| = |\ell_{x_i}(h_S^{\text{Bayes}}) - \ell_{x_i}(h_{S^{\setminus i}}^{\text{Bayes}})| \leq p_v \leq 6\ln\left(\frac{2m}{\delta}\right)m^{-\frac{2}{3}}.$$

Applying McDiarmid's theorem, it follows that $|\ell_1^\delta(S) - \mathbb{E}[\ell_1^\delta]|$ is at most

$$\sqrt{\frac{1}{2}\ln\left(\frac{2}{\delta}\right)m\cdot\left(12\ln\left(\frac{2m}{\delta}\right)m^{-\frac{2}{3}}\right)^2} = \frac{12\ln\left(\frac{2m}{\delta}\right)}{m^{1/6}}\sqrt{\frac{1}{2}\ln\left(\frac{1}{\delta}\right)}\ .$$

■

Lemma 16 $\forall \delta > 0 \quad \forall^\delta S \quad |\ell_2^\delta(S) - \mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')]| \leq \frac{\sqrt{3\ln\left(\frac{2m}{\delta}\right)\ln\left(\frac{2}{\delta}\right)}}{m^{1/4}}$.

Proof Since the expectation is taken over samples S' for which $c_v(S') = c_v(S)$ for each $v \in V$, we get that the value of the random variable $\ell_v(h_S^{\text{Bayes}})$ for each v depends only on the assignment of label for each example. Therefore the random variables $\ell_v(h_S^{\text{Bayes}})$ are all independent of each other when conditioned on $\kappa(S,S')$, and $\ell_2^\delta(S) = \sum_{v\in V_2^\delta}\ell_v(h_S^{\text{Bayes}})$ is a sum of independent random variables. The

expectation of this sum is $\mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')]$. In addition, it is trivial to show that $\ell_v(h_S^{\text{Bayes}}) \in [0, p_v]$ for all v. Thus, by Hoeffding's inequality,

$$\Pr[|\ell_2^\delta(S) - \mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')]| \geq t] \;\leq\; 2e^{-2t^2/\sum_{v\in V_2^\delta} p_v^2}. \tag{29}$$

Using the fact that for v in V_2^δ, $p_v \leq 6\ln\left(\frac{2m}{\delta}\right)/\sqrt{m}$ we obtain that

$$\sum_{v\in V_2^\delta} p_v^2 \;\leq\; \max_{v\in V_2^\delta}\{p_v\} \cdot \sum_{v\in V_2^\delta} p_v \;\leq\; 6\ln\left(\frac{2m}{\delta}\right)/\sqrt{m}\ .$$

Plugging the above into Eq. (29) we get that

$$\Pr[|\ell_2^\delta(S) - \mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')]| \geq t] \;\leq\; 2e^{-2t^2\sqrt{m}/(6\ln\left(\frac{2m}{\delta}\right))}\ .$$

Setting the right-hand side to δ and solving for t, we conclude our proof. ■

So far, we have bounded the terms $\left|\, \ell_1^\delta(S) - \mathbb{E}[\ell_1^\delta] \,\right|$ and $\left|\, \ell_2^\delta(S) - \mathbb{E}[\ell_2^\delta(S') \mid \kappa(S,S')] \,\right|$. In both of these cases, we used the fact that p_v is small for all $v \in V_1^\delta \cup V_2^\delta$. We now turn to bound the term $\left|\, \ell_3^\delta(S) - \mathbb{E}[\ell_3^\delta(S') \mid \kappa(S,S')] \,\right|$. In this case, the probabilities p_v are no longer negligible. Therefore, we use a different technique whereby we analyze the probability of $h_S^{\text{Bayes}}(v)$ to be 'wrong', that is to return the less probable label. Since p_v is no longer small, we expect c_v to be relatively large. The following key lemma bounds the probability of $h_S^{\text{Bayes}}(v)$ to be wrong given that c_v is large. The resulting bound depends on the difference between q_v and $1/2$ and becomes vacuous whenever q_v is close to $1/2$. On the other hand, if q_v is close to $1/2$, the price we pay for a wrong prediction is small. In the second part of this lemma, we balance these two terms and end up with a bound that does not depend on q_v.

Lemma 17 *Let $\bar{Z} = (Z_1, \ldots, Z_k)$ be a sequence of i.i.d. binary random variables such that $\Pr[Z_i = 1] = q$ for all i, and assume that $q \geq \frac{1}{2}$. Then,*

$$\Pr[\sum_i Z_i \leq k/2] \;\leq\; e^{-2(q-\frac{1}{2})^2 k} \quad \textit{and} \quad (2q-1)\Pr[\sum_i Z_i \leq k/2] \;\leq\; \frac{1}{\sqrt{ek}}\ .$$

Proof The first inequality is a direct application of Hoeffding's inequality. Multiplying both sides by $2q-1$ we get that the left-hand side of the second inequality is bounded above by $(2q-1)e^{-2(q-\frac{1}{2})^2 k}$. We now let $x = q - \frac{1}{2}$ and use the inequality $2xe^{-2x^2 k} \leq 1/\sqrt{ek}$, which holds for all $x \geq 0$ and $k > 0$. ■

Based on the above lemma, we now bound $\left|\, \ell_3^\delta(S) - \mathbb{E}[\ell_3^\delta(S') \mid \kappa(S,S')] \,\right|$. First, we show that if $c_v(S)$ is large then $\ell_v(S)$ is likely to be close to the expectation of ℓ_v over samples S' in which $c_v(S) = c_v(S')$. This is equivalent to the claim of the following lemma.

Lemma 18 *Under the same assumptions of Lemma 17. Let $f(\bar{Z})$ be the function*

$$f(\bar{Z}) \;=\; \begin{cases} (1-q) & \text{if } \sum_i Z_i > k/2 \\ q & \text{if } \sum_i Z_i < k/2 \\ \frac{1}{2} & \text{if } \sum_i Z_i = k/2 \end{cases}\ .$$

Then, for all $\delta \in (0, e^{-1/2}]$ we have $\forall^\delta \bar{Z} \quad |f(\bar{Z}) - \mathbb{E}[f]| \;\leq\; \sqrt{\frac{2\ln\left(\frac{1}{\delta}\right)}{ek}}$.

Proof To simplify our notation, denote $\alpha = \Pr[\sum_i Z_i > k/2]$, $\beta = \Pr[\sum_i Z_i < k/2]$, and $\gamma = \Pr[\sum_i Z_i = k/2]$. A straightforward calculation shows that

$$|f(\bar{Z}) - \mathbb{E}[f(\bar{Z})]| \;=\; \begin{cases} (2q-1)\,(\beta+\gamma/2) & \text{with probability } \alpha \\ (2q-1)\,(\alpha+\gamma/2) & \text{with probability } \beta \\ (2q-1)\,(\alpha-\beta) & \text{with probability } \gamma \end{cases} .$$

Using the fact that (α,β,γ) is in the probability simplex we immediately obtain that

$$|f(\bar{z}) - \mathbb{E}[f(\bar{Z})]| \le (2q-1) \ .$$

If $2q-1 \le \sqrt{2\ln\left(\frac{1}{\delta}\right)/k}$ then the bound in the lemma clearly holds. Therefore, from now on we assume that $2q-1 > \sqrt{2\ln\left(\frac{1}{\delta}\right)/k}$. In this case, using the first inequality of Lemma 17 we have that $\beta+\gamma \;\le\; e^{-2(q-\frac{1}{2})^2 k} \;\le\; \delta$. Therefore, $1-\delta < \alpha$, and so with probability of at least $1-\delta$ we have that

$$|f(\bar{Z}) - \mathbb{E}[f(\bar{Z})]| \;=\; (2q-1)\,(\beta+\gamma/2) \;\le\; (2q-1)\,(\beta+\gamma) \ .$$

Applying the second inequality of Lemma 17 on the right-hand side of the above inequality we get that $|f(\bar{Z}) - \mathbb{E}[f(\bar{Z})]| \;\le\; \sqrt{1/ek} \;\le\; \sqrt{2\ln(1/\delta)/ek}$, where the last inequality holds since we assume that $\delta \le e^{-1/2}$. ■

Equipped with the above lemma we are now ready to bound $\left|\ \ell_3^\delta(S) - \mathbb{E}[\ell_3^\delta(S') \mid \kappa(S,S')]\ \right|$.

Lemma 19 *If $m \ge 4$ then* $\quad \forall^{(2\delta)} S \quad |\ell_3^\delta(S) - \mathbb{E}[\ell_3^\delta(S') \mid \kappa(S,S')]| \;\le\; 1/m^{\frac{1}{4}}$.

Proof Recall that $\ell_3^\delta(S) = \sum_{v \in V_3^\delta} \ell_v(S)$. $m \ge 4$, hence $\delta/m \le 1/m \le e^{-1/2}$. Choose $v \in V_3^\delta$ and without loss of generality assume that $q_v \ge 1/2$. Thus, from Lemma 18 and the definition of $\ell_v(S)$ we get that with probability of at least $1-\delta/m$ over the choice of the labels in $S(v)$:

$$|\ell_v(S) - \mathbb{E}[\ell_v(S') \mid \kappa(S,S')]| \;\le\; p_v \sqrt{\frac{2\ln\left(\frac{m}{\delta}\right)}{e \cdot c_v(S)}} \ . \tag{30}$$

By the definition of V_3^δ and Lemma 10, $\forall^\delta S,\ \forall v \in V_3^\delta,\ c_v(S) \ge \rho(\delta/m, p_v, m)$. Using the fact that ρ is monotonically increasing with respect to p_v it is possible to show (see Lemma 21 in the appendix)that $\rho(\delta/m, p_v, m) \ge 2\ln\left(\frac{m}{\delta}\right) m^{1/2}$ for all $v \in V_3^\delta$ for $m \ge 4$. Therefore, if indeed $c_v(S) \ge \rho(\delta/m, p_v, m)$ for any $v \in V_3^\delta$, we have that

$$\sqrt{\frac{2\ln\left(\frac{m}{\delta}\right)}{e \cdot c_v(S)}} \le p_v\, m^{-1/4}.$$

Using a union bound to make sure that this condition holds and Eq. (30) holds for all $v \in V_3^\delta$ simultaneously, we obtain that $\forall^{(2\delta)} S \quad \forall v \in V_3^\delta \quad |\ell_v(S) - \mathbb{E}[\ell_v(S') \mid \kappa(S,S')]| \;\le\; p_v\, m^{-1/4}$. Summing over $v \in V_3^\delta$, using the triangle inequality, and using the fact that $\sum_v p_v = 1$ we conclude the proof. ■

Lemma 20 *For $m \geq 8$,*

$$\forall^{\delta} S \quad |\mathbb{E}[\ell_2^{\delta}(S') + \ell_3^{\delta}(S') \mid \kappa(S,S')] - \mathbb{E}[\ell_2^{\delta}(S') + \ell_3^{\delta}(S')]| \leq \frac{1}{m} + \frac{1}{m^{1/6}}.$$

Proof As in the proof of Lemma 19, we use the definitions of V_3^{δ} and V_2^{δ} along with Lemma 10 and Lemma 21 to get that for $m \geq 8$

$$\forall^{\delta} S \quad \forall v \in V_2^{\delta} \cup V_3^{\delta} \quad c_v(S) \geq \rho(\delta/m, p_v, m) \geq 3\ln(m/\delta)m^{1/3} \ . \tag{31}$$

To bound the difference between the conditional expectation and the unconditional expectation, let us first examine both these quantities for individual values v. To simplify our notation, denote $\alpha_1 = \Pr[\hat{q}_v(S') > 1/2 \mid c_v(S') = c_v(S)]$, $\beta_1 = \Pr[\hat{q}_v(S') < 1/2 \mid c_v(S') = c_v(S)]$, and $\gamma_1 = \Pr[\hat{q}_v(S') = 1/2 \mid c_v(S') = c_v(S)]$. Similarly, denote $\alpha_2 = \Pr[\hat{q}_v(S') > 1/2]$, $\beta_2 = \Pr[\hat{q}_v(S') < 1/2]$, and $\gamma_2 = \Pr[\hat{q}_v(S') = 1/2]$. Using the definition of ℓ_v we have that

$$\mathbb{E}[\ell_v(S') \mid c_v(S) = c_v(S')] = p_v \left((1-q_v)\,\alpha_1 + q\,\beta_1 + \frac{1}{2}\gamma_1 \right) \ .$$

Similarly, for the unconditional expectation:

$$\mathbb{E}[\ell_v(S')] = p_v \left((1-q_v)\,\alpha_2 + q\,\beta_2 + \frac{1}{2}\gamma_2 \right) \ . \tag{32}$$

Subtracting the above two equations and rearranging terms it can be shown that

$$\begin{aligned} \Delta &\stackrel{\Delta}{=} |\mathbb{E}[\ell_v(S') \mid c_v(S) = c_v(S')] - \mathbb{E}[\ell_v(S')]| \\ &= p_v\,(q - \frac{1}{2})\,|\,(\beta_1 + \gamma_1) - (\beta_2 + \gamma_2) + (\gamma_1 - \gamma_2)\,| \ . \end{aligned} \tag{33}$$

Let $Z_1, \ldots, Z_{c_v(S)}$ be an i.i.d. sequence of random variables with $\Pr[Z_i = 1] = q_v$. Then we have $\beta_1 + \gamma_1 = \Pr[\sum_i Z_i \leq c_v(S)/2]$. In addition $c_v(S) \geq \lceil \rho(\delta/m, p_v, m) \rceil \stackrel{\Delta}{=} \rho$. Assume without loss of generality that $q_v \geq 1/2$. Thus we have $\Pr[\sum_{i=1}^{\rho} Z_i \leq \rho/2] \geq \Pr[\sum_{i=1}^{c_v(S)} Z_i \leq c_v(S)/2]$. We clearly have that $0 \leq \beta_1 + \gamma_1 \leq \Pr[\sum_{i=1}^{\rho} Z_i \leq \rho/2]$. We now argue that

$$0 \leq \beta_2 + \gamma_2 \leq \frac{\delta}{m} + \Pr[\sum_{i=1}^{\rho} Z_i \leq \rho/2] \ .$$

The left-hand side inequality is trivial. To prove the right-hand side inequality, we note that

$$\begin{aligned} \beta_2 + \gamma_2 = & \sum_{i=1}^{m} \Pr[c_v(S') = i] \Pr\left[\hat{q}_v(S') \leq \frac{1}{2} \mid c_v(S') = i \right] \\ \leq & \Pr[c_v(S') \leq \rho] + \Pr\left[\hat{q}_v(S') \leq \frac{1}{2} \mid c_v(S') = \rho \right] \\ \leq & \frac{\delta}{m} + \Pr[\sum_{i=1}^{\rho} Z_i \leq \rho/2] \ . \end{aligned}$$

Therefore,

$$|(\beta_1+\gamma_1)-(\beta_2+\gamma_2)| \leq \frac{\delta}{m}+\Pr[\sum_{i=1}^{k} Z_i \leq k/2] \ . \tag{34}$$

Similarly, since $0 \leq \gamma_1 \leq \beta_1+\gamma_1$ and $0 \leq \gamma_2 \leq \beta_2+\gamma_2$ we also have that

$$|\gamma_1-\gamma_2| \leq \frac{\delta}{m}+\Pr[\sum_{i=1}^{\rho} Z_i \leq \rho/2] \ . \tag{35}$$

Combining Eq. (34) and Eq. (35) with Eq. (33) we get that

$$\Delta \ \leq \ p_v(2q-1)\left(\frac{\delta}{m}+\Pr[\sum_{i=1}^{\rho} Z_i \leq \rho/2]\right) \ \leq \ p_v\left(\frac{1}{m}+\frac{1}{\sqrt{e\cdot\rho(\frac{\delta}{m},p_v,m)}}\right) \ ,$$

where the last inequality follows from Lemma 17. Finally, by summing over $v \in V_2^\delta \cup V_3^\delta$ and using Eq. (31) we conclude our proof. ■

5. Experiments

In this section we present experimental results that demonstrate the merits of our feature ranking criterion given in Eq. (7). Throughout this section we compare the following four feature ranking criteria:

1. **IG:** The Information Gain criterion (Quinlan, 1993; de Mantaras, 1991; Mitchell, 1997).
2. **IGR:** The Information Gain Ratio criterion (Quinlan, 1993).
3. **Gini:** The original Gini Index (Breiman et al., 1984), which is given in Eq. (2).
4. **Ginger:** Our modified Gini criterion that aims to minimize the generalization error, given in Eq. (7).

We first present experiments with synthetic data that exemplify the generalization properties of the different criteria. Next, we compare the performance of the different criteria on a natural data set from the UCI repository. Finally, we compare the use of the different ranking criteria for the task of growing a decision tree.

5.1 Synthetic Data

Three synthetic data sets were constructed to exemplify the generalization properties of the different ranking criteria in different scenarios. In all of the synthetic data sets the target label was first sampled according to the probability measure $\Pr[Y=1]=\frac{1}{2}$. Synthetic data set I includes only binary features. The goal of data set I is to show that the Ginger criterion behaves similarly to the Gini criterion on binary features. 11 binary features were constructed. For each $i \in \{0,1,\ldots,10\}$ the ith feature was sampled according to the probability measure $\Pr[X_i=Y|Y]=\frac{1+0.1i}{2}$. Thus, feature X_0 is completely uncorrelated with the label, while feature X_{10} perfectly predicts the label.

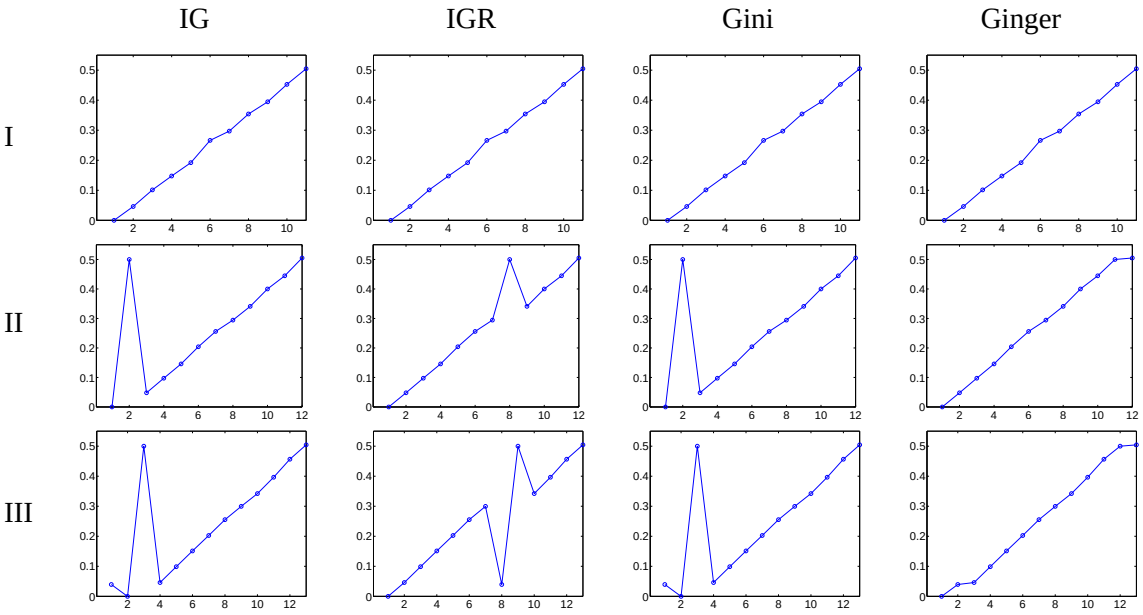

Figure 1: Each of the plots above show the generalization error of each feature (the y axis) against the ranking order of the feature in one of the ranking criteria (the x axis). Each column corresponds to a specific ranking criteria. Each row corresponds to a specific synthetic data set.

A training set of 5000 examples was generated, and the features were ranked using each of the four ranking criteria on the training set. The generalization errors of the 11 classification rules of each feature, defined as in Eq. (5), were measured on a fresh test set of 5000 examples. A plot of the generalization error of each feature against the ranking order of the feature is given for each of the ranking criteria on the top row of Fig. 1. This plot should be monotonically increasing for good feature ranking criteria. As the plots show, all four criteria perform well on this data set.

Data set II is identical to data set I, except that one more feature, indexed X_{11}, was added. X_{11} is simply the index of the example (this simulates an SSN-like feature as described in Sec. 2). Clearly, the generalization error of X_{11} is $\frac{1}{2}$ as no value of the feature that occurred in the training set would occur in a test set. The performance of the four feature ranking criteria on data set II is shown on the second row of Fig. 1. As expected, the Gini criterion and the IG criterion both suffer from overfitting and rank X_{11} very high. The IGR criterion, suggested by Quinlan (1993) attempts to fix the overfitting effect of the IG criterion by dividing IG by the entropy of the feature. As the plots show, this correction indeed causes IGR to rank X_{11} lower than do IG and Gini. However, the correction is not strong enough, as the new feature is still ranked 8th out of 12 features although its generalization error is the worst. Finally, it is clear from the plots that the new Ginger criterion produces a correct ranking of the features in this example.

Data set III is identical to data set II, except that one more feature indexed X_{12} was added. X_{12} was constructed according to the following probability measure:

$$\Pr[X = i \mid Y = 1] = \begin{cases} \frac{1}{2000} & \text{if } i \in \{1,\ldots,2000\} \\ 0 & \text{otherwise} \end{cases} \quad \text{and}$$

$$\Pr[X = i \mid Y = -1] = \begin{cases} \frac{1}{2000} & \text{if } i \in \{2001,\ldots,4000\} \\ 0 & \text{otherwise} \end{cases}$$

X_{12} is thus categorical with many values but it is still highly predictive of the label. The performance of the four feature ranking criteria on data set III is shown on the bottom row of Fig. 1. As the plots show, the rankings of the Gini criterion and of the IG criterion are not adversely affected by the addition of this feature, although they still fail on X_{11}, the SSN-like feature. IGR penalizes X_{12} because it has a large number of values, thus its ranking for this feature is too low. The new Ginger criterion is the only one to rank the features in accordance with their respective generalization error, as is apparent from its monotonically increasing plot.

5.2 Natural Data

To test the ranking criteria on natural data, we used the USCensus1990raw data set from the UCI Repository.[1] This data set contains person records, where each record has 125 features, such as age, salary, marital status etc. Several labeled data sets were constructed from USCensus1990raw by defining a binary target label based on one of the attributes, and using the rest of the attributes as features. For attributes that take more than two values, the binary label was set to 1 if the feature takes its most frequent value and -1 otherwise. Only cases where the probability of the label to be 1 was at least 0.1 and no more than 0.9 were used. This process resulted in 62 binary learning problems.

In Fig. 2, each of the rows corresponds to one learning problem. A plot is shown for each problem and each ranking criterion, depicting the generalization error of each feature against the ranking order of the features. Recall that good ranking criteria should produce monotonically increasing graphs. The plots clearly show that the Ginger criterion produces the most accurate feature ranking. Fig. 3 compares the Ginger criterion to each of the other ranking criteria. In each of the plots, each data point corresponds to one of the 62 learning problems and portrays the difference in generalization error between the feature that was top-ranked by Ginger and the feature that was top-ranked by the other criterion. Positive data points are cases where Ginger outperformed the other criterion. Again, it is apparent that the Ginger criterion outperforms the other criteria.

5.3 Decision Trees

Decision tress are a popular classification tool (see for instance Mitchell, 1997). The process of growing a decision tree is a greedy iterative procedure which is performed as follows: The procedure starts with a tree composed only of a root node. At each iteration, one of the leaves of the tree is turned into an inner node, whose children represent all the possible values of one feature. Choosing

1. The original census data set was used rather than the preprocessed data set. The preprocessed data set obtained from Meek, Thiesson, and Heckerman eliminates categorical attributes that have many values, exactly the type of attributes that this paper addresses. The data set used in our experiments is available through `http://kdd.ics.uci.edu/databases/census1990/USCensus1990raw.data.txt`.

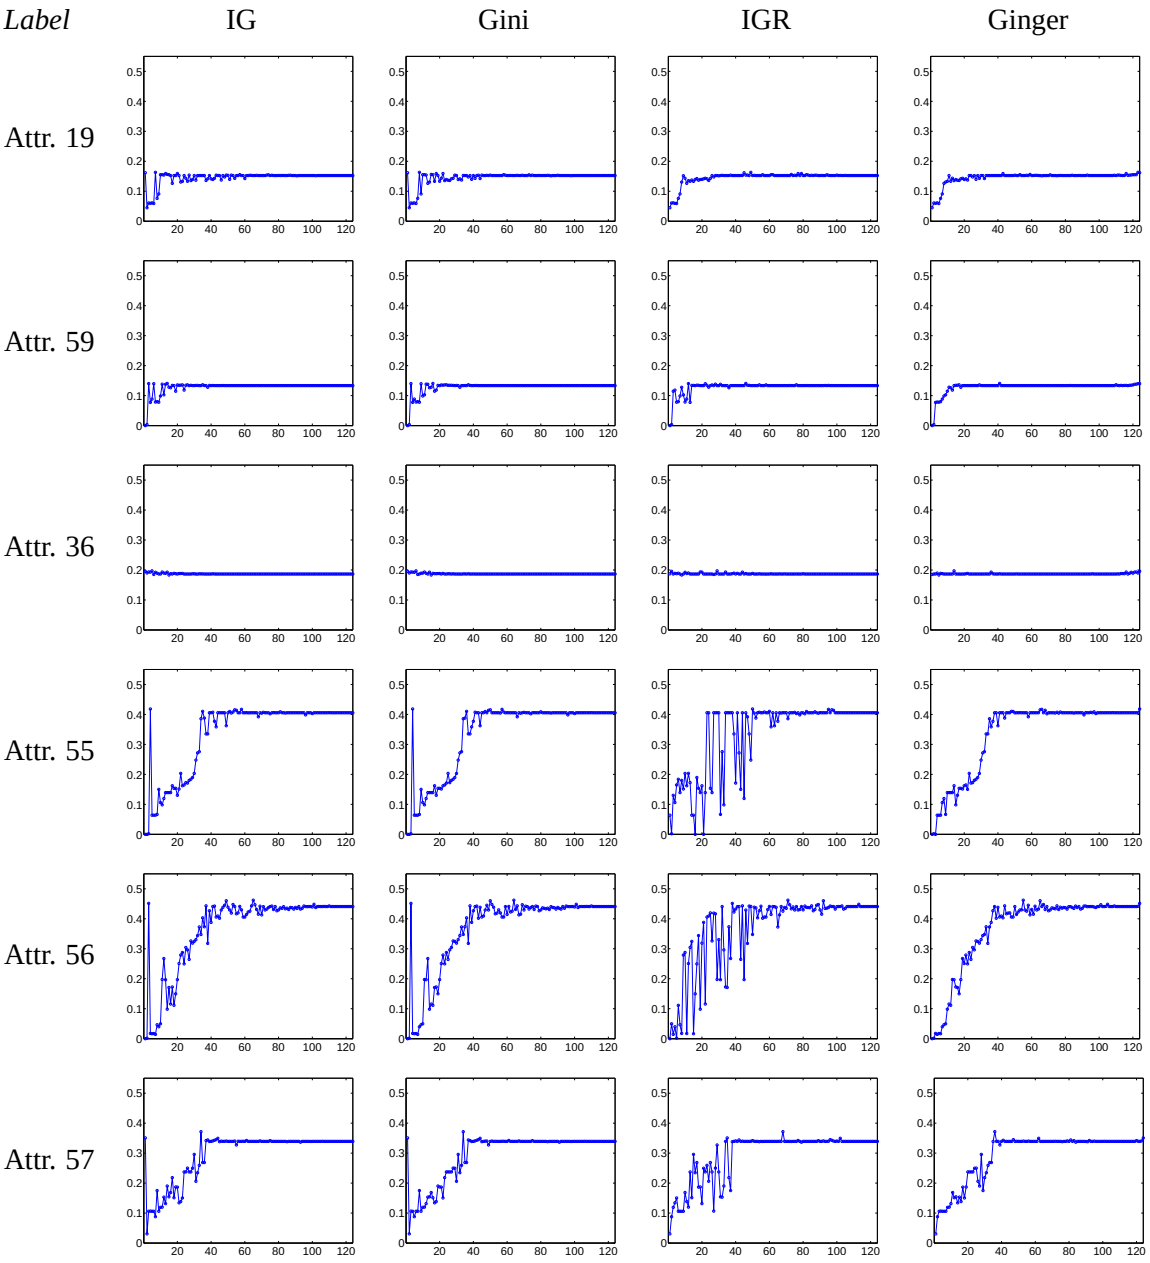

Figure 2: Each of the plots above show the generalization error of the features in a learning problem (the y axis) against the ranking order of the features in one of the ranking criteria (the x axis). Each column corresponds to a specific ranking criterion. Each row corresponds to a specific learning problem, generated from USCensus1990raw by setting the label to be the most common value of one of the attributes.

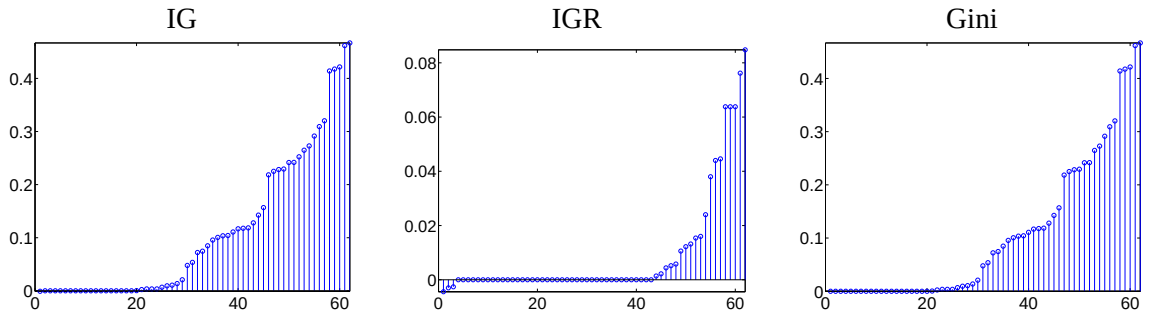

Figure 3: Each plot above portrays the difference in generalization error between the feature that was top-ranked by Ginger and the feature that was top-ranked by one of the other criteria, for each of the 62 learning problems obtained from USCensus1990raw.

which leaf to split and which feature to use for splitting can be based on feature ranking criteria such as the ones discussed in this paper. In our experiments, we compared decision tree learning with each of the four feature ranking criteria: IG, IGR, Gini, and Ginger. The experiments were performed on the 62 learning problems described in Sec. 5.2.

Usually, the iterative process of growing a decision tree continues until no further splits can be made. Then, as a post processing step, the tree is pruned, so as to improve the generalization error of the decision tree. Since this paper focuses on splitting criteria rather then on pruning methods, the experiments do not include tree post-pruning. Instead, the generalization error is measured as a function of the number of splits. Given a ranking criterion, the following procedure is used to choose which leaf to split and which feature to split by: Let m be the number of training examples. A decision tree T with k leaves is equivalent to a mapping $T : \{1,\ldots,m\} \rightarrow \{1,\ldots,k\}$. That is, each example is mapped to one of the leaves of the tree. We can think of the vector $(T(1),\ldots,T(m))$ as the vector of values of a constructed feature. At each iteration of the decision tree learning process, a new tree needs to be generated from the current tree by splitting one of the current tree leaves based on one of the features. Each possible new tree induces a different new constructed feature as described above. To select the leaf to split and the feature to split by, we assess the quality of each new constructed feature based on the ranking criterion in use. The selected leaf and feature are those that correspond to the top-ranked constructed feature.

Fig. 4 shows the training error and generalization error of the Gini, IGR and Ginger splitting criteria as a function of the number of splits, for several learning problems. The IG criterion plot was omitted since its behavior was almost identical to that of the Gini criterion. As can be seen from the plots, the training error of the Gini criterion drops faster, but the resulting tree suffers from severe overfitting. In contrast, the generalization error of the Ginger criterion is much smaller and remains close to the training error, as long as the number of splits is not too large. As expected, after making a large number of splits all criteria exhibit an overfitting effect. Comparing the IGR and the Ginger criteria, we observe that both methods perform rather well, each showing an advantage on some of the learning problems.

Lastly, Fig. 5 compares the performance of the decision tree learning with the Ginger splitting criterion to decision tree learning with the other splitting criteria. In each of the plots, the data points correspond to the 62 learning problems, and portray the difference in the minimal generalization

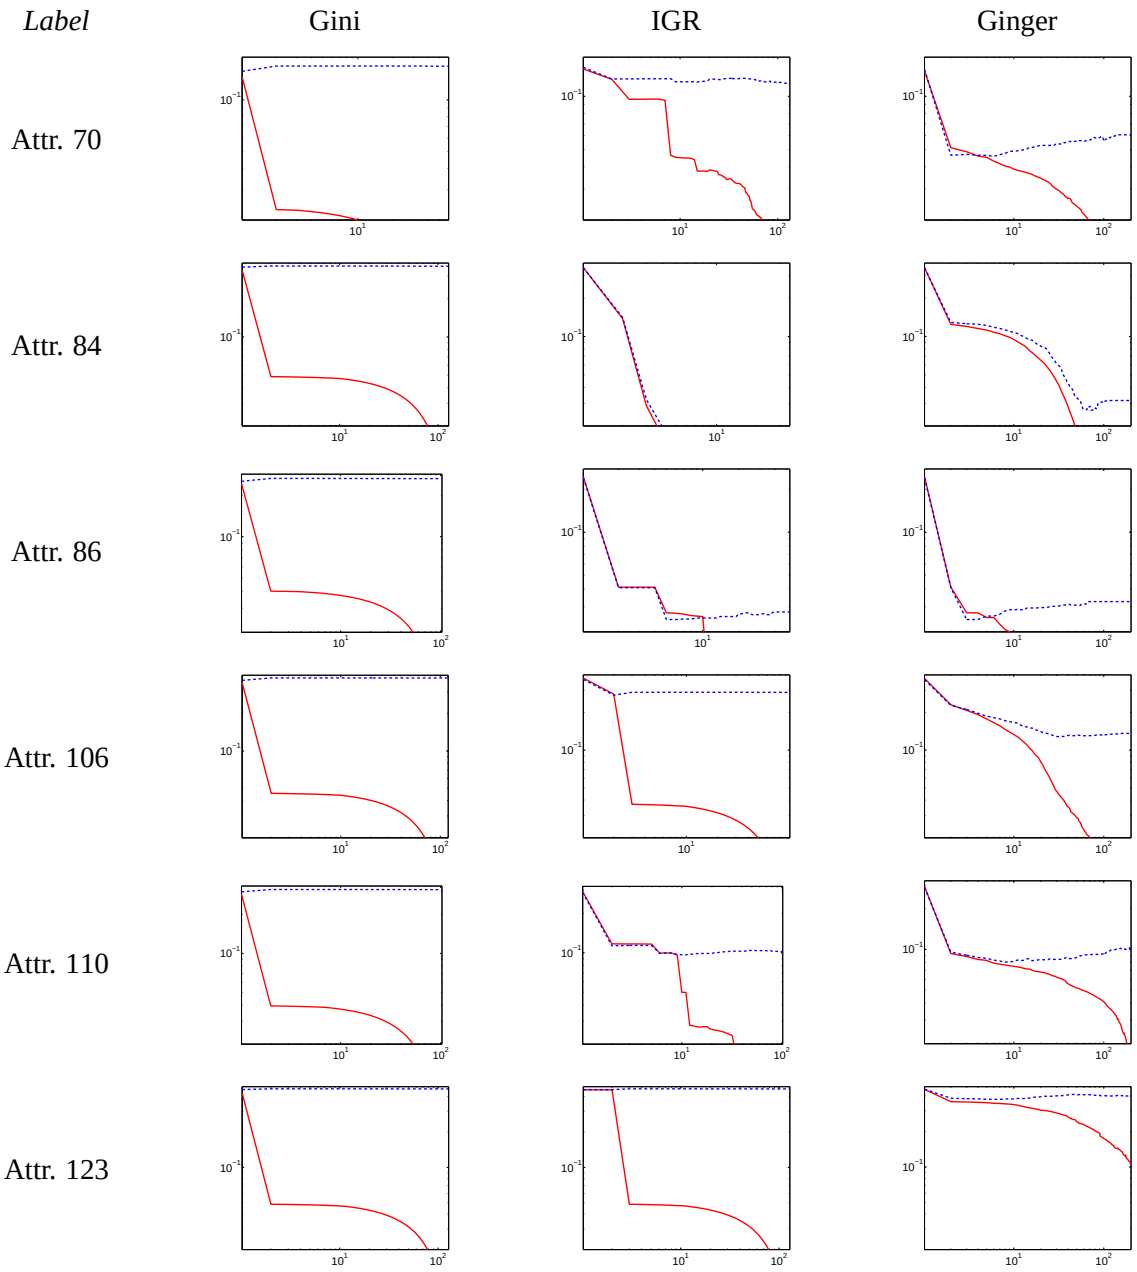

Figure 4: The training error (solid red line) and generalization error (dotted blue line) of decision trees grown according to the Gini, IGR, and Ginger splitting criteria, as a function of the number of splits. Each column corresponds to a specific splitting criterion. Each row corresponds to a specific learning problem, generated from USCensus1990raw by setting the label to be the most common value of one of the attributes.

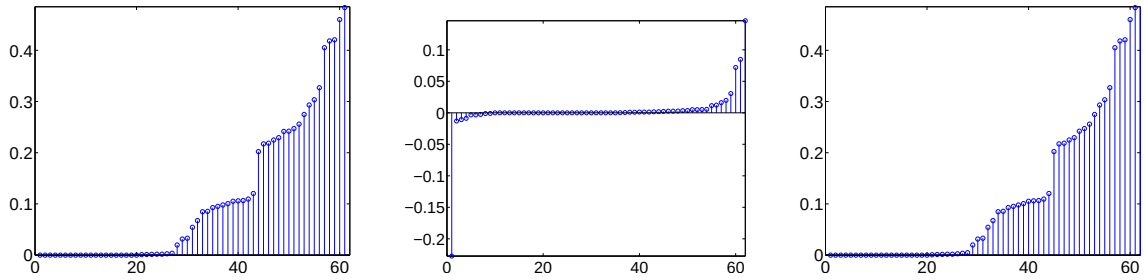

Figure 5: Left: The minimal generalization error of the IG criterion minus the minimal generalization error of the Ginger criterion for each of the labeled data sets. Middle: Same for IGR. Right: Same for Gini.

error achieved by the decision tree grown using Ginger and the one that was achieved using the other criterion. Positive data points are cases where Ginger outperformed the other criterion. The plots show that the Ginger criterion outperforms the IG and Gini criteria, and that in most cases the Ginger criterion outperforms the IGR criterion as well.

6. Discussion

In this paper, a new approach for feature ranking is proposed, based on a direct estimation of the true generalization error of predictors that are deduced from the training set. We focused on two specific predictors, namely h_S^{Gini} and h_S^{Bayes}. An estimator for the generalization error of h_S^{Gini}, termed the Ginger criterion, was proposed and its convergence was analyzed. Experimental evaluation suggests that the Ginger criterion outperforms existing feature ranking methods. We showed that the expected error of h_S^{Bayes} is optimal and proved a concentration bound for this error. Constructing an estimator for h_S^{Bayes} is left for future work.

There are various extensions for this work that we did not pursue. First, it is interesting to analyze the number of categorical features one can rank while avoiding overfitting. The experiments with decision trees suggest that the Ginger criterion has potential to improve the generalization error of decision trees. It may be possible to use the bounds for constructing a stopping criterion for growing the decision tree. Second, our view of a ranking criterion as an estimator for the generalization error of a predictor can be used for constructing new ranking criteria by defining other predictors. Finally, understanding the relationship between this view and information theoretic measures is also an interesting future direction.

Appendix A. Technical Proofs

Lemma 21 *Let c be a positive constant. Then, if $p_v > 6\ln\left(\frac{2}{\delta}\right) m^{-c}$, and $m \geq 2^{\frac{1}{1-c}}$ we have*

$$\forall \delta > 0 \quad \rho(\delta, p_v, m) \geq 3\ln\left(\frac{2}{\delta}\right) m^{1-c}.$$

Proof By the definition of ρ,

$$\rho(\delta, p_v, m) = mp_v - \sqrt{mp_v \cdot 3\ln\left(\frac{2}{\delta}\right)} = \sqrt{mp_v}\left(\sqrt{mp_v} - \sqrt{3\ln\left(\frac{2}{\delta}\right)}\right).$$

Therefore, $\rho(\frac{\delta}{m}, p_v, m)$ is upward monotonic with p_v. Thus if $p_v > 6\ln\left(\frac{2m}{\delta}\right)m^{-c}$,

$$\begin{aligned}
\rho(\delta, p_v, m) &= mp_v - \sqrt{mp_v \cdot 3\ln\left(\frac{2}{\delta}\right)} \\
&\geq 6\ln\left(\frac{2}{\delta}\right)m^{1-c} - \sqrt{6\ln\left(\frac{2}{\delta}\right)m^{1-c} \cdot 3\ln\left(\frac{2}{\delta}\right)} \\
&= 3\ln\left(\frac{2}{\delta}\right)m^{\frac{1-c}{2}}\left(2m^{\frac{1-c}{2}} - \sqrt{2}\right) \\
&= 3\ln\left(\frac{2}{\delta}\right)m^{\frac{1-c}{2}}(m^{\frac{1-c}{2}} + m^{\frac{1-c}{2}} - \sqrt{2}) \\
&\geq 3\ln\left(\frac{2}{\delta}\right)m^{1-c}.
\end{aligned}$$

■

Proof [Lemma 12] Similarly to the proof of Lemma 8, we will bound the effect a single removal of an example from S can have on $\ell(h_S^\delta)$. The maximal effect of a single change in the sample is no larger than twice the maximal effect of a single removal. Assume without loss of generality that the removed example is $x_i = (v, 0)$, and denote the resulting sample by $S^{\setminus i}$. The removal only affects $\ell_v(h_S^\delta)$. Therefore

$$\begin{aligned}
&|\ell(h_S^\delta) - \ell(h_{S^{\setminus i}}^\delta)| = |\ell_v(h_S^\delta) - \ell_v(h_{S^{\setminus i}}^\delta)| \\
&= \left|p_v\left(q_v(1 - h_S^\delta(v)) + (1-q_v)h_S^\delta(v) - p_v q_v(1 - h_{S^{\setminus i}}^\delta(v)) + (1-q_v)h_S^\delta(v)\right)\right| \\
&= \left|p_v(1-2q_v)(h_S^\delta(v) - h_{S^{\setminus i}}^\delta(v))\right| \\
&\leq p_v\left|h_S^\delta(v) - h_{S^{\setminus i}}^\delta(v)\right|.
\end{aligned}$$

For v such that $p_v < \frac{6\ln(\frac{2m}{\delta})}{m}$,

$$|\ell(h_S^\delta) - \ell(h_{S^{\setminus i}}^\delta)| \leq p_v < \frac{6\ln(\frac{2m}{\delta})}{m}. \tag{36}$$

For v such that $p_v \geq \frac{6\ln(\frac{2m}{\delta})}{m}$, we distinguish between three cases by c_v, the number of examples of v in S:

1. $c_v < \rho(\frac{\delta}{m}, p_v, m)$,
2. $\rho(\frac{\delta}{m}, p_v, m) \leq c_v < \rho(\frac{\delta}{m}, p_v, m) + 1$,

3. $\rho(\frac{\delta}{m}, p_v, m) + 1 \leq c_v$.

In case 1,

$$h_S^\delta(v) = \frac{c_v^+ + q_v(\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil - c_v)}{\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil} \text{ and } h_{S^{\setminus i}}^\delta(v) = \frac{c_v^+ + q_v(\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil - (c_v - 1))}{\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil},$$

hence

$$|h_S^\delta(v) - h_{S^{\setminus i}}^\delta(v)| = \frac{q_v}{\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil} .$$

In case 2, $\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil = c_v$, therefore

$$h_S^\delta(v) = h_S^{\text{Gini}}(v) = \frac{c_v^+}{c_v} \text{ and } h_{S^{\setminus i}}^\delta(v) = \frac{c_v^+ + q_v(c_v - (c_v - 1))}{c_v},$$

hence

$$|h_S^\delta(v) - h_{S^{\setminus i}}^\delta(v)| = \frac{q_v}{c_v} = \frac{q_v}{\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil} .$$

In case 3, since $\rho(\frac{\delta}{m}, p_v, m) > 1$ we have $c_v \geq 2$ and

$$h_S^\delta(v) = h_S^{\text{Gini}}(v) = \frac{c_v^+}{c_v} \text{ and } h_{S^{\setminus i}}^\delta(v) = h_{S^{\setminus i}}^\delta(v) = \frac{c_v^+}{c_v - 1}$$

Hence

$$|h_S^\delta(v) - h_{S^{\setminus i}}^\delta(v)| = \frac{c_v^+}{c_v(c_v-1)} \leq \frac{c_v}{c_v(c_v-1)} = \frac{1}{c_v - 1} \leq \frac{1}{\lceil \rho(\frac{\delta}{m}, p_v, m)\rceil} .$$

Therefore, in all cases, for v such that $p_v \geq \frac{6\ln(\frac{2m}{\delta})}{m}$,

$$|\ell(h_S^\delta) - \ell(h_{S^{\setminus i}}^\delta)| \leq p_v \left| h_S^\delta(v) - h_{S^{\setminus i}}^\delta(v) \right| \leq \frac{p_v}{\rho(\frac{\delta}{m}, p_v, m)} = \frac{p_v}{mp_v - \sqrt{mp_v \cdot 3\ln(\frac{2m}{\delta})}}$$

$$= \frac{1}{m} \frac{\sqrt{p_v}}{\sqrt{p_v} - \sqrt{\frac{3\ln(\frac{2m}{\delta})}{m}}} \leq \frac{1}{m} \left(\frac{\sqrt{\frac{6\ln(\frac{2m}{\delta})}{m}}}{\sqrt{\frac{6\ln(\frac{2m}{\delta})}{m}} - \sqrt{\frac{3\ln(\frac{2m}{\delta})}{m}}} \right) = \frac{1}{m} \frac{2}{\sqrt{2}-1} \leq \frac{4}{m} .$$

Combining this with Eq. (36), we have

$$|\ell(h_S^\delta) - \ell(h_{S^{\setminus i}}^\delta)| \leq \max\left\{ \frac{4}{m}, \frac{6\ln(\frac{2m}{\delta})}{m} \right\} = \frac{6\ln(\frac{2m}{\delta})}{m}.$$

Hence, doubling the effect of a single removal, we have that for any two samples S_1 and S_2 such that $d(S_1, S_2) \leq 1$

$$|\ell(h_{S_1}^\delta) - \ell(h_{S_2}^\delta)| \leq \frac{12\ln(\frac{2m}{\delta})}{m} .$$

Abstract

Statistical spam filters are known to be vulnerable to adversarial attacks. One of the more common adversarial attacks, known as the *good word attack*, thwarts spam filters by appending to spam messages sets of "good" words, which are words that are common in legitimate email but rare in spam. We present a counterattack strategy that attempts to differentiate spam from legitimate email in the input space by transforming each email into a bag of multiple segments, and subsequently applying multiple instance logistic regression on the bags. We treat each segment in the bag as an instance. An email is classified as spam if at least one instance in the corresponding bag is spam, and as legitimate if all the instances in it are legitimate. We show that a classifier using our multiple instance counterattack strategy is more robust to good word attacks than its single instance counterpart and other single instance learners commonly used in the spam filtering domain.

Keywords: spam filtering, multiple instance learning, good word attack, adversarial learning

1. Introduction

It has been nearly thirty years since the first email spam appeared on the Arpanet. Today, to most end users, spam does not seem to be a serious threat due to the apparent effectiveness of current spam filters. Behind the scenes, however, is a seemingly never-ending battle between spammers and spam fighters. With millions of email users, profit-driven spammers have great incentives to spam. With as little as 0.001% response rate, a spammer could potentially profit $25,000 on a $50 product (Carpinter and Hunt, 2006). Over the years, spammers have grown in sophistication with cutting-edge technologies and have become more evasive. The best evidence of their growing effectiveness is a recent estimate of over US $10 billion worldwide spam-related cost (Jennings, 2005). In this paper, we target one of the adversarial techniques spammers often use to circumvent existing spam filters.

Adversarial attacks on spam filters have become an increasing challenge to the anti-spam community. The good word attack (Lowd and Meek, 2005b) is one of the techniques most frequently employed by spammers. This technique involves appending sets of so-called "good words" to spam messages. Good words are words that are common to legitimate emails (also called ham) but rare in spam. Spam messages injected with such words are more likely to appear legitimate and bypass spam filters. So far, relatively little research has been done to investigate how spam filters might be

trained to account for such attacks. This paper presents a possible defense strategy using multiple instance learning that has shown promising results in our experiments.

Multiple instance (MI) learning (Dietterich et al., 1997) differs from single instance supervised learning in that an example is represented by a set, or bag, of instances rather than as just a single instance. The bag is assigned a class label (either *positive* or *negative*) based on the instances it contains; however, the instances within the bag are not necessarily labeled. Classic MI learning assumes that a bag is positive if at least one instance in the bag is positive, and negative if all instances are negative. Therefore, the goal of multiple instance learning is to learn a classification function that accurately maps a given bag to a class. Formally, let $B = \{B_1, \ldots, B_i, \ldots, B_m\}$ be a set of bags where $B_i = \{X_{1i}, X_{2i}, \ldots, X_{ji}\}$ is the i^{th} bag and $X_{1i}, X_{2i}, \ldots, X_{ji}$ are the j instances contained in bag B_i. If B is a training set, then every $B_i \in B$ also has a class label $c_i \in C = \{positive, negative\}$ associated with it. The training process, using B as input, yields a binary classification function $f(B_i) : B \rightarrow C$ that maps a bag to a class label.

Our spam filtering strategy adopts the classical MI assumption, which states that a bag is positive if at least one of its instances is positive, and negative if all instances are negative. We treat each email as a bag of instances. Thus, an email is classified as spam if at least one instance in the corresponding bag is spam, and as legitimate if all the instances in it are legitimate. The idea is that by splitting an email into multiple instances, a multiple instance learner will be able to recognize the spam part of the message even if the message has been injected with good words. Our experimental results show that a multiple instance learner, combined with an appropriate technique for splitting emails into multiple instance bags, is more robust to good word attacks than its single instance counterpart and other single instance learners that are commonly used in the spam filtering domain.

The remainder of this paper is organized as follows. First, we discuss recent research that has motivated our work. Next, we formalize the spam filtering problem as a multiple instance learning problem and explain our proposed counterattack strategy in more detail. Following that, we present our experimental results to demonstrate the effectiveness of our filtering strategy. Finally, we conclude our work and discuss future directions.

2. Related Work

Our work is primarily motivated by recent research on adversarial learning (Dalvi et al., 2004; Lowd and Meek, 2005a; Kolter and Maloof, 2005). Dalvi et al. (2004) consider classification to be a game between classifiers and adversaries in problem domains where adversarial attacks are expected. They model the computation of the adversary's optimal strategy as a constrained optimization problem and approximate its solution based on dynamic programming. Subsequently, an optimal classifier is produced against the optimal adversarial strategy. Their experimental results demonstrate that their game-theoretic approach outperforms traditional classifiers in the spam filtering domain. However, in their adversarial classification framework, they assume both the classifier and the adversary have perfect knowledge of each other, which is unrealistic in practice.

Instead of assuming the adversary has perfect knowledge of the classifier, Lowd and Meek (2005a) formalized the task of adversarial learning as the process of reverse engineering the classifier. In their adversarial classifier reverse engineer (ACRE) framework, the adversary aims to identify difficult spam instances (the ones that are hard to detect by the classifier) through membership queries. The goal is to find a set of negative instances with minimum adversarial cost within a polynomial number of membership queries.

Newsome et al. (2006) emphasize the point that the training data used to build classifiers for spam filtering and the similar problem of internet worm detection is, to a large extent, controlled by an adversary. They describe and demonstrate several attacks on the generators of such classifiers in which the adversary is able to significantly impair the learning of accurate classifiers by manipulating the training data, even while still providing correct labels for the training instances. The attacks involve inserting features, in a specific manner, into one or both classes of the training data and are specifically designed to cause a significant increase in false positives or false negatives for the resulting classifier. They conclude that the generation of classifiers for adversarial environments should take into account the fact that training data is controlled by an adversarial source in order to ensure the production of accurate classifiers.

Barreno et al. (2006) explore possible adversarial attacks on machine learning algorithms from multiple perspectives. They present a taxonomy of different types of attacks on machine learning systems. An attack is *causative* if it targets the training data, and is *exploratory* if it aims to discover information through, for example, offline analysis. An attack is *targeted* if it focuses on a small set of points, and is *indiscriminate* if it targets a general class of points. An *integrity* attack leads to false negatives, and an *availability* attack aims to cause (machine learning) system dysfunction by generating many false negatives and false positives. They also discuss several potential defenses against those attacks, and give a lower bound on the adversary's effort in attacking a naïve learning algorithm.

A practical example of adversarial learning is learning in the presence of the good word attack. Lowd and Meek (2005b) present and evaluate several variations of this type of attack on spam filters. They demonstrate two different ways to carry out the attack: passively and actively. Active good word attacks use feedback obtained by sending test messages to a spam filter in order to determine which words are "good". The active attacks were found to be more effective than the passive attacks; however, active attacks are generally more difficult to perform than passive attacks because they require user-level access to the spam filter, which is not always possible. Passive good word attacks, on the other hand, do not involve any feedback from the spam filter, but rather, guesses are made as to which words are considered good. Three common ways for passively choosing good words are identified. First, *dictionary attacks* involve selecting random words from a large collection of words, such as a dictionary. In testing, this method did not prove to be effective; in fact, it actually increased the chances that the email would be classified as spam. Next, *frequent word attacks* involve the selection of words that occur most often in legitimate messages, such as news articles. This method was more effective than the previous one, but it still required as many as 1,000 good words to be added to the original message. Finally, *frequency ratio attacks* involve the selection of words that occur very often in legitimate messages but not in spam messages. The authors' tests showed that this technique was quite effective, resulting in the average spam message being passed off as legitimate by adding as few as 150 good words to it. Preliminary results were also presented that suggested that frequent retraining on attacked messages may help reduce the effect of good word attacks on spam filters.

Webb et al. (2005) also examined the effectiveness of good word attacks on statistical spam filters. They present a "large-scale evaluation" of the effectiveness of the attack on four spam filters: naïve Bayes, support vector machine (SVM), LogitBoost, and SpamProbe. Their experiments were performed on a large email corpus consisting of around a million spam and ham messages, which they formed by combining several public and private corpora. Such a large and diverse corpus more closely simulates the environment of a server-level spam filter than a client-level filter. The

experimental results show that, on normal email, that is, email that has not been modified with good words, each of the filters is able to attain an accuracy as high as 98%. When testing on "camouflaged messages", however, the accuracies of the filters drop to between 50% and 75%. In their experiments, spam emails were camouflaged by combining them with portions of legitimate messages. They experimented with camouflaged messages containing twice as much spam content as legitimate content, and vice versa. They also proposed and demonstrated a possible solution to the attack. By training on a collection of emails consisting of half normal and half camouflaged messages, and treating all camouflaged messages as spam, they were able to improve the accuracy of the filters when classifying camouflaged messages.

Our counterattack strategy against good word attacks is inspired by work in the field of multiple instance (MI) learning. The concept of MI learning was initially proposed by Dietterich et al. (1997) for predicting drug activities. The challenge of identifying a drug molecule that binds strongly to a target protein is that a drug molecule can have multiple conformations, or shapes. A molecule is positive if at least one of its conformations binds tightly to the target, and negative if none of its conformations bind well to the target. The problem was tackled with an MI model that aims to learn axis-parallel rectangles (APR). Later, learning APR in the multiple instance setting was further studied and proved to be NP-complete by several other researchers in the PAC-learning framework (Auer, 1997; Long and Tan, 1998; Blum and Kalai, 1998).

Several probabilistic models: Diverse Density (DD) (Maron and Lozano-Pérez, 1998) and its variation EM-DD (Zhang and Goldman, 2002), and multiple instance logistic regression (MILR) (Ray and Craven, 2005), employ a maximum likelihood estimation to solve problems in the MI domain. The original DD algorithm searches for the target concept by finding an area in the feature space with maximum diverse density, that is, an area with a high density of positive points and a low density of negative points. The diverse density at a point in the feature space is defined to measure probabilistically how many different positive bags have instances near that point, and how far the negative instances are from that point. EM-DD combines EM with the DD algorithm to reduce the multiple instance learning problem to a single-instance setting. The algorithm uses EM to estimate the instance in each bag which is most likely to be the one responsible for the label of the bag. The MILR algorithm presented by Ray and Craven (2005) is designed to learn linear models in a multiple instance setting. Logistic regression is used to model the posterior probability of the label of each instance in a bag, and the bag level posterior probability is estimated by using softmax to combine the posterior probabilities over the instances of the bag. Similar approaches with different combining functions are presented by Xu and Frank (2004).

Many single-instance learning algorithms have been adapted to solve the multiple instance learning problem. For example, Wang and Zucker (2000) propose the lazy MI learning algorithms, namely Bayesian-*k*NN and citation-*k*NN, which solve the multiple instance learning problem by using the Hausdorff distance to measure the distance between two bags of points in the feature space. Chevaleyre and Zucker (2001) propose the multi-instance decision tree ID3-MI and decision rule learner RIPPER-MI by defining a new multiple instance entropy function and a multiple instance coverage function. Other algorithms that have been adapted to multiple instance learning include the neural network MI-NN (Ramon and Raedt, 2000), DD-SVM (Chen and Wang, 2004), MI-SVM and mi-SVM (Andrews et al., 2003), multi-instance kernels (Gärtner et al., 2002), MI-Ensemble (Zhou and Zhang, 2003), and MI-Boosting (Xu and Frank, 2004).

In this paper, we demonstrate that a counterattack strategy against good word attacks, developed in the framework of multiple instance learning, can be very effective, provided that a single instance

can be properly transformed into a bag of instances. We also explore several possible ways to transform emails into bags of instances. Our experiments also verify earlier observations, discussed in other works (Lowd and Meek, 2005b; Webb et al., 2005), that retraining on emails modified during adversarial attacks may improve the performance of the filters against the attack.

3. Problem Definition

Consider a standard supervised learning problem with a set of training data $D = \{< X_1, Y_1 >, \ldots, < X_m, Y_m >\}$, where X_i is an instance represented as a single feature vector, $Y_i = C(X_i)$ is the target value of X_i, where C is the target function. Normally, the task is to learn C given D. The learning task becomes more difficult when there are adversaries who could alter some instance X_i so that $X_i \rightarrow X_i'$ and cause $Y_i \rightarrow Y_i'$, where $Y_i \neq Y_i'$. Let ΔX_i be the difference between X_i and X_i', that is, $X_i' = X_i + \Delta X_i$. In the case of spam filtering, an adversary can modify spam emails by injecting them with good words. So, ΔX_i represents a set of good words added to a spam message by the spammer. There are two cases that need to be studied separately:

1. the filter is trained on normal emails, that is, emails that have not been injected with good words, and tested on emails which have been injected with good words;

2. both the training and testing sets contain emails injected with good words.

In the first case, the classifier is trained on a clean training set. Predictions made for the altered test instances are highly unreliable. In the second case, the classifier may capture some adversarial patterns as long as the adversaries consistently follow a particular pattern.

In both cases, the problem becomes trivial if we know exactly how the instances are altered; we could recover the original data and solve the problem as if no instances were altered by the adversary. In reality, knowing exactly how the instances are altered is impossible. Instead, we seek to approximately separate X_i and ΔX_i and treat them as separate instances in a bag. We then apply multiple instance learning to learn a hypothesis defined over a set of bags.

4. Multiple Instance Bag Creation

We now formulate the spam filtering problem as a multiple instance binary classification problem in the context of adversarial attacks. Note that the adversary is only interested in altering positive instances, that is, spam, by injecting sets of good words that are commonly encountered in negative instances, that is, legitimate emails, or ham. We propose four different approaches to creating multiple instance bags from emails. We call them split-half (split-H), split-term (split-T), split-projection (split-P), and split-subtraction (split-S). We will now discuss each of these splitting methods, in turn. Later, in Section 8, we investigate and discuss possible weaknesses of some of these splitting methods.

4.1 Split-H

The first and simplest splitting method that we considered, which we call *split-half* (split-H), involves splitting an email down the middle into approximately equal halves. Formally, let $B = \{B_1, \ldots, B_i, \ldots, B_m\}$ be a set of bags (emails), where $B_i = \{X_{i1}, X_{i2}\}$ is the i^{th} bag, and X_{i1}, X_{i2} are

the two instances in the i^{th} bag created from the upper half and the lower half of the email respectively. This splitting approach is reasonable in practice because spammers usually append a section of good words to either the beginning or the end of an email to ensure the legibility of the spam message. As will be discussed in Section 8, this splitting method, because it relies on the positions of words in an email, could potentially be circumvented by the spammer. The next three splitting methods do not rely on the positions of the words and thus do not suffer from that problem.

4.2 Split-T

The second splitting method, *split-term* (split-T), partitions a message into three groups of words (terms) depending on whether the word is an indicator of spam, an indicator of ham, or neutral, that is, $B_i = \{X_{is}, X_{in}, X_{ih}\}$, where X_{is} is the spam-likely instance, X_{in} is the neutral instance, and X_{ih} is the ham-likely instance in bag B_i. The instance to which each word is assigned is based on a weight generated for it during preprocessing. These weights are calculated using word frequencies obtained from the spam and legitimate messages in the training corpus. More specifically, the weight of a term W is given as follows:

$$weight(W) = \frac{p(W \mid D_s)}{p(W \mid D_s) + p(W \mid D_h)},$$

where D_s and D_h are the spam and ham emails in the training set respectively. When splitting an email into instances we used two threshold values, $thresh_s$ and $thresh_\ell$, to determine which instance (spam-likely, ham-likely, or neutral) each word in the email should be assigned to, given its weight. We considered any word with a weight greater than $thresh_s$ to be spammy, any word with a weight less than $thresh_\ell$ to be legitimate, and any word with a weight in between to be neutral. In our experiments, reasonable threshold values were determined by using cross-validation on training emails. Given each training set, $thresh_s$ was selected such that some fraction of the terms chosen during attribute selection (discussed in Section 6.2) would have a weight greater than or equal to it. $thresh_\ell$ was selected so that some other fraction of the terms would have a weight less than or equal to it.

4.3 Split-P

The third splitting method, *split-projection* (split-P), transforms each message into a bag of two instances by projecting the message vector onto the spam and ham prototype vectors. The prototype vectors are computed using all the spam and ham messages in the training set. If we view the spam and ham messages in the training set as two clusters, then the prototypes are essentially the centroid of the two clusters. More specifically, let C_s be the set of emails that are spam and C_ℓ be the set of emails that are legitimate. The prototypes are computed using Rocchio's algorithm (Rocchio Jr., 1971) as follows:

$$P_s = \beta \cdot 1/|C_s| \cdot \sum_{i=1}^{|C_s|} C_{s_i} - \gamma \cdot 1/|C_\ell| \cdot \sum_{i=1}^{|C_\ell|} C_{\ell_i},$$

$$P_\ell = \beta \cdot 1/|C_\ell| \cdot \sum_{i=1}^{|C_\ell|} C_{\ell_i} - \gamma \cdot 1/|C_s| \cdot \sum_{i=1}^{|C_s|} C_{s_i}$$

where C_{s_i} is the i^{th} spam message in C_s and C_{ℓ_i} is the i^{th} ham message in C_ℓ, β is a fixed constant suggested to be 16 and γ is a fixed constant suggested to be 4. Given a message M, two new

instances, M_S and M_ℓ, are formed by projecting M onto P_s and P_ℓ:

$$M_s = \frac{M \cdot P_s}{|P_s|^2} P_s,$$
$$M_\ell = \frac{M \cdot P_\ell}{|P_\ell|^2} P_\ell.$$

The rationale of this splitting approach rests on the assumption that a message is close to the spam prototype in terms of cosine similarity if it is indeed spam, and a ham message is close to the ham prototype.

4.4 Split-S

The last splitting method, *split-subtraction* (split-S), like the former, uses prototype (centroid) vectors. In this method, however, the ham and spam prototypes are calculated by averaging the corresponding attribute values of all of the ham and spam emails, respectively:

$$P_s = 1/|C_s| \cdot \sum_{i=1}^{|C_s|} C_{s_i},$$
$$P_\ell = 1/|C_\ell| \cdot \sum_{i=1}^{|C_\ell|} C_{\ell_i}.$$

where C_s is a set of spam and C_{s_i} is the i^{th} spam message in C_s; C_ℓ is a set of ham, and C_{ℓ_i} is the i^{th} ham message in C_ℓ. A message can then be transformed from a single instance attribute vector M into a bag of two instances by subtracting corresponding attribute values in the single instance vector from the ham prototype and the spam prototype, yielding a legitimate instance $M_\ell = M - P_\ell$ and a spam instance $M_s = M - P_s$, respectively (Zhang and Zhou, 2007).

Now that we have devised several techniques for creating multiple instance bags from email messages, we can transform the standard supervised learning problem of spam filtering into a multiple instance learning problem under the standard MI assumption. In this paper, we adopt the multiple instance logistic regression (MILR) model to train a spam filter that is more robust to adversarial good word attacks than traditional spam filters based on single instance models. We chose to use the MILR classifier over other MI classifiers mainly because its single instance counter-part, logistic regression (LR), which has been shown to be very effective in the spam filtering domain (Yih et al., 2006), appeared to be the best among the single instance learners considered in our experiments. The next section outlines multiple instance logistic regression.

5. Multiple Instance Logistic Regression

Given a set of training bags

$$B = \{< B_1, Y_1 >, \ldots, < B_i, Y_i >, \ldots, < B_m, Y_m >\},$$

let $Pr(Y_i = 1 \mid B_i)$ be the probability that the i^{th} bag is positive, and $Pr(Y_i = 0 \mid B_i)$ be the probability that it is negative. Here Y_i is a dichotomous outcome of the i^{th} bag (for example, spam or legitimate). The bag-level binomial log-likelihood function is:

$$L = \sum_{i=1}^{m} [Y_i \log Pr(Y_i = 1|B_i) + (1 - Y_i) \log Pr(Y_i = 0|B_i)].$$

In a single instance setting where logistic regression is used, given an example X_i, we model the expected value of the dichotomous outcome of X_i with a sigmoidal response function, that is, $Pr(Y_i = 1 \mid X_i) = \exp(p \cdot X_i + b)/(1 + \exp(p \cdot X_i + b))$, then estimate the parameters p and b that maximize the log-likelihood function. In a multiple instance setting, we do not have direct measure of bag-level probabilities in the log-likelihood function. However, since individual instances in the bags can also be considered as binary response data, we estimate the instance-level class probabilities $Pr(Y_{ij} = 1 \mid X_{ij})$ with a sigmoidal response function as follows:

$$Pr(Y_{ij} = 1 \mid X_{ij}) = \frac{\exp(p \cdot X_{ij} + b)}{1 + \exp(p \cdot X_{ij} + b)},$$

where X_{ij} is the j^{th} instance in the i^{th} bag, and p and b are the parameters that need to be estimated. Thus $Pr(Y_i = 0 \mid B_i)$ with instance-level class probabilities can be computed as follows:

$$Pr(Y_{ij} = 0 \mid X_{ij}) = \frac{1}{1 + \exp(p \cdot X_{ij} + b)}.$$

Now we can compute the probability that a bag is negative as:

$$\begin{aligned} Pr(Y_i = 0 \mid B_i) &= \prod_{j=1}^{n} Pr(Y_{ij} = 0 \mid X_{ij}) \\ &= \exp(-\sum_{j=1}^{n} (\log(1 + \exp(p \cdot X_{ij} + b)))) \end{aligned}$$

where n is the number of instances in the i^{th} bag. Note that this probability estimate encodes the multiple instance assumption, that is, a bag is negative if and only if every instance in the bag is negative, and thus the probability estimate

$$Pr(Y_i = 1 \mid B_i) = 1 - Pr(Y_i = 0 \mid B_i)$$

encodes that a bag is positive if at least one instance in the bag is positive. In our case, given a set of emails for training, X_{ij} is a vector of the frequency counts (or other variations such as a *tf-idf* weight) of unique terms in each email. We can apply maximum likelihood estimation (MLE) to maximize the bag-level log-likelihood function, and estimate the parameters p and b that maximize the probability of observing the bags in B.

6. Experimental Setup

We evaluated our multiple instance learning counterattack strategy on emails from the 2006 TREC Public Spam Corpus (Cormack and Lynam, 2006). Good word attacks were simulated by generating a list of good words from the corpus and injecting them into spam messages in the training and/or test data sets. We compared our counterattack strategy, using the multiple instance logistic regression model and the four splitting methods introduced above, to its single instance learning

counterpart—logistic regression (LR)—and to the support vector machine (SVM) and the multinomial naïve Bayes (MNB) classifiers. Additionally, we tested a relatively new compression-based spam filter (Bratko and Filipič, 2005) against the good word attack. The information in the next two subsections regarding corpus preprocessing and feature selection and weighting does not apply to the compression-based filter; it will be discussed separately in Section 7.3.

6.1 Experimental Data

Our experimental data consists of 36,674 spam and legitimate email messages from the 2006 TREC spam corpus. We preprocessed the entire corpus by stripping HTML and non-textual parts and applying stemming and stop-list to all terms. The **to**, **from**, **cc**, **subject**, and **received** headers were retained, while the rest of the headers were stripped. Messages that had an empty body after preprocessing were discarded. Tokenization was done by splitting on nonalphanumeric characters. We did not take any measures to counter obfuscated words in the spam messages, as that is out of the scope of this paper. Given that there are a large number of possible ways to disguise a word, most content-based spam filters will not be able to deobfuscate the text of a message efficiently (Carpinter and Hunt, 2006). Recently, an efficient complementary filter (Lee and Ng, 2005) has been demonstrated to be able to effectively deobfuscate text with high accuracy. In practice, this type of technique could be used during preprocessing.

For our experiments we sorted the emails in the corpus chronologically by receiving date and evenly divided them into 11 subsets $\{D_1, \ldots, D_{11}\}$. In other words, the messages in subset n come chronologically before the messages in subset $n+1$. Experiments were run in an on-line fashion, that is, training on subset n and testing on subset $n+1$. Each subset contains approximately 3300 messages. The percentage of spam messages in each subset varies as in the operational setting (see Figure 1). We used the Multiple Instance Learning Tool Kit (MILK) (Xu, 2003) implementation of MILR and the Weka 3.4.7 (Witten and Frank, 2000) implementations of LR, SVM and multinomial naïve Bayes, in our experiments. For the compression-based filter, we used the spam filter described in Bratko and Filipič (2005), which uses the prediction by partial matching algorithm with escape method D (PPMD) and is available as part of the PSMSLib C++ library (Bratko, 2008).

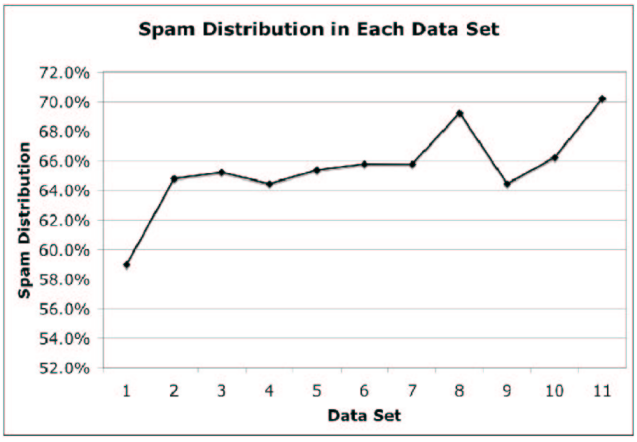

Figure 1: Percentage of emails in each data set that are spam.

6.2 Feature Selection and Weighting

We reduced the feature space used to describe the emails in our experiments to the top 500 features ranked using information gain. Feature selection is necessary for reasons of efficiency and for avoiding the curse of dimensionality. It is also common practice in the spam filtering domain. In our experiments, retaining 500 features appeared to be the best compromise among the classifiers in terms of improved efficiency and impaired performance. Figure 2 shows how the performance of the classifiers varies as the number of retained features increases.

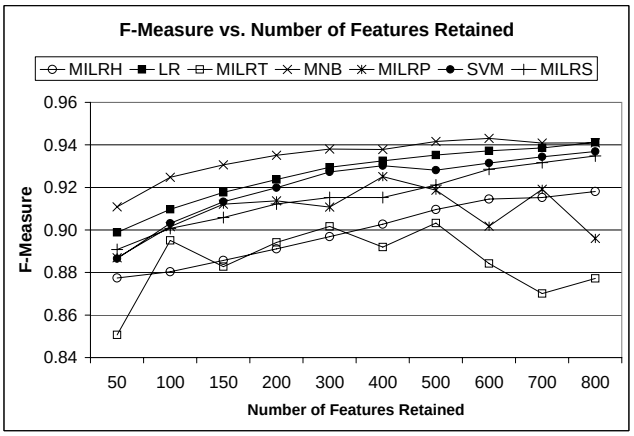

Figure 2: Effect of number of retained features on f-measure.

Attribute values for each email were calculated using the common *tf-idf* (term frequency inverse document frequency) weighting scheme. Under this weighting scheme, attributes are assigned a weight that corresponds to their importance to the email message in the corpus that contains them. The tf-idf weight for a given term in a given email is calculated as follows. Let f be the number of occurrences of the given term in the given email, the *term frequency*. We normalize f by dividing it by the maximum value of f for the given term over all emails in the corpus. Let tf be the normalized value of f. The *inverse document frequency*, idf, is $\log_2(\frac{a}{b})$ where a is the total number of emails in the corpus and b is the number of emails in the corpus that contain the given term. Then the *weight* for the given term is $w = tf \times idf$. Note that tf-idf weighting is widely used in information retrieval and text mining, and has been shown to be able to greatly improve the performance of multinomial naïve Bayes in several text categorization tasks (Kibriya et al., 2004).

6.3 Good Word List Creation

The good word list used in our simulated good word attacks was generated in two different ways: 1) the *global* good word list was generated using all 36,674 messages in the 2006 Trec corpus, 2) and the *local* good word list was generated using messages in the current training set. When generating the global good word list, we ranked every unique word in the corpus according to the ratio of its frequency in the legitimate messages over its frequency in the spam messages. We then selected the top 1,000 words from the ranking to use as our good word list. Generating the good word list in this manner has an important implication. Since the list was generated from the entire corpus rather than from the subset of messages used to train the classifiers, and since we represent emails using a feature vector of 500 features, some of the words in the list will not have an effect

on the classification of messages that they are injected into. Such a list is more representative of the kind of list a spammer would be able to produce in practice, since the spammer would have no way of knowing the exact features used by the target filter. We noticed that in our experiments, only about 10% of the injected good words were actually retained in the feature vector, yet they had a significant impact on the classification. Nevertheless, we also tested the extreme case in which we assumed the adversary has perfect knowledge of the training set and the selected features. We created a local good word list from messages in each training set and kept only the words that are in the selected feature vector.

6.4 Threshold Values for Split-Term

The two threshold values, $thresh_s$ and $thresh_\ell$, must be determined for the splitting method split-term. As mentioned earlier, for each training set, $thresh_s$ was selected such that some fraction of the terms chosen would have a weight greater than or equal to it. $thresh_\ell$ was selected so that some other fraction of the terms would have a weight less than or equal to it. For each of the ten training sets we selected, by using 5-fold cross validation, the best threshold values that divide the terms into three categories—spam, ham, and neutral.

The selected thresholds were used for testing on the test set. Table 1 lists the percentages of the terms divided by the thresholds selected for each training set.

Subset	% of terms with weights $\geq thresh_s$	% of terms with weights $\leq thresh_\ell$
1	20%	50%
2	20%	50%
3	30%	50%
4	10%	50%
5	20%	50%
6	20%	50%
7	10%	50%
8	10%	50%
9	30%	50%
10	30%	50%

Table 1: Percentages of the terms divided by the MILRT threshold values selected for each training set.

7. Experimental Results

We now present the results of two experiments in which we evaluate the effectiveness of our proposed multiple instance counterattack strategy. In the first experiment, we train all of the classifiers on normal email (that is, email that has not been injected with good words) and then test them on email that has been injected with good words. In the second experiment we train on both normal and attacked emails to observe how doing so affects classification of both normal and attacked emails. The compression-based filter and its susceptibility to the good word attack are examined separately in Section 7.3.

7.1 Experiment 1: Attacking the Test Set

In this experiment, we tested the ability of the MILR algorithm, using the four splitting methods introduced above, to classify email injected with good words. We also tested the single instance logistic regression (LR), support vector machine (SVM) and multinomial naïve Bayes (MNB) classifiers for comparison. The classifiers were each trained and tested on the eleven chronologically sorted data sets in an on-line fashion. That is, all of the classifiers were trained on the same unaltered data set D_n, and then tested on the data set D_{n+1}, for $n = 1...10$. Fifteen variations of each test set were created to test the susceptibility of the classifiers to good word attacks of varying strengths. The first version of each test set was left unmodified, that is, no good words were injected. Half of the spam messages (selected at random) in each of the remaining 14 variations of each test set were injected with some quantity of random good words from our global good word list, beginning with 10 words. With each successive version of the test set, the quantity of good words injected into half of the spam messages was increased: first in increments of 10 words, up to 50, and then in increments of 50 words up to 500. The injected words were randomly selected, without replacement, from our global good word list on a message by message basis. We chose to inject good words into only half of the messages in each test set because, in practice, spam messages injected with good words account for only a subset of the spam emails encountered by a given filter. The precision of each classifier was fixed at 0.9 and the corresponding recall on each version of the test set for all 10 test sets was averaged and recorded for each classifier. In our results, we use "MILRH", "MILRT", "MILRP" and "MILRS" where split-H, split-T, split-P and split-S were used with MILR, respectively.

Figure 3 shows how the average recall of each classifier is affected as the good word attack increases in strength (that is, the quantity of good words injected into the spam emails increases). Figures 4-7 and Table 2 show the ROC curves and corresponding AUC values, respectively, for each classifier as the good words are injected. Each ROC graph contains six curves, each corresponding to a specific quantity of good words. We chose not to include curves for all quantities of good words in order to keep the graphs readable. To make comparison easier, Figure 8 shows two ROC graphs containing the ROC curves of all the classifiers when 0 words and 500 words are added to the test set respectively. ROC graphs show the tradeoffs between true positives and false positives and are commonly used to visualize the performance of classifiers (Fawcett, 2006). The total area under a ROC curve (AUC) is also commonly used as a metric to compare classifiers. The AUC of a spam classifier can be interpreted as the probability that the classifier will rate a randomly chosen spam email as more spammy than a randomly chosen legitimate email. In our results, each ROC curve shown is an average of the curves resulting from the ten subsets. The curves were averaged using the vertical averaging algorithm given by Fawcett (2006).

From the results we can see that, with the exception of MILRT, the good word attack significantly affected the ability of each classifier to identify spam emails. MILRT was the most resilient of all the classifiers to the attack, dropping by only 3.7% (from 0.963 to 0.927) in average recall after 500 good words had been added to the spam messages. MILRH and MILRP stood up better to the attack than the single instance classifiers and the MILRS classifier, but the attack still had a very noticeable effect on their ability to classify spam, reducing the average recall of MILRH by 30.8% (from 0.972 to 0.673) and the average recall of MILRP by 35.3% (from 0.938 to 0.607). Of the single instance classifiers, LR was the most resilient; however, the attack still had a very significant effect on its ability to classify spam, reducing its average recall by 42.5% (from 0.986 to 0.567). The

0.531) respectively. MILRS turned out to be nearly as vulnerable to the attack as the single instance classifiers, dropping by 42% (from 0.974 to 0.565) in average recall.

One thing that is clear from these results is that the effectiveness of our multiple instance counterattack strategy is very much dependent on the specific technique used to split emails into multiple instance bags. The success of the split-term method is due to the fact that the classifier is able to consider both spammy and legitimate terms independently, since they are placed into separate instances in the bag created from an email. Under the multiple instance assumption, if at least one instance in a bag is spammy, the entire bag is labeled as spammy. When good words are injected into a spam message they end up in the legitimate instance of the bag and have no effect on the spammy instance; thus the bag still contains a spammy instance and is classified correctly as spam. We verified this by running the experiment again on the following classifier configurations: MILR with no splitting (single instance bags), MILRT with the neutral and hammy instances discarded from each bag, and LR with spammy terms only (all legitimate terms were excluded from the feature vector). We found that using MILR without any of the splitting methods (all bags contained a single instance), caused it to behave almost identically to the way LR behaved in experiment 1. We also found that discarding the neutral and hammy instances from the MILRT bags resulted in a classifier that was unaffected by the good word attack, but was only able to attain a maximum recall of 0.757 and a maximum precision of 0.906. Training LR on spammy terms only produced very similar results; it was unaffected by the good word attack, but only attained a maximum recall of 0.723 and a maximum precision of 0.931.

To test the extreme case, in which an adversary has perfect knowledge of the training set and the selected features, we repeated the experiment using a local good word list for each training set. The words in each of the local good word lists were generated from the respective training set and were

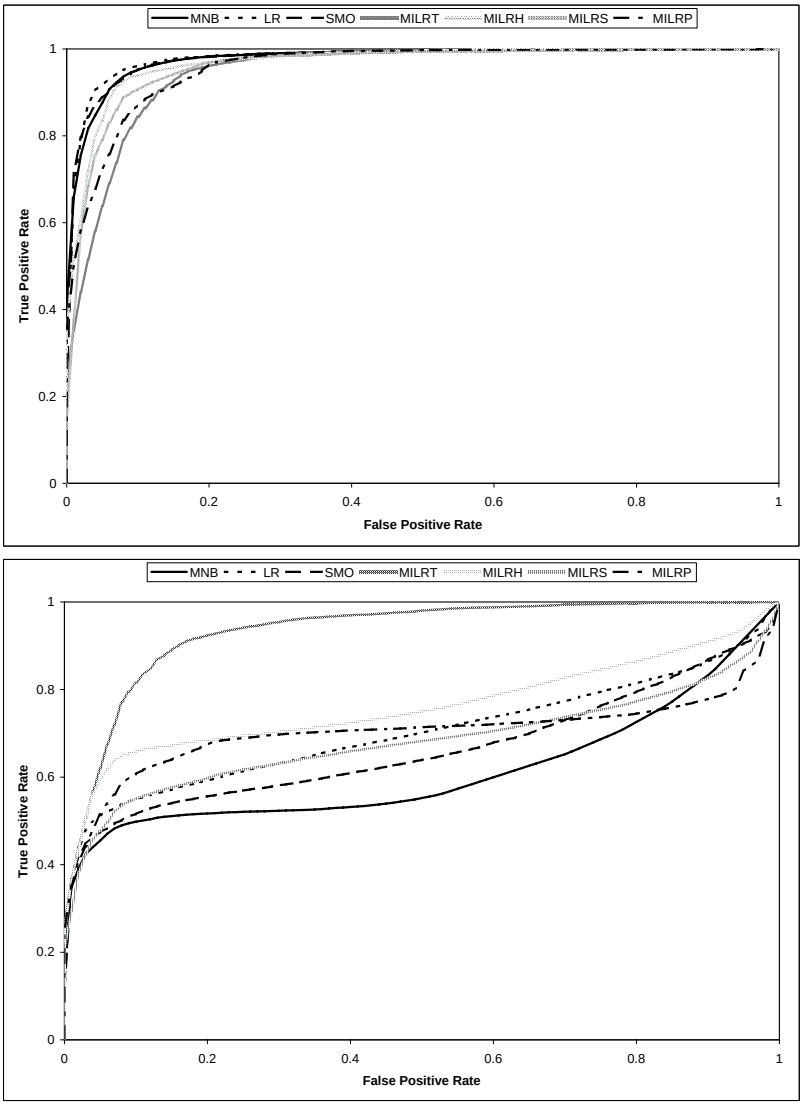

Figure 8: ROC curves for all classifiers when 0 words (top) and 500 words (bottom) have been injected into the test set.

limited to only those good words that were in the selected feature vector for the training set. For each corresponding test set, the entire contents of the local good word list were added to all of the spam messages in the set. Figure 9 shows the result of this attack on each of the classifiers in terms of precision and recall. MILR, with every splitting method, was more resilient to the attack than any of the single instance classifiers. MILRT again was most resilient to the attack. However, the effect of the attack was severe enough for all of the classifiers to consider them defeated for practical purposes. Although it is not realistic to assume that the adversary could obtain perfect knowledge of the target filter in practice, these results serve to illustrate the amount of damage a good word attack could potentially inflict on these classifiers in the extreme cases.

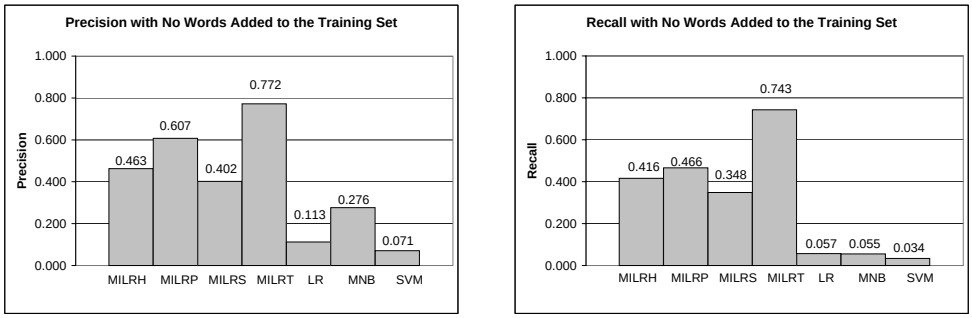

Figure 9: The average precision (left) and recall (right) of each classifier when injecting the entire local good word list into all of the spam messages in the test set.

7.2 Experiment 2: Training on Attacked Spam Messages

In the second experiment, our goal was to observe the effect that training on messages injected with good words has on the susceptibility of the classifiers to attacks on the test set. As in the previous experiment, we tested each of the classifiers on the eleven chronologically sorted data sets in an on-line fashion. This time, however, in addition to creating 15 versions of the test set injected with increasing quantities of good words, we also created 5 versions of the training set. We injected 10 good words into half of the spam messages (selected at random) in the first version of the training set and then increased the number of injected good words by 10 for each subsequent version, up to 50 good words for the fifth version. We also tried injecting larger numbers of good words, but after exceeding 50 words, the additional effect was minimal; therefore, those results are not shown here. For each version of the training set we tested the classifiers on the 15 versions of the corresponding test set. As before, good words were selected from our global good word list randomly and without replacement on a message by message basis. For all ten tests, the precision of each classifier was fixed at 0.9 and the corresponding recall values on each version of the test set were averaged and recorded, separately for each of the 5 versions of the training set. Figures 10– 14 show the change in average recall as the number of good words injected into the training set increased from 10 to 50. Figure 15 shows two graphs containing the ROC curves of all the classifiers when 0 good words and 500 good words are added to the test set respectively and 10 good words are added to the training set. Figure 16 shows the same curves after 50 good words have been added to the training set.

Injecting just 10 good words into half of the spam messages in the training set appeared to lessen the effect of the good word attack for almost all of the classifiers. In particular, the average recall of LR with 500 good words injected into half of the spam messages in the test set was 32.1% higher after 10 good words had been injected into the training set compared to when no good words had been injected into the training set (comparing Figures 3 and 10). Likewise, the average recall values of MNB, SVM, MILRH, MILRP and MILRS were 32.6% higher, 29.4% higher, 10.1% higher, 26.9% higher and 25.8% higher respectively. The average recall for MILRT was actually 5.5% lower even though it was still the best among all the classifiers.

Increasing the number of good words injected into the training set from 10 to 20 (see Figure 11) continued to lessen the effect of the attack for all of the classifiers. After 30 good words had been injected into the training set, the presence of good words in the test messages actually began to increase the likelihood that such messages would be correctly classified as spam. These results

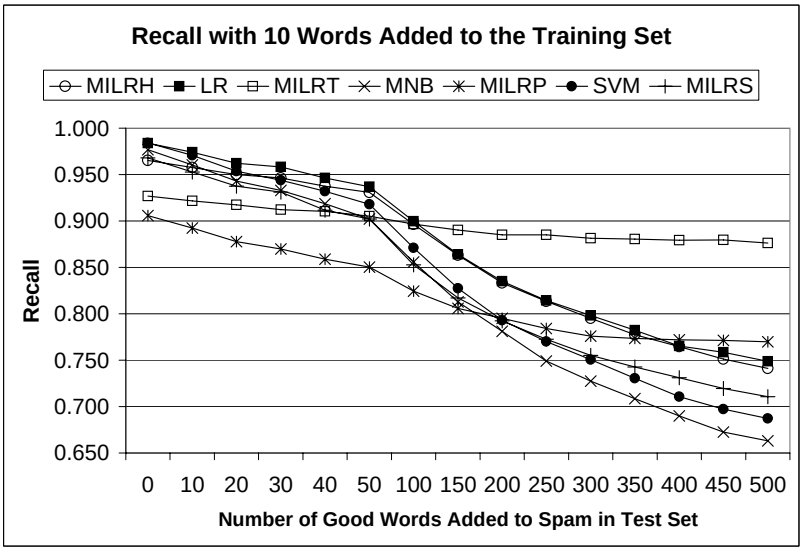

Figure 10: The change in average recall, corresponding to a fixed precision of 0.9, as the number of good words injected into half of the spam messages in the test set increases; 10 good words were also injected into half of the spam messages in the training set.

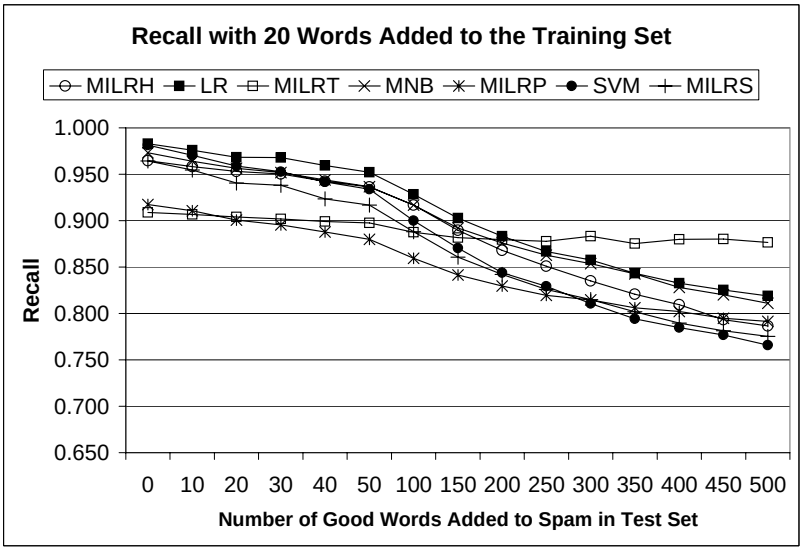

Figure 11: The change in average recall, corresponding to a fixed precision of 0.9, as the number of good words injected into half of the spam messages in the test set increases; 20 good words were also injected into half of the spam messages in the training set.

confirm the observations of several other researchers (Lowd and Meek, 2005b; Webb et al., 2005), that retraining on normal and attacked emails may help to counter the effects of the good word

attack. However, it is important to realize that this would only work in cases where the attacked messages being classified contained the same good words as the attacked messages that the spam filter was trained on. One of the major advantages of our proposed multiple instance strategy is that the spam filter need not be trained on attacked messages in order to be effective against attacks and further, that frequent retraining on attacked messages is not necessary for the strategy to maintain its effectiveness.

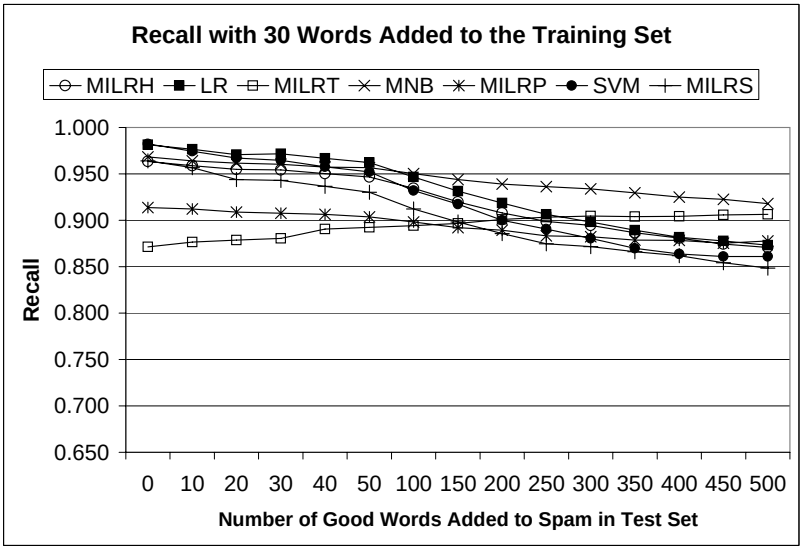

Figure 12: The change in average recall, corresponding to a fixed precision of 0.9, as the number of good words injected into half of the spam messages in the test set increases; 30 good words were also injected into half of the spam messages in the training set.

To test the extreme case, in which an adversary has perfect knowledge of the training set and the selected features, we repeated the experiment using local good word lists for each training set. The words in each of the local good word lists were generated from the respective training set and were limited to only those good words that were in the selected feature vector for the training set. The entire contents of the local good word list were added to all of the spam messages in the corresponding training and test sets. Figure 17 shows the result of this attack on each of the classifiers in terms of precision and recall. Notice that for every classifier, with the exception of multinomial naive Bayes, the effects of the attack on the training set were completely countered by adding the same words to the spam messages in the training set; however, we should again point out that these results are possible only because the good words added to the spam messages in the training and test sets were the same. In practice, there is no such guarantee.

7.3 Attacking the Compression-Based Filter

Relatively new to the spam filtering scene is the idea of using statistical data compression algorithms for spam filtering. Bratko and Filipič (2005) proposed and investigated the use of character-level data compression models for spam filtering. The general idea is to construct two compression models, one from a collection of spam emails and one from a collection of legitimate emails, and

then to classify a message according to which of the resulting models compresses the message more efficiently. Using statistical data compression for spam filtering has a number of advantages over machine learning algorithms that use word-level models. First, the compression algorithms work on the character level rather than the word level. For this reason, preprocessing and feature selection, both of which are highly prone to error, are unnecessary. Instead the algorithm is able to make full use of all message features. Another benefit of the character-level nature of the compression algorithms is that they are more robust to obfuscation. Spammers often disguise spammy words by deliberately misspelling them or by inserting punctuation between characters. This can cause

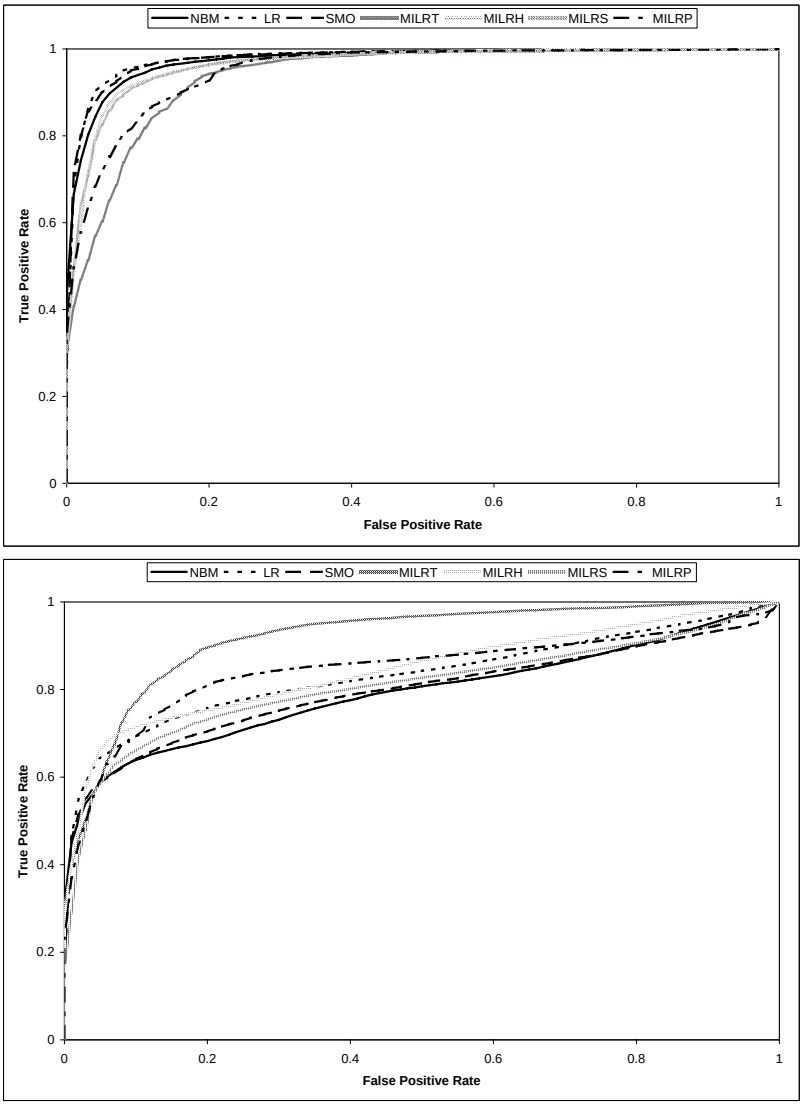

Figure 16: ROC curves for all classifiers when 0 good words (top) and 500 good words (bottom) have been injected into the test set and 50 good words have been injected into the training set.

a word-level spam filter to misclassify emails containing such words unless extra care and effort are expended to detect and deal with these obfuscations. Bratko and Filipič (2005) implemented their compression-based spam filter using the prediction by partial matching algorithm with escape method D (PPMD). Their experiments for the Trec 2005 spam track showed promising results. They also demonstrated that their filter was indeed quite robust to obfuscation. To our knowledge, however, the effects of the good word attack on such filters have not yet been investigated.

We repeated the two experiments from Sections 7.1 and 7.2 on the compression-based spam filter discussed by Bratko and Filipič (2005). Since preprocessing of the input corpus is unnecessary

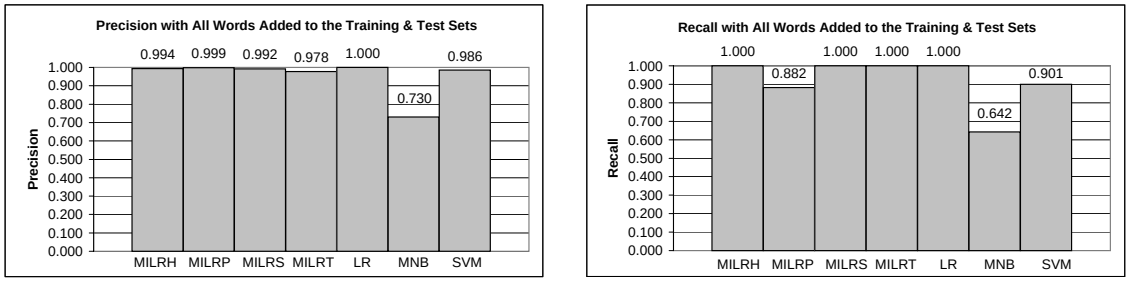

Figure 17: The average precision (left) and recall (right) of each classifier when injecting the entire contents of each local good word list into all of the spam messages in the corresponding training and test sets.

for this type of filter, we ran the experiments using the raw version of the corpus. However, we also ran the two experiments using the preprocessed corpus in order to observe how well the filter stood up against the attack using the same data available to the other filters. Figure 18 shows the results of the first experiment with the PPMD filter on the raw (PPMD1) and preprocessed (PPMD2) corpora. The attack had no effect on the precision of the filter, regardless of which version of the corpus was used; it remained consistently at 0.999 and is not shown on the chart. On the other hand, the recall suffered as a result of the attack, on both corpora. The decrease in recall on the preprocessed corpus was comparable to that of the single instance algorithms. When the raw corpus was used, however, the effect was much less severe. The compression-based filter implementation discussed by Bratko and Filipič (2005), which we used in these experiments, was set by default to truncate all messages to 2500 bytes, presumably for efficiency reasons. However, since our simulated attack appends good words to the bottom of the spam messages, it is possible that truncating the messages could result in some or all of the added good words being removed from spam messages that are longer than 2500 bytes. Therefore, we ran the experiment twice more, truncating at 5000 bytes and 10000 bytes. The result was a drop in average recall (when 500 good words are injected) to 0.702 when truncating at 5000 bytes and a drop to 0.627 when truncating at 10000 bytes, for PPMD1 (raw corpus) (see Figure 19). For PPMD2 (preprocessed corpus) the average recall dropped to 0.503 when truncating at 5000 bytes and dropped to 0.482 when truncating at 10000 bytes (see Figure 20). There was no additional drop in precision when truncating at 5000 or 10000 bytes.

Figure 21 shows the results of the second experiment on the PPMD filter, in terms of average recall, when 10 good words have been injected into the training set. Again, there was virtually no change in average precision so it is not shown on the charts. Apparently injecting 10 good words into the training set was enough to counter any number of good words in the test set. As figure 21 shows, the results of adding up to 50 good words to the training set are nearly identical.

Although it is difficult to directly compare the compression-based filter to the other filters discussed in this paper, due to differences in their modeling and preprocessing requirements, it is safe to say that the compression-based filter is susceptible to good word attacks. However, this type of filter also has a definite advantage over the other algorithms in that it is able to take advantage of message features that the other algorithms cannot easily use, making it more difficult to attack.

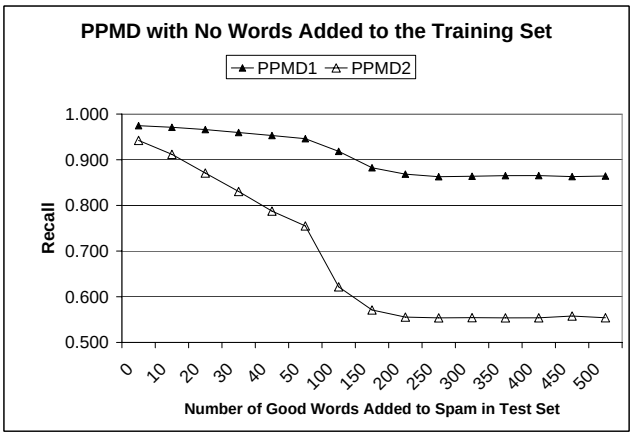

Figure 18: Effect of the good word attack on the PPMD algorithm as the number of good words added into half of the spam messages in the test set increases; no good words were added to the spam in the training set. Messages truncated at 2.5kB.

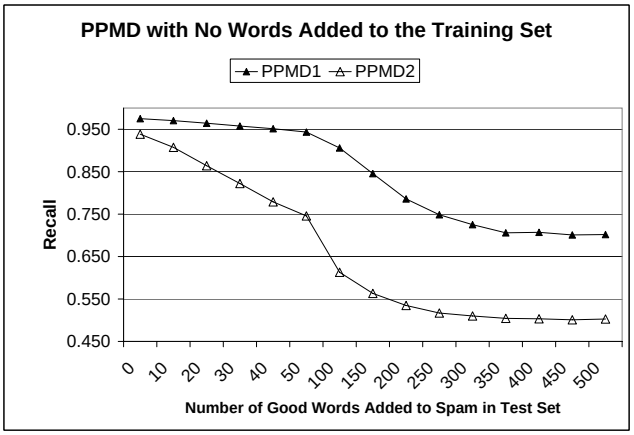

Figure 19: Effect of the good word attack on the PPMD algorithm as the number of good words added into half of the spam messages in the test set increases; no good words were added to the spam in the training set. Messages truncated at 5kB.

8. Potential Attacks on the Splitting Methods

In this section we investigate possible attacks on the splitting methods we have proposed. We recognized two possible ways for a spammer to attack a spam filter equipped with splitting methods like split-H. Both of the attacks work because split-H relies on how the words are physically positioned in an email to split it into multiple instances. One way to attack it is to create a visual pattern with good words so that the original spam message is still legible after the attack, but the spam is fragmented in such a way that "spammy" words are well separated. If this is done correctly, when

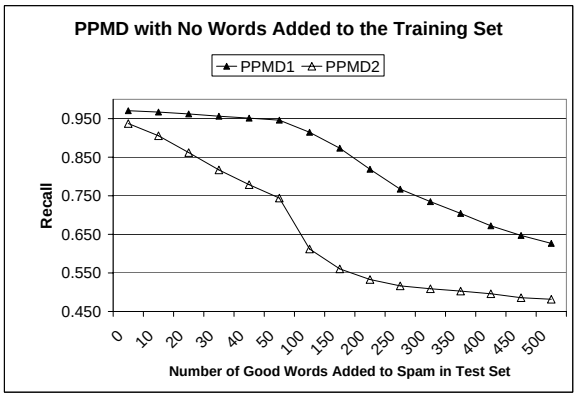

Figure 20: Effect of the good word attack on the PPMD algorithm when half of the spam messages in the test set were altered. Messages truncated at 10kB.

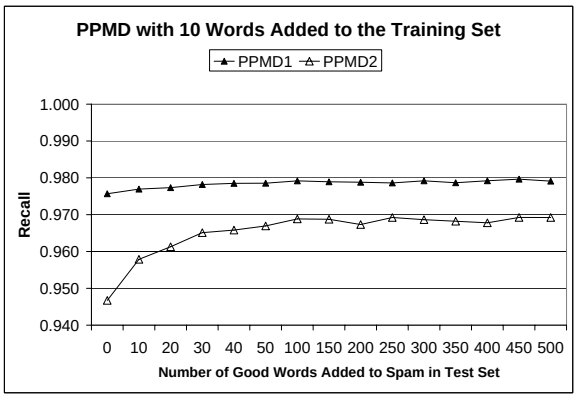

Figure 21: Effect of the good word attack on the PPMD algorithm when half of the spam in the training/test sets were altered; 10 words were added to the training spam.

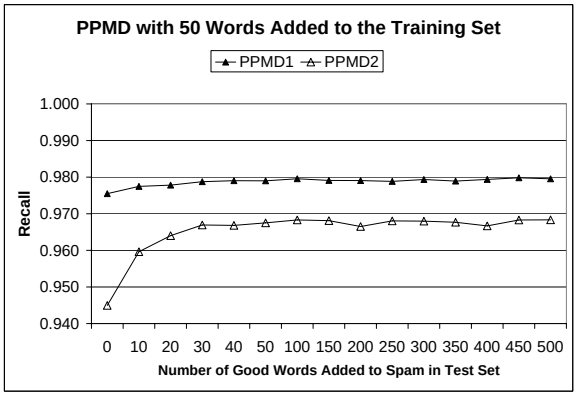

Figure 22: Effect of the good word attack on the PPMD algorithm when half of the spam in the training/test sets were altered; 50 words were added to the training spam.

the attacked message is split, good words should outweigh spammy words in both instances. The example in Table 3 illustrates the idea.

good words	...	**low**	...	good words
good words	...	**mortgage**	...	good words
good words	...	**rate**	...	good words

Table 3: Attacking split-H by fragmenting spam with injected good words.

We tested this attack by running MILRH (MILR with split-H) on the 11 data sets, with the test set at each iteration attacked with 500 good words in the following manner. 50% of the spam messages in each test set were selected at random to be attacked by inserting 3 random good words before and after every 6 words in the message. No more and no less than 500 words were inserted into any message, regardless of the length of the message. That is, in the case of short messages, after 3 good words were inserted before and after every 6 words of the message, words were added to the end of the message until a total of 500 words had been added. For long messages, once 500 words were added, the process was stopped. The good words were selected, without replacement, from the same global good word list used in the other experiments.

Figure 23 compares the effects of adding 500 good words to the messages in the manner just described to the effects of adding 500 good words by appending them to the end of the messages (as in experiment 1), in terms of the recall averaged over the ten tests (corresponding to a fixed precision of 0.9). As the figure shows, attacking the messages in the manner described here drastically decreases the effectiveness of split-H, reducing the average recall of MILRH by 24.8% to 0.506 (compared to that of MILRH in experiment 1 with 500 good words added to the test set, which was 0.673). This attack had the same effect on the other splitting methods as did the attack in experiment 1 (Section 7.1) since the physical position of the words in the attacked messages has no influence on how they are split with those methods; thus, those results are not shown here.

A second way to defeat the split-H method is to append a very large block of good words to the spam messages, so that after the split, good words would still outweigh spammy words in both instances in the bag. In fact, we believe this is exactly what happened in experiment 1. Observe in Figure 3 that the average recall of MILRH did not really begin to drop significantly until after 50 good words had been injected into the spam messages in the test set. As even more good words were injected into the spam messages, the average recall continued to drop as the longer messages began to accumulate enough good words to outweigh the spammy words in both instances. In practice, depending on the length of the spam message, coming up with a large enough block of good words might prove difficult.

9. Conclusions and Future Work

A multiple instance learning counterattack strategy for combating adversarial good word attacks on statistical spam filters has been proposed. In the proposed strategy, emails are treated as multiple

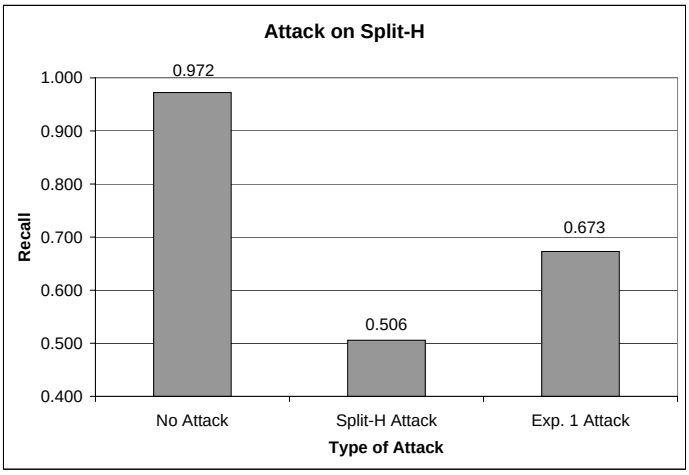

Figure 23: A comparison of the effects of the split-H attack and the experiment 1 style attack, in terms of average recall, with precision fixed at 0.9.

instance bags and a logistic model at the instance level is learned indirectly by maximizing the bag-level binomial log-likelihood function. The proposed counterattack strategy has been demonstrated on good word attacks of varying strength and has been shown to be effective. Additionally, we have confirmed earlier reports that re-training on attacked as well as normal emails may strengthen a spam filter against good word attacks. One of the advantages of our proposed strategy, as demonstrated by our experiments, is that it is effective even when trained on normal email and that frequent re-training on attacked messages is not necessary to maintain that effectiveness. We presented several possible methods for creating multiple instance bags from emails. As was observed from our experimental results, the splitting method used ultimately determines how well the strategy performs. The splitting methods we presented here work fairly well, especially the split-term method, but there are possibly other, perhaps better, methods that could be used. We plan to investigate other possible splitting methods in the future.

Since it is an arms race between spammers and filter designers, we also plan to make our MI strategy adaptive as new spam techniques are devised, and on-line as the concept of spam drifts over time. In addition, we plan to investigate the possibility of extending the proposed multiple instance learning strategy to handle similar adversarial attacks in other domains.

Cross-Validation Optimization for Large Scale Structured Classification Kernel Methods

Matthias W. Seeger SEEGER@TUEBINGEN.MPG.DE

Spemannstr. 38
Tübingen, Germany

Editor: Zoubin Ghahramani

Abstract

We propose a highly efficient framework for penalized likelihood kernel methods applied to multi-class models with a large, structured set of classes. As opposed to many previous approaches which try to decompose the fitting problem into many smaller ones, we focus on a Newton optimization of the complete model, making use of model structure and linear conjugate gradients in order to approximate Newton search directions. Crucially, our learning method is based entirely on matrix-vector multiplication primitives with the kernel matrices and their derivatives, allowing straightforward specialization to new kernels, and focusing code optimization efforts to these primitives only.

Kernel parameters are learned automatically, by maximizing the cross-validation log likelihood in a gradient-based way, and predictive probabilities are estimated. We demonstrate our approach on large scale text classification tasks with hierarchical structure on thousands of classes, achieving state-of-the-art results in an order of magnitude less time than previous work.

Parts of this work appeared in the conference paper Seeger (2007).

Keywords: multi-way classification, kernel logistic regression, hierarchical classification, cross validation optimization, Newton-Raphson optimization

1. Introduction

In recent years, machine learning researchers started to address problems with kernel machines which require models with a large number of dependent variables, and whose fitting demand training samples with very many cases. For example, for multi-way classification models with a hierarchically structured label space (Cai and Hofmann, 2004), modern applications call for predictions on thousands of classes, and very large data sets become available. However, if n and C denote data set size and number of classes respectively, nonparametric kernel methods like *support vector machines* (SVMs) or *Gaussian processes* (GPs) typically scale super-linearly in nC, if dependencies between the latent class functions are represented properly.

Furthermore, most large scale kernel methods proposed so far refrain from solving the problem of learning hyperparameters (kernel or loss function parameters), also known as "learning the kernels". The user has to run cross-validation schemes essentially "by hand", which is not suitable for learning more than a few hyperparameters. However, many models for modern applications come with a large number of hyperparameters (for example to represent dependencies through "mixing" as in independent components analysis), and adjusting them through optimization must make use of gradients.

We propose a general framework for learning in probabilistic kernel classification models. While the models treated here are not novel, a major feature of our approach is the high computational efficiency with which the primary fitting (for fixed hyperparameters) is done. For example, our framework applied to hierarchical classification with hundreds of classes and thousands of data points requires a few minutes for fitting. The central idea is to step back from what seems to be the dominating approach in machine learning at the moment, namely to solve a large convex optimization problem by iteratively solving very many small ones. A popular approach for these small steps is to minimize the criterion w.r.t. a few variables only, keeping the other ones fixed, and many variations of this theme have been proposed. In this paper, we focus on the opposite approach of trying to find directions which lead to fast descent, no matter how many of the variables are involved. This is essentially Newton's method, and one aspect of our work is to find approximate Newton directions very efficiently, making use of model structure and linear conjugate gradients in order to reduce the computation to standard linear algebra primitives on large contiguous chunks of memory. Interestingly, such global approaches are generally favoured in the optimization community for problems (such as kernel methods fitting) which cannot be decomposed naturally into parts. While other gradient-based optimizers such as scaled conjugate gradients could be used as well, they require more fine-tuning (for example, preconditioning) to the specific problem they are applied to, while Newton's method is closer to a "black box" technique and can be transferred to novel situations without many changes.

For multi-way classification, our primary fitting method scales linearly in C, and depends on n mainly via a fixed number of *matrix-vector multiplications* (MVM) with $n \times n$ kernel matrices. In many situations, these MVM primitives can be computed very efficiently, often without having to store the kernel matrices themselves.

We also show how to choose hyperparameters *automatically* by maximizing the cross-validation log likelihood, making use of our primary fitting technology as inner loop in order to compute the CV criterion and its gradient. It is important to note that our hyperparameter learning method works by gradient-based optimization, where the dominating part of the gradient computation does not scale with the number of hyperparameters at all.[1] The gradient computation also requires a number of MVMs with derivatives of kernel matrices, which can be reduced to kernel MVMs for many frequently used kernels (see Section 7.3). Therefore, our approach can in principle be used to learn a large number of hyperparameters without user interaction.

We apply our framework to hierarchical classification with many classes. The hierarchy is represented through an ANOVA setup. While the C latent class functions are fully dependent *a priori*, the scaling of our method stays close to what unstructured (flat) classification with C classes would require. We test our framework on the same tasks treated by Cai and Hofmann (2004), achieving comparable results in at least an order of magnitude less time.

Our proposal to use approximate Newton methods is not novel as such. The Newton method, or a variant of it called Fisher scoring, is the standard approach for fitting generalized linear models in statistics (Green and Silverman, 1994; McCullach and Nelder, 1983), at least if parametric models are fitted to moderately sized samples. Our primary fitting method for flat multi-way classification (see Section 2) appeared in Williams and Barber (1998). However, we demonstrate the usefulness of this principle on a much larger scale, showing how model structure can (and has to) be exploited

1. Such scaling behaviour is fairly standard in Gaussian process marginal likelihood maximization techniques (Williams and Barber, 1998), but has only recently been brought to attention in the SVM community (Keerthi et al., 2007).

in this context. Furthermore, we demonstrate how the secondary task of hyperparameter learning can be reduced to the same underlying primitives.

The structure of the paper is as follows. Our model and method of parameter fitting is given in Section 2. An extension to hierarchical classification is provided in Section 3, and in Section 4 we give our automatic hyperparameter learning procedure. Essential computational details are discussed in Section 5. Experimental results on a very large hierarchical text classification and several standard machine learning problems are given in Section 6. We close with a discussion in Section 7, relating our global direction approach to popular block coordinate descent techniques in Section 7.2, and pointing out future work in Section 7.4.

Optimized C++ software for our framework is available as part of the `LHOTSE` toolbox for adaptive statistical models, which is freely available for non-commercial purposes.[2] The implementation contains the linear kernel case used in Section 6.1 (see Appendix D.3), as well as a generic representation described in Appendix D.1, with which the experiments in Section 6.2, Section 6.3 have been done. It is fairly simple to include new kernels or (approximate) kernel MVM implementations.

2. Penalized Multiple Logistic Regression

In this section, we introduce our framework on a multi-way classification model with C classes, where structure between classes is not modelled. We refer to this setup as *flat classification*, in that the label set is flat (unstructured).

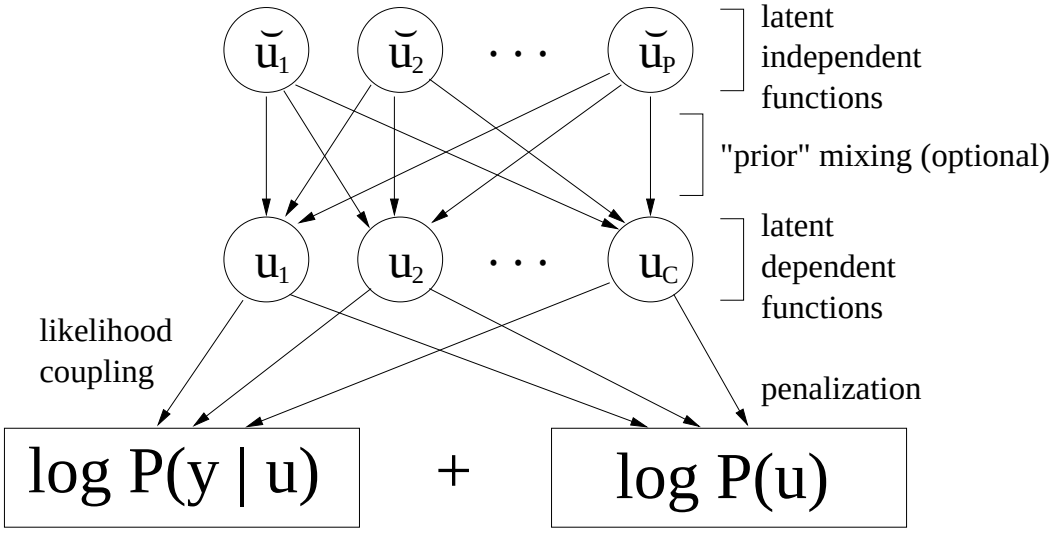

Figure 1: Structure of penalized likelihood optimization.

In general, our framework is applicable to models of the form depicted in Figure 1. A set of latent (unobserved) functions $u_c(\cdot)$ is fitted to observed data by penalized likelihood maximization. For many models, the penalisation term (also called regulariser) corresponds to the logarithm of a prior density over the $u_c(\cdot)$. This primary fitting step corresponds to a convex optimization problem over finitely many variables. Structure in such models is represented either as couplings in the log

2. Available at `www.kyb.tuebingen.mpg.de/bs/people/seeger/lhotse/`.

likelihood function, or in the penalisation (or log prior) term. The latter can be realized through the linear mixing of *a priori* independent functions $\breve{u}_p(\cdot)$, in other words the penaliser over the latter decouples w.r.t. p (our main example of such mixing is hierarchical classification, developed in Section 3).

We now apply this general framework to flat classification, where $y \in \{1,\ldots,C\}$ is to be predicted from $x \in \mathcal{X}$, given some i.i.d. data $D = \{(x_i,y_i) \,|\, i = 1,\ldots,n\}$. Our notation convention for vectors and matrices is detailed in Appendix A, where we also collect all major notational definitions in a table. We code y_i as $y_i \in \{0,1\}^C$, $1^T y_i = 1$ (zero-one coding).[3] We employ the *multiple logistic regression model*, consisting of C latent class functions $u_c(\cdot)$ feeding into the multiple logistic (or softmax) likelihood $P(y_{ic} = 1|x_i, u_i(\cdot)) = e^{u_c(x_i)}/(\sum_{c'} e^{u_{c'}(x_i)})$.

We write $u_c(\cdot) = f_c(\cdot) + b_c$ for intercept (or bias) parameters $b_c \in \mathbb{R}$ and functions $f_c(\cdot)$ living in a reproducing kernel Hilbert space (RKHS) with kernel $K^{(c)} = K^{(c)}(\cdot,\cdot)$ (Schölkopf and Smola, 2002), and consider the *penalized negative log likelihood*

$$\Phi = -\sum_{i=1}^{n} \log P(y_i|u_i) + (1/2)\sum_{c=1}^{C} \| f_c(\cdot)\|_c^2 + (1/2)\sigma^{-2}\|b\|^2, \quad u_i = (u_c(x_i))_c \in \mathbb{R}^C,$$

which we minimize for primary fitting. Here, $\|\cdot\|_c$ is the RKHS norm for kernel $K^{(c)}$. The idea is that deviations in f_c from desired functional properties encoded in $K^{(c)}$ are penalized by a large $\| f_c(\cdot)\|_c^2$. For example, for the Gaussian kernel (7), non-smooth f_c are penalized, and for the linear kernel (Appendix D.3), $\| f_c(\cdot)\|_c^2$ is the squared norm of the weight vector. Details on penalized likelihood kernel methods and RKHS penalisation can be found in Green and Silverman (1994) and Schölkopf and Smola (2002).

The model can also be understood in a Bayesian context, where the penalisation terms come from zero mean Gaussian process priors on the functions $f_c(\cdot)$, and b has a zero mean Gaussian prior with variance σ^2. From this viewpoint, we do a maximum a-posteriori (MAP) approximation here, without however taking covariances into account properly (which would be much more expensive to do). Details on Gaussian processes for machine learning can be found in Seeger (2004) and Rasmussen and Williams (2006).

Since the likelihood depends on the $f_c(\cdot)$ only through the values $f_c(x_i)$ at the data points, every minimizer of Φ must be a kernel expansion: $f_c(\cdot) = \sum_i \alpha_{ic} K^{(c)}(\cdot, x_i)$. This fact is known as representer theorem (Green and Silverman, 1994; Wahba, 1990). Plugging this in, the regulariser becomes $(1/2)\alpha^T K\alpha + (1/2)\sigma^{-2}\|b\|^2$, where $K^{(c)} = (K^{(c)}(x_i,x_j))_{i,j} \in \mathbb{R}^{n,n}$, and $K = \mathrm{diag}(K^{(c)})_c$ is block-diagonal. The kernels $K^{(c)}$ can in general be different, although sharing kernels among classes can lead to computational savings, in that some of the blocks $K^{(c)}$ are identical. Our implementation of block sharing is described in Appendix D.1.

We show in Section 5.1.1 that the b_c may be eliminated as $b = \sigma^2(I \otimes 1^T)\alpha$. Thus, if $\tilde{K} = K + \sigma^2(I \otimes 1)(I \otimes 1^T)$, then our criterion Φ becomes

$$\Phi = \Phi_{lh} + \frac{1}{2}\alpha^T \tilde{K}\alpha, \quad \Phi_{lh} = -y^T u + 1^T l, \quad l_i = \log 1^T \exp(u_i), \quad u = \tilde{K}\alpha. \tag{1}$$

Φ is strictly convex in α, being a sum of linear, quadratic, and *logsumexp* terms of the form $\log 1^T \exp(u_i)$ (Boyd and Vandenberghe, 2002), so it has a unique minimum point $\hat{\alpha}$. The corre-

3. We switch between the formats y_i, y_i. Note that y_{ic} denotes a component in $y_i = (y_{ic})_c$.

sponding kernel expansions are

$$\hat{u}_c(\cdot) = \sum_i \hat{\alpha}_{ic}(K^{(c)}(\cdot, x_i) + \sigma^2).$$

Estimates of the conditional probability on test points x_* are obtained by plugging $\hat{u}_c(x_*)$ into the likelihood. These estimates are asymptotically consistent, although better finite sample estimates could probably be obtained by a more Bayesian treatment.

We note that this setup is related to the multi-class SVM (Crammer and Singer, 2001), where $-\log P(y_i|u_i)$ is replaced by the margin loss $-u_{y_i}(x_i) + \max_c\{u_c(x_i) + 1 - \delta_{c,y_i}\}$. Here, $\delta_{a,b} = \mathrm{I}_{\{a=b\}}$. The negative log multiple logistic likelihood has similar properties, but is smooth as a function of u, and the primary fitting of α does not require constrained convex optimization. Furthermore, universal consistency for estimates of $P(y_*|x_*)$ can be established for the multiple logistic loss, but fails to hold for the SVM variant (Bartlett and Tewari, 2004).

We will minimize Φ using the *Newton-Raphson* (NR) algorithm. The computation of Newton search directions requires solving a system with the Hessian and the gradient of Φ, which we will do approximately using the *linear conjugate gradients* (LCG) algorithm. This can be done without fully computing, storing, or inverting the Hessian, all of which would not be possible for large nC. In fact, the task is reduced to computing $k_1(k_2+2)$ MVMs with K, where k_1 is the number of NR iterations, k_2 the number of LCG steps for computing each Newton direction. Since NR is a second-order convergent method, k_1 is generally small. k_2 determines the quality of each Newton direction, and again, fairly small values seem sufficient (see Section 6.1). Details are provided in Section 5.1.

Finally, some readers may wonder why we favour the NR algorithm here, which in practice can be fairly complicated to implement, while we could do a simpler gradient-based optimization of Φ w.r.t. α, for example by scaled (non-linear) conjugate gradients (SCG). The problem is that on tasks of the size we want to address, non-invariant methods such as SCG tend to fail completely if not properly preconditioned, and we experienced exactly that in preliminary experiments. In contrast to that, NR is invariant to the choice of optimization variables, so does not have to be preconditioned. It is by far the preferred method in the optimization literature (Bertsekas, 1999; Boyd and Vandenberghe, 2002), and many ideas for preconditioning or Quasi-Newton try to approximate the NR directions. We think that a proper SCG implementation can be at least as efficient as NR, but needs fine-tuning to the specific problem, which in the case of hierarchical classification (discussed next) is already quite difficult. More details on this point are given in Section 5.4 and also Section 7.2.

3. Hierarchical Classification

So far we dealt with flat classification, the classes being independent *a priori*, with block-diagonal kernel matrix K. However, if the label set has a known structure,[4] we can benefit from representing it in the model. Here we focus on hierarchical classification, the label set $\{1,\ldots,C\}$ being the leaf nodes of a tree. Classes with lower common ancestor should be more closely related. In this section, we propose a model for this setup and show how it can be dealt with in our framework with minor modifications and reasonable extra cost.

In flat classification, the latent class functions $u_c(\cdot)$ are modelled as *a priori* independent, in that the penaliser (or the log prior in the GP view) is a sum of individual terms for each c, without

4. Learning an unknown label set structure may be achieved by expectation maximization techniques, but this is subject to future work.

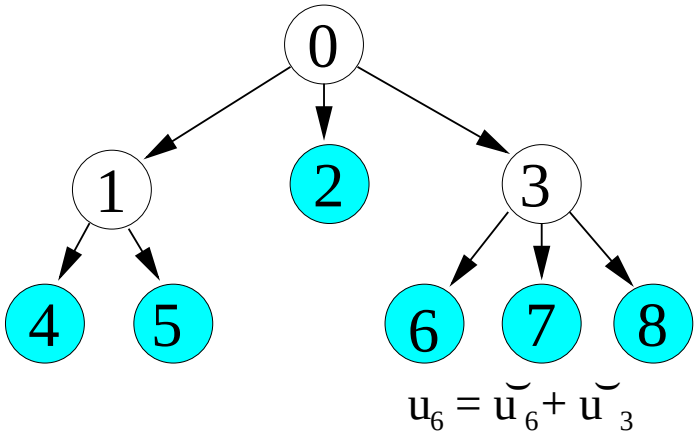

Figure 2: Example of a tree-structured target space, where labels correspond to leaf nodes (shaded).

interaction terms. Analysis of variance (ANOVA) models go beyond such independent designs, they have previously been applied to text classification by Cai and Hofmann (2004), see also Shahbaba and Neal (2007). Let $\{0,\ldots,P\}$ be the nodes of the tree, 0 being the root, and the numbers are assigned breadth first ($1,2,\ldots$ are the root's children). The tree is determined by P and n_p, $p = 0,\ldots,P$, the number of children of node p. Let L be the set of leaf nodes, $|L| = C$. Assign a *pair* of latent functions $u_p, \breve{u}_p$ to each node, except the root. The $\breve{u}_p$ are assumed *a priori* independent, as in flat classification. u_p is the sum of $\breve{u}_{p'}$, where p' is running over the nodes (including p) on the path from the root to p. An example is given in Figure 2. The class functions to be fed into the classification likelihood are the $u_{L(c)}$ of the leafs. This setup represents similarities according to the hierarchy. For example, if leafs $L(c), L(c')$ have the common parent p, then $u_{L(c)} = u_p + \breve{u}_{L(c)}$, $u_{L(c')} = u_p + \breve{u}_{L(c')}$, so the class functions *share* the effect u_p. Since regularisation forces all independent effects $\breve{u}_{p'}$ to be smooth, the classes c, c' are urged to behave similarly *a priori*.

Let $u = (u_p(x_i))_{i,p}$, $\breve{u} = (\breve{u}_p(x_i))_{i,p} \in \mathbb{R}^{nP}$. The vectors are linearly related as $u = (\Phi \otimes I)\breve{u}$, $\Phi \in \{0,1\}^{P,P}$, a special case of the mixing of Figure 1. Importantly, Φ has a simple structure which allows MVM with Φ or Φ^T to be computed easily in $O(P)$, without having to compute or store Φ explicitly. Let $cs_p = \sum_{p'<p} n_{p'}$, and define $\Phi_p \in \mathbb{R}^{d,d}$, $d = cs_p + n_p$, to be the upper left block of Φ, so that $\Phi = \Phi_P$. If p is a leaf node, then $\Phi_p = \Phi_{p-1}$. Otherwise, Φ_p is obtained from Φ_{p-1} by attaching rows $(\delta_p^T \Phi_{p-1}, \delta_j^T)$, $j = 1,\ldots,n_p$, where $\delta_p^T \Phi_{p-1}$ is the p-th row of Φ_{p-1}. This is because $u_{cs_p+j} = u_p + \breve{u}_{cs_p+j}$ for the functions of the children of p. Formally,

$$\Phi_p = \begin{pmatrix} \Phi_{p-1} & 0 \\ 1\delta_p^T \Phi_{p-1} & I \end{pmatrix},$$

where the lower right $I \in \mathbb{R}^{n_p,n_p}$. Note that Φ is lower triangular with $\operatorname{diag}\Phi = I$. This recursive definition directly implies simple methods for computing $v \mapsto \Phi v$ and $v \mapsto \Phi^T v$.

Under the hierarchical model, the class functions $u_{L(c)}$ are strongly dependent *a priori*. Representing this prior coupling in our framework amounts to simply plugging in the implied kernel matrix

$$K = (\Phi_{L,\cdot} \otimes I)\breve{K}(\Phi_{L,\cdot}^T \otimes I), \tag{2}$$

into the flat classification model of Section 2. Here, the inner $\check{K}$ is block-diagonal, while in the flat model, K itself had this property. In the hierarchical case, K is not sparse and certainly not block-diagonal, but we are still able to compute kernel MVMs efficiently: pre- and post-multiplying by Φ is very cheap, and $\check{K}$ is block-diagonal just as in the flat case.

In fact, the step from flat to hierarchical classification requires minor modifications of existing code only. If code for representing a block-diagonal K is available, we can use it to represent the inner $\check{K}$, just replacing C by P. This simplicity carries through to the hyperparameter learning method (see Section 4). The cost of a kernel MVM is increased[5] by a factor $P/C < 2$, which in most hierarchies in practice is close to 1.

However, it would be wrong to claim that hierarchical classification in general comes as cheap as flat classification. In fact, primary fitting becomes more costly, precisely because there is more coupling between the variables. In the flat case, the Hessian of Φ (1) is close to block-diagonal. The LCG algorithm to compute Newton directions converges quickly, because it nearly decomposes into C independent ones, and fewer NR steps are required. In the hierarchical case, this "near-decomposition" does not hold, and both LCG and NR need more iterations to attain the same accuracy, although each LCG step comes at about the same cost as in the flat case.

In numerical mathematics, much work has been done to approximately decouple linear systems by preconditioning. In some of these strategies, knowledge about the structure of the system matrix (in our case: the hierarchy) can be used to drive preconditioning. An important point for future research is to find a good preconditioning strategy for the system (5). However, in all our experiments so far the fitting of the hierarchical model took less than twice the time required for the flat model on the same task.

4. Hyperparameter Learning

Our framework comes with an automatic method for setting free hyperparameters h, by gradient-based maximization of the cross-validation (CV) log likelihood. Our primary fitting method of Section 2 is used here as principal subroutine. Such a setup is commonplace in Bayesian statistics, where (marginal) inference is typically employed as subroutine in parameter learning.

Recall that primary fitting works by minimizing Φ (1) w.r.t. α. Let $\{I_k\}$ be a partition of the data set range $\{1,\ldots,n\}$, with $J_k = \{1,\ldots,n\} \setminus I_k$, and let

$$\Phi_{J_k} = u_{[J_k]}^T((1/2)\alpha_{[J_k]} - y_{J_k}) + 1^T l_{[J_k]}$$

be the negative log likelihood of the subset J_k of the data. Here, $u_{[J_k]} = \tilde{K}_{J_k}\alpha_{[J_k]}$. The $\alpha_{[J_k]}$ are independent variables, *not* part of a common[6] α. The cross-validation criterion is

$$\Psi = \sum_k \Psi_{I_k}, \quad \Psi_{I_k} = -y_{I_k}^T u_{[I_k]} + 1^T l_{[I_k]}, \quad u_{[I_k]} = \tilde{K}_{I_k,J_k}\alpha_{[J_k]}, \tag{3}$$

where $\alpha_{[J_k]}$ is the minimizer of Φ_{J_k}. Since for each k, we fit and evaluate the likelihood on disjoint parts of y, Ψ is an unbiased estimator of the true negative expected log likelihood.

In order to adjust h, we pick a fixed partition at random, then do gradient-based minimization of Ψ w.r.t. h. To this end, we maintain the set $\{\alpha_{[J_k]}\}$ of primary variables, and iterate between re-fitting

5. Nodes with a single child only can be pruned from the hierarchy. Note that our formalism does not require all leaf nodes to have the same depth.

6. Which is why they are not referred to as α_{J_k}.

those for each fold k, and computing Ψ and $\nabla_h \Psi$. The gradient can be determined analytically, using a computation which is equivalent to the Newton direction computations for $\alpha_{[J_k]}$, meaning that the same code can be used. Details are given in Section 5.2. Note that Ψ is not a convex objective.

As for computational complexity, suppose there are q folds. The update of the $\alpha_{[J_k]}$ requires q primary fitting applications, but since they are initialized with the previous values $\alpha_{[J_k]}$, they do converge very rapidly, especially during later iterations. Computing Ψ based on the $\alpha_{[J_k]}$ comes basically for free. The gradient computation decomposes into two parts: accumulation, and kernel derivative MVMs. The accumulation part requires solving q systems of size $((q-1)/q)nC$, thus qk_3 kernel MVMs on the $\tilde{K}_{J_k}$ if linear conjugate gradients (LCG) is used, k_3 being the number of LCG steps. We also need two buffer matrices E, F of qnC elements each. Note that the accumulation step is *independent* of the number of hyperparameters. The second part consists of q kernel derivative MVMs for each independent component of h. This second part is much simpler than the accumulation one, consisting entirely of large matrix operations, which can be run very efficiently using specialized numerical linear algebra code. The method for computing Ψ and $\nabla_h \Psi$ can be plugged into a custom gradient-based optimizer, such as Quasi-Newton or conjugate gradients, in order to learn h.

As shown in Section 5.3, the extension of hyperparameter learning to the hierarchical case of Section 3 is done by wrapping the accumulation part with Φ MVMs, the coding and additional memory effort being minimal.

We finally note from our findings in practice (see Section 6.3) that on large tasks, our automatic method can require some fine-tuning. This is due to the delicate dependencies between the different approximations used. The accuracy of Ψ and $\nabla_h \Psi$ depends on how accurate the inner NR optimizations for $\alpha_{[J_k]}$ turn out, and the latter depend on how many iterations of LCG are done in order to compute search directions. Fortunately, Φ_{J_k} and its gradient w.r.t. $u_{[J_k]}$ can be computed exactly in order to assess inner optimization convergence, so we do at least know when things go wrong. In our implementation, we deem an evaluation of Ψ and $\nabla_h \Psi$ usable if the average of $\|\nabla_{u_{[J_k]}} \Phi_{J_k}\|$ over folds is below a threshold, which depends on the problem and on time constraints. A failed evaluation leads to a right bracket there for the outer optimization line search, in that step sizes beyond the failed one are not accessed. We can now tune the basic running time parameters k_1, k_2 so that Ψ evaluations do not fail too often. In this context, it is important to regard the $\{\alpha_{[J_k]}\}$ as an *inner state* alongside the hyperparameter vector h. Although inner optimizations are convex, for large problems and reasonable k_1, k_2, successive minima are attained only when we start from the previous best inner state. This is true especially during later stages, where for certain problems (see Section 6.3) h attends "extreme" values and the inner optimizations become quite hard.[7] Therefore, the inner state used to initialize a given Ψ evaluation is the final one for the last recent *successful* evaluation.[8] Inner states attained during failed evaluations are discarded.

7. Although inner optimizations are convex, speed of convergence of NR depends strongly on the value of h. For "extreme" values, the Newton direction computation by LCG is harder, and search directions can become large in early NR iterations. The latter may be because we work in u rather than α space, but only the former is really feasible.
8. Within outer line searches, we use $\{\alpha_{[J_k]}\}$ from the last recent successful evaluation *to the left* (along the search direction).

5. Computational Details

In this section, we provide details for the material above. The techniques given here do characterize our framework, they are novel in this combination, and some of them may be useful in other contexts as well. More specific details of our implementation can be found in Appendix D.

5.1 Details for Flat Classification

In this section, we provide details for the primary fitting optimization in the case of flat multi-way classification, introduced in Section 2. Note that this fitting method appeared in Williams and Barber (1998) in the context of approximate Gaussian process inference, although some fairly essential ideas here are novel to our knowledge (symmetrisation of Newton system, pair optimization line search, numerical stability considerations).

Recall that we want to minimize the strictly convex criterion Φ (1) w.r.t. α, using the Newton-Raphson (NR) method. Modern variants of this algorithm iterate line searches along the *Newton directions* $-H^{-1}g$, where g, H are gradient and Hessian of Φ at the current α. We will start with the Newton direction computation in Section 5.1.1, commenting on the line searches afterwards in Section 5.1.2 (it turns out that it basically comes for free). An overview of the fitting algorithm is given in Section 5.1.3.

5.1.1 COMPUTING THE NEWTON DIRECTION

Recall Φ and related variables from (1). Let $\pi_{ic} = P(y_{ic} = 1|u_i)$, $\pi = \exp(u - 1 \otimes l)$, and recall that Φ_{lh} is the likelihood part in Φ. Now,

$$g := \nabla\Phi_{lh} = \pi - y,\ W := \nabla\nabla\Phi_{lh} = D - DP_{cls}D,\ P_{cls} = (1 \otimes I)(1^T \otimes I).$$

Here, $D = \operatorname{diag}\pi$, and gradient and Hessian are taken w.r.t. u (*not* w.r.t. α). Our convention for nC vectors and matrices and the use of $\otimes$ is explained in Appendix A. The form of W can be understood by noting that W is block-diagonal in a *different* ordering, which uses c (classes) as inner and i (data points) as outer index, then switching to our standard ordering.

It is easy to compute gradient and Hessian of Φ w.r.t. α, b. A full (classical) Newton step is given by the system

$$\begin{aligned}
&(I + WK)\alpha' + W(I \otimes 1)b' = Wu - g, \\
&(I \otimes 1^T)WK\alpha' + (I \otimes 1^T)W(I \otimes 1)b' + \sigma^{-2}b' = (I \otimes 1^T)(Wu - g),
\end{aligned}$$

and the Newton search direction is obtained as the difference $\alpha' - \alpha, b' - b$. Subtracting $(I \otimes 1^T)$ times the first from the second, we obtain $b' = \sigma^2(I \otimes 1^T)\alpha'$, and plugging this into the first equation, we have

$$\left(I + W\left(K + \sigma^2 P_{data}\right)\right)\alpha' = Wu - g, \quad P_{data} = (I \otimes 1)(I \otimes 1^T). \tag{4}$$

Note that $P_{data}a = (\sum_{i'} a_{i'})_i$, which does the same as P_{cls}, but on index i rather than c. We denote

$$\tilde{K} = K + \sigma^2 P_{data},$$

noting that this corresponds to $\tilde{K}^{(c)} = K^{(c)} + \sigma^2 11^T$. The correct way of incorporating intercept parameters is to add the constant σ^2 to the kernels, then to obtain $b_c = \sigma^2 \sum_i \alpha_{ic}$. This is the meaning

of "eliminating b" in Section 2. While we could optimize σ^2 as a hyperparameter, we consider it fixed and given for simplicity.[9] In the sequel, we consider b being eliminated from the model by replacing $K \to \tilde{K}$ everywhere. We have $u = \tilde{K}\alpha$.

We can solve the system (4) exactly if we can tolerate a scaling of $O(n^3C)$ and $O(n^2C)$ memory. Note that this scaling is linear rather than cubic in C. The exact solution is derived in Appendix C. It is efficient for moderate n, and generally useful for code debugging, and is supported by our implementation. In the remainder of this section, we focus on approximate computations.

Although we could solve the system using a bi-conjugate gradients solver, we can do much better by transforming it into symmetric positive definite form. First, note that W is positive semidefinite, but singular. This can be seen by noting that the parameterization of our likelihood in terms of u_i is overcomplete, in that $u_i + \kappa 1$ gives the same likelihood values for all κ. We could fix one of the u_i components, which would however lead to subtle dependencies between the remaining $C-1$ functions $u_c(\cdot)$. In order to justify our *a priori* independent treatment of these functions, we have to retain the overcomplete likelihood. The nullspace $\ker W$ is given by $\{(d)_c \,|\, d \in \mathbb{R}^n\}$ and has dimension n. This can be seen by noting that $Wa = 0$ iff $a = (\bar{a})_c$, $\bar{a} = \sum_{c'} a^{(c')}$. W has rank $n(C-1)$. We have $a \in \mathrm{ran}\, W$ iff $\sum_c a^{(c)} = (1^T \otimes I)a = 0$ (recall that $\ker W$ and $\mathrm{ran}\, W$ are orthogonal, and their direct sum is $\mathbb{R}^{nC}$). From (4) we see that $\alpha' + g$ lies in $\mathrm{ran}\, W$. Note that $\sum_c g^{(c)} = \sum_c (\pi^{(c)} - y^{(c)}) = 1 - 1 = 0$, therefore $g \in \mathrm{ran}\, W$, thus $\alpha' \in \mathrm{ran}\, W$. We see that the dual coefficients must fulfill the constraint $\alpha \in \mathrm{ran}\, W$. Note that $\mathrm{ran}\, W$ is in fact independent of D. Whatever starting value is used for α, it should be projected onto $\mathrm{ran}\, W$, which is done by subtracting $C^{-1}P_{cls}\alpha$. The NR updates then make sure that the constraint remains fulfilled.

Next, we need a decomposition $W = VV^T$ of W. Such a V exists (because W is positive semidefinite). In fact,

$$W = ADA^T, \quad A = I - DP_{cls}.$$

This follows easily from $(1^T \otimes I)D(1 \otimes I) = \sum_{c'} D^{(c')} = I$. Thus, $W = VV^T$ with $V = AD^{1/2}$. The matrix A has fixed points $\mathrm{ran}\, W$, namely if $a \in \mathrm{ran}\, W$, then $(1^T \otimes I)a = 0$, so that $Aa = a$.

Since there exists some $\tilde{v}$ (not unique) s.t. $\alpha' = W\tilde{v}$, we can rewrite the system (4) as

$$V\left(I + V^T\tilde{K}V\right)V^T\tilde{v} = V\left(V^Tu - \tilde{g}\right),$$

where $\tilde{g}$ is s.t. $g = V\tilde{g}$ (such a vector exists because $g \in \mathrm{ran}\, W$). This suggests the following procedure for finding α':

$$\left(I + V^T\tilde{K}V\right)\beta = V^Tu - \tilde{g}, \quad \alpha' = V\beta. \tag{5}$$

To see the validity of this approach, simply multiply both sides of (5) by V from the left, which shows that $V\beta$ solves the original system. Since the latter has a unique solution (strict convexity!), we must have $V\beta = \alpha'$. Finally, we note that $\tilde{g} = D^{-1/2}g$ does the job, because $VD^{-1/2}g = Ag = g$. The latter follows because $g \in \mathrm{ran}\, W$.

Thus, in exact arithmetic, the Newton direction computation is implemented in a three-stage procedure. First, compute $\tilde{g} = D^{-1/2}g$. Second, solve the system (5) for β. This is a symmetric positive definite system with the typically well-conditioned matrix $I + V^T\tilde{K}V$, and can be solved efficiently using the linear conjugate gradients (LCG) algorithm (Saad, 1996). The cost of each step is dominated by the MVM $v \mapsto Kv$, which scales linearly in C, due to the block-diagonal structure of K. Third, set $\alpha' = V\beta$. The Newton direction is obtained as $\alpha' - \alpha$.

9. In our experience so far, a good value of σ^2 is fairly robust across different tasks for the same problem, but may differ strongly between different problems. It can be chosen based on some initial experiments.

We can start the LCG run from a good guess as follows. Let α be the current dual vector which solved the last recent system. We would like to initialize β s.t. $\alpha = V\beta = AD^{1/2}\beta$. If we assume that $D^{1/2}\beta \in \mathrm{ran}\, W$, then $\alpha = D^{1/2}\beta$. Therefore, a good initialization is $\beta = D^{-1/2}\alpha$. Alternatively, we may also retain β from the last recent system.

Issues of numerical stability are addressed in Appendix B. Furthermore, the LCG algorithm is hardly ever run without some sort of preconditioning. Our present implementation uses diagonal preconditioning, as described in Appendix B. We have already noted in Section 3 that a non-diagonal preconditioning strategy could be valuable, but this is subject to future work.

5.1.2 THE LINE SEARCH

The classical NR algorithm proceeds doing full steps $\alpha \to \alpha'$, but modern variants typically employ a line search along the Newton direction $\alpha' - \alpha$. In the non-convex case, this ensures global convergence, and even for our convex objective Φ, a line search saves time and leads to numerically more stable behaviour. Interestingly, the special structure of our problem leads to the fact that line searches essentially come for free, certainly compared with the effort of obtaining Newton directions. We refer to this simple idea as *pair optimization*, the reader may be reminded of similar tricks in primal-dual schemes for SVM.

Let $s = \alpha' - \alpha$ be the NR direction, computed as shown above, and set α_0 to α. The line search minimizes (or sufficiently decreases) Φ on the line segment $\alpha_0 + \lambda s$, $\lambda \in (0,1]$, starting with $\lambda = 1$ (which is the classical Newton step). The idea is to treat Φ as a function of the pair (u, α), where $u = \tilde{K}\alpha$. The corresponding line segment is $u = u_0 + \lambda\tilde{s}$, $\tilde{s} = \tilde{K}s$, requiring a single kernel MVM for computing $\tilde{s}$. Let $j = \mathrm{argmax}\,|\tilde{s}_j|$. For an evaluation of Φ at u, we reconstruct $\lambda = (u_j - u_{0,j})/\tilde{s}_j$ and $\alpha = \alpha_0 + \lambda s$, then

$$\Phi = u^T\left((1/2)\alpha - y\right) + 1^T l, \quad \nabla\Phi = \pi - y + \alpha,$$

so that an evaluation comes at the cost $O(nC)$ and does not require additional kernel MVM applications. We now do the line minimization of Φ in the variable u. The driving feature of pair optimization is that we can go back and forth between α and u without significant cost, once the search direction is known w.r.t. both variables.

5.1.3 OVERVIEW OF THE OPTIMIZATION ALGORITHM

In Algorithm 1, we give a schematic overview of the primary fitting algorithm, written in terms of a MVM primitive $v \mapsto Kv$. For simplicity, we do not include the measures discussed in Appendix B to increase numerical stability.

5.2 Details for Hyperparameter Learning

In this section, we provide details for the CV hyperparameter learning scheme, introduced in Section 4. The gradient of the CV criterion Ψ (3) is computed as follows. Ψ is a sum of terms Ψ_{I_k}, one for each fold. We focus on a single term and write $I = I_k$, $J = J_k$. $\alpha_{[J]}$ is determined by the stationary equation $\alpha_{[J]} + g_{[J]} = 0$ (all terms of subscript $[J]$ are as in Section 5.1.1, but for the subset J of the data, and w.r.t. $\alpha_{[J]}$). Taking derivatives gives

$$d\alpha_{[J]} = -W_{[J]}\left((dK_J)\alpha_{[J]} + \tilde{K}_J(d\alpha_{[J]})\right),$$

Algorithm 1 Newton-Raphson optimization to find posterior mode $\hat{\alpha}$.

Require: Starting values for α, b. Targets y.
  $\alpha = \alpha - C^{-1}(\sum_{c'} \alpha^{(c')})_c$, so that $\alpha \in \operatorname{ran} W$. $u = \tilde{K}\alpha$.
  repeat
    Compute $l, \log(\pi)$ from u. Compute Φ.
    if relative improvement in Φ small enough **then**
      Terminate outer loop.
    else if maximum number of iterations done **then**
      Terminate outer loop.
    end if
    Initialize $\beta = D^{-1/2}\alpha$. Compute r.h.s. $r = V^T u - \tilde{g}$, $\tilde{g} = D^{-1/2} g$.
    Compute preconditioner $\operatorname{diag}(I + V^T \tilde{K} V)$.
    Run preconditioned CG algorithm in order to solve the system (5) approximately. The CG code is configured by a primitive to compute $v \mapsto (I + V^T \tilde{K} V)v$, which in turn calls the primitive for $v \mapsto Kv$.
    Compute $\alpha' = AD^{1/2}\beta'$.
    Do line search along $s = \alpha' - \alpha$. This is done in u, along $\tilde{s} = \tilde{K}s$.
    Assign line minimizer to α, u.
  until forever

since $dg_{[J]} = W_{[J]} du_{[J]}$. We obtain a system for $d\alpha_{[J]}$ which is symmetrised as in Section 5.1.1:

$$\left(I + V_{[J]}^T \tilde{K}_J V_{[J]}\right)\beta = -V_{[J]}^T (dK_J)\alpha_{[J]}, \quad d\alpha_{[J]} = V_{[J]}\beta.$$

Also,

$$d\Psi_I = \left(\pi_{[I]} - y_I\right)^T \left((dK_{I,J})\alpha_{[J]} + \tilde{K}_{I,J}(d\alpha_{[J]})\right).$$

With

$$f = I_{\cdot,I}(\pi_{[I]} - y_I) - I_{\cdot,J} V_{[J]} \left(I + V_{[J]}^T \tilde{K}_J V_{[J]}\right)^{-1} V_{[J]}^T \tilde{K}_{J,I}(\pi_{[I]} - y_I),$$

we have that $d\Psi_I = (I_{\cdot,J}\alpha_{[J]})^T (dK) f$.

If we collect these vectors as columns of $E, F \in \mathbb{R}^{nC,q}$, q the number of folds, we have that

$$d\Psi = \operatorname{tr} E^T (dK) F \tag{6}$$

for the complete criterion. The computation of E, F was called "accumulation" in Section 4. It involves a loop over folds, in which $\alpha_{[J_k]}$ is determined by NR optimization, starting from its previous value, then f (column of F) is computed by solving one more system of the same form as is required to compute Newton directions. Importantly, this accumulation phase is independent of the number of hyperparameters. The gradient computation then requires to compute (6) for each component, using kernel derivative MVMs. First of all, $\partial K / \partial h_p$ is block-diagonal just as K, and for many standard kernels, it is a simple expression, involving K itself (see Section 7.3), so one may be able to share computations between the different gradient components. Importantly, the computation of (6) is easily broken down into large numerical linear algebra primitives, for which very efficient code may be used (see Section 7.2). This is a significant advantage in the presence of

many hyperparameters. For moderately many hyperparameters, the accumulation clearly dominates the CV criterion and gradient computation.

The dominating part of the accumulation is the re-optimisation of the $\alpha_{[J]}$, which are done by calling the optimized code for primary fitting (Section 5.1) as subroutine. Here, a feature of our implementation becomes important. Instead of representing each K_{J_k} separately, we represent the full K only for all subset kernel MVMs. The representation depends on the covariance function, and in general on how kernel MVMs are actually done. A generic representation is described in Appendix D.1. In order to work on the data subset J_k, we *shuffle* the representation such that in the permuted kernel matrix, K_{J_k} forms the upper left corner. This means that linear algebra primitives with K_{J_k} can be run without mapping matrix coordinates through an index, which would be many times slower. Details on "covariance shuffling" are given in Appendix D.2.

As mentioned in Section 5.1.1 and detailed in Appendix C, we can also compute Newton directions exactly in $O(Cn^3)$ in the flat classification case. This exact treatment can be extended to the computation of Ψ and its gradient, as is shown in Appendix C. Exact computations lead to more robust behaviour, and may actually run faster for small to moderate n. Exact computations are also useful for debugging purposes.

5.3 Details for Hierarchical Classification

In this section, we provide details for hierarchical classification method, introduced in Section 3. Recall that $u = (\Phi \otimes I)\check{u}$ for an indicator matrix Φ of simple structure, and that MVM with Φ or Φ^T can be computed easily in $O(P)$, without having to store Φ. Since the $\check{u}_p(\cdot)$ are given independent priors (or regularisers), the corresponding kernel matrix $\check{K}$ is block-diagonal. The induced covariance matrix K over u_L is given by (2), and hierarchical classification differs from the flat variant only in that this non-block-diagonal matrix is used.

The MVM primitive $v \mapsto Kv$ is computed in three steps. MVM with $(\Phi_{L,\cdot} \otimes I)$ and $(\Phi_{L,\cdot}^T \otimes I)$ works by computing $S \mapsto S\Phi$, $S \mapsto S\Phi^T$ for $S \in \mathbb{R}^{n,P}$. In between, MVM with $\check{K}$ has to be done in the same way as for flat classification, only that $\check{K}$ has P rather than C diagonal blocks.

The diagonal preconditioning of LCG (see Appendix B) requires the computation of $\operatorname{diag} K \in \mathbb{R}^{nC}$. We have

$$K_{ic,ic} = (\delta_p^T\Phi \otimes \delta_i^T)\check{K}(\Phi^T\delta_p \otimes \delta_i) = \delta_p^T\Phi(\operatorname{diag}(\check{K}_i^{(p')})_{p'})\Phi^T\delta_p, \quad p = L(c),$$

where $\delta_p^T\Phi$ is the p-th row of Φ. From the recursive structure of Φ we know that if $n_p > 0$, then $\delta_{cs_p+j}^T\Phi = \delta_p^T\Phi + \delta_{cs_p+j}^T$, $j = 1,\ldots,n_p$, so if

$$d_{i(cs_p+j)} = d_{ip} + \check{K}_i^{(cs_p+j)}, \ j = 1,\ldots,n_p,$$

then $\operatorname{diag} K = d_L$.

Hyperparameter learning (see Section 5.2) is easily extended to the hierarchical case, recalling (2) and the fact that Φ does not depend on hyperparameters. Define $\tilde{E} = (\Phi_{L,\cdot}^T \otimes I)E \in \mathbb{R}^{nP,q}$, $\tilde{F}$ accordingly, with E, F given in Section 5.2. The gradient components (6) translate to $\operatorname{tr}\tilde{E}^T(d\check{K})\tilde{F}$, where $\check{K}$ is block-diagonal as before. In our implementation, we reserve buffer space for $\tilde{E}, \tilde{F}$, yet build E, F there during accumulation. We then transform them to $\tilde{E}, \tilde{F}$ using in-place computations.

The step from flat to hierarchical classification requires only minor modifications of existing code. Wrappers for MVM and the other primitives essentially pre- and post-multiply their input

with Φ and Φ^T respectively, calling the existing "flat" primitives for $\check{K}$ in between (block-diagonal with P rather than C blocks).

5.4 Why Newton Raphson?

Why do we propose to use the second-order NR method for minimizing Φ, instead of using a simpler gradient-based technique such as scaled conjugate gradients (SCG)? We already motivated our choice at the end of Section 2, but give more details concerning this important point here.

The convex problems we are interested in here live in very high-dimensional spaces and come with complicated couplings between the components which cannot be characterized simply. Certainly, there is no simple decomposition into parts. It is well known in the optimization literature (Bertsekas, 1999) that simple gradient-based techniques such as SCG require well-chosen preconditioning in order to work effectively in such cases.

For example, we could optimize Φ (1) w.r.t. α directly, the gradient requires a single MVM with K rather than solving a system. However, this problem is very ill-conditioned, the Hessian being $\tilde{K}W\tilde{K}+\tilde{K}$ (large kernel matrices are typically very ill-conditioned, and here we deal with K^2), and SCG runs exceedingly slowly to the point of being essentially useless (as we determined in experiments). It can be saved (to our knowledge) only by preconditioning, which in our case requires to solve a system again. Another idea is to optimize Φ w.r.t. u by SCG, which works better. The Hessian is $W+\tilde{K}^{-1}$, whose condition number is similar to K. In preliminary direct comparisons, the NR method still works more efficiently, meaning that SCG would require additional preconditioning specific to the problem at hand, which would likely be different for flat and hierarchical classification. From our experience, and also from the predominance of NR in the optimization literature, we opted for this method which comes with self-tuning capabilities, making it easier to transfer the framework to novel problems.

6. Experiments

In this section, we provide experimental results for our method on a range of flat and hierarchical classification tasks.

6.1 Hierarchical Classification: Patent Texts

We use the WIPO-alpha collection,[10] many thanks to L. Cai, T. Hofmann for providing us with the count data and dictionary. We did Porter stemming, stop word removal, and removal of empty categories. The attributes are bag-of-words over the dictionary. All input vectors x_i were scaled to unit norm. Many thanks to Peter Gehler for helping us with the preprocessing.

These tasks have previously been studied by Cai and Hofmann (2004), where patents (title and claim text) are to be classified w.r.t. the standard taxonomy *IPC*, a tree with 4 levels and 5229 nodes. Sections A, B,..., H form the first level. As in Cai and Hofmann (2004), we concentrate on the 8 subtasks rooted at the sections, ranging in size from D ($n = 1140, C = 160, P = 187$) to B ($n = 9794, C = 1172, P = 1319$). We use linear kernels (see Appendix D.3) with variance parameters v_c.

All experiments are averaged over three training/test splits, different methods using the same ones. The CV criterion Ψ is used with a different (randomly drawn) 5-partition per section and

10. Available at `www.wipo.int/tools/en/dbindex.html`, or google for "Data Collections hosted by WIPO".

split, the same across all methods. Our method outputs a predictive distribution $p_j \in \mathbb{R}^C$ for each test case x_j. The standard prediction $y(x_j) = \text{argmax}_c\, p_{jc}$ maximizes expected accuracy, classes are ranked as $r_j(c) \leq r_j(c')$ iff $p_{jc} \geq p_{jc'}$, where $r_j(c) \in \{1,\ldots,C\}$ is the rank of class c for case x_j. Let y_j denote the true label for x_j. The test scores we use here are the same as in Cai and Hofmann (2004): *accuracy* (acc) $m^{-1}\sum_j \mathrm{I}_{\{y(x_j)=y_j\}}$, *precision* (prec) $m^{-1}\sum_j r_j(y_j)^{-1}$, *parent accuracy* (pacc) $m^{-1}\sum_j \mathrm{I}_{\{\text{par}(y(x_j))=\text{par}(y_j)\}}$, par$(c)$ being the parent of leaf node $L(c)$ (recall that $L(c)$ corresponds to class c). Here, m is the test set size. Let $\Delta(c,c')$ be half the length of the shortest path between leafs $L(c), L(c')$. The *taxo-loss* (taxo) is $m^{-1}\sum_j \Delta(y(x_j), y_j)$. These scores are motivated in Cai and Hofmann (2004). For taxo-loss and parent accuracy, we better choose $y(x_j)$ to minimize expected loss,[11] which is different in general than the standard prediction (the latter maximizes expected accuracy and precision).

We compare methods F1, F2, H1, H2 (F: flat, not using IPC; H: hierarchical). F1: all v_c shared (1); H1: v_c shared across each level of the tree (3). F2, H2: v_c shared across each subtree rooted at root's children (A: 15, B: 34, C: 17, D: 7, E: 7, F: 17, G: 12, H: 5). The numbers in parentheses are the total number of hyperparameters. Recall that there are three parameters determining the running time (see Section 2, Section 4). For hyperparameter learning: $k_1 = 8, k_2 = 4, k_3 = 15$ (F1, F2); $k_1 = 10, k_2 = 4, k_3 = 25$ (H1, H2).[12] For the final fitting (after hyperpars have been learned): $k_1 = 25, k_2 = 12$ (F1, F2); $k_1 = 30, k_2 = 17$ (H1, H2). The optimization is started from $v_c = 5$ for all methods. We set $\sigma^2 = 0.01$ throughout. Results are given in Table 1.

The hierarchical model outperforms the flat one consistently, especially w.r.t. taxo-loss and parent accuracy. Also, minimizing expected loss is consistently better than using the standard rule for the latter, although the differences are not significant. H1 and H2 do not perform differently: choosing many different v_c in the linear kernel seems no advantage here (but see Section 6.2). The results are quite similar to the ones of Cai and Hofmann (2004), obtained with a support vector machine variant. However, for our method, the recommendation in Cai and Hofmann (2004) to use $v_c = 1$ (not further motivated there) leads to significantly worse results in all scores. The v_c chosen by our method are generally larger. Note that their code has not been made publicly available, so a direct comparison with "all other things equal" could not be done.

In Table 2, we present running times[13] for the final fitting and for a single fold during hyperparameter optimization (5 of these are required for Ψ, $\nabla_h \Psi$). In comparison, a final fitting time of 2200*s* on the D section is quoted in Cai and Hofmann (2004), using a SVM variant, while we require 119*s* (more than six times faster).[14] It is precisely this high efficiency of primary fitting, which allows us to use it as inner loop for automatic hyperparameter learning (Cai and Hofmann, 2004, do not adjust hyperparameters to the data). Possible reasons for the performance difference are given in Section 7.2.

11. For parent accuracy, let $p(j)$ be the node with maximal mass (under p_j) of its children which are leafs, then $y(x_j)$ must be a child of $p(j)$.
12. Except for section C, where $k_1 = 14, k_2 = 6, k_3 = 35$.
13. Processor time on 64bit 2.33GHz AMD machines.
14. Cai and Hofmann average over three training/test splits. The timing figure 2200*s* in their paper is for three splits (thanks to one of the reviewers to point this out).

6.2 Flat Classification: Remote Sensing

We use the *satimage* remote sensing task from the *statlog* repository.[15] This task has been used in the extensive SVM multi-class study of Hsu and Lin (2002), where it is among the data sets on which the different methods show the most variance. It has $n = 4435$ training, $m = 2000$ test cases, and $C = 6$ classes. Covariates x have 36 attributes with values in $\{0,\ldots,255\}$. No preprocessing was done.

We use the isotropic *Gaussian* (RBF) covariance function

$$K^{(c)}(x,x') = v_c \exp\left(-\frac{w_c}{2}\|x-x'\|^2\right), \quad v_c, w_c > 0. \tag{7}$$

We compare the methods *mc-sep* (ours with separate kernels for each class; 12 hyperparameters), *mc-tied* (ours with a single shared kernel; 2 hyperparameters), *mc-semi* (ours with single kernel $M^{(1)}$, but different v_c; 7 hyperparameters), *1rest* (one-against-rest; 12 hyperparameters). For *1rest*, C binary classifiers are fitted on the tasks of separating class c from all others. They are combined afterwards by the rule $x_* \mapsto \mathrm{argmax}_c \hat{P}_c(+1|x_*)$, where $\hat{P}_c(+1|x_*)$ is the predictive probability estimate of the c-classifier.[16] Note that *1rest* is arguably the most efficient method, in that its binary classifiers can be fitted separately and in parallel. Even if run sequentially, *1rest* typically requires less memory by a factor of C than a joint multi-class method, although this is not true if the kernel matrices are dominating the memory requirements and they are shared between classes in a multi-class method (as in *mc-tied* and *mc-semi* here).

We use our 5-fold CV criterion Ψ for each method. Results here are averaged over ten randomly drawn 5-partitions of the training set (the same partitions are used for the different methods). All optimizations are started from $v_c = 10$, $w_c = (\sum_j \mathrm{Var}[x_j])^{-1} = 0.017$, $\mathrm{Var}[x_j]$ being the empirical variance of attribute j. We set $\sigma^2 = 16$ throughout. The parameters determining the running time (see Section 2, Section 4) are set to $k_1 = 13, k_2 = 25, k_3 = 40$ during hyperparameter learning, and $k_1 = 30, k_2 = 50$ for final fitting (these are very conservative settings). Error-reject curves are shown in Figure 3.

Test errors are 7.95%($\pm$0.15%) for *mc-sep*, 8.00%($\pm$0.10%) for *1rest*, 8.10%($\pm$0.13%) for *mc-semi*, and 8.35%($\pm$0.20%) for *mc-tied*. Therefore, using a single fixed kernel for all $K^{(c)}$ does significantly worse than allowing for an individual $K^{(c)}$ per class. The test error difference between *mc-sep* and *1rest* is not significant here, but the error-reject curve is significantly better for our method *mc-sep* than for one-against-rest, especially in the domain $\alpha \in [0.025, 0.25]$, arguably most important in practice (where the rejection of a small fraction of test cases may often be an option). This indicates that the predictive probability estimates from our method are better than from one-against-rest, at least w.r.t. their ranking property. The curves for *mc-semi*, *mc-tied* are closer to *1rest*, underlining that different kernels $K^{(c)}$ should be used for each class. The result for *mc-sep* is state-of-the-art. The best SVM technique tested in Hsu and Lin (2002) attained 7.65% (no error-reject curves were given there), and SVM one-against-rest attained 8.3% in this study. To put this into perspective, note that extensive hyperparameter selection by cross-validation is done in Hsu and Lin (2002), in what seems to be a quite user-intensive process, while our method is completely automatic.

15. Available at `http://www.niaad.liacc.up.pt/old/statlog/`.
16. Asymptotically, $\hat{P}_c(+1|x_*)$ converges to the true $P(y_* = c|x_*)$, and this combination rule is optimal. We use our method with $C = 2$ in order to implement the binary classifiers.

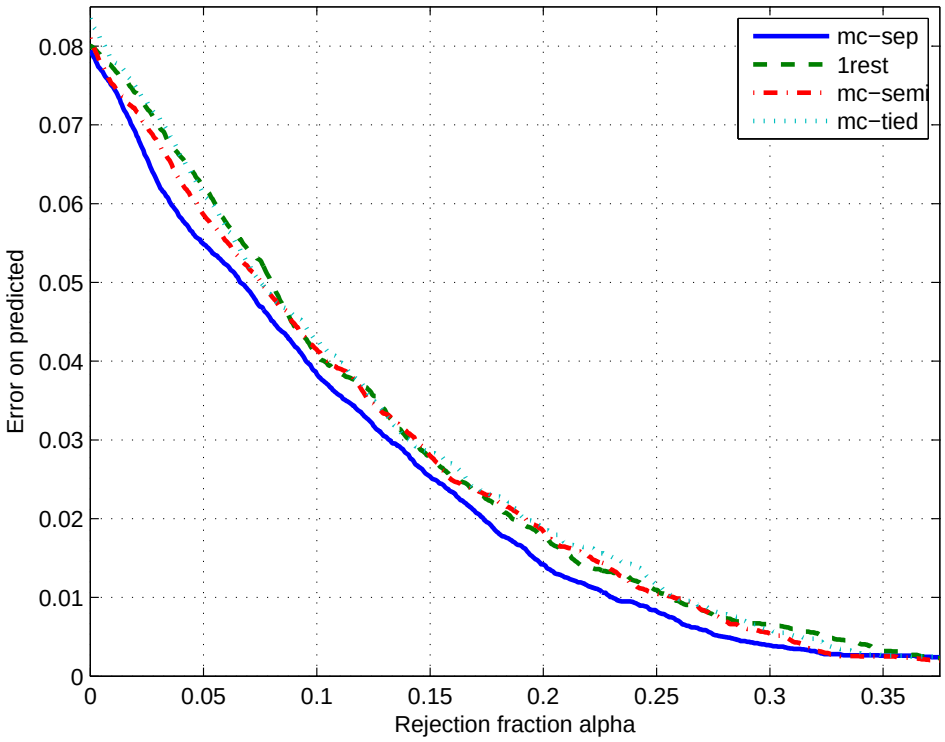

Figure 3: Error-reject curves (averaged over 10 runs) for different methods on the *satimage* task. Curve obtained by allowing the method to abstain from prediction on fraction α of test set, counting errors for predictions only. Depends on ranking of test points. Ranking score (over test points x_*): $\max_c \hat{P}(y_* = c|x_*)$ (*mc-sep*, *mc-semi*, *mc-tied*), $\max_c \hat{P}_c(+1|x_*)$ (*1rest*).

6.3 Flat Classification: Handwritten Digits

We use the *USPS* handwritten digits recognition task (LeCun et al., 1989). The covariates x are 16×16 gray-scale images with values in $\{16k+15\,|\,k = 0,\ldots,30\}$. The task has $n = 7291$ training, $m = 2007$ test cases, and $C = 10$ classes. No preprocessing was done.

We use Gaussian kernels (7) once more, different ones for each class. We do not optimize the 5-fold CV criterion Ψ using the full training set, but subsets of size $n' = 2000$. Our results are averaged over five runs with different randomly drawn training subsets for hyperparameter learning, while we use the full training set for final fitting. All optimizations are started from $v_c = 10$, $w_c = (\sum_j \mathrm{Var}[x_j])^{-1} = 0.0166$, and we set $\sigma^2 = 4$ throughout. The parameters determining the running time are $k_1 = 25$, $k_2 = 35$, $k_3 = 40$ during hyperparameter learning (on $n' = 2000$ points), and $k_1 = 45$, $k_2 = 80$ for final fitting (on $n = 7291$ points). The settings for hyperparameter learning are quite conservative, and the final fitting ones were sufficient for convergence on three of the five runs, whereas on two we had to add another $k_1 = 25$ iterations with $k_2 = 90$. An error-reject curve is shown in Figure 4.

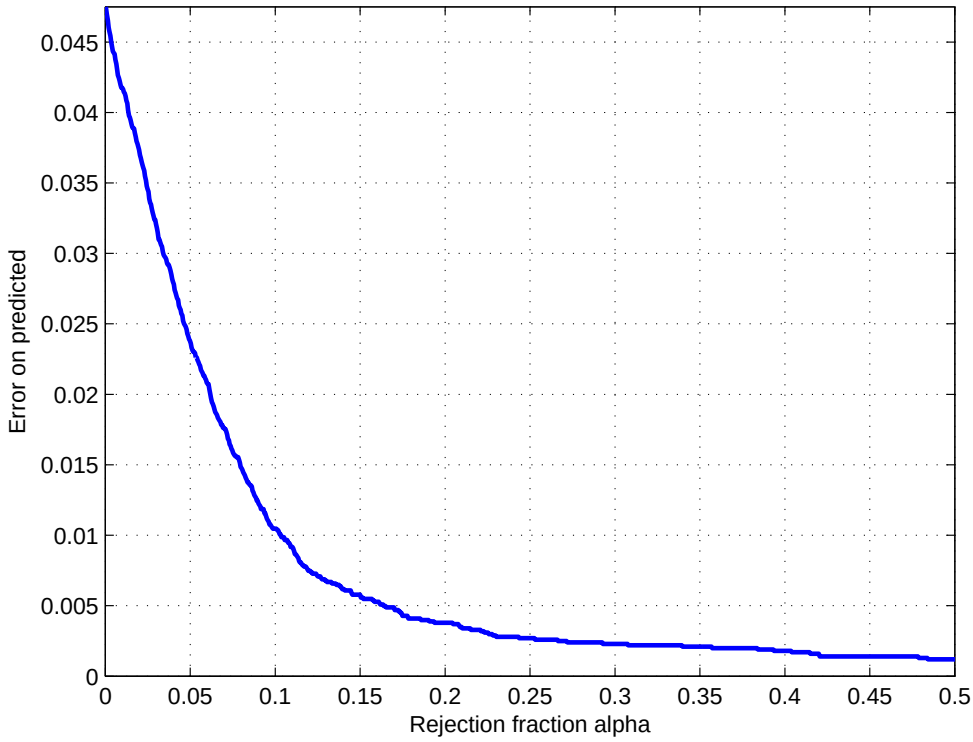

Figure 4: Error-reject curves (averaged over 5 runs) for different methods on the *USPS* task. Curve obtained by allowing the method to abstain from prediction on fraction α of test set, counting errors for predictions only. Depends on ranking of test points.

Test errors are $4.77\%(\pm 0.18\%)$. These results are state-of-the-art for kernel classification. Seeger (2003) reports 4.98% for the IVM (Sect. 4.8.4), where hyperparameters are learned automatically. Csató (2002) states 5.15% for his sparse online method with multiple sweeps over the data (Sect. 5.2). Results for the support vector machine are given in Schölkopf and Smola (2002), Table 18.1, method SV-254, where a combination heuristic based on kernel PCA was used to attain a test error of 4.4%. Crammer and Singer (2001) quote a test error of 4.38%, kernel parameters having been selected by 5-fold cross-validation. All these used the Gaussian kernel as well. The latter studies do not quote fluctuations w.r.t. choices such as the fold partition in CV, which is not negligible in our case here. The SVM-based methods do not attempt test set rankings or predictive probability estimation, and the corresponding studies do not show error-reject (or ROC) curves. Seeger (2003) gives an error-reject curve, which is very similar to ours here.

Note that the harder settings of k_1, k_2 for the final fitting are necessary due to the problem size, and are motivated in Section 4. There are 72910 parameters, and the hyperparameters found through optimizing Ψ spread by 3 orders of magnitude, so that the corresponding final fitting problems are computationally hard to solve without a good initialization of α (in the absence of such, we start with $\alpha = 0$). If we solve for Newton directions using too few LCG steps, the approximations often do not lead to much (or any) descent. Such "stalling" of NR line searches does happen now and then even

after $k_2 = 80$ LCG steps.[17] Lessons learned from these large scale experiments are commented on in Section 4. There are delicate dependencies between k_1, k_2 and the running time to convergence, which need to be explored in large scale settings, but this was not done thoroughly here.

7. Discussion

We have presented a general framework for learning kernel-based penalized likelihood classification methods from data. A central feature of the framework is its high computational efficiency, even though all classes are treated jointly. This is achieved by employing approximate Newton-Raphson optimization for the parameter fitting, which requires few large steps only for convergence. These steps are reduced to matrix-vector multiplication (MVM) primitives with kernel matrices. For general kernels, these MVM primitives can be reduced to large numerical linear algebra primitives, which can be computed very efficiently on modern computer architectures. This is very much in contrast to many chunking algorithms for kernel method fitting, which have been proposed in machine learning, and the advantages of our approach are detailed in Section 7.2. Dependencies between classes can be encoded *a priori* with minor additional efforts, as has been demonstrated for the case of hierarchical classification. Our method provides estimates of predictive probabilities which are asymptotically correct. Hyperparameters can be adjusted automatically, by optimizing a cross-validation log likelihood score in a gradient-based manner, and these computations are once more reduced to the same MVM primitives. This means that within our framework, all code optimization efforts can be concentrated on these essential primitives (see also Section 7.3), rather than having to tune a set of further heuristics.

7.1 Related Work

Our primary fitting optimization for flat multi-way classification appeared in Williams and Barber (1998), although some fairly essential features are novel here. They also did not consider large scale problems or class structures. Empirical Bayesian criteria such as the marginal likelihood are routinely used for hyperparameter learning in Gaussian process models (Williams and Barber, 1998; Williams and Rasmussen, 1996). However, in cases other than regression estimation with Gaussian noise, the marginal likelihood for a GP model cannot be computed analytically, and approximations differ strongly in terms of accuracy and computational complexity. For the multi-class model, Williams and Barber (1998) use an MAP approximation for fixed hyperparameters, just as we do, but their second-order approximation to the marginal likelihood is quite different from our criterion, conceptually as well as computationally (see below). Approximately solving large linear system by linear conjugate gradients (LCG) is standard in numerical mathematics, and has been used in machine learning as well (Gibbs, 1997; Williams and Barber, 1998; Keerthi and DeCoste, 2005).

The idea of optimizing approximations to a cross-validation score for hyperparameter learning is not novel (Craven and Wahba, 1979; Qi et al., 2004). Our approach is different to these, in that the CV score and gradient computations are reduced to elementary steps of the primary fitting method,

17. We cannot obtain a good initial α value from the final $\alpha_{[J_k]}$ of hyperparameter learning, because this is done on training subsets only. Moreover, in our implementation, the "stalling" (no improvement) of a NR step means that LCG is restarted from its last recent β, so that eventually an improvement in Φ is still obtained. Of course, the stalled NR iterations counts as such, and we do k_1 iterations in total.

so both can be done with the same code.[18] In contrast, scores like GCV (Craven and Wahba, 1979) or second order marginal likelihood (Williams and Barber, 1998) come in terms of the form $\mathrm{tr}\, H^{-1}$ or $\log|H|$ for the Hessian H of size nC. There are approximate reductions of computing these terms to solving linear systems (randomized trace estimator, Lanczos), but they rely on additional sampling of Gaussian noise, which introduces significant inaccuracies. In practice, optimizing such "noisy" criteria is quite difficult, whereas our criterion can be optimized using standard optimization code. Qi et al. (2004) propose an interesting approach of approximating leave-one-out CV using expectation propagation, see also Opper and Winther (2000). They use a sparse approximation for efficiency, but they deal with a single-process model only ($C = 1$), and it is not clear how to implement EP efficiently (scaling linearly in C) for the multi-class model. Interestingly, they observe that optimizing their approximate CV score is more robust to overfitting than the marginal likelihood. Finally, none of these papers propose (or achieve) a complete reduction to kernel MVM primitives only, nor do they deal with representing class structures or work on problems of the scale considered here.

Many different multi-class SVM techniques have been proposed, see Crammer and Singer (2001) and Hsu and Lin (2002) for references. These can be split into joint ("all-together") and decomposition methods. The latter reduce the multi-class problem to a set of binary ones ("one-against-rest" of Section 6.2 is a prominent example), with the advantage that good code is available for the binary case. The problem with these methods is that the binary discriminants are fitted separately without knowledge of each other, or of their role in the final multi-way classifier, so information from data is wasted. Also, their post-hoc combination into a multi-way discriminant is heuristic. Joint methods are like ours here, in that all classes are jointly represented. Fitting is a constrained convex problem, and often fairly sparse solutions (many zeros in α) are found. However, in difficult structured label tasks, the degree of sparsity is usually not high, and in these cases, commonly used chunking algorithms for multi-class SVM can be very inefficient (see Section 7.2). We should note that our approach here cannot be applied directly to multi-class SVMs, since they require the solution of a constrained convex problem, but the principles used here should hold there as well. Some novel suggestions here appear independently in Keerthi et al. (2007). SVM methods typically do not come with efficient automatic kernel parameter learning schemes, and they do not provide estimates of predictive probabilities which are asymptotically correct.

On the other hand, in a direct comparison our implementation would still be slower than the highly optimized multi-class SVM code of Crammer and Singer (2001), at least on standard non-structured tasks such as USPS (Section 6.3) or MNIST. Especially on the latter, sparsity in α is clearly present, and years of experience with the SVM problem led to very effective ways of exploiting it. In contrast, α in our approach is not sparse, and it is not our goal here to find a sparse approximation. Hyperparameters are selected "by hand" in their method, not via gradient-based optimization. For a small number of hyperparameters, this traditional approach is often faster than our optimization-based one here, and importantly, it can be fully parallelized. However, our approach is still workable in situations with many dependent hyperparameters (for example, Section 7.4.1), where CV by hand simply cannot be done.

Our ANOVA setup for hierarchical classification is proposed by Cai and Hofmann (2004), whose use it within a SVM "all-together" method. We compare our method against theirs in Sec-

18. A small drawback of our approach is that our CV score Ψ depends on a partitioning of the training set. In our experiments here, we chose this at random. Leave-one-out (LOO) CV does not depend on a partitioning, but it is not clear how to reduce LOO CV to solving a small number of linear systems.

tion 6.1, achieving quite similar results in an order of magnitude less time. They also do not address the problem of hyperparameter learning.

7.2 Global versus Decomposition Methods

In most kernel methods proposed so far in machine learning, the primary fitting to data (for fixed hyperparameters) translates to a convex minimization problem, where the penalisation terms correspond to quadratic expressions with kernel matrices. While kernel matrices may show a rapidly decaying eigenvalue spectrum, they certainly do couple the optimization variables strongly.[19] While a convex function can be optimized by any method which just guarantees descent in each step, there are huge differences in how fast the minimum is attained to a desired accuracy. In fact, in the absence of local minima, the speed of convergence becomes the most important characteristic of a method, besides robustness and ease of implementation.

In machine learning, the most dominant technique for large scale (structured label) kernel classification is what optimization researchers call *block coordinate descent methods* (BCD), see Bertsekas (1999, Sect. 2.7). The idea is to minimize the objective w.r.t. a few variables at a time, keeping all others fixed, and to iterate this process using some scheduling over the variables. Each step is convex again,[20] yet much smaller than the whole, and often the steps can be solved analytically. Ignoring the aspect of scheduling, such methods are simple to implement.

A complementary approach is to find search directions which lead to as fast a descent as possible, these directions typically involve all degrees of freedom of the optimization variables. If local first and second order information can be computed, the optimal search direction is Newton's, which has to be corrected if constraints are present (conditional gradient or gradient projection methods). If the Newton direction cannot be computed feasibly, approximations may be used. Such Newton-like methods are certainly vastly preferred in the optimization community, due to superior convergence rates, but also because features of modern computer architectures are used more efficiently, as is detailed below. In this paper, we advocate to follow this preference for kernel machine fitting in machine learning. We are encouraged not only by our own experiences, but can refer to the fact that (approximate) Newton methods are standard for fitting generalized linear models in statistics, and that such methods are also routinely used for Gaussian process models (Williams and Barber, 1998; Rasmussen and Williams, 2006), albeit typically on problems of smaller scale than treated here.

The dominance of BCD methods for kernel machine fitting, while somewhat surprising, can be attributed to early success stories with SVM training, culminating in the SMO algorithm (Platt, 1998), where only two variables are changed at a time. If an SVM is fitted to a task with low noise, the solution can be highly sparse, and if the active set of "support vectors" is detected early in the optimization process, methods like SMO can be very efficient. Importantly, SMO or other BCD methods are easily implemented. On the other hand, as SVMs are increasingly applied to hard structured label problems which usually do not have very sparse solutions, or whose active sets are hard to find, weaknesses of BCD methods become apparent.

Block coordinate descent methods are often referred to as using the "divide-and-conquer" principle, but this is not the case for kernel method fitting. BCD methods "are often useful in contexts where the cost function and the constraints have a partially decomposable structure with respect to

19. An almost low-rank kernel matrix translates into a coupling of a simple structure, but the dominant couplings are typically strong and not sparse.
20. If $f(x)$ is convex, so is $f(Ax)$ for any matrix A. The same is true for linear constraints.

the problem's optimization variables" (Bertsekas, 1999, p. 269). In kernel methods, such a decomposable structure is not present, because the penalisation terms couple all variables strongly via the kernel matrices. In such cases, chunking techniques *divide without conquering*, often running for very many steps, because improvements w.r.t. some block of variables tend to erase earlier improvements. This central problem of block coordinate descent methods is well known as "zig-zagging" in optimization. It occurs whenever variables not in the same block are significantly coupled, a situation which is to be expected for kernel machines in general. The situation is similar to a number of cases in machine learning and statistics. Iterative proportional fitting (Della Pietra et al., 1997) is a BCD method for learning the potentials of an undirected graphical model (Markov random field), which is all but superseded now by modern global direction methods such as limited memory Quasi-Newton, running orders of magnitude faster. Gibbs sampling is a basic Markov chain Monte Carlo technique for approximate Bayesian inference, which typically is very simple to implement, but is exceedingly slow in the presence of many coupled variables. Modern techniques such as Hybrid Monte Carlo, or Swendsen-Wang can be seen as "global direction" variants of "block coordinate" Gibbs sampling, and while they are harder to implement, they typically run orders of magnitude faster.

Another significant problem with BCD methods may come more as a surprise, namely because it concerns a characteristic which is often sold as advantage of these methods: they make each step as small as possible. Such small steps can often be dealt with analytically, or by using simple methods. This characteristic certainly makes BCD methods easy to implement. However, in light of modern computer architectures, the advice must be to make each step as *large as possible*, with the aim of requiring fewer steps. Modern systems use many internal parallelisms and hierarchies of caching, with the aim of processing vector operations many times faster than an equivalent loop over scalar operations, and large global steps do make use of these features. In contrast, a method which calls very many small steps in a non-linear ordering, runs contrary to these mechanisms. For example, data transfer between cache levels is done in blocks of significant sizes, and a method which accesses memory element-wise from all over the place, leads to inefficiencies up to cache thrashing, where the majority of cache accesses are misses (see Appendix D.3 for an example).

In well-designed global direction methods, the bottleneck operations (where almost all real-world running time is spent) are large vectorised mappings which access memory contiguously. Even better, these operations should lie in a standard class, for which highly optimized implementations are readily available. In our case here, the bottleneck operations are numerical linear algebra primitives from the *basic linear algebra subroutines* (BLAS), a standardized interface for high-performance dense linear algebra code. Very efficient implementations of the BLAS are available for all computer architectures.[21]

In this paper, we advocate to take a step back and to use global direction methods as approximation to Newton's method for kernel machine fitting. The prospect seems daunting, since there are many thousands of variables with complicated couplings, and the reader may be reminded of early disastrous trials of applying off-the-shelf QP packages to SVM fitting, or of ongoing efforts to formulate otherwise tractable machine learning problems as semidefinite programs and "solving" them using $O(n^7)$ SDP packages. This association is wrong. Our advice is to *approximate* the global Newton direction, making use of all structure in the model in order to gain efficiency, which is exactly the opposite of running a black box solver or implementing Newton's method straight

21. ATLAS, a self-tuning BLAS implementation, is available as free software, see `http://math-atlas.sourceforge.net/`.

out of a textbook. In the context of kernel machines, where couplings through large unstructured matrices are present, the large steps of approximating the Newton direction should be reduced to standard linear algebra primitives on dense or sparse matrices, operating on contiguous chunks of memory *as large as possible*, since highly optimized code for such primitives is readily available.

7.3 Matrix-Vector Multiplication

The computational load in our framework is determined by applications of the MVM primitives $v \mapsto K^{(c)}v$ and $v \mapsto (\partial K^{(c)}/\partial h_p)v$. A user only needs to provide those for a kernel of choice. The generic representation of Appendix D.1 applies to general covariance functions, but much more efficient alternatives may be used in special cases (see Appendix D.3).

If the cost for a direct evaluation of these primitives is prohibitive, several well-known approximations may be applied. Its has been suggested to use specialized data structures to approximate MVM with matrices from isotropic kernels (Yang et al., 2005; Shen et al., 2006) such as the Gaussian one (7). For such kernels, the derivative MVM can often be addressed using the same techniques. For the Gaussian kernel, we have $K = v\exp(wA)$, $A = (-(1/2)\|x_i - x_j\|^2)_{i,j}$, in which case $(\partial K/\partial \log v) = K$ and $(\partial K/\partial \log w) = wK \circ A$, where $\circ$ denotes component-wise product. Since the specialized data structures concentrate on approximating A, they apply to all required MVM variants. Our public code could fairly easily be extended, given specialized approximate kernel MVM code is available.

7.4 Extensions and Future Work

Some concrete extensions are mentioned just below. In general, we think that many structured label kernel methods proposed in the SVM context can be addressed in our framework as well. For example, the kernel conditional random field (CRF) (Lafferty et al., 2004) for label sequence learning can be treated by recognizing that MVM with the Hessian of the CRF log likelihood can be implemented efficiently using the method described in Pearlmutter (1994). We also plan to address hierarchical multi-label problems, which differ from hierarchical multi-class in that each instance can have multiple associated labels.

7.4.1 Modelling Dependencies between Classes

In the flat classification application of Section 2, we do not explicitly represent dependencies between classes. This is done in the hierarchical classification application of Section 3, but the dependency structure is fixed *a priori*. In this section, we motivate how dependencies between classes can be learned from data.

Let $B \in \mathbb{R}^{C,C}$ be a nonsingular coupling matrix, which will be a part of the model. In fact, B should be regarded as hyperparameters. In the flat model, we have $u_i = f_i + b$, which is now replaced by $u_i = Bf_i + b$, or

$$u = (B \otimes I)K\alpha + b \otimes 1.$$

This is the same modification which led to the hierarchical extension, only that the fixed coupling matrix Φ is replaced by the variable B. Therefore, the same modification of our method can be done, replacing K by $K^{(B)} = (B \otimes I)K(B^T \otimes I)$. Again, MVM with $K^{(B)}$ is of the same complexity as with K, because MVM with $(B \otimes I)$ can be done in $O(C^2 n)$. Note that B represents *conditional* depen-

dencies between the $u_c(\cdot)$, its role is comparable to the "mixing matrix" in independent components analysis.

We are also interested in learning B, whose elements are taken as hyperparameters. The corresponding gradient of Ψ is obtained in the same way as described in Section 5.2, only that $dK_{[B]}$ now further decomposes into parts for dB and for dK. Note that learning B by non-automatic cross-validation would not be possible, due to the large number of components.

Consider the case where we have many classes C, but not much data for most of them. We can postulate the assumptions that the behaviour of the C class functions $u_c(\cdot)$ is represented by $p \ll C$ underlying latent factors, which are then modelled as independent. This is achieved in our framework by having a non-square mixing matrix $B \in \mathbb{R}^{C,p}$ (the "factor loadings"). It is not hard to adapt our framework to this case, in which it is obviously necessary to learn B as hyperparameters from data. A related model in a Bayesian context was considered in Teh et al. (2005).

7.4.2 UNCERTAIN TARGETS IN HIERARCHICAL CLASSIFICATION

Recall the hierarchical classification setup of Section 3. Suppose that for some patterns x_i, the target is unknown, but we know that the path from its class to the root goes through an inner node p. Denote by L_p the set of leaf nodes of the subtree rooted at p, so that $L_p = \{p\}$ for a leaf node $p \in L$, and $L_0 = L$.

We can allow for such uncertain target information by using pseudo-targets $\tilde{y}_i \in \{1, \ldots, P\}$. If $\tilde{y}_i \notin L$, it is the lowest inner node we are certain about. The corresponding likelihood factor is

$$\sum_{c \in L_{\tilde{y}_i}} P(y_i = c | u_i).$$

Note that the log likelihood is not a concave function anymore, whenever $|L_{\tilde{y}_i}| > 1$, and in the presence of such factors, primary fitting is not a convex problem. However, an expectation-maximization (EM) (Dempster et al., 1977) approach can be used to deal with uncertain targets. Namely, in "E steps" we compute

$$q_{ic} \propto \mathrm{I}_{\{c \in L_{\tilde{y}_i}\}} P(y_i = c | u_i)$$

for the current $u_c(\cdot)$, where $q_i = (q_{ic})_c$ are distributions. "M steps" consists of Newton-Raphson iterations as before, but using $\sum_c q_{ic} \log P(y_i = c | u_i)$ as log likelihood factors. To this end, we just have to replace the vector $y \in \mathbb{R}^{nC}$ by q. Importantly, we only used the properties $1^T y_i = 1$, $y_i \geq 0$ above (but not that $y_{ic} \in \{0, 1\}$), which are true for q just as well.

7.4.3 LOW RANK APPROXIMATIONS

Our generic kernel matrix representation is described in Appendix D.1. If the data set size n is large, we may not be able to keep the correlation matrices $M^{(l)}$ in memory, and MVM with them becomes prohibitively expensive. We can use standard low rank matrix approximations to deal with this problem (see also Section 7.3). Namely, suppose that $M^{(l)}$ is approximated by $P^{(l)} L^{(l)} L^{(l)T} P^{(l)T}$, where $P^{(l)}$ is a permutation matrix, and $L^{(l)} \in \mathbb{R}^{n,d_l}$ for $d_l \ll n$. Denote $I_l \subset \{1, \ldots, n\}$ the active set of size d_l. The approximation may be obtained by an incomplete Cholesky factorization[22] (ICF), which has the special property that only a small set of d_l columns of $M^{(l)}$ (along with its diagonal)

22. Matlab code for ICF (in the form required here) can be downloaded from `http://www.kyb.tuebingen.mpg.de/bs/people/seeger/software.html`.

ever have to be evaluated (Bach and Jordan, 2002). In this case, $L^{(l)}_{1\ldots d_l,\cdot}$ is the lower triangular Cholesky factor of $M^{(l)}_{I_l} \in \mathbb{R}^{d_l,d_l}$, so that $P^{(l)T} M^{(l)}_{\cdot,I_l} = L^{(l)} {L^{(l)}_{1\ldots d_l,\cdot}}^T$. Note that in the ICF case, we have that

$$\mathrm{diag}\left(P^{(l)T} M^{(l)} P^{(l)} - L^{(l)} L^{(l)T}\right) \geq 0$$

point-wise, because the elements are simply the squared pivots for a potential continuation of the factorization (which has been stopped after d_l steps). Therefore, we can correct the approximation by replacing the diagonal of $L^{(l)}L^{(l)T}$ by the true one, ending up with the approximation

$$M^{(l)} \approx \tilde{M}^{(l)} := (\mathrm{diag}^2 M^{(l)}) + P^{(l)}\left(L^{(l)}L^{(l)T} - (\mathrm{diag}^2 L^{(l)}L^{(l)T})\right)P^{(l)T}.$$

Snelson and Ghahramani (2006) motivate this diagonal correction in another context. It is clear that MVM with $\tilde{M}^{(l)}$ can be done in $O(n\,d_l)$.

If $*$ indexes test points different from the training points, then the test-training correlation matrix is

$$M^{(l)}_{*,\cdot} = M^{(l)}_{*,I}(L^{(l)}_{1\ldots d_l,\cdot})^{-T} L^{(l)T} P^{(l)T}.$$

We can also learn parameters of the $M^{(l)}$ functions in this low rank setup by gradient-based optimization, assuming that the choice of I_l does not depend on these kernel parameters, but this is not discussed here.

Acknowledgments

We would like to thank Olivier Chapelle for many useful discussions on approximations of cross-validation optimization, and Peter Gehler for help with preprocessing the WIPO-alpha data, furthermore L. Cai and T. Hofmann for providing us with counts and dictionary data. Dilan Görur gave helpful comments on the NIPS paper related to this work. Supported in part by the IST Programme of the European Community, under the PASCAL Network of Excellence, IST-2002-506778.

Appendix A. Notation

In this section, we describe the notation used in this paper. We denote vectors and matrices by boldface lower-case and upper-case letters, scalars and scalar functions are set normally. Subscripts select parts of objects, they can be single indexes or index sets. For example, $a = (a_i)_i$ is a vector with components a_i, $A = (a_{i,j})_{i,j}$ a matrix with entries $a_{i,j}$. We also write $a = (a_i)$, $A = (a_{i,j})$ if the indexes are clear from context. $A_{\cdot,i}$ is the i-th column of A ("$\cdot$" is short for the full index set). $\otimes$ denotes the Kronecker product, $A \otimes B = (a_{i,j}B)_{i,j}$, 1 (0) the vector of all ones (vector/matrix of all zeros), I the identity matrix, and $\delta_j = (\mathrm{I}_{\{i=j\}})_i$ (columns of I). For a matrix A, $\mathrm{diag}A = (a_{i,i})_i$ extracts the diagonal. For a vector v, $\mathrm{diag}v$ is the corresponding diagonal matrix. We also use this for matrix-valued vectors, an example is the diagonal kernel matrix $K = \mathrm{diag}(K^{(c)})_c$ in flat classification.

Many vectors and matrices are indexed by data points (i) and classes (c) at the same time, for example $u = (u_{ic}) \in \mathbb{R}^{nC}$. We use double indexes ic for these, which are flattened as $i + (c-1)n$, so the component ordering[23] is $u = (u_{11}, u_{21}, \ldots, u_{n1}, u_{12}, \ldots)$. In this context, selection index sets

23. In `Matlab`, `reshape(u,n,C)` would give a matrix in $\mathbb{R}^{n,C}$.

I are applied to the i (data point) index only: $u_I = (u_{ic})_{i\in I,c} \in \mathbb{R}^{|I|C}$. Kronecker product notation works nicely with this double index convention. If $A \otimes B$ is applied to u, A has C, B n columns. We frequently use $(1^T \otimes I)u = \sum_c u^{(c)}$, where $u^{(c)} = (u_{ic})_i \in \mathbb{R}^n$, or $(1 \otimes I)v$ for $v \in \mathbb{R}^n$, which stacks v on top of each other C times. The matrix $P_{cls} = (1 \otimes I)(1^T \otimes I)$ (introduced in Section 5.1) combines these operations:

$$P_{cls}x = \left.\begin{pmatrix} \bar{x} \\ \bar{x} \\ \vdots \end{pmatrix}\right\} C, \quad \bar{x} = \sum_c x^{(c)},$$

and P_{data} does the same, but operating on the i rather than the c index.

All major notational definitions are listed in Table 3 for reference. For kernel matrices (for example, $K^{(c)}$), we do not list the kernel functions (here: $K^{(c)}$), and for evaluation vectors (for example, u), we do not list the underlying functions (here: $u^{(c)}(\cdot)$).

Appendix B. Details for Primary Fitting Algorithm

In this section, we discuss further details of the primary fitting algorithm of Section 2, in addition to Section 5.1.

We need to counter the problem that roundoff errors may lead to numerical instabilities. The criterion we minimize is strictly convex, even if the kernel matrix K is singular (or nearly so). However, problems could arise from components in π becoming very small. Recall that $\log \pi_{ic} = u_{ic} - l_i$. We make use of a threshold $\kappa < 0$ and define

$$I = \{(i,c) \,|\, \log \pi_{ic} < \kappa,\, y_{ic} > 0\}, \quad I_0 = \{(i,c) \,|\, \log \pi_{ic} < \kappa,\, y_{ic} = 0\}.$$

The indices in I can be problematic due to the corresponding component $\tilde{g}_{ic} \approx y_{ic}/\pi_{ic}^{1/2}$ becoming large. Note that this happens only if (x_i, y_i) is a strong outlier w.r.t. the current predictor. Now, from

the system (5) we see that $D^{1/2}\beta = DA^T(u - \tilde{K}\alpha') - g$. Therefore, if $(i,c) \in I$, then $(D^{1/2}\beta)_{ic} \approx -g_{ic} \approx y_{ic}$. The idea is to solve the reduced system on the components in $\setminus I$ for $(D^{1/2}\beta)_{\setminus I}$ and to plug in $(D^{1/2}\beta)_I = y_I$. Finally, within $\setminus I$, the components in I_0 may be problematic when computing the starting value $\beta = D^{-1/2}\alpha$ for the CG run. However, in this case $\tilde{g}_{ic} \approx 0$, leading to $\beta_{ic} \approx 0$ from (5). The corresponding components in the starting value β can therefore be set to zero.

Next, the LCG algorithm for solving systems of the form (5) needs to be preconditioned. Suppose we want to solve $Ax = b$. If we have an approximation $\tilde{A}$ to A so that $v \mapsto \tilde{A}^{-1}v$ can be computed efficiently (essentially in linear time in the size of v), the preconditioned CG algorithm solves the system $\tilde{A}^{-1}Ax = \tilde{A}^{-1}b$ instead. The idea is that $\tilde{A}^{-1}A$ typically has a lower condition number than A, and LCG converges faster and less erratically. Our implementation does preconditioning with the diagonal of the system matrix $I + V^T\tilde{K}V$. Note that $V\delta_{ic} = \pi_{ic}^{1/2}(\delta_c - \pi_i) \otimes \delta_i$, so that

$$\left(I + V^T\tilde{K}V\right)_{ic,ic} = 1 + \pi_{ic}\left((1 - 2\pi_{ic})(K_i^{(c)} + \sigma^2) + \sum_{c'} \pi_i^{(c')2}(K_i^{(c')} + \sigma^2)\right).$$

Therefore, the diagonal can be computed based on the $\mathrm{diag}\,K^{(c)}$ vectors. If the joint kernel matrix K is not block-diagonal (as in hierarchical classification, see Section 3), $\mathrm{diag}\,K$ is not sufficient for computing the system matrix diagonal. Let $v \in \mathbb{R}^{nC}$ be defined via $v_i = K_i\pi_i$, where $K_i = (I \otimes \delta_i^T)K(I \otimes \delta_i) \in \mathbb{R}^{C,C}$. Then, the system matrix diagonal has elements

$$1 + \pi_{ic}\left(K_{ic} + \sigma^2 - 2w_{ic} + \pi_i^T w_i\right), \quad w = v + \sigma^2\pi.$$

Appendix C. Solving Systems Exactly

In this section, we show how to implement our flat multi-class scheme using exact rather than approximate solutions of linear systems, yet still scaling linearly in C (at present, we do not know how to implement hierarchical classification exactly with such scaling).

For a Newton step, we need to solve $(I + W\tilde{K})\alpha' = r$ with $W = D - DP_{cls}D$. This can be written as

$$\left(A - UV^T\right)D^{-1/2}\alpha' = D^{-1/2}r, \quad A = I + D^{1/2}\tilde{K}D^{1/2},$$
$$U = D^{1/2}(1 \otimes I), \quad V = (A - I)U.$$

We now use the Sherman-Morrison-Woodbury formula together with the fact that $U^TU = \sum_c D^{(c)} = I$ to obtain

$$\alpha' = D^{1/2}\left(A^{-1} + A^{-1}U(U^TA^{-1}U)^{-1}U^T(I - A^{-1})\right)D^{-1/2}r.$$

We used that $V^TA^{-1} = U^T(I - A^{-1})$. Note that A^{-1} is block-diagonal, and that

$$U^TA^{-1}U = \sum_c D^{(c)1/2}A^{(c)-1}D^{(c)1/2}.$$

We maintain Cholesky factors of all $A^{(c)}$, as well as the Cholesky decomposition $U^TA^{-1}U = RR^T$ (where $A^{(c)-1}$ are obtained from the Cholesky factors).

For hyperparameter learning, we consider the partitions (I,J) sequentially. Since the $\alpha_{[J]}$ are different across folds, we cannot obtain the $A_{[J]}, H_{[J]}$ as parts of underlying common matrices. Recall Section 5.2. $\alpha_{[J]} + g_{[J]} = 0$ gives $H_{[J]}(d\alpha_{[J]}) = -W_{[J]}(dK_J)\alpha_{[J]}$. With

$$f = I_{\cdot,I}(\pi_{[I]} - y_I) - I_{\cdot,J}W_{[J]}H_{[J]}^{-T}\tilde{K}_{J,I}(\pi_{[I]} - y_I),$$

we have that $d\Psi_I = (I_{\cdot,J}\alpha_{[J]})^T (dK) f$. Again, these vectors are accumulated in matrices E, F. Solving a system with $H_{[J]}^T$ is an obvious variant of the procedure discussed above.

Appendix D. Further Details of the Implementation

Our implementation is designed to be as efficient as possible, while still being general and easy to extend to novel situations. This is achieved mainly by breaking down the problems to calling sequences of MVM primitives. These are then reduced to large numerical linear algebra primitives, where matrices are organized contiguously in memory, in order to exploit modern caching architectures (see Section 7.2).

D.1 A Generic Kernel Matrix Representation

A kernel matrix representation is some data structure which allows to compute kernel matrix MVMs $v \mapsto K^{(c)}v$ efficiently, being the principal primitives of our primary fitting method. Further requirements arise if additional features of our framework are used. For example, if hyperparameters are to be learned as well, derivative MVMs $v \mapsto (\partial K^{(c)}/\partial h_p)v$ are required as well, and "covariance shuffling" should be possible (see Section 5.2).

An efficient representation depends strongly on the covariance function used, and also on whether kernel matrix MVMs are approximated rather than computed exactly. For example, for linear kernels a special representation is used (see Appendix D.3). In this section, we describe a generic representation, which is part of our implementation.

The generic representation can be used with any covariance function, in that no special structure is assumed. It requires kernel matrices to be stored explicitly, which may not be possible for very large n. In general, we allow for different covariance functions $K^{(c)}$ for each class c, although sharing of kernels is supported, in that $K^{(c)}(\cdot,\cdot) = v_c M^{(l_c)}(\cdot,\cdot)$ and $v_c > 0$. Here, $l_c = l_{c'}$ is allowed for $c \neq c'$. The matrices $M^{(l)}$ are stored explicitly. Note that the flexibility of using different variance parameters v_c with the same $M^{(l)}$ does come at no extra cost, except for the fact that these have to be adjusted individually.

Since the $M^{(l)}$ are symmetric, two can be stored each in a $n \times n$ block, say the odd-numbered ones in the lower triangles. Here, the $\mathrm{diag}\, M^{(l)}$ are stored separately, and whenever a specific $M^{(l)}$ is required explicitly, the diagonal is copied into the block. It is important to note that the BLAS (see Section 7.2) directly supports symmetric matrices which are stored in the lower or upper triangle of a rectangular block.

The reader may wonder whether space could be saved by storing intermediates of the $M^{(l)}$ instead. For example, if the $M^{(l)}$ are isotropic kernels of the form $f^{(l)}(\|x - x'\|)$, we could store the inner product matrix $(x_i^T x_j)_{i,j}$ only. In practice, this turns out to be significantly slower (by a factor), the reason being that the optimized BLAS primitives are many times more efficient than applying a non-linear function $f^{(l)}$ point-wise to a matrix, even if the matrix is stored contiguously. For the same reason, computing MVMs on the fly without storing matrices is even more costly.

D.2 Shuffling the Kernel Matrix Representation

Covariance matrix shuffling has been motivated in Section 5.2. It is required during hyperparameter optimization, because the MVM primitives for sub-matrices K_{J_k} have to be driven by a single representation of the complete K (note that each K_{J_k} is of size $n(q-1)/q$, thus almost as large as K).

A simple approach would be to use sub-indexed matrix-vector multiplication code, but this is very inefficient (usually more than one order of magnitude slower than the flat BLAS functions).

Instead, when dealing with fold k, we shuffle the representation so that K_{J_k} moves to the upper left corner of the matrix. How this is done, depends on the representation. In this context, it is important to note that the underlying BLAS explicitly allows working on sub-matrices within upper left corners of larger frames, with virtually no loss in efficiency.[24] In the generic representation of Appendix D.1, we simply permute the kernel matrices $K^{(c)}$ using the index (J_k, I_k). A corresponding de-shuffling operation has to restore the old representation for K.

D.3 The Linear Kernel

Our application described in Section 6.1 uses the linear kernel $K^{(c)}(x,x') = v_c x^T x'$, where x is very high-dimensional (word counts over a dictionary), but also extremely sparse (by far the most entries are zero). The linear kernel fits the setup of Appendix D.1 with a single $M^{(1)} = XX^T$, where $X \in \mathbb{R}^{n,d}$ is the design matrix. X is very sparse, and in our implementation is represented using a standard sparse matrix format.

An MVM is done as $v \mapsto v_c(XX^T v)$, where X is sparse. More generally, we do $S \mapsto XX^T S$ with large matrices S. Kernel matrix shuffling (Appendix D.2) is implemented by simply reordering the non-zero positions for X. In this context, it is interesting to remark a finding which underlines the arguments in Section 7.2. The sparse matrix format is such that $XX^T S$ is reduced to so-called *daxpy* operations ($a = a + \alpha b$) on the *rows* of S. By Fortran (and BLAS) convention, S is stored in column-order, so that rows can only be accessed directly by using a striding value > 1 (the distance between consecutive vector elements in memory). We added a simple trick (called *dimension flipping*) to the implementation, which in essence switches our default ordering of Cn vectors $v = (v_{11}, v_{21}, v_{31}, \ldots)^T$ to $(v_{11}, v_{12}, v_{13}, \ldots)^T$ before major kernel MVM computations are done. This simple modification led to a direct five-times speedup, which underlines the importance of contiguous memory access in the bottleneck computations of a method (which allows optimal usage of cache hierarchies).

Abstract

We consider the least-square regression problem with regularization by a block ℓ_1-norm, that is, a sum of Euclidean norms over spaces of dimensions larger than one. This problem, referred to as the group Lasso, extends the usual regularization by the ℓ_1-norm where all spaces have dimension one, where it is commonly referred to as the Lasso. In this paper, we study the asymptotic group selection consistency of the group Lasso. We derive necessary and sufficient conditions for the consistency of group Lasso under practical assumptions, such as model misspecification. When the linear predictors and Euclidean norms are replaced by functions and reproducing kernel Hilbert norms, the problem is usually referred to as multiple kernel learning and is commonly used for learning from heterogeneous data sources and for non linear variable selection. Using tools from functional analysis, and in particular covariance operators, we extend the consistency results to this infinite dimensional case and also propose an adaptive scheme to obtain a consistent model estimate, even when the necessary condition required for the non adaptive scheme is not satisfied.

Keywords: sparsity, regularization, consistency, convex optimization, covariance operators

1. Introduction

Regularization has emerged as a dominant theme in machine learning and statistics. It provides an intuitive and principled tool for learning from high-dimensional data. Regularization by squared Euclidean norms or squared Hilbertian norms has been thoroughly studied in various settings, from approximation theory to statistics, leading to efficient practical algorithms based on linear algebra and very general theoretical consistency results (Tikhonov and Arsenin, 1997; Wahba, 1990; Hastie et al., 2001; Steinwart, 2001; Cucker and Smale, 2002).

In recent years, regularization by non Hilbertian norms has generated considerable interest in linear supervised learning, where the goal is to predict a response as a linear function of covariates; in particular, regularization by the ℓ_1-norm (equal to the sum of absolute values), a method commonly referred to as the *Lasso* (Tibshirani, 1996; Osborne et al., 2000), allows to perform variable selection. However, regularization by non Hilbertian norms cannot be solved empirically by simple linear algebra and instead leads to general convex optimization problems and much of the early effort has been dedicated to algorithms to solve the optimization problem efficiently. In particular, the *Lars* algorithm of Efron et al. (2004) allows to find the entire regularization path (i.e., the set of solutions for all values of the regularization parameters) at the cost of a single matrix inversion.

As the consequence of the optimality conditions, regularization by the ℓ_1-norm leads to *sparse* solutions, that is, loading vectors with many zeros. Recent works (Zhao and Yu, 2006; Yuan and

Lin, 2007; Zou, 2006; Wainwright, 2006) have looked precisely at the model consistency of the Lasso, that is, if we know that the data were generated from a sparse loading vector, does the Lasso actually recover it when the number of observed data points grows? In the case of a fixed number of covariates, the Lasso does recover the sparsity pattern if and only if a certain simple condition on the generating covariance matrices is verified (Yuan and Lin, 2007). In particular, in low correlation settings, the Lasso is indeed consistent. However, in presence of strong correlations between relevant variables and irrelevant variables, the Lasso cannot be consistent, shedding light on potential problems of such procedures for variable selection. Adaptive versions where data-dependent weights are added to the ℓ_1-norm then allow to keep the consistency in all situations (Zou, 2006).

A related Lasso-type procedure is the *group Lasso*, where the covariates are assumed to be clustered in groups, and instead of summing the absolute values of each individual loading, the sum of Euclidean norms of the loadings in each group is used. Intuitively, this should drive all the weights in one group to zero *together*, and thus lead to group selection (Yuan and Lin, 2006). In Section 2, we extend the consistency results of the Lasso to the group Lasso, showing that similar correlation conditions are necessary and sufficient conditions for consistency. Note that we only obtain results in terms of group consistency, with no additional information regarding variable consistency inside each group. Also, when the groups have size one, then we get back similar conditions than for the Lasso. The passage from groups of size one to groups of larger sizes leads however to a slightly weaker result as we can not get a single necessary and sufficient condition (in Section 2.6, we show that the stronger result similar to the Lasso is not true as soon as one group has dimension larger than one). Also, in our proofs, we relax the assumptions usually made for such consistency results, that is, that the model is completely well-specified (conditional expectation of the response which is linear in the covariates and constant conditional variance). In the context of *misspecification*, which is a common situation when applying methods such as the ones presented in this paper, we simply prove convergence to the best linear predictor (which is assumed to be sparse), both in terms of loading vectors and sparsity patterns.

The group Lasso essentially replaces groups of size one by groups of size larger than one. It is natural in this context to allow the size of each group to grow unbounded, that is, to replace the sum of Euclidean norms by a sum of appropriate Hilbertian norms. When the Hilbert spaces are reproducing kernel Hilbert spaces (RKHS), this procedure turns out to be equivalent to learn the best convex combination of a set of basis positive definite kernels, where each kernel corresponds to one Hilbertian norm used for regularization (Bach et al., 2004a). This framework, referred to as *multiple kernel learning* (Bach et al., 2004a), has applications in kernel selection, data fusion from heterogeneous data sources and non linear variable selection (Lanckriet et al., 2004a). In this latter case, multiple kernel learning can exactly be seen as variable selection in a *generalized additive model* (Hastie and Tibshirani, 1990). We extend the consistency results of the group Lasso to this nonparametric case, by using covariance operators and appropriate notions of functional analysis. These notions allow to carry out the analysis entirely in *"primal/input"* space, while the algorithm has to work in *"dual/feature"* space to avoid infinite dimensional optimization. Throughout the paper, we will always go back and forth between primal and dual formulations, primal formulation for analysis and dual formulation for algorithms.

The paper is organized as follows: in Section 2, we present the consistency results for the group Lasso, while in Section 3, we extend these to Hilbert spaces. Finally, we present the adaptive

schemes in Section 4 and illustrate our set of results with simulations on synthetic examples in Section 5.

2. Consistency of the Group Lasso

We consider the problem of predicting a response $Y \in \mathbb{R}$ from covariates $X \in \mathbb{R}^p$, where X has a block structure with m blocks, that is, $X = (X_1^\top, \ldots, X_m^\top)^\top$ with each $X_j \in \mathbb{R}^{p_j}$, $j = 1, \ldots, m$, and $\sum_{j=1}^m p_j = p$. Throughout this paper, unless otherwise specified, $\|a\|$ will denote the Euclidean norm of a vector a (for all possible dimensions of a, for example, p, n or p_j). The only assumptions that we make on the joint distribution P_{XY} of (X,Y) are the following:

(A1) X and Y have finite fourth order moments: $\mathbb{E}\|X\|^4 < \infty$ and $\mathbb{E}Y^4 < \infty$.

(A2) The joint covariance matrix $\Sigma_{XX} = \mathbb{E}XX^\top - (\mathbb{E}X)(\mathbb{E}X)^\top \in \mathbb{R}^{p \times p}$ is invertible.

(A3) We denote by $(\mathbf{w}, \mathbf{b}) \in \mathbb{R}^p \times \mathbb{R}$ any minimizer of $\mathbb{E}(Y - X^\top w - b)^2$. We assume that $\mathbb{E}((Y - \mathbf{w}^\top X - \mathbf{b})^2 | X)$ is almost surely greater than $\sigma_{\min}^2 > 0$. We denote by $\mathbf{J} = \{j, \mathbf{w}_j \neq 0\}$ the sparsity pattern of $\mathbf{w}$.[1]

The assumption **(A3)** does not state that $\mathbb{E}(Y|X)$ is an affine function of X and that the conditional variance is constant, as it is commonly done in most works dealing with consistency for linear supervised learning. We simply assume that given the best affine predictor of Y given X (defined by $\mathbf{w} \in \mathbb{R}^p$ and $\mathbf{b} \in \mathbb{R}$), there is still a strictly positive amount of variance in Y. If **(A2)** is satisfied, then the full loading vector $\mathbf{w}$ is uniquely defined and is equal to $\mathbf{w} = \Sigma_{XX}^{-1}\Sigma_{XY}$, where $\Sigma_{XY} = \mathbb{E}(XY) - (\mathbb{E}X)(\mathbb{E}Y) \in \mathbb{R}^p$. Note that throughout this paper, we do include a non regularized constant term b but since we use a square loss it will optimized out in closed form by centering the data. Thus all our consistency statements will be stated only for the loading vector w; corresponding results for b then immediately follow.

We often use the notation $\varepsilon = Y - \mathbf{w}^\top X - \mathbf{b}$. In terms of covariance matrices, our assumption **(A3)** leads to: $\Sigma_{\varepsilon\varepsilon|X} = \mathbb{E}(\varepsilon\varepsilon|X) \geqslant \sigma_{\min}^2$ and $\Sigma_{\varepsilon X} = 0$ (but ε might not in general be independent from X).

2.1 Applications of Grouped Variables

In this paper, we assume that the groupings of the univariate variables are known and fixed, that is, the group structure is given and we wish to achieve sparsity at the level of groups. This has numerous applications, for example, in speech and signal processing, where groups may represent different frequency bands (McAuley et al., 2005), or bioinformatics (Lanckriet et al., 2004a) and computer vision (Varma and Ray, 2007; Harchaoui and Bach, 2007) where each group may correspond to different data sources or data types. Note that those different data sources are sometimes referred to as *views* (see, e.g., Zhou and Burges, 2007).

Moreover, we always assume that the number m of groups is fixed and finite. Considering cases where m is allowed to grow with the number of observed data points, in the line of Meinshausen and Yu (2006), is outside the scope of this paper.

1. Note that throughout this paper, we use boldface fonts for population quantities.

2.2 Notations

Throughout this paper, we consider the block covariance matrix Σ_{XX} with m^2 blocks $\Sigma_{X_iX_j}$, $i,j = 1,\dots,m$. We refer to the submatrix composed of all blocks indexed by sets I, J as $\Sigma_{X_IX_J}$. Similarly, our loadings are vectors defined following block structure, $w = (w_1^\top,\dots,w_m^\top)^\top$ and we denote by w_I the elements indexed by I. Moreover we denote by 1_q the vector in $\mathbb{R}^q$ with constant components equal to one, and by I_q the identity matrix of size q.

2.3 Group Lasso

We consider *independent and identically distributed* (i.i.d.) data $(x_i,y_i) \in \mathbb{R}^p \times \mathbb{R}$, $i = 1,\dots,n$, sampled from P_{XY} and the data are given in the form of matrices $\bar{Y} \in \mathbb{R}^n$ and $\bar{X} \in \mathbb{R}^{n\times p}$ and we write $\bar{X} = (\bar{X}_1,\dots,\bar{X}_m)$ where each $\bar{X}_j \in \mathbb{R}^{n\times p_j}$ represents the data associated with group j (i.e., the i-th row of $\bar{X}_j$ is the j-th group variable for x_i, while $\bar{Y}_i = y_i$). Throughout this paper, we make the same i.i.d. assumption; dealing with non identically distributed or dependent data and extending our results in those situations are left for future research.

We use the square loss, that is, $\frac{1}{2n}\sum_{i=1}^n (y_i - w^\top x_i - b)^2 = \frac{1}{2n}\|\bar{Y} - \bar{X}w - b1_n\|^2$, and thus consider the following optimization problem:

$$\min_{w\in\mathbb{R}^p,\ b\in\mathbb{R}} \ \frac{1}{2n}\|\bar{Y} - \bar{X}w - b1_n\|^2 + \lambda_n \sum_{j=1}^m d_j \|w_j\|,$$

where $d = (d_1,\dots,d_m)^\top \in \mathbb{R}^m$ is a vector of strictly positive fixed weights. Note that considering weights in the block ℓ_1-norm is important in practice as those have an influence regarding the consistency of the estimator (see Section 4 for further details). Since b is not regularized, we can minimize in closed form with respect to b, by setting $b = \frac{1}{n}1_n^\top(\bar{Y} - \bar{X}w)$. This leads to the following reduced optimization problem in w:

$$\min_{w\in\mathbb{R}^p} \ \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{XY}^\top w + \frac{1}{2} w^\top \hat{\Sigma}_{XX} w + \lambda_n \sum_{j=1}^m d_j \|w_j\|, \tag{1}$$

where $\hat{\Sigma}_{YY} = \frac{1}{n}\bar{Y}^\top \Pi_n \bar{Y}$, $\hat{\Sigma}_{XY} = \frac{1}{n}\bar{X}^\top \Pi_n \bar{Y}$ and $\hat{\Sigma}_{XX} = \frac{1}{n}\bar{X}^\top \Pi_n \bar{X}$ are empirical covariance matrices (with the centering matrix Π_n defined as $\Pi_n = I_n - \frac{1}{n}1_n 1_n^\top$). We denote by $\hat{w}$ any minimizer of Eq. (1). We refer to $\hat{w}$ as the *group Lasso* estimate.[2] Note that with probability tending to one, if (**A2**) is satisfied (i.e., if Σ_{XX} is invertible), there is a unique minimum.

Problem (1) is a non-differentiable convex optimization problem, for which classical tools from convex optimization (Boyd and Vandenberghe, 2003) lead to the following optimality conditions (see proof by Yuan and Lin, 2006, and in Appendix A.1):

Proposition 1 *A vector $w \in \mathbb{R}^p$ with sparsity pattern $J = J(w) = \{j,\ w_j \neq 0\}$ is optimal for problem (1) if and only if*

$$\forall j \in J^c, \qquad \left\|\hat{\Sigma}_{X_jX} w - \hat{\Sigma}_{X_jY}\right\| \leqslant \lambda_n d_j, \tag{2}$$

$$\forall j \in J, \qquad \hat{\Sigma}_{X_jX} w - \hat{\Sigma}_{X_jY} = -w_j \frac{\lambda_n d_j}{\|w_j\|}. \tag{3}$$

2. We use the convention that all "hat" notations correspond to data-dependent and thus n-dependent quantities, so we do not need the explicit dependence on n.

2.4 Algorithms

Efficient *exact* algorithms exist for the regular Lasso, that is, for the case where all group dimensions p_j are equal to one. They are based on the piecewise linearity of the set of solutions as a function of the regularization parameter λ_n (Efron et al., 2004). For the group Lasso, however, the path is only piecewise differentiable, and following such a path is not as efficient as for the Lasso. Other algorithms have been designed to solve problem (1) for a single value of λ_n, in the original group Lasso setting (Yuan and Lin, 2006) and in the multiple kernel setting (Bach et al., 2004a,b; Sonnenburg et al., 2006; Rakotomamonjy et al., 2007). In this paper, we study path consistency of the group Lasso and of multiple kernel learning, and in simulations we use the publicly available code for the algorithm of Bach et al. (2004b), that computes an approximate but entire path, by following the piecewise smooth path with predictor-corrector methods.

2.5 Consistency Results

We consider the following two conditions:

$$\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \left\| \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{w}_j\|) \mathbf{w}_\mathbf{J} \right\| < 1, \tag{4}$$

$$\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \left\| \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{w}_j\|) \mathbf{w}_\mathbf{J} \right\| \leqslant 1, \tag{5}$$

where $\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)$ denotes the block-diagonal matrix (with block sizes p_j) in which each diagonal block is equal to $\frac{d_j}{\|\mathbf{w}_j\|} I_{p_j}$ (with I_{p_j} the identity matrix of size p_j), and $\mathbf{w}_\mathbf{J}$ denotes the concatenation of the loading vectors indexed by $\mathbf{J}$. Note that the conditions involve the covariance between all active groups X_j, $j \in \mathbf{J}$ and all non active groups X_i, $i \in \mathbf{J}^c$.

These are conditions on both the input (through the joint covariance matrix Σ_{XX}) and on the weight vector $\mathbf{w}$. Note that, when all blocks have size 1, this corresponds to the conditions derived for the Lasso (Zhao and Yu, 2006; Yuan and Lin, 2007; Zou, 2006). Note also the difference between the *strong condition* (4) and the *weak condition* (5). For the Lasso, with our assumptions, Yuan and Lin (2007) has shown that the strong condition (4) is necessary and sufficient for path consistency of the Lasso; that is, the path of solutions consistently contains an estimate which is both consistent for the ℓ_2-norm (regular consistency) and the ℓ_0-norm (consistency of patterns), if and only if condition (4) is satisfied.

In the case of the group Lasso, even with a finite fixed number of groups, our results are not as strong, as we can only get the strict condition as sufficient and the weak condition as necessary. In Section 2.6, we show that this cannot be improved in general. More precisely the following theorem, proved in Appendix B.1, shows that if the condition (4) is satisfied, any regularization parameter that satisfies a certain decay conditions will lead to a consistent estimator; thus the strong condition (4) is sufficient for path consistency:

Theorem 2 *Assume (**A1-3**). If condition (4) is satisfied, then for any sequence λ_n such that $\lambda_n \to 0$ and $\lambda_n n^{1/2} \to +\infty$, the group Lasso estimate $\hat{w}$ defined in Eq. (1) converges in probability to $\mathbf{w}$ and the group sparsity pattern $J(\hat{w}) = \{j, \hat{w}_j \neq 0\}$ converges in probability to $\mathbf{J}$ (i.e., $\mathbb{P}(J(\hat{w}) = \mathbf{J}) \to 1$).*

The following theorem, proved in Appendix B.2, states that if there is a consistent solution on the path, then the weak condition (5) must be satisfied.

Theorem 3 *Assume (**A1-3**). If there exists a (possibly data-dependent) sequence λ_n such that $\hat{w}$ converges to $\mathbf{w}$ and $J(\hat{w})$ converges to $\mathbf{J}$ in probability, then condition (5) is satisfied.*

On the one hand, Theorem 2 states that under the "low correlation between variables in $\mathbf{J}$ and variables in $\mathbf{J}^c$" condition (4), the group Lasso is indeed consistent. On the other hand, the result (and the similar one for the Lasso) is rather disappointing regarding the applicability of the group Lasso as a practical group selection method, as Theorem 3 states that if the weak correlation condition (5) is not satisfied, we cannot have consistency.

Moreover, this is to be contrasted with a thresholding procedure of the joint least-square estimator, which is also consistent with no conditions (but the invertibility of Σ_{XX}), if the threshold is properly chosen (smaller than the smallest norm $\|\mathbf{w}_j\|$ for $j \in \mathbf{J}$ or with appropriate decay conditions). However, the Lasso and group Lasso do not have to set such a threshold; moreover, further analysis show that the Lasso has additional advantages over regular regularized least-square procedure (Meinshausen and Yu, 2006), and empirical evidence shows that in the finite sample case, they do perform better (Tibshirani, 1996), in particular in the case where the number m of groups is allowed to grow. In this paper we focus on the extension from uni-dimensional groups to multi-dimensional groups for finite number of groups m and leave the possibility of letting m grow with n for future research.

Finally, by looking carefully at condition (4) and (5), we can see that if we were to increase the weight d_j for $j \in \mathbf{J}^c$ and decrease the weights otherwise, we could always be consistent: this however requires the (potentially empirical) knowledge of $\mathbf{J}$ and this is exactly the idea behind the adaptive scheme that we present in Section 4. Before looking at these extensions, we discuss in the next Section, qualitative differences between our results and the corresponding ones for the Lasso.

2.6 Refinements of Consistency Conditions

Our current results state that the strict condition (4) is sufficient for joint consistency of the group Lasso, while the weak condition (5) is only necessary. When all groups have dimension one, then the strict condition turns out to be also necessary (Yuan and Lin, 2007).

The main technical reason for those differences is that in dimension one, the set of vectors of unit norm is finite (two possible values), and thus regular squared norm consistency leads to estimates of the signs of the loadings (i.e., their normalized versions $\hat{w}_j/\|\hat{w}_j\|$) which are ultimately constant. When groups have size larger than one, then $\hat{w}_j/\|\hat{w}_j\|$ will not be ultimately constant (just consistent) and this added dependence on data leads to the following refinement of Theorem 2 (see proof in Appendix B.3):

Theorem 4 *Assume (**A1-3**). Assume the weak condition (5) is satisfied and that for all $i \in \mathbf{J}^c$ such that $\frac{1}{d_i}\left\|\Sigma_{X_i X_\mathbf{J}}\Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J}\right\| = 1$, we have*

$$\Delta^\top \Sigma_{X_\mathbf{J} X_i}\Sigma_{X_i X_\mathbf{J}}\Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1}\operatorname{Diag}\left[d_j/\|\mathbf{w}_j\|\left(I_{p_j} - \frac{\mathbf{w}_j\mathbf{w}_j^\top}{\mathbf{w}_j^\top\mathbf{w}_j}\right)\right]\Delta > 0, \tag{6}$$

with $\Delta = -\Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J}$. Then for any sequence λ_n such that $\lambda_n \to 0$ and $\lambda_n n^{1/4} \to +\infty$, the group Lasso estimate $\hat{w}$ defined in Eq. (1) converges in probability to $\mathbf{w}$ and the group sparsity pattern $J(\hat{w}) = \{j, \hat{w}_j \neq 0\}$ converges in probability to $\mathbf{J}$.

This theorem is of lower practical significance than Theorem 2 and Theorem 3. It merely shows that the link between strict/weak conditions and sufficient/necessary conditions are in a sense tight (as soon as there exists $j \in \mathbf{J}$ such that $p_j > 1$, it is easy to exhibit examples where Eq. (6) is or is not satisfied). The previous theorem does not contradict the fact that condition (4) is necessary for path-consistency in the Lasso case: indeed, if w_j has dimension one (i.e., $p_j = 1$), then $I_{p_j} - \frac{\mathbf{w}_j \mathbf{w}_j^\top}{\mathbf{w}_j^\top \mathbf{w}_j}$ is always equal to zero, and thus Eq. (6) is never satisfied. Note that when condition (6) is an equality, we could still refine the condition by using higher orders in the asymptotic expansions presented in Appendix B.3.

We can also further refined the *necessary* condition results in Theorem 3: as stated in Theorem 3, the group Lasso estimator may be both consistent in terms of norm and sparsity patterns only if the condition (5) is satisfied. However, if we require only the consistent sparsity pattern estimation, then we may allow the convergence of the regularization parameter λ_n to a strictly positive limit λ_0. In this situation, we may consider the following population problem:

$$\min_{w \in \mathbb{R}^p} \frac{1}{2}(w - \mathbf{w})^\top \Sigma_{XX}(w - \mathbf{w}) + \lambda_0 \sum_{j=1}^{m} d_j \|w_j\|. \tag{7}$$

If there exists $\lambda_0 > 0$ such that the solution has the correct sparsity pattern, then the group Lasso estimate with $\lambda_n \to \lambda_0$, will have a consistent sparsity pattern. The following proposition, which can be proved with standard M-estimation arguments, make this precise:

Proposition 5 *Assume (**A1-3**). If λ_n tends to $\lambda_0 > 0$, then the group Lasso estimate $\hat{w}$ is sparsity-consistent if and only if the solution of Eq. (7) has the correct sparsity pattern.*

Thus, even when condition (5) is not satisfied, we may have consistent estimation of the sparsity pattern but inconsistent estimation of the loading vectors. We provide in Section 5 such examples.

2.7 Probability of Correct Pattern Selection

In this section, we focus on regularization parameters that tend to zero, at the rate $n^{-1/2}$, that is, $\lambda_n = \lambda_0 n^{-1/2}$ with $\lambda_0 > 0$. For this particular setting, we can actually compute the limit of the probability of correct pattern selection (proposition proved in Appendix B.4). Note that in order to obtain a simpler result, we assume constant conditional variance of Y given $\mathbf{w}^\top X$:

Proposition 6 *Assume (**A1-3**) and $\operatorname{var}(Y|\mathbf{w}^\top x) = \sigma^2$ almost surely. Assume moreover $\lambda_n = \lambda_0 n^{-1/2}$ with $\lambda_0 > 0$. Then, the group Lasso $\hat{w}$ converges in probability to $\mathbf{w}$ and the probability of correct sparsity pattern selection has the following limit:*

$$\mathbb{P}\left(\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \left\| \frac{\sigma}{\lambda_0} t_i - \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}\left(\frac{d_j}{\|\mathbf{w}_j\|} \right) \mathbf{w}_\mathbf{J} \right\| \leqslant 1 \right), \tag{8}$$

where t is normally distributed with mean zero and covariance matrix $\Sigma_{X_{\mathbf{J}^c} X_{\mathbf{J}^c} | X_\mathbf{J}} = \Sigma_{X_{\mathbf{J}^c} X_{\mathbf{J}^c}} - \Sigma_{X_{\mathbf{J}^c} X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \Sigma_{X_\mathbf{J} X_{\mathbf{J}^c}}$ (which is the conditional covariance matrix of $X_{\mathbf{J}^c}$ given $X_\mathbf{J}$).

The previous theorem states that the probability of correct selection tends to the mass under a non degenerate multivariate distribution of the intersection of cylinders. Under our assumptions, this set is never empty and thus the limiting probability is strictly positive, that is, there is (asymptotically)

always a positive probability of estimating the correct pattern of groups (see Bach, 2008a, for application of this result to model consistent estimation of a bootstrapped version of the Lasso, with no consistency condition).

Moreover, additional insights may be gained from Proposition 6, namely in terms of the dependence on σ, λ_0 and the tightness of the consistency conditions. First, when λ_0 tends to infinity, then the limit defined in Eq. (8) tends to one if the strict consistency condition (4) is satisfied, and tends to zero if one of the conditions is strictly not met. This corroborates the results of Theorem 2 and 3. Note however, that only an extension of Proposition 6 to λ_n that may deviate from a $n^{-1/2}$ would actually lead to a proof of Theorem 2, which is a subject of ongoing research.

Finally, Eq. (8) shows that σ has a smoothing effect on the probability of correct pattern selection, that is, if condition (4) is satisfied, then this probability is a decreasing function of σ (and an increasing function of λ_0). Finally, the stricter the inequality in Eq. (4), the larger the probability of correct rank selection, which is illustrated in Section 5 on synthetic examples.

2.8 Loading Independent Sufficient Condition

Condition (4) depends on the loading vector $\mathbf{w}$ and on the sparsity pattern $\mathbf{J}$, which are both a priori unknown. In this section, we consider sufficient conditions that do not depend on the loading vector, but only on the sparsity pattern $\mathbf{J}$ and of course on the covariance matrices. The following condition is sufficient for consistency of the group Lasso, for all possible loading vectors $\mathbf{w}$ with sparsity pattern $\mathbf{J}$:

$$C(\Sigma_{XX}, d, \mathbf{J}) = \max_{i \in \mathbf{J}^c} \max_{\forall j \in \mathbf{J},\ \|u_j\|=1} \left\| \frac{1}{d_i} \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j) u_\mathbf{J} \right\| < 1. \tag{9}$$

As opposed to the Lasso case, $C(\Sigma_{XX}, d, \mathbf{J})$ cannot be readily computed in closed form, but we have the following upper bound:

$$C(\Sigma_{XX}, d, \mathbf{J}) \leqslant \max_{i \in \mathbf{J}^c} \frac{1}{d_i} \sum_{j \in \mathbf{J}} d_j \left\| \sum_{k \in \mathbf{J}} \Sigma_{X_i X_k} \left(\Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \right)_{kj} \right\|,$$

where for a matrix M, $\|M\|$ denotes its maximal singular value (also known as its spectral norm). This leads to the following sufficient condition for consistency of the group Lasso (which extends the condition of Yuan and Lin, 2007):

$$\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \sum_{j \in \mathbf{J}} d_j \left\| \sum_{k \in \mathbf{J}} \Sigma_{X_i X_k} \left(\Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \right)_{kj} \right\| < 1. \tag{10}$$

Given a set of weights d, better sufficient conditions than Eq. (10) may be obtained by solving a semidefinite programming problem (Boyd and Vandenberghe, 2003):

Proposition 7 *The quantity* $\max_{\forall j \in \mathbf{J},\ \|u_j\|=1} \left\| \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j) u_\mathbf{J} \right\|^2$ *is upperbounded by*

$$\max_{M \succcurlyeq 0,\ \operatorname{tr} M_{ii}=1} \operatorname{tr} M \left(\operatorname{Diag}(d_j) \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \Sigma_{X_\mathbf{J} X_i} \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j) \right), \tag{11}$$

where M is a matrix defined by blocks following the block structure of $\Sigma_{X_J X_J}$. Moreover, the bound is also equal to

$$\min_{\lambda\in\mathbb{R}^m,\ \mathrm{Diag}(d_j)\Sigma^{-1}_{X_J X_J}\Sigma_{X_J X_i}\Sigma_{X_i X_J}\Sigma^{-1}_{X_J X_J}\mathrm{Diag}(d_j)\preccurlyeq\mathrm{Diag}(\lambda)} \sum_{j=1}^m \lambda_j.$$

Proof We denote $M = uu^\top \succcurlyeq 0$. Then if all u_j for $j \in \mathbf{J}$ have norm 1, then we have $\mathrm{tr} M_{jj} = 1$ for all $j \in \mathbf{J}$. This implies the convex relaxation. The second problem is easily obtained as the convex dual of the first problem (Boyd and Vandenberghe, 2003). ■

Note that for the Lasso, the convex bound in Eq. (11) is tight and leads to the bound given above in Eq. (10) (Yuan and Lin, 2007; Wainwright, 2006). For the Lasso, Zhao and Yu (2006) consider several particular patterns of dependencies using Eq. (10). Note that this condition (and not the condition in Eq. 9) is independent from the dimension and thus does not readily lead to rules of thumbs allowing to set the weight d_j as a function of the dimension p_j; several rules of thumbs have been suggested, that loosely depend on the dimension on the blocks, in the context of the linear group Lasso (Yuan and Lin, 2006) or multiple kernel learning (Bach et al., 2004b); we argue in this paper, that weights should also depend on the response as well (see Section 4).

2.9 Alternative Formulation of the Group Lasso

Following Bach et al. (2004a), we can instead consider regularization by the square of the block ℓ_1-norm:

$$\min_{w\in\mathbb{R}^p,\ b\in\mathbb{R}} \frac{1}{2n}\|\bar{Y} - \bar{X}w - b1_n\|^2 + \frac{1}{2}\mu_n\left(\sum_{j=1}^m d_j\|w_j\|\right)^2.$$

This leads to the same path of solutions, but it is better behaved because each variable which is not zero is still regularized by the squared norm. The alternative version has also two advantages: (a) it has very close links to more general frameworks for learning the kernel matrix from data (Lanckriet et al., 2004b), and (b) it is essential in our proof of consistency in the functional case. We also get the equivalent formulation to Eq. (1), by minimizing in closed form with respect to b, to obtain:

$$\min_{w\in\mathbb{R}^p} \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{YX}w + \frac{1}{2}w^\top\hat{\Sigma}_{XX}w + \frac{1}{2}\mu_n\left(\sum_{j=1}^m d_j\|w_j\|\right)^2. \tag{12}$$

The following proposition gives the optimality conditions for the convex optimization problem defined in Eq. (12) (see proof in Appendix A.2):

Proposition 8 *A vector $w \in \mathbb{R}^p$ with sparsity pattern $J = \{j,\ w_j \neq 0\}$ is optimal for problem (12) if and only if*

$$\begin{aligned}
\forall j \in J^c, \qquad & \left\|\hat{\Sigma}_{X_jX}w - \hat{\Sigma}_{X_jY}\right\| \leqslant \mu_n d_j\left(\textstyle\sum_{i=1}^n d_i\|w_i\|\right),\\
\forall j \in J, \qquad & \hat{\Sigma}_{X_jX}w - \hat{\Sigma}_{X_jY} = -\mu_n\left(\textstyle\sum_{i=1}^n d_i\|w_i\|\right)\dfrac{d_j w_j}{\|w_j\|}.
\end{aligned}$$

Note the correspondence at the optimum between optimal solutions of the two optimization problems in Eq. (1) and Eq. (12) through $\lambda_n = \mu_n\left(\sum_{i=1}^n d_i\|w_i\|\right)$. As far as consistency results are concerned, Theorem 3 immediately applies to the alternative formulation because the regularization

paths are the same. For Theorem 2, it does not readily apply. But since the relationship between λ_n and μ_n at optimum is $\lambda_n = \mu_n(\sum_{i=1}^n d_i \|w_i\|)$ and that $\sum_{i=1}^n d_i \|\hat{w}_i\|$ converges to a constant whenever $\hat{w}$ is consistent, it does apply as well with minor modifications (in particular, to deal with the case where $\mathbf{J}$ is empty, which requires $\mu_n = \infty$).

3. Covariance Operators and Multiple Kernel Learning

We now extend the previous consistency results to the case of nonparametric estimation, where each group is a potentially infinite dimensional space of functions. Namely, the nonparametric group Lasso aims at estimating a sparse linear combination of functions of separate random variables, and can then be seen as a variable selection method in a generalized additive model (Hastie and Tibshirani, 1990). Moreover, as shown in Section 3.5, the nonparametric group Lasso may also be seen as equivalent to learning a convex combination of kernels, a framework referred to as multiple kernel learning (MKL). In this context it is customary to have a single input space with several kernels (and hence Hilbert spaces) defined on the same input space (Lanckriet et al., 2004b; Bach et al., 2004a).[3] Our framework accommodates this case as well, but our assumption (**A5**) regarding the invertibility of the joint correlation operator states that the kernels cannot span Hilbert spaces which intersect.

In this nonparametric context, covariance operators constitute appropriate tools for the statistical analysis and are becoming standard in the theoretical analysis of kernel methods (Fukumizu et al., 2004; Gretton et al., 2005; Fukumizu et al., 2007; Caponnetto and de Vito, 2005). The following section reviews important concepts. For more details, see Baker (1973) and Fukumizu et al. (2004).

3.1 Review of Covariance Operator Theory

In this section, we first consider a single set $\mathcal{X}$ and a positive definite kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, associated with the reproducing kernel Hilbert space (RKHS) $\mathcal{F}$ of functions from $\mathcal{X}$ to $\mathbb{R}$ (see, e.g., Schölkopf and Smola 2001 or Berlinet and Thomas-Agnan 2003 for an introduction to RKHS theory). The Hilbert space and its dot product $\langle \cdot, \cdot \rangle_{\mathcal{F}}$ are such that for all $x \in \mathcal{X}$, then $k(\cdot, x) \in \mathcal{F}$ and for all $f \in \mathcal{F}$, $\langle k(\cdot, x), f \rangle_{\mathcal{F}} = f(x)$, which leads to the *reproducing property* $\langle k(\cdot, x), k(\cdot, y) \rangle_{\mathcal{F}} = k(x, y)$ for any $(x, y) \in \mathcal{X} \times \mathcal{X}$.

3.1.1 Covariance Operator and Norms

Given a random variable X on $\mathcal{X}$ with bounded second order moment, that is, such that $\mathbb{E}k(X, X) < \infty$, we can define the covariance operator as the bounded linear operator Σ_{XX} from $\mathcal{F}$ to $\mathcal{F}$ such that for all $(f, g) \in \mathcal{F} \times \mathcal{F}$,

$$\langle f, \Sigma_{XX} g \rangle_{\mathcal{F}} = \operatorname{cov}(f(X), g(X)) = \mathbb{E}(f(X)g(X)) - (\mathbb{E}f(X))(\mathbb{E}g(X)).$$

The operator Σ_{XX} is *auto-adjoint*, *non-negative* and *Hilbert-Schmidt*, that is, for any orthonormal basis $(e_p)_{p \geqslant 1}$ of $\mathcal{F}$, then $\sum_{p=1}^{\infty} \|\Sigma_{XX} e_p\|_{\mathcal{F}}^2$ is finite; in this case, the value does not depend on the chosen basis and is referred to as the square of the Hilbert-Schmidt norm. The norm that we use by default in this paper is the operator norm $\|\Sigma_{XX}\|_{\mathcal{F}} = \sup_{f \in \mathcal{F},\ \|f\|_{\mathcal{F}} = 1} \|\Sigma_{XX} f\|_{\mathcal{F}}$, which is dominated by the Hilbert-Schmidt norm. Note that in the finite dimensional case where $\mathcal{X} = \mathbb{R}^p$, $p > 0$ and the

3. Note that the grouplasso can be explicitly seen as a special case of multiple kernel learning. Using notations from Section 2, this is done by considering $X = (X_1, \ldots, X_m)^\top \in \mathbb{R}^m$ and the m kernels $k_m(X, Y) = X_m^\top Y_m$.

kernel is linear, the covariance operator is exactly the covariance matrix, and the Hilbert-Schmidt norm is the Frobenius norm, while the operator norm is the maximum singular value (also referred to as the spectral norm).

The null space of the covariance operator is the space of functions $f \in \mathcal{F}$ such that $\operatorname{var} f(X) = 0$, that is, such that f is constant on the support of X.

3.1.2 EMPIRICAL ESTIMATORS

Given data $x_i \in \mathcal{X}, i = 1, \ldots, n$, sampled i.i.d. from P_X, then the empirical estimate $\hat{\Sigma}_{XX}$ of Σ_{XX} is defined such that $\langle f, \hat{\Sigma}_{XX} g \rangle_{\mathcal{F}}$ is the empirical covariance between $f(X)$ and $g(X)$, which leads to:

$$\hat{\Sigma}_{XX} = \frac{1}{n}\sum_{i=1}^{n} k(\cdot, x_i) \otimes k(\cdot, x_i) - \frac{1}{n}\sum_{i=1}^{n} k(\cdot, x_i) \otimes \frac{1}{n}\sum_{i=1}^{n} k(\cdot, x_i),$$

where $u \otimes v$ is the operator defined by $\langle f, (u \otimes v) g \rangle_{\mathcal{F}} = \langle f, u \rangle_{\mathcal{F}} \langle g, v \rangle_{\mathcal{F}}$. If we further assume that the fourth order moment is finite, that is, $\mathbb{E} k(X, X)^2 < \infty$, then the estimate is uniformly consistent, that is, $\|\hat{\Sigma}_{XX} - \Sigma_{XX}\|_{\mathcal{F}} = O_p(n^{-1/2})$ (see Fukumizu et al., 2007, and Appendix C.1), which generalizes the usual result from finite dimension.[4]

3.1.3 CROSS-COVARIANCE AND JOINT COVARIANCE OPERATORS

Covariance operator theory can be extended to cases with more than one random variables (Baker, 1973). In our situation, we have m input spaces $\mathcal{X}_1, \ldots, \mathcal{X}_m$ and m random variables $X = (X_1, \ldots, X_m)$ and m RKHS $\mathcal{F}_1, \ldots, \mathcal{F}_m$ associated with m kernels $k_1, \ldots, k_m$.

If we assume that $\mathbb{E} k_j(X_j, X_j) < \infty$, for all $j = 1, \ldots, m$, then we can naturally define the cross-covariance operators $\Sigma_{X_i X_j}$ from $\mathcal{F}_j$ to $\mathcal{F}_i$ such that $\forall (f_i, f_j) \in \mathcal{F}_i \times \mathcal{F}_j$,

$$\langle f_i, \Sigma_{X_i X_j} f_j \rangle_{\mathcal{F}_i} = \operatorname{cov}(f_i(X_i), f_j(X_j)) = \mathbb{E}(f_i(X_i) f_j(X_j)) - (\mathbb{E} f_i(X_i))(\mathbb{E} f_j(X_j)).$$

These are also Hilbert-Schmidt operators, and if we further assume that $\mathbb{E} k_j(X_j, X_j)^2 < \infty$, for all $j = 1, \ldots, m$, then the natural empirical estimators converges to the population quantities in Hilbert-Schmidt and operator norms at rate $O_p(n^{-1/2})$. We can now define a joint block covariance operator on $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_m$ following the block structure of covariance matrices in Section 2. As in the finite dimensional case, it leads to a joint covariance operator Σ_{XX} and we can refer to sub-blocks as $\Sigma_{X_I X_J}$ for the blocks indexed by I and J.

Moreover, we can define the bounded (i.e., with finite operator norm) correlation operators through $\Sigma_{X_i X_j} = \Sigma_{X_i X_i}^{1/2} C_{X_i X_j} \Sigma_{X_j X_j}^{1/2}$ (Baker, 1973). Throughout this paper we will make the assumption that those operators $C_{X_i X_j}$ are *compact* for $i \neq j$: compact operators can be characterized as limits of finite rank operators or as operators that can be diagonalized on a countable basis with spectrum composed of a sequence tending to zero (see, e.g., Brezis, 1980). This implies that the joint operator C_{XX}, naturally defined on $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_m$, is of the form "identity plus compact". It thus has a minimum and a maximum eigenvalue which are both between 0 and 1 (Brezis, 1980). If those eigenvalues are strictly greater than zero, then the operator is invertible, as are all the square sub-blocks. Moreover, the joint correlation operator is lower-bounded by a strictly positive constant times the identity operator.

4. A random variable Z_n is said to be of order $O_p(a_n)$ if for any $\eta > 0$, there exists $M > 0$ such that $\sup_n \mathbb{P}(|Z_n| > M a_n) < \eta$. See Van der Vaart (1998) for further definitions and properties of asymptotics in probability.

3.1.4 TRANSLATION INVARIANT KERNELS

A particularly interesting ensemble of RKHS in the context of nonparametric estimation is the set of translation invariant kernels defined over $\mathcal{X} = \mathbb{R}^p$, where $p \geqslant 1$, of the form $k(x,x') = q(x'-x)$ where q is a function on $\mathbb{R}^p$ with pointwise nonnegative integrable Fourier transform (which implies that q is continuous). In this case, the associated RKHS is $\mathcal{F} = \{q_{1/2} * g,\ g \in L^2(\mathbb{R}^p)\}$, where $q_{1/2}$ denotes the inverse Fourier transform of the square root of the Fourier transform of q and $*$ denotes the convolution operation, and $L^2(\mathbb{R}^p)$ denotes the space of square integrable functions. The norm is then equal to

$$\|f\|_{\mathcal{F}}^2 = \int \frac{|F(\omega)|^2}{Q(\omega)} d\omega,$$

where F and Q are the Fourier transforms of f and q (Wahba, 1990; Schölkopf and Smola, 2001). Functions in the RKHS are functions with appropriately integrable derivatives. In this paper, when using infinite dimensional kernels, we use the Gaussian kernel $k(x,x') = q(x-x') = \exp(-b\|x-x'\|^2)$, with $b > 0$.

3.1.5 ONE-DIMENSIONAL HILBERT SPACES

In this paper, we also consider real random variables Y and ε embedded in the natural Euclidean structure of real numbers (i.e., we consider the linear kernel on $\mathbb{R}$). In this setting the covariance operator Σ_{X_jY} from $\mathbb{R}$ to $\mathcal{F}_j$ can be canonically identified as an element of $\mathcal{F}_j$. Throughout this paper, we always use this identification.

3.2 Problem Formulation

We assume in this section and in the remaining of the paper that for each $j = 1,\dots,m$, $X_j \in \mathcal{X}_j$ where $\mathcal{X}_j$ is any set on which we have a reproducible kernel Hilbert spaces $\mathcal{F}_j$, associated with the positive kernel $k_j : \mathcal{X}_j \times \mathcal{X}_j \to \mathbb{R}$. We now make the following assumptions, that extend the assumptions (**A1**), (**A2**) and (**A3**). For each of them, we detail the main implications as well as common natural sufficient conditions. The first two conditions (**A4**) and (**A5**) depend solely on the input variables, while the two other ones, (**A6**) and (**A7**) consider the relationship between X and Y.

(**A4**) For each $j = 1\dots,m$, $\mathcal{F}_j$ is a separable reproducing kernel Hilbert space associated with kernel k_j, and the random variables $k_j(\cdot,X_j)$ are not constant and have finite fourth-order moments, that is, $\mathbb{E}k_j(X_j,X_j)^2 < \infty$.

This is a non restrictive assumption in many situations; for example, when (a) $\mathcal{X}_j = \mathbb{R}^{p_j}$ and the kernel function (such as the Gaussian kernel) is bounded, or when (b) $\mathcal{X}_j$ is a compact subset of $\mathbb{R}^{p_j}$ and the kernel is any continuous function such as linear or polynomial. This implies notably, as shown in Section 3.1, that we can define covariance, cross-covariance and correlation operators that are all Hilbert-Schmidt (Baker, 1973; Fukumizu et al., 2007) and can all be estimated at rate $O_p(n^{-1/2})$ in operator norm.

(**A5**) All cross-correlation operators are compact and the joint correlation operator C_{XX} is invertible.

This is also a condition uniquely on the input spaces and not on Y. Following Fukumizu et al. (2007), a simple sufficient condition is that we have measurable spaces and distributions with joint

density p_X (and marginal distributions $p_{X_i}(x_i)$ and $p_{X_iX_j}(x_i,x_j)$) and that the *mean square contingency* between all pairs of variables is finite, that is,

$$\mathbb{E}\left\{\frac{p_{X_iX_j}(x_i,x_j)}{p_{X_i}(x_i)p_{X_j}(x_j)}-1\right\}<\infty.$$

The contingency is a measure of statistical dependency (Renyi, 1959), and thus this sufficient condition simply states that two variables X_i and X_j cannot be too dependent. In the context of multiple kernel learning for heterogeneous data fusion, this corresponds to having sources which are heterogeneous enough. On top of compacity we impose the invertibility of the joint correlation operator; we use this assumption to make sure that the functions $\mathbf{f}_1,\dots,\mathbf{f}_m$ are unique. This ensures the non existence of any set of functions $f_1,\dots,f_m$ in the closures of $\mathcal{F}_1,\dots,\mathcal{F}_m$, such that $\operatorname{var} f_j(X_j)>0$, for all j, and a linear combination is constant on the support of the random variables. In the context of generalized additive models, this assumption is referred to as the empty *concurvity space* assumption (Hastie and Tibshirani, 1990).

(A6) There exists functions $\mathbf{f}=(\mathbf{f}_1,\dots,\mathbf{f}_m)\in\mathcal{F}=\mathcal{F}_1\times\cdots\times\mathcal{F}_m$, $\mathbf{b}\in\mathbb{R}$, and a function $\mathbf{h}$ of $X=(X_1,\dots,X_m)$ such that $\mathbb{E}(Y|X)=\sum_{j=1}^m\mathbf{f}_j(X_j)+\mathbf{b}+\mathbf{h}(X)$ with $\mathbb{E}\mathbf{h}(X)^2<\infty$, $\mathbb{E}\mathbf{h}(X)=0$ and $\mathbb{E}\mathbf{h}(X)f_j(X_j)=0$ for all $j=1,\dots,m$ and $f_j\in\mathcal{F}_j$. We assume that $\mathbb{E}((Y-\mathbf{f}(X)-\mathbf{b})^2|X)$ is almost surely greater than $\sigma^2_{\min}>0$ and smaller than $\sigma^2_{\max}<\infty$. We denote by $\mathbf{J}=\{j,\mathbf{f}_j\neq 0\}$ the sparsity pattern of $\mathbf{f}$.

This assumption on the conditional expectation of Y given X is not the most general and follows common assumptions in approximation theory (see, e.g., Caponnetto and de Vito, 2005; Cucker and Smale, 2002, and references therein). It allows misspecification, but it essentially requires that the conditional expectation of Y given sums of measurable functions of X_j is attained at functions in the RKHS, and not merely measurable functions. Dealing with more general assumptions in the line of Ravikumar et al. (2008) requires to consider consistency for norms weaker than the RKHS norms (Caponnetto and de Vito, 2005; Steinwart, 2001), and is left for future research. Note also, that to simplify proofs, we assume a finite upper-bound $\sigma^2_{\max}$ on the residual variance.

(A7) For all $j\in\{1,\dots,m\}$, there exists $\mathbf{g}_j\in\mathcal{F}_j$ such that $\mathbf{f}_j=\Sigma^{1/2}_{X_jX_j}\mathbf{g}_j$, that is, each $\mathbf{f}_j$ is in the range of $\Sigma^{1/2}_{X_jX_j}$.

This technical condition, already used by Caponnetto and de Vito (2005), which concerns all RKHS independently, ensures that we obtain consistency for the norm of the RKHS (and not another weaker norm) for the least-squares estimates. Note also that it implies that $\operatorname{var} f_j(X_j)>0$, that is, f_j is not constant on the support of X_j.

This assumption might be checked (at least) in two ways; first, if $(e_p)_{p\geqslant 1}$ is a sequence of eigenfunctions of Σ_{XX}, associated with strictly positive eigenvalues $\lambda_p>0$, then f is in the range of Σ_{XX} if and only if f is constant outside the support of the random variable X and $\sum_{p\geqslant 1}\frac{1}{\lambda_p}\langle f,e_p\rangle^2$ is finite (i.e., the decay of the sequence $\langle f,e_p\rangle^2$ is strictly faster than λ_p).

We also provide another sufficient condition that sheds additional light on this technical condition which is always true for finite dimensional Hilbert spaces. For the common situation where $\mathcal{X}_j=\mathbb{R}^{p_j}$, P_{X_j} (the marginal distribution of X_j) has a density $p_{X_j}(x_j)$ with respect to the Lebesgue measure and the kernel is of the form $k_j(x_j,x_j')=q_j(x_j-x_j')$, we have the following proposition (proved in Appendix C.5):

Proposition 9 *Assume $\mathcal{X} = \mathbb{R}^p$ and X is a random variable on $\mathcal{X}$ with distribution P_X that has a* strictly positive *density $p_X(x)$ with respect to the Lebesgue measure. Assume $k(x,x') = q(x-x')$ for a function $q \in L^2(\mathbb{R}^p)$ has an integrable pointwise positive Fourier transform, with associated RKHS $\mathcal{F}$. If f can be written as $f = q * g$ (convolution of q and g) with $\int_{\mathbb{R}^p} g(x)dx = 0$ and $\int_{\mathbb{R}^p} \frac{g(x)^2}{p_X(x)}dx < \infty$, then $f \in \mathcal{F}$ is in the range of the square root $\Sigma_{XX}^{1/2}$ of the covariance operator.*

The previous proposition gives natural conditions regarding f and p_X. Indeed, the condition $\int \frac{g(x)^2}{p_X(x)}dx < \infty$ corresponds to a natural support condition, that is, f should be zero where X has no mass, otherwise, we will not be able to estimate f; note the similarity with the usual condition regarding the variance of importance sampling estimation (Brémaud, 1999). Moreover, f should be even smoother than a regular function in the RKHS (convolution by q instead of the square root of q). Finally, we provide in Appendix E detailed covariance structures for Gaussian kernels with Gaussian variables.

3.2.1 NOTATIONS

Throughout this section, we refer to functions $f = (f_1, \dots, f_m) \in \mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_m$ and the joint covariance operator Σ_{XX}. In the following, we always use the norms of the RKHS. When considering operators, we use the operator norm. We also refer to a subset of f indexed by J through f_J. Note that the Hilbert norm $\|f_J\|_{\mathcal{F}_J}$ is equal to $\|f_J\|_{\mathcal{F}_J} = (\sum_{j\in J} \|f_j\|_{\mathcal{F}_j})^{1/2}$. Finally, given a nonnegative auto-adjoint operator S, we denote by $S^{1/2}$ its nonnegative autoadjoint square root (Baker, 1973).

3.3 Nonparametric Group Lasso

Given i.i.d data (x_{ij}, y_i), $i = 1, \dots, n$, $j = 1, \dots, m$, where each $x_{ij} \in \mathcal{X}_j$, our goal is to estimate consistently the functions $\mathbf{f}_j$ and which of them are zero. We denote by $\overline{Y} \in \mathbb{R}^n$ the vector of responses. We consider the following optimization problem:

$$\min_{f\in\mathcal{F},\, b\in\mathbb{R}} \frac{1}{2n}\sum_{i=1}^{n}\left(y_i - \sum_{j=1}^{m} f_j(x_{ij}) - b\right)^2 + \frac{\mu_n}{2}\left(\sum_{j=1}^{m} d_j \|f_j\|_{\mathcal{F}_j}\right)^2.$$

By minimizing with respect to b in closed form, we obtain a similar formulation to Eq. (12), where empirical covariance matrices are replaced by empirical covariance operators:

$$\min_{f\in\mathcal{F}} \frac{1}{2}\hat{\Sigma}_{YY} - \langle f, \hat{\Sigma}_{XY}\rangle_{\mathcal{F}} + \frac{1}{2}\langle f, \hat{\Sigma}_{XX} f\rangle_{\mathcal{F}} + \frac{\mu_n}{2}\left(\sum_{j=1}^{m} d_j \|f_j\|_{\mathcal{F}_j}\right)^2. \tag{13}$$

We denote by $\hat{f}$ any minimizer of Eq. (13), and we refer to it as the nonparametric group Lasso estimate, or also the multiple kernel learning estimate. By Proposition 13, the previous problem has indeed minimizers, and by Proposition 14 this global minimum is unique with probability tending to one.

Note that formally, the finite and infinite dimensional formulations in Eq. (12) and Eq. (13) are the same, and this is the main reason why covariance operators are very practical tools for the analysis. Furthermore, we have the corresponding proposition regarding optimality conditions (see proof in Appendix A.3):

Proposition 10 *A function $f \in \mathcal{F}$ with sparsity pattern $J = J(f) = \{j,\ f_j \neq 0\}$ is optimal for problem (13) if and only if*

$$\forall j \in J^c, \qquad \left\|\hat{\Sigma}_{X_jX} f - \hat{\Sigma}_{X_jY}\right\|_{\mathcal{F}_j} \leqslant \mu_n d_j \left(\sum_{i=1}^n d_i \|f_i\|_{\mathcal{F}_i}\right), \tag{14}$$

$$\forall j \in J, \qquad \hat{\Sigma}_{X_jX} f - \hat{\Sigma}_{X_jY} = -\mu_n \left(\sum_{i=1}^n d_i \|f_i\|_{\mathcal{F}_i}\right) \frac{d_j f_j}{\|f_j\|_{\mathcal{F}_j}}. \tag{15}$$

A consequence (and in fact the first part of the proof) is that an optimal function f must be in the range of $\hat{\Sigma}_{XY}$ and $\hat{\Sigma}_{XX}$, that is, an optimal f is supported by the data; that is, each f_j is a linear combination of functions $k_j(\cdot, x_{ij})$, $i = 1, \ldots, n$. This is a rather circumvoluted way of presenting the representer theorem (Wahba, 1990), but this is the easiest for the theoretical analysis of consistency. However, to actually compute the estimate $\hat{f}$ from data, we need the usual formulation with dual parameters (see Section 3.5).

Moreover, one important conclusion is that all our optimization problems in spaces of functions can be in fact transcribed into finite-dimensional problems. In particular, all notions from multivariate differentiable calculus may be used without particular care regarding the infinite dimension.

3.4 Consistency Results

We consider the following strict and weak conditions, which correspond to condition (4) and (5) in the finite dimensional case:

$$\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \left\| \Sigma_{X_iX_i}^{1/2} C_{X_iX_\mathbf{J}} C_{X_\mathbf{J}X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{f}_j\|_{\mathcal{F}_j}) \mathbf{g}_\mathbf{J} \right\|_{\mathcal{F}_i} < 1, \tag{16}$$

$$\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \left\| \Sigma_{X_iX_i}^{1/2} C_{X_iX_\mathbf{J}} C_{X_\mathbf{J}X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{f}_j\|_{\mathcal{F}_j}) \mathbf{g}_\mathbf{J} \right\|_{\mathcal{F}_i} \leqslant 1, \tag{17}$$

where $\operatorname{Diag}(d_j / \|\mathbf{f}_j\|_{\mathcal{F}_j})$ denotes the block-diagonal operator with operators $\frac{d_j}{\|\mathbf{f}_j\|_{\mathcal{F}_j}} I_{\mathcal{F}_j}$ on the diagonal. Note that this is well-defined because C_{XX} is invertible and that it reduces to Eq. (4) and Eq. (5) when the input spaces $\mathcal{X}_j$, $j = 1, \ldots, m$ are of the form $\mathbb{R}^{p_j}$ and the kernels are linear. The main reason of rewriting the conditions in terms of correlation operators rather than covariance operators is that correlation operators are invertible by assumption, while covariance operators are not as soon as the Hilbert spaces have infinite dimensions. The following theorems give necessary and sufficient conditions for the path consistency of the nonparametric group Lasso (see proofs in Appendix C.2 and Appendix C.3):

Theorem 11 *Assume (**A4-7**) and that $\mathbf{J}$ is not empty. If condition (16) is satisfied, then for any sequence μ_n such that $\mu_n \to 0$ and $\mu_n n^{1/2} \to +\infty$, any sequence of nonparametric group Lasso estimates $\hat{f}$ converges in probability to $\mathbf{f}$ and the sparsity pattern $J(\hat{f}) = \{j, \hat{f}_j \neq 0\}$ converges in probability to $\mathbf{J}$.*

Theorem 12 *Assume (**A4-7**) and that $\mathbf{J}$ is not empty. If there exists a (possibly data-dependent) sequence μ_n such $\hat{f}$ converges to $\mathbf{f}$ and $\hat{J}$ converges to $\mathbf{J}$ in probability, then condition (17) is satisfied.*

Essentially, the results in finite dimension also hold when groups have infinite dimensions. We leave the extensions of the refined results in Section 2.6 to future work. Condition (16) might be hard to check in practice since it involves inversion of correlation operators; see Section 3.6 for an estimate from data.

3.5 Multiple Kernel Learning Formulation

Proposition 10 does not readily lead to an algorithm for computing the estimate $\hat{f}$. In this section, following Bach et al. (2004a), we link the group Lasso to the multiple kernel learning framework (Lanckriet et al., 2004b). Problem (13) is an optimization problem on a potentially infinite dimensional space of functions. However, the following proposition shows that it reduces to a finite dimensional problem that we now precise (see proof in Appendix A.4):

Proposition 13 *The dual of problem (13) is*

$$\max_{\alpha\in\mathbb{R}^n,\ \alpha^\top 1_n=0} \left\{ -\frac{1}{2n}\|\bar{Y}-n\mu_n\alpha\|^2 - \frac{1}{2\mu_n}\max_{i=1,\ldots,m}\frac{\alpha^\top K_i\alpha}{d_i^2}\right\}, \tag{18}$$

where $(K_i)_{ab}=k_i(x_a,x_b)$ are the kernel matrices in $\mathbb{R}^{n\times n}$, for $i=1,\ldots,m$. Moreover, the dual variable $\alpha\in\mathbb{R}^n$ is optimal if and only if $\alpha^\top 1_n=0$ and there exists $\eta\in\mathbb{R}_+^m$ such that $\sum_{j=1}^m \eta_j d_j^2=1$ and

$$\left(\sum_{j=1}^m \eta_j K_j + n\mu_n I_n\right)\alpha = \bar{Y}, \tag{19}$$

$$\forall j\in\{1,\ldots,m\},\ \frac{\alpha^\top K_j\alpha}{d_j^2} < \max_{i=1,\ldots,m}\frac{\alpha^\top K_i\alpha}{d_i^2} \Rightarrow \eta_j=0.$$

The optimal function may then be written as $f_j=\eta_j\sum_{i=1}^n \alpha_i k_j(\cdot,x_{ij})$.

Since the problem in Eq. (18) is strictly convex, there is a unique dual solution α. Note that Eq. (19) corresponds to the optimality conditions for the least-square problem:

$$\min_{f\in\mathcal{F}} \frac{1}{2}\hat{\Sigma}_{YY} - \langle f,\hat{\Sigma}_{XY}\rangle_{\mathcal{F}} + \frac{1}{2}\langle f,\hat{\Sigma}_{XX}f\rangle_{\mathcal{F}} + \frac{1}{2}\mu_n \sum_{j,\ \eta_j>0}\frac{\|f_j\|_{\mathcal{F}_j}^2}{\eta_i},$$

whose dual problem is:

$$\max_{\alpha\in\mathbb{R}^n,\ \alpha^\top 1_n=0}\left\{-\frac{1}{2n}\|\bar{Y}-n\mu_n\alpha\|^2 - \frac{1}{2\mu_n}\alpha^\top\left(\sum_{j=1}^m \eta_i K_i\right)\alpha\right\},$$

and unique solution is $\alpha=\Pi_n(\sum_{j=1}^m \eta_j\Pi_n K_j\Pi_n + n\mu_n I_n)^{-1}\Pi_n\bar{Y}$. That is, the solution of the MKL problem leads to dual parameters α and set of weights $\eta\geqslant 0$ such that α is the solution to the least-square problem with kernel $K=\sum_{j=1}^m \eta_j K_j$. Bach et al. (2004a) has shown in a similar context (hinge loss instead of the square loss) that the optimal η in Proposition 13 can be obtained as the minimizer of the optimal value of the regularized least-square problem with kernel matrix $\sum_{j=1}^m \eta_j K_j$, that is:

$$J(\eta)=\max_{\alpha\in\mathbb{R}^n,\ \alpha^\top 1_n=0}\left\{-\frac{1}{2n}\|\bar{Y}-n\mu_n\alpha\|^2 - \frac{1}{2\mu_n}\alpha^\top\left(\sum_{j=1}^m \eta_j K_j\right)\alpha\right\},$$

with respect to $\eta\geqslant 0$ such that $\sum_{j=1}^m \eta_j d_j^2=1$. This formulation allows to derive probably approximately correct error bounds (Lanckriet et al., 2004b; Bousquet and Herrmann, 2003). Besides,

this formulation allows η to be negative, as long as the matrix $\sum_{j=1}^m \eta_j K_j$ is positive semi-definite. However, theoretical advantages of such a possibility still remain unclear.

Finally, we state a corollary of Proposition 13 that shows that under our assumptions regarding the correlation operator, we have a unique solution to the nonparametric groups Lasso problem with probability tending to one (see proof in Appendix A.5):

Proposition 14 *Assume (**A4-5**). The problem (13) has a unique solution with probability tending to one.*

3.6 Estimation of Correlation Condition (16)

Condition (4) is simple to compute while the nonparametric condition (16) might be hard to check even if all densities are known (we provide however in Section 5 a specific example where we can compute in closed form all covariance operators). The following proposition shows that we can consistently estimate the quantities $\left\| \Sigma_{X_i X_i}^{1/2} C_{X_i X_\mathbf{J}} C_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{f}_j\|_{\mathcal{F}_j}) \mathbf{g}_\mathbf{J} \right\|_{\mathcal{F}_i}$ given an i.i.d. sample (see proof in Appendix C.4):

Proposition 15 *Assume (**A4-7**), and $\kappa_n \to 0$ and $\kappa_n n^{1/2} \to \infty$. Let*

$$\alpha = \Pi_n \left(\sum_{j \in \mathbf{J}} \Pi_n K_j \Pi_n + n\kappa_n I_n \right)^{-1} \Pi_n \bar{Y}$$

and $\hat{\eta}_j = \frac{1}{d_j} (\alpha^\top K_j \alpha)^{1/2}$. Then, for all $i \in \mathbf{J}^c$, the norm $\left\| \Sigma_{X_i X_i}^{1/2} C_{X_i X_\mathbf{J}} C_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{f}_j\|) \mathbf{g}_\mathbf{J} \right\|_{\mathcal{F}_i}$ is consistently estimated by:

$$\left\| (\Pi_n K_i \Pi_n)^{1/2} \left(\sum_{j \in \mathbf{J}} \Pi_n K_j \Pi_n + n\kappa_n I_n \right)^{-1} \left(\sum_{j \in \mathbf{J}} \frac{1}{\hat{\eta}_j} \Pi_n K_j \Pi_n \right) \alpha \right\|. \tag{20}$$

4. Adaptive Group Lasso and Multiple Kernel Learning

In previous sections, we have shown that specific necessary and sufficient conditions are needed for path consistency of the group Lasso and multiple kernel learning. The following procedures, adapted from the adaptive Lasso of Zou (2006), lead to two-step procedures that always achieve both consistency, with no condition such as Eq. (4) or Eq. (16). As before, results are a bit different when groups have finite sizes and groups may have infinite sizes.

4.1 Adaptive Group Lasso

The following theorem extends the similar theorem of Zou (2006), and shows that we can get both $O_p(n^{-1/2})$ consistency and correct pattern estimation:

Theorem 16 *Assume (**A1-3**) and $\gamma > 0$. We denote by $\hat{w}^{LS} = \hat{\Sigma}_{XX}^{-1} \hat{\Sigma}_{XY}$ the (unregularized) least-square estimate. We denote by $\hat{w}^A$ any minimizer of*

$$\frac{1}{2} \hat{\Sigma}_{YY} - \hat{\Sigma}_{YX} w + \frac{1}{2} w^\top \hat{\Sigma}_{XX} w + \frac{\mu_n}{2} \left(\sum_{j=1}^m \|\hat{w}_j^{LS}\|^{-\gamma} \|w_j\| \right)^2.$$

If $n^{-1/2} \gg \mu_n \gg n^{-1/2-\gamma/2}$, then $\hat{w}^A$ converges in probability to $\mathbf{w}$, $J(\hat{w}^A)$ converges in probability to $\mathbf{J}$, and $n^{1/2}(\hat{w}^A_{\mathbf{J}} - \mathbf{w}_{\mathbf{J}})$ tends in distribution to a normal distribution with mean zero and covariance matrix $\Sigma^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}}$.

This theorem, proved in Appendix D.1, shows that the adaptive group Lasso exhibit all important asymptotic properties, both in terms of errors and selected models. In the nonparametric case, we obtain a weaker result.

4.2 Adaptive Multiple Kernel Learning

We first begin with the consistency of the least-square estimate (see proof in Appendix D.2):

Proposition 17 *Assume (**A4-7**). The unique minimizer $\hat{f}^{LS}_{\kappa_n}$ of*

$$\frac{1}{2}\hat{\Sigma}_{YY} - \langle \hat{\Sigma}_{XY}, f\rangle_{\mathcal{F}} + \frac{1}{2}\langle f, \hat{\Sigma}_{XX} f\rangle_{\mathcal{F}} + \frac{\kappa_n}{2}\sum_{j=1}^m \|f_j\|^2_{\mathcal{F}_j},$$

converges in probability to f if $\kappa_n \to 0$ and $\kappa_n n^{1/2} \to 0$. Moreover, we have $\|\hat{f}^{LS}_{\kappa_n} - f\|_{\mathcal{F}} = O_p(\kappa_n^{1/2} + \kappa_n^{-1} n^{-1/2})$.

Since the least-square estimate is consistent and we have an upper bound on its convergence rate, we follow Zou (2006) and use it to defined adaptive weights d_j for which we get both sparsity and regular consistency without any conditions on the value of the correlation operators.

Theorem 18 *Assume (**A4-7**) and $\gamma > 1$. Let $\hat{f}^{LS}_{n^{-1/3}}$ be the least-square estimate with regularization parameter proportional to $n^{-1/3}$, as defined in Proposition 17. We denote by $\hat{f}^A$ any minimizer of*

$$\frac{1}{2}\hat{\Sigma}_{YY} - \langle \hat{\Sigma}_{XY}, f\rangle_{\mathcal{F}} + \frac{1}{2}\langle f, \hat{\Sigma}_{XX} f\rangle_{\mathcal{F}} + \frac{\mu_0 n^{-1/3}}{2}\left(\sum_{j=1}^m \|(\hat{f}^{LS}_{\kappa_n})_j\|^{-\gamma}_{\mathcal{F}_j}\|f_j\|_{\mathcal{F}_j}\right)^2.$$

Then $\hat{f}^A$ converges to $\mathbf{f}$ and $J(\hat{f}^A)$ converges to $\mathbf{J}$ in probability.

Theorem 18 allows to set up a specific vector of weights d. This provides a principled way to define data adaptive weights, that allows to solve (at least theoretically) the potential consistency problems of the usual MKL framework (see Section 5 for illustration on synthetic examples). Note that we have no result concerning the $O_p(n^{-1/2})$ consistency of our procedure (as we have for the finite dimensional case) and obtaining precise convergence rates is the subject of ongoing research.

The following proposition gives the expression for the solution of the least-square problem, necessary for the computation of adaptive weights in Theorem 18.

Proposition 19 *The solution of the least-square problem in Proposition 17 is given by*

$$\forall j \in \{1,\dots,m\},\ f^{LS}_j = \sum_{i=1}^n \alpha_i k_j(\cdot, x_{ij}) \text{ with } \alpha = \Pi_n\left(\sum_{j=1}^m \Pi_n K_j \Pi_n + n\kappa_n I_n\right)^{-1}\Pi_n \bar{Y},$$

with norms $\|\hat{F}^{LS}_j\|_{\mathcal{F}_j} = \left(\alpha^\top K_j \alpha\right)^{1/2}$, $j = 1,\dots,m$.

Other weighting schemes have been suggested, based on various heuristics. A notable one (which we use in simulations) is the normalization of kernel matrices by their trace (Lanckriet et al., 2004b), which leads to $d_j = (\mathrm{tr}\hat{\Sigma}_{X_jX_j})^{1/2} = (\frac{1}{n}\mathrm{tr}\Pi_n K_j \Pi_n)^{1/2}$. Bach et al. (2004b) have observed empirically that such normalization might lead to suboptimal solutions and consider weights d_j that grow with the empirical ranks of the kernel matrices. In this paper, we give theoretical arguments that indicate that weights which do depend on the data are more appropriate and work better (see Section 5 for examples).

5. Simulations

In this section, we illustrate the consistency results obtained in this paper with a few simple simulations on synthetic examples.

5.1 Groups of Finite Sizes

In the finite dimensional group case, we sampled $X \in \mathbb{R}^p$ from a normal distribution with zero mean vector and a covariance matrix of size $p = 8$ for $m = 4$ groups of size $p_j = 2$, $j = 1,\ldots,m$, generated as follows: (a) sample an $p \times p$ matrix G with independent standard normal distributions, (b) form $\Sigma_{XX} = GG^\top$, (c) for each $j \in \{1,\ldots,m\}$, rescale $X_j \in \mathbb{R}^2$ so that $\mathrm{tr}\Sigma_{X_jX_j} = 1$. We selected $\mathrm{Card}(\mathbf{J}) = 2$ groups at random and sampled non zero loading vectors as follows: (a) sample each loading from from independent standard normal distributions, (b) rescale those to unit norm, (c) rescale those by a scaling which is uniform at random between $\frac{1}{3}$ and 1. Finally, we chose a constant noise level of standard deviation σ equal to 0.2 times $(\mathbb{E}(\mathbf{w}^\top X)^2)^{1/2}$ and sampled Y from a conditional normal distribution with constant variance. The joint distribution on (X,Y) thus defined satisfies with probability one assumptions (**A1-3**).

For cases when the correlation conditions (4) and (5) were or were not satisfied, we consider two different weighting schemes, that is, different ways of setting the weights d_j of the block ℓ_1-norm: unit weights (which correspond to the unit trace weighting scheme) and adaptive weights as defined in Section 4.

In Figure 1, we plot the regularization paths corresponding to 200 i.i.d. samples, computed by the algorithm of Bach et al. (2004b). We only plot the values of the estimated variables $\hat{\eta}_j, j = 1,\ldots,m$ for the alternative formulation in Section 3.5, which are proportional to $\|\hat{w}_j\|$ and normalized so that $\sum_{j=1}^m \hat{\eta}_j = 1$. We compare them to the population values η_j: both in terms of values, and in terms of their sparsity pattern (η_j is zero for the weights which are equal to zero). Figure 1 illustrates several of our theoretical results: (a) the top row corresponds to a situation where the strict consistency condition is satisfied and thus we obtain model consistent estimates with also a good estimation of the loading vectors (in the figure, only the behavior of the norms of these loading vectors are represented); (b) the right column corresponds to the adaptive weighting schemes which also always achieve the two type of consistency; (c) in the middle and bottom rows, the consistency condition was not satisfied, and in the bottom row, the condition of Proposition 5, that ensures that we can get model consistent estimates without regular consistency, is met, while it is not in the middle row: as expected, in the bottom row, we get some model consistent estimates but with bad norm estimation.

In Figure 2, 3 and 4, we consider the three joint distributions used in Figure 1 and compute regularization paths for several number of samples (10 to 10^5) with 200 replications. This allows

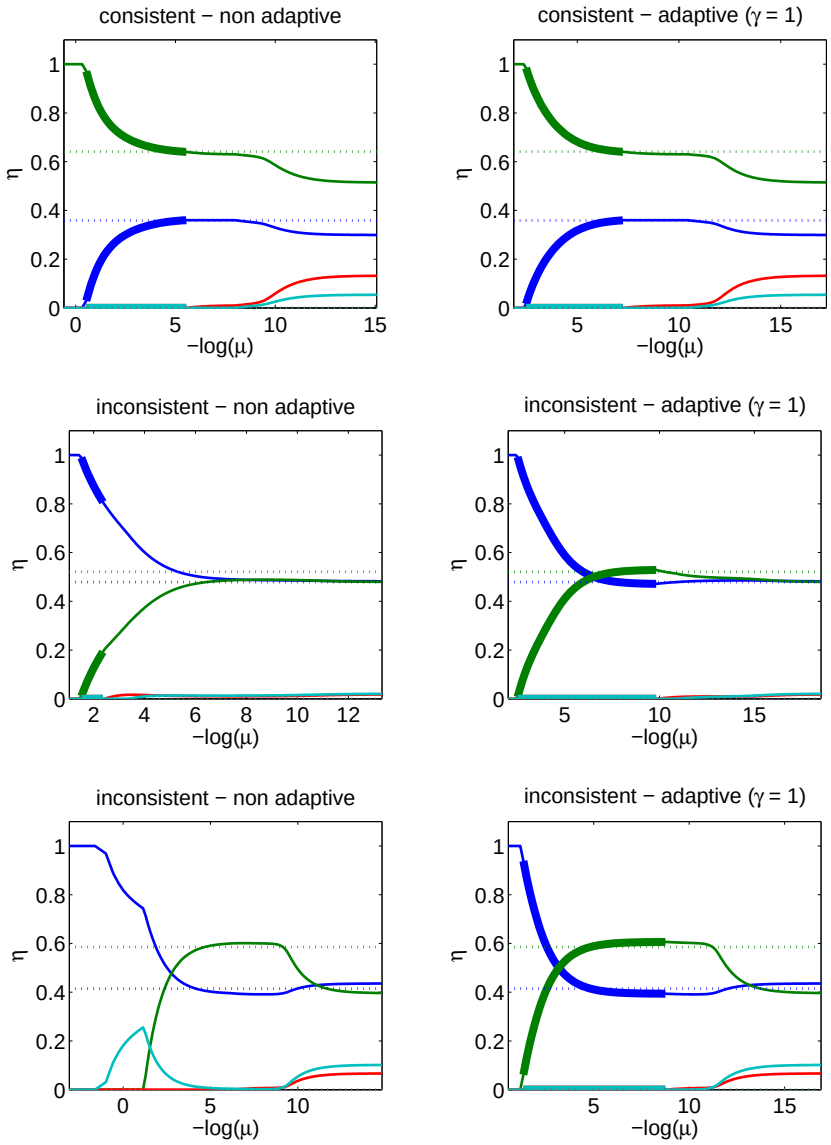

Figure 1: Regularization paths for the group Lasso for two weighting schemes (*left*: non adaptive, *right*: adaptive) and three different population densities (*top*: strict consistency condition satisfied, *middle*: weak condition not satisfied, no model consistent estimates, *bottom*: weak condition not satisfied, some model consistent estimates but without regular consistency). For each of the plots, plain curves correspond to values of estimated $\hat{\eta}_j$, dotted curves to population values η_j, and bold curves to model consistent estimates.

us to estimate both the probability of correct pattern estimation $\mathbb{P}(J(\hat{w}) = \mathbf{J})$ which is considered in Section 2.7, and the logarithm of the expected error $\log \mathbb{E}\|\hat{w} - \mathbf{w}\|^2$.

From Figure 2, it is worth noting (a) the regular spacing between the probability of correct pattern selection for several equally spaced (in log scale) numbers of samples, which corroborates

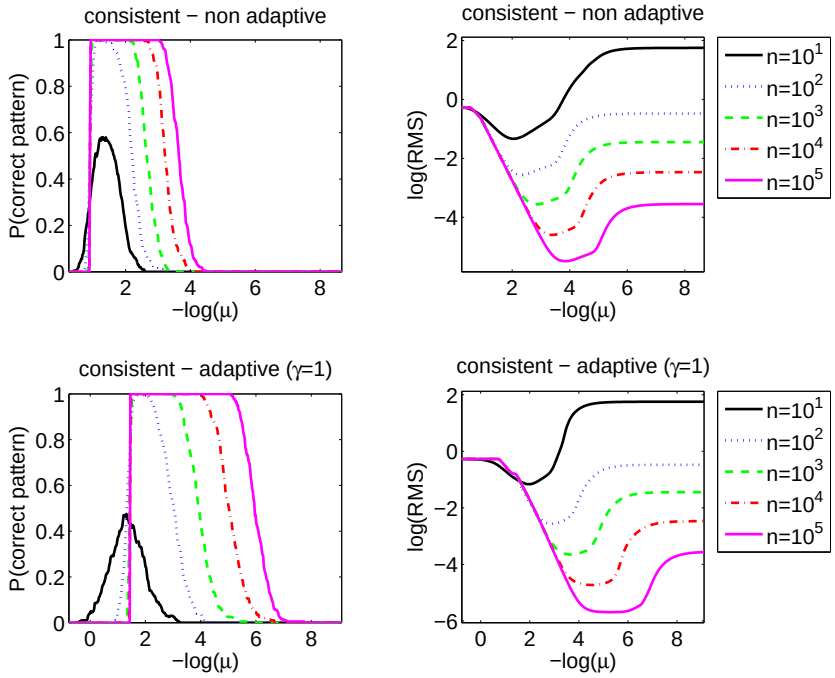

Figure 2: Synthetic example where consistency condition in Eq. (4) is satisfied (same example as the top of Figure 1: probability of correct pattern selection (*left*) and logarithm of the expected mean squared estimation error (*right*), for several number of samples as a function of the regularization parameter, for regular regularization (*top*), adaptive regularization with $\gamma = 1$ (*bottom*).

the asymptotic result in Section 2.7. Moreover, (b) in both rows, we get model consistent estimates with increasingly smaller norms as the number of samples grows. Finally, (c) the mean square errors are smaller for the adaptive weighting scheme.

From Figure 3, it is worth noting that (a) in the non adaptive case, we have two regimes for the probability of correct pattern selection: a regime corresponding to Proposition 6 where this probability can take values in $(0,1)$ for increasingly smaller regularization parameters (when n grows); and a regime corresponding to non vanishing limiting regularization parameters corresponding to Proposition 5: we have model consistency without regular consistency. Also, (b) the adaptive weighting scheme allows both consistencies. In Figure 4 however, the second regime (correct model estimates, inconsistent estimation of loadings) is not present.

In Figure 5, we sampled 10,000 different covariance matrices and loading vectors using the procedure described above. For each of these we computed the regularization paths from 1000 samples, and we classify each path into three categories: (1) existence of model consistent estimates with estimation error $\|\hat{w} - \mathbf{w}\|$ less than 10^{-1}, (2) existence of model consistent estimates but none with estimation error $\|\hat{w} - \mathbf{w}\|$ less than 10^{-1} and (3) non existence of model consistent estimates. In Figure 5 we plot the proportion of each of the three class as a function of the logarithm of $\max_{i \in \mathbf{J}^c} \frac{1}{d_i} \left\| \Sigma_{X_i X_\mathbf{J}} \Sigma_{X_\mathbf{J} X_\mathbf{J}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{w}_j\|) \mathbf{w}_\mathbf{J} \right\|$. The position of the previous value with respect to 1 is indicative of the expected model consistency. When it is less than one, then we get with

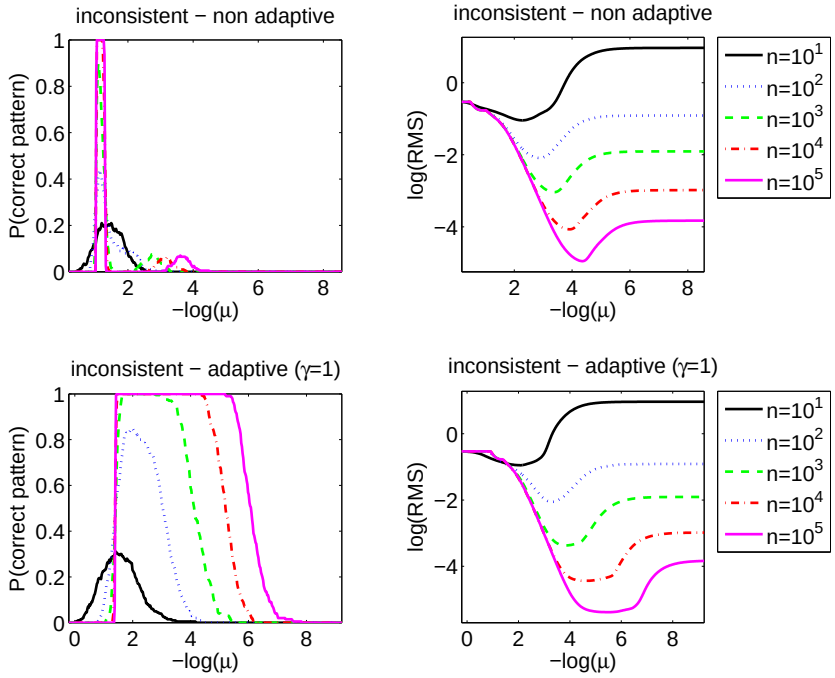

Figure 3: Synthetic example where consistency condition in Eq. (5) is not satisfied (same example as the middle of Figure 1: probability of correct pattern selection (*left*) and logarithm of the expected mean squared estimation error (*right*), for several number of samples as a function of the regularization parameter, for regular regularization (*top*), adaptive regularization with $\gamma = 1$ (*bottom*).

overwhelming probability model consistent estimates with good errors. As the condition gets larger than one, we get fewer such good estimates and more and more model inconsistent estimates.

5.2 Nonparametric Case

In the infinite dimensional group case, we sampled $X \in \mathbb{R}^m$ from a normal distribution with zero mean vector and a covariance matrix of size $m = 4$, generated as follows: (a) sample a $m \times m$ matrix G with independent standard normal distributions, (b) form $\Sigma_{XX} = GG^\top$, (c) for each $j \in \{1,\dots,m\}$, rescale $X_j \in \mathbb{R}$ so that $\Sigma_{X_jX_j} = 1$.

We use the same Gaussian kernel for each variable X_j, $k_j(x_j,x'_j) = e^{-(x_j-x'_j)^2}$, for $j \in \{1,\dots,m\}$. In this situation, as shown in Appendix E we can compute in closed form the eigenfunctions and eigenvalues of the marginal covariance operators; moreover, assumptions (**A4-7**) are satisfied. We then sample functions from random independent components on the first 10 eigenfunctions. Examples are given in Figure 6. Note that although we consider univariate variables, we still have infinite dimensional Hilbert spaces.

In Figure 7, we plot the regularization paths corresponding to 1000 i.i.d. samples, computed by the algorithm of Bach et al. (2004b). We only plot the values of the estimated variables $\hat{\eta}_j, j = 1,\dots,m$ for the alternative formulation in Section 2.9, which are proportional to $\|\hat{w}_j\|$ and normalized so that $\sum_{j=1}^m \hat{\eta}_j = 1$. We compare them to the population values η_j: both in terms of values,

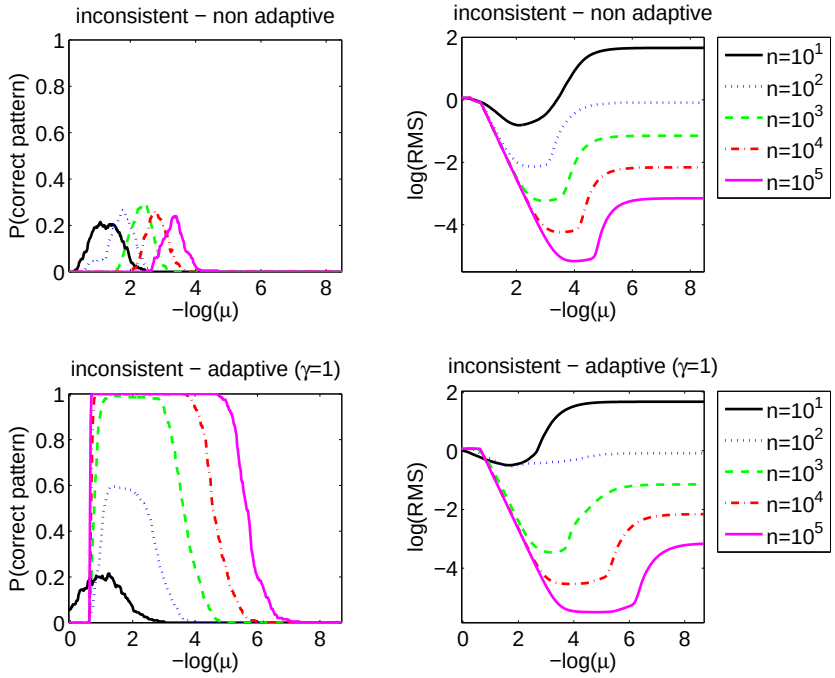

Figure 4: Synthetic example where consistency condition in Eq. (5) is not satisfied (same example as the bottom of Figure 1: probability of correct pattern selection (*left*) and logarithm of the expected mean squared estimation error (*right*), for several number of samples as a function of the regularization parameter, for regular regularization (*top*), adaptive regularization with $\gamma = 1$ (*bottom*).

and in terms of their sparsity pattern (η_j is zero for the weights which are equal to zero). Figure 7 illustrates several of our theoretical results: (a) the top row corresponds to a situation where the strict consistency condition is satisfied and thus we obtain model consistent estimates with also a good estimation of the loading vectors (in the figure, only the behavior of the norms of these loading vectors are represented); (b) in the bottom row, the consistency condition was not satisfied, and we do not get good model estimates. Finally, (b) the right column corresponds to the adaptive weighting schemes which also always achieve the two type of consistency. However, such schemes should be used with care, as there is one added free parameter (the regularization parameter κ of the least-square estimate used to define the weights): if chosen too large, all adaptive weights are equal, and thus there is no adaptation, while if chosen too small, the least-square estimate may overfit.

6. Conclusion

In this paper, we have extended some of the theoretical results of the Lasso to the group Lasso, for finite dimensional groups and infinite dimensional groups. In particular, under practical assumptions regarding the distributions the data are sampled from, we have provided necessary and sufficient conditions for model consistency of the group Lasso and its nonparametric version, multiple kernel learning.

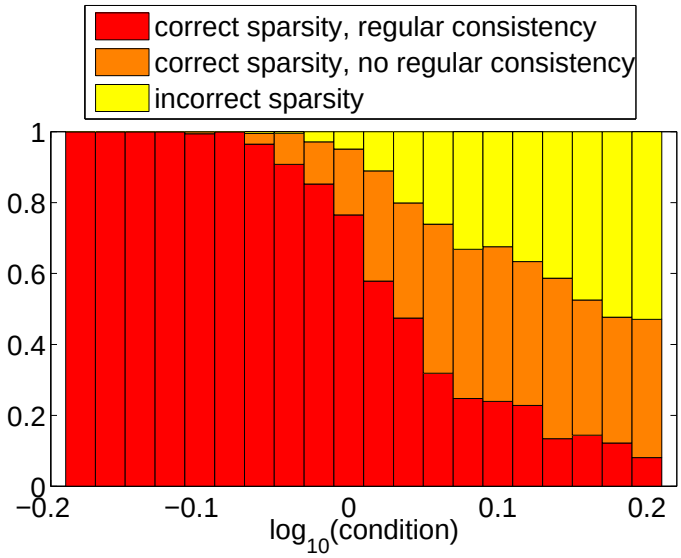

Figure 5: Consistency of estimation vs. consistency condition. See text for details.

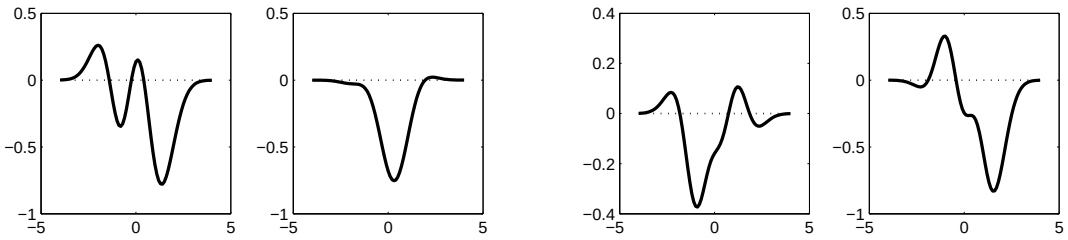

Figure 6: Functions to be estimated in the synthetic nonparametric group Lasso experiments (left: consistent case, right: inconsistent case).

The current work could be extended in several ways: first, a more detailed study of the limiting distributions of the group Lasso and adaptive group Lasso estimators could be carried and then extend the analysis of Zou (2006) or Juditsky and Nemirovski (2000) and Wu et al. (2007), in particular regarding convergence rates. Second, our results should extend to generalized linear models, such as logistic regression (Meier et al., 2006). Also, it is of interest to let the number m of groups or kernels to grow unbounded and extend the results of Zhao and Yu (2006) and Meinshausen and Yu (2006) to the group Lasso. Finally, similar analysis may be carried through for more general norms with different sparsity inducing properties (Bach, 2008b).

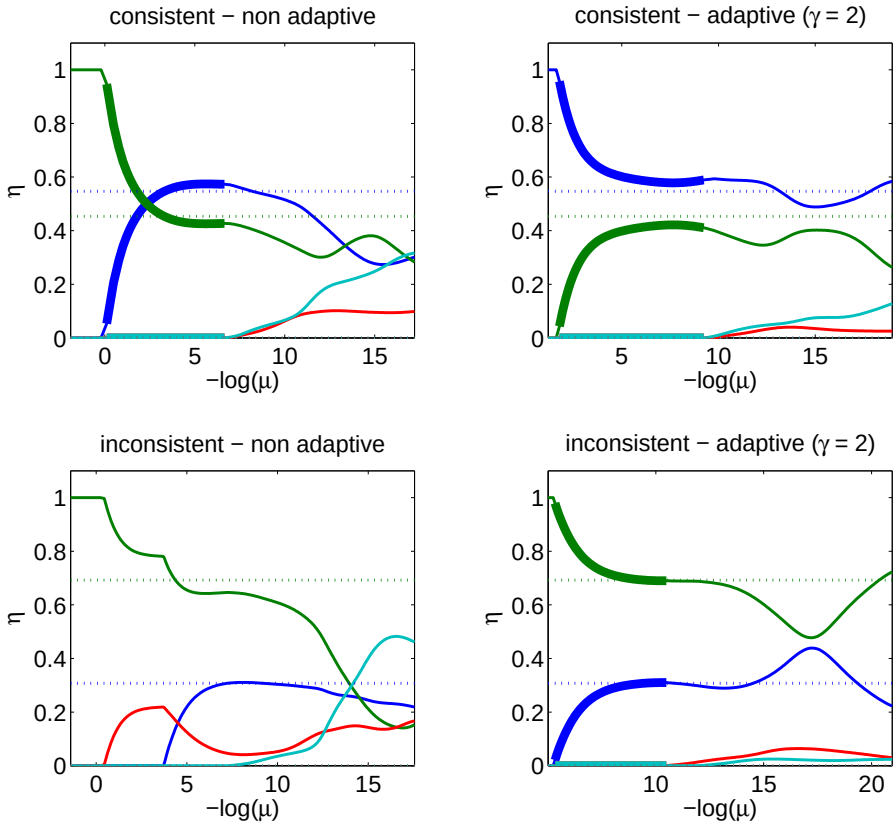

Figure 7: Regularization paths for the group Lasso for two weighting schemes (*left*: non adaptive, *right*: adaptive) and two different population densities (*top*: strict consistency condition satisfied, *bottom*: weak condition not satisfied. For each of the plots, plain curves correspond to values of estimated $\hat{\eta}_j$, dotted curves to population values η_j, and bold curves to model consistent estimates.

I would like to thank Zaïd Harchaoui for fruitful discussions related to this work. This work was supported by a French grant from the Agence Nationale de la Recherche (MGA Project).

Appendix A. Proof of Optimization Results

In this appendix, we give detailed proofs of the various propositions on optimality conditions and dual problems.

A.1 Proof of Proposition 1

We rewrite problem in Eq. (1), in the form

$$\min_{w\in\mathbb{R}^p,\ v\in\mathbb{R}^m} \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{YX}w + \frac{1}{2}w^\top\hat{\Sigma}_{XX}w + \lambda_n\sum_{j=1}^m d_j v_j,$$

with added constraints that $\forall j, \|w_j\| \leqslant v_j$. In order to deal with these constraints we use the tools from conic programming with the second-order cone, also known as the "ice cream" cone (Boyd and Vandenberghe, 2003). We consider the Lagrangian with dual variables $(\beta_j,\gamma_j)\in\mathbb{R}^{p_j}\times\mathbb{R}$ such that $\|\beta_j\|\leqslant\gamma_j$:

$$\mathcal{L}(w,v,\beta,\gamma) = \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{YX}w + \frac{1}{2}w^\top\hat{\Sigma}_{XX}w + \lambda_n d^\top v - \sum_{j=1}^m \begin{pmatrix} w_j \\ v_j\end{pmatrix}^\top \begin{pmatrix}\beta_j\\ \gamma_j\end{pmatrix}.$$

The derivatives with respect to primal variables are

$$\begin{aligned}\nabla_w\mathcal{L}(w,v,\beta,\gamma) &= \hat{\Sigma}_{XX}w - \hat{\Sigma}_{XY} - \beta,\\ \nabla_v\mathcal{L}(w,v,\beta,\gamma) &= \lambda_n d - \gamma.\end{aligned}$$

At optimality, primal and dual variables are completely characterized by w and β. Since the dual and the primal problems are strictly feasible, strong duality holds and the KKT conditions for reduced primal/dual variables (w,β) are

$$\begin{aligned}\forall j,\ \|\beta_j\| &\leqslant \lambda_n d_j && \text{(dual feasibility)},\\ \forall j,\ \beta_j &= \hat{\Sigma}_{X_jX}w - \hat{\Sigma}_{X_jY} && \text{(stationarity)},\\ \forall j,\ \beta_j^\top w_j + \|w_j\|\lambda_n d_j &= 0 && \text{(complementary slackness)}.\end{aligned}$$

Complementary slackness for the second order cone has special consequences: $w_j^\top\beta_j + \|w_j\|\lambda_n d_j = 0$ if and only if (Boyd and Vandenberghe, 2003; Lobo et al., 1998), either (a) $w_j = 0$, or (b) $w_j\neq 0$, $\|\beta_j\| = \lambda_n d_j$ and $\exists\eta_j>0$ such that $w_j = -\frac{\eta_j}{\lambda_n}\beta_j$ (anti-proportionality), which implies $\beta_j = -w_j\frac{\lambda_n d_j}{\|w_j\|}$ and $\eta_j = \|w_j\|/d_j$. This leads to the proposition.

A.2 Proof of Proposition 8

We follow the proof of Proposition 1 and of Bach et al. (2004a). We rewrite problem in Eq. (12), in the form

$$\min_{w\in\mathbb{R}^p,\ v\in\mathbb{R}^m,\ t\in\mathbb{R}} \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{YX}w + \frac{1}{2}w^\top\hat{\Sigma}_{XX}w + \frac{1}{2}\mu_n t^2,$$

with constraints that $\forall j, \|w_j\| \leqslant v_j$ and $d^\top v \leqslant t$. We consider the Lagrangian with dual variables $(\beta_j, \gamma_j) \in \mathbb{R}^{p_j} \times \mathbb{R}$ and $\delta \in \mathbb{R}_+$ such that $\|\beta_j\| \leqslant \gamma_j$, $j = 1, \ldots, m$:

$$\mathcal{L}(w, v, \beta, \gamma, \delta) = \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{YX} w + \frac{1}{2} w^\top \hat{\Sigma}_{XX} w + \frac{1}{2}\mu_n t^2 - \beta^\top w - \gamma^\top v + \delta(d^\top v - t).$$

The derivatives with respect to primal variables are

$$\begin{aligned}
\nabla_w \mathcal{L}(w, v, \beta, \gamma) &= \hat{\Sigma}_{XX} w - \hat{\Sigma}_{XY} - \beta, \\
\nabla_v \mathcal{L}(w, v, \beta, \gamma) &= \delta d - \gamma, \\
\nabla_t \mathcal{L}(w, v, \beta, \gamma) &= \mu_n t - \delta.
\end{aligned}$$

At optimality, primal and dual variables are completely characterized by w and β. Since the dual and the primal problems are strictly feasible, strong duality holds and the KKT conditions for reduced primal/dual variables (w, β) are

$$\begin{aligned}
\forall j, \beta_j &= \hat{\Sigma}_{X_j X} w - \hat{\Sigma}_{X_j Y} && \text{(stationarity - 1)}, \\
\forall j, \sum_{j=1}^m d_j \|w_j\| &= \frac{1}{\mu_n} \max_{i=1,\ldots,m} \frac{\|\beta_i\|}{d_i} && \text{(stationarity - 2)}, \\
\forall j, \left(\frac{\beta_j}{d_j}\right)^\top w_j + \|w_j\| \max_{i=1,\ldots,m} \frac{\|\beta_i\|}{d_i} &= 0 && \text{(complementary slackness)}.
\end{aligned} \tag{21}$$

Complementary slackness for the second order cone implies that:

$$\left(\frac{\beta_j}{d_j}\right)^\top w_j + \|w_j\| \max_{i=1,\ldots,m} \frac{\|\beta_i\|}{d_i} = 0,$$

if and only if, either (a) $w_j = 0$, or (b) $w_j \neq 0$ and $\frac{\|\beta_j\|}{d_j} = \max_{i=1,\ldots,m} \frac{\|\beta_i\|}{d_i}$, and $\exists \eta_j \geqslant 0$ such that $w_j = -\eta_j \beta_j / \mu_n$, which implies $\|w_j\| = \frac{\eta_j d_j}{\mu_n} \max_{i=1,\ldots,m} \frac{\|\beta_i\|}{d_i}$.

By writing $\eta_j = 0$ if $w_j = 0$ (i.e., in order to cover all cases), we have from Eq. (21) $\sum_{j=1}^m d_j \|w_j\| = \frac{1}{\mu_n} \max_{i=1,\ldots,m} \frac{\|\beta_i\|}{d_i}$, which implies $\sum_{j=1}^m d_j^2 \eta_j = 1$ and thus $\forall j,\ \eta_j = \frac{\|w_j\|/d_j}{\sum_i d_i \|w_i\|}$. This leads to $\forall j, \beta_j = -w_j \mu_n / \eta_j = -\frac{w_j}{\|w_j\|} \sum_{i=1}^n d_i \|w_i\|$. The proposition follows.

A.3 Proof of Proposition 10

By following the usual proof of the representer theorem (Wahba, 1990), we obtain that each optimal function f_j must be supported by the data points, that is, there exists $\alpha = (\alpha_1, \ldots, \alpha_m) \in \mathbb{R}^{n \times m}$ such that for all $j = 1, \ldots, m$, $f_j = \sum_{i=1}^n \alpha_{ij} k_j(\cdot, x_{ij})$. When using this representation back into Eq. (13), we obtain an optimization problem that only depends on $\phi_j = G_j^\top \alpha_j$ for $j = 1, \ldots, m$ where G_j denotes any square root of the kernel matrix K_j, that is, $K_j = G_j G_j^\top$. This problem is exactly the finite dimensional problem in Eq. (12), where X_j is replaced by G_j and w_j by ϕ_j. Thus Proposition 8 applies and we can easily derive the current proposition by expressing all terms through the functions f_j. Note that in this proposition, we do not show that the α_j, $j = 1, \ldots, m$, are all proportional to the same vector, as is done in Appendix A.4.

A.4 Proof of Proposition 13

We prove the proposition in the linear case. Going to the general case, can be done in the same way as done in Appendix A.3. We denote by $\bar{X}$ the covariate matrix in $\mathbb{R}^{n\times p}$; we simply need to add a new variable $u = \bar{X}w + b1_n$ and to "dualize" the added equality constraint. That is, we rewrite problem in Eq. (12), in the form

$$\min_{w\in\mathbb{R}^p,\ b\in\mathbb{R},\ v\in\mathbb{R}^m,\ t\in\mathbb{R},\ u\in\mathbb{R}^n} \frac{1}{2n}\|\bar{Y}-u\|^2 + \frac{1}{2}\mu_n t^2,$$

with constraints that $\forall j, \|w_j\| \leqslant v_j$, $d^\top v \leqslant t$ and $\bar{X}w + b1_n = u$. We consider the Lagrangian with dual variables $(\beta_j,\gamma_j) \in \mathbb{R}^{p_j}\times\mathbb{R}$ and $\delta\in\mathbb{R}_+$ such that $\|\beta_j\| \leqslant \gamma_j$, and $\alpha\in\mathbb{R}^n$:

$$\mathcal{L}(w,b,v,u,\beta,\gamma,\alpha,\delta) = \frac{1}{2n}\|\bar{Y}-u\|^2 + \mu_n\alpha^\top(u-\bar{X}w) + \frac{1}{2}\mu_n t^2 - \sum_{j=1}^m \Big\{\beta_j^\top w_j + \gamma_j v_j\Big\} + \delta(d^\top v - t).$$

The derivatives with respect to primal variables are

$$\begin{aligned}
\nabla_w\mathcal{L}(w,v,u,\beta,\gamma,\alpha) &= -\mu_n\bar{X}^\top\alpha - \beta,\\
\nabla_v\mathcal{L}(w,v,u,\beta,\gamma,\alpha) &= \delta d - \gamma,\\
\nabla_t\mathcal{L}(w,v,u,\beta,\gamma,\alpha) &= \mu_n t - \delta,\\
\nabla_u\mathcal{L}(w,v,u,\beta,\gamma,\alpha) &= \frac{1}{n}(u - \bar{Y} + \mu_n n\alpha),\\
\nabla_b\mathcal{L}(w,v,u,\beta,\gamma,\alpha) &= \mu_n\alpha^\top 1_n.
\end{aligned}$$

Equating them to zero, we get the dual problem in Eq. (18). Since the dual and the primal problems are strictly feasible, strong duality holds and the KKT conditions for reduced primal/dual variables (w,α) are

$$\begin{aligned}
\forall j, \bar{X}w - \bar{Y} + \mu_n n\alpha = 0 &\qquad \text{(stationarity - 1)},\\
\forall j, \sum_{j=1}^m d_j\|w_j\| = \max_{i=1,\dots,m}\frac{(\alpha^\top K_i\alpha)^{1/2}}{d_i} &\qquad \text{(stationarity - 2)},\\
\alpha^\top 1_n = 0 &\qquad \text{(stationarity - 3)},\\
\forall j, \left(\frac{-\bar{X}_j^\top\alpha}{d_j}\right)^\top w_j + \|w_j\|\max_{i=1,\dots,m}\frac{(\alpha^\top K_i\alpha)^{1/2}}{d_i} = 0 &\qquad \text{(complementary slackness)}.
\end{aligned}$$

Complementary slackness for the second order cone goes leads to:

$$\left(\frac{-\bar{X}_j^\top\alpha}{d_j}\right)^\top w_j + \|w_j\|\max_{i=1,\dots,m}\frac{(\alpha^\top K_i\alpha)^{1/2}}{d_i} = 0,$$

if and only if, either (a) $w_j = 0$, or (b) $w_j \neq 0$ and $\frac{(\alpha^\top K_j\alpha)^{1/2}}{d_j} = \max_{i=1,\dots,m}\frac{(\alpha^\top K_i\alpha)^{1/2}}{d_i}$, and $\exists\eta_j \geqslant 0$ such that $w_j = -\eta_j\left(-\bar{X}_j^\top\alpha\right)$, which implies $\|w_j\| = \eta_j d_j\max_{i=1,\dots,m}\frac{(\alpha^\top K_i\alpha)^{1/2}}{d_i}$.

By writing $\eta_j = 0$ if $w_j = 0$ (to cover all cases), we have from Eq. (22), $\sum_{j=1}^m d_j\|w_j\| = \max_{i=1,\dots,m}\frac{(\alpha^\top K_i\alpha)^{1/2}}{d_i}$, which implies $\sum_{j=1}^m d_j^2\eta_j = 1$. The proposition follows from the fact that at optimality, $\forall j$, $w_j = \eta_j\bar{X}_j^\top\alpha$.

A.5 Proof of Proposition 14

What makes this proposition non obvious is the fact that the covariance operator Σ_{XX} is not invertible in general. From Proposition 13, we know that each f_j must be of the form $f_j = \eta_j \sum_{i=1}^n \alpha_i k_j(x_{ij}, \cdot)$, where α is *uniquely* defined. Moreover, η is such that

$$\left(\sum_{j=1}^m \eta_j K_j + n\mu_n I_n\right) \alpha = \bar{Y}$$

and such that if $\frac{\alpha^\top K_j \alpha}{d_j^2} < A$, then $\eta_j = 0$ (where $A = \max_{i=1,\ldots,m} \frac{\alpha^\top K_i \alpha}{d_i^2}$). Thus, if the solution is not unique, there exists two vectors $\eta \neq \zeta$ such that η and ζ have zero components on indices j such that $\alpha^\top K_j \alpha < A d_j^2$ (we denote by J the active set and thus J^c this set of indices), and $\sum_{j=1}^m (\zeta_j - \eta_j) K_j \alpha = 0$. This implies that the vectors $\Pi_n K_j \alpha = \Pi_n K_j \Pi_n \alpha$, $j \in J$ are linearly dependent. Those vectors are exactly the centered vector of values of the functions $g_j = \sum_{i=1}^n \alpha_i k_j(x_{ij}, \cdot)$ at the observed data points. Thus, non unicity implies that the empirical covariance matrix of the random variables $g_j(X_j)$, $j \in J$, is non invertible. Moreover, we have $\|g_j\|_{\mathcal{F}_j}^2 = \alpha^\top K_j \alpha = d_j^2 A > 0$ and the empirical marginal variance of $g_j(X_j)$ is equal to $\alpha^\top K_j^2 \alpha > 0$ (otherwise $\|g_j\|_{\mathcal{F}_j}^2 = 0$). By normalizing by the (non vanishing) empirical standard deviations, we thus obtain functions such that the empirical covariance matrix is singular, but the marginal empirical variance are equal to one. Because the empirical covariance operator is a consistent estimator of Σ_{XX} and C_{XX} is invertible, we get a contradiction, which proves the unicity of solutions.

Appendix B. Detailed Proofs for the Group Lasso

In this appendix, detailed proofs of the consistency results for the finite dimensional case (Theorems 2 and 3) are presented. Some of the results presented in this appendix are corollaries of the more general results in Appendix C, but their proofs in the finite dimensional case are much simpler.

B.1 Proof of Theorem 2

We begin with a lemma, which states that if we restrict ourselves to the covariates which we are after (i.e., indexed by $\mathbf{J}$), we get a consistent estimate as soon as λ_n tends to zero:

Lemma 20 *Assume (**A1-3**). Let $\tilde{w}_\mathbf{J}$ any minimizer of*

$$\frac{1}{2n}\|\bar{Y} - \bar{X}_\mathbf{J} w_\mathbf{J}\|^2 + \lambda_n \sum_{j \in \mathbf{J}} d_j \|w_j\| = \frac{1}{2}\hat{\Sigma}_{YY} - \hat{\Sigma}_{YX_\mathbf{J}} w_\mathbf{J} + \frac{1}{2} w_\mathbf{J}^\top \hat{\Sigma}_{X_\mathbf{J} X_\mathbf{J}} w_\mathbf{J} + \lambda_n \sum_{j \in \mathbf{J}} d_j \|w_j\|.$$

If $\lambda_n \to 0$, then $\tilde{w}_\mathbf{J}$ converges to $\mathbf{w}_\mathbf{J}$ in probability.

Proof If λ_n tends to zero, then the cost function defining $\tilde{w}_\mathbf{J}$ converges to $F(w_\mathbf{J}) = \frac{1}{2}\Sigma_{YY} - \Sigma_{YX_\mathbf{J}} w_\mathbf{J} + \frac{1}{2} w_\mathbf{J}^\top \Sigma_{X_\mathbf{J} X_\mathbf{J}} w_\mathbf{J}$ whose unique (because $\Sigma_{X_\mathbf{J} X_\mathbf{J}}$ is positive definite) global minimum is $\mathbf{w}_\mathbf{J}$ (true generating value). The convergence of $\tilde{w}_\mathbf{J}$ is thus a simple consequence of standard results in M-estimation (Van der Vaart, 1998; Fu and Knight, 2000). ■

We now prove Theorem 2. Let $\tilde{w}_\mathbf{J}$ be defined as in Lemma 20. We extend it by zeros on $\mathbf{J}^c$. We already know from Lemma 20 that we have consistency in squared norm. Since with probability

tending to one, the problem has a unique solution (because Σ_{XX} is invertible), we now need to prove that the probability that $\tilde{w}$ is optimal for problem in Eq. (1) is tending to one.

By definition of $\tilde{w}_{\mathbf{J}}$, the optimality condition (3) is satisfied. We now need to verify optimality condition (2), that is, that variables in $\mathbf{J}^c$ may actually be left out. Denoting $\varepsilon = Y - \mathbf{w}^\top X - \mathbf{b}$, we have:

$$\hat{\Sigma}_{XY} = \hat{\Sigma}_{XX}\mathbf{w} + \hat{\Sigma}_{X\varepsilon} = \Big(\Sigma_{XX} + O_p(n^{-1/2})\Big)\mathbf{w} + O_p(n^{-1/2}) = \Sigma_{XX_{\mathbf{J}}}\mathbf{w}_{\mathbf{J}} + O_p(n^{-1/2}),$$

because of classical results on convergence of empirical covariances to covariances (Van der Vaart, 1998), which are applicable because we have the fourth order moment condition (**A1**). We thus have:

$$\hat{\Sigma}_{XY} - \hat{\Sigma}_{XX_{\mathbf{J}}}\tilde{w}_{\mathbf{J}} = \Sigma_{XX_{\mathbf{J}}}(\mathbf{w}_{\mathbf{J}} - \tilde{w}_{\mathbf{J}}) + O_p(n^{-1/2}). \tag{22}$$

From the optimality condition $\hat{\Sigma}_{X_{\mathbf{J}}Y} - \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\tilde{w}_{\mathbf{J}} = \lambda_n \operatorname{Diag}(d_j/\|\tilde{w}_j\|)\tilde{w}_{\mathbf{J}}$ defining $\tilde{w}_{\mathbf{J}}$ and Eq. (22), we obtain:

$$\tilde{w}_{\mathbf{J}} - \mathbf{w}_{\mathbf{J}} = -\lambda_n \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1} \operatorname{Diag}(d_j/\|\tilde{w}_j\|)\tilde{w}_{\mathbf{J}} + O_p(n^{-1/2}). \tag{23}$$

Therefore,

$$\begin{aligned}
\hat{\Sigma}_{X_{\mathbf{J}^c}Y} - \hat{\Sigma}_{X_{\mathbf{J}^c}X_{\mathbf{J}}}\tilde{w}_{\mathbf{J}} &= \Sigma_{X_{\mathbf{J}^c}X_{\mathbf{J}}}(\mathbf{w}_{\mathbf{J}} - \tilde{w}_{\mathbf{J}}) + O_p(n^{-1/2}) \text{ by Eq. (22)}, \\
&= \lambda_n \Sigma_{X_{\mathbf{J}^c}X_{\mathbf{J}}}\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1} \operatorname{Diag}(d_j/\|\tilde{w}_j\|)\tilde{w}_{\mathbf{J}} + O_p(n^{-1/2}) \text{ by Eq. (23)}.
\end{aligned}$$

Since $\tilde{w}$ is consistent, and $\lambda_n n^{1/2} \to +\infty$, then for each $i \in J^c$,

$$\frac{1}{d_i\lambda_n}\left(\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\tilde{w}_{\mathbf{J}}\right)$$

converges in probability to $\frac{1}{d_i}\Sigma_{X_iX_{\mathbf{J}}}\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_{\mathbf{J}}$ which is of norm *strictly* smaller than one because condition (4) is satisfied. Thus the probability that $\tilde{w}$ is indeed optimal, which is equal to

$$\mathbb{P}\left\{\forall i \in \mathbf{J}^c, \frac{1}{d_i\lambda_n}\left\|\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\tilde{w}_{\mathbf{J}}\right\| \leqslant 1\right\} \geqslant \prod_{i\in\mathbf{J}^c}\mathbb{P}\left\{\frac{1}{d_i\lambda_n}\left\|\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\tilde{w}_{\mathbf{J}}\right\| \leqslant 1\right\},$$

is tending to 1, which implies the theorem.

B.2 Proof of Theorem 3

We prove the theorem by contradiction, by assuming that there exists $i \in \mathbf{J}^c$ such that

$$\frac{1}{d_i}\left\|\Sigma_{X_iX_{\mathbf{J}}}\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_{\mathbf{J}}\right\| > 1.$$

Since with probability tending to one $J(\hat{w}) = \mathbf{J}$, with probability tending to one, we have from optimality condition (3):

$$\hat{w}_{\mathbf{J}} = \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\left(\hat{\Sigma}_{X_{\mathbf{J}}Y} - \lambda_n \operatorname{Diag}(d_j/\|\hat{w}_j\|)\hat{w}_{\mathbf{J}}\right),$$

and thus

$$\begin{aligned}
\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\hat{w}_{\mathbf{J}} &= (\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\hat{\Sigma}_{X_{\mathbf{J}}Y}) + \lambda_n\hat{\Sigma}_{X_iX_{\mathbf{J}}}\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\hat{w}_j\|)\hat{w}_{\mathbf{J}} \\
&= A_n + B_n.
\end{aligned}$$

The second term B_n in the last expression (divided by λ_n) converges to

$$v = \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \operatorname{Diag}(d_j / \|\mathbf{w}_j\|) \mathbf{w}_{\mathbf{J}} \in \mathbb{R}^{p_i},$$

because $\hat{w}$ is assumed to converge in probability to $\mathbf{w}$ and empirical covariance matrices converge to population covariance matrices. By assumption $\|v\| > d_i$, which implies that the probability $\mathbb{P}\left\{ \left(\frac{v}{\|v\|} \right)^\top (B_n/\lambda_n) \geqslant (d_i + \|v\|)/2) \right\}$ converges to one.

The first term is equal to (with $\varepsilon_k = y_k - \mathbf{w}^\top x_k - \mathbf{b}_k$ and $\bar{\varepsilon} = \frac{1}{n}\sum_{k=1}^n \varepsilon_k$):

$$\begin{aligned}
A_n &= \hat{\Sigma}_{X_i Y} - \hat{\Sigma}_{X_i X_{\mathbf{J}}} \hat{\Sigma}_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \hat{\Sigma}_{X_{\mathbf{J}} Y} \\
&= \hat{\Sigma}_{X_i X_{\mathbf{J}}} \mathbf{w}_{\mathbf{J}} - \hat{\Sigma}_{X_i X_{\mathbf{J}}} \hat{\Sigma}_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \hat{\Sigma}_{X_{\mathbf{J}} X_{\mathbf{J}}} \mathbf{w}_{\mathbf{J}} + \hat{\Sigma}_{X_i \varepsilon} - \hat{\Sigma}_{X_i X_{\mathbf{J}}} \hat{\Sigma}_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \hat{\Sigma}_{X_{\mathbf{J}} \varepsilon} \\
&= \hat{\Sigma}_{X_i \varepsilon} - \hat{\Sigma}_{X_i X_{\mathbf{J}}} \hat{\Sigma}_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \hat{\Sigma}_{X_{\mathbf{J}} \varepsilon} \\
&= \hat{\Sigma}_{X_i \varepsilon} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \hat{\Sigma}_{X_{\mathbf{J}} \varepsilon} + o_p(n^{-1/2}) \\
&= \frac{1}{n} \sum_{k=1}^n (\varepsilon_k - \bar{\varepsilon}) \left(x_{ki} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} x_{k\mathbf{J}} \right) + o_p(n^{-1/2}) = C_n + o_p(n^{-1/2}).
\end{aligned}$$

The random variable C_n is a is a U-statistic with square integrable kernel obtained from i.i.d. random vectors; it is thus asymptotically normal (Van der Vaart, 1998). We thus simply need to compute the mean and the variance of C_n. We have $\mathbb{E}C_n = 0$ because $\mathbb{E}(X\varepsilon) = \Sigma_{X\varepsilon} = 0$. We denote $D_k = x_{ki} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} x_{k\mathbf{J}} - \frac{1}{n}\sum_{k=1}^n x_{ki} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} x_{k\mathbf{J}}$. We have:

$$\begin{aligned}
\operatorname{var}(C_n) &= \mathbb{E}C_n^2 = \mathbb{E}(\mathbb{E}(C_n^2 | \bar{X})) \\
&= \mathbb{E}\left[\frac{1}{n^2} \sum_{k=1}^n E(\varepsilon_k^2 | \bar{X}) D_k D_k^\top \right] \\
&\succcurlyeq \mathbb{E}\left[\frac{1}{n^2} \sum_{k=1}^n \sigma_{\min}^2 D_k D_k^\top \right] \\
&= \frac{1}{n} \sigma_{\min}^2 \mathbb{E}\left(\hat{\Sigma}_{X_i X_i} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \hat{\Sigma}_{X_{\mathbf{J}} X_i} \right) \\
&= \frac{n-1}{n^2} \sigma_{\min}^2 \left(\Sigma_{X_i X_i} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \Sigma_{X_{\mathbf{J}} X_i} \right),
\end{aligned}$$

where $M \succcurlyeq N$ denotes the partial order between symmetric matrices (i.e., equivalent to $M - N$ positive semidefinite).

Thus $n^{1/2} C_n$ is asymptotically normal with mean 0 and covariance matrix larger than

$$\sigma_{\min}^2 \Sigma_{X_i | X_{\mathbf{J}}} = \sigma_{\min}^2 \times (\Sigma_{X_i X_i} - \Sigma_{X_i X_{\mathbf{J}}} \Sigma_{X_{\mathbf{J}} X_{\mathbf{J}}}^{-1} \Sigma_{X_{\mathbf{J}} X_i})$$

which is positive definite (because this is the conditional covariance of X_i given $X_{\mathbf{J}}$ and Σ_{XX} is assumed invertible). Therefore $\mathbb{P}(n^{1/2} v^\top A_n > 0)$ converges to a constant $a \in (0,1)$, which implies that $\mathbb{P}\left\{ \frac{v}{\|v\|}^\top (A_n + B_n)/\lambda_n \geqslant (d_i + \|v\|)/2 \right\}$ is asymptotically bounded below by a. Thus, since $\|(A_n + B_n)/\lambda_n\| \geqslant \frac{v}{\|v\|}^\top (A_n + B_n)/\lambda_n \geqslant (d_i + \|v\|)/2 > d_i$ implies that $\hat{w}$ is not optimal, we get a contradiction, which concludes the proof.

B.3 Proof of Theorem 4

We first prove the following refinement of Lemma 20:

Lemma 21 *Assume (***A1-3***). Let $\tilde{w}_{\mathbf{J}}$ any minimizer of*

$$\frac{1}{2n}\|\bar{Y}-\bar{X}_{\mathbf{J}}w_{\mathbf{J}}\|^2+\lambda_n\sum_{j\in\mathbf{J}}d_j\|w_j\| = \frac{1}{2}\hat{\Sigma}_{YY}-\hat{\Sigma}_{YX_{\mathbf{J}}}w_{\mathbf{J}}+\frac{1}{2}w_{\mathbf{J}}^\top\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}w_{\mathbf{J}}+\lambda_n\sum_{j\in\mathbf{J}}d_j\|w_j\|.$$

If $\lambda_n\to 0$ and $\lambda_n n^{1/2}\to\infty$, then $\frac{1}{\lambda_n}(\tilde{w}_{\mathbf{J}}-\mathbf{w}_{\mathbf{J}})$ converges in probability to

$$\Delta = -\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_{\mathbf{J}}.$$

Proof We follow Fu and Knight (2000) and write $\tilde{w}_{\mathbf{J}}=\mathbf{w}_{\mathbf{J}}+\lambda_n\tilde{\Delta}$. The vector $\tilde{\Delta}$ is the minimizer of the following function:

$$\begin{aligned}
F(\Delta) &= -\hat{\Sigma}_{YX_{\mathbf{J}}}(\mathbf{w}_{\mathbf{J}}+\lambda_n\Delta)+\frac{1}{2}(\mathbf{w}_{\mathbf{J}}+\lambda_n\Delta)^\top\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}(\mathbf{w}_{\mathbf{J}}+\lambda_n\Delta)+\lambda_n\sum_{j\in\mathbf{J}}d_j\|\mathbf{w}_j+\lambda_n\Delta_j\| \\
&= -\lambda_n\hat{\Sigma}_{YX_{\mathbf{J}}}\Delta+\frac{\lambda_n^2}{2}\Delta^\top\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\Delta+\lambda_n\mathbf{w}_{\mathbf{J}}^\top\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\Delta \\
&\qquad\qquad +\lambda_n\sum_{j\in\mathbf{J}}d_j\left(\|\mathbf{w}_j+\lambda_n\Delta_j\|-\|\mathbf{w}_j\|\right)+\text{ cst} \\
&= -\lambda_n\hat{\Sigma}_{\varepsilon X_{\mathbf{J}}}\Delta+\frac{\lambda_n^2}{2}\Delta^\top\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\Delta+\lambda_n\sum_{j\in\mathbf{J}}d_j\left(\|\mathbf{w}_j+\lambda_n\Delta_j\|-\|\mathbf{w}_j\|\right)+\text{ cst},
\end{aligned}$$

by using $\hat{\Sigma}_{YX_{\mathbf{J}}}=\mathbf{w}_{\mathbf{J}}^\top\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}+\hat{\Sigma}_{\varepsilon X_{\mathbf{J}}}$. The first term is $O_p(n^{-1/2}\lambda_n)=o_p(\lambda_n^2)$, while the last ones are equal to $\|\mathbf{w}_j+\lambda_n\Delta_j\|-\|\mathbf{w}_j\|=\lambda_n\left(\frac{\mathbf{w}_j}{\|\mathbf{w}_j\|}\right)^\top\Delta_j+o_p(\lambda_n)$. Thus,

$$F(\Delta)/\lambda_n^2=\frac{1}{2}\Delta^\top\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}\Delta+\sum_{j\in\mathbf{J}}\frac{d_j\mathbf{w}_j}{\|\mathbf{w}_j\|}^\top\Delta_j+o_p(1).$$

By Lemma 20, $\hat{w}_{\mathbf{J}}$ is $O_p(1)$ and the limiting function has an unique minimum; standard results in M-estimation (Van der Vaart, 1998) shows that $\tilde{\Delta}$ converges in probability to the minimum of the last expression which is exactly $\Delta=-\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_{\mathbf{J}}$. ■

We now turn to the proof of Theorem 4. We follow the proof of Theorem 2. Given $\tilde{w}$ defined through Lemma 20 and 21, we need to satisfy optimality condition (2) for all $i\in\mathbf{J}^c$, with probability tending to one. For all those i such that $\frac{1}{d_i}\left\|\Sigma_{X_iX_{\mathbf{J}}}\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_{\mathbf{J}}\right\|<1$, then we know from Appendix B.1, that the optimality condition is indeed satisfied with probability tending to one. We now focus on those i such that $\frac{1}{d_i}\left\|\Sigma_{X_iX_{\mathbf{J}}}\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_{\mathbf{J}}\right\|=1$, and for which we have the condition in Eq. (6). From Eq. (23) and the few arguments that follow, we get that for all $i\in\mathbf{J}^c$,

$$\hat{\Sigma}_{X_iY}-\hat{\Sigma}_{X_iX_{\mathbf{J}}}\tilde{w}_{\mathbf{J}}=\lambda_n\Sigma_{X_iX_{\mathbf{J}}}\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}^{-1}\operatorname{Diag}(d_j/\|\tilde{w}_j\|)\tilde{w}_{\mathbf{J}}+O_p(n^{-1/2}) \tag{24}$$

Moreover, we have from Lemma 21 and standard differential calculus, that is, the gradient and the Hessian of the function $v \in \mathbb{R}^q \mapsto \|v\| \in \mathbb{R}$ are $v/\|v\|$ and $\frac{1}{\|v\|}\left(I_q - \frac{vv^\top}{v^\top v}\right)$:

$$\frac{\tilde{w}_j}{\|\tilde{w}_j\|} = \frac{\mathbf{w}_j}{\|\mathbf{w}_j\|} + \frac{\lambda_n}{\|\mathbf{w}_j\|}\left(I_{p_j} - \frac{\mathbf{w}_j\mathbf{w}_j^\top}{\mathbf{w}_j^\top\mathbf{w}_j}\right)\Delta_j + o_p(\lambda_n). \tag{25}$$

From Eq. (24) and Eq. (25), we get:

$$\begin{aligned}
\frac{1}{\lambda_n}(\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\tilde{w}_\mathbf{J}) &= O_p(n^{-1/2}\lambda_n^{-1}) + \Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1} \\
&\left\{\mathrm{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J} + \lambda_n\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}\left[d_j/\|\mathbf{w}_j\|\left(I_{p_j} - \frac{\mathbf{w}_j\mathbf{w}_j^\top}{\mathbf{w}_j^\top\mathbf{w}_j}\right)\right]\Delta + o_p(\lambda_n)\right\} \\
&= A + \lambda_n B + o_p(\lambda_n) + O_p(n^{-1/2}\lambda_n^{-1}).
\end{aligned}$$

Since $\lambda_n \gg n^{-1/4}$, we have $O_p(n^{-1/2}\lambda_n^{-1}) = o_p(\lambda_n)$. Thus, since we assumed that $\|A\| = \|\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J}\| = d_i$, we have:

$$\begin{aligned}
\left\|\frac{1}{\lambda_n}(\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\tilde{w}_\mathbf{J})\right\|^2 &= \|A\|^2 + 2\lambda_n A^\top B + o_p(\lambda_n)d_i^2 + o_p(\lambda_n) \\
&= d_i^2 + o_p(\lambda_n) \\
&\quad -2\lambda_n\Delta^\top\Sigma_{X_\mathbf{J}X_i}\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}\left(d_j/\|\mathbf{w}_j\|(I_{p_j} - \frac{\mathbf{w}_j\mathbf{w}_j^\top}{\mathbf{w}_j^\top\mathbf{w}_j})\right)\Delta,
\end{aligned}$$

(note that we have $A = -\Sigma_{X_iX_\mathbf{J}}\Delta$) which is asymptotically strictly smaller than d_i^2 if Eq. (6) is satisfied, which proves optimality and concludes the proof.

B.4 Proof of Proposition 6

As in the proof of Theorem 2 in Appendix B.1, we consider the estimate $\tilde{w}$ built from the reduced problem by constraining $\tilde{w}_{\mathbf{J}^c} = 0$. We consider the following event:

$$E_1 = \{\hat{\Sigma}_{XX} \text{ invertible and } \forall j \in \mathbf{J},\ \tilde{w}_j \neq 0\}.$$

This event has a probability converging to one. Moreover, if E_1 is true, then the group Lasso estimate has the correct sparsity pattern if and only if for all $i \in \mathbf{J}^c$,

$$\left\|\hat{\Sigma}_{X_iX_\mathbf{J}}(\tilde{w}_\mathbf{J} - \mathbf{w}_\mathbf{J}) - \hat{\Sigma}_{X_i\varepsilon}\right\| \leqslant \lambda_n d_i = \lambda_0 n^{-1/2} d_i.$$

Moreover we have by definition of $\tilde{w}_\mathbf{J}$: $\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}}(\tilde{w}_\mathbf{J} - \mathbf{w}_\mathbf{J}) - \hat{\Sigma}_{X_\mathbf{J}\varepsilon} = -\lambda_n\mathrm{Diag}(d_j/\|\tilde{w}_j\|)\tilde{w}_\mathbf{J}$, and thus, we get:

$$\begin{aligned}
&\hat{\Sigma}_{X_iX_\mathbf{J}}(\tilde{w}_\mathbf{J} - \mathbf{w}_\mathbf{J}) - \hat{\Sigma}_{X_i\varepsilon} \\
=\ &\hat{\Sigma}_{X_iX_\mathbf{J}}\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}}^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon} - \hat{\Sigma}_{X_i\varepsilon} - \lambda_0 n^{-1/2}\hat{\Sigma}_{X_iX_\mathbf{J}}\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}(d_j/\|\tilde{w}_j\|)\tilde{w}_\mathbf{J} \\
=\ &\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon} - \hat{\Sigma}_{X_i\varepsilon} - \lambda_0 n^{-1/2}\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J} + O_p(n^{-1})
\end{aligned}$$

The random vector $\Sigma_{X\varepsilon} \in \mathbb{R}^p$ is a multivariate U-statistic with square integrable kernel obtained from i.i.d. random vectors; it is thus asymptotically normal (Van der Vaart, 1998) and we simply need to compute its mean and variance. The mean is zero, and the variance is $\frac{n-1}{n^2}\sigma^2\Sigma_{XX} = n^{-1}\sigma^2\Sigma_{XX} + o(n^{-1})$. This implies that the random vector s of size $\mathrm{Card}(\mathbf{J}^c)$ defined by

$$s_i = n^{1/2}\|\hat{\Sigma}_{X_iX_\mathbf{J}}(\tilde{w}_\mathbf{J} - \mathbf{w}_\mathbf{J}) - \hat{\Sigma}_{X_i\varepsilon}\|,$$

is equal to

$$\begin{aligned} s_i &= \left\|\sigma\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}u_\mathbf{J} - \sigma u_i - \lambda_0\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J}\right\| + O_p(n^{-1/2}) \\ &= f_i(u) + O_p(n^{-1/2}), \end{aligned}$$

where $u = \sigma^{-1}n^{-1/2}\hat{\Sigma}_{X\varepsilon}$ and f_i are deterministic continuous functions. The vector $f(u)$ converges in distribution to $f(v)$ where v is normally distributed with mean zero and covariance matrix Σ_{XX}. By Slutsky's lemma (Van der Vaart, 1998), this implies that the random vector s has the same limiting distribution. Thus, the probability $\mathbb{P}(\max_{i\in\mathbf{J}^c} s_i/d_i \leqslant \lambda_0)$ converges to

$$\mathbb{P}\left(\max_{i\in\mathbf{J}^c}\frac{1}{d_i}\left\|\sigma(\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}v_\mathbf{J} - v_i) - \lambda_0\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J}\right\| \leqslant \lambda_0\right).$$

Under the event E_1 which has probability tending to one, we have correct pattern selection if and only if $\max_{i\in\mathbf{J}^c} s_i/d_i \leqslant \lambda_0$, which leads to

$$\mathbb{P}\left(\max_{i\in\mathbf{J}^c}\frac{1}{d_i}\left\|\sigma t_i - \lambda_0\Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}\mathrm{Diag}(d_j/\|\mathbf{w}_j\|)\mathbf{w}_\mathbf{J}\right\| \leqslant \lambda_0\right),$$

where $t_i = \Sigma_{X_iX_\mathbf{J}}\Sigma_{X_\mathbf{J}X_\mathbf{J}}^{-1}v_\mathbf{J} - v_i$. The vector t is normally distributed and a short calculation shows that its covariance matrix is equal to $\Sigma_{X_{\mathbf{J}^c}X_{\mathbf{J}^c}|X_\mathbf{J}}$, which concludes the proof.

Appendix C. Detailed Proofs for the Nonparametric Formulation

We first prove lemmas that will be useful for further proofs, and then prove the consistency results for the nonparametric case.

C.1 Useful Lemmas on Empirical Covariance Operators

We first have the following lemma, proved by Fukumizu et al. (2007), which states that the empirical covariance estimator converges in probability at rate $O_p(n^{-1/2})$ to the population covariance operators:

Lemma 22 *Assume (**A4**) and (**A6**). Then $\|\hat{\Sigma}_{XX} - \Sigma_{XX}\|_\mathcal{F} = O_p(n^{-1/2})$ (for the operator norm), $\|\hat{\Sigma}_{XY} - \Sigma_{XY}\|_\mathcal{F} = O_p(n^{-1/2})$ and $\|\hat{\Sigma}_{X\varepsilon}\|_\mathcal{F} = O_p(n^{-1/2})$.*

The following lemma is useful in several proofs:

Lemma 23 *Assume (**A4**). Then $\left\|\left(\hat{\Sigma}_{XX} + \mu_n I\right)^{-1}\Sigma_{XX} - \left(\Sigma_{XX} + \mu_n I\right)^{-1}\Sigma_{XX}\right\|_\mathcal{F} = O_p(\frac{\mu_n^{-1}}{n^{1/2}})$, and $\left\|\left(\hat{\Sigma}_{XX} + \mu_n I\right)^{-1}\hat{\Sigma}_{XX} - \left(\Sigma_{XX} + \mu_n I\right)^{-1}\Sigma_{XX}\right\|_\mathcal{F} = O_p(\frac{\mu_n^{-1}}{n^{1/2}})$.*

Proof We have:

$$\begin{aligned} & \left(\hat{\Sigma}_{XX}+\mu_n I\right)^{-1}\Sigma_{XX}-(\Sigma_{XX}+\mu_n I)^{-1}\Sigma_{XX} \\ = \quad & \left(\hat{\Sigma}_{XX}+\mu_n I\right)^{-1}(\Sigma_{XX}-\hat{\Sigma}_{XX})(\Sigma_{XX}+\mu_n I)^{-1}\Sigma_{XX}. \end{aligned}$$

This is the product of operators whose norms are respectively upper bounded by μ_n^{-1}, $O_p(n^{-1/2})$ and 1, which leads to the first inequality (we use $\|AB\|_{\mathcal{F}} \leqslant \|A\|_{\mathcal{F}}\|B\|_{\mathcal{F}}$). The second inequality follows along similar lines. ■

Note that the two previous lemma also hold for any suboperator of Σ_{XX}, that is, for $\Sigma_{X_\mathbf{J}X_\mathbf{J}}$, or $\Sigma_{X_iX_i}$.

Lemma 24 *Assume (**A4**), (**A5**) and (**A7**). There exists $\mathbf{h}_\mathbf{J} \in \mathcal{F}_\mathbf{J}$ such that $\mathbf{f}_\mathbf{J} = \Sigma^{1/2}_{X_\mathbf{J}X_\mathbf{J}}\mathbf{h}_\mathbf{J}$.*

Proof The range condition implies that

$$\mathbf{f}_\mathbf{J} \quad = \quad \mathrm{Diag}(\Sigma^{1/2}_{X_jX_j})\mathbf{g}_\mathbf{J} = \mathrm{Diag}(\Sigma^{1/2}_{X_jX_j})C^{1/2}_{X_\mathbf{J}X_\mathbf{J}}C^{-1/2}_{X_\mathbf{J}X_\mathbf{J}}\mathbf{g}_\mathbf{J}$$

(because C_{XX} is invertible). The result follows from the identity

$$\Sigma_{X_\mathbf{J}X_\mathbf{J}} = \mathrm{Diag}(\Sigma^{1/2}_{X_jX_j})C^{1/2}_{X_\mathbf{J}X_\mathbf{J}}(\mathrm{Diag}(\Sigma^{1/2}_{X_jX_j})C^{1/2}_{X_\mathbf{J}X_\mathbf{J}})^*$$

and the fact that if $\Sigma_{X_\mathbf{J}X_\mathbf{J}} = UU^*$ and $f = U\alpha$ then there exists β such that $f = \Sigma^{1/2}_{X_\mathbf{J}X_\mathbf{J}}\beta$ (Baker, 1973).[5] ■

C.2 Proof of Theorem 11

We now extend Lemma 20 to covariance operators, which requires to use the alternative formulation and a slower rate of decrease for the regularization parameter:

Lemma 25 *Let $\tilde{f}_\mathbf{J}$ be any minimizer of*

$$\frac{1}{2}\hat{\Sigma}_{YY} - \langle \hat{\Sigma}_{X_\mathbf{J}Y}, f_\mathbf{J}\rangle_{\mathcal{F}_\mathbf{J}} + \frac{1}{2}\langle f_\mathbf{J}, \hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} f_\mathbf{J}\rangle_{\mathcal{F}_\mathbf{J}} + \frac{\mu_n}{2}\left(\sum_{j\in\mathbf{J}} d_j \|f_j\|_{\mathcal{F}_j}\right)^2.$$

If $\mu_n \to 0$ and $\mu_n n^{1/2} \to +\infty$, then $\|\tilde{f}_\mathbf{J} - \mathbf{f}_\mathbf{J}\|_{\mathcal{F}_\mathbf{J}}$ converges to zero in probability. Moreover for any η_n such that $\eta_n \gg \mu_n^{1/2} + \mu_n^{-1}n^{-1/2}$ then $\|\tilde{f}_\mathbf{J} - \mathbf{f}_\mathbf{J}\|_{\mathcal{F}_\mathbf{J}} = O_p(\eta_n)$.

Proof Note that from Cauchy-Schwarz inequality, we have:

$$\begin{aligned} \left(\sum_{j\in\mathbf{J}} d_j\|f_j\|_{\mathcal{F}_j}\right)^2 \quad &= \quad \left(\sum_{j\in\mathbf{J}} d_j^{1/2}\|\mathbf{f}_j\|_{\mathcal{F}_j}^{1/2} \times \frac{d_j^{1/2}\|f_j\|_{\mathcal{F}_j}}{\|\mathbf{f}_j\|_{\mathcal{F}_j}^{1/2}}\right)^2 \\ &\leqslant \quad \left(\sum_{j\in\mathbf{J}} d_j\|\mathbf{f}_j\|_{\mathcal{F}_j}\right)\sum_{j\in\mathbf{J}}\frac{d_j\|f_j\|_{\mathcal{F}_j}^2}{\|\mathbf{f}_j\|_{\mathcal{F}_j}}, \end{aligned}$$

5. The adjoint operator V^* of $V : \mathcal{F}_i \to \mathcal{F}_\mathbf{J}$ is so that for all $f \in \mathcal{F}_i$ and $g \in \mathcal{F}_\mathbf{J}$, $\langle f, Vg\rangle_{\mathcal{F}_i} = \langle V^*f, g\rangle_{\mathcal{F}_\mathbf{J}}$ (Brezis, 1980).

with equality if and only if there exists $\alpha > 0$ such that $\|f_j\|_{\mathcal{F}_j} = \alpha \|\mathbf{f}_j\|_{\mathcal{F}_j}$ for all $j \in \mathbf{J}$. We consider the unique minimizer $\bar{f}_{\mathbf{J}}$ of the following cost function, built by replacing the regularization by its upperbound,

$$F(f_{\mathbf{J}}) = \frac{1}{2}\hat{\Sigma}_{YY} - \langle \hat{\Sigma}_{X_{\mathbf{J}}Y}, f_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} + \frac{1}{2}\langle f_{\mathbf{J}}, \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} f_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} + \frac{\mu_n}{2}\left(\sum_{j \in \mathbf{J}} d_j \|\mathbf{f}_j\|_{\mathcal{F}_j} \right) \sum_{j \in \mathbf{J}} \frac{d_j \|f_j\|^2_{\mathcal{F}_j}}{\|\mathbf{f}_j\|_{\mathcal{F}_j}}.$$

Since it is a regularized least-square problem, we have (with $\varepsilon = Y - \sum_{j \in \mathbf{J}} \mathbf{f}_j(X) - \mathbf{b}$):

$$\bar{f}_{\mathbf{J}} = \left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} \mathbf{f}_{\mathbf{J}} + \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon} \right),$$

where $D = \left(\sum_{j \in \mathbf{J}} d_j \|\mathbf{f}_j\| \right) \mathrm{Diag}(d_j / \|\mathbf{f}_j\|)$. Note that D is upperbounded and lowerbounded, as an auto-adjoint operator, by *strictly positive* constants times the identity operator (with probability tending to one), that is, $D_{\max} I_{\mathcal{F}_{\mathbf{J}}} \succcurlyeq D \succcurlyeq D_{\min} I_{\mathcal{F}_{\mathbf{J}}}$ with $D_{\min}, D_{\max} > 0$. We now prove that $\bar{f}_{\mathbf{J}} - \mathbf{f}_{\mathbf{J}}$ is converging to zero in probability. We have:

$$\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon} = O_p(n^{-1/2}\mu_n^{-1}),$$

because of Lemma 22 and $\left\| \left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \right\|_{\mathcal{F}_{\mathbf{J}}} \leqslant D_{\min}^{-1} \mu_n^{-1}$. Moreover, similarly, we have

$$\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} f_{\mathbf{J}} - \left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} \mathbf{f}_{\mathbf{J}} = O_p(n^{-1/2}\mu_n^{-1}).$$

Besides, by Lemma 23,

$$\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} f_{\mathbf{J}} - \left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} f_{\mathbf{J}} = O_p(n^{-1/2}\mu_n^{-1}).$$

Thus $\bar{f}_{\mathbf{J}} - \mathbf{f}_{\mathbf{J}} = V + O_p(n^{-1/2}\mu_n^{-1})$, where

$$V = \left[\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} - I \right] \mathbf{f}_{\mathbf{J}} = -\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-1} \mu_n D \mathbf{f}_{\mathbf{J}}.$$

We have

$$\begin{aligned}
\|V\|^2_{\mathcal{F}_{\mathbf{J}}} &= \mu_n^2 \langle \mathbf{f}_{\mathbf{J}}, D\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D \right)^{-2} D \mathbf{f}_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} \\
&\leqslant D_{\max}^2 \mu_n^2 \langle \mathbf{f}_{\mathbf{J}}, \left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_{\min} I \right)^{-2} \mathbf{f}_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} \\
&\leqslant D_{\max}^2 \mu_n \langle \mathbf{f}_{\mathbf{J}}, \left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_{\min} I \right)^{-1} \mathbf{f}_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} \\
&\leqslant D_{\max}^2 \mu_n \langle \mathbf{h}_{\mathbf{J}}, \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} \left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_{\min} I \right)^{-1} \mathbf{h}_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} \text{ by Lemma 24,} \\
&\leqslant D_{\max}^2 \mu_n \|\mathbf{h}_{\mathbf{J}}\|^2_{\mathcal{F}_{\mathbf{J}}}.
\end{aligned}$$

Finally we obtain $\|\bar{f}_{\mathbf{J}} - \mathbf{f}_{\mathbf{J}}\|_{\mathcal{F}_{\mathbf{J}}} = O_p(\mu_n^{1/2} + n^{-1/2}\mu_n^{-1})$.

We now consider the cost function defining $\tilde{f}_{\mathbf{J}}$:

$$F_n(f_{\mathbf{J}}) = \frac{1}{2}\hat{\Sigma}_{YY} - \langle \hat{\Sigma}_{X_{\mathbf{J}}Y}, f_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} + \frac{1}{2}\langle f_{\mathbf{J}}, \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} f_{\mathbf{J}} \rangle_{\mathcal{F}_{\mathbf{J}}} + \frac{\mu_n}{2}\left(\sum_{j \in \mathbf{J}} d_j \|f_j\|_{\mathcal{F}_j} \right)^2.$$

We have (note that although we seem to take infinite dimensional derivatives, everything can be done in the finite subspace spanned by the data):

$$\begin{aligned} F_n(f_{\mathbf{J}}) - F(f_{\mathbf{J}}) &= \frac{\mu_n}{2}\left[\left(\sum_{j\in\mathbf{J}} d_j \|f_j\|_{\mathcal{F}_j}\right)^2 - \left(\sum_{j\in\mathbf{J}} d_j \|\mathbf{f}_j\|_{\mathcal{F}_j}\right)\sum_{j\in\mathbf{J}} \frac{d_j\|f_j\|_{\mathcal{F}_j}^2}{\|\mathbf{f}_j\|_{\mathcal{F}_j}}\right], \\ \nabla_{f_i} F_n(f_{\mathbf{J}}) - \nabla_{f_i} F(f_{\mathbf{J}}) &= \mu_n\left[\left(\sum_{j\in\mathbf{J}} d_j \|f_j\|_{\mathcal{F}_j}\right)\frac{d_i f_i}{\|f_i\|_{\mathcal{F}_j}} - \left(\sum_{j\in\mathbf{J}} d_j \|\mathbf{f}_j\|_{\mathcal{F}_j}\right)\frac{d_i f_i}{\|\mathbf{f}_i\|_{\mathcal{F}_j}}\right]. \end{aligned}$$

Since the right hand side of the previous equation corresponds to a continuously differentiable function of $f_{\mathbf{J}}$ around $\mathbf{f}_{\mathbf{J}}$ (with upper-bounded derivatives around $\mathbf{f}_{\mathbf{J}}$), we have:

$$\|\nabla_{f_i} F_n(\bar{f}_{\mathbf{J}}) - 0\|_{\mathcal{F}_i} \leqslant C\mu_n \|\mathbf{f}_{\mathbf{J}} - \bar{f}_{\mathbf{J}}\|_{\mathcal{F}_{\mathbf{J}}} = \mu_n O_p(\mu_n^{1/2} + n^{-1/2}\mu_n^{-1}).$$

for some constant $C > 0$. Moreover, on the ball of center $\bar{f}_{\mathbf{J}}$ and radius η_n such that $\eta_n \gg \mu_n^{1/2} + \mu_n^{-1}n^{-1/2}$ (to make sure that it asymptotically contains $\mathbf{f}_{\mathbf{J}}$, which implies that on the ball each f_j, $j \in \mathbf{J}$ are bounded away from zero), and $\eta_n \ll 1$ (so that we get consistency), we have a lower bound on the second derivative of $\left(\sum_{j\in\mathbf{J}} d_j \|f_j\|_{\mathcal{F}_j}\right)$. Thus for any element of the ball,

$$F_n(f_{\mathbf{J}}) \geqslant F_n(\bar{f}_{\mathbf{J}}) + \langle \nabla_{f_{\mathbf{J}}} F_n(\bar{f}_{\mathbf{J}}), (f_{\mathbf{J}} - \bar{f}_{\mathbf{J}})\rangle_{\mathcal{F}_{\mathbf{J}}} + C'\mu_n \|f_{\mathbf{J}} - \bar{f}_{\mathbf{J}}\|_{\mathcal{F}_{\mathbf{J}}}^2,$$

where $C' > 0$ is a constant. This implies that the value of $F_n(f_{\mathbf{J}})$ on the edge of the ball is larger than

$$F_n(\bar{f}_{\mathbf{J}}) + \eta_n\mu_n O_p(\mu_n^{1/2} + n^{-1/2}\mu_n^{-1}) + C'\eta_n^2\mu_n,$$

Thus if $\eta_n^2\mu_n \gg \eta_n\mu_n^{3/2}$ and $\eta_n^2\mu_n \gg n^{-1/2}\eta_n$, then we must have all minima inside the ball of radius η_n (because with probability tending to one, the value on the edge is greater than one value inside and the function is convex) which implies that the global minimum of F_n is at most η_n away from $\bar{f}_{\mathbf{J}}$ and thus since $\bar{f}_{\mathbf{J}}$ is $O(\mu_n^{1/2})$ away from $\mathbf{f}_{\mathbf{J}}$, we have the consistency if

$$\eta_n \ll 1 \text{ and } \eta_n \gg \mu_n^{1/2} + n^{-1/2}\mu_n^{-1},$$

which concludes the proof of the lemma. ■

We now prove Theorem 11. Let $\tilde{f}_{\mathbf{J}}$ be defined as in Lemma 20. We extend it by zeros on $\mathbf{J}^c$. We already know the squared norm consistency by Lemma 20. Since by Proposition 14, the solution is unique with probability tending to one, we need to prove that with probability tending to one $\tilde{f}$ is optimal for problem in Eq. (13). We have by the first optimality condition for $\tilde{f}_{\mathbf{J}}$:

$$\hat{\Sigma}_{X_{\mathbf{J}}Y} - \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\tilde{f}_{\mathbf{J}} = \mu_n \|\tilde{f}\|_d \operatorname{Diag}(d_j/\|\tilde{f}_j\|)\tilde{f}_{\mathbf{J}},$$

where we use the notation $\|f\|_d = \sum_{j=1}^m d_j\|f_j\|_{\mathcal{F}_j}$ (note the difference with the norm $\|f\|_{\mathcal{F}} = (\sum_{j=1}^m \|f_j\|_{\mathcal{F}_j}^2)^{1/2}$). We thus have by solving for $\tilde{f}_{\mathbf{J}}$ and using $\hat{\Sigma}_{X_{\mathbf{J}}Y} = \hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\mathbf{f}_{\mathbf{J}} + \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}$:

$$\tilde{f}_{\mathbf{J}} = \left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\mathbf{f}_{\mathbf{J}} + \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}\right),$$

with the notation $D_n = \|\tilde{f}\|_d \operatorname{Diag}(d_j/\|\tilde{f}_j\|_{\mathcal{F}_j})$. We can now put that back into $\hat{\Sigma}_{X_{\mathbf{J}^c}Y} - \hat{\Sigma}_{X_{\mathbf{J}^c}X_{\mathbf{J}}}\tilde{f}_{\mathbf{J}}$ and show that this will have small enough norm with probability tending to one. We have for all $i \in \mathbf{J}^c$:

$$\begin{aligned}
\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\tilde{f}_{\mathbf{J}} &= \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\mathbf{f}_{\mathbf{J}} + \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}\right) \\
&= -\hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}\mathbf{f}_{\mathbf{J}} \\
&\quad + \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\hat{\Sigma}_{X_{\mathbf{J}}\varepsilon} \\
&= -\hat{\Sigma}_{X_iX_{\mathbf{J}}}\mathbf{f}_{\mathbf{J}} + \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\mu_n D_n\mathbf{f}_{\mathbf{J}} \\
&\quad + \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\hat{\Sigma}_{X_{\mathbf{J}}\varepsilon} \\
&= \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\mu_n D_n\mathbf{f}_{\mathbf{J}} \\
&\quad + \hat{\Sigma}_{X_i\varepsilon} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1}\hat{\Sigma}_{X_{\mathbf{J}}\varepsilon} \qquad (26) \\
&= A_n + B_n.
\end{aligned}$$

The first term A_n (divided by μ_n) is equal to

$$\frac{A_n}{\mu_n} = \hat{\Sigma}_{X_iX_{\mathbf{J}}}\left(\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1} D_n\mathbf{f}_{\mathbf{J}}.$$

We can replace $\hat{\Sigma}_{X_iX_{\mathbf{J}}}$ in $\frac{A_n}{\mu_n}$ by $\Sigma_{X_iX_{\mathbf{J}}}$ at cost $O_p(n^{-1/2}\mu_n^{-1/2})$ because $\langle \mathbf{f}_{\mathbf{J}}, \Sigma^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}}\mathbf{f}_{\mathbf{J}}\rangle_{\mathcal{F}_{\mathbf{J}}} < \infty$ (by Lemma 24). Also, we can replace $\hat{\Sigma}_{X_{\mathbf{J}}X_{\mathbf{J}}}$ in $\frac{A_n}{\mu_n}$ by $\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}$ at cost $O_p(n^{-1/2}\mu_n^{-1})$ as a consequence of Lemma 23. Those two are $o_p(1)$ by assumptions on μ_n. Thus,

$$\frac{A_n}{\mu_n} = \Sigma_{X_iX_{\mathbf{J}}}\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D_n\right)^{-1} D_n\mathbf{f}_{\mathbf{J}} + o_p(1).$$

Furthermore, we denote $D = \|\mathbf{f}\|_d \operatorname{Diag}(d_j/\|\mathbf{f}_j\|_{\mathcal{F}_j})$. From Lemma 25, we know that $D_n - D = o_p(1)$. Thus we can replace D_n by D at cost $o_p(1)$ to get:

$$\frac{A_n}{\mu_n} = \Sigma_{X_iX_{\mathbf{J}}}\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D\right)^{-1} D\mathbf{f}_{\mathbf{J}} + o_p(1) = C_n + o_p(1).$$

We now show that this last deterministic term $C_n \in \mathcal{F}_i$ converges to:

$$C = \Sigma^{1/2}_{X_iX_i} C_{X_iX_{\mathbf{J}}} C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} D\mathbf{g}_{\mathbf{J}},$$

where, from (**A7**), $\forall j \in \mathbf{J}$, $\mathbf{f}_j = \Sigma^{1/2}_{X_jX_j}\mathbf{g}_j$. We have

$$\begin{aligned}
C_n - C &= \Sigma^{1/2}_{X_iX_i} C_{X_iX_{\mathbf{J}}}\left[\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j})\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D\right)^{-1}\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) - C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}}\right] D\mathbf{g}_{\mathbf{J}} \\
&= \Sigma^{1/2}_{X_iX_i} C_{X_iX_{\mathbf{J}}} K_n D\mathbf{g}_{\mathbf{J}}.
\end{aligned}$$

where $K_n = \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j})\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D\right)^{-1}\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) - C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}}$. In addition, we have:

$$\begin{aligned}
\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) C_{X_{\mathbf{J}}X_{\mathbf{J}}} K_n &= \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D\right)^{-1}\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) - \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) \\
&= -\mu_n D\left(\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} + \mu_n D\right)^{-1}\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}).
\end{aligned}$$

Following Fukumizu et al. (2007), the range of the adjoint operator $\left(\Sigma_{X_iX_i}^{1/2} C_{X_iX_\mathbf{J}}\right)^* = C_{X_\mathbf{J}X_i}\Sigma_{X_iX_i}^{1/2}$ is included in the closure of the range of $\mathrm{Diag}(\Sigma_{X_jX_j})$ (which is equal to the range of $\Sigma_{X_\mathbf{J}X_\mathbf{J}}$ by Lemma 24). For any $v_\mathbf{J} \in \mathcal{F}_\mathbf{J}$ in the intersection of two ranges, we have $v_\mathbf{J} = C_{X_\mathbf{J}X_\mathbf{J}}\mathrm{Diag}(\Sigma_{X_jX_j}^{1/2})u_\mathbf{J}$ (note that $C_{X_\mathbf{J}X_\mathbf{J}}$ is invertible), and thus

$$\begin{aligned}\langle K_n D\mathbf{g}_\mathbf{J}, v_\mathbf{J}\rangle_{\mathcal{F}_\mathbf{J}} &= \langle K_n D\mathbf{g}_\mathbf{J}, C_{X_\mathbf{J}X_\mathbf{J}}\mathrm{Diag}(\Sigma_{X_jX_j}^{1/2})u_\mathbf{J}\rangle_{\mathcal{F}_\mathbf{J}} \\ &= \langle -\mu_n D\left(\Sigma_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D\right)^{-1}\mathrm{Diag}(\Sigma_{X_jX_j}^{1/2})D\mathbf{g}_\mathbf{J}, u_\mathbf{J}\rangle_{\mathcal{F}_\mathbf{J}}\end{aligned}$$

which is $O_p(\mu_n^{1/2})$ and thus tends to zero. Since this holds for all elements in the intersection of the ranges, Lemma 9 by Fukumizu et al. (2007) implies that $\|C_n - C\|_{\mathcal{F}_\mathbf{J}}$ converges to zero.

We now simply need to show that the second term B_n is dominated by μ_n. We have: $\|\hat{\Sigma}_{X_i\varepsilon}\|_{\mathcal{F}_i} = O_p(n^{-1/2})$ and $\|\hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D_n\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon}\|_{\mathcal{F}_i} \leqslant \|\hat{\Sigma}_{X_i\varepsilon}\|_{\mathcal{F}_i}$, thus, since $\mu_n n^{1/2} \to +\infty$, $B_n = o_p(\mu_n)$ and therefore for for each $i \in J^c$,

$$\frac{1}{d_i\mu_n\|\mathbf{f}\|_d}\left(\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\tilde{f}_\mathbf{J}\right)$$

converges in probability to $\|C\|_{\mathcal{F}_\mathbf{J}}/d_i\|\mathbf{f}\|_d$ which is strictly smaller than one because Eq. (16) is satisfied. Thus

$$\mathbb{P}\left\{\frac{1}{d_i\mu_n\|\mathbf{f}\|_d}\left\|\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\tilde{f}_\mathbf{J}\right\|_{\mathcal{F}_i} \leqslant 1\right\}$$

is tending to 1, which implies the theorem (using the same arguments than in the proof of Theorem 2 in Appendix B.1).

C.3 Proof of Theorem 12

Before proving the analog of the second group Lasso theorem, we need the following additional proposition, which states that consistency of the patterns can only be achieved if $\mu_n n^{1/2} \to \infty$ (even if chosen in a data dependent way).

Proposition 26 *Assume (**A4-7**) and that* $\mathbf{J}$ *is not empty. If* $\hat{f}$ *is converging in probability to* $\mathbf{f}$ *and* $J(\hat{f})$ *converges in probability to* $\mathbf{J}$*, then* $\mu_n n^{1/2} \to \infty$ *in probability.*

Proof We give a proof by contradiction, and we thus assume that there exists $M > 0$ such that $\liminf_{n\to\infty}\mathbb{P}(\mu_n n^{1/2} < M) > 0$. This imposes that there exists a subsequence which is almost surely bounded by M (Durrett, 2004). Thus, we can take a further subsequence which converges to a limit $\mu_0 \in [0,\infty)$. We now consider such a subsequence (and still use the notation of the original sequence for simplicity).

With probability tending to one, we have the optimality condition (15):

$$\hat{\Sigma}_{X_\mathbf{J}\varepsilon} + \hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}}\mathbf{f}_\mathbf{J} = \hat{\Sigma}_{X_\mathbf{J}Y} = \hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}}\hat{f}_\mathbf{J} + \mu_n\|\hat{f}\|_d\,\mathrm{Diag}(d_j/\|\hat{f}_j\|_{\mathcal{F}_j})\hat{f}_\mathbf{J}.$$

If we denote $D_n = n^{1/2}\mu_n\|\hat{f}\|_d\,\mathrm{Diag}(d_j/\|\hat{f}_j\|_{\mathcal{F}_j})$, we get:

$$D_n\mathbf{f}_\mathbf{J} = \left[\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + D_n n^{-1/2}\right]n^{1/2}\left[\mathbf{f}_\mathbf{J} - \hat{f}_\mathbf{J}\right] + n^{1/2}\hat{\Sigma}_{X_\mathbf{J}\varepsilon},$$

which can be approximated as follows (we denote $D = \|\mathbf{f}\|_d \operatorname{Diag}(d_j/\|\mathbf{f}_j\|_{\mathcal{F}_j})$):

$$\mu_0 D\mathbf{f}_{\mathbf{J}} + o_p(1) = \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} n^{1/2}\left[\mathbf{f}_{\mathbf{J}} - \hat{f}_{\mathbf{J}}\right] + o_p(1) + n^{1/2}\hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}.$$

We can now write for $i \in \mathbf{J}^c$:

$$\begin{aligned} n^{1/2}\left(\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\hat{f}_{\mathbf{J}}\right) &= n^{1/2}\hat{\Sigma}_{X_i\varepsilon} + \hat{\Sigma}_{X_iX_{\mathbf{J}}} n^{1/2}(\mathbf{f}_{\mathbf{J}} - \hat{f}_{\mathbf{J}}) \\ &= n^{1/2}\hat{\Sigma}_{X_i\varepsilon} + \Sigma_{X_iX_{\mathbf{J}}} n^{1/2}(\mathbf{f}_{\mathbf{J}} - \hat{f}_{\mathbf{J}}) + o_p(1). \end{aligned}$$

We now consider an arbitrary vector $w_{\mathbf{J}} \in \mathcal{F}_{\mathbf{J}}$, such that $\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} w_{\mathbf{J}}$ is different from zero (such vector exists because $\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} \neq 0$, as we have assumed in (**A4**) that the variables are not constant). Since the range of $\Sigma_{X_{\mathbf{J}}X_i}$ is included in the range of $\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}}$ (Baker, 1973), there exists $v_i \in \mathcal{F}_i$ such that $\Sigma_{X_{\mathbf{J}}X_i} v_i = \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} w_{\mathbf{J}}$. Note that since $\Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} w_{\mathbf{J}}$ is different from zero, we must have $\Sigma^{1/2}_{X_iX_i} v_i \neq 0$. We have:

$$\begin{aligned} n^{1/2}\langle v_i, \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_{\mathbf{J}}}\hat{f}_{\mathbf{J}}\rangle_{\mathcal{F}_i} &= n^{1/2}\langle v_i, \hat{\Sigma}_{X_i\varepsilon}\rangle_{\mathcal{F}_i} + \langle w_{\mathbf{J}}, \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} n^{1/2}(\mathbf{f}_{\mathbf{J}} - \hat{f}_{\mathbf{J}})\rangle_{\mathcal{F}_{\mathbf{J}}} + o_p(1) \\ &= n^{1/2}\langle v_i, \hat{\Sigma}_{X_i\varepsilon}\rangle_{\mathcal{F}_i} + \langle w_{\mathbf{J}}, \mu_0 D f_{\mathbf{J}} - n^{1/2}\hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}\rangle_{\mathcal{F}_{\mathbf{J}}} + o_p(1) \\ &= \langle w_{\mathbf{J}}, \mu_0 D f_{\mathbf{J}}\rangle_{\mathcal{F}_{\mathbf{J}}} + n^{1/2}\langle v_i, \hat{\Sigma}_{X_i\varepsilon}\rangle_{\mathcal{F}_i} - n^{1/2}\langle w_{\mathbf{J}}, \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}\rangle_{\mathcal{F}_{\mathbf{J}}} + o_p(1). \end{aligned}$$

The random variable $E_n = n^{1/2}\langle v_i, \hat{\Sigma}_{X_i\varepsilon}\rangle - n^{1/2}\langle w_{\mathbf{J}}, \hat{\Sigma}_{X_{\mathbf{J}}\varepsilon}\rangle$ is a U-statistic with square integrable kernel obtained from i.i.d. random vectors; it is thus asymptotically normal (Van der Vaart, 1998) and we simply need to compute its mean and variance. The mean is zero and a short calculation similar to the one found in the proof of Theorem 3 in Appendix B.2 shows that we have:

$$\begin{aligned} \mathbb{E}E_n^2 &\geqslant (1-1/n)\sigma^2_{\min}\langle v_i, \Sigma_{X_iX_i} v_i\rangle_{\mathcal{F}_i} + \sigma^2_{\min}\langle w_{\mathbf{J}}, \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} w_{\mathbf{J}}\rangle_{\mathcal{F}_{\mathbf{J}}} - 2\sigma^2_{\min}\langle v_i, \Sigma_{X_iX_{\mathbf{J}}} w_{\mathbf{J}}\rangle_{\mathcal{F}_i} \\ &= (1-1/n)(\sigma^2_{\min}\langle v_i, \Sigma_{X_iX_i} v_i\rangle_{\mathcal{F}_i} - \sigma^2_{\min}\langle v_i, \Sigma_{X_iX_{\mathbf{J}}} w_{\mathbf{J}}\rangle_{\mathcal{F}_i}). \end{aligned}$$

The operator $C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_i}$ has the same range as $C_{X_{\mathbf{J}}X_{\mathbf{J}}}$ (because C_{XX} is invertible), and is thus included in the closure of the range of $\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j})$ (Baker, 1973). Thus, for any $u \in \mathcal{F}_i$, $C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_i} u$ can be expressed as a limit of terms of the form $\operatorname{Diag}(\Sigma^{1/2}_{X_jX_j})t$ where $t \in \mathcal{F}_{\mathbf{J}}$. We thus have that

$$\langle u, C_{X_iX_{\mathbf{J}}} \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) w_{\mathbf{J}}\rangle_{\mathcal{F}_i} = \langle u, C_{X_iX_{\mathbf{J}}} C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_{\mathbf{J}}} \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) w_{\mathbf{J}}\rangle_{\mathcal{F}_i}$$

can be expressed as a limit of terms of the form

$$\begin{aligned} \langle t, \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) C_{X_{\mathbf{J}}X_{\mathbf{J}}} \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) w_{\mathbf{J}}\rangle_{\mathcal{F}_{\mathbf{J}}} &= \langle t, \Sigma_{X_{\mathbf{J}}X_{\mathbf{J}}} w_{\mathbf{J}}\rangle_{\mathcal{F}_{\mathbf{J}}} = \langle t, \Sigma_{X_{\mathbf{J}}X_i} v_i\rangle_{\mathcal{F}_{\mathbf{J}}} \\ &= \langle t, \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) C_{X_{\mathbf{J}}X_i} \Sigma^{1/2}_{X_iX_i} v_i\rangle_{\mathcal{F}_{\mathbf{J}}} \to \langle u, C_{X_iX_{\mathbf{J}}} C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_i} \Sigma^{1/2}_{X_iX_i} v_i\rangle_{\mathcal{F}_i}. \end{aligned}$$

This implies that $C_{X_iX_{\mathbf{J}}} \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) w_{\mathbf{J}} = C_{X_iX_{\mathbf{J}}} C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_i} \Sigma^{1/2}_{X_iX_i} v_i$, and thus we have:

$$\begin{aligned} \mathbb{E}E_n^2 &\geqslant \sigma^2_{\min}\langle v_i, \Sigma_{X_iX_i} v_i\rangle_{\mathcal{F}_i} - \sigma^2_{\min}\langle v_i, \Sigma^{1/2}_{X_iX_i} C_{X_iX_{\mathbf{J}}} \operatorname{Diag}(\Sigma^{1/2}_{X_jX_j}) w_{\mathbf{J}}\rangle_{\mathcal{F}_i} \\ &= \sigma^2_{\min}\langle v_i, \Sigma_{X_iX_i} v_i\rangle_{\mathcal{F}_i} - \sigma^2_{\min}\langle v_i, \Sigma^{1/2}_{X_iX_i} C_{X_iX_{\mathbf{J}}} C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_i} \Sigma^{1/2}_{X_iX_i} v_i\rangle_{\mathcal{F}_i} \\ &= \sigma^2_{\min}\langle \Sigma^{1/2}_{X_iX_i} v_i, (I_{\mathcal{F}_i} - C_{X_iX_{\mathbf{J}}} C^{-1}_{X_{\mathbf{J}}X_{\mathbf{J}}} C_{X_{\mathbf{J}}X_i}) \Sigma^{1/2}_{X_iX_i} v_i\rangle_{\mathcal{F}_i}. \end{aligned}$$

By assumption (**A5**), the operator $I_{\mathcal{F}_i} - C_{X_iX_\mathbf{J}}C_{X_\mathbf{J}X_\mathbf{J}}^{-1}C_{X_\mathbf{J}X_i}$ is lower bounded by a strictly positive constant times the identity matrix, and thus, since $\Sigma_{X_iX_i}^{1/2}v_i \neq 0$, we have $\mathbb{E}E_n^2 > 0$. This implies that $n^{1/2}\langle v_i, \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\hat{f}_\mathbf{J}\rangle$ converges to a normal distribution with strictly positive variance. Thus the probability $\mathbb{P}\left(n^{1/2}\langle v_i, \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\hat{f}_\mathbf{J}\rangle_{\mathcal{F}_i} \geqslant d_i\|\hat{f}\|_d\|v_i\|_{\mathcal{F}_i} + 1\right)$ converges to a strictly positive limit (note that $\|\hat{f}\|_d$ can be replaced by $\|\mathbf{f}\|_d$ without changing the result). Since $\mu_n n^{1/2} \to \mu_0 < \infty$, this implies that

$$\mathbb{P}\left(\mu_n^{-1}\langle v_i, \hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\hat{f}_\mathbf{J}\rangle_{\mathcal{F}_i} > d_i\|\hat{f}\|_d\|v_i\|_{\mathcal{F}_i}\right)$$

is asymptotically strictly positive (i.e., has a strictly positive $\liminf$). Thus the optimality condition (14) is not satisfied with non vanishing probability, which is a contradiction and proves the proposition.

■

We now go back to the proof of Theorem 12. We prove by contradiction, by assuming that there exists $i \in \mathbf{J}^c$ such that

$$\frac{1}{d_i}\left\|\Sigma_{X_iX_i}^{1/2}C_{X_iX_\mathbf{J}}C_{X_\mathbf{J}X_\mathbf{J}}^{-1}\operatorname{Diag}(d_j/\|\mathbf{f}_j\|_{\mathcal{F}_j})\mathbf{g}_\mathbf{J}\right\|_{\mathcal{F}_i} > 1.$$

Since with probability tending to one $J(\hat{f}) = \mathbf{J}$, with probability tending to one, we have from optimality condition (15), and the usual line of arguments (see Eq. (26) in Appendix B.2) that for every $i \in \mathbf{J}^c$:

$$\begin{aligned}\hat{\Sigma}_{X_iY} - \hat{\Sigma}_{X_iX_\mathbf{J}}\hat{f}_\mathbf{J} &= \mu_n\hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D_n\right)^{-1}D_n\mathbf{f} \\ &\quad + \hat{\Sigma}_{X_i\varepsilon} - \hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D_n\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon},\end{aligned}$$

where $D_n = \|\hat{f}\|_d \operatorname{Diag}(d_j/\|\hat{f}_j\|)$. Following the same argument as in the proof of Theorem 11, (and because $\mu_n n^{1/2} \to +\infty$ as a consequence of Proposition 26), the first term in the last expression (divided by μ_n) converges to

$$v_i = \Sigma_{X_iX_i}^{1/2}C_{X_iX_\mathbf{J}}C_{X_\mathbf{J}X_\mathbf{J}}^{-1}\|\mathbf{f}\|_d \operatorname{Diag}(d_j/\|\mathbf{f}_j\|_{\mathcal{F}_j})\mathbf{g}_\mathbf{J}$$

By assumption $\|v_i\| > d_i\|\mathbf{f}\|_d$. We have the second term:

$$\begin{aligned}&\hat{\Sigma}_{X_i\varepsilon} - \hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n\|\hat{f}\|_d \operatorname{Diag}(d_j/\|\hat{f}_j\|_{\mathcal{F}_j})\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon} \\ = \;& O_p(n^{-1/2}) - \hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n\|\mathbf{f}\|_d \operatorname{Diag}(d_j/\|\mathbf{f}_j\|_{\mathcal{F}_j})\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon} + O_p(n^{-1/2}).\end{aligned}$$

The remaining term can be bounded as follows (with $D = \|\mathbf{f}\|_d \operatorname{Diag}(d_j/\|\mathbf{f}_j\|_{\mathcal{F}_j})$):

$$\begin{aligned}&\mathbb{E}\left(\left\|\hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}\varepsilon}\right\|_{\mathcal{F}_i}^2 | \bar{X}\right) \\ \leqslant\;& \frac{\sigma_{\max}^2}{n}\operatorname{tr}\hat{\Sigma}_{X_iX_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}}\left(\hat{\Sigma}_{X_\mathbf{J}X_\mathbf{J}} + \mu_n D\right)^{-1}\hat{\Sigma}_{X_\mathbf{J}X_i} \\ \leqslant\;& \frac{\sigma_{\max}^2}{n}\operatorname{tr}\hat{\Sigma}_{X_iX_i},\end{aligned}$$

which implies that the full expectation is $O(n^{-1})$ (because our operators are trace-class, that is, have finite trace). Thus the remaining term is $O_p(n^{-1/2})$ and thus negligible compared to μ_n, therefore $\frac{1}{\mu_n \|\hat{f}\|_d}\left(\hat{\Sigma}_{X_i Y} - \hat{\Sigma}_{X_i X_J}\hat{f}_J\right)$ converges in probability to a limit which is of norm strictly greater than d_i. Thus there is a non vanishing probability of being strictly larger than d_i, which implies that with non vanishing probability, the optimality condition (14) is not satisfied, which is a contradiction. This concludes the proof.

C.4 Proof of Proposition 15

Note that the estimator defined in Eq. (20) is exactly equal to

$$\left\|\hat{\Sigma}_{X_i X_J}(\hat{\Sigma}_{X_J X_J} + \kappa_n I)^{-1}\operatorname{Diag}(d_j/\|(\hat{f}^{LS}_{\kappa_n})_j\|_{\mathcal{F}_j})(\hat{f}^{LS}_{\kappa_n})_J\right\|_{\mathcal{F}_i}.$$

Using Proposition 17 and the arguments from Appendix C.2 by replacing $\tilde{f}$ by $\hat{F}_{LS}$, we get the consistency result.

C.5 Range Condition of Covariance Operators

We denote by $C(q)$ the convolution operator by q on the space of real functions on $\mathbb{R}^p$ and $T(p)$ the pointwise multiplication by $p(x)$. In this appendix, we look at different Hilbertian products of functions on $\mathbb{R}^p$, we use the notations $\langle\cdot,\cdot\rangle_{\mathcal{F}}$ and $\langle\cdot,\cdot\rangle_{L^2(p_X)}$ and $\langle\cdot,\cdot\rangle_{L^2(\mathbb{R}^p)}$ for the dot products in the RKHS $\mathcal{F}$, the space $L^2(p_X)$ of square integrable functions with respect to $p(x)dx$, and the space $L^2(\mathbb{R}^p)$ of square integrable functions with respect to the Lebesgue measure. With our assumptions, for all $\tilde{f},\tilde{g}\in L^2(\mathbb{R}^p)$, we have:

$$\langle\tilde{f},\tilde{g}\rangle_{L^2} = \langle C(q)^{1/2}\tilde{f}, C(q)^{1/2}\tilde{g}\rangle_{\mathcal{F}}.$$

Denote by $\{\lambda_k\}_{k\geq 1}$ and $\{e_k\}_{k\geq 1}$ the positive eigenvalues and the eigenvectors of the covariance operator Σ_{XX}, respectively. Note that since $p_X(x)$ was assumed to be strictly positive, all eigenvalues are strictly positive (the RKHS cannot contain any non zero constant functions on $\mathbb{R}^p$). For $k\geqslant 1$, set $f_k = \lambda_k^{-1/2}(e_k - \int_{\mathbb{R}^p} e_k(x)p_X(x)dx)$. By construction, for any $k,\ell\geqslant 1$,

$$\begin{aligned}\lambda_k\delta_{k,\ell} = \langle e_k, \Sigma e_\ell\rangle_{\mathcal{F}} &= \int_{\mathbb{R}^p} p_X(x)(e_k - \textstyle\int_{\mathbb{R}^p} e_k(x)p_X(x)dx)(e_\ell - \int_{\mathbb{R}^p} e_\ell(x)p_X(x)dx)dx \\ &= \lambda_k^{1/2}\lambda_\ell^{1/2}\int_{\mathbb{R}^p} p_X(x)f_k(x)f_\ell(x)dx = \lambda_k^{1/2}\lambda_\ell^{1/2}\langle f_k, f_\ell\rangle_{L^2(p_X)}.\end{aligned}$$

Thus $\{f_k\}_{k\geqslant 1}$ is an orthonormal sequence in $L^2(p_X)$. Let $f = C(q)g$ for $g\in L^2(\mathbb{R}^p)$ such that $\int_{\mathbb{R}^p} g(x)dx = 0$. Note that f is in the range of $\Sigma_{XX}^{1/2}$ if and only if $\langle f,\Sigma^{-1}f\rangle_{\mathcal{F}}$ is finite. We have:

$$\begin{aligned}\langle f,\Sigma^{-1}f\rangle_{\mathcal{F}} = \sum_{p=1}^{\infty}\lambda_p^{-1}\langle e_p,f\rangle_{\mathcal{F}}^2 = \sum_{p=1}^{\infty}\lambda_p^{-1}\langle e_p,g\rangle_{L^2(\mathbb{R}^p)}^2 &= \sum_{p=1}^{\infty}\lambda_p^{-1}\left(\int_{\mathbb{R}^p} g(x)e_p(x)dx\right)^2 \\ &= \sum_{p=1}^{\infty}\langle p_X^{-1}g, f_p\rangle_{L^2(p_X)}^2 \leqslant \|p_X^{-1}g\|_{L^2(p_X)}^2 = \int_{\mathbb{R}^p}\frac{g^2(x)}{p_X(x)}dx,\end{aligned}$$

because $\{f_k\}_{k\geqslant 1}$ is an orthonormal sequence in $L^2(p_X)$. This concludes the proof.

Appendix D. Proof of Results on Adaptive Group Lasso

In this appendix, we give proofs of the consistency of the adaptive group Lasso procedures.

D.1 Proof of Theorem 16

We define $\tilde{w}$ as the minimizer of the same cost function restricted to $w_{\mathbf{J}^c} = 0$. Because $\hat{w}^{LS}$ is consistent, the norms of $\hat{w}_j^{LS}$ for $j \in \mathbf{J}$ are bounded away from zero, and we get from standard results on M-estimation (Van der Vaart, 1998) the normal limit distribution with given covariance matrix if $\mu_n \ll n^{-1/2}$.

Moreover, the patterns of zeros (which is obvious by construction of $\tilde{w}$) converges in probability. What remains to be shown is that with probability tending to one, $\tilde{w}$ is optimal for the full problem. We just need to show that with probability tending to one, for all $i \in \mathbf{J}^c$,

$$\|\hat{\Sigma}_{X_i\varepsilon} - \hat{\Sigma}_{X_iX_\mathbf{J}}(\tilde{w}_\mathbf{J} - w_\mathbf{J})\| \leqslant \mu_n \|\tilde{w}\|_d \|\hat{w}_i^{LS}\|^{-\gamma}. \tag{27}$$

Note that $\|\tilde{w}\|_d$ converges in probability to $\|\mathbf{w}\|_d > 0$. Moreover, $\|\hat{w}_i^{LS} - \mathbf{w}_i\| = O_p(n^{-1/2})$. Thus, if $i \in \mathbf{J}^c$, that is, if $\mathbf{f}_i = 0$, then $\|\hat{w}_i^{LS}\| = O_p(n^{-1/2})$. The left hand side in Eq. (27) is thus upper bounded by $O_p(n^{-1/2})$ while the right hand side is lower bounded asymptotically by $\mu_n n^{\gamma/2}$. Thus if $n^{-1/2} = o(\mu_n n^{\gamma/2})$, then with probability tending to one we get the correct optimality condition, which concludes the proof.

D.2 Proof of Proposition 17

We have:

$$\hat{f}_{\kappa_n}^{LS} = \left(\hat{\Sigma}_{XX} + \kappa_n I_\mathcal{F}\right)^{-1} \hat{\Sigma}_{XY},$$

and thus:

$$\begin{aligned}
\hat{f}_{\kappa_n}^{LS} - \mathbf{f} &= \left(\hat{\Sigma}_{XX} + \kappa_n I_\mathcal{F}\right)^{-1} \hat{\Sigma}_{XX}\mathbf{f} - \mathbf{f} + \left(\hat{\Sigma}_{XX} + \kappa_n I_\mathcal{F}\right)^{-1} \hat{\Sigma}_{X\varepsilon} \\
&= (\Sigma_{XX} + \kappa_n I)^{-1} \Sigma_{XX}\mathbf{f} - \mathbf{f} + O_p(n^{-1/2}\kappa_n^{-1}) \text{ from Lemma 23} \\
&= -\left(\Sigma_{XX} + \kappa_n I_\mathcal{F}\right)^{-1} \kappa_n \mathbf{f} + O_p(n^{-1/2}\kappa_n^{-1}).
\end{aligned}$$

Since $\mathbf{f} = \Sigma_{XX}^{1/2}\mathbf{g}$, we have $\| - \left(\Sigma_{XX} + \kappa_n I_\mathcal{F}\right)^{-1} \kappa_n \mathbf{f}\|_\mathcal{F}^2 \leqslant C\kappa_n \|\mathbf{g}\|_\mathcal{F}^2$, which concludes the proof.

D.3 Proof of Theorem 18

We define $\tilde{f}$ as the minimizer of the same cost function restricted to $f_{\mathbf{J}^c} = 0$. Because $\hat{f}_{n^{-1/3}}^{LS}$ is consistent, the norms of $(\hat{f}_{n^{-1/3}}^{LS})_j$ for $j \in \mathbf{J}$ are bounded away from zero, and Lemma 25 applies with $\mu_n = \mu_0 n^{-1/3}$, that is, $\tilde{f}$ converges in probability to $\mathbf{f}$ and so are the patterns of zeros (which is obvious by construction of $\tilde{f}$). Moreover, for any $\eta > 0$, from Lemma 25, we have $\|\tilde{f}_\mathbf{J} - f_\mathbf{J}\| = O_p(n^{-1/6+\eta})$ (because $\mu_n^{-1/2} + n^{-1/2}\mu_n^{-1} = O_p(n^{-1/6})$).

What remains to be shown is that with probability tending to one, $\tilde{f}$ is optimal for the full problem. We just need to show that with probability tending to one, for all $i \in \mathbf{J}^c$,

$$\|\hat{\Sigma}_{X_i\varepsilon} - \hat{\Sigma}_{X_iX_\mathbf{J}}(\tilde{f}_\mathbf{J} - f_\mathbf{J})\| \leqslant \mu_n \|\tilde{f}\|_d \|(\hat{f}_{n^{-1/3}}^{LS})_i\|_{\mathcal{F}_i}^{-\gamma}. \tag{28}$$

Note that $\|\tilde{f}\|_d$ converges in probability to $\|\mathbf{f}\|_d > 0$. Moreover, by Proposition 17, $\|(\hat{f}_{n^{-1/3}}^{LS})_i - \mathbf{f}_i\| = O_p(n^{-1/6})$. Thus, if $i \in \mathbf{J}^c$, that is, if $\mathbf{f}_i = 0$, then $\|(\hat{f}_{n^{-1/3}}^{LS})_i\|_{\mathcal{F}_i} = O_p(n^{-1/6})$. The left hand side in

Eq. (28) is thus upper bounded by $O_p(n^{-1/2}+n^{-1/6+\eta})$ while the right hand side is lower bounded asymptotically by $n^{-1/3}n^{\gamma/6}$. Thus if $-1/6+\eta<-1/3+\gamma/6$, then with probability tending to one we get the correct optimality condition. As soon as $\gamma>1$, we can find η small enough and strictly positive, which concludes the proof.

Appendix E. Gaussian Kernels and Gaussian Variables

In this section, we consider $X\in\mathbb{R}^m$ with normal distribution with zero mean and covariance matrix S. We also consider Gaussian kernels $k_j(x_j,x'_j)=\exp(-b_i(x_j-x'_j)^2)$ on each of its component. In this situation, we can find orthonormal basis of the Hilbert spaces $\mathcal{F}_j$ where we can compute the coordinates of all covariance operators. This thus allows to check conditions (16) or (17) without using sampling.

We consider the eigenbasis of the non centered covariance operators on each $\mathcal{F}_j$, $j=1,\ldots,m$, which is equal to (Zhu et al., 1998):

$$e_k^j(x_j)=(\lambda_k^j)^{1/2}\left(\frac{c_j^{1/2}}{a_j^{1/2}2^k k!}\right)^{1/2}e^{-(c_j-a_j)u^2}H_k((2c_j)^{1/2}x_j)$$

with eigenvalues $\lambda_k^j=\left(\frac{2a_j}{A_j}\right)^{1/2}(B_j)^k$, where $a_i=1/4S_{ii}$, $c_j=(a_j^2+2a_jb_j)^{1/2}$, $A_j=a_j+b_j+c_j$ and $B_j=b_j/A_j$, and H_k is the k-th Hermite polynomial.

We can then compute all required expectations as follows (note that by definition we have $\mathbb{E}e_k^j(X_j)^2=\lambda_k^i$):

$$\begin{aligned}\mathbb{E}e_{2k+1}^j(X_j) &= 0\\ \mathbb{E}e_{2k}^j(X_j) &= \left(\lambda_{2k}^j\frac{2a_j^{1/2}c_j^{1/2}}{(a_j+c_j)}\binom{2k}{k}\right)^{1/2}\left(\frac{c_j-a_j}{2(c_j+a_j)}\right)^k\end{aligned}$$

$$\mathbb{E}e_k^j(X_j)e_\ell^i(X_i)=\left(\lambda_{2k}^j\lambda_{2\ell}^i\frac{c_j^{1/2}c_i^{1/2}}{a_j^{1/2}a_i^{1/2}2^k2^\ell k!\ell!}\right)^{1/2}\frac{(S_{ii}S_{jj}-S_{ij}^2)^{-1/2}}{4\pi c_i^{1/2}c_j^{1/2}}D_{k\ell}(Q_{ij}),$$

where $Q_{ij}=\begin{pmatrix}\frac{1}{2}(1-a_i/c_i) & 0\\ 0 & \frac{1}{2}(1-a_j/c_j)\end{pmatrix}+\frac{1}{4}\begin{pmatrix}S_{ii}c_i & S_{ij}c_i^{1/2}c_j^{1/2}\\ S_{ij}c_i^{1/2}c_j^{1/2} & S_{jj}c_j\end{pmatrix}^{-1}$ and

$$D_{k\ell}(Q)=\int_{\mathbb{R}^2}\exp\left[-\begin{pmatrix}u\\ v\end{pmatrix}^\top Q\begin{pmatrix}u\\ v\end{pmatrix}\right]H_k(u)H_\ell(v)dudv,$$

for any positive matrix Q. For any given Q, $D_{k\ell}(Q)$ can be computed exactly by using a singular value decomposition of Q and the appropriate change of variables.[6]

6. Matlab code to compute $D_{k\ell}(Q)$ can be downloaded from the author's webpage.

Abstract

We study a generative model in which hidden causes combine competitively to produce observations. Multiple active causes combine to determine the value of an observed variable through a max function, in the place where algorithms such as sparse coding, independent component analysis, or non-negative matrix factorization would use a sum. This max rule can represent a more realistic model of non-linear interaction between basic components in many settings, including acoustic and image data. While exact maximum-likelihood learning of the parameters of this model proves to be intractable, we show that efficient approximations to expectation-maximization (EM) can be found in the case of sparsely active hidden causes. One of these approximations can be formulated as a neural network model with a generalized softmax activation function and Hebbian learning. Thus, we show that learning in recent softmax-like neural networks may be interpreted as approximate maximization of a data likelihood. We use the bars benchmark test to numerically verify our analytical results and to demonstrate the competitiveness of the resulting algorithms. Finally, we show results of learning model parameters to fit acoustic and visual data sets in which max-like component combinations arise naturally.

Keywords: component extraction, maximum likelihood, approximate EM, competitive learning, neural networks

1. Introduction

In recent years, algorithms such as independent components analysis (ICA; Comon, 1994; Bell and Sejnowski, 1997), sparse coding (SC; Olshausen and Field, 1996), and non-negative matrix factorization (NMF; Lee and Seung, 1999) have been used to describe the statistics of the natural environment, and the components extracted by these methods have been linked to sensory neuronal response properties. Stated in the language of probabilistic generative models (see, e.g., Dayan and Abbott, 2001; Rao et al., 2002) these systems describe sensory data as a linear superposition of learned components. For many types of data, including images, this assumed linear cooperation between generative causes is unrealistic. Alternative, more competitive generative models have also been proposed: for instance, Saund (1995) suggests a model in which hidden causes are combined by a noisy-or rule, while Dayan and Zemel (1995) suggest a yet more competitive scheme. Here, we formulate an extreme case of competition, in which the strongest generative influence on an observed variable (e.g., an image pixel) alone determines its value. Such a rule has the property of selecting, for each observed variable, a single generative cause to determine that variable's value.

This form of combination emerges naturally in the context of spectrotemporal masking in mixed audio signals. For image data, occlusion leads to a different combination rule, but one that shares the selection property in that, under constant lighting conditions, the appearance of each observed pixel is determined by a single object.

In parallel to this development of generative approaches, a number of artificial neural network architectures have been designed to tackle the problem of non-linear component extraction, mostly in artificial data (e.g., Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004; Lücke and Bouecke, 2005; Spratling, 2006), although sometimes in natural images (e.g., Harpur and Prager, 1996; Charles et al., 2002; Lücke, 2007). These models often perform quite well with respect to various benchmark tests. However, the relationship between them and the density models that are implicit or explicit in the generative approach has not, thus far, been made clear. We show here that inference and learning in a restricted form of our novel generative model correspond closely in form to the processing and plasticity rules used in such neural network approaches, thus bringing together these two disparate threads of investigation.

The organization of the remainder of this article is as follows. In Section 2 we define the novel generative model and then proceed to obtain the associated parameter update rules in Section 3. In Section 4 we derive computationally efficient approximations to these update rules, in the context of sparsely active hidden causes—that is, when a small number of hidden causes generally suffices to explain the data. In Section 5 we relate a restricted form of the generative model to neural network learning rules with Hebbian plasticity and divisive normalization. Results of numerical experiments in Section 6 show the component extraction performance of the generative schemes as well as a comparison to other algorithms. Finally, in Section 7, we discuss our analytical and numerical results.

2. A Generative Model with Maximum Non-linearity

We consider a generative model for D observed variables y_d, $(d = 1,\ldots,D)$, in which H hidden binary causes s_h, $(h = 1,\ldots,H)$, each taking the value 0 or 1, *compete* to determine the value of each observation (see Figure 1). Associated with each pair (s_h, y_d), is a weight W_{hd}. Given a set of active causes (i.e., those taking the value 1), the distribution of y_d is determined by the *largest* of the weights associated with the active causes and y_d.

Much of our discussion will apply generally to all models of this causal structure, irrespective of the details of the distributions involved. For concreteness, however, we focus on a particular choice, in which the hidden variables are drawn from a multivariate Bernoulli distribution; and the observed variables are non-negative, integer-valued and, given the causes, conditionally independent and Poisson-distributed. Thus, collecting all the causes into a single binary vector $\vec{s} \in \{0,1\}^H$, and all the observed variables into an integer vector $\vec{y} \in \mathbb{Z}_+^D$ we have:

$$p(\vec{s}\,|\,\vec{\pi}) \;=\; \prod_{h=1}^{H} p(s_h\,|\,\pi_h), \quad p(s_h\,|\,\pi_h) = \pi_h^{s_h}(1-\pi_h)^{1-s_h}, \tag{1}$$

$$p(\vec{y}\,|\,\vec{s},W) \;=\; \prod_{d=1}^{D} p(y_d\,|\,\overline{W}_d(\vec{s},W)), \quad p(y_d\,|\,w) = \frac{w^{y_d}}{y_d!}e^{-w}. \tag{2}$$

Here, $\vec{\pi} \in [0,1]^H$ parameterizes the prior distribution on $\vec{s}$, while the weight matrix $W \in \mathrm{R}^{H\times D}$ parameterizes the influence of the hidden causes on the distribution of $\vec{y}$. It will be convenient to

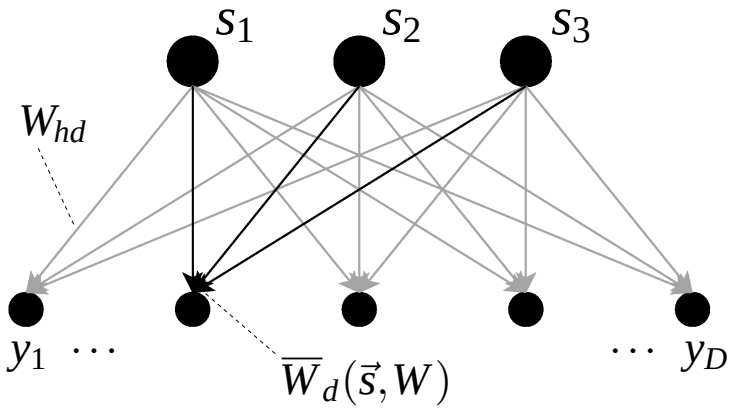

Figure 1: A generative model with $H = 3$ hidden variables and $D = 5$ observed variables. The values y_d of the observed variables are conditionally independent given the values $\vec{s}$ of the hidden variables. The value y_d is drawn from a distribution which is determined by the parameters W_{1d}, W_{2d}, and W_{3d}. For a given binary vector $\vec{s}$ these parameters combine competitively according to the function $\overline{W}_d(\vec{s},W) = \max_h\{s_h W_{hd}\}$.

group these parameters together into $\Theta = (\vec{\pi}, W)$. The function $\overline{W}_d(\vec{s},W)$ in (2) gives the *effective weight* on y_d, resulting from a particular pattern of causes $\vec{s}$. Thus, in the model considered here,

$$\overline{W}_d(\vec{s},W) \quad = \quad \max_h\{s_h W_{hd}\}\,. \tag{3}$$

It is useful to place the model (1)–(3) in context. Models of this general type, in which the observations are conditionally independent of one another given a set of hidden causes, are widespread. They underlie algorithms such as ICA, SC, principal components analysis (PCA), factor analysis (see, e.g., Everitt, 1984), and NMF. In these five cases, and indeed in the majority of such models studied, the effective weights $\overline{W}_d(\vec{s},W)$ are formed by a linear combination of all the weights that link hidden variables to the observation; that is, $\overline{W}_d(\vec{s},W) = \sum_h s_h W_{hd}$. Some other models, notably those of Saund (1995) and Dayan and Zemel (1995), have implemented more competitive combination rules, where larger individual weights dominate the effective combination. The present model takes this competition to an extreme, so that only the single largest weight (amongst those associated with active hidden variables) determines the output distribution. Thus, where ICA, PCA, SC, or NMF use a sum, we use a max. We refer to this new generative model as the Maximal Causes Analysis (MCA) model.

Figure 2 illustrates the difference between linear superposition and competitive combination using (3). Let us suppose that noise-free observations are generated by causes in the form of horizontal and vertical objects with the same gray-value, on a dark (black) background (see Figure 2). If these objects occlude one-another, they may generate an observed image such as that illustrated in Figure 2B. However, if we were to use the actual causes and weights in Figure 2A, but instead combine them linearly, we would obtain the (different) input pattern of Figure 2C. In this case, competitive combination using the max-rule of Equation (3) would result in the correct pattern. This is not, of course, generally true, but for monochrome objects with small variations in their gray-values it

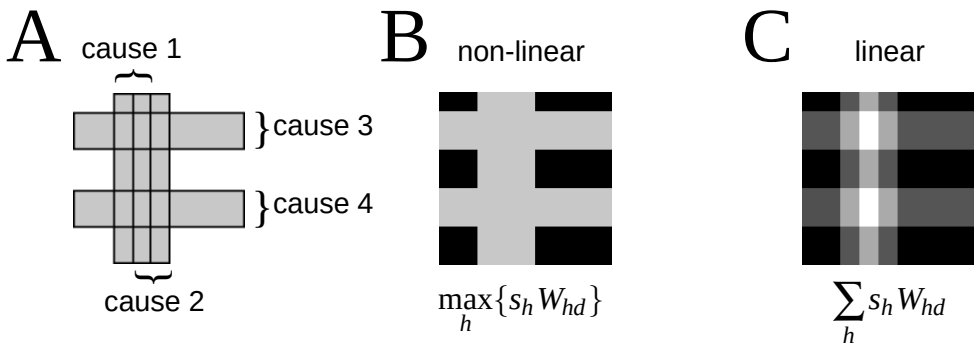

Figure 2: An illustration of non-linear versus linear combination of hidden causes. **A** Four examples of hidden causes with gray-value 200. **B** The input image that may result if sources occlude one another. In this case, the correct function $\overline{W}_d(\vec{s},W)$ (see Figure 1) to combine the hidden causes is the max-operation. **C** The input image that results if the four causes combine linearly (gray-values are scaled to fill the interval [0,255]). For **C**, the correct function $\overline{W}_d(\vec{s},W)$ is linear super-position.

holds approximately. More generally, the maximum combination rule is always closer to the result of occlusion than is the simple sum implied by models such as ICA.

As stated above, although in this paper we focus on the specific distributions given in (1) and (2), much of the analytical treatment is independent of these specific choices. Thus, update rules for learning the weights W from data will be derived in a general form, that can accommodate alternative, non-factored distributions for the binary hidden variables. This general form is also preserved if the Poisson distribution is replaced, for example, by a Gaussian. Poisson variability represents a reasonable choice for the non-negative data considered in this paper, and resembles the cost function introduced by Lee and Seung (1999) for NMF.

3. Maximum Likelihood

Given a set of observed data vectors $Y=\{\vec{y}^{(n)}\}_{n=1,\ldots,N}$, taken to be generated independently from a stationary process, we seek parameter values $\Theta^* = (\vec{\pi}^*, W^*)$ that maximize the likelihood of the data under the generative model of Equations (1) to (3):

$$\Theta^* \;=\; \text{argmax}_\Theta\{\mathcal{L}(\Theta)\} \quad \text{with} \quad \mathcal{L}(\Theta) = \log\Big(p(\vec{y}^{(1)},\ldots,\vec{y}^{(N)}\,|\,\Theta)\Big)\,.$$

We use Expectation-Maximization (EM; Dempster et al. 1977; see also Neal and Hinton 1998, for the formulation that appears here) to maximize the likelihood in this latent variable model. To do so, we introduce the free-energy $\mathcal{F}(\Theta,q)$—a data-dependent function of the parameters Θ and an unknown distribution $q(\vec{s}^{(1)},\ldots,\vec{s}^{(N)})$ over the hidden data or variables—that is always equal to or less than the likelihood evaluated at the same parameter values. For independently generated data vectors $\vec{y}^{(n)}$, the distribution q may be taken (without loss of generality) to factor over the hidden

vectors $q(\vec{s}^{(1)},\ldots,\vec{s}^{(N)}) = \prod_n q_n(\vec{s}^{(n)})$. Then the free-energy is defined as:

$$\mathcal{F}(\Theta,q) = \sum_{n=1}^{N}\left[\sum_{\vec{s}} q_n(\vec{s})\ \left[\log\left(p(\vec{y}^{(n)}\,|\,\vec{s},\Theta)\right)+\log\left(p(\vec{s}\,|\,\Theta)\right)\right]\right]+H(q) \leq \mathcal{L}(\Theta), \tag{4}$$

where $H(q) = \sum_n H(q_n(\vec{s})) = -\sum_n \sum_{\vec{s}} q_n(\vec{s})\log(q_n(\vec{s}))$ is the Shannon entropy of q. The iterations of EM alternately increase $\mathcal{F}$ with respect to the distributions q_n while holding Θ fixed (the E-step), and with respect to Θ while holding the q_n fixed (the M-step). Thus, if we consider a pair of steps beginning from parameters Θ', the E-step first finds new distributions q_n that depend on Θ' and the observations $\vec{y}^{(n)}$, which we write as $q_n(\vec{s};\Theta')$. Ideally, these distributions maximize $\mathcal{F}$ for fixed Θ', in which case it can be shown that $q_n(\vec{s};\Theta') = p(\vec{s}\,|\,\vec{y}^{(n)},\Theta')$ and $\mathcal{F}(\Theta',q_n(\vec{s};\Theta')) = \mathcal{L}(\Theta')$ (Neal and Hinton, 1998). In practice, computation of this exact posterior may be intractable, and it is often replaced by an approximation. After choosing the q_n's in the E-step, we maximize $\mathcal{F}$ with respect to Θ in the M-step while holding the q_n distributions fixed. Thus the free-energy can be re-written in terms of Θ and Θ':

$$\mathcal{F}(\Theta,\Theta') \quad = \quad \sum_{n=1}^{N}\left[\sum_{\vec{s}} \quad q_n(\vec{s};\Theta') \quad \left[\log\left(p(\vec{y}^{(n)}\,|\,\vec{s},\Theta)\right)+\log\left(p(\vec{s}\,|\,\Theta)\right)\right]\right] \ + \ H(\Theta'). \tag{5}$$

where $H(\Theta') = \sum_n H(q_n(\vec{s};\Theta'))$. A necessary condition to achieve this maximum with respect to $W_{id} \in \Theta$, is that (see Appendix A for details):

$$\frac{\partial}{\partial W_{id}}\mathcal{F}(\Theta,\Theta') = \sum_n\sum_{\vec{s}} q_n(\vec{s};\Theta')\left(\frac{\partial}{\partial W_{id}}\overline{W}_d(\vec{s},W)\right)\frac{y_d^{(n)}-\overline{W}_d(\vec{s},W)}{\overline{W}_d(\vec{s},W)} \quad \stackrel{!}{=} \quad 0. \tag{6}$$

Unfortunately, under the max-combination rule of Equation (3), $\overline{W}_d$ is not differentiable. Instead, we define a smooth function $\overline{W}_d^{\rho}$ that converges to $\overline{W}_d$ as ρ approaches infinity:

$$\overline{W}_d^{\rho}(\vec{s},W) \quad := \quad \left(\sum_{h=1}^{H}(s_h W_{hd})^{\rho}\right)^{\frac{1}{\rho}} \ \Rightarrow \ \lim_{\rho\to\infty}\overline{W}_d^{\rho}(\vec{s},W) = \overline{W}_d(\vec{s},W), \tag{7}$$

and replace the derivative of $\overline{W}_d$ by the limiting value of the derivative of $\overline{W}_d^{\rho}$, which we write as $\mathcal{A}_{id}$ (see Appendix A for details):

$$\mathcal{A}_{id}(\vec{s},W) := \lim_{\rho\to\infty}\left(\frac{\partial}{\partial W_{id}}\overline{W}_d^{\rho}(\vec{s},W)\right) = \lim_{\rho\to\infty}\frac{s_i\,(W_{id})^{\rho}}{\sum_h s_h (W_{hd})^{\rho}}. \tag{8}$$

Armed with this definition, a rearrangement of the terms in (6) yields (see Appendix A):

$$W_{id} \ = \ \frac{\sum_n \left\langle \mathcal{A}_{id}(\vec{s},W)\right\rangle_{q_n} y_d^{(n)}}{\sum_n \left\langle \mathcal{A}_{id}(\vec{s},W)\right\rangle_{q_n}}, \tag{9}$$

where $\left\langle \mathcal{A}_{id}(\vec{s},W)\right\rangle_{q_n}$ is the expectation of $\mathcal{A}_{id}(\vec{s},W)$ under the distribution $q_n(\vec{s};\Theta')$:

$$\left\langle \mathcal{A}_{id}(\vec{s},W)\right\rangle_{q_n} = \sum_{\vec{s}} q_n(\vec{s};\Theta')\,\mathcal{A}_{id}(\vec{s},W). \tag{10}$$

Equation (9) represents a set of non-linear equations (one for each W_{id}) that defines the necessary conditions for an optimum of $\mathcal{F}$ with respect to W. The equations do not represent straightforward update rules for W_{id} because the right-hand-side does not depend only on the old values $W' \in \Theta'$. They can, however, be used as fixed-point iteration equations, by simply evaluating the derivatives $\mathcal{A}_{id}$ at W' instead of W. Although there is no guarantee that these iterations converge, if they do converge the corresponding parameters must lie at a stationary point of the free-energy. Numerical experiments described later confirm that this fixed-point approach is, in fact, robust and convergent. Note that the denominator in (9) vanishes only if $q_n(\vec{s};\Theta')\,\mathcal{A}_{id}(\vec{s},W) = 0$ for all $\vec{s}$ and n (assuming positive weights), in which case (6) is already satisfied, and no update of W is required.

Thus far, we have not made explicit reference to the form of prior source distribution, and so the result of Equation (9) is independent of this choice. For our chosen Bernoulli distribution (1), the M-step is obtained by setting the derivative of $\mathcal{F}$ with respect to π_i to zero, giving (after rearrangement):

$$\pi_i \;=\; \frac{1}{N}\sum_n \langle s_i \rangle_{q_n}, \quad \text{with } \langle s_i \rangle_{q_n} = \sum_{\vec{s}} q_n(\vec{s};\Theta')\, s_i\,. \tag{11}$$

Parameter values that satisfy Equations (9) and (11), maximize the free-energy given the distributions $q_n = q_n(\vec{s};\Theta')$. As stated before, the optimum with respect to q (and therefore, exact optimization of the likelihood, since the optimal setting of q forces the free-energy bound to be tight) is obtained by setting the q_n to the posterior distributions:

$$q_n(\vec{s};\Theta') \;=\; p(\vec{s}\,|\,\vec{y}^{(n)},\Theta') \;=\; \frac{p(\vec{s},\vec{y}^{(n)}\,|\,\Theta')}{\sum_{\tilde{\vec{s}}} p(\tilde{\vec{s}},\vec{y}^{(n)}\,|\,\Theta')}, \tag{12}$$

where $p(\vec{s},\vec{y}^{(n)}\,|\,\Theta') = p(\vec{s}\,|\,\vec{\pi}')\,p(\vec{y}^{(n)}\,|\,\vec{s},W')$, and with the latter distributions given by (1) and (2), respectively.

Equations (9) to (12) thus represent a complete set of update rules for maximizing the data likelihood under the generative model. The only approximation made to this point is to use the old values W' on the right-hand-side of the M-step equation in (9). We therefore refer to this set of updates as a pseudo-exact learning rule and call the algorithm they define MCA_{ex}, with the subscript for *exact*. We will see in numerical experiments that MCA_{ex} does indeed maximize the likelihood.

4. E-Step Approximations

The computational cost of finding the exact sufficient statistics $\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n}$, with q_n equal to the posterior probability (12), is intractable in general. It grows exponentially in the smaller of the number of hidden causes H, and the number of observed variables D (see Appendix B for details). A practical learning algorithm, then, must depend on finding a computationally tractable approximation to the true expectation. One approach, a form of variational method (Jordan et al., 1999), would be to optimize the q_n within a constrained class of distributions; for example, distributions that factor over the sources s_h. Unfortunately, this conventional factoring approach provides limited benefit here, as the form of $\mathcal{A}_{id}(\vec{s},W)$ resists straightforward evaluation of the expected value with respect to the individual sources. Instead, we base our approximations on an assumption of sparsity—that only a small number of active hidden sources is needed to explain any one observed

data vector (note that sparsity here refers to the *number* of active hidden sources, rather than to their *proportion*). The resulting expressions relate to those that would be found by a variational optimization constrained to distributions that are sparse in the sense above, but are not identical. The relationship will be explored further in the Discussion.

To develop the sparse approximations, consider grouping the terms in the expected value of Equation (10) according to the number of active sources in the vector $\vec{s}$:

$$\begin{aligned}\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} &= \sum_{\vec{s}} p(\vec{s}|\vec{y}^{(n)},\Theta')\,\mathcal{A}_{id}(\vec{s},W) \qquad (13)\\ &= \sum_a p(\vec{s}_a\,|\vec{y}^{(n)},\Theta')\,\mathcal{A}_{id}(\vec{s}_a,W) + \sum_{\substack{a,b\\a<b}} p(\vec{s}_{ab}\,|\vec{y}^{(n)},\Theta')\,\mathcal{A}_{id}(\vec{s}_{ab},W) + \sum_{\substack{a,b,c\\a<b<c}} \ldots,\end{aligned}$$

where $\vec{s}_a := (0,\ldots,0,1,0,\ldots,0)$ with only $s_a = 1$
$\vec{s}_{ab} := (0,\ldots,0,1,0,\ldots,0,1,0,\ldots,0)$ with only $s_a = 1$, $s_b = 1$, $a \neq b$,
and $\vec{s}_{abc}$ etc. are defined analogously.

Note that $\mathcal{A}_{id}(\vec{0},W) = 0$ because of (7) and (8). Now, each of the conditional probabilities $p(\vec{s}|\vec{y}^{(n)},\Theta')$ implicitly contains a similar sum over $\vec{s}$ for normalization:

$$p(\vec{s}|\vec{y}^{(n)},\Theta') = \frac{1}{\mathcal{Z}}\,p(\vec{s},\vec{y}^{(n)}\,|\,\Theta'), \qquad \mathcal{Z} := \sum_{\vec{s}} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta'), \qquad (14)$$

and the terms of this sum may be grouped in the same way

$$\mathcal{Z} := p(\vec{0},\vec{y}^{(n)}\,|\,\Theta') + \sum_a p(\vec{s}_a,\vec{y}^{(n)}\,|\,\Theta') + \sum_{\substack{a,b\\a<b}} p(\vec{s}_{ab},\vec{y}^{(n)}\,|\,\Theta') + \sum_{\substack{a,b,c\\a<b<c}} p(\vec{s}_{abc},\vec{y}^{(n)}\,|\,\Theta') + \ldots.$$

Combining (13) and (14) yields:

$$\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} = \frac{\sum_a p(\vec{s}_a,\vec{y}^{(n)}\,|\,\Theta')\,\mathcal{A}_{id}(\vec{s}_a,W) + \sum_{\substack{a,b\\a<b}} p(\vec{s}_{ab},\vec{y}^{(n)}\,|\,\Theta')\,\mathcal{A}_{id}(\vec{s}_{ab},W) + \ldots}{p(\vec{0},\vec{y}^{(n)}\,|\,\Theta') + \sum_a p(\vec{s}_a,\vec{y}^{(n)}\,|\,\Theta') + \sum_{\substack{a,b\\a<b}} p(\vec{s}_{ab},\vec{y}^{(n)}\,|\,\Theta') + \ldots}. \qquad (15)$$

A similar grouping of terms is possible for the expectation $\langle s_h\rangle_{q_n}$.

If we now assume that the significant posterior probability mass will concentrate on vectors $\vec{s}$ with only a limited number of non-zero entries, the expanded sums in both numerator and denominator of (15) may be truncated without significant loss. The accuracy of the approximation depends both on the sparsity of the true generative process, and on the distance of the current model parameters (in the current EM iteration) from the true ones. In general, provided that the true process is indeed sparse, a truncated approximation will become more accurate as the estimated parameters approach their maximum likelihood values. The convergence properties and accuracy of algorithms based on this form of approximation will be tested numerically in Section 6.

Different choices of the truncation yield approximate algorithms with different properties. Two of these will be considered here.

4.1 MCA$_3$

In the first approximation, we truncate all but one of the sums that appear in the expansions of $\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n}$ and $\langle s_i\rangle_{q_n}$ after the terms that include three active sources, while truncating the numerator of $\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n}$ after the two-source terms (see Appendix C for details):

$$\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} \approx \frac{\overline{\pi}_i \exp(I_i^{(n)}) + \sum\limits_{c\,(c\neq i)} \overline{\pi}_i\overline{\pi}_c \exp(I_{ic}^{(n)})\,\mathcal{H}(W_{id}-W_{cd})}{1+\sum\limits_h \overline{\pi}_h \exp(I_h^{(n)}) + \frac{1}{2}\sum\limits_{\substack{a,b\\ a\neq b}} \overline{\pi}_a\overline{\pi}_b \exp(I_{ab}^{(n)}) + \frac{1}{6}\sum\limits_{\substack{a,b,c\\ a\neq b\neq c}} \overline{\pi}_a\overline{\pi}_b\overline{\pi}_c \exp(I_{abc}^{(n)})} \tag{16}$$

$$\text{and} \qquad \langle s_i\rangle_{q_n} \approx \frac{\overline{\pi}_i \exp(I_i^{(n)}) + \sum\limits_{c\,(c\neq i)} \overline{\pi}_i\overline{\pi}_c \exp(I_{ic}^{(n)}) + \frac{\alpha}{2}\sum\limits_{b,c\,(b\neq c\neq i)} \overline{\pi}_i\overline{\pi}_b\overline{\pi}_c \exp(I_{ibc}^{(n)})}{1+\sum\limits_h \overline{\pi}_h \exp(I_h^{(n)}) + \frac{1}{2}\sum\limits_{\substack{a,b\\ a\neq b}} \overline{\pi}_a\overline{\pi}_b \exp(I_{ab}^{(n)}) + \frac{1}{6}\sum\limits_{\substack{a,b,c\\ a\neq b\neq c}} \overline{\pi}_a\overline{\pi}_b\overline{\pi}_c \exp(I_{abc}^{(n)})}\,, \tag{17}$$

where

$$\begin{aligned}
&\overline{\pi}_i = \frac{\pi_i}{1-\pi_i}, && I_i^{(n)} = \sum_d \left(\log(W_{id})\, y_d^{(n)} - W_{id}\right),\\
&\tilde{W}_d^{ab} = \max(W_{ad},W_{bd}), && I_{ab}^{(n)} = \sum_d \left(\log(\tilde{W}_d^{ab})\, y_d^{(n)} - \tilde{W}_d^{ab}\right),\\
&\tilde{W}_d^{abc} = \max(W_{ad},W_{bd},W_{cd}), && I_{abc}^{(n)} = \sum_d \left(\log(\tilde{W}_d^{abc})\, y_d^{(n)} - \tilde{W}_d^{abc}\right),
\end{aligned} \tag{18}$$

and where $\mathcal{H}(x) = 1$ for $x > 0$; $\frac{1}{2}$ for $x = 0$; 0 for $x < 0$ is the Heaviside function. The above equations have been simplified by dividing both numerator and denominator by terms that do not depend on $\vec{s}$, for example, by $\prod_{i=1}^{H}(1-\pi_i)$ (see Appendix C). Approximations (16) and (17) are used in the fixed-point updates of Equations (9) and (11), where the parameters that appear on the right-hand-side are held at their current values. Thus all parameters that appear on the right-hand-side of the approximations take values in $\Theta' = (\vec{\pi}', W')$.

The early truncation of the numerator in (16) improves performance in experiments, partly by increasing competition between causes further, and partly by reducing the contribution of more complex data patterns that are better fit, given the current parameter settings, by three active sources than by two. By contrast, the three-source terms are kept in the numerator of (17). In this case, neglecting complex input patterns as in (16) would lead to greater errors in the estimated source activation probabilities π_i. Indeed, even while keeping these terms, π_i tend to be underestimated if the input data include many patterns with more than three active sources. To compensate, we introduce a factor of $\alpha > 1$ multiplying the three-source term in (17) (so that $\alpha = 1$ corresponds to the actual truncated sum), which is updated as described in Appendix C. This scheme yields good estimates of π_i, even if more than three sources are often active in the input data.

The M-step Equations (9) and (11) together with E-step approximations (16) and (17) represent a complete set of update equations for the MCA generative model. The computational cost of one parameter update grows polynomially in the total number of causes, with order H^3. The algorithm that is defined by these updates will therefore be referred to as MCA$_3$.

4.2 R-MCA$_2$

In the second place, we consider a restriction of the generative model in which (i) all s_h are distributed according to the same prior distribution with fixed parameter π; (ii) the weights W_{id} associated with each source variable i are constrained to sum to a constant C:

$$\forall i \in \{1,\ldots,H\}: \quad \pi_i = \pi \quad \text{and} \quad \sum_d W_{id} = C; \tag{19}$$

and (iii) on average, the influence of each hidden source is homogeneously covered by the other sources. This third restriction means that each non-zero generating weight W^{gen}_{id} associated with cause i can be covered by the same number of $W^{\text{gen}}_{cd} \geq W^{\text{gen}}_{id}$:

$$W^{\text{gen}}_{id} > 0 \quad \Rightarrow \quad \sum_{c\neq i} \mathcal{H}(W^{\text{gen}}_{cd} - W^{\text{gen}}_{id}) \approx b_i\,, \tag{20}$$

where $\mathcal{H}$ is the Heaviside function and b_i is the number of causes that can cover cause i. Figure 3 illustrates this condition. Figure 3A,B show weight patterns associated with hidden causes for which the condition is fulfilled; for instance in Figure 3B $b_i = 0$ for all causes with horizontal weight patterns, while $b_i = 1$ for the vertically oriented cause. In Figure 3C the condition is violated. Roughly, these conditions guarantee that all hidden causes have equal average effects on the generated data vectors. They make the development of a more efficient approximate learning algorithm possible but, despite their role in the derivation, the impact of these assumptions is limited in practice, in the sense that the resulting algorithm can perform well even when the input data set violates assumptions (19) and (20). This is demonstrated in a series of numerical experiments detailed below.

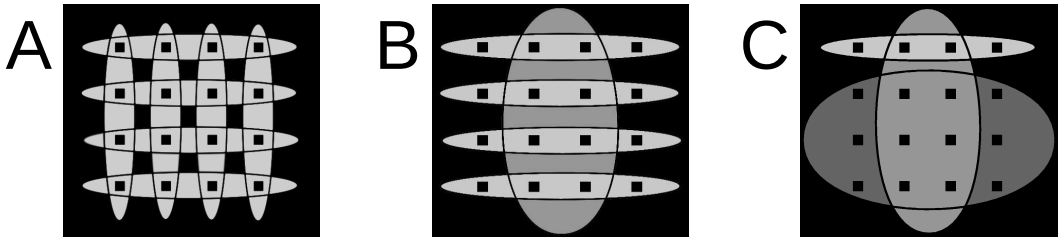

Figure 3: **A** and **B** show patterns of weights that satisfy the uniformity condition (20) whereas weights in **C** violate it. Each hidden cause is symbolized by an ellipse, with the gray-level of the ellipse representing the value W_{id} of each weight within the ellipse. Weights outside the ellipse for each cause are zero (black). The black squares indicate the 4-by-4 grid of observed pixels.

Update rules for the restricted generative model can again be derived by approximate expectation-maximization (see Appendix C). Using both the sum constraint of (19) and the assumption of homogeneous coverage of causes, we obtain the M-step update:

$$W_{id} \quad = \quad C \frac{\sum_n \langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} y^{(n)}_d}{\sum_{d'}\sum_n \langle \mathcal{A}_{id'}(\vec{s},W)\rangle_{q_n} y^{(n)}_{d'}}\,. \tag{21}$$

Empirically, we find that the restricted parameter space of this model means that we can approximate the sufficient statistics $\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n}$ by a more severe truncation than before, now keeping two-source terms in the denominator, but only single-source terms in the numerator, of the expansion (15). This approximation, combined with the fact that any zero-valued observed patterns (i.e., those with $\sum_d y_d^{(n)} = 0$) do not affect the update rule (21) and so can be neglected, yields the expression (see Appendix C):

$$\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} \approx \frac{\exp(I_i^{(n)})}{\sum_h \exp(I_h^{(n)}) + \frac{\overline{\pi}}{2}\sum_{\substack{a,b\\ a\neq b}} \exp(I_{ab}^{(n)})}\,, \quad \overline{\pi} := \frac{\pi}{1-\pi}\,, \tag{22}$$

with abbreviations given in (18). Equations (21) and (22) are update rules for the MCA generative model, subject to the conditions (19) and (20). They define an algorithm that we will refer to as R-MCA$_2$ with R for *restricted* and with *2* indicating a computational cost that grows quadratically with H.

5. Relation to Neural Networks

We now relate component extraction as learned within the MCA framework to that achieved by a family of artificial neural networks. Consider the network of Figure 4 which consists of D input variables (or *units*) with values $y_1,\ldots,y_D$ and H hidden units with values $g_1,\ldots,g_H$. An observation $\vec{y}$ is represented by the values (or *activities*) of the input units, which act through *connections* parameterized by $(\mathcal{W}_{id})$ to determine the activities of the hidden units through an *activation function* $g_i = g_i(\vec{y},\mathcal{W})$. These parameters $(\mathcal{W}_{id})$ are known as the network (or synaptic) *weights*.

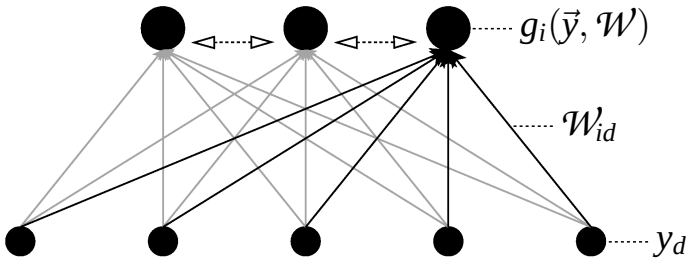

Figure 4: Architecture of a two layer neural network. Input is represented by values y_1 to y_D of D input units (small black circles). These values combine with synaptic weights $\mathcal{W}$ to determine the activities of the hidden units g_1 to g_H (big black circles). The dotted horizontal arrows symbolize lateral information exchange that may be required to compute the functions g_1 to g_H. After the g_i are computed the parameters $(\mathcal{W}_{id})$ are modified using a Δ-rule.

Learning in such a neural network involves adjusting the weights $\mathcal{W}$ in response to a series of input patterns, using a rule that is heuristically designed to extract some form of structure from these

inputs. A standard choice is the Hebbian Δ-rule with divisive normalization:

$$\Delta \mathcal{W}_{id} \;=\; \varepsilon g_i(\vec{y}, \mathcal{W}) y_d \quad \text{and} \quad \mathcal{W}_{id}^{\text{new}} = C \frac{\mathcal{W}_{id} + \Delta \mathcal{W}_{id}}{\sum_{d'} (\mathcal{W}_{id'} + \Delta \mathcal{W}_{id'})}, \tag{23}$$

The normalization step is needed to prevent weights from growing without bound, and the divisive form used here is most common. Here, the constant C defines the value at which $\sum_d \mathcal{W}_{id}$ is held constant; it will be related below to the C appearing in Equation 19. Many neural networks with the structure depicted in Figure 4, and that use a learning rule identical or similar to (23), have been shown to converge to weight values that identify clusters in, or extract useful components from, a set of input patterns (O'Reilly, 2001; Spratling and Johnson, 2002; Yuille and Geiger, 2003; Lücke and von der Malsburg, 2004; Lücke, 2004; Lücke and Bouecke, 2005; Spratling, 2006).

The update rule (23) depends on only one input pattern, and is usually applied *online*, with the weights being changed in response to each pattern in turn. If, instead, we consider the effect of presenting a group of patterns $\{\vec{y}^{(n)}\}$, the net change is approximately (see Appendix D):

$$\mathcal{W}_{id}^{\text{new}} \approx C \frac{\sum_n g_i(\vec{y}^{(n)}, \mathcal{W}) y_d^{(n)}}{\sum_{d'} \sum_n g_i(\vec{y}^{(n)}, \mathcal{W}) y_{d'}^{(n)}}. \tag{24}$$

Now, comparing (24) to (21), we see that if the activation function of a neural network were chosen so that $g_i(\vec{y}^{(n)}, \mathcal{W}) = \langle \mathcal{A}_{id}(\vec{s}, W) \rangle_{q_n}$, then the network would optimize the parameters of the restricted MCA generative model, with $W = \mathcal{W}$ (we drop the distinction between $\mathcal{W}$ and W from now on). Unfortunately, the expectation $\langle \mathcal{A}_{id}(\vec{s}, W) \rangle_{q_n}$ depends on d, and thus exact optimization in the general case would require a modified Hebbian rule. However, the truncated approximation of (22) is the same for all d, and so the changes in each weight depend only on the activities of the corresponding pre- and post-synaptic units. Thus, the Hebbian Δ-rule,

$$\Delta W_{id} \;=\; \varepsilon g_i y_d \quad \text{with} \quad g_i = \frac{\exp(I_i)}{\sum_h \exp(I_h) + \frac{\overline{\pi}}{2} \sum_{\substack{a,b \\ a \neq b}} \exp(I_{ab})} \tag{25}$$

(where I_h, I_{ab}, and $\overline{\pi}$ are the abbreviations introduced in Equations 18 and 22), when combined with divisive normalization, implements an online version of the R-MCA$_2$ algorithm. We refer to this online weight update rule as R-MCA$_{\text{NN}}$ (for Neural Network).

Note that the function g_i in (25) resembles the softmax function (see, e.g., Yuille and Geiger, 2003), but contains an additional term in the denominator. This added term reduces the change in weights when an input pattern results in more than one hidden unit with significant activity. That is, the system tries to explain a given input pattern using the current state of its model parameters W. If one hidden unit explains the input better than any combination of two units, that unit is modified. If the input is better explained by a combination of two units, the total learning rate is reduced.

Soft winner-take-all (WTA) activation functions, such as the softmax, are found in many networks that serve to both cluster *and* extract components from inputs, as appropriate. For clustering, the relationship between WTA-like competition and maximum-likelihood methods is well known (Nowlan, 1990). The connection drawn here offers a probabilistic account of the effectiveness of similar rules for component identification. If the probability of more than one cause being active is small (i.e., π is small), our activation rule for g_i (25) reduces to the standard softmax, suggesting that neural networks with activation and learning functions that resemble Equations (25) may perform well at both component extraction and clustering.

6. Experiments

The MCA generative model, along with the associated learning algorithms that have been introduced here, are designed to extract component features from non-linear mixtures. To study their performance, we employ numerical experiments, using artificial as well as more realistic data. The artificial data sets are based on a widely-used benchmark for non-linear component extraction, while the more realistic data are taken from acoustic recordings in one case and from natural images in the other. The goals of these experiments are (1) to establish whether the approximate algorithms do indeed increase the likelihood of the model parameters; (2) to test convergence and asymptotic accuracy of the algorithms; (3) to compare component extraction using MCA to other component-extraction algorithms; and (4) to demonstrate the applicability of the model and algorithms to more realistic data where non-linear component combinations arise naturally.

6.1 The Bars Test

The data sets used in experiments on artificial data were drawn from variants of the "bars test" introduced by Földiák (1990). Each data vector represents a grayscale image, with a non-linear combination of randomly chosen horizontal and vertical light-colored bars, each extending all the way across a black background. Most commonly, the intensity of the bars is uniform and equal, and the combination rule is such that overlapping regions remain at the same intensity. This type of data is a benchmark for the study of component extraction with non-linear interactions between hidden causes. Many component-extraction algorithms have been applied to a version of the bars test, including some with probabilistic generative semantics (Saund, 1995; Dayan and Zemel, 1995; Hinton et al., 1995; Hinton and Ghahramani, 1997), as well as many with non-generative objective functions (Harpur and Prager, 1996; Hochreiter and Schmidhuber, 1999; Lee and Seung, 2001; Hoyer, 2004) a substantial group of which have been neurally inspired (Földiák, 1990; Fyfe, 1997; O'Reilly, 2001; Charles et al., 2002; Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004; Lücke and Bouecke, 2005; Spratling, 2006; Butko and Triesch, 2007).

In most of the experiments described here the input data were 25-dimensional vectors, representing a 5-by-5 grid of pixels; that is, $D = 5 \times 5$. There were b possible single bars, some of which were superimposed to create each image. On the 5-by-5 grid there are 5 possible horizontal, and 5 vertical, bar positions, so that $b = 10$. Each bar appears independently with a probability π, with areas of overlap retaining the same value as the individual bars. Figure 5A shows an example set of noisy data vectors constructed in this way.

6.2 Annealing

The likelihood surface for the MCA generative model is potentially multimodal. Thus, hill-climbing algorithms based on EM may converge to local optima in the likelihood, which may well be considerably poorer than the global optimum. This tendency to find sub-optimal fixed points can be reduced by incorporating a deterministic annealing, or relaxation, procedure (Ueda and Nakano, 1998; Sahani, 1999), whereby the entropy of the posterior distribution in the free energy (4) is artificially inflated in early iterations, with this inflation progressively reduced in later iterations, under the control of a temperature parameter. All of the experiments discussed here incorporated deterministic annealing, the details of which are given in Appendix E.

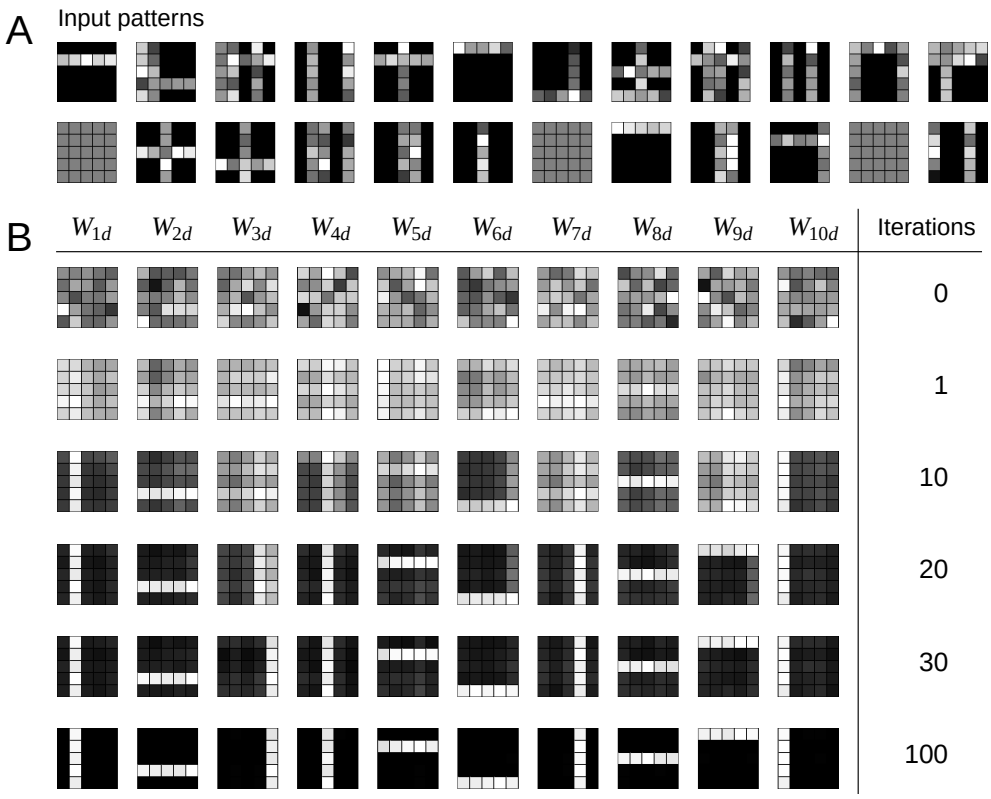

Figure 5: Bars test data with $b = 10$ bars on $D = 5 \times 5$ pixels and a bar appearance probability of $\pi = \frac{2}{10}$. **A** 24 patterns from the set of $N = 500$ input patterns that were generated according to the generative model with Poisson noise. **B** Change of the parameters W if MCA_3 is used for parameter update. Learning stopped automatically after 108 iterations in this trial (see Appendix E).

6.3 Convergence

From a theoretical standpoint, none of the four algorithms MCA_{ex}, MCA_3, R-MCA_2, or R-MCA_{NN}, can be guaranteed to maximize the likelihood of the MCA generative model. All of them update the parameters in the M-step using a fixed-point iteration, rather than either maximization or a gradient step. All but MCA_{ex} also approximate the posterior sufficient statistics (10). Thus, our first numerical experiments are designed to verify that the algorithms do, in fact, increase parameter likelihood in practice, and that they do converge. For this purpose, it is appropriate to use a version of the bars test in which observations are generated by the MCA model.

Thus, we selected MCA parameters that generated noisy bar-like images. There were 10 hidden sources in the generating model, one corresponding to each bar. The associated matrix of generating weights, W^{gen}, was 10×25, with each row representing a horizontal or vertical bar in a 5-by-5 pixel grid. The weights W^{gen}_{id} that correspond to the pixels of the bar were set to 10, the others to 0, so that $\sum_d W^{\text{gen}}_{id} = 50$. Each source was active with probability $\pi^{\text{gen}}_i = \frac{2}{10}$, leading to an average of two

bars appearing in each image. We generated $N = 500$ input patterns (each with 25 elements) using Equations (1) to (3); a subset of the resulting patterns is displayed in Figure 5A.

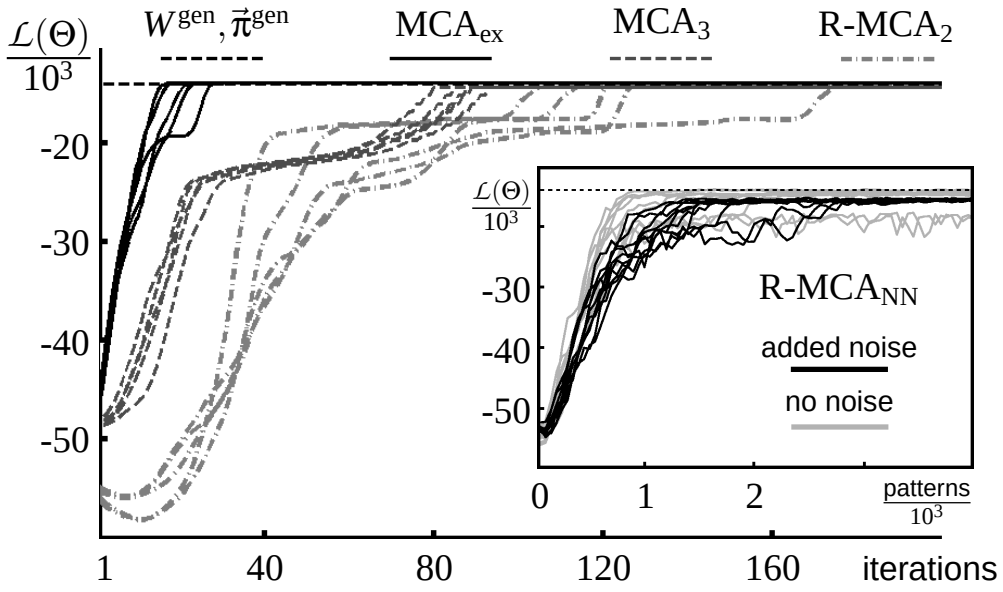

Figure 6: Change of the MCA parameter likelihood under different MCA learning algorithms. Data were generated as in Figure 5. To allow for comparison, the same set of $N = 500$ input patterns was used for all experiments shown. The likelihood of the generating parameters (W^{gen},$\vec{\pi}^{\text{gen}}$) is shown by the dotted horizontal line. The main axes show likelihood values of the batch-mode algorithms MCA_{ex}, MCA_3, and R-MCA_2 as a function of EM iteration. The inset axes shows likelihood values of the online algorithm R-MCA_{NN} as a function of number of input pattern presentations. Patterns were randomly selected from the set of $N = 500$ inputs, and the parameters were updated for each pattern.

Figure 6 shows the evolution of parameter likelihoods, as a function of iteration, for each of the MCA algorithms, with 5 different choices of initial parameters for each. With the exception of the first few iterations of R-MCA_2, the likelihood of the parameters under the batch mode algorithms increased at almost every iteration. The online R-MCA_{NN} showed greater fluctuations as updates based on individual data vectors inevitably perturbed the parameter estimates.

As might be expected, given the observation of increasing likelihoods and the fact that the likelihoods are bounded, each algorithm eventually converged from each initial value used in Figure 6. Furthermore, in each case, the likelihood of the solution found was close to the likelihood of the actual weights used in generation (the dashed horizontal lines). The final likelihood values for MCA_{ex} were slightly higher than the likelihoods of (W^{gen}, $\vec{\pi}^{\text{gen}}$), as is expected for an exact maximum-likelihood algorithm in noisy data; whereas the values achieved by the approximations MCA_3 and R-MCA_2 were slightly lower. In fact, in 100 further experiments, the annealing and parameter initialization schemes described in Appendix E, brought the likelihood close to that of the generating weights in 98 of 100 runs using R-MCA_2 and in 90 of 100 runs using MCA_3. We did not run

these more extensive tests for MCA_{ex} due to its long running time (it is also omitted from similar quantitative analyses below).

The two basic observations, that likelihoods generally increased at each iteration and that the batch-mode algorithms all reliably converged, held true for all of the experiments described here and below, even where data were not generated from a version of the MCA model. Thus, we conclude that these algorithms are generally robust in practice, despite the absence of any theoretical guarantees.

6.4 Parameter Recovery

Figure 5B shows the evolution of parameters W, under the approximate MCA_3 algorithm, showing that the estimated W did indeed converge to values close to the generating parameters W^{gen}, as was suggested by the convergence of the likelihood to values close to that of the generative parameters. While not shown, the convergence of W under MCA_{ex}, R-MCA_2 or R-MCA_{NN} was qualitatively similar to this sequence.

Clearly, if MCA_{ex} finds the global optimum, we would expect the parameters found to be close to those used for generation. The same is not necessarily true of the approximate algorithms. However, both MCA_3 and R-MCA_2 did in fact find weights W that were very close to the generating values whenever an obviously poor local optimum was avoided.

In MCA_3 the average pixel intensity of a bar was estimated to be 10.0 ± 0.5 (standard deviation), taken across all bar pixels in 90 trials where the likelihood increased to a high value. Using R-MCA_2 this value was estimated to be 10.0 ± 0.8 (across all bar pixels on 98 high-likelihood trials). Note that the Poisson distribution (2) results in a considerable variance of bar pixel intensities around the mean of 10.0 (compare Figure 5A) which explains the high standard deviation around the relatively precise mean value. The background pixels (original value zero) are estimated to have an intensity of 0.05 ± 0.02 in MCA_3 and are all virtually zero (all are smaller than 10^{-56}) in R-MCA_2. MCA_3 also estimates the parameters $\vec{\pi}$. Because of the finite number of patterns ($N = 500$) we compared the estimates with the actual frequency of occurrence of each bar i: $\pi'_i = (\text{numb of bars } i \text{ in input})/N$. The mean absolute difference between the estimate π_i and the actual probability π'_i was 0.006 (across the 90 trials with high likelihood), which demonstrates the relative accuracy of the solutions, despite the approximation made in Equation (17).

For the neural network algorithm R-MCA_{NN} given by (25) we observed virtually the same behavior as for R-MCA_2 when using a small learning rate (e.g., $\varepsilon = 0.1$) and the same cooling schedule in both cases (see Lücke and Sahani, 2007). The additional noise introduced by the online updates of R-MCA_{NN} had only a negligible effect. For larger learning rates the situation was different, however. For later comparison to noisy neural network algorithms, we used a version of R-MCA_{NN} with a relatively high learning rate of $\varepsilon = 1.0$. Furthermore, instead of a cooling schedule, we used a fixed temperature $T = 16$ and added Gaussian noise ($\sigma = 0.02$) at each parameter update: $\Delta W_{id} = \varepsilon g_i y_d + \sigma\eta$. With these learning parameters, R-MCA_{NN} learned very rapidly, requiring fewer than 1000 pattern presentations in the majority of trials. Ten plots of likelihoods against number of presented patterns are shown for R-MCA_{NN} in Figure 6 (inset figure, black lines) for the same $N = 500$ patterns as used for the batch-mode algorithms. Because of the additional noise in W, the final likelihood values were somewhat lower than those of the generating weights. Using R-MCA_{NN} with the same parameters but without added noise ($\sigma = 0$), final likelihood values were often higher (inset axes, gray lines) but the algorithm also converged to local optima more often. In

Reliability		
Model	noisy	no noise

R-MCA_2	98%	96%
R-MCA_{NN}	>99%	>99%

Reliability		
Model	no noise	reference
noisy-or	27%	Saund, 1995
competitive	69%*	Dayan/Zemel, 1995
LOCOCODE	96%	Hochreiter/Schmidhuber, 1999

Table 1: Comparison of MCA algorithms with other systems in the standard bars test with $b = 10$ bars ($D = 5 \times 5$, $\pi = \frac{2}{10}$, $N = 500$). For the MCA algorithms reliability values are computed on the basis of 100 trials. Values for these algorithms are also given for the same bars test with Poisson noise. Reliability values for the other systems are taken from the literature. For instance, the model of Hochreiter and Schmidhuber (1999) is reported to fail to extract all bars in one of 25 trials. Two systems, back-propagation (BP) and GeneRec, that are described by O'Reilly (2001) have also been applied to this bars test. In their standard versions, BP and GeneRec achieve 10% and 60% reliability, respectively. Hochreiter and Schmidhuber (1999) report that ICA and PCA extract only subsets of all bars. *Trained without bar overlap.

contrast, R-MCA_{NN} with noise avoided local optima in all 100 trials. In the following, R-MCA_{NN} will therefore refer to the noisy version with $\sigma = 0.02$ unless otherwise stated.

6.5 Comparison to Other Algorithms—Noiseless Bars

To compare the component extraction results of MCA to that of other algorithms reported in the literature, we used a standard version of the bars benchmark test, in which the bars appear with no noise. The competing algorithms do not necessarily employ probabilistic semantics, and may not be explicitly generative; thus, we cannot compare performance in terms of likelihoods, nor in terms of the accuracy with which generative parameters are recovered. Instead, we adopt a commonly used measure, which asks how *reliably* all the different bars are identified (see, e.g., Hochreiter and Schmidhuber, 1999; O'Reilly, 2001; Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004; Spratling, 2006). For each model, an internal variable (say the activities of the hidden units, or the posterior probabilities of each source being active) is identified as the response to an image. The responses evoked in the learned model by each of the possible single-bar images are then considered, and the most active unit or most probable source corresponding to each bar is identified. If the mapping from single-bar images to the most active internal variable is injective—that is, for each single bar a different hidden unit or source is the most active—then this instance of the model is said to have represented all of the bars. The reliability is the frequency with which each model represents all possible bars, when started from random initial conditions, and given a random set of images generated with the same parameter settings. For the MCA algorithms, the responses are defined to be the approximated posterior values for each possible source vector with only one active source, evaluated at the final parameter values after learning: $q(\vec{s}_h;\Theta) \approx p(\vec{s}_h\,|\,\vec{y}^{\,\mathrm{bar}},W)$.

The reliabilities of MCA_3, R-MCA_2, and R-MCA_{NN} as well as some other published component-extraction algorithms are shown in Table 1. These experiments used a configuration of the bars test much as above ($D = 5 \times 5$, $b = 10$, and $\pi^{\mathrm{gen}} = \frac{2}{10}$) which is perhaps the most commonly used

in the literature, (e.g., Saund, 1995; Dayan and Zemel, 1995; Hochreiter and Schmidhuber, 1999; O'Reilly, 2001). The bars have a fixed and equal gray-value. We generated $N = 500$ patterns according to these settings and normalized the input patterns $\vec{y}^{(n)}$ to lie in the interval $[0, 10]$ (i.e., bar pixels have a value of 10 and the background is 0). We considered both the case with Poisson noise (which has been discussed above) and the standard noiseless case. Experiments were run starting from 100 different randomly initialized parameters W. The same algorithms and the same cooling schedule were used (the same fixed T in the case of R-MCA$_{\text{NN}}$) to fit patterns with and without noise.

Without noise, MCA$_3$ with $H = 10$ hidden variables found all 10 bars in 81 of 100 experiments. R-MCA$_2$ with $H = 10$ found all bars in 96 of 100 experiments. Using the criterion of reliability, R-MCA$_{\text{NN}}$ performed best and found all bars in all 100 of 100 experiments. This seems likely to result from the fact that the added Gaussian noise, as well as noise introduced by the online updates, combined to drive the system out of shallow optima. Furthermore, R-MCA$_{\text{NN}}$ was, on average, faster than MCA$_3$ and R-MCA$_2$ in terms of required pattern presentations. It took fewer than 1000 pattern presentations to find all bars in the majority of 100 experiments,[1] although in a few trials learning did take much longer.

On the other hand, MCA$_3$ and R-MCA$_2$ achieved better likelihoods and recovered generative parameters closer to the true values. These algorithms also have the advantage of a well defined stopping criterion. MCA$_3$ learns the parameters of the prior distribution whereas R-MCA$_2$ uses a fixed value. R-MCA$_2$ does, however, remain highly reliable, even when the fixed parameter π differs significantly from the true value π^{gen}.

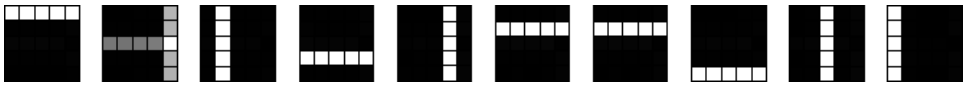

Figure 7: A common local optimum found by MCA$_3$ in the standard bars test. Two weight patterns reflect the same hidden cause, while another represents the superposition of two causes.

As was the case for the noisy bars, the R-MCA algorithms avoided local optima more often. This may well be a result of the smaller parameter space associated with the restricted model. A common local optimum for MCA$_3$ is displayed in Figure 7, where the weights associated with two sources generate the same horizontal bar, while a third source generates a weaker combination of two bars. This local solution is suboptimal, but the fact that MCA$_3$ has parameters to represent varying probabilities for each cause being present, means that it can adjust the corresponding rates to match the data. The fixed setting of π for R-MCA would introduce a further likelihood penalty for this solution.

Many component-extraction algorithms—particularly those based on artificial neural networks—use models with more hidden elements than there are distinct causes in the input data (e.g., Charles et al., 2002; Lücke and von der Malsburg, 2004; Spratling, 2006). If we use $H = 12$ hidden variables, then all the MCA-algorithms (MCA$_3$, R-MCA$_2$, and R-MCA$_{\text{NN}}$) found all of the bars in all of 100 trials.

1. Note that, according to the definition above, all bars are often already represented at intermediate likelihood values.

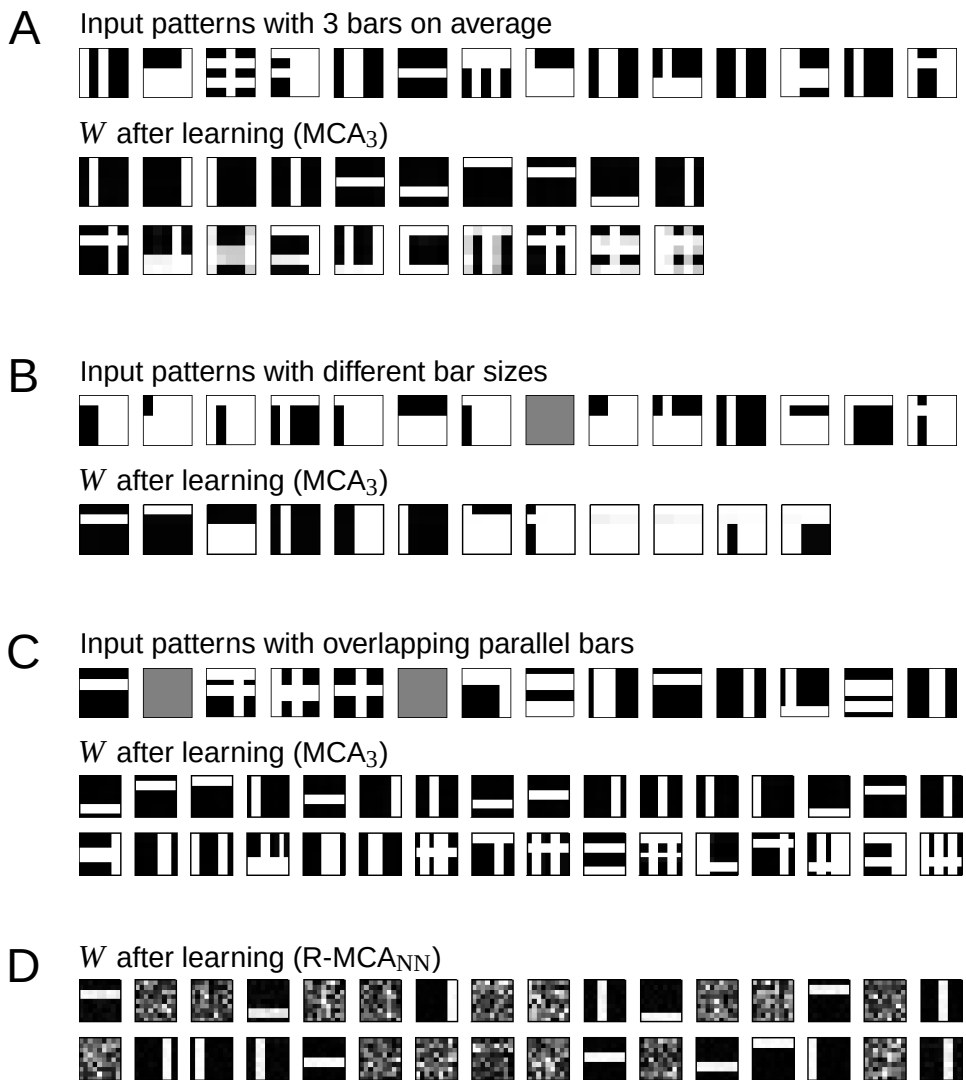

Figure 8: Experiments with increased bar overlap. In **A** bar overlap is increased by increasing the bar appearance probability to $\pi^{\text{gen}} = \frac{3}{10}$ (an average of three bars per pattern). In **B** bar overlap is varied using different bar widths (two one-pixel-wide bars and one three-pixel-wide bar for each orientation). In the bars test in **C** there are 8 (two-pixel-wide) horizontal bars and 8 (two-pixel-wide) vertical bars on a $D = 9 \times 9$ pixel grid. Each bar appears with probability $\pi^{\text{gen}} = \frac{2}{16}$ (two bars per input pattern on average). Each experimental data set is illustrated by 14 typical input patterns. For **A** to **C** the parameters W of a typical trial are shown if MCA$_3$ is used for learning. The vectors $\vec{W}_i = (W_{i1}, \ldots, W_{iD})$ appear in order of decreasing learned appearance probability π_i. In **D** the parameters W for a typical trial using R-MCA$_{\text{NN}}$ are shown.

6.6 Comparison to Other Algorithms—Bar Overlap

For most component-extraction algorithms that have been tested against the bars benchmark, it is difficult to know how specialized they are to the form of this test. The algorithms might, for example, depend on the fact that all bars appear with the same probability, or that they have the same width. Different versions of the bars test have therefore been introduced to probe how generally the different algorithms might succeed. In particular, there has been considerable recent interest in studying robustness to varying degrees of overlap between bars (see, e.g., Lücke and von der Malsburg, 2004; Lücke, 2004; Spratling, 2006). This is because it is the non-linear combination within the regions of overlap that most distinguishes the bars test images from linear superpositions of sources. In three different experiments we varied the degree of overlap in three different ways. Following Spratling (2006), in all experiments the MCA model had twice as many possible sources as there were bars in the generative input. In all experiments we used the same algorithms, initial conditions, and cooling schedules as described above and in Appendix E. Again, each trial used a newly generated set of training patterns and a different randomly generated matrix W. In the following, reliability values are computed on the basis of 25 trials each.

The most straightforward way to increase the degree of bar overlap is to use the standard bars test with an average of three instead of two bars per image, that is, take $\pi = \frac{3}{10}$ for an otherwise unchanged bars test with $b = 10$ bars on $D = 5 \times 5$ pixels (see Figure 8A for some examples). When using $H = 20$ hidden variables, MCA$_3$ extracted all bars in 92% of 25 experiments. Thus the algorithm works well even for relatively high degrees of superposition. The values of W found in a typical trial are shown in Figure 8A. The parameters $\vec{W}_i = (W_{i1}, \ldots, W_{iD})$ that are associated with a hidden variable or unit are sorted according to the learned appearance probabilities π_i. Like MCA$_3$, both R-MCA$_2$ and R-MCA$_{\text{NN}}$ were run without changing any parameters. In the restricted case, this meant that the assumed value for the source probability ($\pi = \frac{2}{10}$) was different from the generating value ($\pi^{\text{gen}} = \frac{3}{10}$). Nevertheless, the performance of both algorithms remained better than that of MCA$_3$, with R-MCA$_2$ and R-MCA$_{\text{NN}}$ finding all 10 bars in 96% and 100% of 25 trials, respectively.

We can also choose unequal bar appearance probabilities (cf., Lücke and von der Malsburg, 2004). For example, half the bars appeared with probability $\pi_h^{\text{gen}} = (1+\gamma)\,\frac{2}{10}$ and the other half[2] appeared with probability $\pi_h^{\text{gen}} = (1-\gamma)\,\frac{2}{10}$, MCA$_3$ extracted all bars in all of 25 experiments for $\gamma = 0.5$. For $\gamma = 0.6$ (when half the bars appeared 4 times more often than the other half) all bars were extracted in 88% of 25 experiments. For $\gamma = 0.6$ R-MCA$_2$ and R-MCA$_{\text{NN}}$ found all bars in 96% and 100% of 25 experiments respectively. Reliability values for R-MCA$_{\text{NN}}$ started to decrease for $\gamma = 0.7$ (92% reliability).

As suggested by Lücke and von der Malsburg (2004), we also varied the bar overlap in a second experiment by choosing bars of different widths. For each orientation we used two one-pixel wide bars and one three-pixel-wide bar. Thus, for this data set, $b = 6$ and $D = 5 \times 5$. The bar appearance probability was $\pi = \frac{2}{6}$, so that an input contained, as usual, two bars on average. Figure 8B shows some examples. MCA$_3$ extracted all bars in 84% of 25 experiments for this test. Reliability values decreased for more extreme differences in the bar sizes. R-MCA$_2$ and R-MCA$_{\text{NN}}$ both found all bars in all 25 trials each. Thus, although the unequal bar sizes violated the assumption $\sum_d W_{id} = C$ that was made in the derivation of R-MCA$_2$ and R-MCA$_{\text{NN}}$, the algorithms' performance in terms of reliability seemed unaffected.

2. If bars are numbered $h = 1$ to 5 for the horizontal and $h = 6$ to 10 for the vertical, we chose the ones with even numbers to appear with the higher probability.

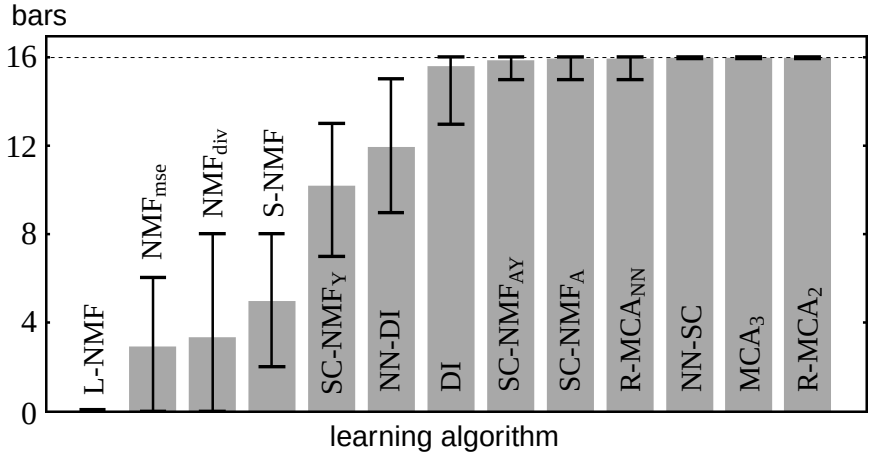

Figure 9: Comparison of MCA$_3$, R-MCA$_2$, and R-MCA$_{NN}$ with other systems in the bars test with increased occlusion (compare Figure 8C and Figure 2). Bars test parameters are $D = 9 \times 9$, $b = 16$, $\pi = \frac{2}{16}$, and $N = 400$. Data for the non-MCA algorithms are taken from Spratling (2006). The bar heights represent the average numbers of extracted bars in 25 trials. Error bars indicate the largest and the lowest number of bars found in a trial. The algorithms NN-DI and DI are feed-forward neural networks of the type depicted in Figure 4. All other (non-MCA) algorithms are versions of NMF with different objectives and constraints (see Appendix E and Spratling, 2006, for details).

In the third experiment we changed the degree of bar overlap more substantially, using a bars test that included overlapping parallel bars as introduced by Lücke (2004). We used eight horizontal and eight vertical bars, each two pixels wide, on a 9-by-9 grid. Thus, two parallel neighboring bars had substantial overlap. Figure 8C shows some typical input patterns. Note that the introductory example of Figure 2A,B is also of this type. To allow for a detailed comparison with other systems we adopted the exact settings used by Spratling (2006), that is, we considered 25 runs of a system with $H = 32$ hidden variables using bars test parameters $D = 9 \times 9$, $\pi^{\text{gen}} = \frac{2}{16}$, and $N = 400$. For these data, MCA$_3$ found all 16 bars in all of 25 experiments. The same is true for R-MCA$_2$ whereas R-MCA$_{NN}$ missed one bar in one of the 25 trials. Figure 9 shows a quantitative comparison with other algorithms that have been applied to this version of the bars test. Of the ten algorithms studied by Spratling (2006) just one, namely non-negative sparse coding (NN-SC; Hoyer, 2002, with sparseness parameter $\lambda = 1$), is as reliable as MCA$_3$ and R-MCA$_2$. The other systems, including forms of NMF both with and without a sparseness constraint, fail partly or entirely in extracting the actual hidden causes. For a typical trial using MCA$_3$ the final parameters W are displayed in Figure 8C. Again the $\vec{W}_i$'s associated with the different hidden variables are sorted according to their learned parameters π_i. A qualitatively different set of $\vec{W}_i$'s was obtained when R-MCA$_{NN}$ was used for learning. Figure 8D shows a typical outcome ($\vec{W}_i$'s are not sorted). In this case, only the actual causes are clearly represented whereas the $\vec{W}_i$'s of the supernumerary units remain unspecialized. The same feature is reported by Spratling (2006) for the algorithms NN-DI and DI used in this same test. Convergence to a representation that contains just the true hidden causes and leaves super-

numerary units unspecialized can improve the interpretability of the result. When using a higher fixed temperature for R-MCA$_{NN}$ all the hidden units represented bars, with some bars represented by more than one unit. However, hidden units that represented more composite inputs, as seen for MCA$_3$, were rarely observed. On the other hand, the parameters found by MCA$_3$ provide an indication of significance of each weight pattern in the appearance probabilities π_i. Thus, in Figure 8C the appearance probabilities for the first 16 sources are much higher than for the others. The later sources may be interpreted as capturing some of the higher-order structure that results from a finite set of input patterns. In contrast to R-MCA, such higher-order representations need not adversely affect the data likelihood because the corresponding appearance probabilities can be relatively small.

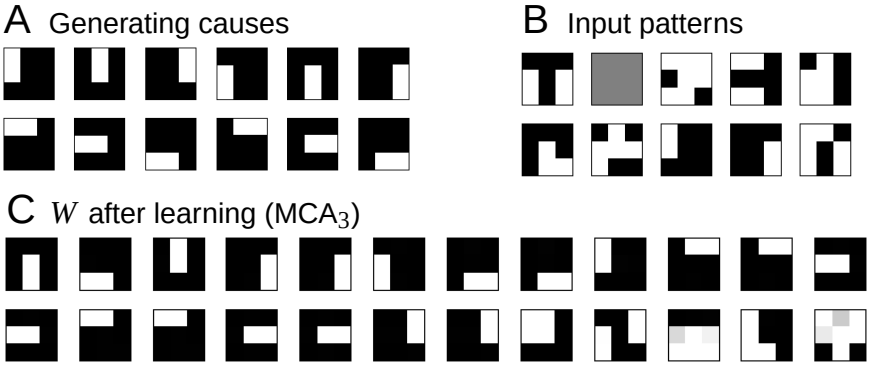

Figure 10: Experiments with more causes and hidden variables than observed variables. **A** The 12 patterns used to generate the data. Each is a 1-by-2 pixel bar on a 3-by-3 grid ($D = 9$). **B** Ten examples of the 500 input patterns generated using the causes shown in **A**. **C** Parameters W found in a typical run of MCA$_3$ with $H = 24$. The vectors $\vec{W}_i = (W_{i1}, \ldots, W_{iD})$ appear in order of decreasing learned appearance probability π_i.

6.7 More Causes than Observed Variables

In the experiments described above, the number of hidden causes was always smaller than the number of observed variables. We next briefly studied the "over-complete" case where data were generated, and models were fit, using more hidden causes than observed variables. We generated $N = 500$ patterns on a 3-by-3 grid ($D = 9$), using sparse combinations of 12 hidden causes corresponding to 6 horizontal and 6 vertical bars, each 1-by-2 pixels in size and thus extending across only a portion of the image (Figure 10A). As in the bars tests above, black was assigned to a value of 0 and white to 10. Patterns were generated without noise, with an average of two bars appearing in each ($\pi = \frac{2}{12}$). Ten such patterns are shown in Figure 10B.

Figure 10C shows the weights learned during a typical run using MCA$_3$ with the same parameter settings as above and twice as many hidden variables than observed ones ($H = 24$). Weights are sorted in order of decreasing inferred appearance probabilities π_i. All 12 causes were identified, with many represented more than once. A few hidden variables, with lower inferred probabilities of

appearance, were associated with more composite patterns. MCA_3 extracted all causes in all of 25 trials. R-MCA_2 also extracted all causes in all of 25 trials, and never represented composite patterns. R-MCA_{NN} only extracted all causes when run at fixed temperatures that were lower than those used for the bars tests above (e.g., $T = 3$), in which case it did so in all of 25 trials. This requirement for a lower temperature was consistent with the observation that a lower data dimension D leads to a decrease in the critical temperatures associated with the algorithms (see Appendix E). For larger values of T (e.g., $T = 16$) R-MCA_{NN} did not extract single causes.

6.8 Violations of Model Assumptions

To optimize the likelihood of the data under the MCA generative model, each of the approximate learning algorithms relies on the fact that, under the Bernoulli prior (1), some number of the observed data vectors will be generated by only a small number of active sources. To highlight this point we explicitly removed such sparse data vectors from a standard bars test, thereby violating the Bernoulli prior assumption of the generative model. We used bars tests as described above, with $b = 10$ or $b = 16$ bars and $\pi = \frac{2}{b}$, generating $N = 500$ (or more) patterns, in each case by first drawing causes from the Bernoulli distribution (1) and then rejecting patterns in which fewer than m causes were active. As might be expected, when m was 3 or greater the approximate algorithms all failed to learn the weights associated with single causes. However, when only patterns with fewer than 2 bars had been removed, MCA_3 was still able to identify all the bars in many of the runs. More precisely, using data generated as above with $b = 10$, $m = 2$ and $N = 500$, MCA_3 with $H = 10$ hidden variables found all causes in 69 of 100 trials with noisy observations and in 37 of 100 trials without noise (the parameters for MCA_3 and the associated annealing schedule were unchanged). Note that in these experiments the average number of active causes per input vector is increased by the removal of sparse data vectors. An increase in reliability in the noisy case is consistent with our other experiments. The relatively low reliability seen for noiseless bars in this experiment may be due to the combined violation of both the assumed prior and noise distributions.

As long as the data set did contain some vectors generated by few sources, the learning algorithms could all relatively robustly identify the causes given sufficient data, even when the average observation contained many active sources. For instance, in a standard noiseless bars test with $b = 16$ bars on an 8×8 grid, and $N = 1000$ patterns with an average of four active causes in each ($\pi = \frac{4}{16}$), all three algorithms still achieved high reliability values, using twice as many hidden variables as actual bars ($H = 32$), and using the same parameters as for the standard bars test above. MCA_3 found all causes in 20 of 25 trials in these data (80% reliability). Reliabilities of R-MCA_2 and R-MCA_{NN} (25 trials each) were 76% and 100%, respectively. The reliabilities of all algorithms fell when the data set contained fewer patterns, or when the average number of bars per pattern was larger.

6.9 Applications to More Realistic Data

We study two examples of component extraction in more realistic settings, applying the MCA algorithms to both acoustic and image data.

Acoustic data. Sound waveforms from multiple different sources combine linearly, and so are conventionally unmixed using algorithms such as ICA applied to simultaneous recordings from multiple microphones. The situation is different, however, for *spectrogram* representations of natural

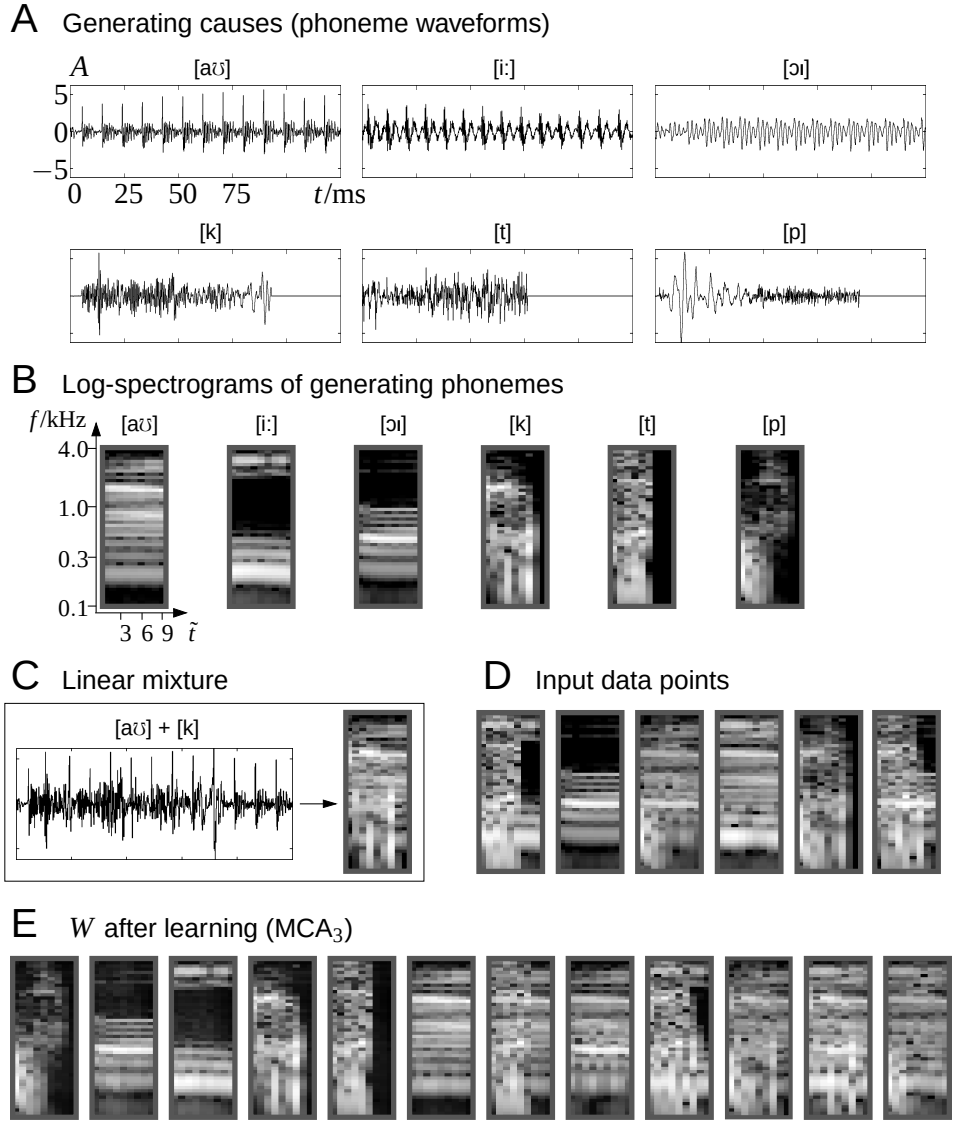

Figure 11: Application to acoustic data. **A** Pressure waveforms of six phonemes spoken by a male voice. Axes here, and for the waveform in **C**, are as shown for [aʊ] (A is a normalized amplitude). **B** The log-spectrograms of the phonemes in **A**. We use 50 frequency channels and nine time windows ($\tilde{t} = 1, \ldots, 9$). Axes of all log-spectrograms in the figure are as shown for [aʊ]. **C** Waveform of the linear mixture of phonemes [aʊ] and [k], and the log-spectrogram of this linear mixture. **D** Six examples of the $N = 500$ data vectors that were used for the experiments. Each data vector is the log-spectrogram of a linear mixture of the phoneme waveforms in **A**. The data sets for the experiments used an average of two waveforms per data vector. **E** Parameters W found by MCA_3 with $H = 12$, using 500 mixture log-spectrograms. The parameter vectors $\vec{W}_i = (W_{i1}, \ldots, W_{iD})$ appear in order of decreasing learned appearance probability π_i and are linearly scaled to fill the gray scale.

sound. The power of natural sounds in individual time-frequency bins varies over many orders of magnitude, and so is typically measured logarithmically and expressed in units of decibels, giving a representation that is closely aligned with the response of the cochlea to the corresponding sound. In this representation, the combination of log-spectrograms of the different sources may be well approximated by the max rule (R. K. Moore, 1983, quoted by Roweis, 2003). In particular, the logarithmic power distribution, as well as the sub-linear power summation due to phase misalignment, both lead to the total power in a time-frequency bin being dominated by the single largest contribution to that bin (see Discussion).

To study the extraction of components from mixtures of sound by MCA, we based the following experiment on six recordings of phonemes spoken by a male voice (see Figure 11A). The phoneme waveforms were mixed *linearly* to generate $N = 500$ superpositions, with each phoneme appearing in each mixture with probability $\pi = \frac{2}{6}$. Thus each mixture comprised two phonemes on average, with a combination rule that resembled the MCA max-rule in the approximate sense described above.

We applied the MCA algorithms to the log-spectrograms of these mixtures. Figure 11B shows the log-spectrograms of the individual phonemes and Figure 11C shows the log-spectrogram of an example phoneme mixture. We used 50 frequency channels and 9 time bins to construct the log-spectrograms. The resulting values were thresholded and then rescaled linearly so that power-levels across all phonemes filled the interval $[0, 10]$, as in the standard bars test. For more details see Appendix E.

The MCA algorithms were used with the same parameter settings as in the bars tests above, except that annealing began at a lower initial temperature (see Appendix E). As in the bars tests with increased overlap, we used twice as many hidden variables ($H = 12$) as there were causes in the input. Figure 11E shows the parameters W learned in one run using MCA_3. The parameter vectors $\vec{W}_i = (W_{i1}, \ldots, W_{iD})$ are displayed in decreasing order of the corresponding learned value of π_i. As can be seen, the first six such vectors converged to spectrogram representations similar to those of the six original phonemes. The six hidden variables associated with lower values of π_i, converged to weight vectors that represented more composite spectrograms. This result is representative of those found with MCA_3. R-MCA_2 also converged to single spectrogram representations, but tended to represent those single spectrograms multiple times rather than representing more composite patterns with the additional components. Results for R-MCA_{NN} were very similar to those for R-MCA_2 when we used a high fixed temperature (see Appendix E for details). For intermediate fixed temperatures, results for R-MCA_{NN} were similar to those of the bars test in Figure 8D in that each cause was represented just once, with additional hidden units displaying little structure in their weights. For lower fixed temperatures (starting from $T \approx 40$) R-MCA_{NN} failed to represent all causes.

In general, the reliability values of all three algorithms were high. These were measured as described for the bars tests above, by checking whether, after learning, inference based on each individual phoneme log-spectrogram led to a different hidden cause being most probable. MCA_3 found all causes in 21 of 25 trials (84% reliability), R-MCA_2 found all causes in all of 25 trials; as did R-MCA_{NN} (with fixed $T = 70$). Reliability for MCA_3 improved to 96% with a slower cooling procedure ($\theta_{\Delta W} = 0.25 \times 10^{-3}$; see Appendix E).

Visual data. Finally, we consider a data set for which the exact hidden sources and their mixing rule are unknown. The data were taken from a single 250-by-250 pixel gray-level image of grass taken

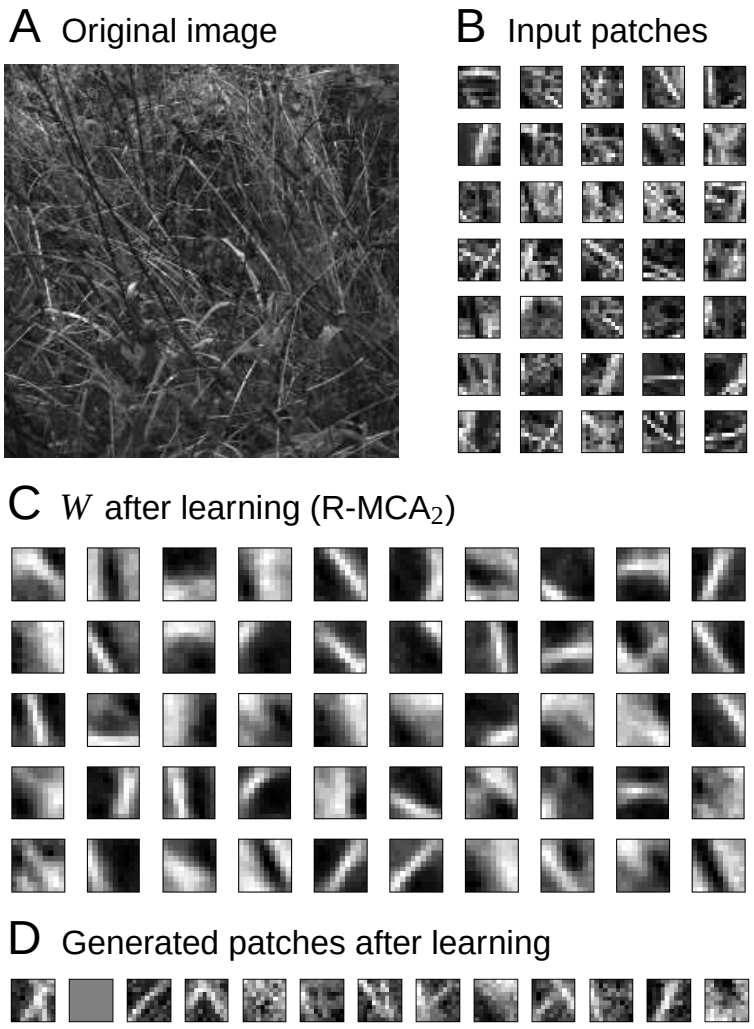

Figure 12: Application to visual data. **A** The 250-by-250 pixel image used as basis for the experiments. The image is taken from the van Hateren database of natural images (see Appendix E). For visualization we have brightened the image (we let values in the lower half of the light intensity range fill the range of gray values from zero to 255 and clamped values in the upper half to value 255). Without brightening, the image would appear unnaturally dark on a finite gray scale because of a small number of pixels with very high values. **B** 35 examples taken from the 5000 10-by-10 pixel patches that were used for numerical experiments. The patches represent light intensities linearly. For visualization, each patch has been scaled to fill the range of gray values. **C** Parameters W resulting from a typical run of R-MCA$_2$ with $H = 50$ hidden variables and $N = 5000$ image patches. For visualization, each parameter vector $\vec{W}_i = (W_{i1}, \ldots, W_{iD})$ has been linearly scaled to fill the range of gray values. **D** Patches generated using the restricted generative model and weights as in **C** (patches have been scaled as in **B** and **C**).

from the van Hateren database (Figure 12A) and linearly rescaled so that pixel intensities filled the interval $[0,10]$. Each data vector was a 10-by-10 pixel patch drawn from a random position in the image (see Figure 12B for some examples).

The image comprised stems and blades of grass which occluded each other. As discussed above (see, e.g., Figure 2), the combination rule for such objects may be well approximated by the max rule of the MCA generative model (at least for the lighting conditions that appear to prevail in Figure 12A). Thus, the MCA learning algorithms may be expected to converge to parameters W that represent intensity images of 'grass'-like object parts. However, each blade of grass might appear at many different positions within the image patches, rather than at a fixed set of possible locations as in the bars test. Thus to recover these grass-like elements in the MCA causal weights requires the use of models with large numbers of hidden variables (and, correspondingly, many data vectors). For the number of patches and hidden variables required, the cubic cost of MCA_3 led to impractically long execution times. In experiments with smaller patch sizes and small H (e.g., $H = 10$ or $H = 20$) some weight patterns did converge to represent 'grass'-like objects, but many converged to less structured configurations.

The computational cost of R-MCA_2 is smaller and we evaluated trials using $H = 50$ hidden variables and $N = 5000$ 10-by-10 patches. R-MCA_2 was used with the same parameter setting as for the bars tests above, except for lower initial and final temperatures for annealing (see Appendix E). Figure 12C shows a typical outcome obtained when cooling from $T = 4.0$ to $T = 1.0$. A large number of weight vectors have converged to represent 'grass'-like object parts, whereas others represent more extensive causes that might be interpreted as capturing background noise. Many of the weight patterns have an orientation similar to the dominant orientation in the original image. Figure 12D shows a selection of patches generated using the learned weights. We used a higher value of C during generation than during learning (the parameter is not learned with R-MCA_2), thus globally rescaling the learned weights, so as to reduce the apparent noise level. In experiments where annealing was terminated at $T = 1.5$ (as in the bars test), the resulting weights were generally similar to the ones in Figure 12C, but with a larger proportion of weight vectors showing little structure. Learning with slower annealing did not result in significantly different weights. With fewer than $N = 5000$ patches for training, the weight patterns were less smooth, presumably reflecting overfitting to the subset of data used.

In experiments applying the online algorithm R-MCA_{NN} to a set of 5000 10-by-10 patches as above, we found that it would converge to 'grass'-like weight patterns provided the learning rate (ε in Equation 25) was set to a much lower value than had been used in the bars tests. A lower learning rate corresponds to effectively averaging over a much larger set of input patterns. With $\varepsilon = 0.02$ (instead of 1.0 as above), and with noise on the weights (σ) scaled down by the same factor, R-MCA_{NN} converged to weights similar to those shown in Figure 12C (for R-MCA_2), although a larger number of hidden units showed relatively uniform weight structure. For R-MCA_{NN} we used a fixed temperature of $T = 2.0$.

7. Discussion

We discuss the applicability of the MCA learning algorithms, and the generality of the MCA framework, before relating the new algorithms to previous methods and neural network systems.

7.1 Applicability of the Model

The MCA generative model and associated learning algorithms are designed to extract causal components from input data in which the components combine non-linearly. More precisely, the generative model assumes that the single active cause with the strongest influence on a particular observed variable alone determines its observed value—something we have referred to here as the max-rule for combination. This stands in contrast to other feature extraction models such as PCA, ICA, NMF, or SC, in which the influences of the different causes are summed.

One context in which data with a superposition property very close to the max-rule arise naturally is the psychoacoustic combination of sounds. The perception of sound is largely driven by the logarithm of the time-varying intensity within each of a bank of narrow-band frequency channels. The narrow-band, short-time intensity of natural sounds may vary over many orders of magnitude. Further, sounds from different sources may have unrelated phases, and so intensities within each channel will generally add sub-linearly. Thus, even though sound *waveforms* from different sources combine linearly, the time- and frequency-local *intensities*, expressed logarithmically (in decibels), are dominated by the loudest of the sounds within each time-frequency bin. Indeed, even if two sounds are of equal loudness, the intensity of the sum is greater than each of them by at most 3 dB. Here, then, the max-rule is a very good approximation to the true generative combination. This observation motivated our use of acoustic data in the experiments shown in Figure 11.

In the image domain, the max-rule's relevance comes from the fact that it matches the true occlusive combination rule more closely than does the more commonly used sum. This is true both quantitatively (see Figure 2 and the discussion thereof), and also qualitatively, in the sense that both occlusion and the max-rule share a property of exclusiveness—that is, only one of the hidden causes determines the value of each pixel. Numerical experiments on raw image data (Figure 12) demonstrate that plausible generative causes are extracted using the MCA approach. The weight patterns associated with the extracted causes resemble images of the single object parts (blades and stems of grass in our example) that combine non-linearly to generate the image. The MCA approach also holds some potential for component extraction in more low-level image processing, for example, if we assume that each input pixel is generated exclusively by one edge instead of a whole object or object part. The application of MCA might, however, be less straight-forward in this case and presumably requires image preprocessing and perhaps a different noise model.

7.2 Generality of the Framework

Many of the details of the algorithms presented here, as well as many of the experiments, have been based on a specific model in which the hidden variables are drawn from a multivariate Bernoulli distribution (1), and the observations are then Poisson, conditioned on these values (2). These choices are natural ones for non-negative data generated from binary sources (cf., NMF; Lee and Seung, 1999, 2001). However, while the details have largely been omitted for brevity, it is straightforward to incorporate alternative generative distributions within the same framework, and with the same approximations.

Thus, the equations that define the M-step (9), as well as the expansion (15) used to approximate the E-step, would hold for any well-behaved prior over binary variables. In particular, the sources need not be marginally independent. This generality contrasts with the key assumption of independence that underlies many linear combination models. It suggests that an extension to a

hierarchical model, in which higher-order statistics in the source distribution were captured by a further parametric model, might be straightforward.

The general formalism also remains unchanged for different noise distributions. Thus, if the conditional distribution of observations given sources, here Poisson, were instead Gaussian, all of the derivations and approximations would essentially remain unchanged, with one exception being the definitions of $I_i^{(n)}$, $I_{ab}^{(n)}$, and $I_{abc}^{(n)}$ in Equation (18). Approximate learning for the additional variance parameter of a Gaussian distribution would also be straightforward, largely following the arguments developed for the parameters W and $\vec{\pi}$. If suited to the data set under consideration, distributions other than Poisson and Gaussian may also be used within this same framework, and combined with different dependent or independent prior distributions.

7.3 Relationship to Variational Approximations

A now standard approach to approximate learning in intractable models is to replace the true posterior distribution of equation (12) by an approximate q_n that is obtained by minimizing the Kullback-Leibler divergence $\mathsf{KL}[q_n \| p(\vec{s}|\vec{y}^{(n)}, \Theta')]$ within a constrained class of functions. This provides a form of variational learning (Jordan et al., 1999), which provably increases a lower bound on the likelihood at every iteration. A common choice of a constrained family might be one which factors over the latent variables. Unfortunately, this common choice is of little benefit in the MCA generative model, as the costs of evaluation of the expected values of the derivatives $\mathcal{A}_{id}(\vec{s}, W)$, given in (8), grows exponentially even under factored distributions.

An alternative approach would be to constrain q_n to place mass only on source configurations where a limited number of causes are active. The minimum Kullback-Leibler divergence under this constraint would then be achieved when the probability of such sparse configurations under q_n was proportional to the corresponding true posterior values. Revisiting the argument leading to equation (15), it is clear that such an approximation would correspond to truncating the sums in both numerator and denominator of (15), as well as the corresponding expression for $\langle s_h \rangle_{q_n}$, at the same point. Our experience has been that the algorithms described here, in which fewer terms are kept in the numerator of (15) than in the denominator, always perform better than this strict variational approach.

7.4 The Different MCA Algorithms

The computational cost of exact expectation-maximization learning (i.e., MCA_{ex}) in the MCA generative model grows exponentially in the smaller of the number of observation dimensions and the number of hidden variables ($\min(D, H)$), and is thus generally intractable. We have introduced three approximations, all based on early truncation of the expanded sums in Equation (15). One of these, MCA_3, with cubic computational complexity, learns all the parameters of the full generative model, including the prior source probabilities. However, if the sums over source distributions are truncated further, to yield an algorithm with quadratic complexity, experimental performance of an otherwise unconstrained algorithm suffers. This difficulty is avoided in the restricted version of the generative model, in which the prior probabilities are held fixed and equal, and the weights associated with the sources satisfy a homogeneous coverage property. In this restricted model, the quadratic-cost algorithm becomes effective, and we have studied both a batch-mode algorithm, R-MCA_2, and an online version R-MCA_{NN}. Experiments showed that these restricted algorithms remained effective in terms of identifying generative weight vectors, even when the data were generated with prior

source probabilities that were substantially different from that assumed by the algorithms (see, e.g., the experiments of Figure 8A or the discussion of violations of model assumptions in Experiments). Furthermore, the R-MCA algorithms were also robust to violations of the assumption of homogeneously distributed hidden causes (20). In some situations, the R-MCA algorithms succeeded in extracting the true causes where MCA_3 did not. We have observed that this is particularly true for bars with large differences in intensity. For this type of data, R-MCA_2 appears to be the most robust of the algorithms (see Lücke and Sahani, 2007). The R-MCA algorithms may also be more robust to greater differences in bar widths than those that we have studied here. Overall, in terms of the reliability with which hidden sources are recovered, R-MCA_2 and R-MCA_{NN} may outperform MCA_3 even in experiments in which the assumptions used to derive them are violated. These results suggest that constrained optimization can improve measures such as reliability or learning time (in terms of pattern presentations), even when the constraint is not exactly valid. Approximately valid constraints may make it easier to avoid local optima, and to learn from fewer examples. However, the more severe approximation of R-MCA_2 and R-MCA_{NN} can affect the likelihood of the parameters found. In this sense, MCA_3 is the more successful algorithm. One approach to increasing the speed of convergence might be to use R-MCA_{NN} to provide initial values to MCA_3, thus reducing the number of cubic-complexity iterations required for final convergence. Such a hybrid algorithm would provide a learning system with relatively short learning times, high final likelihoods and high reliability.

7.5 Relationship to Previous Algorithms

It is helpful to divide the algorithms that have previously been proposed for component extraction into three groups: generative models with linear superposition, competitive generative models, and neural network models in which assumptions about the data are implicit in the network structure and learning algorithm.

7.5.1 LINEAR SUPERPOSITION MODELS

The functional difference between linear superposition and the max-rule has been discussed above. Despite the mismatch in the generative process, linear superposition models have been used within non-linear component extraction contexts, with some success. In particular, the non-negativity constraints of NMF have helped to identify constructively combined features (Lee and Seung, 1999).

For non-negative data, the specific algorithms developed here (MCA_3, R-MCA_2, and R-MCA_{NN}) can all be regarded as explicitly non-linear alternatives to the different versions of NMF. In particular, the Poisson noise distribution matches one of the cost functions often used with NMF (Lee and Seung, 1999). The basic methodology of our MCA development is, however, independent of the assumption of non-negativity.

It is worth noting that non-negativity may be better suited to finding featural sub-parts (cf., Lee and Seung, 1999; Wersing and Körner, 2003) of generative components (as was, in fact, originally proposed) than the entire components. In the bars test (with $b = 16$) Spratling (2006) showed that at least some NMF algorithms succeed in extracting all of the bars. However, if the bar overlap is increased (as in the test depicted in Figure 2 and Figure 8C), most NMF algorithms fail. For such input data, NMF only succeeds if its objective function is extended by an additional term that enforces a form of sparseness. MCA_3 and R-MCA_2 perform better on these data than all other algorithms tested (see Figure 9 for results) except for one sparse-NMF version (NN-SC; Hoyer,

2002) that performs equally well. However, for this and other sparse versions of NMF the sparseness parameter (or parameters) must be chosen either based on prior knowledge about the input, or by trial-and-error (see Spratling, 2006, for a critical discussion).

In contrast, the *generative model* underlying MCA does not assume sparseness. Instead, the notion of sparseness was introduced in the discussion of learning, to justify the tractable approximate learning algorithms MCA_3, R-MCA_2, and R-MCA_{NN}. The truncated approximations that underlie these algorithms are more accurate when the input causes are sparsely active; but this does not incorporate an explicit prior for sparsity in the way that SC, ICA, or sparse-NMF do, and does not enforce a pre-specified degree of sparseness in the learned generative model. Indeed, the MCA algorithms were found to robustly optimize the data likelihood, even for input causes that were not sparsely active on average. It is possible, however, that if data were generated by a process that was substantially different from that assumed by MCA, the approximate algorithms might well introduce a bias towards a sparser solution. These differences in approach to sparsity between MCA and models such as SC, ICA, and sparse-NMF, suggest that MCA might provide a good basis from which to study the relationship between non-linear component combinations and sparsity assumed in learning algorithms.

7.5.2 COMPETITIVE GENERATIVE MODELS

Models that use an explicitly non-linear generative combination rule include those of Saund (1995), which uses a noisy-or rule for binary observations, and of Dayan and Zemel (1995), where the combination scheme is more competitive. The MCA model may be viewed as taking this competition to an extreme, by selecting just one hidden variable to be responsible for each observed one.

Competitive generative models have proven challenging from a learning standpoint, in that published algorithms often converge to local optima. In the bars test ($b = 10$, $N = 500$) the noisy-or algorithm (Saund, 1995) finds all bars in just 27% of trials. The more competitive scheme (Dayan and Zemel, 1995) only extracts all bars if bar overlap is excluded for training, that is, if training patterns only contain parallel bars. In this simplified case the system achieves 69% reliability.

For comparison, the MCA learning algorithms MCA_3, R-MCA_2, and R-MCA_{NN} all show significantly higher values of reliability in the same bars test (see Table 1), at least when combined with an annealing procedure. The reliability can be boosted further in two ways—either by adding Poisson noise to the input (Table 1), or by adding more hidden variables or units to the model (in which case all three MCA algorithms find all 10 bars in all of our experiments).

7.5.3 NEURAL NETWORK MODELS

High reliability in component extraction in the bars test is not a feature exclusive to the new algorithms presented. Other highly reliable systems include some that optimize a non-probabilistic objective function (e.g., Charles and Fyfe, 1998; Hochreiter and Schmidhuber, 1999; Charles et al., 2002) as well as neural network models (Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004; Lücke, 2004; Lücke and Bouecke, 2005; Spratling, 2006; Butko and Triesch, 2007). While the probabilistic generative approach has the advantage of a principled framework, which makes clear the assumptions being made about the data, it has been criticized (Hochreiter and Schmidhuber, 1999; Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004) for not working reliably—that is, for often failing to extract the true causes.

The models and algorithms introduced here show that a generative approach can indeed be made robust. The R-MCA$_{NN}$ algorithm shows that generative and neural network approaches can come together in the form of a competitive neural network model that is both reliable and probabilistically interpretable. Using a high learning rate and additional noise, the network model R-MCA$_{NN}$ avoids local optima and needs few pattern presentations for learning (less than 1000 in the majority of trials). The same is reported for other network models (Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004; Spratling, 2006) which fit into the framework of Equation (23) and Figure 4. The appropriate activation rule for a network to optimize the data likelihood under our generative model turns out to be a generalization of the softmax rule (see Equation 25). For input generated by very sparsely active causes, this generalization reduces to the usual softmax, which is commonly used for clustering (see, e.g., McLachlan and Peel, 2000). The generalized rule (25) therefore offers an explanation for why some networks (Spratling and Johnson, 2002; Lücke and von der Malsburg, 2004; Lücke, 2004) can also be successfully applied to clustering tasks. However, R-MCA$_{NN}$ and standard neural network algorithms can differ in the details of their behavior. On the one hand, for data involving substantial overlap between components (e.g., Figure 9), R-MCA$_{NN}$ seems to be more robust than the DI and NN-DI networks discussed by Spratling (2006). On the other hand, DI and the network of Lücke and von der Malsburg (2004) seem to be more robust to larger differences in component sizes.

A distinguishing feature of our model is the use of the max function. In neural modeling this function has also been used in other contexts and for other purposes. Among other models (e.g., Grzywacz and Yuille, 1990) it has been used as an activation function for hidden units in a feedforward model for visual object recognition (Riesenhuber and Poggio, 1999). However this use in the recognition model should not be confused with our use of the max function in the generative process. Indeed, inference within the MCA model shows that the appropriate activation function of hidden units, for example, (16) or (22), is necessarily more complex. The extraction of input components, for example, in the bars test, fails if a simple max is used for inference instead. However, for input without superposition (and for recognition after learning) a max function as used by Riesenhuber and Poggio (1999) may be interpreted as a further approximation of the generalized softmax in the neural network approximation of R-MCA$_{NN}$.

7.6 Conclusion

To conclude, we have formulated a novel class of generative models that competitively combines hidden causes. In place of the linear superposition of prominent models like PCA, ICA, SC, and NMF, we use the max-operation. We have shown how a new technique for posterior approximation in such models can provide efficient parameter update rules if the input causes are sparsely active. Making specific choices for prior and noise distributions, we obtain efficient algorithms that performed well on artificial and natural non-linear mixtures, and are found to be competitive with the best current performance on standard non-linear benchmarks.

Appendix A. Maximum Likelihood

To maximize $\mathcal{F}(\Theta,\Theta')$ in (5) with respect to W_{id} we require that:

$$\begin{aligned}
& \frac{\partial}{\partial W_{id}}\mathcal{F}(\Theta,\Theta') \;\stackrel{!}{=}\; 0 \\
\Rightarrow\quad & \sum_n \sum_{\vec{s}} q_n(\vec{s};\Theta') \sum_{d'} \left(\frac{\partial}{\partial W_{id}} \log\left(p(y_{d'}^{(n)} \,|\, \overline{W}_{d'}(\vec{s},W)) \right) \right) \;\stackrel{!}{=}\; 0 \\
\Rightarrow\quad & \sum_n \sum_{\vec{s}} q_n(\vec{s};\Theta') \left(\frac{\partial}{\partial W_{id}} \overline{W}_d(\vec{s},W) \right) f(y_d^{(n)}, \overline{W}_d(\vec{s},W)) \;\stackrel{!}{=}\; 0\,, \qquad (26) \\
& \text{where} \qquad f(y,w) = \frac{\partial}{\partial w}\log(p(y\,|\,w))\,, \qquad (27)
\end{aligned}$$

with $p(y|w)$ given in (2). Now, for any well-behaved function g, and large ρ:

$$\mathcal{A}_{id}^{\rho}(\vec{s},W)\, g(\overline{W}_d(\vec{s},W)) \approx \mathcal{A}_{id}^{\rho}(\vec{s},W)\, g(W_{id})\,, \text{ where } \mathcal{A}_{id}^{\rho}(\vec{s},W) := \frac{\partial}{\partial W_{id}} \overline{W}_d^{\rho}(\vec{s},W). \qquad (28)$$

Equation (28) holds because $\mathcal{A}_{id}^{\rho}(\vec{s},W) \approx 0$ whenever $\overline{W}_d(\vec{s},W) \neq W_{id}$. Hence it follows from (26) that:

$$\begin{aligned}
& \sum_n \sum_{\vec{s}} q_n(\vec{s};\Theta')\, \mathcal{A}_{id}^{\rho}(\vec{s},W)\; f(y_d^{(n)}, W_{id}) \;\stackrel{!}{\approx}\; 0\,, \qquad (29) \\
\Rightarrow\quad & \sum_n \sum_{\vec{s}} q_n(\vec{s};\Theta')\, \mathcal{A}_{id}^{\rho}(\vec{s},W) \left(y_d^{(n)} - W_{id} \right) \;\stackrel{!}{\approx}\; 0\,. \qquad (30)
\end{aligned}$$

Equation (9) is obtained in the limit of large ρ. To be more precise, we might have used $\mathcal{A}_{id}^{\rho}(\vec{s},W)$ instead of $\mathcal{A}_{id}(\vec{s},W)$ in the main text. However, we abstained from doing so for the sake of readability, and because only the limit $\rho \to \infty$ is needed to derive the learning algorithms. The expression for this limit given in Equation (8) is found from (7), with the derivative of $\overline{W}_d^{\rho}$ given by:

$$\frac{\partial}{\partial W_{id}} \overline{W}_d^{\rho}(\vec{s},W) = \left(\frac{s_i\,(W_{id})^{\rho}}{\sum_h s_h (W_{hd})^{\rho}} \right) \frac{\left(\sum_h s_h (W_{hd})^{\rho}\right)^{\frac{1}{\rho}}}{s_i\, W_{id}}\,. \qquad (31)$$

In the limit $\rho \to \infty$ this reduces to (8) because the second factor on the right-hand-side converges to 1 whenever the first term is nonzero.

Note that (29) is true for any type of conditionally independent noise distribution. Only in the final step, from Equation (29) to (30), is the specific form of the Poisson distribution needed, where it appears in the derivative (27).

Appendix B. Intractability of Sufficient Statistics

To compute the exact sufficient statistics in (10) requires the evaluation of sums over all possible hidden states $\vec{s}$, suggesting a computational complexity of 2^H. In some cases, however, there may be multiple different source configurations, all of which result in the same effective weights $\overline{W}_d(\vec{s},W)$ for all dimensions $d \in \{1,\ldots,D\}$. In such cases, it might be possible to group these equal terms in each of the sums together, thereby reducing the complexity of the sum to scale with the number of

such groups, rather than with the number of source configurations. In fact, we show below that the complexity of computing these expected values in general scales at least as fast as $2^{\min(H,D)}$.

We examine three cases individually:

$H = D$ Consider parameters W for which, corresponding to each observed node d, there is a hidden node i such that $W_{id} > W_{jd}$ for all $j \neq i$ (beyond this restriction, the entries in W may have arbitrary values). For $H = D$ this condition can be satisfied, and if it is, then for any two hidden vectors $\vec{s}$ and $\vec{s}'$ there is a d such that $\overline{W}_d(\vec{s},W) \neq \overline{W}_d(\vec{s}',W)$. In other words: any change of the hidden vector $\vec{s}$ results in a change of the pre-noise output vector $(\overline{W}_1(\vec{s},W),\ldots,\overline{W}_D(\vec{s},W))$. Hence, each summand in the partition function in (12) contributes a potentially different value, and they must be evaluated one-by-one. Thus, in this case the computational cost scales as 2^H.

$H < D$ Consider a subset of H of the D observed nodes and apply the argument above. Thus, the computational cost scales as 2^H. Note that for fixed H and random parameters W the existence of H (or approximately H) hidden nodes for which the above condition is fulfilled becomes increasingly likely with increasing D.

$H > D$ On the one hand, if we just consider D of the H hidden nodes and apply the argument above, we can infer that the computational complexity grows with at least 2^D. On the other hand, we can obtain at most $H^D + 1$ different vectors $(\overline{W}_1(\vec{s},W),\ldots,\overline{W}_D(\vec{s},W))$ and thus at most $H^D + 1$ groups to sum over. The computational complexity thus lies between 2^D and $H^D + 1$ in this case.

Appendix C. MCA$_3$ and R-MCA$_2$—Details of the Derivations

The update rules that define the algorithms MCA$_3$ and R-MCA$_2$ follow directly from (12) and (15) using the distributions (1) and (2). Note that in (15) the joint probability $p(\vec{s},\vec{y}^{(n)}\,|\,\Theta')$ can be replaced by any function F satisfying $F(\vec{s},\vec{y}^{(n)},\Theta') = \frac{p(\vec{s},\vec{y}^{(n)}\,|\,\Theta')}{A(\vec{y}^{(n)},\Theta')}$, where A is any well-behaved function not depending on $\vec{s}$. For the update rules of MCA$_3$ and R-MCA$_2$ we have used:

$$F(\vec{s},\vec{y}^{(n)},\Theta) = \left(\prod_i \overline{\pi}_i^{s_i}\right) \exp(I^{(n)}), \quad I^{(n)} = \sum_d \left(\log(\overline{W}_d(\vec{s},W))\, y_d^{(n)} - \overline{W}_d(\vec{s},W)\right).$$

C.1 MCA$_3$

The first term in the sum over states $\vec{s}$ in the denominator of (16) and (17) only contributes significantly if $\vec{y}^{(n)} = \vec{0}$, that is, if $F(\vec{0},\vec{y}^{(n)},\Theta) = 1$ (given Poisson noise). In all other cases its contribution is negligible. To derive the numerator of (16) we have used the property:

$$\mathcal{A}_{id}(\vec{s}_h,W) = \delta_{ih}, \qquad \mathcal{A}_{id}(\vec{s}_{ab},W) = \delta_{ia}\,\mathcal{H}(W_{id} - W_{bd}) + \delta_{ib}\,\mathcal{H}(W_{id} - W_{ad}), \tag{32}$$

where $\mathcal{H}$ is the Heaviside function. Note that instead of (32) we also could have used $\mathcal{A}_{id}(\vec{s}_h,W)$ and $\mathcal{A}_{id}(\vec{s}_{ab},W)$ directly or the corresponding expressions of $\mathcal{A}^{\rho}_{id}(\vec{s},W)$ in (31) with high ρ. By using (32) we can simplify the expression of the numerator of (16), however.

The derivation of the numerator of (17) (with $\alpha = 1$) is straightforward. For less sparse input we have to correct for neglecting input patterns which were generated by four or more hidden causes.

We do so by updating α using a consistency argument. On the one hand, using the same arguments as for the derivation of (16) and (17), we can estimate the total number of input patterns generated by less than three causes:

$$\mathcal{N}^{\leq 2}(Y,\Theta) \approx \sum_n \frac{\mathcal{H}(\frac{1}{2}-\sum_d y_d^{(n)}) + \sum_i \overline{\pi}_i \exp(I_i^{(n)}) + \frac{1}{2}\sum_{a,b\,(a\neq b)} \overline{\pi}_a\overline{\pi}_b \exp(I_{ab}^{(n)})}{1+\sum_h \overline{\pi}_h \exp(I_h^{(n)}) + \frac{1}{2}\sum_{\substack{a,b\\a\neq b}} \overline{\pi}_a\overline{\pi}_b \exp(I_{ab}^{(n)}) + \frac{1}{6}\sum_{\substack{a,b,c\\a\neq b\neq c}} \overline{\pi}_a\overline{\pi}_b\overline{\pi}_c \exp(I_{abc}^{(n)})}\,. \tag{33}$$

On the other hand, the same number can be estimated using the prior distributions alone:

$$\tilde{\mathcal{N}}^{\leq 2}(\vec{\pi}) \;=\; N\left(\prod_i (1-\pi_i)\right)\left(1+\sum_h \overline{\pi}_h + \frac{1}{2}\sum_{a,b\,(a\neq b)} \overline{\pi}_a\overline{\pi}_b\right). \tag{34}$$

If the parameters π_i are underestimated using approximation (17), the estimate (33) is smaller than the estimate (34). We change α after each EM iteration until both estimates are consistent ($\mathcal{N}^{\leq 2}(Y,\Theta) \approx \tilde{\mathcal{N}}^{\leq 2}(\vec{\pi})$):

$$\alpha \;=\; \alpha^{\text{old}} + \frac{\varepsilon_\alpha}{N}\left(\tilde{\mathcal{N}}^{\leq 2}(\vec{\pi}) - \mathcal{N}^{\leq 2}(Y,\Theta)\right).$$

Note that the additional computational cost to infer α is small. Computations in (34) scale quadratically with H, and the terms in (33) have to be computed for (17) anyway. In experiments we use $\varepsilon_\alpha = 1$.

C.2 R-MCA$_2$

If we optimize (5) under the constraint $\sum_d W_{id} = C$ in (19), we obtain:

$$\sum_n \langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} \frac{y_d^{(n)} - W_{id}}{W_{id}} + \mu_i = 0\,.$$

The elimination of the Lagrange multipliers μ_i results in:

$$W_{id} \;=\; \frac{\sum_n \langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} y_d^{(n)}}{\frac{1}{C}\sum_{n,d'} \langle \mathcal{A}_{id'}(\vec{s},W)\rangle_{q_n} y_{d'}^{(n)} - \sum_n \left((\sum_{d'} \langle \mathcal{A}_{id'}(\vec{s},W)\rangle_{q_n} \frac{W_{id'}}{C}) - \langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n}\right)}\,.$$

If the model parameters W fulfill condition (20), which can be expected at least close to the maximum likelihood solution, we obtain after the rearrangement of terms, the approximate M-step of Equation (21). To derive the sufficient statistics (22) note that given the update rule (21) we have:

$$W_{id} = C\frac{\sum_n \langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} y_d^{(n)}}{\sum_{d'}\sum_n \langle \mathcal{A}_{id'}(\vec{s},W)\rangle_{q_n} y_{d'}^{(n)}} = C\frac{\sum_{n\in N^{>0}} \langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n} y_d^{(n)}}{\sum_{d'}\sum_{n\in N^{>0}} \langle \mathcal{A}_{id'}(\vec{s},W)\rangle_{q_n} y_{d'}^{(n)}}\,,$$

where $N^{>0}$ is the set of all non-zero input patterns. To approximate $\langle \mathcal{A}_{id}(\vec{s},W)\rangle_{q_n}$ we can therefore assume input statistics that follow from Equations (1) to (3), but in which all inputs exactly equal to zero are omitted. For such modified input statistics, Equation (15) remains unchanged except for the partition function $\mathcal{Z}$ in (14) whose term $p(\vec{0},\vec{y}^{(n)}\,|\,\Theta')$ now equals zero. If we truncate the sum in (15) after terms of order two, we obtain Equation (22).

Appendix D. Neural Network Details

Here we show that the online neural network update rule (23) approaches the batch rule (24) for large data sets and small learning rates. Let $\mathcal{W}^{(n)}$ be the weight matrix at the nth update, and for convenience define the Hebbian correlation signal to be $G_{id}^{(n)} = g_i(\vec{y}^{(n)}, \mathcal{W}^{(n)}) y_d^{(n)}$, and the weight renormalization term to be $z_i^{(n)} = C^{-1} \sum_{d'} \left(\mathcal{W}_{id'}^{(n)} + \varepsilon G_{id'}^{(n)} \right) = (1 + \frac{\varepsilon}{C} \sum_{d'} G_{id'}^{(n)})$ (where we have used the fact that $\sum_{d'} \mathcal{W}_{id'}^{(n)} = C$). Then we can rewrite (23) as

$$\mathcal{W}_{id}^{(n)} = \frac{\mathcal{W}_{id}^{(n-1)} + \varepsilon G_{id}^{(n-1)}}{z_i^{(n-1)}},$$

and by applying N updates starting from initial step t find that

$$\mathcal{W}_{id}^{(t+N)} = \frac{\mathcal{W}_{id}^{(t)} + \varepsilon \sum_{n=1}^{N} G_{id}^{(t+N-n)} \prod_{k=n+1}^{N} z_i^{(t+N-k)}}{\prod_{k=1}^{N} z_i^{(t+N-k)}},$$

where the empty product at $n = N$ is taken equal to 1.

We now make approximations based on the assumptions that N is large, ε is small, and that $\mathcal{W}^{(t)}$ is drawn from the equilibrium distribution over weights. First, as each $z_i^{(n)}$ is (slightly) larger than 0, the sum will be dominated by the leading terms (where n is small). The coefficients of these terms can be approximated, assuming that ε is small, by a logarithmic transform and the weak law of large numbers: $\prod_{k=n+1}^{N} z_i^{(t+N-k)} \approx \exp\left((N-n) \frac{\varepsilon}{C} \sum_{d'} \overline{G}_{id'} \right)$, where $\overline{G}_{id}$ is the expected value of $G_{id}^{(n)}$, which is taken to be stationary by the equilibrium assumption.

Inserting this expression into (35), taking the expected value of the right-hand-side, and summing the resulting geometric series to infinity, we obtain:

$$\mathcal{W}_{id}^{(t+N)} \approx e^{-N\varepsilon \sum_{d'} \overline{G}_{id'}/C} \mathcal{W}_{id}^{(t)} + \varepsilon \overline{G}_{id} \left(\frac{1}{1 - e^{-\varepsilon \sum_{d'} \overline{G}_{id'}/C}} - 1 \right).$$

Finally, assuming $N\varepsilon$ to be large enough for the first term to be negligible, expanding the second, and keeping only terms that do not scale with ε we obtain

$$\mathcal{W}_{id}^{(t+N)} \approx C \frac{\overline{G}_{id}}{\sum_{d'} \overline{G}_{id'}} \approx C \frac{\sum_{n=1}^{N} g_i(\vec{y}^{(n)}, \mathcal{W}^{(t)}) y_d^{(n)}}{\sum_{d'} \sum_{n=1}^{N} g_i(\vec{y}^{(n)}, \mathcal{W}^{(t)}) y_{d'}^{(n)}}.$$

This equivalence of the online and batch rules at equilibrium shows that the average fixed points of R-MCA$_{\text{NN}}$ equal fixed points of R-MCA$_2$. The equivalence becomes inexact away from equilibrium, although our experiments suggest that the behaviour during convergence may nonetheless be similar (Lücke and Sahani, 2007).

Appendix E. Experimental Details

This appendix gives details of the training procedures used for the MCA algorithms, provides more information about the other algorithms used for comparison, and gives particulars of the acoustic and visual data used.

E.1 Initialization

We initialized the parameters W by drawing each W_{id} from a Gaussian distribution with unit mean and standard deviation of $\frac{1}{3}$. Thereafter we normalized such that the average over all W_{id} was W^{init}. For MCA$_3$ we used $W^{\text{init}} = 4$ and for the R-MCA algorithms we used $W^{\text{init}} = 2$ (for this choice the sum, $\sum_d W_{id} = 50$, corresponds to the sum of the parameters used to generate the data). The parameters of the prior distribution were initialized to be $\pi_i = \frac{1}{H}$ for MCA$_3$, that is, half the value of the generating $\pi_i^{\text{gen}} = \frac{2}{H}$ in the standard bars test. For R-MCA$_2$ and R-MCA$_{\text{NN}}$ we initialized with values $\pi_i = \pi = \frac{2}{H}$. The reliability of both R-MCA algorithms is only marginally affected by the exact choices of π and W^{init}. Reliability values remained about the same even if the assumed values of π differed significantly from the generating values π_i^{gen} (see, e.g., the experiments of Figure 8 or the paragraph on 'Violations of model assumptions' in Experiments).

E.2 Annealing

In Equations (16) and (18) we make the following substitutions:

$$\mathcal{H}(x) \rightarrow \mathcal{S}_T(x) = \left(1 + \exp\left(-\tfrac{\lambda}{T-1}x\right)\right)^{-1}, \tag{35}$$

$$\overline{\pi}_i \rightarrow (\overline{\pi}_i)^{\beta}, \;\; I_i^{(n)} \rightarrow \beta I_i^{(n)}, \;\; I_{ab}^{(n)} \rightarrow \beta I_{ab}^{(n)}, \;\; I_{abc}^{(n)} \rightarrow \beta I_{abc}^{(n)}, \;\; \text{with} \;\; \beta = \tfrac{1}{T}. \tag{36}$$

while making only the substitutions of (36) in Equation (33). Here, T plays the role of a 'temperature'. In the limit of $T = 1$, β is equal to one and the sigmoidal function $\mathcal{S}_T(x)$ converges to the Heaviside function, that is, we recover the original Equations (16) and (17). A temperature $T > 1$ has the effect of leveling the differences between the parameter updates to a certain extent. For a high temperature $T \gg 1$, the differences between the parameters associated with different hidden variables vanish after a few iterations.

Smoothing the Heaviside function in (35) is a technique frequently used, for example, in the context of perceptrons, and the substitutions in (36) correspond to the standard annealing procedure for EM (Ueda and Nakano, 1998; Sahani, 1999). The slope of the sigmoidal function $\mathcal{S}_T(x)$ at $x = 0$ is parameterized by λ whose value is set to $\lambda = 0.2$.

In experiments for MCA$_3$ and R-MCA$_2$ we started learning at a relatively high temperature $T_1 > 1$ and cooled to a value T_o close to one. A final temperature $T_o > 1$ makes the system more robust and counteracts over-fitting (Weiss, 1998). Experimental results on artificial data remained essentially the same when we used $T_o = 1$ but the cooling procedure needed to be slower to avoid numerical instabilities in this case. If not otherwise stated, we used $T_o = 1.5$. For MCA$_3$ and R-MCA$_2$ we cooled from T_1 to T_o in steps of $\Delta T = \frac{T_1 - T_o}{50}$ after each iteration. However, we did not change the temperature if the parameters W still changed significantly. More precisely, we only decreased the temperature if the change in W_{id} fell below a threshold $\theta_{\Delta W}$ for all $i = 1, \ldots, H$. In formulas:

$$(\forall i: \;\; \Delta W_i \; < \; \theta_{\Delta W}) \quad \Rightarrow \quad T^{\text{new}} = T^{\text{old}} - \Delta T\,, \tag{37}$$

$$\text{where} \quad \Delta W_i = \frac{\sqrt{\sum_d (W_{id}^{\text{old}} - W_{id}^{\text{new}})^2}}{\sum_d W_{id}^{\text{old}}}\,. \tag{38}$$

Cooling conditioned on small parameter changes in this way allows the use of larger cooling steps ΔT and thus leads to learning in fewer iterations. For all trials we used a threshold of

$\theta_{\Delta W} = 2.5 \times 10^{-3}$, except for the application to more realistic data for which we ran additional trials with $\theta_{\Delta W} = 0.25 \times 10^{-3}$.

In experiments it was observed that a given system had a critical temperature T_c above which the weights did not specialize to different patterns after random initialization. Instead the parameters converged to about the same values for all hidden variables (compare Sahani, 1999; Lücke, 2004). A natural choice of an initial temperature $T_1 > 1$ is therefore a value close to this critical temperature. Experiments on different versions of the bars test showed a roughly linear dependence between the critical temperature T_c and the number of input dimensions D. Thus, in all versions of the bars test we used $T_1 = 0.4D + 1$ and $T_1 = 0.7D + 1$ for MCA$_3$ and R-MCA$_2$, respectively. In the experiments on acoustic and visual data, the critical temperatures are lower than those measured in bars tests with same D, presumably due to more homogeneous distributions of input values in those cases (generating weights in the bars test were all either 0 or 10, whereas generating weights in the naturally-derived data could take on any value in $[0, 10]$). Thus, experiments on phoneme data started at an initial temperature of $T_1 = 70$ for MCA$_3$ and $T_1 = 100$ for R-MCA$_2$; and those on visual data started at $T_1 = 2$ for MCA$_3$ (8-by-8 patches, $H = 20$) and $T_1 = 4$ for R-MCA$_2$ (10-by-10 patches, $H = 50$). In all experiments the temperature was maintained at T_1 during the first ten iterations. After the system had cooled to T_o using (37) and (38) learning was terminated once all ΔW_i remained smaller than $\theta_{\Delta W}$ for 20 iterations.

For R-MCA$_{\text{NN}}$ we used a fixed temperature of $T = 16$ if not otherwise stated, and stopped after all single causes were represented by the same hidden variables for 4000 pattern presentations. In a given trial, the first pattern presentation after which the representation did not change was taken as the learning time of R-MCA$_{\text{NN}}$. For the acoustic data set we used $T = 70$ and additionally report results for $T = 50$ and values $T \leq 40$. For the visual data we used $T = 2$.

For MCA$_{\text{ex}}$ in Figure 6 we have used a relatively fast and fixed cooling schedule.

E.3 Algorithms for the Comparison in Figure 9

For the comparison in Figure 9 we have reproduced data reported by Spratling (2006). While we have adopted the same abbreviations as were used there, we repeat them in Table 2 for the convenience of the reader.

Algorithm	Description
NN-SC	non-negative sparse coding ($\lambda = 1$)
SC-NMF$_{\text{A}}$	NMF with a sparseness constraint of 0.5 on the basis vectors
SC-NMF$_{\text{AY}}$	NMF with a sparseness constraint of 0.5 on the basis vectors and 0.7 on the activations
DI	dendritic inhibition network
NN-DI	dendritic inhibition network with non-negative weights
SC-NMF$_{\text{Y}}$	NMF with a sparseness constraint of 0.7 on the activations
S-NMF	sparse-NMF ($\alpha = 1$)
NMF$_{\text{div}}$	NMF with divergence objective
NMF$_{\text{mse}}$	NMF with Euclidean objective
L-NMF	local NMF

Table 2: Description of the algorithms used for the comparison in Figure 9.

E.4 Acoustic Data

The data used to study component extraction in the acoustic domain were generated from recordings of three vowels (two of them diphthongs), [aʊ], [i:], and [ɔɪ] and three consonants [k], [t], [p]. The phonemes were spoken by a male voice and recorded at 8000Hz. The data were taken from a publicly accessible data base (Sunsite, 1997). To construct spectrograms we used 1000 samples for each of the phonemes, which required truncation in three cases and padding with zeros in the other three cases. The waveforms $z(t)$ were normalized in power such that $\frac{1}{T}\sum_t (z(t))^2 = 1$. The waveforms were then linearly mixed ($z_{\text{mix}}(t) = z(t) + z'(t) + \ldots$) to produce $N = 500$ observed spectrograms. The probability of a phoneme of appearing in a mixed waveform was set to $\frac{2}{6}$. The spectrograms of these mixtures were computed using short-time Fourier transforms with 50 frequency channels ranging from 100 to 4000 Hz, with logarithmic scaling of center frequencies (see Figure 11D). We used 9 Hamming windows of 200 samples each, with successive windows overlapping by 100 samples. We then took the logarithms of the magnitudes of the 50-by-9 spectrogram entries, and linearly rescaled the top 42.8 dB of dynamic range to lie between 0 and 10, with magnitudes more than 42.8 dB below the highest intensity being clipped to 0.

E.5 Visual Data

The image that was used for the experiments on visual data has been taken from the publicly available image database of the van Hateren group at `hlab.phys.rug.nl/imlib/`. Images of the database represent light intensities linearly, which results in most images appearing relatively dark if displayed using a finite gray scale (see van Hateren and van der Schaaf, 1998, for details). We have used image number 2338 (deblurred), cut out a segment of 500-by-500 pixels in the lower left corner and scaled it down to a resolution of 250-by-250 pixels.

Abstract

Given a sample covariance matrix, we examine the problem of maximizing the variance explained by a linear combination of the input variables while constraining the number of nonzero coefficients in this combination. This is known as sparse principal component analysis and has a wide array of applications in machine learning and engineering. We formulate a new semidefinite relaxation to this problem and derive a greedy algorithm that computes a *full set* of good solutions for all target numbers of non zero coefficients, with total complexity $O(n^3)$, where n is the number of variables. We then use the same relaxation to derive sufficient conditions for global optimality of a solution, which can be tested in $O(n^3)$ per pattern. We discuss applications in subset selection and sparse recovery and show on artificial examples and biological data that our algorithm does provide globally optimal solutions in many cases.

Keywords: PCA, subset selection, sparse eigenvalues, sparse recovery, lasso

1. Introduction

Principal component analysis (PCA) is a classic tool for data analysis, visualization or compression and has a wide range of applications throughout science and engineering. Starting from a multivariate data set, PCA finds linear combinations of the variables called *principal components*, corresponding to orthogonal directions maximizing variance in the data. Numerically, a full PCA involves a singular value decomposition of the data matrix.

One of the key shortcomings of PCA is that the factors are linear combinations of *all* original variables; that is, most of factor coefficients (or loadings) are non-zero. This means that while PCA facilitates model interpretation and visualization by concentrating the information in a few factors, the factors themselves are still constructed using all variables, hence are often hard to interpret.

In many applications, the coordinate axes involved in the factors have a direct physical interpretation. In financial or biological applications, each axis might correspond to a specific asset or gene. In problems such as these, it is natural to seek a trade-off between the two goals of *statistical fidelity* (explaining most of the variance in the data) and *interpretability* (making sure that the

factors involve only a few coordinate axes). Solutions that have only a few nonzero coefficients in the principal components are usually easier to interpret. Moreover, in some applications, nonzero coefficients have a direct cost (e.g., transaction costs in finance) hence there may be a direct trade-off between statistical fidelity and practicality. Our aim here is to efficiently derive *sparse principal components*, that is, a set of sparse vectors that explain a maximum amount of variance. Our belief is that in many applications, the decrease in statistical fidelity required to obtain sparse factors is small and relatively benign.

In what follows, we will focus on the problem of finding sparse factors which explain a maximum amount of variance, which can be written:

$$\max_{\|z\|\leq 1} z^T \Sigma z - \rho \, \mathbf{Card}(z) \tag{1}$$

in the variable $z \in \mathbf{R}^n$, where $\Sigma \in \mathbf{S}_n$ is the (symmetric positive semi-definite) sample covariance matrix, ρ is a parameter controlling sparsity, and $\mathbf{Card}(z)$ denotes the cardinal (or ℓ_0 norm) of z, that is, the number of non zero coefficients of z.

While PCA is numerically easy, each factor requires computing a leading eigenvector, which can be done in $O(n^2)$, sparse PCA is a hard combinatorial problem. In fact, Moghaddam et al. (2006b) show that the subset selection problem for ordinary least squares, which is NP-hard (Natarajan, 1995), can be reduced to a sparse generalized eigenvalue problem, of which sparse PCA is a particular intance. Sometimes factor rotation techniques are used to post-process the results from PCA and improve interpretability (see QUARTIMAX by Neuhaus and Wrigley 1954, VARIMAX by Kaiser 1958 or Jolliffe 1995 for a discussion). Another simple solution is to *threshold* the loadings with small absolute value to zero (Cadima and Jolliffe, 1995). A more systematic approach to the problem arose in recent years, with various researchers proposing nonconvex algorithms (e.g., SCoTLASS by Jolliffe et al. 2003, SLRA by Zhang et al. 2002 or D.C. based methods such as (Sriperumbudur et al., 2007) which find modified principal components with zero loadings). The SPCA algorithm, which is based on the representation of PCA as a regression-type optimization problem (Zou et al., 2006), allows the application of the LASSO (Tibshirani, 1996), a penalization technique based on the ℓ_1 norm. With the exception of simple thresholding, all the algorithms above require solving non convex problems. Recently also, d'Aspremont et al. (2007b) derived an ℓ_1 based semidefinite relaxation for the sparse PCA problem (1) with a complexity of $O(n^4\sqrt{\log n})$ for a given ρ. Finally, Moghaddam et al. (2006a) used greedy search and branch-and-bound methods to solve small instances of problem (1) exactly and get good solutions for larger ones. Each step of this greedy algorithm has complexity $O(n^3)$, leading to a total complexity of $O(n^4)$ for a full set of solutions. Moghaddam et al. (2007) improve this bound in the regression/discrimination case.

Our contribution here is twofold. We first derive a greedy algorithm for computing a *full set* of good solutions (one for each target sparsity between 1 and n) at a total numerical cost of $O(n^3)$ based on the convexity of the of the largest eigenvalue of a symmetric matrix. We then derive *tractable* sufficient conditions for a vector z to be a *global* optimum of (1). This means in practice that, given a vector z with support I, we can test if z is a globally optimal solution to problem (1) by performing a few binary search iterations to solve a one dimensional convex minimization problem. In fact, we can take any sparsity pattern candidate from any algorithm and test its optimality. This paper builds on the earlier conference version (d'Aspremont et al., 2007a), providing new and simpler conditions for optimality and describing applications to subset selection and sparse recovery.

While there is certainly a case to be made for ℓ_1 penalized maximum eigenvalues (à la d'Aspremont et al., 2007b), we strictly focus here on the ℓ_0 formulation. However, it was shown recently (see

Candès and Tao 2005, Donoho and Tanner 2005 or Meinshausen and Yu 2006 among others) that there is in fact a deep connection between ℓ_0 constrained extremal eigenvalues and LASSO type variable selection algorithms. Sufficient conditions based on sparse eigenvalues (also called restricted isometry constants in Candès and Tao 2005) guarantee consistent variable selection (in the LASSO case) or sparse recovery (in the decoding problem). The results we derive here produce upper bounds on sparse extremal eigenvalues and can thus be used to prove consistency in LASSO estimation, prove perfect recovery in sparse recovery problems, or prove that a particular solution of the subset selection problem is optimal. Of course, our conditions are only sufficient, not necessary and the duality bounds we produce on sparse extremal eigenvalues cannot always be tight, but we observe that the duality gap is often small.

The paper is organized as follows. We begin by formulating the sparse PCA problem in Section 2. In Section 3, we write an efficient algorithm for computing a full set of candidate solutions to problem (1) with total complexity $O(n^3)$. In Section 4 we then formulate a convex relaxation for the sparse PCA problem, which we use in Section 5 to derive tractable sufficient conditions for the global optimality of a particular sparsity pattern. In Section 6 we detail applications to subset selection, sparse recovery and variable selection. Finally, in Section 7, we test the numerical performance of these results.

1.1 Notation

For a vector $z \in \mathbf{R}$, we let $\|z\|_1 = \sum_{i=1}^n |z_i|$ and $\|z\| = \left(\sum_{i=1}^n z_i^2\right)^{1/2}$, $\mathbf{Card}(z)$ is the cardinality of z, that is, the number of nonzero coefficients of z, while the support I of z is the set $\{i : z_i \neq 0\}$ and we use I^c to denote its complement. For $\beta \in \mathbf{R}$, we write $\beta_+ = \max\{\beta, 0\}$ and for $X \in \mathbf{S}_n$ (the set of symmetric matrix of size $n \times n$) with eigenvalues λ_i, $\mathbf{Tr}(X)_+ = \sum_{i=1}^n \max\{\lambda_i, 0\}$. The vector of all ones is written $\mathbf{1}$, while the identity matrix is written $\mathbf{I}$. The diagonal matrix with the vector u on the diagonal is written $\mathbf{diag}(u)$.

2. Sparse PCA

Let $\Sigma \in \mathbf{S}_n$ be a symmetric matrix. We consider the following sparse PCA problem:

$$\phi(\rho) \equiv \max_{\|z\| \leq 1} z^T \Sigma z - \rho\, \mathbf{Card}(z) \tag{2}$$

in the variable $z \in \mathbf{R}^n$ where $\rho > 0$ is a parameter controlling sparsity. We assume without loss of generality that $\Sigma \in \mathbf{S}_n$ is positive semidefinite and that the n variables are ordered by decreasing marginal variances, that is, that $\Sigma_{11} \geq \ldots \geq \Sigma_{nn}$. We also assume that we are given a square root A of the matrix Σ with $\Sigma = A^T A$, where $A \in \mathbf{R}^{n \times n}$ and we denote by $a_1, \ldots, a_n \in \mathbf{R}^n$ the columns of A. Note that the problem and our algorithms are invariant by permutations of Σ and by the choice of square root A. In practice, we are very often given the data matrix A instead of the covariance Σ.

A problem that is directly related to (2) is that of computing a cardinality constrained maximum eigenvalue, by solving:

$$\begin{array}{ll} \text{maximize} & z^T \Sigma z \\ \text{subject to} & \mathbf{Card}(z) \leq k \\ & \|z\| = 1, \end{array} \tag{3}$$

in the variable $z \in \mathbf{R}^n$. Of course, this problem and (2) are related. By duality, an upper bound on the optimal value of (3) is given by:

$$\inf_{\rho \in P} \phi(\rho) + \rho k.$$

where P is the set of penalty values for which $\phi(\rho)$ has been computed. This means in particular that if a point z is provably optimal for (2), it is also globally optimum for (3) with $k = \mathbf{Card}(z)$.

We now begin by reformulating (2) as a relatively simple convex maximization problem. Suppose that $\rho \geq \Sigma_{11}$. Since $z^T \Sigma z \leq \Sigma_{11}(\sum_{i=1}^n |z_i|)^2$ and $(\sum_{i=1}^n |z_i|)^2 \leq \|z\|^2 \mathbf{Card}(z)$ for all $z \in \mathbf{R}^n$, we have:

$$\begin{array}{rl} \phi(\rho) & = \max_{\|z\| \leq 1} z^T \Sigma z - \rho \, \mathbf{Card}(z) \\ & \leq (\Sigma_{11} - \rho) \, \mathbf{Card}(z) \\ & \leq 0, \end{array}$$

hence the optimal solution to (2) when $\rho \geq \Sigma_{11}$ is $z = 0$. From now on, we assume $\rho \leq \Sigma_{11}$ in which case the inequality $\|z\| \leq 1$ is tight. We can represent the sparsity pattern of a vector z by a vector $u \in \{0,1\}^n$ and rewrite (2) in the equivalent form:

$$\begin{array}{rl} \phi(\rho) & = \max\limits_{u \in \{0,1\}^n} \lambda_{\max}(\mathbf{diag}(u) \Sigma \, \mathbf{diag}(u)) - \rho \mathbf{1}^T u \\ & = \max\limits_{u \in \{0,1\}^n} \lambda_{\max}(\mathbf{diag}(u) A^T A \, \mathbf{diag}(u)) - \rho \mathbf{1}^T u \\ & = \max\limits_{u \in \{0,1\}^n} \lambda_{\max}(A \, \mathbf{diag}(u) A^T) - \rho \mathbf{1}^T u, \end{array}$$

using the fact that $\mathbf{diag}(u)^2 = \mathbf{diag}(u)$ for all variables $u \in \{0,1\}^n$ and that for any matrix B, $\lambda_{\max}(B^T B) = \lambda_{\max}(B B^T)$. We then have:

$$\begin{array}{rl} \phi(\rho) & = \max\limits_{u \in \{0,1\}^n} \lambda_{\max}(A \, \mathbf{diag}(u) A^T) - \rho \mathbf{1}^T u \\ & = \max\limits_{\|x\|=1} \max\limits_{u \in \{0,1\}^n} x^T A \, \mathbf{diag}(u) A^T x - \rho \mathbf{1}^T u \\ & = \max\limits_{\|x\|=1} \max\limits_{u \in \{0,1\}^n} \sum\limits_{i=1}^n u_i ((a_i^T x)^2 - \rho). \end{array}$$

Hence we finally get, after maximizing in u (and using $\max_{v \in \{0,1\}} \beta v = \beta_+$):

$$\phi(\rho) = \max_{\|x\|=1} \sum_{i=1}^n ((a_i^T x)^2 - \rho)_+, \tag{4}$$

which is a nonconvex problem in the variable $x \in \mathbf{R}^n$. We then select variables i such that $(a_i^T x)^2 - \rho > 0$. Note that if $\Sigma_{ii} = a_i^T a_i < \rho$, we must have $(a_i^T x)^2 \leq \|a_i\|^2 \|x\|^2 < \rho$ hence variable i will never be part of the optimal subset and we can remove it.

3. Greedy Solutions

In this section, we focus on finding a good solution to problem (2) using greedy methods. We first present very simple preprocessing solutions with complexity $O(n \log n)$ and $O(n^2)$. We then recall a simple greedy algorithm with complexity $O(n^4)$. Finally, our first contribution in this section is to derive an approximate greedy algorithm that computes a full set of (approximate) solutions for problem (2), with total complexity $O(n^3)$.

3.1 Sorting and Thresholding

The simplest ranking algorithm is to sort the diagonal of the matrix Σ and rank the variables by variance. This works intuitively because the diagonal is a rough proxy for the eigenvalues: the Schur-Horn theorem states that the diagonal of a matrix majorizes its eigenvalues (Horn and Johnson, 1985); sorting costs $O(n \log n)$. Another quick solution is to compute the leading eigenvector of Σ and form a sparse vector by thresholding to zero the coefficients whose magnitude is smaller than a certain level. This can be done with cost $O(n^2)$.

3.2 Full Greedy Solution

Following Moghaddam et al. (2006a), starting from an initial solution of cardinality one at $\rho = \Sigma_{11}$, we can update an increasing sequence of index sets $I_k \subseteq [1,n]$, scanning all the remaining variables to find the index with maximum variance contribution.

Greedy Search Algorithm.

- **Input**: $\Sigma \in \mathbf{R}^{n \times n}$
- **Algorithm**:
  1. Preprocessing: sort variables by decreasing diagonal elements and permute elements of Σ accordingly. Compute the Cholesky decomposition $\Sigma = A^T A$.
  2. Initialization: $I_1 = \{1\}$, $x_1 = a_1 / \|a_1\|$.
  3. Compute $i_k = \operatorname{argmax}_{i \notin I_k} \lambda_{\max} \left(\sum_{j \in I_k \cup \{i\}} a_j a_j^T \right)$.
  4. Set $I_{k+1} = I_k \cup \{i_k\}$ and compute x_{k+1} as the leading eigenvector of $\sum_{j \in I_{k+1}} a_j a_j^T$.
  5. Set $k = k+1$. If $k < n$ go back to step 3.
- **Output**: sparsity patterns I_k.

At every step, I_k represents the set of nonzero elements (or sparsity pattern) of the current point and we can define z_k as the solution to problem (2) given I_k, which is:

$$z_k = \operatorname*{argmax}_{\{z_{I_k^c}=0,\ \|z\|=1\}} z^T \Sigma z - \rho k,$$

which means that z_k is formed by padding zeros to the leading eigenvector of the submatrix Σ_{I_k,I_k}. Note that the entire algorithm can be written in terms of a factorization $\Sigma = A^T A$ of the matrix Σ, which means significant computational savings when Σ is given as a Gram matrix. The matrices Σ_{I_k,I_k} and $\sum_{i \in I_k} a_i a_i^T$ have the same eigenvalues and their eigenvectors are transformed of each other through the matrix A, that is, if z is an eigenvector of Σ_{I_k,I_k}, then $A_{I_k} z / \|A_{I_k} z\|$ is an eigenvector of $A_{I_k} A_{I_k}^T$.

3.3 Approximate Greedy Solution

Computing $n-k$ eigenvalues at each iteration is costly and we can use the fact that uu^T is a subgradient of $\lambda_{\max}$ at X if u is a leading eigenvector of X (Boyd and Vandenberghe, 2004), to get:

$$\lambda_{\max} \left(\sum_{j \in I_k \cup \{i\}} a_j a_j^T \right) \geq \lambda_{\max} \left(\sum_{j \in I_k} a_j a_j^T \right) + (x_k^T a_i)^2,$$

which means that the variance is increasing by at least $(x_k^T a_i)^2$ when variable i is added to I_k. This provides a lower bound on the objective which does not require finding $n-k$ eigenvalues at each iteration. We then derive the following algorithm:

Approximate Greedy Search Algorithm.

- **Input**: $\Sigma \in \mathbf{R}^{n\times n}$
- **Algorithm**:
  1. Preprocessing. Sort variables by decreasing diagonal elements and permute elements of Σ accordingly. Compute the Cholesky decomposition $\Sigma = A^T A$.
  2. Initialization: $I_1 = \{1\}$, $x_1 = a_1/\|a_1\|$.
  3. Compute $i_k = \mathrm{argmax}_{i\notin I_k} (x_k^T a_i)^2$
  4. Set $I_{k+1} = I_k \cup \{i_k\}$ and compute x_{k+1} as the leading eigenvector of $\sum_{j\in I_{k+1}} a_j a_j^T$.
  5. Set $k = k+1$. If $k < n$ go back to step 3.
- **Output**: sparsity patterns I_k.

Again, at every step, I_k represents the set of nonzero elements (or sparsity pattern) of the current point and we can define z_k as the solution to problem (2) given I_k, which is:

$$z_k = \underset{\{z_{I_k^c}=0,\ \|z\|=1\}}{\mathrm{argmax}} \ z^T \Sigma z - \rho k,$$

which means that z_k is formed by padding zeros to the leading eigenvector of the submatrix Σ_{I_k,I_k}. Better points can be found by testing the variables corresponding to the p largest values of $(x_k^T a_i)^2$ instead of picking only the best one.

3.4 Computational Complexity

The complexity of computing a greedy regularization path using the classic greedy algorithm in Section 3.2 is $O(n^4)$: at each step k, it computes $(n-k)$ maximum eigenvalue of matrices with size k. The approximate algorithm in Section 3.3 computes a full path in $O(n^3)$: the first Cholesky decomposition is $O(n^3)$, while the complexity of the k-th iteration is $O(k^2)$ for the maximum eigenvalue problem and $O(n^2)$ for computing all products $(x^T a_j)$. Also, when the matrix Σ is directly given as a Gram matrix $A^T A$ with $A \in \mathbf{R}^{q\times n}$ with $q < n$, it is advantageous to use A directly as the square root of Σ and the total complexity of getting the path up to cardinality p is then reduced to $O(p^3 + p^2 n)$ (which is $O(p^3)$ for the eigenvalue problems and $O(p^2 n)$ for computing the vector products).

4. Convex Relaxation

In Section 2, we showed that the original sparse PCA problem (2) could also be written as in (4):

$$\phi(\rho) = \max_{\|x\|=1} \sum_{i=1}^{n} ((a_i^T x)^2 - \rho)_+.$$

Because the variable x appears solely through $X = xx^T$, we can reformulate the problem in terms of X only, using the fact that when $\|x\| = 1$, $X = xx^T$ is equivalent to $\mathbf{Tr}(X) = 1$, $X \succeq 0$ and $\mathbf{Rank}(X) = 1$. We thus rewrite (4) as:

$$\begin{array}{rll} \phi(\rho) = & \max. & \sum_{i=1}^n (a_i^T X a_i - \rho)_+ \\ & \text{s.t.} & \mathbf{Tr}(X) = 1, \ \mathbf{Rank}(X) = 1 \\ & & X \succeq 0. \end{array}$$

Note that because we are maximizing a convex function over the convex set (spectahedron) $\Delta_n = \{X \in \mathbf{S}_n : \ \mathbf{Tr}(X) = 1, \ X \succeq 0\}$, the solution must be an extreme point of Δ_n (i.e., a rank one matrix), hence we can drop the rank constraint here. Unfortunately, $X \mapsto (a_i^T X a_i - \rho)_+$, the function we are *maximizing*, is convex in X and not concave, which means that the above problem is still hard. However, we show below that on rank one elements of Δ_n, it is also equal to a concave function of X, and we use this to produce a semidefinite relaxation of problem (2).

Proposition 1 *Let $A \in \mathbf{R}^{n\times n}$, $\rho \geq 0$ and denote by $a_1, \ldots, a_n \in \mathbf{R}^n$ the columns of A, an upper bound on:*

$$\begin{array}{rll} \phi(\rho) = & \textit{max.} & \sum_{i=1}^n (a_i^T X a_i - \rho)_+ \\ & \textit{s.t.} & \mathbf{Tr}(X) = 1, \ X \succeq 0, \ \mathbf{Rank}(X) = 1 \end{array}$$

can be computed by solving

$$\begin{array}{rll} \psi(\rho) = & \textit{max.} & \sum_{i=1}^n \mathbf{Tr}(X^{1/2} B_i X^{1/2})_+ \\ & \textit{s.t.} & \mathbf{Tr}(X) = 1, \ X \succeq 0. \end{array} \tag{5}$$

in the variables $X \in \mathbf{S}_n$, where $B_i = a_i a_i^T - \rho \mathbf{I}$, or also:

$$\begin{array}{rll} \psi(\rho) = & \textit{max.} & \sum_{i=1}^n \mathbf{Tr}(P_i B_i) \\ & \textit{s.t.} & \mathbf{Tr}(X) = 1, \ X \succeq 0, \ X \succeq P_i \succeq 0, \end{array} \tag{6}$$

which is a semidefinite program in the variables $X \in \mathbf{S}_n, \ P_i \in \mathbf{S}_n$.

Proof We let $X^{1/2}$ denote the positive square root (i.e., with nonnegative eigenvalues) of a symmetric positive semi-definite matrix X. In particular, if $X = xx^T$ with $\|x\| = 1$, then $X^{1/2} = X = xx^T$, and for all $\beta \in \mathbf{R}$, βxx^T has one eigenvalue equal to β and $n-1$ equal to 0, which implies $\mathbf{Tr}(\beta xx^T)_+ = \beta_+$. We thus get:

$$\begin{array}{rcl} (a_i^T X a_i - \rho)_+ & = & \mathbf{Tr}((a_i^T x x^T a_i - \rho) x x^T)_+ \\ & = & \mathbf{Tr}(x(x^T a_i a_i^T x - \rho) x^T)_+ \\ & = & \mathbf{Tr}(X^{1/2} a_i a_i^T X^{1/2} - \rho X)_+ = \mathbf{Tr}(X^{1/2}(a_i a_i^T - \rho \mathbf{I}) X^{1/2})_+. \end{array}$$

For any symmetric matrix B, the function $X \mapsto \mathbf{Tr}(X^{1/2} B X^{1/2})_+$ is concave on the set of symmetric positive semidefinite matrices, because we can write it as:

$$\begin{array}{rcl} \mathbf{Tr}(X^{1/2} B X^{1/2})_+ & = & \max\limits_{\{0 \preceq P \preceq X\}} \mathbf{Tr}(PB) \\ & = & \min\limits_{\{Y \succeq B, \ Y \succeq 0\}} \mathbf{Tr}(YX), \end{array}$$

where this last expression is a concave function of X as a pointwise minimum of affine functions. We can now relax the original problem into a convex optimization problem by simply dropping the rank constraint, to get:

$$\begin{array}{rll} \psi(\rho) \equiv & \max. & \sum_{i=1}^n \mathbf{Tr}(X^{1/2} a_i a_i^T X^{1/2} - \rho X)_+ \\ & \text{s.t.} & \mathbf{Tr}(X) = 1,\ X \succeq 0, \end{array}$$

which is a convex program in $X \in \mathbf{S}_n$. Note that because B_i has at most one nonnegative eigenvalue, we can replace $\mathbf{Tr}(X^{1/2} a_i a_i^T X^{1/2} - \rho X)_+$ by $\lambda_{\max}(X^{1/2} a_i a_i^T X^{1/2} - \rho X)_+$ in the above program. Using the representation of $\mathbf{Tr}(X^{1/2} B X^{1/2})_+$ detailed above, problem (5) can be written as a semidefinite program:

$$\begin{array}{rll} \psi(\rho) = & \max. & \sum_{i=1}^n \mathbf{Tr}(P_i B_i) \\ & \text{s.t.} & \mathbf{Tr}(X) = 1,\ X \succeq 0,\ X \succeq P_i \succeq 0, \end{array}$$

in the variables $X \in \mathbf{S}_n,\ P_i \in \mathbf{S}_n$, which is the desired result. ■

Note that we always have $\psi(\rho) \geq \phi(\rho)$ and when the solution to the above semidefinite program has rank one, $\psi(\rho) = \phi(\rho)$ and the semidefinite relaxation (6) is *tight*. This simple fact allows us to derive sufficient global optimality conditions for the original sparse PCA problem.

5. Optimality Conditions

In this section, we derive necessary and sufficient conditions to test the optimality of solutions to the relaxations obtained in Sections 3, as well as sufficient condition for the tightness of the semidefinite relaxation in (6).

5.1 Dual Problem and Optimality Conditions

We first derive the dual problem to (6) as well as the Karush-Kuhn-Tucker (KKT) optimality conditions:

Lemma 2 *Let $A \in \mathbf{R}^{n\times n}$, $\rho \geq 0$ and denote by $a_1, \ldots, a_n \in \mathbf{R}^n$ the columns of A. The dual of problem (6):*

$$\begin{array}{rll} \psi(\rho) = & \textit{max.} & \sum_{i=1}^n \mathbf{Tr}(P_i B_i) \\ & \textit{s.t.} & \mathbf{Tr}(X) = 1,\ X \succeq 0,\ X \succeq P_i \succeq 0, \end{array}$$

in the variables $X \in \mathbf{S}_n,\ P_i \in \mathbf{S}_n$, is given by:

$$\begin{array}{ll} \textit{min.} & \lambda_{\max}\left(\sum_{i=1}^n Y_i\right) \\ \textit{s.t.} & Y_i \succeq B_i,\ Y_i \succeq 0, \quad i = 1, \ldots, n. \end{array} \tag{7}$$

in the variables $Y_i \in \mathbf{S}_n$. Furthermore, the KKT optimality conditions for this pair of semidefinite programs are given by:

$$\left\{ \begin{array}{l} \left(\sum_{i=1}^n Y_i\right) X = \lambda_{\max}\left(\sum_{i=1}^n Y_i\right) X \\ (X - P_i) Y_i = 0,\ P_i B_i = P_i Y_i \\ Y_i \succeq B_i,\ Y_i, X, P_i \succeq 0,\ X \succeq P_i,\ \mathbf{Tr}\, X = 1. \end{array} \right. \tag{8}$$

Proof Starting from:

$$\begin{array}{ll} \max. & \sum_{i=1}^n \mathbf{Tr}(P_i B_i) \\ \text{s.t.} & 0 \preceq P_i \preceq X \\ & \mathbf{Tr}(X) = 1,\ X \succeq 0, \end{array}$$

we can form the Lagrangian as:

$$L(X, P_i, Y_i) = \sum_{i=1}^n \mathbf{Tr}(P_i B_i) + \mathbf{Tr}(Y_i(X - P_i))$$

in the variables $X, P_i, Y_i \in \mathbf{S}_n$, with $X, P_i, Y_i \succeq 0$ and $\mathbf{Tr}(X) = 1$. Maximizing $L(X, P_i, Y_i)$ in the primal variables X and P_i leads to problem (7). The KKT conditions for this primal-dual pair of SDP can be derived from Boyd and Vandenberghe (2004, p.267).

■

5.2 Optimality Conditions for Rank One Solutions

We now derive the KKT conditions for problem (6) for the particular case where we are given a rank one candidate solution $X = xx^T$ and need to test its optimality. These necessary and sufficient conditions for the optimality of $X = xx^T$ for the convex relaxation then provide sufficient conditions for *global* optimality for the non-convex problem (2).

Lemma 3 *Let $A \in \mathbf{R}^{n\times n}$, $\rho \geq 0$ and denote by $a_1, \ldots, a_n \in \mathbf{R}^n$ the columns of A. The rank one matrix $X = xx^T$ is an optimal solution of (6) if and only if there are matrices $Y_i \in \mathbf{S}_n,\ i = 1, \ldots, n$ such that:*

$$\begin{cases} \lambda_{\max}\left(\sum_{i=1}^n Y_i\right) = \sum_{i\in I}((a_i^T x)^2 - \rho) \\ x^T Y_i x = \begin{cases} (a_i^T x)^2 - \rho \text{ if } i \in I \\ 0 \text{ if } i \in I^c \end{cases} \\ Y_i \succeq B_i,\ Y_i \succeq 0. \end{cases}$$

where $B_i = a_i a_i^T - \rho \mathbf{I},\ i = 1, \ldots, n$ and I^c is the complement of the set I defined by:

$$\max_{i\notin I}(a_i^T x)^2 \leq \rho \leq \min_{i\in I}(a_i^T x)^2.$$

Furthermore, x must be a leading eigenvector of both $\sum_{i\in I} a_i a_i^T$ and $\sum_{i=1}^n Y_i$.

Proof We apply Lemma 2 given $X = xx^T$. The condition $0 \preceq P_i \preceq xx^T$ is equivalent to $P_i = \alpha_i xx^T$ and $\alpha_i \in [0,1]$. The equation $P_i B_i = X Y_i$ is then equivalent to $\alpha_i(x^T B_i x - x^T Y_i x) = 0$, with $x^T B_i x = (a_i^T x)^2 - \rho$ and the condition $(X - P_i)Y_i = 0$ becomes $x^T Y_i x(1 - \alpha_i) = 0$. This means that $x^T Y_i x = ((a_i^T x)^2 - \rho)_+$ and the first-order condition in (8) becomes $\lambda_{\max}\left(\sum_{i=1}^n Y_i\right) = x^T\left(\sum_{i=1}^n Y_i\right)x$. Finally, we recall from Section 2 that:

$$\begin{aligned} \sum_{i\in I}((a_i^T x)^2 - \rho) &= \max_{\|x\|=1} \max_{u\in\{0,1\}^n} \sum_{i=1}^n u_i((a_i^T x)^2 - \rho) \\ &= \max_{u\in\{0,1\}^n} \lambda_{\max}(A\,\mathbf{diag}(u)A^T) - \rho \mathbf{1}^T u \end{aligned}$$

hence x must also be a leading eigenvector of $\sum_{i\in I} a_i a_i^T$. ■

The previous lemma shows that given a candidate vector x, we can test the optimality of $X = xx^T$ for the semidefinite program (5) by solving a semidefinite feasibility problem in the variables $Y_i \in \mathbf{S}_n$. If this (rank one) solution xx^T is indeed optimal for the semidefinite relaxation, then x must also be *globally* optimal for the original nonconvex combinatorial problem in (2), so the above lemma provides sufficient global optimality conditions for the combinatorial problem (2) based on the (necessary and sufficient) optimality conditions for the convex relaxation (5) given in lemma 2. In practice, we are only given a sparsity pattern I (using the results of Section 3 for example) rather than the vector x, but Lemma 3 also shows that given I, we can get the vector x as the leading eigenvector of $\sum_{i\in I} a_i a_i^T$.

The next result provides more refined conditions under which such a pair (I,x) is optimal for some value of the penalty $\rho > 0$ based on a local optimality argument. In particular, they allow us to fully specify the dual variables Y_i for $i \in I$.

Proposition 4 *Let $A \in \mathbf{R}^{n\times n}$, $\rho \geq 0$ and denote by $a_1,\ldots,a_n \in \mathbf{R}^n$ the columns of A. Let x be the largest eigenvector of $\sum_{i\in I} a_i a_i^T$. Let I be such that:*

$$\max_{i\notin I}(a_i^T x)^2 < \rho < \min_{i\in I}(a_i^T x)^2, \tag{9}$$

the matrix $X = xx^T$ is optimal for problem (6) if and only if there are matrices $Y_i \in \mathbf{S}^n$ satisfying

$$\lambda_{\max}\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x} + \sum_{i\in I^c} Y_i\right) \leq \sum_{i\in I}((a_i^T x)^2 - \rho),$$

with $Y_i \succeq B_i - \frac{B_i xx^T B_i}{x^T B_i x}$, $Y_i \succeq 0$, where $B_i = a_i a_i^T - \rho\mathbf{I}$, $i = 1,\ldots,n$.

Proof We first prove the necessary condition by computing a first order expansion of the functions $F_i : X \mapsto \mathbf{Tr}(X^{1/2} B_i X^{1/2})_+$ around $X = xx^T$. The expansion is based on the results in Appendix A which show how to compute derivatives of eigenvalues and projections on eigensubspaces. More precisely, Lemma 10 states that if $x^T Bx > 0$, then, for any $Y \succeq 0$:

$$F_i((1-t)xx^T + tY) = F_i(xx^T) + \frac{t}{x^T B_i x}\mathbf{Tr}\, B_i xx^T B_i (Y - xx^T) + O(t^{3/2}),$$

while if $x^T Bx < 0$, then, for any $Y \succeq 0$,:

$$F_i((1-t)xx^T + tY) = t_+ \mathbf{Tr}\left(Y^{1/2}\left(B_i - \frac{B_i xx^T B_i}{x^T B_i x}\right)Y^{1/2}\right)_+ + O(t^{3/2}).$$

Thus if $X = xx^T$ is a global maximum of $\sum_i F_i(X)$, then this first order expansion must reflect the fact that it is also local maximum, that is, for all $Y \in \mathbf{S}^n$ such that $Y \succeq 0$ and $\mathbf{Tr}\, Y = 1$, we must have:

$$\lim_{t\to 0_+}\frac{1}{t}\sum_{i=1}^n [F_i((1-t)xx^T + tY) - F_i(xx^T)] \leq 0,$$

which is equivalent to:

$$-\sum_{i\in I} x^T B_i x + \mathbf{Tr}\, Y\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x}\right) + \sum_{i\in I^c}\mathbf{Tr}\left(Y^{1/2}\left(B_i - \frac{B_i xx^T B_i}{x^T B_i x}\right)Y^{1/2}\right)_+ \leq 0.$$

Thus if $X = xx^T$ is optimal, with $\sigma = \sum_{i\in I} x^T B_i x$, we get:

$$\max_{Y\succeq 0, \mathbf{Tr}Y=1} \mathbf{Tr}\, Y\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x} - \sigma \mathbf{I}\right) + \sum_{i\in I^c} \mathbf{Tr}\left(Y^{1/2}\left(B_i - B_i x(x^T B_i x)^\dagger x^T B_i\right)Y^{1/2}\right)_+ \leq 0$$

which is also in dual form (using the same techniques as in the proof of Proposition 1):

$$\min_{\{Y_i \succeq B_i - \frac{B_i xx^T B_i}{x^T B_i x}, Y_i \succeq 0\}} \lambda_{\max}\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x} + \sum_{i\in I^c} Y_i\right) \leq \sigma,$$

which leads to the necessary condition. In order to prove sufficiency, the only non trivial condition to check in Lemma 3 is that $x^T Y_i x = 0$ for $i \in I^c$, which is a consequence of the inequality:

$$x^T\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x} + \sum_{i\in I^c} Y_i\right)x \leq \lambda_{\max}\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x} + \sum_{i\in I^c} Y_i\right) \leq x^T\left(\sum_{i\in I}\frac{B_i xx^T B_i}{x^T B_i x}\right)x.$$

This concludes the proof. ■

The original optimality conditions in (3) are highly degenerate in Y_i and this result refines these optimality conditions by invoking the local structure. The local optimality analysis in proposition 4 gives more specific constraints on the dual variables Y_i. For $i \in I$, Y_i must be equal to $B_i xx^T B_i / x^T B_i x$, while if $i \in I^c$, we must have $Y_i \succeq B_i - B_i xx^T B_i / x^T B_i x$, which is a stricter condition than $Y_i \succeq B_i$ (because $x^T B_i x < 0$).

5.3 Efficient Optimality Conditions

The condition presented in Proposition 4 still requires solving a large semidefinite program. In practice, good candidates for Y_i, $i \in I^c$ can be found by solving for minimum trace matrices satisfying the feasibility conditions of proposition 4. As we will see below, this can be formulated as a semidefinite program which can be solved explicitly.

Lemma 5 *Let $A \in \mathbf{R}^{n\times n}$, $\rho \geq 0$, $x \in \mathbf{R}^n$ and $B_i = a_i a_i^T - \rho\mathbf{I}$ with $a_1, \ldots, a_n \in \mathbf{R}^n$ the columns of A. If $(a_i^T x)^2 < \rho$ and $\|x\| = 1$, an optimal solution of the semidefinite program:*

$$\begin{array}{ll} \textit{minimize} & \mathbf{Tr}\, Y_i \\ \textit{subject to} & Y_i \succeq B_i - \frac{B_i xx^T B_i}{x^T B_i x},\ x^T Y_i x = 0,\ Y_i \succeq 0, \end{array}$$

is given by:

$$Y_i = \max\left\{0, \rho\frac{(a_i^T a_i - \rho)}{(\rho - (a_i^T x)^2)}\right\}\frac{(\mathbf{I} - xx^T)a_i a_i^T(\mathbf{I} - xx^T)}{\|(\mathbf{I} - xx^T)a_i\|^2}. \tag{10}$$

Proof Let us write $M_i = B_i - \frac{B_i xx^T B_i}{x^T B_i x}$, we first compute:

$$\begin{aligned} a_i^T M_i a_i &= (a_i^T a_i - \rho)a_i^T a_i - \frac{(a_i^T a_i a_i^T x - \rho a_i^T x)^2}{(a_i^T x)^2 - \rho} \\ &= \frac{(a_i^T a_i - \rho)}{\rho - (a_i^T x)^2}\rho(a_i^T a_i - (a_i^T x)^2). \end{aligned}$$

When $a_i^T a_i \leq \rho$, the matrix M_i is negative semidefinite, because $\|x\| = 1$ means $a_i^T M a_i \leq 0$ and $x^T M x = a_i^T M x = 0$. The solution of the minimum trace problem is then simply $Y_i = 0$. We now assume that $a_i^T a_i > \rho$ and first check feasibility of the candidate solution Y_i in (10). By construction, we have $Y_i \succeq 0$ and $Y_i x = 0$, and a short calculation shows that:

$$\begin{aligned} a_i^T Y_i a_i &= \rho \frac{(a_i^T a_i - \rho)}{(\rho - (a_i^T x)^2)} (a_i^T a_i - (a_i^T x)^2) \\ &= a_i^T M_i a_i. \end{aligned}$$

We only need to check that $Y_i \succeq M_i$ on the subspace spanned by a_i and x, for which there is equality. This means that Y_i in (10) is feasible and we now check its optimality. The dual of the original semidefinite program can be written:

$$\begin{array}{ll} \text{maximize} & \mathbf{Tr}\, P_i M_i \\ \text{subject to} & \mathbf{I} - P_i + \nu x x^T \succeq 0 \\ & P_i \succeq 0, \end{array}$$

and the KKT optimality conditions for this problem are written:

$$\left\{ \begin{array}{l} Y_i(\mathbf{I} - P_i + \nu x x^T) = 0,\ P_i(Y_i - M_i) = 0, \\ \mathbf{I} - P_i + \nu x x^T \succeq 0, \\ P_i \succeq 0,\ Y_i \succeq 0,\ Y_i \succeq M_i,\ Y_i x x^T = 0, \quad i \in I^c. \end{array} \right.$$

Setting $P_i = Y_i \mathbf{Tr}\, Y_i / \mathbf{Tr}\, Y_i^2$ and ν sufficiently large makes these variables dual feasible. Because all contributions of x are zero, $\mathbf{Tr}\, Y_i(Y_i - M_i)$ is proportional to $\mathbf{Tr}\, a_i a_i^T (Y_i - M_i)$ which is equal to zero and Y_i in (10) satisifies the KKT optimality conditions. ■

We summarize the results of this section in the theorem below, which provides sufficient optimality conditions on a sparsity pattern I.

Theorem 6 *Let $A \in \mathbf{R}^{n \times n}$, $\rho \geq 0$, $\Sigma = A^T A$ with $a_1, \ldots, a_n \in \mathbf{R}^n$ the columns of A. Given a sparsity pattern I, setting x to be the largest eigenvector of $\sum_{i \in I} a_i a_i^T$, if there is a $\rho^* \geq 0$ such that the following conditions hold:*

$$\max_{i \in I^c} (a_i^T x)^2 < \rho^* < \min_{i \in I} (a_i^T x)^2 \quad \textit{and} \quad \lambda_{\max}\left(\sum_{i=1}^n Y_i \right) \leq \sum_{i \in I} ((a_i^T x)^2 - \rho^*),$$

with the dual variables Y_i for $i \in I^c$ defined as in (10) and:

$$Y_i = \frac{B_i x x^T B_i}{x^T B_i x}, \quad \textit{when } i \in I,$$

then the sparsity pattern I is globally optimal for the sparse PCA problem (2) with $\rho = \rho^*$ and we can form an optimal solution z by solving the maximum eigenvalue problem:

$$z = \operatorname*{argmax}_{\{z_{I^c} = 0,\ \|z\| = 1\}} z^T \Sigma z.$$

Proof Following proposition 4 and lemma 5, the matrices Y_i are dual optimal solutions corresponding to the primal optimal solution $X = xx^T$ in (5). Because the primal solution has rank one, the semidefinite relaxation (6) is tight so the pattern I is optimal for (2) and Section 2 shows that z is a globally optimal solution to (2) with $\rho = \rho^*$. ■

5.4 Gap Minimization: Finding the Optimal ρ

All we need now is an efficient algorithm to find ρ^* in theorem 6. As we will show below, when the dual variables Y_i^c are defined as in (10), the duality gap in (2) is a convex function of ρ hence, given a sparsity pattern I, we can efficiently search for the best possible ρ (which must belong to an *interval*) by performing a few binary search iterations.

Lemma 7 *Let $A \in \mathbf{R}^{n\times n}$, $\rho \geq 0$, $\Sigma = A^TA$ with $a_1,\ldots,a_n \in \mathbf{R}^n$ the columns of A. Given a sparsity pattern I, setting x to be the largest eigenvector of $\sum_{i\in I} a_i a_i^T$, with the dual variables Y_i for $i \in I^c$ defined as in (10) and:*

$$Y_i = \frac{B_i x x^T B_i}{x^T B_i x}, \quad \textit{when } i \in I.$$

The duality gap in (2) which is given by:

$$\mathrm{gap}(\rho) \equiv \lambda_{\max}\left(\sum_{i=1}^n Y_i\right) - \sum_{i\in I}((a_i^Tx)^2 - \rho),$$

is a convex function of ρ when

$$\max_{i\notin I}(a_i^Tx)^2 < \rho < \min_{i\in I}(a_i^Tx)^2.$$

Proof For $i \in I$ and $u \in \mathbf{R}^n$, we have

$$u^TY_iu = \frac{(u^Ta_ia_i^Tx - \rho u^Tx)^2}{(a_i^Tx)^2 - \rho},$$

which is a convex function of ρ (Boyd and Vandenberghe, 2004, p.73). For $i \in I^c$, we can write:

$$\frac{\rho(a_i^Ta_i - \rho)}{\rho - (a_i^Tx)^2} = -\rho + (a_i^Ta_i - (a_i^Tx)^2)\left(1 + \frac{(a_i^Tx)^2}{\rho - (a_i^Tx)^2}\right),$$

hence $\max\{0, \rho(a_i^Ta_i - \rho)/(\rho - (a_i^Tx)^2)\}$ is also a convex function of ρ. This means that:

$$u^TY_iu = \max\left\{0, \rho\frac{(a_i^Ta_i - \rho)}{(\rho - (a_i^Tx)^2)}\right\}\frac{(u^Ta_i - (x^Tu)(x^Ta_i))^2}{\|(\mathbf{I} - xx^T)a_i\|^2}$$

is convex in ρ when $i \in I^c$. We conclude that $\sum_{i=1}^n u^TY_iu$ is convex, hence:

$$\mathrm{gap}(\rho) = \max_{\|u\|=1} \sum_{i=1}^n u^TY_iu - \sum_{i\in I}((a_i^Tx)^2 - \rho)$$

is also convex in ρ as a pointwise maximum of convex functions of ρ. ■

This result shows that the set of ρ for which the pattern I is optimal must be an interval. It also suggests an efficient procedure for testing the optimality of a given pattern I. We first compute x as a leading eigenvector $\sum_{i\in I} a_i a_i^T$. We then compute an interval in ρ for which x satisfies the basic consistency condition:

$$\max_{i\notin I}(a_i^T x)^2 \equiv \rho_{\min} \leq \rho \leq \rho_{\max} \equiv \min_{i\in I}(a_i^T x)^2.$$

Note that this interval could be empty, in which case I cannot be optimal. We then minimize $\mathrm{gap}(\rho)$ over the interval $[\rho_{\min},\rho_{\max}]$. If the minimum is zero for some $\rho=\rho^*$, then the pattern I is optimal for the sparse PCA problem in (2) with $\rho=\rho^*$.

Minimizing the convex function $\mathrm{gap}(\rho)$ can be done very efficiently using binary search. The initial cost of forming the matrix $\sum_{i=1}^n Y_i$, which is a simple outer matrix product, is $O(n^3)$. At each iteration of the binary search, a subgradient of $\mathrm{gap}(\rho)$ can then be computed by solving a maximum eigenvalue problem, at a cost of $O(n^2)$. This means that the complexity of finding the optimal ρ over a given interval $[\rho_{\min},\rho_{\max}]$ is $O(n^2\log_2((\rho_{\max}-\rho_{\min})/\varepsilon))$, where ε is the target precision. Overall then, the total cost of testing the optimality of a pattern I is $O(n^3+n^2\log_2((\rho_{\max}-\rho_{\min})/\varepsilon))$.

Note that an additional benefit of deriving explicit dual feasible points Y_i is that plugging these solutions into the objective of problem (7):

$$\begin{array}{ll}\text{min.} & \lambda_{\max}\left(\sum_{i=1}^n Y_i\right)\\ \text{s.t.} & Y_i \succeq B_i,\ Y_i \succeq 0, \quad i=1,\ldots,n.\end{array}$$

produces an *upper bound* on the optimum value of the original sparse PCA problem (2) even when the pattern I is not optimal (all we need is a ρ satisfying the consistency condition).

5.5 Solution Improvements and Randomization

When these conditions are not satisfied, the relaxation (6) has an optimal solution with rank strictly larger than one, hence is not tight. At such a point, we can use a different relaxation such as DSPCA by d'Aspremont et al. (2007b) to try to get a better solution. We can also apply randomization techniques to improve the quality of the solution of problem (6) (Ben-Tal and Nemirovski, 2002).

6. Applications

In this section, we discuss some applications of sparse PCA to subset selection and compressed sensing.

6.1 Subset Selection

We consider p data points in $\mathbf{R}^n$, in a data matrix $X\in\mathbf{R}^{p\times n}$. We assume that we are given real numbers $y\in\mathbf{R}^p$ to predict from X using linear regression, estimated by least squares. We are thus looking for $w\in\mathbf{R}^n$ such that $\|y-Xw\|^2$ is minimum. In the subset selection problem, we are looking for sparse coefficients w, that is, a vector w with many zeros. We thus consider the problem:

$$s(k) = \min_{w\in\mathbf{R}^n,\ \mathbf{Card}\, w\leq k} \|y-Xw\|^2.$$

Using the sparsity pattern $u \in \{0,1\}^n$, and optimizing with respect to w, we have

$$s(\rho) = \min_{u \in \{0,1\}^n,\ \mathbf{1}^T u \leq k} \|y\|^2 - y^T X(u)(X(u)^T X(u))^{-1} X(u)^T y,$$

where $X(u) = X\,\mathbf{diag}(u)$. We can rewrite $y^T X(u)(X(u)^T X(u))^{-1} X(u)^T y$ as the largest generalized eigenvalue of the pair $(X(u)^T yy^T X(u), X(u)^T X(u))$, that is, as

$$y^T X(u)(X(u)^T X(u))^{-1} X(u)^T y = \max_{w \in \mathbf{R}^n} \frac{w^T X(u)^T yy^T X(u) w}{w^T X(u)^T X(u) w}.$$

We thus have:

$$s(k) = \|y\|^2 - \max_{u \in \{0,1\}^n, \mathbf{1}^T u \leq k} \max_{w \in \mathbf{R}^n} \frac{w^T\,\mathbf{diag}(u) X^T yy^T X\,\mathbf{diag}(u) w}{w^T\,\mathbf{diag}(u) X^T X\,\mathbf{diag}(u)) w}.$$

Given a pattern $u \in \{0,1\}^n$, let

$$s_0 = y^T X(u)(X(u)^T X(u))^{-1} X(u)^T y$$

be the largest generalized eigenvalue corresponding to the pattern u. The pattern is optimal if and only if the largest generalized eigenvalue of the pair $\{X(v)^T yy^T X(v), X(v)^T X(v)\}$ is less than s_0 for any $v \in \{0,1\}^n$ such that $v^T \mathbf{1} = u^T \mathbf{1}$. This is equivalent to the optimality of u for the sparse PCA problem with matrix $X^T yy^T X - s_0 X^T X$, which can be checked using the sparse PCA optimality conditions derived in the previous sections.

Note that unlike in the sparse PCA case, this convex relaxation does not immediately give a simple bound on the optimal value of the subset selection problem. However, we get a bound of the following form: when $v \in \{0,1\}^n$ and $w \in \mathbf{R}^n$ is such that $\mathbf{1}^T v = k$ with:

$$w^T \left(X(v)^T yy^T X(v) - s_0 X(v)^T X(v) \right) w \leq B,$$

where $B \geq 0$ (because s_0 is defined from u), we have:

$$\begin{aligned} \|y\|^2 - s_0 \geq s(k) &\geq \|y\|^2 - s_0 - B \left(\min_{v \in \{0,1\}^n, \mathbf{1}^T v = k} \lambda_{\min}(X(v)^T X(v)) \right)^{-1} \\ &\geq \|y\|^2 - s_0 - B \left(\lambda_{\min}(X^T X) \right)^{-1}. \end{aligned}$$

This bound gives a sufficient condition for optimality in subset selection, for any problem instance and any given subset. This is to be contrasted with the sufficient conditions derived for particular algorithms, such as the LASSO (Yuan and Lin, 2007; Zhao and Yu, 2006) or backward greedy selection (Couvreur and Bresler, 2000). Note that some of these optimality conditions are often based on sparse eigenvalue problems (see Meinshausen and Yu, 2006, §2), hence our convex relaxations helps both in checking sufficient conditions for optimality (before the algorithm is run) and in testing a posteriori the optimality of a particular solution.

6.2 Sparse Recovery

Following Candès and Tao (2005) (see also Donoho and Tanner, 2005), we seek to recover a signal $f \in \mathbf{R}^n$ from corrupted measurements $y = Af + e$, where $A \in \mathbf{R}^{m\times n}$ is a coding matrix and $e \in \mathbf{R}^m$ is an unknown vector of errors with low cardinality. This can be reformulated as the problem of finding the sparsest solution to an underdetermined linear system:

$$\begin{array}{ll} \text{minimize} & \|x\|_0 \\ \text{subject to} & Fx = Fy \end{array} \tag{11}$$

where $\|x\|_0 = \mathbf{Card}(x)$ and $F \in \mathbf{R}^{p\times m}$ is a matrix such that $FA = 0$. A classic trick to get good approximate solutions to problem (11) is to substitute the (convex) ℓ_1 norm to the (combinatorial) ℓ_0 objective above, and solve instead:

$$\begin{array}{ll} \text{minimize} & \|x\|_1 \\ \text{subject to} & Fx = Fy, \end{array}$$

which is equivalent to a linear program in $x \in \mathbf{R}^m$. Following Candès and Tao (2005), given a matrix $F \in \mathbf{R}^{p\times m}$ and an integer S such that $0 < S \leq m$, we define its *restricted isometry* constant δ_S as the smallest number such that for any subset $I \subset [1,m]$ of cardinality at most S we have:

$$(1-\delta_S)\|c\|^2 \leq \|F_I c\|^2 \leq (1+\delta_S)\|c\|^2, \tag{12}$$

for all $c \in \mathbf{R}^{|I|}$, where F_I is the submatrix of F formed by keeping only the columns of F in the set I. The following result then holds.

Proposition 8 ***Candès and Tao (2005)***. *Suppose that the restricted isometry constants of a matrix $F \in \mathbf{R}^{p\times m}$ satisfy*

$$\delta_S + \delta_{2S} + \delta_{3S} < 1 \tag{13}$$

for some integer S such that $0 < S \leq m$, then if x is an optimal solution of the convex program:

$$\begin{array}{ll} \textit{minimize} & \|x\|_1 \\ \textit{subject to} & Fx = Fy \end{array}$$

such that $\mathbf{Card}\, x \leq S$ *then x is also an optimal solution of the combinatorial problem:*

$$\begin{array}{ll} \textit{minimize} & \|x\|_0 \\ \textit{subject to} & Fx = Fy. \end{array}$$

In other words, if condition (13) holds for some matrix F such that $FA = 0$, then perfect recovery of the signal f given $y = Af + e$ provided the error vector satisfies $\mathbf{Card}(e) \leq S$. Our key observation here is that the restricted isometry constant δ_S in condition (13) can be computed by solving the following sparse maximum eigenvalue problem:

$$\begin{array}{lll} (1+\delta_S) \leq & \max. & x^T(F^TF)x \\ & \text{s. t.} & \mathbf{Card}(x) \leq S \\ & & \|x\| = 1, \end{array}$$

in the variable $x \in \mathbf{R}^m$ and another sparse maximum eigenvalue problem on $\alpha\mathbf{I} - FF^T$ with α sufficiently large, with δ_S computed from the tightest one. In fact, (12) means that:

$$\begin{aligned}(1+\delta_S) &\leq \max_{\{I\subset[1,m]:\ |I|\leq S\}} \ \max_{\|c\|=1} c^T F_I^T F_I c \\ &= \max_{\{u\in\{0,1\}^n:\ \mathbf{1}^T u\leq S\}} \ \max_{\|x\|=1} x^T \mathbf{diag}(u) F^T F \mathbf{diag}(u) x \\ &= \max_{\{\|x\|=1,\ \mathbf{Card}(x)\leq S\}} x^T F^T F x,\end{aligned}$$

hence we can compute an upper bound on δ_S by duality, with:

$$(1+\delta_S) \leq \inf_{\rho\geq 0} \phi(\rho) + \rho S$$

where $\phi(\rho)$ is defined in (2). This means that while Candès and Tao (2005) obtained an asymptotic proof that some random matrices satisfied the restricted isometry condition (13) with overwhelming probability (i.e., exponentially small probability of failure), whenever they are satisfied, the *tractable* optimality conditions and upper bounds we obtain in Section 5 for sparse PCA problems allow us to prove, *deterministically*, that a finite dimensional matrix satisfies the restricted isometry condition in (13). Note that Candès and Tao (2005) provide a slightly weaker condition than (13) based on restricted orthogonality conditions and extending the results on sparse PCA to these conditions would increase the maximum S for which perfect recovery holds. In practice however, we will see in Section 7.3 that the relaxations in (7) and d'Aspremont et al. (2007b) do provide very tight upper bounds on sparse eigenvalues of random matrices but solving these semidefinite programs for very large scale instances remains a significant challenge.

7. Numerical Results

In this section, we first compare the various methods detailed here on artificial examples, then test their performance on a biological data set. PathSPCA, a MATLAB code reproducing these results may be downloaded from the authors' web pages.

7.1 Artificial Data

We generate a matrix U of size 150 with uniformly distributed coefficients in $[0,1]$. We let $v \in \mathbf{R}^{150}$ be a sparse vector with:

$$v_i = \begin{cases} 1 & \text{if } i \leq 50 \\ 1/(i-50) & \text{if } 50 < i \leq 100 \\ 0 & \text{otherwise.} \end{cases}$$

We form a test matrix $\Sigma = U^T U + \sigma v v^T$, where σ is the signal-to-noise ratio. We first compare the relative performance of the algorithms in Section 3 at identifying the correct sparsity pattern in v given the matrix Σ. The resulting ROC curves are plotted in Figure 1 for $\sigma = 2$. On this example, the computing time for the approximate greedy algorithm in Section 3.3 was 3 seconds versus 37 seconds for the full greedy solution in Section 3.2. Both algorithms produce almost identical answers. We can also see that both sorting and thresholding ROC curves are dominated by the greedy algorithms.

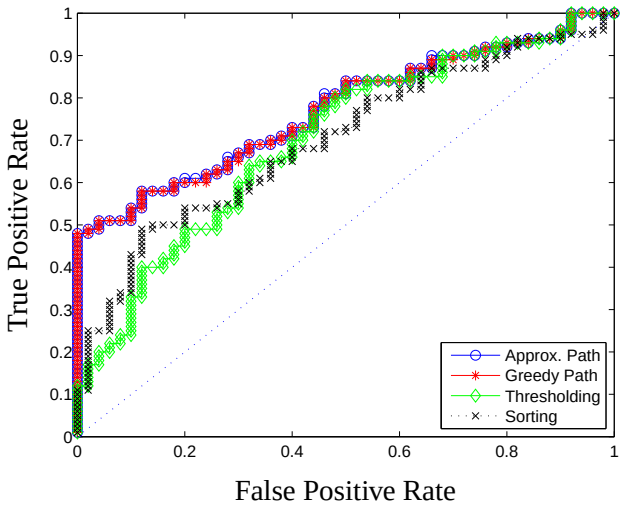

Figure 1: ROC curves for sorting, thresholding, fully greedy solutions (Section 3.2) and approximate greedy solutions (Section 3.3) for $\sigma = 2$.

We then plot the variance versus cardinality tradeoff curves for various values of the signal-to-noise ratio. In Figure 2, We notice that the magnitude of the error (duality gap) decreases with the signal-to-noise ratio. Also, because of the structure of our problem, there is a kink in the variance at the (exact) cardinality 50 in each of these curves. Note that for each of these examples, the error (duality gap) is minimal precisely at the kink.

Next, we use the DSPCA algorithm of d'Aspremont et al. (2007b) to find better solutions where the greedy codes have failed to obtain globally optimal solutions. In d'Aspremont et al. (2007b), it was shown that an upper bound on (2) can be computed as:

$$\phi(\rho) \leq \min_{|U_{ij}| \leq \rho} \lambda_{\max}(\Sigma + U).$$

which is a convex problem in the matrix $U \in \mathbf{S}_n$. Note however that the cost of solving this relaxation for a *single* ρ is $O(n^4\sqrt{\log n})$ versus $O(n^3)$ for a full path of approximate solutions. Also, the results in d'Aspremont et al. (2007b) do not provide any hint on the value of ρ, but we can use the breakpoints coming from suboptimal points in the greedy search algorithms in Section 3.3 and the consistency intervals in Eq. (9). In Figure 2 we plot the variance versus cardinality tradeoff curve for $\sigma = 10$. We plot greedy variances (solid line), dual upper bounds from Section 5.3 (dotted line) and upper bounds computed using DSPCA (dashed line).

7.2 Subset Selection

We now present simulation experiments on synthetic data sets for the subset selection problem. We consider data sets generated from a sparse linear regression problem and study optimality for the subset selection problem, given the exact cardinality of the generating vector. In this setting, it is known that regularization by the ℓ_1-norm, a procedure also known as the Lasso (Tibshirani, 1996), will asymptotically lead to the correct solution if and only if a certain consistency condition is satisfied (Yuan and Lin, 2007; Zhao and Yu, 2006). Our results provide here a tractable test

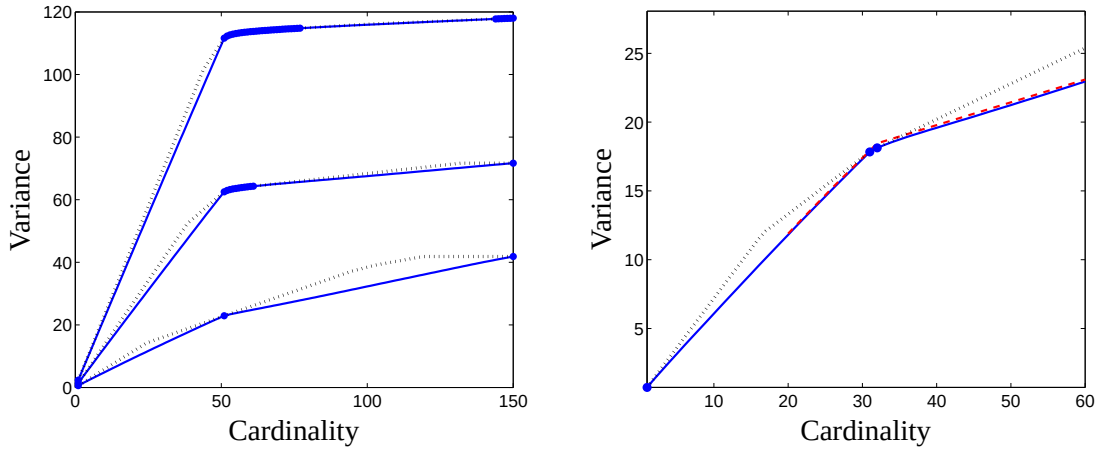

Figure 2: *Left:* variance versus cardinality tradeoff curves for $\sigma = 10$ (bottom), $\sigma = 50$ and $\sigma = 100$ (top). We plot the variance (solid line) and the dual upper bounds from Section 5.3 (dotted line) for each target cardinality. *Right:* variance versus cardinality tradeoff curve for $\sigma = 10$. We plot greedy variances (solid line), dual upper bounds from Section 5.3 (dotted line) and upper bounds computed using DSPCA (dashed line). Optimal points (for which the relative duality gap is less than 10^{-4}) are in bold.

the optimality of solutions obtained from various algorithms such as the Lasso, forward greedy or backward greedy algorithms.

In Figure 3, we consider two pairs of randomly generated examples in dimension 16, one for which the lasso is provably consistent, one for which it isn't. We perform 50 simulations with 1000 samples and varying noise and compute the average frequency of optimal subset selection for Lasso and greedy backward algorithm together with the frequency of provable optimality (i.e., where our method did ensure a posteriori that the point was optimal). We can see that the backward greedy algorithm exhibits good performance (even in the Lasso-inconsistent case) and that our sufficient optimality condition is satisfied as long as there is not too much noise. In Figure 4, we plot the average mean squared error versus cardinality, over 100 replications, using forward (dotted line) and backward (circles) selection, the Lasso (large dots) and exhaustive search (solid line). The plot on the left shows the results when the Lasso consistency condition is satisfied, while the plot on the right shows the mean squared errors when the consistency condition is not satisfied. The two sets of figures do show that the LASSO is consistent only when the consistency condition is satisfied, while the backward greedy algorithm finds the correct pattern if the noise is small enough (Couvreur and Bresler, 2000) even in the LASSO inconsistent case.

7.3 Sparse Recovery

Following the results of Section 6.2, we compute the upper and lower bounds on sparse eigenvalues produced using various algorithms. We study the following problem:

$$\begin{array}{ll} \text{maximize} & x^T \Sigma x \\ \text{subject to} & \mathbf{Card}(x) \leq S \\ & \|x\| = 1, \end{array}$$

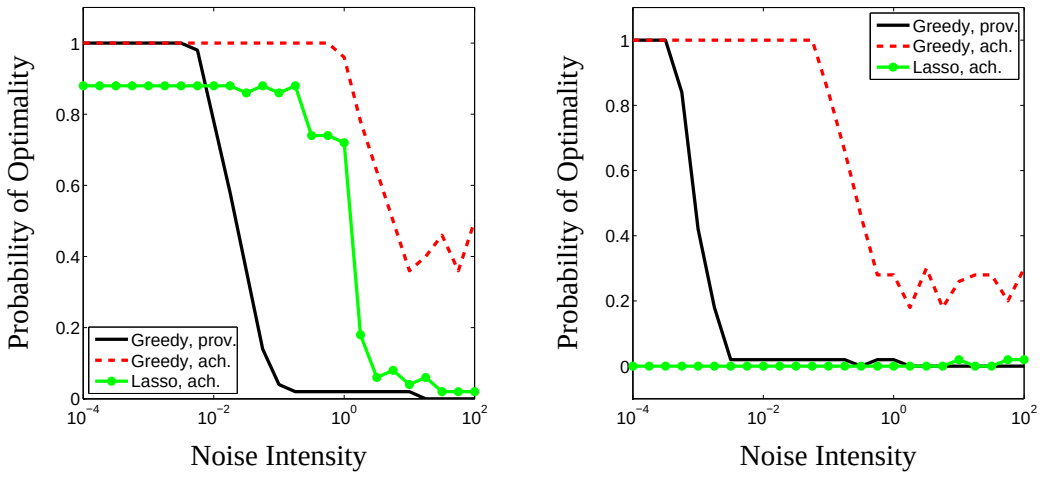

Figure 3: Backward greedy algorithm and Lasso. We plot the probability of achieved (dotted line) and provable (solid line) optimality versus noise for greedy selection against Lasso (large dots), for the subset selection problem on a noisy sparse vector. *Left:* Lasso consistency condition satisfied. *Right:* consistency condition not satisfied.

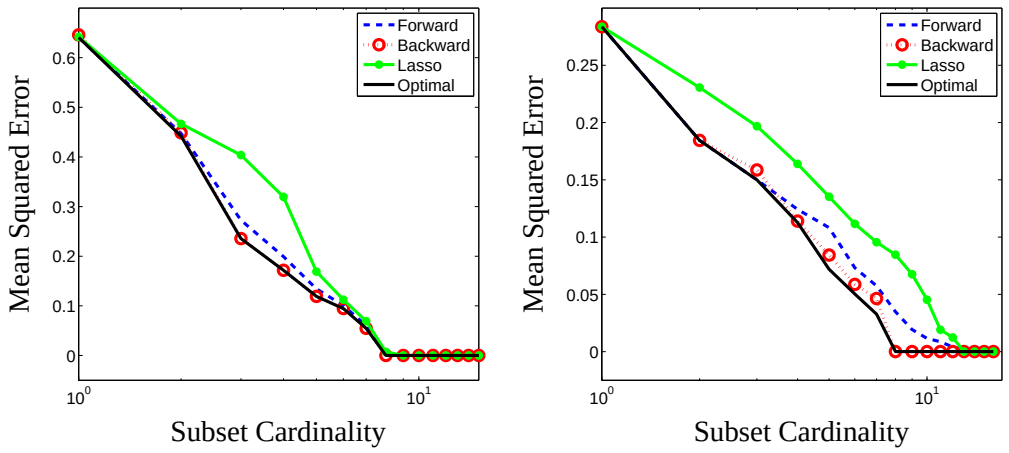

Figure 4: Greedy algorithm and Lasso. We plot the average mean squared error versus cardinality, over 100 replications, using forward (dotted line) and backward (circles) selection, the Lasso (large dots) and exhaustive search (solid line). *Left:* Lasso consistency condition satisfied. *Right:* consistency condition not satisfied.

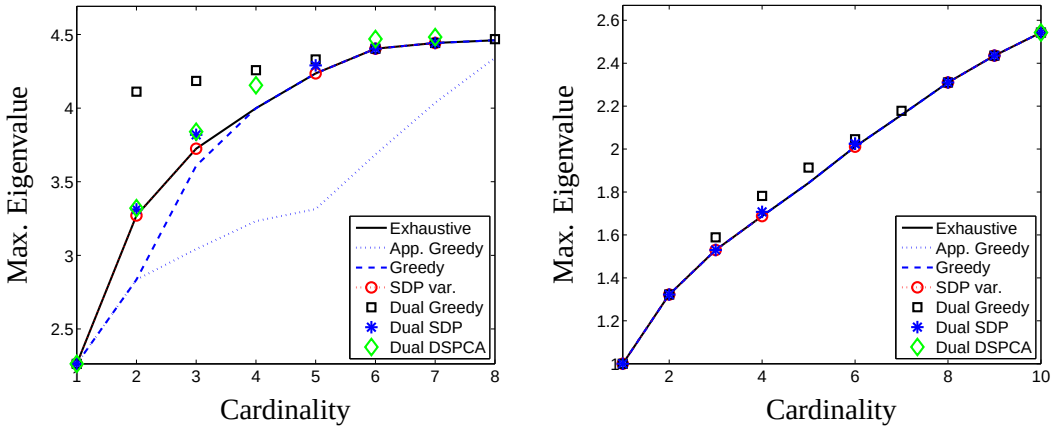

Figure 5: Upper and lower bound on sparse maximum eigenvalues. We plot the maximum sparse eigenvalue versus cardinality, obtained using exhaustive search (solid line), the approximate greedy (dotted line) and fully greedy (dashed line) algorithms. We also plot the upper bounds obtained by minimizing the gap of a rank one solution (squares), by solving the semidefinite relaxation explicitly (stars) and by solving the DSPCA dual (diamonds). *Left:* On a matrix F^TF with F Gaussian. *Right:* On a sparse rank one plus noise matrix.

where we pick F to be normally distributed and small enough so that computing sparse eigenvalues by exhaustive search is numerically feasible. We plot the maximum sparse eigenvalue versus cardinality, obtained using exhaustive search (solid line), the approximate greedy (dotted line) and fully greedy (dashed line) algorithms. We also plot the upper bounds obtained by minimizing the gap of a rank one solution (squares), by solving the semidefinite relaxation explicitly (stars) and by solving the DSPCA dual (diamonds). On the left, we use a matrix $\Sigma = F^TF$ with F Gaussian. On the right, $\Sigma = uu^T/\|u\|^2 + 2V$, where $u_i = 1/i,\ i = 1,\ldots,n$ and V is matrix with coefficients uniformly distributed in $[0,1]$. Almost all algorithms are provably optimal in the noisy rank one case (as well as in many of the biological examples that follow), while Gaussian random matrices are harder. Note however, that the duality gap between the semidefinite relaxations and the optimal solution is very small in both cases, while our bounds based on greedy solutions are not as good. This means that solving the relaxations in (7) and d'Aspremont et al. (2007b) could provide very tight upper bounds on sparse eigenvalues of random matrices. However, solving these semidefinite programs for very large values of n remains a significant challenge.

7.4 Biological Data

We run the algorithm of Section 3.3 on two gene expression data sets, one on Colon cancer from Alon et al. (1999), the other on Lymphoma from Alizadeh et al. (2000). We plot the variance versus cardinality tradeoff curve in Figure 6, together with the dual upper bounds from Section 5.3. In both cases, we consider the 500 genes with largest variance. Note that for many cardinalities, we have optimal or very close to optimal solutions. In Table 1, we also compare the 20 most important genes selected by the second sparse PCA factor on the colon cancer data set, with the top 10 genes selected by the RankGene software by Su et al. (2003). We observe that 6 genes (out of an original 4027 genes) were both in the top 20 sparse PCA genes and in the top 10 Rankgene genes.

Rank	Rankgene	GAN	Description
3	8.6	J02854	Myosin regul.
6	18.9	T92451	Tropomyosin
7	31.5	T60155	Actin
8	25.1	H43887	Complement fact. D prec.
10	2.1	M63391	Human desmin
12	32.3	T47377	S-100P Prot.

Table 1: 6 genes (out of 4027) that were both in the top 20 sparse PCA genes and in the top 10 Rankgene genes.

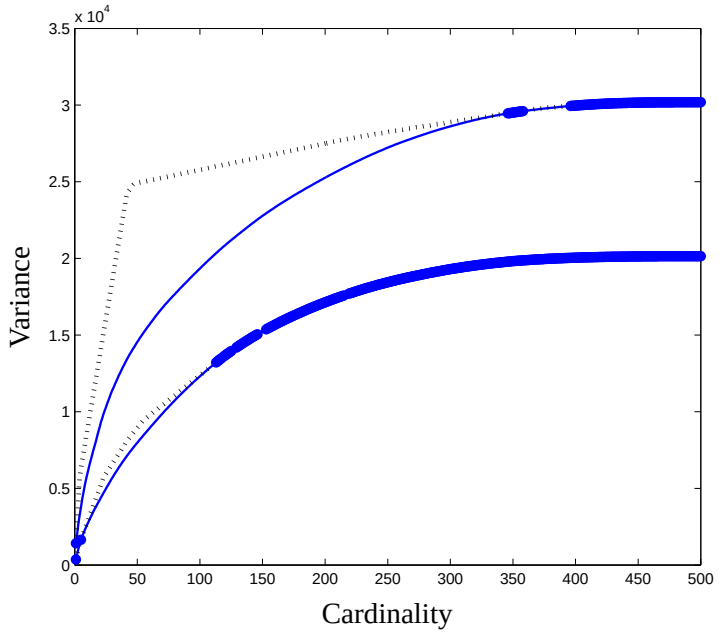

Figure 6: Variance (solid lines) versus cardinality tradeoff curve for two gene expression data sets, lymphoma (top) and colon cancer (bottom), together with dual upper bounds from Section 5.3 (dotted lines). Optimal points (for which the relative duality gap is less than 10^{-4}) are in bold.

8. Conclusion

We have presented a new convex relaxation of sparse principal component analysis, and derived tractable sufficient conditions for optimality. These conditions go together with efficient greedy algorithms that provide candidate solutions, many of which turn out to be optimal in practice. The resulting upper bounds also have direct applications to problems such as sparse recovery, subset selection or LASSO variable selection. Note that we extensively use this convex relaxation to test optimality and provide bounds on sparse extremal eigenvalues, but we almost never attempt to solve it numerically (except in some of the numerical experiments), which would provide optimal

bounds. Having n matrix variables of dimension n, the problem is of course extremely large and finding numerical algorithms to directly optimize these relaxation bounds would be an important extension of this work.

Appendix A. Expansion of Eigenvalues

In this appendix, we consider various results on expansions of eigenvalues we use in order to derive sufficient conditions. The following proposition derives a second order expansion of the set of eigenvectors corresponding to a single eigenvalue.

Proposition 9 *Let $N \in \mathbf{S}^n$. Let λ_0 be an eigenvalue of N, with multiplicity r and eigenvectors $U \in \mathbf{R}^{n\times r}$ (such that $U^TU = \mathbf{I}$). Let Δ be a matrix in $\mathbf{S}^n$. If $\|\Delta\|_F$ is small enough, the matrix $N+\Delta$ has exactly r (possibly equal) eigenvalues around λ_0 and if we denote by $(N+\Delta)_{\lambda_0}$ the projection of the matrix $N+\Delta$ onto that eigensubspace, we have:*

$$\begin{aligned}(N+\Delta)_{\lambda_0} \;=\;& \lambda_0 UU^T + UU^T\Delta UU^T + \lambda_0 UU^T\Delta(\lambda_0\mathbf{I}-N)^\dagger + \lambda_0(\lambda_0\mathbf{I}-N)^\dagger\Delta UU^T\\ &+UU^T\Delta UU^T\Delta(\lambda_0\mathbf{I}-N)^\dagger + (\lambda_0\mathbf{I}-N)^\dagger\Delta UU^T\Delta UU^T + UU^T\Delta(\lambda_0\mathbf{I}-N)^\dagger UU^T\\ &+\lambda_0 UU^T\Delta(\lambda_0\mathbf{I}-N)^\dagger\Delta(\lambda_0\mathbf{I}-N)^\dagger + \lambda_0(\lambda_0\mathbf{I}-N)^\dagger\Delta(\lambda_0\mathbf{I}-N)^\dagger\Delta UU^T\\ &+\lambda_0(\lambda_0\mathbf{I}-M)^\dagger\Delta UU^T\Delta(\lambda_0\mathbf{I}-M)^\dagger + O(\|\Delta\|_F^3)\end{aligned}$$

which implies the following expansion for the sum of the r eigenvalues in the neigborhood of λ_0:

$$\begin{aligned}\mathbf{Tr}(N+\Delta)_{\lambda_0} \;=\;& r\lambda_0 + \mathbf{Tr}\,U^T\Delta U + \mathbf{Tr}\,U^T\Delta(\lambda_0\mathbf{I}-N)^\dagger\Delta U\\ &+\lambda_0\,\mathbf{Tr}(\lambda_0\mathbf{I}-N)^\dagger\Delta UU^T\Delta(\lambda_0\mathbf{I}-N)^\dagger + O(\|\Delta\|_F^3).\end{aligned}$$

Proof We use the Cauchy residue formulation of projections on principal subspaces (Kato, 1966): given a symmetric matrix N, and a simple closed curve $\mathcal{C}$ in the complex plane that does not go through any of the eigenvalues of N, then

$$\Pi_C(N) = \frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda\mathbf{I}-N}$$

is equal to the orthogonal projection onto the orthogonal sum of all eigensubspaces of N associated with eigenvalues in the interior of $\mathcal{C}$ (Kato, 1966). This is easily seen by writing down the eigenvalue decomposition $N = \sum_{i=1}^n \lambda_i u_i u_i^T$, and the Cauchy residue formula ($\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda-\lambda_i} = 1$ if λ_i is in the interior $\mathrm{int}(\mathcal{C})$ of $\mathcal{C}$ and 0 otherwise), and:

$$\frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda\mathbf{I}-N} = \sum_{i=1}^n u_iu_i^T \times \frac{1}{2i\pi}\oint_{\mathcal{C}}\frac{d\lambda}{\lambda-\lambda_i} = \sum_{i,\ \lambda_i\in\mathrm{int}(\mathcal{C})} u_iu_i^T.$$

See Rudin (1987) for an introduction to complex analysis and Cauchy residue formula. Moreover, we can obtain the restriction of N onto a specific sum of eigensubspaces as:

$$N\Pi_C(N) = \frac{1}{2i\pi}\oint_C \frac{Nd\lambda}{\lambda \mathbf{I} - N} = \frac{1}{2i\pi}\oint_C \frac{\lambda d\lambda}{\lambda \mathbf{I} - N}.$$

From there we can easily compute expansions around a given N by using expansions of $(\lambda \mathbf{I} - N)^{-1}$. The proposition follows by considering a circle around λ_0 that is small enough to exclude other eigenvalues of N, and applying several times the Cauchy residue formula. ■

We can now apply the previous proposition to our particular case:

Lemma 10 *For any $a \in \mathbf{R}^n$, $\rho > 0$ and $B = aa^T - \rho \mathbf{I}$, we consider the function $F : X \mapsto \mathbf{Tr}(X^{1/2} B X^{1/2})_+$ from $\mathbf{S}_+^n$ to $\mathbf{R}$. let $x \in \mathbf{R}^n$ such that $\|x\| = 1$. Let $Y \succeq 0$. If $x^T B x > 0$, then*

$$F((1-t)xx^T + tY) = x^T B x + \frac{t}{x^T B x}\mathbf{Tr}\, B x x^T B (Y - xx^T) + O(t^{3/2}),$$

while if $x^T B x < 0$, then

$$F((1-t)xx^T + tY) = \mathbf{Tr}\left(Y^{1/2}\left(B - \frac{Bxx^TB}{x^TBx}\right)Y^{1/2}\right)_+ + O(t^{3/2}).$$

Proof We consider $X(t) = (1-t)xx^T + tY$. We have $X(t) = U(t)U(t)^T$ with $U(t) = \begin{pmatrix} (1-t)^{1/2}x \\ t^{1/2}Y^{1/2} \end{pmatrix}$, which implies that the non zero eigenvalues of $X(t)^{1/2} B X(t)^{1/2}$ are the same as the non zero eigenvalues of $U(t)^T B U(t)$. We thus have

$$F(X(t)) = \mathbf{Tr}(M(t))_+,$$

with

$$\begin{aligned} M(t) &= \begin{pmatrix} (1-t)x^TBx & t^{1/2}(1-t)^{1/2}x^TBY^{1/2} \\ t^{1/2}(1-t)^{1/2}y^TBx & tY^{1/2}BY^{1/2} \end{pmatrix} \\ &= \begin{pmatrix} x^TBx & 0 \\ 0 & 0 \end{pmatrix} + t^{1/2}\begin{pmatrix} 0 & x^TBY^{1/2} \\ Y^{1/2}Bx & 0 \end{pmatrix} + t\begin{pmatrix} -x^TBx & 0 \\ 0 & Y^{1/2}BY^{1/2} \end{pmatrix} + O(t^{3/2}) \\ &= M(0) + t^{1/2}\Delta_1 + t\Delta_2 + O(t^{3/2}). \end{aligned}$$

The matrix $M(0)$ has a single (and simple) non zero eigenvalue which is equal to $\lambda_0 = x^TBx$ with eigenvector $U = (1,0)^T$. The only other eigenvalue of $M(0)$ is zero, with multiplicity n. Proposition 9 can be applied to the two eigenvalues of $M(0)$: there is one eigenvalue of $M(t)$ around x^TBx, while the n remaining ones are around zero. The eigenvalue close to λ_0 is equal to:

$$\begin{aligned} \mathbf{Tr}(M(t))_{\lambda_0} &= t\,\mathbf{Tr}\,U^\top \Delta_2 U + \lambda_0 + t\,\mathbf{Tr}\,U^T\Delta_1(\lambda_0\mathbf{I} - M(0))^\dagger \Delta_1 U \\ &\quad + \lambda_0\,\mathbf{Tr}(\lambda_0\mathbf{I} - M(0))^\dagger \Delta_1 U U^T \Delta_1 (\lambda_0 \mathbf{I} - M(0))^\dagger + O(t^{3/2}) \\ &= x^TBx + \frac{t}{x^TBx}\mathbf{Tr}\,Bxx^TB(Y - xx^T) + O(t^{3/2}). \end{aligned}$$

For the remaining eigenvalues, we get that the projected matrix on the eigensubspace of $M(t)$ associated with eigenvalues around zero is equal to

$$\begin{aligned}(M(t))_0 &= t(\mathbf{I}-UU^T)\Delta_2(\mathbf{I}-UU^T)+t(\mathbf{I}-UU^T)\Delta_1(-M(0))^\dagger(\mathbf{I}-UU^T)+O(t^{3/2}) \\ &= \begin{pmatrix} 0 & 0 \\ 0 & tY^{1/2}(B-\frac{Bxx^TB}{x^TBx})Y^{1/2} \end{pmatrix},\end{aligned}$$

which leads to a positive part equal to $t_+ \mathbf{Tr}\left[Y^{1/2}(B-\frac{Bxx^TB}{x^TBx})Y^{1/2}\right]_+$. When $x^TBx > 0$, then the matrix is negative definite (because $B = aa^T - \rho\mathbf{I}$), and thus the positive part is zero. By summing the two contributions, we obtain the desired result. ■

Abstract

We show how a generic feature-selection algorithm returning strongly relevant variables can be turned into a causal structure-learning algorithm. We prove this under the Faithfulness assumption for the data distribution. In a causal graph, the strongly relevant variables for a node X are its parents, children, and children's parents (or spouses), also known as the Markov blanket of X. Identifying the spouses leads to the detection of the V-structure patterns and thus to causal orientations. Repeating the task for all variables yields a valid partially oriented causal graph. We first show an efficient way to identify the spouse links. We then perform several experiments in the continuous domain using the Recursive Feature Elimination feature-selection algorithm with Support Vector Regression and empirically verify the intuition of this direct (but computationally expensive) approach. Within the same framework, we then devise a fast and consistent algorithm, Total Conditioning (TC), and a variant, TC_{bw}, with an explicit backward feature-selection heuristics, for Gaussian data. After running a series of comparative experiments on five artificial networks, we argue that Markov blanket algorithms such as TC/TC_{bw} or Grow-Shrink scale better than the reference PC algorithm and provides higher structural accuracy.

Keywords: causal structure learning, feature selection, Markov blanket, partial correlation, statistical test of conditional independence

1. Introduction

In this paper, we are interested in using concepts from the feature-selection field to help causal structure learning. Causal structure learning (Pearl, 2000; Spirtes et al., 2001) is a multivariate data-analysis approach that aims to build a directed acyclic graph (DAG) showing direct causal relations among the variables of interest of a given system. These so-called causal graphs can be used together with dedicated rules called *do*-calculus (Pearl, 1995) to predict the effect of interventions, that is, of structural changes in the data-generating process. In this sense, it differs significantly from traditional machine-learning techniques: given a set of interventions, we can predict the behavior of a set of variables whose joint probability distribution has changed since the model was trained.

Building the causal graph is a difficult task, subject to a series of assumptions, and provably correct algorithms have an exponential worst-case complexity. Identifying the exact causal graph is in general impossible. By means of non-interventional data, causal graphs can only be identified up to *observational equivalence*: only adjacencies and so-called V-structures (two independent causes

∗. Also at Pattern Analysis and Machine Learning Group, Swiss Federal Institute of Technology Zurich, Universitätstraße 6, CH–8092 Zurich.

leading to the same effect) can be specified exactly (Pearl, 2000, p. 19). Typical structure-learning algorithms thus return partially directed acyclic graphs (PDAGs). These algorithms can be roughly classified into two categories: the *score-based* algorithms associate a score function with a DAG or PDAG given a training data set and perform, for instance, a greedy search in the space of DAGs or PDAGs (e.g., the GES algorithm, Chickering, 2002); the *constraint-based* algorithms look for dependencies and conditional dependencies in the data and build the causal graph accordingly. Well-known examples are the PC (Spirtes et al., 2001) or the IC (Pearl and Verma, 1991) algorithms. In an effort to get the best of both worlds, other algorithms use both conditional-independence tests and scores to build the network; MMHC (Tsamardinos et al., 2006) is such an example.

The range of data sets that the typical algorithms can deal with is restricted: not any probability distribution can be *faithfully* represented by a DAG. Faithfulness of the distribution is a well-defined condition: it guarantees the existence of a DAG, called a *perfect map*, where there is a one-to-one mapping between the graphical criterion of *d*-separation and conditional independence in the data.[1] Nilsson et al. (2007) discuss faithful distributions and other types of distributions with respect to properties of conditional independence. In the literature, Faithfulness is a precondition to prove correctness of the algorithms.

In practice, both existing score-based and constraint-based techniques deal primarily with discrete data sets. Score-based approaches for continuous variables are computationally expensive;[2] as for the constraint-based approaches, only the multivariate Gaussian case has been dealt with efficiently (Scheines et al., 1995). Margaritis (2005) proposed a distribution-free test of conditional independence, which is very computationally expensive and cannot be readily used with the current constraint-based algorithms for all but very small networks.

Coming from the machine-learning community, feature selection (John et al., 1994; Guyon and Elisseeff, 2003) is a common technique that aims at reducing the number of variables or features used for building more efficient or more robust models. Techniques have evolved to be able to handle nonlinear relationships between variables, redundant variables, in both discrete and continuous domains. Feature selection and causal structure learning are related by a common concept: the *Markov blanket* of a variable X is the smallest set $\mathbf{Mb}(X)$ containing all variables carrying information about X that cannot be obtained from any other variable.[3] In feature selection, this is the set of *strongly relevant* features; that is, of features which carry information about the target that cannot be obtained from any other variable (Kohavi and John, 1997). In a causal graph, this is the set of all parents, children, and spouses of X. The feature-selection task and the causal graph construction task can both be stated to some extent as Markov blanket identification tasks.

Relating feature selection and causal structure learning is not new. Several algorithms identifying the Markov blanket of a single variable with techniques inspired from causal structure learning have been proposed as the optimal solution to the feature-selection problem in the case of a faithful distribution. Tsamardinos and Aliferis (2003) show that for faithful distributions, the Markov blanket of a variable Y is exactly the set of strongly relevant features, and prove its uniqueness. They propose the Incremental Association Markov Blanket (IAMB) algorithm to determine it. With the same Faithfulness assumption, the Min-Max Markov Blanket algorithm (MMMB) (Tsamardinos

1. Conditional independence and *d*-separation are defined formally in Section 2.
2. Computationally tractable methods to learn Bayesian networks from continuous data exist (Fu, 2005), like Bach and Jordan (2003), but do not offer the causality-related theoretical correctness guarantees.
3. Some authors write "Markov blanket" without the notion of minimality, and use "Markov boundary" to note the smallest Markov blanket $\mathbf{Mb}(X)$. Even if defined as minimal, $\mathbf{Mb}(X)$ is generally not unique.

et al., 2003) identifies the Markov blanket of a variable Y by calling a subroutine Min-Max Parents and Children (MMPC). This subroutine finds the direct parents and children of Y with association measures and conditional-independence tests. MMPC is again called on each of these nodes to find potential spouses of Y. False positives are then discarded with conditional-independence tests. MMMB was further discussed by Peña et al. (2005), who propose AlgorithmMB, a similar approach based on scores and conditional-independence tests to retrieve $\mathbf{Mb}(Y)$. The HITON_MB algorithm (Aliferis et al., 2003) is similar in its main steps, and selects an optimal subset of the Markov blanket of a target variable given the Faithfulness assumption. Nilsson et al. (2007) also propose a theoretical algorithm for consistent identification of strongly relevant features in polynomial time for the class of strictly positive distributions. They also argue that some common backward feature-elimination algorithms like Recursive Feature Elimination (Guyon et al., 2002) are actually consistent, in the sense that they return the set of strongly relevant features in the large sample limit.[4]

These are examples of using causal structure learning or similar constraint-based techniques to help feature selection (see Guyon et al., 2007, for a review of those techniques). In this paper, we propose a framework to do the converse. We present a generic approach using the outcome of a consistent feature-selection algorithm *FS* to build an approximate structure of the true causal graph. If we assume that *FS* returns the Markov blanket of the variables, we can show how to turn this approximate result, called *moral graph* (Lauritzen and Spiegelhalter, 1988), into a provably correct PDAG depicting the causal structure. This approach is also used in the Grow-Shrink algorithm (Margaritis and Thrun, 1999), which also builds a moral graph before adjusting the local structure.

This paper contributes a generic algorithm to build a causal graph which clearly separates the Markov blanket identification and the needed local adjustments, an efficient algorithm to perform those adjustments, and two fast instances of the generic algorithm for multivariate Gaussian data sets. This is presented as follows: in Section 2, we first review the needed terms and definitions from feature selection and causality. In Section 3, we make the link from the outcome of a feature-selection algorithm to a causal graph by detailing the needed local adjustments and detail an efficient way to perform them. We directly apply it in Section 4, where we describe how we can build causal graphs using the RFE feature-selection algorithm. As this direct application is very computationally intensive, we then show our more efficient instantiations of the generic algorithm optimized for the multivariate Gaussian case, the TC and TC_{bw} algorithms. We list our experimental results in Section 5, showing through empirical evaluation that Markov blanket algorithms are more scalable and more accurate than the reference PC algorithm. We finally conclude in Section 6 and list proofs in Appendix A.

1.1 Notation

Boldface capitals designate either matrices or sets of random variables or nodes in a graph, depending on the context. $\mathbf{V}$ is the set of all variables in the analysis. Italicized capitals like X, Y, Z are random variables or nodes and elements of $\mathbf{V}$. Vectors are set in boldface lowercase, as $\mathbf{b}$ or $\mathbf{w}$; scalars in italics, as the number of samples n or the number of variables (the problem dimension) d. We indiscriminately write "variable" or "feature" to refer to any variable in the causal analysis or

4. Actually, their definition of consistency has to do with returning the set of features relevant to the Bayes classifier, which is slightly stronger than strong relevance as used here.

any node in a causal graph, and write "predictor" to designate a variable used as input for a given classifier or regression model.

2. Background

We formalize the feature-selection task suited for our needs and provide relevant definitions. We do the same for the causal structure-learning task and prepare the needed basis for drawing the parallels between the two in the next section.

2.1 Feature Selection

We are given a data set of n samples $D = \{(\mathbf{x}_i, y_i), 1 \leq i \leq n\}$. Each data point $(\mathbf{x}_i, y_i)$ has $d-1$ inputs, modeled as a vector $\mathbf{x}_i \in \mathbb{R}^{d-1}$, and an output, or *target*, $y_i \in \mathbb{R}$ (we use $d-1$ and not d for the size of $\mathbf{x}_i$ for consistency with the rest of the paper). The data points are assumed to be drawn i.i.d. from a joint probability distribution over the random variables $\mathbf{V} = \mathbf{X} \cup \{Y\}$. The result of the feature-selection task we are interested in is a set of retained variables $\mathbf{F} \subseteq \mathbf{X}$. How many variables to retain and which variables to retain depends on the particular algorithm, and usually maximizes some tradeoff between efficiency and classification/regression error of a given learning task.

John et al. (1994) propose a classification of the input variables $\mathbf{X}$ with respect to their relevance to the target Y in terms of *conditional independence*.

Definition 1 (Conditional independence) *In a variable set* $\mathbf{V}$*, two random variables* X, Y *are* conditionally independent *given* $\mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\}$*, noted* $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$*, if:*

$$\forall x, y, \mathbf{z} : P(X = x \mid Y = y, \mathbf{Z} = \mathbf{z}) = P(X = x \mid \mathbf{Z} = \mathbf{z}),$$

provided that $\forall \mathbf{z} : P(\mathbf{Z} = \mathbf{z}) > 0$.

Conditional independence is a generalization of the traditional notion of statistical independence. If two variables X and Y are independent, then the joint distribution is the product of the marginals: $P(X = x, Y = y) = P(X = x)P(Y = y)$. If they are dependent given some conditioning set $\mathbf{Z}$, then we can write $P(X = x, Y = y \mid \mathbf{Z} = \mathbf{z}) = P(X = x \mid \mathbf{Z} = \mathbf{z})P(Y = y \mid \mathbf{Z} = \mathbf{z})$. Conditional independence is a key concept in Bayesian networks (Pearl, 1988) because of the factorizations of the joint probability distribution it allows.

In feature selection, relevance of predictors to the target as proposed by John et al. (1994) is expressed in terms of conditional independence. In the following definitions, we write X_i to note the ith input variable, and $\mathbf{X}_{\setminus i}$ to note all input variables but the ith one.

Definition 2 (Strong relevance) *A variable* X_i *is* strongly relevant *to the target* Y *if*

$$P(Y \mid \mathbf{X}_{\setminus i}) \neq P(Y \mid \mathbf{X}_{\setminus i}, X_i).$$

A variable is strongly relevant to the target if it carries information about Y that no other variable carries. This is expressed in the definition by a change in the probability distribution of the target between conditioning on all other variables, $\mathbf{X}_{\setminus i}$, and also including X_i in the conditioning set. If X_i carries no exclusive information about Y, the two distributions will be identical.

Definition 3 (Weak relevance) *A variable X_i is* weakly relevant *to the target Y if it is not strongly relevant and*

$$\exists \mathbf{S} \subseteq \mathbf{X}_{\setminus i} : P(Y \mid \mathbf{S}) \neq P(Y \mid \mathbf{S}, X_i).$$

We speak of weak relevance of a variable X_i when there exists a certain context $\mathbf{S}$ in which it carries information about the target. However, this is not necessarily exclusive information, as it may be possible to obtain it from other variables.

Corollary 4 (Irrelevance) *A variable X_i is* irrelevant *to the target Y if it is neither strongly nor weakly relevant, that is, if*

$$\forall \mathbf{S} \subseteq \mathbf{X}_{\setminus i} : P(Y \mid \mathbf{S}) = P(Y \mid \mathbf{S}, X_i).$$

A variable is irrelevant if carries no information about the target at all, no matter what the context is.

For our purposes, we assume that the feature-selection algorithm returns the set of all strongly relevant variables, and only those.[5] (In Section 5, we discuss with experiments whether this is a reasonable assumption with the RFE algorithm.) Put in terms of conditional independence, the result $\mathbf{F}_Y$ of the feature-selection task with target Y is, with $\mathbf{V} = \mathbf{X} \cup \{Y\}$:

$$\mathbf{F}_Y = \left\{ X \;\middle|\; (X \not\perp\!\!\!\perp Y \mid \mathbf{V} \setminus \{X, Y\}) \right\}. \tag{1}$$

That is the set of the variables that are dependent on the target Y, conditioned on all others. We need this property in Section 3 to use the output of the feature-selection task to build a causal graph. Note that if we repeat the feature-selection task using as target another variable $X \in \mathbf{V}$ yielding a result $\mathbf{F}_X$, we have:

$$X \in \mathbf{F}_Y \iff Y \in \mathbf{F}_X. \tag{2}$$

This follows as a direct consequence of (1) due to the symmetry of the conditional-independence relation $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$ with respect to X and Y.

2.2 Causal Structure Learning

In causal structure learning, we are interested in representing graphically conditional dependencies found in the data. Under a set of assumptions, they have a causal interpretation. For this task, we have a data set of n samples $D = \{\mathbf{v}_i, 1 \leq i \leq n\}$. We do not designate a specific target variable in $\mathbf{V}$ as we are interested in learning the full structure of the network.

The graphical representation of choice for causal models is directed acyclic graphs (DAGs) (Pearl, 2000). In a causal graph represented by a DAG, we want to represent direct causal relations with arcs between pairs of variables. Choosing DAGs for this task implies restrictions, an obvious one of which is that causal feedback loops are excluded from the analysis. More formally, the joint probability distribution has to be *faithful* (or *DAG-isomorphic*, Pearl, 1988, p. 128); that is, there must exist a DAG that represents all (conditional) dependencies and independencies entailed by the distribution. Such a graph is called a *perfect map* of the distribution if there is a one-to-one mapping between the conditional-independence relation defined on variables and the *d-separation criterion* defined on the graphical nodes.

5. In the general case, this set can be empty without excluding the existence of other weakly relevant variables (Tsamardinos and Aliferis, 2003). In the next subsection, we detail the Faithfulness hypothesis, which allows us to exclude this particular case.

Definition 5 (*d*-separation) *In a DAG $\mathcal{G}$, two nodes X, Y are* d-separated *by $\mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\}$, written $(X \nleftrightarrow Y \mid \mathbf{Z})$, if every path from X to Y is blocked by $\mathbf{Z}$. A path is* blocked *if at least one diverging or serially connected node is in $\mathbf{Z}$ or if at least one converging node and all its descendants are not in $\mathbf{Z}$. If X and Y are not* d-*separated by $\mathbf{Z}$, they are* d-*connected: $(X \leftrightarrow Y \mid \mathbf{Z})$.*

Determining whether two nodes in a graph are *d*-separated given some conditioning set is not visually immediate. It may for instance be unintuitive that whereas conditioning on a node W on a directed path $X \to W \to Y$ blocks the path from X to Y, conditioning on a common child Z of two variables X, Y in $X \to Z \leftarrow Y$ connects them. In the latter case, this common child is called a *collider*. If, furthermore, two parents X, Y of a node Z are nonadjacent in the full graph, then Z is called an *unshielded collider* for the pair (X, Y).

The definition of *d*-separation was worked out by Pearl (1988) to match as closely as possible the complicated nature of the conditional-independence relation with a graphical criterion, so that the class of faithful distributions, which can be represented by a perfect map, is as large as possible, while still keeping a natural graphical representation.

Definition 6 (Perfect map) *A DAG $\mathcal{G}$ is a* directed perfect map *of a joint probability distribution $P(\mathbf{V})$ if there is bijection between* d-*separation in $\mathcal{G}$ and conditional independence in P:*

$$\forall X, Y \in \mathbf{V}, \forall \mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\} : \big((X \nleftrightarrow Y \mid \mathbf{Z}) \iff (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \big). \tag{3}$$

If we take apart the perfect-map equivalence, we distinguish two important concepts, known as the Causal Markov condition and the Faithfulness condition (Spirtes et al., 2001, p. 29).

The **Causal Markov condition** is said to hold for a graph $\mathcal{G} = \langle \mathbf{V}, \mathbf{E} \rangle$ and a probability distribution $P(\mathbf{V})$ if every variable is statistically independent of its graphical non-descendants (intuitively, of its non-effects, direct or indirect) conditional on its graphical parents (intuitively, its direct causes) in P. Pairs $\langle \mathcal{G}, P \rangle$ that satisfy the Causal Markov condition satisfy the implication

$$\forall X, Y \in \mathbf{V}, \forall \mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\} : \big((X \nleftrightarrow Y \mid \mathbf{Z}) \implies (X \perp\!\!\!\perp Y \mid \mathbf{Z}) \big).$$

This is called *I-map property* by Pearl (1988).

The **Faithfulness condition** can be interpreted as the converse of the Causal Markov condition, and states that the only conditional independencies to hold are those specified by the Causal Markov condition:

$$\forall X, Y \in \mathbf{V}, \forall \mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\} : \big((X \leftrightarrow Y \mid \mathbf{Z}) \implies (X \not\perp\!\!\!\perp Y \mid \mathbf{Z}) \big).$$

If the Causal Markov and Faithfulness conditions hold together for a pair $\langle \mathcal{G}, P \rangle$, then we find again the equivalence (3), and $\mathcal{G}$ is a perfect map of P.

In practice, the Causal Markov condition is used by the so-called constraint-based algorithms to perform conditional-independence tests on the data and build the graph accordingly, and Faithfulness is assumed to prove that the graph is correct. Hausman and Woodward (1999) discuss and explain in more detail the Causal Markov condition, and Steel (2005) discusses the Faithfulness condition and its motivations, pointing out cases where it can be violated. While the former is in general not violated simply by construction of the causal graph, violation of the latter occurs if the probability distribution is not faithful. A simple example is the *n*-bit parity problem where the prior probability of each bit is uniform, of which the XOR problem is a special case: each variable is

unconditionally independent of every other, but any variable pair becomes dependent conditioned on all other variables. On this problem, current constraint-based algorithms yield an empty graph because of the pairwise unconditional independencies, although it is not true that the data shows no dependency at all since one variable is a well-defined function of all others.

From this point on and for all proofs, we assume that the working data set D has a distribution that does not violate Faithfulness, and that it can thus be represented by a perfect map. In such a context, however, it is still not clear that causation can be inferred from conditional independence. We now proceed to explain the relation between causation and conditional independence.

Assuming Faithfulness, direct causation between X and Y, noted $X \dashrightarrow Y$, implies that X and Y are dependent given any conditioning set (Pearl and Verma, 1991, see definitions of potential and genuine causes):

$$X \dashrightarrow Y \implies \big(\forall \mathbf{S} \subseteq \mathbf{V} \setminus \{X,Y\} : (X \not\perp\!\!\!\perp Y \mid \mathbf{S})\big).$$

We denote the absence of direct causation by $X \not\dashrightarrow Y$. The exact converse of this implication does not hold. If we make the **Causal Sufficiency assumption** (Spirtes et al., 2001), that is, assume that no hidden common cause of two variables exists, we can write:

$$\big(\forall \mathbf{S} \subseteq \mathbf{V} \setminus \{X,Y\} : (X \not\perp\!\!\!\perp Y \mid \mathbf{S})\big) \implies X \dashrightarrow Y \text{ or } Y \dashrightarrow X. \tag{4}$$

Using (4), we can theoretically determine all adjacencies of the causal graph with conditional-independence tests, but we cannot orient the edges. But there is a special causation pattern where conditional-independence tests can reveal the direction of causation. It is known as a **V-structure** (Pearl, 2000): two common causes X, Y, initially independent,[6] become dependent when conditioned on a common effect Z, then acting as a collider. This is noted $X \dashrightarrow Z \dashleftarrow Y$, where we also require $X \not\dashrightarrow Y$ and, symmetrically, $Y \not\dashrightarrow X$. Formally, we have:

$$\begin{aligned} X \dashrightarrow Z \dashleftarrow Y \text{ and } X \not\dashrightarrow Y \text{ and } Y \not\dashrightarrow X \\ \implies \big(\exists \mathbf{S} \subseteq \mathbf{V} \setminus \{X,Y,Z\} : (X \perp\!\!\!\perp Y \mid \mathbf{S}) \text{ and } (X \not\perp\!\!\!\perp Y \mid \mathbf{S} \cup \{Z\})\big). \end{aligned}$$

The exact converse does not hold either. But using (4), we can find an equivalence relation defining a V-structure, still assuming Causal Sufficiency: first, we certify the existence of a link between X and Z and between Y and Z. Z is then identified as an unshielded collider if conditioning on it creates a dependency between X and Y:

$$\begin{aligned} X \dashrightarrow Z \dashleftarrow Y \iff \Big(&\big(\exists \mathbf{S} \subseteq \mathbf{V} \setminus \{X,Y,Z\} : (X \perp\!\!\!\perp Y \mid \mathbf{S}) \text{ and } (X \not\perp\!\!\!\perp Y \mid \mathbf{S} \cup \{Z\})\big) \\ &\text{and } \big(\forall \mathbf{S} \subseteq \mathbf{V} \setminus \{X,Z\} : (X \not\perp\!\!\!\perp Z \mid \mathbf{S})\big) \\ &\text{and } \big(\forall \mathbf{S} \subseteq \mathbf{V} \setminus \{Y,Z\} : (Y \not\perp\!\!\!\perp Z \mid \mathbf{S})\big)\Big). \end{aligned} \tag{5}$$

Actually, typical algorithms first establish the existence of a link between two variables by seeking a certificate equivalent to, or implicating the premise of, (4), and then look for orientation possibilities. Note that there is no guarantee that all links can be oriented into causal arcs, and that in

6. The two causes X and Y actually do not need to be unconditionally independent, but there must exist a (possibly empty) separating set $\mathbf{S}_{XY} \subseteq \mathbf{V} \setminus \{X,Y\}$ such that $(X \perp\!\!\!\perp Y \mid \mathbf{S}_{XY})$ for the collider to be identifiable. This implies that no direct causation $X \dashrightarrow Y$ or $Y \dashrightarrow X$ may exist: the collider must be unshielded.

general we therefore cannot recover the full causal structure with conditional-independence tests. This is the problem known as **causal underdetermination** (Spirtes et al., 2001, p. 62): for the structure-learning task given observational data, a correct graph is specified by its adjacencies and its V-structures only. Partially oriented graphs returned by structure-learning algorithms represent *observationally equivalent classes* of causal graphs (Pearl, 2000, p. 19). This means that for a given joint probability distribution $P(\mathbf{V})$, the set of all conditional-independence statements that hold in P does not yield a unique perfect map in general.

Formally, if we combine (3), (4) and (5), we find, for a perfect causal map $\mathcal{G}$ (using the symbol "$\multimap$" to denote direct causation and "$\rightarrow$" to denote an arc in the graph):

$$\begin{aligned} X,Y \text{ adjacent in } \mathcal{G} &\iff X \multimap Y \text{ or } Y \multimap X \\ X \rightarrow Z \leftarrow Y &\iff X \multimap Z \leftarrow Y. \end{aligned} \tag{6}$$

It is sometimes possible to orient further arcs in a graph by looking at already-oriented arcs and propagating constraints, preventing acyclicity and the creation of additional V-structures other than those already detected. The graph after this constraint-propagation step is called *completed PDAG*, *maximally oriented PDAG* (CPDAG), or *essential graph*, depending on the author.

3. Causal Network Construction Based on Feature Selection

We have looked at the ideal outcome of feature selection in (1) and how to read a causal graph in (6). We now turn to showing how feature selection can be used to build a causal graph. From now on and for the rest of this paper, we assume that the joint probability distribution over all variables $\mathbf{V}$ is faithful.

3.1 Identifying the Markov Blankets

In the context of directed graphical models, the Markov blanket of a node X, noted $\mathbf{Mb}(X)$, is the set of parents, children, and children's parents (spouses) of X. As an easy property, note that we have:

$$X \in \mathbf{Mb}(Y) \iff Y \in \mathbf{Mb}(X).$$

The following statement is a key property of Markov blankets.

Property 7 (Total conditioning) *In the context of a faithful causal graph $\mathcal{G}$, we have:*

$$\forall X,Y \in \mathbf{V}: \left(X \in \mathbf{Mb}(Y) \iff (X \not\perp\!\!\!\perp Y \mid \mathbf{V} \setminus \{X,Y\})\right).$$

(See Appendix A for the proof.) This property says that the Markov blanket of each node is the set of all variables that are dependent on it, conditioned on all other variables. In other words, in a causal graph, the parents, children, and spouses of Y store information about Y that cannot be obtained from any other variable. Note that $\mathbf{Mb}(Y)$ then has exactly the property of the output of feature selection, $\mathbf{F}_Y$, as characterized in (1). This links feature selection and causal structure learning in the sense that

$$\mathbf{F}_Y = \mathbf{Mb}(Y),$$

the Faithfulness assumption guaranteeing the unicity of $\mathbf{Mb}(Y)$. However, Markov blankets alone do not fully specify a causal graph. Thus, feature selection, even if guaranteed to find only strongly relevant features, cannot be directly used to construct the graph as we want it to be. The problem is that spouses of Y, even if not directly linked in the original graph, would be linked in $\mathbf{F}_Y$ and $\mathbf{Mb}(Y)$. An additional step is needed to transform the Markov blankets into parents, children, and spouses.

3.2 Recovering the Local Structure

The result of feature selection can be graphically shown by an undirected graph $\mathcal{G} = \langle \mathbf{V}, \mathbf{E} \rangle$ where $(X,Y) \in \mathbf{E} \Leftrightarrow X \in \mathbf{F}_Y$. This graph is close to the original causal graph in that it contains all arcs as undirected links, and additionally links spouses together, and is called the *moral graph* of the original directed graph (Lauritzen and Spiegelhalter, 1988, p. 166). The extra step needed to transform this graph into a causal PDAG is the deletion of the spouse links and the orientation of the arcs, a task which we call "resolving the Markov blankets."

An existing algorithm can resolve the Markov blankets, that is, use Markov blanket information to infer the local structure around a node: the Grow-Shrink (GS) algorithm, proposed by Margaritis and Thrun (1999). The full algorithm first finds the Markov blanket for each variable, and performs further conditional-independence tests around each variable to infer the structure locally. It then uses a heuristics to remove cycles possibly introduced by previous steps. We list in Algorithm 1 (using our notation) the steps of the algorithm responsible for building the local structure using the Markov blanket information, as this is exactly the task we are trying to solve. In the code, $\mathbf{Bd}(X)$ stands for the *boundary* of X; that is, the set of its direct neighbors in the graph $\mathcal{G}$. It is different from $\mathbf{Mb}(X)$ in that whereas $\mathbf{Mb}(X)$ is passed as input to the algorithm and is fixed, $\mathbf{Bd}(X)$ depends on the graph $\mathcal{G}$, which is modified throughout the algorithm. We note a conditional-independence test with a subroutine call to CONDINDEP$(X,Y,\mathbf{Z})$: ideally, this function returns *true* when $(X \perp\!\!\!\perp Y \mid \mathbf{Z})$ holds, and *false* otherwise. More will be said about the actual implementation of such tests in Section 4. The command **break** is used to break out of the innermost loop, saving unnecessary computations.

The GS algorithm makes two passes over all variables and the members of their Markov blankets (or direct neighbors in the second pass). It first removes the possible spouse links between linked variables X and Y by looking for a d-separating set around X and Y. In a second pass, it orients the arcs whenever it finds that conditioning on a middle node creates a dependency. While searching for the appropriate conditioning set, GS selects the smallest base search set (set **B** in Algorithm 1) for each phase. This has two very desirable effects. First, it reduces the number of tests, which is useful because each phase contains a subset search, exponential in time complexity with respect to the searched set. Second, it reduces the average size of the conditioning set, which increases the power of the statistical tests, and thus helps reduce the number of Type II errors.

While the GS approach considerably reduces the number of tests to be performed with respect to a large subset search, it is possible to perform fewer tests while still identifying correctly the structure and orienting the arcs, and decreasing the average conditioning set size. A helpful observation is that orientation and removal of the spouse links can be done together in a single pass. We know, as discussed in the previous section, that only arcs in V-structures can be oriented: fortunately, V-structures are exactly spotted when we identify a spouse link to be removed. Two spouses X and Y that are not directly linked in the original causal graph can be d-separated by some set of

Algorithm 1 Resolve the Markov Blankets with the Grow-Shrink Algorithm

```

nodes. Thus, if we can find a set $\mathbf{S}_{XY}$ that makes X and Y conditionally independent, we know that the link between them is a spouse link to be removed. Moreover, we know that any node Z part of the intersection of their Markov blankets not included in $\mathbf{S}_{XY}$ is a collider and thus a common child, and that the triplet (X,Z,Y) is actually a V-structure $X \rightarrow Z \leftarrow Y$ in the original graph. This follows from the definition of d-separation. What we need is an efficient search algorithm to find such d-separating sets.

An approach based on this observation has two main benefits. First, it only searches the triangles, that is, the cliques of three nodes, in the moral graph. Assuming that the information about the Markov blanket is correct, only triangles can hide spouse links and V-structures. Second, for each connected pair $X - Y$ in a triangle, decisions about possible spouse links and arc orientation are taken together and thus faster.

Pseudocode for the proposed search algorithm is listed in Algorithm 2, where the notation $\mathcal{G}^{\setminus XY}$ denotes the moral graph $\mathcal{G}$ where all direct links involving X or Y have been removed. The algorithm uses the following concept.

Definition 8 (Collider sets) *In an undirected graph $\mathcal{G} = \langle \mathbf{V}, \mathbf{E} \rangle$, let* $\mathbf{Tri}(X - Y)$ *(with $X, Y \in \mathbf{V}$ and $(X, Y) \in \mathbf{E}$) be the set of vertices forming a triangle with X and Y:*

$$\mathbf{Tri}(X - Y) = \{Z \in \mathbf{V} \mid (X, Z) \in \mathbf{E}, (Y, Z) \in \mathbf{E}\}.$$

Suppose that $\mathcal{G}$ is the moral graph of the DAG representing the causal structure of a faithful data set. A set of vertices $\mathbf{Z} \subseteq \mathbf{Tri}(X - Y)$ then has the Collider Set *property for the pair (X, Y) if it is the largest set that fulfills*

$$\exists \mathbf{S}_{XY} \subseteq \mathbf{V} \setminus \{X, Y\} \setminus \mathbf{Z} : (X \perp\!\!\!\perp Y \mid \mathbf{S}_{XY}) \tag{7}$$

$$\text{and} \quad \forall Z_i \in \mathbf{Z} : (X \not\perp\!\!\!\perp Y \mid \mathbf{S}_{XY} \cup \{Z_i\}). \tag{8}$$

The set $\mathbf{S}_{XY}$ is then a d*-separating set for X, Y.*

Lemma 9 *In the context of a faithful causal graph, the set $\mathbf{Z}$ that has the Collider Set property for a given pair (X, Y) exists if and only if X is neither a direct cause nor a direct effect of Y. This set $\mathbf{Z}$ is unique when it exists. (Proof in Appendix A.)*

The purpose of Algorithm 2 is thus to find these collider sets (in the pseudocode, the symbol $\subsetneq$ denotes the strict subset relation). The algorithm loops over all triangle links and performs a collider set search for each of them. Let $X - Y$ be one of these links: if it is not a spouse link, the search procedure will leave the value of the d-separating set $\mathbf{S}_{XY}$ to its default value, **null**. Otherwise, $\mathbf{S}_{XY}$ will be set to a (possibly empty[7]) set for X and Y. The collider set can be inferred by removing the d-separating set from the triangle nodes $\mathbf{Tri}(X - Y)$: as $\mathbf{Tri}(X - Y)$ contains nodes on a path of length 2 between X and Y, finding a d-separating set that does not contain some of these nodes proves that they can only be colliders according to the definition of d-separation.[8] For instance, if the procedure produces an empty set for a given linked pair $X - Y$, then X and Y are unconditionally independent, and therefore all nodes in $\mathbf{Tri}(X - Y)$ are colliders.

Two caveats have to be observed during this search, however. First, there might be other active, d-connecting paths between X and Y that are not going through any node of $\mathbf{Tri}(X - Y)$. Those nodes must be blocked by appropriate conditioning on the boundary of X or Y as determined by the base conditioning set at line 6. Second, this base conditioning set must be checked not to include any descendant of possible colliders. If it did, it would open a d-connecting path according to Definition 5. This check is performed at lines 13 to 21. At line 13, we build a set $\mathbf{D}$ that includes all possible descendants of currently conjectured colliders that intersect our base conditioning set $\mathbf{B}$. The following loop makes sure none of them was opening a path between X and Y.

Theorem 10 *In the large sample limit, for faithful, causally sufficient data sets, the procedure* RESOLVEMARKOVBLANKETS_COLLIDERSETS *correctly identifies all V-structures and all spouse links, assuming consistent statistical tests. (Proof in Appendix A.)*

This procedure is best understood with a graphical example. Consider the sample local structure in Figure 1, imagine it is part of a larger network, and suppose we are performing the search

7. Note that returning an empty d-separating set in $\mathbf{S}_{XY}$ is different from returning **null**, signaling the absence of any such set.
8. The next paragraphs describe patterns where this is not true and show how the algorithm still deals with them correctly.

Algorithm 2 Resolve the Markov Blankets with Collider Sets

1: **procedure** RESOLVEMARKOVBLANKETS_COLLIDERSETS
Input: $\mathbf{Mb}(\cdot)$: the Markov blanket information for each node $X \in \mathbf{V}$
Output: $\mathcal{G}$: partially oriented DAG
2: $\mathcal{G} \leftarrow$ moral graph according to $\mathbf{Mb}(\cdot)$
3: $\mathbf{C} \leftarrow \{\}$, an empty list of orientation directives
4: **for each** edge $X - Y$ part of a fully connected triangle **do**
5: $\mathbf{S}_{XY} \leftarrow$ **null** /* search for d-separating set */
6: $\mathbf{B} \leftarrow$ smallest set of $\{\mathbf{Bd}(X) \setminus \mathbf{Tri}(X-Y) \setminus \{Y\}, \mathbf{Bd}(Y) \setminus \mathbf{Tri}(X-Y) \setminus \{X\}\}$
7: **for each** $\mathbf{S} \subsetneq \mathbf{Tri}(X-Y)$ **do** /* subset search */
8: $\mathbf{Z} \leftarrow \mathbf{B} \cup \mathbf{S}$
9: **if** CONDINDEP$(X, Y, \mathbf{Z})$ **then**
10: $\mathbf{S}_{XY} \leftarrow \mathbf{Z}$
11: **break** to line 23
12: **end if**
13: $\mathbf{D} \leftarrow \mathbf{B} \cap \left\{\text{nodes reachable by } W \text{ in } \mathcal{G}^{\setminus XY} \mid W \in \left(\mathbf{Tri}(X-Y) \setminus \mathbf{S}\right)\right\}$
14: $\mathbf{B}' \leftarrow \mathbf{B} \setminus \mathbf{D}$
15: **for each** $\mathbf{S}' \subsetneq \mathbf{D}$ **do** /* descendant of collider may be opening a path */
16: $\mathbf{Z} \leftarrow \mathbf{B}' \cup \mathbf{S}' \cup \mathbf{S}$
17: **if** CONDINDEP$(X, Y, \mathbf{Z})$ **then**
18: $\mathbf{S}_{XY} \leftarrow \mathbf{Z}$
19: **break** to line 23
20: **end if**
21: **end for**
22: **end for**
23: **if** $\mathbf{S}_{XY} \neq$ **null then** /* save orientation directive */
24: mark link $X - Y$ as spouse link in $\mathcal{G}$
25: **for each** $Z \in \left(\mathbf{Tri}(X-Y) \setminus \mathbf{S}_{XY}\right)$ **do**
26: $\mathbf{C} \leftarrow \mathbf{C} \cup \{(X \rightarrow Z \leftarrow Y)\}$
27: **end for**
28: **end if**
29: **end for**
30: remove all spouse links (i.e., marked links) from $\mathcal{G}$
31: **for each** orientation directive $(X \rightarrow Z \leftarrow Y) \in \mathbf{C}$ **do** /* orient edges */
32: **if** edges $X - Z$ and $Y - Z$ still exist in $\mathcal{G}$ **then**
33: orient edges as $X \rightarrow Z \leftarrow Y$
34: **end if**
35: **end for**
36: **return** $\mathcal{G}$
37: **end procedure**

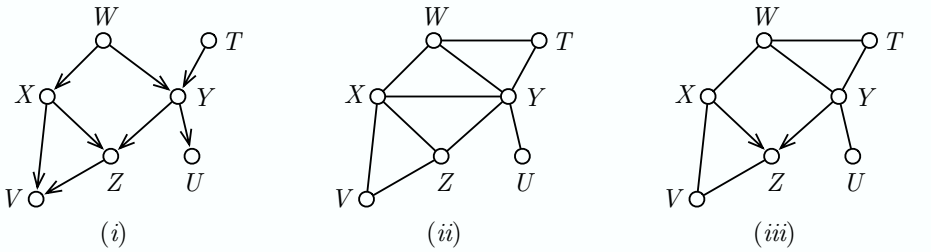

Figure 1: Sample local causal structure (i) and corresponding moral graph (ii). On (iii), the spouse link and orientation information that the collider set search for the linked pair $X-Y$ gives.

starting at line 5 in Algorithm 2. We are looking for a d-separating set for X and Y. Looking at the original graph, we see that $\{W\}$ is the smallest such set; let us see how the algorithm finds it. We have: $\mathbf{Tri}(X-Y)=\{W,Z\}$, $\mathbf{Bd}(X)=\{W,Y,Z,V\}$ and $\mathbf{Bd}(Y)=\{W,X,Z,U,T\}$. The base conditioning set $\mathbf{B}$ will thus be the smallest of $\big\{\{V\},\{U,T\}\big\}$, thus $\mathbf{B}=\{V\}$. At this stage, conditioning on V is justifiable: one cannot exclude situations where X and Y are d-connected given the empty set through T and V, for instance if T and V both had a common cause farther away in the network. But actually in this example, all (perfect) tests containing V in the conditioning set will yield dependence, because it is a descendant of the collider Z and thus opens a path by definition of d-separation. Eventually, in the iteration where $\mathbf{S}=\{W\}$, we will find conditional independence in the nested loop at lines 15 to 21. As $\mathbf{Tri}(X-Y)\setminus\mathbf{S}=\{Z\}$, $\mathbf{D}$ will be assigned the value $\{V\}$ and $\mathbf{B}'$ will be empty, so that we will perform exactly one extra test at line 17 with the conditioning set $\mathbf{S}_{XY}=\{W\}$, which yields independence. This in turn allows us to identify the link $X-Y$ as a spouse link and determine (line 25) that the set $\mathbf{Tri}(X-Y)\setminus\mathbf{S}_{XY}=\{Z\}$ is the set of all direct effects of X and Y; that is, fulfills the Collider Set property.

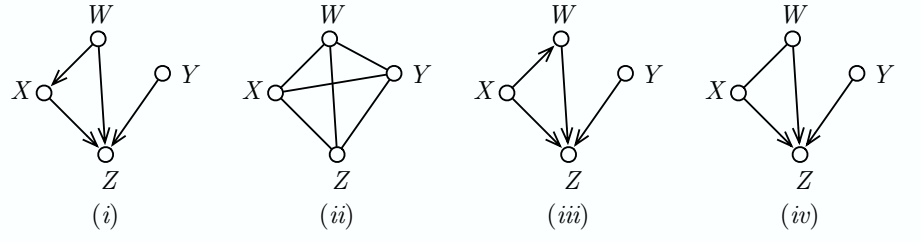

Figure 2: Another sample local causal structure (i) and corresponding moral graph (ii). On (iii), a wrong result if orientation is done immediately at line 26 of Algorithm 2. On (iv), the correct (non-)orientation if the condition at line 32 is added.

For some structures, the order in which arcs are removed and oriented must happen such that all spouse links are removed before proceeding to orientation. Consider another example, shown in Figure 2, and suppose again that that we are looking for a d-separating set for the pair (X,Y). As X and Y are unconditionally independent, $\mathbf{S}_{XY}=\emptyset$ is a valid d-separating set. We may thus remove the link $X-Y$, and considering that $\mathbf{Tri}(X-Y)=\{W,Z\}$, we could want to orient $X\rightarrow Z\leftarrow X$ and

$X \rightarrow W \leftarrow X$ (leaving the spouse link $W - Y$ to be removed later). This would be wrong, precisely because $W - Y$ is a spouse link, and thus the orientation $X \rightarrow W \leftarrow X$ is not allowed if one of the links to be oriented does not actually exist in the original graph. This is the reason why all orientation directives are saved in a list $\mathbf{C}$ at line 26 of Algorithm 2. After all spouse links have been removed, the orientations are done at line 33 only when both links to be oriented still exist, thus ensuring the existence of the V-structure $X \rightarrow Z \leftarrow Y$.

We do not claim that our algorithm uses the smallest possible conditioning set for the tests. There is a tradeoff between obtaining the minimal possible conditioning set and keeping the total number of tests low in the average case. In the empirical evaluation of this algorithm, we examine three behavioral criteria: the total number of tests, the average size of the conditioning set, and the maximum size of the conditioning set.

The complexity of the whole algorithm iterating over all triangle links, in terms of number of calls to CONDINDEP, is $O(d^2 2^{\alpha})$, where d is the number of variables and $\alpha = \max_{X \in \mathbf{V}} |\mathbf{Mb}(X)| - 1$. In the worst case of a fully connected graph, where $\mathbf{Mb}(X) = \mathbf{V} \setminus \{Y\}$, it is exponential in the number of variables due to the subset search. But in practice, the original graphs are often sparse enough so that the actual run time is not exponential. Many algorithms (e.g., MMMB, HITON_MB, AlgorithmMB, GS) perform subset searches in the (possibly augmented) Markov blanket and thus rely on graph sparseness to be efficient. Although the complexity of RESOLVEMARKOVBLANKETS_COLLIDERSETS is the same as that of RESOLVEMARKOVBLANKETS_GROWSHRINK, we show in the experimental results in Section 5 that the former performs fewer tests with a smaller average conditioning set size, while still providing comparable accuracy in structure learning.

3.3 A Generic Algorithm Based on Feature Selection

Thanks to the subroutine explained in the previous section, we can now draft a generic algorithm for structure learning based on feature-selection methods returning strongly relevant features. Algorithm 3 lists pseudocode for the three main steps of this approach:

1. Find the conjectured Markov blanket of each variable with feature selection and build the moral graph;
2. Remove spouse links and orient V-structures using collider sets;
3. Propagate orientation constraints.

For the sake of completeness, the constraint propagation rules of Step 3 have also been listed, in a separate subroutine (see Algorithm 4). They are common in structure learning to obtain a completed PDAG (Pearl and Verma, 1991). Meek (1995) proves that these three rules indeed return the maximally oriented graph when given a PDAG whose V-structures are oriented.

The challenge with this approach is twofold. One issue is efficiency: consistent but slow feature-selection algorithms will not beat existing causal learning algorithms, as they have to be run as many times as the number of variables d. The second and biggest issue is that consistent feature-selection algorithms are needed in order to prove correctness of this generic algorithm, in the sense that the result of feature selection should be equal to the set of strongly relevant features. This requirement is not always fulfilled. Hardin et al. (2004) study an SVM classifier and discuss feature selection based on the $\mathbf{w}$ weights: although irrelevant variables are not selected in the large sample limit, they show that the weights of the weakly relevant variables can be as close as one wishes to that of the strongly relevant variables due to the large-margin behavior of SVMs. Forward feature selection has been

Algorithm 3 Causal Structure Learning with Feature Selection

procedure GENERICSTRUCTURELEARNING
  Input: D : $n \times d$ data set with n d-dimensional data points
  Output: $\mathcal{G}$: maximally oriented partially directed acyclic graph

    $\mathbf{F}_X \leftarrow$ FEATURESELECTIONALGORITHM(X, D)
  end for
  for each pair (X, Y) such that $Y \in \mathbf{F}_X$ and $X \in \mathbf{F}_Y$ **do** /* symmetry check */
    add X to $\mathbf{Mb}(Y)$ and Y to $\mathbf{Mb}(X)$
  end for

  /* Step 2: Spurious arc removal & V-structure detection */
  $\mathcal{G} \leftarrow$ RESOLVEMARKOVBLANKETS$(\mathbf{Mb}(\cdot))$

  /* Step 3: Constraint propagation */
  $\mathcal{G} \leftarrow$ COMPLETEPDAG$(\mathcal{G})$
  return $\mathcal{G}$
end procedure

Algorithm 4 Orient a PDAG maximally

procedure COMPLETEPDAG
  Input: $\mathcal{G}$: partially directed acyclic graph
  Output: $\mathcal{G}$: maximally oriented partially directed acyclic graph

  while $\mathcal{G}$ is changed by some rule **do** /* fixed-point iteration */
    for each X, Y, Z such that $X \rightarrow Y - Z$ **do**
      orient as $X \rightarrow Y \rightarrow Z$ /* no new V-structure */
    end for
    for each X, Y such that $X - Y$ and $\exists$ directed path from X to Y **do**
      orient as $X \rightarrow Y$ /* preserve acyclicity */
    end for
    for each X, Y s.t. $X - Y$ & $\exists$nonadj. Z, W s.t. $X - Z \rightarrow Y$ & $X - W \rightarrow Y$ **do**
      orient as $X \rightarrow Y$ /* three-fork V with married parents */
    end for
  end while
  return $\mathcal{G}$
end procedure

shown to miss strongly relevant variables (Guyon and Elisseeff, 2003). Nilsson et al. (2007) also describe forward selection as inconsistent, but claim that backward feature elimination is actually consistent in the large-sample limit.[9] For finite data sets, Statnikov et al. (2006) further show (among others) that even the weights of the irrelevant variables can get bigger than that of relevant variables, and that weakly relevant variables can be selected more often than strongly relevant variables in some cases.

These considerations are taken into account in our approach. In the next section, we describe an instantiation of the generic algorithm with an existing backward feature-elimination algorithm. Expecting the feature selection to be too inclusive, that is, to include features that are not strongly relevant, we add the filtering condition at line 5 of the generic outline in Algorithm 3: in order to link X and Y in the moral graph, we require the feature selection performed for X to have selected variable Y, and conversely, we require X to have been selected by the feature selection performed for Y. This does not theoretically guarantee the absence of "false positives," however. Further in the section, we replace the feature-selection step with a provably consistent algorithm in the multivariate Gaussian case, and analyze its complexity and behavior.

4. Algorithms for Causal Feature Selection

In this section, we show two algorithms (and a variant) as instantiations of the generic approach previously described. First, we explain an algorithm based on the Recursive Feature Elimination (RFE) algorithm (Guyon et al., 2002) as a direct application of existing methods. We then describe Total Conditioning (TC), a fast algorithm that can be proved correct under the multivariate Gaussian assumption. We also show a variant, TC_{bw}, that improves accuracy with low sample sizes by using an explicit backward feature-selection heuristics. In Section 5, we report on experiments including these algorithms.

4.1 An RFE-Based Approach

To empirically test the soundness of the approach, we propose to use RFE over a Support Vector Regression (SVR) learner (Smola and Schölkopf, 1998) with a linear kernel, assuming for this example that we will deal with multivariate Gaussian data. RFE is an instance of a backward feature-elimination algorithm. Given some learner (in this case, SVR), it iteratively trains it, ranks the features according to some criterion, and remove the feature (or the p features) with the smallest ranking criterion. This criterion can be the weights $\mathbf{w}$ attributed to the features by the learner, or some sensitivity measure of the features (Guyon et al., 2002). In our case, we used the weights $\mathbf{w}$ of SVR as described in Smola and Schölkopf (1998).

Using RFE, the Markov blanket identification is done in two steps:

1. Use RFE to rank the predictors according to their weights in the trained model and to provide what can be seen as a relevance ordering of the predictors;

2. Determine the size of the Markov blanket and thus the number of variables to select from the list returned by RFE.

9. This is subject to the assumption that the underlying classifier must itself be consistent, in the sense that it must return the Bayes classifier in the large-sample limit.

We do not have a theoretical guarantee that RFE/SVR will return the Markov blanket variables. Although Nilsson et al. (2007) shows that RFE/SVM as described in Guyon et al. (2002) is consistent (i.e., returns strongly relevant variables in the large-sample limit), the limitations of ranking variables on the **w** weights of an SVM with finite data sets have also been highlighted (Hardin et al., 2004; Statnikov et al., 2006). For now, we thus use this feature-selection step as a heuristics.

In order to determine the number of variables to select from the ranked list returned by RFE, we use the following criterion: starting with the first variable from the list, accept a new variable in the Markov blanket if the cross-validated training error of the SVR decreases with the new variable, and stop and return the current list if adding the next variable increases the error.

Algorithm 5 An RFE-Based Feature-Selection Step

1: **procedure** RFEFEATURESELECTION
   Input: X : the target variable to perform feature selection for
   D : $n \times d$ data set with n d-dimensional data points
   Output: $\mathbf{S}$: the set of selected variables
2: $\mathbf{w} \leftarrow$ weights of $\mathbf{V} \setminus X$ according to RFE(SVR)
3: $\mathbf{P} \leftarrow$ predictor variables sorted according to $\mathbf{w}$
4: $\mathbf{S} \leftarrow \emptyset$
5: $error_{opt} \leftarrow \text{var}[X]$ /* MSE of constant function */
6: $error \leftarrow$ TRAIN(cross-validated SVR with predictor $(\mathbf{P})_1$)
7: **while** $error < error_{opt}$ **do**
8: $error_{opt} \leftarrow error$
9: $\mathbf{S} \leftarrow \mathbf{S} \cup \{(\mathbf{P})_1\}$ /* add beneficial predictor */
10: $\mathbf{P} \leftarrow \mathbf{P} \setminus \{(\mathbf{P})_1\}$
11: $error \leftarrow$ TRAIN(cross-validated SVR with predictors $\mathbf{S} \cup \{(\mathbf{P})_1\}$)
12: **end while**
13: **return S**
14: **end procedure**

The symmetry condition (2), $X \in \mathbf{F}_Y \Leftrightarrow Y \in \mathbf{F}_X$, might not be satisfied: we rely on the check at line 5 of the generic approach of Algorithm 3 to make sure that we do not select spurious features in the Markov blanket. This conservative approach implies that we expect RFE to select at least all strongly relevant variables, plus possibly some others that we hope to identify with this simple condition.

As a conditional-independence test at lines 9 and 17 of the collider set search in Algorithm 2, we can use the distribution-free Recursive Median (RM) algorithm proposed by Margaritis (2005) to detect the V-structure and remove the spouse links, or a z-test as used in Scheines et al. (1995) in the case of Gaussian data.

Although we expect the resulting graph to be accurate in the large sample limit (see Section 5), we also expect the run time of such an approach to be much higher compared to existing algorithms. Training the SVR has a cubic complexity in terms of the number of samples, $O(n^3)$. To get an accurate ranking, RFE runs the training $d-1$ times. Then, a new SVR learner is trained and cross-validated several times (we used a 5-fold cross-validation) to get the validation error, which is repeated for each variable in the actual Markov blanket. The complexity for the whole feature-selection step is then $O(d^2n^3)$, with a large constant factor. We thus emphasize that this RFE-based

feature selection is not meant as a valid practical instantiation of the generic algorithm, but rather as a proof of concept to validate the approach. In order to be practical, the feature-selection step has to be redesigned so that it is done efficiently when run for all variables. This is what the next algorithm is meant to address in the specific case of multivariate Gaussian variables.

4.2 The TC Algorithm

We now propose in the procedure TCFEATURESELECTION (Algorithm 6) another instantiation of the feature-selection call at line 3 of the generic approach of Algorithm 3. The whole algorithm as determined by the feature-selection, collider-identification, and maximal-orientation steps is equivalent to the TC algorithm described in Pellet and Elisseeff (2007). (We thus write "TC" to refer to the whole algorithm and not only to the feature-selection procedure, referred to as TCFEATURESELECTION.)

For a given target variable X, TC estimates the coefficients of a multiple regression problem, considering all other variables $\mathbf{V} \setminus X$ as predictors. It then returns the significant predictors, according to a t-test on the coefficient of each variable. Its short listing is in Algorithm 6.

Algorithm 6 The Total Conditioning Feature-Selection Step

1: **procedure** TCFEATURESELECTION
   Input: X : the target variable to perform feature selection for
   D : $n \times d$ data set with n d-dimensional data points
   Output: $\mathbf{S}$: the set of selected variables
2: $\mathbf{b} \leftarrow$ weights of $\mathbf{V} \setminus X$ in the problem of regressing X on $\mathbf{V} \setminus X$
3: $\mathbf{S} \leftarrow \{$predictors whose b weight is significant$\}$
4: **return S**
5: **end procedure**

The conditional-independence tests to be performed at lines 9 and 17 of the collider set search of Algorithm 2 are done using partial correlation.

Definition 11 (Partial correlation) *In a variable set* $\mathbf{V}$*, the* partial correlation *between two random variables* $X, Y \in \mathbf{V}$ *given* $\mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\}$*, noted* $\rho_{XY \cdot \mathbf{Z}}$*, is the correlation of the residuals* R_X *and* R_Y *resulting from the least-squares linear regression of* X *on* $\mathbf{Z}$ *and of* Y *on* $\mathbf{Z}$*, respectively.*

TC was shown to be correct in the large sample limit (subject to the consistency of the statistical tests) in Pellet and Elisseeff (2007) under the Faithfulness and Causal Sufficiency assumptions. For the sake of completeness, we add the proof to Appendix A. The main points leading to the correctness of TC are the equivalence of a zero regression weight for some predictor Y while regressing X on all variables $\mathbf{V} \setminus X$ and a zero partial correlation $\rho_{XY \cdot \mathbf{V} \setminus \{X,Y\}}$, and the fact that this is zero if and only if $(X \perp\!\!\!\perp Y \mid \mathbf{V} \setminus \{X, Y\})$ holds in a Gaussian context (Baba et al., 2004). Then, our feature-selection step (Algorithm 6) gives the Markov blanket for each node, and the collider set search (Algorithm 2) then takes care of identifying the V-structures and removing the spouse links.

The other advantage of using linear regression and partial correlation is that it yields a fast algorithm. Actually, *all* regression weights and parameters needed for the feature-selection step of TC can be efficiently computed by inverting the sample correlation matrix $\mathbf{R} \in [-1, 1]^{d \times d}$. Building

graphs by inverting the correlation matrix is typically what is done with Gaussian Markov random fields, a special case of undirected graphical models (see, e.g., Talih, 2003).

The weight computation and the statistical significance tests are performed as follows. Let $\hat{b}_{ij}$ be the maximum likelihood estimator of the true regression weight b_{ij} of predictor X_j when X_i is the dependent variable, such that it solves the multiple regression equation for target X_i in the sense that it minimizes the sum of the squared residuals

$$SS_R = \sum_{k=1}^{n} \left(x_{ik} - \sum_{j=1, j\neq i}^{d} \hat{b}_{ij} x_{jk} \right)^2$$

where x_{ik} is the value of X_i for the kth sample. If we have the inverse correlation matrix $\mathbf{R}^{-1} = (r^{ij})$, the vector $\mathbf{b}$ at line 2 of Algorithm 7 can be found in linear time: $\hat{b}_{ij} = -r^{ij}/r^{ii}$ (Raveh, 1985). For instance, the list of weights to predict variable X_1 with all others is

$$\mathbf{b}_1 = (\hat{b}_{12}, \hat{b}_{13}, \cdots, \hat{b}_{1d}) = -(r^{12}, r^{13}, \cdots, r^{1d})/r^{11}. \tag{9}$$

The distribution of these weights is known (Judge et al., 1988):

$$\frac{\hat{b}_{ij} - b_{ij}}{\hat{\sigma}_{ij}} \sim t_{(n-(d-1))}, \tag{10}$$

where $\hat{\sigma}_{ij}$ is the standard error of the jth predictor for variable X_i; that is, that it follows a t distribution with a number of degrees of freedom $df =$ number of samples $-$ number of predictors $= n-(d-1)$. For our null hypothesis $H_0 : b_{ij} = 0$, we need $\hat{\sigma}_{ij}$ in addition to $\hat{b}_{ij}$ to compute the t-statistics $\hat{b}_{ij}/\hat{\sigma}_{ij}$. The estimate of the coefficient error $\hat{\sigma}_{ij}$ can be expressed as

$$\hat{\sigma}_{ij} = \hat{\sigma}_i \sqrt{\omega^{jj}/n},$$

where $\hat{\sigma}_i$ is an estimator of the standard error of the regression for target X_i, and ω^{jj} is the jth diagonal element of the inverse correlation matrix of the predictors (Judge et al., 1988, p. 243). (How to obtain the inverse correlation matrix of the predictors from the $\mathbf{R}^{-1}$ matrix in quadratic time is discussed in the next subsection.) The standard error $\hat{\sigma}_i$ can also be obtained in linear time from $\mathbf{R}^{-1}$ as follows.

Without loss of generality, we assume a zero mean and a unit standard deviation for all variables. Then $\sigma_i^2 = 1 - R_i^2$, where R_i^2 is the coefficient of determination of the regression for target X_i. This coefficient can be expressed as the scalar product of the $\mathbf{b}_i$ vector with the vector $\mathbf{r}_i$ of the pairwise correlation coefficients of the predictors with the target X_i (Raveh, 1985), which we read directly from the correlation matrix $\mathbf{R}$:

$$R_i^2 = \mathbf{b}_i^T \mathbf{r}_i.$$

An unbiased estimator $\hat{\sigma}_i$ for σ_i is then

$$\hat{\sigma}_i = \sqrt{\frac{n(1 - \mathbf{b}_i^T \mathbf{r}_i)}{n-d}}.$$

To sum up, we have a complexity of $O(nd^3)$ to build and invert the correlation matrix, and $O(d^3)$ to check for significance. This comes from having to obtain d times the inverse correlation matrix of $d-1$ predictors in $O(d^2)$, and then checking their significance in linear time. The overall complexity of TC, including the collider identification and the constraint-propagation steps, is then $O(nd^3+d^2 2^{\alpha})$.

The weaknesses of this approach are its infeasability when the correlation matrix $\mathbf{R}$ does not have full rank (including the special case $n<d$, that is, when there are fewer samples than variables), the low power of the statistical tests with small data sets, and multicollinearity in the predictors. The symptoms of the last two points are that the t-tests do not refute the null hypothesis of zero weight because (i) there is not enough data to support it, or (ii) multicollinearity makes the weights lower than they should be, such that it becomes harder to interpret them as depicting the independent contribution of each predictor. We try to deal with this problem in the next section with the TC_{bw} algorithm.

4.2.1 SIGNIFICANCE TESTS

Independently of low sample sizes or multicollinearity, the statistical tests on the weights of the linear regression equations are a delicate point in TC. The choice of the Type I error rate α needs investigating as it significantly influences the result of the algorithm.

In a network of d nodes, the feature-selection step performs $d(d-1)/2$ tests to determine the undirected skeleton. We will falsely reject the null hypothesis $b_{ij}=0$ about $m\cdot\alpha$ times on average, where $m<d(d-1)/2$ is the difference in the number of edges between the original DAG $\mathcal{G}_0$ and the complete graph. We will thus add on average $m\cdot\alpha$ wrong edges. We can set the significance level for the individual tests to be inversely proportional to $d(d-1)/2$ to avoid this problem (assuming a large m and thus rather sparse graphs), and check that it does not affect the Type II error rate too much, which we do now.

According to (10), the expression $(\hat{b}_{ij}-b_{ij})/\hat{\sigma}_{ij}$ follows a t distribution with $n-(d-1)$ degrees of freedom. If we call $\Psi(\cdot)$ the cumulative distribution function of a t distribution with $n-(d-1)$ degrees of freedom, we can write the Type II error rate β for each regression weight:

$$\beta_{ij}=\Psi(\Psi^{-1}(1-\alpha/2)-|b_{ij}|/\hat{\sigma}_{ij}).$$

The values for $\hat{\sigma}_{ij}$ can be computed from the inverse correlation matrix $\mathbf{R}^{-1}$ and thus depend on the particular data set being analyzed, but the true b_{ij} are unknown. What we could do in theory to optimize α is to minimize the average number of extraneous (T_e) and missing (T_m) links:

$$T=T_e+T_m=m\cdot\alpha+\sum_{(i,j)\in\mathbf{E}}\beta_{ij},$$

where m is the number of edges missing in the original DAG compared to a full graph, and $\mathbf{E}$ is the set of arcs in the original DAG, so that $m+|\mathbf{E}|=d(d-1)/2$. As m, $\mathbf{E}$ and b_{ij} are unknown, we can only find an upper bound for the number of missed links T_m, provided (i) we can estimate the graph sparseness to approximate m; (ii) we assume $|b_{ij}|\geq\delta$; and (iii) we choose $\mathbf{E}^{\star}$ such that it maximizes the sum in (11), with $|\mathbf{E}^{\star}|=d(d-1)/2-m$. Then we have:

$$T_m\leq\sum_{(i,j)\in\mathbf{E}^{\star}}\Psi(\Psi^{-1}(1-\alpha/2)-\delta/\hat{\sigma}_{ij}). \tag{11}$$

Although this bound was found too loose for practical use, we can model the Type I and Type II error rate as a function of α for artificial problems whose sparseness and regression weights are known. This is shown in Figure 3 for a specific instance of an Alarm data set (see Section 5 for details on this network) with two different sample sizes, $n = 50$ (left) and $n = 250$ (right). We did not use this information to tune α in the experiments, as it cannot be obtained without prior knowledge, but the curves showed that an α inversely proportional to $d(d-1)/2$ has the same order of magnitude as the optimal α on the data sets we analyzed.

What we also see is that the Type I error curve rapidly goes up, whereas the Type II error curve is upper-bounded by the total number of links in the original graph. In terms of pure number of errors, setting a low α will thus be more beneficial than setting a higher α to get a low β. It is worth discussing, however, depending on the particular problem to solve, which is more desirable: missing causal links or getting extra causal links. In terms of Bayesian networks, getting too few links prevents the model from being able to reconstruct the full joint probability distribution, because we lose the I-map property; whereas getting too many links implies having to estimate more parameters from the same data and thus complexifies a subsequent parameter learning task.

4.3 The TC_{bw} Algorithm

Despite correctness of TC, with a low number of samples n it fails to have enough evidence for rejecting the null hypothesis of zero regression weight, and thus misses links (see detailed results in Section 5), even for a high α. We now try to address this particular issue by successively eliminating the most insignificant predictors and reevaluating the remaining ones. This is actually a backward stepwise-regression method. Pseudocode for this heuristics is listed in Algorithm 7.

Algorithm 7 The Total Conditioning Backward Feature-Selection Step

```
1:  procedure TCBWFEATURESELECTION
      Input:   X :  the target variable to perform feature selection for
               D :  n × d data set with n d-dimensional data points
      Output:  S :  the set of selected variables
2:    P ← V \ X    /* all predictors */
3:    S ← ∅    /* significant predictors */
4:    while P ≠ ∅ and P ≠ S do
5:      b ← weights of P in the problem of regressing X on P
6:      S ← S ∪ {predictors whose b weight is significant}
7:      P ← P \ {the p less significant predictors}
8:    end while
9:    return S
10: end procedure
```

Intuitively, the problem to solve is that the regression weights cannot be high enough for significance with small sample sizes. By removing the most insignificant predictors and thus the most likely to be actually zero, we scale down the regression problem and increase the power of the tests. How many insignificant predictors to remove can be discussed; in our implementation, we compared $p = 1$ to $p = (\text{number of predictors})/2$ and found that the latter yielded results that were just as good with an important speed gain.

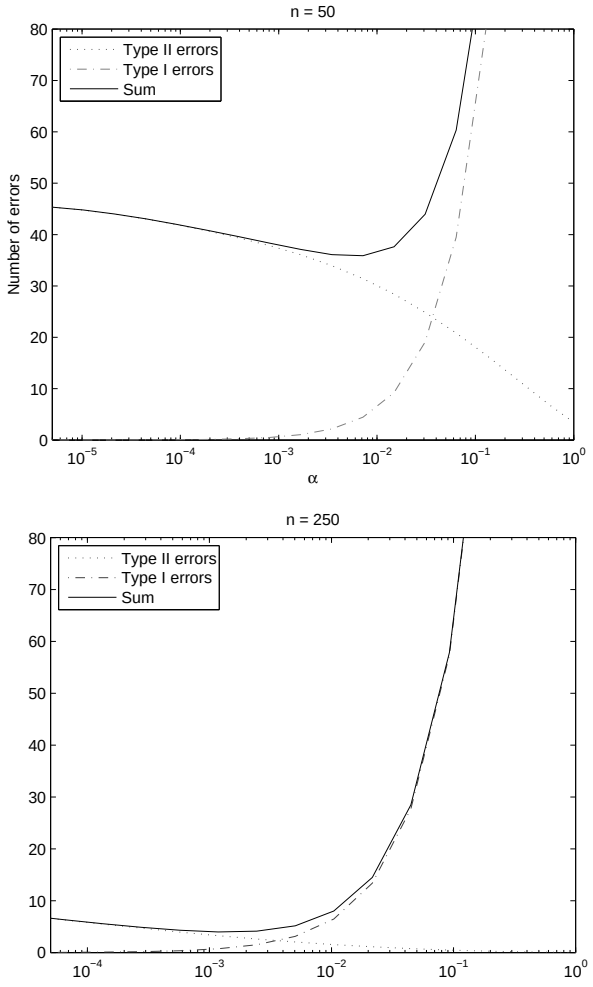

Figure 3: Expected Type I and II errors as a function of α

This stepwise regression raises some issues; notably, Tibshirani (1994) argues that the repeated tests on non-changing data are biased and that the remaining **b** coefficients are too large. We thus expect TC_{bw} to be biased and to include more false positives than TC. Ideally, one would need a criterion to predict when the additional false positives would outweigh the benefits of reducing the false negatives. Whether such a criterion, which would allow us to know a priori whether TC or TC_{bw} should be used, can be found, is an open question.

Solving a standard multiple regression problem with d predictors traditionally has complexity $O(nd^3)$. Naïvely solving $d-1$ regression problems d times in the case $p=1$ would have a complexity of $O(nd^5)$. But we can avoid reinverting matrices in the inner loop of the stepwise regression thanks to the following result.

Let $\Sigma = \mathbf{X}^T\mathbf{X}$ be n times the correlation matrix $\mathbf{R}$, where $\mathbf{X}$ is the $n \times d$ matrix representing a data set where all variables have zero mean and unit standard deviation. Then we can use Σ^{-1} to linearly find the weights of the regression problems and their standard error, which are needed for

the t-tests. Suppose we find that variable X_1 is the weakest predictor, and want to reevaluate the weights of the other predictors at line 5 of TC_{bw}. Let $\mathbf{X}_{\setminus i}$ be the data set where variable X_i has been removed. Then we need the matrix Ω^{-1} to solve the new problem, where $\Omega = \mathbf{X}_{\setminus 1}^T \mathbf{X}_{\setminus 1}$. As a special case of Strassen's blockwise matrix inversion formula, we have:

$$\Sigma = \begin{bmatrix} \sigma_{11} & \mathbf{c}^T \\ \mathbf{c} & \Omega \end{bmatrix}$$

$$\Longrightarrow \quad \Sigma^{-1} = \begin{bmatrix} \dfrac{1}{\sigma_{11} - \mathbf{c}^T \Omega^{-1} \mathbf{c}} & -\dfrac{\mathbf{c}^T \Omega^{-1}}{\sigma_{11} - \mathbf{c}^T \Omega^{-1} \mathbf{c}} \\ -\dfrac{\Omega^{-1} \mathbf{c}}{\sigma_{11} - \mathbf{c}^T \Omega^{-1} \mathbf{c}} & \Omega^{-1} + \dfrac{\Omega^{-1} \mathbf{c} \mathbf{c}^T \Omega^{-1}}{\sigma_{11} - \mathbf{c}^T \Omega^{-1} \mathbf{c}} \end{bmatrix}.$$

Let $\sigma^{ij} = (\Sigma^{-1})_{ij}$ and $\mathbf{b} = \Omega^{-1}\mathbf{c}$. Then $\mathbf{b}$ are the weights of the regression of X_1 on $X_2, \cdots, X_d$ and can be computed without knowing Ω^{-1} (Raveh, 1985), see (9). We have:

$$\sigma^{11} = 1/(\sigma_{11} - \mathbf{c}^T \mathbf{b})$$

and, $(\Sigma^{-1})_{\setminus 1}$ being the matrix Σ^{-1} where the first row and column have been removed,

$$(\Sigma^{-1})_{\setminus 1} = \Omega^{-1} + \mathbf{b}\mathbf{b}^T / (\sigma_{11} - \mathbf{c}^T \mathbf{b}).$$

We can thus compute Ω^{-1} given Σ^{-1} with complexity $O(d^2)$ as follows:

$$\Omega^{-1} = (\Sigma^{-1})_{\setminus 1} - \sigma^{11} \mathbf{b}\mathbf{b}^T. \tag{12}$$

This trick is also used in TC to find the inverse correlation matrix of the predictors from the inverse correlation matrix of the whole variable set.

Equation (12) is implemented in TC_{bw} such that we never need to invert another matrix again once Σ^{-1} has been obtained, and leads to a complexity of $O(d^2)$ for stepwise elimination of a predictor. In the most computationally expensive case $p = 1$, this elimination of row and column of the inverse matrix is repeated at most $d - 2$ for each variable, yielding a complexity of $O(nd^4)$ for the whole feature-selection step for all variables. The overall complexity of TC_{bw} is then $O(nd^4 + d^2 2^{\alpha})$. We are only adding one complexity degree in d with respect to TC with the additional stepwise regression.

5. Experimental Results

In this section, we report on experiments and results on two points separately. First, we test our procedure described in Algorithm 2 to recover the local structure with the collider set search given all Markov blankets, and compare it to the relevant steps of the GS algorithm, which are listed in Algorithm 1, with 5 different network topologies. For the sake of comparison, we also run the reference PC algorithm (Spirtes et al., 2001), initialized with the moral graph instead of the fully connected graph.

Second, we conduct experiments to investigate how the whole structure-learning algorithms behave. We first use the RFE-based approach. We then systematically compare TC, TC_{bw} and several reference algorithms, varying the data set size and the network size. Note that results for some algorithms may be sparser due to their prohibitive run times on some data sets.

5.1 Experimental Setup

In order to test the accuracy of the various algorithms, we chose to sample data from the following known networks, from the Bayes net repository (Elidan, 2001):

- Alarm network (Beinlich et al., 1989). This network has become a de facto standard benchmark for structure-learning algorithms: it contains 37 nodes, 46 arcs, 4 undirected in the PDAG of the equivalence class. It was originally designed to help interpret monitoring data to alert anesthesiologists to various situations in the operating room. It is depicted in Figure 4.

- Insurance (Binder et al., 1997), 27 nodes, 52 arcs, 18 undirected in its PDAG. It was designed to evaluate car insurance risks. This network has fewer nodes than Alarm but is denser, see Figure 5.

- Hailfinder (Abramson et al., 1996), 56 nodes, 66 arcs, 17 undirected in its PDAG. It is a normative system that forecasts severe summer hail in northeastern Colorado. See Figure 6.

- Carpo,[10] 61 nodes, 74 arcs, 24 undirected in its PDAG. It is meant to help diagnose the carpal tunnel syndrome. The version we used has three disconnected subgraphs, one of which is a single variable, and a relatively flat causal structure, as can be seen in Figure 7.

- A subset of Diabetes (Andreassen et al., 1991) with 104 nodes, 149 arcs, 8 undirected in its PDAG, which was designed as a preliminary model for insulin dose adjustment. This subset is made of 6 repeating patterns (there are 24 in the original network) of 17 nodes, plus 2 external nodes linked to every pattern. The first two of these patterns are shown in Figure 8.

We performed three series of experiments.

1. We compared our algorithm resolving the Markov blanket to the relevant steps of the Grow-Shrink algorithm, as described in Section 3.2, and to PC;

2. We tested the RFE-based approach and compared it to PC;

3. Finally, we compared TC and TC_{bw} to three reference algorithms and examine their accuracy, run time, and number of tests while varying the network structure, the network size, and the sample size.

The chosen reference algorithms are:

1. The PC algorithm. PC is, like TC and TC_{bw}, exponential in the worst case, when graphs are not sparse enough: we discuss which structural elements make PC or TC exhibit the exponential behavior;

2. The full Grow-Shrink algorithm, as described in Margaritis and Thrun (1999);

3. A state-of-the-art Bayesian structure-learning algorithm that works with continuous data sets, the Bach-Jordan scoring algorithm (Bach and Jordan, 2003), coupled with a greedy search in the space of DAGs. Note that Bayesian structure-learning algorithms are often score-based and return fully oriented DAGs. Maximizing the chosen score function might not minimize the number of structural errors as we report in these results.

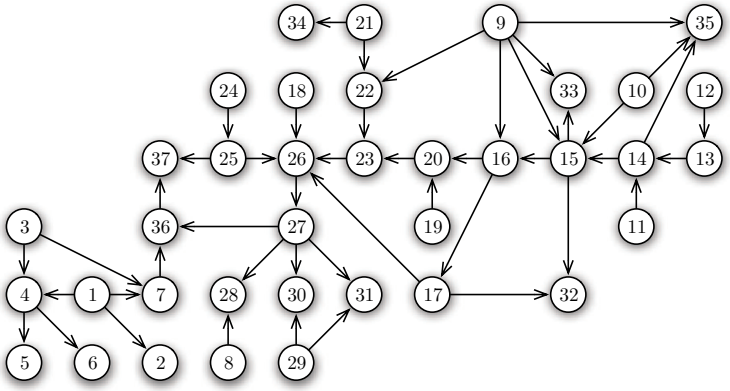

Figure 4: The Alarm network

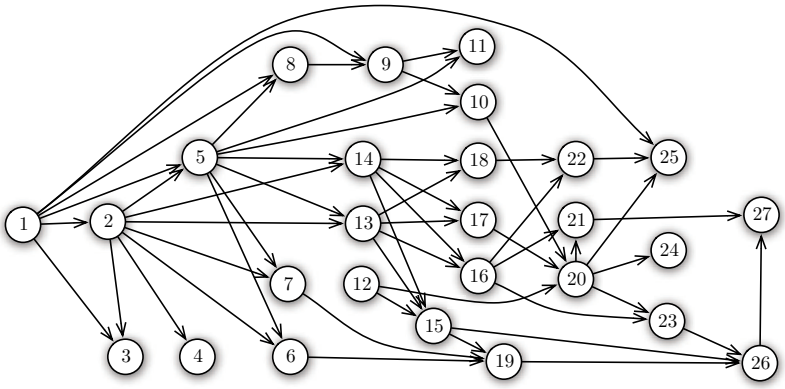

Figure 5: The Insurance network

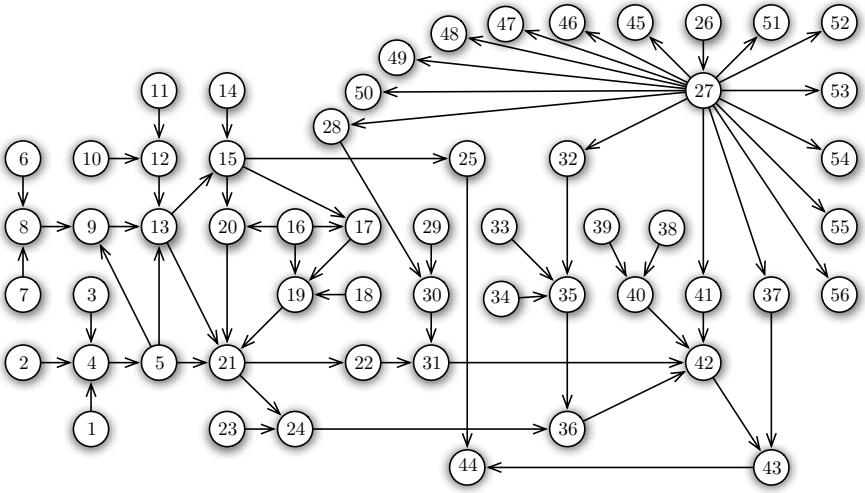

Figure 6: The Hailfinder network

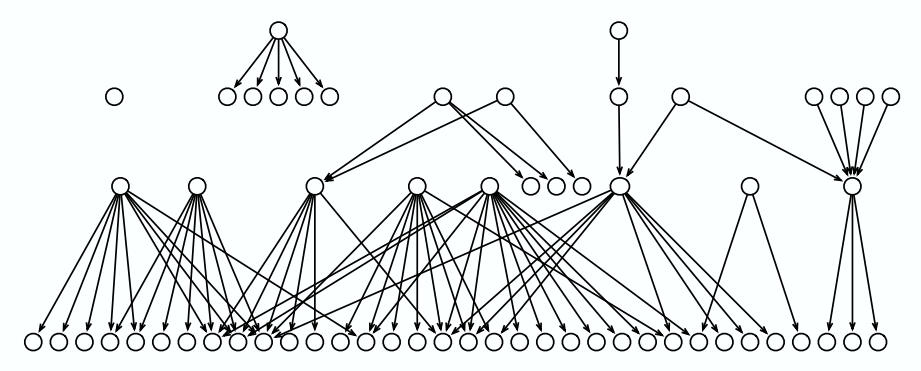

Figure 7: The Carpo network

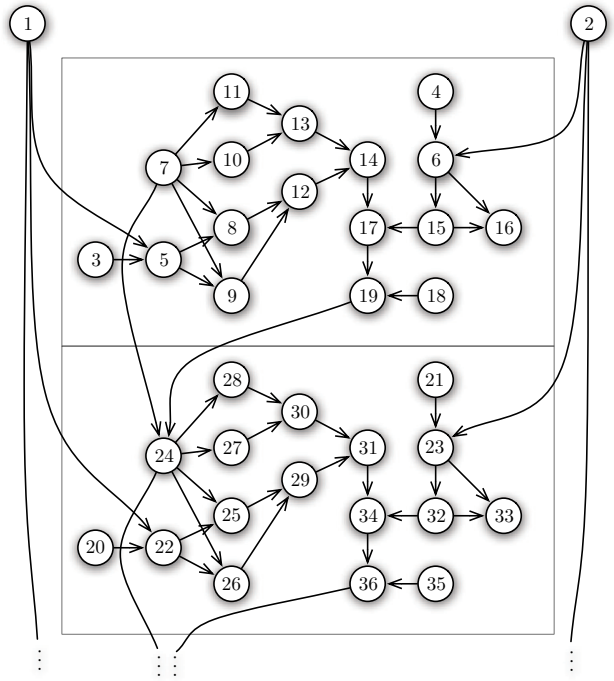

Figure 8: Two of the six patterns of the Diabetes network

For all simulation experiments, we generated the data sets by using the 5 graphs as a structure for a linear structural equations model: the parentless variables were sampled as Gaussians with zero mean and unit standard deviation; the other variables were defined as a linear combination of their parents with coefficients randomly distributed uniformly between 0.2 and 1, similarly to what was done in Scheines et al. (1995) for the evaluation of PC. The disturbance terms were also normally distributed. We compared the number of tests, the size of the conditioning sets, and the

10. Created by Alex Dagum with contributions from Mark Peot, as indicated on its page at the Bayes net repository. No corresponding publication was found.

structural errors in case of runs with artificial data. A structural error is an arc addition, deletion, or reversal with respect to the original graph.

We used the implementation of PC proposed by Leray and François (2004) in the BNT Structure Learning Matlab package. The implementation of TC and TC_{bw} was also done in Matlab. The statistical tests were done using Fisher's *z*-transform of the partial correlation, unless otherwise stated. For PC and GS, we chose the default value of $\alpha = 0.05$; we note though that the optimal value of α is problem dependent and that especially with low sample sizes, hand tuning α can return better results than those listed here. For both TC and TC_{bw}, we set $\alpha = 2/(d(d-1))$, according to the discussion at the end of Section 4.2.

5.2 Local Structure Recovery with Markov Blanket Information

In this series of experiments, we compare RESOLVEMARKOVBLANKETS_COLLIDERSETS (CS) to RESOLVEMARKOVBLANKETS_GROWSHRINK and to a modified version of PC, where the graph being built is initialized with the moral graph (instead of the full graph in the original version of PC). This represents exactly the Markov blanket information available to the two other algorithms and allows a direct comparison. Note that we observe the PDAG that PC obtains *before* the constraint-propagation step building the maximally oriented PDAG, such that, in all three tested algorithms, we only expect the V-structures to be oriented.

We tested the three algorithms on each network using two methods to check for conditional independence: first, using a *d*-separation oracle with the original graph (which is equivalent to a perfect test); and second, using Fisher's *z*-transform of the sample partial correlation coefficient as computed on artificial data, with significance $\alpha = 0.05$. Using the oracle always yields correct graphs.

Table 1 shows the results of these experiments. We first list the results obtained when using a *d*-separation oracle to decide upon conditional independence. For GS, we ran two versions of Algorithm 1: one, which we name GS(1), where the subset searches at lines 5 and 13 proceed with decreasing sizes of the chosen subset $\mathbf{S}$, and another, GS(2), with increasing subset sizes. GS(1) usually leads to fewer tests, but with larger conditioning sets. The order of the subset searches for our method (lines 7 and 15 in Algorithm 2) was fixed to decreasing subset sizes, as this always led to fewer tests *and* smaller conditioning sets.

The results for the modified PC algorithm are only shown for the sake of comparison: PC is a general-purpose algorithm which is not specialized in such local structure recognition given the Markov blankets. What the comparison shows, however, is that, whenever this Markov blanket information is available or cheap to obtain, there are much more efficient approaches.

GS(1) and GS(2) are close to one another in all scores, and outperform PC (by several orders of magnitude) in the number of tests and (significantly) in average and maximum size of the conditioning sets (except, artificially, for the results marked with a star), because it uses the Markov blanket information better. Our approach, however, is one order of magnitude better than GS(1) and GS(2) in terms of number of tests, while still using smaller average and maximum conditioning set sizes in all tested networks. Especially striking are the results on the Carpo network: this is an example where CS saves a lot of time ignoring the numerous links not part of triangles, whereas GS(1) and GS(2) also checks those, with the often large Markov blankets (Figure 7).

We then performed the same experiments, but using the statistical tests on data sampled from the networks as described in the previous sections. We used a fixed sample size $n = 500$ and averaged

Table 1: Number of tests and size of the conditioning sets (noted $\lvert\mathbf{Z}\rvert$) as performed by various algorithms to recover the local network structure of the networks given perfect Markov blanket information. The star (*) notes PC results where the maximum size of the conditioning set has been set to 6 to avoid prohibitive run times.

over 9 different samplings for each network. We only compared PC, GS(1) and CS on this series of experiments, preferring GS(1) to GS(2) because of the lower number of tests it usually performs. The exhaustive results are listed in Table 2 for the sake of completeness, and the sum of the structural errors is also shown in Figure 9 for easier visualization.

First, we see that we get similar results as in Table 1 as far as the number of tests and size of the conditioning sets are concerned: CS is faster and consistently performs fewer tests with smaller conditioning sets, which leads to an increased power of the tests. However, that is sometimes balanced out by the fact that CS relies on a single series of tests both to remove spouse links and to orient (possibly multiple) V-structures at the same time, thus leading to a greater penalty if the outcome of a test is wrong with respect to the initial graph.

We see that GS(1) and PC can beat CS on certain arc scores; PC, in particular, is good at avoiding arc orientation mistakes in these experiments. GS(1), which checks not only triangle links but all links to try to orient them, makes more orientation mistakes, especially on the Carpo network. PC tends to miss a few more arcs than CS, which in turn misses a few more than GS(1). But in total, CS beats GS(1) significantly on Insurance, Hailfinder, and Carpo, while performing slightly better on Alarm and being slightly outperformed on Diabetes. Based on these results, we will now use our collider set search as the method of choice to break up the Markov blankets for the next series of experiments.

Table 2: Number of tests, size of the conditioning sets (noted $\lvert\mathbf{Z}\rvert$), and structural errors as returned by GS(1) and CS to recover the local network structure of the networks given perfect Markov blanket information. Results are given is the form "mean $\pm$ standard deviation over the 9 data sets." The best performer for each type of structural error has been highlighted in bold. All runs of PC were done with a forced maximum size of the conditioning set of 6. The dagger (†) notes PC results from a single data set instead of 9 because of the long completion times. Represented graphically in Figure 9.

5.3 RFE-Based Approach

In this series of experiments, we tested our RFE-based approach on the Alarm network with sample sizes $n = 100$, 200, 300, 400 and 500. Table 3 lists the results and shows the number of errors as measured at different stages of the algorithm:

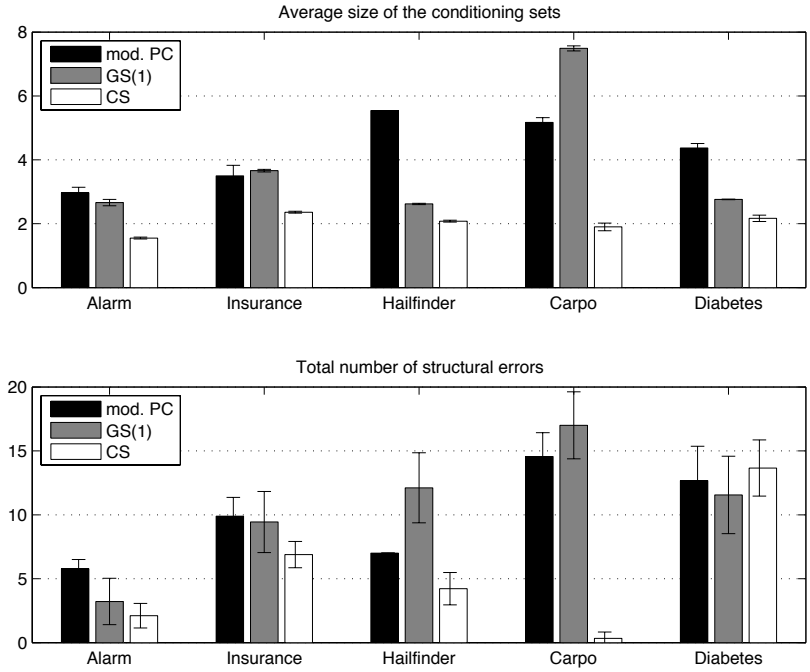

Figure 9: Average size of the conditioning sets and total number of errors for the three local structure discovery algorithms on various networks. Graphical representation corresponding to the results in Table 2.

1. Right after the Markov blanket identification, without adjustment. This compares the true Markov blanket of each variable with the identified Markov blanket as returned by Algorithm 5;

2. After building the moral graph. This notably excludes variables from Markov blankets if they do not satisfy the symmetry condition (2) due to the symmetry check performed at line 5 in the generic approach described in Algorithm 3;

3a. After removal of the spouse links using the Recursive Median (RM) algorithm (Margaritis, 2005) to check for conditional independence in the continuous domain;

3b. Alternatively, after removal of the spouse links using a test on Fisher's *z*-transform of partial correlation;

4a. After removal of the spouse links using RM *and* after maximal orientation. This is actually the result that can be compared to other full structure-learning algorithms;

4b. After removal of the spouse links using partial correlation tests *and* after maximal orientation;

5. Finally, we show how PC performs on the same instance for comparison.

Note that the RM test is a Bayesian distribution-free conditional-independence test. In this case, where we use multivariate Gaussian distributed data, we do not expect it to perform better

than the specialized z-test. We nevertheless include it in this series of experiments for two reasons. First, it allows the collider set search to be also distribution-free, in the sense that if "distribution-free feature selection" can be performed efficiently and consistently in the first phase, applying a subsequent collider set search does not make more assumptions on the distribution. Second, it allows to evaluate the cost of using a distribution-free algorithm on Gaussian data.

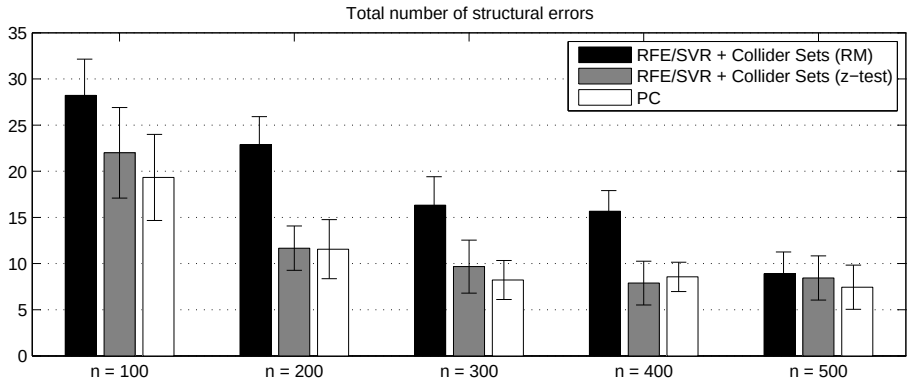

Figure 10: Total number of errors for the CPDAGs returned by the three global structure discovery algorithms on the Alarm network with various sample sizes. Graphical representation corresponding to the results in Table 3.

Detailed results are in Table 3 and the total number of structural errors is shown graphically in Figure 10. What we can read from the results is that, generally, the selected Markov blankets contain all variables from the true Markov blanket plus one or two additional variables. Starting at $n = 300$, on average, less than two variables were missed. Many spurious variable are selected, however, even for the larger data sets. This confirms the expectation the RFE approach also selects weakly relevant features: on average, the Markov blankets in the Alarm network have a size of 3.5, and on average 5.5 variables are selected per variable.

The symmetry check requiring Y to be part of $\mathbf{Mb}(X)$ and X to be part of $\mathbf{Mb}(Y)$ to add a link between X and Y fulfills its purpose, as even in the case $n = 200$ where on average about 73 variables enter wrong Markov blankets, only 4 extra links are added in the moral graph. As a side note, we thus argue that a global analysis can be beneficial to achieve better results on local tasks: we see here that determining via RFE the Markov blanket of a single variable is too inclusive, but that validating the selected variables globally, for instance with our Markov blanket symmetry check, allows to significantly reduce the number of false positives.

After the collider set search, the number of missing and extra arcs can both either increase or decrease. If the number of missing links increases, it is because the collider set search found d-separation too often while variables were actually dependent. If it decreases, it means that the missing arcs in the moral graph were spouse links, as their absence is not penalized in the PDAG any more. If the number of extra arcs increases, then the collider set search failed to identify spouse links; if it decreases, then the collider set search also removed through appropriate conditioning links that were not spouse links (which in turn possibly led to wrong orientations). Also, determining which part of the algorithm is responsible for a missed, extra, or reversed edge in a PDAG or CPDAG is not evident. As the feature-selection step is not alone responsible for the extra or missing links,

Table 3: Structural errors at various stages of the RFE-based approach, showing the missing, extra and reversed arcs with respect to the original graph. For Step 1, identification of the Markov blanket, the figures are averages over the 37 variables; that is, the count of the extra or missing variables per Markov blanket, and thus not directly comparable to the other steps. The sums of the errors for the CPDAGs are represented in Figure 10.

the collider set search is not responsible for all orientation mistakes. In the collider set search, if a wrong spouse link is removed, it is because a wrong V-structure has been identified, so that the absence of an arc will be linked to the wrong orientation of the falsely recognized V-structure. It is also possible to construct cases where missing a variable in the feature-selection step will lead not only to a missing arc, but also to the detection of a spurious V-structure, even if all subsequent tests are perfect.

For the PDAGs obtained using z-tests, the number of missing arcs always decreases with respect to the moral graph, and so does the number of extra links for $n \geq 200$. We find that the more general RM test seems to return independence too often, as for $n \geq 200$ more links are missing in the PDAG than in the moral graph. (On highly nonlinear data, we would, however, expect RM to perform better than a z-test, which assumes Gaussianity.)

The CPDAGs do not have a number of adjacency errors different from their PDAGs; this step can only add directionality errors. We have nevertheless copied the results in order to improve the readability and to make the comparison with PC easier. Although the RFE approach can outperform PC in adjacency errors, PC still consistently makes fewer directionality errors. We remark, however, that the overall performance of RFE/SVR with z-tests is very comparable to that of PC, as also shown in Figure 10, which empirically justifies the intuition behind this approach.

5.4 TC and TC_{bw} vs. Competitors

For this series of experiments, we performed more systematic testing of TC, TC_{bw}, PC, the full GS and the Bach-Jordan method on data sets sampled from Alarm, Insurance, Hailfinder, Carpo, and Diabetes, varying the sample size. The Bach-Jordan method consists of a scoring function based on Mercer kernels coupled with a greedy search in the space of DAGs and was designed to learn Bayesian networks. It does not guarantee that the formal semantics of a causal graph are respected in the large-sample limit, but has been included in the experiments for the sake of comparison. Other possible competitors like SCA (Friedman et al., 2000) or AlgorithmMB (Peña et al., 2005) were inapplicable because generalizing them to handle continuous variables require techniques that are too computationally expensive, notably because of score-based subroutines that are hard to generalize.

The structural errors, like before, are missing, extra, and reversed arcs in the returned CPDAG with respect to the generating graph. For the Bach-Jordan method, similarly to what was done in Fu (2005), we converted the returned DAG to its essential graph first before checking for structural errors to avoid penalizing statistically equivalent structures. For all experiments, we also compare the run times and the number of tests performed by TC, TC_{bw}, GS, and PC.

Specific to the Bach-Jordan method is the issue of choosing the appropriate kernel parameters; that is, in our case, the σ width in the Gaussian kernel. Bach and Jordan (2003) claim that the algorithm is in general robust to the choice of σ. We have found, however, that for varying sample sizes, the number of structural errors is quite sensitive to σ. As the authors do not propose a heuristics to set it, we systematically tested the algorithm with $\sigma = 2$, 1, 0.5, and 0.3 for each run, and chose the outcome with the smallest sum of structural errors. In general, smaller data sets preferred $\sigma = 2$, while the larger ones preferred a smaller σ. The change of σ is not directly visible in the following plots of the errors, but it often leads to "zigzags" in the Bach-Jordan curves. This is due to the fact that we only tested a fixed number of values for σ and did not perform a full optimization of this parameter for each run. The results shown are thus not the best results obtainable with this method.

5.4.1 ALARM

The figures on p. 1330 show the structural errors, run times and number of statistical tests against the number of samples for Alarm. For each sample size, 5 data sets were drawn from the model; the error bars picture the standard deviation over these 5 runs.

The numbers of extra and missing links seem to clearly decrease on average for all algorithms with an increasing number of samples, except for Bach-Jordan, which sometimes has the tendency to add more links when more data points are available. Note that Bach-Jordan's σ changes between the last two runs, explaining the abrupt change in the extra arcs. The number of reversed arcs seems to less satisfactory, in particular for TC. The explanation is that TC misses many arcs with low sample sizes, and thus does not actually get the opportunity to make many directionality errors for these cases. TC_{bw} exhibits a related behavior, although much less stronger. We also see that Bach-Jordan makes the most directionality errors (this is actually valid for all networks). GS reaches repeatedly a zero extra arc score for $n > 1000$, although it misses some more than the others.

Starting at about 200 samples, TC equals or outperforms PC, GS and Bach-Jordan. TC_{bw} beats both TC and PC, and the converging curves of TC and TC_{bw} show that the stepwise regression becomes unnecessary with about 400 samples. On average, TC was about 20 times faster than the implementation of PC we used, although the factor tended to decrease with larger sample sizes. TC_{bw} was naturally slower than TC, although only marginally compared to the speed difference with PC.

Overall, the constraint-based methods seem to perform approximately equally well for $n > 400$, and TC_{bw} and GS perform slightly better than PC for low sample sizes. Note that for low sample sizes, TC is always outperformed by TC_{bw}, PC, and GS, but is often the one to perform best when the sample size gets larger. The graphs in Figure 12 show that TC and TC_{bw} are fastest, although GS performed fewer tests that TC_{bw}.

5.4.2 INSURANCE

For this network, we find similar behaviors to Alarm, shown in the graphs on p. 1331. The most striking difference is the clear tendency of Bach-Jordan to add more arcs when more data is available for this more densely connected network. Between the 5th and 6th sample sizes, there is again a change of σ. Comparing the curves of the missing and extra arcs, we see that this changes the tradeoff between false negatives and false positives.

In this case, too, TC_{bw} outperforms TC with low sample sizes (because it misses fewer arcs) but is outperformed with bigger data sets (because it adds too many). Both PC and GS, while being slightly better than TC_{bw} for $n < 100$, are outperformed starting at about $n = 500$. Note the overall good performance of GS in terms of arc orientation errors. The corresponding curve also decreases more smoothly with larger data sets. The Bach-Jordan method is unexpectedly fast on this data set, although poorly accurate. The pattern of the number of statistical tests is very similar to that of Alarm.

5.4.3 HAILFINDER

This network poses a problem to PC: we divided its run time and the number of tests by 10 in the graphs of Figure 16 on p. 1332. Because of its long run times, PC was run only once for each point in the plots, so that the error bars are missing. PC runs into trouble because of the node cluster around variable 27 in the network (see Figure 6): it tries to separate it from the other nodes by doing

subset searches on its large number of neighbors. In order to speed it up, we set the maximum node fan-in parameter to 6, so that PC would not attempt to conduct conditional-independence tests with conditioning sets larger than 6 (we see in Figure 16 how this imposes an upper bound on the run times of PC). TC and TC_{bw} do not run into this problem, because this cluster is correctly left alone after the feature-selection step, done in $O(d^3)$ operations. Note that TC, TC_{bw}, and GS *would* also spend a long time on this cluster if all neighbors of variable 27 were its parents, because they would contain a lot of extra spouse links to be checked with an exponential number of combinations. But this example shows that a local lack of sparseness is fatal to the efficiency of PC, whereas other algorithms can still deal with it if the density of the connections is caused by children rather than parents.

This network shows more clearly the missing arc problem that TC has with low sample size, and the benefits of using TC_{bw} rather than TC here, at least for $n < 2000$. On this network, GS performs overall well. It is beaten by TC only for $n > 2000$, but performs better than all others for $n < 200$. Bach-Jordan still exhibits the same tendency to add more arcs when more data is available. For this data set, σ changes twice, between the 4th and 5th, and between the 5th and 6th data set sizes. The 5th sample size seems to have generated an unfavorable data set for PC, as the number of extra arcs is particularly high.

Examining the run times designates TC as the fastest. This is important especially with larger sample sizes, as TC is often both the fastest and most accurate algorithm.

5.4.4 CARPO

The results for this network are shown on p. 1333. The structural particularity of this network is multiple cases of a single variable having many children. PC performs overall badly on this network. For $n < 200$, GS is the clear winner: all other algorithms make many more errors. The plain TC especially misses many arcs. For $n > 500$, however, both TC and TC_{bw} slightly but consistently outperform GS. At $n = 800$, TC beats TC_{bw}. Bach-Jordan, although fast on this instance, adds again too many extra links, and makes numerous directionality errors.

5.4.5 DIABETES

This is our largest and final test network. The error patterns are most similar to those of the Insurance network, with the exception of Bach-Jordan, which performs more poorly here. We can detect two changes of σ: between the 3rd and 4th, and between the 5th and 6th sample sizes.

Starting at $n > 1000$, all constraint-based methods seem to yield similar overall accuracy. GS is better in terms of directionality errors; TC and TC_{bw} are better in terms of missed links. For $n > 4000$, TC and TC_{bw} have the same accuracy and slightly beat GS and PC, while they are beaten significantly for $n < 800$. We note that the extra links added by GS seem to allow it to obtain a better directionality accuracy than in our first series of experiments, where it was given the exact moral graph as input.

5.4.6 DISCUSSION

Both TC and TC_{bw} slightly but consistently beat the other competitors when the sample size exceeds one or two thousand, depending on the network. They are usually weaker with low sample sizes because of missed arcs. GS beats TC with small data sets, because of the way that PC goes through conditioning sets for the statistical tests (Tsamardinos et al., 2006, discuss in detail this particular

issue in the case of tests with discrete variables). The score-based Bach-Jordan method was found difficult to tune with the parameter σ. For this multivariate Gaussian case, its performance is usually worse than the other tested algorithms. This also reflects the fact PC, GS, TC and TC_{bw} with *z*-tests are all "tuned" for multivariate Gaussian data. The additional errors made by Bach-Jordan reflect the price of being more generic.

In terms of run time, PC is slowed down by nodes with a high degree, whereas TC or GS handle them without the exponential time complexity growth if they are not part of triangles, as in Hailfinder. In general, TC and TC_{bw} resolve all conditional-independence relations (up to married parents) in the feature-selection step in $O(d^3)$ and $O(d^4)$, respectively, whereas all PC can do in $O(d^{2+\alpha})$ is resolve conditional-independence relations with conditioning sets of cardinality α. It is then reasonable to expect algorithms like GS, TC and TC_{bw} to scale better than PC on sparse networks where nodes have a small number of parents. The exponential growth in PC can be seen in case the nodes have a high degree, be it parents or children; in TC and GS, it is due to large fully-connected triangle structures and to spouse links coming from the Markov blanket-construction step. And whereas these large structures imply a high degree, the converse is not true (for instance in the Hailfinder network). So, PC will exhibit an exponential behavior on all problem instances where TC and GS also exhibits this behavior, but the converse is not true.

It is interesting to investigate what kind of high-degree structure is more likely to appear. If it is a node with many children (as node 27 in Hailfinder), which we call an *explosion pattern*, TC can handle it efficiently. If it is a node with many parents, an *implosion pattern*, then none of these algorithms can recognize it in polynomial time. Explosion patterns correspond to a single cause that has many effects; implosion patterns correspond to many causes leading to the same effect. It remains open for discussion to know which one is more likely to occur with real-life data sets.

GS could not be beaten on small sample sizes. It is yet an unsolved challenge for TC and TC_{bw} to handle problems where the number of variables exceeds the number of samples, as in gene expression networks, thus leading to an attempt at inverting a matrix that does not have full rank. Regularizing the covariance matrix might help make TC_{bw} more robust in this case. Computationally, TC_{bw} does add a degree of complexity with respect to TC, and the number of tests that TC_{bw} performs is usually comparable to GS.

TC_{bw} helps solving problems with TC and small data sets, but still cannot operate below the $n = d$ threshold. The exact sample size where TC_{bw} stops performing better than TC does not appear to be a simple function of the n or d but depends on the structure of the network. It would be useful to investigate when the feature-selection addition of TC_{bw} becomes irrelevant. And as GS is more accurate with small sample sizes, finding a similarly testable condition predicting the threshold where TC is more accurate than GS would allow to merge the approaches into a single algorithm that knows which Markov blanket approach to use in order to achieve better results.

6. Conclusion

Causal discovery and feature selection are closely related: optimal feature selection discovers Markov blanket as sets of strongly relevant features, and causal discovery discovers Markov blankets as direct causes, direct effects, and common causes of direct effects. By performing perfect feature selection on each variable, we get the undirected moral graph as an approximation of the causal graph. An extra step, the collider set identification, is needed in order to transform the Markov blankets into parents, children, and spouses. This step is exponential in the worst case,

but is actually efficient provided the graph is sparse enough—a common assumption of many algorithms. We proposed an algorithm to do this task and compared it favorably to the similar steps of the Grow-Shrink algorithm.

Determining the Markov blanket with existing backward feature elimination like RFE eliminates the irrelevant variables in the large sample limit, but remains too inclusive. Global corrections have to be made, such as for instance insuring that a variable in the selected Markov blanket of a target also includes this target in its own selected Markov blanket. We conducted experiments that confirmed that this adjustment discards most false positives, and thus provided a hint that the approach is consistent in the large-sample limit. The main challenge is to perform feature selection for all variables in an efficient way. This task is tractable with the multivariate Gaussian assumption. We presented the TC and the TC_{bw} algorithms, which fit into the described framework, and compared them to PC, GS, and a Bayesian structure-learning method. For small sample sizes, GS usually makes fewer structural errors, and TC/TC_{bw} are better for larger samples sizes.

We are convinced of the superiority of the Markov blanket approaches as described in this paper. We invoke as support for this claim the high run times of PC, and the good low and high sample size accuracy of GS and TC/TC_{bw}, respectively. Not only are Markov blanket techniques much more scalable, they can be more accurate; they are also more easily modifiable to construct only parts the network deemed relevant by some criterion.

The biggest challenges we face now with causal structure learning include robust and consistent distribution-free structure learning with continuous and potentially highly nonlinear data. In the future, we intend to make use of this framework to develop such techniques and thus try to get rid of the Gaussianity assumption, often impractical with real-life data sets.

Acknowledgments

We would like to thank Dimitris Margaritis, who kindly provided us with his C implementation of the Recursive Median conditional-independence test; and Francis Bach and Lawrence Fu, who provided us with a Matlab/C implementation of the Bach-Jordan algorithm. We also thank the anonymous reviewers for their helpful comments and pointers, which led to a significantly enhanced version of this paper.

Appendix A.

For all proofs, we assume the given data set D is faithful.

Lemma 12 *In a DAG $\mathcal{G}$, any (undirected) path π of length $\ell(\pi) > 2$ can be blocked by conditioning on any two consecutive nodes in π.*

Proof It follows from Definition 5 that a path π is blocked when either at least one collider (or one of its descendants) is not in the conditioning set $\mathbf{S}$, or when at least one non-collider is in $\mathbf{S}$. It therefore suffices to show that conditioning on two consecutive nodes always includes a non-collider. This is the case because two consecutive colliders would require bidirected arrows, which is a structural impossibility with simple DAGs. ■

Lemma 13 *In a DAG $\mathcal{G}$, two nodes X,Y are* d*-connected given all other nodes $\mathbf{S} = \mathbf{V} \setminus \{X,Y\}$ if and only if any of the following conditions holds:*

(i) There is an arc from X to Y or from Y to X (i.e., $X \to Y$ or $X \leftarrow Y$);
(ii) X and Y have a common child Z (i.e., $X \to Z \leftarrow Y$).

Proof We prove this by first proving an implication and then its converse.

($\Longleftarrow$) If (i) holds, then X and Y cannot be d-separated by any set. If (ii) holds, then Z is included in the conditioning set and d-connects X and Y by Definition 5.

($\Longrightarrow$) X and Y are d-connected given a certain conditioning set when at least one path remains open. Using the conditioning set $\mathbf{S}$, paths of length > 2 are blocked by Lemma 12 since $\mathbf{S}$ contains all nodes on those paths. Paths of length 2 contain a mediating variable Z between X and Y; by Definition 5, $\mathbf{S}$ blocks them unless Z is a common child of X and Y. Paths of length 1 cannot be blocked by any conditioning set. So the two possible cases where X and Y will be d-connected are (i) or (ii). ■

Corollary 14 *Two variables X,Y are dependent given all other variables $\mathbf{S} = \mathbf{V} \setminus \{X,Y\}$ if and only if any of the following conditions holds:*

(i) X causes Y or Y causes X;
(ii) X and Y have a common effect Z.

Proof It follows directly from Lemma 13 due to the faithful structure, which ensures that there exists a DAG where conditional independence and d-separation map one-to-one. Lemma 13 can then be reread in terms of conditional independence and causation instead of d-separation and arcs. ■

Property 7 (Total conditioning) *In the context of a faithful causal graph $\mathcal{G}$, we have:*

$$\forall X,Y \in \mathbf{V}: \ \big(X \in \mathbf{Mb}(Y) \iff (X \not\perp\!\!\!\perp Y \mid \mathbf{V} \setminus \{X,Y\})\big).$$

Proof This is a direct consequence of Corollary 14, where points *(i)* and *(ii)* lead to the definition of the Markov blanket of Y as *(i)* all its causes and effects, and *(ii)* the other direct causes of its effects. This is equivalent to $\mathbf{Mb}(Y)$ in $\mathcal{G}$. ■

Lemma 15 *When it exists, the subset $\mathbf{Z}$ that has the Collider Set property for the pair (X,Y) is the set of all direct common effects of X and Y.*

Proof We prove this using $\mathbf{Z}$ and a corresponding $\mathbf{S}_{XY}$ that fulfills (7).

($\Longrightarrow$) ($Z_i \in \mathbf{Z} \implies X \to Z_i \leftarrow Y$.) By (7) and (8), we know that each Z_i opens a dependence path between X and Y (which are independent given $\mathbf{S}_{XY}$) by conditioning on $\mathbf{S}_{XY} \cup \{Z_i\}$. By Definition 5, conditioning on Z_i opens a path if Z_i is either a colliding node or one of its descendants. As, by

definition, $\mathbf{Z} \subseteq \mathbf{Tri}(X - Y)$, we are in the first case. We conclude that Z_i is a direct effect of both X and Y.

($\Longleftarrow$) ($X \twoheadrightarrow Z_i \twoheadleftarrow Y \implies Z_i \in \mathbf{Z}$.) Note that (7) and (8) together are implied in presence of a V-structure $X \twoheadrightarrow Z_i \twoheadleftarrow Y$. Thus, a direct effect is compatible with the conditions. The fact that $\mathbf{Z}$ captures all direct effects follows from the maximization of its cardinality. ■

Lemma 9 *In the context of a faithful causal graph, the set* $\mathbf{Z}$ *that has the Collider Set property for a given pair* (X,Y) *exists if and only if* X *is neither a direct cause nor a direct effect of* Y*, and is unique when it exists.*

Proof The fact that $\mathbf{Z}$ exists if and only if X is neither a direct cause nor a direct effect of Y is a direct consequence of (7), which states that X and Y can be made conditionally independent. This is in contradiction with direct causation.

We now show unicity, using interchangeably the criteria of d-separation and conditional independence, as allowed by the Faithfulness assumption. Suppose that, for a pair (X,Y), two sets $\mathbf{Z}$, $\mathbf{W}$ have been found that fulfill the Collider Set property, with the corresponding d-separating sets $\mathbf{S}_{XY}^{\mathbf{Z}} \subseteq \mathbf{V} \setminus \{X,Y\} \setminus \mathbf{Z}$ and $\mathbf{S}_{XY}^{\mathbf{W}} \subseteq \mathbf{V} \setminus \{X,Y\} \setminus \mathbf{W}$ fulfilling (7). Let $\mathbf{Z}^\star = \mathbf{Z} \setminus \mathbf{W}$. Due to symmetry, proving that $\mathbf{Z}^\star$ is empty proves that $\mathbf{Z} = \mathbf{W}$.

Suppose that $\mathbf{Z}^\star \neq \emptyset$; that is, $\exists Z \in \mathbf{Z}^\star$. Then, by definition, we have that $\left(X \perp\!\!\!\perp Y \;\middle|\; \mathbf{S}_{XY}^{\mathbf{Z}}\right)$ and $\left(X \not\perp\!\!\!\perp Y \;\middle|\; \mathbf{S}_{XY}^{\mathbf{Z}} \cup \{Z\}\right)$. We now have two cases: either (i) $Z \notin \mathbf{S}_{XY}^{\mathbf{W}}$, or (ii) $Z \in \mathbf{S}_{XY}^{\mathbf{W}}$. In the former case (i), consider the set $\mathbf{W}' = \mathbf{W} \cup \{Z\}$. Then $\mathbf{W}'$ also fulfills the Collider Set property with the same d-separating set $\mathbf{S}_{XY}^{\mathbf{W}}$: the only additional condition is $\left(X \not\perp\!\!\!\perp Y \;\middle|\; \mathbf{S}_{XY}^{\mathbf{W}} \cup \{Z\}\right)$. This holds because, as shown by Lemma 15, Z is a direct child of X and Y, and conditioning on it opens a path, no matter what the conditioning set is. But all this is in contradiction with the definition stating that any set fulfilling this property must be the largest set to do so, because the cardinality of $\mathbf{W}'$ is greater than that of $\mathbf{W}$.

In the latter case (ii), the d-separating set $\mathbf{S}_{XY}^{\mathbf{W}}$ contains Z. But this is impossible due to the same reason that Z is a direct child of both X and Y and that thus any set containing Z cannot d-separate X and Y. We therefore conclude $\mathbf{Z}^\star = \emptyset$ and $\mathbf{Z} = \mathbf{W}$, which leads to the uniqueness of the set fulfilling the Collider Set property. ■

Theorem 10 *In the large sample limit, for faithful, causally sufficient data sets, the procedure* RESOLVEMARKOVBLANKETS_COLLIDERSETS *correctly identifies all V-structures and all spouse links, assuming consistent statistical tests.*

Proof First, we note that in a moral graph, a node X is connected to its parents, children, and spouses. Thus, all spouse links to be removed are in the moral graph, and, by the definition of spouse, each spouse link between X and Y corresponds to at least one unshielded collider for the pair (X,Y). Additionally, by the definition of unshielded collider, X and Y are nonadjacent, so that for each spouse link $X - Y$ there is a set $\mathbf{S}_{XY}$ such that $(X \perp\!\!\!\perp Y \mid \mathbf{S}_{XY})$ by the contraposition of (4). So, when such a set $\mathbf{S}_{XY}$ is found, the link $X - Y$ is removed, and for each Z such that $X - Z - Y$ and $Z \notin \mathbf{S}_{XY}$, we orient the triplet as $X \rightarrow Z \leftarrow Y$ for the exact same reason that allows IC (or PC) to do the same in Step 2 of the algorithm (Pearl, 2000). The proof boils down to proving that the proposed search procedure always identify a d-separating set $\mathbf{S}_{XY}$ when there is one.

If some S_{XY} exists, then the link between X and Y is a spouse link by definition of a moral graph, which implies that X and Y have a nonempty set of common effects $\mathbf{Z}$. Each $Z \in \mathbf{Z}$ is linked to both X in Y and is thus in $\mathbf{Tri}(X-Y)$ by definition. Let us assume we can d-separate X and Y by some set: then, by the definition of d-separation, only conditioning on a common effect or a descendant of a common effect can create a dependency. In Algorithm 2, all possible colliders (line 7) and descendants of currently conjectured colliders (line 13) undergo a subset search, such that there will always be one iteration where all colliders and their descendants will be left out of the conditioning set. It is then enough to show that all d-connecting paths between X and Y that are not due to conditioning on a collider or collider's descendant go through the base conditioning set as determined at line 6.

To prove this, we note that the subset search at line 7 will always go through an iteration where it blocks all such d-connecting paths of length 2, that is, patterns of the type $X \to W \to Y$ and $X \leftarrow W \to Y$. As a direct consequence of the fact that we are working on the moral graph, all longer dependency paths go both through a node W in the set of immediate neighbors $\mathbf{Bd}(X)$ of X, and through a node in $\mathbf{Bd}(Y)$. Let us look at $\mathbf{Bd}(X)$. We have two cases: either (i) $W \in \mathbf{Tri}(X-Y)$ and will eventually be blocked by the subset search at line 7, or (ii) $W \in \mathbf{Bd}(X) \setminus \mathbf{Tri}(X-Y)$ (and thus $W \in \mathbf{Bd}(X) \setminus \mathbf{Tri}(X-Y) \setminus \{Y\}$ because $W \neq Y$). This set is exactly the set selected as base conditioning set at line 6, blocking all such paths, up to some symmetry with Y. The fact that we may choose the smaller of the two possible base conditioning sets is due to symmetry reasons. ■

Theorem 16 *If the variables are jointly distributed according to a multivariate Gaussian, TC returns the maximally oriented PDAG of the Markov equivalence class of the DAG representing the causal structure of the data-generating process in the large sample limit, assuming statistically consistent tests.*

Proof An edge is added between X and Y in the feature selection if we find that $\rho_{XY \cdot \mathbf{V} \setminus \{X,Y\}} \neq 0$. We conclude $(X \not\perp\!\!\!\perp Y \mid \mathbf{V} \setminus \{X,Y\})$ owing to the multivariate Gaussian distribution. Corollary 14 says that this implies that X causes Y or Y causes X, or that they share a common child. Therefore, each V-structure is turned into a triangle by the end of the feature-selection step. The collider set search then examines each link $X-Y$ part of a triangle, and by Lemma 15, we know that if the search for a set $\mathbf{Z}$ that has the Collider Set property succeeds, there must be no link between X and Y. We know by the same lemma that this set includes all colliders for the pair (X,Y), so that all V-structures are correctly identified. Step 3 is the same as in the IC or PC algorithms; see Pearl and Verma (1991) and Spirtes et al. (2001). ■

Abstract

The support vector machine has been successful in a variety of applications. Also on the theoretical front, statistical properties of the support vector machine have been studied quite extensively with a particular attention to its Bayes risk consistency under some conditions. In this paper, we study somewhat basic statistical properties of the support vector machine yet to be investigated, namely the asymptotic behavior of the coefficients of the linear support vector machine. A Bahadur type representation of the coefficients is established under appropriate conditions, and their asymptotic normality and statistical variability are derived on the basis of the representation. These asymptotic results do not only help further our understanding of the support vector machine, but also they can be useful for related statistical inferences.

Keywords: asymptotic normality, Bahadur representation, classification, convexity lemma, Radon transform

1. Introduction

The support vector machine (SVM) introduced by Cortes and Vapnik (1995) has been successful in many applications due to its high classification accuracy and flexibility. For reference, see Vapnik (1996), Schölkopf and Smola (2002), and Cristianini and Shawe-Taylor (2000). In parallel with a wide range of applications, statistical properties of the SVM have been studied by many researchers recently in addition to the statistical learning theory by Vapnik (1996) that originally motivated the SVM. These include studies on the Bayes risk consistency of the SVM (Lin, 2002; Zhang, 2004; Steinwart, 2005) and its rate of convergence to the Bayes risk (Lin, 2000; Blanchard, Bousquet, and Massart, 2008; Scovel and Steinwart, 2007; Bartlett, Jordan, and McAuliffe, 2006). While the

existing theoretical analysis of the SVM largely concerns its asymptotic risk, there are some basic statistical properties of the SVM that seem to have eluded our attention. For example, to the best of our knowledge, large sample properties of the coefficients in the linear SVM have not been studied so far although the magnitude of each coefficient is often the determining factor of feature selection for the SVM in practice.

In this paper, we address this basic question of the statistical behavior of the linear SVM as a first step to the study of more general properties of the SVM. We mainly investigate asymptotic properties of the coefficients of variables in the SVM solution for linear classification. The investigation is done in the standard way that parametric methods are studied in a finite dimensional setting, that is, the number of variables is assumed to be fixed and the sample size grows to infinity. Additionally, in the asymptotics, the effect of regularization through maximization of the class margin is assumed to vanish at a certain rate so that the solution is ultimately governed by the empirical risk. Due to these assumptions, the asymptotic results become more pertinent to the classical parametric setting where the number of features is moderate compared to the sample size and the virtue of regularization is minute than to the situation with high dimensional inputs. Despite the difference between the practical situation where the SVM methods are effectively used and the setting theoretically posited in this paper, the asymptotic results shed a new light on the SVM from a classical parametric point of view. In particular, we establish a Bahadur type representation of the coefficients as in the studies of sample quantiles and estimates of regression quantiles. See Bahadur (1966) and Chaudhuri (1991) for reference. It turns out that the Bahadur type representation of the SVM coefficients depends on Radon transform of the second moments of the variables. This representation illuminates how the so called margins of the optimal separating hyperplane and the underlying probability distribution within and around the margins determine the statistical behavior of the estimated coefficients. Asymptotic normality of the coefficients then follows immediately from the representation. The proximity of the hinge loss function that defines the SVM solution to the absolute error loss and its convexity allow such asymptotic results akin to those for least absolute deviation regression estimators in Pollard (1991).

In addition to providing an insight into the asymptotic behavior of the SVM, we expect that our results can be useful for related statistical inferences on the SVM, for instance, feature selection. For introduction to feature selection, see Guyon and Elisseeff (2003), and for an extensive empirical study of feature selection using SVM-based criteria, see Ishak and Ghattas (2005). In particular, Guyon, Weston, Barnhill, and Vapnik (2002) proposed a recursive feature elimination procedure for the SVM with an application to gene selection in microarray data analysis. Its selection or elimination criterion is based on the absolute value of a coefficient not its standardized value. The asymptotic variability of estimated coefficients that we provide can be used in deriving a new feature selection criterion which takes inherent statistical variability into account.

This paper is organized as follows. Section 2 contains the main results of a Bahadur type representation of the linear SVM coefficients and their asymptotic normality under mild conditions. An illustrative example is then provided in Section 3 followed by simulation studies in Section 4 and a discussion in Section 5. Proofs of technical lemmas and theorems are collected in Section 6.

2. Main Results

In this section, we first introduce some notations and discuss our asymptotic results for the linear SVM coefficients.

2.1 Preliminaries

Let (X,Y) be a pair of random variables with $X \in \mathcal{X} \subset \mathbb{R}^d$ and $Y \in \{1,-1\}$. The marginal distribution of Y is given by $\mathbb{P}(Y=1)=\pi_+$ and $\mathbb{P}(Y=-1)=\pi_-$ with $\pi_+,\pi_- > 0$ and $\pi_+ + \pi_- = 1$. Let f and g be the densities of X given $Y=1$ and -1 with respect to the Lebesgue measure. Let $\{(X^i,Y^i)\}_{i=1}^n$ be a set of training data, independently drawn from the distribution of (X,Y). Denote the input variables as $x=(x_1,\ldots,x_d)^\top$ and their coefficients as $\beta_+=(\beta_1,\ldots,\beta_d)^\top$. Let $\widetilde{x}=(\widetilde{x}_0,\ldots,\widetilde{x}_d)^\top=(1,x_1,\ldots,x_d)^\top$ and $\beta=(\beta_0,\beta_1,\ldots,\beta_d)^\top$. We consider linear classifications with hyperplanes defined by $h(x;\beta)=\beta_0+x^\top\beta_+=\widetilde{x}^\top\beta$. Let $\|\cdot\|$ denote the Euclidean norm of a vector. For separable cases, the SVM finds the hyperplane that maximizes the geometric margin, $2/\|\beta_+\|^2$ subject to the constraints $y^i h(x^i;\beta)\geq 1$ for $i=1,\ldots,n$. For non-separable cases, a soft-margin SVM is introduced to minimize

$$C\sum_{i=1}^n \xi_i + \frac{1}{2}\|\beta_+\|^2$$

subject to the constraints $\xi_i \geq 1-y^i h(x^i;\beta)$ and $\xi_i \geq 0$ for $i=1,\ldots,n$, where $C>0$ is a tuning parameter and $\{\xi_i\}_{i=1}^n$ are called the slack variables. Equivalently, the SVM minimizes the unconstrained objective function

$$l_{\lambda,n}(\beta)=\frac{1}{n}\sum_{i=1}^n\Big[1-y^i h(x^i;\beta)\Big]_+ + \frac{\lambda}{2}\|\beta_+\|^2 \tag{1}$$

over $\beta\in\mathbb{R}^{d+1}$, where $[z]_+=\max(z,0)$ for $z\in\mathbb{R}$ and $\lambda>0$ is a penalization parameter; see Vapnik (1996) for details. Let the minimizer of (1) be denoted by $\widehat{\beta}_{\lambda,n}=\arg\min_\beta l_{\lambda,n}(\beta)$. Note that $C=(n\lambda)^{-1}$. Choice of λ depends on the data, and usually it is estimated via cross validation in practice. In this paper, we consider only nonseparable cases and assume that $\lambda\to 0$ as $n\to\infty$. We note that separable cases require a different treatment for asymptotics because λ has to be nonzero in the limit for the uniqueness of the solution.

Before we proceed with a discussion of the asymptotics of the $\widehat{\beta}_{\lambda,n}$, we introduce some notation and definitions first. The population version of (1) without the penalty term is defined as

$$L(\beta)=\mathbb{E}\Big[1-Yh(X;\beta)\Big]_+ \tag{2}$$

and its minimizer is denoted by $\beta^*=\arg\min_\beta L(\beta)$. Then the population version of the optimal hyperplane defined by the SVM is

$$\widetilde{x}^\top\beta^*=0. \tag{3}$$

Sets are identified with their indicator functions. For example, $\int_{\mathcal{X}} x_j\{x_j>0\}f(x)dx = \int_{\{x\in\mathcal{X}\,:\,x_j>0\}} x_j f(x)dx$. Letting $\psi(z)=\{z\geq 0\}$ for $z\in\mathbb{R}$, we define $S(\beta)=(S(\beta)_j)$ to be the $(d+1)$-dimensional vector given by

$$S(\beta)=-\mathbb{E}\Big(\psi(1-Yh(X;\beta))Y\widetilde{X}\Big)$$

and $H(\beta)=(H(\beta)_{jk})$ to be the $(d+1)\times(d+1)$-dimensional matrix given by

$$H(\beta)=\mathbb{E}\Big(\delta(1-Yh(X;\beta))\widetilde{X}\widetilde{X}^\top\Big),$$

where δ denotes the Dirac delta function with $\delta(t) = \psi'(t)$ in distributional sense. Provided that $S(\beta)$ and $H(\beta)$ are well-defined, $S(\beta)$ and $H(\beta)$ are considered as the gradient and Hessian matrix of $L(\beta)$, respectively. Formal proofs of these relationships are given in Section 6.1.

For explanation of $H(\beta)$, we introduce a Radon transformation. For a function s on $\mathcal{X}$, define the Radon transform $\mathcal{R}s$ of s for $p \in \mathbb{R}$ and $\xi \in \mathbb{R}^d$ as

$$(\mathcal{R}s)(p,\xi) = \int_{\mathcal{X}} \delta(p - \xi^\top x) s(x) dx.$$

For $0 \le j,k \le d$, the (j,k)-th element of the Hessian matrix $H(\beta)$ is given by

$$H(\beta)_{jk} = \pi_+ (\mathcal{R}f_{jk})(1-\beta_0, \beta_+) + \pi_- (\mathcal{R}g_{jk})(1+\beta_0, -\beta_+), \tag{4}$$

where $f_{jk}(x) = \widetilde{x}_j \widetilde{x}_k f(x)$ and $g_{jk}(x) = \widetilde{x}_j \widetilde{x}_k g(x)$. Equation (4) shows that the Hessian matrix $H(\beta)$ depends on the Radon transforms of f_{jk} and g_{jk} for $0 \le j,k \le d$. For Radon transform and its properties in general, see Natterer (1986), Deans (1993), or Ramm and Katsevich (1996).

For a continuous integrable function s, it can be easily proved that $\mathcal{R}s$ is continuous. If f and g are continuous densities with finite second moments, then f_{jk} and g_{jk} are continuous and integrable for $0 \le j,k \le d$. Hence $H(\beta)$ is continuous in β when f and g are continuous and have finite second moments.

2.2 Asymptotics

Now we present the asymptotic results for $\widehat{\beta}_{\lambda,n}$. We state regularity conditions for the asymptotics first. Some remarks on the conditions then follow for exposition and clarification. Throughout this paper, we use $C_1, C_2, \ldots$ to denote positive constants independent of n.

(A1) The densities f and g are continuous and have finite second moments.

(A2) There exists $B(x_0, \delta_0)$, a ball centered at x_0 with radius $\delta_0 > 0$ such that $f(x) > C_1$ and $g(x) > C_1$ for every $x \in B(x_0, \delta_0)$.

(A3) For some $1 \le i^* \le d$,

$$\int_{\mathcal{X}} \{x_{i^*} \ge G_{i^*}^-\} x_{i^*} g(x) dx < \int_{\mathcal{X}} \{x_{i^*} \le F_{i^*}^+\} x_{i^*} f(x) dx$$

or

$$\int_{\mathcal{X}} \{x_{i^*} \le G_{i^*}^+\} x_{i^*} g(x) dx > \int_{\mathcal{X}} \{x_{i^*} \ge F_{i^*}^-\} x_{i^*} f(x) dx.$$

Here $F_{i^*}^+, G_{i^*}^+ \in [-\infty, \infty]$ are upper bounds such that $\int_{\mathcal{X}} \{x_{i^*} \le F_{i^*}^+\} f(x) dx = \min\left(1, \frac{\pi_-}{\pi_+}\right)$ and $\int_{\mathcal{X}} \{x_{i^*} \le G_{i^*}^+\} g(x) dx = \min\left(1, \frac{\pi_+}{\pi_-}\right)$. Similarly, lower bounds $F_{i^*}^-$ and $G_{i^*}^-$ are defined as $\int_{\mathcal{X}} \{x_{i^*} \ge F_{i^*}^-\} f(x) dx = \min\left(1, \frac{\pi_-}{\pi_+}\right)$ and $\int_{\mathcal{X}} \{x_{i^*} \ge G_{i^*}^-\} g(x) dx = \min\left(1, \frac{\pi_+}{\pi_-}\right)$.

(A4) For an orthogonal transformation A_{j^*} that maps $\beta_+^*/\|\beta_+^*\|$ to the j^*-th unit vector e_{j^*} for some $1 \le j^* \le d$, there exist rectangles

$$\mathcal{D}^+ = \{x \in M^+ : l_i \le (A_{j^*}x)_i \le v_i \text{ with } l_i < v_i \text{ for } i \ne j^*\}$$

and

$$\mathcal{D}^- = \{x \in M^- : l_i \le (A_{j^*}x)_i \le v_i \text{ with } l_i < v_i \text{ for } i \ne j^*\}$$

such that $f(x) \ge C_2 > 0$ on $\mathcal{D}^+$, and $g(x) \ge C_3 > 0$ on $\mathcal{D}^-$, where $M^+ = \{x \in \mathcal{X} \mid \beta_0^* + x^\top \beta_+^* = 1\}$ and $M^- = \{x \in \mathcal{X} \mid \beta_0^* + x^\top \beta_+^* = -1\}$.

Remark 1

- *(A1) ensures that $H(\beta)$ is well-defined and continuous in β.*
- *When f and g are continuous, the condition that $f(x_0) > 0$ and $g(x_0) > 0$ for some x_0 implies (A2).*
- *The technical condition in (A3) is a minimal requirement to guarantee that β_+^*, the normal vector of the theoretically optimal hyperplane is not zero. Roughly speaking, it says that for at least one input variable, the mean values of the class conditional distributions f and g have to be different in order to avoid the degenerate case of $\beta_+^* = 0$. Some restriction of the supports through $F_{i^*}^+$, $G_{i^*}^+$, $F_{i^*}^-$ and $G_{i^*}^-$ is necessary in defining the mean values to adjust for potentially unequal class proportions. When $\pi_+ = \pi_-$, $F_{i^*}^+$ and $G_{i^*}^+$ can be taken to be $+\infty$ and $F_{i^*}^-$ and $G_{i^*}^-$ can be $-\infty$. In this case, (A3) simply states that the mean vectors for the two classes are different.*
- *(A4) is needed for the positive-definiteness of $H(\beta)$ around β^*. The condition means that there exist two subsets of the classification margins, M^+ and M^- on which the class densities f and g are bounded away from zero. For mathematical simplicity, the rectangular subsets $\mathcal{D}^+$ and $\mathcal{D}^-$ are defined as the mirror images of each other along the normal direction of the optimal hyperplane. This condition can be easily met when the supports of f and g are convex. Especially, if $\mathbb{R}^d$ is the support of f and g, it is trivially satisfied. (A4) requires that $\beta_+^* \ne 0$, which is implied by (A1) and (A3); see Lemma 4 for the proof. For the special case $d = 1$, M^+ and M^- consist of a point. $\mathcal{D}^+$ and $\mathcal{D}^-$ are the same as M^+ and M^-, respectively, and hence (A4) means that f and g are positive at those points in M^+ and M^-.*

Under the regularity conditions, we obtain a Bahadur-type representation of $\widehat{\beta}_{\lambda,n}$ (Theorem 1). The asymptotic normality of $\widehat{\beta}_{\lambda,n}$ follows immediately from the representation (Theorem 2). Consequently, we have the asymptotic normality of $h(x;\widehat{\beta}_{\lambda,n})$, the value of the SVM decision function at x (Corollary 3).

Theorem 1 *Suppose that (A1)-(A4) are met. For $\lambda = o(n^{-1/2})$, we have*

$$\sqrt{n}(\widehat{\beta}_{\lambda,n} - \beta^*) = -\frac{1}{\sqrt{n}} H(\beta^*)^{-1} \sum_{i=1}^{n} \psi(1 - Y^i h(X^i;\beta^*)) Y^i \widetilde{X}^i + o_{\mathbb{P}}(1).$$

Theorem 2 *Suppose (A1)-(A4) are satisfied. For $\lambda = o(n^{-1/2})$,*

$$\sqrt{n}(\widehat{\beta}_{\lambda,n} - \beta^*) \to N\Big(0, H(\beta^*)^{-1} G(\beta^*) H(\beta^*)^{-1}\Big)$$

in distribution, where

$$G(\beta) = \mathbb{E}\Big(\psi(1 - Y h(X;\beta)) \widetilde{X}\widetilde{X}^\top\Big).$$

Remark 2 *Since $\widehat{\beta}_{\lambda,n}$ is a consistent estimator of β^* as $n \to \infty$, $G(\beta^*)$ can be estimated by its empirical version with β^* replaced by $\widehat{\beta}_{\lambda,n}$. To estimate $H(\beta^*)$, one may consider the following nonparametric estimate:*

$$\frac{1}{n}\left[\sum_{i=1}^{n} p_b\Big(1 - Y^i h(X^i;\widehat{\beta}_{\lambda,n})\Big)\widetilde{X}^i(\widetilde{X}^i)^\top\right],$$

where $p_b(t) \equiv p(t/b)/b$, $p(t) \geq 0$ and $\int_{\mathbb{R}} p(t)dt = 1$. Note that $p_b(\cdot) \to \delta(\cdot)$ as $b \to 0$. However, estimation of $H(\beta^*)$ requires further investigation.

Corollary 3 *Under the same conditions as in Theorem 2,*

$$\sqrt{n}\Big(h(x;\widehat{\beta}_{\lambda,n}) - h(x;\beta^*)\Big) \to N\Big(0, \tilde{x}^\top H(\beta^*)^{-1}G(\beta^*)H(\beta^*)^{-1}\tilde{x}\Big)$$

in distribution.

Remark 3 *Corollary 3 can be used to construct a confidence bound for $h(x;\beta^*)$ based on an estimate $h(x;\widehat{\beta}_{\lambda,n})$, in particular, to judge whether $h(x;\beta^*)$ is close to zero or not given x. This may be useful if one wants to abstain from prediction at a new input x if it is close to the optimal classification boundary $h(x;\beta^*) = 0$.*

3. An Illustrative Example

In this section, we illustrate the relation between the Bayes decision boundary and the optimal hyperplane determined by (2) for two multivariate normal distributions in $\mathbb{R}^d$. Assume that f and g are multivariate normal densities with different mean vectors μ_f and μ_g and a common covariance matrix Σ. Suppose that $\pi_+ = \pi_- = 1/2$.

We verify the assumptions (A1)-(A4) so that Theorem 2 is applicable. For normal densities f and g, (A1) holds trivially, and (A2) is satisfied with

$$C_1 \;=\; |2\pi\Sigma|^{-1/2}\exp\left(-\sup_{\|x\|\leq\delta_0}\Big\{(x-\mu_f)^\top\Sigma^{-1}(x-\mu_f),(x-\mu_g)^\top\Sigma^{-1}(x-\mu_g)\Big\}\right)$$

for $\delta_0 > 0$. Since $\mu_f \neq \mu_g$, there exists $1 \leq i^* \leq d$ such that i^*-th elements of μ_f and μ_g are different. By taking $F^+_{i^*} = G^+_{i^*} = +\infty$ and $F^-_{i^*} = G^-_{i^*} = -\infty$, we can show that one of the inequalities in (A3) holds as mentioned in Remark 1. Since $\mathcal{D}^+$ and $\mathcal{D}^-$ can be taken to be bounded sets of the form in (A4) in $\mathbb{R}^{d-1}$, and the normal densities f and g are bounded away from zero on such $\mathcal{D}^+$ and $\mathcal{D}^-$, (A4) is satisfied. In particular, $\beta^*_+ \neq 0$ as implied by Lemma 4.

Denote the density and cumulative distribution function of $N(0,1)$ as ϕ and Φ, respectively. Note that β^* should satisfy the equation $S(\beta^*) = 0$, or

$$\Phi(a_f) = \Phi(a_g) \tag{5}$$

and

$$\mu_f\Phi(a_f) - \phi(a_f)\Sigma^{1/2}\omega^* = \mu_g\Phi(a_g) + \phi(a_g)\Sigma^{1/2}\omega^*, \tag{6}$$

where $a_f = \dfrac{1-\beta_0^*-\mu_f^\top\beta_+^*}{\|\Sigma^{1/2}\beta_+^*\|}$, $a_g = \dfrac{1+\beta_0^*+\mu_g^\top\beta_+^*}{\|\Sigma^{1/2}\beta_+^*\|}$ and $\omega^* = \Sigma^{1/2}\beta_+^*/\|\Sigma^{1/2}\beta_+^*\|$. From (5) and the definition of a_f and a_g, we have $a^* \equiv a_f = a_g$. Hence

$$(\beta_+^*)^\top(\mu_f+\mu_g) = -2\beta_0^*. \tag{7}$$

It follows from (6) that

$$\beta_+^*/\|\Sigma^{1/2}\beta_+^*\| = \frac{\Phi(a^*)}{2\phi(a^*)}\Sigma^{-1}(\mu_f-\mu_g). \tag{8}$$

First we show the existence of a proper constant a^* satisfying (8) and its relationship with a statistical distance between the two classes. Define $\Upsilon(a) = \phi(a)/\Phi(a)$ and let $d_\Sigma(u,v) = \{(u-v)^\top\Sigma^{-1}(u-v)\}^{1/2}$ denote the Mahalanobis distance between u and $v \in \mathbb{R}^d$. Since $\|\omega^*\| = 1$, we have $\Upsilon(a^*) = \|\Sigma^{-1/2}(\mu_f-\mu_g)\|/2$. Since $\Upsilon(a)$ is monotonically decreasing in a, there exists $a^* = \Upsilon^{-1}(d_\Sigma(\mu_f,\mu_g)/2)$ that depends only on μ_f, μ_g, and Σ. For illustration, when the Mahalanobis distances between the two normal distributions are 2 and 3, a^* is given by $\Upsilon^{-1}(1) \approx -0.303$ and $\Upsilon^{-1}(1.5) \approx -0.969$, respectively. The corresponding Bayes error rates are about 0.1587 and 0.06681. Figure 1 shows a graph of $\Upsilon(a)$ and a^* when $d_\Sigma(\mu_f,\mu_g)$=2 and 3.

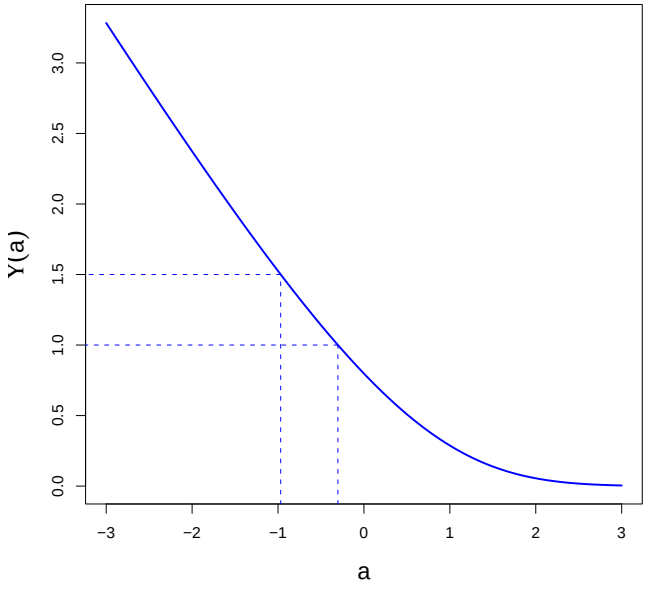

Figure 1: A plot of Υ function. The dashed lines correspond to the inverse mapping from the Mahalanobis distances of 2 and 3 to $a^* \approx -0.303$ and -0.969, respectively.

Once a^* is properly determined, we can express the solution β^* explicitly by (7) and (8):

$$\beta_0^* = -\frac{(\mu_f-\mu_g)^\top\Sigma^{-1}(\mu_f+\mu_g)}{2a^*d_\Sigma(\mu_f,\mu_g)+d_\Sigma(\mu_f,\mu_g)^2}$$

and

$$\beta_+^* = \frac{2\Sigma^{-1}(\mu_f - \mu_g)}{2a^* d_\Sigma(\mu_f,\mu_g) + d_\Sigma(\mu_f,\mu_g)^2}.$$

Thus the optimal hyperplane (3) is

$$\frac{2}{2a^* d_\Sigma(\mu_f,\mu_g) + d_\Sigma(\mu_f,\mu_g)^2}\left\{\Sigma^{-1}(\mu_f-\mu_g)\right\}^\top\left\{x - \frac{1}{2}(\mu_f+\mu_g)\right\} = 0,$$

which is equivalent to the Bayes decision boundary given by

$$\left\{\Sigma^{-1}(\mu_f-\mu_g)\right\}^\top\left\{x - \frac{1}{2}(\mu_f+\mu_g)\right\} = 0.$$

This shows that the linear SVM is equivalent to Fisher's linear discriminant analysis in this setting. In addition, $H(\beta^*)$ and $G(\beta^*)$ can be shown to be

$$G(\beta^*) = \frac{\Phi(a^*)}{2}\begin{bmatrix} 2 & (\mu_f+\mu_g)^\top \\ \mu_f+\mu_g & G_{22}(\beta^*) \end{bmatrix}$$

and

$$H(\beta^*) = \frac{\phi(a^*)}{4}(2a^* + d_\Sigma(\mu_f,\mu_g))\begin{bmatrix} 2 & (\mu_f+\mu_g)^\top \\ \mu_f+\mu_g & H_{22}(\beta^*) \end{bmatrix},$$

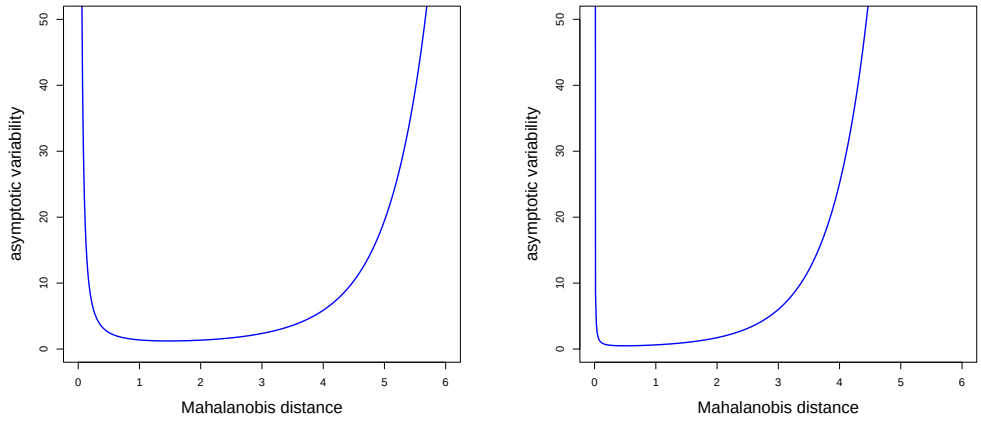
where

$$\begin{aligned} G_{22}(\beta^*) &= \mu_f\mu_f^\top + \mu_g\mu_g^\top + 2\Sigma - \left(\frac{a^*}{d_\Sigma(\mu_f,\mu_g)} + 1\right)(\mu_f-\mu_g)(\mu_f-\mu_g)^\top \text{ and} \\ H_{22}(\beta^*) &= \mu_f\mu_f^\top + \mu_g\mu_g^\top + 2\Sigma \\ &\quad + 2\left(\left(\frac{a^*}{d_\Sigma(\mu_f,\mu_g)}\right)^2 + \frac{a^*}{d_\Sigma(\mu_f,\mu_g)} - \frac{1}{d_\Sigma^2(\mu_f,\mu_g)}\right)(\mu_f-\mu_g)(\mu_f-\mu_g)^\top. \end{aligned}$$

For illustration, we consider the case when $d = 1$, $\mu_f + \mu_g = 0$, and $\sigma = 1$. The asymptotic variabilities of the intercept and the slope for the optimal decision boundary are calculated according to Theorem 2. Figure 2 shows the asymptotic variabilities as a function of the Mahalanobis distance between the two normal distributions, $|\mu_f - \mu_g|$ in this case. Also, it depicts the asymptotic variance of the estimated classification boundary value $(-\hat{\beta}_0/\hat{\beta}_1)$ by using the delta method. Although the Mahalanobis distance roughly in the range of 1 to 4 would be of practical interest, the plots show a notable trend in the asymptotic variances as the distance varies. When the two classes get very close, the variances shoot up due to the difficulty in discriminating them. On the other hand, as the Mahalanobis distance increases, that is, the two classes become more separated, the variances become increasingly large. A possible explanation for the trend is that the intercept and the slope of the optimal hyperplane are determined by only a small fraction of data falling into the margins in this case.

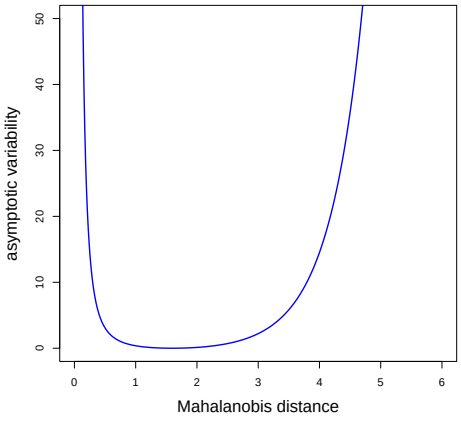
4. Simulation Studies

In this section, simulations are carried out to illustrate the asymptotic results and their potential for feature selection.



(a)

(b)



(c)

Figure 2: The asymptotic variabilities of estimates of (a) the intercept, (b) the slope, and (c) their ratio for the optimal hyperplane as a function of the Mahalanobis distance.

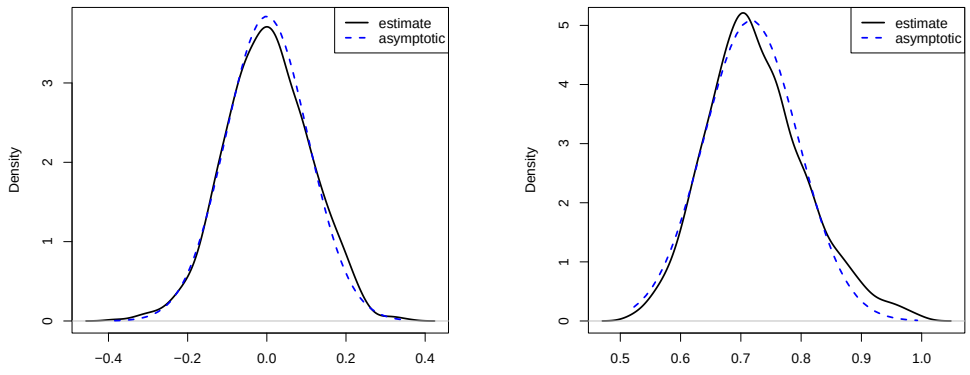
4.1 Bivariate Case

Theorem 2 is numerically illustrated with the multivariate normal setting in the previous section. Consider a bivariate case with mean vectors $\mu_f = (1,1)^\top$ and $\mu_g = (-1,-1)^\top$ and a common covariance matrix $\Sigma = I_2$. This example has $d_\Sigma(\mu_f, \mu_g) = 2\sqrt{2}$ and the corresponding Bayes error rate is 0.07865. Data were generated from the two normal distributions with an equal probability for each class. The total sample size was varied from 100 to 500. To see the direct effect of the hinge loss on the SVM coefficients without regularization as in the way the asymptotic properties in Section 2 are characterized ultimately, we estimated the coefficients of the linear SVM without the penalty term by linear programming. Such a simulation was repeated 1,000 times for each sample

size, and Table 1 summarizes the results by showing the averages of the estimated coefficients of the SVM over 1,000 replicates. As expected, the averages get closer to the theoretically optimal coefficients β^* as the sample size grows. Moreover, the sampling distributions of $\hat{\beta}_0$, $\hat{\beta}_1$, and $\hat{\beta}_2$ approximate their theoretical counterparts for a large sample size as shown in Figure 3. The solid lines are the estimated density functions of $\hat{\beta}_0$ and $\hat{\beta}_1$ for $n = 500$, and the dotted lines are the corresponding asymptotic normal densities in Theorem 2.

Coefficients	Sample size n			Optimal values
	100	200	500	
β_0	0.0006	-0.0013	0.0022	0
β_1	0.7709	0.7450	0.7254	0.7169
β_2	0.7749	0.7459	0.7283	0.7169

Table 1: Averages of estimated and optimal coefficients over 1,000 replicates.



(a) (b)

Figure 3: Estimated sampling distributions of (a) $\hat{\beta}_0$ and (b) $\hat{\beta}_1$ with the asymptotic normal densities overlaid.

4.2 Feature Selection

Clearly the results we have established have implications to statistical inferences on the SVM. Among others, feature selection is of particular interest. By using the asymptotic variability of estimated coefficients, one can derive a new feature selection criterion based on the standardized coefficients. Such a criterion will take inherent statistical variability into account. More generally, this consideration of new criteria opens the possibility of casting feature selection for the SVM formally in the framework of hypothesis testing and extending standard variable selection procedures in regression to classification.

We investigate the possibility of using the standardized coefficients of $\hat{\beta}$ for selection of variables. For practical applications, one needs to construct a reasonable nonparametric estimator of the asymptotic variance-covariance matrix, whose entries are defined through line integrals. A similar technical issue arises in quantile regression. See Koenker (2005) for some suggested variance estimators in the setting.

For the sake of simplicity in the second set of simulation, we used the theoretical asymptotic variance in standardizing $\hat{\beta}$ and selected those variables with the absolute standardized coefficient exceeding a certain critical value. And we mainly monitored the type I error rate of falsely declaring the significance of a variable when it is not, over various settings of a mixture of two multivariate normal distributions. Different combinations of the sample size (n) and the number of variables (d) were tried. For a fixed even d, we set $\mu_f = (\mathbf{1}_{d/2}, \mathbf{0}_{d/2})^\top$, $\mu_g = \mathbf{0}_d^\top$, and $\Sigma = I_d$, where $\mathbf{1}_p$ and $\mathbf{0}_p$ indicate p-vectors of ones and zeros, respectively. Thus only the first half of the d variables have nonzero coefficients in the optimal hyperplane of the linear SVM. Table 2 shows the minima, median, and maxima of such type I error rates in selection of relevant variables over 200 replicates when the critical value was $z_{0.025} \approx 1.96$ (5% level of significance). If the asymptotic distributions were accurate, the error rates would be close to the nominal level of 0.05. On the whole, the table suggests that when d is small, the error rates are very close to the nominal level even for small sample sizes, while for a large d, n has to be quite large for the asymptotic distributions to be valid. This pattern is clearly seen in Figure 4, which displays the median values of the type I error rates. In passing, we note that changing the proportion of relevant variables did not seem to affect the error rates, which are not shown here.

	Number of variables (d)			
n	6	12	18	24
250	[0.050, 0.060, 0.090]	[0.075, 0.108, 0.145]	[0.250, 0.295, 0.330]	[0.665, 0.698, 0.720]

750	[0.030, 0.055, 0.070]	[0.035, 0.065, 0.090]	[0.055, 0.095, 0.115]	[0.135, 0.185, 0.205]
1000	[0.050 ,0.065, 0.065]	[0.060, 0.068, 0.095]	[0.040, 0.075, 0.095]	[0.105, 0.135, 0.175]
1250	[0.065, 0.065, 0.070]	[0.035, 0.045, 0.050]	[0.055, 0.080, 0.105]	[0.070, 0.095, 0.125]
1500	[0.035, 0.050, 0.065]	[0.040, 0.058, 0.085]	[0.055, 0.075, 0.090]	[0.050, 0.095, 0.135]
1750	[0.030, 0.035, 0.060]	[0.035, 0.045, 0.075]	[0.040, 0.065, 0.095]	[0.055, 0.080, 0.120]
2000	[0.035, 0.040, 0.060]	[0.040, 0.065, 0.080]	[0.060, 0.070, 0.100]	[0.055, 0.075, 0.105]

Table 2: The minimum, median, and maximum values of the type I error rates of falsely flagging an irrelevant variable as relevant over 200 replicates by using the standardized SVM coefficients at 5% significance level.

We leave further development of asymptotic variance estimators for feature selection and comparison with risk based approaches such as the recursive feature elimination procedure as a future work.

5. Discussion

In this paper, we have investigated asymptotic properties of the coefficients of variables in the SVM solution for nonseparable linear classification. More specifically, we have established a Bahadur

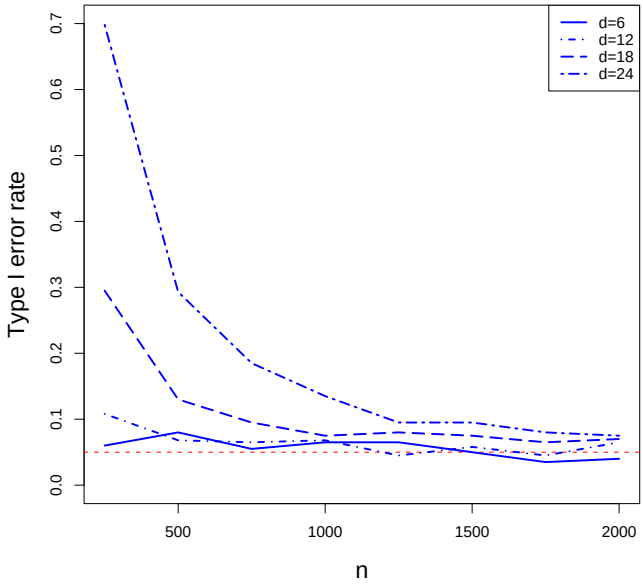

Figure 4: The median values of the type I error rates in variable selection depending on the sample size n and the number of variables d. The horizontal, dashed line indicates the nominal level of 0.05.

type representation of the coefficients and their asymptotic normality using Radon transformation of the second moments of the variables. The representation shows how the statistical behavior of the coefficients is determined by the margins of the optimal hyperplane and the underlying probability distribution. Shedding a new statistical light on the SVM, these results provide an insight into its asymptotic behavior and can be used to improve our statistical practice with the SVM in various aspects.

There are several issues yet to be investigated. The asymptotic results that we have obtained so far pertain only to the linear SVM in nonseparable cases. Although it may be of more theoretical consideration than practical, a similar analysis of the linear SVM in the separable case is anticipated, which will ultimately lead to a unified theory for separable as well as nonseparable cases. The separable case would require a slightly different treatment than the nonseparable case because the regularization parameter λ needs to remain positive in the limit to guarantee the uniqueness of the solution. An extension of the SVM asymptotics to the nonlinear case is another direction of interest. In this case, the minimizer defined by the SVM is not a vector of coefficients of a fixed length but a function in a reproducing kernel Hilbert space. So, the study of asymptotic properties of the minimizer in the function space essentially requires investigation of its pointwise behavior or its functionals in general as the sample size grows. A general theory in Shen (1997) on asymptotic normality and efficiency of substitution estimates for smooth functionals is relevant. In particular, Theorem 2 in Shen (1997) provides the asymptotic normality of the penalized sieve MLE, char-

acterization of which bears a close resemblance with function estimation for the nonlinear case. However, the theory was developed under the assumption of the differentiability of the loss, and it has to be modified for proper theoretical analysis of the SVM. As in the approach for the linear case presented in this paper, one may get around the non-differentiability issue of the hinge loss by imposing appropriate regularity conditions to ensure that the minimizer is unique and the expected loss is differentiable and locally quadratic around the minimizer.

Consideration of these extensions will lead to a more complete picture of the asymptotic behavior of the SVM solution.

6. Proofs

In this section, we present technical lemmas and prove the main results.

6.1 Technical Lemmas

Lemma 1 shows that there is a finite minimizer of $L(\beta)$, which is useful in proving the uniqueness of the minimizer in Lemma 6. In fact, the existence of the first moment of X is sufficient for Lemmas 1, 2, and 4. However, (A1) is needed for the existence and continuity of $H(\beta)$ in the proof of other lemmas and theorems.

Lemma 1 *Suppose that (A1) and (A2) are satisfied. Then $L(\beta) \to \infty$ as $\|\beta\| \to \infty$ and the existence of β^* is guaranteed.*

Proof. Without loss of generality, we may assume that $x_0 = 0$ in (A2) and $B(0,\delta_0) \subset \mathcal{X}$. For any $\varepsilon > 0$,

$$\begin{aligned}
L(\beta) &= \pi_+ \int_{\mathcal{X}} [1 - \tilde{x}^\top \beta]_+ f(x)dx + \pi_- \int_{\mathcal{X}} [1 + h(x;\beta)]_+ g(x)dx \\
&\geq \pi_+ \int_{\mathcal{X}} \{h(x;\beta) \leq 0\}(1 - h(x;\beta)) f(x)dx + \pi_- \int_{\mathcal{X}} \{h(x;\beta) \geq 0\}(1 + h(x;\beta)) g(x)dx \\
&\geq \pi_+ \int_{\mathcal{X}} \{h(x;\beta) \leq 0\}(-h(x;\beta)) f(x)dx + \pi_- \int_{\mathcal{X}} \{h(x;\beta) \geq 0\} h(x;\beta) g(x)dx \\
&\geq \int_{\mathcal{X}} |h(x;\beta)| \min(\pi_+ f(x), \pi_- g(x))\, dx \\
&\geq C_1 \min(\pi_+, \pi_-) \int_{B(0,\delta_0)} |h(x;\beta)| dx \\
&= C_1 \min(\pi_+, \pi_-) \|\beta\| \int_{B(0,\delta_0)} |h(x;w)| dx \\
&\geq C_1 \min(\pi_+, \pi_-) \|\beta\| \mathrm{vol}(\{|h(x;w)| \geq \varepsilon\} \cap B(0,\delta_0))\, \varepsilon,
\end{aligned}$$

where $w = \beta/\|\beta\|$ and $\mathrm{vol}(A)$ denotes the volume of a set A.

Note that $-1 \le w_0 \le 1$. For $0 \le w_0 < 1$ and $0 < \varepsilon < 1$,

$$\begin{aligned} & \mathrm{vol}\left(\{|h(x;w)| \ge \varepsilon\} \cap B(0,\delta_0)\right) \\ \ge\ & \mathrm{vol}\left(\{h(x;w) \ge \varepsilon\} \cap B(0,\delta_0)\right) \\ =\ & \mathrm{vol}\left(\left\{x^\top w_+ / \sqrt{1-w_0^2} \ge (\varepsilon - w_0)/\sqrt{1-w_0^2}\right\} \cap B(0,\delta_0)\right) \\ \ge\ & \mathrm{vol}\left(\left\{x^\top w_+ / \sqrt{1-w_0^2} \ge \varepsilon\right\} \cap B(0,\delta_0)\right) \equiv V(\delta_0,\varepsilon) \end{aligned}$$

since $(\varepsilon - w_0)/\sqrt{1-w_0^2} \le \varepsilon$. When $-1 < w_0 < 0$, we obtain

$$\mathrm{vol}_B(h(x;w) \le -\varepsilon) \ge V(\delta_0,\varepsilon)$$

in a similar way. Note that $V(\delta_0,\varepsilon)$ is independent of β and $V(\delta_0,\varepsilon) > 0$ for some $\varepsilon < \delta_0$. Consequently, $L(\beta) \ge C_1 \min(\pi_+,\pi_-)\|\beta\| V(\delta_0,\varepsilon)\varepsilon \to \infty$ as $\|\beta\| \to \infty$. The case $w_0 = \pm 1$ is trivial.

Since the hinge loss is convex, $L(\beta)$ is convex in β. Since $L(\beta) \to \infty$ as $\|\beta\| \to \infty$, the set, denoted by $\mathcal{M}$, of minimizers of $L(\beta)$ forms a bounded connected set. The existence of the solution β^* of $L(\beta)$ easily follows from this. ■

In Lemmas 2 and 3, we obtain explicit forms of $S(\beta)$ and $H(\beta)$ for non-constant decision functions.

Lemma 2 *Assume that (A1) is satisfied. If $\beta_+ \ne 0$, then we have*

$$\frac{\partial L(\beta)}{\partial \beta_j} = S(\beta)_j$$

for $0 \le j \le d$.

Proof. It suffices to show that

$$\frac{\partial}{\partial \beta_j} \int_{\mathcal{X}} [1 - h(x;\beta)]_+ f(x)dx = -\int_{\mathcal{X}} \{h(x;\beta) \le 1\} \widetilde{x}_j f(x)dx.$$

Define $\Delta(t) = [1 - h(x;\beta) - t\widetilde{x}_j]_+ - [1 - h(x;\beta)]_+$. Let $t > 0$.

First, consider the case $\widetilde{x}_j > 0$. Then,

$$\Delta(t) = \begin{cases} 0 & \text{if} \quad h(x;\beta) > 1 \\ h(x;\beta) - 1 & \text{if} \quad 1 - t\widetilde{x}_j < h(x;\beta) \le 1 \\ -t\widetilde{x}_j & \text{if} \quad h(x;\beta) \le 1 - t\widetilde{x}_j. \end{cases}$$

Observe that

$$\begin{aligned} \int_{\mathcal{X}} \Delta(t)\{\widetilde{x}_j > 0\} f(x)dx \ =\ & \int_{\mathcal{X}} \{1 - t\widetilde{x}_j < h(x;\beta) \le 1\}(h(x;\beta) - 1) f(x)dx \\ & -t\int_{\mathcal{X}} \{h(x;\beta) \le 1 - t\widetilde{x}_j, \widetilde{x}_j > 0\} \widetilde{x}_j f(x)dx \end{aligned}$$

and that

$$\left| \frac{1}{t} \int_{\mathcal{X}} \{1 - t\widetilde{x}_j < h(x;\beta) \le 1\}(h(x;\beta) - 1) f(x)dx \right| \le \int_{\mathcal{X}} \{1 - t\widetilde{x}_j < h(x;\beta) \le 1\} \widetilde{x}_j f(x)dx.$$

By Dominated Convergence Theorem,

$$\lim_{t\downarrow 0}\int_{\mathcal{X}}\{1-t\widetilde{x}_j < h(x;\beta)\le 1\}\widetilde{x}_j f(x)dx = \int_{\mathcal{X}}\{h(x;\beta)=1\}\widetilde{x}_j f(x)dx = 0$$

and

$$\lim_{t\downarrow 0}\int_{\mathcal{X}}\{h(x;\beta)\le 1-t\widetilde{x}_j,\widetilde{x}_j>0\}\widetilde{x}_j f(x)dx = \int_{\mathcal{X}}\{h(x;\beta)\le 1,\widetilde{x}_j>0\}\widetilde{x}_j f(x)dx.$$

Hence

$$\lim_{t\downarrow 0}\frac{1}{t}\int_{\mathcal{X}}\Delta(t)\{\widetilde{x}_j>0\}f(x)dx = -\int_{\mathcal{X}}\{h(x;\beta)\le 1,\widetilde{x}_j>0\}\widetilde{x}_j f(x)dx. \tag{9}$$

Now assume that $\widetilde{x}_j<0$. Then,

$$\Delta(t)=\begin{cases} 0 & \text{if} \quad h(x;\beta)>1-t\widetilde{x}_j \\ 1-h(x;\beta)-t\widetilde{x}_j & \text{if} \quad 1<h(x;\beta)\le 1-t\widetilde{x}_j \\ -t\widetilde{x}_j & \text{if} \quad h(x;\beta)\le 1. \end{cases}$$

In a similar fashion, one can show that

$$\lim_{t\downarrow 0}\frac{1}{t}\int_{\mathcal{X}}\Delta(t)\{\widetilde{x}_j<0\}f(x)dx = -\int_{\mathcal{X}}\{h(x;\beta)\le 1,\widetilde{x}_j<0\}\widetilde{x}_j f(x)dx. \tag{10}$$

Combining (9) and (10), we have shown that

$$\lim_{t\downarrow 0}\frac{1}{t}\int_{\mathcal{X}}\Delta(t)f(x)dx = -\int_{\mathcal{X}}\{h(x;\beta)\le 1\}\widetilde{x}_j f(x)dx.$$

The proof for the case $t<0$ is similar. ■

The proof of Lemma 3 is based on the following identity

$$\int\delta(Dt+E)T(t)dt = \frac{1}{|D|}T(-E/D) \tag{11}$$

for constants D and E. This identity follows from the fact that $\delta(at)=\delta(t)/|a|$ and $\int\delta(t-a)T(t)dt = T(a)$ for a constant a.

Lemma 3 *Suppose that (A1) is satisfied. Under the condition that $\beta_+\neq 0$, we have*

$$\frac{\partial^2 L(\beta)}{\partial\beta_j\partial\beta_k} = H(\beta)_{jk},$$

for $0\le j,k\le d$.

Proof. Define

$$\Psi(\beta)=\int_{\mathcal{X}}\{x^\top\beta_+<1-\beta_0\}s(x)dx$$

for a continuous and integrable function s defined on $\mathcal{X}$. Without loss of generality, we may assume that $\beta_1\neq 0$. It is sufficient to show that for $0\le j,k\le d$,

$$\frac{\partial^2}{\partial\beta_j\partial\beta_k}\int_{\mathcal{X}}[1-h(x;\beta)]_+ f(x)dx = \int_{\mathcal{X}}\delta(1-h(x;\beta))\widetilde{x}_j\widetilde{x}_k f(x)dx.$$

Define $\mathcal{X}_{-j} = \{(x_1,\ldots,x_{j-1},x_{j+1},\ldots,x_d) \,:\, (x_1,\ldots,x_d) \in \mathcal{X}\}$ and $\mathcal{X}_j = \{x_j \,:\, (x_1,\ldots,x_d) \in \mathcal{X}\}$. Observe that

$$\frac{\partial \Psi(\beta)}{\partial \beta_0} = -\frac{1}{|\beta_1|}\int_{\mathcal{X}_{-1}} s\left(\frac{1-h(x;\beta)+\beta_1 x_1}{\beta_1}, x_2,\ldots,x_d\right) dx_{-1} \tag{12}$$

and that for $k \neq 1$,

$$\frac{\partial \Psi(\beta)}{\partial \beta_k} = -\frac{1}{|\beta_1|}\int_{\mathcal{X}_{-1}} x_k s\left(\frac{1-h(x;\beta)+\beta_1 x_1}{\beta_1}, x_2,\ldots,x_d\right) dx_{-1}. \tag{13}$$

If $\beta_p = 0$ for any $p \neq 1$, then

$$\frac{\partial \Psi(\beta)}{\partial \beta_1} = -\frac{1-\beta_0}{\beta_1|\beta_1|}\int_{\mathcal{X}_{-1}} s\left(\frac{1-\beta_0}{\beta_1}, x_2,\ldots,x_d\right) dx_{-1}. \tag{14}$$

If there is $p \neq 1$ with $\beta_p \neq 0$, then we have

$$\frac{\partial \Psi(\beta)}{\partial \beta_1} = -\frac{1}{|\beta_p|}\int_{\mathcal{X}_{-p}} x_1 s\left(x_1,\ldots,x_{p-1}, \frac{1-h(x;\beta)+\beta_p x_p}{\beta_p}, x_{p+1},\ldots,x_d\right) dx_{-p}. \tag{15}$$

Choose $D = \beta_1$, $E = \widetilde{x}^\top\beta - \beta_1 x_1 - 1$, $t = x_1$ in (11). It follows from (13) and (15) that

$$\begin{aligned}
\frac{\partial \Psi(\beta)}{\partial \beta_k} &= -\frac{1}{|\beta_1|}\int_{\mathcal{X}_{-1}} x_k s\left(\frac{1-h(x;\beta)+\beta_1 x_1}{\beta_1}, x_2,\ldots,x_d\right) dx_{-1} \\
&= -\int_{\mathcal{X}_{-1}}\int_{\mathcal{X}_1} x_k s(x)\delta(h(x;\beta)-1)dx_1 dx_{-1} \\
&= -\int_{\mathcal{X}} \delta(1-h(x;\beta)) x_k s(x) dx.
\end{aligned} \tag{16}$$

Similarly, we have

$$\frac{\partial \Psi(\beta)}{\partial \beta_0} = -\int_{\mathcal{X}} \delta(1-h(x;\beta)) s(x) dx \tag{17}$$

by (12).

Choosing $D = \beta_1$, $E = \beta_0 - 1$, $t = x_1$ in (11), we have

$$\int_{\mathcal{X}_1} \delta(\beta_1 x_1 - 1 + \beta_0) x_1 s(x) dx_1 = \frac{1}{|\beta_1|}\left(\frac{1-\beta_0}{\beta_1}\right) s\left(\frac{1-\beta_0}{\beta_1}, x_2,\ldots,x_d\right)$$

by (14). This implies (16) for $k = 1$. The desired result now follows from (16) and (17). ■

The following lemma asserts that the optimal decision function is not a constant under the condition that the centers of two classes are separated.

Lemma 4 *Suppose that (A1) is satisfied. Then (A3) implies that* $\beta_+^* \neq 0$.

Proof. Suppose that

$$\int_{\mathcal{X}} \{x_{i^*} \geq G_{i^*}^-\} x_{i^*} g(x) dx < \int_{\mathcal{X}} \{x_{i^*} \leq F_{i^*}^+\} x_{i^*} f(x) dx \tag{18}$$

in (A3). We will show that

$$\min_{\beta_0} L(\beta_0, 0, \ldots 0) > \min_{\beta_0, \beta_{i^*} > 0} L(\beta_0, 0, \ldots, 0, \beta_{i^*}, 0, \ldots, 0), \tag{19}$$

implying that $\beta_+^* \neq 0$. Henceforth, we will suppress β's that are equal to zero in $L(\beta)$. The population minimizer $(\beta_0^*, \beta_{i^*}^*)$ is given by the minimizer of

$$L(\beta_0, \beta_{i^*}) = \pi_+ \int_{\mathcal{X}} [1 - \beta_0 - \beta_{i^*} x_{i^*}]_+ f(x)dx + \pi_- \int_{\mathcal{X}} [1 + \beta_0 + \beta_{i^*} x_{i^*}]_+ g(x)dx.$$

First, consider the case $\beta_{i^*} = 0$.

$$L(\beta_0) = \begin{cases} \pi_-(1+\beta_0), & \beta_0 > 1 \\ 1 + (\pi_- - \pi_+)\beta_0, & -1 \leq \beta_0 \leq 1 \\ \pi_+(1-\beta_0), & \beta_0 < -1 \end{cases}$$

with its minimum

$$\min_{\beta_0} L(\beta_0) = 2\min(\pi_+, \pi_-). \tag{20}$$

Now consider the case $\beta_{i^*} > 0$, where

$$\begin{aligned} L(\beta_0, \beta_{i^*}) = {} & \pi_+ \int_{\mathcal{X}} \left\{ x_{i^*} \leq \frac{1-\beta_0}{\beta_{i^*}} \right\} (1 - \beta_0 - \beta_{i^*} x_{i^*}) f(x)dx \\ & + \pi_- \int_{\mathcal{X}} \left\{ x_{i^*} \geq \frac{-1-\beta_0}{\beta_{i^*}} \right\} (1 + \beta_0 + \beta_{i^*} x_{i^*}) g(x)dx. \end{aligned}$$

Let $\widetilde{\beta}_0$ denote the minimizer of $L(\beta_0, \beta_{i^*})$ for a given β_{i^*}. Note that $\partial L(\beta_0, \beta_{i^*})/\partial \beta_0$ is given as

$$\begin{aligned} & \frac{\partial L(\beta_0, \beta_{i^*})}{\partial \beta_0} \\ = {} & -\pi_+ \int_{\mathcal{X}} \left\{ x_{i^*} \leq \frac{1-\beta_0}{\beta_{i^*}} \right\} f(x)dx + \pi_- \int_{\mathcal{X}} \left\{ x_{i^*} \geq \frac{-1-\beta_0}{\beta_{i^*}} \right\} g(x)dx, \end{aligned} \tag{21}$$

which is monotonic increasing in β_0 with $\lim_{\beta_0 \to -\infty} \frac{\partial L(\beta_0, \beta_{i^*})}{\partial \beta_0} \to -\pi_+$ and $\lim_{\beta_0 \to \infty} \frac{\partial L(\beta_0, \beta_{i^*})}{\partial \beta_0} \to \pi_-$. Hence $\widetilde{\beta}_0$ exists for a given β_{i^*}.

When $\pi_- < \pi_+$, we can easily check that $F_{i^*}^+ < \infty$ and $G_{i^*}^- = -\infty$. $F_{i^*}^+$ and $G_{i^*}^-$ may not be determined uniquely, meaning that there may exist an interval with probability zero. There is no significant change in the proof under the assumption that $F_{i^*}^+$ and $G_{i^*}^-$ are unique. Note that

$$\frac{1 - \widetilde{\beta}_0}{\beta_{i^*}} \leq F_{i^*}^+$$

by definition of $F_{i^*}^+$ and (21). Then,

$$\frac{-1 - \widetilde{\beta}_0}{\beta_{i^*}} \leq F_{i^*}^+ - \frac{2}{\beta_{i^*}} \to -\infty \text{ as } \beta_{i^*} \to 0,$$

and

$$\frac{1 - \widetilde{\beta}_0}{\beta_{i^*}} \to F_{i^*}^+ \text{ as } \beta_{i^*} \to 0.$$

¿From (18),

$$\pi_- \int_{\mathcal{X}} x_{i^*} g(x)dx < \pi_+ \int_{\mathcal{X}} \{x_{i^*} \leq F_{i^*}^+\} x_{i^*} f(x)dx. \tag{22}$$

Now consider the minimum of $L(\widetilde{\beta}_0, \beta_{i^*})$ with respect to $\beta_{i^*} > 0$. From (21),

$$\begin{aligned} & L(\widetilde{\beta}_0, \beta_{i^*}) \qquad (23) \\ = \; & \pi_+ \int_{\mathcal{X}} \left\{ x_{i^*} \le \frac{1-\widetilde{\beta}_0}{\beta_{i^*}} \right\} (1 - \widetilde{\beta}_0 - \beta_{i^*} x_{i^*}) f(x) dx \\ & + \pi_- \int_{\mathcal{X}} \left\{ x_{i^*} \ge \frac{-1-\widetilde{\beta}_0}{\beta_{i^*}} \right\} (1 + \widetilde{\beta}_0 + \beta_{i^*} x_{i^*}) g(x) dx \\ = \; & 2\pi_- \int_{\mathcal{X}} \left\{ x_{i^*} \ge \frac{-1-\widetilde{\beta}_0}{\beta_{i^*}} \right\} g(x) dx \\ & + \beta_{i^*} \left(\pi_- \int_{\mathcal{X}} \left\{ x_{i^*} \ge \frac{-1-\widetilde{\beta}_0}{\beta_{i^*}} \right\} x_{i^*} g(x) dx - \pi_+ \int_{\mathcal{X}} \left\{ x_{i^*} \le \frac{1-\widetilde{\beta}_0}{\beta_{i^*}} \right\} x_{i^*} f(x) dx \right) \end{aligned}$$

By (22), it can be easily seen that the second term in (23) is negative for sufficiently small $\beta_{i^*} > 0$, implying

$$L(\widetilde{\beta}_0, \beta_{i^*}) < 2\pi_- \quad \text{for some } \beta_{i^*} > 0.$$

If $\pi_- > \pi_+$, then $F_{i^*}^+ = \infty$ and $G_{i^*}^- > -\infty$. Similarly, it can be checked that

$$L(\widetilde{\beta}_0, \beta_{i^*}) < 2\pi_+ \quad \text{for some } \beta_{i^*} > 0.$$

Suppose that $\pi_- = \pi_+$. Then it can be verified that

$$\frac{1-\widetilde{\beta}_0}{\beta_{i^*}} \to \infty \text{ as } \beta_{i^*} \to 0,$$

and

$$\frac{-1-\widetilde{\beta}_0}{\beta_{i^*}} \to -\infty \text{ as } \beta_{i^*} \to 0.$$

In this case, $L(\widetilde{\beta}_0, \beta_{i^*}) < 1$.

Hence, under (18), we have shown that

$$L(\widetilde{\beta}_0, \beta_{i^*}) < 1 \quad \text{for some } \beta_{i^*} > 0.$$

This, together with (20), implies (19). For the second case in (A3), the same arguments hold with $\beta_{i^*} < 0$. ■

Note that (A1) implies that H is well-defined and continuous in its argument. (A4) ensures that $H(\beta)$ is positive definite around β^* and thus we have a lower bound result in Lemma 5.

Lemma 5 *Under (A1), (A3) and (A4),*

$$\beta^\top H(\beta^*)\beta \ge C_4 \|\beta\|^2,$$

where C_4 may depend on β^*.

Proof. Since the proof for the case $d = 1$ is trivial, we consider the case $d \geq 2$ only. Observe that

$$\begin{aligned}
\beta^\top H(\beta^*)\beta &= \mathbb{E}\Big(\delta(1 - Yh(X;\beta^*))h^2(X;\beta)\Big) \\
&= \pi_+ \int_{\mathcal{X}} \delta(1 - h(x;\beta^*))h^2(x;\beta) f(x)dx + \pi_- \int_{\mathcal{X}} \delta(1 + h(x;\beta^*))h^2(x;\beta)g(x)dx \\
&= \pi_+(\mathcal{R}h^2 f)(1 - \beta_0^*, \beta_+^*) + \pi_-(\mathcal{R}h^2 g)(1 + \beta_0^*, -\beta_+^*) \\
&= \pi_+(\mathcal{R}h^2 f)(1 - \beta_0^*, \beta_+^*) + \pi_-(\mathcal{R}h^2 g)(-1 - \beta_0^*, \beta_+^*).
\end{aligned}$$

The last equality follows from the homogeneity of Radon transform.

Recall that $\beta_+^* \neq 0$ by Lemma 4. Without loss of generality, we assume that $j^* = 1$ in (A4). Let $A_1\beta_+ = a = (a_1, \ldots, a_d)$ and $z = (A_1 x)/\|\beta_+^*\|$. Given $u = (u_2, \ldots, u_d)$, let $u^* = \Big((1 - \beta_0^*)/\|\beta_+^*\|, u\Big)$. Define $\mathcal{Z} = \{z = (A_1 x)/\|\beta_+^*\| : x \in \mathcal{X}\}$ and $\mathcal{U} = \{u : u_j = \|\beta_+^*\| z_j \text{ for } j = 2, \ldots, d, \text{ and } z \in \mathcal{Z}\}$. Note that $\det A_1 = 1$, $du = \|\beta_+^*\|^{d-1} dz_2 \ldots dz_d$,

$$\|\beta_+^*\| A_1^\top z\Big|_{z_1 = (1-\beta_0^*)/\|\beta_+^*\|^2} = A_1^\top \begin{pmatrix} (1 - \beta_0^*)/\|\beta_+^*\| \\ \|\beta_+^*\| z_2 \\ \vdots \\ \|\beta_+^*\| z_d \end{pmatrix} = A_1^\top u^*$$

and

$$\begin{aligned}
\beta_0 + \|\beta_+^*\| a^\top z\Big|_{z_1 = (1-\beta_0^*)/\|\beta_+^*\|^2} &= \beta_0 + \|\beta_+^*\| \Big(a_1(1 - \beta_0^*)/\|\beta_+^*\|^2 + \sum_{j=2}^d a_j z_j\Big) \\
&= \beta_0 + a_1(1 - \beta_0^*)/\|\beta_+^*\| + \|\beta_+^*\| \sum_{j=2}^d a_j z_j.
\end{aligned}$$

Using the transformation A_1, we have

$$\begin{aligned}
& (\mathcal{R}h^2 f)(1 - \beta_0^*, \beta_+^*) \\
= & \int_{\mathcal{Z}} \delta\left(1 - \beta_0^* - \|\beta_+^*\|(A_1\beta_+^*)^\top z\right) h^2\left(\|\beta_+^*\| A_1^\top z; \beta\right) f\left(\|\beta_+^*\| A_1^\top z\right) \|\beta_+^*\|^d dz \\
= & \int_{\mathcal{Z}} \delta\left(1 - \beta_0^* - \|\beta_+^*\|^2 e_1^\top z\right) \left(\beta_0 + \|\beta_+^*\|(A_1\beta_+)^\top z\right)^2 f\left(\|\beta_+^*\| A_1^\top z\right) \|\beta_+^*\|^d dz \\
= & \int_{\mathcal{Z}} \delta\left(1 - \beta_0^* - \|\beta_+^*\|^2 z_1\right) \left(\beta_0 + \|\beta_+^*\| a^\top z\right)^2 f\left(\|\beta_+^*\| A_1^\top z\right) \|\beta_+^*\|^d dz \\
= & \frac{1}{\|\beta_+^*\|} \int_{\mathcal{U}} \Big(\beta_0 + a_1(1 - \beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j u_j\Big)^2 f(A_1^\top u^*) du.
\end{aligned}$$

The last equality follows from the identity (11). Let $\mathcal{D}_*^+ = \{u : A_1^\top u^* \in \mathcal{D}^+\}$. By (A4), there exists a constant $C_2 > 0$ and a rectangle $\mathcal{D}_*^+$ on which $f(A_1^\top u^*) \geq C_2$ for $u \in \mathcal{D}_*^+$. Then

$$\begin{aligned}
& (\mathcal{R}h^2 f)(1-\beta_0^*, \beta_+^*) \\
\geq\ & \frac{1}{\|\beta_+^*\|} \int_{\mathcal{D}_*^+} \Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j u_j\Big)^2 f(A_1^\top u^*) du \\
\geq\ & \frac{1}{\|\beta_+^*\|} \cdot C_2 \int_{\mathcal{D}_*^+} \Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j u_j\Big)^2 du \\
=\ & \frac{1}{\|\beta_+^*\|} \cdot C_2 \cdot \mathrm{vol}(\mathcal{D}_*^+) \mathbb{E}^u \Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j U_j\Big)^2 \\
=\ & \frac{1}{\|\beta_+^*\|} \cdot C_2 \cdot \mathrm{vol}(\mathcal{D}_*^+) \Big\{ \Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \mathbb{E}^u \sum_{j=2}^d a_j U_j\Big)^2 + \mathbb{V}^u\Big(\sum_{j=2}^d a_j U_j\Big)\Big\},
\end{aligned}$$

where U_j for $j = 2, \ldots, d$ are independent and uniform random variables defined on $\mathcal{D}_*^+$, and $\mathbb{E}^u$ and $\mathbb{V}^u$ denote the expectation and variance with respect to the uniform distribution.

Letting $m_i = (l_i + v_i)/2$, we have

$$\begin{aligned}
& (\mathcal{R}h^2 f)(1-\beta_0^*, \beta_+^*) \qquad (24) \\
\geq\ & \frac{1}{\|\beta_+^*\|} \cdot C_2 \cdot \mathrm{vol}(\mathcal{D}_*^+) \Big\{ \Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j m_j\Big)^2 + \min_{2\leq j\leq d} \mathbb{V}^u(U_j) \sum_{j=2}^d a_j^2 \Big\}.
\end{aligned}$$

Similarly, it can be shown that

$$\begin{aligned}
& (\mathcal{R}h^2 g)(-1-\beta_0^*, \beta_+^*) \qquad (25) \\
\geq\ & \frac{1}{\|\beta_+^*\|} \cdot C_3 \cdot \mathrm{vol}(\mathcal{D}_*^-) \Big\{ \Big(\beta_0 - a_1(1+\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j m_j\Big)^2 + \min_{2\leq j\leq d} \mathbb{V}^u(U_j) \sum_{j=2}^d a_j^2 \Big\},
\end{aligned}$$

where $\mathcal{D}_*^- = \Big\{u : A_1^\top \Big((-1-\beta_0^*)/\|\beta_+^*\|, u\Big) \in \mathcal{D}^-\Big\}$.

Combining (24)-(25) and letting $C_5 = 2/\|\beta_+^*\| \min\Big(\pi_+ C_2 \cdot \mathrm{vol}(\mathcal{D}_*^+), \pi_- C_3 \cdot \mathrm{vol}(\mathcal{D}_*^-)\Big)$ and $C_6 = \min\Big(1, \min_{2\le j\le d} \mathbb{V}^u(U_j)\Big)$, we have

$$\begin{aligned}
& \beta^\top H(\beta^*)\beta \\
\geq\ & \frac{\pi_+}{\|\beta_+^*\|} \cdot C_2 \cdot \mathrm{vol}(\mathcal{D}_*^+)\Big\{\Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j m_j\Big)^2 + \min_{2\le j\le d} \mathbb{V}^u(U_j) \sum_{j=2}^d a_j^2\Big\} \\
& + \frac{\pi_-}{\|\beta_+^*\|} \cdot C_3 \cdot \mathrm{vol}(\mathcal{D}_*^-)\Big\{\Big(\beta_0 - a_1(1+\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j m_j\Big)^2 + \min_{2\le j\le d} \mathbb{V}^u(U_j) \sum_{j=2}^d a_j^2\Big\} \\
\geq\ & C_5 C_6\Big\{\Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j m_j\Big)^2 \\
& + \Big(\beta_0 - a_1(1+\beta_0^*)/\|\beta_+^*\| + \sum_{j=2}^d a_j m_j\Big)^2 + 2\sum_{j=2}^d a_j^2\Big\}/2 \\
=\ & C_5 C_6\Big\{\Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\|\Big)^2 + \Big(\beta_0 - a_1(1+\beta_0^*)/\|\beta_+^*\|\Big)^2 \\
& + 4\Big(\beta_0 - a_1\beta_0^*/\|\beta_+^*\|\Big)\sum_{j=2}^d a_j m_j + 2\Big(\sum_{j=2}^d a_j m_j\Big)^2 + 2\sum_{j=2}^d a_j^2\Big\}/2.
\end{aligned}$$

Note that

$$\begin{aligned}
& \Big(\sum_{j=2}^d a_j m_j\Big)^2 + 2\Big(\beta_0 - a_1\beta_0^*/\|\beta_+^*\|\Big)\sum_{j=2}^d a_j m_j \\
=\ & \Big(\sum_{j=2}^d a_j m_j + \beta_0 - a_1\beta_0^*/\|\beta_+^*\|\Big)^2 - \Big(\beta_0 - a_1\beta_0^*/\|\beta_+^*\|\Big)^2
\end{aligned}$$

and

$$\Big(\beta_0 + a_1(1-\beta_0^*)/\|\beta_+^*\|\Big)^2 + \Big(\beta_0 - a_1(1+\beta_0^*)/\|\beta_+^*\|\Big)^2 - 2\Big(\beta_0 - a_1\beta_0^*/\|\beta_+^*\|\Big)^2 = 2a_1^2/\|\beta_+^*\|^2.$$

Thus, the lower bound of $\beta^\top H(\beta^*)\beta$ except for the constant C_5C_6 allows the following quadratic form in terms of $\beta_0, a_1, \ldots, a_d$. Let

$$Q(\beta_0, a_1, \ldots, a_d) = a_1^2/\|\beta_+^*\|^2 + \Big(\sum_{j=2}^d a_j m_j + \beta_0 - a_1\beta_0^*/\|\beta_+^*\|\Big)^2 + \sum_{j=2}^d a_j^2.$$

Obviously $Q(\beta_0, a_1, \ldots, a_d) \ge 0$ and $Q(\beta_0, a_1, \ldots, a_d) = 0$ implies that $a_1 = \ldots = a_d = 0$ and $\beta_0 = 0$. Therefore Q is positive definite. Letting $\nu_1 > 0$ be the smallest eigenvalue of the matrix corresponding to Q, we have proved

$$\beta^\top H(\beta^*)\beta \quad \geq \quad C_5C_6\nu_1(\beta_0^2 + \sum_{j=1}^d a_j^2) = C_5C_6\nu_1(\beta_0^2 + \sum_{j=1}^d \beta_j^2).$$

The last equality follows from the fact that $A_1\beta_+ = a$ and the transformation A_1 preserves the norm. With the choice of $C_4 = C_5C_6\nu_1 > 0$, the result follows. ■

Lemma 6 *Suppose that (A1)-(A4) are met. Then $L(\beta)$ has a unique minimizer.*

Proof. By Lemma 1, we may choose any minimizer $\beta^* \in \mathcal{M}$. By Lemma 4 and 5, $H(\beta)$ is positive definite at β^*. Then $L(\beta)$ is locally strictly convex at β^*, so that $L(\beta)$ has a local minimum at β^*. Hence the minimizer of $L(\beta)$ is unique. ■

6.2 Proof of Theorems 1 and 2

For fixed $\theta \in \mathbb{R}^{d+1}$, define

$$\Lambda_n(\theta) = n\Big(l_{\lambda,n}(\beta^* + \theta/\sqrt{n}) - l_{\lambda,n}(\beta^*)\Big)$$

and

$$\Gamma_n(\theta) = \mathbb{E}\Lambda_n(\theta).$$

Observe that

$$\Gamma_n(\theta) = n\left(L(\beta^* + \theta/\sqrt{n}) - L(\beta^*)\right) + \frac{\lambda}{2}\left(\|\theta_+\|^2 + 2\sqrt{n}{\beta^*_+}^\top \theta_+\right).$$

By Taylor series expansion of L around β^*, we have

$$\Gamma_n(\theta) = \frac{1}{2}\theta^\top H(\widetilde{\beta})\theta + \frac{\lambda}{2}\left(\|\theta_+\|^2 + 2\sqrt{n}{\beta^*_+}^\top \theta_+\right),$$

where $\widetilde{\beta} = \beta^* + (t/\sqrt{n})\theta$ for some $0 < t < 1$. Define $D_{jk}(\alpha) = H(\beta^* + \alpha)_{jk} - H(\beta^*)_{jk}$ for $0 \le j,k \le d$. Since $H(\beta)$ is continuous in β, there exists $\delta_1 > 0$ such that $|D_{jk}(\alpha)| < \varepsilon_1$ if $\|\alpha\| < \delta_1$ for any $\varepsilon_1 > 0$ and all $0 \le j,k \le d$. Then, as $n \to \infty$,

$$\frac{1}{2}\theta^\top H(\widetilde{\beta})\theta = \frac{1}{2}\theta^\top H(\beta^*)\theta + o(1).$$

It is because for sufficiently large n such that $\|(t/\sqrt{n})\theta\| < \delta_1$,

$$\begin{aligned}\left|\theta^\top\Big(H(\widetilde{\beta}) - H(\beta^*)\Big)\theta\right| &\le \sum_{j,k}|\theta_j||\theta_k|\left|D_{jk}\left(\frac{t}{\sqrt{n}}\theta\right)\right| \\ &\le \varepsilon_1\sum_{j,k}|\theta_j||\theta_k| \le 2\varepsilon_1\|\theta\|^2.\end{aligned}$$

Together with the assumption that $\lambda = o(n^{-1/2})$, we have

$$\Gamma_n(\theta) = \frac{1}{2}\theta^\top H(\beta^*)\theta + o(1).$$

Define $W_n = -\sum_{i=1}^n \zeta^i Y^i \widetilde{X}^i$ where $\zeta^i = \Big\{Y^i h(X^i;\beta^*) \le 1\Big\}$. Then $\frac{1}{\sqrt{n}}W_n$ follows asymptotically $N\Big(0, nG(\beta^*)\Big)$ by central limit theorem. Note that

$$\mathbb{E}\left(\zeta^i Y^i \widetilde{X}^i\right) = 0 \quad \text{and} \quad \mathbb{E}\left(\zeta^i Y^i \widetilde{X}^i (\zeta^i Y^i \widetilde{X}^i)^\top\right) = \mathbb{E}\left(\zeta^i \widetilde{X}^i (\widetilde{X}^i)^\top\right). \tag{26}$$

Recall that β^* is characterized by $S(\beta^*)=0$ implying the first part of (26). If we define

$$R_{i,n}(\theta)=\Big[1-Y^ih(X^i;\beta^*+\theta/\sqrt{n})\Big]_+-\Big[1-Y^ih(X^i;\beta^*)\Big]_+-\zeta^iY^ih(X^i;\theta/\sqrt{n}),$$

then we see that

$$\Lambda_n(\theta)=\Gamma_n(\theta)+W_n^\top\theta/\sqrt{n}+\sum_{i=1}^n\Big(R_{i,n}(\theta)-\mathbb{E}R_{i,n}(\theta)\Big)$$

and

$$\Big|R_{i,n}(\theta)\Big|\le\Big|h(X^i;\theta)/\sqrt{n}\Big|U\left(\Big|h(X^i;\theta)/\sqrt{n}\Big|\right), \tag{27}$$

where

$$U(t)=\Big\{\Big|1-Y^ih(X^i;\beta^*)\Big|\le t\Big\}\qquad\text{for}\quad t\in\mathbb{R}.$$

To verify (27), let $\zeta=\{a\le 1\}$ and $R=[1-z]_+-[1-a]_++\zeta(z-a)$. If $a>1$, then $R=(1-z)\{z\le 1\}$; otherwise, $R=(z-1)\{z>1\}$. Hence,

$$\begin{aligned}R&=(1-z)\{a>1,z\le 1\}+(z-1)\{a<1,z>1\}\\&\le|z-a|\{a>1,z\le 1\}+|z-a|\{a<1,z>1\}\\&=|z-a|\Big(\{a>1,z\le 1\}+\{a<1,z>1\}\Big)\\&\le|z-a|\{|1-a|\le|z-a|\}.\end{aligned}\tag{28}$$

Choosing $z=Y^ih(X^i;\beta^*+\theta/\sqrt{n})$ and $a=Y^ih(X^i;\beta^*)$ in (28) yields (27).

Since cross-product terms in $\mathbb{E}(\sum_i(R_{i,n}-\mathbb{E}R_{i,n}))^2$ cancel out, we obtain from (27) that for each fixed θ,

$$\begin{aligned}\sum_{i=1}^n\mathbb{E}\left(|R_{i,n}(\theta)-\mathbb{E}R_{i,n}(\theta)|^2\right)&\le\sum_{i=1}^n\mathbb{E}\left(R_{i,n}(\theta)^2\right)\\&\le\sum_{i=1}^n\mathbb{E}\left(\left(h(X^i;\theta)/\sqrt{n}\right)^2U\left(|h(X^i;\theta)/\sqrt{n}|\right)\right)\\&\le\sum_{i=1}^n\mathbb{E}\left((1+\|X^i\|^2)\|\theta\|^2/n\,U\left(\sqrt{1+\|X^i\|^2}\|\theta\|/\sqrt{n}\right)\right)\\&=\|\theta\|^2\mathbb{E}\left((1+\|X\|^2)\,U\left(\sqrt{1+\|X\|^2}\|\theta\|/\sqrt{n}\right)\right).\end{aligned}$$

(A1) implies that $\mathbb{E}\left(\|X\|^2\right)<\infty$. Hence, for any $\varepsilon>0$, choose C_7 such that $\mathbb{E}\Big((1+\|X\|^2)\{\|X\|>C_7\}\Big)<\varepsilon/2$. Then

$$\begin{aligned}&\mathbb{E}\left((1+\|X\|^2)\,U\left(\sqrt{1+\|X\|^2}\|\theta\|/\sqrt{n}\right)\right)\\\le\;&\mathbb{E}\Big((1+\|X\|^2)\{\|X\|>C_7\}\Big)+(1+C_7^2)\mathbb{P}\left(U\left(\sqrt{1+C_7^2}\|\theta\|/\sqrt{n}\right)\right)\end{aligned}$$

By (A1), the distribution of X is not degenerate, which in turn implies that $\lim_{t\downarrow 0}\mathbb{P}(U(t))=0$. We can take a large N such that $\mathbb{P}\left(U\left(\sqrt{1+C_7^2}\|\theta\|/\sqrt{n}\right)\right)<\varepsilon/(2(1+C_7^2))$ for $n\geq N$. This proves that

$$\sum_{i=1}^{n}\mathbb{E}\left(|R_{i,n}(\theta)-\mathbb{E}R_{i,n}(\theta)|^2\right)\to 0$$

as $n\to\infty$. Thus, for each fixed θ,

$$\Lambda_n(\theta)=\frac{1}{2}\theta^\top H(\beta^*)\theta+W_n^\top\theta/\sqrt{n}+o_{\mathbb{P}}(1).$$

Let $\eta_n=-H(\beta^*)^{-1}W_n/\sqrt{n}$. By Convexity Lemma in Pollard (1991), we have

$$\Lambda_n(\theta)=\frac{1}{2}(\theta-\eta_n)^\top H(\beta^*)(\theta-\eta_n)-\frac{1}{2}\eta_n^\top H(\beta^*)\eta_n+r_n(\theta),$$

where, for each compact set K in $\mathbb{R}^{d+1}$,

$$\sup_{\theta\in K}|r_n(\theta)|\to 0\qquad\text{in probability.}$$

Because η_n converges in distribution, there exists a compact set K containing B_ε, where B_ε is a closed ball with center η_n and radius ε with probability arbitrarily close to one. Hence we have

$$\Delta_n=\sup_{\theta\in B_\varepsilon}|r_n(\theta)|\to 0\qquad\text{in probability.}\tag{29}$$

For examination of the behavior of $\Lambda_n(\theta)$ outside B_ε, consider $\theta=\eta_n+\gamma v$, with $\gamma>\varepsilon$ and v, a unit vector and a boundary point $\theta^*=\eta_n+\varepsilon v$. By Lemma 5, convexity of Λ_n, and the definition of Δ_n, we have

$$\begin{aligned}\frac{\varepsilon}{\gamma}\Lambda_n(\theta)+\left(1-\frac{\varepsilon}{\gamma}\right)\Lambda_n(\eta_n) &\geq \Lambda_n(\theta^*)\\ &\geq \frac{1}{2}(\theta^*-\eta_n)^\top H(\beta^*)(\theta^*-\eta_n)-\frac{1}{2}\eta_n^\top H(\beta^*)\eta_n-\Delta_n\\ &\geq \frac{C_4}{2}\varepsilon^2+\Lambda_n(\eta_n)-2\Delta_n,\end{aligned}$$

implying that

$$\inf_{\|\theta-\eta_n\|>\varepsilon}\Lambda_n(\theta)\geq\Lambda_n(\eta_n)+\left(\frac{C_4}{2}\varepsilon^2-2\Delta_n\right).$$

By (29), we can take Δ_n so that $2\Delta_n<C_4\varepsilon^2/4$ with probability tending to one. So the minimum of Λ_n cannot occur at any θ with $\|\theta-\eta_n\|>\varepsilon$. Hence, for each $\varepsilon>0$ and $\widehat{\theta}_{\lambda,n}=\sqrt{n}(\widehat{\beta}_{\lambda,n}-\beta^*)$,

$$\mathbb{P}\Big(\|\widehat{\theta}_{\lambda,n}-\eta_n\|>\varepsilon\Big)\to 0.$$

This completes the proof of Theorems 1 and 2. ■

Abstract

Linear support vector machines (SVM) are useful for classifying large-scale sparse data. Problems with sparse features are common in applications such as document classification and natural language processing. In this paper, we propose a novel coordinate descent algorithm for training linear SVM with the L2-loss function. At each step, the proposed method minimizes a one-variable sub-problem while fixing other variables. The sub-problem is solved by Newton steps with the line search technique. The procedure globally converges at the linear rate. As each sub-problem involves only values of a corresponding feature, the proposed approach is suitable when accessing a feature is more convenient than accessing an instance. Experiments show that our method is more efficient and stable than state of the art methods such as Pegasos and TRON.

Keywords: linear support vector machines, document classification, coordinate descent

1. Introduction

Support vector machines (SVM) (Boser et al., 1992) are a popular data classification tool. Given a set of instance-label pairs $(\mathbf{x}_j, y_j), j = 1, \ldots, l,\ \mathbf{x}_j \in R^n,\ y_j \in \{-1, +1\}$, SVM solves the following unconstrained optimization problem:

$$\min_{\mathbf{w}} f(\mathbf{w}) = \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{j=1}^{l} \xi(\mathbf{w}; \mathbf{x}_j, y_j), \tag{1}$$

where $\xi(\mathbf{w}; \mathbf{x}_j, y_j)$ is a loss function, and $C \in R$ is a penalty parameter. There are two common loss functions. L1-SVM uses the sum of losses and minimizes the following optimization problem:

$$f(\mathbf{w}) = \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{j=1}^{l} \max(1 - y_j\mathbf{w}^T\mathbf{x}_j, 0), \tag{2}$$

while L2-SVM uses the sum of squared losses, and minimizes

$$f(\mathbf{w}) = \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{j=1}^{l} \max(1 - y_j\mathbf{w}^T\mathbf{x}_j, 0)^2. \tag{3}$$

SVM is related to regularized logistic regression (LR), which solves the following problem:

$$\min_{\mathbf{w}} f(\mathbf{w}) = \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{j=1}^{l}\log(1+e^{-y_j\mathbf{w}^T\mathbf{x}_j}). \tag{4}$$

In some applications, we include a bias term b in SVM problems. For convenience, one may extend each instance with an additional dimension to eliminate this term:

$$\mathbf{x}_j^T \leftarrow [\mathbf{x}_j^T, 1] \qquad \mathbf{w}^T \leftarrow [\mathbf{w}^T, b].$$

SVM usually maps training vectors into a high-dimensional (and possibly infinite dimensional) space, and solves the dual problem of (1) with a nonlinear kernel. In some applications, data appear in a rich dimensional feature space, so that with/without nonlinear mapping obtain similar performances. If data are not mapped, we call such cases linear SVM, which are often encountered in applications such as document classification. While one can still solve the dual problem for linear SVM, directly solving (2) or (3) is possible. The objective function of L1-SVM (2) is nondifferentiable, so typical optimization methods cannot be directly applied. In contrast, L2-SVM (3) is a piecewise quadratic and strongly convex function, which is differentiable but not twice differentiable (Mangasarian, 2002). We focus on studying L2-SVM in this paper because of its differentiability.

In recent years, several optimization methods are applied to solve linear SVM in large-scale scenarios. For example, Keerthi and DeCoste (2005); Mangasarian (2002) propose modified Newton methods to train L2-SVM. As (3) is not twice differentiable, to obtain the Newton direction, they use the generalized Hessian matrix (i.e., generalized second derivative). A trust region Newton method (TRON) (Lin et al.) is proposed to solve logistic regression and L2-SVM. For large-scale L1-SVM, SVM$^{\text{perf}}$ (Joachims, 2006) uses a cutting plane technique to obtain the solution of (2). Smola et al. (2008) apply bundle methods, and view SVM$^{\text{perf}}$ as a special case. Zhang (2004) proposes a stochastic gradient method; Pegasos (Shalev-Shwartz et al., 2007) extends Zhang's work and develops an algorithm which alternates between stochastic gradient descent steps and projection steps. The performance is reported to be better than SVM$^{\text{perf}}$. Another stochastic gradient implementation similar to Pegasos is by Bottou (2007). All the above algorithms are iterative procedures, which update $\mathbf{w}$ at each iteration and generate a sequence $\{\mathbf{w}^k\}_{k=0}^{\infty}$. To distinguish these approaches, we consider the two extremes of optimization methods mentioned in the paper (Lin et al.):

$$\begin{array}{l}\text{Low cost per iteration;}\\ \text{slow convergence.}\end{array} \longleftrightarrow \begin{array}{l}\text{High cost per iteration;}\\ \text{fast convergence.}\end{array}$$

Among methods discussed above, Pegasos randomly subsamples a few instances at a time, so the cost per iteration is low, but the number of iterations is high. In contrast, Newton methods such as TRON take significant efforts at each iteration, but converge at fast rates. In large-scale scenarios, usually an approximate solution of the optimization problem is enough to produce a good model. Thus, methods with a low-cost iteration may be preferred as they can quickly generate a reasonable model. However, if one specifies an unsuitable stopping condition, such methods may fall into the situation of lengthy iterations. A recent overview on the tradeoff between learning accuracy and optimization cost is by Bottou and Bousquet (2008).

Coordinate descent is a common unconstrained optimization technique, but its use for large linear SVM has not been exploited much.[1] In this paper, we aim at applying it to L2-SVM. A coor-

1. For SVM with kernels, decomposition methods are popular, and they are related to coordinate descent methods. Since we focus on linear SVM, we do not discuss decomposition methods in this paper.

dinate descent method updates one component of $\mathbf{w}$ at a time by solving a one-variable sub-problem. It is competitive if one can exploit efficient ways to solve the sub-problem. For L2-SVM, the sub-problem is to minimize a single-variable piecewise quadratic function, which is differentiable but not twice differentiable. An earlier paper using coordinate descents for L2-SVM is by Zhang and Oles (2001). The algorithm, called CMLS, applies a modified Newton method to approximately solve the one-variable sub-problem. Here, we propose another modified Newton method, which obtains an approximate solution by line searches. Two key properties differentiate our method and CMLS:

1. Our proposed method attempts to use the full Newton step if possible, while CMLS takes a more conservative step. Our setting thus leads to faster convergence.

2. CMLS maintains the strict decrease of the function value, but does not prove the convergence. We prove that our method globally converges to the unique minimum.

We say $\hat{\mathbf{w}}$ is an ε-accurate solution if

$$f(\hat{\mathbf{w}}) \leq \min_{\mathbf{w}} f(\mathbf{w}) + \varepsilon.$$

We prove that our process obtains an ε-accurate solution in $O\left(nC^3P^6(\#\text{nz})^3\log(1/\varepsilon)\right)$ iterations, where the definitions of #nz and P can be found in the end of this section. Experiments show that our proposed method is more efficient and stable than existing algorithms.

Subsequent to this work, we and some collaborators propose a dual coordinate descent method for linear SVM (Hsieh et al., 2008). The method performs very well on document data (generally better than the primal-based method here). However, the dual method is not be stable for some non-document data with a small number of features. Clearly, if the number of features is much smaller than the number of instances, one should solve the primal form, which has less variables. In addition, the primal method uses the column format to store data (see Section 3.1). It is thus suitable for data stored as some form of inverted index in a very large database.

The organization of this paper is as follows. In Section 2, we describe and analyze our algorithm. Several implementation issues are discussed in Section 3. In Sections 4 and 5, we describe existing methods such as Pegasos, TRON and CMLS, and compare them with our approach. Results show that the proposed method is efficient and stable. Finally, we give discussions and conclusions in Section 6.

Notation The following notations are used in this paper. The input vectors are $\{\mathbf{x}_j\}_{j=1,\ldots,l}$, and x_{ji} is the ith feature of $\mathbf{x}_j$. For the problem size, l is the number of instances, n is number of features, and #nz is total number of nonzero values of training data.

$$m = \frac{\#\text{nz}}{n} \tag{5}$$

is the average number of nonzero values per feature, and

$$P = \max_{ji} |x_{ji}| \tag{6}$$

represents the upper bound of x_{ji}. We use $\|\cdot\|$ to represent the 2-norm of a vector.

Algorithm 1 Coordinate descent algorithm for L2-SVM

1. Start with any initial $\mathbf{w}^0$.
2. For $k = 0, 1, \ldots$ (outer iterations)
   (a) For $i = 1, 2, \ldots, n$ (inter iterations)
      i. Fix $w_1^{k+1}, \ldots, w_{i-1}^{k+1}, w_{i+1}^k, \ldots, w_n^k$ and approximately solve the sub-problem (7) to obtain w_i^{k+1}.

2. Solving Linear SVM via Coordinate Descent

In this section, we describe our coordinate descent method for solving L2-SVM given in (3). The algorithm starts from an initial point $\mathbf{w}^0$, and produces a sequence $\{\mathbf{w}^k\}_{k=0}^{\infty}$. At each iteration, $\mathbf{w}^{k+1}$ is constructed by sequentially updating each component of $\mathbf{w}^k$. This process generates vectors $\mathbf{w}^{k,i} \in R^n$, $i = 1, \ldots, n$, such that $\mathbf{w}^{k,1} = \mathbf{w}^k$, $\mathbf{w}^{k,n+1} = \mathbf{w}^{k+1}$, and

$$\mathbf{w}^{k,i} = [w_1^{k+1}, \ldots, w_{i-1}^{k+1}, w_i^k, \ldots, w_n^k]^T \text{ for } i = 2, \ldots, n.$$

For updating $\mathbf{w}^{k,i}$ to $\mathbf{w}^{k,i+1}$, we solve the following one-variable sub-problem:

$$\begin{aligned} &\min_z f(w_1^{k+1}, \ldots, w_{i-1}^{k+1}, w_i^k + z, w_{i+1}^k, \ldots, w_n^k) \\ \equiv &\min_z f(\mathbf{w}^{k,i} + z\mathbf{e}_i), \end{aligned} \tag{7}$$

where $\mathbf{e}_i = [\underbrace{0, \ldots, 0}_{i-1}, 1, 0, \ldots, 0]^T$. A description of the coordinate descent algorithm is in Algorithm 1. The function in (7) can be rewritten as

$$\begin{aligned} D_i(z) &= f(\mathbf{w}^{k,i} + z\mathbf{e}_i) \\ &= \frac{1}{2}(\mathbf{w}^{k,i} + z\mathbf{e}_i)^T(\mathbf{w}^{k,i} + z\mathbf{e}_i) + C \sum_{j \in I(\mathbf{w}^{k,i} + z\mathbf{e}_i)} (b_j(\mathbf{w}^{k,i} + z\mathbf{e}_i))^2, \end{aligned} \tag{8}$$

where

$$b_j(\mathbf{w}) = 1 - y_j \mathbf{w}^T \mathbf{x}_j \text{ and } I(\mathbf{w}) = \{j \mid b_j(\mathbf{w}) > 0\}.$$

In any interval of z where the set $I(\mathbf{w}^{k,i} + z\mathbf{e}_i)$ does not change, $D_i(z)$ is quadratic. Therefore, $D_i(z), z \in R$, is a piecewise quadratic function. As Newton method is suitable for quadratic optimization, here we apply it for minimizing $D_i(z)$. If $D_i(z)$ is twice differentiable, then the Newton direction at a given $\bar{z}$ would be

$$\frac{-D_i'(\bar{z})}{D_i''(\bar{z})}.$$

The first derivative of $D_i(z)$ is:

$$D_i'(z) = w_i^{k,i} + z - 2C \sum_{j \in I(\mathbf{w}^{k,i} + z\mathbf{e}_i)} y_j x_{ji} (b_j(\mathbf{w}^{k,i} + z\mathbf{e}_i)). \tag{9}$$

Unfortunately, $D_i(z)$ is not twice differentiable as the last term of $D_i'(z)$ is not differentiable at $\{z \mid b_j(\mathbf{w}^{k,i}+z\mathbf{e}_i)=0 \text{ for some } j\}$. We follow Mangasarian (2002) to define the generalized second derivative:

$$\begin{aligned} D_i''(z) &= 1+2C \sum_{j\in I(\mathbf{w}^{k,i}+z\mathbf{e}_i)} y_j^2 x_{ji}^2 \\ &= 1+2C \sum_{j\in I(\mathbf{w}^{k,i}+z\mathbf{e}_i)} x_{ji}^2. \end{aligned} \tag{10}$$

A simple Newton method to solve (7) begins with $z^0=0$ and iteratively updates z by the following way until $D_i'(z)=0$:

$$z^{t+1} = z^t - D_i'(z^t)/D_i''(z^t) \text{ for } t=0,1,\ldots. \tag{11}$$

Mangasarian (2002) proved that under an assumption, this procedure terminates in finite steps and solves (7). Coordinate descent methods are known to converge if at each inner iteration we uniquely attain the minimum of the sub-problem (Bertsekas, 1999, Proposition 2.7.1). Unfortunately, the assumption by Mangasarian (2002) may not hold in real cases, so taking the full Newton step (11) may not decrease the function $D_i(z)$. Furthermore, solving the sub-problem exactly is too expensive.

An earlier approach of using coordinate descents for L2-SVM without exactly solving the sub-problem is by Zhang and Oles (2001). In their algorithm CMLS, the approximate solution is restricted within a region. By evaluating the upper bound of generalized second-order derivatives in this region, one replaces the denominator of the Newton step (11) with that upper bound. This setting guarantees the decrease of $D_i(z)$. However, there are two problems. First, function decreasing does not imply that $\{\mathbf{w}^k\}$ converges to the global optimum. Secondly, the step size generated by evaluating the upper bound of generalized second derivatives may be too conservative. We describe details of CMLS in Section 4.3.

While coordinate descent methods have been well studied in optimization, most convergence analyses assume that the one-variable sub-problem is exactly solved. We consider the result by Grippo and Sciandrone (1999), which establishes the convergence by requiring only the following sufficient decrease condition:

$$D_i(z) - D_i(0) \le -\sigma z^2, \tag{12}$$

where z is the step taken and σ is any constant in (0, 1/2). Since we intend to take the Newton direction

$$d = \frac{-D_i'(0)}{D_i''(0)}, \tag{13}$$

it is important to check if $z=d$ satisfies (12). The discussion below shows that in general the condition hold. If the function $D_i(z)$ is quadratic around 0, then

$$D_i(z) - D_i(0) = D_i'(0)z + \frac{1}{2}D_i''(0)z^2.$$

Using $D_i''(0) > 1$ in (10), $z=d=-D_i'(0)/D_i''(0)$ leads to

$$-\frac{D_i'(0)^2}{2D_i''(0)} \le -\sigma \frac{D_i'(0)^2}{D_i''(0)^2},$$

so (12) holds. As $D_i(z)$ is only piecewise quadratic, (12) may not hold using $z=d$. However, we can conduct a simple line search. The following theorem shows that there is a $\lambda \in (0,1)$ such that $z=\lambda d$ satisfies the sufficient decrease condition:

Algorithm 2 Solving the sub-problem using Newton direction with the line search.

1. Given $\mathbf{w}^{k,i}$. Choose $\beta \in (0,1)$ (e.g., $\beta = 0.5$).
2. Calculate the Newton direction $d = -D_i'(0)/D_i''(0)$.
3. Compute $\lambda = \max\{1, \beta, \beta^2, \ldots\}$ such that $z = \lambda d$ satisfies (12).

Theorem 1 *Given the Newton direction d as in* (13)*. Then $z = \lambda d$ satisfies* (12) *for all $0 \le \lambda \le \bar{\lambda}$, where*

$$\bar{\lambda} = \frac{D_i''(0)}{H_i/2 + \sigma} \text{ and } H_i = 1 + 2C \sum_{j=1}^{l} x_{ji}^2. \tag{14}$$

The proof is in Appendix A.1. Therefore, at each inner iteration of Algorithm 1, we take the Newton direction d as in (13), and then sequentially check $\lambda = 1, \beta, \beta^2, \ldots$, where $\beta \in (0,1)$, until λd satisfies (12). Algorithm 2 lists the details of a line search procedure. We did not specify how to approximately solve sub-problems in Algorithm 1. From now on, we assume that it uses Algorithm 2.

Calculating $D_i(\lambda d)$ is the main cost of checking (12). We can use a trick to reduce the number of $D_i(\lambda d)$ calculations. Theorem 1 indicates that if

$$0 \le \lambda \le \bar{\lambda} = \frac{D_i''(0)}{H_i/2 + \sigma}, \tag{15}$$

then $z = \lambda d$ satisfies the sufficient decrease condition (12). H_i is independent of $\mathbf{w}$, so it can be precomputed before training. Furthermore, we already evaluate $D_i''(0)$ in computing the Newton step, so it takes only constant time to check (15). At Step 3 of Algorithm 2, we sequentially use $\lambda = 1, \beta, \beta^2, \ldots$, etc. Before calculating (12) using a smaller λ, we check if λ satisfies (15). If it does, then there is no need to evaluate the new $D_i(\lambda d)$. If $\lambda = 1$ already satisfies (15), the line search procedure is essentially waived. Thus the computational time is effectively reduced.

We discuss parameters in our algorithm. First, as $\lambda = 1$ is often successful, our algorithm is insensitive to β. We choose β as 0.5. Secondly, there is a parameter σ in (12). The smaller value of σ leads to a looser sufficient decrease condition, which reduces the time of line search, but increases the number of outer iterations. A common choice of σ is 0.01 in unconstrained optimization algorithms.

It is important to study the convergence properties of Algorithm 1. An excellent study on the convergence rate of coordinate descent methods is by Luo and Tseng (1992). They assume that each sub-problem is exactly solved, so we cannot apply their results here. The following theorem proves the convergence results of Algorithm 1.

Theorem 2 *The sequence $\{\mathbf{w}^k\}$ generated by Algorithm 1 linearly converges. That is, there is a constant $\mu \in (0,1)$ such that*

$$f(\mathbf{w}^{k+1}) - f(\mathbf{w}^*) \le (1-\mu)(f(\mathbf{w}^k) - f(\mathbf{w}^*)), \forall k.$$

Moreover, the sequence $\{\mathbf{w}^k\}$ globally converges to $\mathbf{w}^*$. The algorithm obtains an ε-accurate solution in

$$O\left(nC^3P^6(\#nz)^3 \log(1/\varepsilon)\right) \tag{16}$$

iterations.

The proof is in Appendix A.2. Note that as data are usually scaled before training, $P \leq 1$ in most practical cases.

Next, we investigate the computational complexity per outer iteration of Algorithm 1. The main cost comes from solving the sub-problem by Algorithm 2. At Step 2 of Algorithm 2, to evaluate $D_i'(0)$ and $D_i''(0)$, we need $b_j(\mathbf{w}^{k,i})$ for all j. Here we consider sparse data instances. Calculating $b_j(\mathbf{w}), j = 1,\ldots,l$ takes $O(\#\text{nz})$ operations, which are large. However, one can use the following trick to save the time:

$$b_j(\mathbf{w}+z\mathbf{e}_i) = b_j(\mathbf{w}) - zy_jx_{ji}, \tag{17}$$

If $b_j(\mathbf{w}), j = 1,\ldots,l$ are available, then obtaining $b_j(\mathbf{w}+z\mathbf{e}_i)$ involves only nonzero x_{ji}'s of the ith feature. Using (17), obtaining all $b_j(\mathbf{w}+z\mathbf{e}_i)$ costs $O(m)$, where m, the average number of nonzero values per feature, is defined in (5). To have $b_j(\mathbf{w}^0)$, we can start with $\mathbf{w}^0 = \mathbf{0}$, so $b_j(\mathbf{w}^0) = 1, \forall j$. With $b_j(\mathbf{w}^{k,i})$ available, the cost of evaluating $D_i'(0)$ and $D_i''(0)$ is $O(m)$. At Step 3 of Algorithm 2, we need several line search steps using $\lambda = 1, \beta, \beta^2, \ldots$, etc. For each λ, the main cost is on calculating

$$\begin{aligned} D_i(\lambda d) - D_i(0) = &\frac{1}{2}(w_i^{k,i}+\lambda d)^2 - \frac{1}{2}(w_i^{k,i})^2 \\ &+ C\Big(\sum_{j\in I(\mathbf{w}^{k,i}+\lambda d\mathbf{e}_i)} (b_j(\mathbf{w}^{k,i}+\lambda d\mathbf{e}_i))^2 - \sum_{j\in I(\mathbf{w}^{k,i})} (b_j(\mathbf{w}^{k,i}))^2\Big). \end{aligned} \tag{18}$$

Note that from (17), if $x_{ji} = 0$,

$$b_j(\mathbf{w}^{k,i}+\lambda d\mathbf{e}_i) = b_j(\mathbf{w}^{k,i}).$$

Hence, (18) involves no more than $O(m)$ operations. In summary, Algorithm 2 costs

$$\begin{aligned} & O(m) \text{ for evaluating } D_i'(0) \text{ and } D_i''(0) \\ + \quad & O(m) \times \#\text{ line search steps.} \end{aligned}$$

From the explanation earlier and our experiments, in general the sufficient decrease condition holds when $\lambda = 1$. Then the cost of Algorithm 2 is about $O(m)$. Therefore, in general the complexity per outer iteration is:

$$O(nm) = O(\#\text{nz}). \tag{19}$$

3. Implementation Issues

In this section, we discuss some techniques for a fast implementation of Algorithm 1. First, we aim at suitable data representations. Secondly, we show that the order of sub-problems at each iteration can be any permutation of $\{1,\ldots,n\}$. Experiments in Section 5 indicate that the performance of using a random permutation is superior to that of using the fixed order $1,\ldots,n$. Finally, we present an online version of our algorithm.

3.1 Data Representation

For sparse data, we use a sparse matrix

$$X = \begin{bmatrix} \mathbf{x}_1^T \\ \vdots \\ \mathbf{x}_l^T \end{bmatrix} \tag{20}$$

to store the training instances. There are several ways to implement a sparse matrix. Two common ones are "row format" and "column format" (Duff et al., 1989). For data classification, using column (row) format allows us to easily access any particular feature (instance). In our case, as we decompose the problem (3) into sub-problems over features, the column format is more suitable.

3.2 Random Permutation of Sub-problems

In Section 2, we propose a coordinate descent algorithm which solves the one-variable sub-problems in the order of $w_1, \ldots, w_n$. As the features may be correlated, the order of features may affect the training speed. One can even use an arbitrary order of sub-problems. To prove the convergence, we require that each sub-problem is solved once at one outer iteration. Therefore, at the kth iteration, we construct a random permutation π_k of $\{1, \ldots, n\}$, and sequentially minimize with respect to variables $w_{\pi(1)}, w_{\pi(2)}, \ldots, w_{\pi(n)}$. Similar to Algorithm 1, the algorithm generates a sequence $\{\mathbf{w}^{k,i}\}$ such that $\mathbf{w}^{k,1} = \mathbf{w}^k$, $\mathbf{w}^{k,n+1} = \mathbf{w}^{k+1,1}$ and

$$w_t^{k,i} = \begin{cases} w_t^{k+1} & \text{if } \pi_k^{-1}(t) < i, \\ w_t^k & \text{if } \pi_k^{-1}(t) \geq i. \end{cases}$$

The update from $\mathbf{w}^{k,i}$ to $\mathbf{w}^{k,i+1}$ is by

$$w_t^{k,i+1} = w_t^{k,i} + \arg\min_z f(\mathbf{w}^{k,i} + z\mathbf{e}_{\pi_k(i)}) \quad \text{if } \pi_k^{-1}(t) = i.$$

We can prove the same convergence result:

Theorem 3 *Results in Theorem 2 hold for Algorithm 1 with random permutations π_k.*

The proof is in Appendix A.3. Experiments in Section 5 show that a random permutation of sub-problems leads to faster training.

3.3 An Online Algorithm

If the number of features is very large, we may not need to go through all $\{w_1, \ldots, w_n\}$ at each iteration. Instead, one can have an online setting by arbitrarily choosing a feature at a time. That is, from $\mathbf{w}^k$ to $\mathbf{w}^{k+1}$ we only modify one component. A description is in Algorithm 3. The following theorem indicates the convergence rate in expectation:

Theorem 4 *Let $\delta \in (0,1)$. Algorithm 3 requires $O\left(nl^2C^3P^6(\#nz)\log(\frac{1}{\delta\varepsilon})\right)$ iterations to obtain an ε-accurate solution with confidence $1-\delta$.*

The proof is in Appendix A.4.

4. Related Methods

In this section, we discuss three existing schemes for large-scale linear SVM. They will be compared in Section 5. The first one is Pegasos (Shalev-Shwartz et al., 2007), which is notable for its efficiency in training linear L1-SVM. The second one is a trust region Newton method (Lin et al.). It is one of the fastest implementations for L2-SVM. The last one is CMLS, which is a coordinate descent method proposed by Zhang and Oles (2001).

Algorithm 3 An online coordinate descent algorithm

1. Start with any initial $\mathbf{w}^0$.
2. For $k = 0, 1, \ldots$
   (a) Randomly choose $i_k \in \{1, 2, \ldots, n\}$.
   (b) Fix $w_1^k, \ldots, w_{i_k-1}^k, w_{i_k+1}^k, \ldots, w_n^k$ and approximately solve the sub-problem (7) to obtain $w_{i_k}^{k+1}$.

Coordinate descent methods have been used in other machine learning problems. For example, Rätsch et al. (2002) discuss the connection between boosting/logistic regression and coordinate descent methods. Their strategies for selecting coordinates at each outer iteration are different from ours. We do not discuss details here.

4.1 Pegasos for L1-SVM

We briefly introduce the Pegasos algorithm (Shalev-Shwartz et al., 2007). It is an efficient method to solve the following L1-SVM problem:

$$\min_{\mathbf{w}} g(\mathbf{w}) = \frac{\lambda}{2}\mathbf{w}^T\mathbf{w} + \frac{1}{l}\sum_{j=1}^{l} \max(1 - y_j \mathbf{w}^T \mathbf{x}_j, 0). \tag{21}$$

By setting $\lambda = \frac{1}{Cl}$, we have

$$g(\mathbf{w}) = f(\mathbf{w})/Cl, \tag{22}$$

where $f(\mathbf{w})$ is the objective function of (2). Thus (21) and (2) are equivalent. Pegasos has two parameters. One is the subsample size K, and the other is the penalty parameter λ. It begins with an initial $\mathbf{w}^0$ whose norm is at most $1/\sqrt{\lambda}$. At each iteration k, it randomly selects a set $A_k \subset \{\mathbf{x}_j, y_j\}_{j=1,\ldots,l}$ of size K as the subsamples of training instances and sets a learning rate

$$\eta_k = \frac{1}{\lambda k}. \tag{23}$$

Then it updates $\mathbf{w}^k$ with the following rules:

$$\begin{aligned}
\mathbf{w}^{k+1} &= \min\left(1, \frac{1/\sqrt{\lambda}}{\|\mathbf{w}^{k+\frac{1}{2}}\|}\right)\mathbf{w}^{k+\frac{1}{2}}, \\
\mathbf{w}^{k+\frac{1}{2}} &= \mathbf{w}^k - \eta_k \nabla_k, \\
\nabla_k &= \lambda \mathbf{w}^k - \frac{1}{K}\sum_{j \in A_k^+(\mathbf{w}^k)} y_j \mathbf{x}_j, \\
A_k^+(\mathbf{w}) &= \{j \in A_k \mid 1 - y_j \mathbf{w}^T \mathbf{x}_j > 0\},
\end{aligned} \tag{24}$$

where ∇_k is considered as a sub-gradient of the approximate objective function:

$$\frac{\lambda}{2}\mathbf{w}^T\mathbf{w} + \frac{1}{K}\sum_{j \in A_k} \max(1 - y_j \mathbf{w}^T \mathbf{x}_j, 0).$$

Algorithm 4 Pegasos algorithm for solving L1-SVM.

1. Given λ, K, and $\mathbf{w}^0$ with $\|\mathbf{w}^0\| \leq 1/\sqrt{\lambda}$.
2. For $k = 0, 1, \ldots$
   (a) Select a set $A_k \in \{\mathbf{x}_j, y_j \mid j = 1 \ldots l\}$, and the learning rate η by (23).
   (b) Obtain $\mathbf{w}^{k+1}$ by (24).

Here $\mathbf{w}^{k+1/2}$ is a vector obtained by the stochastic gradient descent step, and $\mathbf{w}^{k+1}$ is the projection of $\mathbf{w}^{k+1/2}$ to the set $\{\mathbf{w} \mid \|\mathbf{w}\| \leq 1/\sqrt{\lambda}\}$. Algorithm 4 lists the detail of Pegasos. The parameter K decides the number of training instances involved at an iteration. If $K = l$, Pegasos considers all examples at each iteration, and becomes a subgradient projection method. In this case the cost per iteration is $O(\#\text{nz})$. If $K < l$, Pegasos is a randomized algorithm. For the extreme case of $K = 1$, Pegasos chooses only one training instance for updating. Thus the average cost per iteration is $O(\#\text{nz}/l)$. In subsequent experiments, we set the subsample size K to one as Shalev-Shwartz et al. (2007) suggested.

Regarding the complexity of Pegasos, we first compare Algorithm 1 with Pegasos ($K = l$). Both algorithms are deterministic and cost $O(\#\text{nz})$ per iteration. Shalev-Shwartz et al. (2007) prove that Pegasos with $K = l$ needs $\tilde{O}(R^2/(\varepsilon_g \lambda))$ iterations to achieve an ε_g-accurate solution, where $R = \max_j \|\mathbf{x}_j\|$, and $\tilde{O}(h(n))$ is shorthand for $O(h(n)\log^k h(n))$, for some $k \geq 0$. We use ε_g as Pegasos considers $g(\mathbf{w})$ in (22), a scaled form of $f(\mathbf{w})$. From (1), an ε_g-accurate solution for $g(\mathbf{w})$ is equivalent to an (ε/Cl)-accurate solution for $f(\mathbf{w})$. With $\lambda = 1/Cl$ and $R^2 = O(P^2(\#\text{nz})/l)$, where P is defined in (6), Pegasos takes

$$\tilde{O}\left(\frac{C^2P^2l(\#\text{nz})}{\varepsilon}\right)$$

iterations to achieve an ε-accurate solution. One can compare this value with (16), the number of iterations by Algorithm 1.

Next, we compare two random algorithms: Pegasos with $K = 1$ and our Algorithm 3. Shalev-Shwartz et al. (2007) prove that Pegasos takes $\tilde{O}(\frac{R^2}{\lambda\delta\varepsilon_g})$ iterations to obtain an ε_g-accurate solution with confidence $1 - \delta$. Using a similar derivation in the last paragraph, we can show that this is equivalent to $\tilde{O}(C^2P^2l(\#\text{nz})/\delta\varepsilon)$. As the cost per iteration is $O(\#\text{nz}/l)$, the overall complexity is

$$\tilde{O}\left(\frac{C^2P^2(\#\text{nz})^2}{\delta\varepsilon}\right).$$

For our Algorithm 3, each iteration costs $O(m)$, so following Theorem 4 the overall complexity is $O\left(l^2C^3P^6(\#\text{nz})^2\log(\frac{1}{\delta\varepsilon})\right)$.

Based on the above analysis, the number of iterations required for our algorithm is proportional to $O(\log(1/\varepsilon))$, while that for Pegasos is $O(1/\varepsilon)$. Therefore, our algorithm tends to have better final convergence than Pegasos for both deterministic and random settings. However, for the dependence on the size of data (number of instances and features), our algorithm is worse.

Regarding the stopping condition, as at each iteration Pegasos only takes one sample for updating $\mathbf{w}$, neither function nor gradient information is available. This keeps Pegasos from designing a suitable stopping condition. Shalev-Shwartz et al. (2007) suggest to set a maximal number of

iterations. However, deciding a suitable value may be difficult. We will discuss stopping conditions of Pegasos and other methods in Section 5.3.

4.2 Trust Region Newton Method (TRON) for L2-SVM

Recently, Lin et al. introduced a trust region Newton method for logistic regression. Their proposed method can be extended to L2-SVM. In this section, we briefly discuss their approach. For convenience, in subsequent sections, we use TRON to indicate the trust region Newton method for L2-SVM, and TRON-LR for logistic regression

The optimization procedure of TRON has two layers of iterations. At each outer iteration k, TRON sets a size Δ_k of the trust region, and builds a quadratic model

$$q_k(\mathbf{s}) = \nabla f(\mathbf{w}^k)^T\mathbf{s} + \frac{1}{2}\mathbf{s}^T\nabla^2 f(\mathbf{w}^k)\mathbf{s}$$

as the approximation of the value $f(\mathbf{w}^k+\mathbf{s}) - f(\mathbf{w}^k)$, where $f(\mathbf{w})$ is the objective function in (3) and $\nabla^2 f(\mathbf{w})$ is the generalized Hessian (Mangasarian, 2002) of $f(\mathbf{w})$. Then an inner conjugate gradient procedure approximately finds the Newton direction by minimizing the following optimization problem:

$$\begin{aligned} \min_{\mathbf{s}} \quad & q_k(\mathbf{s}) \\ \text{subject to} \quad & \|\mathbf{s}\| \le \Delta_k. \end{aligned} \tag{25}$$

TRON updates $\mathbf{w}^k$ and Δ_k by the following rules:

$$\begin{aligned} \mathbf{w}^{k+1} &= \begin{cases} \mathbf{w}^k + \mathbf{s}^k & \text{if } \rho_k > \eta_0, \\ \mathbf{w}^k & \text{if } \rho_k \le \eta_0, \end{cases} \\ \Delta_{k+1} &\in \begin{cases} [\sigma_1 \min\{\|\mathbf{s}^k\|, \Delta_k\}, \sigma_2\Delta_k] & \text{if } \rho_k \le \eta_1, \\ [\sigma_1\Delta_k, \sigma_3\Delta_k] & \text{if } \rho_k \in (\eta_1, \eta_2), \\ [\Delta_k, \sigma_3\Delta_k] & \text{if } \rho_k \ge \eta_2, \end{cases} \\ \rho_k &= \frac{f(\mathbf{w}^k + \mathbf{s}^k) - f(\mathbf{w}^k)}{q_k(\mathbf{s}^k)}, \end{aligned} \tag{26}$$

where ρ_k is the ratio of the actual reduction in the objective function to the approximation model $q_k(\mathbf{s})$. Users pre-specify parameters $\eta_0 > 0$, $1 > \eta_2 > \eta_1 > 0$, and $\sigma_3 > 1 > \sigma_2 > \sigma_1 > 0$. We use

$$\begin{aligned} \eta_0 &= 10^{-4}, \eta_1 = 0.25, \eta_2 = 0.75, \\ \sigma_1 &= 0.25, \sigma_2 = 0.5, \sigma_3 = 4, \end{aligned}$$

as suggested by Lin et al.. The procedure is listed in Algorithm 5.

For the computational complexity, the main cost per TRON iteration is

$$O(\#\text{nz}) \times (\#\text{ conjugate gradient iterations}). \tag{27}$$

Compared to our approach or Pegasos, the cost per TRON iteration is high. It keeps TRON from quickly obtaining a usable model. However, when $\mathbf{w}$ gets close to the minimum, TRON takes the Newton step to achieve fast convergence. We give more observations in the experiment section.

Algorithm 5 Trust region Newton method for L2-SVM.

1. Given $\mathbf{w}^0$.
2. For $k = 0, 1, \ldots$
   (a) Find an approximate solution $\mathbf{s}^k$ of the trust region sub-problem (25).
   (b) Update $\mathbf{w}^k$ and Δ_k according to (26).

4.3 CMLS: A Coordinate Descent Method for L2-SVM

In Sections 2 and 3, we introduced our coordinate descent method for solving L2-SVM. Here, we discuss the previous work (Zhang and Oles, 2001), which also applies the coordinate descent technique. Zhang and Oles refer to their method as CMLS. At each outer iteration k, it sequentially minimizes sub-problems (8) by updating one variable of (3) at a time. In solving the sub-problem, Zhang and Oles (2001) mention that using line searches may result in small step sizes. Hence, CMLS applies a technique similar to the trust region method. It sets a size $\Delta^{k,i}$ of the trust region, evaluates the first derivative (9) of (8), and calculates the upper bound of the generalized second derivative subject to $|z| \le \Delta^{k,i}$:

$$U_i(z) = 1 + \sum_{j=1}^{l} \beta_j(\mathbf{w}^{k,i} + z\mathbf{e}_i),$$

$$\beta_j(\mathbf{w}) = \begin{cases} 2C & \text{if } y_j \mathbf{w}^T \mathbf{x}_j \le 1 + |\Delta^{k,i} x_{ij}|, \\ 0 & \text{otherwise.} \end{cases}$$

Then we obtain the step z as:

$$z = \min(\max(-\frac{D_i'(z)}{U_i(z)}, -\Delta^{k,i}), \Delta^{k,i}). \tag{28}$$

The updating rule of Δ is:

$$\Delta^{k+1,i} = 2|z| + \varepsilon, \tag{29}$$

where ε is a small constant.

In order to speed up the process, Zhang and Oles (2001) smooth the objective function of sub-problems with a parameter $c_k \in [0, 1]$:

$$D_i(z) = \frac{1}{2}(\mathbf{w}^{k,i} + z\mathbf{e}_i)^T(\mathbf{w}^{k,i} + z\mathbf{e}_i) + C\sum_{j=1}^{l}(b_j(\mathbf{w}^{k,i} + z\mathbf{e}_i))^2,$$

where

$$b_j(\mathbf{w}) = \begin{cases} 1 - y_j \mathbf{w}^T \mathbf{x}_j & \text{if } 1 - y_j \mathbf{w}^T \mathbf{x}_j > 0, \\ c_k(1 - y_j \mathbf{w}^T \mathbf{x}_j) & \text{otherwise.} \end{cases}$$

Following the setting by (Zhang and Oles, 2001), we choose

$$c_k = \max(0, 1 - k/50), \tag{30}$$

Algorithm 6 CMLS algorithm for solving L2-SVM.

1. Given $\mathbf{w}^0$ and set initial $\Delta^{0,i} = 10, \forall i$.
2. For $k = 0, 1, \ldots$
   (a) Set c_k by (30). Let $\mathbf{w}^{k,1} = \mathbf{w}^k$.
   (b) For $i = 1, 2, \ldots, n$
      i. Evaluate z by (28).
      ii. $\mathbf{w}^{k,i+1} = \mathbf{w}^{k,i} + z\mathbf{e}_i$.
      iii. Update Δ by (29).
   (c) Let $\mathbf{w}^{k+1} = \mathbf{w}^{k,n+1}$.

Table 1: Data set statistics: l is the number of instances and n is the number of features.

and set the initial $\mathbf{w} = \mathbf{0}$ and $\Delta^{0,i} = 10, \forall i$. We find that the result is insensitive to these parameters. The detail of CMLS algorithm is listed in Algorithm 6.

Zhang and Oles (2001) prove that if $c_k = 0, \forall k$, then the objective function of (3) is decreasing after each inner iteration. However, such a property may not imply that Algorithm 6 converges to the minimum. In addition, CMLS updates $\mathbf{w}$ by (28), which is more conservative than Newton steps. In Section 5, we show that CMLS takes more time and iterations than ours to obtain a solution.

5. Experiments and Analysis

In this section, we conduct two experiments to investigate the performance of our proposed coordinate descent algorithm. The first experiment compares our method with other L2-SVM solvers in terms of the speed to reduce function/gradient values. The second experiment evaluates various state of the art linear classifiers for L1-SVM, L2-SVM, and logistic regression. We also discuss the stopping condition of these methods.

5.1 Data Sets

Table 1 lists the number of instances (l), features (n), and non-zero elements (#nz) of six data sets. All sets are from document classification. Past studies show that linear SVM performs as good as kernelized ones for such data. Details of astro-physic are mentioned in Joachims (2006), while others are in Lin et al.. Three data sets real-sim, news20 and rcv1 are publicly available

Data set	CDPER	CD	TRON	CMLS
astro-physic	**0.5**	1.2	1.2	2.6
real-sim	**0.2**	0.3	0.9	2.0
news20	2.4	**1.0**	5.2	5.3
yahoo-japan	**2.9**	9.3	38.2	13.5
rcv1	**5.1**	10.8	18.6	54.8
yahoo-korea	**18.4**	58.1	286.1	146.3

Table 2: The training time for an L2-SVM solver to reduce the objective value to within 1% of the optimal value. Time is in seconds. We use $C = 1$. The approach with the shortest running time is boldfaced.

at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets`. A brief reminder for each data set can be found below.

- astro-physic: This set is a classification problem of scientific papers from Physics ArXiv.
- real-sim: This set includes some Usenet articles.
- news20: This is a collection of news documents, and was preprocessed by Keerthi and DeCoste (2005).
- yahoo-japan: We use binary term frequencies and normalize each instance to unit length.
- rcv1: This set (Lewis et al., 2004) is an archive of manually categorized newswire stories from Reuters Ltd. Each vector is a cosine normalization of a log transformed TF-IDF (term frequency, inverse document frequency) feature vector.
- yahoo-korea: Similar to yahoo-japan, we use binary term frequencies and normalize each instance to unit length.

To examine the testing accuracy, we use a stratified selection to split each set to $4/5$ training and $1/5$ testing.

5.2 Comparisons

We compare the following six implementations. TRON-LR is for logistic regression, Pegasos is for L1-SVM, and all others are for L2-SVM.

1. CD: the coordinate descent method described in Section 2. We choose σ in (12) as 0.01.
2. CDPER: the method modified from CD by permuting sub-problems at each outer step. See the discussion in Section 3.2.
3. CMLS: a coordinate descent method for L2-SVM (Zhang and Oles, 2001, Algorithm 3). It is discussed in Section 4.3.
4. TRON: the trust region Newton method (Lin et al.) for L2-SVM. See the discussion in Section 4.2. We use the L2-loss linear SVM implementation in the software LIBLINEAR (version 1.21 with option `-s 2`; `http://www.csie.ntu.edu.tw/~cjlin/liblinear`).

Data set	L2-SVM		L1-SVM		LR	
	C	Accuracy	C	Accuracy	C	Accuracy
astro-physic	0.5	97.14	1.0	97.09	8.0	97.03
real-sim	1.0	97.59	1.0	97.52	8.0	97.57

yahoo-korea	2.0	87.51	4.0	87.42	64.0	87.31

Table 3: The best parameter C and the corresponding testing accuracy of L1-SVM, L2-SVM and logistic regression (LR). We conduct five-fold cross validation to select C.

5. TRON-LR: the trust region Newton method for logistic regression introduced by Lin et al.. Similar to TRON, we use the implementation in the software LIBLINEAR with option `-s 0`.

6. Pegasos: the primal estimated sub-gradient solver for L1-SVM (Shalev-Shwartz et al., 2007). See the discussion in Section 4.1. The source code is available online at `http://ttic.uchicago.edu/~shai/code`.

We do not include the bias term in all the solvers. All the above algorithms are implemented in C++ with double-precision floating-point numbers. Using single precision (e.g., Bottou, 2007) may reduce the computational time in some situations, but this setting may cause numerical inaccuracy. We conduct experiments on an Intel 2.66GHz processor with 8GB of main memory under Linux.

In our first experiment, we compare L2-SVM solvers (with $C = 1$) in term of the speed to reduce function/gradient values. In Table 2, we check their CPU time of reducing the relative difference of the function value to the optimum,

$$\frac{f(\mathbf{w}^k) - f(\mathbf{w}^*)}{|f(\mathbf{w}^*)|}, \tag{31}$$

to within 0.01. We run TRON with the stopping condition $\|\nabla f(\mathbf{w}^k)\| \leq 0.01$ to obtain the reference solutions. Since objective values are stable under such strict stopping conditions, these solutions are seen to be very close to the optima. Overall, our proposed algorithms CDPER and CD perform well on all the data sets. For the large data sets (rcv1, yahoo-japan, yahoo-korea), CD is significantly better than TRON and CMLS. With the permutation of sub-problems, CDPER is even better than CD. To show more detailed comparisons, Figure 1 presents time versus relative difference (31). As a reference, we draw a horizontal dotted line to indicate the relative difference 0.01. Consistent with the observation in Table 2, CDPER is more efficient and stable than others.

In addition, we are interested in how fast these methods decrease the norm of gradients. Figure 2 shows the result. Overall, CDPER converges faster in the beginning, while TRON is the best for final convergence.

The second experiment is to check the relationship between training time and testing accuracy using our implementation and other solvers: CMLS, TRON (L2-SVM and logistic regression), and Pegasos. That is, we investigate which method achieves reasonable testing accuracy more quickly. To have a fair evaluation, we conduct five-fold cross validation to select the best parameter C for each learning method. Using the selected C, we then train the whole training set and predict the

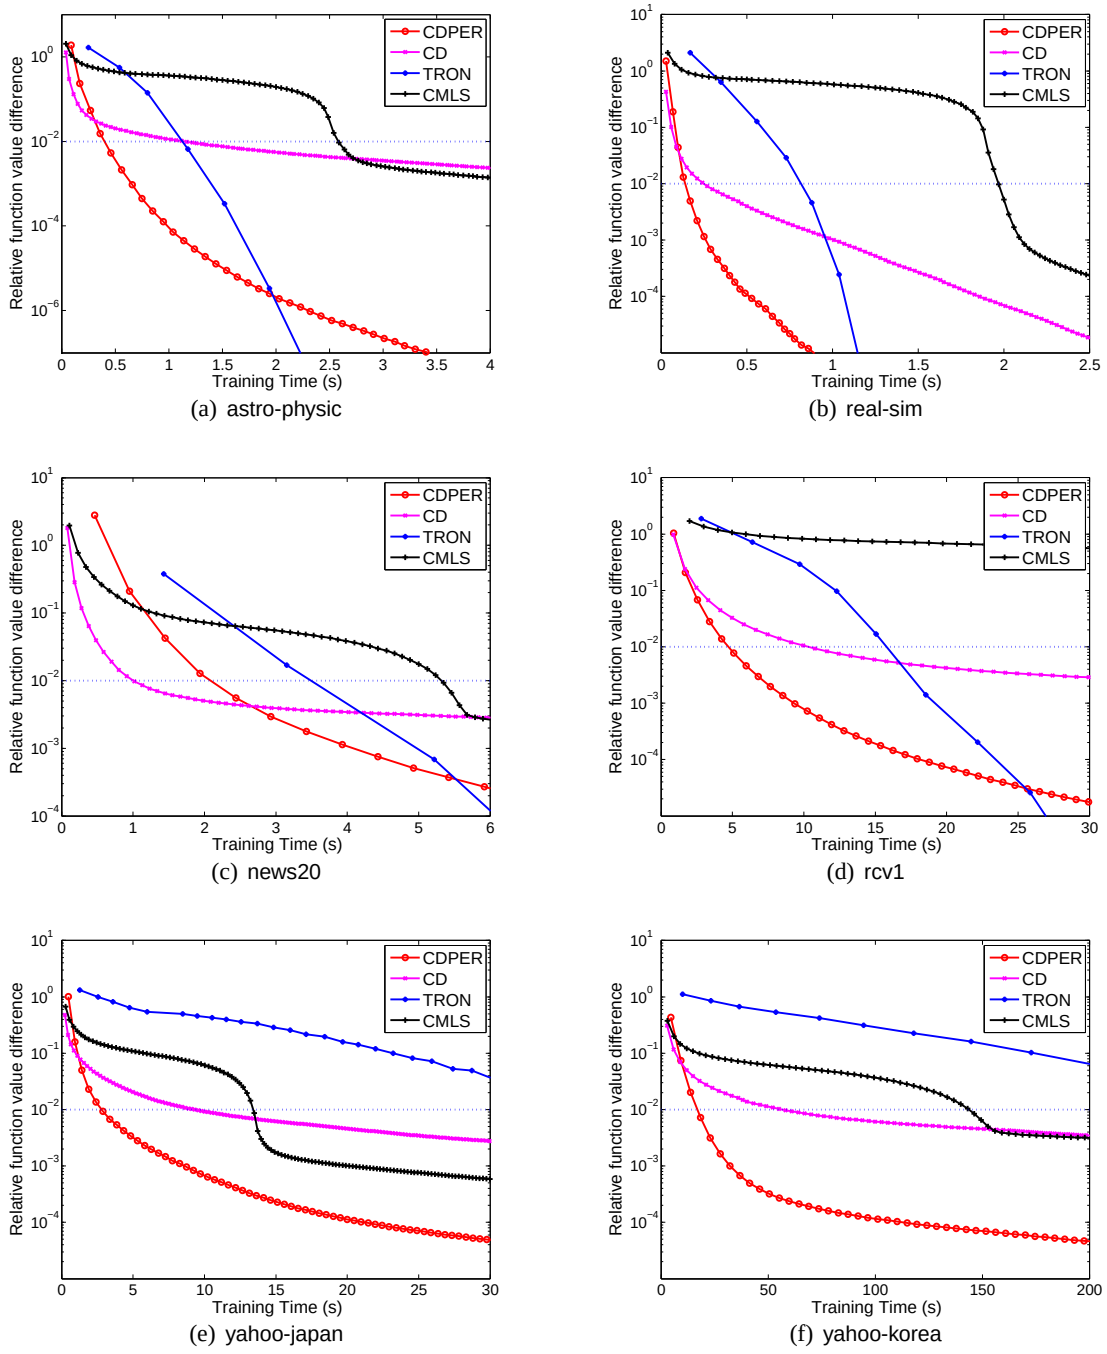

Figure 1: Time versus the relative difference of the objective value to the minimum. The dotted line indicates the relative difference 0.01. We show the training time for each solver to reach this ratio in Table 2. Time is in seconds. $C = 1$ is used.

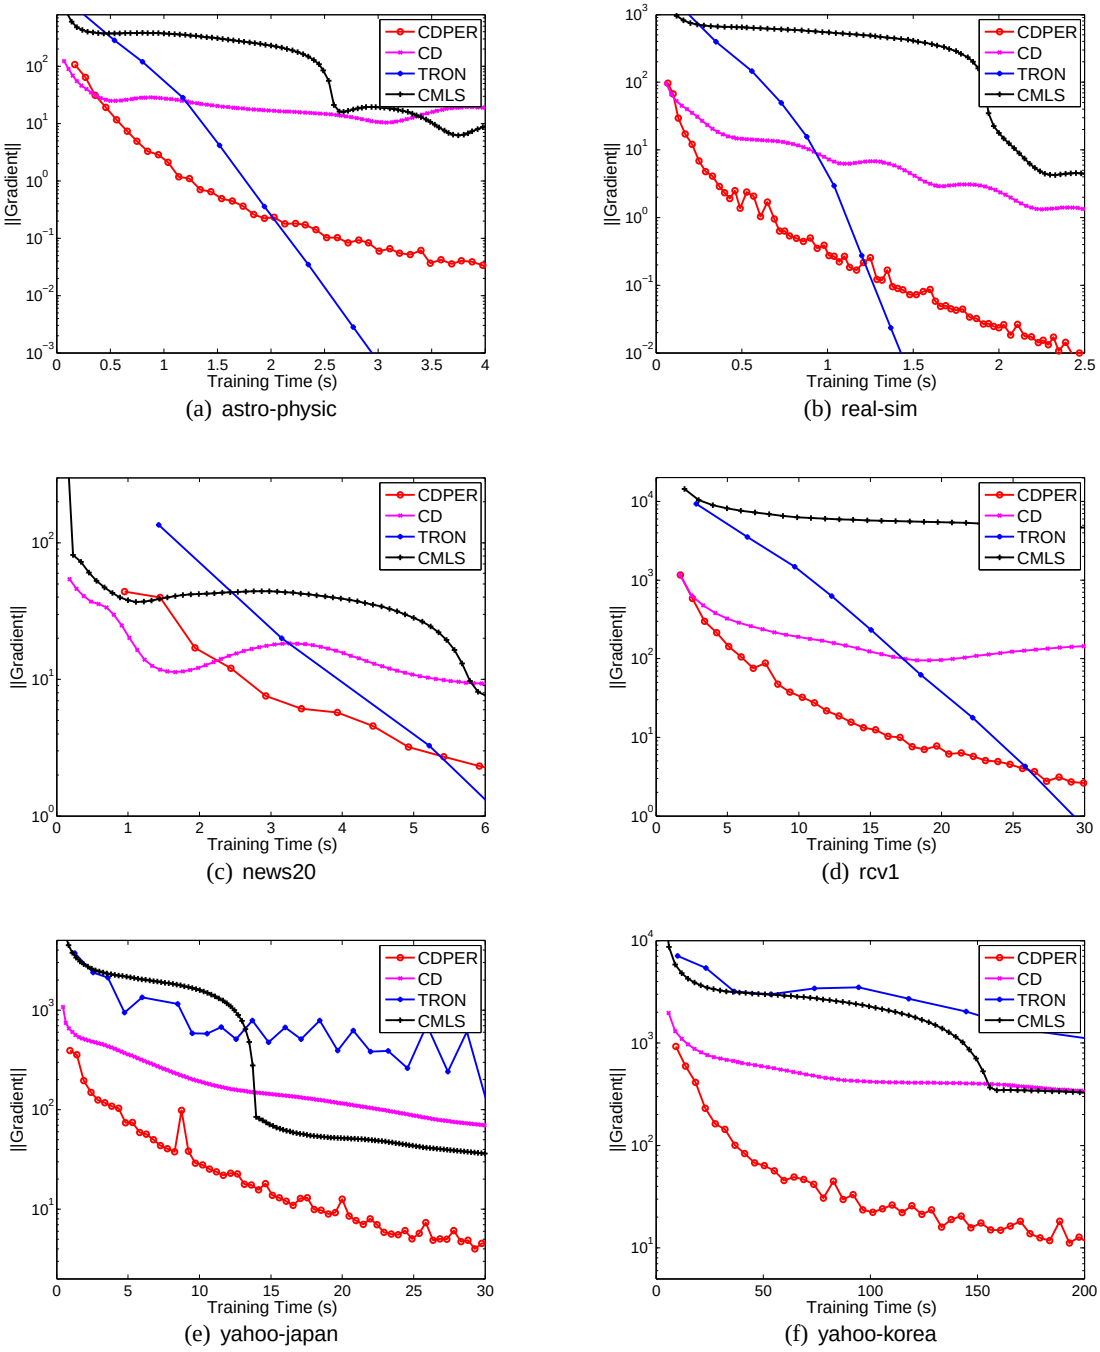

Figure 2: The two-norm of gradient versus the training time. Time is in seconds. $C = 1$ is used.

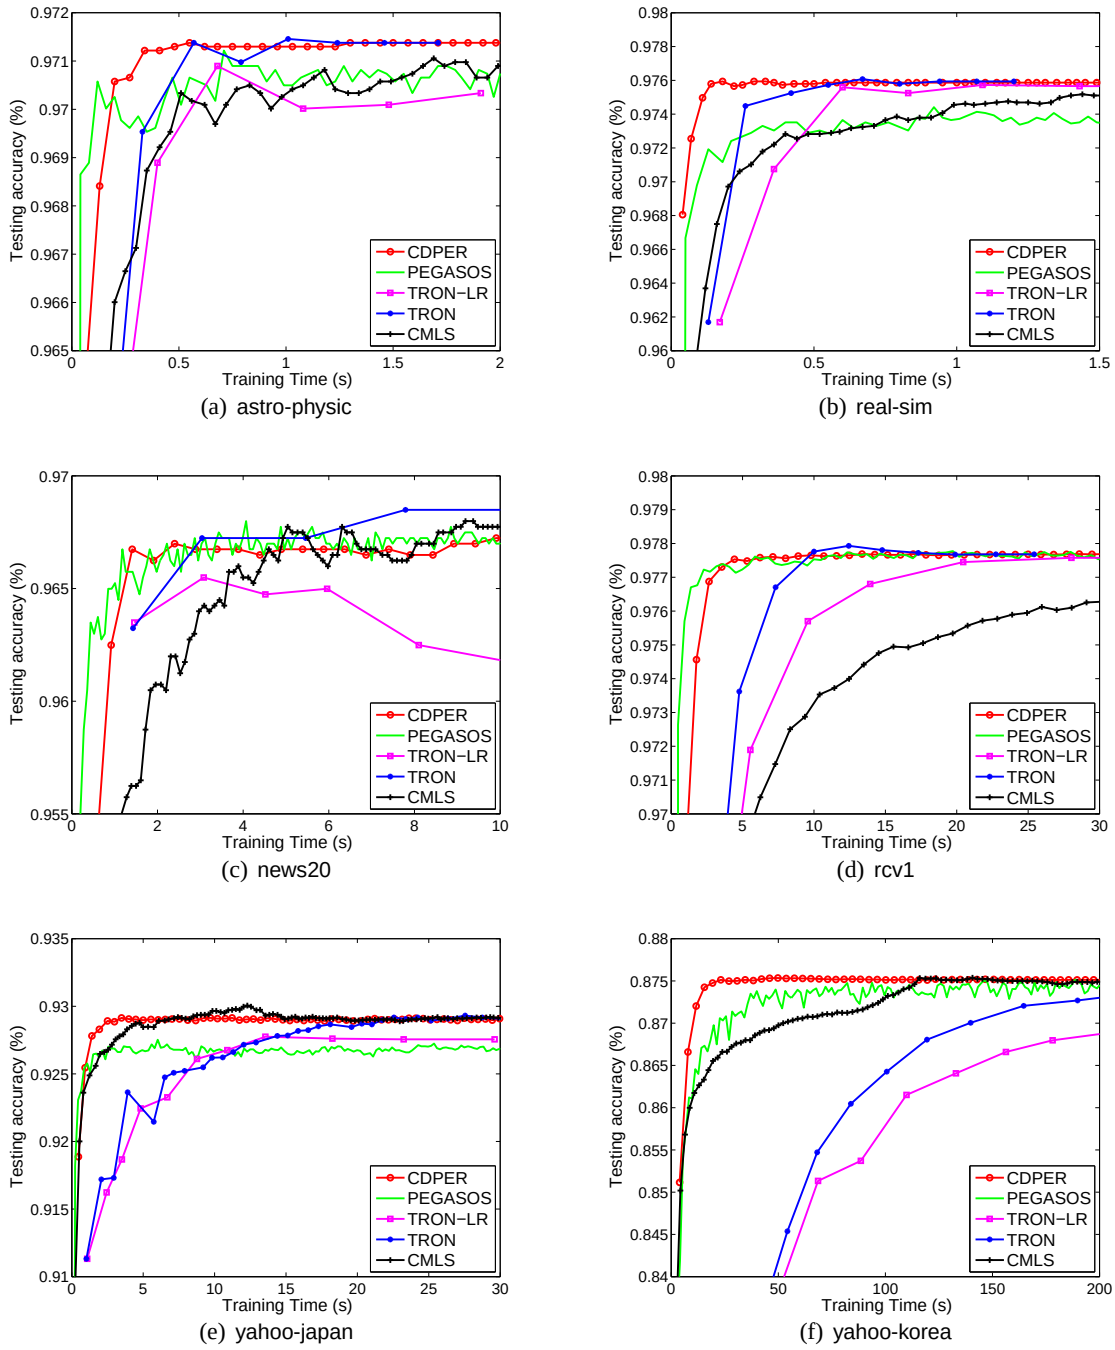

Figure 3: Testing accuracy versus the training time. Time is in seconds. We train each data set using the best C from cross validation. (see Table 3 for details.)

testing set. Table 3 presents the testing accuracy. Notice that some solvers scale the SVM formulation, so we adjust their regularization parameter C accordingly.[2] With the best parameter setting, SVM (L1 and L2) and logistic regression give comparable generalization performances. In Figure 3, we present the testing accuracy along the training time. As an accurate solution of the SVM optimization problem does not imply the best testing accuracy, some implementations achieve higher accuracy before reaching the minimal function value. Below we give some observations of the experiments.

We do not include CD in Figure 3, because CDPER is better than it in almost all situations. One may ask if simply shuffling features once in the beginning can give similar performances to CDPER. Moreover, we can apply permutation schemes to CMLS as well. In Section 6.1, we give a detailed discussion on the issue of feature permutations.

Regarding the online setting of randomly selecting only one feature at each step (Algorithm 3), we find that results are similar to those of CDPER.

From the experimental results, CDPER converges faster than CMLS. Both are coordinate descent methods, and the cost per iteration is similar. However, CMLS suffers from lengthy iterations because its modified Newton method takes a conservative step size. In Figure 3(d), the testing accuracy even does not reach a reasonable value after 30 seconds. Conversely, CDPER usually uses full Newton steps, so it converges faster. For example, CDPER takes the full Newton step in 99.997% inner iterations for solving rcv1 (we check up to 5.96 seconds).

Though Pegasos is efficient for several data sets, the testing accuracy is sometimes unstable (see Figure 3(c)). As Pegasos only subsamples one training data to update $\mathbf{w}^k$, it is influenced more by noisy data. We also observe slow final convergence on the function value. This slow convergence may make the selection of stopping conditions (maximal number of iterations for Pegasos) more difficult.

Finally, compared to TRON and TRON-LR, CDPER is more efficient to yield good testing accuracy (See Table 2 and Figure 3); however, if we check the value $||\nabla f(\mathbf{w}^k)||$, Figure 2 shows that TRON converges faster in the end. This result is consistent with what we discussed in Section 1 on distinguishing various optimization methods. We indicated that a Newton method (where TRON is) has fast final convergence. Unfortunately, since the cost per TRON iteration is high, and the Newton direction is not effective in the beginning, TRON is less efficient in the early stage of the optimization procedure.

5.3 Stopping Conditions

In this section, we discuss stopping conditions of our algorithm and other existing methods. In solving a strictly convex optimization problem, the norm of gradients is often considered in the stopping condition. The reason is that

$$\|\nabla f(\mathbf{w})\| = 0 \iff \mathbf{w} \text{ is the global minimum.}$$

For example, TRON checks whether the norm of gradient is small enough for stopping. However, as our coordinate descent method updates one component of $\mathbf{w}$ at each inner iteration, we have only $D_i'(0) = \nabla f(\mathbf{w}^{k,i})_i, i = 1,\ldots,n$. Theorem 2 shows that $\mathbf{w}^{k,i} \to \mathbf{w}^*$, so we have

$$D_i'(0) = \nabla f(\mathbf{w}^{k,i})_i \to 0, \forall i.$$

2. The objective function of Pegasos and (2) are equivalent by setting $\lambda = 1/(C \times \text{number of instances})$, where λ is the penalty parameter used by Shalev-Shwartz et al. (2007).

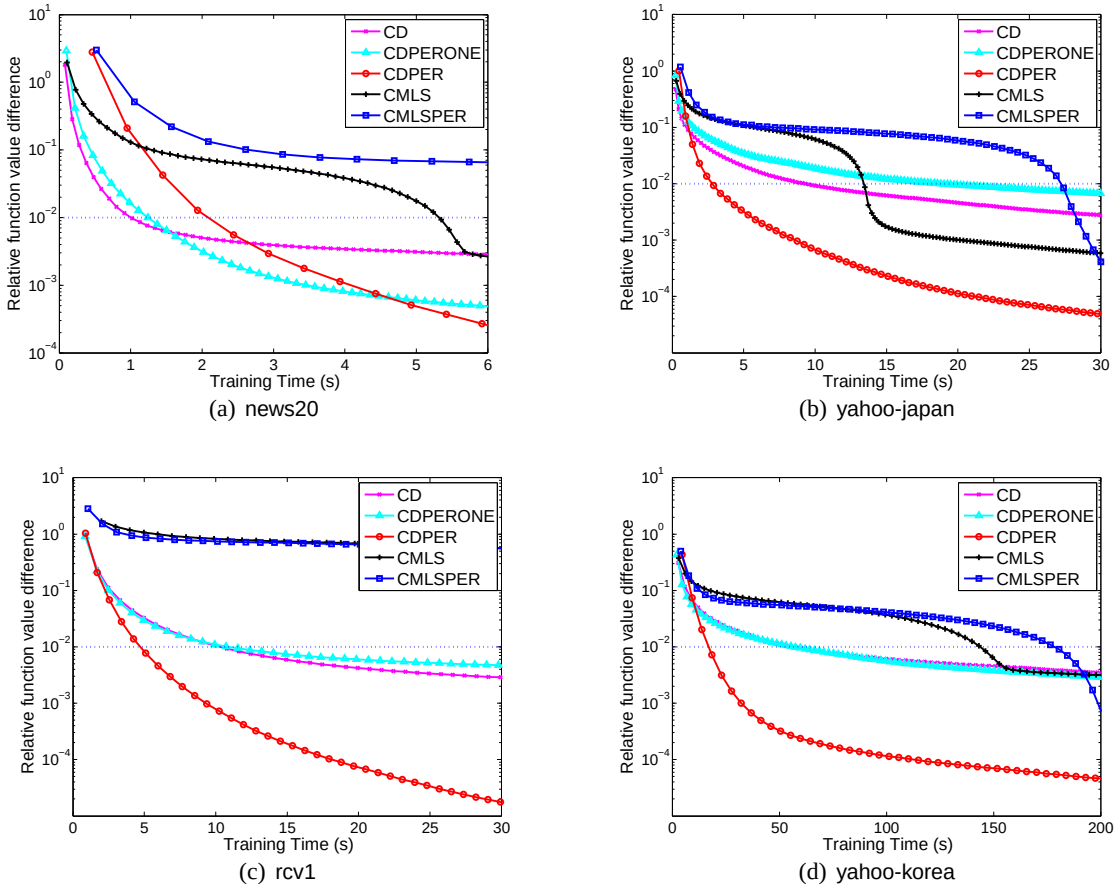

Figure 4: Results of different orders of sub-problems at each outer iteration. We present time versus the relative difference of the objective value to the minimum. Time is in second.

Therefore, by storing $D_i(0), \forall i$, at the end of the kth iteration, one can check if $\sum_{i=1}^{n} D_i'(0)^2$ or $\max_i |D_i'(0)|$ is small enough. For Pegasos, we mentioned in Section 4.1 that one may need a maximal number of iterations as the stopping condition due to the lack of function/gradient information. Another possible condition is to check the validation accuracy. That is, the training procedure terminates after reaching a stable validation accuracy value.

6. Discussion and Conclusions

In this section, we discuss some related issues and give conclusions.

6.1 Order of Sub-problems at Each Outer Iteration

In Section 5.2, we show that a random order of the sub-problems helps our coordinate descent method to converge faster in most cases. In this section, we give detailed experiments. Following the same setting in Figure 1, we compare our coordinate descent method with/without permutation

of sub-problems (CDPER and CD), with permutation only once before training (CDPERONE), and CMLS with/without permuting sub-problems (CMLS and CMLSPER). Figure 4 shows the relative difference of the objective value to the minimum along time. Overall, CDPER converges faster than CDPERONE and CD, but CMLSPER does not improve over CMLS much.

With the permutation of features at each iteration, the cost per CDPER iteration is slightly higher than CD, but CDPER requires much fewer iterations to achieve a similar accuracy value. This result seems to indicate that if the sub-problem order is fixed, the update of variables becomes slower. However, as CD sequentially accesses features, it has better data locality in the computer memory hierarchy. An example is news20 in Figure 4(a). As the number of features is much larger than the number of instances, two adjacent sub-problems of CDPER may access two very far away features. Then the cost per CD iteration is only 1/5 of CDPER, so CD is better in the beginning. CDPER catches up in the end due to its faster convergence.

For CMLS and CMLSPER, the latter is only faster in the final stage (see the right end of Figures 4(b) and 4(d)). Since the function reduction of CMLS (or CMLSPER) is slow, the advantage of doing permutations appears after long training time.

The main difference between CDPERONE and CDPER is that the former only permutes features once in the beginning. Figure 4 clearly shows that CDPER is better than CDPERONE, so permuting features only once is not enough. If we compare CD and CDPERONE, there is no definitive winner. This result seems to indicate that feature ordering affects the performance of the coordinate descent method. By using various feature orders, CDPER avoids taking a bad one throughout all iterations.

6.2 Coordinate Descents for Logistic Regression

We can apply the proposed coordinate descent method to solve logistic regression, which is twice differentiable. An earlier study of using coordinate decent methods for logistic regression/maximum entropy is by Miroslav et al. (2004). We compare an implementation with TRON-LR. Surprisingly, our method is not better in most cases. Experiments show that for training rcv1, our coordinate descent method takes 93.1 seconds to reduce the objective value to within 1% of the optimal value, while TRON-LR takes 27.9 seconds. Only for yahoo-japan and yahoo-korea, where TRON-LR is slow (see Figure 3), the coordinate descent method is competitive. This result is contrast to earlier experiments for L2-SVM, where the coordinate descent method more quickly obtains a useful model than TRON. We give some explanations below.

With the logistic loss, the objective function is (4). The single-variable function $D_i(z)$ is non-linear, so we use Algorithm 2 to obtain an approximate minimum. To use the Newton direction, similar to $D_i'(z)$ and $D_i''(z)$ in (9) and (10), we need

$$D_i'(0) = \nabla_i f(\mathbf{w}) = w_i + C \sum_{j:x_{ji}\neq 0} \frac{-y_j x_{ji} e^{-y_j \mathbf{w}^T \mathbf{x}_j}}{1+e^{-y_j \mathbf{w}^T \mathbf{x}_j}},$$

$$D_i''(0) = \nabla_{ii}^2 f(\mathbf{w}) = 1 + C \sum_{j:x_{ji}\neq 0} \frac{x_{ji}^2 e^{-y_j \mathbf{w}^T \mathbf{x}_j}}{(1+e^{-y_j \mathbf{w}^T \mathbf{x}_j})^2},$$

where we abbreviate $\mathbf{w}^{k,i}$ to $\mathbf{w}$, and use $y_j = \pm 1$. Then $|\{j \mid x_{ji} \neq 0\}|$ exponential operations are conducted. If we assume that $\lambda = 1$ satisfies the sufficient decrease condition (12), then the cost per outer iteration is

$$O(\#\text{nz}) + (\#\text{nz exponential operations}). \tag{32}$$

This complexity is the same as (19) for L2-SVM. However, since each exponential operation is expensive (equivalent to tens of multiplications/divisions), in practice (32) is much more time consuming. For TRON-LR, a trust region Newton method, it calculates $\nabla f(\mathbf{w})$ and $\nabla^2 f(\mathbf{w})$ at the beginning of each iteration. Hence l exponential operations are needed for $\exp(-y_j \mathbf{w}^T \mathbf{x}_j), j = 1, \ldots, l$. From (27), the cost per iteration is

$$O(\#\text{nz}) \times (\#\text{ conjugate gradient iterations}) + (l \text{ exponential operations}). \tag{33}$$

Since $l \ll \#\text{nz}$, exponential operations are not significant in (33). Therefore, the cost per iteration of applying trust region Newton methods to L2-SVM and logistic regression does not differ much. In contrast, (32) shows that coordinate descent methods are less suitable for logistic regression than L2-SVM. However, we may avoid expensive exponential operations if all the elements of $\mathbf{x}_j$ are either 0 or the same constant. By storing $\exp(-y_j \mathbf{w}^T \mathbf{x}_j), j = 1, \ldots, l$, one updates $\exp(-y_j (\mathbf{w}^{k,i})^T \mathbf{x}_j)$ by multiplying it by $\exp(-z y_j x_{ji})$. Using $y_j = \pm 1$, $\exp(-z y_j x_{ji}) = (\exp(-z x_{ji}))^{y_j}$. As x_{ji} is zero or a constant for all j, the number of exponential operations per inner iteration is reduced to one. In addition, applying fast approximations of exponential operations such as Schraudolph (1999) may speed up the coordinate descent method for logistic regression.

6.3 Conclusions

In summary, we propose and analyze a coordinate descent method for large-scale linear L2-SVM. The new method possesses sound optimization properties. The method is suitable for data with an easy access of any feature. Experiments indicate that our method is more stable and efficient than most existing algorithms. We plan to extend our work to other challenging problems such as training large data which can not fit into memory.

Appendix A. Proofs

In this section, we prove theorems appeared in the paper. First, we discuss some properties of our objective function $f(\mathbf{w})$. Consider the following piecewise quadratic strongly convex function:

$$g(\mathbf{s}) = \frac{1}{2}\mathbf{s}^T \mathbf{s} + C\|(A\mathbf{s} - \mathbf{h})_+\|^2, \tag{34}$$

where $(\cdot)_+$ is the operator that replaces negative components of a vector with zeros. Mangasarian (2002) proves the following inequalities for all $\mathbf{s}, \mathbf{v} \in R^n$:

$$(\nabla g(\mathbf{s}) - \nabla g(\mathbf{v}))^T (\mathbf{s} - \mathbf{v}) \geq \|\mathbf{s} - \mathbf{v}\|^2, \tag{35}$$

$$|g(\mathbf{v}) - g(\mathbf{s}) - \nabla g(\mathbf{s})^T (\mathbf{v} - \mathbf{s})| \leq \frac{K}{2}\|\mathbf{v} - \mathbf{s}\|^2, \tag{36}$$

where

$$K = 1 + 2C\|A\|_2^2.$$

Our objective function $f(\mathbf{w})$ is a special case of (34) with $A = YX$ (X is defined in Eq. 20) and $\mathbf{h} = -\mathbf{1}$, where Y is a diagonal matrix with $Y_{jj} = y_j$, $j = 1,\ldots,l$ and $\mathbf{1}$ is the vector of all ones. With $y_i = \pm 1$, $f(\mathbf{w})$ satisfies (35) and (36) with

$$K = 1 + 2C\|X\|_2^2. \tag{37}$$

To derive properties of the subproblem $D_i(z)$ (defined in Eq. 8), we set

$$A = -\begin{bmatrix} y_1 x_{1i} \\ \vdots \\ y_l x_{li} \end{bmatrix} \text{ and } \mathbf{h} = \begin{bmatrix} y_1 \mathbf{w}^T \mathbf{x}_1 - y_1 w_i x_{1i} - 1 \\ \vdots \\ y_l \mathbf{w}^T \mathbf{x}_l - y_l w_i x_{li} - 1 \end{bmatrix},$$

where we abbreviate $\mathbf{w}^{k,i}$ to $\mathbf{w}$. Since

$$D_i(z) = \frac{1}{2}\mathbf{w}^T\mathbf{w} - \frac{1}{2}w_i^2 + \left(\frac{1}{2}(z+w_i)^2 + \|(A(z+w_i) - \mathbf{h})_+\|^2\right),$$

the first and second terms of the above form are constants. Hence, $D_i(z)$ satisfies (35) and (36) with

$$K = 1 + 2C\sum_{j=1}^{l} x_{ji}^2.$$

We use H_i to denote $D_i(z)$'s corresponding K. This definition of H_i is the same as the one in (14). We then derive several lemmas.

Lemma 5 *For any $i \in \{1,\ldots,n\}$, and any $z \in R$,*

$$D_i'(0)z + \frac{1}{2}H_i z^2 \geq D_i(z) - D_i(0) \geq D_i'(0)z + \frac{1}{2}z^2. \tag{38}$$

Proof There are two inequalities in (38). The first inequality directly comes from (36) using $D_i(z)$ as $g(\mathbf{s})$ and H_i as K. To derive the second inequality, if $z < 0$, using $D_i(z)$ as $g(\mathbf{s})$ in (35) yields

$$D_i'(z) \leq D_i'(0) + z.$$

Then,

$$D_i(z) - D_i(0) = -\int_{t=z}^{0} D_i'(t)dt \geq D_i'(0)z + \frac{1}{2}z^2.$$

The situation for $z \geq 0$ is similar.

■

Lemma 6 *There exists a unique optimum solution for* (3).

Proof From Weierstrass' Theorem, any continuous function on a compact set attains its minimum. We consider the level set $A = \{\mathbf{w} \mid f(\mathbf{w}) \leq f(\mathbf{0})\}$. If A is not bounded, there is a sub-sequence $\{\mathbf{w}^k\} \subset A$ such that $\|\mathbf{w}^k\| \to \infty$. Then

$$f(\mathbf{w}^k) \geq \frac{1}{2}\|\mathbf{w}^k\|^2 \to \infty.$$

This contradicts $f(\mathbf{w}^k) \leq f(\mathbf{0})$, so A is bounded. Thus there is at least one optimal solution for (3). Combining with the strict convexity of (3), a unique global optimum exists. ■

A.1 Proof of Theorem 1

Proof By Lemma 5, we let $z = \lambda d$ and have

$$\begin{aligned} & D_i(\lambda d) - D_i(0) + \sigma\lambda^2 d^2 \\ \leq\ & D_i'(0)\lambda d + \frac{1}{2}H_i\lambda^2 d^2 + \sigma\lambda^2 d^2 \\ =\ & -\lambda\frac{D_i'(0)^2}{D_i''(0)} + \frac{1}{2}H_i\lambda^2\frac{D_i'(0)^2}{D_i''(0)^2} + \sigma\lambda^2\frac{D_i'(0)^2}{D_i''(0)^2} \\ =\ & \lambda\frac{D_i'(0)^2}{D_i''(0)}\left(\lambda(\frac{H_i/2+\sigma}{D_i''(0)}) - 1\right). \end{aligned} \tag{39}$$

If we choose $\bar{\lambda} = \frac{D_i''(0)}{H_i/2+\sigma}$, then for $\lambda \leq \bar{\lambda}$, (39) is non-positive. Therefore, (12) is satisfied for all $0 \leq \lambda \leq \bar{\lambda}$. ■

A.2 Proof of Theorem 2 (convergence of Algorithm 1)

Proof By setting $\pi_k(i) = i$, this theorem is a special case of Theorem 3. ■

A.3 Proof of Theorem 3 (Convergence of Generalized Algorithm 1)

Proof To begin, we define 1-norm and 2-norm of a vector $\mathbf{w} \in R^n$:

$$\|\mathbf{w}\|_1 = \sum_{i=1}^{n}|w_i|, \quad \|\mathbf{w}\|_2 = \sqrt{\sum_{i=1}^{n} w_i^2}.$$

The following inequality is useful:

$$\|\mathbf{w}\|_2 \leq \|\mathbf{w}\|_1 \leq \sqrt{n}\|\mathbf{w}\|_2, \quad \forall \mathbf{w} \in R^n. \tag{40}$$

By Theorem 1, any $\lambda \in [\beta\bar{\lambda}, \bar{\lambda}]$ satisfies the sufficient decrease condition (12), where $\beta \in (0,1)$ and $\bar{\lambda}$ is defined in (14). Since Algorithm 2 selects λ by trying $\{1, \beta, \beta^2, \dots\}$, the value λ selected by Algorithm 2 satisfies

$$\lambda \geq \beta\bar{\lambda} = \frac{\beta}{H_i/2+\sigma}D''_{\pi_k(i)}(0).$$

This and (13) suggest that the step size $z = \lambda d$ in Algorithm 2 satisfies

$$|z| = \lambda\left|\frac{-D'_{\pi_k(i)}(0)}{D''_{\pi_k(i)}(0)}\right| \geq \frac{\beta}{H_i/2+\sigma}|D'_{\pi_k(i)}(0)|. \tag{41}$$

Assume

$$H = \max(H_1, \dots, H_n) \text{ and } \gamma = \frac{\beta}{H/2+\sigma}. \tag{42}$$

We use $\mathbf{w}$ and $f(\mathbf{w})$ to rewrite (41):

$$|w^{k,i+1}_{\pi_k(i)} - w^{k,i}_{\pi_k(i)}| \geq \gamma |\nabla f(\mathbf{w}^{k,i})_{\pi_k(i)}|, \tag{43}$$

where we use the fact

$$D'_{\pi_k(i)}(0) = \nabla f(\mathbf{w}^{k,i})_{\pi_k(i)}.$$

Taking the summation of (43) from $i = 1$ to n, we have

$$\begin{aligned}
\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 &\geq \gamma \sum_{i=1}^{n} |\nabla f(\mathbf{w}^{k,i})_{\pi_k(i)}| \\
&\geq \gamma \sum_{i=1}^{n} (|\nabla f(\mathbf{w}^{k,1})_{\pi_k(i)}| - |\nabla f(\mathbf{w}^{k,i})_{\pi_k(i)} - \nabla f(\mathbf{w}^{k,1})_{\pi_k(i)}|) \\
&= \gamma \left(\|\nabla f(\mathbf{w}^{k,1})\|_1 - \sum_{i=1}^{n} |\nabla f(\mathbf{w}^{k,i})_{\pi_k(i)} - \nabla f(\mathbf{w}^{k,1})_{\pi_k(i)}| \right).
\end{aligned} \tag{44}$$

By the definition of $f(\mathbf{w})$ in (3),

$$\nabla f(\mathbf{w}) = \mathbf{w} - 2C \sum_{j=1}^{l} y_j \mathbf{x}_j \max(1 - y_j \mathbf{w}^T \mathbf{x}_j, 0).$$

With $y_j = \pm 1$,

$$\begin{aligned}
&\sum_{i=1}^{n} |\nabla f(\mathbf{w}^{k,i})_{\pi_k(i)} - \nabla f(\mathbf{w}^{k,1})_{\pi_k(i)}| \\
\leq &\sum_{i=1}^{n} \left(|w^{k,i}_{\pi_k(i)} - w^{k,1}_{\pi_k(i)}| + 2C \sum_{j=1}^{l} |x_{j\pi_k(i)}| \, |(\mathbf{w}^{k,i})^T \mathbf{x}_j - (\mathbf{w}^{k,1})^T \mathbf{x}_j| \right) \\
\leq &\sum_{i=1}^{n} \left(|w^{k+1}_{\pi_k(i)} - w^{k}_{\pi_k(i)}| + 2C \sum_{j=1}^{l} |x_{j\pi_k(i)}| \sum_{q=1}^{n} |x_{jq}| \, |w^{k,i}_q - w^{k,1}_q| \right) \\
= &\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 + 2C \sum_{i=1}^{n} \sum_{j=1}^{l} \sum_{q=1}^{n} |x_{j\pi_k(i)}| \, |x_{jq}| \, |w^{k,i}_q - w^{k,1}_q| \\
\leq &\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 + 2C \sum_{q=1}^{n} |w^{k+1}_q - w^k_q| \sum_{i,j: x_{j\pi_k(i)} \neq 0} P^2 \\
= &(1 + 2CP^2(\#\text{nz})) \|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1,
\end{aligned} \tag{45}$$

where P is defined in (6). From (44) and (45), we have

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 \geq \frac{\gamma}{1 + \gamma + 2\gamma CP^2(\#\text{nz})} \|\nabla f(\mathbf{w}^{k,1})\|_1.$$

With (40),

$$\begin{aligned}
&\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_2 \geq \frac{1}{\sqrt{n}} \|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 \\
\geq &\frac{\gamma}{\sqrt{n}(1 + \gamma + 2\gamma CP^2(\#\text{nz}))} \|\nabla f(\mathbf{w}^k)\|_1 \geq \frac{\gamma}{\sqrt{n}(1 + \gamma + 2\gamma CP^2(\#\text{nz}))} \|\nabla f(\mathbf{w}^k)\|_2.
\end{aligned} \tag{46}$$

From Lemma 6, there is a unique global optimum $\mathbf{w}^*$ for (3). The optimality condition shows that

$$\nabla f(\mathbf{w}^*) = \mathbf{0}. \tag{47}$$

From (35) and (47),

$$\|\mathbf{w}^k - \mathbf{w}^*\|_2 \le \|\nabla f(\mathbf{w}^k) - \nabla f(\mathbf{w}^*)\|_2 = \|\nabla f(\mathbf{w}^k)\|_2. \tag{48}$$

With (46),

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_2 \ge \tau \|\mathbf{w}^k - \mathbf{w}^*\|_2, \quad \text{where } \tau = \frac{\gamma}{\sqrt{n}(1+\gamma+2\gamma CP^2(\#\text{nz}))}. \tag{49}$$

From (12) and (49),

$$\begin{aligned} f(\mathbf{w}^k) - f(\mathbf{w}^{k+1}) &= \sum_{i=1}^{n} (f(\mathbf{w}^{k,i}) - f(\mathbf{w}^{k,i+1})) \\ &\ge \sum_{i=1}^{n} \sigma (w^{k,i+1}_{\pi_k(i)} - w^{k,i}_{\pi_k(i)})^2 = \sigma \|\mathbf{w}^{k+1} - \mathbf{w}^k\|_2^2 \ge \sigma\tau^2 \|\mathbf{w}^k - \mathbf{w}^*\|_2^2. \end{aligned}$$

By (36) and (47),

$$f(\mathbf{w}^k) - f(\mathbf{w}^*) \le \frac{K}{2} \|\mathbf{w}^k - \mathbf{w}^*\|_2^2, \tag{50}$$

where K is defined in (37). Therefore, we have

$$f(\mathbf{w}^k) - f(\mathbf{w}^{k+1}) \ge \frac{2\sigma\tau^2}{K} (f(\mathbf{w}^k) - f(\mathbf{w}^*)).$$

This is equivalent to

$$(f(\mathbf{w}^k) - f(\mathbf{w}^*)) + (f(\mathbf{w}^*) - f(\mathbf{w}^{k+1})) \ge \frac{2\sigma\tau^2}{K} (f(\mathbf{w}^k) - f(\mathbf{w}^*)).$$

Finally, we have

$$f(\mathbf{w}^{k+1}) - f(\mathbf{w}^*) \le (1 - \frac{2\sigma\tau^2}{K})(f(\mathbf{w}^k) - f(\mathbf{w}^*)). \tag{51}$$

With $\tau \le 1$ from (49), $K \ge 1$ from (37) and $\sigma < 1/2$, we have $2\sigma\tau^2/K < 1$. Hence, (51) ensures that $f(\mathbf{w}^k)$ approaches $f(\mathbf{w}^*)$.

From (51), $\{f(\mathbf{w}^k)\}$ converges to $f(\mathbf{w}^*)$. We can then prove that $\{\mathbf{w}^k\}$ globally converges to $\mathbf{w}^*$. If this result does not hold, there is a sub-sequence $\{\mathbf{w}^k\}_M$ converging to a point $\bar{\mathbf{w}} \ne \mathbf{w}^*$. However, Lemma 6 shows that $f(\bar{\mathbf{w}}) > f(\mathbf{w}^*)$, so $\lim_{k \in M} f(\mathbf{w}^k) > f(\mathbf{w}^*)$, a contradiction.

Let $\mu = 2\sigma\tau^2/K$, (51) implies

$$f(\mathbf{w}^k) - f(\mathbf{w}^*) \le (1-\mu)^k (f(\mathbf{w}^0) - f(\mathbf{w}^*)), \ \forall k.$$

To achieve an ε-accurate solution, we need the right-hand side to be smaller than ε. Thus,

$$k \ge \frac{\log(f(\mathbf{w}^0) - f(\mathbf{w}^*)) + \log(1/\varepsilon)}{-\log(1-\mu)}.$$

From the inequality

$$\log(1-x) \leq -x \text{ if } x < 1,$$

we have

$$k \geq \frac{\log(f(\mathbf{w}^0) - f(\mathbf{w}^*)) + \log(1/\varepsilon)}{\mu}. \tag{52}$$

In following we discuss the order of $\mu^{-1} = \frac{K}{2\sigma\tau^2}$. From (37),

$$K = 2C\|X\|_2^2 + 1 \leq 2C\|X\|_F^2 + 1 \leq 2CP^2(\#\text{nz}) + 1, \tag{53}$$

where $\|\cdot\|_F$ is the Frobenious norm. From (49),

$$\tau^{-1} = \sqrt{n}\left(\frac{1}{\gamma} + 2CP^2(\#\text{nz}) + 1\right).$$

Since $\gamma = \frac{\beta}{\sigma + H/2}$, from (14) and (42) we have

$$\gamma^{-1} = O(lCP^2 + 1) \leq O(CP^2(\#\text{nz}) + 1). \tag{54}$$

As #nz is usually large, we omit the constant term $O(1)$ in the following discussion. Then $\tau^{-1} = O(\sqrt{n}CP^2(\#\text{nz}))$. Thus,

$$\mu^{-1} = \frac{K}{2\sigma\tau^2} = O(nC^3P^6(\#\text{nz})^3). \tag{55}$$

From (52) and (55), Algorithm 1 obtains an ε-accurate solution in

$$O\left(nC^3P^6(\#\text{nz})^3\log(1/\varepsilon)\right)$$

iterations. ■

A.4 Proof of Theorem 4 (Linear Convergence of the Online Setting)

Proof To begin, we denote the expectation value of a function g of a random variable y to be

$$E_y(g(y)) = \sum_y P(y)g(y).$$

Then for any vector $\mathbf{s} \in R^n$ and a random variable I where

$$P(I = i) = \frac{1}{n},\ \forall i \in \{1, \ldots, n\},$$

we have

$$E_I(s_I^2) = \sum_{i=1}^{n} \frac{s_i^2}{n} = \frac{1}{n}\|\mathbf{s}\|_2^2. \tag{56}$$

At each iteration k ($k = 0, 1, \ldots$) of Algorithm 3, we randomly choose one index i_k and update $\mathbf{w}^k$ to $\mathbf{w}^{k+1}$. The expected function value after iteration k can be represented as

$$E_{i_0,\ldots,i_{k-1},i_k}(f(\mathbf{w}^{k+1})).$$

From (12), (43), (56), (48), and (50), we have

$$\begin{aligned}
& E_{i_0,\ldots,i_{k-1}} E_{i_k}(f(\mathbf{w}^k) - f(\mathbf{w}^{k+1})) \\
\geq\ & \sigma E_{i_0,\ldots,i_{k-1}} E_{i_k}(|w_{i_k}^{k+1} - w_{i_k}^k|^2) \\
\geq\ & \sigma\gamma^2 E_{i_0,\ldots,i_{k-1}} E_{i_k}(|\nabla f(\mathbf{w}^k)_{i_k}|^2) \\
=\ & \frac{\sigma\gamma^2}{n} E_{i_0,\ldots,i_{k-1}}(\|\nabla f(\mathbf{w}^k)\|_2^2) \\
\geq\ & \frac{\sigma\gamma^2}{n} E_{i_0,\ldots,i_{k-1}}(\|\mathbf{w}^k - \mathbf{w}^*\|_2^2) \\
\geq\ & \frac{2\sigma\gamma^2}{nK} E_{i_0,\ldots,i_{k-1}}(f(\mathbf{w}^k) - f(\mathbf{w}^*)).
\end{aligned}$$

This is equivalent to

$$E_{i_0,\ldots,i_k}(f(\mathbf{w}^{k+1})) - f(\mathbf{w}^*) \leq \left(1 - \frac{2\sigma\gamma^2}{nK}\right)\left(E_{i_0,\ldots,i_{k-1}}(f(\mathbf{w}^k)) - f(\mathbf{w}^*)\right).$$

From Markov inequality $P(|Z| \geq a) \leq E(|Z|)/a$ for any random variable Z and the fact $f(\mathbf{w}^{k+1}) \geq f(\mathbf{w}^*)$, we have

$$P\left(f(\mathbf{w}^k) - f(\mathbf{w}^*) \geq \varepsilon\right) \leq E\left(f(\mathbf{w}^k) - f(\mathbf{w}^*)\right)/\varepsilon. \tag{57}$$

To achieve an ε-accurate solution with confidence $1-\delta$, we need the right-hand side of (57) to be less than δ. This indicates the iteration number k must satisfy

$$E_{i_0,\ldots,i_{k-1}}(f(\mathbf{w}^k)) - f(\mathbf{w}^*) \leq (f(\mathbf{w}^0) - f(\mathbf{w}^*))\left(1 - \frac{2\sigma\gamma^2}{nK}\right)^k \leq \varepsilon\delta.$$

By a derivation similar to Theorem 3, we can show that after $O(\frac{nK}{\sigma\gamma^2}\log(\frac{1}{\delta\varepsilon}))$ iterations, with confidence $1-\delta$, we obtain an ε-accurate solution. From (53) and (54), we have

$$K \leq 2CP^2(\#\text{nz}) + 1 \text{ and } \gamma^{-1} = O(lCP^2 + 1).$$

Therefore,

$$O\left(\frac{nK}{\sigma\gamma^2}\log(\frac{1}{\delta\varepsilon})\right) = O\left(nl^2C^3P^6(\#\text{nz})\log(\frac{1}{\delta\varepsilon})\right).$$

Abstract

We describe and analyze an algorithmic framework for online classification where each online trial consists of *multiple* prediction tasks that are tied together. We tackle the problem of updating the online predictor by defining a projection problem in which each prediction task corresponds to a single linear constraint. These constraints are tied together through a single slack parameter. We then introduce a general method for approximately solving the problem by projecting *simultaneously* and independently on each constraint which corresponds to a prediction sub-problem, and then averaging the individual solutions. We show that this approach constitutes a feasible, albeit not necessarily optimal, solution of the original projection problem. We derive concrete simultaneous projection schemes and analyze them in the mistake bound model. We demonstrate the power of the proposed algorithm in experiments with synthetic data and with multiclass text categorization tasks.

Keywords: online learning, parallel computation, mistake bounds, structured prediction

1. Introduction

We discuss and analyze an algorithmic framework for complex prediction problems in the online learning model. Our construction unifies various complex prediction tasks by considering a setting in which at each trial the learning algorithm should make multiple binary decisions. We present a simultaneous online update rule that uses the entire set of binary examples received at each trial while retaining the simplicity of algorithms whose update is based on a single binary example.

Online learning is performed in a sequence of consecutive trials. At the beginning of each trial, the algorithm first receives an instance and is required to make a prediction in some complex domain. The prediction is generated using an hypothesis constructed by the algorithm. Once the algorithm makes a prediction it receives the correct target and is allowed to update its hypothesis. In this paper we consider an online learning model in which the complex prediction task can be cast as multiple binary decisions. Such a view is common in Multiclass categorization tasks, for example in Crammer et al. (2006), Crammer and Singer (2003), and Allwein et al. (2000). There,

the complex problem of predicting which label out of k possible labels is the correct label is cast as a set of binary prediction problems, each of which focuses on two labels.

Previous approaches to this construction can be roughly divided into two paradigms. The first paradigm, which we term the *max update*, tackles the problem by selecting a *single* binary problem and updating the algorithm's hypothesis based on that problem solely. While this approach is sub-optimal, it is often very simple to implement and quite effective in practice. The second approach considers all the binary problems and incorporates the entire information contained for updating the hypothesis. The second approach thus performs an optimal update at the price of often incurring higher computational costs.

We introduce a third approach, which enjoys the simplicity and performance of the max-update approach, while incorporating information expressed in *all* binary problems. Our family of algorithms achieves this goal by considering each instance *separately* and acting *simultaneously*. An update is constructed for each binary sub-problem, and then all the updates are combine together to form the new online hypothesis. As we show in the sequel, the update rule due to each binary example amounts to a projection operation. We thus denote our approach as the *simultaneous projections* approach.

We propose a simple, general, and efficient framework for online learning of a wide variety of complex problems. We do so by casting the online update task as an optimization problem in which the newly devised hypothesis is required to be close to the current hypothesis while attaining a small loss on *multiple* binary prediction problems. Casting the online learning task as a sequence of instantaneous optimization problems was first suggested and analyzed by Kivinen and Warmuth (1997) for binary classification and regression problems. In our optimization-based approach, the complex decision problem is cast as an optimization problem that consists of *multiple* linear constraints each of which represents a single binary example. These constraints are tied through a *single* slack variable whose role is to assess the *overall* prediction quality for the complex problem.

The max-update approach described above selects a single binary example, which translates into a single constraint. Performing the update thus becomes a simple projection task, where an analytical solution can often be easily devised. In contrast, the optimal update seeks the optimal solution of the instantaneous optimization problem. However, in the general case no analytical solution can be found, and the algorithm is required to resort to a full scale numeric solver.

We describe and analyze a family of two-phase algorithms. In the first phase, the algorithms solve *simultaneously* multiple sub-problems. Each sub-problem distills to an optimization problem with a *single* linear constraint from the original multiple-constraints problem. The simple structure of each single-constraint problem results in an analytical solution, which is efficiently computable. In the second phase, the algorithms take a convex combination of the independent solutions to obtain a solution for the multiple-constraints problem. We further explore the structure of our problem and attain an update form that combines the two phases while maintaining the simplicity of the simultaneous projection scheme. The end result is an approach whose time complexity and mistake bounds are equivalent to approaches which solely deal with the worst-violating constraint (Crammer et al., 2006). In practice, though, the performance of the simultaneous projection framework is much better than update schemes that are based on a single-constraint .

We introduce an additive and multiplicative variants of our framework. The additive framework extends additive algorithms such as the Perceptron (Rosenblatt, 1958) and the family of Passive-Aggressive algorithms (Crammer et al., 2006) to our settings. We then present a multiplicative family of simultaneous algorithms that extends the Winnow family of algorithms (Littlestone, 1988).

We further extend our model showing its applicability when working with a larger family of loss functions. Finally we present a unified analysis in the mistake bound model, based on the primal-dual analysis presented in Shalev-Shwartz and Singer (2006a). Our results are on par with the best known mistake bounds for multiclass algorithms.

1.1 Related Work

The task of multiclass categorization can be thought of as a specific case of our construction. In multiclass categorization the task is to predict a *single* label out of k possible outcomes. Our simultaneous projection approach is based on the fact that we can retrospectively (after receiving the correct label) cast the problem as the task of making $k-1$ binary decisions, each of which involves the correct label and one of the competing labels. Our framework then performs an update on each of the problems separately and then combines the updates to form a new hypothesis. The performance of the $k-1$ predictions is measured through a single loss function. Our approach stands in contrast to previously studied methods which can be roughly be partitioned into three paradigms. The first paradigm follows the max update paradigm presented above. For example, the algorithms by Crammer and Singer (2003) and Crammer et al. (2006) focus on the single, worst performing, derived sub-problem. While this approach adheres with the original structure of the problem, the resulting update mechanism is by construction sub-optimal as it oversees almost all of the constraints imposed by the complex prediction problem. (See also Shalev-Shwartz and Singer, 2006a, for analysis and explanation of the sub-optimality of this approach).

Since applying full scale numeric solvers in each online trial is usually prohibitive due to the high computational cost, the optimal paradigm for dealing with complex problems is to tailor a specific efficient solution for the problem on hand. While this approach yielded highly efficient learning algorithms for multiclass categorization problems (Crammer and Singer, 2003; Shalev-Shwartz and Singer, 2006b) and aesthetic solutions for structured output problems (Taskar et al., 2003; Tsochantaridis et al., 2004), devising these algorithms required dedicated efforts. Moreover, tailored solutions typically impose rather restrictive assumptions on the representation of the data in order to yield efficient algorithmic solutions.

The third (and probably the simplest) previously studied approach is to break the problem into multiple *decoupled* problems that are solved *independently*. Such translation effectively changes the problem definition. Thus, the simplicity of this approach also underscores its deficiency as it is detached from the original loss of the complex decision problem. Such an approach was used for instance for batch learning of multiclass support vector machines (Weston and Watkins, 1999) and boosting algorithms (Schapire and Singer, 1999). Decoupling approaches have further been extended to various ways. Hastie and Tibshirani (1998) considered construction of a binary problem for each pair of classes. In Dietterich and Bakiri (1995), Allwein et al. (2000) and Crammer and Singer (2002) error correcting output codes are applied to solve the multiclass problem as separate binary problems.

It is interesting to note that the methods for performing multiple projections simultaneously have been studied in a different context in the optimization community. Similar ideas which can be broadly characterized as row-action methods date back more than 50 years, see for example Hildreth (1957), Bregman (1967), and Pierro and Iusem (1986). These methods are used to find the optimal solution of a convex function subject to a very large number of constraints. The core idea behind row-action methods is to consider and isolate a few number of constraints and repeatedly perform

a projection on a small subset (typically a single constrain) until convergence. Pierro and Iusem (1986) introduced the concept of averaging to the general family of Bregmans methods, where the projection step is relaxed and the new solution is the *average* of the previous solution and the result of the projection. Censor and Zenios (1997) introduces a parallel version of the row-action methods. The parallel algorithms perform the projection step on each constraint separately and update the new solution to the average of all these projections. For further extensive description of row-action methods see Censor and Zenios (1997). Row-actions methods have recently received attention in the learning community, for problems such as finding the optimal solution of SVM. For instance the SMO technique of Platt (1998) can be viewed as a row-action optimization method that manipulates two constraints at a time. In this paper we take a different approach, and *decompose* a single complex constraint into multiple projections problem which are tied together through a single slack variable.

The rest of the paper is organized as follows. We start with a description of the problem setting in Sec. 2. In Sec. 3 we describe two complex decision tasks that can be tackled by our approach. A template algorithm for additive simultaneous projection in an online learning setting with multiple instances is described in Sec. 4. We propose concrete schemes for selecting an update form in Sec. 5 and analyze our algorithms within the mistake bound model in Sec. 6. We extend our algorithm to a large family of losses in Sec. 7 and derive family of multiplicative algorithms in Sec. 8. We demonstrate the merits of our approach in a series of experiments with synthetic and real data sets in Sec. 9 and conclude in Sec. 10.

2. Problem Setting

In this section we introduce the notation used throughout the paper and formally describe our problem setting. We denote vectors by lower case bold face letters (e.g., $\mathbf{x}$ and $\boldsymbol{\omega}$) where the j'th element of $\mathbf{x}$ is denoted by x_j. We denote matrices by upper case bold face letters (e.g., $\mathbf{X}$), where the j'th row of $\mathbf{X}$ is denoted by $\mathbf{x}_j$. The set of integers $\{1,\ldots,k\}$ is denoted by $[k]$. Finally, we use the hinge function $[a]_+ = \max\{0,a\}$.

Online learning is performed in a sequence of trials. At trial t the algorithm receives a matrix $\mathbf{X}^t$ of size $k_t \times n$, where each row of $\mathbf{X}^t$ is an instance, and is required to make a prediction on the label associated with each instance. We denote the vector of predicted labels by $\hat{\mathbf{y}}^t$. We allow $\hat{y}^t_j$ to take any value in $\mathbb{R}$, where the actual label being predicted is $\mathrm{sign}(\hat{y}^t_j)$ and $|\hat{y}^t_j|$ is the confidence in the prediction. After making a prediction $\hat{\mathbf{y}}^t$ the algorithm receives the correct labels $\mathbf{y}^t$ where $y^t_j \in \{-1,1\}$ for all $j \in [k_t]$. In this paper we assume that the predictions in each trial are formed by calculating the inner product between a weight vector $\boldsymbol{\omega}^t \in \mathbb{R}^n$ with each instance in $\mathbf{X}^t$, thus $\hat{\mathbf{y}}^t = \mathbf{X}^t\boldsymbol{\omega}^t$. Our goal is to *perfectly* predict the entire vector $\mathbf{y}^t$. We thus say that the vector $\mathbf{y}^t$ was *imperfectly* predicted if there exists an outcome j such that $y^t_j \neq \mathrm{sign}(\hat{y}^t_j)$. That is, we suffer a unit loss on trial t if there exists j, such that $\mathrm{sign}(\hat{y}^t_j) \neq y^t_j$. Directly minimizing this combinatorial error is a computationally difficult task. Therefore, we use an adaptation of the *hinge-loss*, defined $\ell(\hat{\mathbf{y}}^t,\mathbf{y}^t) = \max_j \left[1 - y^t_j \hat{y}^t_j\right]_+$, as a proxy for the combinatorial error. The quantity $y^t_j \hat{y}^t_j$ is often referred to as the (signed) *margin* of the prediction and ties the correctness and the confidence in the prediction. We use $\ell(\boldsymbol{\omega}^t;(\mathbf{X}^t,\mathbf{y}^t))$ to denote $\ell(\hat{\mathbf{y}}^t,\mathbf{y}^t)$ where $\hat{\mathbf{y}}^t = \mathbf{X}^t\boldsymbol{\omega}^t$. We also denote the set of instances whose labels were predicted incorrectly by $\mathcal{M}^t = \{j \,|\, \mathrm{sign}(\hat{y}^t_j) \neq y^t_j\}$, and similarly the set of instances whose hinge-losses are greater than zero by $\Gamma^t = \{j \,|\, [1 - y^t_j \hat{y}^t_j]_+ > 0\}$.

3. Derived Problems

In this section we further explore the motivation for our problem setting by describing two different complex decision tasks and showing how they can be cast as special cases of our setting. We also would like to note that our approach can be employed in other prediction problems (see Sec. 10).

3.1 Multilabel Categorization

In the multilabel categorization task each instance is associated with a set of relevant labels from the set $[k]$. The multilabel categorization task can be cast as a special case of a ranking task in which the goal is to rank the relevant labels above the irrelevant ones. Many learning algorithms for this task employ class-dependent features (for example, see Schapire and Singer, 2000). For simplicity, assume that each class is associated with n features and denote by $\phi(\mathbf{x},r)$ the feature vector for class r. We would like to note that features obtained for different classes typically relay different information and are often substantially different.

A categorizer, or label ranker, is based on a weight vector ω. A vector ω induces a score for each class $\omega\cdot\phi(\mathbf{x},r)$ which, in turn, defines an ordering of the classes. A learner is required to build a vector ω that successfully ranks the labels according to their relevance, namely for each pair of classes (r,s) such that r is relevant while s is not, the class r should be ranked higher than the class s. Thus we require that $\omega\cdot\phi(\mathbf{x},r)>\omega\cdot\phi(\mathbf{x},s)$ for every such pair (r,s). We say that a label ranking is imperfect if there exists *any* pair (r,s) which violates this requirement. The loss associated with each such violation is $[1-(\omega\cdot\phi(\mathbf{x},r)-\omega\cdot\phi(\mathbf{x},s))]_+$ and the loss of the categorizer is defined as the maximum over the losses induced by the violated pairs. In order to map the problem to our setting, we define a virtual instance for every pair (r,s) such that r is relevant and s is not. The new instance is the n dimensional vector defined by $\phi(\mathbf{x},r)-\phi(\mathbf{x},s)$. The label associated with all of the instances is set to 1. It is clear that an imperfect categorizer makes a prediction mistake on at least one of the instances, and that the losses defined by both problems are the same.

3.2 Ordinal Regression

In the problem of ordinal regression an instance $\mathbf{x}$ is a vector of n features that is associated with a target rank $y\in[k]$. A learning algorithm is required to find a vector ω and k thresholds $b_1\leq\cdots\leq b_{k-1}\leq b_k=\infty$. The value of $\omega\cdot\mathbf{x}$ provides a score from which the prediction value can be defined as the smallest index i for which $\omega\cdot\mathbf{x}<b_i$, $\hat{y}=\min\{i|\omega\cdot\mathbf{x}<b_i\}$. In order to obtain a correct prediction, an ordinal regressor is required to ensure that $\omega\cdot\mathbf{x}\geq b_i$ for all $i<y$ and that $\omega\cdot\mathbf{x}<b_i$ for $i\geq y$. It is considered a prediction mistake if any of these constraints is violated. In order to map the ordinal regression task to our setting, we introduce $k-1$ instances. Each instance is a vector in $\mathbb{R}^{n+k-1}$. The first n entries of the vector are set to be the elements of $\mathbf{x}$, the remaining $k-1$ entries are set to $-\delta_{i,j}$. That is, the i'th entry in the j'th vector is set to -1 if $i=j$ and to 0 otherwise. The label of the first $y-1$ instances is 1, while the remaining $k-y$ instances are labeled as -1. Once we learned an expanded vector in $\mathbb{R}^{n+k-1}$, the regressor ω is obtained by taking the first n components of the expanded vector and the thresholds $b_1,\ldots,b_{k-1}$ are set to be the last $k-1$ elements. A prediction mistake of any of the instances corresponds to an incorrect rank in the original problem.

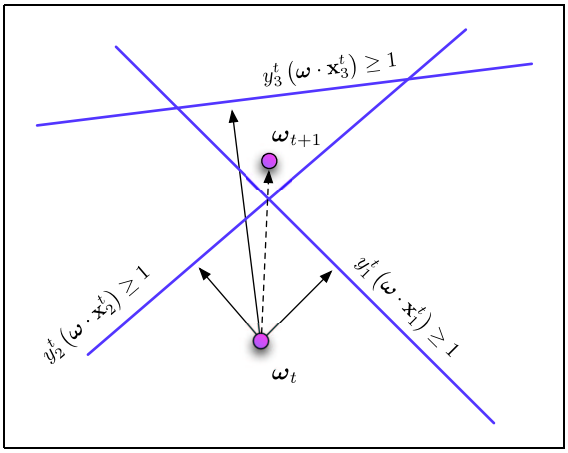

Figure 1: Illustration of the simultaneous projections algorithm: each instance casts a constraint on ω and each such constraint defines a halfspace of feasible solutions. We project on each halfspace in parallel and the new vector is a weighted average of these projections

4. Simultaneous Projection Algorithms

Recall that on trial t the algorithm receives a matrix, $\mathbf{X}^t$, of k_t instances, and predicts $\hat{\mathbf{y}}^t = \mathbf{X}^t \omega^t$. After performing its prediction, the algorithm receives the corresponding labels $\mathbf{y}^t$. Each instance-label pair casts a constraint on ω_t, $y_j^t \left(\omega^t \cdot \mathbf{x}_j^t\right) \geq 1$. If all the constraints are satisfied by ω^t then ω^{t+1} is set to be ω^t and the algorithm proceeds to the next trial. Otherwise, we would like to set ω^{t+1} as close as possible to ω^t while satisfying all constraints.

Such an aggressive approach may be sensitive to outliers and over-fitting. Thus, we allow some of the constraints to remain violated by introducing a trade-off between the change to ω^t and the loss attained on $(\mathbf{X}^t, \mathbf{y}^t)$. Formally, we would like to set ω^{t+1} to be the solution of the following minimization problem,

$$\min_{\omega \in \mathbb{R}^n} \tfrac{1}{2} \|\omega - \omega^t\|^2 + C\,\ell(\omega; (\mathbf{X}^t, \mathbf{y}^t)), \tag{1}$$

where C is a trade-off parameter. As we discuss below, this formalism effectively translates to a cap on the maximal change to ω^t. We rewrite the above optimization by introducing a *single* slack variable as follows:

$$\begin{aligned} &\min_{\omega \in \mathbb{R}^n, \xi \geq 0} \frac{1}{2} \left\|\omega - \omega^t\right\|^2 + C\xi \\ &\text{s.t.} \qquad \forall j \in [k_t]: \; y_j^t \left(\omega \cdot \mathbf{x}_j^t\right) \geq 1 - \xi \qquad \xi \geq 0 \end{aligned} \quad . \tag{2}$$

We denote the objective function of Eq. (2) by $\mathcal{P}^t$ and refer to it as the *instantaneous* primal problem to be solved on trial t. The dual optimization problem of $\mathcal{P}^t$ is the maximization problem

$$\max_{\alpha_1^t, .., \alpha_{k_t}^t} \; \sum_{j=1}^{k_t} \alpha_j^t - \frac{1}{2} \left\| \omega^t + \sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t \right\|^2 \quad \text{s.t.} \quad \sum_{j=1}^{k_t} \alpha_j^t \leq C \;\; , \;\; \forall j : \alpha_j^t \geq 0 \quad . \tag{3}$$

The complete derivation is given in Appendix A.

Input:
Aggressiveness parameter $C > 0$
Initialize:
$\omega_1 = (0, \ldots, 0)$
For $t = 1, 2, \ldots, T$:
Receive instance matrix $X^t \in \mathbb{R}^{k_t \times n}$
Predict $\hat{\mathbf{y}}^t = \mathbf{X}^t \omega^t$
Receive correct labels $\mathbf{y}^t$
Suffer loss $\ell(\omega^t; (\mathbf{X}^t, \mathbf{y}^t))$
If $\ell > 0$:
Choose importance weights μ^t s.t.
$\mu^t_j \geq 0$ and $\sum_{j=1}^{k_t} \mu^t_j = 1$
Choose individual dual solutions α^t_j
Update $\omega^{t+1} = \omega^t + \sum_{j=1}^{k_t} \mu^t_j \alpha^t_j y^t_j \mathbf{x}^t_j$

Figure 2: Template of simultaneous projections algorithm.

Each dual variable corresponds to a single constraint of the primal problem. The minimizer of the primal problem is calculated from the optimal dual solution as follows, $\omega^{t+1} = \omega^t + \sum_{j=1}^{k_t} \alpha^t_j y^t_j \mathbf{x}^t_j$.

Unfortunately, in the common case, where each $\mathbf{x}^t_j$ is in an arbitrary orientation, there does not exist an analytic solution for the dual problem (Eq. 3). The difficulty stems from the fact that the sum of the weights α^t_j cannot exceed C. We tackle the problem by breaking it down into k_t reduced problems, each of which focuses on a single dual variable. By doing so we replace the global sum constraint, $\sum_{j=1}^{k_t} \alpha^t_j$, with multiple box constraints, $\alpha^t_j \leq C$, which can easily be dealt with. Formally, for the j'th variable, the j'th reduced problem solves Eq. (3) while fixing $\alpha^t_{j'} = 0$ for all $j' \neq j$. Each reduced optimization problem amounts to the following problem

$$\max_{\alpha^t_j} \ \alpha^t_j - \frac{1}{2} \left\| \omega^t + \alpha^t_j y^t_j \mathbf{x}^t_j \right\|^2 \quad \text{s.t.} \quad \alpha^t_j \in [0, C] \ . \tag{4}$$

As we demonstrate in the sequel, this reduction into independent problems serves two roles. First, it leads to simple solutions for the reduced problems. Second, and more important, the individual solutions can and are grouped into a feasible solution of the original problem for which we can prove various loss bounds.

We thus next obtain an exact or approximate solution for each reduced problem as if it were independent of the rest. We then choose a non-negative vector $\mu \in \Delta_{k_t}$ where Δ_{k_t} is the k_t dimension probability simplex, formally $\mu_i \geq 0$ and $\sum_{j=1}^{k_t} \mu_j = 1$. Given the vector μ, we multiply each α^t_j by a corresponding value μ^t_j. Our choice of μ assures us $\{\mu^t_j \alpha^t_j\}$ constitutes a feasible solution to the dual problem defined in Eq. (3) for the following reason. Each $\mu^t_j \alpha^t_j \geq 0$ and the fact that $\alpha^t_j \leq C$ implies that $\sum_{j=1}^{k_t} \mu^t_j \alpha^t_j \leq C$. Finally, the algorithm uses the combined solution and sets $\omega^{t+1} = \omega^t + \sum_{j=1}^{k_t} \mu^t_j \alpha^t_j y^t_j \mathbf{x}^t_j$. An illustration of the algorithm is provided in Fig. 4.

Variant	Choosing μ_j^t	Choosing α_j^t

Figure 3: Schemes for choosing μ and α.

5. Solving the Reduced Problems

We next present four schemes to obtain a solution for the reduced problem (Eq. 4) and then combine the solution into a single update. The first three schemes provide feasible solutions for the reduced problems and are easy to implement. However, these solutions are not necessarily optimal. In Sec. 5.4 we describe a rather involved yet efficient procedure for finding the optimal solution of each reduced problem along side with their weight vector μ which constitute the means for combining the individual solutions.

5.1 Simultaneous Perceptron

The simplest of the update forms generalizes the famous Perceptron algorithm from Rosenblatt (1958) by setting α_j^t to C if the j'th instance is incorrectly labeled, and to 0 otherwise. We then set the weight of μ_j^t to $\frac{1}{|\mathcal{M}^t|}$ for $j \in \mathcal{M}^t$ and to 0 otherwise. We abbreviate this scheme as the *SimPerc* algorithm.

5.2 Soft Simultaneous Projections

The soft simultaneous projections scheme uses the fact that each reduced problem has an analytic solution, which yields $\alpha_j^t = \min\left\{C, \ell\left(\omega^t;(\mathbf{x}_j^t,y_j^t)\right) / \left\|\mathbf{x}_j^t\right\|^2\right\}$. We independently assign each α_j^t this optimal solution. We next set μ_j^t to be $\frac{1}{|\Gamma^t|}$ for $j \in \Gamma^t$ and to 0 otherwise. We would like to comment that this solution may update α_j^t also for instances which were correctly classified as long as the margin they attain is not sufficiently large. We abbreviate this scheme as the *SimProj* algorithm.

5.3 Conservative Simultaneous Projections

Combining ideas from the above methods, the conservative simultaneous projections scheme optimally sets α_j^t according to the analytic solution. It differs from the SimProj algorithm in the way it selects μ^t. In the conservative scheme only the instances which were incorrectly predicted ($j \in \mathcal{M}^t$) are assigned a positive weight. Put another way, μ_j^t is set to $\frac{1}{|\mathcal{M}^t|}$ for $j \in \mathcal{M}^t$ and to 0 otherwise. We abbreviate this scheme as the *ConProj* algorithm.

5.4 Jointly Optimizing μ and α

Recall that our goal is to propose a feasible solution to Eq. (3) and we do so by independently considering the optimization problem of Eq. (4) for each j. Following, we multiply each α_j^t by a coefficient μ_j^t so that all $\mu_j^t \alpha_j^t$ form a feasible solution. The following analysis shows that the two steps can be unified. For brevity, we omit the superscript t. The task of jointly optimizing both μ and α casts a seemingly non-convex optimization and finding the optimal solution is a priori a hard problem. In this section we derive a somewhat counterintuitive result. By exploring the structure of the problem on hand we show that this joint optimization problem can efficiently be solved in $k_t \log k_t$ time. .

We begin by taking the derivative of the optimal values for α_j while assuming that the values μ_j are fixed and define a convex combination. The reduced problem of Eq. (4) becomes

$$\begin{aligned} \max_{\alpha_j} \ & \mu_j \alpha_j - \frac{1}{2} \left\| \omega + \mu_j \alpha_j y_j \mathbf{x}_j \right\|^2 \\ \text{s.t.} \quad & \alpha_j \in [0, C] \end{aligned} ,$$

which can be rewritten as

$$\max_{\alpha_j} \mu_j \alpha_j \left(1 - y_j \left(\omega \cdot \mathbf{x}_j\right)\right) - \frac{1}{2} \mu_j^2 \alpha_j^2 \left\|\mathbf{x}_j\right\|^2 - \frac{1}{2} \left\|\omega\right\|^2 \quad \text{s.t.} \quad \alpha_j \in [0, C] \ .$$

For brevity, we denote the squared norm of $\mathbf{x}_j$ by ν_j. Thus, omitting constants that do not depend on α_j and μ_j, the above optimization problem can be written as

$$\max_{\alpha_j} \ \mu_j \alpha_j \left(1 - y_j \left(\omega \cdot \mathbf{x}_j\right)\right) - \frac{1}{2} \mu_j^2 \alpha_j^2 \nu_j \quad \text{s.t.} \quad 0 \le \alpha_j \le C \ . \tag{5}$$

Let us denote the hinge-loss on instance j, $\max\{0, 1 - y_j \left(\omega \cdot \mathbf{x}_j\right)\}$ by ℓ_j. By taking the derivative of the Lagrangian with respect to α_j and equating the result with zero, we get that

$$\alpha_j = \min \left\{ C, \frac{l_j}{\mu_j \nu_j} \right\} \ .$$

We can now look at two disjoint cases. The first case is when $\alpha_j = \frac{l_j}{\mu_j \nu_j} < C$. In this case α_j takes the value of $\frac{l_j}{\mu_j \nu_j}$ and the value of the optimization problem above becomes

$$\frac{\ell_j^2}{\nu_j} - \frac{1}{2} \frac{\ell_j^2}{\nu_j} = \frac{1}{2} \frac{l_j^2}{\nu_j} \ .$$

We note in passing that this expression does not depend on μ_j.

The second case is when $\alpha_j = C$. Plugging α_j into Eq. (5) we get the following expression, as a function of μ, which we denote by $f_j(\mu_j)$,

$$f_j(\mu_j) = \mu_j C \ell_j - \frac{1}{2} \mu_j^2 C^2 \nu_j \ . \tag{6}$$

We next take the derivative of f_j above with respect to μ_j and obtain

$$\frac{\partial f}{\partial \mu_j} = C \ell_j - \mu_j C^2 \nu_j \ ,$$

from which we conclude that the optimal value for μ_j is

$$\frac{\ell_j}{C\nu_j} \ .$$

Plugging the optimal value for μ_j back in Eq. (6) we get that the maximum of $f_j(\mu_j)$ is

$$f_j\left(\frac{\ell_j}{C\nu_j}\right) = \frac{\ell_j^2}{\nu_j} - \frac{1}{2}\frac{\ell_j^2}{\nu_j} = \frac{1}{2}\frac{\ell_j^2}{\nu_j} \ .$$

To recap, we may express the optimal value of Eq. (5) as a function of μ_j as follows.

$$f_j(\mu_j) = \begin{cases} \mu_j C\ell_j - \frac{1}{2}\mu_j^2 C^2\nu_j & \mu_j \leq \frac{\ell_j}{C\nu_j} \\ \frac{1}{2}\frac{\ell_j^2}{\nu_j} & \text{otherwise} \end{cases} \ .$$

Thus, f_j is monotonically increasing in the range $0 \leq \mu_j \leq \frac{\ell_j}{C\nu_j}$ and is constant for values greater than $\frac{\ell_j}{C\nu_j}$.

Recall that our primary goal is to find a convex combination of μ_j. Thus, we would like to find the optimal assignment to μ given that α is set optimally. We end up with the following optimization problem.

$$\begin{aligned} &\max \sum_j f_j(\mu_j) \\ &\text{s.t.} \qquad \forall j : \mu_j \geq 0 \qquad \sum_j \mu_j = 1 \end{aligned} \ . \tag{7}$$

As previously discussed, for all j, f_j increases in the range $0 \leq \mu_j \leq \frac{\ell_j}{C\nu_j}$ and is constant afterwards. We may use this fact to further classify the structure of the optimal solution of Eq. (7). Assume first that $\sum_j \frac{\ell_j}{C\nu_j} \leq 1$. In this case we can increment each, $\mu_j = \frac{\ell_j}{C\nu_j} + B$, where B is a non-negative constant which assures that $\sum_j \mu_j = 1$. This assignment of μ is clearly optimal, as f_j is increasing and reaches its maximum obtainable value for $\mu_j \geq \frac{\ell_j}{C\nu_j}$.

Now, suppose $\sum_j \frac{\ell_j}{C\nu_j} > 1$. In such a case there exists an optimal solution with $\mu_j \leq \frac{\ell_j}{C\nu_j}$ for all j. Suppose in contrary that for every optimal solution μ there exists some $\hat{j}$ where $\mu_{\hat{j}} = \frac{\ell_{\hat{j}}}{C\nu_{\hat{j}}} + \varepsilon$ for some non-negative ε. Since $\sum_j \frac{\ell_j}{C\nu_j} > 1$ there exists some j' with $\mu_{j'} < \frac{\ell_{j'}}{C\nu_{j'}}$. Since $f_{j'}$ monotonely increases when $\mu_{j'} < \frac{\ell_{j'}}{C\nu_{j'}}$, while $f_{\hat{j}}$ is constant for $\mu_{\hat{j}} > \frac{\ell_{\hat{j}}}{C\nu_{\hat{j}}}$ we can create a new assignment $\mu^\star$ increasing the value of the sum $\sum_j f_j(\mu_j)$ by setting $\mu^\star_{\hat{j}} = \frac{\ell_{\hat{j}}}{C\nu_{\hat{j}}}$ and add ε to $\mu^\star_{j'}$. We thus conclude that for each solution where for some $\mu_{\hat{j}} > \frac{\ell_{\hat{j}}}{C\nu_{\hat{j}}}$ there exists an assignment $\mu^\star$ where for all j, $\mu_j \leq \frac{\ell_j}{C\nu_j}$ and the objective of Eq. (7) is at least as high.

Thus, when $\sum_j \frac{\ell_j}{C\nu_j} > 1$ we may add the constraint that $\mu_j \leq \frac{\ell_j}{C\nu_j}$ and obtain the following optimization problem.

$$\begin{aligned} &\max_\mu \sum_j f_j(\mu_j) \\ &\text{s.t.} \qquad \forall j : 0 \leq \mu_j \leq \frac{\ell_j}{C\nu_j} \qquad \sum_j \mu_j = 1 \end{aligned} \ .$$

We next introduce non-negative Lagrange multipliers τ, $\{\beta_j\}$, and $\{\eta_j\}$ to obtain the following Lagrangian,

$$L = \sum_j C\ell_j\mu_j - \frac{1}{2}\mu_j^2 C^2\nu_j - \sum_j \beta_j\mu_j - \tau\left(\sum_j \mu_j - 1\right) + \sum_j \eta_j\left(\mu_j - \frac{\ell_j}{C\nu_j}\right) \ .$$

Taking the derivative with respect to μ_j and comparing to 0 we get the following condition.

$$C\ell_j - \mu_j C^2\nu_j - \beta_j - \tau + \eta_j = 0 \ ,$$

or

$$\mu_j = \frac{C\ell_j - \beta_j - \tau + \eta_j}{C^2\nu_j} \ .$$

The complementary slackness assures us that when $\mu_j > 0$ then $\beta_j = 0$ and thus

$$\mu_j = \frac{C\ell_j - \tau + \eta_j}{C^2\nu_j} \ .$$

Similarly, $\eta_j > 0$ only when $\mu_j = \frac{\ell_j}{C\nu_j}$ and is used only when τ is negative, However, τ may be negative only when $\sum_j \frac{\ell_j}{C\nu_j} < 1$, which we covered before. To summarize, we can write the optimal solution as

$$\mu_j = \max\{0, \frac{C\ell_j - \tau}{C^2\nu_j}\} \ . \tag{8}$$

We now focus our attention on the task of finding the value of τ. First, note that every value of τ partitions the set $1,\ldots,k_t$ into two sets, indices j whose $\mu_j > 0$ and indices for which $\mu_j = 0$. Formally, let $H = \left\{j | C\ell_j > \tau\right\}$ and $L = [k_t] \setminus H$ denote the two sets partitioned according to τ. Clearly $j \in H \iff \mu_j > 0$. Clearly, knowing the value τ allows us to compute the partition to H and L. The converse, however, is also true. Had we known H and L it would have been straightforward to compute τ by using the fact that μ is in the probability simplex, $\sum_j \mu_j = 1$, to get that

$$\sum_{j\in H} \frac{C\ell_j - \tau}{C^2\nu_j} = 1 \ . \tag{9}$$

Eq. (9) allows us to easily compute τ and obtain

$$\tau = \frac{\sum_{j\in H} \frac{C\ell_j}{C^2\nu_j} - 1}{\sum_{j\in H} \frac{1}{C^2\nu_j}} \ . \tag{10}$$

In order to verify τ serve as a feasible solution, we're required to verify that $\sum_{j\in H} \mu_j = 1$ and that for all $j \in L:\ C\ell_j - \tau \leq 0$. The following lemma states that there is only a single feasible value for τ.

Lemma 1 *Let ℓ_j denote the hinge-loss of instance j, $\max\{0, 1 - y_j(\omega\cdot\mathbf{x}_j)\}$. Let ν_j denote the squared norm of $\mathbf{x}_j$. Denote by f_j the function of μ_j given by $f_j(\mu_j) = \mu_j C\ell_j - \frac{1}{2}\mu_j^2 C^2\nu_j$. Finally let μ denote an optimal solution to Eq. (7) computed according to Eq. (8) and $H(\tau)$ denote the set of indices j for which $C\ell_j > \tau$. Then, there is a single value τ that satisfies that $\sum_{j\in H\tau} \mu_j = 1$ while maintaining that $\forall\, j \notin H : \mu_j = 0$.*

Input:
$\ell_j, \nu_j \quad j \in [k_t]$
Algorithm:
Sort the indices $\{1,\ldots,k_t\}$ by decreasing order of ℓ_j
For $i = 2,\ldots,k_t$:
Define $H = \{1,\ldots,i-1\}$
Compute $\tau = \frac{\sum_{j\in H} \frac{C\ell_j}{C^2\nu_j} - 1}{\sum_{j\in H} \frac{1}{C^2\nu_j}}$
Validate $C\ell_i \leq \tau$. If not, continue to next iteration
Set $\mu_j = \frac{C\ell_j - \tau}{C^2\nu_j}$
Set $\alpha_j = \min\left\{C, \frac{l_j}{\mu_j \nu_j}\right\}$

Figure 4: Calculating μ and α efficiently.

Proof Suppose by contradiction that there are two feasible values for τ, and denote these values as τ_1 and τ_2. Denote $H(\tau_1)$ and $H(\tau_2)$ by H_1 and H_2 respectively. Assume without loss of generality that $\tau_1 < \tau_2$.

First we note that $H_2 \subset H_1$. However,

$$1 = \sum_{j\in H_1} \frac{C\ell_j - \tau_1}{C^2\nu_j} > \sum_{j\in H_1} \frac{C\ell_j - \tau_2}{C^2\nu_j} \quad ,$$

where the inequality is due to our assumption that $\tau_1 < \tau_2$. Since $\sum_{j\in H_2} \frac{C\ell_j - \tau_2}{C^2\nu_j}$ must equal 1, we conclude that H_2 must strictly contain more items than H_1. We have thus obtained a contradiction. ■

Using Lemma 1 we can devise an efficient algorithm for finding the optimal value for τ. We first sort the indices $1,\ldots,k_t$ by decreasing order of ℓ_j. Then, for every $i = 2,\ldots,k_t$, we define $H_i = \{1,\ldots,i-1\}$ and compute the value suitable value of τ according to Eq. (10). Finally we verify if $C\ell_i \leq \tau$. The algorithm for finding τ is formally given in Fig. 4.

To recap, we have suggested a mechanism for jointly optimizing both μ and α. We showed that it suffices to find a value τ which consistently divides the set $[k_t]$ into two sets as follows. The first set corresponds to indices j for which μ_j is zero and the second includes the non-zero components of μ. Furthermore, we showed that once τ is known, obtaining the vector μ is a simple task. Last, we described how Lemma 1 translates into an efficient algorithm for finding τ. We thus derived another simultaneous projections scheme, denoted by *SimOpt*, which jointly optimized α and μ. This variant of the simultaneous projections framework is guaranteed to yield the largest increase in the dual compared to all other simultaneous projections schemes. We describe empirical results which validate experimentally this property in Sec. 9.

6. Analysis

The algorithms described in the previous section perform updates in order to increase the instantaneous dual problem defined in Eq. (3). We now use the mistake bound model to derive an upper

bound on the number of trials on which the predictions of SimPerc and ConProj algorithms are imperfect. Following Shalev-Shwartz and Singer (2006a), the first step in the analysis is to tie the instantaneous dual problems to a global loss function. To do so, we introduce a primal optimization problem defined over the *entire* sequence of examples as follows,

$$\min_{\omega\in\mathbb{R}^n} \frac{1}{2}\|\omega\|^2 + C\sum_{t=1}^{T} \ell\left(\omega; \left(X^t, Y^t\right)\right) \quad .$$

We rewrite the optimization problem as the following equivalent constrained optimization problem,

$$\min_{\omega\in\mathbb{R}^n,\xi\in\mathbb{R}^T} \frac{1}{2}\|\omega\|^2 + C\sum_{t=1}^{T}\xi_t \quad \text{s.t.} \quad \forall t\in[T], \forall j\in[k_t] : y_j^t\left(\omega\cdot\mathbf{x}_j^t\right) \geq 1-\xi_t \quad \forall t : \xi_t \geq 0 \quad . \tag{11}$$

We denote the value of the objective function at (ω,ξ) for this optimization problem by $\mathcal{P}(\omega,\xi)$. A competitor who may see the entire sequence of examples in advance may in particular set (ω,ξ) to be the minimizer of the problem which we denote by $(\omega^\star,\xi^\star)$. Standard usage of Lagrange multipliers yields that the dual of Eq. (11) is,

$$\max_{\lambda} \sum_{t=1}^{T}\sum_{j=1}^{k_t}\lambda_{t,j} - \frac{1}{2}\left\|\sum_{t=0}^{T}\sum_{j=1}^{k_t}\lambda_{t,j}y_j^t\mathbf{x}_j^t\right\|^2 \quad \text{s.t.} \quad \forall t : \sum_{j=1}^{k_t}\lambda_{t,j} \leq C \quad \forall t,j : \lambda_{t,j}\geq 0 \quad . \tag{12}$$

We denote the value of the objective function of Eq. (12) by $\mathcal{D}(\lambda_1,\cdots,\lambda_T)$, where each λ_t is a vector in $\mathbb{R}^{k_t}$. Through our derivation we use the fact that any set of dual variables $\lambda_1,\cdots,\lambda_T$ defines a feasible solution $\omega = \sum_{t=1}^{T}\sum_{j=1}^{k_t}\lambda_{t,j}y_j^t\mathbf{x}_j^t$ with a corresponding assignment of the slack variables.

Clearly, the optimization problem given by Eq. (12) depends on all the examples from the first trial through time step T and thus can only be solved in hindsight. We note however, that if we ensure that $\lambda_{s,j}=0$ for all $s>t$ then the dual function no longer depends on instances occurring on rounds proceeding round t. As we show next, we use this primal-dual view to derive the skeleton algorithm presented in Fig. 2 by finding a new feasible solution for the dual problem on every trial. Formally, the instantaneous dual problem, given by Eq. (3), is equivalent (after omitting an additive constant) to the following constrained optimization problem,

$$\max_{\lambda} \mathcal{D}(\lambda_1,\cdots,\lambda_{t-1},\lambda,\mathbf{0},\cdots,\mathbf{0}) \quad \text{s.t.} \quad \lambda\geq\mathbf{0} \quad , \quad \sum_{j=1}^{k_t}\lambda_j \leq C \quad . \tag{13}$$

That is, the instantaneous dual problem is obtained from $\mathcal{D}(\lambda_1,\cdots,\lambda_T)$ by fixing $\lambda_1,\ldots,\lambda_{t-1}$ to the values set in previous rounds, forcing λ_{t+1} through λ_T to the zero vectors, and choosing a feasible vector for λ_t. Given the set of dual variables $\lambda_1,\ldots,\lambda_{t-1}$ it is straightforward to show that the prediction vector used on trial t is $\omega^t = \sum_{s=1}^{t-1}\sum_j \lambda_{s,j}y_j^s\mathbf{x}_j^s$. Equipped with these relations and omitting constants which do not depend on λ_t, Eq. (13) can be rewritten as,

$$\max_{\lambda_1,\ldots,\lambda_{k_t}} \sum_{j=1}^{k_t}\lambda_j - \frac{1}{2}\left\|\omega^t + \sum_{j=1}^{k_t}\lambda_j y_j^t\mathbf{x}_j^t\right\|^2 \quad \text{s.t.} \quad \forall j : \lambda_j\geq 0, \quad \sum_{j=1}^{k_t}\lambda_j \leq C \quad . \tag{14}$$

The problems defined by Eq. (14) and Eq. (3) are equivalent. Thus, weighing the variables $\alpha_1^t,\ldots,\alpha_{k_t}^t$ by $\mu_1^t,\ldots,\mu_{k_t}^t$ also yields a feasible solution for the problem defined in Eq. (13), namely $\lambda_{t,j} = \mu_j^t\alpha_j^t$. We now tie all of these observations together by using the weak-duality theorem. Our first bound is given for the SimPerc algorithm.

Theorem 2 *Let $\left(\mathbf{X}^1,\mathbf{y}^1\right),\ldots,\left(\mathbf{X}^T,\mathbf{y}^T\right)$ be a sequence of examples where $\mathbf{X}^t$ is a matrix of k_t examples and $\mathbf{y}^t$ are the associated labels. Assume that for all t and j the norm of an instance $\mathbf{x}_j^t$ is at most R. Then, for any $\omega^\star \in \mathbb{R}^n$ the number of trials on which the prediction of SimPerc is imperfect is at most,*

$$\frac{\frac{1}{2}\|\omega^\star\|^2 + C\sum_{t=1}^T \ell\left(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t)\right)}{C-\frac{1}{2}C^2R^2} \quad .$$

Proof To prove the theorem we make use of the weak-duality theorem. Recall that any dual feasible solution induces a value for the dual's objective function which is upper bounded by the optimum value of the primal problem, $\mathcal{P}\left(\omega^\star,\xi^\star\right)$. In particular, the solution obtained at the end of trial T is dual feasible, and thus $\mathcal{D}(\lambda_1,\ldots,\lambda_T) \leq \mathcal{P}(\omega^\star,\xi^\star)$. We now rewrite the left-hand side of the above equation as the following sum,

$$\mathcal{D}(\mathbf{0},\ldots,\mathbf{0}) + \sum_{t=1}^T \left[\mathcal{D}(\lambda_1,\ldots,\lambda_t,\mathbf{0},\ldots,\mathbf{0}) - \mathcal{D}(\lambda_1,\ldots,\lambda_{t-1},\mathbf{0},\ldots,\mathbf{0})\right] \quad .$$

Note that $\mathcal{D}(\mathbf{0},\ldots,\mathbf{0})$ equals 0. Therefore, denoting by Δ_t the difference in two consecutive dual objective values, $\mathcal{D}(\lambda_1,\ldots,\lambda_t,\mathbf{0},\ldots,\mathbf{0}) - \mathcal{D}(\lambda_1,\ldots,\lambda_{t-1},\mathbf{0},\ldots,\mathbf{0})$, we get that $\sum_{t=1}^T \Delta_t \leq \mathcal{P}(\omega^\star,\xi^\star)$. We now turn to bounding Δ_t from below. First, note that if the prediction on trial t is perfect ($\mathcal{M}^t = \emptyset$) then SimPerc sets λ_t to the zero vector and thus $\Delta_t = 0$. We can thus focus on trials for which the algorithm's prediction is imperfect. We remind the reader that by unraveling the update of ω^t we get that $\omega^t = \sum_{s<t}\sum_{j=1}^{k_s} \lambda_{s,j} y_j^s \mathbf{x}_j^s$. We now rewrite Δ_t as follows,

$$\Delta_t = \sum_{j=1}^{k_t} \lambda_{t,j} - \frac{1}{2}\left\|\omega^t + \sum_{j=1}^{k_t} \lambda_{t,j} y_j^t \mathbf{x}_j^t\right\|^2 + \frac{1}{2}\left\|\omega^t\right\|^2 \quad . \tag{15}$$

By construction, $\lambda_{t,j} = \mu_j^t \alpha_j^t$ and $\sum_{j=1}^{k_t} \mu_j^t = 1$, which lets us further expand Eq. (15) and write,

$$\Delta_t = \sum_{j=1}^{k_t} \mu_j^t \alpha_j^t - \frac{1}{2}\left\|\omega^t + \sum_{j=1}^{k_t} \mu_j^t \alpha_j^t y_j^t \mathbf{x}_j^t\right\|^2 + \frac{1}{2}\sum_{j=1}^{k_t} \mu_j^t \left\|\omega^t\right\|^2 \quad .$$

The squared norm, $\|\cdot\|^2$ is a convex function in its vector argument and thus Δ_t is concave, which yields the following lower bound on Δ_t,

$$\Delta_t \geq \sum_{j=1}^{k_t} \mu_j^t \left[\alpha_j^t - \frac{1}{2}\left\|\omega^t + \alpha_j^t y_j^t \mathbf{x}_j^t\right\|^2 + \frac{1}{2}\left\|\omega^t\right\|^2\right] \quad . \tag{16}$$

The SimPerc algorithm sets μ_j^t to be $1/|\mathcal{M}^t|$ for all $j \in \mathcal{M}^t$ and to be 0 otherwise. Furthermore, for all $j \in \mathcal{M}^t$, α_j^t is set to C. Thus, the right-hand side of Eq. (16) can be further simplified and written as,

$$\Delta_t \geq \sum_{j \in \mathcal{M}^t} \mu_j^t \left[C - \frac{1}{2}\left\|\omega^t + C y_j^t \mathbf{x}_j^t\right\|^2 + \frac{1}{2}\left\|\omega^t\right\|^2\right] \quad .$$

In order to further explore Eq. (6) we require the following simple lemma

Lemma 3 *Let ω^t denote the predictor used by the SimPerc scheme on trial t. Let $j \in \mathcal{M}^t$ denote an index of a mispredicted instance on trial t. Then*

$$\frac{1}{2}\left\|\omega^t + Cy_j^t \mathbf{x}_j^t\right\|^2 - \frac{1}{2}\left\|\omega^t\right\|^2 \leq \frac{1}{2}C^2\left\|y_j^t \mathbf{x}_j^t\right\|^2 \quad .$$

Proof We start by expanding the norm of the vector after the update,

$$\frac{1}{2}\left\|\omega^t + Cy_j^t \mathbf{x}_j^t\right\|^2 = \frac{1}{2}\left\|\omega^t\right\|^2 + Cy_j^t \omega^t \cdot \mathbf{x}_j^t + \frac{1}{2}C^2\left\|y_j^t \mathbf{x}_j^t\right\|^2 \quad .$$

Thus, the change in the norm is,

$$\begin{aligned}\frac{1}{2}\left\|\omega^t + Cy_j^t \mathbf{x}_j^t\right\|^2 - \frac{1}{2}\left\|\omega^t\right\|^2 &= \frac{1}{2}\left\|\omega^t\right\|^2 + Cy_j^t \omega^t \cdot \mathbf{x}_j^t + \frac{1}{2}C^2\left\|y_j^t \mathbf{x}_j^t\right\|^2 - \frac{1}{2}\left\|\omega^t\right\|^2 \\ &= Cy_j^t \omega^t \cdot \mathbf{x}_j^t + \frac{1}{2}C^2\left\|y_j^t \mathbf{x}_j^t\right\|^2 \quad .\end{aligned}$$

The set $\mathcal{M}^t$ consists of indices of instances which were incorrectly classified. Thus, $y_j^t(\omega^t \cdot \mathbf{x}_j^t) \leq 0$ for every $j \in \mathcal{M}^t$. The equation above can thus be further bounded by $\frac{1}{2}C^2\left\|y_j^t \mathbf{x}_j^t\right\|^2$. ■

Lemma 3 assures us that for all instances whose $\mu_j > 0$ the term $\frac{1}{2}\left\|\omega^t + Cy_j^t \mathbf{x}_j^t\right\|^2 - \frac{1}{2}\left\|\omega^t\right\|^2$ can be upper bounded. Therefore, Δ_t can further be bounded from below as follows,

$$\Delta_t \geq \sum_{j \in \mathcal{M}^t} \mu_j^t \left[C - \frac{1}{2}C^2\left\|y_j^t \mathbf{x}_j^t\right\|^2\right] \geq \sum_{j \in \mathcal{M}^t} \mu_j^t \left[C - \frac{1}{2}C^2R^2\right] = C - \frac{1}{2}C^2R^2 \quad ,$$

where for the second inequality we used the fact that the norm of all the instances is bounded by R. To recap, we have shown that on trials for which the prediction is imperfect $\Delta_t \geq C - \frac{1}{2}C^2R^2$, while in perfect trials where no mistake is made $\Delta_t = 0$. Putting all the inequalities together we obtain the following bound,

$$\left(C - \frac{1}{2}C^2R^2\right)\varepsilon \leq \sum_{t=1}^{T} \Delta_t = \mathcal{D}(\lambda_1, \ldots, \lambda_T) \leq \mathcal{P}(\omega^\star, \xi^\star) \quad ,$$

where ε is the number of imperfect trials. Finally, rewriting $\mathcal{P}(\omega^\star, \xi^\star)$ as

$$\frac{1}{2}\|\omega^\star\|^2 + C\sum_{t=1}^{T} \ell(\omega^\star; (\mathbf{X}^t, \mathbf{y}^t) \quad ,$$

yields the bound stated in the theorem. ■

The ConProj algorithm updates the same set of dual variables as the SimPerc algorithm. However, it selects α_j^t to be the optimal solution of Eq. (4). Thus, the value of Δ_t attained by the ConProj algorithm is never lower than the value attained by the SimPerc algorithm, assuming both versions start with the same predictor ω_t. The case of the SimOpt algorithm is very similar, as it promises to optimally increase the value of Δ_t and thus is never lower than the value attained by the SimPerc algorithm. The following corollary is a direct consequence of these observations.

Corollary 4 *Under the same conditions of Thm. 2 and for any $\omega^\star \in \mathbb{R}^n$, the number of trials on which the prediction of either ConProj or SimOpt is imperfect is at most,*

$$\frac{\frac{1}{2}\|\omega^\star\|^2 + C\sum_{t=1}^{T}\ell\left(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t)\right)}{C-\frac{1}{2}C^2R^2} \quad .$$

Note that the predictions of the SimPerc algorithm do not depend on the specific value of C, thus for $R=1$ and an optimal choice of C the bound attained in Thm. 2 now becomes.

$$\varepsilon \le \ell\left(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t)\right) + \frac{1}{2}\|\omega^\star\|^2 + \frac{1}{2}\sqrt{\|\omega^\star\|^4 + \|\omega^\star\|^2\sum_{t=1}^{T}\ell\left(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t)\right)} \quad .$$

See Appendix B for a complete analysis.

We conclude this section with a few closing words about the SimProj variant. The SimPerc and ConProj algorithms ensure a minimal increase in the dual by focusing solely on classification errors and ignoring margin errors. While this approach ensures a sufficient increase of the dual, in practice it appears to be a double edged sword as the SimProj algorithm performs empirically better. This superior empirical performance can be motivated by a viewing the similarity of the update forms performed by the SimProj and SimOpt variants, which means that the actual increase in the dual attained by the SimProj algorithm is larger than can be guaranteed using worst case analysis.

7. Decomposable Losses

Recall that our algorithms tackle complex decision problems by decomposing each instance into multiple binary decision tasks, thus, on trial t the algorithm receives k_t instances. The classification scheme is evaluated by looking at the maximal violation of the margin constraints $\ell(\hat{\mathbf{y}}^t,\mathbf{y}^t) = \max_j \left[1-y_j^t\hat{y}_j^t\right]_+$. While such approach often captures the inherent relation between the multiple binary tasks, it may often be desired to introduce more complex evaluation measures. In this section we introduce a generalization of the algorithm for various decomposable losses. As a corollary we obtain a *Simultaneous Projection* algorithm that is competitive with the average performance error on each set of k_t instances.

First, we introduce the notion of the decomposable losses. On trial t the algorithms receives a partition of the k_t instances into r_t sets. Let $S_1^t,\ldots,S_{r_t}^t$ denote a partition of $[k_t]$ into r_t sets, namely, $\cup_l S_l^t = [k_t]$ and $\forall l \neq k:\ S_l^t \cap S_k^t = \emptyset$. A set S_l ties the instances in the sense that failing to predict *any* instance in S_l amounts to the same error as failing to predict all of them. We thus suffer a unit loss at trial t for each set S_l that was imperfectly predicted. The definition of the loss is extended to

$$\hat{\ell}\left(\hat{\mathbf{y}}^t,\mathbf{y}^t\right) = \frac{1}{r_t}\sum_{l=1}^{r_t}\max_{j\in S_l^t}\left[1-y_j^t\hat{y}_j^t\right]_+ \quad . \tag{17}$$

By construction, the setting suggested in Sec. 2 is a special case of the setting we consider in this section. We show in the sequel though that our original analysis carries over this this more general setting.

Thus, each iteration the algorithm receives k_t instances and a partition of the labels into sets $S_1^t,\ldots,S_{r_t}^t$. The instantaneous primal (Eq. 2) is thus extended to include a single slack variable for

Input:
Aggressiveness parameter $C > 0$
Initialize:
$\omega_1 = (0, \ldots, 0)$
For $t = 1, 2, \ldots, T$:
Receive instance matrix $X^t \in \mathbb{R}^{k_t \times n}$
Predict $\hat{\mathbf{y}}^t = \mathbf{X}^t \omega^t$
Receive correct labels $\mathbf{y}^t$
Receive partition of labels $S_1^t, \ldots, S_{r_t}^t$
Suffer loss $\hat{\ell}(\omega^t; (\mathbf{X}^t, \mathbf{y}^t))$
If $\hat{\ell} > 0$:
Choose importance weights μ^t s.t. for each set S_l^t, $\sum_{j \in S_l^t} \mu_j^t = 1$
Choose individual dual solutions α_j^t
Update $\omega^{t+1} = \omega^t + \sum_{l=1}^{r_t} \sum_{j \in S_l^t} \mu_j^t \alpha_j^t y_j^t \mathbf{x}_j^t$

Figure 5: The extended simultaneous projections algorithm for decomposable losses.

each set as follows:

$$\begin{aligned} &\min_{\omega \in \mathbb{R}^n, \xi \geq 0} \frac{1}{2} \left\| \omega - \omega^t \right\|^2 + \frac{C}{r_t} \sum_{l=1}^{r_t} \xi_l \\ &\text{s.t.} \qquad \forall l \in [r_t],\ \forall j \in S_l^t :\ \ y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \geq 1 - \xi_l \qquad \forall l \in [r_t] :\ \ \xi_l \geq 0 \end{aligned} \quad . \tag{18}$$

The dual of Eq. (18) is thus

$$\begin{aligned} &\max_{\alpha_1^t, \ldots, \alpha_{k_t}^t} \ \sum_{j=1}^{k_t} \alpha_j^t - \frac{1}{2} \left\| \omega^t + \sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t \right\|^2 \\ &\text{s.t.} \qquad \forall l : \sum_{j \in S_l^t} \alpha_j^t \leq \frac{C}{r_t} \qquad \forall j : \alpha_j^t \geq 0 \end{aligned} \quad .$$

Note that since $\forall k \neq l : S_l^t \cap S_k^t = \emptyset$ then the induced constraint $\sum_{j \in S_l^t} \alpha_j^t \leq \frac{C}{r_t}$ corresponds to a unique set of dual variables α_j^t. We can thus apply the same technique and select a non-negative vector μ where the entries corresponding to each set S_l^t form a probability distribution, namely $\forall l : \sum_{j \in S_l^t} \mu_j^t = 1$. To recap, we can employ any of the variants on each set *separately* and attain a dual feasible solution. We denote these variants as the decomposition variants. In Fig. 5 we provide the pseudo-code of the algorithm.

We next show that our mistake bound analysis can be extended to the decomposable loss. The analysis follows closely to the analysis presented in Sec. 6, where the global primal and global dual are modified so as to use the decomposition loss. We therefore focus only on highlighting the necessary changes. Eq. (11) thus becomes

$$\begin{aligned} &\min_{\omega \in \mathbb{R}^n, \xi \in \mathbb{R}^T} \frac{1}{2} \left\| \omega \right\|^2 + C \sum_{t=1}^{T} \sum_{l=1}^{r_t} \frac{\xi_{t,l}}{r_t} \\ &\text{s.t.} \qquad \forall t \in [T], \forall l \in [r_t], \forall j \in S_l^t : y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \geq 1 - \xi_{t,l} \qquad \forall t \forall l : \xi_{t,l} \geq 0 \end{aligned} \quad . \tag{19}$$

and its dual is

$$\max_{\lambda} \sum_{t=1}^{T}\sum_{j=1}^{k_t}\lambda_{t,j} - \frac{1}{2}\left\|\sum_{t=0}^{T}\sum_{j=1}^{k_t}\lambda_{t,j}y_j^t\mathbf{x}_j^t\right\|^2 \quad \text{s.t.} \quad \forall t\forall l\in[r_t]:\sum_{j\in S_l^t}\lambda_{t,j}\le\frac{C}{r_t} \quad \forall t,j:\lambda_{t,j}\ge 0 \ .$$

Clearly, the instantaneous dual can still be seen as optimizing the global dual, while fixing the dual variables $\lambda_{t',j}$ for all $t'\neq t$.

To recap, we replace the loss of the instantaneous optimization problem defined in Eq. (1) with the average over a decomposition of losses $\hat{\ell}$ as defined by Eq. (17). Next, in order to obtain a mistake bound, we look at the global optimization task defined by Eq. (19). As previously showed, the simultaneous projection scheme can be viewed as an incremental update to the dual of Eq. (19). It is interesting to note that for every decomposition of the k_t instances into sets, the value of $\hat{\ell}(\omega;(\mathbf{X}^t,\mathbf{y}^t))$ is upper bounded by $\ell(\omega;(\mathbf{X}^t,\mathbf{y}^t))$, as $\hat{\ell}$ is the average over the margin violations while ℓ corresponds to the *worst* margin violation. Thus, the loss underpinning the global optimization from Eq. (11) upper bounds the loss yielding Eq. (19). The following corollary immediately holds.

Corollary 5 *Under the same conditions of Thm. 2, the loss suffered along the run of either decomposition variant is at most,*

$$\frac{\frac{1}{2}\|\omega^\star\|^2 + C\sum_{t=1}^{T}\hat{\ell}(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t))}{C-\frac{1}{2}C^2R^2} \ .$$

In conclusion, the simultaneous projection scheme allows us to easily obtain online algorithms and update schemes for complex problems, such algorithms are obtained by decomposing a complex problem into multiple binary problems. It is often the case where the maximal violation over all binary problems correctly captures the inherent violation of the original complex problem. In this section we explored cases where a more refined definition of error is required. Specifically, if we define each binary instance in a separate set, we obtain an algorithmic framework where our competitor is evaluated according to the average loss.

8. Simultaneous Multiplicative Updates

In this section we describe and analyze a multiplicative version of the simultaneous projection scheme. Recall that our motivation was to introduce a solution to the instantaneous optimization problem given in Eq. (2). The instantaneous objective captures the following trade-off. On one hand we would like to set ω to be as *close* as possible to ω^t. On the other hand, we would like to minimize the loss incurred by the instances received on trial t. In previous sections we used the squared Euclidean norm to define the measure of distance between ω^t and ω. In this section we take a different approach and use the relative entropy as the notion of closeness between two vectors. By doing so we derive a multiplicative version of our online algorithmic framework. In this section we confine ourselves to linear predictors that lie in the probability simplex, that is, we consider non-negative vectors ω such that $\sum_{i=1}^{n}\omega_i = 1$. Previously, we used a fixed value of 1 for the margin that is needed in order to suffer no loss, where it was understood that we may simultaneously scale the prediction vector and the margin. Since we now prevent such scaling due to the choice of the simplex domain, we need to slightly modify the definition of the loss and introduce the following definition, $\ell_\gamma(\hat{\mathbf{y}}^t,\mathbf{y}^t) = \max_j\left[\gamma - y_j^t\hat{y}_j^t\right]_+$.

Recall that on trial t the algorithm receives k_t instances arranged in a matrix $\mathbf{X}^t$. After extending a prediction vector, $\omega^t \mathbf{X}^t$, the algorithm receives the vector of correct labels $\mathbf{y}^t$ and suffers a loss for any incorrect prediction. If no mistake is made the algorithm proceeds to the next round. Otherwise we would like to set ω^t to be the solution of the following optimization problem

$$\min_{\omega \in \Delta_n} D_{\mathrm{KL}}(\omega \| \omega^t) + C\,\ell_\gamma(\omega; (\mathbf{X}^t, \mathbf{y}^t)) \quad , \tag{20}$$

where C is a trade-off parameter. The term D_{KL} is the relative entropy operator, also known as the Kullback-Leibler divergence, and is defined as

$$D_{\mathrm{KL}}(\omega \| \omega^t) = \sum_{i=1}^{n} \omega_i \log \frac{\omega_i}{\omega_i^t} \quad .$$

The dual problem of Eq. (20) is,

$$\begin{aligned} & \gamma \sum_{j=1}^{k_t} \alpha_j^t - \log\left(\sum_{i=1}^{n} \omega_i^t \exp\left(\sum_{j=1}^{k_t} \tau_i^j \right) \right) \\ & \text{s.t.} \qquad \sum_{j=1}^{k_t} \alpha_j^t \le C \qquad \forall j : \alpha_j^t \ge 0 \qquad \forall j : \tau^j = \alpha_j^t y_j^t \mathbf{x}_j^t \end{aligned} \quad . \tag{21}$$

The prediction vector ω is set as follows,

$$\omega_i = \omega_i^t \frac{\exp\left(\sum_{j=1}^{k_t} \tau_i^j \right)}{\sum_{l=1}^{n} \omega_l^t \exp\left(\sum_{j=1}^{k_t} \tau_i^j \right)} \quad . \tag{22}$$

The complete derivation of the dual problem and the update of ω is given in Appendix A.

We follow the same technique suggested in Sec. 4 and decompose Eq. (21) into k_t separate problems, each concerning a single dual variable. The resulting j'th reduced dual problem is thus

$$\begin{aligned} & \gamma \alpha_j^t - \log\left(\sum_{i=1}^{n} \omega_i^t \exp\left(\tau_i^j \right) \right) \\ & \text{s.t.} \qquad 0 \le \alpha_j^t \le C \qquad \tau^j = \alpha_j^t y_j^t \mathbf{x}_j^t \end{aligned} \quad . \tag{23}$$

We next obtain an exact or approximate solution for each reduced problem as if it were independent of the rest. We follow by choosing a vector $\mu \in \Delta_{k_t}$, and multiply each α_j^t by a corresponding value μ_j^t. Our choice of μ assures us $\{\mu_j^t \alpha_j^t\}$ constitutes a feasible solution to the dual problem defined in Eq. (21) for the following reason. Each $\mu_j^t \alpha_j^t \ge 0$ and the fact that $\alpha_j^t \le C$ implies that $\sum_{j=1}^{k_t} \mu_j^t \alpha_j^t \le C$. Finally, the algorithm uses the combined solution and sets ω^{t+1} according to Eq. (22). The template of the multiplicative simultaneous projections algorithm is described in Fig. 6.

We may now apply the methods introduced in Sec. 5 and introduce the multiplicative schemes. The SimPerc scheme can be trivially applied to the multiplicative setting. We next show a closed-form solution to α_j^t for each reduced problem if the components of each instance are from $\{-1, 0, 1\}^n$. To so we need to introduce the following notation.

$$W_j^+ = \frac{\sum_{i: y_j^t x_{ji}^t = 1} \omega_i^t}{\sum_{l=1}^{n} \omega_l^t} \;,\; W_j^- = \frac{\sum_{i: y_j^t x_{ji}^t = -1} \omega_i^t}{\sum_{l=1}^{n} \omega_l^t} \;,\; \text{and } W_j^0 = 1 - W_j^+ - W_j^- \quad .$$

Input:
Aggressiveness parameter $C > 0$
Initialize:
$\omega_1 = (\frac{1}{n}, \ldots, \frac{1}{n})$
For $t = 1, 2, \ldots, T$:
Receive instance matrix $X^t \in \mathbb{R}^{k_t \times n}$
Predict $\hat{\mathbf{y}}^t = \mathbf{X}^t \omega^t$
Receive correct labels $\mathbf{y}^t$
Suffer loss $\ell(\omega^t; (\mathbf{X}^t, \mathbf{y}^t))$
If $\ell > 0$:
Choose importance weights μ^t s.t. $\sum_{j=1}^{k_t} \mu_j^t = 1$
Choose individual dual solutions α_j^t
Compute $\tau^j = \alpha_j^t y_j^t \mathbf{x}_j^t$
Update $\omega_i^{t+1} = \frac{\omega_i^t \exp\left(\sum_{j=1}^{k_t} \mu_j^t \tau_i^j\right)}{\sum_l \omega_l^t \exp\left(\sum_{j=1}^{k_t} \mu_j^t \tau_l^j\right)}$

Figure 6: The multiplicative simultaneous projections algorithm.

The optimal value of α_j^t is thus log of the root of a quadric equation with W_j^+, W_j^-, W_j^0 as coefficients. We also need to take into account the boundary constraints on α_j^t, namely, $0 \leq \alpha_j^t \leq C$. Thus, α_j^t is the minimum between the following root and C,

$$\log\left(\frac{\gamma W_j^0 + \sqrt{\gamma^2 (W_j^0)^2 + 4(1-\gamma^2) W_j^+ W_j^-}}{2(1-\gamma) W_j^+}\right) ,$$

The derivation can be found at Appendix C. Using the closed-form solution for α_j^t we can adapt both the ConProj and SimProj scheme to the multiplicative setting.

We next turn our attention to the analysis of the multiplicative algorithm and focus on the SimPerc scheme. The analysis here follows closely the analysis presented in Sec. 6. Hence, the remainder of this section focuses on highlighting the key changes that are required. Formally, we prove the following theorem.

Theorem 6 *Let $\left(\mathbf{X}^1, \mathbf{y}^1\right), \ldots, \left(\mathbf{X}^T, \mathbf{y}^T\right)$ be a sequence of examples where $\mathbf{X}^t$ is a matrix of k_t examples and $\mathbf{y}^t$ are the associated labels. Assume that for all t and j the ℓ_∞ norm of an instance $\mathbf{x}_j^t$ is at most R. Then, for any $\omega^\star \in \Delta_n$ the number of trials on which the prediction of SimPerc is imperfect is at most,*

$$\frac{\sum_{i=1}^n \omega_i^\star \log \frac{\omega_i^\star}{1/n} + C \sum_{t=1}^T \ell_\gamma(\omega^\star; (\mathbf{X}^t, \mathbf{y}^t))}{C - \frac{1}{2} C^2 R^2} .$$

Proof Following the technique introduced in Sec. 6, our goal is to upper bound the number of imperfect trials compared to the performance of any fixed competitor, even one defined in hindsight.

Our competitor is thus evaluated using the global optimization problem given by,

$$\begin{aligned} &\min_{\omega\in\Delta_n,\xi\geq 0} \sum_{i=1}^{n} \omega_i \log\frac{\omega_i}{\omega_i^t} + C\sum_{t=1}^{T}\xi_t \\ &\text{s.t.} \qquad \forall t\in[T], \forall j\in[k_t] : y_j^t\left(\omega\cdot\mathbf{x}_j^t\right) \geq \gamma - \xi_t \qquad \forall t : \xi_t \geq 0 \end{aligned} \quad . \tag{24}$$

The dual of Eq. (24) is

$$\begin{aligned} &\gamma\sum_{t=1}^{T}\sum_{j=1}^{k_t}\lambda_j^t - \log\left(\sum_{i=1}^{n}\exp\left(\sum_{t=1}^{T}\sum_{j=1}^{k_t}\tau_i^{tj}\right)\right) \\ &\text{s.t.} \qquad \forall t\in[T] : \sum_{j=1}^{k_t}\lambda_j^t \leq C \qquad \forall t, \forall : \lambda_j^t \geq 0 \qquad \forall t, \forall j : \tau^{tj} = \lambda_j^t y_j^t \mathbf{x}_j^t \end{aligned} \quad . \tag{25}$$

We denote the objective of Eq. (25) by $\mathcal{D}(\lambda_1,\ldots,\lambda_T)$. The instantaneous dual of Eq. (21) can be seen as incrementally building an assignment for the dual: At trial t we fix λ^s for $s<t$ to their previous values, and fix λ^s for $s>t$ to 0. Thus ω^t is defined as follows

$$\omega_i^t = \frac{\exp\left(\sum_{s=1}^{t}\sum_{j=1}^{k_s}\tau_i^{sj}\right)}{\sum_{l=1}^{n}\exp\left(\sum_{s=1}^{T}\sum_{j=1}^{k_s}\tau_l^{sj}\right)} \quad .$$

The key difference between the multiplicative schemes and the previously analyzed scheme lies in Lemma 3. We thus progress to derive a similar lemma for the multiplicative setting.

Lemma 7 *Let $\theta = \sum_{l=1}^{t-1}\sum_{j=1}^{k_l}\lambda_j^t y_j^t \mathbf{x}_j^t$ denote the dual variables assigned in trials prior to t by the SimPerc scheme. Let $j\in\mathcal{M}^t$ denote an index of a mispredicted instance on trial t. Then, the difference,*

$$\log\left(\sum_{i=1}^{n}\exp\left(\theta_i + Cx_{ji}^t y_j^t\right)\right) - \log\left(\sum_{i=1}^{n}\exp\left(\theta_i\right)\right) \quad ,$$

is upper bounded by $\frac{1}{2}C^2\left\|\mathbf{x}\right\|_\infty^2$.

Proof Denote the vector $C\mathbf{x}_j^t y_j^t$ by τ. Let $F(\theta)$ denote the value of $\log\left(\sum_{i=1}^{n}e^{\theta_i}\right)$. Hence, we would like to upper bound the difference $F(\theta+\tau)-F(\theta)$. We prove the lemma based on the following inequality

$$F(\theta+\tau) - F(\theta) \;\leq\; \sum_{i=1}^{n}\frac{e^{\theta_i}}{\sum_l e^{\theta_l}}\tau_i + \frac{1}{2}\max_i \tau_i^2 \quad .$$

The above inequality was used and proved in numerous previous analyses of multiplicative update methods. See for instance Examples 2 and 5 in Kivinen and Warmuth (2001). Consider the term $\sum_{i=1}^{n}\frac{e^{\theta_i}}{\sum_l e^{\theta_l}}\tau_i$. Recall that the prediction in trial t is made by using the predictor defined by Eq. (22). Thus, the above term is the following inner product between the vector τ and the predictor used on round t,

$$\sum_{i=1}^{n}\frac{e^{\theta_i}}{\sum_l e^{\theta_l}}\tau_i = \sum_{i=1}^{n}\omega_i^t\tau_i = \langle\omega^t,\tau\rangle = Cy_j^t\langle\omega^t,\mathbf{x}_j^t\rangle \leq 0 \quad ,$$

where the last inequality is due to the fact that we assume $j \in \mathcal{M}^t$ (the prediction was incorrect) and the inner-product is non-positive. Therefore, we obtain the required upper bound

$$F(\theta+\tau) - F(\theta) \leq \frac{1}{2}\max_i \tau_i^2 \frac{1}{2}\|\tau\|_\infty^2 = \frac{1}{2}C^2 \left\|\mathbf{x}_j^t\right\|_\infty^2 \quad .$$

■

To recap, we showed that the instantaneous dual can be seen as incrementally constructing an assignment for a global dual function (Eq. 25). Furthermore, we showed that Lemma 3 can be adapted to the multiplicative settings. The rest of the proof follows the same lines of the proof given in Sec. 6. Namely, trials in which a prediction mistake was made, the SimPerc scheme is guaranteed a substantial increase in the incremental dual buildup. Finally, using weak-duality we obtain that the evaluation measure for the competitor is the lower bounded by,

$$\frac{\sum_{i=1}^n \omega_i^\star \log \frac{\omega_i^\star}{1/n} + C\sum_{t=1}^T \ell_\gamma(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t))}{C - \frac{1}{2}C^2R^2} \quad .$$

■

The multiplicative ConProj scheme assigns α_j^t the value which maximizes the reduced instantaneous dual. The ConProj scheme thus maximizes the difference between the value of the global dual in two consecutive rounds. We thus obtain an equivalent corollary of Corollary 4 for the multiplicative setting.

Corollary 8 *Under the same conditions of Thm. 6 and for any $\omega^\star \in \mathbb{R}^n$, the number of trials on which the prediction of the ConProj scheme is imperfect is at most,*

$$\frac{\sum_{i=1}^n \omega_i^\star \log \frac{\omega_i^\star}{1/n} + C\sum_{t=1}^T \ell_\gamma(\omega^\star;(\mathbf{X}^t,\mathbf{y}^t))}{C - \frac{1}{2}C^2R^2} \quad .$$

We thus showed that the multiplicative SimPerc and ConProj schemes entertain a similar mistake bound as the original formulation. Note, however, that in the multiplicative settings we assume that the ℓ_∞ norm of all instances are bounded by R, while in the additive settings, we have assumed that the ℓ_2 norm of the instances is bounded by R.

9. Experiments

In this section we describe experiments we performed with synthetic and real data sets. The goal of the experiments is to underscore the properties of the simultaneous projection algorithms and to demonstrate some of their merits. Specifically, we examine how the various simultaneous projections variants perform with respect to the size of each block, how does the performance deteriorate with label noise, and the dependency of the algorithms on the number of relevant features. Our experiments with synthetic data are followed with email categorization experiments. On the synthetic data we compare our simultaneous projections algorithms with a commonly used technique whose updates are based on the most violating constraint on each online round (see for instance Crammer

et al., 2006). In the multiclass email categorization experiment, we also use the Sopopo algorithm described in Shalev-Shwartz and Singer (2006b) and a numerical solver which finds the optimal solution of the optimization problem on hand. To recap, we experimented with the following three families of online algorithms.

Simultaneous Projections Algorithms We evaluated all the variants given in Fig. 3, in both their additive and multiplicative forms. We denote the different variants using the notation `name`.A or `name.M` where `name` denotes the specific simultaneous projection scheme as given in Fig. 3 and the .A or .M suffix designate whether the update took an additive or multiplicative form. For example the additive SimProj algorithm is denoted by SimProj.A

MaxPA The algorithm extends the binary Passive-Aggressive family of algorithms (Crammer et al., 2006) to structured prediction problems. The algorithm uses a construction which is similar to our instantaneous primal objective (Eq. 2), and analogously attempts to obtain a feasible solution to its dual. The difference lies in the fact that the MaxPA algorithm focuses on a single instance whose margin constraint is mostly violated and updates *only* its corresponding dual variable, while fixing all other dual variables to zero. The single dual variable is then optimally computed. This update form constitutes a feasible solution to the instantaneous dual and casts a simple update for the online algorithm.

Optimal Solver The optimal solver algorithm employs a numerical solver on each iteration, and solves optimally the instantaneous primal given by Eq. (2). Specifically, we used the Pegasos algorithm from Shalev-Shwartz et al. (2007) to perform the optimization task. We chose this algorithm since it provides a simple solver which proved superior to second order methods in various classification tasks (Shalev-Shwartz et al., 2007).

Sopopo The Sopopo[1] algorithm is a novel algorithm for label ranking and is thus used only in our label ranking experiments with email data. The Sopopo algorithm computes the *optimal* solution to an instantaneous optimization problem similar cast by Eq. (2) while using a slightly different setting. We further elaborate on the different setting in Sec. 9.2.

9.1 Experiments with Synthetic Data

We tested the performance of the additive and the multiplicative variants of our algorithm in a series of experiments using synthetic data. Our goal in this section is to underscore the merits of our simultaneous projections approach in comparison with the commonly used max update techniques (MaxPA). Since it is often computationally prohibitive to run a full numerical solver on each iteration, we omitted the optimal solver from this set comparisons.

Before we describe the results of our experiments with synthetic data, let us first discuss the procedures used to generate the data. In order to compare both the additive and the multiplicative versions of our framework, we confined ourselves to the more restrictive setting of the multiplicative schemes as described in Sec. 8. Specifically, the data was generated by randomly constructing instances $\mathbf{x}^t \in \{-1,0,1\}^n$ and classification was performed by selecting a probability vector $\omega \in \Delta_n$. We used a sparse classifier where the number of relevant features in ω varied from 10% to 50% active features. The non-zero components of ω were chosen uniformly at random from $[0,1]$. We

1. The name Sopopo stands for SOft Projection Onto Polyhedra.

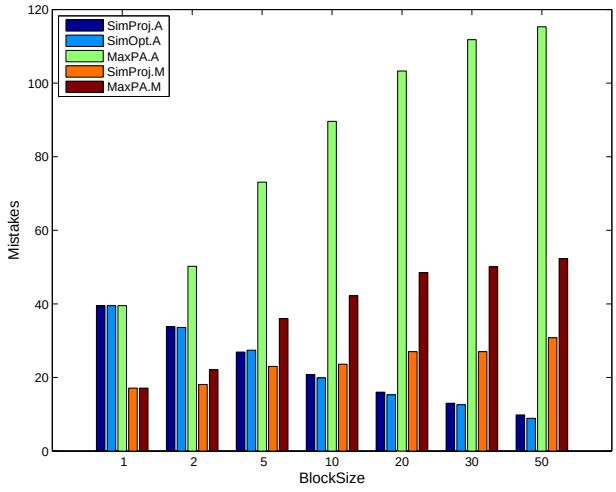

Figure 7: The number of mistakes suffered by the various the additive and multiplicative simultaneous projections methods. The performance of the algorithms is compared as a function of the block size.

then normalized the vector such that its L_1 norm would be one. We generated linearly separable data whose margin was calculated as follows. Each entry in $\mathbf{x}$ was set to 0 with probability p and otherwise it was chosen from $\{-1,1\}$ with equal probability. We then computed the value of γ for which 75% of all instances sampled from the process above would fall inside a margin of γ. We then repeatedly generated and rejected instances, until we managed to construct sufficient number of examples. We refer to a set examples grouped together into a single classification task as a block.

We ran each online experiment for 1000 trials and recorded the number of mistakes performed by the online algorithms. Each experiment was repeated 10 times. The results we present are the averages of these runs. For each experiment, we performed a search for a good value of C. We checked 9 values for C, ranging from 2^{-5} to 2^3. For the multiplicative variants, we also performed a search for a good value of γ by examining values in the range 0.5 to 2 times the margin used during the data generation process. We compared all simultaneous projection variants presented earlier, as well as the multiplicative and additive versions of the MaxPA update.

The first experiment with synthetic data assesses the performance of the various update schemes as a function of the block sizes. We used instances in $\{-1,0,1\}^{500}$ where ω contained 50 relevant features. The results are described in Fig. 7. We clearly see that while both schemes entertain the same mistake bound, in practice the SimProj algorithms always perform better than the maximal update. The difference in practical performance can be attributed to the fact that the simultaneous projections mechanism uses more information regarding the structure of the problem at hand.

Note that for both the *MaxPA.A* scheme and the multiplicative schemes the performance deteriorates as the block size increases. A converse trend is exhibited in the case of *SimProj.A* and *SimOpt.A*. One possible explanation for the improvement with block size increase may be observed by considering the geometrical structure of the instances. Recall that we generate uniformly selected linearly separable data. Thus, the update form the additive variants apply can be seen as performing the update using the average instance. For large blocks the average instance is equivalent to the vec-

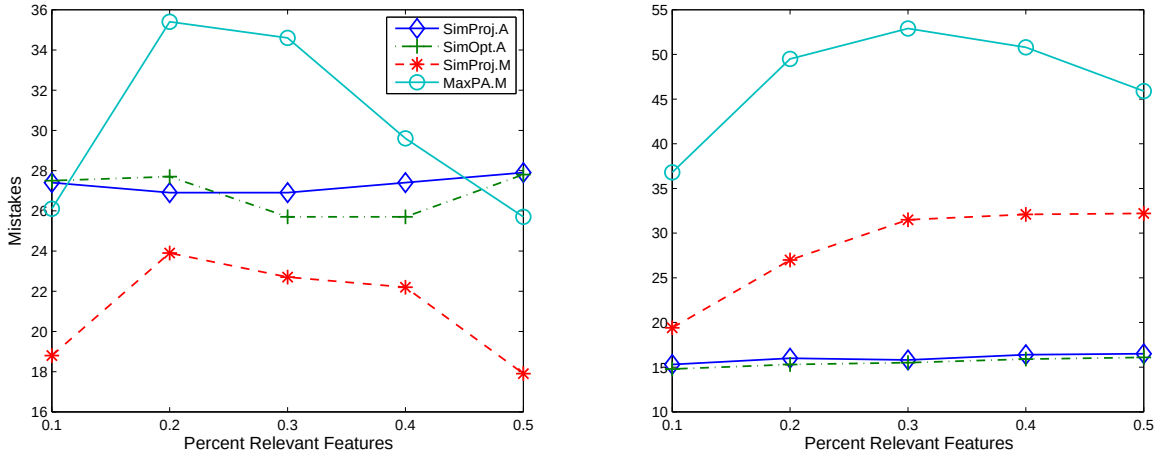

Figure 8: The performance of the additive and multiplicative simultaneous projections algorithms as a function of the sparsity of the hypothesis generating the data. Results are shown for block size of 5 instances (left) and of 20 instances (right).

tor used to describe the separating hyperplane. Such averaging does not occur in the multiplicative case, or the *MaxPA.A* scheme.

Our second experiment examines the effect of the sparsity of ω on the performance of the algorithms. As before, we used instances in $\{-1,0,1\}^{500}$. We varied the number of non-zero elements of ω from 50 to 250. The results of this experiments are plotted in Fig. 8. We ran this experiment with a block size of 5 instances per trial (Fig. 8 left) and a block size of 20 (Fig. 8 right). We omit the plot of *MaxPA.A* as its performance is much worse than any of the other algorithms. It is apparent that the additive versions are rather insensitive to the sparsity of the prediction matrix. The converse is true for the multiplicative variants. For both block sizes, we see that the performance of the multiplicative versions deteriorate as we increase the percentage of relevant features from 10% to 30%. This decrease in performance is then replaced with a gradual increase in performance once the number of relevant features is over 30%. This increase in performance may be attributed to the fact that there are more relevant features which are set approximately uniformly. Thus, the optimal solution is rather close to the initial vector and the multiplicative algorithm converges faster.

Our last experiment with synthetic data examines the effect of label noise on the performance of the simultaneous projections algorithms. We employed the same settings as in the previous experiment with instances of 500 dimensions and 50 non-zero entries in ω. After the data was generated, we chose to contaminate with label noise each trial with a fixed probability. If the block was selected for contamination, we flipped the label of each the instances in the block with probability 0.4. We repeated the experiment with varying probabilities of picking a block for contamination. We tested values from the set $\{0$ (no label noise), 0.05,0.1,0.15, $0.2\}$. To avoid too aggressive online updates, we increased the range of the search for C to be in $[2^{-9},2^{3}]$. The results of this experiment are plotted in Fig. 9. We ran this experiment with a block size of 5 instances per trials (Fig. 9 left) and block size of 20 (Fig. 9 right) instances per trial.

We can clearly see that the number of mistakes of all the SimProj variants scale linearly with the noise rate. It is also apparent that the number of mistakes of the MaxPA.A algorithm scales super

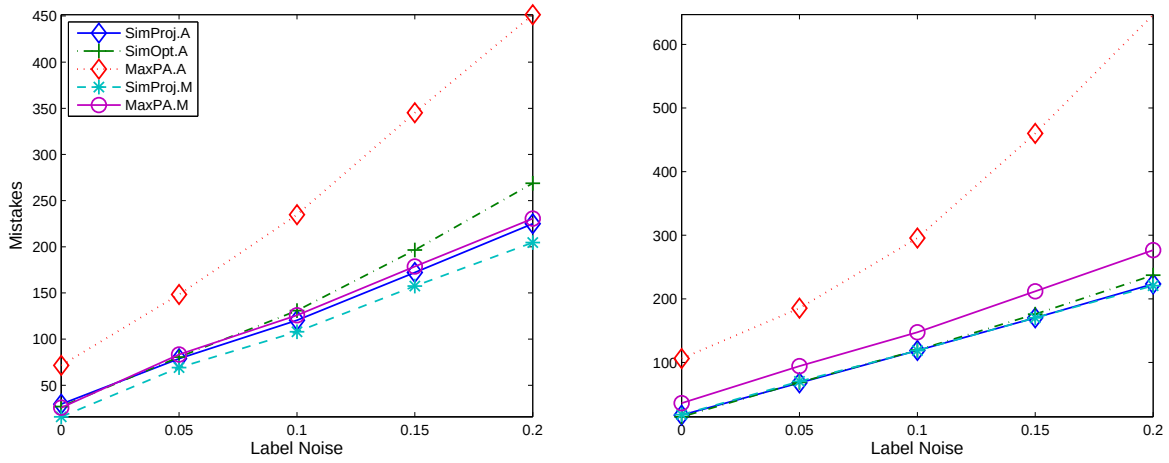

Figure 9: The number of mistakes of the additive and multiplicative simultaneous projections algorithms as a function of the label noise. Results are depicted for block sizes of 5 instances (left) and 20 instances (right) per trial.

linearly with the noise rate. The simultaneous projections variants (both additive and multiplicative) exhibit the best performance. We see that for the smaller block sizes (Fig. 9 left) the best performing version is the *SimProj.M* variant. Note, however, that the variants of SimOpt perform worse than the variants of SimProj . This fact can possibly attributed to the more aggressive update taken by the SimOpt variant when a mistake occurs. As the number of instances per trial increases, the performance of all of simultaneous projections variants is comparable and they all perform better than any of the MaxPA variants.

9.2 Email Classification Experiments

We next tested performance of the different additive and multiplicative simultaneous projection methods described in Sec. 5 on multiclass email categorization tasks and compared them to previously studied algorithms for multiclass categorization. We compared our algorithms to the MaxPA

algorithms and to the optimal solver. The experiments were performed with the Enron email data set. The data set is available from http://www.cs.cmu.edu/∼enron/enron_mail_030204.tar.gz. The learning goal is to correctly classify email messages into user defined folders. Thus, the instances in this data set are email messages, while the set of classes are the user defined folders denoted by $\{1,\ldots,k\}$. We ran the experiments on the sequence of email messages from 7 different users.

Since each user employs different criteria for email classification, we treated each person as a separate online learning problem. We represented each email message as a vector with a component for every word in the corpus. In order to apply our algorithms, we next describe the class-dependent map we use for the additive algorithms. On each trial, and for each class r, we constructed class-dependent vectors as follows. We set $\phi_j(\mathbf{x}^t,r)$ to 2 if the j'th word appeared in the message and it also appeared in a fifth of the messages previously assigned to folder r. Similarly, we set $\phi_j(\mathbf{x}^t,r)$ to -1 if the j'th word appeared in the message but appeared in less than 2 percent of previous messages. In all other cases, we set $\phi_j(\mathbf{x}^t,r)$ to 0. This class-dependent construction is very similar to the construction used in Fink et al. (2006), which yielded high classification accuracy. Next, we employed the mapping described in Sec. 3, and defined a set of $k-1$ instances for each message as follows. Let the relevant class of an instance be denoted by y. Then, for every irrelevant class $s \neq y$, we define an instance $\mathbf{x}_s^t = \phi(\mathbf{x}^t,y) - \phi(\mathbf{x}^t,s)$ and set its label to 1. All these instances were combined into a single matrix $\mathbf{X}^t$ and were provided to the algorithm in trial t.

For the multiplicative algorithms we took a slightly different approach. Recall that the multiplicative variants assume that the components of each instance are in $\{-1,0,1\}$. Hence, in order to adhere to this requirement, $\phi_j(\mathbf{x}^t,r)$ was set to 1 if the j'th word appeared in the message and it also appeared in a fifth of the messages previously assigned to folder r and to 0 in all other cases. Note that this feature generation is performed without knowing the correct label of the instance $\mathbf{x}^t$ and is thus limited to the information available to the online algorithm.

We repeated all tests for 11 values of the trade-off parameter C, testing values from 2^{-5} to 2^5. For each algorithm we present the results for the best choice of C. We first compare the results of the various additive approaches. The results of this experiments are described in Fig. 1. It is apparent that the SimProj and SimOpt variants consistently perform better than the MaxPA variant, and their performance is on par with the performance of the optimal solver. It is interesting to note that in 3 of the 7 users, the SimProj algorithm actually performs better than the optimal solver. The superior performance of the SimProj algorithm may most likely attributed to to the fact that the optimal solver is more aggressive in its update, and is thus more sensitive to noise. We can also see that the SimOpt version, while guaranteeing a larger increase in the global dual, does not necessarily assure better empirical performance. The performances of SimPerc and ConProj are comparable with no obvious winner. Last, we would like to note that the computational cost of the simultaneous projections algorithms is comparable to that of the MaxPA algorithm.

In Fig. 10 we plot the relative number of mistakes of each algorithm with respect to the number of mistakes made by the optimal solver as a function of the number trials for 6 of the 7 users. (The user williams-w3 was omitted as he classifies most his emails into a single folder.) In order to keep the graphs intelligible, we use the optimal solver algorithm as the baseline and plot the difference in performance of the other additive variants. The graphs clearly indicate the superiority of the SimProj and SimOpt variants over the MaxPA algorithm, and show that SimProj often exhibits the best accuracy.

We next compared the performance of the multiplicative and additive variants. The results of this experiments are summarized in Table 2. Observe that the multiplicative versions usually

Table 2: The percentage of online mistakes of three additive variants and the MaxPA algorithm compared to their multiplicative counterparts. Experiments were performed on seven users of the Enron data set.

perform on par or slightly worse than the additive versions. This possibly surprising result may be partially attributed to the slightly different feature selection process we used for the multiplicative algorithms. The result also underscores the conjecture that we surfaced above when discussing the synthetic experiments. Namely, the additive simultaneous projections algorithms seem to better capture the structure of the data at hand. The multiplicative versions, however, seem to be less sensitive to the trade-off parameter C taking a preference to the larger values in our test setting.

In our last experiment, we compared the results of our algorithms to the Sopopo algorithm from Shalev-Shwartz and Singer (2006b). The results of this experiment are described in Table 3. Before we discuss the results of this comparison, it is important to note the difference in the model the algorithms use. The algorithms we compare can be roughly divided into two classes of learning algorithms: *single*-prototype algorithms and *multi*-prototype algorithms. As the name imply, the single prototype algorithms maintain a single hypothesis on each online trial. The prediction is obtained by taking the inner-product of the hypothesis with some class dependent map of the instance at hand. The class attaining the highest score is considered the predicted label. All the simultaneous projections algorithms as well as the single prototype version of MaxPA fall into this category. Multi-prototype algorithms take a different approach. On each trial, the online algorithm maintains an hypothesis *for each* possible output class. In order to make a prediction, the algorithm computes the inner product between *each* hypothesis and the instance at hand. The class attaining the largest product is the predicted label. We can see that the various SimProj variants are comparable to the Sopopo algorithm, while the former often performs better (4 of the 7 users we have). It is worth nothing that the Sopopo algorithm exploits the specific settings present in multi-prototype multiclass problems, and efficiently finds the optimum of a projection problem on each trial while our algorithms only find an approximate solution. However, Sopopo is a multi prototype algorithm and thus employs a larger hypothesis space which is more difficult to learn in an online setting. In addition, by employing a single vector representation of the email message, Sopopo cannot benefit from the on-the-fly feature selection which results in class-dependent features.

10. Discussion

We presented a new approach for online categorization with complex output structure. Our algorithms decouples the complex optimization task into multiple sub-tasks, each of which is simple

enough to be solved analytically. While the dual representation of the online problem imposes a global constraint on *all* the dual variables, namely $\sum_j \alpha_j^t \leq C$, our framework of simultaneous projections which are followed by averaging the solutions automatically adheres with this constraint and hence constitute a feasible solution. It is worthwhile noting that our approach can also cope with *multiple* constraints of the more general form $\sum_j \nu_j \alpha_j \leq C$, where $\nu_j \geq 0$ for all j. The box constraint implied for each individual projection problem distils to $0 \leq \alpha_j \leq C/\nu_j$ and thus the simultaneous projection algorithm can be used verbatim.

The main scope of this paper is prediction tasks for complex structured decision problems, such as multiclass classification. We approach this problem by first describing the structured problem as a complex optimization problem dealing with multiple binary problems simultaneously. We then use our simultaneous projections scheme to propose a feasible solution to the optimization problem which competes with any decomposition loss (see Sec. 7).

While such an approach is very natural for various structured problems, it is interesting to consider settings in which multiple unrelated binary problems, should be served simultaneously. This approach was the basis for our synthetic experiments, which showed us that the simultaneous projections methods perform much better than the MaxPA approach even though their theoretical bound is similar. One possible explanation of this phenomenon may be attributed to the structure of the space spanned by the examples. In order to illustrate this point, consider for example, the case where all instances on trial t are of similar norm and are orthogonal to each other. The update performed by the simultaneous projections approach is thus optimal. If, on the other hand, all instances received on trial t are exactly the same, then the simultaneous projections approach cannot hope to attain anything better than the MaxPA algorithm. These two extreme cases suggests that further analysis may show that the geometrical structure of the data may shed more light on the progress attained by the simultaneous projections approach.

It is also interesting to explore settings in which the simultaneous projections approach is not immediately applicable. The simultaneous projections approach easily captures the structural requirements expressed by the box constraint $\sum_{j=1}^{k_t} \alpha_j^t \leq C$. While there are many practical problems where such constraints suffice to capture the structure of the problem, more complex constraints are quite prevalent. A notable examples for such a complex setting is the framework of the max-margin

Markov (MMM) networks (Taskar et al., 2003). While the original learning setting of MMM networks was cast for the batch setting, an equivalent online formulation can be easily obtained. In the MMM framework, the dual problems has dual variables whose number is *exponential* in the original size of the problem. These variables are tied via a simple box constraint. The dual is then transformed into an equivalent form with a much smaller number of variables which are strongly tied with multiple constraints involving all these new variables. While the simultaneous projections approach is well suited for the original formulation, the exponential size of the problem renders such approach unsuitable. On the other hand, the simultaneous projections approach cannot easily construct a feasible dual solution where multiple equality constraints are required. It is thus interesting to explore alternative approaches in which the direct dual whose size is infeasible is reduced to many reduced smaller problems, and only a polynomial subset of which are considered and solved.

Appendix A. Derivation of the Dual Problems

In this section we derive the dual problems of the primal problems presented in the main sections. We start with the derivation of the dual of the optimization problem given in Eq. (2). Using Lagrange multipliers, we rewrite Eq. (2) as follows

$$\min_{\omega\in\mathbb{R}^n,\xi}\ \max_{\alpha^t\geq 0,\beta\geq 0}\ \frac{1}{2}\left\|\omega-\omega^t\right\|^2+C\xi+\sum_{j=1}^{k_t}\alpha_j^t\left(1-\xi-y_j^t\left(\omega\cdot\mathbf{x}_j^t\right)\right)-\beta\xi_t \ .$$

We rearrange the terms in the above equation and rewrite it as follows,

$$\min_{\omega\in\mathbb{R}^n,\xi}\ \max_{\alpha^t\geq 0,\beta\geq 0}\ \sum_{j=1}^{k_t}\alpha_j^t+\frac{1}{2}\left\|\omega-\omega^t\right\|^2-\sum_{j=1}^{k_t}\alpha_j^t y_j^t\left(\omega\cdot\mathbf{x}_j^t\right)+\xi\left(C-\sum_{j=1}^{k_t}\alpha_j^t-\beta\right) \ . \tag{26}$$

The dual of Eq. (26) is attained by changing the order of the min and max and is given by

$$\max_{\alpha^t\geq 0,\beta\geq 0}\ \min_{\omega\in\mathbb{R}^n}\ \sum_{j=1}^{k_t}\alpha_j^t+\frac{1}{2}\left\|\omega-\omega^t\right\|^2-\sum_{j=1}^{k_t}\alpha_j^t y_j^t\left(\omega\cdot\mathbf{x}_j^t\right)+\min_{\xi}\xi\left(C-\sum_{j=1}^{k_t}\alpha_j^t-\beta\right) \ . \tag{27}$$

The equation above can be written equivalently as

$$\max_{\alpha^t\geq 0}\ \min_{\omega\in\mathbb{R}^n}\ \underbrace{\sum_{j=1}^{k_t}\alpha_j^t+\frac{1}{2}\left\|\omega-\omega^t\right\|^2-\sum_{j=1}^{k_t}\alpha_j^t y_j^t\left(\omega\cdot\mathbf{x}_j^t\right)}_{\mathcal{L}(\alpha,\omega)}\qquad \text{s.t.}\qquad \sum_{j=1}^{k_t}\alpha_j^t\leq C \ . \tag{28}$$

In order to see that Eq. (28) and Eq. (27) are equivalent, note that the expression

$$\min_{\xi}\xi\left(C-\sum_{j=1}^{k_t}-\beta\right) \ ,$$

takes the value of $-\infty$ when $\sum_{j=1}^{k_t}\alpha_j^t+\beta\neq C$. Such an assignment for α^t and β cannot constitute the optimal solution for the maximization problem. The constraint $\beta\geq 0$ thus translates to the constraint $\sum_{j=1}^{k_t}\alpha_j^t\leq C$. Fixing α^t, the derivative of $\mathcal{L}$ with respect to ω is given by

$$\frac{\partial\mathcal{L}}{\partial\omega}=\omega-\omega^t-\sum_{j=1}^{k_t}\alpha_j^t y_j^t\mathbf{x}_j^t \ .$$

Comparing the derivative to 0, yields the following equation, $\omega = \omega^t + \sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t$. Plugging this equality of ω Eq. (28) yields the following simplified constrained optimization problem,

$$\begin{aligned} &\max_{\alpha^t \geq 0} \sum_{j=1}^{k_t} \alpha_j^t + \frac{1}{2} \left\| \sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t \right\|^2 - \sum_{j=1}^{k_t} \alpha_j^t y_j^t \left(\left(\omega^t + \sum_{l=1}^{k_t} \alpha_l^t y_l^t \mathbf{x}_l^t \right) \cdot \mathbf{x}_j^t \right) \\ &\text{s.t.} \qquad \sum_{j=1}^{k_t} \alpha_j^t \leq C \end{aligned} .$$

Rearranging the terms and adding constants which do not depend of α^t, we obtain the following dual problem,

$$\begin{aligned} &\max_{\alpha^t} \sum_{j=1}^{k_t} \alpha_j^t - \frac{1}{2} \left\| \omega^t + \sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t \right\|^2 \\ &\text{s.t.} \qquad \sum_{j=1}^{k_t} \alpha_j^t \leq C \qquad \forall j \in [k_t] : \ \alpha_j^t \geq 0 \end{aligned} .$$

We now turn our attention to the derivation of the dual of the optimization problem given by Eq. (20). Eq. (20) can be rewritten as follows

$$\begin{aligned} &\min_{\omega \in \Delta_n, \xi \geq 0} \sum_{i=1}^{n} \omega_i \log \frac{\omega_i}{\omega_i^t} + C\xi \\ &\text{s.t.} \qquad \forall j \in [k_t] : \ y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \geq \gamma - \xi \qquad \xi_l \geq 0 \end{aligned} . \tag{29}$$

We again use Lagrange theory and rewrite the optimization task above as,

$$\min_{\omega \in \Delta_n, \xi \geq 0} \max_{\alpha_j^t \geq 0} \sum_{i=1}^{n} \omega_i \log \frac{\omega_i}{\omega_i^t} + C\xi + \sum_{j=1}^{k_t} \alpha_j^t \left(\gamma - \xi - y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \right) .$$

Rearranging the terms in the above expression we obtain

$$\min_{\omega \in \Delta_n, \xi \geq 0} \max_{\alpha_j^t \geq 0} \sum_{i=1}^{n} \omega_i \log \frac{\omega_i}{\omega_i^t} + \xi \left(C - \sum_{j=1}^{k_t} \alpha_j^t \right) + \sum_{j=1}^{k_t} \alpha_j^t \left(\gamma - y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \right) . \tag{30}$$

The dual of Eq. (30) is thus obtained by reversing the order of the min and max and is thus given by

$$\max_{\alpha_j^t \geq 0} \min_{\omega \in \Delta_n, \xi \geq 0} \sum_{i=1}^{n} \omega_i \log \frac{\omega_i}{\omega_i^t} + \xi \left(C - \sum_{j=1}^{k_t} \alpha_j^t \right) + \sum_{j=1}^{k_t} \alpha_j^t \left(\gamma - y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \right) . \tag{31}$$

The equation above can be rewritten equivalently as follows

$$\begin{aligned} &\max_{\alpha_j^t, \beta^t} \min_{\omega \in \mathbb{R}^n} \sum_{i=1}^{n} \omega_i \log \frac{\omega_i}{\omega_i^t} + \sum_{j=1}^{k_t} \alpha_j^t \left(\gamma - y_j^t \left(\omega \cdot \mathbf{x}_j^t \right) \right) + \beta^t \left(\sum_{i=1}^{n} \omega_i - 1 \right) \\ &\text{s.t.} \qquad \sum_{j=1}^{k_t} \alpha_j^t \leq C \qquad \forall j : \alpha_j^t \geq 0 \end{aligned} . \tag{32}$$

In order to see Eq. (32) and Eq. (31) are equivalent, note that the expression $\min_\xi \xi \left(C - \sum_{j=1}^{k_t} \alpha_j^t\right)$ takes the value of $-\infty$ when $\sum_{j=1}^{k_t} \alpha_j^t > C$. Since our goal is to maximize the dual, such solution cannot constitute the optimal assignment for α^t. Similarly, when $\sum_{i=1}^{n} \omega_i \neq 1$, the maximization takes the value ∞, thus such a solution cannot constitute the optimal assignment of minimization problem. Finally, we may ignore the constraint $\omega_i \geq 0$ as the optimal solution to the above problem always yields a solution that satisfies this constraint.

In order to further analyze the Eq. (32), let us first denote the vector $\sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t$ by τ. Taking the derivative of Eq. (32) with respect to ω and comparing the result to 0 yields the following,

$$\omega_i = \omega_i^t e^{\tau_i - 1 + \beta} \quad .$$

Recall that β is the Lagrange multiplier associated with the constraint $\sum_{i=1}^{n} \omega_i = 1$, thus $e^{-1+\beta}$ serves as a normalization constant, and the optimal assignment for ω_i takes the following form.

$$\omega_i = \frac{\omega_i^t e^{\tau_i}}{\sum_{l=1}^{n} \omega_l^t e^{\tau_l}} \quad .$$

Plugging the value for ω into Eq. (32) yields the following dual problem for Eq. (29)

$$\max_{\alpha_j^t} \gamma \sum_{j=1}^{k_t} \alpha_j^t - \log\left(\sum_{i=1}^{n} \omega_i^t e^{\tau_i}\right) \qquad \text{s.t.} \qquad \sum_{j=1}^{k_t} \alpha_j^t \leq C \qquad \forall j : \alpha_j^t \geq 0 \qquad \tau = \sum_{j=1}^{k_t} \alpha_j^t y_j^t \mathbf{x}_j^t \quad .$$

Appendix B. Derivation of the SimPerc Mistake Bound

Thm. 2 assures us that the number of mistakes performed by the SimPerc algorithm is bound by

$$\frac{\frac{1}{2}\|\omega^\star\|^2 + C\sum_{t=1}^{T} \ell(\omega^\star; (\mathbf{X}^t, \mathbf{y}^t))}{C - \frac{1}{2}C^2R^2} \quad . \tag{33}$$

Observe that the prediction made by the SimPerc algorithm does not depend on the value of C. We may thus choose C as to tighten the above bound. Assume $R = 1$ and denote $\sum_{t=1}^{T} \ell(\omega^\star; (\mathbf{X}^t, \mathbf{y}^t))$ by L and $\|\omega^\star\|^2$ by B. It is easy to verify that if $L = 0$, the optimal assignment for C is attained by setting $C = 1$. The bound in this case distills to B. Otherwise, assume $L > 0$. Then, Eq. (33) can be written as

$$\varphi(C) = \frac{\frac{1}{2}B + CL}{C - \frac{1}{2}C^2} \quad . \tag{34}$$

The above expression is convex with respect to the parameter C. Hence, in order to find the optimal value of C, it suffices to take the derivative of Eq. (34) with respect to C and compare the result to 0, which yields,

$$\frac{L(C - \frac{1}{2}C^2) - (\frac{1}{2}B + CL)(1 - C)}{\left(C - \frac{1}{2}C^2\right)^2} = 0 \quad ,$$

which implies that,

$$LC^2 + BC - B = 0 \quad . \tag{35}$$

The largest root of Eq. (35) is given by

$$\begin{aligned} C = \frac{-B+\sqrt{B^2+4BL}}{2L} &= \frac{-B+\sqrt{B^2+4BL}}{2L} \cdot \frac{-B-\sqrt{B^2+4BL}}{-B-\sqrt{B^2+4BL}} \\ &= \frac{B^2-B^2-4BL}{2L\left(-B-\sqrt{B^2+4BL}\right)} \\ &= \frac{2}{\left(1+\sqrt{1+4\frac{L}{B}}\right)} \end{aligned} \quad ,$$

It is easy to verify that for $L > 0$ this value of C lies in $(0,2)$ and thus constitutes the optimal solution of Eq. (34). Plugging Eq. (35) into Eq. (33) yields the following

$$\begin{aligned} \frac{\frac{1}{2}B+CL}{C-\frac{1}{2}C^2} &= \frac{\frac{B}{C}+L}{1-\frac{1}{2}C} \\ &= \frac{\frac{1}{2}B\left(1+\sqrt{1+4\frac{L}{B}}\right)+2L}{2\left(1-\frac{1}{2}\frac{2}{\left(1+\sqrt{1+4\frac{L}{B}}\right)}\right)} \\ &= \frac{\left(1+\sqrt{1+4\frac{L}{B}}\right)\left(\frac{1}{2}B\left(1+\sqrt{1+4\frac{L}{B}}\right)+2L\right)}{2\left(\sqrt{1+4\frac{L}{B}}\right)} \\ &= \frac{\frac{1}{2}B+2L}{\frac{1}{2}\left(\sqrt{1+4\frac{L}{B}}\right)} + \frac{1}{4}B + \frac{1}{4}B\left(1+\sqrt{1+4\frac{L}{B}}\right)+L \\ &= \frac{1}{2}B+L+\frac{1}{2}\sqrt{B^2+4LB} \end{aligned} \quad .$$

Using the definition of L and B to expand the above expression completes our proof.

Appendix C. An Analytic Solution for the Multiplicative Framework

Recall that throughout Sec. 8 section we assumed that the entries of each instance $\mathbf{x}_j^t$ lie in $\{-1,0,1\}$. On trial t we would like to find the optimal solution to the reduced problem given by Eq. (23). To do so we recall the notation used in Sec. 8,

$$W_j^+ = \frac{\sum_{i:y_j^t x_{ji}^t=1} \omega_i^t}{\sum_{l=1}^n \omega_l^t} \;,\; W_j^- = \frac{\sum_{i:y_j^t x_{ji}^t=-1} \omega_i^t}{\sum_{l=1}^n \omega_l^t} \;,\; \text{and } W_j^0 = 1 - W_j^+ - W_j^- \quad .$$

The optimization problem defined by Eq. (23) can thus be rewritten as

$$\begin{aligned} &\gamma\alpha_j^t - \log\left(W_j^+ e^{\alpha_j^t} + W_j^- e^{-\alpha_j^t} + W_j^0\right) \\ &\text{s.t.} \qquad 0 \le \alpha_j^t \le C \end{aligned} \quad .$$

Taking the derivative of the above equation with respect to α_j^t and comparing the result to zero yields the following,

$$\gamma - \frac{W^+ e^{\alpha_j^t} - W^- e^{-\alpha_j^t}}{W^+ e^{\alpha_j^t} + W^- e^{-\alpha_j^t} + W^0} = 0 \ . \tag{36}$$

Rearranging terms, Eq. (36) reduces to

$$\gamma\left(W^+ e^{\alpha_j^t} + W^- e^{-\alpha_j^t} + W^0\right) = W^+ e^{\alpha_j^t} - W^- e^{-\alpha_j^t} \ \Rightarrow \ (1-\gamma)W^+ e^{\alpha_j^t} - (1+\gamma)W^- e^{-\alpha_j^t} - \gamma W^0 = 0 \ .$$

For brevity, we denote $e^{\alpha_j^t}$ by β. The equation above is equivalent to the following equation in β,

$$(1-\gamma)W^+\beta - (1+\gamma)W^-\beta^{-1} - \gamma W^0 = 0 \ .$$

Multiplying both sides of the above equation by β, we obtain the following quadratic equation

$$(1-\gamma)W^+\beta^2 - \gamma W^0\beta - (1+\gamma)W^- \ ,$$

whose largest root (the second root is negative) is

$$\beta = \frac{\gamma W^0 + \sqrt{\gamma^2 (W^0)^2 + 4(1-\gamma^2)W^+W^-}}{2(1-\gamma)W^+} \ .$$

Since α_j^t must reside in $[0, C]$ we set α_j^t to be the minimum between $\log(\beta)$ and C, yielding,

$$\alpha_j^t = \min\left\{C, \log\left(\frac{\gamma W^0 + \sqrt{\gamma^2 (W^0)^2 + 4(1-\gamma^2)W^+W^-}}{2(1-\gamma)W^+}\right)\right\} \ .$$
