Abstract

Efficient and expressive comparison of sequences is an essential procedure for learning with sequential data. In this article we propose a generic framework for computation of similarity measures for sequences, covering various kernel, distance and non-metric similarity functions. The basis for comparison is embedding of sequences using a formal language, such as a set of natural words, *k*-grams or all contiguous subsequences. As realizations of the framework we provide linear-time algorithms of different complexity and capabilities using sorted arrays, tries and suffix trees as underlying data structures.

Experiments on data sets from bioinformatics, text processing and computer security illustrate the efficiency of the proposed algorithms—enabling peak performances of up to 10^6 pairwise comparisons per second. The utility of distances and non-metric similarity measures for sequences as alternatives to string kernels is demonstrated in applications of text categorization, network intrusion detection and transcription site recognition in DNA.

Keywords: string kernels, string distances, learning with sequential data

1. Introduction

Sequences of discrete symbols are one of the fundamental data representations in computer science. A great deal of applications—from search engines to document ranking, from gene finding to prediction of protein functions, from network surveillance tools to anti-virus programs—critically depend on analysis of sequential data. Providing an interface to sequential data is therefore an essential prerequisite for applications of machine learning in these domains.

Machine learning algorithms have been traditionally designed for vectorial data—probably due to the availability of well-defined calculus and mathematical analysis tools. A large body of such learning algorithms, however, can be formulated in terms of pairwise relationships between objects, which imposes a much looser constraint on the type of data that can be handled. Thus, a powerful abstraction between algorithms and data representations can be established.

The most prominent example of such abstraction is *kernel-based learning* (e.g., Müller et al., 2001; Schölkopf and Smola, 2002) in which pairwise relationships between objects are expressed by a Mercer kernel, an inner product in a reproducing kernel Hilbert space. Following the seminal work of Boser et al. (1992), various learning methods have been re-formulated in terms of kernels, such as PCA (Schölkopf et al., 1998b), ridge regression (Cherkassky et al., 1999), ICA (Harmeling et al., 2003) and many others. Although the initial motivation for the "kernel trick" was to allow efficient computation of an inner product in high-dimensional feature spaces, the importance of an

abstraction from data representation has been quickly realized (e.g., Vapnik, 1995). Consequently kernel-based methods have been proposed for non-vectorial domains, such as analysis of images (e.g., Schölkopf et al., 1998a; Chapelle et al., 1999), sequences (e.g., Jaakkola et al., 2000; Watkins, 2000; Zien et al., 2000) and structured data (e.g., Collins and Duffy, 2002; Gärtner et al., 2004).

Although kernel-based learning has gained significant attention in recent years, a Mercer kernel is only one of many possibilities for defining pairwise relationships between objects. Numerous applications exist for which relationships are defined as metric or non-metric distances (e.g., Anderberg, 1973; Jacobs et al., 2000; von Luxburg and Bousquet, 2004), similarity or dissimilarity measures (e.g., Graepel et al., 1999; Roth et al., 2003; Laub and Müller, 2004; Laub et al., 2006) or non-positive kernel functions (e.g., Ong et al., 2004; Haasdonk, 2005). It is therefore imperative to address pairwise comparison of objects in a most general setup.

The aim of this contribution is to develop a *general framework* for pairwise comparison of sequences. Its generality is manifested by the ability to handle a large number of kernel functions, distances and non-metric similarity measures. From considerations of efficiency, we focus on algorithms with linear-time asymptotic complexity in the sequence lengths—at the expense of narrowing the scope of similarity measures that can be handled. For example, we do not consider super-linear comparison algorithms such as the Levenshtein distance (Levenshtein, 1966) and the all-subsequences kernel (Lodhi et al., 2002).

The basis of our framework is embedding of sequences in a high-dimensional feature space using a *formal language*, a classical tool of computer science for modeling semantics of sequences. Some examples of such languages have been previously used for string kernels, such as the bag-of-words, k-gram or contiguous-subsequence kernel. Our formalization allows one to use a much larger set of possible languages in a unified fashion, for example subsequences defined by a finite set of delimiters or position-dependent languages. A further advantage of embedding using formal languages is separation of embedding models from algorithms, which allows one to investigate different data structures to obtain optimal efficiency in practice.

Several data structures have been previously considered for specific similarity measures, such as hash tables (Damashek, 1995), sorted arrays (Sonnenburg et al., 2007), tries (Leslie et al., 2002; Shawe-Taylor and Cristianini, 2004; Rieck et al., 2006), suffix trees using matching statistics (Vishwanathan and Smola, 2004), suffix trees using recursive matching (Rieck et al., 2007) and suffix arrays (Teo and Vishwanathan, 2006). All of these data structures allow one to develop linear-time algorithms for computation of certain similarity measures. Most of them are also suitable for the general framework developed in this paper; however, certain trade-offs exist between their asymptotic run-time complexity, implementation difficulty and restrictions on embedding languages they can handle. To provide an insight into these issues, we propose and analyze three data structures suitable for our framework: *sorted arrays*, *tries* and *suffix trees* with an extension to suffix arrays. The message of our analysis, supported by experimental evaluation, is that the choice of an optimal data structure depends on the embedding language to be used.

This article is organized as followed: In Section 2 we review related work on sequence comparison. In Section 3 we introduce a general framework for computation of similarity measures for sequences. Algorithms and data structures for linear-time computation are presented in Section 4. We evaluate the run-time performance and demonstrate the utility of distinct similarity measures in Section 5. The article is concluded in Section 6

2. Related Work

Assessing the similarity of two sequences is a classical problem of computer science. First approaches, the string distances of Hamming (1950) and Levenshtein (1966), originated in the domain of telecommunication for detection of erroneous data transmissions. The degree of dissimilarity between two sequences is determined by computing the shortest trace of operations—insertions, deletions and substitutions—that transform one sequence into the other (Sankoff and Kruskal, 1983). Applications in bioinformatics motivated extensions and adaptions of this concept, for example defining sequence similarity in terms of local and global alignments (Needleman and Wunsch, 1970; Smith and Waterman, 1981). However, similarity measures based on the Hamming distance are restricted to sequences of equal length and measures derived from the Levenshtein distance (e.g., Liao and Noble, 2003; Vert et al., 2004), come at the price of computational complexity: No linear-time algorithm for determining the shortest trace of operations is currently known. One of the fastest exact algorithms runs in $O(n^2/\log n)$ for sequences of length n (Masek and Patterson, 1980).

A different approach to sequence comparison originated in the field of information retrieval with the vector space or bag-of-words model (Salton et al., 1975; Salton, 1979). Textual documents are embedded into a vector space spanned by weighted frequencies of contained words. The similarity of two documents is assessed by an inner-product between the corresponding vectors. This concept was extended to k-grams—k consecutive characters or words—in the domain of natural language processing and computer linguistic (e.g., Suen, 1979; Cavnar and Trenkle, 1994; Damashek, 1995). The idea of determining similarity of sequences by an inner-product was revived in kernel-based learning in the form of bag-of-words kernels (e.g., Joachims, 1998; Drucker et al., 1999; Joachims, 2002) and various string kernels (e.g., Zien et al., 2000; Leslie et al., 2002; Vishwanathan and Smola, 2004). Moreover, research in bioinformatics and text processing advanced the capabilities of string kernels, for example, by considering gaps, mismatches and positions in sequences (e.g., Lodhi et al., 2002; Leslie et al., 2003; Leslie and Kuang, 2004; Rousu and Shawe-Taylor, 2005; Rätsch et al., 2007). The comparison framework proposed in this article shares the concept of embedding sequences with all of the above kernels, in fact most of the linear-time string kernels (e.g., Joachims, 1998; Leslie et al., 2002; Vishwanathan and Smola, 2004) are enclosed in the framework.

A further alternative for comparison of sequences are kernels derived from generative probability models, such as the Fisher kernel (Jaakkola et al., 2000) and the TOP kernel (Tsuda et al., 2002). Provided a generative model, for example a HMM trained over a corpus of sequences or modeled from prior knowledge, these kernel functions essentially correspond to inner-products of partial derivatives over model parameters. The approach enables the design of highly specific similarity measures which exploit the rich structure of generative models, for example, for prediction of DNA splice sites (Rätsch and Sonnenburg, 2004). The run-time complexity of the kernel computation, however, is determined by the number of model parameters, so that only simple models yield run-time linear in the sequence lengths. Moreover, obtaining a suitable parameter estimate for a probabilistic model can be difficult or even infeasible in practical applications.

3. Similarity Measures for Sequential Data

Before introducing the framework for computation of similarity measures, we need to establish some basic notation. A *sequence* $\mathbf{x}$ is a concatenation of symbols from an *alphabet* $\mathcal{A}$. The set of all possible concatenations of symbols from $\mathcal{A}$ is denoted by $\mathcal{A}^*$ and the set of all concatenations

of length k by $\mathcal{A}^k$. A *formal language* $L \subseteq \mathcal{A}^*$ is any set of finite-length sequences drawn from $\mathcal{A}$ (Hopcroft and Motwani, 2001). The length of a sequence $\mathbf{x}$ is denoted by $|\mathbf{x}|$ and the size of the alphabet by $|\mathcal{A}|$. A contiguous subsequence w of $\mathbf{x}$ is denoted by $w \sqsubseteq \mathbf{x}$, a prefix of $\mathbf{x}$ by $w \sqsubseteq_p \mathbf{x}$ and a suffix by $w \sqsubseteq_s \mathbf{x}$. Alternatively, a subsequence w of $\mathbf{x}$ ranging from position i to j is referred to as $\mathbf{x}[i..j]$.

3.1 Embedding Sequences using a Formal Language

The basis for embedding of a sequence $\mathbf{x}$ is a formal language L, whose elements are sequences spanning an $|L|$-dimensional feature space. We refer to L as the *embedding language* and to a sequence $w \in L$ as a *word* of L. There exist numerous ways to define L reflecting particular aspects of application domains, yet we focus on three definitions that have been widely used in previous research:

1. **Bag-of-words**. In this model, L corresponds to a set of words from a natural language. L can be either defined explicitly by providing a dictionary or implicitly by partitioning sequences according to a set of delimiter symbols $D \subset \mathcal{A}$ (e.g., Salton, 1979; Joachims, 2002).

$$L = \text{Dictionary (explicit)}, \quad L = (\mathcal{A} \setminus D)^* \text{ (implicit)}.$$

2. **K-grams** and **blended k-grams**. For the case of k-grams (in bioinformatics often referred to as k-mers), L is the set of all sequences of length k (e.g., Damashek, 1995; Leslie et al., 2002). The model of k-grams can further be "blended" by considering all sequences from length j up to k (e.g., Shawe-Taylor and Cristianini, 2004).

$$L = \mathcal{A}^k \text{ (k-grams)}, \quad L = \bigcup_{i=j}^{k} \mathcal{A}^i \text{ (blended k-grams)}.$$

3. **Contiguous sequences**. In the most general case, L corresponds to the set of all contiguous sequences or alternatively to blended k-grams with infinite k (e.g., Vishwanathan and Smola, 2004; Rieck et al., 2007).

$$L = \mathcal{A}^* \quad \text{or} \quad L = \bigcup_{i=1}^{\infty} \mathcal{A}^i.$$

Note that the alphabet $\mathcal{A}$ in the embedding languages may also be composed of higher semantic constructs, such as natural words or syntactic tokens. In these cases a k-gram corresponds to k consecutive words or tokens, and a bag-of-words models could represent textual clauses or phrases.

Given an embedding language L, a sequence $\mathbf{x}$ can be mapped into the $|L|$-dimensional feature space by calculating a function $\phi_w(\mathbf{x})$ for every $w \in L$ appearing in $\mathbf{x}$. The embedding function Φ for a sequence $\mathbf{x}$ is given by

$$\Phi : \mathbf{x} \mapsto (\phi_w(\mathbf{x}))_{w \in L} \text{ with } \phi_w(\mathbf{x}) := \text{occ}(w, \mathbf{x}) \cdot \mathcal{W}_w \tag{1}$$

where $\text{occ}(w, \mathbf{x})$ is the number of occurrences of w in the sequence $\mathbf{x}$ and $\mathcal{W}_w$ a weighting assigned to individual words. Alternatively $\text{occ}(w, \mathbf{x})$ may be defined as frequency, probability or binary flag for the occurrences of w in $\mathbf{x}$.

While the choice and design of an embedding language L offer a large degree of flexibility, it is often necessary to refine the amount of contribution for each word $w \in L$, for example it is a common practice in text processing to ignore stop words and terms that do not carry semantic content. In the embedding function (1) such refinement is realized by the weighting term $\mathcal{W}_w$. The following three weighting schemes for defining $\mathcal{W}_w$ have been proposed in previous research:

1. **Corpus dependent weighting.** The weight $\mathcal{W}_w$ is based on the occurrences of w in the corpus of sequences (see Salton et al., 1975). Most notable is the inverse document frequency (IDF) weighting, in which $\mathcal{W}_w$ is defined over the number of documents N and the frequency $d(w)$ of w in the corpus.
$$\mathcal{W}_w = \log_2 N - \log_2 d(w) + 1.$$
If $\mathrm{occ}(w, \mathbf{x})$ is the frequency of w in $\mathbf{x}$, the embedding function (1) corresponds to the well-known term frequency and inverse document frequency (TF-IDF) weighting scheme.

2. **Length dependent weighting.** The weight $\mathcal{W}_w$ is based on the length $|w|$ (see Shawe-Taylor and Cristianini, 2004; Vishwanathan and Smola, 2004), for example, so that longer words contribute more than shorter words to a similarity measure. A common approach is defining $\mathcal{W}_w$ using a decay factor $0 \leq \lambda \leq 1$.
$$\mathcal{W}_w = \lambda^{-|w|}.$$

3. **Position dependent weighting.** The weight $\mathcal{W}_w$ is based on the position of w in $\mathbf{x}$. Vishwanathan and Smola (2004) propose a direct weighting scheme, in which $\mathcal{W}_w$ is defined over positional weights $\mathcal{W}(k, \mathbf{x})$ for each position k in $\mathbf{x}$ as
$$\mathcal{W}_w = \mathcal{W}_{\mathbf{x}[i..j]} = \sum_{k=i}^{j} \mathcal{W}(k, \mathbf{x}).$$
An indirect approach to position dependent weighting can be implemented by extending the alphabet $\mathcal{A}$ with positional information to $\tilde{\mathcal{A}} = \mathcal{A} \times \mathbb{N}$, so that every element $(a, k) \in \tilde{A}$ of the extended alphabet is a pair of a symbol a and a position k.

The introduced weighting schemes can be coupled to further refine the embedding based on L, for example, in text processing the impact of a particular term might be influenced by the term frequency, inverse document frequency and its length.

3.2 Vectorial Similarity Measures for Sequences

With an embedding language L at hand, we can now express common vectorial similarity measures in the domain of sequences. Table 1 and 2 list well-known kernel and distance functions (see Vapnik, 1995; Schölkopf and Smola, 2002; Webb, 2002) in terms of L. The histogram intersection kernel in Table 1 derives from computer vision (see Swain and Ballard, 1991; Odone et al., 2005) and the Jensen-Shannon divergence in Table 2 is defined using $H(x, y) = x \log \frac{2x}{x+y} + y \log \frac{2y}{x+y}$.

A further and rather exotic class of vectorial similarity measures are *similarity coefficients* (see Sokal and Sneath, 1963; Anderberg, 1973). These coefficients have been designed for comparison of binary vectors and often express non-metric properties. They are constructed using three summation variables a, b and c, which reflect the number of matching components $(1/1)$, left mismatching

Kernel	$k(\mathbf{x},\mathbf{y})$
Linear	$\sum_{w\in L}\phi_w(\mathbf{x})\phi_w(\mathbf{y})$
Polynomial	$\left(\sum_{w\in L}\phi_w(\mathbf{x})\phi_w(\mathbf{y})+\theta\right)^p$
Sigmoidal	$\tanh\left(\sum_{w\in L}\phi_w(\mathbf{x})\phi_w(\mathbf{y})+\theta\right)$
Gaussian	$\exp\left(\frac{-d(\mathbf{x},\mathbf{y})^2}{2\sigma^2}\right)$
Histogram intersection	$\sum_{w\in L}\min(\phi_w(\mathbf{x}),\phi_w(\mathbf{y}))$

Table 1: Kernel functions for sequential data.

Distance	$d(\mathbf{x},\mathbf{y})$	**Distance**	$d(\mathbf{x},\mathbf{y})$
Manhattan	$\sum_{w\in L}\lvert\phi_w(\mathbf{x})-\phi_w(\mathbf{y})\rvert$	Chebyshev	$\max_{w\in L}\lvert\phi_w(\mathbf{x})-\phi_w(\mathbf{y})\rvert$
χ^2 distance	$\sum_{w\in L}\frac{(\phi_w(\mathbf{x})-\phi_w(\mathbf{y}))^2}{\phi_w(\mathbf{x})+\phi_w(\mathbf{y})}$	Geodesic	$\arccos\sum_{w\in L}\phi_w(\mathbf{x})\phi_w(\mathbf{y})$
Canberra	$\sum_{w\in L}\frac{\lvert\phi_w(\mathbf{x})-\phi_w(\mathbf{y})\rvert}{\phi_w(\mathbf{x})+\phi_w(\mathbf{y})}$	Hellinger^2	$\sum_{w\in_L}(\sqrt{\phi_w(\mathbf{x})}-\sqrt{\phi_w(\mathbf{y})})^2$
Minkowski^p	$\sum_{w\in L}\lvert\phi_w(\mathbf{x})-\phi_w(\mathbf{y})\rvert^p$	Jensen-Shannon	$\sum_{w\in L}H(\phi_w(\mathbf{x}),\phi_w(\mathbf{y}))$

Table 2: Distance functions for sequential data.

components $(0/1)$ and right mismatching components $(1/0)$ in two binary vectors. Common similarity coefficients are given in Table 3. For application to non-binary vectors the summation variables a,b,c can be extended in terms of an embedding language L (Rieck et al., 2006):

$$
\begin{aligned}
a &= \sum_{w\in L}\min(\phi_w(\mathbf{x}),\phi_w(\mathbf{y})),\\
b &= \sum_{w\in L}[\phi_w(\mathbf{x})-\min(\phi_w(\mathbf{x}),\phi_w(\mathbf{y}))],\\
c &= \sum_{w\in L}[\phi_w(\mathbf{y})-\min(\phi_w(\mathbf{x}),\phi_w(\mathbf{y}))].
\end{aligned}
$$

The above definition of a matches the histogram intersection kernel k provided in Table 1, so that alternatively all summation variables can be expressed by

$$
a = k(\mathbf{x},\mathbf{y}),\ b = k(\mathbf{x},\mathbf{x})-k(\mathbf{x},\mathbf{y}),\ c = k(\mathbf{y},\mathbf{y})-k(\mathbf{x},\mathbf{y}). \tag{2}
$$

Sim. Coeff.	$s(\mathbf{x},\mathbf{y})$	**Sim. Coeff.**	$s(\mathbf{x},\mathbf{y})$
Simpson	$a/\min(a+b,a+c)$	Kulczynski (1)	$a/(b+c)$
Jaccard	$a/(a+b+c)$	Kulczynski (2)	$\frac{1}{2}(a/(a+b)+a/(a+c))$
Braun-Blanquet	$a/\max(a+b,a+c)$	Otsuka, Ochiai	$a/\sqrt{(a+b)(a+c)}$
Czekanowski, Sørensen-Dice	$2a/(2a+b+c)$	Sokal-Sneath, Anderberg	$a/(a+2(b+c))$

Table 3: Similarity coefficients for sequential data

Hence, one can consider the similarity coefficients given in Table 3 as variations of the histogram intersection kernel, for example, the Jaccard coefficient can be formulated solely in terms of k:

$$s(\mathbf{x},\mathbf{y}) = \frac{a}{a+b+c} = \frac{k(\mathbf{x},\mathbf{y})}{k(\mathbf{x},\mathbf{x})+k(\mathbf{y},\mathbf{y})-k(\mathbf{x},\mathbf{y})}.$$

3.3 A Generic Framework for Similarity Measures

All of the similarity measures introduced in the previous section share a similar mathematical construction: an inner component-wise function is aggregated over each dimension using an outer operator, for example, the linear kernel is defined as the sum of component-wise products and the Chebyshev distance as the maximum of component-wise absolute differences.

One can exploit this shared structure to derive a unified formulation for similarity measures (Rieck et al., 2006, 2007), consisting of an inner function m and an outer operator $\oplus$ as follows

$$s(\mathbf{x},\mathbf{y}) = \bigoplus_{w\in L} m(\phi_w(\mathbf{x}),\phi_w(\mathbf{y})). \tag{3}$$

For convenience in later design of algorithms, we introduce a "multiplication" operator $\otimes$ which corresponds to executing the $\oplus$ operation k times. Thus, for any $n \in \mathbb{N}$ and $x \in \mathbb{R}$, we define $\otimes$ as

$$x \otimes n := \underbrace{x \oplus \ldots \oplus x}_{n}.$$

Given the unified form (3), kernel and distance functions presented in Table 1 and 2 can be re-formulated in terms of $\oplus$ and m. Adaptation of similarity coefficients to the unified form (3) involves a re-formulation of the summation variables a, b and c. The particular definitions of outer and inner functions for the presented similarity measures are given in Table 4. The polynomial and sigmoidal kernels as well as the Geodesic distance are not shown since they can be expressed using a linear kernel. For the Chebyshev distance the operator $\otimes$ represents the identity function, while for all other similarity measures it represents a multiplication.

Kernel	$\oplus$	$m(x,y)$
Linear	$+$	$x \cdot y$
Histogram inters.	$+$	$\min(x,y)$

Sim. Coef.	$\oplus$	$m(x,y)$
Variable a	$+$	$\min(x,y)$
Variable b	$+$	$x - \min(x,y)$
Variable c	$+$	$y - \min(x,y)$

Distance	$\oplus$	$m(x,y)$
Manhattan	$+$	$\lvert x-y\rvert$
χ^2 distance	$+$	$(x-y)^2/(x+y)$
Canberra	$+$	$\lvert x-y\rvert/(x+y)$
Minkowski^p	$+$	$\lvert x-y\rvert^p$
Chebyshev	max	$\lvert x-y\rvert$
Hellinger^2	$+$	$(\sqrt{x}-\sqrt{y})^2$
Jensen-Shannon	$+$	$H(x,y)$

Table 4: Unified formulation of similarity measures.

As a last step towards the development of comparison algorithms, we need to address the high dimensionality of the feature space induced by the embedding language L. The unified form (3) theoretically involves computation of m over all $w \in L$, which is practically infeasible for most L. Yet the feature space induced by L is sparse, since a sequence $\mathbf{x}$ comprises only a limited number of contiguous subsequences—at most $(|\mathbf{x}|^2+|\mathbf{x}|)/2$ subsequences. As a consequence of the sparseness

only very few terms $\phi_w(\mathbf{x})$ and $\phi_w(\mathbf{y})$ in the unified form (3) have non-zero values. We exploit this fact by defining $m(0,0) = \mathbf{e}$, where $\mathbf{e}$ is the neutral element for the operator $\oplus$, so that for any $x \in \mathbb{R}$ holds

$$x \oplus \mathbf{e} = x, \quad \mathbf{e} \oplus x = x.$$

By assigning $m(0,0)$ to $\mathbf{e}$, the computation of a similarity measure can be reduced to cases where either $\phi_w(\mathbf{x}) > 0$ or $\phi_w(\mathbf{y}) > 0$, as the term $m(0,0)$ does not affect the result of expression (3). We can now refine the unified form (3) by partitioning the similarity measures into *conjunctive* and *disjunctive* measures using an auxiliary function $\tilde{m}$:

$$s(\mathbf{x}, \mathbf{y}) = \bigoplus_{w \in L} \tilde{m}(\phi_w(\mathbf{x}), \phi_w(\mathbf{y})).$$

1. **Conjunctive similarity measures.** The inner function m only accounts pairwise non-zero components, so that for any $x \in \mathbb{R}$ holds $m(x,0) = \mathbf{e}$ and $m(0,x) = \mathbf{e}$.

   $$\tilde{m}(x,y) = \begin{cases} m(x,y) & \text{if } x > 0 \textbf{ and } y > 0 \\ \mathbf{e} & \text{otherwise.} \end{cases}$$

   Kernel functions fall into this class, except for the distance-based RBF kernel. By using a kernel to express similarity coefficients as shown in expression (2), similarity coefficients also exhibit the conjunctive property.

2. **Disjunctive similarity measures.** The inner function m requires at least one component to be non-zero, otherwise $m(0,0) = \mathbf{e}$ holds.

   $$\tilde{m}(x,y) = \begin{cases} m(x,y) & \text{if } x > 0 \textbf{ or } y > 0 \\ \mathbf{e} & \text{otherwise.} \end{cases}$$

   Except for the Geodesic distance, all of the presented distances fall into this class. Depending on the embedding language, this class is computational more expensive than conjunctive measures.

As a result, any similarity measure, including those in Table 1, 2 and 3, composed of an inner and outer function can be applied for efficient comparison of embedded sequences, if (a) a neutral element $\mathbf{e}$ for the outer function $\oplus$ exists and (b) the inner function m is either conjunctive or disjunctive, that is at least $m(0,0) = \mathbf{e}$ holds.

4. Algorithms and Data Structures

We now introduce data structures and algorithms for efficient computation of the proposed similarity measures. In particular, we present three approaches differing in capabilities and implementation complexity covering simple sorted arrays, tries and generalized suffix trees. For each approach, we briefly present the involved data structure, provide a discussion of the comparison algorithm and give run-time bounds for extraction and comparison of embedded sequences. Additionally, we provide implementation details that improve run-time performance in practice.

As an example running through this section we consider the two sequences $\mathbf{x} = abbaa$ and $\mathbf{y} = baaaab$ from the binary alphabet $\mathcal{A} = \{a, b\}$ and the embedding language of 3-grams, $L = \mathcal{A}^3$. For a data structure storing multiple words $w \in L$ of possibly different lengths, we denote by k the length of longest words.

4.1 Sorted Arrays

Data structure. A simple and intuitive representation for storage of embedded sequences are *sorted arrays* or alternatively sorted lists (Joachims, 2002; Rieck et al., 2006; Sonnenburg et al., 2007). Given an embedding language L and a sequence $\mathbf{x}$, all words $w \in L$ satisfying $w \sqsubseteq \mathbf{x}$ are maintained in an array X along with their embedding values $\phi_w(\mathbf{x})$. Each field x of X consists of two attributes: the stored word $word[x]$ and its embedding value $phi[x]$. The length of an array X is denoted by $|X|$. In order to support efficient comparison, the fields of X are sorted by contained words, for example, using the lexicographical order of the alphabet $\mathcal{A}$. Figure 1 illustrates the sorted arrays of 3-grams extracted from the two example sequences $\mathbf{x}$ and $\mathbf{y}$.

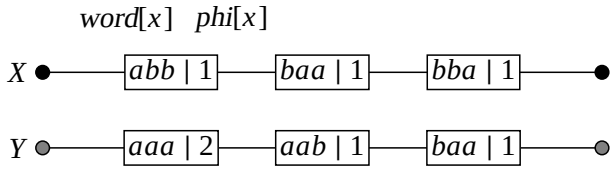

Figure 1: Sorted arrays of 3-grams for $\mathbf{x} = abbaa$ and $\mathbf{y} = baaaab$. The number in each field indicates the number of occurrences.

Algorithm. Comparison of two sorted arrays X and Y is carried out by looping over the fields of both arrays in the manner of merging sorted arrays (Knuth, 1973). During each iteration the inner function m is computed over contained words and aggregated using the operator $\oplus$. The corresponding comparison procedure in pseudo-code is given in Algorithm 1. Herein, we denote the case where a word w is present in $\mathbf{x}$ and $\mathbf{y}$ as *match* and the case of w being contained in either $\mathbf{x}$ or $\mathbf{y}$ as *mismatch*. For run-time improvement, these mismatches can be ignored in Algorithm 1 if a conjunctive similarity measure is computed (cf. Section 3.3).

Algorithm 1 Array-based sequence comparison

```
1:  function COMPARE(X, Y : Array) : ℝ
2:      s ← e, i ← 1, j ← 1
3:      while i ≤ |X| or j ≤ |Y| do
4:          x ← X[i], y ← Y[j]
5:          if y = NIL or word[x] < word[y] then                ▷ Mismatch at x
6:              s ← s ⊕ m(phi[x], 0)
7:              i ← i + 1
8:          else if x = NIL or word[x] > word[y] then           ▷ Mismatch at y
9:              s ← s ⊕ m(0, phi[y])
10:             j ← j + 1
11:         else                                                ▷ Match at x and y
12:             s ← s ⊕ m(phi[x], phi[y])
13:             i ← i + 1, j ← j + 1
14:     return s
```

Run-time. The comparison algorithm based on sorted arrays is simple to implement, yet it does not enable linear-time comparison for all embedding languages, for example, if $L = \mathcal{A}^*$. However, sorted arrays enable linear-time similarity measures, if there exist $O(|\mathbf{x}|)$ words with $w \sqsubseteq \mathbf{x}$, which implies all $w \in L$ have no or constant overlap in $\mathbf{x}$. Examples are the common bag-of-words and k-gram embedding languages.

Under these constraints a sorted array is extracted from a sequence $\mathbf{x}$ in $O(k|\mathbf{x}|)$ time using linear-time sorting, for example, radix sort (Knuth, 1973), where k is the maximum length of all words $w \in L$ in $\mathbf{x}$. The comparison algorithm requires at most $|\mathbf{x}| + |\mathbf{y}|$ iterations, so that the worst-case run-time is $O(k(|\mathbf{x}| + |\mathbf{y}|))$. For extraction and comparison the run-time complexity is linear in the sequence lengths due to the constraint on constant overlap of words, which implies $k|\mathbf{x}| \in O(|\mathbf{x}|)$ for any k and $\mathbf{x}$.

Implementation notes. The simple design of the sorted array approach enables a very efficient extension. If we consider a CPU with registers of b bits, we restrict the maximum word length k, so that every word fits into a CPU register. This restriction enables storage and comparison operations to be performed directly on the CPU, that is operations on words w with $|w| \leq k$ are executed in $O(1)$ time. Depending on the size of the alphabet $|\mathcal{A}|$ and the CPU bits b, the maximum word length is $\lfloor b / \log_2 |\mathcal{A}| \rfloor$. In many practical applications one can strongly benefit from this extensions, as k is either bounded anyway, for example, for k-grams, or longer words are particular rare and do not increase accuracy significantly. For example on current 64 bit CPU architectures one can restrict k to 32 for DNA sequences with $|\mathcal{A}| = 4$ and to $k = 10$ for textual documents with $|\mathcal{A}| \leq 64$. Alternatively, embedded words may also be represented using hash values of b bits, which enables considering words of arbitrary length, but introduces a probability for hash collisions (Knuth, 1973).

Another extension for computation of conjunctive measures using sorted arrays has been proposed by Sonnenburg et al. (2007). If two sequences $\mathbf{x}$ and $\mathbf{y}$ have unbalanced sizes $|\mathbf{x}| \ll |\mathbf{y}|$, one loops over the shorter sorted array X and performs a binary search procedure on Y, in favor of processing both sorted arrays in parallel. The worst-case run-time for this comparison is $O(k(|\mathbf{x}| \log_2 |\mathbf{y}|))$, so that one may automatically apply this extension if for two sequences $\mathbf{x}$ and $\mathbf{y}$ holds $|\mathbf{x}| \log_2 |\mathbf{y}| < |\mathbf{x}| + |\mathbf{y}|$.

4.2 Tries

Data structure. A *trie* is a tree structure for storage and retrieval of sequences. The edges of a trie are labeled with symbols of $\mathcal{A}$ (Fredkin, 1960; Knuth, 1973). A path from the root to a marked node x represents a stored sequence, hereafter denoted by $\bar{x}$. A trie node x contains a vector of size $|\mathcal{A}|$ linking to child nodes, a binary flag to indicate the end of a sequence $\mathit{mark}[x]$ and an embedding value $\mathit{phi}[x]$.[1] The i-th child node representing the i-th symbol in $\mathcal{A}$ is accessed via $\mathit{child}[x, i]$. If the i-th child is not present $\mathit{child}[x, i] = \text{NIL}$.

A sequences $\mathbf{x}$ is embedded using a trie X by storing all $w \in L$ with $w \sqsubseteq \mathbf{x}$ and corresponding $\phi_w(\mathbf{x})$ in X (Shawe-Taylor and Cristianini, 2004). Figure 2 shows tries of 3-grams for the two example sequences $\mathbf{x}$ and $\mathbf{y}$. Note, that for the embedding language of k-grams considered in Figure 2 all marked nodes are leaves, while for other embedding languages they may correspond to inner nodes, for example, for the case of blended k-grams, where every node in a trie marks the end of a sequence.

1. For convenience, we assume that child nodes are maintained in a vector, while in practice sorted lists, balanced trees or hash tables may be preferred.

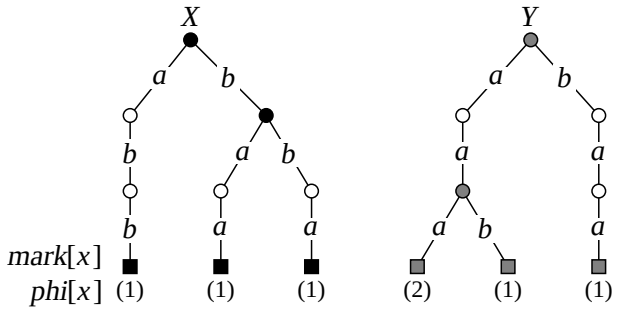

Figure 2: Tries of 3-grams for $\mathbf{x} = abbaa$ and $\mathbf{y} = baaaab$. The number in brackets at leaves indicate the number of occurrences. Marked nodes are squared. White nodes are implicit and not maintained in a compact trie representation.

Algorithm. Comparison of two tries is performed as in Algorithm 2: Starting at the root nodes, one recursively traverses both tries in parallel. If the traversal passes at least one marked node the inner function m is computed as either a matching or mismatching word occurred (Rieck et al., 2006). To simplify presentation of the algorithm, we assume that $mark[\text{NIL}]$ returns false and $child[\text{NIL}, i]$ returns NIL.

Algorithm 2 Trie-based sequence comparison

```
1:  function COMPARE(X, Y : Trie) : ℝ
2:      s ← e
3:      if X = NIL and Y = NIL then                          ▷ Base case
4:          return s
5:      for i ← 1, |A| do
6:          x ← child[X, i],  y ← child[Y, i]
7:          if mark[x] and not mark[y] then                  ▷ Mismatch at x
8:              s ← s ⊕ m(phi[x], 0)
9:          if not mark[x] and mark[y] then                  ▷ Mismatch at y
10:             s ← s ⊕ m(0, phi[y])
11:         if mark[x] and mark[y] then                      ▷ Match at x and y
12:             s ← s ⊕ m(phi[x], phi[y])
13:         s ← s ⊕ COMPARE(x, y)
14:     return s
```

Run-time. The trie-based approach enables linear-time similarity measures over a larger set of formal languages than sorted arrays. For tries we require all $w \in L$ with $w \sqsubseteq \mathbf{x}$ to have either constant overlap in $\mathbf{x}$ or to be prefix of another word, for example, as for the blended k-gram embedding languages.

To determine the run-time complexity on tries, we need to consider the following property: A trie storing n words of maximum length k has depth k and at most kn nodes. Thus, a sequence $\mathbf{x}$ containing $O(|\mathbf{x}|)$ words of maximum length k is embedded using a trie in $O(k|\mathbf{x}|)$ run-time. As an

invariant for the comparison procedure, the nodes x and y in Algorithm 2 stay at the same depth in each recursion. Hence, the comparison algorithm visits at most $k|\mathbf{x}| + k|\mathbf{y}|$ nodes, which results in a worst-case run-time of $O(k(|\mathbf{x}| + |\mathbf{y}|))$. The extraction and comparison run-time is linear in the sequence lengths, as we require words to either have constant overlap, which implies $k|\mathbf{x}| \in O(|\mathbf{x}|)$, or to be prefix of another word, which implies that both words share an identical path in the trie.

Implementation notes. The first extension for the trie data structure is aggregation of embedding values in nodes. If in Algorithm 2 a mismatch occurs at node x, the algorithm recursively descends to all child nodes of x. At this point, however, it is clear that all nodes below x will also be mismatches, as all words w with $\bar{x} \sqsubseteq_p w$ are not present in the compared trie. This fact can be exploited by maintaining an aggregated value φ_x at each node x given by

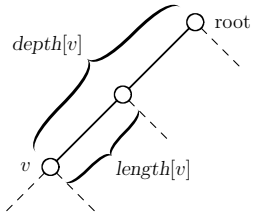
$$\varphi_x := \bigoplus_{w \in I} \phi_w(\mathbf{x}) \;\text{ with }\; I = \{w \in L \mid \bar{x} \sqsubseteq_p w\}.$$

Instead of recursively descending at a mismatching node x, one uses φ_x to retrieve the aggregation of all lower embedding values. The extension allows disjunctive similarity measures to be computed as efficient as conjunctive measures at a worst-case run-time of $O(k \min(|\mathbf{x}|, |\mathbf{y}|))$.

The second extension originates from the close relation of tries and suffix trees. The nodes of a trie can be classified as *implicit* if they link to only one child node and as *explicit* otherwise. By iteratively removing implicit nodes and appending their labels to edges of explicit parent nodes one obtains a *compact trie* (cf. Knuth, 1973; Gusfield, 1997). Edges are labeled by subsequences encoded using indices i and j pointing to $\mathbf{x}[i..j]$. The major benefit of compact tries is reduced space complexity, which decreases from $O(k|\mathbf{x}|)$ to $O(|\mathbf{x}|)$ independent of the maximum length k of stored words.

4.3 Generalized Suffix Trees

Data structure. A *generalized suffix tree* (GST) is a compact trie containing all suffixes of a set of sequences $\mathbf{x}_1, \ldots, \mathbf{x}_l$ (Gusfield, 1997). Every path in a GST from the root to a leaf corresponds to one suffix. A GST is obtained by extending each sequence $\mathbf{x}_i$ with a delimiter $\$_i \notin \mathcal{A}$ and constructing a suffix tree from the concatenation $\mathbf{z} = \mathbf{x}_1\$_1 \ldots \mathbf{x}_l\$_l$.



For each GST node v we denote by *children*$[v]$ the set of child nodes, by *length*$[v]$ the number of symbols on the incoming edge, by *depth*$[v]$ the total number of symbols on the path from the root node to v and by *phi*$[v, i]$ the number of suffixes of $\mathbf{x}_i$ passing through node v. As every subsequence of $\mathbf{x}_i$ is a prefix of some suffix, *phi*$[v, i]$ reflects the occurrences (alternatively frequency or binary flag) for all subsequences terminating on the edge to v. An example of a GST is given in Figure 3. In the remaining part we focus on the case of two sequences $\mathbf{x}$ and $\mathbf{y}$ delimited by $\$_1$ and $\$_2$, computation of similarity measures over a set of sequences being a straightforward extension.

Algorithm. Computation of similarity measures is carried out by traversing a GST in depth-first order (Rieck et al., 2007). An implementation in pseudo-code is given in Algorithm 3. At each node v the inner function m is computed using *phi*$[v, 1]$ and *phi*$[v, 2]$. To account for different words along an edge and to support various embedding languages the function FILTER is employed, which selects appropriate contributions similar to the weighting introduced by Vishwanathan and

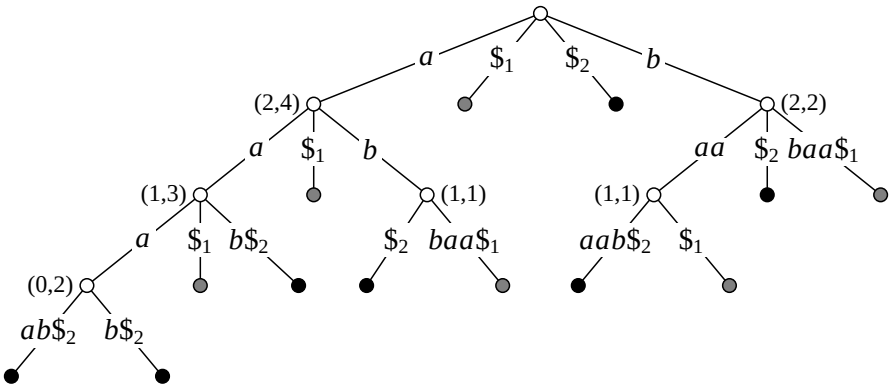


Figure 3: Generalized suffix tree for $\mathbf{x} = abbaa\$_1$ and $\mathbf{y} = baaaab\$_2$. The numbers in brackets at each inner node v correspond to $phi[v,1]$ and $phi[v,2]$. Edges are shown with associated subsequences instead of indices.

Smola (2004). At a node v the function takes $length[v]$ and $depth[v]$ of v as arguments to determine how much the node and its incoming edge contribute to the similarity measure, for example, for the embedding language of k-grams only nodes up to a path depth of k need to be considered.

Algorithm 3 GST-based sequence comparison

```
1:  function COMPARE(X, Y : A*) : R
2:      T ← CONCAT(X, Y)
3:      S ← SUFFIXTREE(T)
4:      return TRAVERSE(root[S])
5:  function TRAVERSE(v : Node) : R
6:      s ← e
7:      for c ← children[v] do
8:          s ← s ⊕ TRAVERSE(c)                ▷ Depth-first traversal
9:      n ← FILTER(length[v], depth[v])        ▷ Filter words on edge to v
10:     s ← s ⊕ m(phi[v,1], phi[v,2]) ⊗ n
11:     return s
```

Algorithm 4 shows a filter function for k-grams. The filter returns 0 for all edges that do not correspond to a k-gram, either because they are too shallow or too deep in the GST, and returns 1 if a k-gram terminates on the edge to a node v.

Algorithm 4 Filter function for k-grams, $L = \mathcal{A}^k$

```
function FILTER(v : Node) : N
    if depth[v] ≥ k and depth[v] − length[v] < k then
        return 1
    return 0
```

Another example of a filter is given in Algorithm 5. The filter implements the embedding language $L = \mathcal{A}^*$. The incoming edge to a node v contributes to a similarity measure by *length*[v], because exactly *length*[v] contiguous subsequences terminate on the edge to v.

Algorithm 5 Filter function for all contiguous subsequences, $L = \mathcal{A}^*$

```
function FILTER(v : Node) : ℕ
    return length[v]
```

The bag-of-words model can be implemented either by encoding each word as a symbol of $\mathcal{A}$ or by augmenting nodes to indicate the presence of delimiter symbols on edges. Further definitions of weighting schemes for string kernels, which are suitable for Algorithm 3, are given by Vishwanathan and Smola (2004).

Run-time. Suffix trees are well-known for their ability to enhance run-time performance of string algorithms (Gusfield, 1997). The advantage exploited herein is that a suffix tree comprises a quadratic amount of information, namely all suffixes, in a linear representation. Thus, a GST enables linear-time computation of similarity measures, even if a sequence $\mathbf{x}$ contains $O(|\mathbf{x}|^2)$ words and the embedding language corresponds to $L = \mathcal{A}^*$.

There are well-known algorithms for linear-time construction of suffix trees (e.g., Weiner, 1973; McCreight, 1976; Ukkonen, 1995), so that a GST for two sequences $\mathbf{x}$ and $\mathbf{y}$ can be constructed in $O(|\mathbf{x}| + |\mathbf{y}|)$ using the concatenation $\mathbf{z} = \mathbf{x}\$_1\mathbf{y}\$_2$. As a GST contains at most $2|\mathbf{z}|$ nodes, the worst-case run-time of any traversal is $O(|\mathbf{z}|) = O(|\mathbf{x}| + |\mathbf{y}|)$. Consequently, computation of similarity measures between sequences using a GST can be realized in time linear in the sequence lengths independent of the complexity of L.

Implementation notes. In practice the GST algorithm may suffer from high memory consumption, due to storage of child nodes and suffix links. To alleviate this problem an alternative data structure with similar properties—*suffix arrays*—was proposed by Manber and Myers (1993). A suffix array is an integer array enumerating the suffixes of a sequence $\mathbf{z}$ in lexicographical order. It can be constructed in linear run-time, however, algorithms with super-linear run-time are surprisingly faster on real-world data (see Manzini and Ferragina, 2004; Maniscalco and Puglisi, 2007).

Abouelhoda et al. (2004) propose a generic procedure for replacing suffix trees with enhanced suffix array, for example, as performed for the string kernel computation of Teo and Vishwanathan (2006). This procedure involves several auxiliary data structures for maintenance of child nodes and suffix links. In our implementation we follow a different approach based on the work of Kasai et al. (2001a) and Kasai et al. (2001b). Using a suffix array and an array of longest-common prefixes (LCP) for suffixes, we replace the traversal of the GST by looping over a generalized suffix array in linear time.

Application of suffix arrays reduces memory requirements by a factor of 4. About $11|\mathbf{z}|$ bytes are required for the modified GST algorithm: 8 bytes for a suffix and inverse suffix array, 2 bytes for sequence indices and on average 1 byte for an LCP array. In comparison, a suffix tree usually requires over $40|\mathbf{z}|$ bytes (Abouelhoda et al., 2004) and the enhanced suffix array of Teo and Vishwanathan (2006) about $19|\mathbf{z}|$ bytes.

5. Experiments and Applications

In order to evaluate the run-time performance of the proposed comparison algorithms in practice and to investigate the effect of different similarity measures on sequential data, we conducted experiments on real world sequences. We chose nine data sets from the domains of bioinformatics, text processing and computer security. Details about each data set, contained sequences and references are given in Table 5.

Name	**Sequence type**	**#**	$\lvert\mathcal{A}\rvert$	$\lvert\mathbf{x}\rvert_\mu$	**Reference**
Bioinformatics

Table 5: Data sets of sequences. The number of sequences in each set is denoted by #, the alphabet size by $|\mathcal{A}|$ and the average sequence length by $|\mathbf{x}|_\mu$.

5.1 Run-time Experiments

The linear-time algorithms presented in Section 4 build on data structures of increasing complexity and capability—sorted arrays are simple but limited in capabilities, tries are more involved, yet they do not cover all embedding languages and generalized suffix trees are relatively complex and support the full range of embedding languages. In practice, however, it is the absolute and not asymptotic run-time that matters. Since the absolute run-time is affected by hidden constant factors, depending on design and implementation of an algorithm, it can only be evaluated experimentally.

Therefore each algorithm was implemented using enhancements covered in implementation notes. In particular, for Algorithm 1 we incorporated 64-bit variables to realize a sorted 64-bit array, for Algorithm 2 we implemented a compact trie representation and for Algorithm 3 we used generalized suffix arrays in favor of suffix trees. For each of these algorithms we conducted experiments using different embedding languages to assess the run-time on the data sets given in Table 5.

We applied the following experimental procedure and averaged run-time over 10 individual runs: 500 sequences are randomly drawn from a data set and a 500×500 matrix is computed for the Manhattan distance using a chosen embedding language. The run-time of the matrix computation is measured and reported in pairwise comparisons per second. Note, that due to the symmetry of the Manhattan distance only $(n^2+n)/2$ comparisons need to be performed for an $n \times n$ matrix.

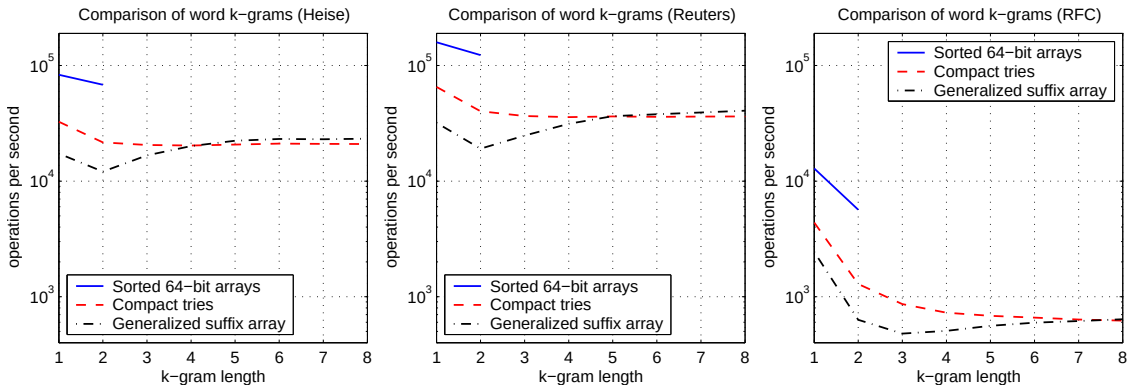

Figure 4: Run-time of sequences comparison over word k-grams for different algorithms. The x-axis gives the word k-gram lengths. The y-axis shows the number of comparison operations per second in log-scale.

Embedding language: bag-of-words. As a first embedding language, we consider the bag-of-words model. Since natural words can be defined only for textual data, we limit the focus of this experiment to text data sets in Table 5. In particular, we use the embedding language of *word k-grams*—covering the classic "bag of words" as word 1-grams—by using an alphabet of words instead of characters. Each symbol of the alphabet is stored in 32 bits, so that up to 2^{32} different words can be represented. Experiments are conducted for values of k ranging from 1 to 8.

Figure 4 shows the run-time performance of the implemented algorithms as a function of k on the Reuters, Heise and RFC data sets. The sorted array approach significantly outperforms the other algorithms on all data sets, yet it can only be applied for $k \leq 2$, as it is limited to 64 bits. For small values of k suffix arrays require more time for each comparison compared to compact tries, while for $k > 5$ their performance is similar to compact tries. This difference is explained by the number of unique k-grams $\nu_{\mathbf{x}}$ in each sequence $\mathbf{x}$. For small values of k often holds $\nu_{\mathbf{x}} < |\mathbf{x}|$, so that a trie comparison requires $O(k(\nu_{\mathbf{x}} + \nu_{\mathbf{y}}))$ time in contrast to $O(|\mathbf{x}| + |\mathbf{y}|)$ for a suffix array. The worse run-time performance on the RFC data set is due to longer sequences.

Embedding language: k-grams. For this experiment we focus on the embedding language of k-grams, which is not limited to a particular type of sequences, so that experiments were conducted for all data sets in Table 5. In contrast to the previous setup, k-grams are associated with the original alphabet of each data set: DNA bases and proteins for bioinformatics, characters for texts, and system calls and bytes for computer security. For each data set the value of k is varied from 1 to 19.

The run-time as a function of k for each data set and algorithm is given in Figure 5. The sorted array approach again yields the best performance on all data sets. Moreover, the limitation of sorted arrays to 64 bits does not effect all data sets, so that for DNA all k-gram lengths can be computed. The suffix array slightly outperforms the trie comparison for larger value of k, as its worst-case run-time is independent of the length of k-grams. Absolute performance in terms of the number of comparisons per second differs among data sets due to different average sequence lengths. For data sets with short sequences (e.g., HIDS, ARTS) performance rates up to 10^6 comparisons per second

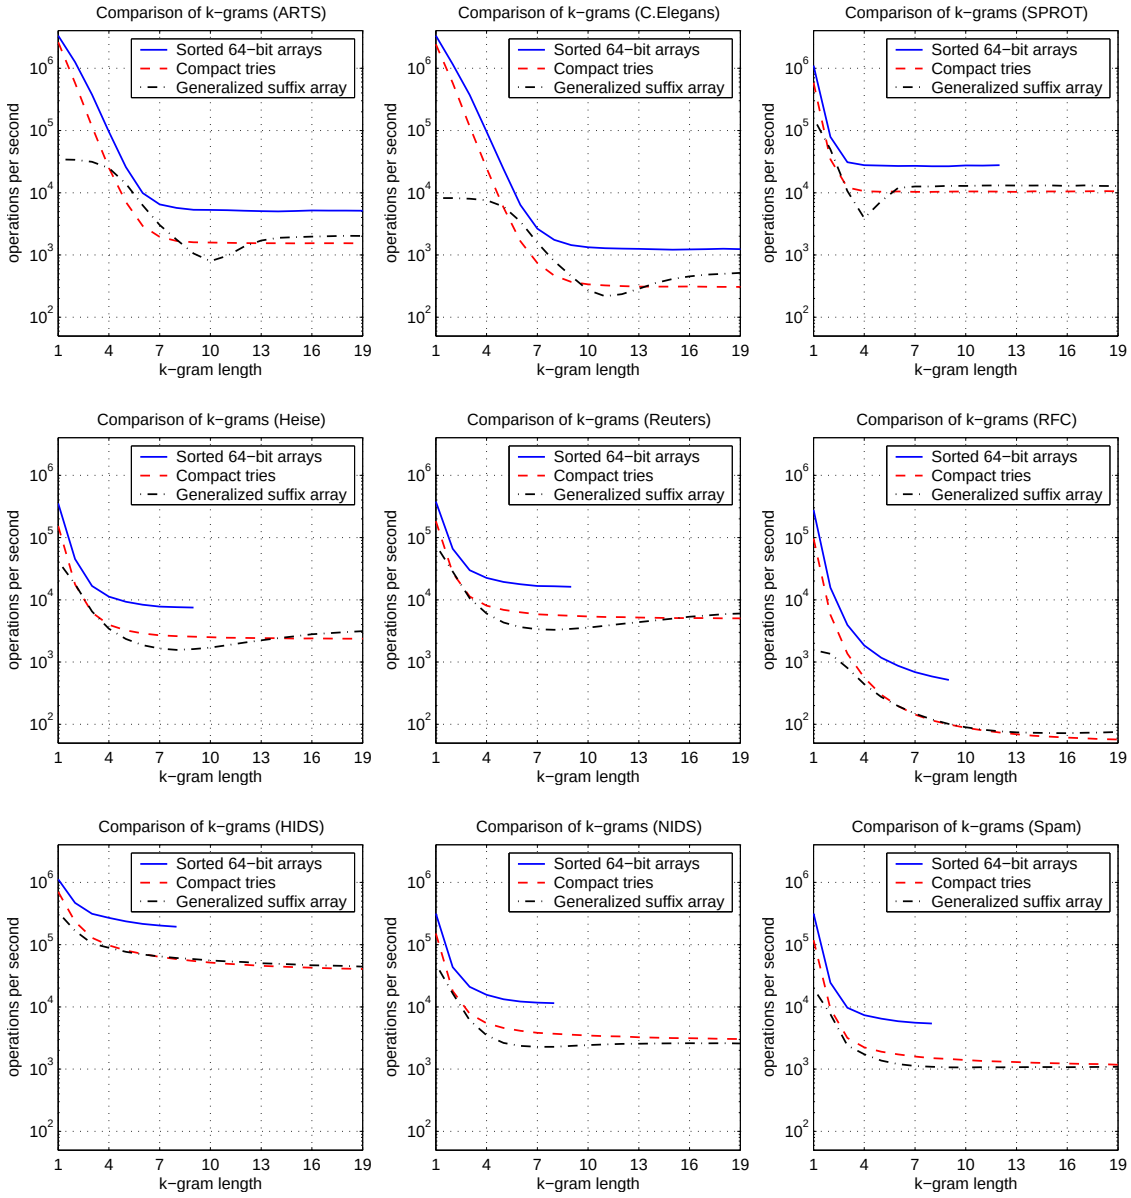

Figure 5: Run-time of sequences comparison over k-grams for different algorithms. The x-axis gives the k-gram lengths. The y-axis shows the number of comparison operations per second in log-scale.

are attainable, while for data sets with longer sequences (e.g., Spam, RFC) generally up to $10^3 - 10^4$ comparisons per second are achievable at best.

5.2 Applications

We now demonstrate that the ability of our approach to compute diverse similarity measures is beneficial in real applications, especially in unsupervised learning scenarios. Our experiments are performed for: (a) categorization of news articles, (b) intrusion detection in network traffic (c) transcription start site recognition in DNA sequences.

Unsupervised text categorization. For this experiment news articles from the topics "Coffee", "Interest", "Sugar" and "Trade" in the Reuters data set are selected. The learning task is to categorize these articles using clustering, without any prior knowledge of labels. As preprocessing we remove all stop words and words that occur in single articles only. We then compute dissimilarity matrices for the Euclidean, Manhattan and Jensen-Shannon distances using the bag-of-words embedding language as discussed in Section 3. The embedded articles are finally assigned to four clusters using complete linkage clustering (see Duda et al., 2001).

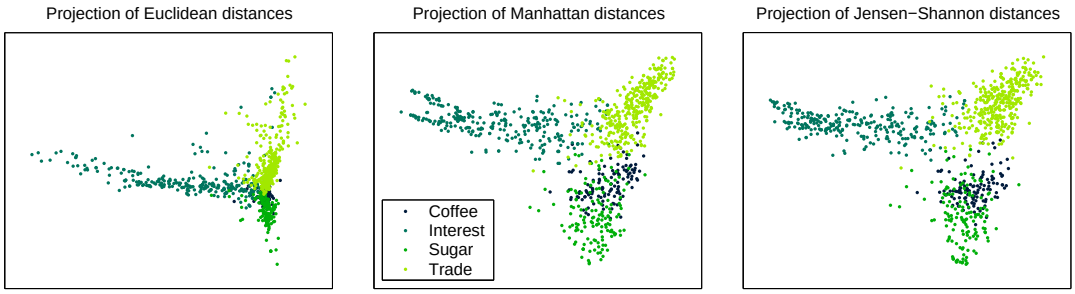
Figure 6(a) shows projections of the embedded articles obtained from the dissimilarity matrices using multidimensional scaling (see Duda et al., 2001). Although projections are limited in describing high-dimensional data, they visualize structure and, thus, help to interpret clustering results. For example, the projection of the Euclidean distances in Figure 6(a) noticeably differs in shape compared to the Manhattan and Jensen-Shannon distances.

The cluster assignments are presented in Figure 6(b) and the distribution of topic labels among clusters is given in Figure 6(c). For the Euclidean distance the clustering fails to unveil features discriminative for article topics, as the majority of articles is assigned to a single cluster. In comparison, the Manhattan and Jensen-Shannon distance allow categorization of the topics "Coffee" and "Sugar", due to observed high frequencies of respective words in articles. However, the Manhattan distance does no allow discrimination of the other two topics, as both are mixed among two clusters. The Jensen-Shannon distance enables better separation of all four topics. The topics "Coffee" and "Sugar" are almost perfectly assigned to clusters and the topics "Interest" and "Trade" each constitute the majority in a respective cluster.

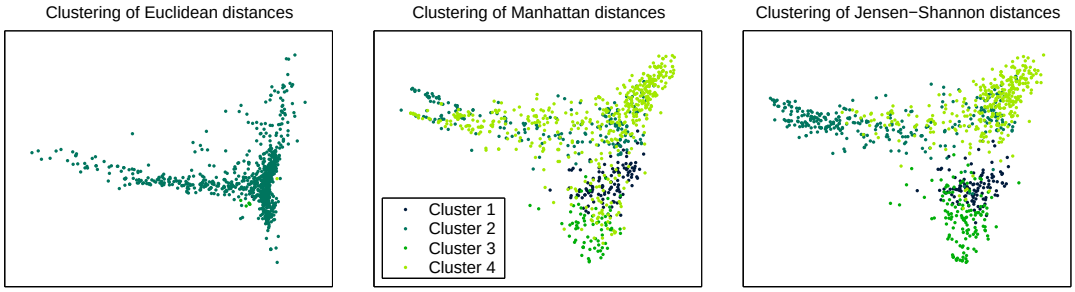
Network intrusion detection. Network intrusion detection aims to automatically identify hacker attacks in network traffic. As labels for such data are hard to obtain in practice, unsupervised learning has gained attention in intrusion detection research. The NIDS data set used for the runtime experiments (cf. Table 5) is known to contain major artifacts (see McHugh, 2000). In order to provide a fair investigation of the impact of various similarity measures on detection of attacks, we generated a smaller private data set. Normal traffic was recorded from the members of our laboratory by providing a virtual network. Additionally attacks were injected by a security expert.

For this experiment we pursue an unsupervised learning approach to network intrusion detection (Rieck and Laskov, 2007). The incoming byte sequences of network connections are embedded using the language of 5-grams, and Zeta, an unsupervised anomaly detection method based on k-nearest neighbors, is applied over the following similarity measures: the Euclidean, Manhattan and Jensen-Shannon distance and the second Kulczynski coefficient (see Section 3.2).

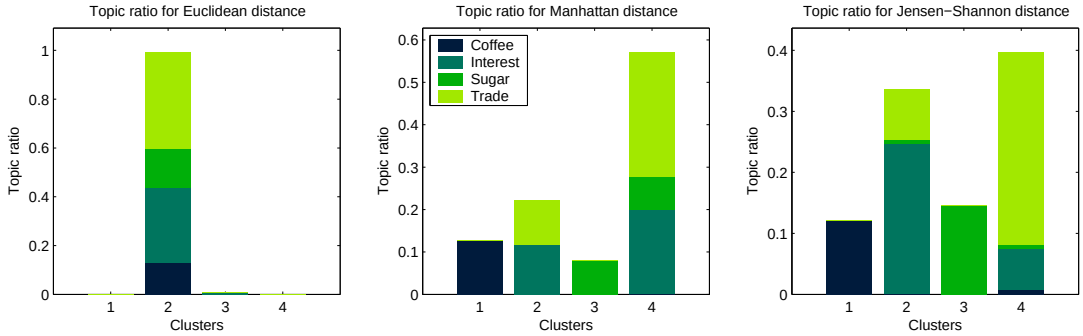
ROC curves for the detection of attacks in the network protocols HTTP, FTP and SMTP are shown in Figure 7. Application of the Jensen-Shannon distance and second Kulczynski coefficient



(a) Projection of embedded articles with true topic label assignments



(b) Projection of embedded articles with cluster assignments



(c) Ratio of topic labels in clusters of embedded articles

Figure 6: Clustering of Reuters articles using different similarity measures (bag-of-words).

yield the highest detection accuracy. Over 78% of all attacks are identified with no false-positives in an unsupervised setup. In comparison, the Euclidean and Manhattan distance give significantly lower detection rates on the FTP and SMTP protocols. The poor detection performance of the latter two similarity measures emphasizes that choosing a discriminative similarity measure is crucial for achieving high accuracy in a particular application.

Transcription start site recognition. The last application focuses on recognition of transcription start sites (TSS), which mark the beginning of genes in DNA. We consider the ARTS data set, which comprises human DNA sequences that either cover the TSS of protein coding genes or have been extracted randomly from the interior of genes. Following the approach of Sonnenburg et al. (2006) these sequences are embedded using the language of 6-grams and a support vector machine (SVM) and a bagged k-nearest neighbor classifier are trained and evaluated on the different partitions of

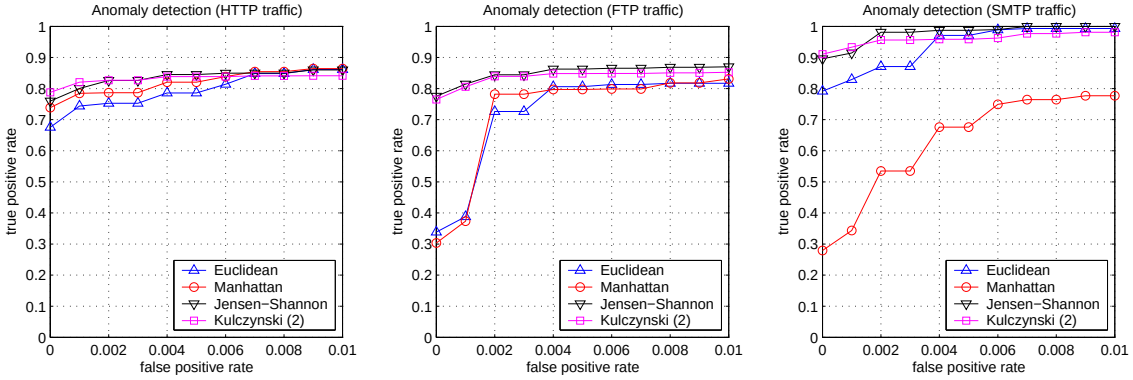


Figure 7: ROC curves for unsupervised anomaly detection on 5-grams of network connections and attacks recorded at our laboratory.

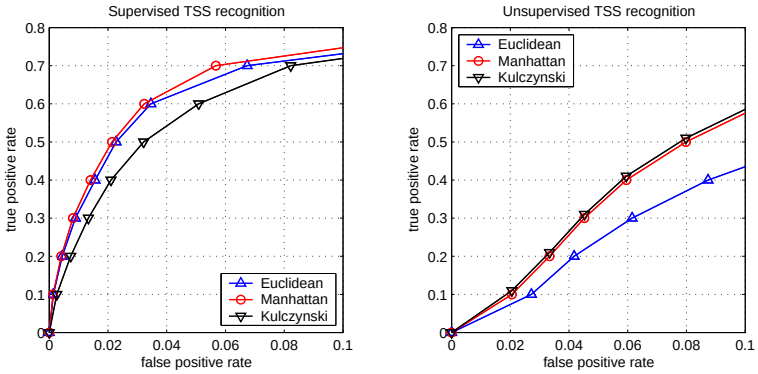

Figure 8: ROC curves for supervised and unsupervised recognition of transcription start sites (TSS) on 6-grams of DNA sequences (ARTS data set).

the data set. Each method is evaluated for the Euclidean distance, the Manhattan distance and the second Kulczynski coefficient. As only 10% of the sequences in the data set correspond to transcription start sites, we additionally apply the unsupervised outlier detection method Gamma (Harmeling et al., 2006), which is similar to the method employed in the previous experiment.

Figure 8 shows the performance achieved by the bagged k-nearest neighbor classifier and the unsupervised learning method.[2] The accuracy in both setups strongly depends on the chosen similarity measures. The metric distances yield better accuracy in the supervised setup. The second Kulczynski coefficient and also the Manhattan distance perform significantly better than the Euclidean distance in unsupervised application. In the absence of labels these measures express better discriminative properties for TSS recognition, that are difficult to access through Euclidean distances. For the supervised application, the classification performance is limited for all similarity

2. Results for the SVM are similar to the bagged k-nearest neighbor classifier and have been omitted.

measures, as only some discriminative features for TSS recognition are encapsulated in k-gram models (cf. Sonnenburg et al., 2006).

6. Conclusions

The framework for comparison of sequences proposed in this article provides means for efficient computation of a large variety of similarity measures, including kernels, distances and non-metric similarity coefficients. The framework is based on embedding of sequences in a high-dimensional feature space using formal languages, such as k-grams, contiguous subsequences, etc. Three implementations of the proposed framework using different data structures have been discussed and experimentally evaluated.

Although all three data structures that were considered—sorted arrays, tries and generalized suffix trees—have asymptotically linear run-time, significant differences in the absolute run-time have been observed in our experiments. The constant factors are affected by various design issues illustrated by our remarks on implementation of the proposed algorithms. In general, we have observed a consistent trade-off between run-time efficiency and complexity of embedding languages a particular data structure can handle. Sorted arrays are the most efficient data structure; however, their applicability is limited to k-grams and bag-of-words models. On the other end of the spectrum are generalized suffix trees (and their more space-efficient implementation using suffix arrays) that can handle unrestricted embedding languages—at a cost of more complicated algorithms and lower efficiency. The optimal data structure for computation of similarity measures thus depends on the embedding language to be used in a particular application.

The proposed framework offers machine learning researchers an opportunity to use a large variety of similarity measures for applications that involve sequential data. Although an optimal similarity measure—as it is well known and has been also observed in our experiments—depends on a particular application, the technical means for seamless incorporation of various similarity measures can be of great utility in practical applications of machine learning. Especially appealing is the possibility for efficient computation of non-Euclidean distances over embedded sequences, which extend applicable similarity measures for sequences beyond inner-products and kernel functions.

In general, the proposed framework demonstrates an important advantage of abstracting data representation—in the form of pairwise relationships—from learning algorithms, which will hopefully motivate further investigation of learning algorithms using a general form of such abstraction.

Abstract

Conventional SVM-based image coding methods are founded on independently restricting the distortion in every image coefficient at some particular image representation. Geometrically, this implies allowing arbitrary signal distortions in an n-dimensional rectangle defined by the ε-insensitivity zone in each dimension of the selected image representation domain. Unfortunately, not every image representation domain is well-suited for such a simple, scalar-wise, approach because statistical and/or perceptual interactions between the coefficients may exist. These interactions imply that scalar approaches may induce distortions that do not follow the image statistics and/or are perceptually annoying. Taking into account these relations would imply using non-rectangular ε-insensitivity regions (allowing coupled distortions in different coefficients), which is beyond the conventional SVM formulation.

In this paper, we report a condition on the suitable domain for developing efficient SVM image coding schemes. We analytically demonstrate that no linear domain fulfills this condition because of the statistical and perceptual inter-coefficient relations that exist in these domains. This theoretical result is experimentally confirmed by comparing SVM learning in previously reported linear domains and in a recently proposed non-linear perceptual domain that simultaneously reduces the statistical and perceptual relations (so it is closer to fulfilling the proposed condition). These results highlight the relevance of an appropriate choice of the image representation before SVM learning.

Keywords: image coding, non-linear perception models, statistical independence, support vector machines, insensitivity zone

1. Problem Statement: The Diagonal Jacobian Condition

Image coding schemes based on support vector machines (SVM) have been successfully introduced in the literature. SVMs have been used in the spatial domain (Robinson and Kecman, 2000), in the block-DCT domain (Robinson and Kecman, 2003), and in the wavelet domain (Ahmed, 2005; Jiao et al., 2005). These coding methods take advantage of the ability of the support vector regression (SVR) algorithm for function approximation using a small number of parameters (signal samples, or support vectors) (Smola and Schölkopf, 2004). In all current SVM-based image coding techniques, a representation of the image is described by the entropy-coded weights associated to the support vectors necessary to approximate the signal with a given accuracy. Relaxing the accuracy bounds reduces the number of needed support vectors. In a given representation domain, reducing the number of support vectors increases the compression ratio at the expense of bigger distortion (lower image quality). By applying the standard SVR formulation, a certain amount of distortion in each sample of the image representation is allowed. In the original formulation, scalar restrictions on the errors are introduced using a constant ε-insensitivity value for every sample.

Recently, this procedure has been refined by Gómez-Pérez et al. (2005) using a profile-dependent SVR (Camps-Valls et al., 2001) that considers a different ε for each sample or frequency. This frequency-dependent insensitivity, ε_f, accounts for the fact that, according to simple (linear) perception models, not every sample in linear frequency domains (such as DCT or wavelets) contributes to the perceived distortion in the same way.

Despite different domains have been proposed for SVM training (spatial domain, block-DCT and wavelets) and different ε insensitivities per sample have been proposed, in conventional SVR formulation, the particular distortions introduced by regression in the different samples are not coupled. In all the reported SVM-based image coding schemes, the RBF kernel is used and the penalization parameter is fixed to an arbitrarily large value. In this setting, considering n-sample signals as n-dimensional vectors, the SVR guarantees that the approximated vectors are confined in n-dimensional rectangles around the original vectors. These rectangles are just n-dimensional cubes in the standard formulation or they have certain elongation if different ε_f are considered in each axis, f. Therefore, in all the reported SVM-based coding methods, these rectangles are always oriented along the axes of the (linear) image representation. According to this, a common feature of these (scalar-wise) approaches is that they give rise to decoupled distortions in each dimension. Pérez-Cruz et al. (2002) proposed a hyperspherical insensitivity zone to correct the penalization factor in each dimension of multi-output regression problems, but again, restrictions to each sample were still uncoupled.

This scalar-wise strategy is not the best option in domains where the different dimensions of the image representation are not independent. For instance, consider the situation where actually independent components, $\mathbf{r}_f$, are obtained from a given image representation, $\mathbf{y}$, applying some eventually non-linear transform, R:

$$\mathbf{y} \xrightarrow{R} \mathbf{r}.$$

In this case, SVM regression with scalar-wise error restriction makes sense in the $\mathbf{r}$ domain. However, the original $\mathbf{y}$ domain will not be suitable for the standard SVM regression unless the matrix ∇R is diagonal (up to any permutation of the dimensions, that is, only one non-zero element per row). Therefore, if transforms that achieve independence have non-diagonal Jacobian, scalar-wise restrictions in the original (coupled coefficients) domain $\mathbf{y}$ are not allowed.

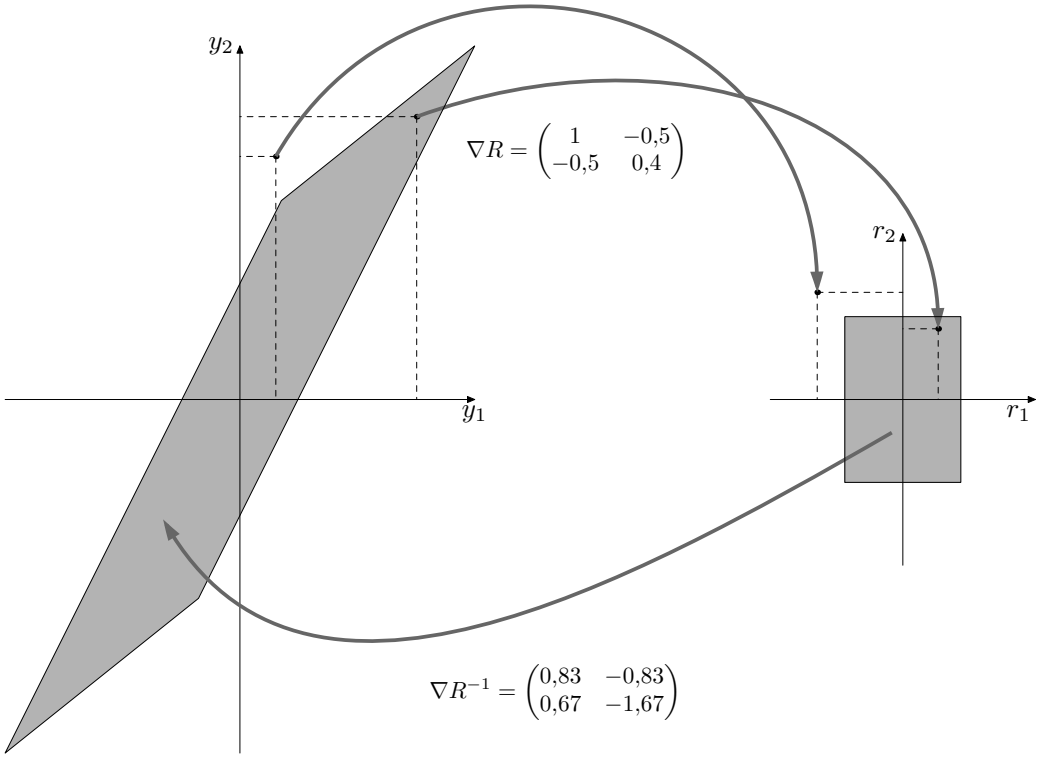

Figure 1: Insensitivity regions in different representation domains, **y** (left) and **r** (right), related by a non-diagonal transform ∇R and its inverse ∇R^{-1}.

Figure 1 illustrates this situation. The shaded region in the right plot (**r** domain) represents the *n*-dimensional box determined by the ε_f insensitivities in each dimension (f=1,2), in which a scalar-wise approach is appropriate due to independence among signal coefficients. Given that the particular ∇R transform is not diagonal, the corresponding shaded region in the left plot (the original **y** domain) is not aligned along the axes of the representation. This has negative implications: note that for the highlighted points, smaller distortions in both dimensions in the **y** domain (as implied by SVM with tighter *but scalar* ε_f insensitivities) do not necessarily imply lying inside the insensitivity region in the final truly independent (and meaningful) **r** domain. Therefore, the original **y** domain is not suitable for the direct application of conventional SVM, and consequently, non-trivial coupled insensitivity regions are required.

Summarizing, in the image coding context, the condition for an image representation **y** to be strictly suitable for conventional SVM learning is that *the transform that maps the original representation* **y** *to an independent coefficient representation* **r** *must be locally diagonal*.

As will be reviewed below, independence among coefficients (and the transforms to obtain them) may be defined in both statistical and perceptual terms (Hyvarinen et al., 2001; Malo et al., 2001; Epifanio et al., 2003; Malo et al., 2006). On the one hand, a locally diagonal relation to a statistically independent representation is desirable because independently induced distortions (as the conventional SVM approach does) will preserve the statistics of the distorted signal, that is, it will not introduce artificial-looking artifacts. On the other hand, a locally diagonal relation to a perceptually

independent representation is desirable because independently induced distortions do not give rise to increased subjective distortions due to non-trivial masking or facilitation interactions between the distortions in each dimension (Watson and Solomon, 1997).

In this work, we show that conventional linear domains do not fulfill the diagonal Jacobian condition in either the statistical case or in the perceptual case. This theoretical result is experimentally confirmed by comparing SVM learning in previously reported linear domains (Robinson and Kecman, 2003; Gómez-Pérez et al., 2005) and in a recently proposed non-linear perceptual domain that simultaneously reduces the statistical and the perceptual relations (Malo et al., 2006), thus, this non-linear perceptual domain is closer to fulfilling the proposed condition.

The rest of the paper is structured as follows. Section 2 reviews the fact that linear coefficients of the image representations commonly used for SVM training are neither statistically independent nor perceptually independent. Section 3 shows that transforms for obtaining statistical and/or perceptual independence from linear domains have non-diagonal Jacobian. This suggests that there is room to improve the performance of conventional SVM learning reported in linear domains. In Section 4, we propose the use of a perceptual representation for SVM training because it strictly fulfills the diagonal Jacobian condition in the perceptual sense and increases the statistical independence among coefficients, bringing it closer to fulfilling the condition in the statistical sense. The experimental image coding results confirm the superiority of this domain for SVM training in Section 5. Section 6 presents the conclusions and final remarks.

2. Statistical and Perceptual Relations Among Image Coefficients

Statistical independence among the coefficients of a signal representation refers to the fact that the joint PDF of the class of signals to be considered can be expressed as a product of the marginal PDFs in each dimension (Hyvarinen et al., 2001). Simple (second-order) descriptions of statistical dependence use the non-diagonal nature of the covariance matrix (Clarke, 1985; Gersho and Gray, 1992). More recent and accurate descriptions use higher-order moments, mutual information, or the non-Gaussian nature (sparsity) of marginal PDFs (Hyvarinen et al., 2001; Simoncelli, 1997).

Perceptual independence refers to the fact that the visibility of errors in coefficients of an image may depend on the energy of neighboring coefficients, a phenomenon known in the perceptual literature as *masking* or *facilitation* (Watson and Solomon, 1997). Perceptual dependence has been formalized just up to second order, and this may be described by the non-Euclidean nature of the perceptual metric matrix (Malo et al., 2001; Epifanio et al., 2003; Malo et al., 2006).

2.1 Statistical Relations

In recent years, a variety of approaches, known collectively as "independent component analysis" (ICA), have been developed to exploit higher-order statistics for the purpose of achieving a unique *linear* solution for coefficient independence (Hyvarinen et al., 2001). The basis functions obtained when these methods are applied to images are spatially localized and selective for both orientation and spatial frequency (Olshausen and Field, 1996; Bell and Sejnowski, 1997). Thus, they are similar to basis functions of multi-scale wavelet representations.

Despite its name, linear ICA does *not* actually produce statistically independent coefficients when applied to photographic images. Intuitively, independence would seem unlikely, since images are not formed from linear superpositions of independent patterns: the typical combination rule for the elements of an image is *occlusion*. Empirically, the coefficients of natural image decom-

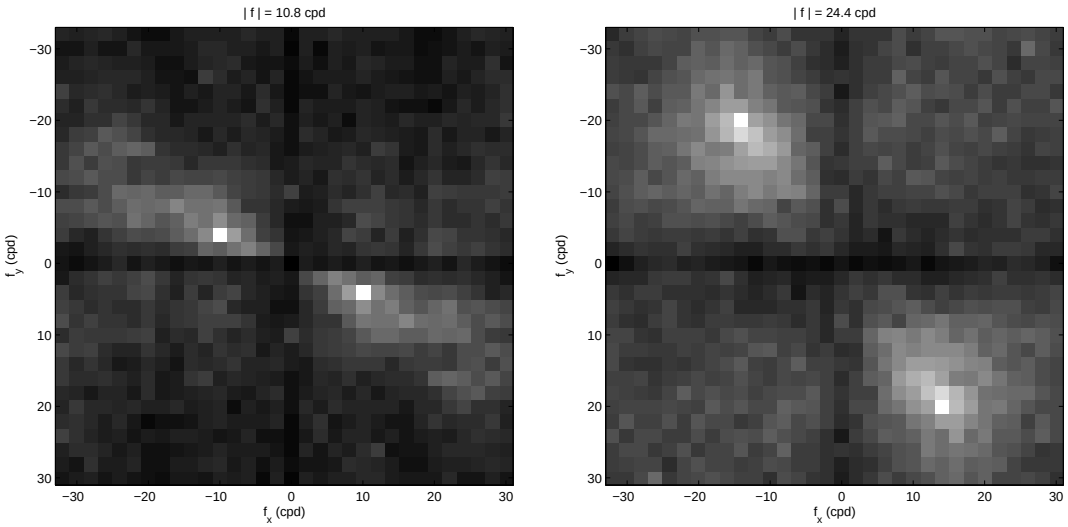

Figure 2: Statistical interaction of two particular coefficients of the local Fourier Transform with their neighbors in a natural image database. The absolute value of the frequency of these coefficients is $|f| = 10.8$ and $|f| = 24.4$ cycles/degree (cpd).

positions in spatially localized oscillating basis functions are found to be fairly well decorrelated (i.e., their covariance is almost zero). However, the amplitudes of coefficients at nearby spatial positions, orientations, and scales are highly correlated (even with orthonormal transforms) (Simoncelli, 1997; Buccigrossi and Simoncelli, 1999; Wainwright et al., 2001; Hyvarinen et al., 2003; Gutiérrez et al., 2006; Malo et al., 2006; Malo and Gutiérrez, 2006). This suggests that achieving statistical independence requires the introduction of non-linearities beyond linear ICA transforms.

Figure 2 reproduces one of many results that highlight the presence of statistical relations of natural image coefficients in block PCA or linear ICA-like domains: the energy of spatially localized oscillating filters is correlated with the energy of neighboring filters in scale and orientation (see Gutiérrez et al., 2006). A remarkable feature is that the interaction width increases with frequency, as has been reported in other domains, for example, wavelets (Buccigrossi and Simoncelli, 1999; Wainwright et al., 2001; Hyvarinen et al., 2003), and block-DCT (Malo et al., 2006).

In order to remove the remaining statistical relations in the linear domains $\mathbf{y}$, non-linear ICA methods are necessary (Hyvarinen et al., 2001; Lin, 1999; Karhunen et al., 2000; Jutten and Karhunen, 2003). Without lack of generality, non-linear ICA transforms can be schematically understood as a two-stage process (Malo and Gutiérrez, 2006):

$$\mathbf{x} \underset{\mathbf{T}^{-1}}{\overset{\mathbf{T}}{\rightleftarrows}} \mathbf{y} \underset{R^{-1}}{\overset{R}{\rightleftarrows}} \mathbf{r}\,, \tag{1}$$

where $\mathbf{x}$ is the image representation in the spatial domain, and $\mathbf{T}$ is a global unitary linear transform that removes second-order and eventually higher-order relations among coefficients in the spatial domain. Particular examples of $\mathbf{T}$ include block PCA, linear ICAs, DCT or wavelets. In the ICA literature notation, $\mathbf{T}$ is the *separating matrix* and $\mathbf{T}^{-1}$ is the *mixing matrix*. The second transform

R is an additional non-linearity that is introduced in order to remove the statistical relations that still remain in the **y** domain.

2.2 Perceptual Relations

Perceptual dependence among coefficients in different image representations can be understood by using the current model of V1 cortex. This model can also be summarized by the two-stage (linear and non-linear) process described in Equation (1). In this perceptual case, **T** is also a linear filter bank applied to the original input image in the spatial domain. This filter bank represents the linear behavior of V1 neurons whose receptive fields happen to be similar to wavelets or linear ICA basis functions (Olshausen and Field, 1996; Bell and Sejnowski, 1997). The second transform, *R*, is a non-linear function that accounts for the masking and facilitation phenomena that have been reported in the linear **y** domain (Foley, 1994; Watson and Solomon, 1997). Section 3.2 gives a parametric expression for the second non-linear stage, *R*: the divisive normalization model (Heeger, 1992; Foley, 1994; Watson and Solomon, 1997).

This class of models is based on psychophysical experiments assuming that the last domain, **r**, is perceptually Euclidean (i.e., perfect perceptual independence). An additional confirmation of this assumption is the success of (Euclidean) subjective image distortion measures defined in that domain (Teo and Heeger, 1994). Straightforward application of Riemannian geometry to obtain the perceptual metric matrix in other domains shows that the coefficients of linear domains **x** and **y**, or any other linear transform of them, are not perceptually independent (Epifanio et al., 2003).

Figure 3 illustrates the presence of perceptual relations between coefficients when using linear block frequency or wavelet-like domains, **y**: the *cross-masking* behavior. In this example, the visibility of the distortions added on top of the background image made of periodic patterns has to be assessed. This is a measure of the sensitivity of a particular perceptual mechanism to distortions in that dimension, Δy_f, when mechanisms tuned to other dimensions are simultaneously active, that is, $y_{f'} \neq 0$, with $f' \neq f$. As can be observed, low frequency noise is more visible in high frequency backgrounds than in low frequency backgrounds (e.g., left image). Similarly, high frequency noise is more visible in low frequency backgrounds than in high frequency ones (e.g., right image). That is to say, a signal of a specific frequency strongly masks the corresponding frequency analyzer, but it induces a smaller sensitivity reduction in the analyzers that are tuned to different frequencies. In other words, the reduction in sensitivity of a specific analyzer gets larger as the distance between the background frequency and the frequency of the analyzer gets smaller. The response of each frequency analyzer not only depends on the energy of the signal for that frequency band, but also on the energy of the signal in other frequency bands (cross-masking). This implies that a different amount of noise in each frequency band may be acceptable depending on the energy of that frequency band and on the energy of neighboring bands. This is what we have called *perceptual dependence* among different coefficients in the **y** domain.

At this point, it is important to stress the similarity between the set of computations to obtain statistically decoupled image coefficients and the known stages of biological vision. In fact, it has been hypothesized that biological visual systems have organized their sensors to exploit the particular statistics of the signals they have to process. See Barlow (2001), Simoncelli and Olshausen (2001), and Simoncelli (2003) for reviews on this hypothesis.

In particular, both the linear and the non-linear stages of the cortical processing have been successfully derived using redundancy reduction arguments: nowadays, the same class of linear

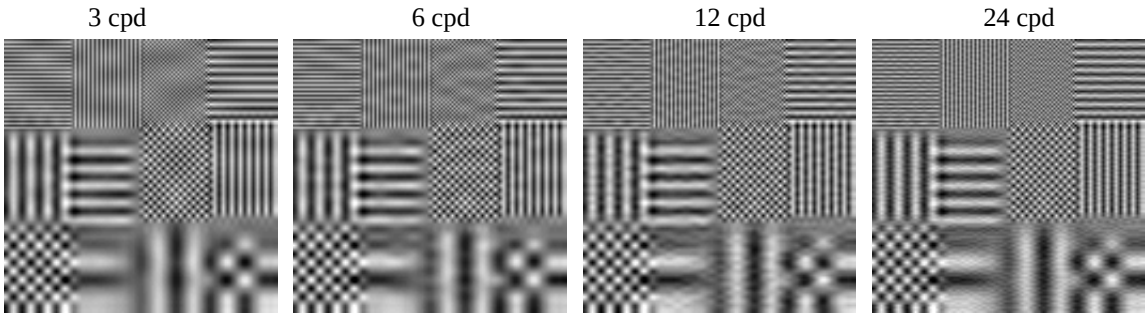

Figure 3: Illustrative example of perceptual dependence (cross-masking phenomenon). Equal energy noise of different frequency content, 3 cycl/deg (cpd), 6 cpd, 12 cpd and 24 cpd, shown on top of a background image. Sampling frequency assumes that these images subtend an angle of 3 deg.

stage **T** is used in transform coding algorithms and in vision models (Olshausen and Field, 1996; Bell and Sejnowski, 1997; Taubman and Marcellin, 2001), and new evidence supports the same idea for the second non-linear stage (Schwartz and Simoncelli, 2001; Malo and Gutiérrez, 2006). According to this, the statistical and perceptual transforms, R, that remove the above relations from the linear domains, **y**, would be very similar if not the same.

3. Statistical and Perceptual Independence Imply Non-diagonal Jacobian

In this section, we show that both statistical redundancy reduction transforms (e.g., non-linear ICA) and perceptual independence transforms (e.g., divisive normalization), have non-diagonal Jacobian for any linear image representation, so they are not strictly suitable for conventional SVM training.

3.1 Non-diagonal Jacobian in Non-linear ICA Transforms

One possible approach for dealing with global non-linear ICA is to act differentially by breaking the problem into local linear pieces that can then be integrated to obtain the global independent coefficient domain (Malo and Gutiérrez, 2006). Each differential sub-problem around a particular point (image) can be locally solved using the standard linear ICA methods restricted to the neighbors of that point (Lin, 1999).

Using the differential approach in the context of a two-stage process such as the one in Equation (1), it can be shown that (Malo and Gutiérrez, 2006):

$$\mathbf{r} = \mathbf{r_0} + \int_{\mathbf{x}_0}^{\mathbf{x}} \mathbf{T}_\ell(\mathbf{x}')\, d\mathbf{x}' = \mathbf{r_0} + \int_{\mathbf{x}_0}^{\mathbf{x}} \nabla R(\mathbf{T}\mathbf{x}')\, \mathbf{T}\, d\mathbf{x}', \tag{2}$$

where $\mathbf{T}_\ell(\mathbf{x}')$ is the local separating matrix for a neighborhood of the image $\mathbf{x}'$, and $\mathbf{T}$ is the global separating matrix for the whole PDF. Therefore, the Jacobian of the second non-linear stage is:

$$\nabla R(\mathbf{y}) = \nabla R(\mathbf{T}\mathbf{x}) = \mathbf{T}_\ell(\mathbf{x})\, \mathbf{T}^{-\mathbf{1}}. \tag{3}$$

As local linear independent features around a particular image, $\mathbf{x}$, differ in general from global linear independent features, that is, $\mathbf{T}_\ell(\mathbf{x}) \neq \mathbf{T}$, the above product is not the identity nor diagonal in general.

3.2 Non-diagonal Jacobian in Non-linear Perceptual Transforms

The current response model for the cortical frequency analyzers is non-linear (Heeger, 1992; Watson and Solomon, 1997). The outputs of the filters of the first linear stage, $\mathbf{y}$, undergo a non-linear sigmoid transform in which the energy of each linear coefficient is weighted by a linear *Contrast Sensitivity Function* (CSF) (Campbell and Robson, 1968; Malo et al., 1997) and is further normalized by a combination of the energies of neighbor coefficients in frequency,

$$r_f = R(\mathbf{y})_f = \frac{\mathrm{sgn}(y_f)\,|\alpha_f y_f|^\gamma}{\beta_f + \sum_{f'=1}^{n} h_{ff'}|\alpha_{f'} y_{f'}|^\gamma}, \tag{4}$$

where α_f (Figure 4[top left]) are CSF-like weights, β_f (Figure 4[top right]) control the sharpness of the response saturation for each coefficient, γ is the so called excitation exponent, and the matrix $h_{ff'}$ determines the interaction neighborhood in the non-linear normalization of the energy. This interaction matrix models the cross-masking behavior (cf. Section 2.2). The interaction in this matrix is assumed to be Gaussian (Watson and Solomon, 1997), and its width increases with the frequency. Figure 4[bottom] shows two examples of this Gaussian interaction for two particular coefficients in a local Fourier domain. Note that the width of the perceptual interaction neighborhood increases with the frequency in the same way as the width of the statistical interaction neighborhood shown in Figure 2. We used a value of $\gamma = 2$ in the experiments.

Taking derivatives in the general divisive normalization model, Equation (4), we obtain

$$\nabla R(\mathbf{y})_{ff'} = \mathrm{sgn}(y_f)\gamma\left(\frac{\alpha_f\,|\alpha_f y_f|^{\gamma-1}}{\beta_f + \sum_{f'=1}^{n} h_{ff'}|\alpha_{f'} y_{f'}|^\gamma}\delta_{ff'} - \frac{\alpha_{f'}|\alpha_f y_f|^\gamma|\alpha_{f'} y_{f'}|^{\gamma-1}}{(\beta_f + \sum_{f'=1}^{n} h_{ff'}|\alpha_{f'} y_{f'}|^\gamma)^2}h_{ff'}\right), \tag{5}$$

which is not diagonal because of the interaction matrix, h, which describes the cross-masking between each frequency f and the remaining $f' \neq f$.

Note that the intrinsic non-linear nature of both the statistical and perceptual transforms, Equations (3) and (5), makes the above results true for any linear domain under consideration. Specifically, if any other possible linear domain for image representation is considered, $\mathbf{y}' = \mathbf{T}'\mathbf{y}$, then the Jacobian of the corresponding independence transform, R', is

$$\nabla R'(\mathbf{y}') = \nabla R(\mathbf{y})\,\mathbf{T}'^{-\mathbf{1}},$$

which, in general, will also be non-diagonal because of the non-diagonal and point-dependent nature of $\nabla R(\mathbf{y})$.

To summarize, since no linear domain fulfills the diagonal Jacobian condition in either statistical or perceptual terms, the negative situation illustrated in Figure 1 may occur when using SVM in these domains. Therefore, improved results could be obtained if SVM learning were applied after some transform achieving independent coefficients, R.

4. SVM Learning in a Perceptually Independent Representation

In order to confirm the above theoretical results (i.e., the unsuitability of linear representation domains for SVM learning) and to assess the eventual gain that can be obtained from training SVR

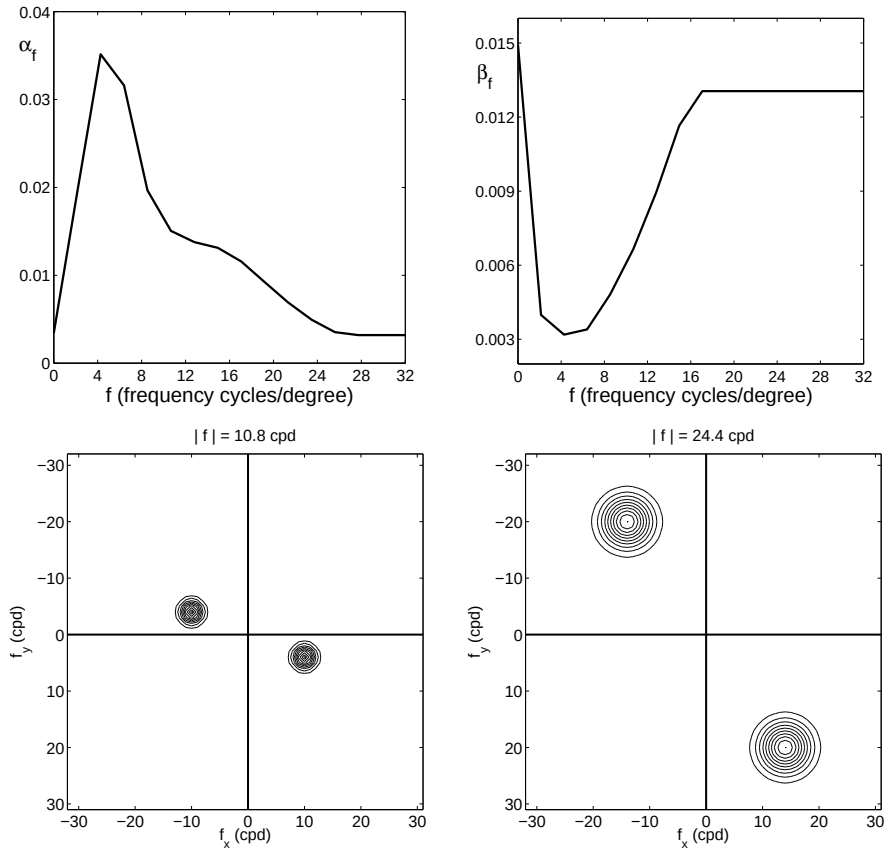

Figure 4: Parameters of the perceptual model: α_f (top left), β_f (top right). Bottom figures represent perceptual interaction neighborhoods $h_{ff'}$ of two particular coefficients of the local Fourier domain.

in a more appropriate domain, we should compare the performance of SVRs in previously reported linear domains (e.g., block-DCT or wavelets) and in one of the proposed non-linear domains (either the statistically independent domain or the perceptually independent domain).

Exploration of the statistical independence transform may have academic interest but, in its present formulation, it is not practical for coding purposes: direct application of non-linear ICA as in Equation (2) is very time-consuming for high dimensional vectors since lots of local ICA computations are needed to transform each block, and a very large image database is needed for a robust and significant computation of R. Besides, an equally expensive differential approach is also needed to compute the inverse R^{-1} for image decoding. In contrast, the perceptual non-linearity (and its inverse) are analytical. These analytical expressions are feasible for reasonable block sizes, and there are efficient iterative methods that can be used for larger vectors (Malo et al., 2006). In this paper, we explore the use of a psychophysically-based divisive normalized domain: first compute a block-DCT transform and then apply the divisive normalization model described above for each block. The results will be compared to the first competitive SVM coding results (Robinson

and Kecman, 2003) and the posterior improvements reported by Gómez-Pérez et al. (2005), both formulated in the linear block-DCT domain.

As stated in Section 2, by construction, the proposed domain is perceptually Euclidean with perceptually independent components. The Euclidean nature of this domain has an additional benefit: the ε-insensitivity design is very simple because a constant value is appropriate due to the constant perceptual relevance of all coefficients. Thus, direct application of the standard SVR method is theoretically appropriate in this domain.

Moreover, beyond its built-in perceptual benefits, this psychophysically-based divisive normalization has attractive statistical properties: it strongly reduces the mutual information between the final coefficients $\mathbf{r}$ (Malo et al., 2006). This is not surprising according to the hypothesis that try to explain the early stages of biological vision systems using information theory arguments (Barlow, 1961; Simoncelli and Olshausen, 2001). Specifically, dividing the energy of each linear coefficient by the energy of the neighbors, which are statistically related with it, cf. Figure 2, gives coefficients with reduced statistical dependence. Moreover, as the empirical non-linearities of perception have been reproduced using non-linear ICA in Equation (2) (Malo and Gutiérrez, 2006), the empirical divisive normalization can be seen as a convenient parametric way to obtain statistical independence.

5. Performance of SVM Learning in Different Domains

In this section, we analyze the performance of SVM-based coding algorithms in linear and non-linear domains through rate-distortion curves and explicit examples for visual comparison. In addition, we discuss how SVM selects support vectors in these domains to represent the image features.

5.1 Model Development and Experimental Setup

In the (linear) block-DCT domain, $\mathbf{y}$, we use the method introduced by Robinson and Kecman (2003) (RKi-1), in which the SVR is trained to learn a fixed (low-pass) number of DCT coefficients (those with frequency bigger than 20 cycl/deg are discarded); and the method proposed by Gómez-Pérez et al. (2005) (CSF-SVR), in which the relevance of all DCT coefficients is weighted according to the CSF criterion using an appropriately modulated ε_f. In the non-linear domain, $\mathbf{r}$, we use the SVR with constant insensitivity parameter ε (NL-SVR). In all cases, the block-size is 16×16, that is, $\mathbf{y}, \mathbf{r} \in \mathbb{R}^{256}$. The behavior of JPEG standard is also included in the experiments for comparison purposes.

As stated in Section 1, we used the RBF kernel and arbitrarily large penalization parameter in every SVR case. In all experiments, we trained the SVR models without the bias term, and modelled the absolute value of the DCT, $\mathbf{y}$, or response coefficients, $\mathbf{r}$. All the remaining free parameters (ε-insensitivity and Gaussian width of the RBF kernel σ) were optimized for all the considered models and different compression ratios. In the NL-SVM case, the parameters of the divisive normalization used in the experiments are shown in Figure 4. After training, the signal is described by the uniformly quantized Lagrange multipliers of the support vectors needed to keep the regression error below the thresholds ε_f. The last step is entropy coding of the quantized weights. The compression ratio is controlled by a factor applied to the thresholds, ε_f.

5.2 Model Comparison

In order to assess the quality of the coded images, three different measures were used: the standard (Euclidean) RMSE, the Maximum Perceptual Error (MPE) (Malo et al., 2000; Gómez-Pérez et al., 2005; Malo et al., 2006) and the also perceptually meaningful Structural SIMilarity (SSIM) index (Wang et al., 2004). Eight standard 256×256 monochrome 8 bits/pix images were used in the experiments. Average rate-distortion curves are plotted in Figure 5 in the range [0.05, 0.6] bits/pix (bpp). According to these entropy-per-sample data, original file size was 64 KBytes in every case, while the compressed image sizes were in the range [0.4, 4.8] KBytes. This implies that the compression ratios were in the range [160:1, 13:1].

In general, a clear gain over standard JPEG is obtained by all SVM-based methods. According to the standard Euclidean MSE point of view, the performance of RKi-1 and CSF-SVR algorithms is basically the same (note the overlapped curves in Figure 5(a)). However, it is widely known that the MSE results are not useful to represent the subjective quality of images, as extensively reported elsewhere (Girod, 1993; Teo and Heeger, 1994; Watson and Malo, 2002). When using more appropriate (perceptually meaningful) quality measures (Figures 5(b)-(c)), the CSF-SVR obtains a certain advantage over the RKi-1 algorithm for all compression rates, which was already reported by Gómez-Pérez et al. (2005). In all measures, and for the whole considered entropy range, the proposed NL-SVR clearly outperforms all previously reported methods, obtaining a noticeable gain at medium-to-high compression ratios (between 0.1 bpp (80:1) and 0.3 bpp (27:1)). Taking into account that the recommended bit rate for JPEG is about 0.5 bpp, from Figure 5 we can also conclude that the proposed technique achieves the similar quality levels at a lower bit rate in the range [0.15, 0.3] bpp.

Figure 6 shows representative visual results of the considered SVM strategies on standard images (Lena and Barbara) at the same bit rate (0.3 bpp, 27:1 compression ratio or 2.4 KBytes in 256×256 images). The visual inspection confirms that the *numerical* gain in MPE and SSIM shown in Figure 5 is also *perceptually significant*. Some conclusions can be extracted from this figure. First, as previously reported by Gómez-Pérez et al. (2005), RKi-1 leads to poorer (blocky) results because of the crude approximation of the CSF (as an ideal low-pass filter) and the equal relevance applied to the low-frequency DCT-coefficients. Second, despite the good performance yielded by the CSF-SVR approach to avoid blocking effects, it is worth noting that high frequency details are smoothed (e.g., see Barbara's scarf). These effects are highly alleviated by introducing SVR in the non-linear domain. See, for instance, Lena's eyes, her hat's feathers or the better reproduction of the high frequency pattern in Barbara's clothes.

Figure 7 shows the results obtained by all considered methods at a very high compression ratio for the Barbara image (0.05 bpp, 160:1 compression ratio or 0.4 KBytes in 256×256 images). This experiment is just intended to show the limits of methods performance since it is out of the recommended rate ranges. Even though this scenario is unrealistic, differences among methods are still noticeable: the proposed NL-SVR method reduces the blocky effects (note for instance that the face is better reproduced). This is due to a better distribution of support vectors in the perceptually independent domain.

5.3 Support Vector Distribution

The observed different perceptual image quality obtained with each approach is a direct consequence of support vector distribution in different domains. Figure 8 shows a representative example

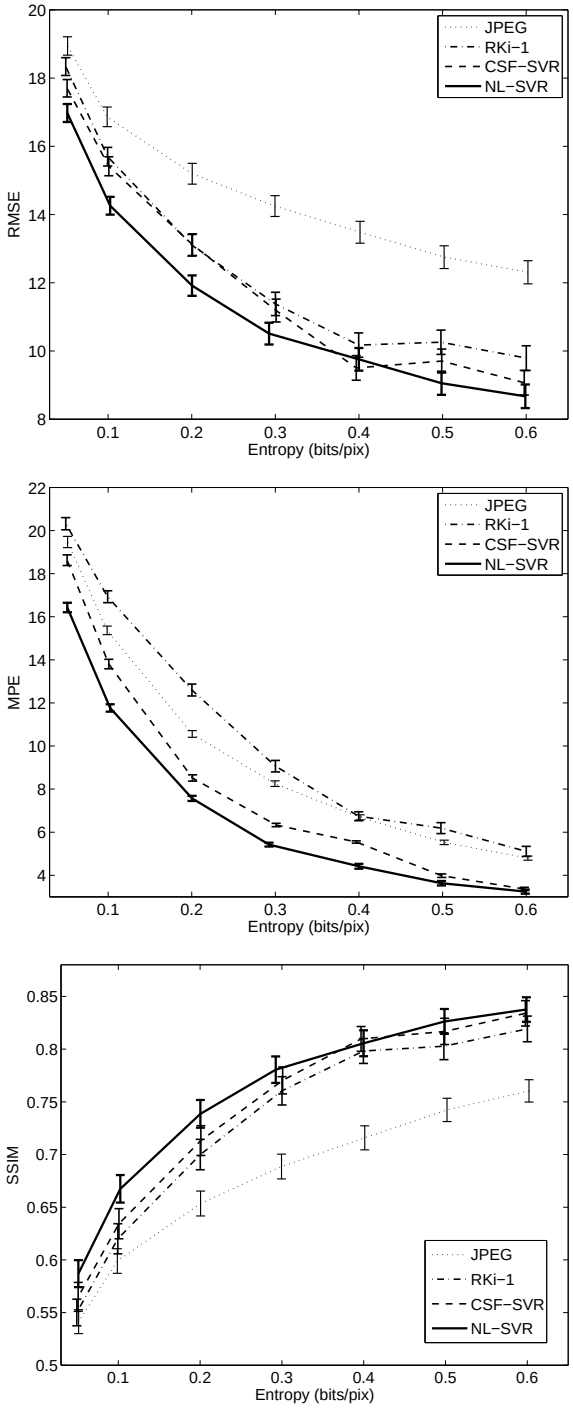

Figure 5: Average rate distortion curves over eight standard images (Lena, Barbara, Boats, Einstein, Peppers, Mandrill, Goldhill, Camera man) using objective and subjective measures for the considered JPEG (dotted) and the SVM approaches (RKi-1 dash-dotted, CSF-SVR dashed and NL-SVR solid). RMSE distortion (top), Maximum Perceptual Error, MPE (middle) (Malo et al., 2000; Gómez-Pérez et al., 2005; Malo et al., 2006), and Structural SIMilarity index, SSIM (bottom) (Wang et al., 2004).

Figure 6: Examples of decoded Lena (left) and Barbara (right) images at 0.3 bits/pix. From top to bottom: JPEG, RKi-1, CSF-SVR, and NL-SVR.

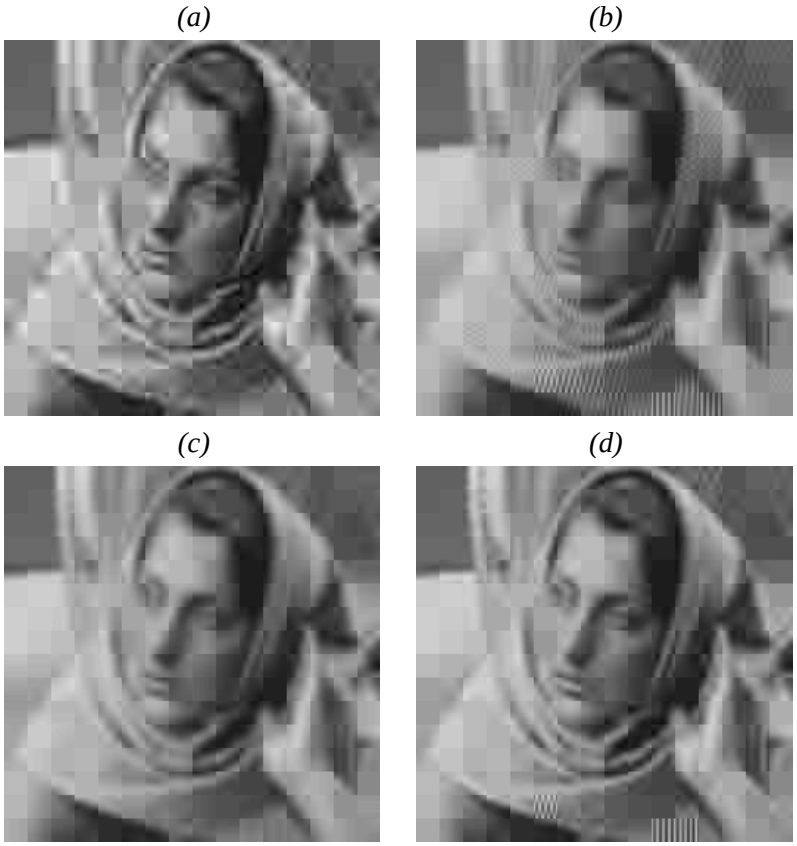

Figure 7: Examples of decoded Barbara images at a high compression ratio of 0.05 bits/pix (160:1) for (a) JPEG, (b) RKi-1, (c) CSF-SVR, and (d) NL-SVR.

of the distribution of the selected support vectors by the RKi-1 and the CSF-SVR models working in the linear DCT domain, and the NL-SVM working in the perceptually independent non-linear domain $\mathbf{r}$. Specifically, a block of Barbara's scarf at different compression ratios is used for illustration purposes.

The RKi-1 approach (Robinson and Kecman, 2003) uses a constant ε but, in order to consider the low subjective relevance of the high-frequency region, the corresponding coefficients are neglected. As a result, this approach only allocates support vectors in the low/medium frequency regions. The CSF-SVR approach uses a variable ε according to the CSF and gives rise to a more natural concentration of support vectors in the low/medium frequency region, which captures medium to high frequency details at lower compression rates (0.5 bits/pix). Note that the number of support vectors is bigger than in the RKi-1 approach, but it selects some necessary high-frequency coefficients to keep the error below the selected threshold. However, for bigger compression ratios (0.3 bits/pix), it misrepresents some high frequency, yet relevant, features (e.g., the peak from the stripes). The NL-SVM approach works in the non-linear transform domain, in which a more uniform coverage

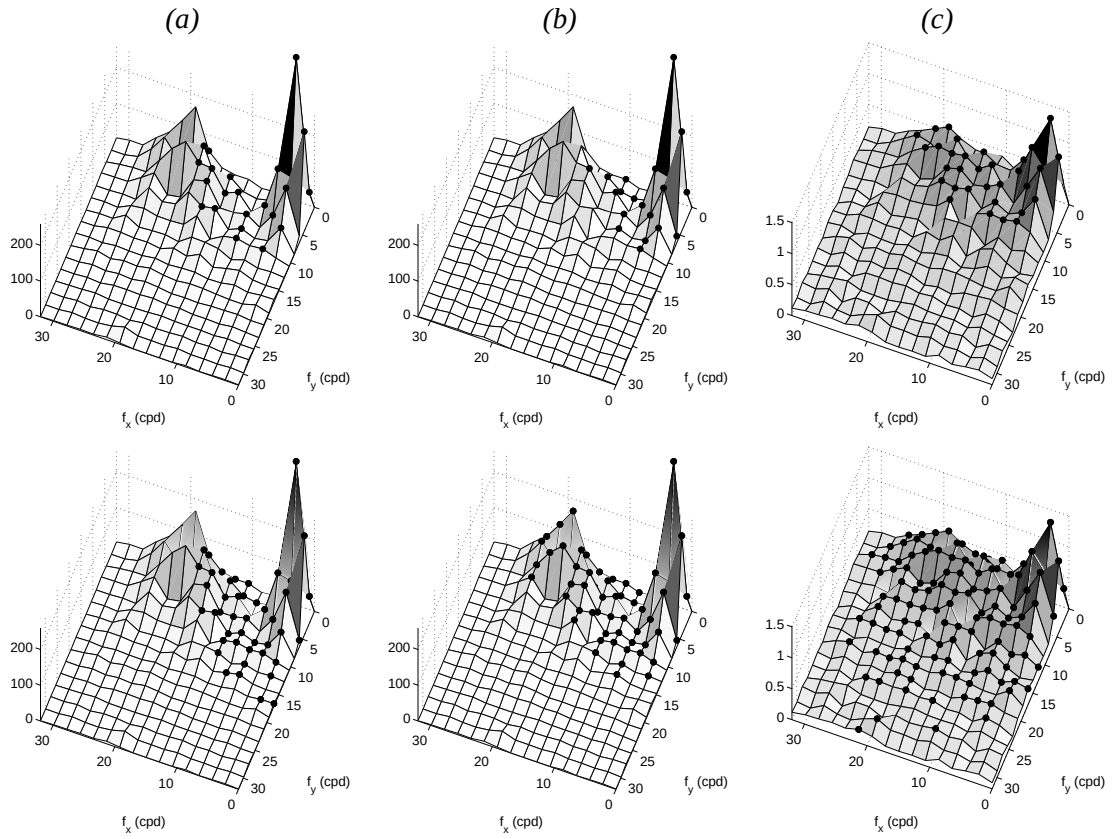

Figure 8: Signal in different domains and the selected support vectors by the SVM models in a block of the Barbara image at 0.3 bits/pix (top row) and 0.5 bits/pix (bottom row). Different domains are analyzed: (a) linear DCT using RKi-1, (b) linear DCT with CSF-SVM, and (c) non-linear perceptual domain with standard ε-SVM (NL-SVR).

of the domain is done, accounting for richer (and perceptually independent) coefficients to perform efficient sparse signal reconstruction.

It is important to remark that, for a given method (or domain), tightening ε_f implies (1) considering more support vectors, and (2) an increase in entropy (top and bottom rows in Figure 8, 0.3 bpp to 0.5 bpp). However, note that the relevant measure is the entropy and not the number of support vectors: even though the number of selected support vectors in the **r** domain is higher, their variance is lower, thus giving rise to the same entropy after entropy coding.

6. Conclusions

In this paper, we have reported a condition on the suitable domain for developing efficient SVM image coding schemes. The so-called *diagonal Jacobian condition* states that SVM regression with scalar-wise error restriction in a particular domain makes sense only if the transform that maps this domain to an independent coefficient representation is locally diagonal. We have demonstrated that,

in general, linear domains do not fulfill this condition because non-trivial statistical and perceptual inter-coefficient relations do exist in these domains.

This theoretical finding has been experimentally confirmed by observing that improved compression results are obtained when SVM is applied in a non-linear perceptual domain that starts from the same linear domain used by previously reported SVM-based image coding schemes. These results highlight the relevance of an appropriate image representation choice before SVM learning.

Further work is tied to the use of SVM-based coding schemes in statistically, rather than perceptually, independent non-linear ICA domains. In order to do so, local PCA instead of local ICA may be used in the local-to-global differential approach (Malo and Gutiérrez, 2006) to speed up the non-linear computation.

Abstract

The max-sum classifier predicts *n*-tuple of labels from *n*-tuple of observable variables by maximizing a sum of quality functions defined over neighbouring pairs of labels and observable variables. Predicting labels as MAP assignments of a Random Markov Field is a particular example of the max-sum classifier. Learning parameters of the max-sum classifier is a challenging problem because even computing the response of such classifier is NP-complete in general. Estimating parameters using the Maximum Likelihood approach is feasible only for a subclass of max-sum classifiers with an acyclic structure of neighbouring pairs. Recently, the discriminative methods represented by the perceptron and the Support Vector Machines, originally designed for binary linear classifiers, have been extended for learning some subclasses of the max-sum classifier. Besides the max-sum classifiers with the acyclic neighbouring structure, it has been shown that the discriminative learning is possible even with arbitrary neighbouring structure provided the quality functions fulfill some additional constraints. In this article, we extend the discriminative approach to other three classes of max-sum classifiers with an arbitrary neighbourhood structure. We derive learning algorithms for two subclasses of max-sum classifiers whose response can be computed in polynomial time: (i) the max-sum classifiers with supermodular quality functions and (ii) the max-sum classifiers whose response can be computed exactly by a linear programming relaxation. Moreover, we show that the learning problem can be approximately solved even for a general max-sum classifier.

Keywords: max-xum classifier, hidden Markov networks, support vector machines

1. Introduction

Let $(\mathcal{T},\mathcal{E})$ be an undirected graph, where $\mathcal{T}$ is a finite *set of objects* and $\mathcal{E} \subseteq \binom{\mathcal{T}}{2}$ is a set of object pairs defining *a neighborhood structure*. A pair $\{t,t'\}$ of objects belonging to $\mathcal{E}$ will be called *neighbors* or *neighboring objects*. Let each object $t \in \mathcal{T}$ be characterized by an observation x_t and a label y_t which take values from a finite set $\mathcal{X}$ and $\mathcal{Y}$, respectively. We denote an ordered $|\mathcal{T}|$-tuple of observations by $\mathbf{x} = (x_t \in \mathcal{X} \mid t \in \mathcal{T})$ and an ordered $|\mathcal{T}|$-tuple of labels by $\mathbf{y} = (y_t \in \mathcal{Y} \mid t \in \mathcal{T})$. Each object $t \in \mathcal{T}$ is assigned a function $q_t \colon \mathcal{Y} \times \mathcal{X} \to \mathbb{R}$ which determines a *quality* of a label y_t given an observation x_t. Each object pair $\{t,t'\} \in \mathcal{E}$ is assigned a function $g_{tt'} \colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$

∗. Secondary address for the first author is Center for Machine Perception, Czech Technical University, Faculty of Electrical Engineering, Technicka 2, 166 27 Prague 6, Czech Republic.

which determines the *quality* of labels y_t and $y_{t'}$. We adopt the convention $g_{tt'}(y,y') = g_{t't}(y',y)$. Let $\mathbf{q} \in \mathbb{R}^{|\mathcal{T}||\mathcal{X}||\mathcal{Y}|}$ and $\mathbf{g} \in \mathbb{R}^{|\mathcal{E}||\mathcal{Y}|^2}$ be ordered tuples which contain elements $q_t(y,x)$, $t \in \mathcal{T}$, $x \in \mathcal{X}$, $y \in \mathcal{Y}$ and $g_{tt'}(y,y')$, $\{t,t'\} \in \mathcal{E}$, $y,y' \in \mathcal{Y}$, respectively. We consider a class of *structured classifiers* $f\colon \mathcal{X}^{\mathcal{T}} \to \mathcal{Y}^{\mathcal{T}}$ parametrized by $(\mathbf{q},\mathbf{g})$ that predict labeling $\mathbf{y}$ from observations $\mathbf{x}$ by selecting the labeling with the maximal quality, that is,

$$f(\mathbf{x};\mathbf{q},\mathbf{g}) = \operatorname*{argmax}_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g}) = \operatorname*{argmax}_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} \left[\sum_{t\in\mathcal{T}} q_t(y_t,x_t) + \sum_{\{t,t'\}\in\mathcal{E}} g_{tt'}(y_t,y_{t'}) \right]. \tag{1}$$

We will call the classification rule of the form (1) a *max-sum classifier*. The problem of computing the output of the max-sum classifier, that is, the evaluation of the right-hand side of (1) is called the *max-sum labeling problem* or shortly the *max-sum problem* (it is also known as the weighted constraint satisfaction problem). The max-sum problem is known to be NP-complete in general. We will use the six-tuple $(\mathcal{T},\mathcal{E},\mathcal{Y},\mathbf{q},\mathbf{g},\mathbf{x})$ to denote a max-sum problem instance which must be solved to classify $\mathbf{x}$.

This article deals with a problem of learning the parameters $(\mathbf{q},\mathbf{g})$ of a max-sum classifier from a finite training set $\mathcal{L} = \left\{(\mathbf{x}^j,\mathbf{y}^j) \in \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \mid j \in \{1,\dots,m\}\right\}$. Henceforth we will use the shortcut $\mathcal{J} = \{1,\dots,m\}$.

A typical example of a max-sum classifier is the maximum aposteriori (MAP) estimation in Markov models. In this case, the observations $\mathbf{x}$ and the labels $\mathbf{y}$ are assumed to be realizations of random variables $\mathbf{X} = (X_t \mid t \in \mathcal{T})$ and $\mathbf{Y} = (Y_t \mid t \in \mathcal{T})$. It is assumed that only the pairs of variables (X_t,Y_t), $t \in \mathcal{T}$ and $(Y_t,Y_{t'})$, $\{t,t'\} \in \mathcal{E}$ are directly statistically dependent. Then the joint probability of $\mathbf{X}$ and $\mathbf{Y}$ is given by the Gibbs distribution

$$P(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g}) = \frac{1}{Z} \exp F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g}), \tag{2}$$

where Z is the *partition function* which normalizes the distribution. The optimal Bayesian classifier which minimizes the probability of misclassification $f(\mathbf{x}) \neq \mathbf{y}$ assigns labels according to $\mathbf{y}^* = \operatorname{argmax}_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} P(\mathbf{y}\,|\,\mathbf{x})$. It is easy to see that the classifier (1) coincides with the optimal one which minimizes the misclassifications.

Applications of the classifier (1) are image de-noising (Besag, 1986), image labeling (Chou and Brown, 1990) stereo matching (Boykov et al., 2001), natural language processing (Collins, 2002), 3D image segmentation (Anguelov et al., 2005), etc.

1.1 Existing Approaches to Learning Max-Sum Classifiers

A *generative approach* to learning a max-sum classifier is based on an estimation of parameters $(\mathbf{q},\mathbf{g})$ of the Gibbs distribution (2). Having the distribution estimated, a classifier minimizing an expected risk (Bayesian risk) for a given loss function can be inferred using the Bayesian decision making framework. Maximum-Likelihood (ML) estimation methods are well known for Markov models with an acyclic graph $(\mathcal{T},\mathcal{E})$ (see, for example, Schlesinger and Hlaváč, 2002). In the general case, however, the ML estimation is not tractable because no polynomial time algorithm is known for computing a partition function exactly. Approximate methods to compute the partition function are based on a Gibbs sampler (Hinton and Sejnowski, 1986; Jerrum and Sinclair, 1993). Another disadvantage of the generative approach is the fact that little is known about an expected risk of the classifiers inferred from an imprecisely estimated statistical model.

A *discriminative approach* is an alternative method which does not require explicit modeling of the underlying probability distribution. It is based on a direct optimization of classifier parameters $(\mathbf{q},\mathbf{g})$ in order to minimize an error estimate of a classifier performance computed on a finite training set. It is easy to see that the score function $F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g})$ of the max-sum classifier (1) is linear in its parameters $(\mathbf{q},\mathbf{g})$ which allows to exploit methods for learning linear classifiers. In the case of a consistent training set, that is, if there exists a classifier with zero empirical error, the problem of learning a linear classifier can be expressed as a problem of satisfying a set of linear inequalities. This problem is efficiently solvable by the perceptron algorithm. Variants of the perceptron algorithm for learning parameters of the max-sum classifier (1) with a chain and tree neighborhood structure were published in Schlesinger and Hlaváč (2002) and Collins (2002). These algorithms exploit the fact that a perceptron can be used whenever the response of the learned classifier can be computed efficiently. This applies for the acyclic neighbourhood structure since the response of the max-sum classifier can be computed by the *dynamic programming* (DP).

The *Support Vector Machines* (SVM) (Vapnik, 1998) are another representative of a discriminative approach for learning linear classifiers which has proved to be successful in numerous applications. Unlike the perceptron algorithm, the SVMs allows learning also from an inconsistent training set. Learning is formulated as minimization of a regularized risk functional which can be further transformed to a convex quadratic programming (QP) task suitable for optimization. The original SVMs are designed for learning the classifiers which estimate a single label. In the recent years, the SVMs have been extended for learning linear classifiers which can estimate a set of interdependent labels. In particular, the Hidden Markov Support Vector Machines (Altun and Hofmann, 2003; Altun et al., 2003) and the Max-Margin Markov Networks (Taskar et al., 2004b) were proposed for learning max-sum classifiers with an acyclic neighboring structure. In this case, learning requires solving a QP task with a huge number of linear constraints proportional to the cardinality of the output space of the classifier. In analogy to the perceptron, this task is tractable if there exists an efficient algorithm that solves the *loss-augmented classification* (LAC) task which involves optimizing (1) with the loss function added to the objective function $F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g})$ (c.f. Section 3.2 for details). For additively decomposable loss functions, the LAC task becomes an instance of the max-sum problem easily solvable by the DP provided the neighbourhood structure is acyclic.

Learning of the Associative Markov Networks (AMN) with an arbitrary neighbourhood structure $\mathcal{E}$ was proposed by Taskar et al. (2004a). The AMN is the max-sum classifier with the quality functions $\mathbf{g}$ restricted in a way similar to the Potts model. The LAC task was approximated by a linear programming (LP) relaxation specially derived for the AMN model. Incorporating an LP relaxation into the SVM QP task, Taskar et al. (2004a) constructed a new compact QP task which has only a polynomial number of constraints. Even though the resulting QP task is polynomially solvable, general purpose QP solvers do not provide a practical solution since they scale poorly with the problem and training set size. Recently, Taskar et al. (2006) proposed a reformulation of the structured learning problem as a convex-concave saddle-point problem which is efficiently solvable by the dual extragradient algorithm. This new framework is applicable for structured classifiers for which a certain projection step can be solved. Taskar et al. (2006) showed that the projection step is tractable for the max-sum classifiers with supermodular functions $\mathbf{g}$ and binary labels $|\mathcal{Y}| = 2$.

Tsochantaridis et al. (2005) proposed a general framework for learning linear classifiers with an interdependent labels. Their approach is based on solving the underlying SVM QP task by a cutting plane algorithm which requires as a subroutine an algorithm solving the LAC task for the particular classifier. The approach cannot be directly applied for the general max-sum classifiers since the

LAC task is not tractable. An alternative approach to the cutting plane algorithm was proposed by Ratliff and Bagnell (2006) who used subgradient methods for optimizing the SVM QP task. This approach also relies on an efficient solution to the LAC task.

An approximated cutting plane algorithm was proposed in Finley and Joachims (2005) to learn a specific structured model for correlation clustering. The inference as well as the corresponding LAC task of this clustering model are NP-complete. The authors suggested to replace an exact solution of the LAC task required in the cutting plane algorithm by its polynomially solvable LP relaxation.

1.2 Contributions

In this article, we build on the previously published approaches which use the perceptron and the SVMs for learning the max-sum classifiers. We propose learning algorithms for three classes of max-sum classifiers for which, up to our knowledge, the discriminative approaches have not been applied yet. Namely, the contributions of the article are as follows:

- We formulate and solve the problem of learning the supermodular max-sum classifier with an arbitrary neighbourhood structure $\mathcal{E}$ and without any restriction on the number of labels $|\mathcal{Y}|$ (Taskar et al., 2006, consider only two labels). We propose a variant of the perceptron algorithm for learning from a consistent training set. For an inconsistent training set, we extend the cutting plane algorithm of Tsochantaridis et al. (2005) such that it maintains the quality functions $\mathbf{g}$ supermodular during the course of the algorithm thus making the LAC task efficiently solvable.

- We formulate and solve the problem of learning the *max-sum classifier with a strictly trivial equivalent* which is a subclass of *max-sum classifiers with a trivial equivalent*. We will show in Section 2 that the latter class can be equivalently characterized by the fact that the LP relaxation (Schlesinger, 1976; Koster et al., 1998; Chekuri et al., 2001; Wainwright et al., 2002) is tight for it. It is known, that the class of problems with a trivial equivalent contains acyclic problems (Schlesinger, 1976) and supermodular problems (Schlesinger and Flach, 2000). We will extend this result to show that problems with a strictly trivial equivalent which we can learn contain the acyclic and the supermodular max-sum problems with a unique solution.

  Learning of the max-sum classifiers with a strictly trivial equivalent leads to an optimization problem with a polynomial number of linear constraints. We propose variants of the perceptron and of the cutting plane algorithm for learning from a consistent and an inconsistent training set, respectively. In this case, the LAC task does not require any specialized max-sum solver since it can be solved exhaustively. Moreover, the QP task to which we transform the learning problem is of the same form as the QP task required for ordinary multi-class SVMs (Crammer and Singer, 2001) which allows using existing optimization packages.

- We formulate the problem of learning the general max-sum classifier, that is, without any restriction on the neighborhood structure $\mathcal{E}$ and the quality functions $\mathbf{g}$. We show that the learning problem can be solved approximately by a variant of the cutting plane algorithm proposed by Finley and Joachims (2005) which uses the LP relaxation to solve the LAC task approximately. In contrast to Taskar et al. (2004a), we do not incorporate the LP relaxation

to the SVM QP task but we keep it separately which allows to exploit existing solvers for LP relaxation of the max-sum problem.

For a simplicity, we will concentrate on the max-sum classifier (1). All the proposed methods, however, are applicable whenever the set of labels $\mathcal{Y}$ is finite and the quality functions are linear in parameters, that is, they are of the form $q_t(x_t,y_t) = \langle \mathbf{w}, \Psi_t(x_t,y_t)\rangle$ and $g_{tt'}(y_t,y_t) = \langle \mathbf{w}, \Psi_{tt'}(y_t,y_{t'})\rangle$ where $\mathbf{w} \in \mathbb{R}^d$ is a parameter vector and $\Psi_t \colon \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$, $\Psi_{tt'} \colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^d$ are arbitrary fixed mappings. Furthermore, all the proposed algorithms can be introduced in the form containing only dot products between $\Psi_t(x,y)$ and $\Psi_{tt'}(y,y')$ which allows to use the kernel functions (Vapnik, 1998).

1.3 Structure of the Article

The article is organized as follows. In Section 2, we describe three classes of the max-sum classifiers for which we will later derive learning algorithms. Perceptron algorithm and the SVM framework for learning linear classifiers with an interdependent labels is reviewed in Section 3. In Section 4, we formulate problems of learning the max-sum classifiers from a consistent training set and we propose variants of the perceptron algorithm for their solution. In Section 5, we formulate problems of learning the max-sum classifiers from inconsistent training set using the SVM framework. In Section 6, we propose an extended cutting plane algorithm to solve the learning problem defined in Section 5. Section 7 describes experiments. Finally, in Section 8 we give conclusions.

2. Classes of Max-Sum Problems

In the rest of the article, we consider the max-sum problems $P = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x})$ in which $(\mathcal{T}, \mathcal{E})$ is an arbitrary undirected connected graph and $\mathbf{q}$ are arbitrary quality functions. The three classes of the max-sum problems described below differ in the structure of the finite set of labels $\mathcal{Y}$ and the quality functions $\mathbf{g}$.

2.1 General Max-Sum Problem and LP Relaxation

The first class which we consider is the general max-sum problem with no restrictions imposed on $\mathcal{Y}$ and $\mathbf{g}$. Solving (1) when P is a general max-sum problem is known to be NP-complete. An approximate solution can be found by the linear programming (LP) relaxation proposed independently by Schlesinger (1976), Koster et al. (1998), Chekuri et al. (2001), and Wainwright et al. (2002). We introduce only the basic concepts of the LP relaxation necessary for this article. For more details on the topic we refer to the mentioned publications or to a comprehensive survey in Werner (2007) from which we adopted notation and terminology.

Let $(\mathcal{T} \times \mathcal{Y}, \mathcal{E}_{\mathcal{Y}})$ denote an undirected graph with edges $\mathcal{E}_{\mathcal{Y}} = \{\{(t,y),(t',y')\} \mid \{t,t'\} \in \mathcal{E}, y,y' \in \mathcal{Y}\}$. This graph corresponds to the *trellis diagram* used to visualize Markov chains. Each *node* $(t,y) \in \mathcal{T} \times \mathcal{Y}$ and each *edge* $\{(t,y),(t',y')\} \in \mathcal{E}_{\mathcal{Y}}$ is assigned the numbers $\beta_t(y)$ and $\beta_{tt'}(y,y')$, respectively. Let $\boldsymbol{\beta} \in \mathbb{R}^{|\mathcal{T}||\mathcal{Y}|+|\mathcal{E}||\mathcal{Y}|^2}$ be an ordered tuple which contains elements $\beta_t(y)$, $(t,y) \in \mathcal{T} \times \mathcal{Y}$ and $\beta_{tt'}(y,y')$, $\{(t,y),(t',y')\} \in \mathcal{E}_{\mathcal{Y}}$. Let Λ_P denote a set of *relaxed labelings* which contains vectors $\boldsymbol{\beta}$ satisfying

$$\sum_{y' \in \mathcal{Y}} \beta_{tt'}(y,y') = \beta_t(y)\,, \;\; \{t,t'\} \in \mathcal{E}\,, y \in \mathcal{Y}\,, \qquad \sum_{y \in \mathcal{Y}} \beta_t(y) = 1\,, \;\; t \in \mathcal{T}\,, \qquad \boldsymbol{\beta} \geq \mathbf{0}\,.$$

The LP relaxation of (1) reads

$$\boldsymbol{\beta}^* = \operatorname*{argmax}_{\boldsymbol{\beta}\in\Lambda_P} \left[\sum_{t\in\mathcal{T}} \sum_{y\in\mathcal{Y}} \beta_t(y) q_t(y,x_t) + \sum_{(t,t')\in\mathcal{E}} \sum_{(y,y')\in\mathcal{Y}^2} \beta_{tt'}(y,y') g_{tt'}(y,y') \right]. \tag{3}$$

It can be seen that solving (3) with an additional constraint $\boldsymbol{\beta} \in \{0,1\}^{\mathcal{T}}$ is an integer programming problem equivalent to (1). Further, we will introduce concepts of *equivalent problems*, *equivalent transformations* and *trivial problems* which are tightly connected to the LP relaxation.

A representation of the max-sum problem $P = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x})$ is not minimal since there exists an infinite number of equivalent max-sum problems $P' = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}', \mathbf{g}', \mathbf{x})$ with different quality functions $(\mathbf{q}', \mathbf{g}')$ but the same quality for all labelings: the max-sum problems P and P' are called *equivalent* if $F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g}) = F(\mathbf{x},\mathbf{y};\mathbf{q}',\mathbf{g}')$ for all $\mathbf{y} \in \mathcal{Y}^{\mathcal{T}}$ (Schlesinger, 1976; Wainwright et al., 2002).

Next, we introduce a transformation of a max-sum problem to its arbitrary equivalent. These *equivalent transformations* are originally due to Schlesinger (1976) and recently are also known as *reparametrization* in Wainwright et al. (2002) and Kolmogorov (2006). Let $\varphi_{tt'} \colon \mathcal{Y} \to \mathbb{R}$ and $\varphi_{t't} \colon \mathcal{Y} \to \mathbb{R}$ be a pair of functions introduced for each pair of neighbouring objects $\{t,t'\} \in \mathcal{E}$, that is, we have $2|\mathcal{E}|$ functions in total. The value $\varphi_{tt'}(y)$ is called *potential* at label y of an object t in the direction t'. Note that the potentials correspond to messages in belief propagation (see, for example, Pearl, 1988; Yedidia et al., 2005). We will use $\boldsymbol{\varphi} \in \mathbb{R}^{2|\mathcal{E}||\mathcal{Y}|}$ to denote an ordered tuple which contains elements $\varphi_{tt'}(y)$, $\{t,t'\} \in \mathcal{E}$, $y \in \mathcal{Y}$ and $\varphi_{t't}(y')$, $\{t,t'\} \in \mathcal{E}$, $y' \in \mathcal{Y}$. Let $\mathcal{N}(t) = \{t' \in \mathcal{T} \mid \{t,t'\} \in \mathcal{E}\}$ denote the set of objects neighbouring with the object $t \in \mathcal{T}$. Finally, let $P^{\boldsymbol{\varphi}} = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}^{\boldsymbol{\varphi}}, \mathbf{g}^{\boldsymbol{\varphi}}, \mathbf{x})$ denote the max-sum problem constructed from the max-sum problem $P = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x})$ by the following transformation

$$g^{\boldsymbol{\varphi}}_{tt'}(y,y') = g_{tt'}(y,y') + \varphi_{tt'}(y) + \varphi_{t't}(y'), \quad \{t,t'\} \in \mathcal{E}, y, y' \in \mathcal{Y}, \tag{4a}$$

$$q^{\boldsymbol{\varphi}}_{t}(y,x_t) = q_t(y,x_t) - \sum_{t'\in\mathcal{N}(t)} \varphi_{tt'}(y), \quad t \in \mathcal{T}, y \in \mathcal{Y}. \tag{4b}$$

By substituting (4) to $F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g}) = F(\mathbf{x},\mathbf{y};\mathbf{q}',\mathbf{g}')$ it is easy to show that the problems P and $P^{\boldsymbol{\varphi}}$ are equivalent for arbitrary potentials $\boldsymbol{\varphi}$. Moreover, it has been shown (Schlesinger, 1976; Kolmogorov, 2006) that the converse is also true, that is, if any two max-sum problems are equivalent then they are related by (4) for some potentials $\boldsymbol{\varphi}$.

Now, we can define the class of *trivial max-sum problems*. Node (t,y) is called *maximal* if $q_t(y,x_t) = \max_{y\in\mathcal{Y}} q_t(y,x_t)$ and edge $\{(t,y),(t',y')\}$ is called maximal if $g_{tt'}(y,y') = \max_{y,y'\in\mathcal{Y}} g_{tt'}(y,y')$. The max-sum problem P is called *trivial* if there exists a labeling $\mathbf{y}$ which can be formed only from the maximal nodes and edges. Checking whether a given P is trivial leads to an instance of a *constraint satisfaction problem* CSP (also called *consistent labeling problem*) (Rosenfeld et al., 1976; Haralick and Shapiro, 1979). The CSP is NP-complete in general and it is equivalent to solving a max-sum problem when the quality functions $(\mathbf{q},\mathbf{g})$ take only two values $\{-\infty, 0\}$. Let $U(\mathbf{x};\mathbf{q},\mathbf{g})$ be a *height* (also called *energy*) of the max-sum problem P defined as a sum of qualities of the maximal nodes and the maximal edges, that is,

$$U(\mathbf{x};\mathbf{q},\mathbf{g}) = \sum_{t\in\mathcal{T}} \max_{y\in\mathcal{Y}} q_t(y,x_t) + \sum_{\{t,t'\}\in\mathcal{E}} \max_{y,y'\in\mathcal{Y}} g_{tt'}(y,y'). \tag{5}$$

Comparing (1) and (5) shows that $U(\mathbf{x};\mathbf{q},\mathbf{g})$ is an upper bound on the quality of the optimal labeling, that is, $U(\mathbf{x};\mathbf{q},\mathbf{g}) \geq \max_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g})$. It is easy to see that the upper bound is tight if and only if the max-sum problem is trivial. The following result is central to the LP relaxation:

Theorem 1 *Schlesinger (1976); Werner (2005) Let $\mathcal{C}$ be a class of equivalent max-sum problems. Let C contain at least one trivial problem. Then any problem in C is trivial if and only if it has minimal height.*

This suggests to solve the max-sum problem P by searching for an equivalent $P^{\boldsymbol{\varphi}}$ with the minimal height, which leads to

$$\boldsymbol{\varphi}^* = \operatorname*{argmin}_{\boldsymbol{\varphi}} U(\mathbf{x}; \mathbf{q}^{\boldsymbol{\varphi}}, \mathbf{g}^{\boldsymbol{\varphi}}) \,. \tag{6}$$

The problem (6) can be expressed as an LP task which is known to be a *dual to the LP relaxation* (3). Having $\boldsymbol{\varphi}^*$ one can try to verify whether $P^{\boldsymbol{\varphi}^*}$ is trivial, that is, whether there exists a labeling composed of the maximal nodes and edges of $P^{\boldsymbol{\varphi}^*}$. If such labeling is found then it is the optimal solution of the max-sum problem P. Otherwise, one can use heuristics to find an approximate solution by searching for such labeling which contains as much maximal nodes and edges as possible.

Though (6) is solvable in polynomial time, a general purpose LP solvers are applicable only for small instances. A specialized solvers for LP relaxation were published in Koval and Schlesinger (1976). Recently, Wainwright et al. (2002) and Kolmogorov (2006) proposed a tree-reweighted algorithm based on minimizing a more general upper bound composed of trees spanning the graph $(\mathcal{T}, \mathcal{E})$ of which (5) is a special case.

We propose a learning algorithm for a general max-sum classifier which requires an arbitrary LP relaxation solver as a subroutine. We only require that the LP solver returns an approximate solution $\hat{\mathbf{y}}$ and an upper bound on $\max_{\mathbf{y} \in \mathcal{Y}^{\mathcal{T}}} F(\mathbf{x}, \mathbf{y}; \mathbf{q}, \mathbf{g})$.

2.2 Supermodular Max-Sum Problems

Definition 1 *A function $g_{tt'} : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ is* supermodular *if*

1. *The set of labels $\mathcal{Y}$ is totally ordered; w.l.o.g. we consider $\mathcal{Y} = \{1, 2, \ldots, |\mathcal{Y}|\}$ endowed with the natural order.*
2. *For each four-tuple $(y_t, y'_t, y_{t'}, y'_{t'}) \in \mathcal{Y}^4$ of labels such that $y_t > y'_t$ and $y_{t'} > y'_{t'}$ the following inequality holds:*

$$g_{tt'}(y_t, y_{t'}) + g_{tt'}(y'_t, y'_{t'}) \geq g_{tt'}(y_t, y'_{t'}) + g_{tt'}(y'_t, y_{t'}). \tag{7}$$

A max-sum problem in which the label set $\mathcal{Y}$ is totally ordered and all the functions $\mathbf{g}$ are supermodular is called a *supermodular max-sum problem*. In addition, we will also consider the max-sum problem in which the inequalities (7) are fulfilled strictly. In this case the corresponding max-sum problem will be called *strictly supermodular*.

A naive approach to check whether a given max-sum problem is supermodular amounts to verifying all $|\mathcal{E}| \cdot |\mathcal{Y}|^4$ inequalities in (7). We will use a more effective way which requires to check only $|\mathcal{E}| \cdot (|\mathcal{Y}| - 1)^2$ inequalities thanks to the following well-known theorem:

Theorem 2 *The function $g_{tt'} : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ is* supermodular *if for each each pair of labels $(y, y') \in \mathcal{Y}^2$ such that $y + 1 \in \mathcal{Y}$, $y' + 1 \in \mathcal{Y}$ the following inequality holds*

$$g_{tt'}(y, y') + g_{tt'}(y + 1, y' + 1) \geq g_{tt'}(y, y' + 1) + g_{tt'}(y + 1, y'). \tag{8}$$

Proof The proof follows trivially from the equality

$$g_{tt'}(y_t,y_{t'})+g_{tt'}(y'_t,y'_{t'})-g_{tt'}(y_t,y'_{t'})-g_{tt'}(y'_t,y_{t'}) \\ = \sum_{\substack{y_t>z\geq y'_t \\ y_{t'}>z'\geq y'_{t'}}} \Big[g_{tt'}(z,z')+g_{tt'}(z+1,z'+1)-g_{tt'}(z,z'+1)-g_{tt'}(z+1,z') \Big],$$

and the fact that all the summands are non-negative by the condition (8). ■

A similar proposition holds for strictly supermodular problems: a max-sum problem is *strictly supermodular* if for each pair of neighboring objects $\{t,t'\} \in \mathcal{E}$ and for each pair of labels $(y,y') \in \mathcal{Y}^2$ such that $y+1 \in \mathcal{Y}$, $y'+1 \in \mathcal{Y}$ the following inequality holds:

$$g_{tt'}(y,y')+g_{tt'}(y+1,y'+1) > g_{tt'}(y,y'+1)+g_{tt'}(y+1,y'). \tag{9}$$

In this paper, we exploit the fact that the optimal solution of the supermodular problems can be found in a polynomial time (Schlesinger and Flach, 2000). Kolmogorov and Zabih (2002) proposed an efficient algorithm for the binary case $|\mathcal{Y}|=2$ which is based on transforming the supermodular max-sum problem to the max-flow problem from the graph theory. A not widely known extension for a general case $|\mathcal{Y}|>2$ was proposed in Kovtun (2004) and Schlesinger (2005). We will propose learning algorithms which require an arbitrary solver for the supermodular max-sum problem as a subroutine.

2.3 Max-Sum Problems with Strictly Trivial Equivalent

In this section we consider *max-sum problems with a strictly trivial equivalent* which is a subclass of *problems with a trivial equivalent* described in Section (2.1). The main reason for defining this subclass is that these problems are more suitable for learning than problems with a trivial equivalent. It was shown (Schlesinger, 1976; Schlesinger and Flach, 2000) that problems with a trivial equivalent contain two well-known polynomially solvable subclasses of max-sum problems: (i) the problems with an acyclic neighborhood structure $\mathcal{E}$ and (ii) the supermodular problems. We will give a similar result which applies for the problems with a strictly trivial equivalent. In particular, we will show that the class of problems with a strictly trivial equivalent contains all acyclic and supermodular problems which have a unique solution. This shows that learning algorithms for the max-sum classifiers with a strictly trivial equivalent introduced below are applicable for a wide range of polynomially solvable problems.

Max-sum problems with a trivial equivalent are those for which LP relaxation (6) is tight, that is, $U(\mathbf{x};\mathbf{q}^{\boldsymbol{\varphi}^*},\mathbf{g}^{\boldsymbol{\varphi}^*}) = \max_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g})$, and thus $\max_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g})$ can be computed in a polynomial time. The tight LP relaxation, however, does not imply that the optimal solution $\mathbf{y}^* = \operatorname{argmax}_{\mathbf{y}\in\mathcal{Y}^{\mathcal{T}}} F(\mathbf{x},\mathbf{y};\mathbf{q},\mathbf{g})$ can be found in a polynomial time. As we mentioned, to find $\mathbf{y}^*$ from $(\mathbf{q}^{\boldsymbol{\varphi}^*},\mathbf{g}^{\boldsymbol{\varphi}^*})$ requires searching for a labeling formed only by the maximal nodes and edges which need not be unique. Finding such labeling leads to the CSP which is NP-complete. We exploit the fact that the labeling can be found trivially if all the maximal nodes and edges are unique. As a result, the optimal solution $\mathbf{y}^*$ can be found in a polynomial time by solving the LP relaxation and finding the maximal nodes and edges.

Definition 2 *Max-sum problem P is* strictly trivial *if:*

1. *There exists a unique maximal node (t,y) for each object $t \in \mathcal{T}$.*
2. *For each maximal edge $\{(t,y),(t',y')\} \in \mathcal{E}_{\mathcal{Y}}$ the nodes (t,y) and (t',y') are maximal.*

It is clear that a strictly trivial problem has a unique solution which is composed of all maximal nodes and edges. Checking whether a given problem is strictly trivial requires only $O(|\mathcal{T}||\mathcal{Y}| + |\mathcal{E}||\mathcal{Y}|^2)$ operations, that is, finding the maximal nodes and edges and checking if they are unique and if they form a labeling.

Recall that the max-sum problem P has a *strictly trivial equivalent* if there exists a strictly trivial problem which is equivalent to P. Finally, we give a theorem which asserts that the class of problems with a strictly trivial equivalent includes at least the acyclic problems and the supermodular problems which have a unique solution.

Theorem 3 *Let $P = (\mathcal{T},\mathcal{E},\mathcal{Y},\mathbf{q},\mathbf{g},\mathbf{x})$ be a max-sum problem and let P have a unique solution. If $(\mathcal{T},\mathcal{E})$ is an acyclic graph or quality functions $\mathbf{g}$ are supermodular then P is equivalent to some strictly trivial problem.*

Proof is given in Appendix A.

3. Discriminative Approach to Learning Structured Linear Classifiers

In this section, we review the discriminative approach to learning linear classifiers which we will later apply to the max-sum classifiers.

Let $\mathbf{x} \in \boldsymbol{\mathcal{X}}$ and $\mathbf{y} \in \boldsymbol{\mathcal{Y}}$ be observations and labels generated according to some fixed unknown distribution $P(\mathbf{x},\mathbf{y})$. We are interested in designing a classifier $f\colon \boldsymbol{\mathcal{X}} \to \boldsymbol{\mathcal{Y}}$ which estimates labels from observations. Let $L\colon \boldsymbol{\mathcal{Y}} \times \boldsymbol{\mathcal{Y}} \to \mathbb{R}$ be a loss function penalizing a prediction $f(\mathbf{x})$ by a penalty $L(\mathbf{y}, f(\mathbf{x}))$ provided the true output is $\mathbf{y}$. The goal is to find a classifier which minimizes the *expected (Bayesian) risk*

$$R[f] = \int_{\boldsymbol{\mathcal{X}}\times\boldsymbol{\mathcal{Y}}} L(\mathbf{y}, f(\mathbf{x}))\, dP(\mathbf{x},\mathbf{y})\,.$$

The risk $R[f]$ cannot be directly minimized because the distribution $P(\mathbf{x},\mathbf{y})$ is unknown. Instead, we are given a finite training set $\mathcal{L} = \{(\mathbf{x}^j,\mathbf{y}^j) \in \boldsymbol{\mathcal{X}} \times \boldsymbol{\mathcal{Y}} \mid j \in \mathcal{J}\}$ i.i.d. sampled from $P(\mathbf{x},\mathbf{y})$.

The discriminative approach to learning classifiers does not require estimation of a probability distribution. It is based on direct optimization of parameters of a classifier in order to minimize a substitutional risk functional which approximates the desired risk $R[f]$ and can be computed from a finite training set. Let us consider a class of linear classifiers

$$f(\mathbf{x};\mathbf{w}) = \operatorname*{argmax}_{\mathbf{y}\in\boldsymbol{\mathcal{Y}}} \langle \mathbf{w}, \Psi(\mathbf{x},\mathbf{y})\rangle\,. \tag{10}$$

The classifier is determined by a parameter vector $\mathbf{w} \in \mathbb{R}^d$ and some fixed mapping $\Psi\colon \boldsymbol{\mathcal{X}} \times \boldsymbol{\mathcal{Y}} \to \mathbb{R}^d$. A simple proxy for $R[f(\bullet;\mathbf{w})]$ is the *empirical risk*

$$R_{\text{emp}}[f(\bullet;\mathbf{w})] = \frac{1}{m}\sum_{j\in\mathcal{J}} L(\mathbf{y}^j, f(\mathbf{x}^j;\mathbf{w}))\,.$$

Let us assume a class of loss functions which satisfy $L(\mathbf{y},\mathbf{y}')=0$ if $\mathbf{y}=\mathbf{y}'$ and $L(\mathbf{y},\mathbf{y}')>0$ if $\mathbf{y}\neq\mathbf{y}'$. Further, we will distinguish two learning scenarios: (i) learning from a *consistent training set* and (ii) learning from an *inconsistent training set*. The training set $\mathcal{L}$ is *consistent* if there exists a parameter vector $\mathbf{w}^*$ such that the empirical risk of the linear classifier is zero, that is, $R_{\text{emp}}[f(\bullet;\mathbf{w}^*)]=0$. In the opposite case, the training set is *inconsistent*.

In Section 3.1, we review the perceptron algorithm suitable for learning linear classifiers from a consistent training set. The Support Vector Machine (SVM) approach to learning from an inconsistent training set is described in Section 3.2.

3.1 Learning from a Consistent Training Set Using the Perceptron Algorithm

In the case of a consistent training set $\mathcal{L}$, the learning problem is to find parameters $\mathbf{w}^*$ of the linear classifier (10) such that the empirical risk $R_{\text{emp}}[f(\bullet;\mathbf{w}^*)]=0$. This amounts to finding parameters $\mathbf{w}^*$ which satisfy the set of non-linear equations

$$\mathbf{y}^j = \operatorname*{argmax}_{\mathbf{y}\in\mathcal{Y}} \langle \mathbf{w}, \Psi(\mathbf{x},\mathbf{y})\rangle\,, \quad j\in\mathcal{J}\,. \tag{11}$$

In the rest of the article, we will assume that the training set does not contain examples with the same observations $\mathbf{x}^j=\mathbf{x}^{j'}$ but different labelings $\mathbf{y}^j\neq\mathbf{y}^{j'}$, that is, we will search for a classifier which returns a unique labeling for each example from the training set. It is convenient to transform (11) to an equivalent problem of solving a set of linear strict inequalities

$$\langle \mathbf{w}, \Psi(\mathbf{x}^j,\mathbf{y}^j)\rangle > \langle \mathbf{w}, \Psi(\mathbf{x}^j,\mathbf{y})\rangle\,, \quad j\in\mathcal{J}, \mathbf{y}\in\mathcal{Y}\setminus\{\mathbf{y}^j\}\,,$$

which, using $\hat{\Psi}(\mathbf{x}^j,\mathbf{y}^j,\mathbf{y}) = \Psi(\mathbf{x}^j,\mathbf{y}^j) - \Psi(\mathbf{x}^j,\mathbf{y})$, can be written in a compact form

$$\langle \mathbf{w}, \hat{\Psi}(\mathbf{x}^j,\mathbf{y}^j,\mathbf{y})\rangle > 0\,, \quad j\in\mathcal{J}, \mathbf{y}\in\mathcal{Y}\setminus\{\mathbf{y}^j\}\,. \tag{12}$$

An efficient method to solve the problem (12) is the *perceptron* algorithm:

Algorithm 1 Perceptron algorithm

1: Set $\mathbf{w} := 0$.

2: Find a violated inequality in (12), that is, find indices $j^*\in\mathcal{J}$, $\mathbf{y}^*\in\mathcal{Y}\setminus\{\mathbf{y}^{j^*}\}$ such that

$$\langle \mathbf{w}, \hat{\Psi}(\mathbf{x}^{j^*},\mathbf{y}^{j^*},\mathbf{y}^*)\rangle \leq 0\,.$$

3: If there is no violated inequality then $\mathbf{w}$ solves (12) and the algorithm halts. Otherwise update the current solution

$$\mathbf{w} := \mathbf{w} + \hat{\Psi}(\mathbf{x}^{j^*},\mathbf{y}^{j^*},\mathbf{y}^*)\,,$$

and go to Step 2.

Provided the training set $\mathcal{L}$ is consistent, that is, the inequalities (12) are satisfiable, the perceptron terminates after a finite number of iterations (Novikoff, 1962). The number of iterations of the perceptron algorithm does not depend on the number of inequalities of (12). This property is crucial for the problems with a very large number of inequalities, which are of interest in our article.

In Step 2, the perceptron algorithm needs to find a violated inequality in (12). This subtask can be solved by computing the classifier responses $\hat{\mathbf{y}}^j = f(\mathbf{x}^j;\mathbf{w})$, $j \in \mathcal{J}$ by evaluating (10). If for some $j \in \mathcal{J}$ the response $\hat{\mathbf{y}}^j \neq \mathbf{y}^j$, that is, the classifier commits an error on the j-th example, then the indices $(j,\hat{\mathbf{y}}^j)$ identify the violated inequality. As a result, the perceptron algorithm is applicable for learning of an arbitrary linear classifier for which the classification task (10) can be evaluated efficiently.

In case of a general max-sum classifier, the classification task is NP-complete so that using the perceptron algorithm is not feasible. In Section 4 we will show, however, how to use the perceptron for learning the strictly supermodular max-sum classifiers and the max-sum classifiers with a strictly trivial equivalent.

3.2 Learning from Inconsistent Training Set Using SVM Approach

In practical applications, the training set is often inconsistent. SVMs (Vapnik, 1998) constitute a popular approach to learning linear classifiers applicable to both consistent and inconsistent training sets. The SVM learning is based on minimizing *regularized risk* which is a sum of the empirical risk $R_{\text{emp}}[f(\bullet;\mathbf{w})]$ and a regularization term. Minimization of the regularization term corresponds to the notion of large margin introduced to prevent over-fitting. Since the empirical risk is not convex for most loss functions used in classification it is replaced by a convex piece-wise linear upper bound which is more suitable for optimization. Originally, SVMs were designed for a binary case $|\boldsymbol{\mathcal{Y}}| = 2$ and $0/1$-loss function $L_{0/1}(\mathbf{y},\mathbf{y}') = [\![\mathbf{y} \neq \mathbf{y}']\!]$ where $[\![\bullet]\!]$ equals 1 if the term inside the brackets is satisfied and it is 0 otherwise. The multi-class variant of SVMs ($|\boldsymbol{\mathcal{Y}}| > 2$) were introduced in Vapnik (1998) and Crammer and Singer (2001) but it still assumes the $0/1$-loss only function.

Taskar et al. (2004b) extended SVMs for learning the max-sum classifiers (1) with an acyclic neighbourhood structure and they proposed using the additive loss function (14) suitable for these problems. Recently, the approach was generalized by Tsochantaridis et al. (2005) who consider an arbitrary structured linear classifier (10) and a general loss function. Learning of structured SVMs classifiers leads to the following convex QP task

$$(\mathbf{w}^*,\boldsymbol{\xi}^*) = \operatorname*{argmin}_{\mathbf{w},\boldsymbol{\xi}} \left[\frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{m}\sum_{j\in\mathcal{J}} \xi_j \right], \tag{13a}$$

subject to

$$\langle \mathbf{w}, \Psi(\mathbf{x}^j,\mathbf{y}^j) - \Psi(\mathbf{x}^j,\mathbf{y}) \rangle \geq L(\mathbf{y}^j,\mathbf{y}) - \xi_j, \qquad j \in \mathcal{J}, \mathbf{y} \in \boldsymbol{\mathcal{Y}}. \tag{13b}$$

The objective function of (13) comprises the regularization term $\frac{1}{2}\|\mathbf{w}\|^2$ and the sum $\frac{1}{m}\sum_{j\in\mathcal{J}}\xi_j$ weighted by the regularization constant $C > 0$. It can be shown (Tsochantaridis et al., 2005) that the sum $\frac{1}{m}\sum_{j\in\mathcal{J}}\xi_j$ is an upper bound on the empirical risk $R_{\text{emp}}[f(\bullet;\mathbf{w})]$ of the linear classifier (10). Thus the learning objective is to minimize an upper bound on the empirical risk and to penalize parameters with high $\|\mathbf{w}\|^2$. The loss function can be an arbitrary function $L\colon \boldsymbol{\mathcal{Y}} \times \boldsymbol{\mathcal{Y}} \to \mathbb{R}$ which satisfies $L(\mathbf{y},\mathbf{y}') = 0$ if $\mathbf{y} = \mathbf{y}'$ and $\infty > L(\mathbf{y},\mathbf{y}') > 0$ if $\mathbf{y} \neq \mathbf{y}'$. In cases which are of interest in our article, the set $\boldsymbol{\mathcal{Y}} = \mathcal{Y}^{\mathcal{T}}$ and a reasonable choice is the *additive loss function*, also known as the Hamming distance, which is defined as

$$L_\Delta(\mathbf{y},\mathbf{y}') = \sum_{t\in\mathcal{T}} [\![y_t \neq y'_t]\!], \tag{14}$$

that is, it counts the number of misclassified objects. The trade-off between the regularization term and the upper bound is controlled by the constant C. A suitable setting is usually found by tuning C on an independent data set or using the cross-validation.

The number of constraints (13b) equals to $m|\mathcal{Y}|$. In the structured learning $|\mathcal{Y}|$ is huge, for example, in the case of the max-sum classifiers it grows exponentially because $|\mathcal{Y}| = |\mathcal{Y}|^{|T|}$. As a result, the QP task (13) is not tractable for general purpose QP solvers. Tsochantaridis et al. (2005) proposed a specialized cutting plane algorithm to approximate (13) by a reduced QP task which has the same objective function (13a) but uses only a small subset of the constraints (13b). The efficiency of the approximation relies on the sparseness of the solution (13) which means that majority of the linear inequality constraints (13b) are inactive and they can be excluded without affecting the solution. To select the constraints, the cutting plane algorithm requires solving the LAC task

$$\mathbf{y}^* = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} \left[L(\mathbf{y}^j, \mathbf{y}) + \left\langle \mathbf{w}, \Psi(\mathbf{x}^j, \mathbf{y}) \right\rangle \right]. \tag{15}$$

Similarly to the perceptron algorithm, the cutting plane algorithm is applicable for learning of an arbitrary linear classifier for which the LAC task (15) can be solved efficiently.

In case of a general max-sum classifier and an additive loss function the LAC task becomes an instance of a general max-sum problem. Even though a general max-sum problem can be solved only approximately, we will show that it suffices to solve the learning problem (13) with a good precision. Moreover, we will be able to determine how the found solution differs from the optimal one. In case of a supermodular max-sum classifier we will augment the learning problem (13) in such a way that the obtained quality functions will be supermodular and thus the task (15) becomes solvable precisely in a polynomial time. Finally, in case of a max-sum problem with a strictly trivial equivalent, we will give a new formulation of the learning problem which does not require solving the task (15) at all since the number of constraints will be sufficiently small to use an exhaustive search.

4. Learning a Max-Sum Classifier from a Consistent Training Set

In this section, we assume that the training set is consistent with respect to a given max-sum classifier. This means that there exists at least one max-sum classifier in a given class which classifies all training examples correctly. We will introduce variants of the perceptron algorithm which, provided the assumption holds, find a classifier in a finite number of iterations. In practice, however, there is no general way to verify whether the assumption holds unless the perceptron halts. Consequently, if the perceptron algorithm does not halt after a reasonable number of iterations we cannot draw any conclusion about the solution. In Section 5, we will avoid this drawback using the SVM approach able to deal with inconsistent training sets.

To use the perceptron algorithm, we will reformulate the learning problem as an equivalent task of satisfying a set of linear strict inequalities. A keystone of the perceptron algorithm is an efficient procedure to find a violated inequality in the underlying set which amounts to classifying the examples from the training set. Therefore, using the perceptron algorithm is not feasible for the general max-sum problem whose evaluation is NP-complete. Nevertheless, we will formulate the learning problem even for this case because it will serve as a basis for constructing the algorithm for an inconsistent training set. Next, we will derive learning algorithms for strictly supermodular max-sum classifiers and max-sum classifiers with a strictly trivial equivalent. For these two classes, max-

sum classifiers can be evaluated efficiently by polynomial-time algorithms which makes possible to use the perceptron. Moreover, in the case of a max-sum classifier with a strictly trivial equivalent, learning will require finding a violated inequality from only a polynomially-sized set which can be accomplished exhaustively without any max-sum solver.

4.1 General Max-Sum Classifier

Problem 1 *(Learning a general max-sum classifier from a consistent training set). For a given training set* $\mathcal{L} = \{(\mathbf{x}^j, \mathbf{y}^j) \in \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \mid j \in \mathcal{J}\}$ *find quality functions* $\mathbf{q}$ *and* $\mathbf{g}$ *such that*

$$\mathbf{y}^j = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}^{\mathcal{T}}} F(\mathbf{x}^j, \mathbf{y}; \mathbf{q}, \mathbf{g}), \qquad j \in \mathcal{J}. \tag{16}$$

It can be seen, that the general max-sum classifier (1) can be represented as the linear classifier (10). In particular, the quality functions $\mathbf{q}$ and $\mathbf{g}$ are merged to a single parameter vector $\mathbf{w} = (\mathbf{q}; \mathbf{g}) \in \mathbb{R}^d$ of dimension $d = |\mathcal{T}||\mathcal{Y}||\mathcal{X}| + |\mathcal{E}||\mathcal{Y}|^2$. Further, we have $\boldsymbol{\mathcal{X}} = \mathcal{X}^{\mathcal{T}}$ and $\boldsymbol{\mathcal{Y}} = \mathcal{Y}^{\mathcal{T}}$. The mapping $\Psi\colon \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \to \mathbb{R}^d$ can be constructed of indicator functions in such a way that $F(\mathbf{x}, \mathbf{y}; \mathbf{q}, \mathbf{g}) = \langle \mathbf{w}, \Psi(\mathbf{x}, \mathbf{y}) \rangle$.

Following the approach of learning linear classifiers described in Section 3.1, we can reformulate Problem 1 to an equivalent problem of solving a huge set of linear inequalities

$$F(\mathbf{x}^j, \mathbf{y}^j; \mathbf{q}, \mathbf{g}) > F(\mathbf{x}^j, \mathbf{y}; \mathbf{q}, \mathbf{g}), \quad j \in \mathcal{J}, \mathbf{y} \in \mathcal{Y}^{\mathcal{T}} \setminus \{\mathbf{y}^j\}. \tag{17}$$

To find a solution of (17) by the perceptron, we would need an efficient algorithm to compute a response of a general max-sum classifier. Because solving a max-sum problem is NP-complete in general, using the perceptron algorithm is not tractable. In Section 5.1, we will use the formulation (17) as a basis for constructing an algorithm for learning from an inconsistent training set. In this case, it will be possible to use the LP relaxation to approximate the response of a max-sum classifier.

4.2 Strictly Supermodular Max-Sum Classifier

Problem 2 *(Learning strictly supermodular max-sum classifier from a consistent training set). For a given training set* $\mathcal{L} = \{(\mathbf{x}^j, \mathbf{y}^j) \in \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \mid j \in \mathcal{J}\}$ *find quality functions* $\mathbf{q}$ *and* $\mathbf{g}$ *such that equations (16) are satisfied and the quality functions* $\mathbf{g}$ *are strictly supermodular, that is,* $\mathbf{g}$ *satisfy the condition (9).*

Similarly to the general case, we reformulate Problem 2 as an equivalent problem of solving a set of strict linear inequalities

$$F(\mathbf{x}^j, \mathbf{y}^j; \mathbf{q}, \mathbf{g}) > F(\mathbf{x}^j, \mathbf{y}; \mathbf{q}, \mathbf{g}), \quad j \in \mathcal{J}, \mathbf{y} \in \mathcal{Y}^{\mathcal{T}} \setminus \{\mathbf{y}^j\}, \tag{18a}$$

$$\left.\begin{aligned} g_{tt'}(y, y') + g_{tt'}(y+1, y'+1) > g_{tt'}(y, y'+1) + g_{tt'}(y+1, y'), \\ \{t, t'\} \in \mathcal{E}, (y, y') \in \{1, \ldots, |\mathcal{Y}| - 1\}^2. \end{aligned}\right\} \tag{18b}$$

The system (18) comprises two sets of linear inequalities (18a) and (18b). The inequalities (18a) enforce an error-less response of a max-sum classifier on the training set. The inequalities (18b), if satisfied, guarantee that the quality functions $\mathbf{g}$ are strictly supermodular (c.f. Section 2.2).

To apply the perceptron algorithm we need an efficient method to find a violated inequality in (18). In the case of the inequalities (18b), it can be accomplished by an exhaustive search since there are only $|\mathcal{E}|(|\mathcal{Y}|-1)^2$ inequalities. To find a violated inequality in (18a), where the number $m(|\mathcal{Y}|^{|\mathcal{T}|}-1)$ grows exponentially, we need to compute the response of a max-sum classifier on the training examples. This can be done efficiently provided the inequalities (18b) are already satisfied as it guarantees that the qualities $\mathbf{g}$ are supermodular. Thus we use the perceptron algorithm to repeatedly solve the inequalities (18b) and, as soon as (18b) are satisfied, we find a violated inequality in (18a) by solving a supermodular max-sum problem. The proposed variant of the perceptron to solve (18) is as follows:

Algorithm 2 Learning strictly supermodular max-sum classifier by perceptron

1: Set $\mathbf{q} := \mathbf{0}$ and $\mathbf{g} := \mathbf{0}$.

2: Find a violated inequality in (18b), that is, find a quadruple $\{t,t'\} \in \mathcal{E}$, $y,y' \in \mathcal{Y}$ such that

$$g_{tt'}(y,y') + g_{tt'}(y+1,y'+1) - g_{tt'}(y,y'+1) - g_{tt'}(y+1,y') \leq 0\,.$$

3: If no such quadruple (t,t',y,y') exists then ($\mathbf{g}$ are already supermodular) go to Step 4. Otherwise use the found (t,t',y,y') to update current $\mathbf{g}$ by

$$\begin{array}{rclrcl} g_{tt'}(y,y') & := & g_{tt'}(y,y')+1\,, & g_{tt'}(y+1,y'+1) & := & g_{tt'}(y+1,y'+1)+1\,, \\ g_{tt'}(y,y'+1) & := & g_{tt'}(y,y'+1)-1\,, & g_{tt'}(y+1,y') & := & g_{tt'}(y+1,y')-1\,, \end{array}$$

and go to Step 2.

4: Find a violated inequality in (18a), that is, find an index $j \in \mathcal{J}$ and a labeling $\mathbf{y}$ such that

$$\mathbf{y}^j \neq \mathbf{y} := \operatorname*{argmax}_{\mathbf{y}' \in \mathcal{Y}^{\mathcal{T}}} F(\mathbf{x}^j, \mathbf{y}'; \mathbf{q}, \mathbf{g})\,.$$

5: If no such $(j, \mathbf{y})$ exist than $(\mathbf{q}, \mathbf{g})$ solve the task (18) and the algorithm halts. Otherwise use the found $(j, \mathbf{y})$ to update current $\mathbf{q}$ and $\mathbf{g}$ by

$$\begin{array}{rclrcll} g_{tt'}(y_t^j, y_{t'}^j) & := & g_{tt'}(y_t^j, y_{t'}^j)+1, & g_{tt'}(y_t, y_{t'}) & := & g_{tt'}(y_t, y_{t'})-1\,, & \{t,t'\} \in \mathcal{E}\,, \\ q_t(y_t^j, x_t^j) & := & q_t(y_t^j, x_t^j)+1, & q_t(y_t, x_t^j) & := & q_t(y_t, x_t^j)-1\,, & t \in \mathcal{T}\,. \end{array}$$

and go to Step 2.

Since Algorithm 2 is nothing but the perceptron algorithm applied to the particular set of linear constraints (18), the Novikoff's theorem (Novikoff, 1962) readily applies. Thus Algorithm 2 terminates in a finite number of iterations provided (18) is satisfiable, that is, if there exists a supermodular max-sum classifier $f(\bullet; \mathbf{q}, \mathbf{g})$ with zero empirical error risk on the training set $\mathcal{L}$.

4.3 Max-Sum Classifier with a Strictly Trivial Equivalent

Problem 3 *(Learning max-sum classifier with a strictly trivial equivalent from a consistent training set). For a given training set* $\mathcal{L} = \{(\mathbf{x}^j, \mathbf{y}^j) \in \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \mid j \in \mathcal{J}\}$ *find quality functions* $\mathbf{q}$ *and* $\mathbf{g}$ *such that equations (16) are satisfied and the max-sum problems* $P^j = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x}^j)$, $j \in \mathcal{J}$ *have a strictly trivial equivalent.*

In Problem 3, we again search for a max-sum classifier which classifies all training examples correctly but, in addition, all max-sum problems P^j, $j \in \mathcal{J}$ should have a strictly trivial equivalent. This means that if we compute a response of a max-sum classifier which solves Problem 3 for each training example using LP relaxation we get a unique labeling equal to that in the training set.

Because the equivalent transformations (4) cover the whole class of equivalent problems, the problem $P = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x})$ has a strictly trivial equivalent if and only if there exist potentials $\boldsymbol{\varphi}$ such that $P^{\boldsymbol{\varphi}}$ is strictly trivial. Recall that the strictly trivial problem has unique maximal nodes and edges (cf. Definition 2). Consequently, if the problem P has a strictly trivial equivalent and its optimal solution is $\mathbf{y}^*$ then there must exist potentials $\boldsymbol{\varphi}$ such that the following set of linear inequalities holds

$$q_t^{\boldsymbol{\varphi}}(y_t^*, x_t) > q_t^{\boldsymbol{\varphi}}(y, x_t), \quad t \in \mathcal{T}, y \in \mathcal{Y} \setminus \{y_t^*\}, \tag{19a}$$

$$g_{tt'}^{\boldsymbol{\varphi}}(y_t^*, y_{t'}^*) > g_{tt'}^{\boldsymbol{\varphi}}(y, y'), \quad \{t, t'\} \in \mathcal{E}, (y, y') \in \mathcal{Y}^2 \setminus \{(y_t^*, y_{t'}^*)\}. \tag{19b}$$

Note, that (19) is a set of $|\mathcal{T}||\mathcal{Y}| + |\mathcal{E}||\mathcal{Y}|^2$ strict inequalities which are linear in $(\mathbf{q}, \mathbf{g})$ and $\boldsymbol{\varphi}$ as can be seen after substituting (4) to (19). By replicating (19) for max-sum problems $P^j = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x}^j)$, $j \in \mathcal{J}$ whose unique solutions are required to be $\mathbf{y}^j$, $j \in \mathcal{J}$ we obtain an equivalent formulation of Problem 3 which requires satisfaction of a set of strict linear inequalities

$$q_t^{\boldsymbol{\varphi}^j}(y_t^j, x_t^j) > q_t^{\boldsymbol{\varphi}^j}(y, x_t^j), \quad j \in \mathcal{J}, t \in \mathcal{T}, y \in \mathcal{Y} \setminus \{y_t^j\}, \tag{20a}$$

$$g_{tt'}^{\boldsymbol{\varphi}^j}(y_t^j, y_{t'}^j) > g_{tt'}^{\boldsymbol{\varphi}^j}(y, y'), \quad j \in \mathcal{J}, \{t, t'\} \in \mathcal{E}, (y, y') \in \mathcal{Y}^2 \setminus \{(y_t^j, y_{t'}^j)\}. \tag{20b}$$

The system (20) is to be solved with respect to the quality functions $(\mathbf{q}, \mathbf{g})$ and the potentials $\boldsymbol{\varphi}^j$, $j \in \mathcal{J}$ introduced for each P^j, $j \in \mathcal{J}$. Note that the number of inequalities in the problem (20) is substantially smaller compared to the learning of a general max-sum classifier. In particular, (20) contains only $m|\mathcal{T}|(|\mathcal{Y}|-1) + m|\mathcal{E}|(|\mathcal{Y}|^2-1)$ inequalities compared to $m(|\mathcal{Y}|^{|\mathcal{T}|}-1)$ for a general max-sum classifier. Therefore a violated inequality in (20) can be easily selected by an exhaustive search. The proposed variant of the perceptron to solve (20) is as follows:

Algorithm 3 Learning the max-sum classifier with a strictly equivalent by perceptron

1: Set $\mathbf{g} := 0$, $\mathbf{q} := 0$, $\boldsymbol{\varphi}^j := 0$, $j \in \mathcal{J}$.

2: Find a violated inequality in (20a), that is, find a triplet $j \in \mathcal{J}$, $t \in \mathcal{T}$, $y \in \mathcal{Y} \setminus \{y_t^j\}$ such that

$$q_t(y_t^j, x_t^j) - \sum_{t' \in \mathcal{N}(t)} \varphi_{tt'}^j(y_t^j) \le q_t(y, x_t^j) - \sum_{t' \in \mathcal{N}(t)} \varphi_{tt'}^j(y).$$

3: If no such triplet (j, t, y) exists then go to Step 4. Otherwise update $\mathbf{q}$ and $\boldsymbol{\varphi}^j$ by

$$\begin{aligned} \varphi_{tt'}^j(y_t^j) &:= \varphi_{tt'}^j(y_t^j) - 1, \quad \varphi_{tt'}^j(y) := \varphi_{tt'}^j(y) + 1, \quad t' \in \mathcal{N}(t), \\ q_t(y_t^j, x_t^j) &:= q_t(y_t^j, x_t^j) + 1, \quad q_t(y, x_t^j) := q_t(y, x_t^j) - 1. \end{aligned}$$

4: Find a violated inequality in (20b), that is, find a quintuple $j \in \mathcal{J}$, $\{t,t'\} \in \mathcal{E}$, $(y,y') \in \mathcal{Y}^2 \setminus \{(y^j_t, y^j_{t'})\}$ such that

$$g_{tt'}(y^j_t, y^j_{t'}) + \varphi^j_{tt'}(y^j_t) + \varphi^j_{t't}(y^j_{t'}) \leq g_{tt'}(y,y') + \varphi^j_{tt'}(y) + \varphi^j_{t't}(y') \,.$$

5: If no such quintuple (j,t,t',y,y') exists and no update was made in Step 3 then the current $(\mathbf{q}, \mathbf{g}, \boldsymbol{\varphi}^j, j \in \mathcal{J})$ solves the task (20) and the algorithm halts. Otherwise update $\mathbf{g}$ and $\boldsymbol{\varphi}^j$ by

$$\begin{array}{rcrrcr} \varphi^j_{tt'}(y^j_t) & := & \varphi^j_{tt'}(y^j_t) + 1 \,, & \varphi^j_{t't}(y^j_{t'}) & := & \varphi^j_{t't}(y^j_{t'}) + 1 \,, \\ \varphi^j_{tt'}(y) & := & \varphi^j_{tt'}(y) - 1 \,, & \varphi^j_{t't}(y') & := & \varphi^j_{t't}(y') - 1 \,, \\ g_{tt'}(y^j_t, y^j_{t'}) & := & g_{tt'}(y^j_t, y^j_{t'}) + 1 \,, & g_{tt'}(y,y') & := & g_{tt'}(y,y') - 1 \,. \end{array}$$

and go to Step 2.

By the Novikoff's theorem, Algorithm 3 terminates in a finite number of iterations provided (20) is satisfiable, that is, if there exists a max-sum classifier $f(\bullet; \mathbf{q}, \mathbf{g})$ with zero empirical risk on $\mathcal{L}$ and all max-sum problems $P^j = (\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x}^j)$, $j \in \mathcal{J}$ have a strictly trivial equivalent.

5. Learning a Max-Sum Classifier from an Inconsistent Training Set

In this section, we formulate problems of learning max-sum classifiers from an inconsistent training set using the SVM framework described in Section 3.2. We will formulate the learning problems for a general max-sum classifier, a supermodular max-sum classifier, and a max-sum classifier with a strictly trivial equivalent. In all cases, learning will amount to solving an instance of a convex QP task. In Section 6, we will propose an extended version of the cutting plane algorithm (Tsochantaridis et al., 2005) which can solve these QP tasks efficiently.

In Section 4, we showed that learning of max-sum classifiers can be expressed as satisfying a set of strict linear inequalities. In the case of an inconsistent training set, however, these linear inequalities become unsatisfiable. Therefore we augment linear inequalities with non-negative slack variables, which relaxes the problem and makes it always satisfiable. In analogy to the SVM, we will minimize the Euclidean norm of an optimized parameters and the sum of slack variables. The problems are formulated in such a way that the sum of slack variables is a piece-wise linear upper bound on the empirical risk for a certain loss function. We will consider two different loss functions. In case of a general max-sum classifier and a supermodular max-sum classifier, we will use the *additive loss function* $L_\Delta(\mathbf{y}, \mathbf{y}') = \sum_{t \in \mathcal{T}} L_t(y_t, y'_t)$ where $L_t \colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ is any function which satisfies $L_t(y,y') = 0$ for $y = y'$ and $L_t(y,y') > 0$ otherwise. The Hamming distance $L_\Delta(\mathbf{y}, \mathbf{y}') = \sum_{t \in \mathcal{T}} [\![\mathbf{y} \neq \mathbf{y}']\!]$ is the particular case of the additive loss which seems to be a reasonable choice in many (not necessarily all) applications. In case of a max-sum classifier with a strictly trivial equivalent, we will consider the *0/1-loss function* $L_{0/1}(\mathbf{y}, \mathbf{y}') = [\![\mathbf{y} \neq \mathbf{y}']\!]$. The 0/1-loss function penalizes equally all incorrect predictions regardless of how many labels are misclassified. The additive loss is preferable to the 0/1-loss function in most structured classification problems. On the other hand, there are applications for which the 0/1-loss function is a natural choice, for example, problems with small number of objects like the one presented in Section 7.2.

5.1 General Max-Sum Classifier

Problem 4 *(Learning a general max-sum classifier from an inconsistent training set). For a given training set* $\mathcal{L} = \left\{(\mathbf{x}^j, \mathbf{y}^j) \in \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \,\middle|\, j \in \mathcal{J}\right\}$ *and a regularization constant* C *find quality functions* $\mathbf{q}$ *and* $\mathbf{g}$ *solving the following QP task*

$$(\mathbf{g}^*, \mathbf{q}^*, \boldsymbol{\xi}^*) = \operatorname*{argmin}_{\mathbf{g},\mathbf{q},\boldsymbol{\xi}} \left[\frac{1}{2}\left(\|\mathbf{g}\|^2 + \|\mathbf{q}\|^2\right) + \frac{C}{m}\sum_{j\in\mathcal{J}} \xi_j\right], \tag{21a}$$

subject to

$$F(\mathbf{x}^j, \mathbf{y}^j; \mathbf{q}, \mathbf{g}) - F(\mathbf{x}^j, \mathbf{y}; \mathbf{q}, \mathbf{g}) \geq L_\Delta(\mathbf{y}^j, \mathbf{y}) - \xi_j\,, \quad j \in \mathcal{J}, \mathbf{y} \in \mathcal{Y}^{\mathcal{T}}\,. \tag{21b}$$

The QP task (21) fits to the formulation (13) of structured SVM learning with the max-sum classifier (1) plugged in. The number of optimized parameters $(\mathbf{q};\mathbf{g}) \in \mathbb{R}^d$ equals to $d = |\mathcal{X}||\mathcal{Y}||\mathcal{T}| + |\mathcal{Y}|^2|\mathcal{E}|$. The main difficulty in solving (21) stems from the huge number $n = m|\mathcal{Y}|^{|\mathcal{T}|}$ of the linear inequalities (21b) which define the feasible set.

For a later use, it is convenient to rewrite the QP task (21) using a compact notation

$$\begin{aligned} (\mathbf{w}^*, \boldsymbol{\xi}^*) &= \operatorname*{argmin}_{\mathbf{w},\boldsymbol{\xi}} Q_P(\mathbf{w}, \boldsymbol{\xi}) = \operatorname*{argmin}_{\mathbf{w},\boldsymbol{\xi}} \left[\frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{m}\sum_{j\in\mathcal{J}} \xi_j\right], \\ \text{s.t.} \quad & \langle \mathbf{w}, \mathbf{z}_i \rangle \geq b_i - \xi_j\,, \quad j \in \mathcal{J}, i \in I_j\,, \end{aligned} \tag{22}$$

where $I_1 \cup \cdots \cup I_m = I = \{1, \ldots, n\}$, $I_u \cap I_v = \{\emptyset\}$, $u \neq v$, denote disjoint sets of indices such that each $i \in I$ has assigned an unique pair $(j, \mathbf{y})$, $j \in \mathcal{J}$, $\mathbf{y} \in \mathcal{Y}^{\mathcal{T}}$; the vector $\mathbf{w} = (\mathbf{q};\mathbf{g}) \in \mathbb{R}^d$ comprises both the optimized quality functions and $(\mathbf{z}_i \in \mathbb{R}^d, b_i \in \mathbb{R})$, $i \in I$, are constructed correspondingly to inscribe the inequalities (21b).

In Section 6, we will introduce a variant of the cutting plane algorithm to solve the QP task (21) (or (22), respectively). The cutting plane algorithm requires a subroutine which solves the LAC task (15). Using the compact notation, the LAC task reads $u_j = \operatorname{argmax}_{i\in I_j}(b_i - \langle \mathbf{w}, \mathbf{z}_i \rangle)$. Since this is NP-complete in general, we will use an LP relaxation which solves the task approximately. We will show that it is possible to assess the quality of the found solution $(\mathbf{w}, \boldsymbol{\xi})$ in terms of the objective of the learning task, that is, it is possible to bound the difference $Q_P(\mathbf{w}, \boldsymbol{\xi}) - Q_P(\mathbf{w}^*, \boldsymbol{\xi}^*)$. Further, we will prove that when the LAC task is solved exactly then the cutting plane algorithm finds an arbitrary precise solution $Q_P(\mathbf{w}, \boldsymbol{\xi}) - Q_P(\mathbf{w}^*, \boldsymbol{\xi}^*) \leq \varepsilon$, $\varepsilon > 0$, after a finite number of iterations. This guarantee does not apply for learning of the general max-sum classifier when an LP relaxation providing only an approximate solution is used. Though there is no theoretical guarantee, we will experimentally show that using an LP relaxation is sufficient to find a practically useful solution.

5.2 Supermodular Max-Sum Classifier

Problem 5 *(Learning a supermodular max-sum classifier from an inconsistent training set). For a given training set* $\mathcal{L} = \left\{(\mathbf{x}^j, \mathbf{y}^j) \in \mathcal{X}^{\mathcal{T}} \times \mathcal{Y}^{\mathcal{T}} \,\middle|\, j \in \mathcal{J}\right\}$ *and a regularization constant* C *find quality functions* $\mathbf{q}$ *and* $\mathbf{g}$ *solving the following QP task*

$$(\mathbf{g}^*, \mathbf{q}^*, \boldsymbol{\xi}^*) = \operatorname*{argmin}_{\mathbf{g},\mathbf{q},\boldsymbol{\xi}} \left[\frac{1}{2}\left(\|\mathbf{g}\|^2 + \|\mathbf{q}\|^2\right) + \frac{C}{m}\sum_{j\in\mathcal{J}} \xi_j\right], \tag{23a}$$

subject to

$$F(\mathbf{x}^j,\mathbf{y}^j;\mathbf{q},\mathbf{g}) - F(\mathbf{x}^j,\mathbf{y};\mathbf{q},\mathbf{g}) \geq L_\Delta(\mathbf{y}^j,\mathbf{y}) - \xi_j\,, \quad j \in \mathcal{J}, \mathbf{y} \in \mathcal{Y}^\mathcal{T}\,, \tag{23b}$$

$$\left.\begin{aligned} g_{tt'}(y,y') + g_{tt'}(y+1,y'+1) \geq g_{tt'}(y,y'+1) + g_{tt'}(y+1,y')\,, \\ \{t,t'\} \in \mathcal{E}\,, (y,y') \in \{1,\ldots,|\mathcal{Y}|-1\}^2\,. \end{aligned}\right\} \tag{23c}$$

Compared to the task (21) of learning a general max-sum classifier, the task (23) defined for the supermodular max-sum classifier contains additional linear constraints (23c). The added constraints (23c), when satisfied, guarantee that the found quality function $\mathbf{g}$ is supermodular. The total number of constraints increases to $n = m|\mathcal{Y}|^{|\mathcal{T}|} + |\mathcal{E}|(|\mathcal{Y}|-1)^2$. A compact form of the QP task (23) reads

$$\begin{aligned} (\mathbf{w}^*,\boldsymbol{\xi}^*) = \operatorname*{argmin}_{\mathbf{w},\boldsymbol{\xi}} & \left[\frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{m}\sum_{j\in\mathcal{J}}\xi_j\right], \\ \text{s.t.} \quad \langle \mathbf{w},\mathbf{z}_i\rangle &\geq b_i\,, \qquad i \in I_0\,, \\ \langle \mathbf{w},\mathbf{z}_i\rangle &\geq b_i - \xi_j\,, \quad j \in \mathcal{J}\,, i \in I_j\,, \end{aligned} \tag{24}$$

where $b_i = 0$, $i \in I_0$, and $\mathbf{z}_i$, $i \in I_0$, account for the added supermodular constraints (23c).

In Section 6, we introduce a variant of the cutting plane algorithm which maintains the constraints (23c) satisfied. Thus the quality functions are always supermodular and the LAC task can be solved precisely by efficient polynomial-time algorithms. As a result, we can guarantee that the cutting plane algorithm finds a solution with an arbitrary finite precision in a finite number of iterations.

5.3 Max-sum Classifier with Strictly Trivial Equivalent

Problem 6 *(Learning a max-sum classifier with a strictly trivial equivalent from an inconsistent training set). For a given training set* $\mathcal{L} = \{(\mathbf{x}^j,\mathbf{y}^j) \in \mathcal{X}^\mathcal{T} \times \mathcal{Y}^\mathcal{T} \,\big|\, j \in \mathcal{J}\}$ *and regularization constant* C *find quality functions* $\mathbf{q}$ *and* $\mathbf{g}$ *that solve the following QP task*

$$(\mathbf{g}^*,\mathbf{q}^*,\boldsymbol{\xi}^*,\boldsymbol{\varphi}^{j*}, j\in\mathcal{J}) = \operatorname*{argmin}_{\mathbf{g},\mathbf{q},\boldsymbol{\xi},\boldsymbol{\varphi}^j, j\in\mathcal{J}} \left[\frac{1}{2}\big(\|\mathbf{g}\|^2 + \|\mathbf{q}\|^2 + \sum_{j\in\mathcal{J}}\|\boldsymbol{\varphi}^j\|^2\big) + \frac{C}{m}\sum_{j\in\mathcal{J}}\xi_j\right], \tag{25a}$$

subject to

$$\begin{aligned} q_t^{\boldsymbol{\varphi}^j}(y_t^j,x_t^j) - q_t^{\boldsymbol{\varphi}^j}(y,x_t^j) &\geq 1-\xi_j\,, \quad j\in\mathcal{J}\,, t\in\mathcal{T}\,, y\in\mathcal{Y}\setminus\{y_t^j\}\,, \\ g_{tt'}^{\boldsymbol{\varphi}^j}(y_t^j,y_{t'}^j) - g_{tt'}^{\boldsymbol{\varphi}^j}(y,y') &\geq 1-\xi_j\,, \quad j\in\mathcal{J}\,, \{t,t'\}\in\mathcal{E}\,, (y,y')\in\mathcal{Y}^2\setminus\{(y_t^j,y_{t'}^j)\}\,, \\ \xi_j &\geq 0\,, \qquad j\in\mathcal{J}\,. \end{aligned} \tag{25b}$$

The problem (25) is derived from the problem (20) which was formulated for a consistent training set. In the consistent case, it is required that each max-sum problem P^j has a strictly trivial equivalent whose unique solution equals to the desired labeling $\mathbf{y}^j$ given in the training set. In the case of an inconsistent training set, we allow some max-sum problems to violate this requirement. To this end, each subset of linear inequalities in (25b) which corresponds to the given max-sum problem P^j is relaxed by a single non-negative slack variable ξ_j. If a slack variable $\xi_j \geq 1$ then either the solution of the max-sum problem P^j differs from $\mathbf{y}^j$ or P^j has no trivial equivalent. The number of

such max-sum problems is upper bounded by $\sum_{j\in\mathcal{J}}^{m}\xi_j$ which is included into the objective function of (25a). Thus it corresponds to minimization of an upper bound on the empirical risk with the $0/1$-loss functions. The objective function also contains the Euclidean norm of the quality functions $(\mathbf{q},\,\mathbf{g})$ and the potentials $\boldsymbol{\varphi}^j$. Including the potentials $\boldsymbol{\varphi}^j$ into the objective function is somewhat arbitrary since it penalizes the transformation of max-sum problems to their trivial equivalents. An advantage of including the potentials is the fact that the dual representation of the task (25) has a simpler form which corresponds to the QP task of an ordinary multi-class SVM. Another variant is to remove the potentials from the objective function which corresponds to including a set of linear constraints to the dual task of (25) making the problem more difficult.

Compared to the previous learning problems, the number of variables $d=|\mathcal{X}||\mathcal{Y}||\mathcal{T}|+|\mathcal{Y}|^2|\mathcal{E}|+2m|\mathcal{E}||\mathcal{Y}|$ in (25) is increased by $2m|\mathcal{E}||\mathcal{Y}|$, however, the number of linear constraints $n=m|\mathcal{E}|(|\mathcal{Y}|^2-1)+m|\mathcal{T}|(|\mathcal{Y}|-1)+m$ is drastically smaller. In particular, n grows only polynomially compared to the exponential growth in the previous cases.

The QP task (25) can be rewritten into the compact form (22), that is, the same QP task as required when learning the general max-sum classifier. Unlike the general case, the optimized parameters $\mathbf{w}$ now comprise $\mathbf{w}=(\mathbf{q};\mathbf{g};\boldsymbol{\varphi}^1;\ldots;\boldsymbol{\varphi}^m)\in\mathbb{R}^d$ and the vectors $\mathbf{z}_i$, $i\in I$, are constructed correspondingly. However, as mentioned above, the main difference is much smaller $n=|I|$. As a result, the LAC task required by the cutting plane algorithm can be easily accomplished by an exhaustive search.

6. Algorithm for Quadratic Programming Tasks

In this section, we propose an algorithm to solve the QP tasks (21), (23) and (25) required for learning the max-sum classifiers from inconsistent training sets. We extend the cutting plane algorithm by Tsochantaridis et al. (2005) and its approximate version by Finley and Joachims (2005) in two directions. First, we will consider a more general QP task (23) which contains linear inequalities both with and without slack variables. Moreover, the inequalities without slack variables are required to be satisfied during the whole course of the algorithm. This extension is necessary for learning a supermodular max-sum classifier. Second, we propose to use a different stopping conditions to halt the algorithm. The original algorithm by Tsochantaridis et al. (2005) halts the optimization as soon as the linear constraints of a QP task are violated by a prescribed constant $\bar{\varepsilon}>0$ at most. We will use a stopping condition which is based on the duality gap. This allows us to control the precision of the found solution directly in terms of the optimized objective function. Moreover, the stopping condition can be easily evaluated even when the LAC task is solved only approximately by an LP relaxation which is useful for learning general max-sum classifiers. Finally, we will prove that the proposed algorithm converges in a finite number of iterations even in the case of a general max-sum classifier where the LAC task is NP-complete. We point out that the proof is similar to that of Tsochantaridis et al. (2005) but is technically simpler and it applies for the extended cutting plane algorithm proposed here. A general QP task which covers all the QP tasks (21), (23) and (25) reads

$$
\begin{aligned}
&(\mathbf{w}^*,\boldsymbol{\xi}^*)=\operatorname*{argmin}_{\mathbf{w},\boldsymbol{\xi}} Q_P(\mathbf{w},\boldsymbol{\xi})=\operatorname*{argmin}_{\mathbf{w},\boldsymbol{\xi}}\left[\frac{1}{2}\|\mathbf{w}\|^2+\frac{C}{m}\sum_{j\in\mathcal{J}}\xi_j\right],\\
&\text{s.t.}\qquad \begin{array}{lll}\langle\mathbf{w},\mathbf{z}_i\rangle & \geq & b_i\,, \qquad i\in I_0\,,\\ \langle\mathbf{w},\mathbf{z}_i\rangle & \geq & b_i-\xi_j\,, \quad j\in\mathcal{J}, i\in I_j\,,\end{array}
\end{aligned}
\tag{26}
$$

where $I = I_0 \cup I_1 \cup \cdots \cup I_m = \{1,\ldots,n\}$, $I_i \cap I_j = \{\emptyset\}$, $i \neq j$ are index sets. Note that we obtain the QP task (21) and (25) by setting $I_0 = \{\emptyset\}$. The Wolf dual of (26) reads

$$\begin{aligned} \boldsymbol{\alpha}^* &= \operatorname*{argmax}_{\boldsymbol{\alpha}} Q_D(\boldsymbol{\alpha}) = \operatorname*{argmax}_{\boldsymbol{\alpha}} \left[\langle \mathbf{b}, \boldsymbol{\alpha} \rangle - \frac{1}{2} \langle \boldsymbol{\alpha}, \mathbf{H}\boldsymbol{\alpha} \rangle \right], \\ \text{s.t.} \quad \sum_{i \in I_j} \alpha_i &= \frac{C}{m}, \quad j \in \mathcal{J}, \\ \alpha_i &\geq 0, \quad i \in I, \end{aligned} \tag{27}$$

where $\mathbf{H}$ is a positive semi-definite matrix $[n \times n]$ which contains the dot products $H_{i,j} = \langle \mathbf{z}_i, \mathbf{z}_j \rangle$. The primal variables $(\mathbf{w}^*, \boldsymbol{\xi}^*)$ can be computed from the dual variables $\boldsymbol{\alpha}^*$ by

$$\mathbf{w}^* = \sum_{i \in I} \alpha_i^* \mathbf{z}_i, \quad \xi_j^* = \max_{i \in I_j} (b_i - \langle \mathbf{w}^*, \mathbf{z}_i \rangle), \ j \in \mathcal{J}.$$

Note that the vectors $\mathbf{z}_i$, $i \in I$ appear in (27) only as dot products and thus the kernel functions can be potentially used.

It is not tractable to solve the QP task directly neither in the primal form nor in the dual form due to the exponential number of constraints or variables, respectively. The cutting plane algorithm alleviates the problem by exploiting the sparseness of maximal margin classifiers. Sparseness means that only a small portion of constraints of the primal task are active in the optimal solution, or equivalently, a small portion of dual variables are non-zero.

We denote $\overline{I} = I_0 \cup \overline{I}_1 \cup \cdots \cup \overline{I}_m$ disjoint subsets of selected indices from $I = I_0 \cup I_1 \cup \cdots \cup I_m$, that is, $\overline{I}_j \subseteq I_j$, $j \in \mathcal{J}$, while I_0 is always the same. The reduced task is obtained from (27) by considering only the selected variables $\{\alpha_i \mid i \in \overline{I}\}$ while the remaining variables $\{\alpha_i \mid i \in I \setminus \overline{I}\}$ are fixed to zero, that is, the reduced dual QP task reads

$$\overline{\boldsymbol{\alpha}} = \operatorname*{argmax}_{\boldsymbol{\alpha}} \left[\sum_{i \in \overline{I}} \alpha_i b_i - \frac{1}{2} \sum_{i \in \overline{I}} \sum_{j \in \overline{I}} \alpha_i \alpha_j H_{ij} \right], \tag{28a}$$

$$\begin{aligned} \text{s.t.} \quad \sum_{i \in \overline{I}_j} \alpha_i &= \frac{C}{m}, \quad j \in \mathcal{J}, \\ \alpha_i &\geq 0, \quad i \in \overline{I}, \\ \alpha_i &= 0, \quad i \in I \setminus \overline{I}. \end{aligned} \tag{28b}$$

To solve the reduced task (28), it is enough to maintain explicitly just the selected variables and thus its size scales only with $|\overline{I}|$. The cutting plane algorithm tries to select the subsets $\overline{I} = I_0 \cup \overline{I}_1 \cup \cdots \cup \overline{I}_m$ such that (i) $|\overline{I}|$ is sufficiently small to make the reduced task (28) solvable by standard optimization packages and (ii) the obtained solution well approximates the original task. The proposed extension of the cutting plane algorithm is as follows:

Algorithm 4 A cutting plane algorithm for QP task (26)

1: Select arbitrarily $\left(\overline{I}_j := \{u_j\}, u_j \in I_j\right)$, $j \in \mathcal{J}$. Set the desired precision $\varepsilon > 0$.

2: For selected indices $\overline{I} = I_0 \cup \overline{I}_1 \cup \cdots \cup \overline{I}_m$ solve the reduced task (28) to obtain $\overline{\boldsymbol{\alpha}}$ and compute the primal variable $\overline{\mathbf{w}} := \sum_{i \in \overline{I}} \overline{\alpha}_i \mathbf{z}_i$.

3: For all $j \in \mathcal{J}$ do:

3a: Solve the LAC task

$$u_j := \operatorname*{argmax}_{i \in I_j} \left(b_i - \langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle \right) , \tag{29}$$

and set $\overline{\xi}_j := b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle$. If (29) is solved only approximately (when using LP relaxation) then set $\overline{\xi}_j$ to the smallest available upper bound on $b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle$.

3b: Set $\overline{I}_j := \overline{I}_j \cup \{u_j\}$ provided the following condition holds

$$\frac{C}{m}(b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle) - \sum_{i \in \overline{I}_j} \overline{\alpha}_i (b_i - \langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle) > \frac{\varepsilon}{m} . \tag{30}$$

4: If the current solution $(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}, \overline{\boldsymbol{\alpha}})$ satisfies the stopping condition

$$Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_D(\overline{\boldsymbol{\alpha}}) \leq \varepsilon , \tag{31}$$

or if the condition (30) was violated for all $j \in \mathcal{J}$ then halt. Otherwise go to Step 2.

Note that Algorithm (4) explicitly maintains only the selected variables $\{\alpha_i \mid i \in \overline{I}\}$ and the corresponding pairs $\{(b_i, \mathbf{z}_i) \mid i \in \overline{I}\}$. In Step 3a, the algorithm requires a subroutine to solve the LAC task (29). We consider two different variants of the algorithm. First, the task (29) can be solved precisely which applies to learning of supermodular max-sum classifiers and max-sum classifiers with a strictly trivial equivalent. Second, the task (29) can be solved only approximately, which applies to the general case when the max-sum problem is solved by an LP relaxation. The key property of an LP relaxation which we exploit here is that it provides an upper bound on the optimal solution of a max-sum problem, that is, an upper bound on the quantity $b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle$.

In Step 3b, the condition (30) is evaluated to decide whether adding the constraint $\langle \mathbf{w}, \mathbf{z}_{u_j} \rangle \geq b_{u_j} - \xi_j$ to the reduced QP task (28) brings a sufficient improvement or not. In Lemma 1 introduced below, we show that adding at least one constraint guarantees a minimal improvement regardless of whether the LAC problem is solved precisely or approximately. The algorithm halts when no constraint is added in Step 3b. This situation occurs only if the algorithm has converged to a solution which satisfies the stopping condition (31) provided the LAC task is solved exactly (cf. Theorem 4 and its proof).

Let us discuss the stopping condition (31). Note that the primal $(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}})$ and the dual variables $\overline{\boldsymbol{\alpha}}$ are feasible during entire progress of the algorithm. This holds even in the case when an LP relaxation is used to solve (29) since the $\overline{\xi}_j$, $j \in \mathcal{J}$ are set to upper bounds on their optimal values. Having feasible primal and dual variables, we can use the weak duality theorem to write

$$Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_P(\mathbf{w}^*, \boldsymbol{\xi}^*) \leq Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_D(\overline{\boldsymbol{\alpha}}) ,$$

which implies that any solution satisfying the stopping condition (31) differs from the optimal solution by at most ε. Note that the precision parameter $\bar{\varepsilon}$ used in the original stopping condition of Tsochantaridis et al. (2005) can also be related to the duality gap. Namely, it can be shown that $\bar{\varepsilon}$ approximate solution satisfies $Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_D(\overline{\boldsymbol{\alpha}}) \leq C\bar{\varepsilon}$.

Finally, we show that the algorithm converges in a finite number of iterations. The proof is based on Lemma 1 which asserts that a minimal improvement $\Delta_{\min} > 0$ of the dual objective function is guaranteed provided at least one new variable was added in Step 3(b) to the reduced task, that is, the condition (30) was satisfied for at least one $j \in \mathcal{J}$.

Lemma 1 *Provided at least one new variable was added in Step 3(b) of Algorithm 4 the improvement in the dual objective function $Q_D(\boldsymbol{\alpha})$ obtained after solving the reduced task is not less that*

$$\Delta_{\min} = \min\left\{\frac{\varepsilon}{2m}, \frac{\varepsilon^2}{8C^2R^2}\right\}, \quad \textit{where} \quad R = \max_{j\in\mathcal{J}} \max_{i\in I_j} \|\mathbf{z}_i\|\,.$$

Proof of Lemma 1 is given in Appendix B.

Using Lemma 1, it is easy to show that Algorithm 4 halts after a finite number of iterations. Note that the proof applies even for the case when the LAC task (29) is solved only approximately.

Theorem 4 *Let us assume that the primal QP task (26) is bounded and feasible. Algorithm 4 halts for arbitrary $\varepsilon > 0$ after at most T iterations, where*

$$T = \left(Q_D(\boldsymbol{\alpha}^*) - Q_D(\overline{\boldsymbol{\alpha}}^1)\right) \max\left\{\frac{2m}{\varepsilon}, \frac{8C^2R^2}{\varepsilon^2}\right\}, \qquad R = \max_{j\in\mathcal{J}} \max_{i\in I_j} \|\mathbf{z}_i\|\,,$$

and $\overline{\boldsymbol{\alpha}}^1$ is the solution of the reduced task obtained after the first iteration of Algorithm 4.

Proof Algorithm 4 halts if either the stopping condition (31) holds or no new variable was added in Step 3(b). Provided the algorithm does not halt in Step 4, the dual objective functions $Q_D(\boldsymbol{\alpha})$ is improved by at least $\Delta_{\min} > 0$ which is given in Lemma 1. Since the difference $Q_D(\boldsymbol{\alpha}^*) - Q_D(\overline{\boldsymbol{\alpha}}^1)$ is bounded from above the algorithm cannot pass through the Step 4 infinite number times and we can write

$$T \leq \frac{Q_D(\boldsymbol{\alpha}^*) - Q_D(\overline{\boldsymbol{\alpha}}^1)}{\Delta_{\min}} = \left(Q_D(\boldsymbol{\alpha}^*) - Q_D(\overline{\boldsymbol{\alpha}}^1)\right) \max\left\{\frac{2m}{\varepsilon}, \frac{8C^2R^2}{\varepsilon^2}\right\} < \infty\,.$$

■

The bound on a maximal number of iterations (or the bound on $\Delta_{\min}$, respectively) given in Theorem 4 is obtained based on the worst case analysis. As a result, the bound is an over-pessimistic estimate of the number of iterations usually required in practice. Because the bound is not useful for computing practical estimates of the number of iterations, we do not derive its particular variants for the QP tasks (21), (23) and (25).

Finally, we give a theorem which asserts that the stopping condition (31) is always satisfied after Algorithm 4 halts provided the LAC task (29) is solved exactly, that is, the found solution achieves the desired precision $Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_P(\mathbf{w}^*, \boldsymbol{\xi}^*) \leq \varepsilon$.

Theorem 5 *Let us assume that the LAC task (29) is solved exactly and the assumptions of Theorem 4 hold. In this case the condition (31) holds after Algorithm 4 halts.*

Proof We show that the assumption that no new variable was added in Step 3(b) and the condition (31) is violated leads to a contradiction. If no variable was added then the condition (30) is violated for all $j \in \mathcal{J}$. Summing up the violated conditions (30) yields

$$\sum_{j\in\mathcal{J}} \left[\frac{C}{m}\left(b_{u_j} - \langle\overline{\mathbf{w}}, \mathbf{z}_{u_j}\rangle\right) - \sum_{i\in\overline{I}_j} \overline{\alpha}_i \left(b_i - \langle\overline{\mathbf{w}}, \mathbf{z}_i\rangle\right)\right] \leq \sum_{j\in\mathcal{J}} \frac{\varepsilon}{m}\,. \tag{32}$$

The vector $\overline{\boldsymbol{\alpha}}$ is the optimal solution of the reduced task which includes all the variables $\{\alpha_i \,|\, i \in I_0\}$. Therefore by the complementary slackness (Karush-Kuhn-Tucker conditions) we have

$$\sum_{i \in I_0} \overline{\alpha}_i (b_i - \langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle) = 0 \,. \tag{33}$$

By adding (33) to (32) and using $\overline{\mathbf{w}} = \sum_{i \in \overline{I}} \overline{\alpha}_i \mathbf{z}_i$, $\overline{\xi}_j = b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle$ we get

$$\begin{aligned}
\sum_{j \in \mathcal{J}} \left[\frac{C}{m} \left(b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle \right) - \sum_{i \in \overline{I}_j} \overline{\alpha}_i \left(b_i - \langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle \right) \right] - \sum_{i \in \overline{I}_0} \overline{\alpha}_i \left(b_i - \langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle \right) &\leq \varepsilon \\
\frac{C}{m} \sum_{j \in \mathcal{J}} \left(b_{u_j} - \langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle \right) - \sum_{i \in \overline{I}} \overline{\alpha}_i \left(b_i - \langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle \right) &\leq \varepsilon \\
\frac{C}{m} \sum_{j \in \mathcal{J}} \overline{\xi}_j - \sum_{i \in \overline{I}} \overline{\alpha}_i b_i + \langle \overline{\mathbf{w}}, \overline{\mathbf{w}} \rangle &\leq \varepsilon \,.
\end{aligned}$$

The last inequality can be equivalently written as $Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_D(\overline{\boldsymbol{\alpha}}) \leq \varepsilon$ which is in contradiction to the assumption that (31) is violated. ■

To summarize, in case when the LAC task (29) is solved exactly Algorithm 4 finds a solution with an arbitrary finite precision $\varepsilon > 0$ in a finite number of iterations. In case when the task (29) is solved only approximately by an LP relaxation Algorithm 4 always halts after a finite number of iterations but there is no guarantee that the desired precision was attained. The attained precision, however, can be determined by evaluating the duality gap $Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_D(\overline{\boldsymbol{\alpha}}) \geq Q_P(\overline{\mathbf{w}}, \overline{\boldsymbol{\xi}}) - Q_P(\mathbf{w}^*, \boldsymbol{\xi}^*)$.

In next sections, we will apply Algorithm 4 to the three particular instances of the QP tasks (21), (23) and (25).

6.1 General Max-Sum Classifier

In this section, we discuss optimization of the QP task (21) (or its compact form (22), respectively) using Algorithm 4.

In Step 1 of Algorithm 4, we have to select the initial subsets $(\overline{I}_j = \{u_j\}, u_j \in I_j), j \in \mathcal{J}$. A simple way is to use $u_j = (j, \mathbf{y}^j)$, which is equivalent to selecting the primal constraints $\langle \mathbf{w}, \mathbf{z}_i \rangle \geq b_i - \xi_j$ with $\mathbf{z}_i = \mathbf{0}$ and $b_i = 0$. Note that the task (21) does not contain the primal constraints without slack variables which implies that the subset $I_0 = \{\emptyset\}$.

The LAC task (29) required in Step 2a of Algorithm 4 amounts to solving an instance of a general max-sum problem

$$\begin{aligned}
\hat{\mathbf{y}}^j &= \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}^{\mathcal{T}}} \left[L_\Delta(\mathbf{y}, \mathbf{y}^j) - F(\mathbf{x}^j, \mathbf{y}^j; \mathbf{q}, \mathbf{g}) + F(\mathbf{x}^j, \mathbf{y}; \mathbf{q}, \mathbf{g}) \right] \\
&= \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}^{\mathcal{T}}} \left[\sum_{t \in \mathcal{T}} \left(q_t(y_t, x_t^j) + [\![y_t^j \neq y_t]\!] \right) + \sum_{\{t,t'\} \in \mathcal{E}} g_{tt'}(y_t, y_{t'}) \right] .
\end{aligned} \tag{34}$$

The obtained labeling $\hat{\mathbf{y}}^j$ is then used to construct the vector $\mathbf{z}_{(j,\hat{\mathbf{y}}^j)} = \Psi(\mathbf{x}^j, \mathbf{y}^j) - \Psi(\mathbf{x}^j, \hat{\mathbf{y}}^j)$. Because the task (34) is NP-complete in general, we use an LP relaxation discussed in Section 2.1. This

means that the found $\hat{\mathbf{y}}^j$ is not optimal but it is usually good enough to satisfy the condition (30) which then leads to a guaranteed improvement of the optimized dual objective (cf. Lemma 1). LP relaxation algorithms also provides an upper bound UB_j on the optimal solution of (34) which is essential to compute feasible $\overline{\xi}_j$, $j \in \mathcal{J}$ in Step 3(a) of Algorithm 4. In particular, $\overline{\xi}_j$ is computed as $\overline{\xi}_j = \mathrm{UB}_j - F(\mathbf{x}^j, \mathbf{y}^j; \mathbf{q}, \mathbf{g})$.

6.2 Supermodular Max-Sum Classifier

In this section, we discuss optimization of the QP task (23) (or its compact form (24), respectively) using Algorithm 4.

The initialization in Step 1 of Algorithm 4 can be carried out in the same way as described in Section 6.1. Since the QP task (24) involves the primal constraints $\langle \mathbf{w}, \mathbf{z}_i \rangle \geq b_i$, $i \in I_0$, without slack variables the corresponding $\mathbf{z}_i$, $i \in I_0$, must be included in the reduced QP task during the entire progress of Algorithm 4. The size $|I_0| = |\mathcal{E}|(|\mathcal{Y}|-1)^2$ grows only quadratically which allows to use standard optimization packages.

The LAC task (29) is of the same form as that for a general max-sum problem, that is, it requires solving (34). Unlike the general case, the task (34) can be solved exactly by a polynomial-time algorithms provided the quality functions $\mathbf{g}$ obey the supermodularity condition. The requirement of supermodularity is expressed by the primal conditions $\langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle \geq 0$, $i \in I_0$ which are always included in the reduced task (28) and thus they should be always satisfied. There is one numerical issue, however, concerning a finite precision of QP solvers used to optimize the reduced task. It is possible that the primal constraints on supermodularity are slightly violated even if the reduced task is solved with a high precision. This might potentially (even though we have not observed the problem in practice) cause problems when solving the LAC task which relies on the supermodularity of $\mathbf{g}$. An easy solution to avoid the problem is to add the primal constraints $\langle \overline{\mathbf{w}}, \mathbf{z}_i \rangle \geq 0$, $i \in I_0$ with $\overline{\mathbf{w}} = \sum_{i \in \overline{I}} \alpha_i \mathbf{z}_i$ to the dual reduced task (28). In particular, we can solve the reduced task (28) subject to the constraints (28b) augmented by additional constraints $\sum_{i \in \overline{I}} \alpha_i H_{ij} \geq 0\,, \quad j \in I_0$. Note that adding of the additional constraints changes just the feasible set but it does not change the solution. Solving the reduced task with the added constraints by using any QP solver which produces a feasible solution with a finite precision (e.g., *interior point methods*) guarantees that the supermodularity constraints are satisfied.

6.3 Max-Sum Classifier with Strictly Trivial Equivalent

Unlike the previous two cases, the QP task (25) (or its compact form (22) respectively) contains only $n = m|\mathcal{E}|(|\mathcal{Y}|^2-1) + m|\mathcal{T}|(|\mathcal{Y}|-1) + m$ linear constraints. The form of the QP task (25) is the same as required for learning of an ordinary multi-class SVM (Crammer and Singer, 2001) which makes it possible to use existing optimization packages. The problem can be also solved by the proposed Algorithm 4. In this case, an initialization of the subset $(\overline{I}_j = \{u_j\}, u_j \in I_j), j \in \mathcal{J}$ performed in Step 1, can simply select the indices which correspond to the constraints $\xi_j \geq 0$, $j \in \mathcal{J}$. The LAC task (29) required in Step 3a can be solved exhaustively which means that we do not need any max-sum solver during the learning stage.

7. Experiments

Even though this article focuses primarily on theory, we present some examples to demonstrate functionality of the proposed learning algorithms. The examples are not meant to be a comprehensive evaluation.

7.1 Image Segmentation

We consider the problem of learning a classifier for segmentation of color images. We compare a general max-sum classifier, a supermodular max-sum classifier and a standard multi-class SVMs classifier (Crammer and Singer, 2001) as a baseline approach. In particular, we used the formulations given in Problem 4 and Problem 5 for learning the general and supermodular classifiers from the inconsistent training sets. To solve the LAC task required by Algorithm 4, we used an LP relaxation solver based on the Augmented Directed Acyclic Graph (ADAG) algorithm (Schlesinger 1976; see also the tutorial by Werner 2007).

We used the following three sets of color images (see Figure 1):

Microsoft Research (MSR) database: The original database [1] contains 240 images of 9 objects along with their manual segmentation. We selected a subset of 32 images each of which contains a combination of the following four objects: *cow*, *grass*, *water* and *void*. All images are of size 213×320 pixels. We created 3 random splits of the images into 10 training, 9 validation and 13 testing images. Reported results are averages taken over these three splits.

Shape-Sorter: We collected snapshots of a toy shape-sorter puzzle placed on a carpet. The snapshots are taken under varying view-angle and lighting conditions. The images contain 6 objects of different colors which we manually segmented. We split the images into a training set containing 14 images of size 100×100 pixels, validation and testing sets each containing 4 images of size 200×200 pixels.

Landscape: The data set is created from a single landscape image of size 280×600 which was manually segmented into *sky*, *border line* and *ground* areas. We divided the landscape image into 20 non-overlapping sub-windows of size 70×120 pixels. Finally, we split the 20 images into 5 training, 4 validation and 11 testing images.

In this experiment we define the max-sum classifier as follows. The set of objects $\mathcal{T} = \{(i,j) \mid i \in \{1,\dots,H\}, j \in \{1,\dots,W\}\}$ corresponds to the pixels of the input image of size $H \times W$. We consider a 4-neighborhood structure of image pixels, that is, $\mathcal{E}$ contains undirected edges between all pixels $(i,j) \in \mathcal{T}$ and $(i',j') \in \mathcal{T}$ which satisfy $|i-i'|+|j-j'|=1$. Each pixel $t \in \mathcal{T}$ is characterized by its observable state x_t and a label y_t. The observable state $x_t \in \mathcal{X} = \mathbb{R}^3$ is a vector containing RGB color values of t-th pixel. The label $y_t \in \mathcal{Y} = \{1,\dots,N\}$ assigns t-th pixel to one of N segments. We assume that the quality functions $q\colon \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ and $g\colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ do not depend on pixel $t \in \mathcal{T}$ (so called homogeneous model). The quality function $q(x,y) = \langle \mathbf{w}_y, x \rangle$ is linear in parameter $\mathbf{w}_y \in \mathbb{R}^3$, $y \in \mathcal{Y}$, as well as the function $g(y,y')$ represented by a vector $\mathbf{g} \in \mathbb{R}^{N^2}$. Hence the learned parameter vector $\mathbf{w} = (\mathbf{w}_1;\dots;\mathbf{w}_N;\mathbf{g}) \in \mathbb{R}^d$ is of dimension $d = 3N + N^2$. For the baseline approach we used a linear multi-class SVM which is equivalent to a max-sum classifier with a constant quality function $g(y,y')$, that is, the interrelation between labels is neglected.

1. Database B1 can be found at https://research.microsoft.com/vision/cambridge/recognition/default.htm.

	Multi-class SVM	General max-sum	Supermodular max-sum
MSR-database	21.74%	14.16%	14.03%
Shape-Sorter	1.31%	0.91%	0.92%
Landscape	6.22%	0.69%	0.65%

Table 1: Performance of max-sum classifiers compared to an ordinary SVM classifier on three segmentation data sets. The table contains average percentages of misclassified pixels per image.

We stopped the cutting plane Algorithm 4 when either the precision $(Q_P(\mathbf{w},\boldsymbol{\xi}) - Q_D(\boldsymbol{\alpha}))/Q_P(\mathbf{w},\boldsymbol{\xi}) \leq 10^{-2}$ was attained or no improving constraint was found after solving the LAC task. For the supermodular max-sum classifier the required precision was always attained since the LAC can be solved exactly. For the general max-sum classifier the algorithm failed to converge only in a few cases when the regularization constant C was set too high. The average time required for learning on an ordinary desktop PC was around 11 hours for the MSR-database, 3 hours for the Shape-Sorter data set and 6 minutes for the Landscape data set. The bottleneck is solving the LAC task by the ADAG max-sum solver which takes approximately 95% of the training time. Though we have not fully exploited this possibility, the training time for the supermodular max-sum classifier can be considerably reduced by using min-cut/max-flow algorithms to solve the LAC task. The min-cut/max-flow algorithms optimized for a grid neighbourhood structure can achieve near real-time performance (Boykov and Kolmogorov, 2004). For this reason the supermodular max-sum classifier is favourable when the training time or the classification time is of importance.

The only free parameter of the learning algorithm is the regularization constant C which we tuned on the validation images. The classifier with the best performance on the validation set was then assessed on independent testing images. Due to a different size of images it is convenient to present errors in terms of the normalized additive loss function $L(\mathbf{y},\mathbf{y}') = \frac{100}{|\mathcal{T}|}\sum_{t\in\mathcal{T}}[\![y_t \neq y'_t]\!]$ corresponding to percentage of misclassified pixels in the image. Obtained results are summarized in Table 1. It is seen that the max-sum classifiers significantly outperformed the multi-class SVM on all data sets. Performances of the general and the supermodular max-sum classifiers are almost identical. This shows a good potential of the learning algorithm to extend applicability of the polynomially solvable class of supermodular max-sum problems. Note that selecting a proper supermodular function by hand is difficult due to an unintuitive form of the supermodularity conditions (7). Figure 1 shows examples of testing images and their labeling estimated by the max-sum classifier.

7.2 Learning the Rules of Sudoku

In this section, we demonstrate the algorithm for learning the max-sum classifier with a strictly trivial equivalent. We will consider a problem of learning the game rules of a logic-based number placement puzzle Sudoku[2]. Figures 2(a) and 2(b) show an example of the Sudoku puzzle and its solution, respectively. The aim of the puzzle is to fill in a 9×9 grid such that each column, each row and each of 9 non-overlapping 3×3 boxes contains the numbers from 1 to 9. A player starts

2. For more details and references see http://en.wikipedia.org/wiki/Sudoku .

(c)

Figure 2: Example of Sudoku puzzle: (a) input puzzle; (b) solution; (c) handwritten Sudoku grid created from the USPS database.

from an incompletely filled grid which is constructed such a way that the proper puzzle has a unique solution.

Our goal is to learn a max-sum classifier (artificial player) able to solve arbitrary Sudoku puzzle. A part of the rules is a priori known to the system while the rest is learned from examples of incomplete puzzle and its correct solution. In a standard scenario, the learned classifier is validated on a testing set. In this particular case, however, it is possible to show that the found max-sum classifier solves correctly all the Sudoku puzzles (the number of Sudoku solutions is approximately 6.6×10^{27}, that is, the number of puzzles is much larger).

Note, that the Sudoku puzzle can be naturally expressed as solving the *constraint satisfaction problem* CSP which is a subclass of a max-sum labeling problem when the quality functions attain only two values $\{0, -\infty\}$. From this viewpoint, a max-sum classifier is a richer model than necessarily needed for Sudoku puzzle.

Let us define the learning problem using the notation of this paper. Solving the puzzle is equivalent to solving the max-sum problem $(\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x})$. The set of objects $\mathcal{T} = \{(i, j) \mid i \in \{1, \ldots, 9\}, j \in \{1, \ldots, 9\}\}$ corresponds to the cells of a 9×9 grid. The neighbourhood structure

$$\mathcal{E} = \{\{(i, j), (i', j')\} \mid i = i' \vee j = j' \vee (\lceil i/3 \rceil = \lceil i'/3 \rceil \wedge \lceil j/3 \rceil = \lceil j'/3 \rceil)\},$$

contains pairs of cells whose relation plays a role in the game rules, that is, the cells in rows, columns, and the 3×3 boxes. The set of observations $\mathcal{X} = \{\square, 1, \ldots, 9\}$ represents the input filling of cells where the special symbol $\square$ means an empty cell. The set of labels $\mathcal{Y} = \{1, \ldots, 9\}$ corresponds to numbers which a player can fill in. The quality functions $\mathbf{q}$ and $\mathbf{g}$ are assumed to be homogeneous, that is, $q_t(x, y) = q(x, y)$ and $g_{tt'}(y, y') = g(y, y')$. Moreover, the structure of quality function $q(y, x)$ is assumed to be $q(y, x) = q(y)$ for $y = x$ and $q(y, x) = q_\square$ for $x = \square$ or $x \neq y$. The particular values of quality functions $(\mathbf{q}; \mathbf{g}) \in \mathbb{R}^{9 \times 9 + 10}$, which specify the rules of the game, are unknown to the system.

Using the setting introduced above, it is easy to see that the solution of a max-sum problem $(\mathcal{T}, \mathcal{E}, \mathcal{Y}, \mathbf{q}, \mathbf{g}, \mathbf{x})$ is a correct solution of the Sudoku puzzles if for any triplet $(y, y', y'') \in \mathcal{Y}^3$ such

$q(y,x)$

Table 2: The quality functions **q** and **g** learned from examples. The learned functions **q** and **g** satisfy the conditions (35) which guarantee the optimal solution.

that $y' \neq y''$ the quality functions satisfy the following conditions

$$q_\square < q(y) \qquad \text{and} \qquad g(y,y) < g(y',y'')\,. \tag{35}$$

The first condition just forces the max-sum classifier to use the numbers from filled in cells as labels. The second condition, in compliance with to the Sudoku rules, ensures that neighbouring cells will not be assigned the same label. The conditions (35) allows us to verify whether the found classifier is an optimal one.

Because a proper Sudoku puzzle have a unique solution it is natural to require that the max-sum classifier also guarantees this condition. The conditions (35) show that the ground truth quality function $g(y,y')$ is not supermodular. For this reasoning, Algorithm 3 for learning of the max-sum classifier with a strictly trivial solution seems to be a reasonable choice.

We created 18 distinct training sets each containing a single example of an incomplete puzzle and its correct solution. In all cases, the proposed Algorithm 3 converged to a solution after the number of iterations ranging 12×10^3 to 95×10^3 approximately, which took less than one minute on an ordinary desktop PC. The conditions (35) were satisfied for all the solutions found by an algorithm, that is, an optimal max-sum classifier was found just from a single example (using more general **q** and **g** would probably require more examples). Table 2 shows an example of the found quality functions **q** and **g**. In this case, it is even possible to precisely compute the output of the max-sum classifier by branch-and-bound algorithm since the depth searching tree is limited due the requirement on a unique solution of the Sudoku and modest complexity tractable for human players. Note, however, that no max-sum solver was required during the course of the learning algorithm.

Table 3: Recognition of Sudoku grids created from the USPS database.

7.3 Handwritten Character Recognition with Structured Outputs

In this section, we compare the max-sum classifier with a strictly trivial equivalent learned by the Perceptron Algorithm 3 against an ordinary multi-class SVM classifier. To this end, we modified the Sudoku problem from Section 7.2 in two ways. Firstly, the input observations are handwritten digits taken from the USPS database. In particular, the input observation $x \in \mathcal{X} = \mathbb{R}^{256}$ is a vector containing pixels of a grey-scale image 16×16 which depicts a digit from 1 to 9. Secondly, the input of the classifier is a fully solved Sudoku grid, that is, $\mathcal{Y} = \{1,\dots,9\}$, as the multi-class SVM cannot solve an incomplete puzzle unlike the max-sum classifier. The neighbourhood structure $(\mathcal{T},\mathcal{E})$ is the same as in the experiment from Section 7.2. Figure 2(c) shows and example of input observations and Figure2(b) shows a corresponding labeling to be estimated by the max-sum classifier.

Similarly to the experiment in Section 7.2, we considered a quality function $g(y,y')$ of a general form $\mathbf{g} \in \mathbb{R}^{|\mathcal{Y}|^2}$. However, we used two different forms of the quality functions $q(x,y)$. First, a linear function $q(x,y) = \langle \mathbf{w}_y, x\rangle$ which lead to learning a parameter vector $\mathbf{w} = (\mathbf{w}_1;\dots;\mathbf{w}_{|\mathcal{Y}|};\mathbf{g}) \in \mathbb{R}^d$ of dimension $d = 256|\mathcal{Y}| + |\mathcal{Y}|^2 = 2385$. Second, we applied the Gaussian kernel function defined as $k(x,x') = \exp(-\sigma\|x-x'\|^2)$ for some $\sigma > 0$. In this case, the quality function is $q(x,y) = \langle \mathbf{v}_y, \mathbf{k}(x)\rangle$ where $\mathbf{k}(x) = (k(x,x_t^j) \mid t \in \mathcal{T}, j = 1,\dots,m)$ denotes a vector of kernel functions centered in all training observations. The corresponding parameter vector $\mathbf{w} = (\mathbf{v}_1;\dots;\mathbf{v}_{|\mathcal{Y}|};\mathbf{g}) \in \mathbb{R}^d$ was of dimension $d = m|\mathcal{T}||\mathcal{Y}| + |\mathcal{Y}|^2 = 7371$.

We created a set of 30 examples of Sudoku grids $\mathbf{x} = (x_t \in \mathcal{X} \mid t \in \mathcal{T})$ and their solutions $\mathbf{y} = (y_t \in \mathcal{Y} \mid t \in \mathcal{T})$. Note that a single grid $\mathbf{x}$ contains $9 \times 9 = 81$ digits from the USPS database. We generated 3 random splits of the 30 examples into 10 training, 10 validation and 10 testing examples. The Perceptron Algorithm 3 required a few seconds to converge to a solution with zero training error when the linear kernel was used and around 3 minutes for the Gaussian kernel. The optimal kernel width σ was tuned on the validation data. In addition, we also tuned the regularization constant C for the multi-class SVM. The model with the best performance on the validation set was then assessed on the testing data. Table 3 shows the average classification performance computed over the 3 random splits.

It is seen that the max-sum classifier significantly outperforms the multi-class SVM regardless of the used kernel functions. The classification error 5.80% achieved for the multi-class SVM with the Gaussian kernel is slightly higher than 4.00% reported in Schölkopf et al. (1995). The reason is that we trained on a smaller number of examples (namely, 810 compared to 7291). On the other hand, the smaller training set is sufficient to achieve nearly error-less performance when the structure in the output space is considered. In particular, the error of the max-sum classifier with the Gaussian kernel is 0.04%. Note that without considering the structure a human recognition rate is 2.5% and the best published machine performance is 2.6% (Schölkopf et al., 1995).

8. Conclusions

In this article we have examined discriminative learning of max-sum classifiers. Learning of a max-sum classifier leads to satisfying a set of linear inequalities or solving a QP task with linear inequality constraints. A characteristic feature of these tasks is a huge number of linear constraints which is proportional to the number of possible responses (labelings) of a max-sum classifier. Efficient optimization methods for solving these tasks are the perceptron and the cutting plane algorithm, respectively. These methods manage to solve large problems provided the response of a max-sum classifier can be evaluated efficiently. Direct application of these methods is not tractable because computing a response of a general max-sum classifier is NP-complete.

We have proposed variants of the perceptron and the cutting plane algorithm for learning supermodular max-sum classifiers whose response can be computed efficiently in polynomial time. We have augmented the optimization tasks by additional linear constraints which guarantee that a max-sum classifier is supermodular. The perceptron and the cutting plane algorithm are modified such that added constraints on supermodularity are maintained satisfied during the course of optimization. This modification allows to compute the response of a max-sum classifier efficiently thus making the learning problem tractable.

We have defined a class of max-sum classifiers with a strictly trivial equivalent which are solvable exactly in polynomial time by an LP relaxation. We have showed that this class covers at least acyclic and supermodular max-sum classifiers with a unique solution. Another favorable property of this class is that the learning problems contain only polynomially-sized sets of linear constraints. As a result, the perceptron and the cutting plane algorithms do not require to call any max-sum solver during the course of optimization.

We have proposed a variant of the cutting plane algorithm which can approximately solve the learning problem formulated for the general max-sum classifier. The response of the max-sum classifier is approximated by an LP relaxation for which specialized optimization algorithms exist. Using an approximate response prohibits a guarantee that the cutting plane algorithm finds a solution with an arbitrary precision. This is not an obstacle, however, for using the algorithm in practice as we demonstrated experimentally.

Acknowledgments

Authors are deeply grateful to Prof. Michail I. Schlesinger for inspiring this work by many important ideas which he delivered in personal communication and during his lectures on structural pattern recognition. Our special thanks go to Tomáš Werner for reading this article and giving us many valuable comments.

The authors would like to acknowledged the support from the EU INTAS project PRINCESS 04-77-7347. The main part of this work has been done while the first author was with the Center for Machine Perception. The first author was also supported by Marie Curie Intra-European Fellowship grant SCOLES (MEIF-CT-2006-042107) during his current fellowship in Fraunhofer-FIRST.IDA institute.

Appendix A.

In this appendix we prove Theorem 3 introduced in Section 2.3. Prior to proving the theorem, we will introduce the concept of *local consistency* (Schlesinger, 1976) and the theorem asserting that the problems with a trivial equivalent contain the acyclic and supermodular problems (Schlesinger, 1976; Schlesinger and Flach, 2000).

Definition 3 *The maximal node* (t,y) *is called* locally consistent *if for each neighboring object* $t' \in \mathcal{N}(t)$ *there exists a maximal edge* $\{(t,y),(t',y')\}$. *The maximal edge* $\{(t,y),(t',y')\}$ *is called* locally consistent *if the nodes* (t,y) *and* (t',y') *are maximal.*

The maximal nodes and maximal edges which do not satisfy Definition 3 will be called *locally inconsistent*.

Theorem 6 *Schlesinger (1976); Schlesinger and Flach (2000) Let* $P = (\mathcal{T},\mathcal{E},\mathcal{Y},\mathbf{q},\mathbf{g},\mathbf{x})$ *be a max-sum problem. If* $(\mathcal{T},\mathcal{E})$ *is an acyclic graph or quality functions* $\mathbf{g}$ *are supermodular then* P *is equivalent to a trivial problem.*

Recall, that P with the optimal solution $\mathbf{y}^* \in \mathcal{Y}^{\mathcal{T}}$ has a trivial equivalent $P^{\boldsymbol{\varphi}}$ if there exist potentials $\boldsymbol{\varphi}$ such that the following set of linear inequalities holds

$$\begin{array}{rcll} q_t^{\boldsymbol{\varphi}}(y_t^*,x_t) & \geq & q_t^{\boldsymbol{\varphi}}(y,x_t)\,, & t \in \mathcal{T}\,, y \in \mathcal{Y} \setminus \{y_t^*\}\,, \\ g_{tt'}^{\boldsymbol{\varphi}}(y_t^*,y_{t'}^*) & \geq & g_{tt'}^{\boldsymbol{\varphi}}(y_t,y_{t'})\,, & \{t,t'\} \in \mathcal{E}\,, (y,y') \in \mathcal{Y}^2 \setminus \{(y_t^*,y_{t'}^*)\}\,. \end{array} \tag{36}$$

The system (36) differs from the definition of problems with a strictly trivial equivalent (19) just by using the non-strict inequalities. Finally, we will prove two auxiliary lemmas:

Lemma 2 *Let* P *be an acyclic problem which has a unique solution* $\mathbf{y}^*$ *and let* $P^{\boldsymbol{\varphi}}$ *be a trivial equivalent of* P. *Then only two cases can occur: (i)* $P^{\boldsymbol{\varphi}}$ *is strictly trivial or (ii) there is at least one maximal locally inconsistent node or edge.*

Proof We will show that violating both the assertions (i) and (ii) contradicts the assumption that $\mathbf{y}^*$ is unique. Assuming $P^{\boldsymbol{\varphi}}$ is not strictly trivial implies that there exists a maximal node (t,y_t^0) such that $y_t^0 \neq y_t^*$. Let us construct a labeling $\mathbf{y}^0$ such that y_t^0 belongs to $\mathbf{y}^0$. The remaining labels are determined by repeating the following procedure $(|\mathcal{T}|-1)$ times:

- Let $t' \in \mathcal{T}$ be an object whose label $y_{t'}^0$ has been already determined and let $t'' \in \mathcal{N}(t')$ be an object whose label $y_{t''}^0$ has not been determined yet. Then set up the label $y_{t''}^0$ such that $\{(t',y_{t'}^0),(t'',y_{t''}^0)\}$ is a maximal edge.

The constructed labeling $\mathbf{y}^0$ is the optimal solution of P because it is composed of maximal nodes and edges. Note that this simple construction of the optimal labeling is possible because the graph $(\mathcal{T},\mathcal{E})$ is acyclic. Thus we have $\mathbf{y}^0 \neq \mathbf{y}^*$ because $y_t^0 \neq y_t^*$ which implies that $\mathbf{y}^*$ is not unique. ■

Lemma 3 *Let* P *be a supermodular problem with an unique solution* $\mathbf{y}^*$ *and let* $P^{\boldsymbol{\varphi}}$ *be a trivial equivalent of* P. *Then only two cases can occur: (i)* $P^{\boldsymbol{\varphi}}$ *is strictly trivial or (ii) there is at least one maximal locally inconsistent node or edge.*

Proof We will show that violating both the assertions (i) and (ii) contradicts the assumption that $\mathbf{y}^*$ is unique. Let $\mathcal{Y}_t^0 = \{(t,y) \mid q_t^{\boldsymbol{\varphi}}(y,x_t) = \max_{y' \in \mathcal{Y}} q_t^{\boldsymbol{\varphi}}(y',x_t)\}$ denote a set of all maximal nodes corresponding to the object $t \in \mathcal{T}$. Let us construct the labeling $\mathbf{y}^h = (y_t^h \mid t \in \mathcal{T})$ composed of the highest maximal nodes; (t,y_t^h) is the highest maximal node if $(t,y_t^h) \in \mathcal{Y}_t^0$ and $y_t^h > y$ for all $(t,y) \in \mathcal{Y}_t^0 \setminus \{t,y_t^0\}$. Recall, that the labels are fully ordered for the supermodular problems.

Now, we show that the labeling $\mathbf{y}^h$ is optimal since all its edges $\{(t,y_t^h),(t',y_{t'}^h)\} \in \mathcal{E}_{\mathcal{Y}}$ are also maximal. Let us assume that there exists an edge $\{(t,y_t^h),(t',y_{t'}^h)\}$ which is not maximal. Then, by assumption of local consistency, there exist edges $\{(t,y_t^h),(t',y_{t'})\}$ and $\{(t,y_t),(t',y_{t'}^h)\}$ which are maximal. Note that $y_t < y_t^h$ and $y_{t'} < y_{t'}^h$ because (t,y_t^h) and $(t',y_{t'}^h)$ are the highest nodes. From the condition of supermodularity (7) and (4a) we have

$$\begin{aligned} 0 \leq g_{tt'}(y_t^h,y_{t'}^h) + g_{tt'}(y_t,y_{t'}) - g_{tt'}(y_t^h,y_{t'}) - g_{tt'}(y_t,y_{t'}^h) \\ = g_{tt'}^{\boldsymbol{\varphi}}(y_t^h,y_{t'}^h) + g_{tt'}^{\boldsymbol{\varphi}}(y_t,y_{t'}) - g_{tt'}^{\boldsymbol{\varphi}}(y_t^h,y_{t'}) - g_{tt'}^{\boldsymbol{\varphi}}(y_t,y_{t'}^h)\,. \end{aligned}$$

This condition, however, cannot be satisfied if the edge $\{(t,y_t^h),(t',y_{t'}^h)\}$ is not maximal which is a contradiction. Similarly, we can show that the labeling $\mathbf{y}^l$ composed of the lowest maximal nodes (defined analogically) is also optimal.

Finally, the assumption that $P^{\boldsymbol{\varphi}}$ is not strictly trivial implies that for some object $t \in \mathcal{T}$ there exists a maximal node (t,y_t^0) such that $y_t^0 \neq y_t^*$. W.l.o.g. we can select (t,y_t^0) which is either the highest maximal or the lowest maximal node. Thus $y_{t^*}^0$ belongs either to the labeling $\mathbf{y}^h$ or $\mathbf{y}^l$ which are optimal and differ from $\mathbf{y}^*$. This contradicts the assumption that $\mathbf{y}^*$ is unique. ■

Proof of Theorem 3: Let P be an acyclic or supermodular max-sum problem with the unique solution $\mathbf{y}^* \in \mathcal{Y}^{\mathcal{T}}$. Let $\boldsymbol{\varphi}$ be the potentials such that the max-sum problem $P^{\boldsymbol{\varphi}}$ is a trivial equivalent of P. The existence of such $P^{\boldsymbol{\varphi}}$ is guaranteed by Theorem 6. Then, by Lemma 2 and Lemma 3, $P^{\boldsymbol{\varphi}}$ is either strictly trivial or there exists a maximal node (t,y_t^0) or a maximal edge $\{(t,y_t^0),(t',y_{t'}^0)\}$ which are locally inconsistent, that is, (t,y_t^0) and $\{(t,y_t^0),(t',y_{t'}^0)\}$ do not belong to $\mathbf{y}^*$. We will introduce a procedure which changes the potentials $\boldsymbol{\varphi}$ in such a way that the inconsistent maximal node (t,y_t^0) or inconsistent maximal edge $\{(t,y_t^0),(t',y_{t'}^0)\}$, respectively, become non-maximal while other maximal (non-maximal) nodes or edges remain maximal (non-maximal). Repeating this procedure for all inconsistent maximal nodes and edges makes the inequalities (36) satisfied strictly, that is, the problem $P^{\boldsymbol{\varphi}}$ becomes strictly trivial which is to be proven. The procedures for elimination of inconsistent nodes and edges read:

Elimination of the inconsistent maximal node (t,y_t^0)**:** Let $t' \in \mathcal{N}(t)$ be such a neighbor of t that the set of edges $\mathcal{E}_{tt'}(y_t^0) = \{\{(t,y_t^0),(t',y_{t'})\} \mid y_{t'} \in \mathcal{Y}\}$ does not contain any maximal edge. Let ε be a number computed as

$$\varepsilon = \frac{1}{2}\left[\max_{(y,y') \in \mathcal{Y}^2} g_{tt'}^{\boldsymbol{\varphi}}(y,y') - \max_{y' \in \mathcal{Y}} g_{tt'}^{\boldsymbol{\varphi}}(y_t^0,y')\right].$$

Since $\mathcal{E}_{tt'}(y_t^0)$ does not contain maximal edges this implies $\varepsilon > 0$. Adding ε to the potential $\varphi_{tt'}(y_t^0) := \varphi_{tt'}(y_t^0) + \varepsilon$ decreases the quality $q_t^{\boldsymbol{\varphi}}(y_t^0,x_t) = q_t(y_t^0,x_t) - \sum_{t'' \in \mathcal{N}(t)} \varphi_{tt''}(y_t^0)$ by ε and increases the qualities $g_{tt'}^{\boldsymbol{\varphi}}(y,y') = g_{tt'}(y,y') + \varphi_{tt'}(y) + \varphi_{t't}(y')$, $\{(t,y),(t',y')\} \in \mathcal{E}_{tt'}(y_t^0)$ by ε. This change makes the node (t,y_t^0) non-maximal while the edges $\mathcal{E}_{tt'}(y_t^0)$ remain non-maximal as before. The qualities of other nodes and edges remain unchanged.

Elimination of the inconsistent maximal edge $\{(t,y_t^0),(t',y_{t'}^0)\}$**:** W.l.o.g. let $(t',y_{t'}^0)$ be a non-maximal node. Notice, that all edges from $\mathcal{E}_{t't}(y_{t'}^0) = \{(t,y_t),(t',y_{t'}^0)\} \mid y_t \in \mathcal{Y}\}$ are locally inconsistent and they cannot be a part of the optimal solution. Let ε be a number computed as

$$\varepsilon = \frac{1}{2}\left[\max_{y\in\mathcal{Y}} q_{t'}^{\boldsymbol{\varphi}}(y,x_{t'}) - q_{t'}^{\boldsymbol{\varphi}}(y_{t'}^0,x_{t'})\right].$$

Because $(t',y_{t'}^0)$ is non-maximal $\varepsilon > 0$. Subtracting ε from the potential $\varphi_{t't}(y_{t'}^0) := \varphi_{t't}(y_{t'}^0) - \varepsilon$ decreases the qualities $g_{tt'}^{\boldsymbol{\varphi}}(y,y') = g_{tt'}(y,y') + \varphi_{tt'}(y) + \varphi_{t't}(y')$, $\{(t,y),(t',y')\} \in \mathcal{E}_{t't}(y_{t'}^0)$ by ε and increases the quality $q_{t'}^{\boldsymbol{\varphi}}(y_{t'}^0,x_{t'}) = q_{t'}(y_{t'}^0,x_{t'}) - \sum_{t''\in\mathcal{N}(t')}\varphi_{tt''}(y_{t'}^0)$ by ε. This change makes all edges from $\mathcal{E}_{t't}(y_{t'}^0)$ non-maximal while the node $(t',y_{t'}^0)$ remains non-maximal as before. The qualities of other nodes and edges remain unchanged. ■

Appendix B.

In this appendix we prove Lemma 1 given in Section 6.

Proof of Lemma 1: We show that if a new variable was added then we can construct a vector $\overline{\boldsymbol{\beta}}$ such that optimizing the dual objective $Q_D(\boldsymbol{\alpha})$ over a line segment between the current solution $\overline{\boldsymbol{\alpha}}$ and the vector $\overline{\boldsymbol{\beta}}$ yields a guaranteed improvement. Since the reduced QP task solved in Step 2 optimizes in the space of all selected variables which contains the line segment between $\overline{\boldsymbol{\alpha}}$ and $\overline{\boldsymbol{\beta}}$, the obtained improvement cannot be smaller.

Let us assume an optimization of the dual objective $Q_D(\boldsymbol{\alpha})$ of the QP task (27) w.r.t. a line segment between the current solution $\overline{\boldsymbol{\alpha}}$ and an arbitrary feasible vector $\overline{\boldsymbol{\beta}}$. The problem is equivalent to searching for the maximum of an univariate quadratic function

$$\begin{aligned} Q_L(\tau) &= Q_D\Big((1-\tau)\overline{\boldsymbol{\alpha}} + \tau\overline{\boldsymbol{\beta}}\Big) \\ &= (1-\tau)\langle \mathbf{b}, \overline{\boldsymbol{\alpha}}\rangle + \tau\langle \mathbf{b}, \overline{\boldsymbol{\beta}}\rangle - \frac{1}{2}(1-\tau)^2\langle \overline{\boldsymbol{\alpha}}, \mathbf{H}\overline{\boldsymbol{\alpha}}\rangle - \tau(1-\tau)\langle \overline{\boldsymbol{\beta}}, \mathbf{H}\overline{\boldsymbol{\alpha}}\rangle - \frac{1}{2}\tau^2\langle \overline{\boldsymbol{\beta}}, \mathbf{H}\overline{\boldsymbol{\beta}}\rangle\,, \end{aligned}$$

over the closed interval $0 \le \tau \le 1$. The maximum is attained at the vector

$$\overline{\boldsymbol{\alpha}}_{\text{new}} = (1-\overline{\tau})\overline{\boldsymbol{\alpha}} + \overline{\tau}\overline{\boldsymbol{\beta}} \tag{37}$$

where

$$\overline{\tau} = \operatorname*{argmax}_{0\le\tau\le 1} Q_L(\tau)\,. \tag{38}$$

The derivative of $Q_L(\tau)$ reads

$$\frac{\partial Q_L(\tau)}{\partial \tau} = \langle \mathbf{b}, \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}\rangle + (1-\tau)\langle \overline{\boldsymbol{\alpha}}, \mathbf{H}\overline{\boldsymbol{\alpha}}\rangle - (1-2\tau)\langle \overline{\boldsymbol{\beta}}, \mathbf{H}\overline{\boldsymbol{\alpha}}\rangle - \tau\langle \overline{\boldsymbol{\beta}}, \mathbf{H}\overline{\boldsymbol{\beta}}\rangle\,.$$

An objective function is improved, that is, $Q_D(\overline{\boldsymbol{\alpha}}_{\text{new}}) - Q_D(\overline{\boldsymbol{\alpha}}) > 0$, iff the vector $\overline{\boldsymbol{\beta}}$ satisfies

$$\left.\frac{\partial Q_L(\tau)}{\partial \tau}\right|_{\tau=0} = \langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}}\rangle > 0\,. \tag{39}$$

Provided (39) holds, the maximum of $Q_L(\tau)$ w.r.t. $0 \le \tau \le 1$ is attained within the open interval $0 < \tau < 1$ or on its boundary $\tau = 1$. The maximum of $Q_L(\tau)$ w.r.t. unbounded τ can be found by solving $\frac{\partial Q_L}{\partial \tau} = 0$ for τ. If the resulting τ exceeds 1 then the optimum of the line segment optimization is attained at $\overline{\tau} = 1$. Thus we can write the solution of (38) in a closed form

$$\overline{\tau} = \min \left\{ 1, \frac{\langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}} \rangle}{\langle \overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}, \mathbf{H}(\overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}) \rangle} \right\} . \tag{40}$$

Analytical formulas for improvement can be derived substituting (37) and (40) to $\Delta = Q_D(\overline{\boldsymbol{\alpha}}_{\text{new}}) - Q_D(\overline{\boldsymbol{\alpha}})$. For $\overline{\tau} < 1$ we get

$$\Delta = \frac{\langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}} \rangle^2}{2\langle \overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}, \mathbf{H}(\overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}) \rangle} , \tag{41}$$

and for $\overline{\tau} = 1$ we get

$$\Delta \quad = \quad \langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}} \rangle - \frac{1}{2}\langle \overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}, \mathbf{H}(\overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}) \rangle \ge \frac{1}{2}\langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}} \rangle . \tag{42}$$

The last inequality in (42) follows from $\langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}} \rangle \ge \langle \overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}, \mathbf{H}(\overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}) \rangle$ which holds for $\overline{\tau} = 1$ as seen from (40).

Let us consider that a new variable with index u_j was added in Step 3(b), that is, the condition (30) was satisfied. Using $\langle \overline{\mathbf{w}}, \mathbf{z}_{u_j} \rangle = [\mathbf{H}\boldsymbol{\alpha}]_{u_j}$ we can rewrite the condition (30) as

$$\frac{C}{m}[\mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}}]_{u_j} - \sum_{i \in I_j} \overline{\alpha}_i [\mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}}]_i > \frac{\varepsilon}{m} . \tag{43}$$

Let us construct the feasible vector $\overline{\boldsymbol{\beta}} = (\overline{\beta}_1, \ldots, \overline{\beta}_n)^T$ as follows

$$\overline{\beta}_i = \begin{cases} \frac{C}{m} & \text{if} \quad i = u_j , \\ 0 & \text{if} \quad i \in I_j \setminus \{u_j\} , \\ \overline{\alpha}_i & \text{if} \quad i \in I \setminus I_j . \end{cases} \tag{44}$$

As was shown above, optimization over the line segment yields an improvement provided (39) holds. Substituting $\overline{\boldsymbol{\beta}}$ constructed by (44) into the formula (39) we get

$$\frac{dQ_L}{d\tau}\Big|_{\tau=0} = \langle \overline{\boldsymbol{\beta}} - \overline{\boldsymbol{\alpha}}, \mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}} \rangle = \frac{C}{m}[\mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}}]_{u_j} - \sum_{i \in I_j} \overline{\alpha}_i [\mathbf{b} - \mathbf{H}\overline{\boldsymbol{\alpha}}]_i > \frac{\varepsilon}{m} , \tag{45}$$

where the last inequality follows from (43). This implies that optimizing w.r.t. line segment between $\overline{\boldsymbol{\alpha}}$ and the vector $\overline{\boldsymbol{\beta}}$ yields positive improvement. Now, we derive a lower bound on this improvement. Combining (45) with (42) we immediately get

$$\Delta \ge \frac{\varepsilon}{2m} \quad \text{for} \quad \overline{\tau} = 1 . \tag{46}$$

Before deriving the bound for $\bar{\tau} < 1$, we must find an upper bound on the denominator of (41). Let us define $\mathcal{A}_j = \left\{\boldsymbol{\alpha} \,|\, \sum_{i \in I_j} \alpha_i = \frac{C}{m}\,, \alpha_i \geq 0\,, \forall i \in I_j\right\}$. Then we can write

$$\begin{aligned}
\langle \overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}, \mathbf{H}(\overline{\boldsymbol{\alpha}} - \overline{\boldsymbol{\beta}}) \rangle &\leq \max_{j \in \mathcal{J}} \left\| \sum_{i \in I_j} \overline{\alpha}_i \mathbf{z}_i - \sum_{i \in I_j} \overline{\beta}_i \mathbf{z}_i \right\|^2 \\
&\leq \left(2 \max_{j \in \mathcal{J}} \max_{\boldsymbol{\alpha} \in \mathcal{A}_j} \left\| \sum_{i \in I_j} \alpha_i \mathbf{z}_i \right\| \right)^2 \qquad (47) \\
&= \frac{4C^2}{m^2} \max_{j \in \mathcal{J}} \max_{i \in I_j} \|\mathbf{z}_i\|^2 \,.
\end{aligned}$$

Combining (45) and (47) with (41) yields

$$\Delta \geq \frac{\varepsilon^2}{8C^2R^2} \quad \text{for} \quad \bar{\tau} = 1 \quad \text{and} \quad R = \max_{j \in \mathcal{J}} \max_{i \in I_j} \|\mathbf{z}_i\| \,. \qquad (48)$$

Taking the minimum of improvements (46) and (48) gives the bound on the minimal improvement. ■

Abstract

We introduce a computationally feasible, "constructive" active learning method for binary classification. The learning algorithm is initially formulated for separable classification problems, for a hyperspherical data space with constant data density, and for great spheres as classifiers. In order to reduce computational complexity the version space is restricted to spherical simplices and learning procedes by subdividing the edges of maximal length. We show that this procedure optimally reduces a tight upper bound on the generalization error. The method is then extended to other separable classification problems using products of spheres as data spaces and isometries induced by charts of the sphere. An upper bound is provided for the probability of disagreement between classifiers (hence the generalization error) for non-constant data densities on the sphere. The emphasis of this work lies on providing mathematically exact performance estimates for active learning strategies.

Keywords: active learning, spherical subdivision, error bounds, simplex halving

1. Introduction

Active learning methods seek a solution to inductive learning problems by incorporating the selection of training data into the learning process. In these schemes, the labeling of a data point occurs only after the algorithm has explicitly asked for the corresponding label, and the goal of the "active" data selection is to reach the same accuracy as standard "passive" algorithms—but with less labeled data points. In many practical tasks, the acquisition of unlabeled data can be automated, while the actual labeling must often be done by humans and is therefore time consuming and costly. In these cases, active learning methods—which usually trade labeling costs against the computational burden required for optimal data selection—can be a valuable alternative.

There are two approaches to active learning. So-called query filtering methods (Freund et al., 1997; Opper et al., 1992) operate on a given pool of unlabeled data and select—at every learning step—a "most informative" data point for subsequent labeling. So-called constructive methods lit-

erally "construct" an unlabeled datum and ask the user to provide a label. There is strong empirical evidence for many learning scenarios and for different selection procedures, that active learning methods can reduce the number of labeled training data which are needed to reach a predefined generalization performance (see Balcan et al., 2006; Fine et al., 2002; Freund et al., 1997; Tong and Koller, 2001; Warmuth et al., 2002). In addition, theoretical work has shown that active learning strategies can achieve an exponential reduction of the generalization error *with high probability* (see Balcan et al., 2006; Freund et al., 1997). In this contribution, we put the emphasis on a mathematically rigorous derivation of *hard* upper bounds for the generalization error. This is in contrast to other studies which give bounds in probability (see Freund et al., 1997) or discuss asymptotic behavior (see Bach, 2007).

We use a geometrical approach to active learning which is based on the concept of a version space (see Mitchell, 1982; Tong and Koller, 2001). Loosely speaking, given a set of predictors and a set of labeled training data, "version space" denotes the set of models whose predictions are consistent with the training data. If a version space can be defined, active learning strategies should evaluate data points which allow the learning machine to maximally reduce the "size" of its version space at every learning step. Some active learning algorithms try to halve the volume of the version space (see Tong and Koller, 2001). In contrast to this, our approach is to reduce the *maximal distance* between pairs of points that belong to the version space. We prefer distance over volume simply because it is impossible to compute the exact volume of version space in high dimensions. A detailed discussion of this problem can be found at the end of Section 7. For special types of data spaces, our method of maximal length reduction coincides with volume reduction. In this case, we observe a rapid (that is, exponential) progress in learning, as is explicitly shown in Section 4 and Proposition 9 of Section 6 for data which is arbitrarily distributed on an n-dimensional torus.

In the following we will consider the simple case of a separable, binary classification problem. Assuming the knowledge of the data density μ on the data space M, the generalization distance $d^G(c_1,c_2)$ of two classifiers $c_1,c_2 : M \to \mathbb{Z}_2 := \{0,1\}$ is given by the integral

$$d^G(c_1,c_2) := \frac{1}{\mathrm{Vol}(M)} \int_{D(c_1,c_2)} \omega,$$

where $D(c_1,c_2) := \{x \in M \mid c_1(x) \neq c_2(x)\}$ is the set of points which are classified differently by the two classifiers, and ω denotes the volume form of M (see Section 2). If we further assume the labeling of the data to be generated by an unknown classifier $c^* : M \to \mathbb{Z}_2$, the important question is: *Can we give tight upper bounds on the generalization error $d^G(c,c^*)$ of some classifier c, and can we reduce this bound during learning in an optimal way?* Inspired by this question, we introduce a constructive active learning algorithm which reduces such a bound by successive subdivisions of the version space on a hypersphere. This then allows us to compute exact and tight generalization error bounds for several classes of data densities. After deriving the bounds for the case of an uniform distribution on the hypersphere, we use the notion of Riemannian isometries to extend the algorithm and the error bounds to a set of selected data densities on other data spaces including $\mathbb{R}^n$. In a second step, we extend our results to product manifolds in order to obtain sharp error bounds for a larger set of data densities. Finally, we provide bounds for arbitrary densities on $\mathbb{R}^n$, hyperspheres and products thereof.

The article is organized as follows: After introducing the geometric setup of active learning for binary classification (Section 2), we formulate a learning method for data distributed on the unit sphere $S^n \subset \mathbb{R}^{n+1}$ (Section 3). Thereafter, we extend the basic algorithm to a broader class

of separable, binary classification problems using isometries induced by charts of the sphere and products of hyperspheres (Sections 4, 5). This will include perceptrons (that is, linear classifiers with bias on $\mathbb{R}^n$) as a special case. Upper bounds are provided for the generalization error for non-constant data densities for binary classification problems on the sphere (Section 6) and for linear classifiers without bias in $\mathbb{R}^n$ (Section 7). Finally, Section 8 provides an empirical evaluation of the geometric method. As our focus lies on a theoretical analysis of active learning algorithms, applications of the proposed algorithm to concrete problems have to be of second importance.

2. A Geometric Setup for Active Learning

In the sequel, we will apply some standard constructions from differential geometry. We refer to Appendix B for a quick introduction to the terminology.

Let M be an n-dimensional compact manifold, the *data space*, equipped with a Riemannian metric g. One might object to this type of data space, since the compactness assumption seems to rule out the most important instance of data space, the Euclidean space $\mathbb{R}^n$. However, this is not the case, because $\mathbb{R}^n$, or any submanifold therein, can be embedded into S^n, the n-sphere, by the inverse of stereographic projection (see Section 4). Recently, spherical data spaces have received some attention in machine learning (see Lebanon and Lafferty, 2004; Belkin and Niyogi, 2004; Minh et al., 2006).

We assume the existence of an *unknown binary classifier* $c^* : M \to \mathbb{Z}_2 := \{0,1\}$ and a given set of labeled data points $\{(x_1,y_1),\ldots,(x_I,y_I))\}$, $(x_i,y_i) \in M \times \mathbb{Z}_2$, with correct labels, that is, $c^*(x_i) = y_i$. Now, the *binary classification problem* asks for an approximation $c : M \to \mathbb{Z}_2$ which minimizes the *generalization error*, that is, the probability of misclassification of data points. This can be formalized as follows.

The Riemannian volume form ω which belongs to the metric g is given in local coordinates $x : M \supset U \to \mathbb{R}^n$ by

$$\omega = \sqrt{\det(g)}dx_1 \wedge \ldots \wedge dx_n, \tag{1}$$

where U is some open chart domain in M. We assume that the Riemannian volume form ω (see Equation 1) represents up to a scaling factor $\mathrm{Vol}(M) := \int_M \omega$ the p.d.f. of the data points $x \in M$. This allows us to interpret the probability of disagreement between two classifiers c_1, c_2 as a distance measure[1] on the set of all classifiers:

$$d^G(c_1,c_2) := \frac{1}{\mathrm{Vol}(M)} \int_{D(c_1,c_2)} \omega, \tag{2}$$

where $D(c_1,c_2) := \{x \in M \mid c_1(x) \neq c_2(x)\}$ is called the *disagreement area*. In these terms, the generalization error of c is given by $d^G(c,c^*)$.

3. Subdivisions of the Sphere

In order to be able to compute upper bounds on d^G, we need to impose restrictions on the data space M as well as on the set of classifiers.

1. Depending on the regularity conditions imposed on the classifiers, it might happen that $d^G(c_1,c_2) = 0$ while $c_1 \neq c_2$ on a set of measure zero.

We start with the following simple setup: Let $M = S^n = \{x \in \mathbb{R}^{n+1} \mid \langle x,x\rangle = 1\}$, the n-sphere with its canonical Riemannian metric and denote by C the set of *hemisphere classifiers*

$$c : S^n \to \mathbb{Z}_2, \quad c(x) := \begin{cases} 1 & : \quad \langle x,p\rangle \geq 0 \\ 0 & : \quad \langle x,p\rangle < 0 \end{cases} .$$

Here, $p \in S^n$ is the center of the hemisphere, and $\langle .,. \rangle$ denotes the Euclidean scalar product in $\mathbb{R}^{n+1}$. This setup implies that the data are uniformly distributed on the sphere. The use of closed hemispheres as classifiers is appropriate for spherical data, since hemispheres are the direct analog to half spaces in Euclidean geometry. A simple, yet crucial, observation is the duality $C = S^n$. By a slight abuse of notation, we use the symbol c to denote both, the classifier and the center of the hemisphere. Concerning the generalization distance of two classifiers we have the following proposition.

Proposition 1 *For hemispheres $c_1, c_2 \in C$*

$$d^G(c_1,c_2) = \frac{1}{\pi} d(c_1,c_2),$$

where $d(c_1,c_2) := \arccos(\langle c_1,c_2\rangle)$ is the geodesic distance on S^n.

Proof The disagreement area $D(c_1,c_2)$ consists of two congruent lunes on the sphere. The area of a lune is proportional to its opening angle $\alpha = d(c_1,c_2)$. Since the total volume of the unit sphere $V := \int_{S^n} \omega$ with respect to its canonical Riemannian metric and volume form is not equal to one, we have to normalize:

$$d^G(c_1,c_2) = \frac{1}{V} \int_{D(c_1,c_2)} \omega = \frac{1}{V} \left(\frac{\alpha}{\pi} V \right) = \frac{1}{\pi} d(c_1,c_2).$$

■

We assume the true classifier c^* to be some unknown hemisphere. If $(x,1)$ is a labeled data point, it follows that c^* is contained in the closed hemisphere around x. Thus, given a labeled set $\{(x_1,y_1),\ldots,(x_I,y_I))\}$, c^* is contained in the intersection V of the corresponding hemispheres. The *version space* of a labeled set (see Mitchell, 1982; Tong and Koller, 2001) is defined as the set of classifiers which are consistent with the given labeled data. In our case, the version space coincides with the intersection V. Geometrically, V is a convex spherical polytope, a high-dimensional generalization of a spherical polygon whose edges are segments of great circles and whose $(n-1)$-dimensional facets are segments of $(n-1)$-dimensional great spheres within S^n.

In theory, one can compute the vertices of the version space of any finite labeled set. An iterative algorithm would reduce this polytope by taking intersections with hemispheres corresponding to new data points. Unfortunately, during this process, the number of vertices of the polytope grows exponentially. Thus, the computational costs render its explicit computation impossible even for low dimensions.

One possibility to reduce the immense computational complexity of polytopes is to work with *spherical simplices*. This motivates the following active learning algorithm:

Definition 2 (Simplex algorithm)

1. *Specify some maximal edge length $\varepsilon > 0$ as termination criterion. Choose a random orthogonal matrix. Ask for the labels of the $n+1$ column vectors. This results in a set of admissible classifiers $S \subset S^n$ which is an equilateral simplex on S^n.*
2. *Select one of the edges of maximal length of the current simplex S. If its length is less than ε, go to step 7. Otherwise, compute its midpoint m.*
3. *Compute a unit normal u of the plane in $\mathbb{R}^{n+1}$ spanned by m together with all vertices of S which do not belong to the edge through m.*
4. *Ask for the label l of u. If $l = 0$, replace u by $-u$.*
5. *Replace the old simplex S by the part* in direction of *u, that is, the simplex which has as vertices m as well as all vertices of S with exception of that end point e of the chosen longest edge for which $\langle u, e \rangle < 0$.*
6. *Repeat with step 2.*
7. *Return the simplex' center of mass $c \in S$ as the learned classifier.*

Figure 1 illustrates one iteration of the simplex algorithm on the sphere S^2. The "random orthogonal

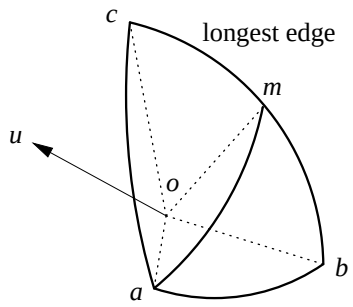

Figure 1: The drawing above shows one iteration of the simplex algorithm for the two-dimensional case, that is, for spherical triangles on the unit sphere S^2. The current version space is the spherical triangle (a,b,c). The longest edge (b,c) is about to be cut at its midpoint m. Together with the origin o, the vertex a and the point m define a plane in $\mathbb{R}^3$ one of whose unit normal vectors is $u \in S^2$. Depending on the label of u, the new triangle will be either (a,b,m) or (a,m,c).

matrix" that occurs in step one of the algorithm is meant to be drawn from the uniform distribution on the Lie group

$$O(n) = \{A \in GL(n) \mid AA^t = I\}$$

of orthogonal real matrices. A practical approach to the problem of generating such matrices can be found in Stewart (1980). The worst case generalization error after each iteration can be computed

by evaluating the maximum spherical distance of the chosen classifier to the vertices of the spherical simplex. To be explicit, the following statement holds:

Proposition 3 *If S is the current simplex from the simplex algorithm (see Definition 2) with vertices $v_1, \ldots, v_{n+1} \in S^n$, and $c \in S$ some classifier,*

$$d^G(c^*, c) \leq \max_{i,j} d(v_i, v_j) = \max_{i,j} \arccos\langle v_i, v_j \rangle.$$

This bound is tight and attainable if we allow any element of the version space to be the learned classifier. Moreover, if $c \in S$ denotes the center of mass, then

$$d^G(c^*, c) \leq \max_{i} d(c, v_i) = \max_{i} \arccos\langle c, v_i \rangle$$

is a tight and attainable upper bound for the generalization error.

Proof Within a simplex, the maximal distance of two points is realized by pairs of vertices. Now the first inequality follows from proposition 1. If all elements of the simplex are admissible classifiers, the bound is tight. The second inequality follows from the convexity of the simplex. ■

Clearly, the maximal edge length of the simplex S converges to zero. In Appendix A, we derive $O((n+1)^3)$ as a rough complexity estimate for one iteration of the simplex algorithm (see Definition 2).

Another question concerning the convergence of the algorithm is: How many iterations are needed until the maximum edge length of the initial simplex starts to drop? To this end, we have the following proposition whose proof is given in Appendix A.

Proposition 4 *Let S be the initial equilateral simplex from the simplex algorithm (see Definition 2). Let $k \in \mathbb{N}$ be the number of steps needed until the maximum of the edge lengths drops. Then*

$$n \leq k \leq \frac{n(n+1)}{2},$$

and these bounds are tight and attainable.

4. Extensions by Isometries

We will now extend our results to other data spaces by applying the concept of isometries. The easiest method to obtain isometries from the n-sphere to other data spaces is to consider charts of the sphere together with the induced metric. Being isometries, they preserve the geometry, and any generalization bounds derived for the sphere can be applied without modifications. Combining isometries with the product construction of Section 5, we end up with a large family of data densities on $\mathbb{R}^n$ to which our results are directly applicable. In Section 6, we will loosen our preconditions even further and consider the general case of arbitrary data densities.

We begin with the discussion of the stereographic chart of the n-sphere.

Stereographic chart. The stereographic projection

$$\sigma_N : S^n \setminus \{N\} \to \mathbb{R}^n,$$
$$(x_1, \ldots, x_{n+1}) \mapsto \frac{(x_1, \ldots, x_n)}{1 - x_{n+1}},$$

where $N = (0,\ldots,0,1)$ denotes the north pole, is an isometry of $S^n \setminus \{N\}$ to $(\mathbb{R}^n, g)$, where the Riemannian metric g is given by

$$g_x(v,w) = \frac{4}{(1+\|x\|^2)^2}\langle v,w\rangle.$$

See Figure 2 for an illustration of the two-dimensional case. Hence, we can *identify* $S^n \setminus \{N\}$ with

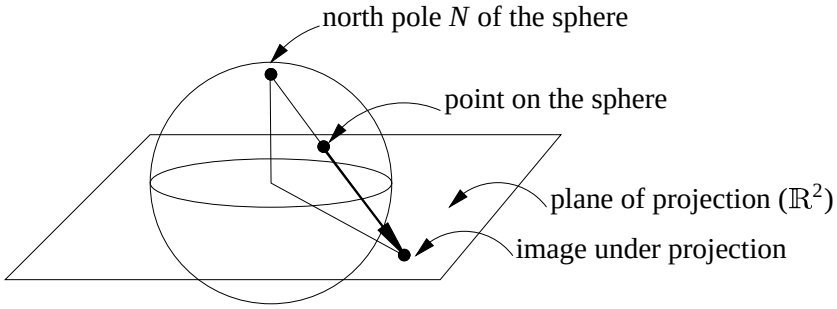

Figure 2: The stereographic projection $S^2 \setminus \{N\} \to \mathbb{R}^2$ is a diffeomorphism from the sphere with the north pole removed to the plane. It distorts lengths but preserves angles. If one considers a ray from the north pole to some point on the plane, the stereographic projection will map the intersection point of this ray with the sphere onto its intersection point with the plane.

$(\mathbb{R}^n, g)$, and the induced Riemannian volume form is

$$\omega_x = \frac{2^n}{(1+\|x\|^2)^n} dx_1 \wedge \ldots \wedge dx_n,$$

where $dx_1 \wedge \ldots \wedge dx_n$ denotes the Euclidean volume on $\mathbb{R}^n$ (the determinant). If the given data density on $\mathbb{R}^n$ is (up to a constant factor) equal to ω, the data can be considered to lie on S^n with constant density, and our error bounds hold. When viewed under stereographic projection, our spherical classifiers fall in three categories: If the boundary of the hemisphere, which is a great $(n-1)$-sphere within S^n, contains the north pole, its projection is a hyperplane through the origin in $\mathbb{R}^n$. The equatorial great sphere $\{x \in S^n \subset \mathbb{R}^{n+1} \mid x_{n+1} = 0\}$ is projected onto $S^{n-1} \subset \mathbb{R}^n$. All other great spheres become spheres intersecting $S^{n-1} \subset \mathbb{R}^n$ orthogonally. Hence, any data which is separable by these classes of hypersurfaces in $\mathbb{R}^n$ is separable by great spheres on S^n and vice versa.

Gnomonic chart. The gnomonic projection

$$\varphi : S^n \supset \{x_{n+1} > 0\} \to \mathbb{R}^n,$$
$$(x_1,\ldots,x_{n+1}) \mapsto \frac{(x_1,\ldots,x_n)}{x_{n+1}},$$

generates on $\mathbb{R}^n$ the metric

$$g = \frac{1}{(1+x_1^2+\ldots+x_n^2)^2} \begin{pmatrix} s_1 & & -x_i x_j \\ & \ddots & \\ -x_i x_j & & s_n \end{pmatrix},$$

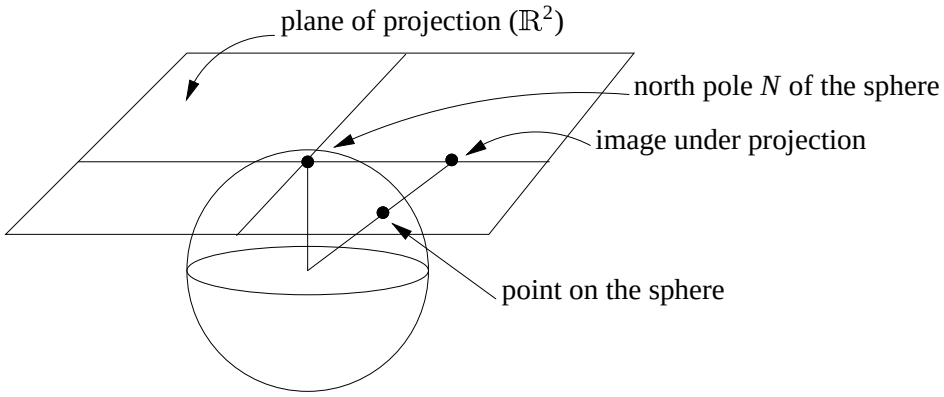

Figure 3: Illustration of the gnomonic projection for the case $S^2 \supset \{x_3 > 0\} \to \mathbb{R}^2$. In this case, we embed $\mathbb{R}^2$ at height one into $\mathbb{R}^3$, such that it touches the sphere at the north pole. Rays are sent from the center of the sphere. Their intersection points with the sphere are mapped to the corresponding intersection points with the plane. The gnomonic projection distorts lengths as well as angles, but maps great circles to straight lines.

where we have used the abbreviation $s_i := 1 + x_1^2 + \ldots + x_n^2 - x_i^2$. Figure 3 illustrates the gnomonic projection in two dimensions. As was the case with the stereographic chart, gnomonic projection is an isometry from the upper half-sphere to $(\mathbb{R}^n, g)$. Using Equation 1, we have for $x_2 = \ldots = x_n = 0$

$$\sqrt{\det(g)} = \frac{1}{(1+x_1^2)^{\frac{n+1}{2}}}.$$

Since the scaling function of the volume form ω has to be rotationally symmetric, it follows that

$$\omega_x = \frac{1}{(1+\|x\|^2)^{\frac{n+1}{2}}}\, dx_1 \wedge \ldots \wedge dx_n. \tag{3}$$

Note that our separating great spheres are projected to affine hyperplanes in $\mathbb{R}^n$. Therefore, the classical approach to the binary classification problem using *linear classifiers with bias* can be considered a special case of our spherical setup. More precisely, the strict error bounds derived for our algorithm apply to linear classifiers with bias on $\mathbb{R}^n$ if and only if the data density on $\mathbb{R}^n$ is given by Equation 3. For an analysis that applies to a greater variety of densities we refer to Section 6.

As a byproduct, formula 3 also clarifies the arguments given in the proof of Theorem 4 of Freund et al. (1997) which estimates the information gain of queries made by the Query by Committee algorithm. In the proof, the scaling factor of the volume form of the gnomonic chart is estimated using infinitesimals. The explicit formula for the volume form given above makes this more lucid.

5. Products of Spheres

We now extend the simplex algorithm (see Definition 2) to other data manifolds and other sets of classifiers using a simple product construction. The main purpose of this section is to obtain

building blocks for data manifolds and data densities which later can be combined to produce more sophisticated examples. We consider product data manifolds of the type

$$(M,g) = (S^{n_1},g^1) \times \ldots \times (S^{n_k},g^k), \tag{4}$$

where each factor (S^{n_j},g^j) is a unit sphere of dimension n_j with its standard metric g^j. For a point $x = (x_1,\ldots,x_k) \in M$ and tangent vectors $X = (X_1,\ldots,X_k), Y = (Y_1,\ldots,Y_k) \in T_xM$ we have

$$g_x(X,Y) = \sum_{j=1}^{k} g^j_{x_j}(X_j,Y_j).$$

The Riemannian volume form of the product is given in local coordinates by

$$\omega = \prod_{j=1}^{k} \sqrt{\det(g^j)} = \bigwedge_{j=1}^{k} \omega^j,$$

where ω^j denotes the volume form of the jth factor. On the product manifold M, we consider classifiers which are products of hemispheres, that is, $C = C^1 \times \ldots \times C^k$, where the $C^j = S^{n_j}$ are the individual sets of hemispheres defined in Section 3 and a classifier $c \in C$ is given by

$$c : M \to \mathbb{Z}_2, \quad c(x) := \begin{cases} 1 & : \quad \langle x, c_j \rangle \geq 0 \, \forall \, j \\ 0 & : \quad \text{otherwise} \end{cases} .$$

Due to the simplicity of the product structure, we arrive at the following formula for the generalization metric:

Proposition 5 *For products of hemispheres $c^1, c^2 \in C$,*

$$d^G(c^1,c^2) = \frac{1}{2^{k-1}} \left(1 - \frac{1}{\pi^k} \prod_{j=1}^{k} (\pi - d_j(c^1_j, c^2_j)), \right)$$

where d_j is the geodesic distance on S^{n_j}.

Proof Since each component of a classifier is a hemisphere,

$$\mathrm{Vol}(c^1_j \cap c^2_j) = \mathrm{Vol}(S^{n_j}) \frac{\pi - d_j(c^1_j, c^2_j)}{2\pi}.$$

Furthermore, the volume of a product of such hemispheres is given by

$$\mathrm{Vol}(c^1) = \prod_{j=1}^{k} \mathrm{Vol}(c^1_j) = \prod_{j=1}^{k} \frac{\mathrm{Vol}(S^{n_j})}{2} = \frac{\mathrm{Vol}(M)}{2^k}.$$

Inserting this into

$$\mathrm{Vol}(D(c^1,c^2)) = \mathrm{Vol}(c^1) + \mathrm{Vol}(c^2) - 2\mathrm{Vol}(c^1 \cap c^2)$$

where $D(c^1,c^2)$ denotes the disagreement area, yields the proposition. ■

This leads to the extended spherical simplex algorithm:

Definition 6 (Extended simplex algorithm)

1. *Specify some maximal edge length* $\varepsilon > 0$ *as termination criterion. For each factor* S^{n_j}*, create an initial simplex using a random orthogonal matrix whose columns are interpreted as a basis for* $\mathbb{R}^{n_j+1}$*. This results in a product S of equilateral simplices.*

2. *Find one of the edges of maximal length of each factor of the current simplex product S. If all the respective lengths are less than* ε*, go to step 7. Otherwise, compute the midpoints* $m_1, \ldots, m_k$*.*

3. *Compute the corresponding unit normals* u_j*.*

4. *Ask for the labels* l_j *of* u_j*. If* $l_j = 0$*, replace* u_j *by* $-u_j$*.*

5. *Replace the old simplex product S by the product of the parts* in direction of u_j*.*

6. *Repeat with step 2.*

7. *For each factor, compute its center of mass* c_j*, and return* $(c_1, \ldots, c_k) \in S$ *as the learned classifier.*

In parallel to the case of a single sphere, the minimization of maximal edge lengths forces convergence. Note, that if k denotes the number of factors in the product of spheres, then k training points are needed to carry out one iteration of the algorithm. The worst case generalization error after each step is bounded as follows.

Proposition 7 *If S is the current product simplex from the extended simplex algorithm (see Definition 6) with maximal edge lengths* $d_1, \ldots, d_k$ *of its factors, and* $c \in S$ *some classifier,*

$$d^G(c^*, c) \leq \frac{1}{2^{k-1}} \left(1 - \frac{1}{\pi^k} \prod_{j=1}^{k} (\pi - d_j) \right).$$

This bound is tight and attainable if we allow any element of the version space to be the learned classifier.

Proof In analogy to the case of a single sphere, this follows from proposition 5. ■

The complexity estimate for one iteration of the extended simplex algorithm is

$$O((n_1+1)^3 + \ldots + (n_k+1)^3).$$

Here, $n_1, \ldots, n_k$ denote the dimensions of the k individual factors of the product data space. This estimate can be deduced directly from the complexity analysis of the simplex algorithm given in Appendix A.

Products combined with isometries. We now apply the isometries discussed in Section 4 to product manifolds. For each factor in Equation 4, we may choose one of stereographic or gnomonic projection.

$$\begin{array}{rccc} M^{n_1+\ldots+n_k} = & S^{n_1} & \times\ldots\times & S^{n_k}, \\ & f_1\downarrow & \cdots & \downarrow f_k \\ \mathbb{R}^{n_1+\ldots+n_k} = & \mathbb{R}^{n_1} & \times\ldots\times & \mathbb{R}^{n_k}. \end{array}$$

This results in product densities on $\mathbb{R}^n = \mathbb{R}^{n_1+\ldots+n_k}$, represented by the volume form

$$\omega = \prod_{j=1}^{k} \omega^j$$

with factors ω^j given by either

$$\omega_x^j = \frac{2^{n_j}}{(1+\|x\|^2)^{n_j}} dx_1 \wedge \ldots \wedge dx_{n_j}$$

(stereographic projection) or

$$\omega_x^j = \frac{1}{(1+\|x\|^2)^{\frac{n_j+1}{2}}} dx_1 \wedge \ldots \wedge dx_{n_j}$$

(gnomonic projection). Similarly, the projected separating hypersurfaces are products of the individual projections. One could now go on to produce *many* more families of compatible densities by working with different charts, but instead we turn our attention to an important special case.

The *n*-torus. A particular case is the gnomonic projection of the *n*-torus

$$T^n = \underbrace{S^1 \times \ldots \times S^1}_{n \text{ factors}},$$

which yields a scaled version of the Cauchy distribution on $\mathbb{R}^n$:

$$\omega_x = \prod_{i=1}^{n} \frac{1}{1+x_i^2} dx_1 \wedge \ldots \wedge dx_n.$$

Here, we take S^1 to be the unit circle which results in T^n having total mass $(2\pi)^n$. Since there is one circle S^1 per axis, the projected classifiers are *axis parallel corners* in $\mathbb{R}^n$. One iteration of the algorithm consumes n labeled data points, because T^n is made up of n individual factors. At each step of the extended simplex algorithm, the version space is a *hypercube* of equal edge length l. Therefore, we do not need to compare edge lengths. One step results in halving all the edges, and the volume is divided by 2^n. Hence, if V_i denotes the volume after i iterations, we have

$$V_i = \frac{\pi}{2^{in}}.$$

In analogy, the maximal generalization error G_i of the center of mass classifier after i steps is given by

$$G_i = \frac{\sqrt{n}\pi}{2^i}.$$

Thus, we observe an exponential decrease in volume and in the tight upper bound for the generalization error.

6. Aspherical Data Manifolds

Up to now, our methods apply only to such data manifolds which are isometric to products of subsets of unit spheres. We now loosen this assumption by looking at all oriented Riemannian data manifolds M which admit an orientation preserving[2] diffeomorphism

$$\Phi : M \to S^n,$$

that is, Φ is a smooth bijective map which has a smooth inverse. The Riemannian volume form belonging to the metric g on M induces a volume form $\widetilde{\omega}$ on S^n which, in general, is not equal to the spherical volume ω. More precisely,

$$\widetilde{\omega} = f\omega$$

with some smooth positive scaling function $f : S^n \to \mathbb{R}^+$. Note that *all* volume forms (or smooth positive densities) on S^n can be written in this form. This results in the formula

$$d^G(c_1, c_2) := \frac{1}{\widetilde{\mathrm{Vol}}(S^n)} \int_{D(c_1,c_2)} f\omega$$

for the generalization metric. An illustation of a non-uniform density on the sphere is given in Figure 4 in Section 8 where the reader also finds empirical results for this case.

Concerning the set of admissible classifiers, let us keep the assumption that the Φ-image of the data is separable by hemisphere classifiers. If we know that the true classifier c^* lies in some subset $S \subset S^n$ the worst case generalization error of some classifier $c \in S$ is bounded from above by

$$d^G(c, c^*) \leq \sup_{\widetilde{c} \in S} d^G(\widetilde{c}, c^*).$$

Therefore, the simplex algorithm (see Definition 2) will still converge, as it reduces an upper bound of the generalization error. Its rate of convergence will depend on the properties of the density.

Nevertheless, we can force a simple upper bound by assuming the deviation of the induced volume form from spherical volume to be small:

$$\sup_{x \in S^n} |1 - f(x)| < \varepsilon.$$

This implies

Proposition 8 *Let ω be the canonical volume form of S^n. Denote by $d^{\widetilde{G}}$ the generalization distance induced by the scaled volume form $\widetilde{\omega} = f\omega$ where $f : S^n \to \mathbb{R}^+$ is some positive smooth scaling function. If $\sup_{x \in S^n} |1 - f(x)| < \varepsilon$ for some $\varepsilon > 0$ then*

$$d^{\widetilde{G}}(c_1, c_2) \leq \frac{(1+\varepsilon)\mathrm{Vol}(S^n)}{\pi \widetilde{\mathrm{Vol}}(S^n)} d(c_1, c_2),$$

where d is the canonical geodesic distance of S^n. In this formula, $\mathrm{Vol}(S^n) := \int_{S^n} \omega$ and $\widetilde{\mathrm{Vol}}(S^n) := \int_{S^n} \widetilde{\omega}$ denote the volumina of S^n with respect to ω and $\widetilde{\omega} := f\omega$.

2. A map between oriented Riemannian manifolds is orientation preserving if its functional determinant is positive.

Proof Using the definition of the generalization distance in Equation 2 and applying proposition 1, we compute

$$\begin{aligned} d^{\widetilde{G}}(c_1,c_2) &= \frac{1}{\widetilde{\mathrm{Vol}}(S^n)} \int_{D(c_1,c_2)} f\omega \\ &\leq \frac{1}{\widetilde{\mathrm{Vol}}(S^n)} \int_{D(c_1,c_2)} (1+\varepsilon)\omega \\ &= \frac{(1+\varepsilon)\mathrm{Vol}(S^n)}{\widetilde{\mathrm{Vol}}(S^n)} d^G(c_1,c_2) \\ &= \frac{(1+\varepsilon)\mathrm{Vol}(S^n)}{\pi\widetilde{\mathrm{Vol}}(S^n)} d(c_1,c_2). \end{aligned}$$

■

Inserting the above upper bound into proposition 3 we obtain

Proposition 9 *Let S be the current simplex from the simplex algorithm (see Definition 2) with vertices $v_1,\ldots,v_{n+1} \in S^n$, and $c \in S \subset S^n$ an arbitrary classifier, not necessarily the center of mass. If $c^* \in S^n$ denotes the unknown true classifier, the generalization error of c is bounded by*

$$d^{\widetilde{G}}(c,c^*) \leq \frac{(1+\varepsilon)\mathrm{Vol}(S^n)}{\pi\widetilde{\mathrm{Vol}}(S^n)} \max_{i,j} d(v_i,v_j),$$

where $d(v_i,v_j)$ denotes the spherical distance of the vertices.

The usefulness of the above proposition depends on how much the scaled volume form $f\omega$ deviates from the canonical spherical volume ω. In the case of the n-torus, the same arguments as given at the end of Section 4 yield an exponential decrease of the volume of the version space as well as of the upper bound for the generalization error—*regardless of the data density under consideration*. The only difference is the newly introduced constant ε which may affect the absolute rate but not the functional form of convergence.

7. Linear Classifiers without Bias

We now return to the case of linear classifiers on the Euclidean space $\mathbb{R}^n$ which commonly appear in the machine learning literature. The corresponding separating hypersurfaces are linear subspaces, that is, hyperplanes through the origin, of $\mathbb{R}^n$.

Consider the data space $M = \mathbb{R}^n$. Then, the set C of *linear classifiers without bias* consists of maps

$$c : \mathbb{R}^n \to \mathbb{Z}_2, \quad c(x) := \begin{cases} 1 & : \quad \langle x,p\rangle \geq 0 \\ 0 & : \quad \langle x,p\rangle < 0 \end{cases},$$

where $p \in S^n$ is the unit normal vector of an oriented $(n-1)$-dimensional plane through the origin. Therefore, we can identify C with the unit n-sphere, $C = S^n$. In the following, we use c to denote both, the classifier and its corresponding unit normal.

Consider some data density $f : \mathbb{R}^n \to \mathbb{R}$. Since the origin is always classified as $+1$ by all classifiers we may remove it from the data space, and the remaining data space is given by

$$M = \mathbb{R}^n \setminus \{0\}.$$

Using polar coordinates (s,r), we can write M as the product[3]

$$M = S^{n-1} \times \mathbb{R}^+, \quad s = \frac{x}{\|x\|}, r = \|x\|.$$

For a given $s \in S^{n-1}$, we will call the subset $F_s := \{(s,r) \mid r > 0\}$ the *fiber* over s. Since the data is assumed to be separable by at least one element of C any two points belonging to the same fiber have the same label.

The area $D(c_1,c_2)$ of disagreement between two classifiers c_1, c_2 is given by

$$D(c_1,c_2) = \{(s,r) \in M \mid \langle c_1, rs\rangle\langle c_2, rs\rangle < 0\} = \{(s,r) \in M \mid \langle c_1, s\rangle\langle c_2, s\rangle < 0\}.$$

The generalization distance is given by

$$d^G(c_1,c_2) = \int_{D(c_1,c_2)} f dx = \int_{\{s \in S^{n-1} \mid F_s \subset D(c_1,c_2)\}} \left(\int_{F_s} f(s,.) dr \right) ds, \tag{5}$$

where dx, dr, ds denote the canonical volume forms on $\mathbb{R}^n$, F_s, and S^{n-1}. It may happen that different fibers F_s have different mass in the sense that

$$S^{n-1} \to \mathbb{R}, \quad s \mapsto \int_{F_s} f(s,.) dr$$

is a non-constant function. If we rule out this case we end up with the following proposition:

Proposition 10 *The generalization distance of any two linear classifiers c_1, c_2 is given by*

$$d^G(c_1,c_2) = \frac{\lambda}{\pi} d(c_1,c_2),$$

where $d(c_1,c_2) = \arccos\langle c_1, c_2\rangle$ is the geodesic distance on S^n, if and only if the fiber mass is equal to a positive constant,

$$\int_{F_s} f(s,.) dr = \lambda > 0 \ \ \forall s \in S^n.$$

Proof This follows by applying proposition 1 to Equation 5. ■

The precondition of proposition 10 does *not* assume that the density f is rotationally invariant on $\mathbb{R}^{n+1}$. Instead, it assumes the *accumulated* density to be invariant on the sphere. Linear classification problems on non-constant densities which fulfill this condition map to classification problems with hemisphere classifiers for the uniform density on the sphere. Consequently, all results derived for the spherical simplex algorithm (see Definition 2) apply, including the hard upper bounds on the generalization error. In particular, we deduce the following result from Proposition 3

3. We use the convention $\mathbb{R}^+ := \{r \in \mathbb{R} \mid r > 0\}$.

Proposition 11 *If S is the current simplex from the simplex algorithm (see Definition 2) with vertices $v_1, \ldots, v_{n+1} \in S^n$, c^* denotes the unknown true classifier and $c \in S$ an arbitrary classifier,*

$$d^G(c^*, c) \leq \lambda \max_{i,j} d(v_i, v_j) = \lambda \max_{i,j} \arccos\langle v_i, v_j \rangle.$$

As in Proposition 10, $\lambda > 0$ denotes the fiber mass. This bound is tight and attainable if we allow any element of the version space to be the learned classifier. Moreover, if $c \in S$ denotes the center of mass, then

$$d^G(c^*, c) \leq \lambda \max_{i} d(c, v_i) = \lambda \max_{i} \arccos\langle c, v_i \rangle.$$

is a tight and attainable upper bound for the generalization error.

Relation to SVM methods. Proposition 10 also sheds new light on some active learning strategies that use Support Vector Machines (SVM). A SVM classifier can be interpreted as an approximation of the center of the largest inscribable hypersphere of the version space on S^{n-1} (see Herbrich, 2002). Let us denote this center by $p^* \in V \subset S^{n-1}$, where $V \subset S^{n-1}$ is the version space (a spherical polytope, see Section 3) on the hypersphere.

Tong and Koller (2001) argue that, despite its dependence on the particular shape of the version space, the center of the maximal inscribable hypersphere often lies close to "the center of the version space". Motivated by these insights, they propose the following pool-based strategy for selecting an unlabeled data point $x \in S^{n-1}$ to be labeled: Choose x such that the (spherical) distance from the $(n-2)$-dimensional great sphere

$$X := \{s \in S^{n-1} \mid \langle x, s \rangle = 0\}$$

to p^* is minimal. After the data point x is labeled, the version space will be cut into two pieces along the great sphere $X \subset S^{n-1}$. The goal of this strategy is to reduce the volume of the spherical polytope V as quickly as possible. Similar strategies can be found in Warmuth et al. (2002). Up to now, a closed formula for the volume of a n-spherical simplex *is not known*, not to speak of polytopes, hence, there is *no way* of computing the exact volume of a version space on a hypersphere. We refer to Milnor (1994) for a detailed discussion of this topic. Nevertheless, Monte-Carlo methods can be applied to obtain volume estimates.

Proposition 10 can now be applied. The SVM algorithm works with the Euclidean scalar product on $\mathbb{R}^n$, and therefore implicitly assumes the canonical Riemannian metric and volume form on the unit sphere. Proposition 10 tells us that the SVM approximation is theoretically justified if and only if the given data density induces (up to a constant factor) the uniform density on the sphere.

8. Experimental Results

The following results were obtained from a C++ implementation of the simplex algorithm (see Definition 2). The numerically most sensitive operation of the algorithm is the computation of a normal vector $u \in S^n$ to the hyperplane $H \subset \mathbb{R}^{n+1}$ whose intersection $I = H \cap S^n$ with S^n cuts the current simplex S into two pieces. In higher dimensions, say $n > 50$,

$$\int_{S^n \setminus \{x \in S^n \mid d(x,I) < \delta\}} \omega$$

becomes very small even for small values $\delta > 0$.[4] This means, nearly all the mass of S^n is concentrated within a thin tube of radius δ around I, which makes it hard to compute normal vectors. We avoid numerical problems by using the following procedure:

1. Select the basis of H given by the midpoint of the longest edge and all vertices of the simplex excluding the end points of the longest edge. Construct a corresponding orthonormal basis using the modified Gram-Schmidt algorithm (see Meyer, 2000).

2. Choose random points $x \in S^n$ until the projected length $\sqrt{\sum_i \langle x, h_i \rangle}$, where h_i are the orthonormal basis vectors of H, is less than a given constant $\varepsilon < 1$.

3. Use x to construct a unit vector which is orthogonal to all basis vectors h_i.

In order to test the performance of the simplex algorithm on spheres of different dimensions a series of numerical experiments was conducted, where the following quantities were measured.

Maximal edge length: If $(v_1, \ldots, v_{n+1})$ denote the vertices of the current simplex S of the simplex algorithm, the maximal edge length

$$\max_{i,j} d(v_1, v_j)$$

is an upper bound on the generalization error, regardless which point of the simplex is chosen as the learned classifier.

Maximal distance from center of mass: Let $c \in S$ denote the center of mass of S. Then the maximal distance between c and any other classifier from S is given by

$$\max_i d(c, v_i).$$

This yields a tight upper bound on the generalization error if we choose the center of mass as the learned classifier.

Approximate generalization error for the center of mass classifier c: We estimated the generalization error of c using the empirical average of the individual errors for 50,000 randomly selected "test" data points. Test data were sampled (i) from a uniform density on the sphere and (ii) from an aspherical density with two distinct "clusters" at opposite poles. The aspherical density was constructed by mapping the uniform distribution from an open parameter cuboid onto the sphere using n-spherical coordinates.

Figure 4 illustrates the relation between a sample drawn from this density on the sphere S^2 and its stereographic projection onto the plane $\mathbb{R}^2$. Densities of this kind are typical for binary classification problems. Any density with two peaks at $p_1, p_2 \in \mathbb{R}^n$ can be identified with a density on S^n with peaks at opposite poles: Firstly, we apply a translation to move the midpoint of the line $\overline{p_1 p_2}$ to the origin. Then we use a rotation to place p_1, p_2 on the x_1-axis. After a scaling, $p_1 = (-1, 0, \ldots, 0)$ and $p_2 = (+1, 0, \ldots, 0)$. Now inverse stereographic projection will map the peaks onto opposite poles.

4. For a comprehensive discussion of these effects we refer to Gromov (1999).

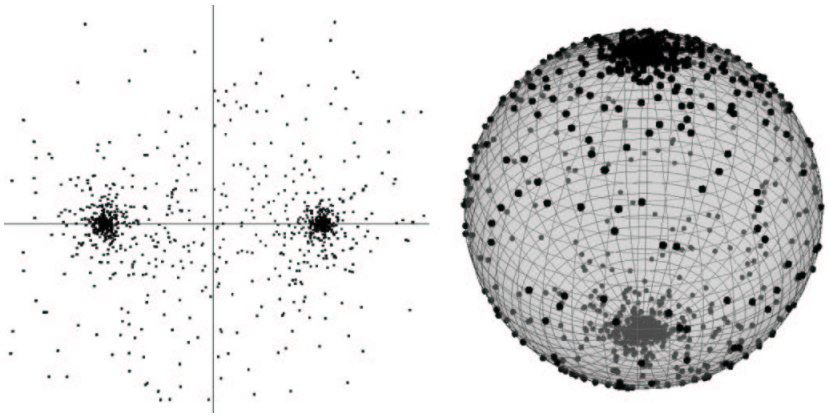

Figure 4: A data sample from a density with two peaks on $\mathbb{R}^2$ (left) and S^2 (right). The data points on the plane are the stereographic projections of the points on the sphere. On S^2, the two peaks are located at opposite poles.

The above quantities were computed for each step of the simplex algorithm. Averages and variances were calculated for 1,000 simulations, and averages were normalized to lie within the interval $[0,1]$. For every simulation, a true classifier was drawn from the uniform distribution on the sphere. Figures 5 and 6 show the resulting learning curves for the spheres $S^9 \subset \mathbb{R}^{10}$, $S^{29} \subset \mathbb{R}^{30}$, $S^{49} \subset \mathbb{R}^{50}$, and $S^{79} \subset \mathbb{R}^{80}$. The average maximal edge length as a function of the number of selected training data

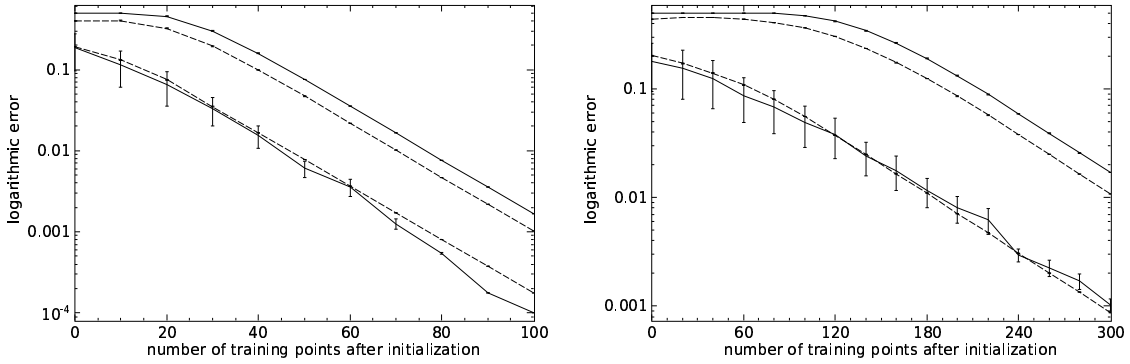

Figure 5: Learning curves on $S^9 \subset \mathbb{R}^{10}$ (left) and on $S^{29} \subset \mathbb{R}^{30}$ (right). The figures show the average maximal edge length (upper solid line), the average maximal distance from the simplex's center of mass (upper dashed line), and the average approximate generalization errors for the uniform (lower dashed line) and aspherical (lower solid line) data densities as a function of the number of selected training examples. Error bars indicate variances, however, only the approximate generalization error for the aspherical data density shows large fluctuations between simulation runs. Proposition 4 yields the bounds $9 \leq k_9 \leq 45$ and $29 \leq k_{29} \leq 435$ for the number k of steps needed before the maximal edge length starts to drop on S^9 and S^{29}.

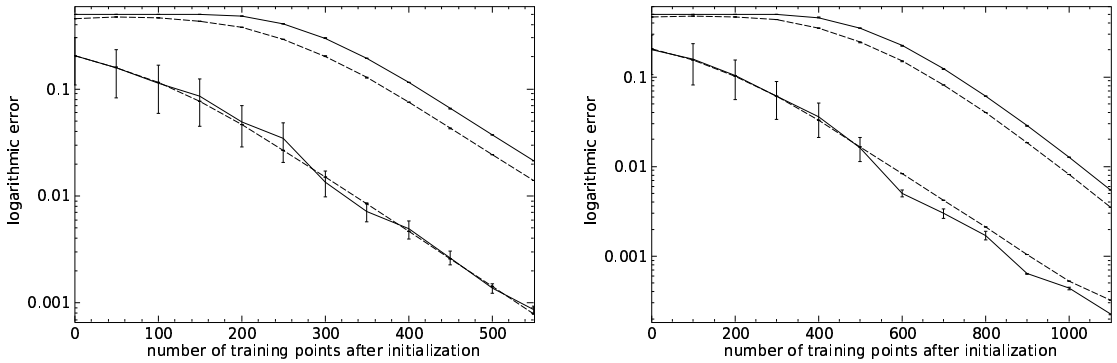

Figure 6: Learning curves on $S^{49} \subset \mathbb{R}^{50}$ (left) and $S^{79} \subset \mathbb{R}^{80}$ (right). For details see legend of Figure 5. Proposition 4 yields the bounds $49 \leq k_{49} \leq 1225$ and $79 \leq k_{79} \leq 3160$ for the number k of steps needed before the maximal edge length starts to drop on S^{49} and S^{79}.

shows an initial plateau, until the values begin to decrease in an approximately exponential fashion. The length of the plateau increases with the dimensionality of the sphere and is a direct result of Proposition 4. The average maximal distance from the center of mass rises initially (see Figure 7 for a magnified version of the initial segment of the learning curve), until a sudden drop occurs, again followed by a roughly exponential decrease. This can be explained as follows. The simplex algorithm is initialized with an equilateral simplex. During the first learning steps, the center of mass moves towards those vertices whose adjacent edges are cut already. This results in a slight increase of the maximal distance of the vertices from the center of mass. The simplex becomes a "thin pyramid" with small base, and the following drop in the plots then corresponds to a cut of a line connecting the apex to the base. The ratio between the edges connecting the apex to the base and the edges which are contained within the base is given by $\frac{2}{n-1}$, where n is the dimensionality of the sphere. Since this number tends to zero for $n \to \infty$ the sudden drop disappears in higher dimensions.

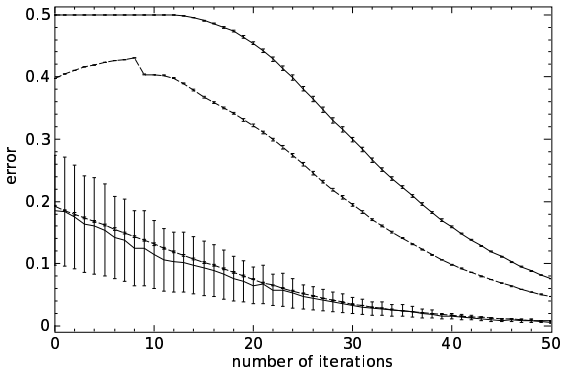

Figure 7: Initial learning curves on $S^9 \subset \mathbb{R}^{10}$ (see Figure 5, left), now plotted on a linear scale. For details see legend of Figure 5.

If the data is drawn from the spherical distribution, the approximate generalization error changes smoothly with the number of selected training data, and its variance is very small. For data distributed according to the aspherical (two cluster) density, the average approximate generalization error is similar, but the variance increases dramatically. Nevertheless, the numerical experiments show that the spherical simplex algorithm performs well even in the case of non-uniform densities.

Experimental results on product manifolds. So far, we restricted the experiments to single spheres instead of products, because the simulation of the extended simplex algorithm on

$$M = S^{n_1} \times \ldots \times S^{n_k},$$

is equivalent to the parallel execution of several copies of the basic algorithm. Nevertheless, it might be interesting to consider the special case of the n-torus T^n (see Section 5):

$$T^n = \underbrace{S^1 \times \ldots \times S^1}_{n \text{ factors}}.$$

The product structure of the torus reflects the fact that data is distributed independently on each factor. For the standard product density on T^n, volume and distances can be computed explicitly. Therefore, we consider only the non-uniform case. We consider a von Mises density (see Devroye, 1986) on the unit circle:

$$f : S^1 = \mathbb{R}/2\pi \to \mathbb{R}, \quad f(x) = \frac{\exp(\kappa \cos(x-\mu))}{2\pi I_0(\kappa)}.$$

with center $\mu \in [0, 2\pi]$ and width $\kappa \geq 0$. The symbol I_0 in the equation above denotes the modified Bessel function of the first kind of order zero. A technique for simulating the von Mises distribution can be found in Best and Fisher (1979). In order to obtain a density with two peaks on opposite poles of the circle, we superimpose two copies of f with $\mu = 0$ and $\mu = \pi$. This construction is applied to every factor S^1 of the torus $T^n = S^1 \times \ldots \times S^1$.

We implemented the extended simplex algorithm on the n-torus. Due to the product structure, numerical problems like those described at the beginning of Section 8 do not arise. For the case $n = 2$, the torus can be embedded into $\mathbb{R}^3$ using

$$S^1 \times S^1 \to \mathbb{R}^3, \quad (s,t) \mapsto \begin{pmatrix} (2+\cos t)\cos s \\ (2+\cos t)\sin s \\ \sin t \end{pmatrix}.$$

Using this mapping, we can visualize the iterations of the extended simplex algorithm on von Mises distributed data. Figure 8 shows a data sample as well as several iterations of the algorithm on the embedded torus. Figure 9 depicts the stereographic projection of a sample drawn from the von Mises distribution together with the projected classifier in $\mathbb{R}^2$.

Finally, we conducted experiments on the n-torus in order to obtain learning curves analogous to those on the n-sphere. As was shown in Section 5 distances and volumina on the n-torus can be computed explicitly provided the data density is uniform. Therefore, we focus on the approximal generalization error for data distributed according to the modified von Mises density described above. The approximation was done by evaluating the performance of the classifier on a data sample of 50,000 test points after each training step. The resulting values were averaged over 1,000

Figure 8: The extended simplex algorithm on the 2-torus. The large dot on the upper part of the torus represents the true classifier. Small dots depict positively (light gray) and negatively (dark) classified points drawn from the modified von Mises distribution. The meaning of the nested regions is the following (light to dark): positively classified area of the true classifier, version space after initialization (step one of the extended simplex algorithm), version space after first iteration, version space after second iteration.

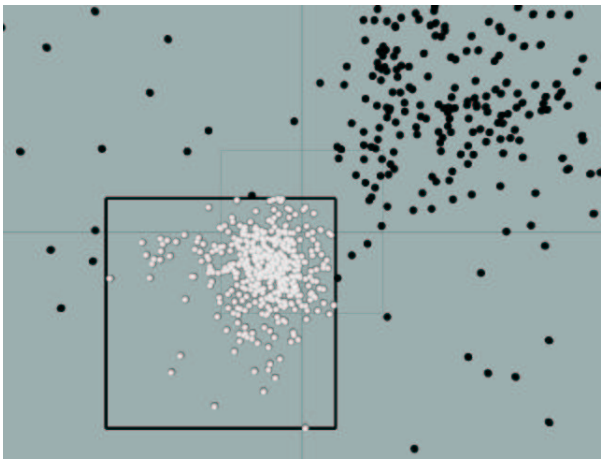

Figure 9: The image of a data sample from two superposed von Mises distributions on the two-dimensional torus under the stereographic projection (defined in Section 4) to $\mathbb{R}^2$. The black square represents the projected classifier. Light dots are classified positively, dark dots negatively.

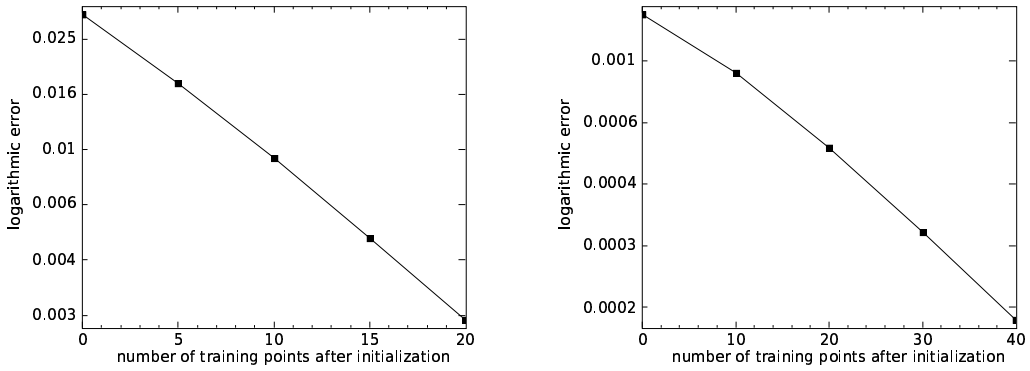

Figure 10: Learning curves on the 5-dimensional torus (left) and on the 10-dimensional torus (right). The figures show the average approximate generalization errors for the modified von Mises density as a function of the number of selected training examples. Since the variances are almost zero, they are not included in the diagram.

simulations. For every simulation, a true classifier was drawn from the uniform distribution on the torus. The resulting learning curves for dimensions $n = 5$ and $n = 10$ are shown in Figure 10.

Due to the product structure of the torus, volumina of rectangular subsets are given by the products of their side lengths. For higher dimensions, the volume of the initial version space becomes very small. Therefore, the initialization of the extended simplex algorithm yields a classifier whose error is by far smaller than the average generalization error of its spherical counterpart. This effect reflects the *statistical independence* of the data which makes the learning task a lot easier. For dimensions $n > 15$, the initialization of the algorithm alone provides a classifier with almost vanishing average generalization error. As the curves depicted in Figure 10 show the error decreases exponentially.

9. Conclusion

In this contribution we provided exact upper bounds for the generalization performace of binary classifiers. In order to do so, we used an active learning scheme for model selection, and we designed a constructive method which reduces such a bound by successive subdivisions of a version space.

The algorithm was first formulated for the generic case of a binary classification problem, where data lies on a n-dimensional hypersphere and where both classes are separable using $(n-1)$-dimensional great spheres as classifiers. We derived tight upper bounds for the case that the density of data is constant (cf. Proposition 3) as well as for cases, where at least an upper bound of the deviation from the constant density is known (cf. Proposition 9).

We then showed, using the concept of isometries, that abovementioned results are not restricted to hyperspherical data spaces. We showed that if a data space can be mapped onto (a subset of) a hypersphere using an isometry, the constructive active learning method can be applied and Propositions 3 and 9 remain valid and can be used to calculate the bound. In particular, the constructive algorithm can be applied to linear classification in the widely used Euclidean data space $\mathbb{R}^n$, and the corresponding bounds hold. A further extension to binary classification on products of spheres

is straightforward. As a simple example, we considered binary classification on products of circles and proved the exponential decrease of the upper bound for arbitrary densities. Using isometries we showed that this problem can be mapped, for example, onto a binary classification problem in $\mathbb{R}^n$ with axis-parallel hypercube classifiers for which the same exponential decrease holds.

The theoretical results were illustrated using a number of classification tasks using flat as well as non-constant densities, and the derived bounds were compared with the classification error on a test set as a standard method for assessing prediction quality. Since our focus lies on a theoretical analysis of active learning methods (the constructive methods being a vehicle of this analysis), an empirical evaluation and applications of the proposed algorithm to real world problems are of second importance here. Still, a few comments can be made. The computational complexity of the method is $O((n+1)^3)$ where n is the dimension of the hypersphere, hence the method works in practice. Empirically, it also provides good results for non-constant densities. The main current limitation, however, is the restriction of the method to separable classification problems.

Appendix A.

The purpose of this appendix is to give a more detailed analysis of the complexity of the simplex algorithm (see Definition 2) as well as a proof of Proposition 4.

Complexity analysis. We first consider step two. The edge lengths

$$d(v_i, v_j) := \arccos(\langle v_i, v_j \rangle),$$

between vertices v_i, v_j of the simplex must be computed in order to determine which edge is to be cut next. To reduce the number of scalar products that actually need to be evaluated we keep a record of all edge lengths of the current simplex. After step 2, the current simplex is cut by a plane through the midpoint m of some edge (a,b). Assume b gets thrown out. Then all $\frac{n(n-1)}{2}$ edges of the facet opposite to b stay untouched. Further, the length of the new edge (a,m) is one half of the length of (a,b). It is left to compute the lengths of all other edges that contain m. Therefore, we need to compute

$$\frac{n(n+1)}{2} - \frac{n(n-1)}{2} - 1 = n-1$$

scalar products of vectors in $\mathbb{R}^{n+1}$ which gives us an additive term of order $O(n-1)$. In step three, one has to apply an orthonormalization procedure. The modified Gram-Schmidt algorithm (see Meyer, 2000) gives us another summand $O((n+1)^3)$. Since the computational complexity of the other steps is negligible we obtain $O((n+1)^3)$ as a rough complexity estimate for one iteration of the simplex algorithm (see Definition 2). Steps one and seven are performed only once. The initialization by choosing a random orthogonal matrix can be implemented by using an algorithm of Stewart (1980). The complexity of this algorithm is $O(n^2)$ plus the time needed for generating n pseudo-random vectors according to the standard normal distribution. The computation of the center of mass in step seven amounts to adding up all vertex vectors of the current simplex and normalizing their sum to length one. Hence, $O((n+1)^3)$ is a complexity estimate for the final step.

We now restate and prove Proposition 4 from Section 3:

Proposition 12 *Let S be the initial equilateral simplex from the simplex algorithm (see Definition 2). Let $k \in \mathbb{N}$ be the number of steps needed until the maximum of the edge lengths drops. Then*

$$n \leq k \leq \frac{n(n+1)}{2},$$

and these bounds are tight and attainable.

Proof The proof consists of four steps:

1. n is a lower bound: Assume $k \leq n-1$ and do k iterations of the algorithm. Since the degree of each vertex is n, each vertex of the initial simplex is end point of an edge of full length. Thus, if one of these initial vertices is contained in the new subsimplex, the subsimplex contains the adjacent edge of full length, too. The $k \leq n-1$ subdivisions have created at most $n-1$ new vertices. Thus, the new subsimplex contains at least two vertices of the initial simplex. Hence, its maximal edge length is still $\frac{\pi}{2}$.

2. The lower bound is tight: Choose some vertex e. Subdivide all n edges adjacent to e and keep the subsimplex containing the vertex e. All edges starting from e now have length $\frac{\pi}{4}$. The angle enclosed by any two edges at e is $\frac{\pi}{2}$. Now the spherical law of cosines tells us that all edges *not* adjacent to e have length $\frac{\pi}{3}$. This implies that the constructed subsimplex realizes the lower bound.

3. $\frac{n(n+1)}{2}$ is an upper bound: This is clear since $\frac{n(n+1)}{2}$ is the number of edges of the simplex.

4. The upper bound is tight: This is clear for $n = 1$.

The induction step $(n-1) \to n$ goes as follows: Use $\frac{n(n-1)}{2}$ steps to subdivide a facet F of the simplex. Then all edges contained in F are shortened, while the n edges connecting F with the opposite vertex e still have full length. Now subdivide the connecting edges, and always choose the subsimplex which contains e. In this case, e is the only common vertex belonging to the newly subdivided edge and the rest of the edges of full length. Hence, in each of these last n steps, only one edge length is reduced. An illustration of this case is shown in Figure 11. ■

Appendix B.

The purpose of this appendix is to introduce some differential geometric notions used in the main text. For a comprehensive treatise of Riemannian manifolds we refer to Gallot et al. (1990).

A *manifold* M is a generalization of Euclidean space $\mathbb{R}^n$. It is covered by *coordinate charts*, that is, bijective maps $u : U \to \mathbb{R}^n$, where $U \subset M$ is an open subset. The inverse of u is called a *parametrization*. For our work, the most important example of a manifold is the n-sphere $S^n = \{p \in \mathbb{R}^{n+1} \mid \|p\| = 1\}$. It can be covered by two charts, stereographic projection from the north and south pole. Another system of charts is given by the gnomonic projections. Both are discussed in detail in Section 4.

At each point $p \in M$, the manifold is approximated by its *tangent space* T_pM, which generalizes the tangent of a smooth curve. In the case of S^n, the space T_pS^n can be identified with the linear subspace

$$T_pS^n = \{X \in \mathbb{R}^{n+1} \mid \langle p, X \rangle = 0\}.$$

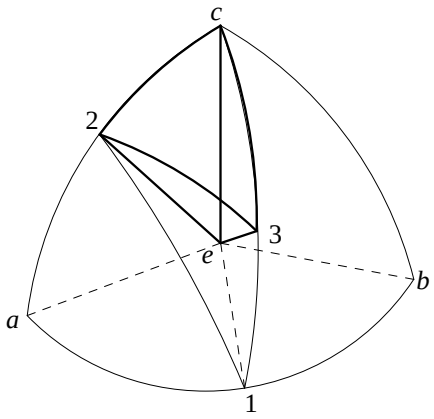

Figure 11: The figure shows a subdivision of a spherical simplex on $S^3 \subset \mathbb{R}^4$ under stereographic projection (see Section 4). The initial simplex, a tetrahedron, is (a,b,c,e). All of its edges have *spherical* length $\frac{\pi}{2}$. After three iterations, indicated by their midpoints $1,2,3$, the subsimplex with edges drawn in bold face still contains three edges (those starting from vertex e) of full length.

A *Riemannian metric* is a choice of a scalar product g_p for each tangent space T_pM. The pair (M,g) is called a *Riemannian manifold*. The canonical Riemannian metric of S^n is given by the restriction of the Euclidean scalar product on $\mathbb{R}^{n+1}$ to the subspace T_pS^n. Given some parametrization $f : \mathbb{R}^n \to U \subset S^n \subset \mathbb{R}^{n+1}$ of a subset U of the sphere, the matrix representation of g is computed by

$$g_{ij} = \langle \frac{\partial f}{\partial x_i}, \frac{\partial f}{\partial x_j} \rangle,$$

where $\langle , \rangle$ denotes the Euclidean scalar product on $\mathbb{R}^{n+1}$. We use this equality in Section 4 to compute the metric in stereographic and gnomonic coordinates.

Let M,N be manifolds of dimensions $\dim M = m$ and $\dim N = n$. Let $p \in M$ be some point in M. A map $f : M \to N$ is called *smooth at* p if there are charts $u : M \supset U \to \mathbb{R}^m$, $v : N \supset V \to \mathbb{R}^n$ with $p \in U$, $f(p) \in V$ such that the composition $\widetilde{f} = v \circ f \circ u^{-1} : \mathbb{R}^m \to \mathbb{R}^n$ is infinitely differentiable in the usual sense. We denote by $df : T_pM \to T_{f(p)}N$ the total differential of f at p. The map f is called *smooth* if it is smooth at all points of M.

A smooth bijective map $f : (M,g) \to (N,h)$ with smooth inverse is called a *diffeomorphism*. If f additionally preserves the metric,

$$g_p(X,Y) = h_{f(p)}(df(X), df(Y)),$$

we call f an *isometry*.

Given a metric g we can measure the length of a curve $\gamma : [a,b] \to M$ by integrating the norm of its tangent vector:

$$L(\gamma) = \int_a^b \|\dot{\gamma}(t)\| \, dt = \int_a^b \sqrt{g_{\gamma(t)}(\dot{\gamma}(t), \dot{\gamma}(t))} dt.$$

The *geodesic distance* $d(p,q)$ of two points $p,q \in M$ is defined to be the infimum of lengths of all curves joining p with q. The minimizing curves are called *geodesics*. In the majority of cases, there

is no explicit formula for $d(p,q)$. Nevertheless, in the case of S^n with its canonical metric it is given by $d(p,q) = \arccos(\langle p,q\rangle)$. Here, the geodesic distance is realized by segments of great circles.

For each Riemannian metric g, there exists a corresponding *Riemannian volume form* ω given in local coordinates $u = (u_1,\ldots,u_m) : M \supset U \to \mathbb{R}^m$ by

$$\omega = \sqrt{\det(g)}du_1 \wedge \ldots \wedge du_n.$$

This can be viewed as a scaled version of the determinant that depends on the base point. Using a coordinate chart u, the volume of a subset A of M is given by

$$\mathrm{Vol}_g(A) = \int_A \omega = \int_{u(A)} \sqrt{\det(g)}du,$$

where the integration on the right hand side is performed in $\mathbb{R}^n$.

Abstract

The statistical perspective on boosting algorithms focuses on optimization, drawing parallels with maximum likelihood estimation for logistic regression. In this paper we present empirical evidence that raises questions about this view. Although the statistical perspective provides a theoretical framework within which it is possible to derive theorems and create new algorithms in general contexts, we show that there remain many unanswered important questions. Furthermore, we provide examples that reveal crucial flaws in the many practical suggestions and new methods that are derived from the statistical view. We perform carefully designed experiments using simple simulation models to illustrate some of these flaws and their practical consequences.

Keywords: boosting algorithms, LogitBoost, AdaBoost

1. Introduction

As the AdaBoost algorithm of Freund and Schapire (1996) gained popularity in the computer science community because of its surprising success with classification, the statistics community focused its efforts on understanding how and why the algorithm worked. Friedman, Hastie and Tibshirani in 2000 made great strides toward understanding the AdaBoost algorithm by establishing a statistical point of view. Among the many ideas in the Friedman, Hastie and Tibshirani *Annals of Statistics* paper, the authors identified a stagewise optimization in AdaBoost, and they related it to the maximization of the likelihood function in logistic regression. Much work has followed from this paper: extensions of the algorithm to the regression setting (e.g., Buhlmann and Yu, 2003), modification of the loss function (e.g., Hastie et al., 2001), and work on regularization methods for the original AdaBoost algorithm and variants (e.g., Lugosi and Vayatis, 2004). This broad statistical view of boosting is fairly mainstream in the statistics community. In fact, the statistics community has taken to attaching the *boosting* label to *any* classification or regression algorithm that incorporates a stagewise optimization.

Despite the enormous impact of the Friedman, Hastie and Tibshirani paper, there are still questions about the success of AdaBoost that are left unanswered by this statistical view of boosting. Chief among these is the apparent resistance to overfitting observed for the algorithm in countless examples from both simulated and real data sets. This disconnect was noted in some of the dis-

cussions published along with the original 2000 *Annals of Statistics* paper. For instance, Freund and Schapire (2000) note that, "one of the main properties of boosting that has made it interesting to statisticians and others is its relative (but not complete) immunity to overfitting," and write that the paper by Friedman, Hastie and Tibshirani "does not address this issue." Also Breiman (2000) writes, "a crucial property of AdaBoost is that it almost never overfits the data no matter how many iterations it is run," and states "unless I am missing something, there is no explanation in the paper."

Various arguments are given in response to the question of why boosting seems to not overfit. A view popular in computer science attributes the lack of overfitting to boosting's ability to achieve a large *margin* separating the two classes, as discussed by Schapire et al. (1998). A number of different opinions exist in the statistics community. Many statisticians simply argue that boosting does in fact overfit and construct examples to prove it (e.g., Ridgeway, 2000). While single examples certainly disprove claims that boosting *never* overfits, they do nothing to help us understand why boosting resists overfitting and performs very well for the large collection of examples that raised the question in the first place. Others argue that boosting will eventually overfit in most all cases if run for enough iterations, but that the number of iterations needed can be quite large since the overfitting is quite slow. Such a notion is difficult to disprove through real examples since any finite number of iterations may not be enough. Furthermore, it is difficult to prove limiting results for an infinite number of iterations without substantially over-simplifying the algorithm. Some evidence supporting the argument that boosting will eventually overfit can be found in Grove and Schuurmans (1998) which has examples for which boosting overfits when run for a very large number of iterations. Another argument often used is that boosting's success is judged with respect to 0/1 misclassification loss, which is a loss function that is not very sensitive to overfitting (e.g., Friedman et al., 2000b). More detailed explanations attribute the lack of overfitting to the stagewise nature of the algorithm (e.g., Buja, 2000). Along this same line, it has also been observed that the repeated iterations of the algorithm give rise to a self-averaging property (e.g., Breiman, 2000). This self-averaging works to reduce overfitting by reducing variance in ways similar to bagging (Breiman, 1996) and Random Forests (Breiman, 2001).

Whatever the explanation for boosting's resistance to overfitting in so many real and important examples, the statistical view of boosting as an optimization does little to account for this. In fact the statistical framework as proposed by Friedman, Hastie and Tibshirani does exactly the opposite; it suggests that *overfitting should be a major concern*. Still, in the final analysis, we do not imply that the statistical view is wrong. Indeed, we agree with Buja (2000) who writes, "There is no single *true* interpretation of anything; interpretation is a vehicle in the service of human comprehension. The value of an interpretation is in enabling others to fruitfully think about an idea." Certainly the paper of Friedman, Hastie and Tibshirani and other related work is quite valuable in this regard. However, any view or theoretical understanding generally gives rise to practical suggestions for implementation. Due to the disconnect between the statistical view and reality, many of these resulting practical suggestions are misguided and empirical performance suffers accordingly. In this paper we focus on illustrating this phenomenon through simulation experiments.

It is important to note that although this paper deals with "the statistical view of boosting", it is an overgeneralization to imply there is only one single view of boosting in the statistical community. All statisticians are not of a single mindset, and much literature has been produced subsequent to the Friedman, Hastie and Tibshirani *Annals of Statistics* paper. Much of what we categorize as the statistical view of boosting can be found in that original paper, but other ideas, especially those in Sections 3.9, 3.10, 4.9 and 4.10, are attributable to other researchers and subsequent publications in

the statistics community. For this reason, we are careful to provide references and direct quotations throughout this paper.

The following section describes the general setting for classification and the AdaBoost algorithm. Sections 3 and 4 consider a collection of practical suggestions, commonly held beliefs and modifications to the AdaBoost algorithm based on the statistical view. For each one, a simulation providing contradictory evidence is included. Section 5 mentions a slightly different set of simulations to consider, and finally Section 6 offers practical advice in light of the evidence presented in this paper as well as some concluding remarks.

2. The Classification Problem and Boosting

In this section we will begin by describing the general problem of classification in statistics and machine learning. Next we will describe the AdaBoost algorithm and give details of our implementation.

2.1 Classification

The problem of classification is an instance of what is known as *supervised learning* in machine learning. We are given training data $x_1,...,x_n$ and $y_1,...,y_n$ where each x_i is a $d-$dimensional vector of predictors $(x_i^{(1)},...,x_i^{(d)})$ and $y_i \in \{-1,+1\}$ is the associated observed class label. To justify generalization, it is usually assumed that the training data are *iid* samples of random variables (X,Y) having some unknown distribution. The goal is to learn a rule $\hat{C}(x)$ that assigns a class label in $\{-1,+1\}$ to any new observation x. The performance of this rule is usually measured with respect to misclassification error, or the rate at which new observations drawn from the same population are incorrectly labelled. Formally we can define the misclassification error for a classification rule $\hat{C}(x)$ as $\mathrm{P}(\hat{C}(X) \neq Y)$.

For any given data set misclassification error can be estimated by reserving a fraction of the available data for test data and then computing the percent of incorrect classifications resulting from the classifier trained on the remainder of the data. Various cross-validation techniques improve upon this scheme by averaging over different sets of test data. In this paper we will consider only examples of simulated data so that the joint distribution of X and Y is known. This will enable us to estimate misclassification error as accurately as desired by simply repeatedly simulating training and test data sets and averaging the misclassification errors from the test sets.

2.2 Boosting

AdaBoost (Freund and Schapire, 1996) is one of the first and the most popular boosting algorithms for classification. The algorithm is as follows. First let $F_0(x_i) = 0$ for all x_i and initialize weights $w_i = 1/n$ for $i = 1,...,n$. Then repeat the following for m from 1 to M:

- Fit the classifier g_m to the training data using weights w_i where g_m maps each x_i to -1 or 1.
- Compute the weighted error rate $\varepsilon_m \equiv \sum_{i=1}^{n} w_i \mathrm{I}[y_i \neq g_m(x_i)]$ and half its log-odds, $\alpha_m \equiv \frac{1}{2}\log\frac{1-\varepsilon_m}{\varepsilon_m}$.
- Let $F_m = F_{m-1} + \alpha_m g_m$.
- Replace the weights w_i with $w_i \equiv w_i e^{-\alpha_m g_m(x_i) y_i}$ and then renormalize by replacing each w_i by $w_i/(\sum w_i)$.

The final classifier is 1 if $F_M > 0$ and -1 otherwise. The popularity of this algorithm is due to a vast amount of empirical evidence demonstrating that the algorithm yields very small misclassification error relative to competing methods. Further, the performance is remarkably insensitive to the choice of the total number of iterations M. Usually any sufficiently large value of M works well. For the simulations in this paper we will take $M = 1000$, with the single exception of the simulation in Section 4.7 where it is instructive to consider $M = 5000$.

Many variations of the AdaBoost algorithm now exist. We will visit some of these in Sections 3 and 4 and compare their performance to the original AdaBoost algorithm. Further, these variations as well as AdaBoost itself are very flexible in the sense that the class of classifiers from which each g_m is selected can be quite general. However, the superior performance of AdaBoost is generally in the context of classification trees. For this reason we will use classification trees in our experiments. Specifically, the trees will be fit using the "rpart" function in the "R" statistical software package (http://www.r-project.org/). The R code for all the experiments run in this paper is available on the web page http://www.davemease.com/contraryevidence.

3. Experiments Which Contradict the Statistical View of Boosting

In this section we describe the results of several experiments based on simulations from the model introduced below. Each experiment is meant to illustrate particular inconsistencies between that which is suggested by the statistical view of boosting and what is actually observed in practice.

For the experiments we will consider in this section we will simulate data from the model

$$\mathrm{P}(Y = 1|x) = q + (1-2q)\ \mathrm{I}\left[\sum_{j=1}^{J} x^{(j)} > J/2\right].$$

We will take X to be distributed *iid* uniform on the d-dimensional unit cube $[0,1]^d$. The constants n, d, J and q will be set at different values depending on the experiment. Note that q is the Bayes error and $J \leq d$ is the number of effective dimensions. Recall n is the number of observations used to train the classifier. The unconditional probabilities for each of the two classes are always equal since $\mathrm{P}(Y = 1) = \mathrm{P}(Y = 0) = 1/2$. The only exceptions to this are experiments in which we take $J = 0$ for which the sum (and thus the indicator) is taken to be always zero. In these cases the model reduces to the "pure noise" model $\mathrm{P}(Y = 1|x) \equiv q$ for all x.

3.1 Should Stumps Be Used for Additive Bayes Decision Rules?

Additive models are very popular in many situations. Consider the case in which the Bayes decision rule is additive in the space of the predictors $x^{(1)},...,x^{(d)}$. By this we mean that the Bayes decision rule can be written as the sign of $\sum_{i=1}^{d} h_i(x^{(i)})$ for some functions $h_1,...,h_d$. This is true, for example, for our simulation model. The classification rule produced by AdaBoost is itself necessarily additive in the classifiers g_m. Thus when the g_m are functions of only single predictors the AdaBoost classification rule is additive in the predictor space. For this reason it has been suggested that one should use stumps (2-node trees) if one believes the optimal Bayes rule is approximately additive, since stumps are trees which only involve single predictors and thus yield an additive model in the predictor space for AdaBoost. It is believed that using trees of a larger size will lead to overfitting because it introduces higher-level interactions. This argument is made explicit in Hastie et al. (2001) on pages 323-324 and in Friedman et al. (2000a) on pages 360-361.

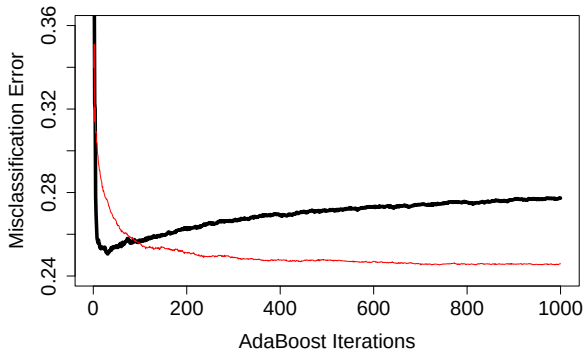

Figure 1: Comparison of AdaBoost with Stumps (Black, Thick) and 8-Node Trees (Red, Thin) for an Additive Bayes Rule

Despite the logic of this argument which is based on the idea that one should use an additive model when fitting an additive function, it can be observed that often, in fact, using larger trees is more effective than using stumps even when the Bayes rule is additive. The reason has to do with the fact that boosting with larger trees actually often overfits *less* than boosting with smaller trees in practice since the larger trees are more orthogonal and a self-averaging process prevents overfitting. We do not endeavor to make this argument rigorous here, but we will provide a compelling example.

For our example we will use our model with a Bayes error rate of $q = 0.1$, a training sample size of $n = 200$ and $d = 20$ dimensions of which $J = 5$ are active. Figure 1 displays the misclassification error of AdaBoost based on hold out samples of size 1000 (also drawn *iid* on $[0,1]^d$) as a function of the iterations. The results are averaged over 100 repetitions of the simulation. While AdaBoost with stumps (thick, black curve) leads to overfitting very early on, AdaBoost with 8-node trees (thin, red curve) does not suffer from overfitting and leads to smaller misclassification error. In fact, the misclassification error by 1000 iterations was smaller for the 8-node trees in 96 of the 100 simulations. The average (paired) difference in misclassification error was 0.031 with a standard error of $0.018/\sqrt{100} = 0.0018$. Also note that both algorithms here perform considerably worse than the Bayes error rate of $q = 0.1$.

The R code for this experiment as well as all others in this paper can be found at http://www.davemease.com/contraryevidence. We encourage the reader to appreciate the reproducibility of the qualitative result by running the code for various values of the parameters q, n, d and J.

It is worth further commenting on the fact that in this simulation AdaBoost with stumps leads to overfitting while AdaBoost with the larger 8-node trees does not, at least by 1000 iterations. This is of special interest since many of the examples other researchers provide to show AdaBoost can in fact overfit often use very small trees such as stumps as the base learner. Some such examples of overfitting can be found in Friedman et al. (2000a), Jiang (2000) and Ridgeway (2000) as well as Leo Breiman's 2002 Wald Lectures on Machine Learning.[1] The belief is that if stumps overfit then so will larger trees since the larger trees are more complex. (Clearly the example presented

1. Breiman's lecture notes can be found at http://www.stat.berkeley.edu/users/breiman/wald2002-1.pdf.

in this section shows that this is not the case.) To illustrate this viewpoint consider the quote from Jiang (2001) who writes, "all these base systems, even the ones as simple as the 'stumps', will unavoidably lead to suboptimal predictions when boosted forever." Additionally, such examples in which overfitting is observed also often deal with extremely low-dimensional cases such as $d = 2$ or even $d = 1$. By experimenting with the simulation code provided along with this paper one can confirm that in general AdaBoost is much more likely to suffer from overfitting in trivial low-dimensional examples as opposed to high-dimensional situations where it is more often used.

3.2 Should Smaller Trees Be Used When the Bayes Error is Larger?

Similar arguments to those in the previous section suggest that it is necessary to use smaller trees for AdaBoost when the Bayes error is larger. The reasoning is that when the Bayes error is larger, the larger trees lead to a more complex model which is more susceptible to overfitting noise. However, in practice we can often observe the opposite to be true. The higher Bayes error rate actually can favor the larger trees. This counterintuitive result may be explained by the self-averaging which occurs during the boosting iterations as discussed by Krieger et al. (2001). Conversely, the smaller trees often work well for lower Bayes error rates, provided they are rich enough to capture the complexity of the signal.

We illustrate this phenomenon by re-running the experiment in the previous section, this time using $q = 0$, which implies the Bayes error is zero. The average misclassification error over the 100 hold out samples is displayed in the top panel of Figure 2. It can now be observed that AdaBoost with stumps performs better than AdaBoost with 8-node trees. In fact, this was the case in 81 out of the 100 simulations (as opposed to only 4 of the 100 for $q = 0.1$ from before). The mean difference in misclassification error after 1000 iterations was 0.009 with a standard error of $0.011/\sqrt{100} = 0.0011$. The bottom panel of Figure 2 confirms that AdaBoost with stumps outperforms AdaBoost with 8-node tress only for very small values of q with this simulation model.

3.3 Should LogitBoost Be Used Instead of AdaBoost for Noisy Data?

The LogitBoost algorithm was introduced by Friedman et al. (2000a). The algorithm is similar to AdaBoost, with the main difference being that LogitBoost performs stagewise minimization of the negative binomial log likelihood while AdaBoost performs stagewise minimization of the exponential loss. By virtue of using the binomial log likelihood instead of the exponential loss, the LogitBoost algorithm was believed to be more "gentle" and consequently likely to perform better than AdaBoost for classification problems in which the Bayes error is substantially larger than zero. For instance, on page 309 Hastie et al. (2001) write, "it is therefore far more robust in noisy settings where the Bayes error rate is not close to zero, and especially in situations where there is misspecification of the class labels in the training data."

Despite such claims, we often observe the opposite behavior. That is, when the Bayes error is not zero, LogitBoost often overfits while AdaBoost does not. As an example, we consider the performance of AdaBoost and LogitBoost on the simulation from Section 3.1 in which the Bayes error was $q = 0.1$. The base learners used are 8-node trees. Figure 3 displays the performance averaged over 100 hold out samples. It is clear that LogitBoost (blue, thick) begins to overfit after about 200 iterations while AdaBoost (red, thin) continues to improve. After 1000 iterations the mean difference was 0.031 with a standard error of $0.017/\sqrt{100}$=0.0017. The misclassification error for LogitBoost at 1000 iterations was larger than that of AdaBoost in all but 4 of the 100 simulations.

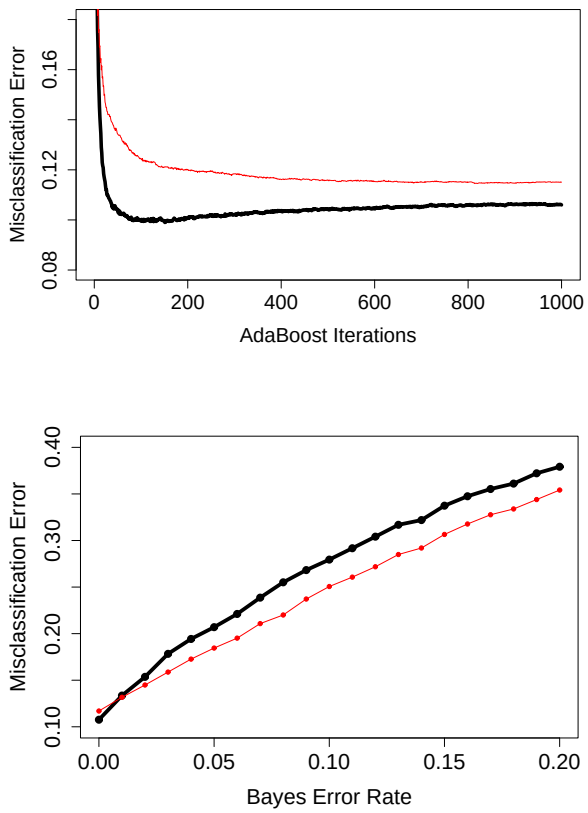

Figure 2: Comparison of AdaBoost with Stumps (Black, Thick) and 8-Node Trees (Red, Thin) for an Additive Bayes Rule. Top Panel: Misclassification Error for Zero Bayes Error as a Function of the Iterations. Bottom Panel: Misclassification Error at 1000 Iterations as a Function of the Bayes Error Rate q.

Other examples of this phenomenon of LogitBoost overfitting noisy data when AdaBoost does not can be found in Mease et al. (2007).

The R code used for LogitBoost was written by Marcel Dettling and Peter Buhlmann and can be found at http://stat.ethz.ch/∼dettling/boosting.html. Two small modifications were made to the code in order to fit 8-node trees, as the original code was written for stumps.

It should be noted that LogitBoost differs from AdaBoost not only in the loss function which it minimizes, but also in the Newton style minimization that it employs to carry out the minimization. For this reason it would be of interest to examine the performance of the algorithm in Collins et al. (2000) which minimizes the negative binomial log likelihood in a manner more analogous to AdaBoost. We do not consider that algorithm in this paper since our focus is mainly on the work of Friedman et al. (2000a) and the implications in the statistical community.

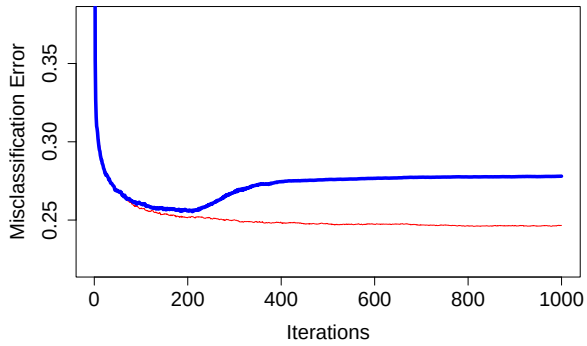

Figure 3: Comparison of AdaBoost (Red, Thin) and LogitBoost (Blue, Thick) with 8-Node Trees

3.4 Should Early Stopping Be Used to Prevent Overfitting?

In order to prevent overfitting, one popular regularization technique is to stop boosting algorithms after a very small number of iterations, such as 10 or 100. The statistics community has put a lot of emphasis on early stopping as evidenced by the large number of papers on this topic. For example, the paper "Boosting with Early Stopping: Convergence and Consistency" by Zhang and Yu (2005) tells readers that "boosting forever can overfit the data" and that "therefore in order to achieve consistency, it is necessary to stop the boosting procedure early." Standard implementations of boosting such as the popular gbm package for R by Ridgeway (2005) implement data-derived early stopping rules.

The reasoning behind early stopping is that after enough iterations have occurred so that the complexity of the algorithm is equal to the complexity of the underlying true signal, then any additional iterations will lead to overfitting and consequently larger misclassification error. However, in practice we can often observe that additional iterations beyond the number necessary to match the complexity of the underlying true signal actually reduce the overfitting that has already occurred rather than causing additional overfitting. This is likely due to the self-averaging property of AdaBoost to which we eluded earlier.

To illustrate this we use a somewhat absurd example. We take $J = 0$ in our simulation model, so that there is no signal at all, only noise. We have $\mathrm{P}(Y = 1|x) \equiv q$ so that Y does not depend on x in any way. We take a larger sample size of $n = 5000$ this time, and also use larger $2^8 = 256$-node trees. The experiment is again averaged over 100 repetitions, each time drawing the $n = 5000$ x values from $[0,1]^d$ with $d = 20$. The 100 hold out samples are also drawn from $[0,1]^{20}$ each time. The Bayes error rate is $q = 0.2$.

Since there is no signal to be learned, we can observe directly the effect of AdaBoost's iterations on the noise. We see in Figure 4 that early on there is some overfitting, but this quickly goes away and the misclassification error decreases and appears to asymptote very near the Bayes error rate of $q = 0.2$. In fact, the final average after 1000 iterations (to three decimals accuracy) is 0.200 with a standard error of $0.013/\sqrt{100}$=0.0013. Even more interesting, the misclassification error after 1000 iterations is actually less than that after the first iteration (i.e., the misclassification error for a single 2^8-node tree). The mean difference between the misclassification error after one iteration and that after 1000 iterations was 0.012 with a standard error of $0.005/\sqrt{100}$=0.0005. The difference was

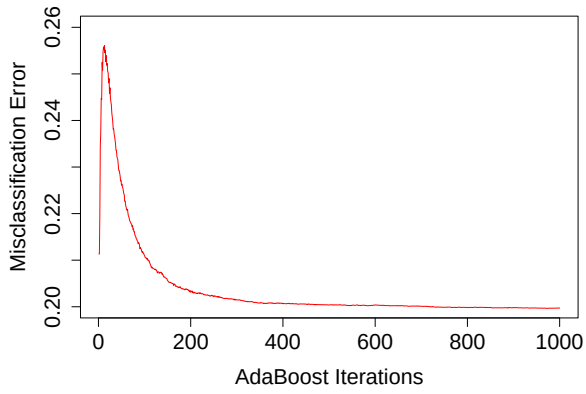

Figure 4: AdaBoost on 20% Pure Noise

positive in 99 of the 100 repetitions. Thus we see that not only does AdaBoost resist overfitting the noise, it actually fits a classification rule that is less overfit than its own 2^8-node tree base classifier.

3.5 Should Regularization Be Based on the Loss Function?

Since the statistical view of boosting centers on the stagewise minimization of a certain loss function on the training data, a common suggestion is that regularization should be based on the behavior of that loss function on a hold out or cross-validation sample. For example, the implementation of the AdaBoost algorithm in the gbm package (Ridgeway, 2005) uses the exponential loss $\sum_{i=1}^{n} e^{-y_i F_m(x_i)}$ to estimate the optimal stopping time. Indeed, if early stopping is to be used as regularization, the statistical view would suggest stopping when this exponential loss function begins to increase on a hold out sample. However, in practice the misclassification error often has little to do with the behavior of the exponential loss on a hold out sample. To illustrate this, we return to the experiment in Section 3.1. If we examine the exponential loss on hold out samples for AdaBoost with the 8-node trees, it can be seen that this loss function is exponentially increasing throughout the 1000 iterations. This is illustrated in Figure 5 which shows the linear behavior of the log of the exponential loss for a single repetition from this experiment on a hold out sample of size 1000. Thus, early stopping regularization based on the loss function would suggest stopping after just one iteration, when in fact Figure 1 shows we do best to run the 8-node trees for the full 1000 iterations. This behavior has also been noted for LogitBoost as well (with respect to the negative log likelihood loss) in Mease et al. (2007) and in Dettling and Buhlmann (2003). In the latter reference the authors estimated a stopping parameter for the number of iterations using cross-validation but observed that they "could not exploit significant advantages of estimated stopping parameters" over allowing the algorithm to run for the full number of iterations (100 in their case).

3.6 Should the Collection of Basis Functions Be Restricted to Prevent Overfitting?

Another popular misconception about boosting is that one needs to restrict the class of trees in order to prevent overfitting. The idea is that if AdaBoost is allowed to use *all* 8-node trees for instance, then the function class becomes too rich giving the algorithm too much flexibility which

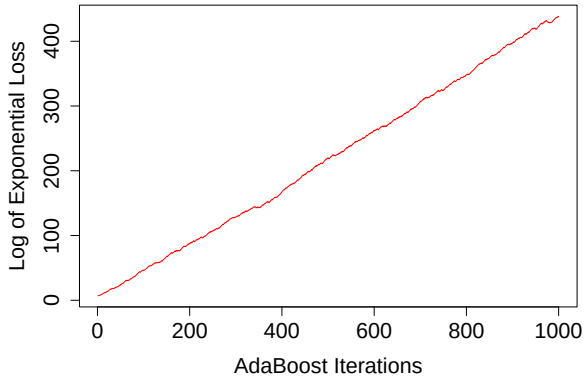

Figure 5: The Log of the Exponential Loss for AdaBoost on a Hold Out Sample

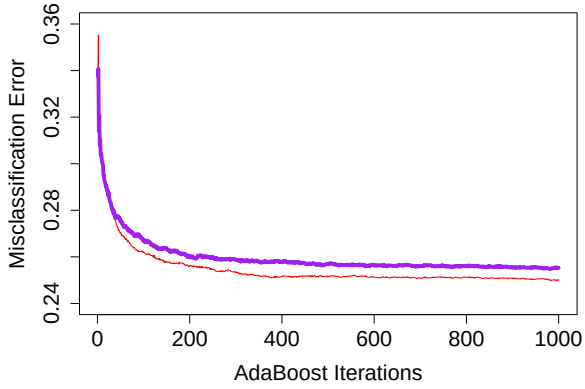

Figure 6: Comparison of AdaBoost with 8-Node Trees (Red, Thin) to AdaBoost with 8-Node Trees Restricted to Have at Least 15 Observations in Each Terminal Node (Purple, Thick)

leads to overfitting. This line of thinking gives rise to various methods for restricting or regularizing the individual trees themselves as a method of regularizing the AdaBoost algorithm. For instance, the implementation of AdaBoost in the gbm code (Ridgeway, 2005) has a parameter called "n.minobsinnode" which is literally the minimum number of observations in the terminal nodes of the trees. The default of this value is not 1, but 10.

In spite of this belief, it can be observed that the practice of limiting the number of observations in the terminal nodes will often degrade the performance of AdaBoost. It is unclear why this happens; however, we note that related tree ensemble algorithms such as PERT (Cutler and Zhao, 2001) have demonstrated success by growing the trees until only a single observation remains in each terminal node.

As an example of this performance degradation, we again revisit the simulation in Section 3.1 and compare the (unrestricted) 8-node trees used there to 8-node trees restricted to have at least 15

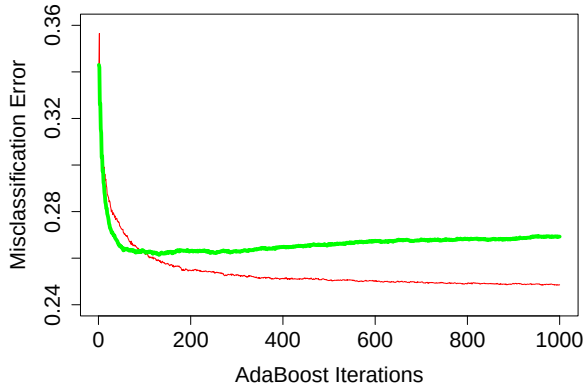

Figure 7: Comparison of AdaBoost (Red, Thin) and AdaBoost with Shrinkage (Green, Thick)

observations in each terminal node. (This is done in R by using the option "minbucket=15" in the "rpart.control" syntax.) Figure 6 shows the results with the unrestricted 8-node trees given by the red (thin) curve and the restricted 8-node trees given by the purple (thick) curve. The degradation in performance is evident, although not extremely large. The mean difference in misclassification error at 1000 iterations was 0.005 with a standard error of $0.010/\sqrt{100}$=0.001. AdaBoost with unrestricted 8-node trees gave a lower misclassification error in 67 of the 100 repetitions.

3.7 Should Shrinkage Be Used to Prevent Overfitting?

Shrinkage is yet another form of regularization that is often used for boosting algorithms. In the context of AdaBoost, shrinkage corresponds to replacing the α_m in the update formula $F_m = F_{m-1} + \alpha_m g_m$ by $\nu\alpha_m$ where ν is any positive constant less than one. The value $\nu = 0.1$ is popular. In the statistical view of boosting, shrinkage is thought to be extremely important. It is believed to not only reduce overfitting but also to increase the maximum accuracy (i.e., the minimum misclassification error) over the iterations. For instance, Friedman et al. (2000b) write, "the evidence so far indicates that the smaller the value of ν, the higher the overall accuracy, as long as there are enough iterations."

Despite such claims, it can be observed that shrinkage often does not improve performance and instead can actually cause AdaBoost to overfit in situations where it otherwise would not. To understand why this happens one needs to appreciate that it is the suboptimal nature of the stagewise fitting of AdaBoost that helps it to resist overfitting. Using shrinkage can destroy this resistance. For an example, we again revisit the simulation in Section 3.1 using the 8-node trees. In Figure 7 the red (thin) curve corresponds to the misclassification error for the 8-node trees just as in Section 3.1 and the green (thick) curve now shows the effect of using a shrinkage value of $\nu = 0.1$. It is clear that the shrinkage causes overfitting in this simulation. By 1000 iterations shrinkage gave a larger misclassification error in 95 of the 100 repetitions. The mean difference in misclassification error at 1000 iterations was 0.021 with a standard error of $0.012/\sqrt{100}$=0.0012.

3.8 Is Boosting Estimating Probabilities?

The idea that boosting produces probability estimates follows directly from the statistical view through the stagewise minimization of the loss function. Specifically, the exponential loss $\sum_{i=1}^{n} e^{-y_i F_m(x_i)}$, which is minimized at each stage by AdaBoost, achieves its minimum when the function $F_m(x)$ relates to the true conditional class probabilities $p(x) \equiv \mathrm{P}(Y=1|x)$ by the formula $F_m(x) = \frac{1}{2}\log\frac{p(x)}{1-p(x)}$. This leads to the estimator of $p(x)$ after m iterations given by

$$\hat{p}_m(x) = 1/(1+e^{-2F_m(x)}).$$

This relationship between the score function F_m in AdaBoost and conditional class probabilities is given explicitly in Friedman et al. (2000a). An analogous formula is also given for obtaining probability estimates from LogitBoost. Standard implementations of boosting such as Dettling and Buhlmann's LogitBoost code at http://stat.ethz.ch/∼dettling/boosting.html as well as the gbm LogitBoost code by Ridgeway (2005) output conditional class probabilities estimates directly.

Despite the belief that boosting is estimating probabilities, the estimator $\hat{p}_m(x)$ given above is often extremely overfit in many cases in which the classification rule from AdaBoost shows no signs of overfitting and performs quite well. An example is given by the experiment in Section 3.1. In Figure 1 we saw that the classification rule using 8-node trees performed well and did not overfit even by 1000 iterations. Conversely, the probability estimates are severely overfit early on. This is evidenced by the plot of the exponential loss in Figure 5. In this context the exponential loss can be thought of as an estimate of a *probability scoring rule* which quantifies the average disagreement between a true probability p and an estimate $\hat{p}$ using only binary data (Buja et al., 2006). For the exponential loss the scoring rule is $p\sqrt{(1-\hat{p})/\hat{p}} + (1-p)\sqrt{\hat{p}/(1-\hat{p})}$. The fact that the plot in Figure 5 is increasing shows that the probabilities become worse with each iteration as judged by this scoring rule. Similar behavior can be seen using other scoring rules such as the squared loss $(p-\hat{p})^2$ and the log loss $-p\log\hat{p} - (1-p)\log(1-\hat{p})$ as shown in Mease et al. (2007). This reference also shows the same behavior for the probability estimates from LogitBoost, despite the fact that efficient probability estimation is the main motivation for the LogitBoost algorithm.

The reason for the overfitting of these probability estimators is that as more and more iterations are added to achieve a good classification rule, the value of $|F_m|$ at any point is increasing quickly. The classification rule only depends on the sign of F_m and thus is not affected by this. However, this increasing tendency of $|F_m|$ impacts the probability estimates by causing them to quickly diverge to 0 and 1. Figure 8 shows the probability estimates $\hat{p}_m(x_i) = 1/(1+e^{-2F_m(x_i)})$ for AdaBoost from a single repetition of the experiment in Section 3.1 using 8-node trees on a hold out sample of size 1000. The top histogram corresponds to $m = 10$ iterations and the bottom histogram shows $m = 1000$ iterations. The histograms each have 100 equal width bins. It can be seen that after only 10 iterations almost all of the probability estimates are greater than 0.99 or less than 0.01, and even more so by 1000 iterations. This indicates a poor fit since we know all of the true probabilities are either 0.1 or 0.9.

Other researchers have also noted this type of overfitting with boosting and have used it as an argument in favor of regularization techniques. For instance, it is possible that using a regularization technique such as shrinkage or the restriction to stumps as the base learners in this situation could produce better probability estimates. However, from what we have seen of some regularization techniques in this paper, we know that regularization techniques often severely degenerate the classification performance of the algorithm. Furthermore, some are not effective at all in many

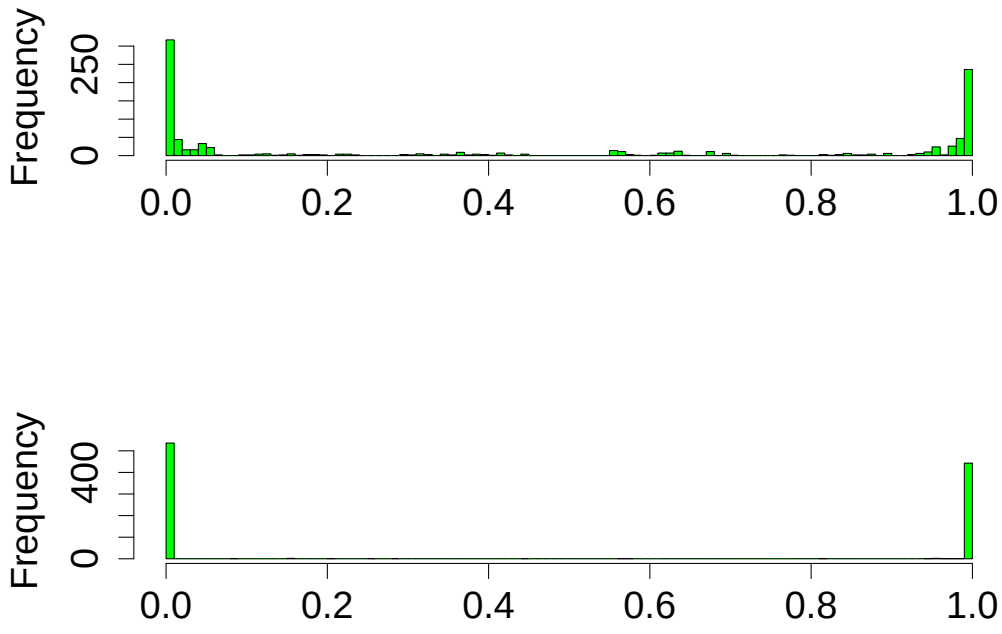

Figure 8: Probability Estimates From AdaBoost at $m = 10$ Iterations (Top) and $m = 1000$ Iterations (Bottom)

situations. For instance, early stopping, one of the most popular regularization techniques, is of little help when the probabilities overfit from the outset as in Figure 5. For a technique that achieves conditional probability estimation using AdaBoost without modification or regularization the reader should see Mease et al. (2007).

3.9 Is Boosting Similar to the One Nearest Neighbor Classifier?

In all the experiments considered in this paper, AdaBoost achieves zero misclassification error on the training data. This characteristic is quite typical of AdaBoost and has led some researchers to draw parallels to the (one) nearest neighbor classifier, a classifier which necessarily also yields zero misclassification error on the training data. This characteristic has also been suggested as a reason why AdaBoost will overfit when the Bayes error is not zero.

The belief in a similarity between boosting and the nearest neighbor classifier was not expressed in the original paper of Friedman et al. (2000a), but rather has been expressed more recently in the statistics literature on boosting by authors such as Wenxin Jiang in papers such as Jiang (2000), Jiang (2001) and Jiang (2002). In Jiang (2000), the equivalence between AdaBoost and the nearest neighbor classifier is established only for the case of $d = 1$ dimension. In the $d = 1$ case, the equivalence is merely a consequence of fitting the training data perfectly (and following Jiang's

convention of using midpoints of the training data for the classification tree splits). However, as we will see from the experiment in this section, the behavior of AdaBoost even in $d = 2$ dimensions is radically different from the nearest neighbor rule.

Despite this difference, Jiang goes on to suggest that the performance of AdaBoost in higher dimensions might be similar to the case of $d = 1$ dimension. For instance in "Is Regularization Unnecessary for Boosting?" Jiang (2001) writes, "it is, however, plausible to conjecture that even in the case of higher dimensional data running AdaBoost forever can still lead to a suboptimal prediction which does not perform much better than the nearest neighbor rule." Further, Jiang (2002) writes, "the fit will be perfect for almost all sample realizations and agree with the nearest neighbor rule at all the data points as well as in some of their neighborhoods" and that "the limiting prediction presumably cannot perform much better than the nearest neighbor rule."

To understand why equivalent behavior on the training data (or "data points" using Jiang's terminology above) does not imply similar performance for classification rules for $d > 1$, it is important to remember that in the case of continuous data the training data has measure zero. Thus the behavior on the training data says very little about the performance with respect to the population. This is well illustrated by the pure noise example from Section 3.4. For any point in the training data for which the observed class differs from the class given by the Bayes rule, both AdaBoost and nearest neighbor will classify this point as the observed class and thus disagree with the Bayes rule. However, the volume of the affected neighborhood surrounding that point can be arbitrarily small with AdaBoost, but will necessarily be close to $1/n$ of the total volume with nearest neighbor.

To help the reader visualize this, we consider a $d = 2$-dimensional version of the pure noise example from Section 3.4. We again use a Bayes error rate of $q = 0.2$ but now take only $n = 200$ points spread out evenly according to a Latin hypercube design. The left plot in Figure 9 shows the resulting classification of AdaBoost using 8-node trees after 1000 iterations and the right plot shows the rule for nearest neighbor. The training points with $Y = -1$ are colored black and those with $Y = +1$ are colored yellow. Regions classified as -1 are colored purple and those classified as $+1$ are colored light blue. Since the Bayes rule is to classify the entire area as -1, we can measure the overfitting of the rules by the fraction of the total area colored as light blue. The nearest neighbor classifier has 20% of the region colored as light blue (as expected), while AdaBoost has only 16%. The two classifiers agree "at all the [training] data points as well as in some of their neighborhoods" as stated by Jiang, but the "some" here is relatively small.

In higher dimensions this effect is even more pronounced. For the $d = 20$-dimensional example from Section 3.4 the area (volume) of the light blue region would be essentially zero for AdaBoost (as evidenced by its misclassification error rate matching almost exactly that of the Bayes error), while for nearest neighbor it remains at 20% as expected. Thus we see that the nearest neighbor classifier differs from the Bayes rule for 20% of the points in both the training data and the population while AdaBoost differs from the Bayes rule for 20% of the points in the training data but virtually none in the population.

The differences between the nearest neighbor classifier and AdaBoost are obvious in the other experiments in this paper as well. For instance, for the experiment in Section 3.1 the nearest neighbor classifier had an average misclassification error rate of 0.376 versus 0.246 for AdaBoost with the 8-node trees.

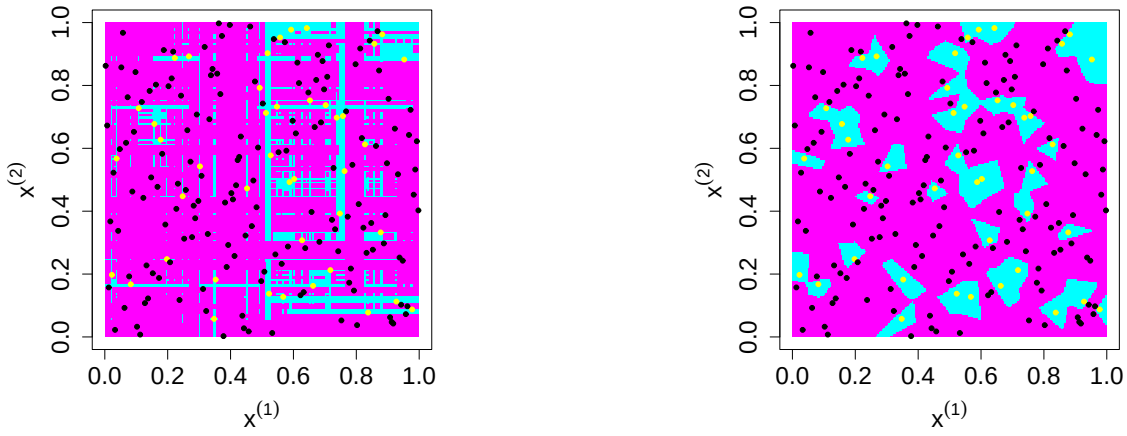

Figure 9: Comparison of AdaBoost (Left) and Nearest Neighbor (Right) on 20% Pure Noise

3.10 Is Boosting Consistent?

An important question to ask about any estimator is whether or not it is consistent. A consistent estimator is defined to be any estimator for which the estimated quantity converges in probability to the true quantity. In our context, to ask if AdaBoost is a consistent estimator is to ask if its classification rule converges in probability to the Bayes rule. If it is consistent, then with a sufficiently large training sample size n its misclassification error will come arbitrarily close to the Bayes error.

The belief in the statistics community is that AdaBoost is not consistent unless regularization is employed. The main argument given is that if AdaBoost is left unregularized it will eventually fit all the data thus making consistency impossible as with the nearest neighbor classifier. Consequently, all work on the consistency of boosting deals with regularized techniques. While we have noted in Section 3.9 that it is characteristic of AdaBoost to achieve zero misclassification error on the training data, we have also discussed the fact that this in no way determines its performance in general, as the training data has measure zero in the case of continuous data. In fact in Section 3.4 we observed that with a sample size of $n = 5000$ AdaBoost with 2^8-node trees achieved the Bayes error rate to three decimals on a 20% pure noise example despite fitting all the training data.

In this section we consider a simulation with this same sample size and again 2^8-node trees but we now include a signal in addition to the noise. We take $J = 1$ and use $d = 5$ dimensions and fix the Bayes error rate at $q = 0.1$. The resulting misclassification error rate averaged over 100 repetitions each with a hold out sample of size 1000 is shown in Figure 10. As before, AdaBoost fits all the training data early on, but the misclassification error after 1000 iterations averages only 0.105 with a standard error of $0.010/\sqrt{100}$=0.001. This is quite close to the Bayes error rate $q = 0.1$ and can be observed to come even closer by increasing the sample size. It should also be noted that this error rate is much below the limit of $2q(1-q) = 0.18$ that holds for the nearest neighbor classifier in this case.

The belief that unregularized AdaBoost can not be consistent is promoted by Wenxin Jiang's work mentioned in Section 3.9 connecting the performance of AdaBoost and the nearest neighbor classifier. His result for $d = 1$ rules out consistency in that case since the nearest neighbor rule is

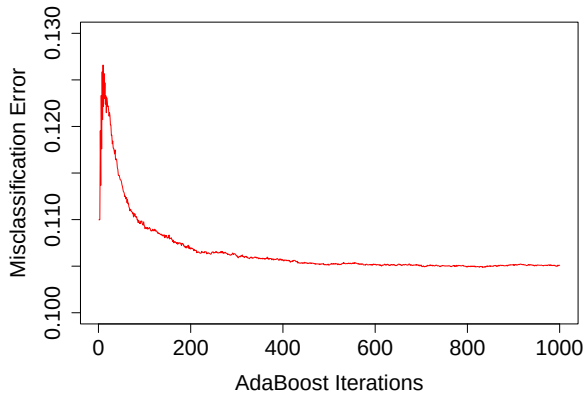

Figure 10: Performance of AdaBoost for a Simulation with a Bayes Error of 0.1

not consistent, but nothing is established for $d > 1$ with regard to AdaBoost. Jiang (2002) admits this when he writes, "what about boosting forever with a higher dimensional random continuous predictor x with $\dim(x) > 1$? We do not have theoretical results on this so far."

4. More Experiments Which Contradict the Statistical View of Boosting

In this section we revisit the experiments from Section 3 using a different simulation model. The purpose here is to show that the results are reproducible and do not depend on a particular simulation model. We also encourage readers to experiment with other simulation models by modifying the code provided on the web page.

The simulations in this section will use the model

$$P(Y=1|x) = \begin{cases} q & x^{(1)} \in [0,0.1) \cup [0.2,0.3) \cup [0.4,0.5) \cup [0.6,0.7) \cup [0.8,0.9) \\ 1-q & x^{(1)} \in [0.1,0.2) \cup [0.3,0.4) \cup [0.5,0.6) \cup [0.7,0.8) \cup [0.9,1]. \end{cases}$$

We will rerun each experiment from Section 3 using this model. Throughout this section we will use $d = 20$ dimensions and take X to be distributed *iid* uniform on the 20-dimensional unit cube $[0,1]^{20}$. For each experiment we will use twice the sample size of the analogous experiment in Section 3 and the same Bayes error q. The single exception will be the experiment in Section 4.9 in which we use a Bayes error of $q = 0.1$ and $d = 2$ dimensions for visualization purposes.

Note that while the experiments in Section 3 had $J \leq d$ effective dimensions, the experiments in this section will all have only one effective dimension as a result of this simulation model. The plots in Figure 19 are useful for visualizing this model in $d = 2$ dimensions.

4.1 Should Stumps Be Used for Additive Bayes Decision Rules?

As in Section 3.1 we use a Bayes error rate of $q = 0.1$ and $d = 20$ dimensions. We use the new simulation model with a training sample size of $n = 400$. Figure 11 displays the misclassification error of AdaBoost based on hold out samples of size 1000 (also drawn *iid* on $[0,1]^{20}$) as a function of the iterations. The results are again averaged over 100 repetitions of the simulation.

As in Section 3.1, Adaboost with 8-node trees (thin, red curve) does not show any signs of overfitting while AdaBoost with stumps (thick, black curve) leads to overfitting. The overfitting

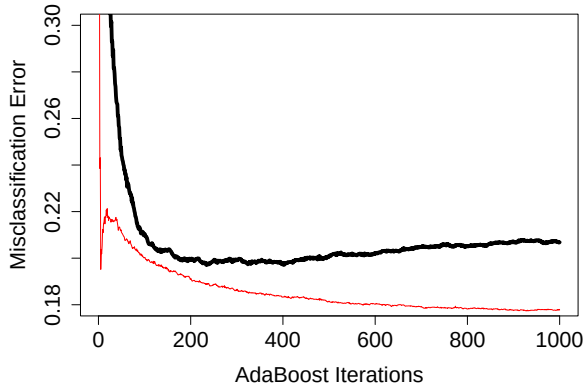

Figure 11: Comparison of AdaBoost with Stumps (Black, Thick) and 8-Node Trees (Red, Thin) for an Additive Bayes Rule

is evident in this experiment after about 400 iterations. Furthermore, AdaBoost with 8-node trees outperforms AdaBoost with stumps throughout the entire 1000 iterations. The misclassification error by 1000 iterations was smaller for the 8-node trees in 93 of the 100 simulations. The average (paired) difference in misclassification error after 1000 iterations was 0.029 with a standard error of $0.018/\sqrt{100} = 0.0018$. As before, since the simulation model used here has an additive Bayes decision rule, this evidence is directly at odds with the recommendation in Hastie et al. (2001) and Friedman et al. (2000a) that stumps are preferable for additive Bayes decision rules.

4.2 Should Smaller Trees Be Used When the Bayes Error is Larger?

As in Section 3.2, we observe that when we decrease the Bayes error rate from $q = 0.1$ to $q = 0$, the 8-node trees no longer have an advantage over the stumps. Figure 12 displays the results of the simulation in Section 4.1 using a Bayes error rate of $q = 0$. We see that the advantage of the 8-node trees has completely disappeared, and now the 8-node trees and stumps are indistinguishable. By 1000 iterations the misclassification errors for both are identical in all of the 100 repetitions.

Thus we see that the advantage of the larger trees in Section 4.1 is a result of the non-zero Bayes error, again suggesting that larger trees are in some way better at handling noisy data. This directly contradicts the conventional wisdom that boosting with larger trees is more likely to overfit on noisy data than boosting with smaller trees.

4.3 Should LogitBoost Be Used Instead of AdaBoost for Noisy Data?

We now rerun the experiment in Section 4.1 using AdaBoost and LogitBoost both with 8-node trees. Figure 13 displays the results with AdaBoost in red (thin) and LogitBoost in blue (thick). While LogitBoost performs better early on, it eventually suffers from overfitting near 400 iterations while AdaBoost shows no overfitting. Furthermore, the misclassification error for AdaBoost after 1000 iterations is (slightly) lower than the minimum misclassification error achieved by LogitBoost. After 1000 iterations the mean difference in misclassification error between LogitBoost and AdaBoost

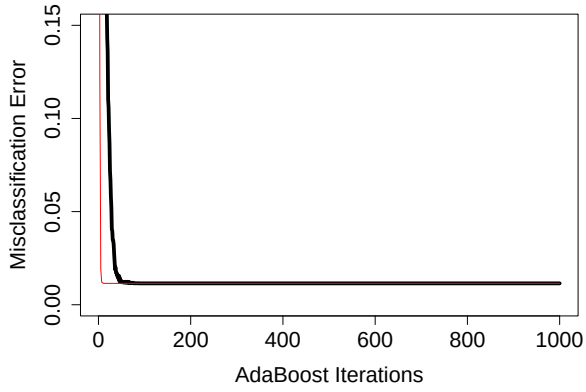

Figure 12: Comparison of AdaBoost with Stumps (Black, Thick) and 8-Node Trees (Red, Thin) for an Additive Bayes Rule with Zero Bayes Error

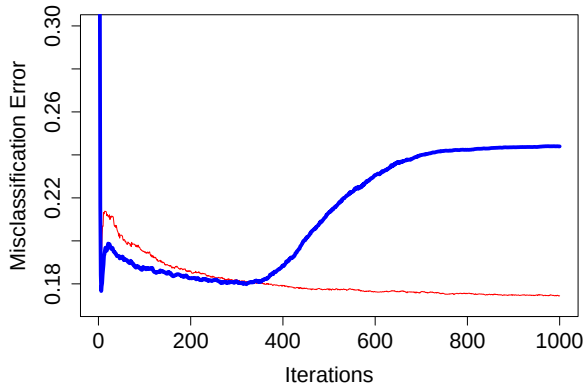

Figure 13: Comparison of AdaBoost (Red, Thin) and LogitBoost (Blue, Thick) with 8-Node Trees

was 0.069 with a standard error of $0.021/\sqrt{100}$=0.0021. The misclassification error for LogitBoost at 1000 iterations was larger than that of AdaBoost in all of the 100 repetitions.

Thus we again see that although LogitBoost was invented to perform better than AdaBoost for data with non-zero Bayes error, LogitBoost actually overfits the data while AdaBoost does not.

4.4 Should Early Stopping Be Used to Prevent Overfitting?

In this section we repeat the simulation from Section 3.4 using the new simulation model. Just as in Section 3.4 we use large $2^8 = 256$-node trees, a Bayes error rate of $q = 0.2$ and $d = 20$ dimensions. We now take twice the training sample size of Section 3.4 so that we have $n = 10,000$ points.

Figure 14 shows the resulting misclassification error averaged over 100 repetitions for hold out samples of size 1000. Although there is overfitting early on, the best performance is again achieved

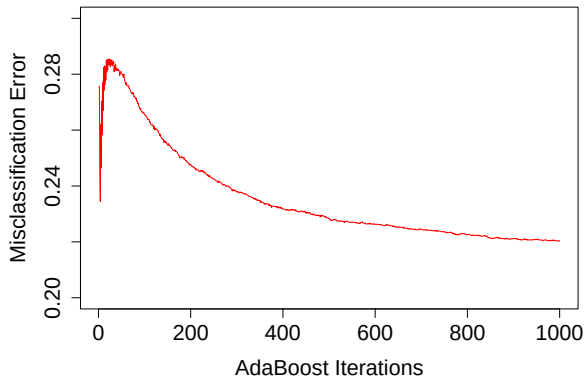

Figure 14: AdaBoost with 20% Bayes Error Using 256-Node Trees

by running the algorithm for the full 1000 iterations. We note that conventional early stopping rules here would be especially harmful since they would stop the algorithm after only a few iterations when the overfitting first takes place. Consequently any such early stopping rule would miss the optimal rule of running for the full 1000 iterations.

It should also be noted that the $2^8 = 256$-node trees used here are much richer than needed to fit the simple one-dimensional Bayes decision rule for this simulation model. Despite this, the misclassification error after 1000 iterations was lower than the misclassification error after the first iteration in all 100 of the reptitions. Thus it is again the self-averaging property of boosting that improves the performance as more and more iterations are run. Early stopping in this example would destroy the benefits of this property.

4.5 Should Regularization Be Based on the Loss Function?

As discussed in Section 3.5, regularization techniques for boosting such as early stopping are often based on minimizing a loss function such as the exponential loss in the case of AdaBoost. However, the performance of AdaBoost with regard to misclassification loss often has very little to do with the exponential loss function in practice.

In this section we examine the exponential loss for the experiment in Section 4.1 using 8-node trees. Figure 15 shows the increasing linear behavior for the log of the exponential loss for a single repetition of this experiment with a hold out sample of size 1000. Thus, just as in Section 3.5, the exponential loss increases exponentially as more iterations are run, while the misclassification error continues to decrease. Choosing regularization to minimize the exponential loss is again not useful for minimizing the misclassification error.

4.6 Should the Collection of Basis Functions Be Restricted to Prevent Overfitting?

In Section 3.6 we saw that restricting the number of observations in the terminal nodes of the trees to be at least 15 degraded the performance of AdaBoost, despite the common belief that such restrictions should be beneficial. In this section we rerun the experiment in Section 4.1 but again consider this same restriction.

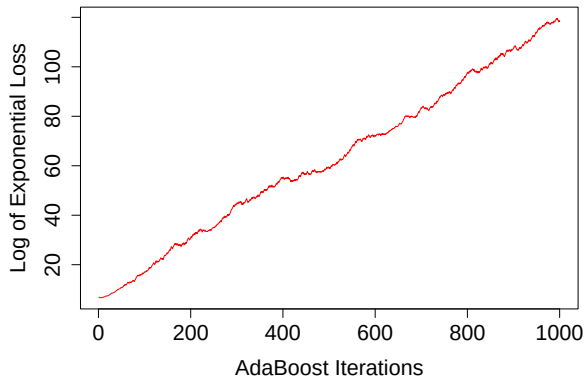

Figure 15: The Log of the Exponential Loss for AdaBoost on a Hold Out Sample

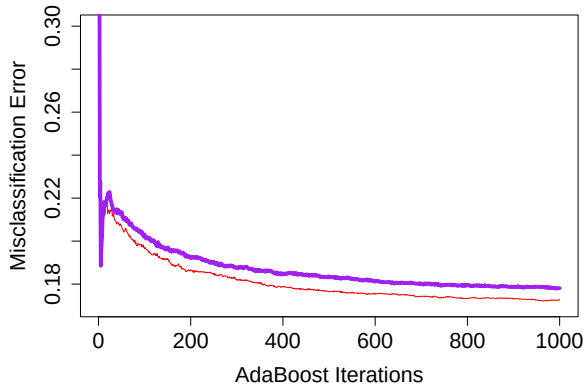

Figure 16: Comparison of AdaBoost with 8-Node Trees (Red, Thin) to AdaBoost with 8-Node Trees Restricted to Have at Least 15 Observations in the Terminal Nodes (Purple, Thick)

Figure 16 shows the results with the unrestricted 8-node trees given by the red (thin) curve and the 8-node trees restricted to have at least 15 observations in the terminal nodes given by the purple (thick) curve. As in Section 3.6, degradation in performance is evident. The mean difference in misclassification error at 1000 iterations was 0.005 with a standard error of $0.010/\sqrt{100}$=0.001. AdaBoost with unrestricted 8-node trees gave a lower misclassification error at 1000 iterations in 65 of the 100 repetitions for this simulation model.

4.7 Should Shrinkage Be Used to Prevent Overfitting?

In Section 3.7 we saw that shrinkage actually caused AdaBoost to overfit in a situation where it otherwise would not have, in spite of the popular belief that shrinkage prevents overfitting. In this section we rerun the experiment in Section 4.1 with 8-node trees again using a shrinkage value of

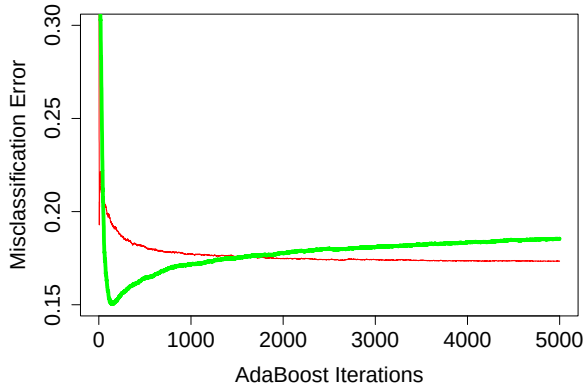

Figure 17: Comparison of AdaBoost (Red, Thin) and AdaBoost with Shrinkage (Green, Thick)

$\nu = 0.1$. Figure 17 shows the results with the red (thin) curve corresponding to no shrinkage and the green (thick) curve showing the results for shrinkage. The plot shows that again shrinkage causes overfitting.

It is interesting to note that in this simulation, unlike the simulation in Section 3.7, shrinkage has the beneficial effect of producing a lower misclassification error very early on in the process, despite causing the eventual overfitting. This suggests that a stopping rule which could accurately estimate the optimal number of iterations combined with shrinkage may prove very effective for this particular simulation. As a result of the good performance early on, the shrinkage actually gives a lower misclassification error at our chosen stopping point of 1000 iterations than without the shrinkage. However, if we run for enough iterations (the plot shows 5000 iterations) the overfitting caused by the shrinkage eventually overwhelms this advantage. By 5000 iterations the shrinkage leads to a larger misclassification error in 87 of the 100 repetitions. The mean difference in misclassification error at 5000 iterations was 0.012 with a standard error of $0.012/\sqrt{100}$=0.0012.

4.8 Is Boosting Estimating Probabilities?

In Section 3.8 we saw that the probability estimates suggested by Friedman et al. (2000a) for AdaBoost diverge quickly to 0 and 1 and consequently perform very poorly even for cases where the AdaBoost classification rule performs well. In this section we examine the probability estimates for a single repetition of the experiment in Section 4.1 on a hold out sample of size 1000.

The two histograms in Figure 18 show the resulting probability estimates for $m = 10$ iterations and $m = 1000$ iterations respectively using 8-node trees. Both histograms have 100 equal width bins. At 10 iterations the estimates have not yet diverged, but by 1000 iterations almost all of the probability estimates are greater than 0.99 or less than 0.01, just as we saw in Section 3.8. As before, this indicates a poor fit since with this simulation model all of the true probabilities are either 0.1 or 0.9.

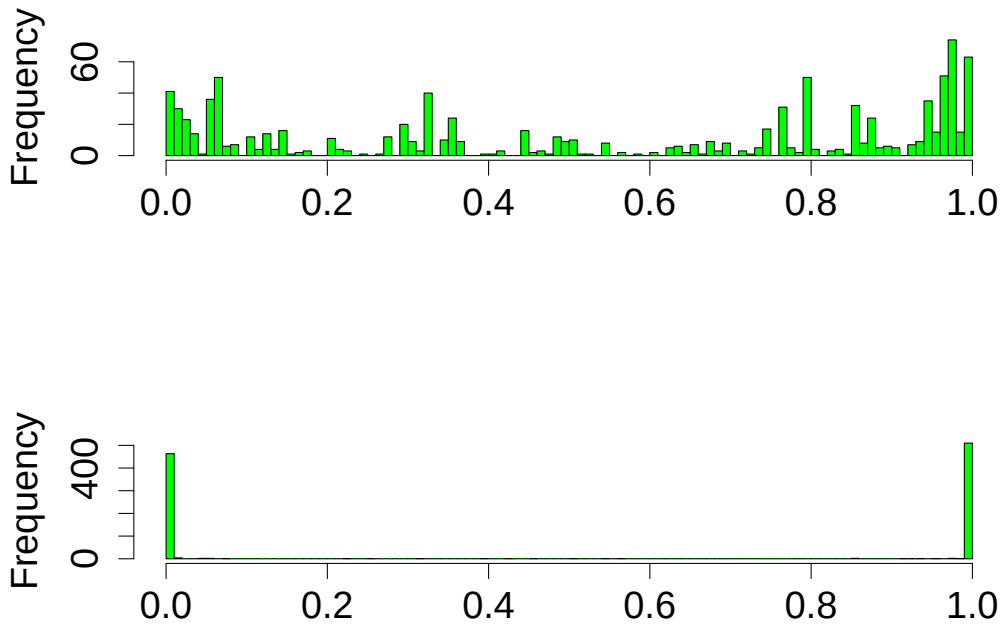

Figure 18: The Probability Estimates From AdaBoost at $m = 10$ Iterations (Top) and $m = 1000$ Iterations (Bottom)

4.9 Is Boosting Similar to the One Nearest Neighbor Classifier?

In Section 3.9 we saw that despite the fact that boosting agrees with the nearest neighbor classifier on all the training data, its performance elsewhere is quite different for $d > 1$ dimensions. For AdaBoost, areas surrounding points in the training data for which the observed class differs from that of the Bayes rule are classified according to the Bayes rule more often than they would be using the nearest neighbor rule.

We illustrate this again using $d = 2$ dimensions for visualization purposes. We use a Bayes error rate of $q = 0.1$ and take $n = 400$ points spread out evenly according to a Latin hypercube design. The plot on the left in Figure 19 shows the resulting classification rule of AdaBoost with 8-node trees at 1000 iterations for a single repetition using the new simulation model. The plot on the right shows the nearest neighbor rule. Both plots use the same color scheme as Figure 9. For the nearest neighbor rule, 21% of the points in the hold out sample disagree with the Bayes rule. This number is only 6% for AdaBoost, despite the fact that both classifiers classify every point in the training data according to the observed class label.

The difference between AdaBoost and the nearest neighbor rule is also well illustrated by other experiments in Section 4. For instance, in Section 4.1 the misclassification error for the nearest neighbor classifier was 0.499 but only 0.178 for AdaBoost with the 8-node trees.

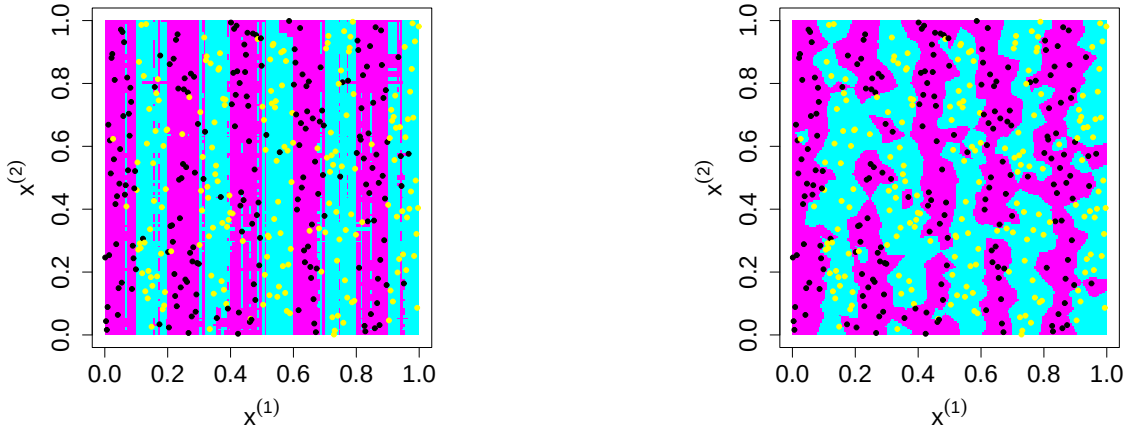

Figure 19: Comparison of AdaBoost (Left) and Nearest Neighbor (Right) with 10% Bayes Error

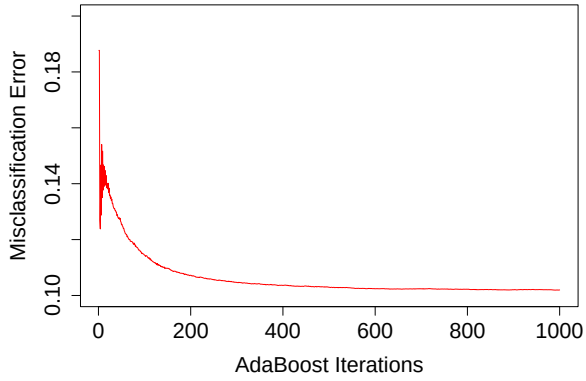

Figure 20: Performance of AdaBoost for a Simulation with a Bayes Error of 0.1

4.10 Is Boosting Consistent?

In Section 3.10 we illustrated that with a large sample size n, the misclassification error for AdaBoost can come quite close to the Bayes error rate, despite the fact that AdaBoost fits the training data perfectly. We illustrate this again in this section. As in Section 3.10, we use 2^8-node trees and a Bayes error rate of $q = 0.1$ but now take $n = 10,000$ and use the new simulation model.

Figure 20 shows the misclassification error averaged over 100 repetitions using hold out samples of size 1000. The mean misclassification error after 1000 iterations was 0.102 with a standard error of $0.009/\sqrt{100}$=0.0009. As we saw in Section 3.10, this is extremely close to the Bayes error rate and much less than the nearest neighbor bound of $2q(1-q) = 0.18$. We encourage readers to rerun the simulation with larger n to make the misclassification error even closer to the Bayes error.

5. Additional Experiments Which Contradict the Statistical View of Boosting

As mentioned at the beginning of Section 4, we encourage the reader to try simulation models other than those considered in this paper by using the R code provided on the web page http://www.davemease.com/contraryevidence. The simulation model can be specified by changing only three lines of this code in most cases. We have only considered two simulation models in this paper due to space constraints.

One criticism of the two simulation models considered in this paper is that both have a discontinuous (piecewise constant) conditional class probability function $p(x) \equiv \mathrm{P}(Y = 1|x)$. An argument can be made that both AdaBoost and LogitBoost can not provide a good fit to these models because of the discontinuities. To investigate this, we examined additional experiments from the simulation model specified by

$$p(x) = 1/(1 + e^{k(\sum_{j=1}^{J} x^{(j)} - J/2)})$$

where J is the number of effective dimensions as in Section 3 and k is a constant which determines the Bayes error rate. We note that this model has the same Bayes decision boundary as the model in Section 3 but now has a smooth conditional class probability function without any discontinuities. The results for this model are not included in the paper but are qualitatively extremely similar to those in Section 3. We encourage the reader to investigate this further.

6. Concluding Remarks and Practical Suggestions

By way of the simulations in Sections 3 and 4 we have seen that there are many problems with the statistical view of boosting and practical suggestions arising from that view. We do not endeavor to explain in this paper why these inconsistencies exist, nor do we offer a more complete view of boosting. Simply put, the goal of this paper has been to call into question this view of boosting that has come to dominate in the statistics community. The hope is that by doing so we have opened the door for future research toward a more thorough understanding of this powerful classification technique.

The statistical view of boosting focuses only on one aspect of the algorithm - the optimization. A more comprehensive view of boosting should also consider the stagewise nature of the algorithm as well as the empirical variance reduction that can be observed on hold out samples as with the experiments in this paper. Much insight on such ideas can be gained from reading work by the late Leo Breiman (e.g., Breiman, 2000, 2001) who subsequently abandoned interest in boosting and went on to work on his own classification technique known as Random Forests. The Random Forests algorithm achieves variance reduction directly through averaging as opposed to AdaBoost for which the variance reduction seems to happen accidently.

While we do not offer much in the way of an explanation for the behavior of AdaBoost in this paper, we will conclude with some practical advice in light of the evidence presented. First of all, AdaBoost remains one of, if not *the*, most successful boosting algorithms. One should not assume that newer, regularized and modified versions of boosting are necessarily better. We encourage readers to try standard AdaBoost along with these newer algorithms. If AdaBoost is not available as an option in your preferred software package, it is only a few lines of code to write yourself. Secondly, if classification is your goal, the best way to judge the effectiveness of boosting is by monitoring the misclassification error on hold out (or cross-validation) samples. We have seen that other loss functions are not necessarily indicative of the performance of boosting's classification

rule. Finally, much of the evidence we have presented is indeed counter-intuitive. For this reason, a practitioner needs to keep an open mind when experimenting with AdaBoost. For example, if stumps are causing overfitting, be willing to try larger trees. Intuition may suggest the larger trees will overfit even more, but we have seen that is not necessarily true.

1. Introduction

Mease and Wyner (MW) argue experimentally that the statistical view of boosting does not account for its success and that following the now conventional wisdom arising from this view in Friedman et al. (2000) does not necessarily lead to choices in the boosting algorithm that improve generalization. The authors did an excellent job of defining a set of experiments in which small changes in the boosting algorithm (such as changing the hypothesis space, loss function, and shrinkage) produce significant changes in generalization that were unintuitive given the statistical view of AdaBoost (Freund and Schapire, 1996) expressed in Friedman et al. (2000).

The authors state "The statistical view focuses only on one aspect of the algorithm - the optimization." But one can argue just the opposite, that some of the problems and surprises come from not enough of the optimization perspective instead of too much. Analyzing AdaBoost's performance as an optimization algorithm in terms of convergence rates and optimality conditions (measured on the training data) can be quite revealing. First, we observe that the experiments in MW make dramatic changes in the convergence rates of AdaBoost and that these convergence rates are closely associated with the margin of the classifier. AdaBoost may avoid overfitting for two completely different reasons. Sometimes the algorithm is converging so slowly that stopping at a large number of iterations is still early stopping. At other times, AdaBoost converges relatively quickly and is in essence "overtrained" way past reasonable measures of the optimality conditions. In this case the classifier has converged and is no longer changing much, so the classifier does not overfit. Indeed, some overtraining appears to help improve the classifier slightly. Second, we observe that AdaBoost cannot be trained forever. For the separable case, overtraining AdaBoost and LogitBoost will eventually produce numeric problems that can produce artifacts in the generalization error. In Experiments 3.3 and 4.3 in MW, LogitBoost was overtrained to the point of failure. The so called overfitting observed for LogitBoost was really an algorithmic issue that is quite fixable. If LogitBoost is stopped appropriately or another stepsize strategy is used, the results for LogitBoost are as good as or better than those for AdaBoost. More discussion of these results can be found below.

2. A Mathematical Programmer's View of AdaBoost

AdaBoost optimizes a linear combination of weak hypotheses with respect to the exponential loss. AdaBoost is a coordinate descent (CD) algorithm, that iteratively optimizes the problem with respect to one hypothesis at a time using column generation (Bennett et al., 2000). The weak learner seeks the hypothesis that maximizes the inner product with the function gradient (Mason et al., 2000). The convergence properties of such coordinate descent algorithms have been extensively studied in the mathematical programming community and a full analysis of relevant CD results and their extension to the boosting case can be found in Rätsch (2001).

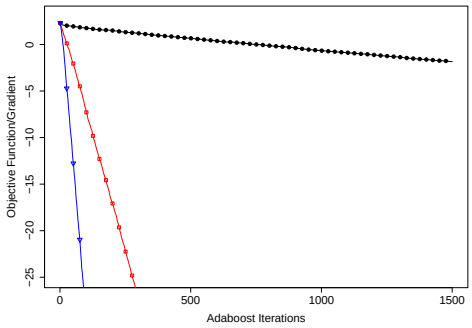
Thus from the mathematical programming perspective, we know AdaBoost inherits both the beneficial and potentially problematic properties of CD. We know from both the CD and original AdaBoost theoretical results that the AdaBoost *objective* converges linearly to the optimal objective. The simplicity of CD and its suitability for column generation make coordinate descent an attractive algorithm, but in practice coordinate descent is not widely used because it can be very slow and it has a tendency to cycle. CD guarantees that the objective function converges to the minimum but there is no guarantee that optimal hypothesis coefficients are attained, and cycling is possible. The AdaBoost loss function is particularly problematic since the exponential function is not strongly convex and the Hessian is rank deficient when the size of the hypothesis space exceeds the number of points. Overall, mathematical programming tells us that we can expect the AdaBoost objective value to converge linearly and the convergence rate to be slow, especially when cycling occurs. The paper on the dynamics of AdaBoost (Rudin et al., 2004) investigates this cycling behavior.

The MW experiments focus on the degenerate case in which the optimal objective value of the underlying exponential optimization problem is zero. LogitBoost and AdaBoost are functions of the form $min_{\alpha} J(f)\ s.t.\ f = Ha$ where H is the hypothesis space matrix containing all possible weak learners for that data set. In every case, there exists some linear combination of weak learners that classifies the points with no error, and therefore the objective can be driven to zero. The AdaBoost exponential loss function is $\sum \exp(-y_i f_i)$. The function space gradient is $\frac{\partial J(f)}{\partial f_i} = -y_i exp(-y_i f_i)$. Note the 1-norm of the function space gradient is the same as the objective, $\left\| \frac{\partial J(f)}{\partial f} \right\|_1 = \sum \exp(-y_i f(x_i))$ for two-class classification. The optimality condition is that the gradient with respect to α is zero, $\frac{\partial J(Ha)}{\partial \alpha} = H' \frac{\partial J(f)}{\partial f} = 0$. In theory, to check this gradient we need to know the weak learners for the full hypothesis space, H. But, for cases where the misclassification error is driven to 0, it is sufficient to monitor the gradient in function space. Fortunately, the norm of the function space gradient provides an upper bound on the norm of the true gradient since $\left\| H' \frac{\partial J(f)}{\partial f} \right\| \leq C \left\| \frac{\partial J(f)}{\partial f} \right\|$ for some fixed $C > 0$.

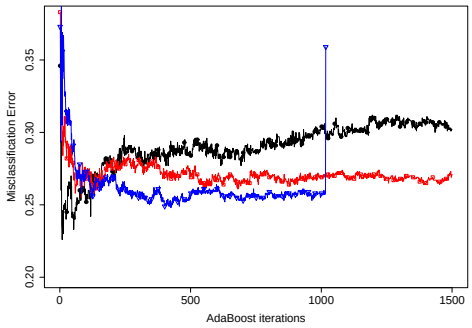
From a mathematical programming perspective, we are optimizing a degenerate, poorly-scaled problem for which the optimal objective value of 0 can only be achieved in the limit using a slower algorithm prone to cycling that may become numerically unstable. Clearly, convergence of the algorithm should be monitored closely. Yet, in most machine learning boosting papers, the focus is on generalization for a fixed number of iterations and rarely on optimization performance.

3. Convergence Rate of AdaBoost

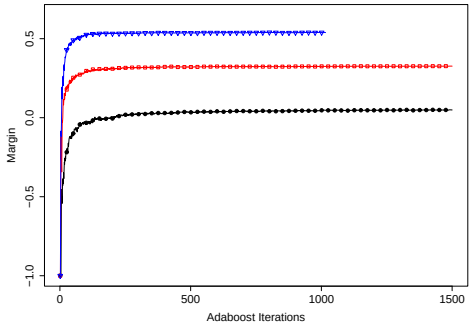
Let's examine the convergence rate and optimality conditions of AdaBoost in the MW experiments. Figure 1 contains three plots, one each for the log base 10 of the objective (or equivalently the 1-



(a) Objective/Gradient (log10)



(b) Test Error

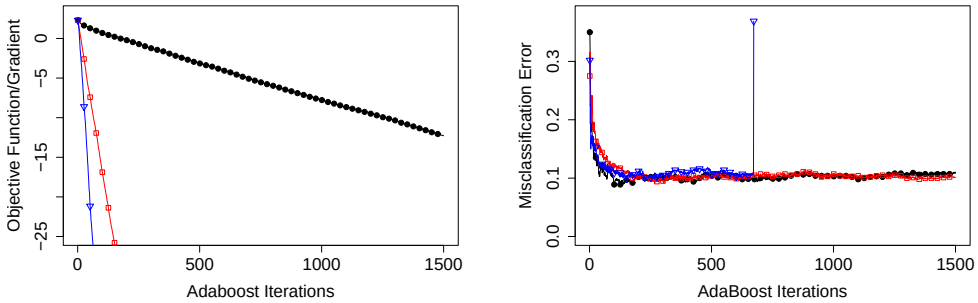


(c) Margin

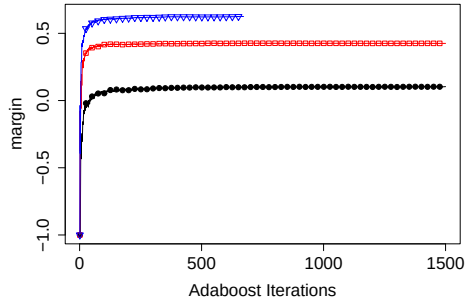
Figure 1: 1 trial of Experiment 3.1 (10% Bayes Error) for AdaBoost + stumps (black, dots), AdaBoost + 8-node trees (red, squares), and AdaBoost + 16-node trees (blue, triangles).

norm of the gradient), the testing error, and the training margin ($\frac{\min_i(y_i f_i)}{\sum_m \alpha_m}$) for 1500 iterations for the first trial of the experiment with 10% Bayes error in section 3.1 of MW. The graphs contain results for AdaBoost with stumps (black, dots), AdaBoost with 8-node trees (red, squares) and AdaBoost with 16-node trees (blue, triangles). Observe that the loss function and gradient are driven to zero for all three hypothesis spaces and that the remarkably different convergence rates are inversely proportional to the size of the trees being boosted. The results for AdaBoost with 16-node trees end at 1017 iterations because the objective becomes less than 10^{-322}, so a divide-by-zero error occurs. In general, AdaBoost with bigger trees achieves bigger margins and obtains better generalization. AdaBoost with stumps converges incredibly slowly and arguably should be run for more than 1500 iterations if early stopping is not desired.

Figure 2 contains the same three graphs for the first trial for the experiment with no Bayes Error in section 3.2. The objective/gradient and margin graphs are qualitatively similar for experiments 3.1 and 3.2. Note that the 16 node tree Adaboost algorithm underflows at 673 iterations. The testing error graph for experiment 3.2 is quite different. The performance for AdaBoost with stumps is much improved and now competitive or better than AdaBoost with 8 or 16 node trees. Here the margin results do not predict which type of boosted trees will generalize best. MW found at least one simple example in which margins don't work well.



a) Objective/Gradient (log10) (b) Test Error



(c) Margin

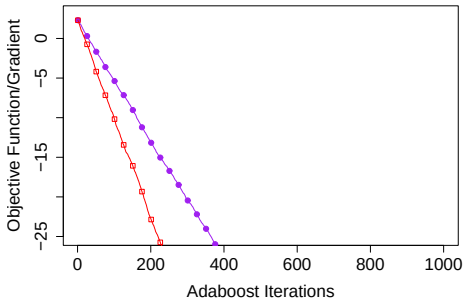
Figure 2: 1 trial of Experiment 3.2 (0 Bayes Error) for AdaBoost + stumps (black, dots), AdaBoost + 8-node trees (red, squares), and AdaBoost + 16-node trees (blue, triangles).

Figure 3 shows the results for AdaBoost with 8-node trees and AdaBoost with 8-node trees restricted to 15 nodes for the first trial of experiment 3.6. Here we see that restricting the trees slows convergence, decreases margins, and increases error.

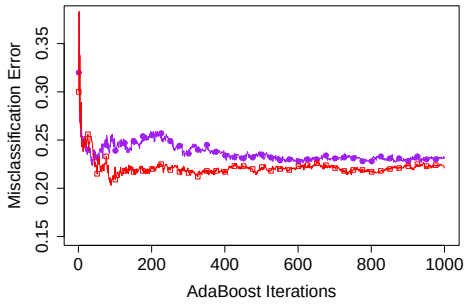
Figure 4 shows the results for AdaBoost with 8-node trees with no shrinkage (red, squares), .1 shrinkage (purple, dots), and .5 shrinkage (blue, triangles) for the first trial of experiment 3.3 (10 % Bayes error). Here we see that shrinkage can speed up or slow down the convergence rates. For .1 shrinkage compared to no shrinkage, the convergence rate was slower, the margin smaller, and the test error larger. For .5 shrinkage, the convergence rate was faster and the margin was larger than for the .1 shrinkage case. If the .5 shrinkage algorithm is terminated at using reasonable stopping criteria, the performance is quite comparable with the no shrinkage case, and improved over the .1 shrinkage case.

We present the following conjectures based on observations of this and other MW experiments for the separable case and leave fuller investigation to later work.

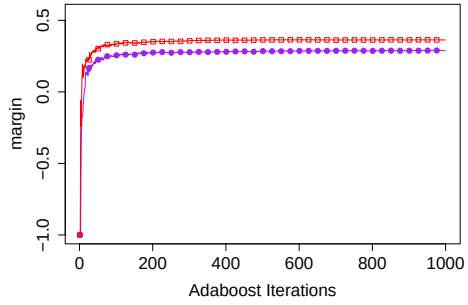
- *The convergence rate of AdaBoost is dependent on the space spanned by the weak learner and larger hypothesis spaces converge faster.* The weak learners produced by stumps are a subset of those from the 8-node decision tree which are in turn a subset of those produced by the 16-node decision tree. The bigger the decision tree, the better the weak learner can match



(a) Objective/Gradient (log10)



(b) Test Error

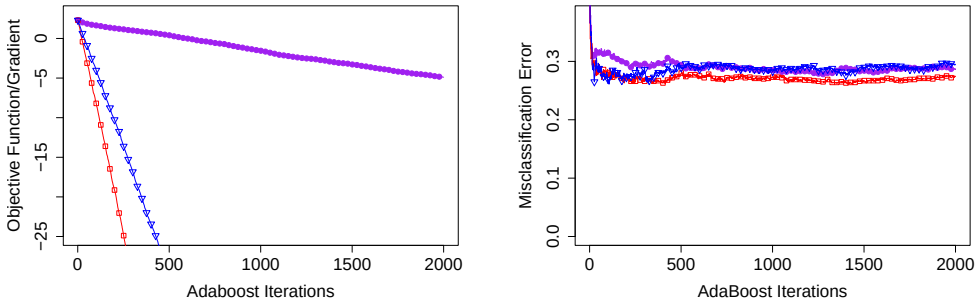


(c) Margin

Figure 3: 1 trial of Experiment 3.6 (10% Bayes Error) for AdaBoost + 8-node trees (red, squares), and AdaBoost + 8-node trees restricted to at least 15 observations in terminal nodes (purple, dots).

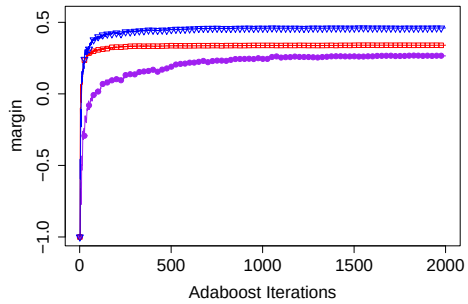
the gradient at each iteration (as reflected by weighted misclassification error). So AdaBoost can obtain a better decrease in the objective value. This conjecture is also supported by the fact that in Figure 3's run of experiment 3.6, decreasing the hypothesis space by restricting the terminal node size, also reduced the convergence rate.

- *For a fixed separable problem, faster convergence rates of AdaBoost can result in larger margins.* AdaBoost is known to approximately optimize the margin as measured by the 1-norm (Rosset et al., 2004; Schapire et al., 1998). The objective decreases the numerator of the margin and the iterations increase the denominator, so getting a smaller objective quicker creates a better margin. Bigger hypothesis spaces allow bigger steps resulting in larger margins. This finding is also supported by the fact that when shrinkage is used to change the convergence rate, the resulting margins changed as well (see Figure 4). For problems with no training error, we expect larger margins to translate to better generalization rates. But MW's experiments 3.2 and 4.2 show that this is not always the case. Figure 2 shows the margin for 1 run of Experiment 3.2. So MW are quite right in their conclusion that there is more to the



(a) Objective/Gradient (log10)

(b) Test Error



(c) Margin

Figure 4: 1 trial of Experiment 3.7 (10% Bayes Error) for AdaBoost + 8-node trees (red, squares), AdaBoost + 8-node trees with .5 shrinkage (blue, triangles) and AdaBoost + 8-node trees with .1 shrinkage (purple, dots).

generalization of AdaBoost then just optimizing the loss. Adding consideration of the margin is not enough either.

- *For slowly converging problems, AdaBoost will frequently be regularized by early stopping.* In experiments 3.1 and 3.2, AdaBoost with stumps is overfitting and the early stopping in MW at 1000 iterations helps the generalization error. For this specific experiment, the slow convergence is a result of cycling. For the first trial in experiments 3.1 and 3.2, AdaBoost with stumps only generated 158 and 156 distinct weak learners in 1000 iterations respectively. The weak learners generated by AdaBoost with 8-node trees and 16-node trees were distinct except for 2. By cycling through relatively few weak learners, AdaBoost with stumps strongly weights a few trees. This appears to be bad for generalization in experiment 3.1 and good for generalization for the no noise case in experiment 3.2.

- *For more rapidly converging problems, AdaBoost will converge and enter an overtraining phase.* For the larger tree cases, the objective and margins converge rapidly. Typically one would halt an optimization algorithm when the gradient became near 0. In the MW experiments, AdaBoost with 8-node trees is overtrained past the point where one would normally

halt an optimization algorithm based on gradient criteria (Gill et al.). AdaBoost doesn't overfit in this overtraining phase because it has converged and only very small changes are being made. Perhaps the overtraining phase contributes to the robustness of AdaBoost, since AdaBoost is performing the self-averaging discussed in MW and acting more like bagging. In the MW experiments, AdaBoost achieves better generalization when trained to an extraordinarily high degree of accuracy, a fact contrary to the usual loose convergence criteria used in support vector machines (Bennett and Parrado-Hernández, 2006). But care must be taken to halt the boosting algorithm before the overtraining produces numeric problems due to finite precision problems. As shown in Figure 1, AdaBoost with 16-node trees underflows at 1017 iterations for the 10% Bayes error case and at 673 iterations for the 0 error case. AdaBoost with 8-node trees also underflows eventually as well.

4. LogitBoost versus AdaBoost

Experiments 3.4 and 4.4 compare LogitBoost and AdaBoost and conclude LogitBoost overfits. Tracking the convergence of LogitBoost shows that this is not quite the case. We show our results repeating experiment 4.4 exactly as in the paper for AdaBoost and LogitBoost. Recall LogitBoost differs from AdaBoost in two ways. First, it uses the logistic loss instead of the exponential loss and second, it uses a Newton step instead of an exact step size. The Newton step for logistic loss works out to be 1/2 at each iteration. AdaBoost's stepsize is adaptive. The CD convergence results do not apply directly to LogitBoost as implemented in the paper because of the Newton step.

Figure 4 shows the average objective and misclassification results for 100 trials with 8-node trees. Note that at about 375 iterations, LogitBoost fails to obtain a decrease in the objective because the Newton step is too large when the objective is very small. From that point, the testing error declines. LogitBoost with shrinkage converges more slowly, so it can go more iterations before the step size fails. Once the objective becomes too small, the stepsize fails and the generalization performance of LogitBoost decreases remarkably. The LogitBoost objective is still small and continues to decrease slightly, but the self-averaging properties observed in AdaBoost in the overtraining phase are lost. Note that up until it missteps, LogitBoost is very competitive with AdaBoost. If LogitBoost and AdaBoost were halted at the same high degree of accuracy (e.g., 10^{-8}), there is no evidence of overfitting.

5. Conclusion

MW are correct is saying that optimization provides only part of the picture because optimization tells us nothing about generalization. Mathematical programming theory tells us that more well-posed boosting problems with well-conditioned loss functions (like the hinge loss) and explicit regularization in the objective should produce boosting algorithms with better behavior from an optimization perspective. But AdaBoost's ill-conditioning appears to be one of the secrets of its success. More investigation is needed comparing Adaboost with its regularized counterparts. Certainly machine learning researchers should mind their optimization theory and track the convergence of their algorithms. Optimality conditions should be used to halt and compare boosting algorithms instead of fixed iteration limits.

We thank the authors for writing a thought-provoking piece that may ruffle the feathers of recent orthodoxies in boosting. We also thank JMLR for publishing this article! Since the late 1990s, boosting has undergone the equivalent of a simultaneous X-ray, fMRI and PET exam, and the common view these days is that boosting is a kind of model fitting. As such, it is subjected to assumptions that are common in non-parametric statistics, such as: limiting the complexity of the base learner, building up complexity gradually by optimization, and preventing overfitting by early stopping or by regularizing the criterion with a complexity penalty. The theories backing this up use VC dimensions and other measures to show that, if the complexity of fits grows sufficiently slowly, asymptotic guarantees can be given. Into this orthodox scene Mease and Wyner throw one of the most original mind bogglers we have seen in a long time: "if stumps are causing overfitting, be willing to try larger trees." In other words, if boosting a low-complexity base learner leads to overfit, try a higher-complexity base learner; boosting it might just not overfit. Empirical evidence backs up the claim.

Is this counterintuitive wisdom so surprising? Yes, if seen from the point of view of orthodoxy, but less so when reviving some older memories. We may remind ourselves how boosting's fame arose in statistics when the late Leo Breiman stated in a discussed 1998 Annals of Statistics article (based on a 1996 report) that boosting algorithms are "the most accurate ... off-the-shelf classifiers on a wide variety of data sets." We should further remind ourselves what this praise was based on: boosting of the full CART algorithm by Breiman himself, and boosting of the full C4.5 algorithm by others. In other words, the base learners were anything but 'weak' in the sense of today's orthodoxy, where 'weak' means 'low complexity, low variance, and generally high bias.' (Few people today use PAC theory's untenable notion of weak learner, which was gently demolished by Breiman in the appendix of this same article.) Breiman's (1998b, p. 802) 02) major conclusion at the time was: "The main effect of both bagging and [boosting] is to reduce variance." It appears, therefore, that his notion of 'weak learner' was one of 'high complexity, high variance, and low bias'! This was before the low-variance orthodoxy set in and erased the memories of the early boosting experiences.

Unfortunately, soon thereafter Breiman saw his own assumptions thrown into question when he learned from Schapire et al.'s (1998) work that excellent results could also be achieved by boosting

stumps. This experience was later reinforced when Friedman et al. (2000) introduced the interpretation of boosting as model fitting: the base learner now had to be weak in the sense of low variance. Ever since, theoretical attempts at 'explaining boosting' have relied on low complexity of the base learner and controlling complexity of the final classifier to assure good generalization properties. These 'explanations,' however, have never been able to explain why boosting is relatively immune to overfitting, even when not stopped and not regularized and used with a high complexity base learner.

Mease and Wyner's achievement is to pull the messy truth out from under the rug of the low-variance orthodoxy. They do so with the equivalent of boy scout tools, some simple but telling simulations, which reinforce the idea that our reasonings about early stopping, regularization, low variance of the base learner, and the specifics of the surrogate loss function, are not or not the only essence of boosting. To explain why this is so, Mease and Wyner do not give us hard theory, but they point in a direction, essentially by recovering memories that predate the low-variance orthodoxy: "self-averaging" for variance reduction, which is the principle behind bagging and random forests.

While variance reduction is an aspect that has been ignored by the low-variance orthodoxy, the orthodoxy's implicit dogma, that boosting can reduce bias, is also true. As asserted and documented empirically a decade ago by Schapire et al. (1998, Section 5.3), boosting can do both. Depending on the data and the base learner, the effect that dominates may be bias reduction *or* variance reduction. In this regard Schapire et al.'s (1998) simulation results as summarized in their Table 1 (p. 1673) are illuminating, and had we taken them seriously sooner, we would be less surprised by Mease and Wyner's messages. Arguing against Breiman (1998b), Schapire et al. used the table to make the now orthodox point that boosting can reduce bias. An unprejudiced look shows, however, that the winner in all four scenarios is boosting C4.5, not boosting stumps, and when C4.5 is the base learner the overwhelming story is indeed variance reduction. With this information, the Mease-Wyner mind boggler is a touch less mind boggling indeed: From the combined evidence of Breiman (1998b) and Schapire et al. (1998), we should expect that boosting high-variance base learners generally outperforms boosting low-variance base learners. For the practitioner the recommendation should be to boost CART or C4.5. In theoretical terms, one should let most of the bias removal be done by the base learner and take advantage of boosting's variance removal; at the same time, boosting may further reduce the base learner's bias by another notch if that is possible.

Where does this leave us in terms of theory? The implications of Mease and Wyner's unorthodoxies stand: Complexity controlling theories of bias removal are off the mark; they are not incorrect but misleading, and they ignore a whole other dimension that matters hugely for the practice of boosting. What we need is a theory that explains bias and variance reduction in a single framework. We do not even know of a unified general theory of variance reduction, although some interesting work has been done in the area of bagging (Bühlmann and Yu, 2002) and random forests (Amit et al., 2001). The real jackpot, however, would be a theory that explains how and when boosting reduces bias *and* variance.

Meanwhile we are left with some tantalizing clues, above all Breiman's hunch (1999, p. 3): "AdaBoost has no random elements .... But just as a deterministic random number generator can give a good imitation of randomness, my belief is that in its later stages AdaBoost is emulating a random forest." If born out, this conjecture would have theoretical and practical implications. For one, it would mean that the initial stages of boosting may remove bias, whereas the later stages remove variance. According to Breiman (1998b, p. 803), boosting a high-variance base learner does not yield convergence but exhibits "back and forth rocking" of the weights, and "This variability

may be an essential ingredient of successful [boosting] algorithms." Breiman implies that at some point boosting iterations turn into a pseudo-random process whose behavior may resemble more the purely random iterations of bagging than those of a minimization process. This random process may be able to achieve the self-averaging effect of variance reduction that is so prominent when boosting high-variance base learners. If this view is correct, one may have to rethink the role of the surrogate loss function that is minimized by boosting. Its main role is to produce structured weights in the iterations, but with noisy errors, these weights may for practical purposes be as much random as they are systematic. This insight jibes with Wyner's (2002) malicious experiments in which he doubled the step size of discrete AdaBoost with C4.5, thereby assuring that the exponential loss never decreased and in fact provably remained at a constant level; his empirical results indicated that on average this SOR (successively over-relaxed) form of boosting performs as well as regular AdaBoost. These results may be taken as evidence that the minimization aspect is of little importance for a high-variance base learner; of greater importance may be a pseudo-random aspect of the reweighting scheme that achieves variance reduction similar to bagging, just more successfully due to a sort of adaptivity in the reweighting that improves over the purely random resampling of bagging.

If the pseudo-random aspect of boosting is critical for high-variance base learners, one may draw consequences and implement boosting with proper pseudo-random processes. So did Breiman. He didn't attempt a theory of boosting for high-variance base learners, and instead he put his intuitions to use in further proposals such as in his work on "half & half bagging" (Breiman, 1998a), apparently with success. Another example that benefited from Breiman's inspiration was Friedman's (2002) "stochastic gradient boosting" which inhibits convergence of boosting by computing gradient steps from random subsamples drawn without replacement. Friedman (ibid., p. 9) observes improvements over deterministic boosting in a majority of situations, above all for small samples and "high capacity" (high variance) base learners. He admits that "the reason why this randomization produces improvement is not clear," but suggests "that variance reduction is an important ingredient." Friedman goes on to suggest that stochastic AdaBoost with sampling from the weights rather than reweighting may have similar variance-reducing effects. In early boosting approaches such sampling (with replacement) was performed to match the given sample size, but Friedman suggests that further variance reduction could be gained by choosing smaller resamples.

An implication of Breiman's hunch is that the real difference between LogitBoost and AdaBoost is not so much due to the differences in loss functions as to the minimization method, at least when the base learner has relatively high variance, or generally in the late stages of boosting. AdaBoost can be interpreted as constrained gradient descent on the exponential loss, whereas LogitBoost is Newton descent on the logistic loss (Friedman et al., 2000). The two minimization schemes produce very different reweighting schemes, and they work off different working responses during the iterations. We are currently ignorant about whether LogitBoost develops pseudo-random behavior late in the iterations, similar to AdaBoost. If it does, the cause may be traced to the base learner, and the phenomenon may be robust to the specifics not only of loss functions but of algorithms as well.

Another implication of Breiman's hunch is that boosting does both, reduce bias and variance, in the same problem, but each primarily at different stages of the boosting iterations. If it is true that variance reduction occurs during later iterations, then this should go a long way to explain boosting's relative immunity to overfitting. By comparison, conventional fitting mechanisms only know how to do one thing: follow the data ever more closely, thereby continually reduce bias and continually

accumulate variance. According to orthodoxy, therefore, the art is to find the proper balance, and to this end auxiliary devices such as early stopping, regularization penalties and cross-validation come into play. Boosting seems to be different, but we do not have the theory yet to prove it.

All that we said so far is based on out-of-sample classification error. A peculiarity of classification error is that it is not the criterion being minimized in-sample because of its discontinuous nature. The role of minimizing a smooth surrogate loss function is to trace a path that leads to low classification error, but the surrogate loss is not of interest in itself. Yet, for the variance reducing properties of the resulting classifier, the surrogate loss is of interest. First of all, the surrogate loss should keep decreasing because for example discrete AdaBoost is constrained gradient descent with line search (Friedman et al., 2000). This explains why in terms of the surrogate loss, the fitted class probability estimates end up vastly overfitting the data, confirming the orthodox view in terms of the surrogate loss. Yet, two phenomena are also observed: in terms of out-of-sample classification error, no overfitting is taking place, and, according to Breiman, no convergence of the weights is taking place. The bouncing of the weights would indicate that, in spite of a well-behaved convex loss function, the descent directions chosen by the base learner become erratic. Such behavior would be plausible if the base learner is of the high-variance type, but the specifics of why the variance component of out-of-sample classification error is improved is not explained. It is quite clear, though, that explaining boosting's variance reduction would be a greater achievement than explaining its bias reduction. Bias can be largely taken care of by the base learner, variance can't.

If the peculiarities we observe in boosting are due to the use of two loss functions, one may ask whether any lessons learned carry over to other parts of statistics. The "statistical view" has indeed produced generalizations of boosting to other areas, such as regression: Bühlmann and Yu's L_2-boosting (2003), Friedman's gradient boosting in their deterministic and stochastic forms (2001; 2002), and boosting of exponential and survival models by Ridgeway (1999). In these single-loss function contexts, the paradoxical phenomena should no longer be visible, as they aren't for boosting if judged in terms of the surrogate loss function. Yet, Friedman's stochastic gradient boosting shows that adding an element of variance reduction with randomization may just be what the doctor ordered in most statistical model fitting contexts even with a single loss function. We should therefore aim for a variance reduction theory for all of statistics, reaching beyond classification.

Another question that may be raised for binary, or categorical response data in general, is whether classification error is as desirable a loss function as suggested by the attention it has received. Classification error is a bottom line number that may be appropriate in industrial contexts where real large scale engineering problems are solved, for example, in document retrieval. One might characterize these contexts as "the machine learner's black box problems." There do exist other contexts, though, and one might characterize them as "the problems of the interpreting statistician." When interpretation is the problem, attaining the last percent of classification accuracy is not the goal. Instead, one hopes to develop a functional form that reasonably fits the data but also "speaks," that is, lends itself to statements about what variables are associated with the categorical response. Fitting good conditional class probabilities takes on greater importance because associations and effects can then be measured in terms of differences in the logits of class 1 (for example) for a unit or percentage difference in the predictor variables. Interpretability is a problem for nonparametric model fits such as boosted trees. The decomposition of complex fits into interpretable components, for example with an ANOVA decomposition as suggested by Friedman et al. (2000), takes on considerable importance. In the end, one may want to produce a few telling plots explaining functional form and a few numbers summarizing the strengths of various associations. When

fitting models for conditional class probabilities, the surrogate loss becomes the primary loss function because it can be interpreted as a loss function for fitted class probabilities. It is one of the achievements of Friedman et al. (2000) to have shown that this is true for exponential loss as much as for logistic loss, even though there is a misperception, as pointed out by Mease and Wyner, that LogitBoost was specifically designed to recover class probabilities that AdaBoost couldn't. Exponential loss does similar things as logistic loss in Friedman et al.'s analysis, and they provide the appropriate link functions for both. All this is relevant only if minimization of the "surrogate/now-primary loss" is prevented from overfitting, with cross-validated early stopping, penalization, or variance-reducing randomization, and it comes at the cost of diminished classification performance, one of Mease and Wyner's points.

Diminished classification performance when estimating class probabilities is easily explained; it is due to a compromise that class probability estimation has to strike. It effectively attempts good classification simultaneously at *all* misclassification cost ratios. (Note that this ratio is assumed to be one in most of the boosting literature.) This statement can be made precise in a technical sense: unbiased loss functions for class probabilities, so-called "proper scoring rules," are weighted mixtures of cost-weighted misclassification losses Buja et al. (2005). After mapping exponential and logistic losses to probability scales with their associated inverse link functions, they turn into proper scoring rules and therefore exhibit the mixture structure just described. It follows that both loss functions attempt compromises across classification problems with non-equal misclassification costs. Both loss functions give inordinate attention to extreme cost ratios, but exponential loss even more so than logistic loss. At any rate, the nature of the compromise is such that no cost ratio, in particular not equal costs, is served optimally if the exponential or logistic losses are tuned to high out-of-sample performance. By comparison, overfitting these losses in-sample seems to provide benefits in terms of classification error. However, once we change our priorities from black-box performance to interpretation, and hence from classification to class probability estimation, we may prefer tuning surrogate loss and accept the increased classification error.

Anticipating an objection by Mease and Wyner, we should disclose that one of us (Buja) collaborated with them on an article that is relevant here (Mease et al., 2007). In this work we traveled the opposite of the usual direction by composing class probability estimates from layered classification regions, estimated at a grid of misclassification cost ratios. Presumably such class probability estimation inherits superior performance from boosting in classification. When interpretation is the goal, however, a simple functional form that "speaks" might be more desirable than the increased performance of the layered estimates we provide in our joint proposal. The problem is that our proposal inherits the interpretative disadvantages of boosted classification regions, which tend to be jagged around the edges and pockmarked with holes—not a credible feature when it comes to interpretation.

We started this discussion joining Mease and Wyner in their argument against today's boosting orthodoxy. We ended by questioning the single-minded reliance on classification error as the only yard stick of performance. Still, Mease and Wyner's call should be heard because the orthodoxy misattributes the causes of boosting's success and makes invalid recommendations.

For such a simple algorithm, it is fascinating and remarkable what a rich diversity of interpretations, views, perspectives and explanations have emerged of AdaBoost. Originally, AdaBoost was proposed as a "boosting" algorithm in the technical sense of the word: given access to "weak" classifiers, just slightly better in performance than random guessing, and given sufficient data, a true boosting algorithm can provably produce a combined classifier with nearly perfect accuracy (Freund and Schapire, 1997). AdaBoost has this property, but it also has been shown to be deeply connected with a surprising range of other topics, such as game theory, on-line learning, linear programming, logistic regression and maximum entropy (Breiman, 1999; Collins et al., 2002; Demiriz et al., 2002; Freund and Schapire, 1996, 1997; Kivinen and Warmuth, 1999; Lebanon and Lafferty, 2002). As we discuss further below, AdaBoost can been seen as a method for maximizing the "margins" or confidences of the predictions made by its generated classifier (Schapire et al., 1998). The current paper by Mease and Wyner, of course, focuses on another perspective, the so-called statistical view of boosting. This interpretation, particularly as expounded by Friedman et al. (2000), focuses on the algorithm as a stagewise procedure for minimizing the exponential loss function, which is related to the loss minimized in logistic regression, and whose minimization can be viewed, in a certain sense, as providing estimates of the conditional probability of the label.

Taken together, these myriad interpretations of AdaBoost form a robust theory of the algorithm that provides understanding from an extraordinary range of points of view in which each perspective tells us something unique about the algorithm. The statistical view, for instance, has been of tremendous value, allowing for the practical conversion of AdaBoost's predictions into conditional probabilities, as well as the algorithm's generalization and extension to many other loss functions and learning problems.

Still, each perspective has its weaknesses, which are important to identify to keep our theory in touch with reality. The current paper is superb in exposing empirical phenomena that are apparently difficult to understand according to the statistical view. From a theoretical perspective, the statistical interpretation has other weaknesses. As discussed by Mease and Wyner, this interpretation does not explain AdaBoost's observed tendency not to overfit, particularly in the absence of regularization

or early stopping. It also says little about how well AdaBoost will generalize when provided with a finite data set, nor how its ability to generalize is dependent on the complexity or simplicity of the base classifiers, an issue that arises in the experiments comparing decision stumps and decision trees in this role.

Much of the difficulty arises from the fact that AdaBoost is a *classification* algorithm (at least as it is used and studied in the current paper). This means that AdaBoost's purpose is to find a rule h that, given X, predicts one of the labels $h(X)$, and that attempts to achieve minimal probability of an incorrect classification (in which $h(X)$ disagrees with the true label Y). This is quite different from the problem of estimating the conditional probability $P(Y|X)$. An accurate estimate of this conditional probability is a sufficient, but certainly not a necessary, condition for minimizing the classification error. A weaker requirement that is still sufficient is to estimate the set of inputs for which $P(Y = +1|X) > 1/2$. In most cases, this requirement is much weaker than the requirement of getting good estimates of conditional probabilities. For example, if $P(Y = +1|X) = 0.49$ then our estimate of the conditional probability need be accurate to within 1%, while if $P(Y = +1|X) = 0.2$ the accuracy we need is only 30%.

This simple observation demonstrates a crucial shortcoming in the statistical interpretation of Adaboost, and undermines many of its apparent consequences, including the following:

- *Adaboost can be interpreted as a method for maximizing conditional likelihood.* If the goal is not to estimate the conditional probability, there is no reason to maximize likelihood.

- *A question of central importance is whether Adaboost is asymptotically consistent.* When evaluating probability estimators, it is standard procedure to start by verifying that the estimator is unbiased. Once the estimator is confirmed to be unbiased, the next question is the rate at which its variance decreases with the size of the sample. Again, as the learning problem in the case of classification is a weaker one, it is not clear that this is the relevant sequence of questions that a theoretician should ask.

- *Decision stumps should be used as base classifiers when the input variables are independent* This argument is based on the assumption that the goal is to estimate probabilities.

The view of AdaBoost as a method for minimizing exponential loss, though in some ways quite useful, can also lead us very much astray, as pointed out to some degree by Mease and Wyner. Taken to an extreme, this view suggests that any method for minimizing exponential loss will be equally effective, and is likely to be much better if designed with speed and this explicit goal in mind. However, this is quite false. Indeed, any real-valued classifier F which classifies the training examples perfectly, so that $y_i F(x_i) > 0$ for each training example (x_i, y_i), can be modified to minimize the exponential loss $\sum_i e^{-y_i F(x_i)}$ simply by multiplying F by an arbitrarily large positive constant. This scaling of F of course has no impact on the classifications that it makes. Thus, in the common case in which an exponential loss of zero is possible, minimization of this loss means nothing more than that the computed classifier F has a classification error of zero on the training set. The minimization of this particular loss tells us nothing more, and leaves us as open to overfitting as any other method whose only purpose is minimization of the training error.

This means that, in order to understand AdaBoost, which does indeed minimize exponential loss, we need to go well beyond this narrow view. In particular, we need to consider the *dynamics* of AdaBoost—not just *what* it is minimizing, but *how* it goes about doing it.

Like other interpretations of AdaBoost, although the statistical view has its weaknesses, it also has its strengths, as noted above. Still, to fully understand AdaBoost, particularly in the face of such deficiencies, it seems unavoidable that we consider a range of explanations and modes of understanding. Where the statistical view may be lacking, the margins explanation in particular can often shed considerable light.

Briefly, the *margin* of a labeled example with respect to a classifier is a real number that intuitively measures the confidence of the classifier in its prediction on that example. More precisely, in the notation of Mease and Wyner, the margin on labeled example (x,y) is defined to be $yF_M(x)/\sum_m \alpha_m$. Equivalently, viewing the prediction of AdaBoost's combined classifier as a weighted majority vote of the base classifiers, the margin is the weighted fraction of base classifiers voting for the correct label minus the weighted fraction voting for the incorrect label.

The margins theory (Schapire et al., 1998) provides a complete analysis of AdaBoost in two parts: First, AdaBoost's generalization error can be bounded in terms of the distribution of margins of training examples, as well as the number of training examples and the complexity of the base classifiers. And second, it can be proved that AdaBoost's dynamics have a strong tendency to increase the margins of the training examples in a manner that depends on the accuracy of the base classifiers on the distributions on which they are trained.

This theory is quite useful for understanding AdaBoost in many ways (despite a few shortcomings of its own—see, for instance, Breiman (1999) as well as the recent work of Reyzin and Schapire (2006)). For starters, the theory, in which performance depends on margins rather than the number of rounds of boosting, predicts the same lack of overfitting commonly observed in practice. The theory provides non-asymptotic bounds which, although usually too loose for practical purposes, nevertheless illuminate qualitatively how the generalization error depends on the number of training examples, the margins, and the accuracy and complexity of the base classifiers. Finally, the theory is concerned directly with classification accuracy, rather than the algorithm's ability to estimate conditional probabilities, which is in fact entirely irrelevant to the theory.

Moreover, some of the phenomena observed by Mease and Wyner do not appear so mysterious when viewed in terms of the margins theory. For instance, the experiments in Section 3.1 show AdaBoost overfitting with stumps but not decision trees. In terms of margins, decision trees have higher complexity, which tends to hurt generalization, but also tend to produce much larger margins, which tend to improve generalization, an effect that can easily be strong enough to compensate for the increased complexity. Moreover, according to the theory, these larger margins tend to provide immunity against overfitting, and indeed, overfitting is expected exactly in the case that we are using base classifiers producing small margins, such as decision stumps. This is just what is observed in Figure 1.

In sum, the various theories of boosting, including the margins theory and the statistical view, are all imperfect but are largely complementary, each with its strengths and weaknesses, and each providing another piece of the AdaBoost puzzle. It is when they are taken together that we have the most complete picture of the algorithm, and the best chances of understanding, generalizing and improving it.

1. Introduction

This is an interesting and thought-provoking paper. We especially appreciate the fact that the authors have supplied R code for their examples, as this allows the reader to understand and assess their ideas. The paper inspired us to re-visit many of these issues underlying boosting methods. However in the end we do not believe that the examples provided in the paper contradict our statistical view, although other views may well prove informative.

2. Our Statistical View of Boosting

Friedman et al. (2000) and our book (Hastie et al., 2001) argue that boosting methods have three important properties that contribute to their success:

1. they fit an additive model in a flexible set of basis functions
2. they use a suitable loss function for the fitting process
3. they regularize by forward stagewise fitting; with shrinkage this mimics an L_1 (lasso) penalty on the weights.

In many cases the paper ascribes consequences of this statistical view that are not the case. For example, it does not follow that smaller trees are necessarily better than larger ones for noisier problems (Sections 3.2 and 4.2), that the basis should necessarily be restricted as described in Sections 3.6 and 4.6, or that regularization should be based on the loss function used for fitting (Sections 3.5 and 4.5). To the extent possible model selection should be based on the ultimate loss associated with the application. Also, there is no requirement that test error have a unique minimum as a function of the number of included terms (Sections 3.4 and 4.4). However, to the extent that these are commonly held beliefs, the paper provides a valuable service by pointing out that they need not hold in all applications.

There is no direct relation between the application of shrinkage and overfitting (Sections 3.7 and 4.7). Heavy shrinkage emulates L_1 regularization, whereas its absence corresponds to stagewise

fitting approximating L_0 regularization. There is nothing in the statistical view that requires L_1 to be superior to L_0 in every application, although this is often the case. The best regularizer depends on the problem: namely the nature of the true target function, the particular basis used, signal-to-noise ratio, and sample size.

Finally, there is nothing in our statistical interpretation suggesting that boosting is similar to one nearest neighbor classification (Sections 3.9 and 4.9).

None-the-less, the paper does provide some interesting examples that appear to contradict the statistical interpretation. However these examples may have been carefully chosen, and the effects seems to vanish under various perturbations of the problem.

3. Can the "Wrong" Basis Work Better than the Right One?

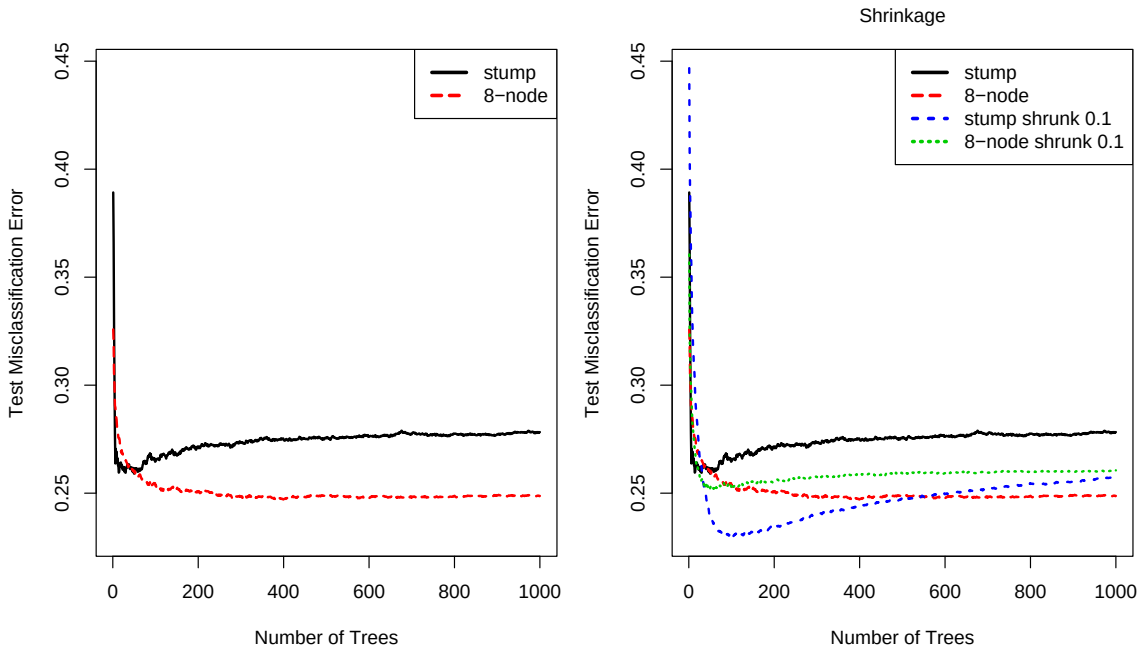

Figure 1: Average test misclassification error for 20 replications of Mease and Wyner's example used in their Figure 1. We used the package GBM in R, with the "adaboost" option. The left panel shows that 8-node trees outperform stumps. The right panel shows that stumps with shrinkage win handily.

The left panel of Figure 1 shows a version of the paper's Figure 1. We see that boosting with 8 node trees seems to outperform stumps, despite the fact that the generative model is additive in the predictor variables. However the right panel shows what happens to both stumps and 8 nodes trees when shrinkage is applied. Here shrinkage helps in both cases, and we see that stumps with shrinkage work the best of all.

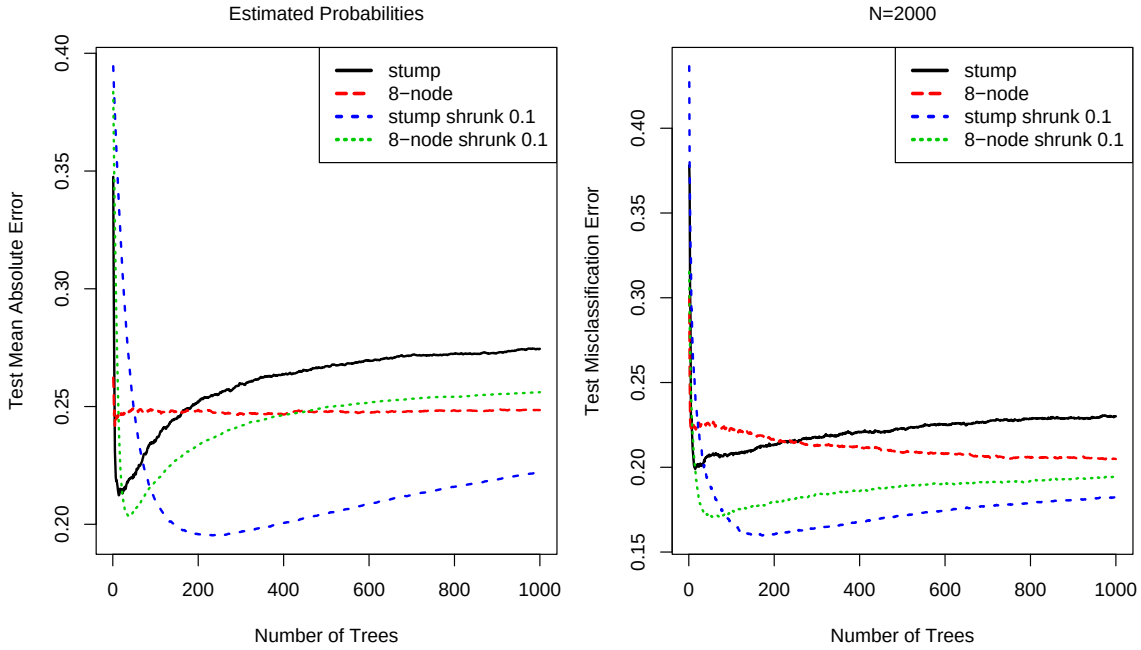

Figure 2: Left panel: average absolute deviations of the fitted probabilities from the true probabilities for the same simulations as in Figure 1. Right panel: average test misclassification error for the same simulations as in Figure 1, except using 2000 rather than 200 training examples.

We are not sure why unshrunken 8 node trees outperform unshrunken stumps in this example. As in the paper, we speculate that the extra splits in the 8 node tree might act as a type of regularizer, and hence they help avoid the overfitting displayed by unshrunken stumps in this example. All but the first split will tend to be noisy attempts at the other variables, which when averaged will have a "bagging" effect.

However this explanation becomes less convincing and indeed the effect itself seems to fade when we look more deeply. Figure 2 [left panel] shows the average absolute error in the estimated probabilities, while Figure 2[right panel] shows what happens when we increase the sample size to 2000. In Figure 3[left panel] we use the Bernoulli loss rather than exponential of Adaboost, and Figure 3[right panel] shows results for the regression version of this problem. In every case, the effect noted by the authors goes away and both the correct bases and shrinkage help performance. We repeated these runs on the second simulation example of Section 4, and the results were similar. Thus the effect illustrated by the authors is hard to explain, and seems to hold only for misclassification error. It depends on a very carefully chosen set of circumstances. Most importantly, we have to remember the big picture. Looking at the right panel of Figure 1, which method would anyone choose? Clearly, shrunken stumps work best here, just as might be expected from the statistical view.

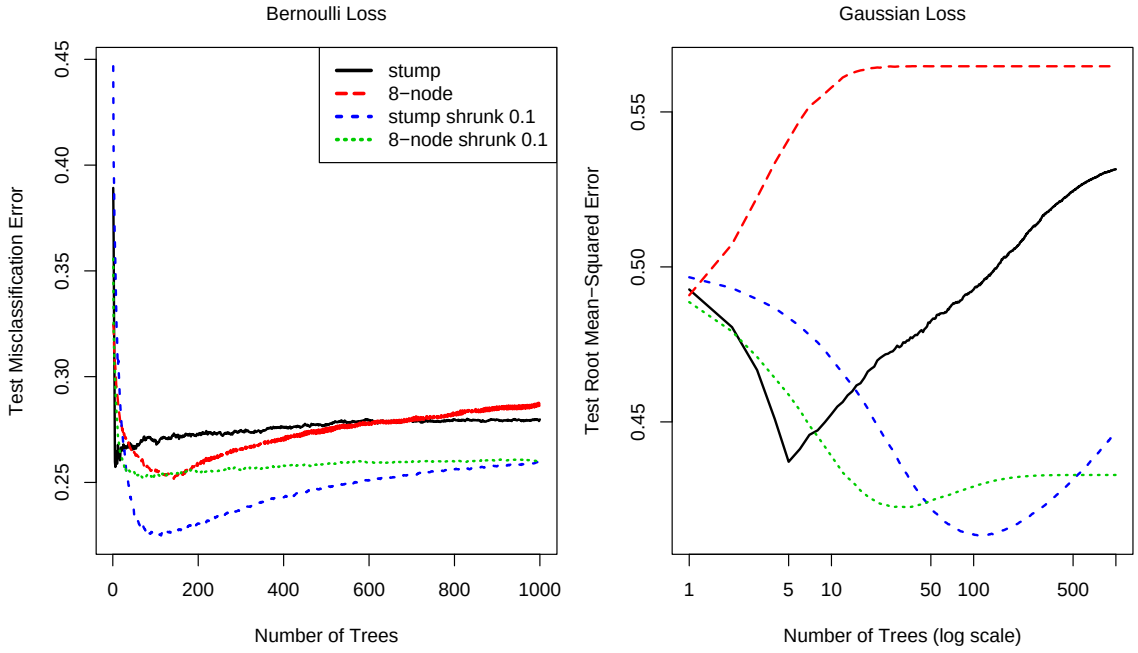

Figure 3: Left panel: test misclassification error when boosting with Bernoulli loss for the same simulations as in Figure 1. Right panel: root mean-squared test error when boosting with squared-error loss for the same simulations as in Figure 1 (legend as in left panel).

Figure 4 shows the fitted probabilities over the 20 runs, separately for each class, when using 250 shrunken stumps. Here 250 was chosen since it corresponds to the minimum in Figure 2[left panel]. This is an appropriate tradeoff curve if we are interested in probabilities; test deviance would also be fine. We see that the estimates are biased toward 0.5, which is expected when regularization is used. Hence they are underfit, rather than overfit.

A similar argument can be made concerning the paper's Figure 3. Yes, AdaBoost works better than Logitboost in this example. But using the statistical view of boosting, we have moved on and developed better methods like gradient boosting (Friedman, 2001) that typically outperform both of these methods.

Hastie et al. (2007) add further support to (3) of the statistical interpretation of boosting: they show that the incremental forward stagewise procedure used in boosting (with shrinkage) optimizes a criterion similar to but smoother than the L_1 penalized loss.

4. Conclusion

No theory, at least initially, can fully explain every observed phenomenon. Everything about regularized regression is not yet fully understood. There is still considerable ongoing research in the literature concerning the interplay between the target function, basis used, and regularization method. Hopefully, some of the apparent anomalies illustrated in this paper will eventually be explained with

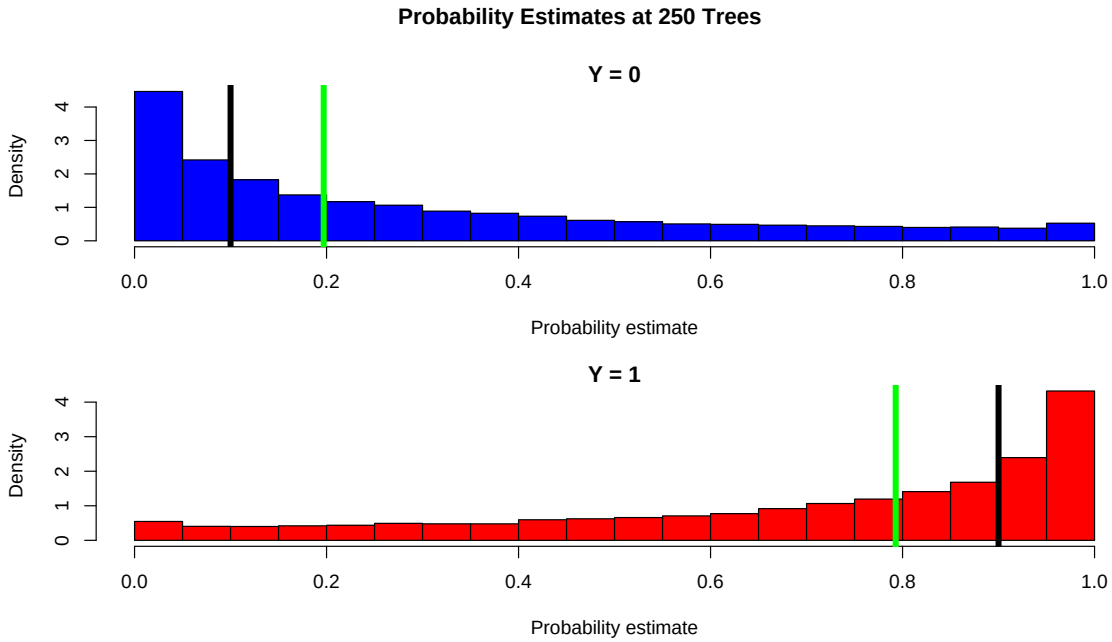

Figure 4: Fitted probabilities shown for the two classes, at 250 shrunken stumps. The vertical black bars are the target probabilities for this problem, and the green bars are the median of the estimates in each class.

a more thorough understanding of these issues. The paper provides a service in reminding us that there is still work remaining.

Although we would not begin to suggest that our statistical view of boosting has anywhere near the substance or importance of the Darwin's theory of evolution, the latter provides a useful analogy. The proponents of Intelligent Design point out that the theory of evolution does not seem to explain certain observed biological phenomena. And therefore they argue that evolution must be wrong despite the fact that it *does* explain an overwhelming majority of observed phenomena, and without offering an alternative *testable* theory.

We are sure that the authors will mount counter-arguments to our remarks, and due to the (standard format) of this discussion, they will have the last word. We look forward to *constructive* counter-arguments and alternative explanations for the success of boosting methods that can be used to extend their application and produce methods that perform better in practice (as in the right panel of Figure 1).

Galileo: God help us, I'm not half as sharp as those gentlemen in the philosophy department. I'm stupid, I understand absolutely nothing, so I'm compelled to fill the gaps in my knowledge... Sir, my branch of knowledge is still avid to know. The greatest problems still find us with nothing but hypotheses to go on. Yet we keep asking ourselves for proofs. Brecht (1980)

This is a "sock it to them" paper—though much less so than the previous versions one of us have seen.

The authors argue in the paper that AdaBoost (without early stopping) is one of, if not the, most successful boosting algorithms, and they present this paper as a disproof of what the , rather amorphous community of statistical practitioners, represented by Friedman, Hastie and Tibshirani have:

(i) Pointed out as remediable flaws of the original Freund-Schapire boosting algorithm;

(ii) Given as remedies.

Evidently, that community should be able to respond on its own. We in fact, agree with some of the hypotheses Mease and Wyner's limited simulations lead them to, whether these are or are not embraced by statistical practitioners. But others we find dubious and unproven. Let us stress the positive first.

1. They argue that boosting does not behave like nearest neighbor for $d > 1$. Not only do we agree with this but would conjecture even further without any proof:

2. That, for reasonable sequences of d dimensional distributions, the random classification rules induced by the stationary measures corresponding to boosting forever, should in a suitable sense as $n, d \to \infty$ concentrate near the Bayes rule. However, an example below shows that the improvement from $d = 1$ to $d = 2$ can be slight.

3. We don't believe that boosting is consistent, in the sense of section 3.10, for any d, but indeed there is no disproof for $d > 1$.

4. We agree that a sharp explanation why, for classification, boosting *may* not overfit—that is, continues to reduce the probability of misclassification long past the point where all training sample observations are correctly classified has not been provided in the statistical (or the machine learning) literature.

5. We agree that using more complex basis functions may actually improve performance. This was analyzed theoretically for L_2 boosting by Bühlmann and Yu (2003).

6. We agree that there is a need for a convincing argument for basing an early-stopping algorithm of a classifier on a loss function that is not the classification loss. *A-priori* we do not expect that stopping on any criterion, other than minimum classification error will work in general, even if the classifier itself is based on minimizing this indirectly relevant criterion. However, it certainly can be that a good early stopping algorithm will be based on estimate of the loss with respect to something other than from the classification error. It was proven to be so, for example, with L_2-boost.

Since we have never been persuaded on theoretical grounds of the superiority of other "boosts", logit or L_2, over AdaBoost , we leave this battle to others.

Where we really part company with the authors of this "against the heretics" paper is on the issue of the desirability of early stopping.

Galileo tries to explain his young student, Andrea, the structure of the Copernican system, to make it so simple that Andrea will be able to explain it to his mother. He rotates him on a chair, and tells him that an apple in the center is the earth. However, Andrea is smart enough to understand that so far and not more can be deduced from examples.
Andrea: Examples always work if you're clever. Only I can't lug my mother round in a chair like you did me. So you see it's a rotten example really. And suppose your apple is the earth like you say? Nothing follows. Brecht (1980)

Everybody can produce examples. The authors gave two examples. Other commentators will bring their own. Here are ours. We consider $X \in \mathbb{R}^2$ uniform on 5 concentric circles. The classes were randomly assigned according to $P(Y=1|x) = \text{logit}(4\text{sgn}\,(\xi)\sqrt{(}\xi))$ where $\xi = \|x\| - 2|x_1|$ and $\text{logit}(\zeta) = e^{\zeta}/(1+e^{\zeta})$. The training sample includes 500 i.i.d. observations. 200 more observations were used for early stopping. I.e., stopping when the mean empirical classification error on these 200 observations was minimal. Finally another set of 1500 observations was used to evaluate the mean classification error of the AdaBoost procedure as a function of the number of observations. See Figure 1 for a plot of typical set of Xs and $P(Y=1|X))$. The weak classifier we used was a standard classification tree with 8-terminal nodes. The simulations were run with slightly different set-ups a few tens of times. There was no case that contradicted the results of the single experiment we will present next (but see later). Our example is small. Since the goal of the discussed paper is to suggest policy on the basis of two examples, even one (we believe) reasonable counterexample should give some pause.

In Figure 2(a) we show the classification error as a function of the number of iterations. The horizontal lines are, from the top down: The risk of the closest neighbor, the risk of AdaBoost with early stopping, and the Bayes Risk. It is clear in this example that AdaBoost starts quite nicely. The primitive early stopping technique we employed is enough to give a decent performance. However, the performance of AdaBoost starts to degenerate after some tens of iterations. After 800 hundred

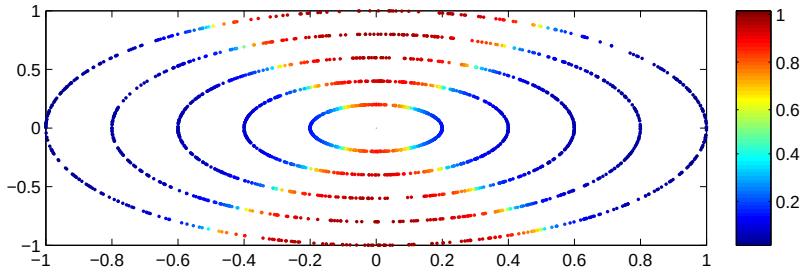

Figure 1: $P(Y=1|X)$ as function of location.

iterations it is only slightly better than the nearest neighbor classifier. Within the context of this example the "does not over-fit" property, can be understood at best as "it is simply a slow algorithm".

Figure 2(b) shows the root mean square error of AdaBoost implicit estimate of the probability as function of the number of iterations. It is clear that it degenerate much faster than AdaBoost performance. However, the implicit probability estimate is fair, as long as the classifier is in its prime. So, the authors' doubt whether boosting estimate probabilities cannot be based on this example.

However, we should mention that the apparent failure of the boosting algorithm to estimate probabilities is somewhat misleading. In Figure 2(c) we plot $F_m - F^0$, where F^0 is the ideal value, as a function of $P(Y=1|x)$ after $m=200$ iterations. $P(Y=1|x)$ is used here as proxy for the distance of the point from the $P(Y=1|x)=0.5$ boundary. What can be seen is that most of the error in the estimation of the $P(Y=1|x)$ comes from the easy to classify points. So, the boosting algorithm fails to estimate the probability where it does not really matter.

There are facts in life. One cannot invoke the church teaching or Aristotle's books in face of empirical facts. Galileo get annoyed by the insistence of the philosopher and the mathematician on using irrelevant arguments.

Galileo: My reasons! When a single glance at the stars themselves and my own notes make the phenomenon evident? Sir, your disputation becoming absurd. Brecht (1980)

The authors used a smart device to present the discrepancy between the one nearest neighbor classifier and AdaBoost. Namely, they compare their performance under a null hypothesis, where $P(Y=1|x)$ does not depend on x (this is true for Section 3.9 but not for 4.9, where for some unknown reasons something else was done). We did the same. The distribution of X and the sample sizes are as above, while $P(Y=1|x)\equiv 0.2$. The results are presented in Figure 3. The graphs are similar to Figure 2(a-b), in description and in essence. Boosting without early stopping is not like 1-NN, but it is not much better, at least for this tiny example.

We did observe a further interesting phenomenon when we added irrelevant explanatory variables. That is, 8 independent variables $X_3,\ldots,X_{10}$ were added, while the distribution of (X_1,X_2,Y) remains as above. The result was surprising. Adding these irrelevant variables improved the performance of "boosting-for-ever" to the level of the early stopping algorithm. This gives some credence to our conjecture 2.

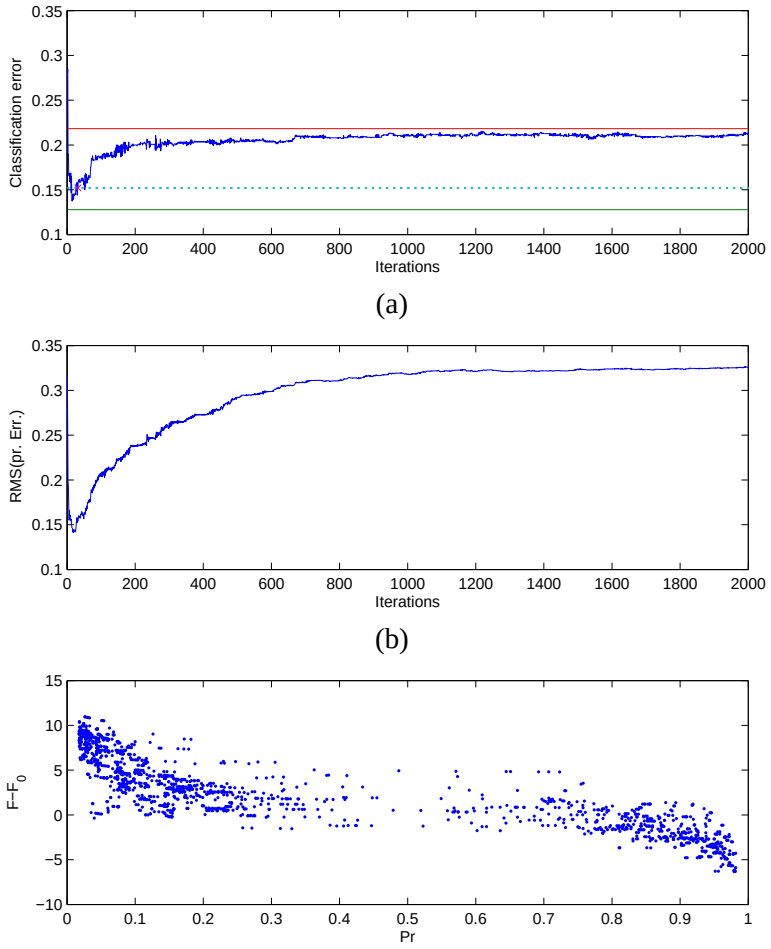

Figure 2: AdaBoost, with and without early stopping.

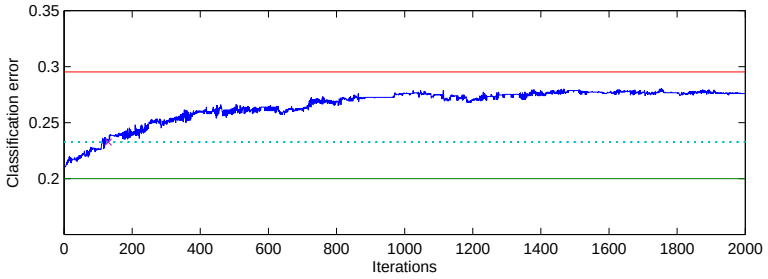
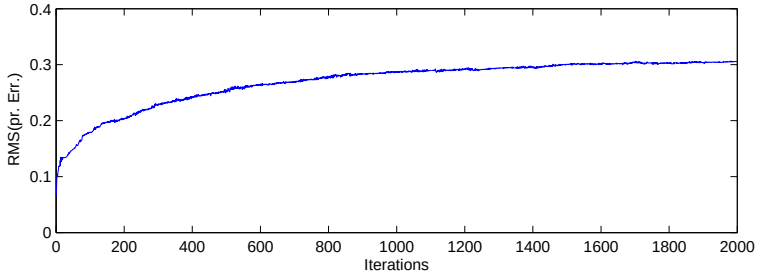


(a)



(b)

Figure 3: AdaBoost under the null hypothesis.

But, this is not the end of the story. We changed the the distribution a little. We left $P(Y|X_1,\ldots,X_{10}) = P(Y|X_1,X_2)$ as above. $X_3,\ldots,X_{10}$ are still independent of each other and independent of (X_1,X_2). However the distribution of (X_1,X_2) was changed to be discrete with 24 well isolated atoms. One can conceive the distribution as that of 24 columns with $500/24$ on the average observations. The Ys are i.i.d. given the column. AdaBoost with early stopping handled this situation very well and stopped after very few (e.g., 2) iterations. It essentially isolated the columns and left them intake. Boosting-for-ever stabilized nicely after very few iterations. However, as could be expected, it did break the columns. The result was that the misclassification error of boosting-for-ever was almost in the middle between the early stopping algorithm, and the strictly inferior 1-NN estimator.

A further point. The phenomenon of not overfitting for a long time is certainly interesting to investigate, but why this should be a virtue of a procedure is unclear, since it merely increases computation time at an often (perhaps usually) negligible improvement over stopping early.

AdaBoost is a mystery, but we, the weak, can solve only one toy problem at a time.
Galileo: Why try to be so clever now, that we at last have a chance of being less stupid? Brecht (1980)

AdaBoost was crowned by Leo Breiman as the best off-the-shelf classifier. It has some mysterious properties, particularly, sometimes continuing to improve off-sample performance even after completely collapsing on the data. It behaves better, sometimes, with 8-nodes trees, some other times with 256-node trees, and other times, mainly when examined by some statisticians, stumps are superior. It presents some mathematical challenges, which should be carefully investigated. However, many examples appearing in the literature are either very artificial, or the investigators

don't have a gold standard like the Bayes risk. We hope that this technique will grow out of its status of something like an art, to a scientifically justified method. But this is only a hope.

We would like to thank the authors for their provocative view on boosting. Their view is built upon some "contrary" evidence based on a particular simulation model. In our discussion, we argue that the structure of the simulation model explains many aspects of the "contrary" evidence. We touch upon the issue of shrinkage or small step-sizes, and we conclude that the "statistical view" provides constructive insights for applying boosting in a highly successful way.

The gradient and "statistical" point of view The gradient point of view of AdaBoost is, in our opinion, a great leap forward for understanding AdaBoost and deriving new variants of boosting now meaning much more than just AdaBoost. This view, which seems to be called the "statistical view" by Mease and Wyner (MW), has been pioneered by Breiman (1998, 1999), Friedman et al. (2000), Mason et al. (2000) Rätsch et al. (2001) and is not just a product of the statistics community. The gradient view of boosting allows transferring of the boosting methodology to many other contexts than just classification, see for example Meir and Rätsch (2003) or Bühlmann and Hothorn (2007) for an overview. We should also emphasize that the gradient view has never promised to explain everything about AdaBoost. Hence we are puzzled by the negative picture of this view painted in the paper under discussion: it differs greatly for most part from our experience and understanding of the statistical research on boosting. In particular, the MW paper seems to ignore simulation, real data and theoretical evidence about overfitting and early stopping (cf. Bartlett and Traskin 2007 regarding asymptotic theory for AdaBoost). We will discuss these issues in more details below.

The relevance of MW's counter-examples The evidences in MW are simulated "counter-examples". It is questionable that they are representative of situations encountered in practice. More importantly, with one exception, evidence of differences shown contradicting the so-called "statistical view" are 1 or 2 % in error rate. One wonders how important or meaningful these differences are in practice, even though they might be statistically significant. In any real world situation, the model used is for sure wrong and the approximation error of the model to the real situation could easily swallow these small differences in performance.

Furthermore, all the evaluation metrics in the MW paper are on statistical performance without any consideration of the computation involved or the meaning of the model derived. For large data problems, computation is an indispensable player and needs to be in the picture.

Additive decision boundary but non-additive logit-probabilities MW's model (in Section 3) is additive for the decision boundary. In terms of conditional probabilities $p(x) = \mathbb{P}[Y = 1|X = x]$ on the logit-scale, $\text{logit}(p(x))$ is *not* an additive function in the (feature) components of x.

Since the population minimizer of (gradient) AdaBoost or also of LogitBoost equals

$$F_{\text{pop}}(x) = 0.5 \cdot \text{logit}(p(x)) = 0.5 \cdot \log\left(\frac{p(x)}{1-p(x)}\right),$$

a (boosting) estimate will be good if it involves an effective parameterization. We believe that this is a central insight, which has been pioneered by Breiman (1998, 1999), Friedman et al. (2000) and which has been further developed by more recent asymptotic results on boosting. In the MW model, $F_{\text{pop}}(x)$ is non-additive in x while boosting with stumps yields an estimate $\hat{f}(x)$ which is additive in x. We think that this is the main reason why some of the figures in MW lead to "contrary" evidence: with our model, as illustrated below, the comparison of stumps versus larger trees for weak learners is always in favor of stumps, that is, stumps yield better performance and larger trees are more heavily overfitting which is the opposite finding to Figures 1, 2, and 11 in MW. MW's model in Section 4 involves only a single component of x and hence it is additive also on the logit-scale for the probabilities. But our own model described below does not confirm MW's statement that their findings "do not depend on a particular simulation model".

Other issues in MW concerning "contrary" evidence cannot be easily explained by the nature of the model.

Figure 3 intends to show that LogitBoost is worse than AdaBoost. The MW finding might seem relevant at 1000 iterations. But one doesn't need to go that far for both methods by early stopping. 100 or so iterations seems enough for stumps and 400 for 8-node trees. The performance difference is then less than 1%. Thus, having some computation savings in mind, early stopped LogitBoost is preferable.

Figure 4 tries to make the point that early stopping could hurt to lose about 1% performance when the total Bayes error is 20% and there is no structure to be learned. However, the 1000 iteration model undoubt-fully gives the wrong impression that something is there, while the early stopped model gives the correct impression that not much is to be learned. Hence we think early stopping is not hurting here. In addition, the starting value of boosting matters but this issue is ignored in standard AdaBoost. A (gradient) boosting algorithm should be started with $F_{init} = F_0 \equiv 0.5\log(\hat{p}/(1-\hat{p}))$ where $\hat{p}$ is the empirical frequency of $Y = 1$, cf. Bühlmann and Hothorn (2007). That is, boosting would (try to) improve upon the MLE from the "pure noise" model. Then, it is expected - and we checked this using gradient LogitBoost on the unbalanced example corresponding to Figure 4 in MW - that boosting will overfit from the beginning because the underlying structure is pure noise. The same idea could be applied to AdaBoost as well: in contrast, standard AdaBoost and MW start with the naive value $F_{init} = F_0 \equiv 0$.

Shrinkage and small step-sizes: another dimension for regularization MW makes some claims about additional shrinking using small step-sizes. As we understand Friedman (2001), he *never* intended to say that a shrinkage factor would avoid overfitting. Instead, he argued that introducing a shrinkage factor may improve the performance. Later, Efron et al. (2004) made the connection,

in the setting of linear models, that boosting with an infinitesimally small shrinkage step is equivalent to the Lasso under some conditions, and for general situations, Zhao and Yu (2007) showed that appropriate backward steps need to be added to boosting to get Lasso. This intriguing connection shows again that the shrinkage factor cannot eliminate overfitting. All what it achieves is a different, usually more powerful solution path (with a new regularization dimension through the step-size) than without shrinkage.

Our own findings with an additive model for logit-probabilities Now we devise our own simulation model to clarify some issues regarding overfitting, choice of weak learner and the estimation of probabilities via boosting. Arguably, as emphasized above, examples should not be overinterpreted. However, in view of many reported findings similar to what we show here, we feel that our examples are rather "representative" and we are reporting major instead of slight differences.

Our model is in the spirit of MW but on the logit-scale:

$$\begin{aligned}&\text{logit}(p(x)) = 8\sum_{j=1}^{5}(x_j - 0.5)\\ &Y \sim \text{Bernoulli}(p(x)),\end{aligned}$$

where $p(x) = \mathbb{P}[Y|X = x]$. This model has Bayes error rate approximately equal to 0.1 (as in the MW paper). We use this model as it is additive on the *logit-scale* for the probabilities since the population minimizer of (gradient) AdaBoost and (gradient) LogitBoost is $0.5\text{logit}(p(x))$. We use $n = 100$, $d = 20$ (i.e., 15 ineffective features), x as in MW and we show the results for one representative example with test set of size 2000. We skipped the repetition step over many realizations from the model: again, we think that one realization is representative and it mimics somewhat better the situation of analyzing one real data set.

We consider the misclassification test error, the surrogate loss test error (e.g., the test set average of $\exp(-y\hat{f})$ for AdaBoost) and the absolute error for probabilities

$$\frac{1}{2000}\sum_{i=1}^{2000}|\hat{p}(X_i) - p(X_i)|,$$

where averaging is over the test set.

All our computations have been done with MW's code for AdaBoost and the `R`-package `mboost` from Bühlmann and Hothorn (2007): we used stumps and larger trees as weak learners. By the way, MW's code is *not* implementing 8 node trees but trees which have on average about 6-8 terminal nodes (during the boosting iterations for this model). The results are displayed in Figures 1- 3. A comparison is also made to the naive estimator with $\hat{p}(x) \equiv 0.5$.

From this very limited experiment we find all facts that we view as important and typical for boosting:

1. Overfitting can be a severe issue when considering the test surrogate loss or for estimating conditional probabilities. In fact, overfitting is seen clearly for all three methods, that is gradient AdaBoost, LogitBoost and AdaBoost. In addition, the misclassification loss is much more insensitive with respect to overfitting. This has been pointed out very clearly in Bühlmann and Yu (2000) and in the rejoinder of Friedman et al. (2000).

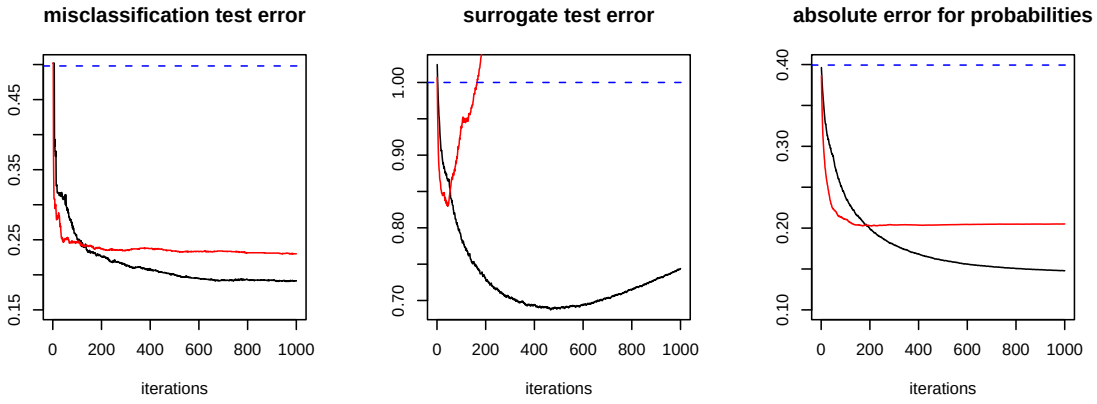

Figure 1: Gradient boosting with exponential loss (gradient AdaBoost). Left panel: Test set misclassification error; Middle panel: test set surrogate loss; Right panel: test set absolute error for probabilities. Black: stumps; Red: larger tree; Blue dashed line: naive estimator.

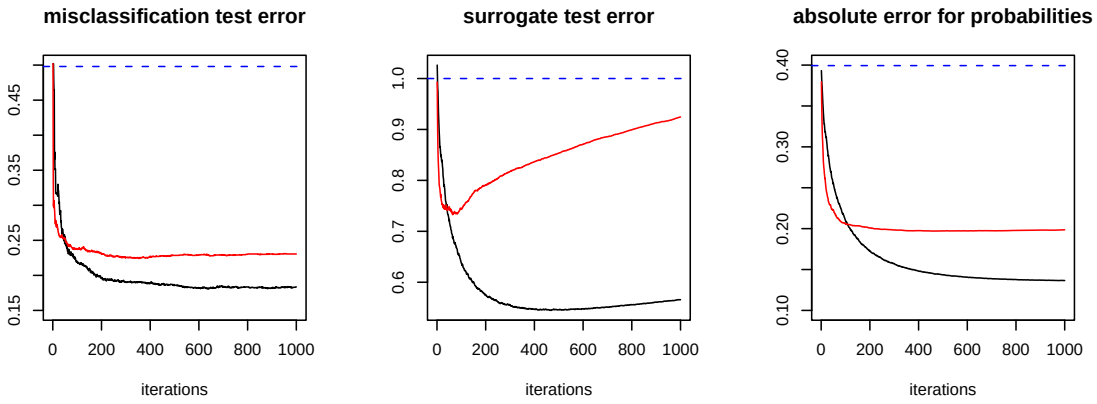

Figure 2: Gradient boosting with Binomial log-likelihood (gradient LogitBoost). Left panel: Test set misclassification error; Middle panel: test set surrogate loss; Right panel: test set absolute error for probabilities. Black: stumps; Red: larger tree; Blue dashed line: naive estimator.

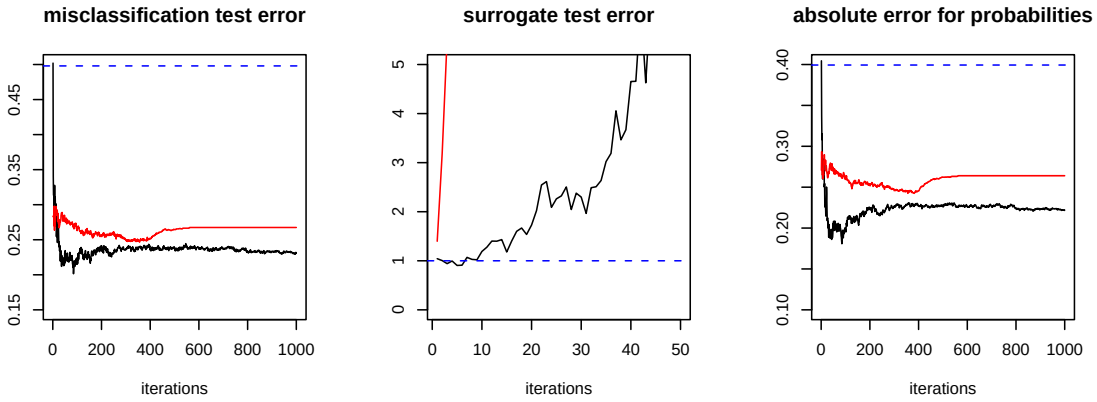

Figure 3: AdaBoost (as in MW). Left panel: Test set misclassification error; Middle panel: test set surrogate loss; Right panel: test set absolute error for probabilities. Black: stumps; Red: larger tree; Blue dashed line: naive estimator. More details are described in point 4 of our summary of findings.

2. Estimating conditional probabilities is quite reasonable when stopping early: as in point 1 above, we see very clearly that early stopping is absolutely crucial for all three methods. And LogitBoost with early stopping gives the best misclassification error and best probability estimate among the three.

3. Regarding the weak learner, larger trees are worse than stumps for our model where the conditional probability function is additive on the logit scale. The "statistical view" reveals the model behind AdaBoost and LogitBoost: we have to consider the logit-scale (the MW model is *not* additive in terms of the logit of conditional probabilities; note that for the decision boundary the scale doesn't matter while it does play a role for conditional probabilities).

   Larger trees do overfit more heavily for probability estimation or with respect to surrogate test loss. For non-additive models (for probabilities on the logit-scale), the overfitting will kick in later for large trees as the the underlying model requires a more complex fit to balance approximation ("bias") and stochastic error ("variance").

4. Somewhat more in line with the MW paper, the original AdaBoost has less a tendency to overfit than the gradient boosting version. The reason why AdaBoost with the larger tree in Figure 3 is staying constant after a while is due to the fact that the algorithm gets "stuck": it alternates back and forth and hence, the amount of overfitting is limited. At this stage of alternating behavior the estimated conditional class probabilities are very much concentrated around either zero or one (not shown but similar to Fig. 18 in MW), that is, overfitting has kicked in severely. We are not convinced that this "getting stuck" property of the algorithm is desirable, despite the consequence that a bound on overfitting is then obviously in action. The surrogate loss function in AdaBoost explodes much earlier (w.r.t. boosting iterations) and one needs to implement an upper bound in the program in order to avoid NA values (MW's code needs some small modification here!).

Our general understanding about Boosting and it's success Instead of going through all issues in MW, we choose instead to repeat several general understandings about boosting which were incorrectly questioned by the paper under discussion:

A. Overfitting does matter, and it is a function of the both the "bias" and "variance". Large trees do not overfit heavily in terms of classification error because:
(i) the misclassification loss is very insensitive to overfitting (see Bühlmann and Yu 2000 and the rejoinder of Friedman et al. 2000);
(ii) larger trees are not as "complex" as the number of nodes in them indicates since they are fitted in a greedy fashion (e.g., 8-node trees fitted by boosting are not 4 times as complex as stumps with two nodes).

   Most probably, the difference between plain vanilla AdaBoost and a gradient version of AdaBoost (as in MW) will *not* play a crucial role in terms of overfitting behavior; but gradient-based boosting seems somewhat more exposed to overfitting while AdaBoost can get stuck which naturally limits the amount of overfitting (on a single data-set).

B. Early stopping, particularly for probability estimation, is very important (because of overfitting) and brings computational savings. The supporting theory is given in, for example, Zhang and Yu (2005), Bühlmann (2006), Bartlett and Traskin (2007) and Bissantz et al. (2007).

C. Estimating probability via boosting is often quite reasonable. It is essential though to tune the boosting algorithm appropriately: a good choice is to do early stopping with respect to the log-likelihood test score (see next point regarding surrogate and evaluating loss).

D. It is important to distinguish between surrogate loss (implementing loss) and loss (evaluating loss) function. For example, there is no surprise that it can happen with AdaBoost that the training misclassification error is zero while the test set misclassification still decreases.

The usage of boosting as we have advocated in our works, and this is very much in line with Friedman et al. (2000) and their subsequent works, has proven to be very competitive and successful in applications. Gao et al. (2006) describe a successful application of boosting to a language transliteration problem. Lutz (2006) has won the performance prediction challenge of the world congress in computational intelligence in 2006 (WCCI 2006): he was using early-stopped LogitBoost with stumps. Part of his success is probably due to careful choice of choosing the stopping iteration: according to personal communication (he has been a former PhD student of the first author of this discussion), he stopped before reaching the minimal value of a cross-validation scheme. In summary, he did not take any of the findings from MW into account (he didn't know the paper at that time, of course). Maybe his success is more convincing evidence that LogitBoost with (i) its "natural" loss function for a binary classification problem, and using (ii) early stopping, (iii) simple weak learners and (iv) a small step size (i.e., shrinkage factor) often works surprisingly well. Other references about successful applications of gradient-based boosting can be found in Bühlmann and Hothorn (2007) which includes the `R` package `mboost` (standing for model-based boosting) for numerous application areas ranging from classification, regression, generalized regression to survival analysis.

Evidence Contrary to the Statistical View of Boosting: A Rejoinder to Responses

1. Introduction

We thank the discussants for their comments on our paper. We also thank the editors for arranging the discussions. Many interesting points have been raised by the discussants. We can not respond to everything, but we do include a section addressing the main points of each discussant. Following these, we provide a final section in which we give some general concluding remarks.

Many of the discussants comment on the overfitting of boosting. Different authors will have different ideas of what the term overfitting means in the context of boosting, but for clarification throughout this rejoinder we will define overfitting as a positive slope for a specified loss metric as a function of the iterations. Specifically, the loss metric we focus on is misclassification error, although we understand that some of the discussants are concerned about other loss functions which quantify probability estimation accuracy rather than classification accuracy. The importance of focusing on misclassification error is underscored in the discussion by Freund and Schapire who remind us that AdaBoost is an algorithm for carrying out classification, not probability estimation.

2. Rejoinder for Kristin P. Bennett

Bennett provides a useful perspective on the situation by studying the convergence of boosting algorithms from the optimization point of view. We agree that this aspect of the problem is too often overlooked by researchers.

In studying the convergence of the algorithms, Bennett touches on a number of important considerations. For example, she mentions cycling in the context of stumps and notes that the cycling results in boosting using only a small number of unique trees. The number of unique trees is rarely noted by researchers in empirical investigations. Bennett's studies also lead her to concur that boosting algorithms sometimes benefit from a bagging type of self-averaging during what she calls the "overtraining" stage. ("Overtraining" as defined by Bennett should not be confused with "over*fitting*" as we have defined it). Another point on which we strongly agree with Bennett is that

boosting's resistance to overfitting can occur for different reasons in different contexts. We believe that this is one reason why researchers have difficulty in coming to agreement regarding various explanations for boosting.

In addition to studying convergence, Bennett also looks at the margin of the classification rules. We mentioned margin theory in our paper only briefly since our focus was on the statistical view of boosting, and margin theory is generally separate from this view. It is our hope, however, that by finding holes in the accepted statistical view we are encouraging researchers to approach the problem from different perspectives to help explain the phenomena left unexplained by the statistical view. Unfortunately, in this case Bennett points out that examination of the margin still fails to explain the results of the experiment in Section 3.2.

We believe that studying boosting as an algorithm (rather than as a statistical model) in the way Bennett has done can be quite helpful in understanding some of its remaining mysteries. We are glad that our examples have inspired this type of investigation.

3. Rejoinder for Andreas Buja and Werner Stuetzle

One of the main points argued by Buja and Stuetzle is that most of the current literature on boosting does not explain its variance reduction. They argue that a complete view of boosting should explain both its ability to reduce bias and variance. We certainly agree with this point. In fact, some of the examples in our paper such as those in Sections 3.4 and 4.4 illustrate this quite well. It is interesting that Buja and Stuetzle site references from the early research on boosting which argue in this same direction. It is a shame that more attention has not been given to boosting's ability to reduce variance in addition to bias in more recent research. We hope that our paper helps to rejuvenate research on this aspect of boosting.

Buja and Stuetzle go on to argue that there is often a need for more than a black box classifier which produces small misclassification error. Some applications call for interpretable and diagnostic models and/or conditional class probability estimates. This is certainly true, and we agree that research that extends boosting in these directions is quite welcome. However, in carrying out this research it is important to be honest about situations in which the theory does not explain the performance of traditional boosting algorithms for classification. One of our purposes in writing this paper was to promote this honesty.

4. Rejoinder for Yoav Freund and Robert E. Schapire

Freund and Schapire focus their discussion on margin theory. It is quite interesting that margin theory has not been embraced much at all by the statistical community. In fact, Freund and Schapire's paper "Boosting the Margin: A New Explanation for the Effectiveness of Voting Methods" appeared less than two years before the Friedman, Hastie and Tibshirani paper "Additive Logistic Regression: A Statistical View Of Boosting" in the same journal (*Annals of Statistics*). Despite this, the statistics community has largely ignored it in favor of the more familiar theory in the latter paper.

Freund and Schapire make a case for margin theory by arguing that this theory explains the results of the experiment in Section 3.1 while obviously the statistical theory does not. However, it should be noted that Bennett believes margin theory still does not explain the results for Section 3.2. Despite this, we still believe that margin theory is worth pursuing, especially given the large number of inconsistencies between the statistical view and the reality of the simulations presented

in our paper. As we have mentioned, we wrote the paper with the goal of promoting alternative explanations for boosting other than the statistical view, which leaves much unexplained. Margin theory is one such alternative explanation.

Additionally, Freund and Schapire make a number of other points on which we agree and wish to underscore. They argue that in the statistics research on boosting too much importance is placed on class probability estimation over class estimation, the use of stumps over larger trees and theoretical questions of consistency and asymptotic variance over more relevant theoretical questions.

5. Rejoinder for Jerome Friedman, Trevor Hastie and Robert Tibshirani

Friedman, Hastie and Tibshirani argue that many of the ten statements made in our paper should not be ascribed to the statistical view as laid out in Friedman et al. (2000). This is understandable, and in the case of the similarity with nearest neighbor algorithms, for example, we have even noted this in our original paper. However, other statements could be argued to follow fairly directly, whether that is the intent of the authors or the fault of the reader. At the very least, we believe it is fair to say the statistical view offers very little to help explain the non-intuitive nature of the results in our paper.

Of all ten statements, the most direct relationship to the work of Friedman, Hastie and Tibshirani is the idea in Sections 3.1 and 4.1 that stumps should be used for additive Bayes rules. We believe the authors would agree that this is the strongest connection to their work, which is why they focused the majority of their discussion on the experiment in Section 3.1. We also think it is refreshing that they admit that they "are not sure why" the results of this experiment are such, but they do produce some graphs to try to understand this better. Some of their graphs show the performance of the probability estimates. It is argued in the discussion by Freund and Schapire that probability estimation for boosting has very little to do with boosting's classification performance. We agree and for this reason we will not comment on the graphs for probability estimation. However, the graphs showing misclassification error are of interest and we discuss these below.

Friedman, Hastie and Tibshirani's Figure 1 shows that using shrinkage in our original experiment causes stumps to "win handily". We note, however, that the shrinkage causes overfitting, so it also becomes necessary to stop the boosting process before 600 iterations to realize any advantage over the 8-node trees. In practice the optimal stopping time is not known, and a fair comparison would require incorporating the uncertainty in the estimation of this value.

The right panel of their Figure 2 shows that with a larger training sample size of $n = 2000$ the overfitting caused by shrinkage is not as severe and the stumps maintain their advantage over the full 1000 iterations. However, by 1000 iterations the overfitting for the stumps has caused the gap with the 8-node trees to close considerably and extrapolation would suggest that additional iterations would result in this gap becoming even smaller or disappearing altogether. Meanwhile, the 8-node trees again show no signs of overfitting.

We believe the more interesting research question with regard to Friedman, Hastie and Tibshirani's Figures 1 and 2 is not which algorithm performs best for a certain stopping time and sample size, but rather why all algorithms display overfitting with regard to misclassification error except the 8-node trees without shrinkage. The authors state that the larger trees can have a bagging effect, and we certainly agree with this. We feel that understanding this effect better (as well as understanding why shrinkage can destroy this effect) is essential to gaining a better understanding of boosting.

The left panel of Friedman, Hastie and Tibshirani's Figure 3 shows the effect of using Bernoulli loss rather than exponential loss. With Bernoulli loss all algorithms show overfitting. This is another curiosity not explained by the statistical view of boosting. In fact, the paper by Friedman et al. (2000) seems to suggest the opposite should be expected.

In their final paragraph Friedman, Hastie and Tibshirani welcome "*constructive* counter-arguments and alternative explanations for the success of boosting methods." We will make a couple of comments here in response to this. First, we believe that explanations such as the variance reducing bagging effect of boosting fall into this category. Our paper is certainly not the first to suggest this notion, nor do we offer a theoretical explanation for the phenomenon, but our paper does stress the importance of not overlooking this effect and thus we hope promotes constructive research on this topic. Secondly, we feel that researchers currently embrace the statistical view too strongly, and for this reason it is difficult for researchers to offer any alternative explanations without first tearing down the current beliefs to some degree. We base this statement on our own experience. For instance, an early version of Mease et al. (2007) was rejected for publication by a different outlet. That paper offers a method for estimating probabilities using AdaBoost. Two of the three referees rejected the paper arguing that in order to estimate probabilities using boosting it would be sufficient to use LogitBoost in place of AdaBoost.

6. Rejoinder for P. J. Bickel and Ya'acov Ritov

Bickel and Ritov begin by identifying some points we made in our paper with which they agree. The amount of agreement is substantial. The disagreement is focused largely on what is generally regarded to be the most mysterious property of the AdaBoost algorithm: its ability to reduce the (test) error rate long after the training data has been fit without error. Other classifiers such as CART, neural nets, LDA and logistic regression perform optimally only with some sort of appropriate early stopping to prevent over parameterization and overfitting of the data. It is understandable that Bickel and Ritov's negative remarks focus on this particular issue, as it is the feature of AdaBoost most at odds with the statistical view.

The example provided by Bickel and Ritov is a model for which early stopping is essential to achieve optimal classification performance. If AdaBoost is not stopped after 10 or 20 iterations in their example, it will overfit the data and the generalization error will increase steadily. Their example is not the first of its kind, but rather is typical of the simulations used to provide empirical support for the statistical view. We addressed this point directly in our paper:

> *Such examples in which overtting is observed often deal with extremely low-dimensional cases such as $d = 2$ or even $d = 1$. By experimenting with the simulation code provided along with this paper, one can confirm that in general AdaBoost is much more likely to suffer from overtting in trivial low-dimensional examples as opposed to high-dimensional situations where it is more often used.*

The example provided by Bickel and Ritov is of this same spirit. It is a $d = 2$ dimensional model that lives on $d = 1$ dimensional circular manifolds. Since it is well known that AdaBoost will converge to the nearest neighbor classifier in one dimension, the results for this simulation are not unexpected. Along these same lines, Bickel and Ritov provide further evidence for our claim that overfitting is largely a symptom of trivial low dimensional examples by observing that when

they add 8 additional dimensions with no signal the overfitting disappears. The authors refer to this phenomenon as "surprising", but we would argue that this should also be expected.

Bickel and Ritov note interesting changes when they discretize some of the predictors. We did not discuss this in our paper, but the difference in behavior for discrete data and continuous data is tremendous. We learned first hand about this in Mease et al. (2007) when we artificially introduced discreteness by adding replicates. Because of this difference, we focused our current paper on the case of continuous data. The case of discrete data relates more to what Friedman et al. (2000) called the *population version* of boosting. The statistical view of boosting is largely based on this population version of boosting, and thus the statistical view becomes more relevant for discrete data.

Bickel and Ritov also bring up probability estimation in their discussion. Probability estimation is a popular topic among statisticians with regard to boosting, but again we will not go into any detail here because we agree with Freund and Schapire that probability estimation is not the central topic, but rather classification. It is curious, however, that Bickel and Ritov state that "most of the error in the estimation" of the probabilities "comes from the easy to classify points". The truth of this statement depends on how one measures the error in probability estimates. For example, if one computes the RMSE between the true probabilities and the estimated probabilities for the data in Bickel and Ritov's Figure 2(c), it can be observed that the RMSE is actually highest near the points with a true probability of 1/2.

In conclusion, Bickel and Ritov have presented a couple of low dimensional examples in which overfitting occurs unless early stopping is applied, while our paper presents higher dimensional examples where this is not the case. Since "everybody can produce examples" as Bickel and Ritov state, one may wonder which set of examples is more useful to study for the purpose of understanding boosting. We make the argument for our examples based on the fact that higher dimensional examples are more common of a use case for boosting, and that our examples are more similar to the many examples in which overfitting does not occur that first led practitioners to be attracted to boosting originally. We feel that understanding such examples is most useful for understanding boosting.

7. Rejoinder for Peter Buhlmann and Bin Yu

Of the six discussions, Buhlmann and Yu seem to be the least accepting of the empirical findings in our paper. They state that the "main reason" why we obtain contrary evidence in many cases is the functional form of the simulation model, and they propose considering a model that is additive on the logit scale. The model they propose turns out to be a special case of our model in Section 5 with $k = 8$. As stated in the paper, we had already considered the results for this specific model carefully using various values of k, and those results were consistent qualitatively with the other simulations in the paper. Thus, we were surprised to read that Buhlmann and Yu based any disagreement on results from this model. On closer inspection, we learned that the discrepancy is most likely due to sampling error. Buhlmann and Yu considered only a single repetition. The plot in the first panel of their Figure 3 shows that for that single repetition, the 8-node trees begin to overfit near 400 iterations and the stumps have a lower misclassification error throughout the 1000 iterations. However, if the results are averaged over many repetitions, one can learn that this behavior is not true in aggregate. The first plot in Figure 1 in this rejoinder shows the misclassification error for the Buhlmann and Yu model averaged over 100 repetitions. The stumps overfit while the 8-node trees do not, and the 8-node trees achieve a lower misclassification error than the stumps at 1000

iterations. Thus, the results for the Buhlmann and Yu model are consistent with the results for the other simulations in our paper.

It should be noted that with the small sample size of $n = 100$ chosen by Buhlmann and Yu, there is indeed often a problem with floating point overflow errors in R as they mention. They dealt with this issue by making a modification to our code (which is an alternative explanation for the discrepancies in the results). We avoided this issue when making the first plot in Figure 1 in this rejoinder by considering 100 randomly chosen repetitions for which the floating point overflow error did not occur. For readers who are uncomfortable with this, there are a couple of other ways of handling the problem. First, if a larger sample size is chosen then the problem goes away completely. For example, the second plot in Figure 1 in this rejoinder considers our original sample size of $n = 200$. For this sample size there were no problems with overflow errors in 100 repetitions. Again, one can see that the 8-node trees lead to a lower misclassification error at 1000 iterations and do not overfit, while the stumps do overfit. A second way of dealing with the overflow errors for the sample size of $n = 100$ is to consider only the first 500 iterations. When we ran only 500 iterations we did not observe any overflow errors in 100 repetitions, and the results were consistent with those in the first plot in Figure 1 in this rejoinder.

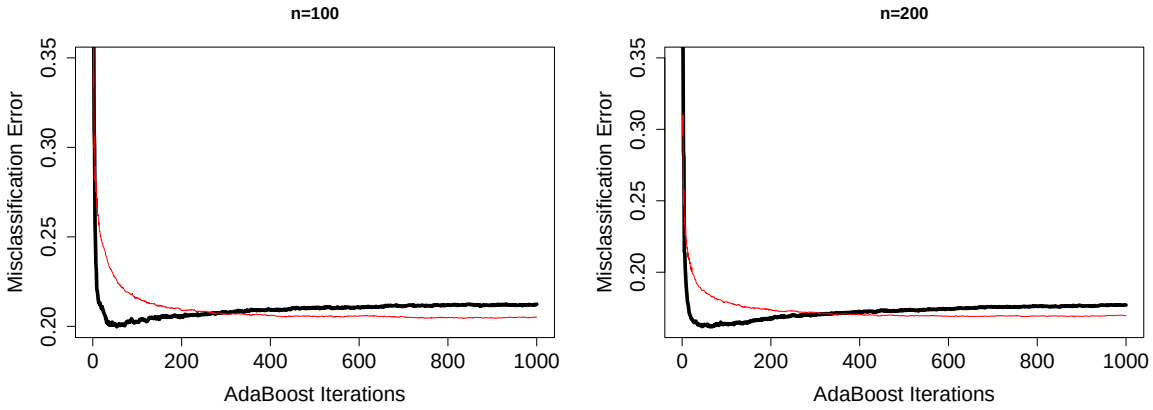

Figure 1: Comparison of AdaBoost with Stumps (Black, Thick) and 8-Node Trees (Red, Thin) for the Buhlmann and Yu Model Using 100 Repetitions and Sample Sizes of $n = 100$ and $n = 200$

Thus, concerning this simulation model proposed by Buhlmann and Yu, we conclude that the results are largely consistent with the other results in our paper. However, Buhlmann and Yu also discuss our Figures 3 and 4 independently of their simulation model. We address this below.

With regard to LogitBoost in our Figure 3, Buhlmann and Yu mention that with early stopping LogitBoost does almost as well as AdaBoost. This assumes one can estimate the optimal stopping time well, when in practice the stopping time estimation using LogitBoost can be difficult. In fact, we mentioned in our paper that the authors of the particular LogitBoost code we used reported that the stopping estimation was not effective for their purposes. Conversely AdaBoost performs fine in our Figure 3 without early stopping. Also, considering that the creators of LogitBoost (Friedman, Hastie and Tibshirani) mentioned in their discussion that they "have moved on" from LogitBoost, there seems to be little left to be said in its defense.

With regard to our Figure 4, Buhlmann and Yu seem unimpressed by this example which shows how AdaBoost can reduce variance. In fact, despite its excellent performance they lament that the classifier "gives the wrong impression." This is an interesting statement and illustrates the desire on the part of the statistical community to view AdaBoost as an interpretable model rather than a black box classifier. Certainly a model can give one the wrong impression but a classifier arguably only classifies well or does not classify well.

In conclusion, Buhlmann and Yu are considerably opposed to our most important claims: 1) that large trees generally work better than stumps and 2) that overfitting is usually not a problem and 3) that early stopping initiatives are often not only unnecessary but also counterproductive. With regard to classification we have shown that their simulation does not provide strong evidence to support their case. However, when the goal is the more difficult problem of conditional probability estimation, we will not offer any disagreement. We have not focused our analysis on this problem, and we do not feel that boosting algorithms should be regarded as "state-of-the-art" probability estimators, since they are usually outperformed by competitors like Random Forests or even logistic regression. Rather, it is the statistical view that asserts that AdaBoost works, erroneously in our opinion, because it estimates probabilities. Indeed, the efforts of Buhlmann and Yu to understand and improve the performance of boosting for probability estimation is productive and worthwhile. Where we part company is in name only. We question whether it is logical to continue to call the algorithms boosting algorithms since there is a considerable disconnect from the original AdaBoost algorithm for classification.

8. Conclusion

We believe the discussions provided by the six sets of authors have been extremely valuable. We are encouraged by the amount of discussion of two main ideas which we feel will lead to a better understanding of boosting.

First, the discussions have helped to clarify that (out of sample) minimization of the surrogate loss function (and equivalently probability estimation) is often a very different problem from (out of sample) minimization of misclassification error. The original AdaBoost algorithm was intended for the latter but much research in the statistical community has focused on the former.

Secondly, with regard to minimization of misclassification error, the idea that boosting is reducing variance has been acknowledged in the discussions. The extent to which this phenomenon is essential for boosting's success and of interest as a research topic can be debated, but we are encouraged to see it acknowledged by such a prominent group of researchers.

Editor: Nello Cristianini

Abstract

Due to its wide applicability, the problem of semi-supervised classification is attracting increasing attention in machine learning. Semi-Supervised Support Vector Machines (S^3VMs) are based on applying the margin maximization principle to both labeled and unlabeled examples. Unlike SVMs, their formulation leads to a non-convex optimization problem. A suite of algorithms have recently been proposed for solving S^3VMs. This paper reviews key ideas in this literature. The performance and behavior of various S^3VM algorithms is studied together, under a common experimental setting.

Keywords: semi-supervised learning, support vector machines, non-convex optimization, transductive learning

1. Introduction

In many applications of machine learning, abundant amounts of data can be cheaply and automatically collected. However, manual labeling for the purposes of training learning algorithms is often a slow, expensive, and error-prone process. The goal of semi-supervised learning is to employ the large collection of unlabeled data jointly with a few labeled examples for improving generalization performance.

The design of Support Vector Machines (SVMs) that can handle partially labeled data sets has naturally been a vigorously active subject. A major body of work is based on the following idea: solve the standard SVM problem while treating the unknown labels as additional optimization variables. By maximizing the margin in the presence of unlabeled data, one learns a decision boundary that traverses through low data-density regions while respecting labels in the input space. In other words, this approach implements the *cluster assumption* for semi-supervised learning—that is,

∗. Most of the work was done while at MPI for Biological Cybernetics,Tübingen, Germany.

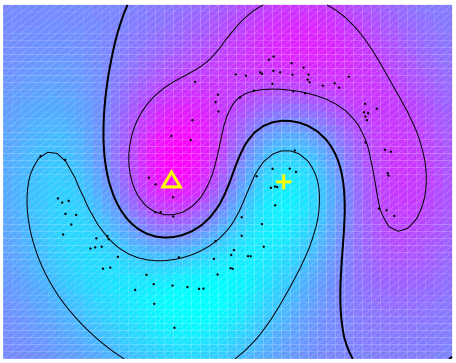

Figure 1: Two moons. There are 2 labeled points (the triangle and the cross) and 100 unlabeled points. The global optimum of S^3VM correctly identifies the decision boundary (black line).

points in a data cluster have similar labels (Seeger, 2006; Chapelle and Zien, 2005). Figure 1 illustrates a low-density decision surface implementing the cluster assumption on a toy two-dimensional data set. This idea was first introduced by Vapnik and Sterin (1977) under the name *Transductive SVM*, but since it learns an inductive rule defined over the entire input space, we refer to this approach as *Semi-Supervised SVM* (S^3VM).

Since its first implementation by Joachims (1999), a wide spectrum of techniques have been applied to solve the non-convex optimization problem associated with S^3VMs, for example, local combinatorial search (Joachims, 1999), gradient descent (Chapelle and Zien, 2005), continuation techniques (Chapelle et al., 2006a), convex-concave procedures (Fung and Mangasarian, 2001; Collobert et al., 2006), semi-definite programming (Bie and Cristianini, 2006; Xu et al., 2004), non-differentiable methods (Astorino and Fuduli, 2007), deterministic annealing (Sindhwani et al., 2006), and branch-and-bound algorithms (Bennett and Demiriz, 1998; Chapelle et al., 2006c).

While non-convexity is partly responsible for this diversity of methods, it is also a departure from one of the nicest aspects of SVMs. Table 1 benchmarks the empirical performance of various S^3VM implementations against the globally optimal solution obtained by a Branch-and-Bound algorithm. These empirical observations strengthen the conjecture that the performance variability of S^3VM implementations is closely tied to their susceptibility to sub-optimal local minima. Together with several subtle implementation differences, this makes it challenging to cross-compare different S^3VM algorithms.

The aim of this paper is to provide a review of optimization techniques for semi-supervised SVMs and to bring different implementations, and various aspects of their empirical performance, under a common experimental setting.

In Section 2 we discuss the general formulation of S^3VMs. In Sections 3 and 4 we provide an overview of various methods. We present a detailed empirical study in Section 5 and present a discussion on complexity in Section 6.

	∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton	BB
Coil3	61.6	61	56.6	56.7	61.6	61.5	0
2moons	61	37.7	63.1	68.8	22.5	11	0

Table 1: Generalization performance (error rates) of different S^{3}VM algorithms on two (small) data sets Coil3 and 2moons. Branch and Bound (BB) yields the globally optimal solution which gives perfect separation. BB can only be applied to small data sets due to its high computational costs. See Section 5 for experimental details.

2. Semi-Supervised Support Vector Machines

We consider the problem of binary classification. The training set consists of l labeled examples $\{(\mathbf{x}_i, y_i)\}_{i=1}^{l}$, $y_i = \pm 1$, and u unlabeled examples $\{\mathbf{x}_i\}_{i=l+1}^{n}$, with $n = l+u$. In the linear S^{3}VM classification setting, the following minimization problem is solved over *both* the hyperplane parameters $(\mathbf{w}, b)$ and the label vector $\mathbf{y}_u := [y_{l+1} \dots y_n]^\top$,

$$\min_{(\mathbf{w},b),\ \mathbf{y}_u} I(\mathbf{w}, b, \mathbf{y}_u) = \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{l} V(y_i, o_i) + C^\star \sum_{i=l+1}^{n} V(y_i, o_i) \tag{1}$$

where $o_i = \mathbf{w}^\top \mathbf{x}_i + b$ and V is a loss function. The Hinge loss is a popular choice for V,

$$V(y_i, o_i) = \max(0, 1 - y_i o_i)^p . \tag{2}$$

It is common to penalize the Hinge loss either linearly ($p = 1$) or quadratically ($p = 2$). In the rest of the paper, we will consider $p = 2$. Non-linear decision boundaries can be constructed using the *kernel trick* (Vapnik, 1998).

The first two terms in the objective function I in (1) define a standard SVM. The third term incorporates unlabeled data. The loss over labeled and unlabeled examples is weighted by two hyperparameters, C and $C^\star$, which reflect confidence in labels and in the cluster assumption respectively. In general, C and $C^\star$ need to be set at different values for optimal generalization performance.

The minimization problem (1) is solved under the following class balancing constraint,

$$\frac{1}{u}\sum_{i=l+1}^{n} \max(y_i, 0) = r \quad \text{or equivalently} \quad \frac{1}{u}\sum_{i=l+1}^{n} y_i = 2r - 1. \tag{3}$$

This constraint helps in avoiding unbalanced solutions by enforcing that a certain user-specified fraction, r, of the unlabeled data should be assigned to the positive class. It was introduced with the first S^{3}VM implementation (Joachims, 1999). Since the true class ratio is unknown for the unlabeled data, r is estimated from the class ratio on the labeled set, or from prior knowledge about the classification problem.

There are two broad strategies for minimizing I:

1. **Combinatorial Optimization:** For a given fixed $\mathbf{y}_u$, the optimization over $(\mathbf{w}, b)$ is a standard SVM training.[1] Let us define:

$$\mathcal{J}(\mathbf{y}_u) = \min_{\mathbf{w},b} \ I(\mathbf{w}, b, \mathbf{y}_u). \tag{4}$$

1. The SVM training is slightly modified to take into account different values for C and $C^\star$.

The goal now is to minimize $\mathcal{J}$ over a set of binary variables. This combinatorial view of the optimization problem is adopted by Joachims (1999), Bie and Cristianini (2006), Xu et al. (2004), Sindhwani et al. (2006), Bennett and Demiriz (1998), and Chapelle et al. (2006c). There is no known algorithm that finds the global optimum efficiently. In Section 3 we review this class of techniques.

2. **Continuous Optimization:** For a fixed $(\mathbf{w}, b)$, $\arg\min_y V(y, o) = \text{sign}(o)$. Therefore, the optimal $\mathbf{y}_u$ is simply given by the signs of $o_i = \mathbf{w}^\top \mathbf{x}_i + b$. Eliminating $\mathbf{y}_u$ in this manner gives a continuous objective function over $(\mathbf{w}, b)$:

$$\frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{l} \max(0, 1 - y_i o_i)^2 + C^\star \sum_{i=l+1}^{n} \max(0, 1 - |o_i|)^2 . \tag{5}$$

This form of the optimization problem illustrates how S^{3}VMs implement the cluster assumption. The first two terms in (5) correspond to a standard SVM. The last term (see Figure 2) drives the decision boundary, that is, the zero output contour, away from unlabeled points. From Figure 2, it is clear that the objective function is non-convex.

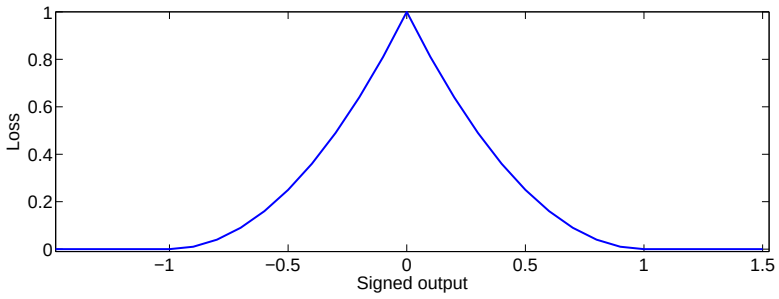

Figure 2: The effective loss $\max(0, 1 - |o|)^2$ is shown above as a function of $o = (\mathbf{w}^\top \mathbf{x} + b)$, the real-valued output at an unlabeled point $\mathbf{x}$.

Note that in this form, the balance constraint becomes $\frac{1}{u}\sum_{i=l+1}^{n} \text{sign}(\mathbf{w}^\top \mathbf{x}_i + b) = 2r - 1$ which is non-linear in $(\mathbf{w}, b)$ and not straightforward to enforce. In Section 4 we review this class of methods (Chapelle and Zien, 2005; Chapelle et al., 2006a; Fung and Mangasarian, 2001; Collobert et al., 2006).

3. Combinatorial Optimization

We now discuss combinatorial techniques in which the labels $\mathbf{y}_u$ of the unlabeled points are explicit optimization variables. Many of the techniques discussed in this section call a standard (or slightly modified) supervised SVM as a subroutine to perform the minimization over $(\mathbf{w}, b)$ for a fixed $\mathbf{y}_u$ (see 4).

3.1 Branch-and-Bound (BB) for Global Optimization

The objective function (4) can be globally optimized using Branch-and-Bound techniques. This was noted in the context of S^3VM by Wapnik and Tscherwonenkis (1979) but no details were presented there. In general, global optimization can be computationally very demanding. The technique described in this section is impractical for large data sets. However, with effective heuristics it can produce globally optimal solutions for small-sized problems. This is useful for benchmarking practical S^3VM implementations. Indeed, as Table 1 suggests, the exact solution can return excellent generalization performance in situations where other implementations fail completely. Branch-and-Bound was first applied by Bennett and Demiriz (1998) in association with integer programming for solving linear S^3VMs. More recently Chapelle et al. (2006c) presented a Branch-and-Bound (BB) algorithm which we outline in this section. The main ideas are illustrated in Figure 3.

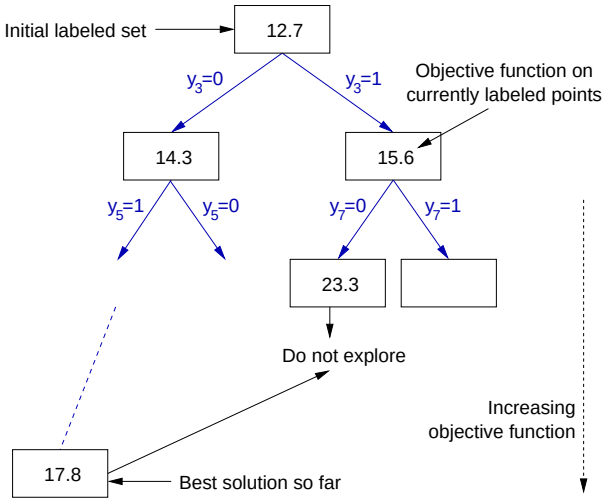

Figure 3: Branch-and-Bound Tree

Branch-and-Bound effectively performs an exhaustive search over $\mathbf{y}_u$, pruning large parts of the solution space based on the following simple observation: suppose that a lower bound on $\min_{\mathbf{y}_u \in A} \mathcal{J}(\mathbf{y}_u)$, for some subset A of candidate solutions, is greater than $\mathcal{J}(\tilde{\mathbf{y}}_u)$ for some $\tilde{\mathbf{y}}_u$, then A can be safely discarded from exhaustive search. BB organizes subsets of solutions into a binary tree (Figure 3) where nodes are associated with a fixed partial labeling of the unlabeled data set and the two children correspond to the labeling of some new unlabeled point. Thus, the root corresponds to the initial set of labeled examples and the leaves correspond to a complete labeling of the data. Any node is then associated with the subset of candidate solutions that appear at the leaves of the subtree rooted at that node (all possible ways of completing the labeling, given the partial labeling at that node). This subset can potentially be pruned from the search by the Branch-and-Bound procedure if a lower bound over corresponding objective values turns out to be worse than an available solution.

The effectiveness of BB depends on the following design issues: (1) the lower *bound* at a node and (2) the sequence of unlabeled examples to *branch* on. For the lower bound, Chapelle et al. (2006c) use the objective value of a standard SVM trained on the associated (extended) labeled

set.[2] As one goes down the tree, this objective value increases as additional loss terms are added, and eventually equals $\mathcal{J}$ at the leaves. Note that once a node violates the balance constraint, it can be immediately pruned by resetting its lower bound to ∞. Chapelle et al. (2006c) use a labeling-confidence criterion to choose an unlabeled example and a label on which to branch. The tree is explored on the fly by depth-first search. This confidence-based tree exploration is also intuitively linked to Label Propagation methods (Zhu and Ghahramani, 2002) for graph-transduction. On many small data sets (e.g., Table 1 data sets have up to 200 examples) BB is able to return the globally optimal solution in reasonable amount of time. We point the reader to Chapelle et al. (2006c) for pseudocode.

3.2 S^{3}VM^{light}

S^{3}VM^{light} (Joachims, 1999) refers to the first S^{3}VM algorithm implemented in the popular SVM^{light} software.[3] It is based on local combinatorial search guided by a label switching procedure. The vector $\mathbf{y}_u$ is initialized as the labeling given by an SVM trained on the labeled set, thresholding outputs so that $u \times r$ unlabeled examples are positive. Subsequent steps in the algorithm comprise of switching labels of two examples in opposite classes, thus always maintaining the balance constraint. Consider an iteration of the algorithm where $\mathbf{y}_u$ is the temporary labeling of the unlabeled data and let $(\tilde{\mathbf{w}}, \tilde{b}) = \text{argmin}_{\mathbf{w},b} \;\; I(\mathbf{w}, b, \mathbf{y}_u)$ and $\mathcal{J}(\mathbf{y}_u) = I(\tilde{\mathbf{w}}, \tilde{b}, \mathbf{y}_u)$. Suppose a pair of unlabeled examples indexed by (i, j) satisfies the following condition,[4]

$$y_i = 1, y_j = -1, V(1, o_i) + V(-1, o_j) > V(-1, o_i) + V(1, o_j) \tag{6}$$

where o_i, o_j are outputs of $(\tilde{\mathbf{w}}, \tilde{b})$ on the examples $\mathbf{x}_i, \mathbf{x}_j$. Then after switching labels for this pair of examples and retraining, the objective function $\mathcal{J}$ can be easily shown to strictly decrease. S^{3}VM^{light} alternates between label-switching and retraining. Since the number of possible $\mathbf{y}_u$ is finite, the procedure is guaranteed to terminate in a finite number of steps at a local minima of (4), that is, no further improvements are possible by interchanging two labels.

In an outer loop, S^{3}VM^{light} gradually increases the value of $C^\star$ from a small value to the final value. Since $C^\star$ controls the non-convex part of the objective function (4), this annealing loop can be interpreted as implementing a "smoothing" heuristic as a means to protect the algorithm from sub-optimal local minima. The pseudocode is provided in Algorithm 1.

3.3 Deterministic Annealing S^{3}VM

Deterministic annealing (DA) is a global optimization heuristic that has been used to approach hard combinatorial or non-convex problems. In the context of S^{3}VMs (Sindhwani et al., 2006), it consists of relaxing the discrete label variables $\mathbf{y}_u$ to real-valued variables $\mathbf{p}_u = (p_{l+1}, \ldots, p_{l+u})$ where p_i is interpreted as the probability that $y_i = 1$. The following objective function is now considered:

$$\begin{aligned} I'(\mathbf{w}, b, \mathbf{p}_u) &= E\left[I(\mathbf{w}, b, \mathbf{y}_u)\right] \\ &= \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{l} V(y_i, o_i) + C^\star \sum_{i=l+1}^{n} p_i V(1, o_i) + (1 - p_i) V(-1, o_i) \end{aligned} \tag{7}$$

2. Note that in this SVM training, the loss terms associated with (originally) labeled and (currently labeled) unlabeled examples are weighted by C and $C^\star$ respectively.
3. Note that in the S^{3}VM literature, this particular implementation is often referred as "TSVM" or "Transductive SVM".
4. This switching condition is slightly weaker than that proposed by Joachims (1999).

Algorithm 1 S^3VM^{light}

Train an SVM with the labeled points. $o_i \leftarrow \mathbf{w} \cdot \mathbf{x}_i + b$.
Assign $y_i \leftarrow 1$ to the ur largest o_i, -1 to the others.
$\tilde{C} \leftarrow 10^{-5} C^\star$
while $\tilde{C} < C^\star$ **do**
  repeat
    Minimize (1) with $\{y_i\}$ fixed and $C^\star$ replaced by $\tilde{C}$.
    if $\exists (i, j)$ satisfying (6) **then**
      Swap the labels y_i and y_j
    end if
  until No labels have been swapped
  $\tilde{C} \leftarrow \min(1.5C, C^\star)$
end while

where E denotes expectation under the probabilities $\mathbf{p}_u$. Note that at optimality with respect to $\mathbf{p}_u$, p_i must concentrate all its mass on $y_i = \text{sign}(\mathbf{w}^\top \mathbf{x}_i + b)$ which leads to the smaller of the two losses $V(1, o_i)$ and $V(-1, o_i)$. Hence, this relaxation step does not lead to loss of optimality and is simply a reformulation of the original objective in terms of continuous variables. In DA, an additional entropy term $-H(\mathbf{p}_u)$ is added to the objective,

$$I''(\mathbf{w}, b, \mathbf{p}_u; T) = I'(\mathbf{w}, b, \mathbf{p}_u) - TH(\mathbf{p}_u)$$
$$\text{where } H(\mathbf{p}_u) = -\sum_i p_i \log\ p_i + (1 - p_i)\ \log\ (1 - p_i),$$

and $T \geq 0$ is usually referred to as 'temperature'. Instead of (3), the following class balance constraint is used,

$$\frac{1}{u} \sum_{i=l+1}^{n} p_i = r.$$

Note that when $T = 0$, I'' reduces to (7) and the optimal $\mathbf{p}_u$ identifies the optimal $\mathbf{y}_u$. When $T = \infty$, I'' is dominated by the entropy term resulting in the maximum entropy solution ($p_i = r$ for all i). T parameterizes a family of objective functions with increasing degrees of non-convexity (see Figure 4 and further discussion below).

At any T, let $(\mathbf{w}_T, b_T, \mathbf{p}_{uT}) = \text{argmin}_{(\mathbf{w},b),\mathbf{p}_u} I''(\mathbf{w}, b, \mathbf{p}_u; T)$. This minimization can be performed in different ways:

1. *Alternating Minimization*: We sketch here the procedure proposed by Sindhwani et al. (2006). Keeping $\mathbf{p}_u$ fixed, the minimization over $(\mathbf{w}, b)$ is standard SVM training—each unlabeled example contributes two loss terms weighted by $C^\star p_i$ and $C^\star(1 - p_i)$. Keeping $(\mathbf{w}, b)$ fixed, I'' is minimized subject to the balance constraint $\frac{1}{u}\sum_{i=l+1}^{n} p_i = r$ using standard Lagrangian techniques. This leads to:

$$p_i = \frac{1}{1 + e^{(g_i - \nu)/T}} \tag{8}$$

where $g_i = C^\star[V(1, o_i) - V(-1, o_i)]$ and ν, the Lagrange multiplier associated with the balance constraint, is obtained by solving the root finding problem that arises by plugging (8) back in the balance constraint. The alternating optimization proceeds until $\mathbf{p}_u$ stabilizes in a KL-divergence sense. This method will be referred to as DA in the rest of the paper.

2. *Gradient Methods*: An alternative possibility[5] is to substitute the optimal $\mathbf{p}_u$ (8) as a function of $(\mathbf{w}, b)$ and obtain an objective function over $(\mathbf{w}, b)$ for which gradient techniques can be used:

$$\mathcal{S}(\mathbf{w}, b) := \min_{\mathbf{p}_u} I''(\mathbf{w}, b, \mathbf{p}_u; T). \tag{9}$$

$\mathcal{S}(\mathbf{w}, b)$ can be minimized by conjugate gradient descent. The gradient of $\mathcal{S}$ is easy to compute. Indeed, let us denote by $\mathbf{p}_u^*(\mathbf{w}, b)$ the argmin of (9). Then,

$$\frac{\partial \mathcal{S}}{\partial w_i} = \frac{\partial I''}{\partial w_i} + \sum_{j=l+1}^{n} \underbrace{\frac{\partial I''}{\partial p_j}\bigg|_{\mathbf{p}_u = \mathbf{p}_u^*(\mathbf{w}, b)}}_{0} \frac{\partial p_j^*(\mathbf{w})}{\partial w_i} = \frac{\partial I'(\mathbf{w}, b, \mathbf{p}_u^\star(\mathbf{w}))}{\partial w_i}.$$

The partial derivative of I'' with respect to p_j is 0 by the definition of $\mathbf{p}_u^*(\mathbf{w}, b)$. The argument goes through even in the presence of the constraint $\frac{1}{u}\sum p_i = r$; see Chapelle et al. (2002, Lemma 2) for a formal proof. In other words, we can compute the gradient of (7) with respect to $\mathbf{w}$ and consider $\mathbf{p}_u$ fixed. The same holds for b. This method will be referred to as ∇DA in the rest of the paper.

Figure 4 shows the effective loss terms in $\mathcal{S}$ associated with an unlabeled example for various values of T. In an outer loop, starting from a high value, T is decreased geometrically by a constant factor. The vector $\mathbf{p}_u$ is then tightened back close to discrete values (its entropy falls below some threshold), thus identifying a solution to the original problem. The pseudocode is provided in Algorithm 2.

Table 2 compares the DA and ∇DA solutions as $T \to 0$ at two different hyperparameter settings.[6] Because DA does alternate minimization and ∇DA does direct minimization, the solutions returned by them can be quite different. Since ∇DA is faster than DA, we only report ∇DA results in the Section 5.

Algorithm 2 DA/∇DA

Initialize $p_i = r \quad i = l+1, \ldots, n$
Set $T = 10C^\star$, $R = 1.5$, $\varepsilon = 10^{-6}$.
while $H(\mathbf{p}_{uT}) > \varepsilon$ **do**
  Solve $(\mathbf{w}_T, b_T, \mathbf{p}_{uT}) = \text{argmin}_{(\mathbf{w},b),\mathbf{p}_u} I''(\mathbf{w}, b, \mathbf{p}_u; T)$ subject to: $\frac{1}{u}\sum_{i=l+1}^{n} p_i = r$
  (find local minima starting from previous solution—alternating optimization or gradient methods can be used.)
  $T = T/R$
end while
Return $\mathbf{w}_T, b_T$

3.4 Convex Relaxation

We follow Bie and Cristianini (2006) in this section, but outline the details for the squared Hinge loss (see also Xu et al., 2004, for a similar derivation). Rewriting (1) as the familiar constrained

5. Strictly speaking, this approach is more along the lines of methods discussed in Section 4.
6. In Sindhwani et al. (2006), the best solution in the optimization path is returned.

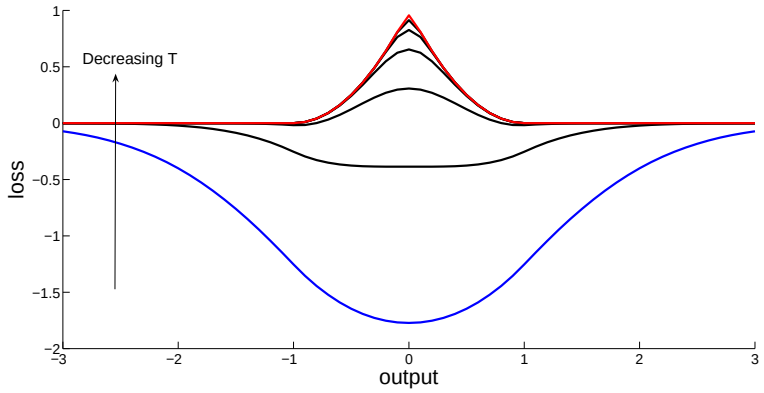

Figure 4: DA parameterizes a family of loss functions (over unlabeled examples) where the degree of non-convexity is controlled by T. As $T \to 0$, the original loss function (Figure 2) is recovered.

	DA	∇DA	DA	∇DA
g50c	6.5	7	8.3	6.7
Text	13.6	5.7	6.2	6.5
Uspst	22.5	27.2	11	11
Isolet	38.3	39.8	28.6	26.9
Coil20	3	12.3	19.2	18.9
Coil3	49.1	61.6	60.3	60.6
2moons	36.8	22.5	62.1	30

Table 2: Generalization performance (error rates) of the two DA algorithms. DA is the original algorithm (alternate optimization on $\mathbf{p}_u$ and $\mathbf{w}$). ∇DA is a direct gradient optimization on $(\mathbf{w}, b)$, where $\mathbf{p}_u$ should be considered as a function of $(\mathbf{w}, b)$. The first two columns report results when $C^\star = C$ and the last columns report results when $C^\star = C/100$. See Section 5 for more experimental details.

optimization problem of SVMs:

$$\min_{(\mathbf{w},b),\mathbf{y}_u} \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{l}\xi_i^2 + C^\star\sum_{i=l+1}^{n}\xi_i^2 \text{ subject to: } y_i o_i \geq 1-\xi_i \;\; i=1,\ldots,n.$$

Consider the associated dual problem:

$$\min_{\{y_i\}}\max_{\alpha} \sum_{i=1}^{n}\alpha_i - \frac{1}{2}\sum_{i,j=1}^{n}\alpha_i\alpha_j y_i y_j K_{ij} \text{ subject to: } \sum_{i=1}^{n}\alpha_i y_i = 0, \;\; \alpha_i \geq 0$$

where $K_{ij} = \mathbf{x}_i^\top \mathbf{x}_j + D_{ij}$ and D is a diagonal matrix given by $D_{ii} = \frac{1}{2C}$, $i = 1,\ldots,l$ and $D_{ii} = \frac{1}{2C^\star}$, $i = l+1,\ldots,n$.

Introducing an $n \times n$ matrix Γ, the optimization problem can be reformulated as:

$$\min_{\Gamma} \max_{\alpha} \quad \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{n} \alpha_i \alpha_j \Gamma_{ij} K_{ij} \tag{10}$$

$$\text{under constraints} \quad \sum \alpha_i y_i = 0, \;\; \alpha_i \geq 0, \;\; \Gamma = yy^\top. \tag{11}$$

The objective function (10) is now convex since it is the pointwise supremum of linear functions. However the constraint (11) is not. The idea of the relaxation is to replace the constraint $\Gamma = yy^\top$ by the following set of convex constraints:

$$\begin{aligned} &\Gamma \succeq 0, \\ &\Gamma_{ij} = y_i y_j, \;\; 1 \leq i, j \leq l, \\ &\Gamma_{ii} = 1, \;\; l+1 \leq i \leq n. \end{aligned}$$

Though the original method of Bie and Cristianini (2006) does not incorporate the class balancing constraint (3), one can additionally enforce it as $\frac{1}{u^2} \sum_{i,j=l+1}^{n} \Gamma_{ij} = (2r-1)^2$. Such a soft constraint is also used in the continuous S^{3}VM optimization methods of Section 4.

The convex problem above can be solved through Semi-Definite Programming. The labels of the unlabeled points are estimated from Γ (through one of its columns or its largest eigenvector).

This method is very expensive and scales as $O((l+u^2)^2(l+u)^{2.5})$. It is possible to try to optimize a low rank version of Γ, but the training remains slow even in that case. We therefore do not conduct empirical studies with this method.

4. Continuous Optimization

In this section we consider methods which do not include $\mathbf{y}_u$, the labels of unlabeled examples, as optimization variables, but instead solve suitably modified versions of (5) by continuous optimization techniques. We begin by discussing two issues that are common to these methods.

Balancing Constraint The balancing constraint (3) is relatively easy to enforce for all algorithms presented in Section 3. It is more difficult for algorithms covered in this section. The proposed workaround, first introduced by Chapelle and Zien (2005), is to instead enforce a linear constraint:

$$\frac{1}{u} \sum_{i=l+1}^{n} \mathbf{w}^\top \mathbf{x}_i + b = 2\tilde{r} - 1, \tag{12}$$

where $\tilde{r} = r$. The above constraint may be viewed as a "relaxation" of (3). For a given $\tilde{r}$, an easy way of enforcing (12) is to translate all the points such that the mean of the unlabeled points is the origin, that is, $\sum_{i=l+1}^{n} \mathbf{x}_i = 0$. Then, by fixing $b = 2\tilde{r} - 1$, we have an unconstrained optimization problem on $\mathbf{w}$. We will assume that the $\mathbf{x}_i$ are translated and b is fixed in this manner; so the discussion will focus on unconstrained optimization procedures for the rest of this section. In addition to being easy to implement, this linear constraint may also add some robustness against uncertainty about the true unknown class ratio in the unlabeled set (see also Chen et al., 2003, for related discussion).

However, since (12) relaxes (3),[7] the solutions found by algorithms in this section cannot strictly be compared with those in Section 3. In order to admit comparisons (this is particularly important for the empirical study in Section 5), we vary $\tilde{r}$ in an outer loop and do a dichotomic search on this value such that (3) is satisfied.

7. Note that simply setting $\tilde{r} = r$ in (12) will not enforce (3) exactly.

Primal Optimization For linear classification, the variables in $\mathbf{w}$ can be directly optimized. Nonlinear decision boundaries require the use of the "kernel trick" (Boser et al., 1992) using a kernel function $k(\mathbf{x},\mathbf{x}')$. While most of the methods of Section 3 can use a standard SVM solver as a subroutine, the methods of this section need to solve (5) with a non-convex loss function over unlabeled examples. Therefore, they cannot directly use off-the-shelf dual-based SVM software. We use one of the following primal methods to implement the techniques in this section.

Method 1 We find $\mathbf{z}_i$ such that $\mathbf{z}_i \cdot \mathbf{z}_j = k(\mathbf{x}_i,\mathbf{x}_j)$. If B is a matrix having columns $\mathbf{z}_i$, this can be written in matrix form as $B^\top B = K$. The Cholesky factor of K provides one such B. This decomposition was used for ∇S^{3}VM (Chapelle and Zien, 2005). Another possibility is to perform the eigendecomposition of K as $K = U\Lambda U^\top$ and set $B = \Lambda^{1/2}U^\top$. This latter case corresponds to the *kernel PCA map* introduced by Schölkopf and Smola (2002, Section 14.2). Once the $\mathbf{z}_i$ are found, we can simply replace $\mathbf{x}_i$ in (5) by $\mathbf{z}_i$ and solve a linear classification problem. For more details, see Chapelle et al. (2006a).

Method 2 We set $\mathbf{w} = \sum_{i=1}^n \beta_i \phi(\mathbf{x}_i)$ where ϕ denotes a higher dimensional feature map associated with the nonlinear kernel. By the Representer theorem (Schölkopf and Smola, 2002), we indeed know that the optimal solution has this form. Substituting this form in (5) and using the kernel function yields an optimization problem with β as the variables.

Note that the centering mentioned above to implement (12) corresponds to using the modified kernel Schölkopf and Smola (2002, page 431) defined by:

$$k(\mathbf{x},\mathbf{x}') := k(\mathbf{x},\mathbf{x}') - \frac{1}{u}\sum_{i=l+1}^{n} k(\mathbf{x},\mathbf{x}_i) - \frac{1}{u}\sum_{i=l+1}^{n} k(\mathbf{x}',\mathbf{x}_i) + \frac{1}{u^2}\sum_{i,j=l+1}^{n} k(\mathbf{x}_i,\mathbf{x}_j). \tag{13}$$

All the shifted kernel elements can be computed in $O(n^2)$ operations.

Finally, note that these methods are very general and can also be applied to algorithms of Section 3.

4.1 Concave Convex Procedure (CCCP)

The CCCP method (Yuille and Rangarajan, 2003) has been applied to S^{3}VMs by Fung and Mangasarian (2001), Collobert et al. (2006), and Wang et al. (2007). The description given here is close to that in Collobert et al. (2006).

CCCP essentially decomposes a non-convex function f into a convex component f_{vex} and a concave component f_{cave}. At each iteration, the concave part is replaced by a linear function (namely, the tangential approximation at the current point) and the sum of this linear function and the convex part is minimized to get the next iterate. The pseudocode is shown in Algorithm 3.

Algorithm 3 CCCP for minimizing $f = f_{vex} + f_{cave}$

Require: Starting point $\mathbf{x}_0$
  $t \leftarrow 0$
  while $\nabla f(\mathbf{x}_t) \neq 0$ **do**
    $\mathbf{x}_{t+1} \leftarrow \arg\min_{\mathbf{x}} f_{vex}(\mathbf{x}) + \nabla f_{cave}(\mathbf{x}_t) \cdot \mathbf{x}$
    $t \leftarrow t+1$
  end while

In the case of S^{3}VM, the first two terms in (5) are convex. Splitting the last non-convex term corresponding to the unlabeled part as the sum of a convex and a concave function, we have:

$$\max(0,1-|t|)^2 = \underbrace{\max(0,1-|t|)^2+2|t|}_{\text{convex}} \underbrace{-2|t|}_{\text{concave}}.$$

If an unlabeled point is currently classified positive, then at the next iteration, the effective (convex) loss on this point will be

$$\tilde{L}(t) = \begin{cases} 0 & \text{if } t \geq 1, \\ (1-t)^2 & \text{if } |t| < 1, \\ -4t & \text{if } t \leq -1. \end{cases}$$

A corresponding $\tilde{L}$ can be defined for the case of an unlabeled point being classified negative. The CCCP algorithm specialized to S^{3}VMs is given in Algorithm 4. For optimization variables we employ method 1 given at the beginning of this section.

Algorithm 4 CCCP for S^{3}VMs

Starting point: Use the $\mathbf{w}$ obtained from the supervised SVM solution.
repeat
$y_i \leftarrow \text{sign}(\mathbf{w}\cdot\mathbf{x}_i+b),\ \ l+1 \leq i \leq n.$
$(\mathbf{w},b) = \arg\min \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{l}\max(0,1-y_i(\mathbf{w}\cdot\mathbf{x}_i+b))^2 + C^\star\sum_{i=l+1}^{n}\tilde{L}(y_i(\mathbf{w}\cdot\mathbf{x}_i+b)).$
until convergence of $y_i,\ l+1 \leq i \leq n.$

The CCCP method given in Collobert et al. (2006) does not use annealing, that is, increasing $C^\star$ slowly in steps as in S^{3}VM^{light} to help reduce local minima problems. We have however found performance improvements with annealing (see Table 12).

4.2 ∇S^{3}VM

This method is proposed by Chapelle and Zien (2005) to minimize directly the objective function (5) by gradient descent. For optimization variables, method 1 given at the beginning of this section is used. Since the function $t \mapsto \max(0,1-|t|)^2$ is not differentiable, it is replaced by $t \mapsto \exp(-st^2)$, with $s = 5$ (see Figure 5), to get the following smooth optimization problem:[8]

$$\min_{\mathbf{w},b}\ \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{l}\max(0,1-y_i(\mathbf{w}\cdot\mathbf{x}_i+b))^2 + C^\star\sum_{i=l+1}^{n}\exp(-s(\mathbf{w}\cdot\mathbf{x}_i+b)^2). \qquad (14)$$

As for S^{3}VM^{light}, ∇S^{3}VM performs annealing in an outer loop on $C^\star$. In the experiments we followed the same annealing schedule as in Chapelle and Zien (2005): $C^\star$ is increased in 10 steps to its final value. More precisely, at the ith step, $C^\star$ is set to $2^{i-10}C^\star_{final}$.

4.3 Continuation S^{3}VM (cS^{3}VM)

Closely related to ∇S^{3}VM, Chapelle et al. (2006a) proposes a *continuation* method for minimizing (14). Gradient descent is performed on the same objective function (with the same loss for the

8. Chapelle and Zien (2005) used $s = 3$ with hinge loss, $p = 1$ in (2), but $s = 5$ seems to be a better choice for quadratic hinge loss ($p = 2$).

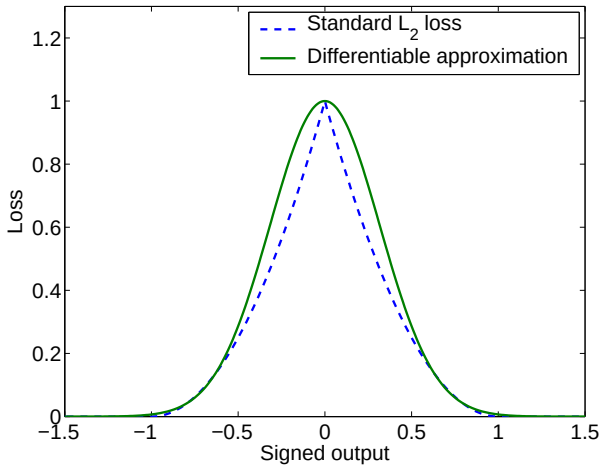

Figure 5: The loss function on the unlabeled points $t \mapsto \max(0, 1-|t|)^2$ is replaced by a differentiable approximation $t \mapsto \exp(-5t^2)$.

unlabeled points as shown in Figure 5), but the method used for annealing is different. Instead of slowly increasing $C^\star$, it is kept fixed, and a continuation technique is used to transform the objective function.

This kind of method belongs to the field of global optimization techniques (Wu, 1996). The idea is similar to deterministic annealing (see Figure 6). A smoothed version of the objective function is first minimized. With enough smoothing the global minimum can hopefully be easily found. Then the smoothing is decreased in steps and the minimum is tracked—the solution found in one step serves as the starting point for the next step. The method is continued until there is no smoothing and so we get back to the solution of (14). Algorithm 5 gives an instantiation of the method in which smoothing is achieved by convolution with a Gaussian, but other smoothing functions can also be used.

Algorithm 5 Continuation method for solving $\min_{\mathbf{x}} f(\mathbf{x})$

Require: Function $f : \mathbb{R}^d \mapsto \mathbb{R}$, initial point $\mathbf{x}_0 \in \mathbb{R}^d$
Require: Sequence $\gamma_0 > \gamma_1 > \ldots \gamma_{p-1} > \gamma_p = 0$.
  Let $f_\gamma(\mathbf{x}) = (\pi\gamma)^{-d/2} \int f(\mathbf{x}-\mathbf{t}) \exp(-\|\mathbf{t}\|^2/\gamma) d\mathbf{t}$.
  for $i = 0$ to p **do**
    Starting from $\mathbf{x}_i$, find local minimizer $\mathbf{x}_{i+1}$ of f_{γ_i}.
  end for

It is not clear if one should only smooth the last non-convex term of (14) (the first two terms are convex) or the whole objective as in Chapelle et al. (2006a). It is noteworthy that since the loss for the unlabeled points is bounded, its convolution with a Gaussian of infinite width tends to the zero function. In other words, with enough smoothing, the unlabeled part of the objective function vanishes and the optimization is identical to a standard SVM.

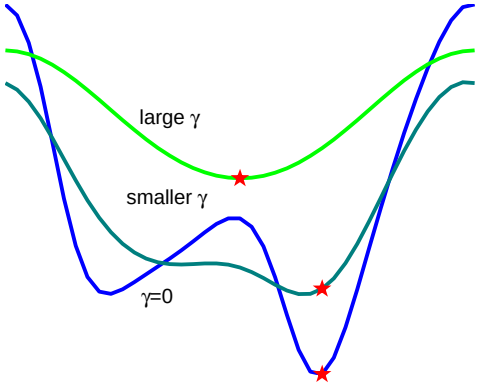

Figure 6: Illustration of the continuation method: the original objective function in blue has two local minima. By smoothing it, we find one global minimum (the red star on the green curve). By reducing the smoothing, the minimum moves toward the global minimum of the original function.

4.4 Newton S^{3}VM

One difficulty with the methods described in sections 4.2 and 4.3 is that their complexity scales as $O(n^3)$ because they employ an unlabeled loss function that does not have a linear part, for example, see (14). Compared to a method like S^{3}VM^{light} (see Section 3.2), which typically scales as $O(n_{\mathsf{sv}}^3 + n^2)$, this can make a large difference in efficiency when n_{sv} (the number of support vectors) is small. In this subsection we propose a new loss function for unlabeled points and an associated Newton method (along the lines of Chapelle, 2007) which brings down the $O(n^3)$ complexity of the ∇S^{3}VM method.

To make efficiency gains we employ method 2 described at the beginning of this section (note that method 1 requires an $O(n^3)$ preprocessing step) and perform the minimization on β, where $\mathbf{w} = \sum_{i=1}^{n} \beta_i \phi(\mathbf{x}_i)$. Note that the β_i are expansion coefficients and not the Lagrange multipliers α_i in standard SVMs. Let us consider general loss functions, ℓ_L for the labeled points, ℓ_U for the unlabeled points, replace $\mathbf{w}$ by β as the variables in (5), and get the following optimization problem,

$$\min_{\beta} \frac{1}{2}\beta^\top K\beta + C\sum_{i=1}^{l} \ell_L(y_i(K_i^\top \beta + b)) + C^\star \sum_{i=l+1}^{n} \ell_U(K_i^\top \beta + b), \tag{15}$$

where K is the kernel matrix with $K_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ and K_i is the i^{th} column of K.[9]

As we will see in detail below, computational time is dictated by n_{sv}, the number of points that lie in the domain of the loss function where curvature is non-zero. With this motivation we choose the differentiable loss function plotted in Figure 7 having several linear and flat parts which are smoothly connected by small quadratic components.[10]

9. Note that, the kernel elements used here correspond to the modified kernel elements in (13).
10. The CCCP method of Collobert et al. (2006) also considers a loss function with a flat middle part, but it was not motivated by computational gains.

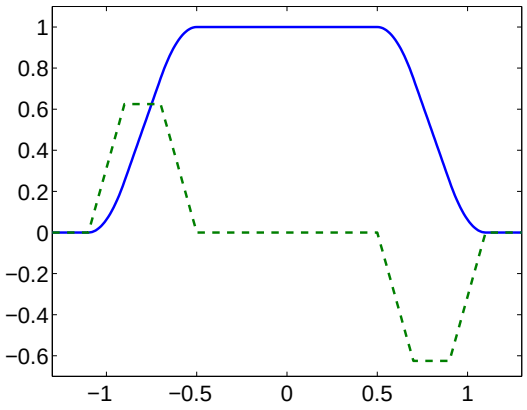

Figure 7: The piecewise quadratic loss function ℓ_U and its derivative (divided by 4; dashed line).

Consider the solution of (15) with this choice of loss function. The gradient of (15) is

$$K\mathbf{g} \text{ with } g_i = \begin{cases} \beta_i + C\ell'_L(y_i(K_i^\top \beta + b))y_i & 1 \le i \le l \\ \beta_i + C^\star \ell'_U(K_i^\top \beta + b) & l+1 \le i \le n \end{cases}. \tag{16}$$

Using a gradient based method like nonlinear conjugate gradient would sill be costly because each evaluation of the gradient requires $O(n^2)$ effort. To improve the complexity when n_{sv} is small, one can use Newton's method instead. Let us now go into these details.

The Hessian of (15) is

$$K + KDK, \text{ with } D \text{ diagonal, } D_{ii} = \begin{cases} C\ell''_L(y_i(K_i^\top \beta + b)) & 1 \le i \le l \\ C^\star \ell''_U(K_i^\top \beta + b) & l+1 \le i \le n \end{cases}. \tag{17}$$

The corresponding Newton update is $\beta \leftarrow \beta - (K + KDK)^{-1} K\mathbf{g}$. The advantage of Newton optimization on this problem is that the step can be computed in $O(n_{\mathsf{sv}}^3 + n^2)$ time[11] as we will see below (see also Chapelle, 2007, for a similar derivation). The number of Newton steps required is usually a small finite constant.

A problem in performing a Newton optimization with a non-convex optimization function is that the step might not be a descent direction because the Hessian is not necessarily positive definite. To avoid this problem, we use the Levenberg-Marquardt algorithm (Fletcher, 1987, Algorithm 5.2.7). Roughly speaking, this algorithm is the same as Newton minimization, but a large enough ridge is added to the Hessian such that it becomes positive definite. For computational reasons, instead of adding a ridge to the Hessian, we will add a constant times K.

The goal is to choose a $\lambda \ge 1$ such that $\lambda K + KDK$ is positive definite and solve $(\lambda K + KDK)^{-1} K\mathbf{g}$ efficiently. For this purpose, we reorder the points such that $D_{ii} \neq 0,\ i \le n_{\mathsf{sv}}$ and $D_{ii} = 0,\ i > n_{\mathsf{sv}}$. Let A be the Cholesky decomposition of K:[12] A is the upper triangular matrix satisfying $A^\top A = K$. We suppose that K (and thus A) is invertible. Let us write

$$\lambda K + KDK = A^\top(\lambda I_n + ADA^\top)A.$$

11. Consistent with the way we defined earlier, note here that n_{sv} is the number of "support vectors" where a support vector is defined as a point $\mathbf{x}_i$ such that $D_{ii} \neq 0$.
12. As we will see below, we will not need the Cholesky decomposition of K but only that of of K_{sv}.

The structure of K and D implies that

$$\lambda K + KDK \succ 0 \Leftrightarrow B := \lambda I_{n_{\mathsf{sv}}} + A_{\mathsf{sv}} D_{\mathsf{sv}} A_{\mathsf{sv}}^\top \succ 0,$$

where A_{sv} is the Cholesky decomposition of K_{sv} and K_{sv} is the matrix formed using the first n_{sv} rows and columns of K. After some block matrix algebra, we can also get the step as

$$-(\lambda K + KDK)^{-1} K\mathbf{g} = \begin{pmatrix} A_{\mathsf{sv}}^{-1} B^{-1} A_{\mathsf{sv}} (\mathbf{g}_{\mathsf{sv}} - \frac{1}{\lambda} D_{\mathsf{sv}} K_{\mathsf{sv},\mathsf{nsv}} \mathbf{g}_{\mathsf{nsv}}) \\ \frac{1}{\lambda} \mathbf{g}_{\mathsf{nsv}} \end{pmatrix}, \tag{18}$$

where nsv refers to the indices of the "non support vectors", that is, $\{i,\ D_{ii} = 0\}$. Computing this direction takes $O(n_{\mathsf{sv}}^3 + n^2)$ operations. The checking of the positive definiteness of B can be done by doing Cholesky decomposition of K_{sv}. This decomposition can then be reused to solve the linear system involving B. Full details, following the ideas in Fletcher (1987, Algorithm 5.2.7), are given in Algorithm 6.

Algorithm 6 Levenberg-Marquardt method

$\beta \leftarrow 0$.
$\lambda \leftarrow 1$.
repeat
  Compute $\mathbf{g}$ and D using (16) and (17)
  $\mathsf{sv} \leftarrow \{i,\ D_{ii} \neq 0\}$ and $\mathsf{nsv} \leftarrow \{i,\ D_{ii} = 0\}$.
  $A_{\mathsf{sv}} \leftarrow$ Cholesky decomposition of K_{sv}.
  Do the Cholesky decomposition of $\lambda I_{n_{\mathsf{sv}}} + A_{\mathsf{sv}} D_{\mathsf{sv}} A_{\mathsf{sv}}^\top$. If it fails, $\lambda \leftarrow 4\lambda$ and try again.
  Compute the step $\mathbf{s}$ as given by (18).
  $\rho \leftarrow \frac{\Omega(\beta+\mathbf{s}) - \Omega(\beta)}{\frac{1}{2}\mathbf{s}^\top (K+KDK)\mathbf{s} + \mathbf{s}^\top K\mathbf{g}}$. % If the obj fun Ω were quadratic, ρ would be 1.
  If $\rho > 0$, $\beta \leftarrow \beta + s$.
  If $\rho < 0.25$, $\lambda \leftarrow 4\lambda$.
  If $\rho > 0.75$, $\lambda \leftarrow \min(1, \frac{\lambda}{2})$.
until $\mathrm{Norm}(\mathbf{g}) \leq \varepsilon$

As discussed above, the flat part in the loss (cf. Figure 7) provides computational value by reducing n_{sv}. But we feel it may also possibly help in leading to better local minimum. Take for instance a Gaussian kernel and consider an unlabeled point far from the labeled points. At the beginning of the optimization, the output on that point will be 0.[13] This unlabeled point does not contribute to pushing the decision boundary one way or the other. This seems like a satisfactory behavior: it is better to wait to have more information before taking a decision on an unlabeled point for which we are unsure. In Table 3 we compare the performance of the flat loss in Figure 7 and the original quadratic loss used in (5). The flat loss yields a huge gain in performance on `2moons`. On the other data sets the two losses perform somewhat similarly. From a computational point of view, the flat part in the loss can sometimes reduce the training time by a factor 10 as shown in Table 3.

5. Experiments

This section is organized around a set of empirical issues:

13. This is true only for balanced problems; otherwise, the output is b.

	Error rate		Training time	
	Flat	Quadratic	Flat	Quadratic
g50c	6.1	5.3	15	39
Text	5.4	7.7	2180	2165
Uspst	18.6	15.9	233	2152
Isolet	32.2	27.1	168	1253
Coil20	24.1	24.7	152	1244
Coil3	61.5	58.4	6	8
2moons	11	66.4	1.7	1.2

Table 3: Comparison of the Newton-S^3VM method with two different losses: the one with a flat part in the middle (see Figure 7) and the standard quadratic loss (Figure 2). Left: error rates on the unlabeled set; right: average training time in seconds for one split and one binary classifier training (with annealing and dichotomic search on the threshold as explained in the experimental section). The implementations have not been optimized, so the training times only constitute an estimate of the relative speeds.

1. While S^3VMs have been very successful for text classification (Joachims, 1999), there are many data sets where they do not return state-of-the-art empirical performance (Chapelle and Zien, 2005). This performance variability is conjectured to be due to local minima problems. In Section 5.3, we discuss the suitability of the S^3VM objective function for semi-supervised learning. In particular, we benchmark current S^3VM implementations against the exact, globally optimal solution and we discuss whether one can expect significant improvements in generalization performance by better approaching the global solution.

2. Several factors influence the performance and behavior of S^3VM algorithms. In Section 5.4 we study their quality of optimization, generalization performance, sensitivity to hyperparameters, effect of annealing and the robustness to uncertainty in class ratio estimates.

3. S^3VMs were originally motivated by Transductive learning, the problem of estimating labels of unlabeled examples without necessarily producing a decision function over the entire input space. However, S^3VMs are also semi-supervised learners as they are able to handle unseen test instances. In Section 5.5, we run S^3VM algorithms in an inductive mode and analyze performance differences between unlabeled and test examples.

4. There is empirical evidence that S^3VMs exhibit poor performances on "manifold" type data (where graph-based methods typically excel) or when the data has many distinct sub-clusters (Chapelle and Zien, 2005). We explore the issue of data geometry and S^3VM performance in Section 5.6.

At the outset, we point out that this section does not provide an exhaustive cross-comparison between algorithms. Such a comparison would require, say, cross-validation over multiple hyperparameters, randomization over choices of labels, dichotomic search to neutralize balance constraint differences and handling different choices of annealing sequences. This is computationally quite demanding and, more seriously, statistically brittle due to the lack of labeled validation data in

semi-supervised tasks. Our goal, therefore, is not so much to establish a ranking of algorithms reviewed in this paper, but rather to observe their behavior under a neutral experimental protocol.

We next describe the data sets used in our experiments. Note that our choice of data sets is biased towards multi-class manifold-like problems which are particularly challenging for S^3VMs. Because of this choice, the experimental results do not show the typically large improvements one might expect over standard SVMs. We caution the reader not to draw the conclusion that S^3VM is a weak algorithm in general, but that it often does not return state-of-the-art performance on problems of this nature.

5.1 Data Sets

Most data sets come from Chapelle and Zien (2005). They are summarized in Table 4.

data set	classes	dims	points	labeled
g50c	2	50	550	50
Text	2	7511	1946	50
Uspst	10	256	2007	50
Isolet	9	617	1620	50
Coil20	20	1024	1440	40
Coil3	3	1024	216	6
2moons	2	102	200	2

Table 4: Basic properties of benchmark data sets.

The artificial data set g50c is inspired by Bengio and Grandvalet (2004): examples are generated from two standard normal multi-variate Gaussians, the labels correspond to the Gaussians, and the means are located in 50-dimensional space such that the Bayes error is 5%. The real world data sets consist of two-class and multi-class problems. The Text data set is defined using the classes mac and mswindows of the Newsgroup20 data set preprocessed as in Szummer and Jaakkola (2001). The Uspst set contains the test data part of the well-known USPS data on handwritten digit recognition. The Isolet is a subset of the *ISOLET spoken letter database* (Cole et al., 1990) containing the speaker sets 1, 2 and 3 and 9 confusing letters {B,C,D,E,G,P,T,V,Z}. In Coil20 (respectively Coil3), the data are gray-scale images of 20 (respectively 3) different objects taken from different angles, in steps of 5 degrees (Nene et al., 1996). The Coil3 data set has been used first by Chapelle et al. (2006c) and is particularly difficult since the 3 classes are 3 cars which look alike (see Figure 8).

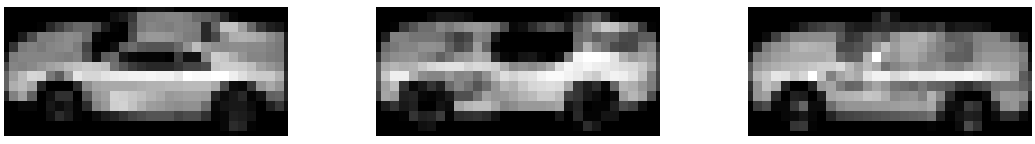

Figure 8: The 3 cars from the COIL data set, subsampled to 32×32

Finally, `2moons` has been used extensively in the semi-supervised learning literature (see for instance Zhu and Ghahramani, 2002, and Figure 1). For this data set, the labeled points are fixed and new unlabeled points are randomly generated for each repetition of the experiment.

5.2 Experimental Setup

To minimize the influence of external factors, unless stated otherwise, the experiments were run in the following normalized way:

Hyperparameters The Gaussian kernel $k(\mathbf{x},\mathbf{y}) = \exp(-\|\mathbf{x}-\mathbf{y}\|^2/2\sigma^2)$ was used. For simplicity the constant $C^\star$ in (1) was set to C.[14] The same hyperparameters C and σ have been used for all the methods. They are found with cross-validation by training an inductive SVM on the entire data set (the unlabeled points being assigned their real label). These values are reported in Table 5. Even though it seems fair to compare the algorithms with the same hyperparameters, there is a possibility that some regime of hyperparameter settings is more suitable for a particular algorithm than for another. We discuss this issue in section 5.4.3.

Multi-class Data sets with more than two classes are learned with a one-versus-the-rest approach. The reported objective value is the mean of the objective values of the different classifiers. We also conducted experiments on pair-wise binary classification problems (cf. Section 5.6.1) constructed from the multi-class data sets.

Objective value Even though the objective function that we want to minimize is (5), some algorithms like ∇S^{3}VM use another (differentiable) objective function. In order to compare the objective values of the different algorithms, we do the following: after training, we predict the labels of the unlabeled points and train a standard SVM on this augmented labeled set (with $p = 2$ in (2) and C, $C^\star$ weightings on originally labeled and unlabeled terms respectively). The objective value reported is the one of this SVM.

Balancing constraint For the sake of simplicity, we set r in the balancing constraint (3) to the true ratio of the positive points in the unlabeled set. This constraint is relatively easy to enforce for all algorithms presented in Section 3. It is more difficult for algorithms in Section 4 and, for them we used the dichotomic search described at the beginning of Section 4.

For a given data set, we randomly split the data into a labeled set and an unlabeled set. We refer to the error rate on the unlabeled set as the *unlabeled error* to differentiate it from the *test error* which would be computed on an unseen test set. Results are averaged over 10 random splits. The difference between unlabeled and test performance is discussed in Section 5.5.

5.3 Suitability of the S^{3}VM Objective Function

Table 1 shows unlabeled error rates for common S^{3}VM implementations on two small data sets `Coil3` and `2moons`. On these data sets, we are able to also run Branch-and-Bound and get the true globally optimal solution. We see that the global optimum corresponds to a perfect solution, while the local minima found by approximate implementations yield very poor accuracies. From these results, it appears that the minimization of the S^{3}VM objective function makes good sense, even

14. Alternatively, one could set $C^\star = C\frac{l}{u}$ to have equal contribution from labeled and unlabeled points.

	σ	C
g50c	38	19
Text	3.5	31
Uspst	7.4	38
Isolet	15	43
Coil20	2900	37
Coil3	3000	100
2moons	0.5	10

Table 5: Values of the hyperparameters used in the experiments.

though the performance of practical S^3VM may not consistently reflect this due to local minima problems.

Table 6 records the rank correlation between unlabeled error and objective function. The rank correlation has been computed in the following way. For each split, we take 10 different solutions and compute the associated unlabeled error and objective value. Ideally, we would like to sample these solutions at random around local minima. But since it is not obvious how to do such a sampling, we simply took the solution given by the different S^3VM algorithms as well as 4 "intermediate" solutions obtained as follows. A standard SVM is trained on the original labeled set and a fraction of the unlabeled set (with their true labels). The fraction was either 0, 10, 20 or 30%. The labels of the remaining unlabeled points are assigned through a thresholding of the real value outputs of the SVM. This threshold is such that the balancing constraint (3) is satisfied. Finally, an SVM is retrained using the entire training set. By doing so, we "sample" solutions varying from an inductive SVM trained on only the labeled set to the optimal solution. Table 6 provides evidence that the unlabeled error is correlated with the objective values.

	Coefficient
g50c	0.2
Text	0.67
Uspst	0.24
Isolet	0.23
Coil20	0.4
Coil3	0.17
2moons	0.45

Table 6: Kendall's rank correlation (Abdi, 2006) between the unlabeled error and the objective function averaged over the 10 splits (see text for details).

5.4 Behavior of S^3VM Algorithms

Several factors influence the performance and behavior of S^3VM algorithms. We study their quality of optimization, generalization performance, sensitivity to hyperparameters, effect of annealing and the robustness to uncertainty in class ratio estimates.

5.4.1 QUALITY OF MINIMIZATION

In Table 7 we compare different algorithms in terms of minimization of the objective function. ∇S^{3}VM and cS^{3}VM appear clearly to be the methods achieving the lowest objective values. However, as we will see in the next section, this does not necessarily translate into lower unlabeled errors.

∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton
1.7	1.9	4.5	4.9	4.3	3.7

Table 7: For each data set and each split, the algorithms were ranked according to the objective function value they attained. This table shows the average ranks. These ranks are only about objective function values; error rates are discussed below.

5.4.2 QUALITY OF GENERALIZATION

Table 8 reports the unlabeled errors of the different algorithms on our benchmark data sets. A first observation is that most algorithms perform quite well on `g50c` and `Text`. However, the unlabeled errors on the other data sets, `Uspst`, `Isolet`, `Coil20`, `Coil3`, `2moons` (see also Table 1) are poor and sometimes even worse than a standard SVM. As pointed out earlier, these data sets are particularly challenging for S^{3}VMs. Moreover, the honors are divided and no algorithm clearly outperforms the others. We therefore cannot give a recommendation on which one to use.

	∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton	SVM	SVM-5cv
`g50c`	6.7	6.4	6.3	6.2	7	6.1	8.2	4.9
`Text`	5.1	5.3	8.3	8.1	5.7	5.4	14.8	2.8
`Uspst`	15.6	36.2	16.4	15.5	27.2	18.6	20.7	3.9
`Isolet`	25.8	59.8	26.7	30	39.8	32.2	32.7	6.4
`Coil20`	25.6	30.7	26.6	25.3	12.3	24.1	24.1	0

Table 8: Unlabeled errors of the different S^{3}VMs implementations. The next to the last column is an SVM trained only on the labeled data, while the last column reports 5 fold cross-validation results of an SVM trained on the whole data set using the labels of the unlabeled points. The values in these two columns can be taken as upper and lower bounds on the best achievable error rates. See Table 1 for results on `Coil3` and `2moons`.

Note that these results may differ from the ones previously reported by Chapelle and Zien (2005), Collobert et al. (2006), Sindhwani et al. (2006), and Chapelle et al. (2006a) on the same data sets. Most of this difference comes from the choice of the hyperparameters. Indeed, as explained below, several algorithms are rather sensitive to the choice of hyperparameters. The exact experimental setting is also different. In results reported elsewhere, r is often estimated from the labeled set and the constraint is often a "soft" one. In Table 8, the hard balance constraint is enforced for all methods assuming r to be known exactly. Finally, in Chapelle et al. (2006a), only pair-wise

binary problems were considered for the cS^{3}VM algorithm, while results in Table 8 for multiclass data sets are obtained under a one-versus-the-rest setup.

5.4.3 SENSITIVITY TO HYPERPARAMETERS

As mentioned before, it is possible that different algorithms excel in different hyperparameter regimes. This is more likely to happen due to better local minima at different hyperparameters as opposed to a better global solution (in terms of error rates).

Due to computational constraints, instead of setting the three hyperparameters ($C, C^\star$ and the Gaussian kernel width, σ) by cross-validation for each of the methods, we explored the influence of these hyperparameters on one split of the data. More specifically, Table 9 shows the *relative* improvement (in %) that one can gain by selecting other hyperparameters. These numbers may be seen as a measure of the *robustness* of a method. Note that these results have to be interpreted carefully because they are only on one split: for instance, it is possible that"by chance" the method did not get stuck in a bad local minimum for one of the hyperparameter settings, leading to a larger number in Table 9.

	∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton
g50c	31.2	31.2	27.8	13.3	35	7.7
Text	22	7.1	29.2	19.9	34.4	1.1
Uspst	12	70.2	19.2	0	41	15.6
Isolet	7.6	57.6	8	0	4.9	2.6
Coil20	46.4	42.7	27.9	5.8	5.7	16.9
Coil3	32.6	39.2	15.3	20.2	5.8	24.6
2moons	45.6	50	54.1	13.5	23.5	0
Mean	28.2	42.6	25.9	10.4	21.5	9.8

Table 9: On the 1st split of each data set, 27 set of hyperparameters $(\sigma', C', C^{\star\prime})$ have been tested from $\sigma' \in \{\frac{1}{2}\sigma, \sigma, 2\sigma\}, C' \in \{\frac{1}{10}C, C, 10C\}, C^{\star\prime} \in \{\frac{1}{100}C', \frac{1}{10}C', C'\}$. The table shows the *relative* improvement (in %) by taking the best hyperparameters over default ones.

By measuring the variation of the unlabeled errors with respect to the choice of the hyperparameters, Table 10 records an indication of the sensitivity of the method with respect to that choice. From this point of view S^{3}VM^{light} appears to be the most stable algorithm.

∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton
6.8	8.5	6.5	2.7	8.4	8.7

Table 10: The variance of the unlabeled errors have been averaged over the 27 possible hyperparameters (cf. Table 9). The table shows those variance averaged over the data sets. A small number shows that a given method is not too sensitive to the choice of the hyperparameters.

Finally, from the experiments in Table 9, we observed that in some cases a smaller value of $C^\star$ is helpful. We have thus rerun the algorithms on all the splits with $C^\star$ divided by 100: see Table 11. The overall performance does not necessarily improve, but the very poor results become better (see for instance `Uspst,Isolet,Coil20` for cS^{3}VM).

	∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton
`g50c`	8.3	8.3	8.5	8.4	6.7	7.5
`Text`	5.7	5.8	8.5	8.1	6.5	14.5
`Uspst`	14.1	15.6	14.9	14.5	11	19.2
`Isolet`	27.8	28.5	25.3	29.1	26.9	32.1
`Coil20`	23.9	23.6	23.6	21.8	18.9	24.6
`Coil3`	60.8	55.0	56.3	59.2	60.6	60.5
`2moons`	65.0	49.8	66.3	68.7	30	33.5

Table 11: Same as Table 8, but with $C^\star$ divided by 100.

5.4.4 EFFECT OF ANNEALING SCHEDULE

All the algorithms described in this paper use some sort of annealing (e.g., gradually decreasing T in DA or increasing $C^\star$ in S^{3}VM^{light} in an outer loop) where the role of the unlabeled points is progressively increased. The three ingredients to fix are:

1. The starting point which is usually chosen in such a way that the unlabeled points have very little influence and the problem is thus almost convex.
2. The stopping criterion which should be such that the annealed objective function and the original objective function are very close.
3. The number of steps. Ideally, one would like to have as many steps as possible, but for computational reasons the number of steps is limited.

In the experimental results presented in Figure 9, we only varied the number of steps. The starting and final values are as indicated in the description of the algorithms. The original CCCP paper did not have annealing and we used the same scheme as for ∇S^{3}VM: $C^\star$ is increased exponentially from $10^{-3}C$ to C. For DA and ∇DA, the final temperature is fixed at a small constant and the decrease rate R is such that we have the desired number of steps. For all algorithms, one step means that there is no annealing.

One has to be cautious when drawing conclusion from this plot. Indeed, the results are only for one data set, one split and fixed hyperparameters. The goal is to get an idea of whether the annealing for a given method is useful; and if so, how many steps should be taken. From this plot, it seems that:

- All methods, except Newton, seem to benefit from annealing. However, on some other data sets, annealing improved the performances of Newton's method (results not shown).
- Most methods do not require a lot of steps. More precisely, we have noticed that the number of steps does not matter as much as the minimization around a "critical" value of the annealing parameter; if that point is missed, then the results can be bad.

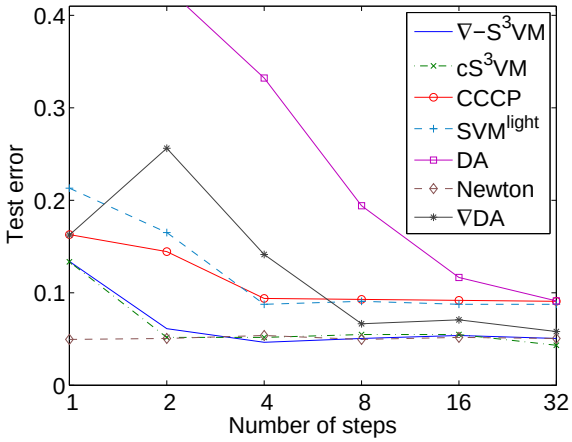

Figure 9: Influence of the number of annealing steps on the first split of `Text`.

	No annealing	Annealing
`g50c`	7.9	6.3
`Text`	14.7	8.3
`Uspst`	21.3	16.4
`Isolet`	32.4	26.7
`Coil20`	26.1	26.6
`Coil3`	49.3	56.6
`2moons`	67.1	63.1

Table 12: Performance of CCCP with and without annealing. The annealing schedule is the same as the one used for ∇S^{3}VM and Newton: $C^\star$ is increased in 10 steps from its final value divided by 1000.

- DA seems the method which relies the most on a relatively slow annealing schedule, while ∇DA can have a faster annealing schedule.

- CCCP was originally proposed without annealing, but it seems that its performance can be improved by annealing. To confirm this fact, Table 12 compares the results of CCCP with and without annealing on the 10 splits of all the data sets.

The results provided in Table 8 are with annealing for all methods.

5.4.5 ROBUSTNESS TO CLASS RATIO ESTIMATE

Several results reported in the previous tables are better than, for instance, the results in Chapelle and Zien (2005); Chapelle et al. (2006a). This is because (a) we took into account the knowledge of the true class ratio among the unlabeled examples, and (b) we enforced the constraint (3) exactly (with the dichotomic search described at the beginning of Section 4).

Of course, in practice the true number of positive points is unknown. One can estimate it from the labeled points as:

$$r = \frac{1}{2}\left(\frac{1}{l}\sum_{i=1}^{l} y_i + 1\right).$$

Table 13 presents the generalization performances in this more realistic context where class ratios are estimated as above and original soft balance constraint is used where applicable (recall the discussion in Section 4).

	∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton	SVM
g50c	7.2	6.6	6.7	7.5	8.4	5.8	9.1
Text	6.8	5	12.8	9.2	8.1	6.1	23.1
Uspst	24.1	41.5	24.3	24.4	29.8	25	24.2
Isolet	48.4	58.3	43.8	36	46	45.5	38.4
Coil20	35.4	51.5	34.5	25.3	12.3	25.4	26.2
Coil3	64.4	59.7	59.4	56.7	61.7	62.9	51.8
2moons	62.2	33.7	55.6	68.8	22.5	8.9	44.4

Table 13: Constant r estimated from the labeled set. For methods of Section 4, the original constraint (12) is used; there is no dichotomic search (see beginning of Section 4).

5.5 Transductive Versus Semi-supervised Learning

S^{3}VMs were introduced as *Transductive* SVMs, originally designed for the task of directly estimating labels of unlabeled points. However S^{3}VMs provide a decision boundary in the entire input space, and so they can provide labels of unseen test points as well. For this reason, we believe that S^{3}VMs are inductive semi-supervised methods and not strictly transductive. A discussion on the differences between semi-supervised learning and transduction can be found in Chapelle et al. (2006b, Chapter 25).[15]

We expect S^{3}VMs to perform equally well on the unlabeled set and on an unseen test set. To test this hypothesis, we took out 25% of the unlabeled set that we used as a unseen test set. We performed 420 experiments (6 algorithms, 7 data sets and 10 splits). Based on these 420 pairs of error rates, we did not observe a significant difference at the 5% confidence level. Also, for each of the 7 data sets (resp 6 algorithms), there was no statistical significant differences in the 60 (resp 70) pairs of error rates.

Similar experiments were performed by Collobert et al. (2006, Section 6.2). Based on 10 splits, the error rate was found to be better on the unlabeled set than on the test set. The authors made the hypothesis that when the test and training data are not identically distributed, transduction can be helpful. Indeed, because of small sample effect, the unlabeled and test set could appear as not coming from the same distribution (this is even more likely in high dimension).

We considered the g50c data set and biased the split between unlabeled and test set such that there is an angle between the principal directions of the two sets. Figure 10 shows a correlation

15. Paper is available at http://www.kyb.tuebingen.mpg.de/ssl-book/discussion.pdf.

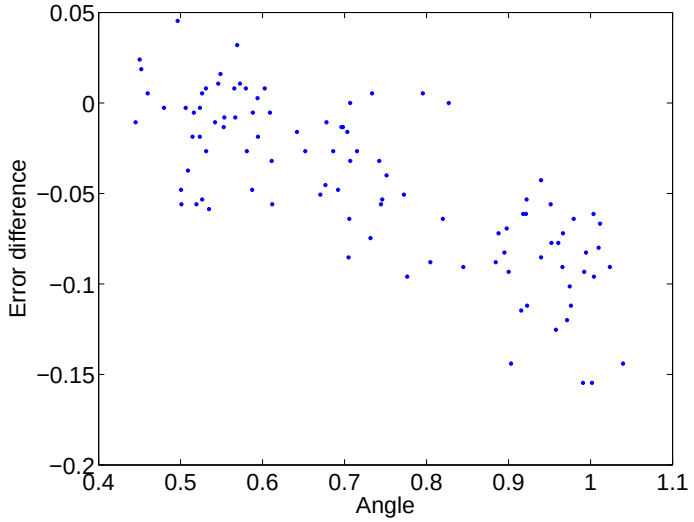

Figure 10: The test set of g50c has been chosen with a bias such that there is an angle between the principal directions of the unlabeled and test sets. The figure shows the difference in error rates (negative means better error rate on the unlabeled set) as a function of the angle for different random (biased) splits.

between the difference in error rates and this angle: the error on the test set deteriorates as the angle increases. This confirms the hypothesis stated above.

5.6 Role of Data Geometry

There is empirical evidence that S^3VMs exhibit poor performances on "manifold" type data or when the data has many distinct sub-clusters (Chapelle and Zien, 2005). We now explore this issue and propose an hybrid method combining the S^3VM and LapSVM (Sindhwani et al., 2005).

5.6.1 EFFECT OF MULTIPLE CLUSTERS

In Chapelle et al. (2006a), cS^3VM exhibited poor performance in multiclass problems with one-versus-the-rest training, but worked well on pairwise binary problems that were constructed (using all the labels) from the same multiclass data sets. Note that in practice it is not possible to do semi-supervised one-vs-one multiclass training because the labels of the unlabeled points are truly unknown.

We compared different algorithms on pairwise binary classification tasks for all the multiclass problems. Results are shown in the first 4 rows of Table 14. Except on Coil3, most S^3VM algorithms show improved performances. There are two candidate explanations for this behavior:

1. The binary classification problems in one-versus-the-rest are unbalanced and this creates difficulties for S^3VMs.

	∇S^{3}VM	cS^{3}VM	CCCP	S^{3}VM^{light}	∇DA	Newton	SVM	SVM-5cv
Uspst	1.9	2	2.8	2.9	4	1.9	5.3	0.9
Isolet	4.8	11.8	5.5	5.7	5	6.3	7.3	1.2
Coil20	2.8	3.9	2.9	3.1	2.7	2.4	3.3	0
Coil3	45.8	48.7	40.3	41.3	44.5	47.2	36.7	0
Uspst2	15.6	25.7	16.6	16.1	20	16	17.7	3

Table 14: Experiments in a pairwise binary setting. Uspst2 is the same set as Uspst but where the task is to classify digits 0 to 4 versus 5 to 9.

2. In a one-versus-the-rest approach, the negative class is the concatenation of several classes and is thus made up of several clusters. This might accentuate the local minimum problem of S^{3}VMs.

To test these hypothesis, we created a binary version of Uspst by classifying digits 0 to 4 versus 5 to 9: this data set (Uspst2 in Table 14) is balanced but each class is made of several clusters. The fact that the S^{3}VMs algorithms were not able to perform significantly better than the SVM baseline tends to accredit the second hypothesis: S^{3}VM results deteriorate when there are several clusters per class.

5.6.2 HYBRID S^{3}VM-GRAPH METHODS

Recall that the results in Table 8 boost the empirical evidence that S^{3}VMs do not return state-of-the-art performance on "manifold"-like data sets. On these data sets the cluster assumption is presumably satisfied under an intrinsic "geodesic" distance rather than the original euclidean distance between data points. It is reasonable, therefore, to attempt to combine S^{3}VMs with choices of kernels that conform to the particular geometry of the data.

LapSVM (Sindhwani et al., 2005) is a popular semi-supervised algorithm in which a kernel function is constructed from the Laplacian of an adjacency graph that models the data geometry; this kernel is then used with a standard SVM. This procedure was shown to be very effective on data sets with a manifold structure. In Table 15 we report results with a hybrid S^{3}VM-graph method: the kernel is constructed as in LapSVM,[16] but then it is plugged into S^{3}VM^{light}. Such a hybrid was first described in Chapelle et al. (2006a) where cS^{3}VM was combined with LapSVM.

The results of this hybrid method is very satisfactory, often outperforming both LapSVM and S^{3}VM^{light}.

Such a method complements the strengths of both S^{3}VM and Graph-based approaches: the S^{3}VM adds robustness to the construction of the graph, while the graph enforces the right cluster structure to alleviate local minima problems in S^{3}VMs. We believe that this kind of technique is probably one of the most robust and powerful way for a semi-supervised learning problem.

16. Hyperparameters were chosen based on experiments in Sindhwani et al. (2005) without any extensive tuning.

		Exact r	(Table 8 setting)	Estimated r	(Table 13 setting)
	LapSVM	S^3VM^{light}	LapSVM-S^3VM^{light}	S^3VM^{light}	LapSVM-S^3VM^{light}
g50c	6.4	6.2	4.6	7.5	6.1
Text	11	8.1	8.3	9.2	9.0
Uspst	11.4	15.5	8.8	24.4	19.6
Isolet	41.2	30.0	46.5	36.0	49.0
Coil20	11.9	25.3	12.5	25.3	12.5
Coil3	20.6	56.7	17.9	56.7	17.9
2moons	7.8	68.8	5.1	68.8	5.1

Table 15: Comparison of a Graph-based method, LapSVM (Sindhwani et al., 2005), with S^3VM^{light} and hybrid LapSVM-S^3VM^{light} results under the settings of Table 8 and 13.

6. A Note on Computational Complexity

Even though a detailed comparison of the computational complexity of the different algorithms is out of the scope of this paper, we can still give the following rough picture.

First, all methods use annealing and so the complexity depends on the number of annealing steps. This dependency is probably sublinear because when the number of steps is large, retraining after each (small) step is less costly. We can divide the methods in two categories:

1. Methods whose complexity is of the same order as that of a standard SVM trained with the predicted labels of the unlabeled points, which is $O(n_{\mathsf{sv}}^3 + n^2)$ where n_{sv} is the number of points which are in a non-linear part of the loss function. This is clearly the case for S^3VM^{light} since it relies on an SVM optimization. Note that the training time of this algorithm can be sped up by swapping labels in "batch" rather than one by one (Sindhwani and Keerthi, 2006). CCCP is also in this category as the optimization problem it has to solve at each step is very close to an SVM. Finally, even if the Newton method is not directly solved via SVM, its complexity is also $O(n_{\mathsf{sv}}^3 + n^2)$ and we include it in this category. For both CCCP and Newton, the possibility of having a flat part in the middle of the loss function can reduce n_{sv} and thus the complexity. We have indeed observed with the Newton method that the convergence can be an order of magnitude faster when the loss includes this flat part in the middle (see Table 3).

2. Gradient based methods, namely ∇S^3VM, cS^3VM and ∇DA do not have any linear part in the objective function and so they scale as $O(n^3)$. Note that it is possible to devise a gradient based method and a loss function that contains some linear parts. The complexity of such an algorithm would be $O(nn_{\mathsf{sv}}^2 + n^2)$.

The original DA algorithm alternates between optimization of $\mathbf{w}$ and $\mathbf{p}_u$ and can be understood as block coordinate optimization. We found that it was significantly slower than the other algorithms; its direct gradient-based optimization counterpart, ∇DA, is usually much faster.

Finally, note that even if the algorithms of the second category have a complexity of $O(n^3)$, one can find an approximate solution by reducing the dimensionality of the problem from n to m and get a complexity of $O(nm^2)$. For instance, Chapelle et al. (2006a) reports a speed-up of 100 times without loss in accuracy for cS^3VM.

Ultimately a semi-supervised learning algorithm should be able to handle data sets with millions of unlabeled points. The best way of scaling up S^3VMs is still an open question and should be the topic of future research.

7. Conclusion

When practical S^3VM implementations fail to give good results on a problem, one might suspect that either: (a) the cluster assumption does not hold; or, (b) the cluster assumption holds but local minima problems are severe; or, (c) the S^3VM objective function is unable to implement the cluster assumption. We began our empirical study by benchmarking current S^3VM implementations against a global optimizer. Our results (see Section 5.3) narrowed the cause for performance loss down to suboptimal local minima, and established a correlation between generalization performance and the S^3VM objective function. For problems where the cluster assumption is true, we expect the S^3VM objective to indeed be an appropriate quantity to minimize. Due to non-convexity however, this minimization is not completely straightforward—an assortment of optimization techniques have been brought to bear on this problem with varying degrees of success. In this paper, we have reviewed these techniques and studied them empirically, taking several subtle differences into account. In a neutral experimental protocol, we were unable to identify any single technique as being consistently superior to another in terms of generalization performance. We believe better methods are still needed to optimize the S^3VM objective function.

While S^3VMs return good performance on textual data sets, they are currently not competitive with graph-methods on domains such as image classification often characterized by multiple, highly non-Gaussian clusters. A particularly promising class of techniques (see Section 5.6.2) is based on combining S^3VMs with graph methods.

S^3VMs have been sparingly explored in domains other than text and image classification. New application domains may provide additional insight into the behavior of S^3VM methods while enhancing their general appeal for semi-supervised learning. Another major theme is the extension of S^3VMs for structured output problems, possibly building on one of several recent lines of work for handling complex supervised learning tasks. A first step towards such an extension would require a clear statement of the cluster assumption applicable to the semi-supervised structured output setting. These are fertile areas for future research.

Abstract

When monitoring spatial phenomena, which can often be modeled as Gaussian processes (GPs), choosing sensor locations is a fundamental task. There are several common strategies to address this task, for example, geometry or disk models, placing sensors at the points of highest entropy (variance) in the GP model, and A-, D-, or E-optimal design. In this paper, we tackle the combinatorial optimization problem of maximizing the *mutual information* between the chosen locations and the locations which are not selected. We prove that the problem of finding the configuration that maximizes mutual information is NP-complete. To address this issue, we describe a polynomial-time approximation that is within $(1-1/e)$ of the optimum by exploiting the *submodularity* of mutual information. We also show how submodularity can be used to obtain online bounds, and design branch and bound search procedures. We then extend our algorithm to exploit lazy evaluations and local structure in the GP, yielding significant speedups. We also extend our approach to find placements which are robust against node failures and uncertainties in the model. These extensions are again associated with rigorous theoretical approximation guarantees, exploiting the submodularity of the objective function. We demonstrate the advantages of our approach towards optimizing mutual information in a very extensive empirical study on two real-world data sets.

Keywords: Gaussian processes, experimental design, active learning, spatial learning; sensor networks

1. Introduction

When monitoring spatial phenomena, such as temperatures in an indoor environment as shown in Figure 1(a), using a limited number of sensing devices, deciding where to place the sensors is

a fundamental task. One approach is to assume that sensors have a fixed sensing radius and to solve the task as an instance of the art-gallery problem (cf. Hochbaum and Maas, 1985; Gonzalez-Banos and Latombe, 2001). In practice, however, this geometric assumption is too strong; sensors make noisy measurements about the nearby environment, and this "sensing area" is not usually characterized by a regular disk, as illustrated by the temperature correlations in Figure 1(b). In addition, note that correlations can be both positive and negative, as shown in Figure 1(c), which again is not well-characterized by a disk model. Fundamentally, the notion that a single sensor needs to predict values in a nearby region is too strong. Often, correlations may be too weak to enable prediction from a single sensor. In other settings, a location may be "too far" from existing sensors to enable good prediction if we only consider one of them, but combining data from multiple sensors we can obtain accurate predictions. This notion of combination of data from multiple sensors in complex spaces is not easily characterized by existing geometric models.

An alternative approach from spatial statistics (Cressie, 1991; Caselton and Zidek, 1984), making weaker assumptions than the geometric approach, is to use a pilot deployment or expert knowledge to learn a *Gaussian process* (GP) model for the phenomena, a non-parametric generalization of linear regression that allows for the representation of uncertainty about predictions made over the sensed field. We can use data from a pilot study or expert knowledge to learn the (hyper-)parameters of this GP. The learned GP model can then be used to predict the effect of placing sensors at particular locations, and thus optimize their positions.[1]

Given a GP model, many criteria have been proposed for characterizing the quality of placements, including placing sensors at the points of highest entropy (variance) in the GP model, and A-, D-, or E-optimal design, and mutual information (cf. Shewry and Wynn, 1987; Caselton and Zidek, 1984; Cressie, 1991; Zhu and Stein, 2006; Zimmerman, 2006). A typical sensor placement technique is to greedily add sensors where uncertainty about the phenomena is highest, that is, the highest entropy location of the GP (Cressie, 1991; Shewry and Wynn, 1987). Unfortunately, this criterion suffers from a significant flaw: entropy is an *indirect* criterion, not considering the prediction quality of the selected placements. The highest entropy set, that is, the sensors that are most uncertain about each other's measurements, is usually characterized by sensor locations that are as far as possible from each other. Thus, the entropy criterion tends to place sensors along the borders of the area of interest (Ramakrishnan et al., 2005), for example, Figure 4. Since a sensor usually provides information about the area around it, a sensor on the boundary "wastes" sensed information.

An alternative criterion, proposed by Caselton and Zidek (1984), *mutual information*, seeks to find sensor placements that are most informative about unsensed locations. This optimization criterion *directly* measures the effect of sensor placements on the posterior uncertainty of the GP. In this paper, we consider the combinatorial optimization problem of selecting placements which maximize this criterion. We first prove that maximizing mutual information is an NP-complete problem. Then, by exploiting the fact that mutual information is a *submodular* function (cf. Nemhauser et al., 1978), we design the first approximation algorithm that guarantees a *constant-factor approximation* of the best set of sensor locations in polynomial time. To the best of our knowledge, no such guarantee exists for any other GP-based sensor placement approach, and for any other criterion. This guarantee

1. This initial GP is, of course, a rough model, and a sensor placement strategy can be viewed as an inner-loop step for an *active learning* algorithm (MacKay, 2003). Alternatively, if we can characterize the uncertainty about the parameters of the model, we can explicitly optimize the placements over possible models (Zidek et al., 2000; Zimmerman, 2006; Zhu and Stein, 2006).

holds both for placing a fixed number of sensors, and in the case where each sensor location can have a different cost.

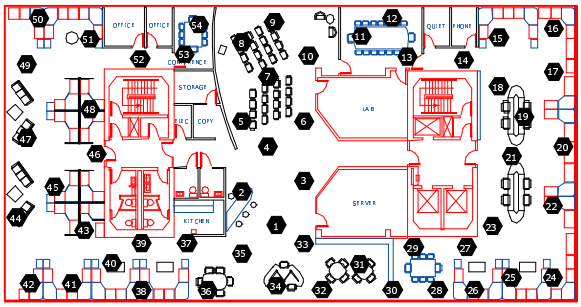
Though polynomial, the complexity of our basic algorithm is relatively high—$O(kn^4)$ to select k out of n possible sensor locations. We address this problem in two ways: First, we develop a lazy evaluation technique that exploits submodularity to reduce significantly the number of sensor locations that need to be checked, thus speeding up computation. Second, we show that if we exploit locality in sensing areas by trimming low covariance entries, we reduce the complexity to $O(kn)$.

We furthermore show, how the submodularity of mutual information can be used to derive tight online bounds on the solutions obtained by any algorithm. Thus, if an algorithm performs better than our simple proposed approach, our analysis can be used to bound how far the solution obtained by this alternative approach is from the optimal solution. Submodularity and these online bounds also allow us to formulate a mixed integer programming approach to compute the optimal solution using Branch and Bound. Finally, we show how mutual information can be made robust against node failures and model uncertainty, and how submodularity can again be exploited in these settings.

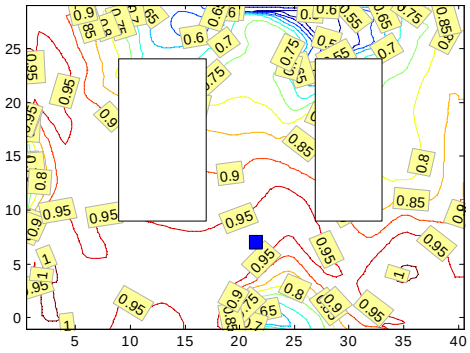
We provide a very extensive experimental evaluation, showing that data-driven placements outperform placements based on geometric considerations only. We also show that the *mutual information* criterion leads to improved prediction accuracies with a reduced number of sensors compared to several more commonly considered experimental design criteria, such as an entropy-based criterion, and A-optimal, D-optimal and E-optimal design criteria.

In summary, our main contributions are:

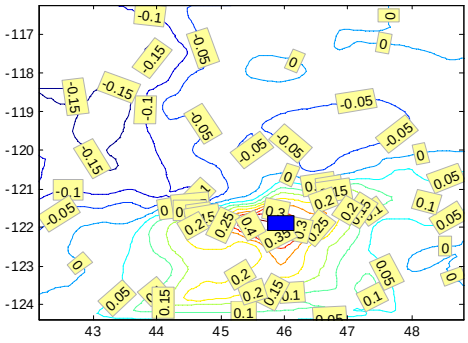
- We tackle the problem of maximizing the information-theoretic *mutual information* criterion of Caselton and Zidek (1984) for optimizing sensor placements, empirically demonstrating its advantages over more commonly used criteria.
- Even though we prove NP-hardness of the optimization problem, we present a polynomial time approximation algorithm with constant factor approximation guarantee, by exploiting *submodularity*. To the best of our knowledge, no such guarantee exists for any other GP-based sensor placement approach, and for any other criterion.
- We also show that submodularity provides online bounds for the quality of our solution, which can be used in the development of efficient branch-and-bound search techniques, or to bound the quality of the solutions obtained by other algorithms.
- We provide two practical techniques that significantly speed up the algorithm, and prove that they have no or minimal effect on the quality of the answer.
- We extend our analysis of mutual information to provide theoretical guarantees for placements that are robust against failures of nodes and uncertainties in the model.
- Extensive empirical evaluation of our methods on several real-world sensor placement problems and comparisons with several classical design criteria.



(a) *54 node sensor network deployment*



(b) *Temperature correlations*



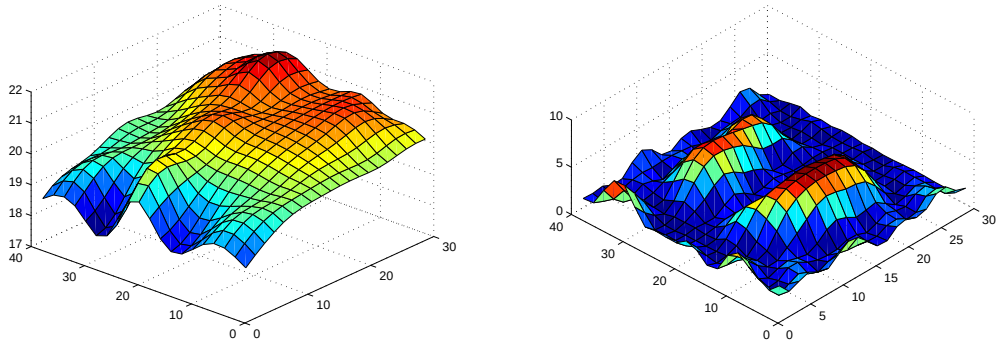
(c) *Precipitation correlations*

Figure 1: (a) A deployment of a sensor network with 54 nodes at the Intel Berkeley Lab. Correlations are often nonstationary as illustrated by (b) temperature data from the sensor network deployment in Figure 1(a), showing the correlation between a sensor placed on the blue square and other possible locations; (c) precipitation data from measurements made across the Pacific Northwest, Figure 11(b).

The paper is organized as follows. In Section 2, we introduce Gaussian Processes. We review mutual information criterion in Section 3, and describe our approximation algorithm to optimize mutual information in Section 4. Section 5 presents several approaches towards making the optimization more computationally efficient. In Section 6, we discuss how we can extend mutual information to be robust against node failures and uncertainty in the model. Section 8 relates our approach to other possible optimization criteria, and Section 7 describes related work. Section 9 presents our experiments.

2. Gaussian Processes

In this section, we review *Gaussian Processes*, the probabilistic model for spatial phenomena that forms the basis of our sensor placement algorithms.



(a) *Temperature prediction using GP* (b) *Variance of temperature prediction*

Figure 2: Posterior mean and variance of the temperature GP estimated using all sensors: (a) Predicted temperature; (b) predicted variance.

2.1 Modeling Sensor Data Using the Multivariate Normal Distribution

Consider, for example, the sensor network we deployed as shown in Figure 1(a) that measures a temperature field at 54 discrete locations. In order to predict the temperature at one of these locations from the other sensor readings, we need the joint distribution over temperatures at the 54 locations. A simple, yet often effective (cf. Deshpande et al., 2004), approach is to assume that the temperatures have a (multivariate) Gaussian joint distribution. Denoting the set of locations as $\mathcal{V}$, in our sensor network example $|\mathcal{V}| = 54$, we have a set of $n = |\mathcal{V}|$ corresponding random variables $X_{\mathcal{V}}$ with joint distribution:

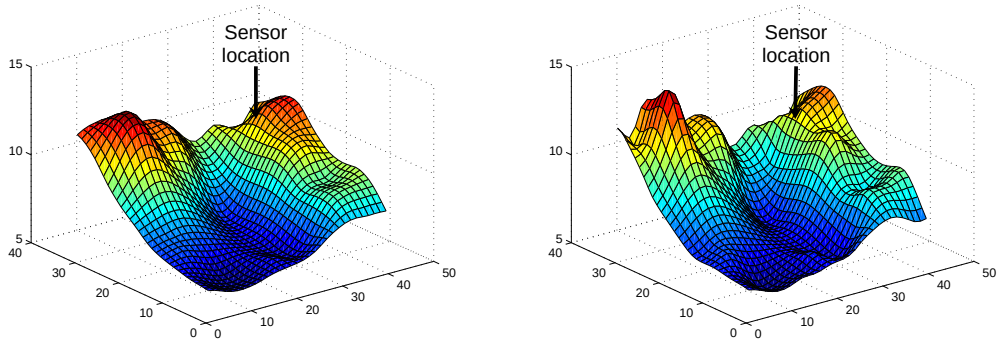
$$P(X_{\mathcal{V}} = \mathbf{x}_{\mathcal{V}}) = \frac{1}{(2\pi)^{n/2}|\Sigma_{\mathcal{V}\mathcal{V}}|} e^{-\frac{1}{2}(\mathbf{x}_{\mathcal{V}}-\mu_{\mathcal{V}})^T \Sigma^{-1}_{\mathcal{V}\mathcal{V}}(\mathbf{x}_{\mathcal{V}}-\mu_{\mathcal{V}})},$$

where $\mu_{\mathcal{V}}$ is the mean vector and $\Sigma_{\mathcal{V}\mathcal{V}}$ is the covariance matrix. Interestingly, if we consider a subset, $\mathcal{A} \subseteq \mathcal{V}$, of our random variables, denoted by $X_{\mathcal{A}}$, then their joint distribution is also Gaussian.

2.2 Modeling Sensor Data Using Gaussian Processes

In our sensor network example, we are not just interested in temperatures at sensed locations, but also at locations where no sensors were placed. In such cases, we can use regression techniques to perform prediction (Golub and Van Loan, 1989; Hastie et al., 2003). Although linear regression often gives excellent predictions, there is usually no notion of uncertainty about these predictions, for example, for Figure 1(a), we are likely to have better temperature estimates at points near existing sensors, than in the two central areas that were not instrumented. A *Gaussian process* (GP) is a natural generalization of linear regression that allows us to consider uncertainty about predictions.

Intuitively, a GP generalizes multivariate Gaussians to an infinite number of random variables. In analogy to the multivariate Gaussian above where the index set $\mathcal{V}$ was finite, we now have a (possibly uncountably) infinite index set $\mathcal{V}$. In our temperature example, $\mathcal{V}$ would be a subset of $\mathbb{R}^2$, and



(a) *Example kernel function.* (b) *Data from the empirical covariance matrix.*

Figure 3: Example kernel function learned from the Berkeley Lab temperature data: (a) learned covariance function $\mathcal{K}(x,\cdot)$, where x is the location of sensor 41; (b) "ground truth", interpolated empirical covariance values for the same sensors. Observe the close match between predicted and measured covariances.

each index would correspond to a position in the lab. GPs have been widely studied (cf. MacKay, 2003; Paciorek, 2003; Seeger, 2004; O'Hagan, 1978; Shewry and Wynn, 1987; Lindley and Smith, 1972), and generalize Kriging estimators commonly used in geostatistics (Cressie, 1991).

An important property of GPs is that for every finite subset $\mathcal{A}$ of the indices $\mathcal{V}$, which we can think about as locations in the plane, the joint distribution over the corresponding random variables $X_\mathcal{A}$ is Gaussian, for example, the joint distribution over temperatures at a finite number of sensor locations is Gaussian. In order to specify this distribution, a GP is associated with a *mean function* $\mathcal{M}(\cdot)$, and a symmetric positive-definite *kernel function* $\mathcal{K}(\cdot,\cdot)$, often called the covariance function. For each random variable with index $u \in \mathcal{V}$, its mean μ_u is given by $\mathcal{M}(u)$. Analogously, for each pair of indices $u,v \in \mathcal{V}$, their covariance σ_{uv} is given by $\mathcal{K}(u,v)$. For simplicity of notation, we denote the mean vector of some set of variables $X_\mathcal{A}$ by $\mu_\mathcal{A}$, where the entry for element u of $\mu_\mathcal{A}$ is $\mathcal{M}(u)$. Similarly, we denote their covariance matrix by $\Sigma_{\mathcal{A}\mathcal{A}}$, where the entry for u,v is $\mathcal{K}(u,v)$.

The GP representation is extremely powerful. For example, if we observe a set of sensor measurements $X_\mathcal{A} = \mathbf{x}_\mathcal{A}$ corresponding to the finite subset $\mathcal{A} \subset \mathcal{V}$, we can predict the value at any point $y \in \mathcal{V}$ conditioned on these measurements, $P(X_y \mid x_\mathcal{A})$. The distribution of X_y given these observations is a Gaussian whose conditional mean $\mu_{y|\mathcal{A}}$ and variance $\sigma^2_{y|\mathcal{A}}$ are given by:

$$\mu_{y|\mathcal{A}} = \mu_y + \Sigma_{y\mathcal{A}}\Sigma^{-1}_{\mathcal{A}\mathcal{A}}(x_\mathcal{A} - \mu_\mathcal{A}), \quad (1)$$

$$\sigma^2_{y|\mathcal{A}} = \mathcal{K}(y,y) - \Sigma_{y\mathcal{A}}\Sigma^{-1}_{\mathcal{A}\mathcal{A}}\Sigma_{\mathcal{A}y}, \quad (2)$$

where $\Sigma_{y\mathcal{A}}$ is a covariance vector with one entry for each $u \in \mathcal{A}$ with value $\mathcal{K}(y,u)$, and $\Sigma_{\mathcal{A}y} = \Sigma^T_{y\mathcal{A}}$. Figure 2(a) and Figure 2(b) show the posterior mean and variance derived using these equations on 54 sensors at Intel Labs Berkeley. Note that two areas in the center of the lab were not instrumented. These areas have higher posterior variance, as expected. An important property of GPs is that the posterior variance (2) does not depend on the actual observed values $x_\mathcal{A}$. Thus, for a given kernel function, the variances in Figure 2(b) will not depend on the observed temperatures.

2.3 Nonstationarity

In order to compute predictive distributions using (1) and (2), the mean and kernel functions have to be known. The mean function can usually be estimated using regression techniques. Estimating kernel functions is difficult, and usually, strongly limiting assumptions are made. For example, it is commonly assumed that the kernel $\mathcal{K}(u,v)$ is *stationary*, which means that the kernel depends only on the difference between the locations, considered as vectors v, u, that is, $\mathcal{K}(u,v) = \mathcal{K}_\theta(u-v)$. Hereby, θ is a set of parameters. Very often, the kernel is even assumed to be *isotropic*, which means that the covariance only depends on the distance between locations, that is, $\mathcal{K}(u,v) = \mathcal{K}_\theta(||u-v||_2)$. Common choices for isotropic kernels are the exponential kernel, $\mathcal{K}_\theta(\delta) = \exp(-\frac{|\delta|}{\theta})$, and the Gaussian kernel, $\mathcal{K}_\theta(\delta) = \exp(-\frac{\delta^2}{\theta^2})$. These assumptions are frequently strongly violated in practice, as illustrated in the real sensor data shown in Figures 1(b) and 1(c). In Section 8.1, we discuss how placements optimized from models with isotropic kernels reduce to geometric covering and packing problems.

In this paper, we *do not* assume that $\mathcal{K}(\cdot,\cdot)$ is stationary or isotropic. Our approach is general, and can use *any* kernel function. In our experiments, we use the approach of Nott and Dunsmuir (2002) to estimate nonstationary kernels from data collected by an initial deployment. More specifically, their assumption is that an estimate of the empirical covariance $\Sigma_{\mathcal{A}\mathcal{A}}$ at a set of observed locations is available, and that the process can be locally described by a collection of isotropic processes, associated with a set of reference points. An example of a kernel function estimated using this method is presented in Figure 3(a). In Section 9.2, we show that placements based on such nonstationary GPs lead to far better prediction accuracies than those obtained from isotropic kernels.

3. Optimizing Sensor Placements

Usually, we are limited to deploying a small number of sensors, and thus must carefully choose where to place them. In spatial statistics this optimization is called *sampling* or *experimental design*: finding the k best sensor locations out of a finite subset $\mathcal{V}$ of possible locations, for example, out of a grid discretization of $\mathbb{R}^2$.

3.1 The Entropy Criterion

We first have to define what a good design is. Intuitively, we want to place sensors which are most informative with respect to the entire design space. A natural notion of uncertainty is the conditional entropy of the unobserved locations $\mathcal{V}\setminus\mathcal{A}$ after placing sensors at locations $\mathcal{A}$,

$$H(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathcal{X}_{\mathcal{A}}) = -\int p(\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}}, \mathbf{x}_{\mathcal{A}}) \log p(\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathbf{x}_{\mathcal{A}}) d\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}} d\mathbf{x}_{\mathcal{A}}, \tag{3}$$

where we use $\mathcal{X}_{\mathcal{A}}$ and $\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}}$ to refer to sets of random variables at the locations $\mathcal{A}$ and $\mathcal{V}\setminus\mathcal{A}$. Intuitively, minimizing this quantity aims at finding the placement which results in the lowest uncertainty about all uninstrumented locations $\mathcal{V}\setminus\mathcal{A}$ after observing the placed sensors $\mathcal{A}$. A good placement would therefore minimize this conditional entropy, that is, we want to find

$$\mathcal{A}^* = \operatorname{argmin}_{\mathcal{A}\subset\mathcal{V}:|\mathcal{A}|=k} H(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathcal{X}_{\mathcal{A}}).$$

Using the identity $H(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathcal{X}_{\mathcal{A}}) = H(\mathcal{X}_{\mathcal{V}}) - H(\mathcal{X}_{\mathcal{A}})$, we can see that

$$\mathcal{A}^* = \text{argmin}_{\mathcal{A}\subset\mathcal{V}:|\mathcal{A}|=k} H(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathcal{X}_{\mathcal{A}}) = \text{argmax}_{\mathcal{A}\subset\mathcal{V}:|\mathcal{A}|=k} H(\mathcal{X}_{\mathcal{A}}).$$

So we can see that we need to find a set of sensors $\mathcal{A}$ which is most uncertain about each other. Unfortunately, this optimization problem, often also referred to as D-optimal design in the experiment design literature (cf. Currin et al., 1991), has been shown to be NP-hard (Ko et al., 1995):

Theorem 1 (Ko et al., 1995) *Given rational M and rational covariance matrix $\Sigma_{\mathcal{V}\mathcal{V}}$ over Gaussian random variables $\mathcal{V}$, deciding whether there exists a subset $\mathcal{A} \subseteq \mathcal{V}$ of cardinality k such that $H(\mathcal{X}_{\mathcal{A}}) \geq M$ is NP-complete.*

Therefore, the following greedy heuristic has found common use (McKay et al., 1979; Cressie, 1991): One starts from an empty set of locations, $\mathcal{A}_0 = \emptyset$, and greedily adds placements until $|\mathcal{A}| = k$. At each iteration, starting with set $\mathcal{A}_i$, the greedy rule used is to add the location $y^*_H \in \mathcal{V} \setminus \mathcal{A}$ that has highest conditional entropy,

$$y^*_H = \text{argmax}_y H(\mathcal{X}_y \mid \mathcal{X}_{\mathcal{A}_i}), \tag{4}$$

that is, the location we are most uncertain about given the sensors placed thus far. If the set of selected locations at iteration i is $\mathcal{A}_i = \{y_1, \ldots, y_i\}$, using the chain-rule of entropies, we have that:

$$H(\mathcal{X}_{\mathcal{A}_i}) = H(\mathcal{X}_{y_i} \mid \mathcal{X}_{\mathcal{A}_{i-1}}) + \ldots + H(\mathcal{X}_{y_2} \mid \mathcal{X}_{\mathcal{A}_1}) + H(\mathcal{X}_{y_1} \mid \mathcal{X}_{\mathcal{A}_0}).$$

Note that the (differential) entropy of a Gaussian random variable $\mathcal{X}_y$ conditioned on some set of variables $\mathcal{X}_{\mathcal{A}}$ is a monotonic function of its variance:

$$H(\mathcal{X}_y \mid \mathcal{X}_{\mathcal{A}}) = \frac{1}{2}\log(2\pi e \sigma^2_{\mathcal{X}_y|\mathcal{X}_{\mathcal{A}}}) = \frac{1}{2}\log\sigma^2_{\mathcal{X}_y|\mathcal{X}_{\mathcal{A}}} + \frac{1}{2}(\log(2\pi)+1), \tag{5}$$

which can be computed in closed form using Equation (2). Since for a fixed kernel function, the variance does not depend on the observed values, this optimization can be done before deploying the sensors, that is, a sequential, closed-loop design taking into account previous measurements bears no advantages over an open-loop design, performed before any measurements are made.

3.2 An Improved Design Criterion: Mutual Information

The entropy criterion described above is intuitive for finding sensor placements, since the sensors that are most uncertain about each other should cover the space well. Unfortunately, this entropy criterion suffers from the problem shown in Figure 4, where sensors are placed far apart along the boundary of the space. Since we expect predictions made from a sensor measurement to be most precise in a region around it, such placements on the boundary are likely to "waste" information. This phenomenon has been noticed previously by Ramakrishnan et al. (2005), who proposed a weighting heuristic. Intuitively, this problem arises because the entropy criterion is *indirect*: the criterion only considers the entropy of the selected sensor locations, rather than considering prediction quality over the space of interest. This indirect quality of the entropy criterion is surprising, since

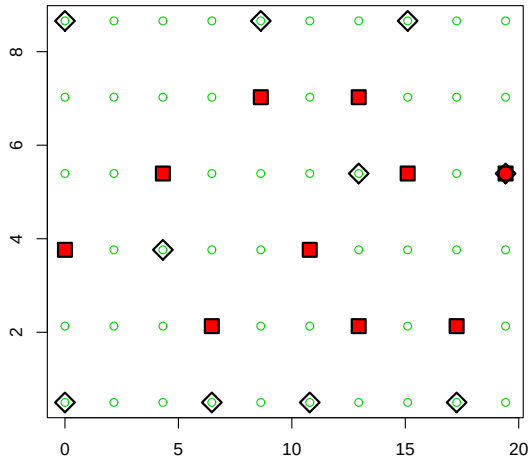


Figure 4: An example of placements chosen using entropy and mutual information criteria on a subset of the temperature data from the Intel deployment. Diamonds indicate the positions chosen using entropy; squares the positions chosen using MI.

the criterion was derived from the "predictive" formulation $H(\mathcal{V} \setminus \mathcal{A} \mid \mathcal{A})$ in Equation (3), which is equivalent to maximizing $H(\mathcal{A})$.

Caselton and Zidek (1984) proposed a different optimization criterion, which searches for the subset of sensor locations that most significantly reduces the uncertainty about the estimates in the rest of the space. More formally, we consider our space as a discrete set of locations $\mathcal{V} = \mathcal{S} \cup \mathcal{U}$ composed of two parts: a set $\mathcal{S}$ of possible positions where we can place sensors, and another set $\mathcal{U}$ of positions of interest, where no sensor placements are possible. The goal is to place a set of k sensors that will give us good predictions at all uninstrumented locations $\mathcal{V} \setminus \mathcal{A}$. Specifically, we want to find

$$\mathcal{A}^* = \operatorname{argmax}_{\mathcal{A} \subseteq \mathcal{S}: |\mathcal{A}| = k} H(\mathcal{X}_{\mathcal{V} \setminus \mathcal{A}}) - H(\mathcal{X}_{\mathcal{V} \setminus \mathcal{A}} \mid \mathcal{X}_{\mathcal{A}}),$$

that is, the set $\mathcal{A}^*$ that maximally reduces the entropy over the rest of the space $\mathcal{V} \setminus \mathcal{A}^*$. Note that this criterion $H(\mathcal{X}_{\mathcal{V} \setminus \mathcal{A}}) - H(\mathcal{X}_{\mathcal{V} \setminus \mathcal{A}} \mid \mathcal{X}_{\mathcal{A}})$ is equivalent to finding the set that maximizes the *mutual information* $I(\mathcal{X}_{\mathcal{A}}; \mathcal{X}_{\mathcal{V} \setminus \mathcal{A}})$ between the locations $\mathcal{A}$ and the rest of the space $\mathcal{V} \setminus \mathcal{A}$. In their follow-up work, Caselton et al. (1992) and Zidek et al. (2000), argue against the use of mutual information in a setting where the entropy $H(\mathcal{X}_{\mathcal{A}})$ in the observed locations constitutes a significant part of the total uncertainty $H(\mathcal{X}_{\mathcal{V}})$. Caselton et al. (1992) also argue that, in order to compute $\mathrm{MI}(\mathcal{A})$, one needs an accurate model of $P(\mathcal{X}_{\mathcal{V}})$. Since then, the entropy criterion has been dominantly used as a placement criterion. Nowadays however, the estimation of complex nonstationary models for $P(\mathcal{X}_{\mathcal{V}})$, as well as computational aspects, are very well understood and handled. Furthermore, we show empirically, that even in the sensor selection case, mutual information outperforms entropy on several practical placement problems.

On the same simple example in Figure 4, this mutual information criterion leads to intuitively appropriate central sensor placements that do not have the "wasted information" property of the entropy criterion. Our experimental results in Section 9 further demonstrate the advantages in performance of the mutual information criterion. For simplicity of notation, we will often use $\mathrm{MI}(\mathcal{A}) = I(\mathcal{X}_{\mathcal{A}}; \mathcal{X}_{\mathcal{V} \setminus \mathcal{A}})$ to denote the mutual information objective function. Notice that in this no-

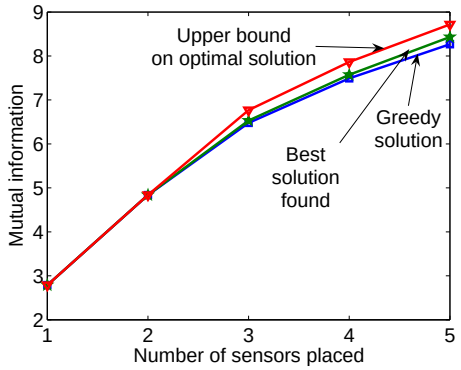

Figure 5: Comparison of the greedy algorithm with the optimal solutions on a small problem. We select from 1 to 5 sensor locations out of 16, on the Intel Berkeley temperature data set as discussed in Section 9. The greedy algorithm is always within 95 percent of the optimal solution.

tation the process $\mathcal{X}$ and the set of locations $\mathcal{V}$ is implicit. We will also write $H(\mathcal{A})$ instead of $H(\mathcal{X}_\mathcal{A})$.

The mutual information is also hard to optimize:

Theorem 2 *Given rational M and a rational covariance matrix $\Sigma_{\mathcal{V}\mathcal{V}}$ over Gaussian random variables $\mathcal{V} = \mathcal{S} \cup \mathcal{U}$, deciding whether there exists a subset $\mathcal{A} \subseteq \mathcal{S}$ of cardinality k such that $\mathrm{MI}(\mathcal{A}) \geq M$ is NP-complete.*

Proofs of all results are given in Appendix A. Due to the problem complexity, we cannot expect to find optimal solutions in polynomial time. However, if we implement the simple greedy algorithm for the mutual information criterion (details given below), and optimize designs on real-world placement problems, we see that the greedy algorithm gives almost optimal solutions, as presented in Figure 5. In this small example, where we could compute the optimal solution, the performance of the greedy algorithm was at most five percent worse than the optimal solution. In the following sections, we will give theoretical bounds and empirical evidence justifying this near-optimal behavior.

4. Approximation Algorithm

Optimizing the mutual information criterion is an NP-complete problem. We now describe a polynomial time algorithm with a constant-factor approximation guarantee.

4.1 The Algorithm

Our algorithm is greedy, simply adding sensors in sequence, choosing the next sensor which provides the maximum increase in mutual information. More formally, using $\mathrm{MI}(\mathcal{A}) = I(\mathcal{X}_\mathcal{A}; \mathcal{X}_{\mathcal{V}\setminus\mathcal{A}})$,

Input: Covariance matrix $\Sigma_{\mathcal{V}\mathcal{V}}$, k, $\mathcal{V} = \mathcal{S} \cup \mathcal{U}$
Output: Sensor selection $\mathcal{A} \subseteq \mathcal{S}$
begin
  $\mathcal{A} \leftarrow \emptyset$;
  for $j = 1$ **to** k **do**
    for $y \in \mathcal{S} \setminus \mathcal{A}$ **do** $\delta_y \leftarrow \dfrac{\sigma_y^2 - \Sigma_{y\mathcal{A}}\Sigma_{\mathcal{A}\mathcal{A}}^{-1}\Sigma_{\mathcal{A}y}}{\sigma_y^2 - \Sigma_{y\bar{\mathcal{A}}}\Sigma_{\bar{\mathcal{A}}\bar{\mathcal{A}}}^{-1}\Sigma_{\bar{\mathcal{A}}y}}$;
1
    $y^* \leftarrow \operatorname{argmax}_{y \in \mathcal{S}\setminus\mathcal{A}} \delta_y$;
2
    $\mathcal{A} \leftarrow \mathcal{A} \cup y^*$;
end

Algorithm 1: Approximation algorithm for maximizing mutual information.

our goal is to greedily select the next sensor y that maximizes:

$$\begin{aligned} \mathrm{MI}(\mathcal{A}\cup y) - \mathrm{MI}(\mathcal{A}) &= H(\mathcal{A}\cup y) - H(\mathcal{A}\cup y \mid \bar{\mathcal{A}}) - \left[H(\mathcal{A}) - H(\mathcal{A} \mid \bar{\mathcal{A}}\cup y)\right] \\ &= H(\mathcal{A}\cup y) - H(\mathcal{V}) + H(\bar{\mathcal{A}}) - \left[H(\mathcal{A}) - H(\mathcal{V}) + H(\bar{\mathcal{A}}\cup y)\right] \\ &= H(y \mid \mathcal{A}) - H(y \mid \bar{\mathcal{A}}), \end{aligned} \tag{6}$$

where, to simplify notation, we write $\mathcal{A}\cup y$ to denote the set $\mathcal{A}\cup\{y\}$, and use $\bar{\mathcal{A}}$ to mean $\mathcal{V}\setminus(\mathcal{A}\cup y)$. Note that the greedy rule for entropy in Equation (4) only considers the $H(y \mid \mathcal{A})$ part of Equation (6), measuring the uncertainty of location y with respect to the placements $\mathcal{A}$. In contrast, the greedy mutual information trades off this uncertainty with $-H(y \mid \bar{\mathcal{A}})$, which forces us to pick a y that is "central" with respect to the unselected locations $\bar{\mathcal{A}}$, since those "central" locations will result in the least conditional entropy $H(y \mid \bar{\mathcal{A}})$. Using the definition of conditional entropy in Equation (5), Algorithm 1 shows our greedy sensor placement algorithm.

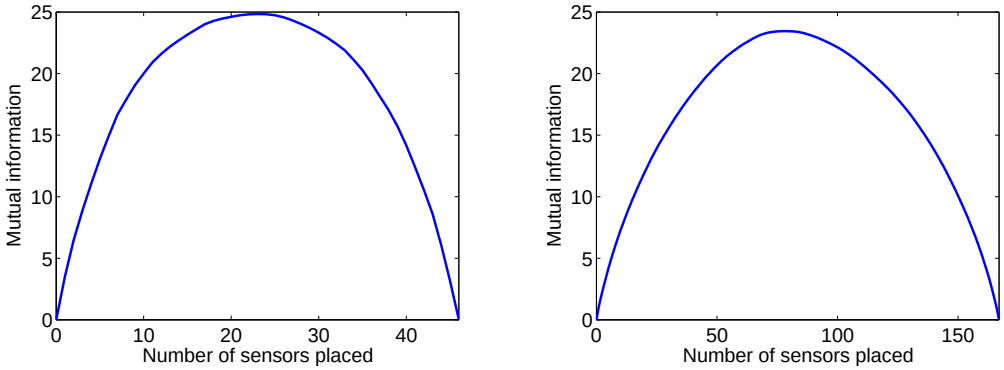
4.2 An Approximation Bound

We now prove that, if the discretization $\mathcal{V}$ of locations of interest in the Gaussian process is fine enough, our greedy algorithm gives a $(1-1/e)$ approximation, approximately 63% of the optimal sensor placement: If the algorithm returns set $\widehat{A}$, then

$$\mathrm{MI}(\widehat{A}) \geq (1-1/e) \max_{\mathcal{A}\subset\mathcal{S},|\mathcal{A}|=k} \mathrm{MI}(\mathcal{A}) - k\varepsilon,$$

for some small $\varepsilon > 0$. To prove this result, we use *submodularity* (cf. Nemhauser et al., 1978). Formally, a set function F is called *submodular*, if for all $\mathcal{A},\mathcal{B} \subseteq \mathcal{V}$ it holds that $F(\mathcal{A}\cup\mathcal{B}) + F(\mathcal{A}\cap\mathcal{B}) \leq F(\mathcal{A}) + F(\mathcal{B})$. Equivalently, using an induction argument as done by Nemhauser et al. (1978), a set function is submodular if for all $\mathcal{A} \subseteq \mathcal{A}' \subseteq \mathcal{V}$ and $y \in \mathcal{V}\setminus\mathcal{A}'$ it holds that $F(\mathcal{A}\cup y) - F(\mathcal{A}) \geq F(\mathcal{A}'\cup y) - F(\mathcal{A}')$. This second characterization intuitively represents "diminishing returns": adding a sensor y when we only have a small set of sensors $\mathcal{A}$ gives us more advantage than adding y to a larger set of sensors $\mathcal{A}'$. Using the "information never hurts" bound, $H(y \mid \mathcal{A}) \geq H(y \mid \mathcal{A}\cup\mathcal{B})$ (Cover and Thomas, 1991), note that our greedy update rule maximizing $H(y \mid \mathcal{A}) - H(y \mid \bar{\mathcal{A}})$ implies

$$\mathrm{MI}(\mathcal{A}'\cup y) - \mathrm{MI}(\mathcal{A}') \leq \mathrm{MI}(\mathcal{A}\cup y) - \mathrm{MI}(\mathcal{A}),$$



(a) *Temperature data* (b) *Precipitation data*

Figure 6: Mutual information of greedy sets of increasing size. It can be seen that clearly mutual information is not monotonic. MI is monotonic, however, in the initial part of the curve corresponding to small placements. This allows us to prove approximate monotonicity.

whenever $\mathcal{A} \subseteq \mathcal{A}'$, and any $y \in \mathcal{V} \setminus \mathcal{A}'$, that is, adding y to $\mathcal{A}$ helps more than adding y to $\mathcal{A}'$. In fact, this inequality holds for arbitrary sets $\mathcal{A} \subseteq \mathcal{A}' \subseteq \mathcal{V}$ and $y \in \mathcal{V} \setminus \mathcal{A}'$, not just for the sets considered by the greedy algorithm. Hence we have shown:

Lemma 3 *The set function $\mathcal{A} \mapsto \mathrm{MI}(\mathcal{A})$ is submodular.*

A submodular set function F is called monotonic if $F(\mathcal{A} \cup y) \geq F(\mathcal{A})$ for $y \in \mathcal{V}$. For such functions, Nemhauser et al. (1978) prove the following fundamental result:

Theorem 4 (Nemhauser et al., 1978) *Let F be a monotone submodular set function over a finite ground set $\mathcal{V}$ with $F(\emptyset) = 0$. Let $\mathcal{A}_G$ be the set of the first k elements chosen by the greedy algorithm, and let* $\mathrm{OPT} = \max_{\mathcal{A} \subset \mathcal{V}, |\mathcal{A}| = k} F(\mathcal{A})$. *Then*

$$F(\mathcal{A}_G) \geq \left(1 - \left(\frac{k-1}{k}\right)^k\right) \mathrm{OPT} \geq (1 - 1/e)\,\mathrm{OPT}\,.$$

Hence the greedy algorithm guarantees a performance guarantee of $(1-1/e)\,\mathrm{OPT}$, where OPT is the value of the optimal subset of size k. This greedy algorithm is defined by selecting in each step the element $y^* = \mathrm{argmax}_y F(\mathcal{A} \cup y) - F(\mathcal{A})$. This is exactly the algorithm we proposed in the previous section for optimizing sensor placements (Algorithm 1).

Clearly, $\mathrm{MI}(\emptyset) = I(\emptyset; \mathcal{V}) = 0$, as required by Theorem 4. However, the monotonicity of mutual information is not apparent. Since $\mathrm{MI}(\mathcal{V}) = I(\mathcal{V}, \emptyset) = 0$, the objective function will increase and then decrease, and, thus, is not monotonic, as shown in Figures 6(a) and 6(b). Fortunately, the proof of Nemhauser et al. (1978) does not use monotonicity for all possible sets, it is sufficient to prove that MI is monotonic for all sets of size up to $2k$. Intuitively, mutual information is not monotonic when the set of sensor locations approaches $\mathcal{V}$. If the discretization level is significantly larger than $2k$ points, then mutual information should meet the conditions of the proof of Theorem 4.

Thus the heart of our analysis of Algorithm 1 will be to prove that if the discretization of the Gaussian process is fine enough, then mutual information is *approximately monotonic* for sets of size up to $2k$. More precisely, we prove the following result:

Lemma 5 *Let $\mathcal{X}$ be a Gaussian process on a compact subset $\mathcal{C}$ of $\mathbb{R}^m$ with a positive-definite, continuous covariance kernel $\mathcal{K}: \mathcal{C} \times \mathcal{C} \rightarrow \mathbb{R}_0^+$. Assume the sensors have a measurement error with variance at least σ^2. Then, for any $\varepsilon > 0$, and any finite maximum number k of sensors to place there exists a discretization $\mathcal{V} = \mathcal{S} \cup \mathcal{U}$, $\mathcal{S}$ and $\mathcal{U}$ having mesh width δ such that $\forall y \in \mathcal{V} \setminus \mathcal{A}, \mathrm{MI}(\mathcal{A} \cup y) \geq \mathrm{MI}(\mathcal{A}) - \varepsilon$ for all $\mathcal{A} \subseteq \mathcal{S}$, $|\mathcal{A}| \leq 2k$.*

If the covariance function is Lipschitz-continuous, such as the Gaussian Radial Basis Function (RBF) kernel, the following corollary gives a bound on the required discretization level with respect to the Lipschitz constant:

Corollary 6 *If $\mathcal{K}$ is Lipschitz-continuous with constant L, then the required discretization is*

$$\delta \leq \frac{\varepsilon \sigma^6}{4kLM\left(\sigma^2 + 2k^2M + 6k^2\sigma^2\right)},$$

where $M = \max_{x \in C} \mathcal{K}(x,x)$, for $\varepsilon < \min(M, 1)$.

Corollary 6 guarantees that for any $\varepsilon > 0$, a polynomial discretization level is sufficient to guarantee that mutual information is $\varepsilon-$approximately monotonic. These bounds on the discretization are, of course, worst case bounds. The worst-case setting occurs when the sensor placements $\mathcal{A}$ are arbitrarily close to each other, since the entropy part $H(y \mid \mathcal{A})$ in Equation (6) can become negative. Since most GPs are used for modeling physical phenomena, both the optimal sensor placement and the sensor placement produced by the greedy algorithm can be expected to be spread out, and not condensed to a small region of the sensing area. Hence we expect the bounds to be very loose in the situations that arise during normal operation of the greedy algorithm.

Combining our Lemmas 3 and 5 with Theorem 4, we obtain our constant-factor approximation bound on the quality of the sensor placements obtained by our algorithm:

Theorem 7 *Under the assumptions of Lemma 5, Algorithm 1 is guaranteed to select a set $\mathcal{A}$ of k sensors for which*

$$\mathrm{MI}(\mathcal{A}) \geq (1 - 1/e)(\mathrm{OPT} - k\varepsilon),$$

where OPT *is the value of the mutual information for the optimal placement.*

Note that our bound has two implications: First, it shows that our greedy algorithm has a guaranteed minimum performance level of $1 - 1/e$ when compared to the optimal solution. Second, our approach also provides an upper-bound on the value of the optimal placement, which can be used to bound the quality of the placements by other heuristic approaches, such as local search, that may perform better than our greedy algorithm on specific problems.

4.3 Sensor Placement with Non-constant Cost Functions

In many real-world settings, the cost of placing a sensor depends on the specific location. Such cases can often be formalized by specifying a total budget L, and the task is to select placements $\mathcal{A}$ whose total cost $c(\mathcal{A})$ is within our budget. Recently, the submodular function maximization approach of Nemhauser et al. (1978) has been extended to address this budgeted case (Sviridenko, 2004; Krause and Guestrin, 2005), in the case of modular cost functions, that is, $c(\mathcal{A}) = \sum_{i=1}^{k} c(\mathcal{X}_i)$, where $\mathcal{A} = \{\mathcal{X}_1, \ldots, \mathcal{X}_k\}$ and $c(\mathcal{X}_i)$ is the cost for selecting element $\mathcal{X}_i$. The combination of the

analysis in this paper with these new results also yields a constant-factor $(1-1/e)$ approximation guarantee for the sensor placement problem with non-uniform costs.

The algorithm for this budgeted case first enumerates all subsets of cardinality at most three. For each of these candidate subsets, we run a greedy algorithm, which adds elements until the budget is exhausted. The greedy rule optimizes a benefit cost ratio, picking the element for which the increase of mutual information divided by the cost of placing the sensor is maximized: More formally, at each step, the greedy algorithm adds the element y^* such that

$$y^* = \text{argmax}_{y \in \mathcal{S} \setminus \mathcal{A}} \frac{H(y \mid \mathcal{A}) - H(y \mid \bar{\mathcal{A}})}{c(y)}.$$

Krause and Guestrin (2005) show that this algorithm achieves an approximation guarantee of

$$(1-1/e)\,\text{OPT} - \frac{2L\varepsilon}{c_{\min}},$$

where L is the available budget, and $c_{\min}$ is the minimum cost of all locations. A requirement for this result to hold is that mutual information is ε-monotonic up to sets of size $\frac{2L}{c_{\min}}$. The necessary discretization level can be established similarly as in Corollary 6, with k replaced by $\frac{L}{c_{\min}}$.

4.4 Online Bounds

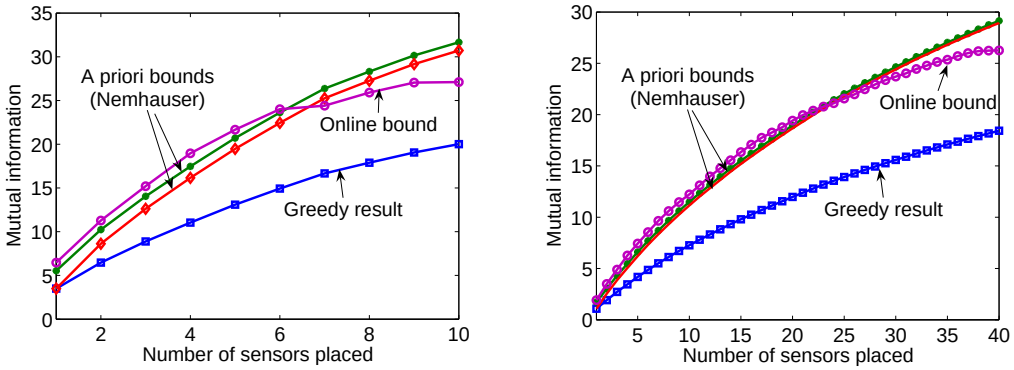
Since mutual information is approximately monotonic and submodular, Theorem 7 proves an *a priori* approximation guarantee of $(1-1/e)$. For most practical problems however, this bound is very loose. The following observation allows to compute online bounds on the optimal value:

Proposition 8 *Assume that the discretization is fine enough to guarantee ε-monotonicity for mutual information, and that the greedy algorithm returns an approximate solution $\mathcal{A}_k$, $|\mathcal{A}_k| = k$. For all $y \in \mathcal{S}$, let $\delta_y = \text{MI}(\mathcal{A} \cup y) - \text{MI}(\mathcal{A})$. Sort the δ_y in decreasing order, and consider the sequence $\delta^{(1)}, \ldots, \delta^{(k)}$ of the first k elements. Then* $\text{OPT} \leq \text{MI}(\mathcal{A}_k) + \sum_{i=1}^{k} \delta^{(i)} + k\varepsilon$.

The proof of this proposition follows directly from submodularity and ε-monotonicity. In many applications, especially for large placements, this bound can be much tighter than the bound guaranteed by Theorem 7. Figures 7(a) and 7(b) compare the a priori and online bounds for the data sets discussed in Section 9.1.

4.5 Exact Optimization and Tighter Bounds Using Mixed Integer Programming

There is another way to get even tighter bounds, or even compute the optimal solution. This approach is based on branch & bound algorithm for solving a mixed integer program for monotonic submodular functions (Nemhauser and Wolsey, 1981). We used this algorithm to bound the value of the optimal solution in Figure 5.



(a) *Temperature data* (b) *Precipitation data*

Figure 7: Online bounds: mutual information achieved by the greedy algorithm, the $(1-1/e)$ and $1-(1-1/k)^k$ a priori bounds and the online bound described in Section 4.4.

The mixed integer program is given by:

$$\begin{aligned}
&\max \eta; \\
&\quad \eta \;\leq\; \mathrm{MI}(\mathcal{B}) + \sum_{y_i \in \mathcal{S}\setminus\mathcal{B}} \alpha_i [\mathrm{MI}(\mathcal{B}\cup y_i) - \mathrm{MI}(\mathcal{B})], \quad \forall \mathcal{B} \subseteq \mathcal{S}; && (7)\\
&\sum_i \alpha_i \;\leq\; k, \quad \forall i; && (8)\\
&\quad \alpha_i \;\in\; \{0,1\}, \quad \forall i;
\end{aligned}$$

where $\alpha_i = 1$ means that location y_i should be selected. Note that this MIP can be easily extended to handle the case in which each location can have a different cost, by replacing the constraint (8) by $\sum_i \alpha_i c_i \leq L$, where L is the budget and $c_i = c(y_i)$.

Unfortunately, this MIP has exponentially many constraints. Nemhauser and Wolsey (1981) proposed the following constraint generation algorithm: Let $\alpha^{\mathcal{A}}$ denote an assignment to $\alpha_1, \ldots, \alpha_n$ such that $\alpha_i = 1$ iff $y_i \in \mathcal{A}$. Starting with no constraints of type (7), the MIP is solved, and one checks whether the current solution $(\eta, \alpha^{\mathcal{B}})$ satisfies $\eta \leq \mathrm{MI}(\mathcal{B})$. If it does not, a violated constraint has been found. Since solving individual instances (even with only polynomially many constraints) is NP-hard, we need to resort to search heuristics such as Branch and Bound and Cut during the constraint generation process.

The analysis of this MIP, as presented by Nemhauser and Wolsey (1981), assumes monotonicity. In the case of mutual information, the objective is only approximately monotonic. In particular, consider a a placement defined by $\alpha^{\mathcal{A}}$. Then, by submodularity, for all $\mathcal{B}$, we have that:

$$\begin{aligned}
\mathrm{MI}(\mathcal{B}) + \sum_{y_i \in \mathcal{S}\setminus\mathcal{B}} \alpha_i^{\mathcal{A}} [\mathrm{MI}(\mathcal{B}\cup y_i) - \mathrm{MI}(\mathcal{B})] &= \mathrm{MI}(\mathcal{B}) + \sum_{y_i \in \mathcal{A}\setminus\mathcal{B}} [\mathrm{MI}(\mathcal{B}\cup y_i) - \mathrm{MI}(\mathcal{B})], \\
&\geq \mathrm{MI}(\mathcal{A}\cup\mathcal{B}).
\end{aligned}$$

By approximate monotonicity:

$$\mathrm{MI}(\mathcal{A}\cup\mathcal{B}) \geq \mathrm{MI}(\mathcal{A}) - k\varepsilon.$$

Thus, $(\hat{\eta}, \alpha^{\mathcal{A}})$, for $\hat{\eta} \leq \mathrm{MI}(\mathcal{A}) - k\varepsilon$ is a feasible solution for the mixed integer program. Since we are maximizing η, for the optimal solution $(\eta^*, \alpha^{\mathcal{A}^*})$ of the MIP it holds that

$$\mathrm{MI}(\mathcal{A}^*) \geq \mathrm{OPT} - k\varepsilon.$$

There is another MIP formulation for maximizing general submodular functions without the ε-monotonicity requirement. The details can be found in Nemhauser and Wolsey (1981). We however found this formulation to produce much looser bounds, and to take much longer to converge.

5. Scaling Up

Greedy updates for both entropy and mutual information require the computation of conditional entropies using Equation (5), which involves solving a system of $|\mathcal{A}|$ linear equations. For entropy maximization, where we consider $H(y \mid \mathcal{A})$ alone, the complexity of this operation is $O(k^3)$. To maximize the mutual information, we also need $H(y \mid \bar{\mathcal{A}})$ requiring $O(n^3)$, for $n = |\mathcal{V}|$. Since we need to recompute the score of all possible locations at every iteration of Algorithm 1, the complexity of our greedy approach for selecting k sensors is $O(kn^4)$, which is not computationally feasible for very fine discretizations (large n). In Section 5.1 we propose a lazy strategy which often allows to reduce the number of evaluations of the greedy rule, thereby often reducing the complexity to $O(kn^3)$. In Section 5.2 we present a way of exploiting the problem structure by using local kernels, which often reduces the complexity to $O(kn)$. Both approaches can be combined for even more efficient computation.

5.1 Lazy Evaluation Using Priority Queues

It is possible to improve the performance of Algorithm 1 directly under certain conditions by lazy evaluation of the incremental improvements in Line 1. A similar algorithm has been proposed by Robertazzi and Schwartz (1989) in the context of D-optimal design. At the start of the algorithm, all δ_y will be initialized to $+\infty$. The algorithm will maintain information about which δ_y are current, that is, have been computed for the current locations $\mathcal{A}$. Now, the greedy rule in Line 2 will find the node y largest δ_y. If this δ_y has not been updated for the current $\mathcal{A}$, the value is updated and reintroduced into the queue. This process is iterated until the location with maximum δ_y is has an updated value. The algorithm is presented in Algorithm 2. The correctness of this lazy procedure directly follows from submodularity: For a fixed location y, the sequence δ_y must be monotonically decreasing during course of the algorithm.

To understand the efficacy of this procedure, consider the following intuition: If a location y^* is selected, nearby locations will become significantly less desirable and their marginal increases δ_y will decrease significantly. When this happens, these location will not be considered as possible maxima for the greedy step for several iterations. This approach can save significant computation time—we have noticed a decrease of mutual information computations by a factor of six in our experiments described in Section 9.6.

This approach can be efficiently implemented by using a priority queue to maintain the advantages δ_y. Line 2 calls **deletemax** with complexity $O(\log n)$ and Line 3 uses the **insert** operation with com-

Input: Covariance matrix $\Sigma_{\mathcal{V}\mathcal{V}}$, k, $\mathcal{V} = \mathcal{S} \cup \mathcal{U}$
Output: Sensor selection $\mathcal{A} \subseteq \mathcal{S}$
begin
  $\mathcal{A} \leftarrow \emptyset$;
  foreach $y \in \mathcal{S}$ **do** $\delta_y \leftarrow +\infty$;
  for $j = 1$ **to** k **do**
1 **foreach** $y \in \mathcal{S} \setminus \mathcal{A}$ **do** $current_y \leftarrow$ **false**;
  while true do
2 $y^* \leftarrow \text{argmax}_{y \in \mathcal{S} \setminus \mathcal{A}} \delta_y$;
  if $current_{y^*}$ **then break**;
3 $\delta_{y^*} \leftarrow H(y \mid \mathcal{A}) - H(y \mid \bar{\mathcal{A}})$;
  $current_{y^*} \leftarrow$ **true**
  $\mathcal{A} \leftarrow \mathcal{A} \cup y^*$;
end

Algorithm 2: Approximation algorithm for maximizing mutual information efficiently using lazy evaluation.

plexity $O(1)$. Also, as stated Line 1 has an $O(n)$ complexity, and was introduced for simplicity of exposition. In reality, we annotate the δ_y's with the last iteration that they were updated, completely eliminating this step.

5.2 Local Kernels

In this section, we exploit locality in the kernel function to speed up the algorithm significantly: First, we note that, for many GPs, correlation decreases exponentially with the distance between points. Often, variables which are far apart are actually independent. These weak dependencies can be modeled using a covariance function $\mathcal{K}$ for which $\mathcal{K}(x,\cdot)$ has compact support, that is, that has non-zero value only for a small portion of the space. For example, consider the following isotropic covariance function proposed by Storkey (1999):

$$\mathcal{K}(x,y) = \begin{cases} \frac{(2\pi-\Delta)(1+(\cos\Delta)/2)+\frac{3}{2}\sin\Delta}{3\pi}, & \text{for } \Delta < 2\pi, \\ 0, & \text{otherwise,} \end{cases} \tag{9}$$

where $\Delta = \beta\|x-y\|_2$, for $\beta > 0$. This covariance function resembles the Gaussian kernel $\mathcal{K}(x,y) = \exp(-\beta\|x-y\|_2^2/(2\pi))$ as shown in Figure 8, but is zero for distances larger than $2\pi/\beta$.

Even if the covariance function does not have compact support, it can be appropriate to compute $H(y \mid \tilde{\mathcal{B}}) \approx H(y \mid \mathcal{B})$ where $\tilde{\mathcal{B}}$ results from removing all elements x from $\mathcal{B}$ for which $|\mathcal{K}(x,y)| \leq \varepsilon$ for some small value of ε. This truncation is motivated by noting that:

$$\sigma^2_{y|\mathcal{B}\setminus x} - \sigma^2_{y|\mathcal{B}} \leq \frac{\mathcal{K}(y,x)^2}{\sigma_x^2} \leq \frac{\varepsilon^2}{\sigma_x^2}.$$

This implies that the decrease in entropy $H(y \mid \mathcal{B}\setminus x) - H(y \mid \mathcal{B})$ is at most $\varepsilon^2/(\sigma^2\sigma_x^2)$ (using a similar argument as the one in the proof of Lemma 5), assuming that each sensor has independent Gaussian

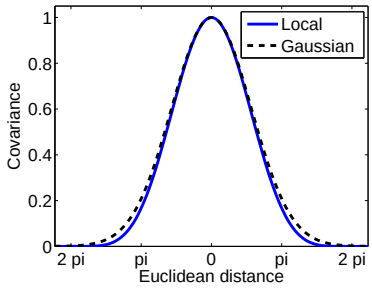


Figure 8: Comparison of local and Gaussian kernels.

Input: Covariance $\Sigma_{\mathcal{V}\mathcal{V}}$, k, $\mathcal{V} = \mathcal{S} \cup \mathcal{U}, \varepsilon > 0$
Output: Sensor selection $\mathcal{A} \subseteq \mathcal{S}$
begin
  $\mathcal{A} \leftarrow \emptyset$;
  foreach $y \in \mathcal{S}$ **do**
1 $\delta_y \leftarrow H(y) - \tilde{H}_\varepsilon(y \mid \mathcal{V} \setminus y)$;
  for $j = 1$ **to** k **do**
2 $y^* \leftarrow \arg\max_y \delta_y$;
  $\mathcal{A} \leftarrow \mathcal{A} \cup y^*$;
  foreach $y \in N(y^*; \varepsilon)$ **do**
3 $\delta_y \leftarrow \tilde{H}_\varepsilon(y \mid \mathcal{A}) - \tilde{H}_\varepsilon(y \mid \bar{\mathcal{A}})$;
end

Algorithm 3: Approximation algorithm for maximizing mutual information using local kernels.

measurement error of at least σ^2. The total decrease of entropy $H(y \mid \tilde{\mathcal{B}}) - H(y \mid \mathcal{B})$ is bounded by $n\varepsilon^2/\sigma^4$. This truncation allows to compute $H(y \mid \bar{\mathcal{A}})$ much more efficiently, at the expense of this small absolute error. In the special case of isotropic kernels, the number d of variables x with $\mathcal{K}(x,y) > \varepsilon$ can be computed as a function of the discretization and the covariance kernel. This reduces the complexity of computing $H(y \mid \bar{\mathcal{A}})$ from $O(n^3)$ to $O(d^3)$, which is a constant.

Our truncation approach leads to the more efficient optimization algorithm shown in Algorithm 3. Here, $\tilde{H}_\varepsilon$ refers to the truncated computation of entropy as described above, and $N(y^*; \varepsilon) \leq d$ refers to the set of elements $x \in \mathcal{S}$ for which $|\mathcal{K}(y^*, x)| > \varepsilon$. Using this approximation, our algorithm is significantly faster: Initialization (Line 1) requires $O(nd^3)$ operations. For each one of the k iterations, finding the next sensor (Line 2) requires $O(n)$ comparisons, and adding the new sensor y^* can only change the score of its neighbors ($N(y^*; \varepsilon) \leq d$), thus Line 3 requires $O(d \cdot d^3)$ operations. The total running time of Algorithm 3 is $O(nd^3 + kn + kd^4)$, which can be significantly lower than the $O(kn^4)$ operations required by Algorithm 1. Theorem 9 summarizes our analysis:

Theorem 9 *Under the assumptions of Lemma 5, guaranteeing ε_1-approximate monotonicity and truncation parameter ε_2, Algorithm 3 selects $\mathcal{A} \subseteq \mathcal{S}$ such that*

$$\mathrm{MI}(\mathcal{A}) \geq (1 - 1/e)(\mathrm{OPT} - k\varepsilon_1 - 2kn\varepsilon_2/\sigma^4),$$

in time $O(nd^3 + nk + kd^4)$.

This approach can be efficiently implemented by using a priority queue to maintain the advantages δ_y. Using for example a Relaxed Heaps data structure, the running time can be decreased to $O(nd^3 + kd \log n + kd^4)$: Line 1 uses the **insert** operation with complexity $O(1)$, Line 2 calls **deletemax** with complexity $O(\log n)$, and Line 3 uses **delete** and **insert**, again with complexity $O(\log n)$. This complexity improves on Algorithm 3 if $d \log n \ll n$. This assumption is frequently met in practice, since d can be considered a constant as the size n of the sensing area grows. Of course, this procedure can also be combined with the lazy evaluations described in the previous section for further improvement in running time.

6. Robust Sensor Placements

In this section, we show how the mutual information criterion can be extended to optimize for placements which are robust against failures of sensor nodes, and against uncertainty in the model parameters. The submodularity of mutual information will allow us to derive approximation guarantees in both cases.

6.1 Robustness Against Failures of Nodes

As with any physical device, sensor nodes are susceptible to failures. For example, the battery of a wireless sensor can run out, stopping it from making further measurements. Networking messages containing sensor values can be lost due to wireless interference. In the following, we discuss how the presented approach can handle such failures. We associate with each location $y_i \in \mathcal{S}$ a discrete random variable Z_i such that $Z_i = 0$ indicates that a sensor placed at location y_i has failed and will not produce any measurements, and $Z_i = 1$ indicates that the sensor is working correctly. For a placement $\mathcal{A} \subset \mathcal{S}$, denote by $\mathcal{A}_{\mathbf{z}}$ the subset of locations $y_i \in \mathcal{A}$ such that $z_i = 1$, that is, the subset of functional sensors. Then, the robust mutual information

$$\mathrm{MI}_R(\mathcal{A}) = \mathbb{E}_{\mathbf{Z}}[\mathcal{A}_{\mathbf{z}}] = \sum_{\mathbf{z}} P(\mathbf{z}) \, \mathrm{MI}(\mathcal{A}_{\mathbf{z}}),$$

is an expectation of the mutual information for placement $\mathcal{A}$ where all possible failure scenarios are considered.

Proposition 10 $\mathrm{MI}_R(\mathcal{A})$ *is submodular and, under the assumptions of Lemma 5, approximately monotonic.*

Proof This is a straightforward consequence of the fact that the class of submodular functions are closed under taking expectations. The approximate monotonicity can be verified directly from the approximate monotonicity of mutual information. ■

Unfortunately, the number of possible failure scenarios grows exponentially in $|\mathcal{S}|$. However, if the Z_i are i.i.d., and the failure probability $P(Z_i = 0) = \theta$ is low enough, MI_R can be approximated well, for example, by only taking into account scenarios were none or at most one sensor fails. This simplification often works in practice (Lerner and Parr, 2001). These $|\mathcal{S}| + 1$ scenarios can easily

be enumerated. For more complex distributions over Z, or higher failure probabilities θ, one might have to resort to sampling in order to compute MI_R.

The discussion above presents a means for explicitly optimizing placements for robustness. However, we can show that even if we do not specifically optimize for robustness, our sensor placements will be inherently robust:

Proposition 11 (Krause et al., 2006) *Consider a submodular function $F(\cdot)$ on a ground set $\mathcal{S}$, a set $\mathcal{B} \subseteq \mathcal{S}$, and a probability distribution over subsets $\mathcal{A}$ of $\mathcal{B}$ with the property that, for some constant ρ, we have $\Pr[v \in \mathcal{A}] \geq \rho$ for all $v \in \mathcal{B}$. Then $\mathbb{E}[F(\mathcal{A})] \geq \rho F(\mathcal{B})$.*

When applying this proposition, the set $\mathcal{B}$ will correspond to the selected sensor placement. The (randomly chosen) set $\mathcal{A}$ denotes the set of fully functioning nodes. If each node fails independently with probability $1-\rho$, that implies that $\Pr[c \in \mathcal{A}] \geq \rho$, and hence the expected mutual information of the functioning nodes, $\mathbb{E}[\mathrm{MI}(\mathcal{A})]$, is at least ρ times the mutual information $\mathrm{MI}(\mathcal{B})$, that is, when no nodes fail. Proposition 11 even applies if the node failures are not independent, but for example are spatially correlated, as can be expected in practical sensor placement scenarios.

6.2 Robustness Against Uncertainty in the Model Parameters

Often, the parameters θ of the GP prior, such as the amount of variance and spatial correlation in different areas of the space, are not known. Consequently, several researcher (Caselton et al., 1992; Zimmerman, 2006; Zhu and Stein, 2006) have proposed approaches to explicitly address the uncertainty in the model parameters, which are discussed in Section 7.

We want to exploit submodularity in order to get performance guarantees on the placements. We take a Bayesian approach, and equip θ with a prior. In this case, the objective function becomes

$$\mathrm{MI}_M(\mathcal{A}) = \mathbb{E}_\theta[I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A} \mid \theta)] = \int p(\theta) I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A} \mid \theta) d\theta.$$

Since the class of submodular functions is closed under expectations, MI_M is still a submodular function. However, the approximate monotonicity requires further assumptions. For example, if the discretization meshwidth is fine enough to guarantee approximate monotonicity for all values of θ for which $p(\theta) > 0$, then approximate monotonicity still holds, since

$$\begin{aligned}\mathrm{MI}_M(\mathcal{A} \cup y) - \mathrm{MI}_M(\mathcal{A}) &= \int p(\theta)[I(\mathcal{A} \cup y; \mathcal{V} \setminus (\mathcal{A} \cup y) \mid \theta) - I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A} \mid \theta)] d\theta \\ &\geq \int p(\theta)[-\varepsilon] d\theta = -\varepsilon.\end{aligned}$$

A weaker assumption also suffices: If there exists a (nonnegative) function $\eta(\theta)$ such that $I(\mathcal{A} \cup y; \mathcal{V} \setminus (\mathcal{A} \cup y) \mid \theta) - I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A} \mid \theta) \geq -\eta(\theta)$, and $\int p(\theta)[-\eta(\theta)] d\theta \geq -\varepsilon$, then MI_M is still ε-approximately monotonic. Such a function would allow the level ε of ε-approximately monotonicity to vary for different values of θ.

Note that in this setting however, the predictive distributions (1) and (2) cannot be computed in closed form anymore, and one has to resort to approximate inference techniques (cf. Rasmussen and Williams, 2006).

The advantage of exploiting submodularity for handling uncertainty in the model parameters is that the offline and online bounds discussed in Section 4.4 still apply. Hence, contrary to existing work, our approach provides strong theoretical guarantees on the achieved solutions.

7. Related Work

There is a large body of work related to sensor placement, and to the selection of observations for the purpose of coverage and prediction. Variations of this problem appear in spatial statistics, active learning, and experimental design. Generally, the methods define an objective function (Section 7.1), such as area coverage or predictive accuracy, and then apply a computational procedure (Section 7.2) to optimize this objective function. We also review related work on extensions to this basic scheme (Section 7.3), the related work in Machine Learning in particular (Section 7.4), and our previous work in this area (Section 7.5).

7.1 Objective Functions

We distinguish *geometric* and *model-based* approaches, which differ according to their assumptions made about the phenomenon to be monitored.

7.1.1 GEOMETRIC APPROACHES

Geometric approaches do not build a probabilistic model of the underlying process, but instead use geometric properties of the space in which the process occurs. The goal is typically a sensor placement that covers the space. The most common approaches for optimizing sensor placements using geometric criteria assume that sensors have a fixed region (cf. Hochbaum and Maas, 1985; Gonzalez-Banos and Latombe, 2001; Bai et al., 2006). These regions are usually convex or even circular. Furthermore, it is assumed that everything within this region can be perfectly observed, and everything outside cannot be measured by the sensors. In Section 8.1, we relate these geometric approaches to our GP-based formulation.

In the case where the sensing area is a disk (the *disk model*), Kershner (1939) has shown that an arrangement of the sensors in the centers of regular hexagons is asymptotically optimal, in the sense that a given set is fully covered by uniform disks. In Section 9.3, we experimentally show that when we apply the disk model to nonstationary placement problems, as considered in this paper, the geometric disk model approach leads to worse placements in terms of prediction accuracy, when compared to model-based approaches.

If many sensors are available then one can optimize the deployment density instead of the placement of individual sensors (Toumpis and Gupta, 2005). The locations of placed sensors are then assumed to be randomly sampled from this distribution. In the applications we consider, sensors are quite expensive, and optimal placement of a small set of them is desired.

7.1.2 MODEL-BASED APPROACHES

This paper is an example of a model-based method, one which takes a model of the world (here, a GP) and places sensors to optimize a function of that model (here, mutual information).

Many different objective functions have been proposed for model-based sensor placement. In the statistics community, classical and Bayesian experimental design focused on the question of selecting observations to maximize the quality of parameter estimates in linear models (cf. Atkinson, 1988; Lindley, 1956). In spatial statistics, information-theoretic measures, notably entropy, have been frequently used (Caselton and Hussain, 1980; Caselton and Zidek, 1984; Caselton et al., 1992; Shewry and Wynn, 1987; Federov and Mueller, 1989; Wu and Zidek, 1992; Guttorp et al., 1992). These objectives minimize the uncertainty in the prediction, after the observations are made.

Classical Experimental Design Criteria. In the statistics literature, the problem of optimal experimental design has been extensively studied (cf. Atkinson, 1988, 1996; Pukelsheim, 1987; Boyd and Vandenberghe, 2004). The problem commonly addressed there is to estimate the parameters θ of a function,

$$y = f_\theta(\mathbf{x}) + w,$$

where w is normally distributed measurement noise with zero mean and variance σ^2, y a scalar output and $\mathbf{x}$ a vectorial input. The assumption is, that the input $\mathbf{x}$ can be selected from a menu of design options, $\{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$. Each input corresponds to a possible experiment which can be performed. In our sensor placement case, one $\mathbf{x}$ would be associated with each location, y would be the measurement at the location, and θ would correspond to the values of the phenomenon at the unobserved locations. Usually, the assumption is that f_θ is linear, that is, $y = \theta^T \mathbf{x} + w$.

For the linear model $y = \theta^T \mathbf{x} + w$, if all n observations were available, then

$$\begin{aligned} \mathrm{Var}(\hat{\theta}) &= \sigma^2 (X^T X)^{-1} \\ \mathrm{Var}(\hat{y}_i) &= \sigma^2 \mathbf{x}_i^T (X^T X)^{-1} \mathbf{x}_i, \end{aligned} \tag{10}$$

where X is the design matrix, which consists of the inputs $\mathbf{x}_1, \ldots, \mathbf{x}_n$ as its rows. We can see that the variance of both the parameter estimate $\hat{\theta}$ and the predictions $\hat{y}_i$ depends on the matrix $M = (X^T X)^{-1}$, which is called the inverse moment matrix. If this matrix is "small", then the parameter estimates and predictions will be accurate. A design consists of a selection $\mathcal{A}$ of the inputs (with repetitions allowed). We write $\mathcal{X}_\mathcal{A}$ to denote the selected experiments, and $M_\mathcal{A}$ for the corresponding inverse moment matrix. Classical experimental design considers different notions of "smallness" for this inverse moment matrix $M_\mathcal{A}$; D-optimality refers to the determinant, A-optimality to the trace and E-optimality to the spectral radius (the maximum eigenvalue). There are several more scalarizations of the inverse moment matrix, and they are commonly referred to as "alphabetical" optimality criteria.

An example of the relationship between this formalism and sensor placements in GPs, as well as experimental comparisons, are presented in Section 9.5.

Equation (10) shows that the distribution of the test data is not taken into account, when attempting to minimizing the inverse moment matrix $M_\mathcal{A}$. Yu et al. (2006) extend classical experimental design

to the transductive setting, which takes the distribution of test data into account. The information-theoretic approaches, which we use in this paper, also directly take into account the unobserved locations, as they minimize the uncertainty in the posterior $P(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathcal{X}_{\mathcal{A}})$.

Bayesian Design Criteria. Classical experimental design is a Frequentist approach, which attempts to minimize the estimation error of the maximum likelihood parameter estimate. If one places a prior on the model parameters, one can formalize a Bayesian notion of experimental design. In its general form, Bayesian experimental design was pioneered by Lindley (1956). The users encode their preferences in a utility function $U(P(\Theta), \theta^\star)$, where the first argument, $P(\Theta)$, is a distribution over states of the world (i.e., the parameters) and the second argument, $\theta^\star$, is the true state of the world. Observations $\mathbf{x}_{\mathcal{A}}$ are collected, and the change in expected utility under the prior $P(\Theta)$ and posterior $P(\Theta \mid \mathcal{X}_{\mathcal{A}} = \mathbf{x}_{\mathcal{A}})$ can be used as a design criterion. By using different utility functions, Bayesian versions of *A*-, *D*-, and *E*- optimality can be developed (Chaloner and Verdinelli, 1995). If we have the posterior covariance matrix $\Sigma_{\theta|A}$, whose maximum eigenvalue is $\lambda_{\max}$, then Bayesian *A*-, *D*-, and *E*- optimality minimizes $\mathrm{tr}\left(\Sigma_{\theta|A}\right)$, $\det\left(\Sigma_{\theta|A}\right)$, and $\lambda_{\max}\left(\Sigma_{\theta|A}\right)$, respectively.

Usually, Bayesian experimental design considers the task of parameter estimation (Sebastiani and Wynn, 2000; Paninski, 2005; Ylvisaker, 1975). Lindley (1956) suggested using negative Shannon information, which is equivalent to maximizing the expected Kullback-Leibler divergence between the posterior and prior over the parameters:

$$\int P(\mathbf{x}_{\mathcal{A}}) \int P(\theta \mid \mathbf{x}_{\mathcal{A}}) \log \frac{P(\theta \mid \mathbf{x}_{\mathcal{A}})}{P(\theta)} \, d\theta d\mathbf{x}_{\mathcal{A}}. \tag{11}$$

If we consider distributions $P(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}})$ over the unobserved locations $\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}}$ instead of distributions over parameters $P(\Theta)$, (11) leads to the following criterion:

$$\int P(\mathbf{x}_{\mathcal{A}}) \int P(\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathbf{x}_{\mathcal{A}}) \log \frac{P(\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathbf{x}_{\mathcal{A}})}{P(\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}})} \, d\mathbf{x}_{\mathcal{V}\setminus\mathcal{A}} d\mathbf{x}_{\mathcal{A}}. \tag{12}$$

Note that Equation (12) is exactly the mutual information between the observed and unobserved sensors, $I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A})$. For a linear-Gaussian model, where the mean and covariance are known, we get the mutual information criterion of Caselton and Zidek (1984), which we use in this paper.

Information-Theoretic Criteria. The special case of Bayesian experimental design, where an information-theoretic functional (such as entropy or mutual information) is used as a utility function, and where the predictive uncertainty in the unobserved variables is concerned (as in Equation 12) is of special importance for spatial monitoring.

Such information-theoretic criteria have been used as design criteria in a variety of fields and applications. Maximizing the entropy $H(\mathcal{A})$ of a set of observations, as discussed in Section 3, has been used in the design of computer experiments (Sacks et al., 1989; Currin et al., 1991), function interpolation (O'Hagan, 1978) and spatial statistics (Shewry and Wynn, 1987). This criterion is sometimes also referred to as D-optimality, since the scalarization of the posterior variance in the spatial literature and the scalarization of the parameter variance in classical experimental design

both involve a determinant. In the context of parameter estimation in linear models and independent, homoscedastic noise, maximizing the entropy $H(\mathcal{A})$ is equivalent to Bayesian D-optimal design (which maximizes the information gain $H(\Theta) - H(\Theta \mid \mathcal{A})$ about the parameters), as discussed by Sebastiani and Wynn (2000) (see also Section 8.4).

Maximizing mutual information between sets of random variables has a long history of use in statistics (Lindley, 1956; Bernardo, 1979), machine learning (Luttrell, 1985; MacKay, 1992). The specific form addressed in this paper, $I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A})$, has been used in spatial statistics (Caselton and Zidek, 1984; Caselton et al., 1992). Mutual information requires an accurate estimate of the joint model $P(\mathcal{X}_{\mathcal{V}})$, while entropy only requires an accurate estimate at the selected locations, $P(\mathcal{X}_{\mathcal{A}})$. Caselton et al. (1992) argue that latter is easier to estimate from a small amount of data, thus arguing against mutual information. We however contend that nowadays effective techniques for learning complex nonstationary spatial models are available, such as the ones used in our experiments, thus mitigating these concerns and enabling the optimization of mutual information.

7.2 Optimization Techniques

All of the criteria discussed thus far yield challenging combinatorial optimization problems. Several approaches are used to solve them in the literature, which can be roughly categorized into those that respect the integrality constraint and those which use a continuous relaxation.

7.2.1 COMBINATORIAL SEARCH

For both geometric and model-based approaches, one must search for the best design or set of sensor locations among a very (usually exponentially) large number of candidate solutions. In a classical design, for example, the inverse moment matrix on a set of selected experiments $\mathcal{X}_{\mathcal{A}}$ can be written as

$$M_{\mathcal{A}} = \left(\sum_{i=1}^{n} k_i \mathbf{x}_i \mathbf{x}_i^T \right)^{-1},$$

where k_i is the number of times experiment $\mathbf{x}_i$ is performed in design $\mathcal{A}$. Since k_i must be an integer, a combinatorial number of potential experimental designs has to be searched. Similarly, when placing a set $\mathcal{A}$ of k sensors out of a set $\mathcal{V}$ of possible locations, as we do in this paper, all sets of size k have to be searched. For both entropy (Ko et al., 1995) and mutual information (this paper), this search has been shown to be NP-hard, hence efficient exact solutions are likely not possible.

Since exhaustive search is usually infeasible, local, heuristic searches without theoretical guarantees have commonly been applied. Approaches to the difficult combinatorial optimization include simulated annealing (Meyer and Nachtsheim, 1988), pairwise exchange (Fedorov, 1972; Mitchell, 1974a,b; Cook and Nachtsheim, 1980; Nguyen and Miller, 1992), forward and backward greedy heuristics (MacKay, 1992; Caselton and Zidek, 1984). All these approaches provide no guarantees about the quality of the solution. Since optimal solutions are highly desirable, branch-and-bound approaches to speed up the exhaustive search have been developed (Welch, 1982; Ko et al., 1995).

Although they enable exhaustive search for slightly larger problem instances, the computational complexity of the problems puts strong limits on their effectiveness.

By exploiting submodularity of mutual information, in this paper, we provide the first approach to information-theoretic sensor placement which has guarantees both on the runtime and on the quality of the achieved solutions.

7.2.2 CONTINUOUS RELAXATION

In some formulations, the integrality constraint is relaxed. For example, in classical experimental design, the number of experiments to be selected is often large compared to the number of design choices. In these cases, one can find a fractional design (i.e., a non-integral solution defining the proportions by which experiments should be performed), and round the fractional solutions. In the fractional formulation, A-, D-, and E-optimality criteria can be solved exactly using a semi-definite program (Boyd and Vandenberghe, 2004). There are however no known bounds on the integrality gap, that is, the loss incurred by this rounding process.

In other approaches (Seo et al., 2000; Snelson and Ghahramani, 2005), a set of locations is chosen not from a discrete, but a continuous space. If the objective function is differentiable with respect to these locations, gradient-based optimization can be used instead of requiring combinatorial search techniques. Nevertheless, optimality of the solution is not guaranteed since there is no known bound on the discrepancy between local and global optima.

Another method that yields a continuous optimization, in the case of geometric objective functions, is the potential field approach (Heo and Varshney, 2005; Howard et al., 2002). An energy criterion similar to a spring model is used. This optimization results in uniformly distributed (in terms of inter-sensor distances), homogeneous placements. The advantage of these approaches is that they can adapt to irregular spaces (such as hallways or corridors), where a simple grid-based deployment is not possible. Since the approach uses coordinate ascent, it can be performed using a distributed computation, making it useful for robotics applications where sensors can move.

7.3 Related Work on Extensions

In this section, we discuss prior work related to our extensions on sensor placement under model uncertainty (Section 6) and on the use of non-constant cost functions (Section 4.3).

7.3.1 PLACEMENT WITH MODEL UNCERTAINTY

The discussion thus far has focused on the case where the joint model $P(\mathcal{X}_\mathcal{V})$ is completely specified, that is, the mean and covariance of the GP are known.[2] With model uncertainty, one has to distinguish between observation selection for predictive accuracy in a fixed model and observation selection for learning parameters. Model uncertainty also introduces computational issues. If the mean and covariance are fixed in a Gaussian process then the posterior is Gaussian. This makes it

2. Or one assumes the uncertainty on these parameters is small enough that their contribution to the predictive uncertainty is negligible.

easy to compute quantities such as entropy and mutual information. If the mean and covariance are unknown, and we have to learn hyperparameters (e.g., kernel bandwidth of an isotropic process), then the predictive distributions and information-theoretic quantities often lack a closed form.

Caselton et al. (1992) extend their earlier work on maximum entropy sampling to the case where the mean and covariance are unknown by using a conjugate Bayesian analysis. The limitations of this approach are that the conjugate Bayesian analysis makes spatial independence assumptions in the prior and that complete data with repeated observations are required at every potential sensing site. This leads to a determinant maximization problem, much like *D*-optimality, that precludes the use of submodularity.

Another approach is the development of hybrid criteria, which balance parameter estimation and prediction. For example, Zimmerman (2006) proposes local EK-optimality, a linear combination of the maximum predictive variance and a scalarization of the covariance of the maximum likelihood parameter estimate. While this criterion selects observations which reduce parameter uncertainty and predictive uncertainty given the *current parameter*, it does not take into account the effect of parameter uncertainty on prediction error. To address this issue, Zhu and Stein (2006) derive an iterative algorithm which alternates between optimizing the design for covariance estimation and spatial prediction. This procedure does not provide guarantees on the quality of designs.

An alternative approach to addressing model uncertainty, in the context of classical experimental design, is presented by Flaherty et al. (2006). There, instead of committing to a single value, the parameters of a linear model are constrained to lie in a bounded interval. Their robust design objective, which is based on E-optimality, is then defined with respect to the worst-case parameter value. Flaherty et al. (2006) demonstrate how a continuous relaxation of this problem can be formulated as a SDP, which can be solved exactly. No guarantees are given however on the integrality gap on this relaxation.

In our approach, as discussed in Section 6, we show how submodularity can be exploited even in the presence of parameter uncertainty. We do not address the computational issues, which depend on the particular parameterization of the GP used. However, in special cases (e.g., uncertainty about the kernel bandwidth), one can apply sampling or numerical integration, and still get guarantees about the achieved solution.

7.3.2 NON-CONSTANT COST FUNCTIONS

In Section 4.3, we discuss the case where every sensor can have a different cost, and one has a budget which one can spend. An alternate approach to sensor costs is presented by Zidek et al. (2000). They propose a criterion that makes a trade off between achieved reduction in entropy using an entropy-to-cost conversion factor, that is, they optimize the sum of the entropy with a factor times the cost of the placements. This criterion yields an unconstrained optimization problem. Our approach to sensor costs (Section 4.3) yields a constrained optimization, maximizing our criteria given a fixed budget that can be spent when placing sensors. Such a budget-based approach seems more natural in real problems (where one often has a fixed number of sensors or amount of money to spend). Moreover, our approach provides strong a priori theoretical guarantees and tighter online bounds, which are not available for the approach of Zidek et al. (2000).

7.4 Related Work in Machine Learning

In Machine Learning, several related techniques have been developed for selecting informative features, for active learning and for speeding up GP inference.

7.4.1 FEATURE SELECTION AND DIMENSION REDUCTION

Given that the joint distribution of X_A and $X_{V \setminus A}$ is Gaussian, their mutual information is also

$$\mathrm{MI}(A) = -\frac{1}{2}\sum_i \log\left(1-\rho_i^2\right) \tag{13}$$

where $\rho_1^2 \geq \cdots \geq \rho_{|V|}^2$ are the canonical correlation coefficients between X_A and $X_{V \setminus A}$ (Caselton and Zidek, 1984). McCabe (1984) show that maximizing the canonical correlations between observed and unobserved variables can be interpreted as a form of principal components analysis, where one realizes that selecting subsets of variables is a special kind of linear projection. A similar analysis is presented for entropy and other common design criteria. Using Equation (13), a similar relationship can be made to canonical correlation analysis (CCA; Hotelling, 1936), which finds linear projections for $V \setminus A$ and A that maximize the correlations in the lower dimensional space. By considering these lower-dimensional projections, one can determine how much variance is shared (jointly explained) by $V \setminus A$ and A.

While dimension reduction techniques such as Principal Component Analysis (PCA) or CCA can be used to find a lower dimensional representation of a high dimensional problem, these techniques usually find projections which are non-sparse, that is, which are linear combinations of (almost) all input variables. However, for interpretation purposes (and considering data acquisition cost), one often desires *sparse* projections, which are linear combinations of only a small subset of input variables. Moghaddam et al. (2005) and Moghaddam et al. (2006) consider the problem of selecting such sparse linear projections (subject to a constraint on the number of nonzero entries) of minimum reconstruction error (for PCA) and class separation (for LDA). In order to find these sparse projections, they propose two approaches: A mixed integer program, which can solve the problem optimally—albeit generally not in polynomial time, and a heuristic approach, using a greedy forward search followed by a greedy backward elimination. They provide several theoretical bounds, including a guarantee that this backward greedy algorithm achieves a solution of at least $\frac{k}{n}\lambda_{\max}$ where $n = |V|$, and k is the number of chosen observations (Moghaddam, 2007).

7.4.2 ACTIVE LEARNING

In the machine learning community, information-theoretic criteria have been used for active learning, techniques which allow the learning algorithm to influence the choice of training samples. For example, information-theoretic criteria have been used in the analysis of query-by-committee to select samples (Sollich, 1996; Freund et al., 1997; Axelrod et al., 2001). Following Lindley (1956), MacKay (1992) proposes selecting observations that maximize expected information gain, either in terms of entropy or cross entropy, using Federov exchange. As opposed to this paper, which addresses the optimization problem, MacKay (1992) focuses on comparing the different objective

criteria. Cohn (1994) proposes scoring each potential observation by measuring the average reduction in predicted variance at a set of reference points. There is some evidence which suggests that this approach can improve prediction in Gaussian process regression (Seo et al., 2000). Common to all these active learning approaches, as well as to this paper, is the problem of selecting a set of most informative observation. Unlike this paper, we are not aware of any prior work in this area which provides rigorous approximation guarantees for this problem.

7.4.3 FAST GAUSSIAN PROCESS METHODS

Information-theoretic criteria are also used in sparse GP modeling, which attempts to reduce the cost of inference by selecting a representative subset of the training data. Sample selection criteria have included KL-divergence (Seeger et al., 2003) and entropy (Lawrence et al., 2003). In contrast to sensor placement, where locations are chosen to minimize predictive uncertainty, in sparse GP methods, the samples are chosen such that the approximate posterior matches the true posterior (which uses the entire training set) as accurately as possible. Instead of choosing a subset of the training data, Snelson and Ghahramani (2005) propose to optimize the location of a set of "hallucinated" inputs. This approach results in a continuous optimization problem, which appears to be easier to solve (albeit with no performance guarantees) than the discrete subset selection problem.

7.5 Relationship to Previous Work of the Authors

An earlier version of this paper appeared as (Guestrin et al., 2005). The present version is substantially extended by new experiments on nonstationarity (Section 9.3, Section 9.2) and comparisons to classical experimental design (Section 9.5). New are also the discussion of robust placements in Section 6 and several extensions in Section 4 and Section 5.

Additionally, Krause et al. (2006) presented an approximation algorithm for optimizing node placements for sensor networks using GPs that takes into account both the informativeness of placements (analogously to the discussion in this paper) and the communication cost required to retrieve these measurements. Their approach uses GPs both for modeling the monitored phenomenon as well as the link qualities of the sensor network. Singh et al. (2007) consider the case of planning informative paths for multiple robots. Here, the goal is to select observations which are both informative, but also lie on a collection of paths, one for each robot, of bounded length. They develop an approximation algorithm with theoretical guarantees on the quality of the solution. In the setting of Krause et al. (2006) and Singh et al. (2007)—unlike the case considered in this paper, where there are no constraints on the location of the sensors—the greedy algorithm performs arbitrarily badly, and the papers describe more elaborate optimization algorithms. In these algorithms, the submodularity of mutual information is again the crucial property which allows the authors to obtain approximation guarantees for their approach.

8. Notes on Optimizing Other Objective Functions

In this section, we discuss some properties of alternative optimality criteria for sensor placement.

8.1 A Note on the Relationship with the Disk Model

The disk model for sensor placement (cf. Hochbaum and Maas, 1985; Bai et al., 2006) assumes that each sensor can perfectly observe everything within a radius of r and nothing else. Hence we can associate with every location $y \in \mathcal{V}$ a sensing region D_y, which, for a discretization of the space, corresponds to the locations contained within radius r of location y. For a set of locations $\mathcal{A}$, we can define the coverage $F_D(\mathcal{A}) = \bigcup_{y \in \mathcal{A}} D_y$. It can be easily seen that this criterion is monotonic, submodular and $F(\emptyset) = 0$. Hence optimizing placements for the disk model criterion is a submodular maximization problem, and the greedy algorithm can guarantee a constant factor $(1 - 1/e)\,\mathrm{OPT}$ approximation guarantee for finding the placement of k sensors with maximum coverage.

There is a sense, in which the approach of sensor placements in GPs can be considered a generalization of the disk model. If we assume an isotropic GP with local kernel function as the one presented in Figure 8, then a sensor measurement is correlated exactly with the locations within a disk around its location. If the process has constant variance, then the greedy algorithm will, for the first few sensors placed, only try to achieve a disjoint placement of the disks, and as such behave just like the greedy algorithm for disk covering.

However, once enough sensors have been placed so that these "disks" start to overlap, the behavior of the two approaches begins to differ: in a disk model there is no advantage in placing sensors that lead to overlapping disks. In a GP model, even an isotropic one, "overlapping disks" lead to better predictions in the overlapping area, a very natural consequence of the representation of the uncertainty in the process.

8.2 A Note on Maximizing the Entropy

As noted by Ko et al. (1995), entropy is also a submodular set function, suggesting a possible application of the result of Nemhauser et al. (1978) to the entropy criterion. The corresponding greedy algorithm adds the sensor y maximizing $H(\mathcal{A} \cup y) - H(\mathcal{A}) = H(y \mid \mathcal{A})$. Unfortunately, our analysis of approximate monotonicity does not extend to the entropy case: Consider $H(y \mid \mathcal{A})$ for $\mathcal{A} = \{z\}$, for sufficiently small measurement noise σ^2, we show that $H(y \mid \mathcal{A})$ can become arbitrarily negative as the mesh width of the discretization decreases. Thus, (even approximate) monotonicity does not hold for entropy, suggesting that the direct application of the result of Nemhauser et al. (1978) is not possible. More precisely, our negative result about the entropy criterion is:

Remark 12 *Under the same assumptions as in Lemma 5, for any $\varepsilon > 0$, there exists a mesh discretization width $\delta > 0$ such that for any discretization level δ', where $0 < \delta' \leq \delta$, entropy violates the monotonicity criterion by at least ε, if $\sigma^2 < \frac{1}{4\pi e}$.*

8.3 A Note on Maximizing the Information Gain

Another objective function of interest is the *information gain* of a sensor placement with respect to some distinguished variables of interest $\mathcal{U}$, that is, $\mathrm{IG}(\mathcal{A}) = I(\mathcal{A}; \mathcal{U}) = H(\mathcal{U}) - H(\mathcal{U} \mid \mathcal{A})$. Unfortunately, this objective function is *not* submodular, even in the case of multivariate normal distributions: Let $\mathcal{X} = (\mathcal{X}_1, \mathcal{X}_2, \mathcal{X}_3)$ be distributed according to a multivariate Gaussian with zero mean and

covariance

$$\Sigma = \begin{bmatrix} 2 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 2 \end{bmatrix}.$$

Let $\mathcal{U} = \{X_3\}$. Here, X_2 and X_3 are marginally independent. Thus, alone, X_2 provides no gain in information. However, X_2 does provide information about X_1. Thus, if we first place a sensor at position 1, placing a sensor at position 2 does help. More formally, $\mathrm{IG}(\{X_2\}) - \mathrm{IG}(\emptyset) = H(X_3) - H(X_3 \mid X_2) < H(X_3 \mid X_1) - H(X_3 \mid X_1, X_2) = \mathrm{IG}(\{X_1, X_2\}) - \mathrm{IG}(\{X_1\})$. Hence adding X_2 to the empty set achieves strictly less increase in information gain than adding X_2 to the singleton set containing X_1, contradicting the submodularity assumption.

Remark 13 *The information gain,* $\mathrm{IG}(\mathcal{A}) = I(\mathcal{A}; \mathcal{U})$ *is not submodular in* $\mathcal{A}$.

8.4 A Note on Using Experimental Design for Sensor Placement

As discussed in Section 7.1, the goal of classical experimental design is to find a set $\mathcal{A}$ of experimental stimuli $\{\mathbf{x}_1, \ldots, \mathbf{x}_k\}$ such that the parameter estimation error covariance $M_{\mathcal{A}} = (X_{\mathcal{A}}^T X_{\mathcal{A}})^{-1}$ is as small as possible, where $X_{\mathcal{A}}$ is a matrix containing the $\mathbf{x}_i$ as rows. The different optimality criteria vary in the criteria used for measuring the smallness of $M_{\mathcal{A}}$. Consider the case where the number p of parameters θ is greater than 1, as in the sensor placement setting, where θ are the uninstrumented locations. If we select less than p observations, that is, $|\mathcal{A}| \leq p$, then $(X_{\mathcal{A}}^T X_{\mathcal{A}})$ is not full rank, and $M_{\mathcal{A}}$ is infinite. Hence, for $|\mathcal{A}| < p$, all alphabetical optimality criteria are infinite. Consequently, the A-, D- and E-optimality criteria are infinite as well for all discrete designs $\mathcal{A}$ of size less than p, and hence two such designs are incomparable under these criteria. This incomparability implies that the greedy algorithm will have no notion of improvement, and cannot be used for optimizing discrete classical experimental designs. Hence, discrete classical design cannot be addressed using the concept of submodularity.[3]

In the case of Bayesian experimental design, the parameters are equipped with a prior, and hence the posterior error covariance will not be infinite. In this case however, none of Bayesian A-, D- and E-optimality can be optimized using the result by Nemhauser et al. (1978) in general:

- **Bayesian A-optimality.** Let $y = \theta^T X + w$ where $X = \begin{bmatrix} 1 & 1 & 2 \\ 1 & 2 & 1 \end{bmatrix}$. Also let $\theta = (\theta_1, \theta_2)$ as well as the noise $w = (w_1, w_2, w_3)$ have independent normal priors with mean 0 and variance 1. Then the joint distribution of (y, θ) is multivariate normal with mean 0 and covariance

$$\Sigma = \begin{bmatrix} 3 & 3 & 3 & 1 & 1 \\ 3 & 6 & 4 & 1 & 2 \\ 3 & 4 & 6 & 2 & 1 \\ 1 & 1 & 2 & 1 & 0 \\ 1 & 2 & 1 & 0 & 1 \end{bmatrix}.$$

3. Note that generally, GPs are infinite-dimensional objects, so using classical experimental design for finite linear models only makes limited sense for sensor placement, for example, if an appropriate discretization is chosen.

The goal of A-optimality is to maximally reduce the variance in the posterior distribution over θ, that is, we want to select $\mathcal{A} \subseteq \mathcal{V} = \{y_1, y_2, y_3\}$ in order to maximize $F(\mathcal{A}) = \mathrm{tr}(\Sigma_\theta) - \mathrm{tr}(\Sigma_{\theta|\mathcal{A}})$. Now, we can verify that $F(\{y_1,y_2,y_3\}) - F(\{y_1,y_2\}) \geq F(\{y_1,y_3\}) - F(\{y_1\})$, contradicting submodularity.

- **Bayesian D-optimality.** As shown, for example, by Sebastiani and Wynn (2000), in the case of Bayesian experimental design for linear regression with independent, homoscedastic noise, D-optimality is actually equivalent to the entropy criterion, that is, $\mathrm{argmax}_{|\mathcal{A}|\leq k} I(\Theta, \mathcal{A}) = \mathrm{argmax}_{|\mathcal{A}|\leq k} H(\mathcal{A})$. Hence, the same counterexample as in Section 8.2 shows, that, while Bayesian D-optimality is submodular in this case, it is arbitrarily non-monotonic, and hence the result of Nemhauser et al. (1978) does not apply. In the more general case of dependent, heteroscedastic noise, D-optimality is equivalent to the information gain criterion with $\mathcal{U} = \{\theta\}$ and the counterexample of Section 8.3 applies, contradicting submodularity.

- **Bayesian E-optimality.** Consider the case where $\theta = (\theta_1, \theta_2)$ equipped with a normal prior with zero mean and covariance $diag([1,1])$. Let $y_i = \theta^T \mathbf{x}_i + w$ where w is Gaussian noise with mean zero and variance ε. Let $\mathbf{x}_1 = (1,0)^T$ and $\mathbf{x}_2 = (0,1)^T$. In this setting, the goal of E-optimality is to maximize $F(\mathcal{A}) = \lambda_{\max}(\Sigma_\theta) - \lambda_{\max}(\Sigma_{\theta|\mathcal{A}})$. If we perform no experiment ($\mathcal{A} = \emptyset$), then the posterior error covariance, $\Sigma_{\theta|\mathcal{A}} = \Sigma_\theta$, and hence the maximum eigenvalue is 1. If we observe either y_1 or y_2, the largest eigenvalue is still $\lambda_{\max}(\Sigma_{\theta|x_\mathcal{A}}) = 1$, and hence $F(\emptyset) = F(\{y_1\}) = F(\{y_2\}) = 0$. But if we observe both y_1 and y_2, then $\lambda_{\max}(\Sigma_{\theta|\mathcal{A}}) = \frac{\varepsilon}{1+\varepsilon}$, and $F(\{y_1,y_2\}) > 0$. Hence $F(\{y_2,y_1\}) - F(\{y_1\}) > F(\{y_2\}) - F(\emptyset)$, that is, adding y_2 helps more if we add it to y_1 than if we add it to the empty set, contradicting submodularity.

Remark 14 *The analysis of Nemhauser et al. (1978) applies to neither of Bayesian A-, D-, and E-optimality in general.*

However, Das and Kempe (2008) show that in certain cases, under a condition of *conditional suppressor-freeness*, the variance reduction F (and hence Bayesian A-optimality) can indeed be shown to be submodular.

9. Experiments

We performed experiments on two real-world data sets, which are described in Section 9.1. In Section 9.2 we compare placements on stationary and nonstationary GP models. In Sections 9.3, 9.4 and 9.5 we compare mutual information with the disk model, with entropy and with other classical experimental design criteria, in terms of prediction accuracy. In 9.6 we compare the performance of the greedy algorithm with other heuristics, and in Section 9.7 we analyze the effect of exploiting local kernels.

9.1 Data Sets

We first introduce the data sets we consider in our experiments. In our first data set, we analyze temperature measurements from the network of 46 sensors shown in Figure 1(a). Our training data consisted of samples collected at 30 sec. intervals on 3 consecutive days (starting Feb. 28th 2004), the testing data consisted of the corresponding samples on the two following days.

Our second data set consists of precipitation data collected during the years 1949 - 1994 in the states of Washington and Oregon (Widmann and Bretherton, 1999). Overall 167 regions of equal area, approximately 50 km apart, reported the daily precipitation. To ensure the data could be reasonably modeled using a Gaussian process we applied a log-transformation, removed the daily mean, and only considered days during which rain was reported. After this preprocessing, we selected the initial two thirds of the data as training instances, and the remaining samples for testing purposes. From the training data, we estimated the mean and empirical covariance, and regularized it by adding independent measurement noise[4] of $\sigma^2 = 0.1$.

We computed error bars for the prediction accuracies in all of our experiments, but due to the violated independence of the collected samples (which are temporally correlated), these error bars are overconfident and hence not reported here. The estimated standard errors under the independence assumption are too small to be visible on the plots.

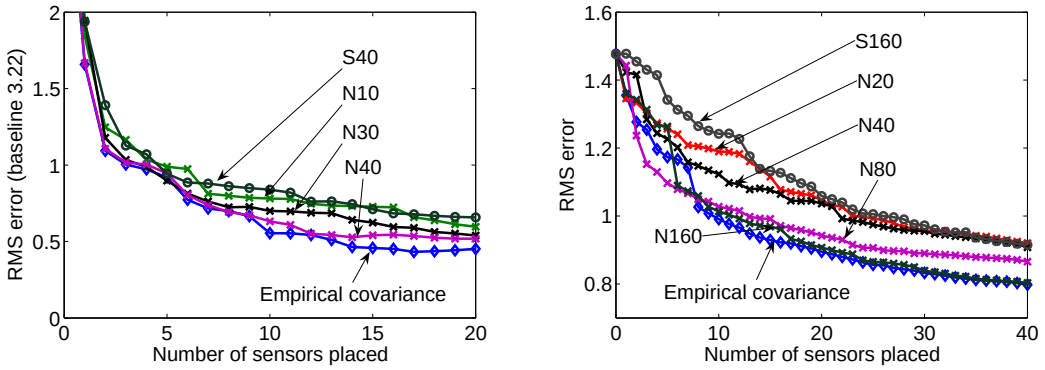
9.2 Comparison of Stationary and Non-stationary Models

To see how well both the stationary and nonstationary models capture the phenomenon, we performed the following experiment: We learned both stationary and non-stationary GP models from an increasing number of sensors. The model with stationary correlation function used an isotropic Exponential kernel with bandwidth fitted using least-squares fit of the empirical variogram (Cressie, 1991). We also learned a nonstationary GP using the technique from Nott and Dunsmuir (2002). Both GP models were estimated from an initial deployment of an increasing number of sensors. We used non-stationary the same variance process for both stationary and nonstationary models (i.e., giving more information to the stationary model than commonly done). Since with increasing amount of data, the empirical covariance matrix will exactly capture the underlying process, we consider the empirical covariance as the ground truth both for placements and prediction. Hence we also selected placements using the entire estimated covariance matrix.

We optimized the designs using mutual information on all the models. We evaluate the prediction accuracy for an increasing number of near-optimally placed sensors, using the estimated model and the measured values for the selected sensors. Figure 9(a) presents the results for the temperature data set. We can see that the nonstationary model learned from 10 sensors performs comparably to the stationary model with 40 sensors, even with non-stationary variance process. As we increase the number of sensors in the initial deployment, the Root Mean Squared error (RMS) prediction accuracies we get for placements of increasing size converge to those obtained for optimizing the placements based on the empirical covariance matrix.

Figure 9(b) presents the results of the same experiment for the precipitation data. Here we can see that the nonstationary model estimated using 20 sensors leads to better RMS accuracies than the stationary model, even if latter is estimated using 160 sensors.

4. The measurement noise σ^2 was chosen by cross-validation.



(a) *Comparison of fits for temperature data.* (b) *Comparison of fits for precipitation data.*

Figure 9: RMS curves for placements of increasing size, optimized using stationary and nonstationary GPs. Prediction is done using estimated models. (a) Stationary GP estimated for the temperature data from 40 sensors (S40), nonstationary GPs estimated from 10, 30 and 40 sensors (N10, N30, N40). (b) Stationary GP estimated for the precipitation data from 160 sensors (S160), nonstationary GPs estimated from 20, 40, 80 and 160 sensors (N20, N40, N80, N160).

9.3 Comparison of Data-driven Placements with Geometric Design Criteria

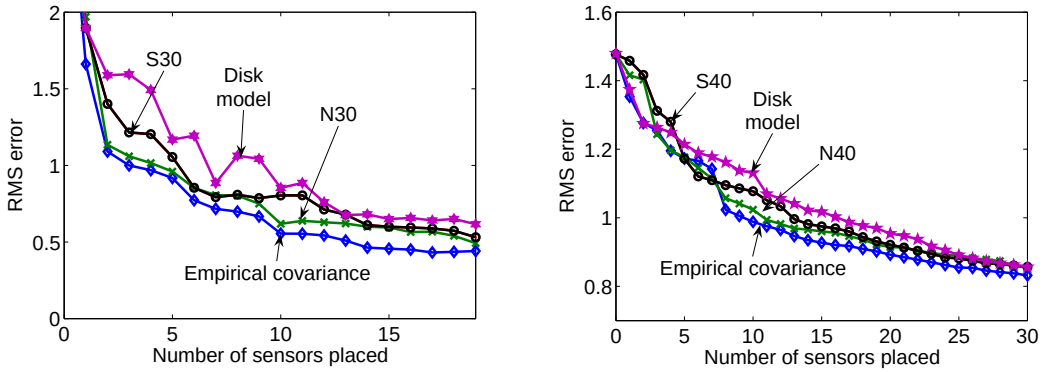
We now compare placements based on our data-driven GP models with those based on the traditional disk model. This model assumes that every sensor can perfectly measure the phenomenon within a radius of r, and have no information outside this radius. Since choosing an appropriate radius for the disk model is very difficult in practice, we decided to choose $r = 5m$ since for this radius 20 sensors could just spatially cover the entire space. We also learned stationary and non-stationary GP models as discussed in Section 9.2.

For the disk model, we used the greedy set covering algorithm. The design on both GP models was done using our greedy algorithm to maximize mutual information. For an increasing number of sensors, we compute the Root Mean Squares (RMS) prediction error on the test data. In order to separate the placement from the prediction task, we used the empirical covariance matrix estimated from the training data on all 46 locations for prediction, for all three placements.

Figure 10(a) presents the results of this experiment. We can see that the geometrical criterion performs poorly compared to the model based approaches. We can see that the placements based on the empirical covariance matrix perform best, quite closely followed by the accuracies obtained by the designs based on the nonstationary process. Figure 10(b) shows the results for the same experiment on the precipitation data set.

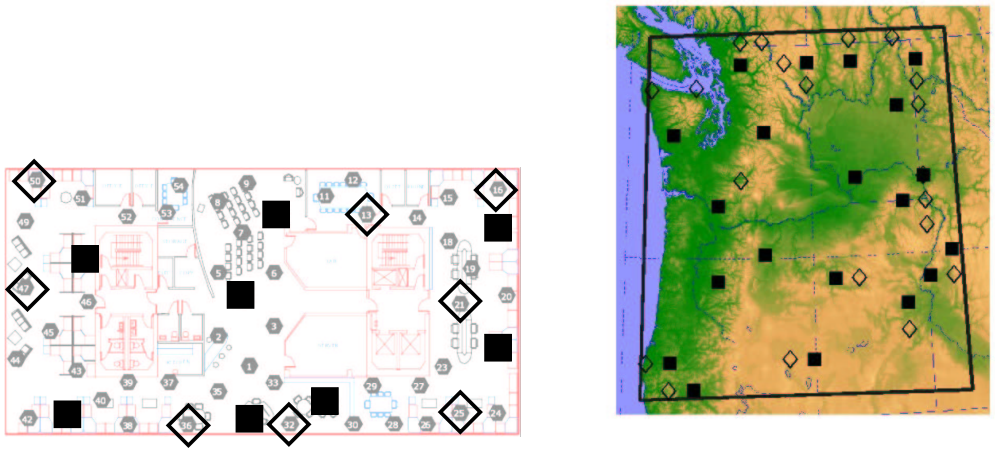
9.4 Comparison of the Mutual Information and Entropy Criteria

We also compared the mutual information criterion to other design criteria. We first compare it against the entropy (variance) criterion. Using the empirical covariance matrix as our process, we use the greedy algorithm to select placements of increasing size, both for mutual information and for entropy. Figure 12(a) and Figure 12(b) show the results of this comparison on models estimated



(a) *Comparison with disk model (Temperature)* (b) *Comparison with disk model (Precipitation)*

Figure 10: RMS curves for placements of increasing size, optimized using the disk model, stationary and nonstationary GPs. Prediction for all placements is done using the empirical covariance. Stationary GPs and nonstationary GPs estimated from 30 sensors (N30, S30, for temperature data) or 40 sensors (N40, S40, for precipitation data).



(a) *Placements of temperature sensors* (b) *Placements of rain sensors*

Figure 11: Example sensor placements for temperature and precipitation data. Squares indicate locations selected by mutual information, diamonds indicate those selected by entropy. Notice how entropy places sensors closer to the border of the sensing field.

for the morning (between 8 am and 9 am) and noon (between 12 pm and 1 pm) in the Intel lab data. Figure 12(a) and Figure 12(b) plot the log-likelihood of the test set observations with increasing number of sensors for both models. Figure 12(e) presents the RMS error for a model estimated for the entire day. We can see that mutual information in almost all cases outperforms entropy, achieving better prediction accuracies with a smaller number of sensors.

Figure 12(f) presents the same results for the precipitation data set. Mutual information significantly outperforms entropy as a selection criterion—often several sensors would have to be additionally placed for entropy to reach the same level of prediction accuracy as mutual information. Figure 11(b) shows where both objective values would place sensors to measure precipitation. It can be seen that entropy is again much more likely to place sensors around the border of the sensing area than mutual information.

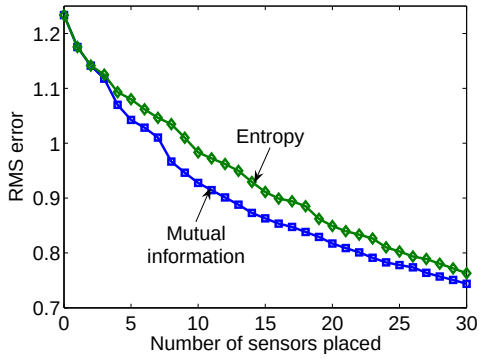
(e) *Entire day*



(f) *Precipitation RMS*

Figure 12: Prediction error and log-likelihood on test data for temperatures (a-e) and precipitation (f) in sensor network deployment, for an increasing number of sensors.

To gain further insight into the qualitative behavior of the selection criteria we learned a GP model using all sensors over one hour starting at noon. The model was fit with a isotropic Gaussian kernel and quadratic trend for the mean, using the *geoR* Toolkit (Ribeiro Jr. and Diggle, 2001). Fig-

ures 13(a) and 13(b) show the posterior mean and variance for the model. Using our algorithms, 22 sensors were chosen using the entropy and mutual information criteria. For each set of selected sensors, additional models were trained using only the measurements of the selected sensors. Predicted temperature surfaces for the entropy and mutual information configurations are presented in Figures 13(c) and 13(d). Entropy tends to favor placing sensors near the boundary as observed in Section 3, while mutual information tends to place the sensors on the top and bottom sides, which exhibited the most complexity and should have a higher sensor density. The predicted variances for each model are shown in figures 13(e) and 13(f). The mutual information version has significantly lower variance than the entropy version almost everywhere, displaying, as expected, higher variance in the unsensed areas in the center of the lab.

9.5 Comparison of Mutual Information with Classical Experimental Design Criteria

In order to compare the mutual information placements with the classical optimality criteria, we performed the following experiment. We uniformly selected 12 target locations $\mathcal{U}$ in the lab as locations of interest. We then set up the linear model

$$\mathbf{x}_{\mathcal{S}} = \Sigma_{\mathcal{S}\mathcal{U}}\Sigma_{\mathcal{U}\mathcal{U}}^{-1}\,\mathbf{x}_{\mathcal{U}} + \mathbf{w}.$$

Hereby, $\mathbf{x}_{\mathcal{S}}$ denotes measurements at the locations $\mathcal{S}$, among which we choose our placement, $\mathbf{x}_{\mathcal{U}}$ are the values at the locations of interest (no sensors can be placed there), and $\mathbf{w}$ models independent normal measurement noise with constant variance. After subtraction of the training set mean, this model uses the Best Linear Unbiased (Kriging) estimator for predicting $\mathbf{x}_{\mathcal{S}}$ from $\mathbf{x}_{\mathcal{U}}$.

The problem becomes to select the sensor locations $\mathcal{A} \subset \mathcal{S}$ which allow most precise prediction of the variables of interest, in the sense of minimizing the error covariance $\frac{1}{\sigma^2}(A^TA)^{-1}$, where $A = \Sigma_{\mathcal{S}\mathcal{U}}\Sigma_{\mathcal{U}\mathcal{U}}^{-1}$. The different classical design criteria vary in how the scalarization of the error covariance is done. D-optimal design minimizes the log-determinant, A-optimal design minimizes the trace, and E-optimal design minimizes the spectral radius (the magnitude of the largest eigenvalue) of the error covariance. Note that this problem formulation favors the classical design criteria, which are tailored to minimize the error of predicting the values at the target locations $\mathcal{U}$, whereas mutual information and entropy just try to decrease the uncertainty in the entire space.

In order to solve the classical experimental design problems, we use the formulations as a semidefinite program (SDP) as discussed by Boyd and Vandenberghe (2004). We use SeDuMi (Sturm, 1999) for solving these SDPs. Since the integral optimization is hard, we solve the SDP relaxation to achieve a fractional design. This fractional solution defines the best way to distribute an infinite (or very large) budget of experiments to the different choices on the design menu (the variables in $\mathcal{S}$). In the sensor selection problem however, we have to solve the integral problem, since we face the binary decision of whether a sensor should be placed at a particular location or not. This is a hard combinatorial optimization problem. Since no near-optimal solution is known, we select the locations corresponding to the top k coefficients of the design menu, as is common practice. We compare the placements using the classical design criteria to those using the mutual information and entropy criteria, and evaluate each of them on the RMS prediction accuracy on the hold-out locations $\mathcal{U}$.

Figure 13: Comparison of predictive quality of subsets selected using MI and entropy.

Figure 14(a) presents the results of this experiment on the temperature data. We can see that even though mutual information optimizes for prediction accuracy in the entire space and not specifically for the target locations $\mathcal{U}$, it incurs the least RMS prediction error, apart from the placements consisting only of a single sensor. E-optimal design performs comparably with the entropy criterion, and D- and A-optimality perform worse.

Figure 14: Comparison with classical experimental design. We plot RMS prediction error on 25% hold out target locations $\mathcal{U}$.

When we performed the same experiment with the precipitation data, SeDuMi ran out of memory (1 GB) for the SDP required to solve the A-optimality criterion. The largest subsample we could solve for all A-, D- and E-optimality on this data set was limited to 111 locations. Figure 14(b) presents the results. For the entire data set of 167 locations, we could still solve the D- and E-optimality SDPs. The results are presented in Figure 14(c). We can observe that for the 111 locations, D-optimality slightly outperforms mutual information. We have to consider, however, that the classical criteria are optimized to minimize the error covariance with respect to the locations $\mathcal{U}$ of interest, whereas mutual information merely tries to achieve uniformly low uncertainty over the entire space. For the full set of 167 locations, mutual information outperforms the other design criteria.

Figure 14(d) presents the running time for optimizing A-, D-, E-optimality, and mutual information, mutual information with truncation parameter $\varepsilon = 1$ and entropy on the 111 node subsample of the precipitation data on a Pentium M 1.7 GHz processor. We can see that optimizing entropy is fastest, closely followed by the truncated mutual information criterion described in Section 5.2 that is further evaluated in Section 9.7. Even without truncation, optimizing mutual information is three times faster than (fractionally) optimizing D-optimality and 24 times faster than A-optimality.

Figure 15: Comparison of the greedy algorithm with several heuristics.

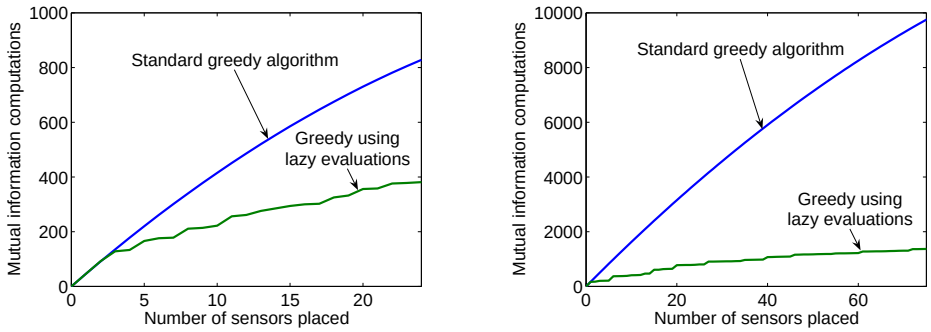
9.6 Empirical Analysis of the Greedy Algorithm

To study the effectiveness of the greedy algorithm, we compared the mutual information of the sets selected by our greedy algorithm to random selections, to a hill climbing method that uses a pairwise exchange heuristic, and—for small subsamples—to the bounds proved by the MIP as discussed in Section 4.5.

In this experiment, we used the empirical covariance matrix as the input to the algorithms. Figure 15(b) shows that the greedy algorithm provided significantly better results than the random selections, and even the maximum of a hundred random placements did not reach the quality of the greedy placements. Furthermore, we enhanced the random and greedy selections with the pairwise exchange (PE) heuristic, which iteratively finds exchanges of elements $y \in \mathcal{A}$ and $y' \in \mathcal{S} \setminus \mathcal{A}$ such that exchanging y and y' improves the mutual information score. Figure 15(a) presents objective values of these enhanced selection methods for a subset size of 12, for which the maximum over 100 random selections enhanced with PE actually exceeded the greedy score (unlike with most other subset sizes, where random + PE did about as well as the greedy algorithm). Typically, the objective values of random + PE, greedy + PE and greedy did not differ much. Note that as mentioned in Section 4, the performance guarantee for the greedy algorithm always provides an online approximation guarantee for the other heuristics.

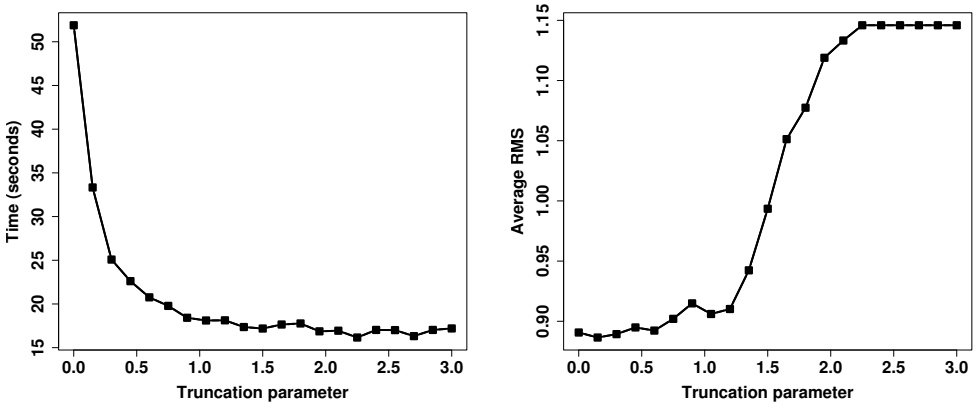
For a 16 node subsample of the temperature data set, we used the MIP from Section 4.5 to compute bounds on the optimal mutual information. Figure 5 presents the results. It can be seen, that for this small subsample, the greedy solution is never more than 5 percent away from the optimal solution, which is a much tighter bound than the a priori approximation factor of $(1-1/e)$.

We also experimented with the lazy evaluation strategy discussed in Section 5.1. For example when picking placements of size 50 for the precipitation data set, the number of mutual information computations decreased from 7125 to 1172, and the computation time on a Pentium M 1.7 GHz processor decreased from 41.3 seconds to 8.7 seconds. The results for both temperature and precipitation data sets are presented in Figures 16(a) and 16(b).



(a) *Temperature data* (b) *Precipitation data*

Figure 16: Performance improvements by using lazy evaluations of mutual information.



(a) *Running time* (b) *Approximation error*

Figure 17: Analysis of the experiments with local kernels. (a) running times for increasing level of truncation. (b) increase of average RMS error with increasing level of truncation. Note that for a truncation between 0.5 and 1.2, a good tradeoff between running time and error is achieved.

9.7 Results on Local Kernels

We also performed experiments to assess the running time versus quality trade-off incurred by using approximate local kernels. To provide intuition about the covariance structure, note that the 25, 50 and 75 percentiles of the absolute covariance entries were 0.122, 0.263 and 0.442, the maximum was 3.51, the minimum was $8.78E{-}6$. For the variance (the diagonal entries), the median was 1.70, and the minimum was 0.990. Figure 17(a) shows that the computation time can be drastically decreased as we increase the truncation parameter ε from 0 to the maximum variance. Figure 17(b) shows the RMS prediction accuracy for the 20 element subsets selected by Algorithm 3. According to the graphs, the range $\varepsilon \in [0.5, 1]$ seems to provide the appropriate trade-off between computation time and prediction accuracy.

In order to study the effect of local kernels on the placements, we performed the following experiment. We created a regular 7 by 7 grid with unit distance between neighboring grid points, and generated covariance matrices using two different GPs, one using the Gaussian (squared exponential) kernel, and the other using the local kernel (Equation 9). We exponentially increased the bandwidth in eight steps from 0.1 to 12.8. Figures 18 and 19 show the corresponding place-

ments using mutual information to select the locations. From this experiment, we can see that the placements obtained using the non-local Gaussian kernel tend to be spread out slightly more, as one might expect. Overall, however, the placements appear to be very similar. In light of the computational advantages provided by local kernels, these results provide further evidence in the spirit of Section 9.7, namely that local kernels can be a valuable tool for developing efficient model-based sensor placement algorithms.

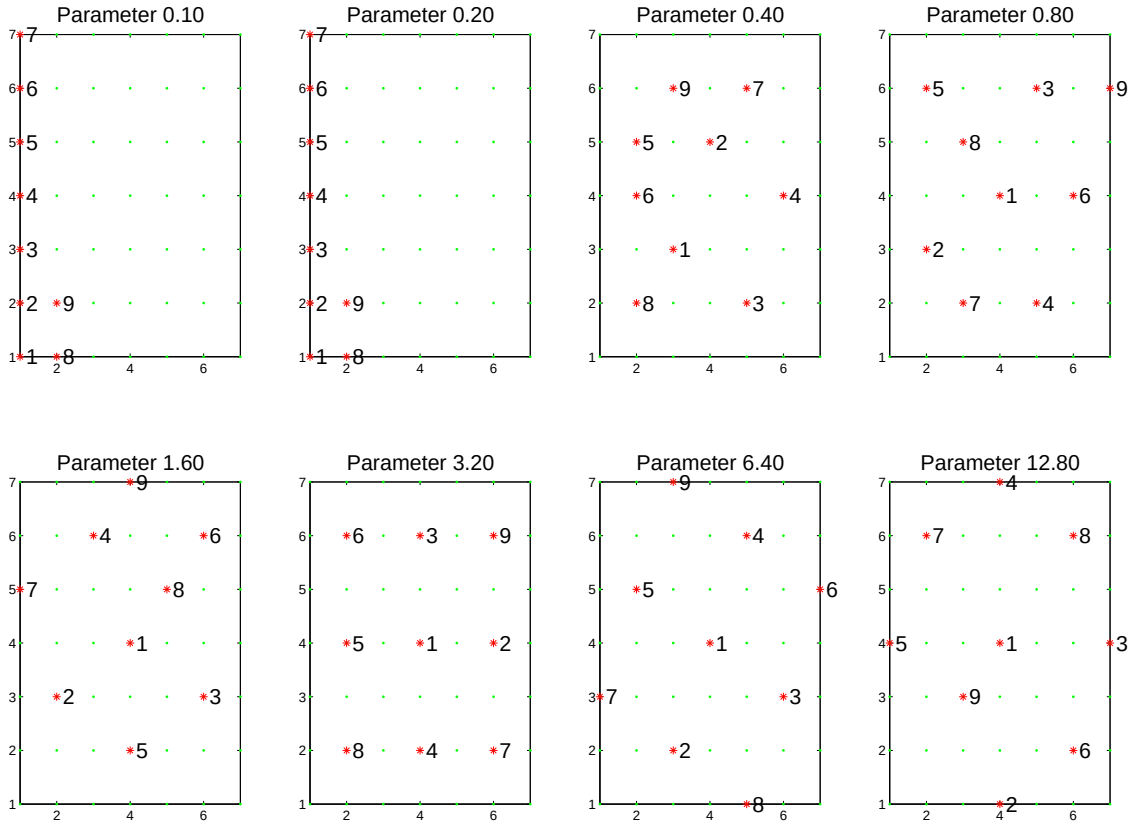


Figure 18: Placements under Gaussian kernel, mutual information criterion, increasing bandwidth

10. Future Work

There are several interesting possible extensions to the present work. Since the predictive variance in (2) does not depend on the actual observations, any closed-loop strategy which sequentially decides on the next location to measure, surprisingly, is equivalent to an open loop placement strategy which selects locations to make observations independently of the measured values. If there is uncertainty about the model parameters however, such as about the kernel bandwidths, then this is no longer true. In this case, we expect a sequential, closed-loop strategy to be more effective for predicting spatial phenomena. Krause and Guestrin (2007) present bounds comparing the performance of the optimal sequential strategy with the optimal fixed placement. This bound essentially depends on the

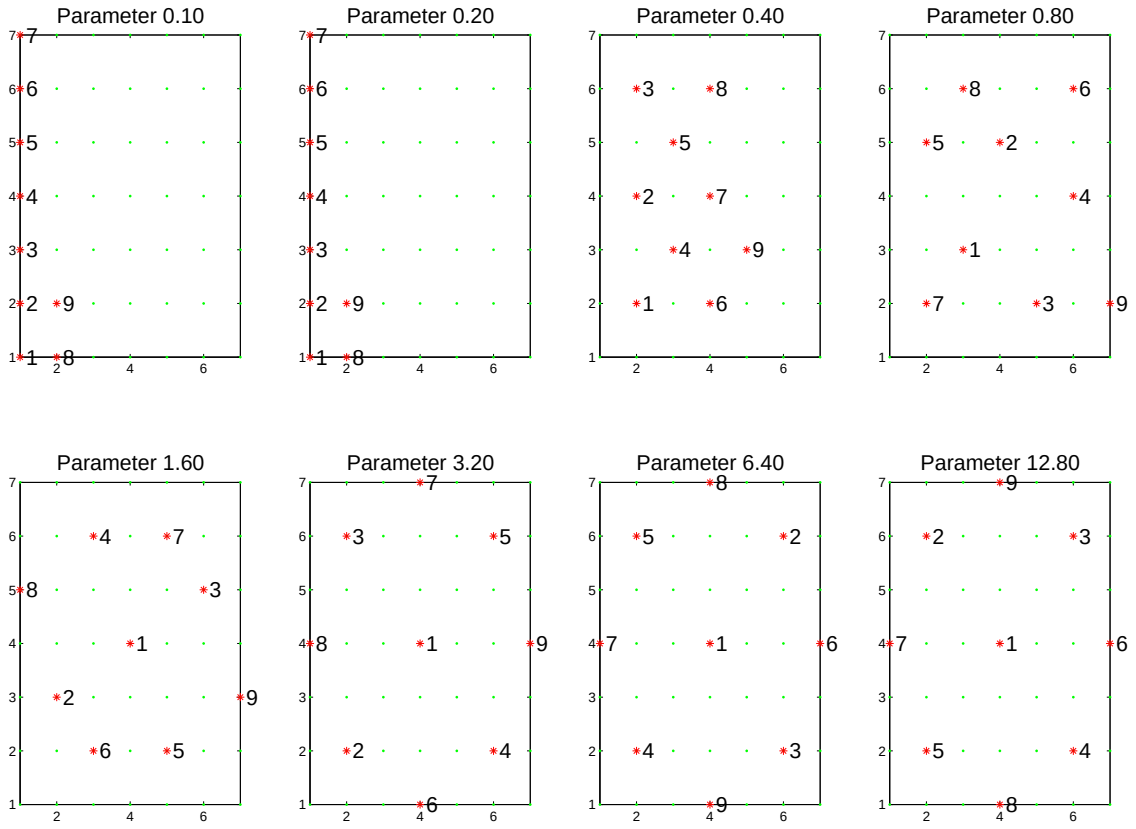

Figure 19: Placements under local kernel, mutual information criterion, increasing bandwidth

parameter entropy. We consider several exploration strategies for effectively reducing this parameter entropy and present sample complexity bounds. However, more work is needed in this area.

Another interesting open question is whether an approximation algorithm can be found for optimizing sensor placements subject to *submodular* cost functions—usually, the more sensors we have to buy, the cheaper they become per unit. To address this problem, Narasimhan and Bilmes (2006) present a submodular-supermodular procedure for bicriteria-optimization of a submodular function of which a submodular cost is subtracted. This procedure, while elegant, unfortunately can not provide approximation guarantees for this problem.

Of further interest are also constrained sensor placement problems, in which, for example, the placed sensors have to be connected in a routing tree, or have to lie on a collection of paths. Krause et al. (2006) provide evidence that submodularity can be leveraged to derive approximation algorithms for sensor placement even in these combinatorially even more challenging constrained optimization problems. However, there are still many open issues subject to further research.

11. Conclusions

In this paper, we tackle the problem of maximizing mutual information in order to optimize sensor placements. We prove that the exact optimization of mutual information is NP-complete, and provide an approximation algorithm that is within $(1-1/e)$ of the maximum mutual information configuration by exploiting the submodularity in the criterion. We also illustrate that submodularity can be used to obtain online bounds, which are useful for bounding the quality of the solutions obtained by any optimization method, and for designing branch and bound algorithms for the mutual information criterion. In order to scale up the application of our approach, show how to exploit lazy evaluations and local structure in GPs to provide significant speed-ups. We also extend our submodularity-based analysis of mutual information to incorporate robustness to sensor failures and model uncertainty.

Our very extensive empirical results indicate that data-driven placements can significantly improve the prediction accuracy over geometric models. We find, in contrast to previous work (Caselton et al., 1992; Zidek et al., 2000), that the mutual information criterion is often better than entropy and other classical experimental design criteria, both qualitatively and in prediction accuracy. In addition, the results show that a simple greedy algorithm for optimizing mutual information provides performance that is very close to the optimal solution in problems that are small enough to be solved exactly, and comparable to more complex heuristics in large problems.

We believe this work can be used to increase the efficacy of monitoring systems, and is a step towards well-founded active learning algorithms for spatial and structured data.

Appendix A. Proofs

Proof [Theorem 2] Our reduction builds on the proof by Ko et al. (1995), who show that for any graph G, there exists a polynomially related, symmetric positive-definite matrix Σ such that Σ has a subdeterminant (of a submatrix resulting from the selection of k rows and columns $i_1,\ldots,i_k$) greater than some M if G has a clique of size at least k, and Σ does not have a subdeterminant greater than $M-\varepsilon$ for some (polynomially-large) $\varepsilon > 0$ if G does not have such a clique. Let G be a graph, and let Σ be the matrix constructed in Ko et al. (1995). We will consider Σ as the covariance matrix of a multivariate Gaussian distribution with variables $\mathcal{X}_U = \{X_1,\ldots,X_n\}$. Introduce additional variables $\mathcal{X}_S = \{y_1,\ldots,y_n\}$ such that $y_i|X_i = x \sim \mathcal{N}(x,\sigma^2)$. Note that a subset

$\mathcal{A} \subseteq \mathcal{S}$, $|\mathcal{A}| = k$, has maximum entropy of all such subsets if and only if the parents $\Gamma_{\mathcal{A}} \subset \mathcal{U}$ of $\mathcal{A}$ have maximum entropy among all such subsets of $\mathcal{U}$. Now note that $I(\mathcal{A}; (\mathcal{U} \cup \mathcal{S}) \setminus \mathcal{A}) = H(\mathcal{A}) - H(\mathcal{A} \mid (\mathcal{U} \cup \mathcal{S}) \setminus \mathcal{A}) = H(\mathcal{A}) - H(\mathcal{A} \mid \mathcal{U})$, because y_i and y_j are conditionally independent given $\mathcal{U}$. Furthermore, again because of independence, $H(\mathcal{A} \mid \mathcal{U})$ is a constant only depending on the cardinality of $\mathcal{A}$. Assume we could decide efficiently whether there is a subset $\mathcal{A} \subset \mathcal{S}$ such that $I(\mathcal{A}; \mathcal{V} \setminus \mathcal{A}) \geq M'$. If we choose σ^2 small enough, then this would allow us to decide whether G has a clique of size k, utilizing the gap ε. ■

Proof [Lemma 5] Define $\hat{\mathcal{K}}(x,y) = \mathcal{K}(x,y)$ for $x \neq y$ and $\hat{\mathcal{K}}(x,x) = \mathcal{K}(x,x) + \sigma^2$ to include the sensor noise σ^2. Since $\mathcal{C}$ is compact and $\mathcal{K}$ continuous, $\mathcal{K}$ is uniformly continuous over $\mathcal{C}$. Hence, for any ε_1, there exists a δ_1 such that for all $x, x', y, y', \|x - x'\|_2 \leq \delta_1, \|y - y'\|_2 \leq \delta_1$ it holds that $|\mathcal{K}(x,y) - \mathcal{K}(x',y')| \leq \varepsilon_1$. Assume $\mathcal{C}_1 \subset \mathcal{C}$ is a finite mesh grid with mesh width $2\delta_1$. We allow sensor placement only on grid $\mathcal{C}_1$. Let $\mathcal{C}_2 \subset \mathcal{C}$ be a mesh grid of mesh width $2\delta_1$, which is derived by translating $\mathcal{C}_1$ by δ_1 in Euclidean norm, and let G_1, G_2 denote the restriction of the GP G to $\mathcal{C}_1, \mathcal{C}_2$. We assume $\mathcal{C}_1, \mathcal{C}_2$ cover $\mathcal{C}$ in the sense of compactness. We use the notation $\tilde{\cdot}$ to refer to the translated version in G_2 of the random variable $\cdot$ in G_1. $\hat{\mathcal{K}}$ is a symmetric strictly positive definite covariance function and $|\hat{\mathcal{K}}(X,y) - \hat{\mathcal{K}}(\tilde{X}, \tilde{y})| \leq \varepsilon_1$ for all $X, y \in G_1$. Moreover, since $\mathcal{K}$ is positive semidefinite, the smallest eigenvalue of any covariance matrix derived from $\hat{\mathcal{K}}$ is at least σ^2.

Let $\mathcal{A}$ be a subset of $\mathcal{C}_1$ and $X \in \mathcal{C}_1 \setminus \mathcal{A}$. Using (5), we first consider the conditional variance $\sigma^2_{X|\mathcal{A}}$. By definition, $\|y - \tilde{y}\|_2 \leq \delta_1$, and hence $|\hat{\mathcal{K}}(X,y) - \hat{\mathcal{K}}(X,\tilde{y})| \leq \varepsilon_1$ for all $y \in \mathcal{A}$. Hence we know that $\|\Sigma_{\mathcal{A}\mathcal{A}} - \Sigma_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\|_2 \leq \|\Sigma_{\mathcal{A}\mathcal{A}} - \Sigma_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\|_F \leq k^2\varepsilon_1$. We furthermore note that $\|\Sigma^{-1}_{\mathcal{A}\mathcal{A}}\|_2 = \lambda^{max}(\Sigma^{-1}_{\mathcal{A}\mathcal{A}}) = \lambda^{min}(\Sigma_{\mathcal{A}\mathcal{A}})^{-1} \leq \sigma^{-2}$, and hence

$$\begin{aligned}\|\Sigma^{-1}_{\mathcal{A}\mathcal{A}} - \Sigma^{-1}_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\|_2 &= \|\Sigma^{-1}_{\mathcal{A}\mathcal{A}}(\Sigma_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}} - \Sigma_{\mathcal{A}\mathcal{A}})\Sigma^{-1}_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\|_2 \\ &\leq \|\Sigma^{-1}_{\mathcal{A}\mathcal{A}}\|_2 \|\Sigma_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}} - \Sigma_{\mathcal{A}\mathcal{A}}\|_2 \|\Sigma^{-1}_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\|_2 \leq \sigma^{-4}k^2\varepsilon_1.\end{aligned}$$

We derive $\|\Sigma_{X\tilde{\mathcal{A}}} - \Sigma_{X\mathcal{A}}\|_2 \leq \|\varepsilon_1 \mathbf{1}^T\|_2 = \varepsilon_1\sqrt{k}$, hence

$$\begin{aligned}|\sigma^2_{X|A} - \sigma^2_{X|\tilde{\mathcal{A}}}| &= |\Sigma_{X\mathcal{A}}\Sigma^{-1}_{\mathcal{A}\mathcal{A}}\Sigma_{\mathcal{A}X} - \Sigma_{X\tilde{\mathcal{A}}}\Sigma^{-1}_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\Sigma_{\tilde{\mathcal{A}}X}| \\ &\leq 2\|\Sigma_{X\mathcal{A}} - \Sigma_{X\tilde{\mathcal{A}}}\|_2 \|\Sigma^{-1}_{\mathcal{A}\mathcal{A}}\|_2 \|\Sigma_{X\mathcal{A}}\|_2 + \|\Sigma^{-1}_{\mathcal{A}\mathcal{A}} - \Sigma^{-1}_{\tilde{\mathcal{A}}\tilde{\mathcal{A}}}\|_2 \|\Sigma_{X\mathcal{A}}\|_2^2 + O(\varepsilon_1^2) \\ &\leq 2\varepsilon_1\sqrt{k}\sigma^{-2}M\sqrt{k} + \sigma^{-4}k^2\varepsilon_1 M^2 k + O(\varepsilon_1^2) \\ &\leq \varepsilon_1 k\sigma^{-2}M\left(2 + \sigma^{-2}k^2M\right) + O(\varepsilon_1^2),\end{aligned}$$

where $M = \max_{x \in C} \mathcal{K}(x,x)$. We choose δ such that the above difference is bounded by $\sigma^2\varepsilon$. We note that (assuming w.l.o.g. $H(X \mid \mathcal{A}) \geq H(X \mid \tilde{\mathcal{A}})$)

$$H(X \mid \mathcal{A}) - H(X \mid \tilde{\mathcal{A}}) = \frac{1}{2}\log\frac{\sigma^2_{X|\mathcal{A}}}{\sigma^2_{X|\tilde{\mathcal{A}}}} \leq \frac{\log(1+\varepsilon)}{2} \leq \frac{\varepsilon}{2}.$$

which concludes the argument. ■

Proof [Corollary 6] The higher order terms $O(\varepsilon_1^2)$ can be worked out as $k\sigma^{-2}\varepsilon^2(1 + Mk^2\sigma^{-2} + \varepsilon k^2\sigma^{-2})$. Assuming that $\varepsilon < \min(M, 1)$, this is bounded by $3k^3M\sigma^{-4}\varepsilon$. Using the Lipschitz assumption, we can directly compute δ_1 from ε_1 in the above proof, by letting $\delta = \varepsilon_1/L$. Let $R =$

$k\sigma^{-2}M\left(2+\sigma^{-2}k^2M\right)+3k^3M\sigma^{-4}$. We want to choose δ such that $\varepsilon_1 R \leq \sigma^2\varepsilon$. Hence if we choose $\delta \leq \frac{\sigma^2\varepsilon}{LR}$, then $|H(X \mid \mathcal{A}) - H(X \mid \tilde{\mathcal{A}})| \leq \varepsilon$ uniformly as required. Note that in order to apply the result from Nemhauser et al. (1978), the approximate monotonicity has to be guaranteed for subsets of size $2k$, which results in the stated bound. ■

Proof [Theorem 7] The following proof is an extension of the proof by Nemhauser et al. (1978), using some simplifications by Jon Kleinberg.

Let $s_1,\ldots,s_k$ be the locations selected by the greedy algorithm. Let $\mathcal{A}_i = \{s_1,\ldots,s_i\}$, $\mathcal{A}^*$ be the optimal solution, and $\delta_i = \mathrm{MI}(\mathcal{A}_i) - \mathrm{MI}(\mathcal{A}_{i-1})$. By *Lemma* 5, we have, for all $1 \leq i \leq k$,

$$\mathrm{MI}(\mathcal{A}_i \cup \mathcal{A}^*) \geq \mathrm{MI}(\mathcal{A}^*) - k\varepsilon.$$

We also have, for $0 \leq i < k$,

$$\mathrm{MI}(\mathcal{A}_i \cup \mathcal{A}^*) \leq \mathrm{MI}(\mathcal{A}_i) + k\delta_{i+1} = \sum_{j=1}^{i} \delta_j + k\delta_{i+1}.$$

Hence we have the following sequence of inequalities:

$$\begin{aligned}
\mathrm{MI}(\mathcal{A}^*) - k\varepsilon &\leq k\delta_1 \\
\mathrm{MI}(\mathcal{A}^*) - k\varepsilon &\leq \delta_1 + k\delta_2 \\
&\vdots \\
\mathrm{MI}(\mathcal{A}^*) - k\varepsilon &\leq \sum_{j=1}^{k-1} \delta_j + k\delta_k.
\end{aligned}$$

Now we multiply both sides of the i-th inequality by $\left(1-\frac{1}{k}\right)^{k-1}$, and add all inequalities up. After cancellation, we get

$$\left(\sum_{i=0}^{k-1} (1-1/k)^i\right)(\mathrm{MI}(\mathcal{A}^*) - k\varepsilon) \leq k\sum_{i=1}^{k} \delta_i = k\,\mathrm{MI}(\mathcal{A}_k).$$

Hence, as claimed, with $\mathcal{A}_G = \mathcal{A}_k$ (i.e., $\mathcal{A}_G$ is the k-element greedy solution)

$$\mathrm{MI}(\mathcal{A}_G) \geq \left(1-(1-1/k)^k\right)(\mathrm{MI}(\mathcal{A}^*) - k\varepsilon) \geq (1-1/e)(\mathrm{MI}(\mathcal{A}^*) - k\varepsilon).$$

■

Proof [Remark 12] We have that $H(y \mid Z) < 0 \Leftrightarrow \mathcal{K}(y,y) + \sigma^2 - \frac{\mathcal{K}(Z,y)^2}{\mathcal{K}(Z,Z)+\sigma^2} < \frac{1}{2\pi e}$. Using a similar argument as the proof of Lemma 5, for very fine discretizations, there exists a y arbitrarily close to Z, such that for any $\alpha > 0$, $|\mathcal{K}(Z,Z) - \mathcal{K}(y,y)| \leq \alpha$ and $|\mathcal{K}(Z,Z) - \mathcal{K}(Z,y)| \leq \alpha$. Plugging these bounds into the definition of $H(y \mid Z)$ and some algebraic manipulation proves the claim. ■

Abstract

Ensemble learning algorithms such as boosting can achieve better performance by averaging over the predictions of some base hypotheses. Nevertheless, most existing algorithms are limited to combining only a finite number of hypotheses, and the generated ensemble is usually sparse. Thus, it is not clear whether we should construct an ensemble classifier with a larger or even an infinite number of hypotheses. In addition, constructing an infinite ensemble itself is a challenging task. In this paper, we formulate an infinite ensemble learning framework based on the support vector machine (SVM). The framework can output an infinite and nonsparse ensemble through embedding infinitely many hypotheses into an SVM kernel. We use the framework to derive two novel kernels, the stump kernel and the perceptron kernel. The stump kernel embodies infinitely many decision stumps, and the perceptron kernel embodies infinitely many perceptrons. We also show that the Laplacian radial basis function kernel embodies infinitely many decision trees, and can thus be explained through infinite ensemble learning. Experimental results show that SVM with these kernels is superior to boosting with the same base hypothesis set. In addition, SVM with the stump kernel or the perceptron kernel performs similarly to SVM with the Gaussian radial basis function kernel, but enjoys the benefit of faster parameter selection. These properties make the novel kernels favorable choices in practice.

Keywords: ensemble learning, boosting, support vector machine, kernel

1. Introduction

Ensemble learning algorithms, such as boosting (Freund and Schapire, 1996), are successful in practice (Meir and Rätsch, 2003). They construct a classifier that averages over some base hypotheses in a set $\mathcal{H}$. While the size of $\mathcal{H}$ can be infinite, most existing algorithms use only a finite subset of $\mathcal{H}$, and the classifier is effectively a finite ensemble of hypotheses. Some theories show that the finiteness places a restriction on the capacity of the ensemble (Freund and Schapire, 1997), and some theories suggest that the performance of boosting can be linked to its asymptotic behavior when the ensemble is allowed to be of an infinite size (Rätsch et al., 2001). Thus, it is possible that an infinite ensemble is superior for learning. Nevertheless, the possibility has not been fully explored because constructing such an ensemble is a challenging task (Vapnik, 1998).

In this paper, we conquer the task of infinite ensemble learning, and demonstrate that better performance can be achieved by going from finite ensembles to infinite ones. We formulate a framework for infinite ensemble learning based on the support vector machine (SVM) (Vapnik, 1998). The key of the framework is to embed an infinite number of hypotheses into an SVM kernel.

Such a framework can be applied both to construct new kernels for SVM, and to interpret some existing ones (Lin, 2005). Furthermore, the framework allows us to compare SVM and ensemble learning algorithms in a fair manner using the same base hypothesis set.

Based on the framework, we derive two novel SVM kernels, the stump kernel and the perceptron kernel, from an ensemble learning perspective (Lin and Li, 2005a). The stump kernel embodies infinitely many decision stumps, and as a consequence measures the similarity between examples by the ℓ_1-norm distance. The perceptron kernel embodies infinitely many perceptrons, and works with the ℓ_2-norm distance. While there exist similar kernels in literature, our derivation from an ensemble learning perspective is nevertheless original. Our work not only provides a feature-space view of their theoretical properties, but also broadens their use in practice. Experimental results show that SVM with these kernels is superior to successful ensemble learning algorithms with the same base hypothesis set. These results reveal some weakness in traditional ensemble learning algorithms, and help understand both SVM and ensemble learning better. In addition, SVM with these kernels shares similar performance to SVM with the popular Gaussian radial basis function (Gaussian-RBF) kernel, but enjoys the benefit of faster parameter selection. These properties make the two kernels favorable choices in practice.

We also show that the Laplacian-RBF kernel embodies infinitely many decision trees, and hence can be viewed as an instance of the framework. Experimentally, SVM with the Laplacian-RBF kernel performs better than ensemble learning algorithms with decision trees. In addition, our derivation from an ensemble learning perspective helps to explain the success of the kernel on some specific applications (Chapelle et al., 1999).

The paper is organized as follows. In Section 2, we review the connections between SVM and ensemble learning. Next in Section 3, we propose the framework for embedding an infinite number of hypotheses into a kernel. We then derive the stump kernel in Section 4, the perceptron kernel in Section 5, and the Laplacian-RBF kernel in Section 6. Finally, we show the experimental results in Section 7, and conclude in Section 8.

2. Support Vector Machine and Ensemble Learning

In this section, we first introduce the basics of SVM and ensemble learning. Then, we review some established connections between the two in literature.

2.1 Support Vector Machine

Given a training set $\{(x_i,y_i)\}_{i=1}^N$, which contains input vectors $x_i \in \mathcal{X} \subseteq \mathbb{R}^D$ and their corresponding labels $y_i \in \{-1,+1\}$, the soft-margin SVM (Vapnik, 1998) constructs a classifier

$$g(x) = \text{sign}\big(\langle w, \phi_x \rangle + b\big)$$

from the optimal solution to the following problem:[1]

$$\begin{aligned} (P_1) \quad \min_{w\in\mathcal{F},b\in\mathbb{R},\xi\in\mathbb{R}^N} \quad & \frac{1}{2}\langle w,w\rangle + C\sum_{i=1}^N \xi_i & \\ \text{s.t.} \quad & y_i\big(\langle w,\phi_{x_i}\rangle + b\big) \geq 1-\xi_i, & \text{for } i=1,2,\ldots,N, \\ & \xi_i \geq 0, & \text{for } i=1,2,\ldots,N. \end{aligned}$$

1. When η is nonzero, $\text{sign}(\eta) \equiv \frac{\eta}{|\eta|}$. We shall let $\text{sign}(0) \equiv 0$ to make some mathematical setup cleaner.

Here $C > 0$ is the regularization parameter, and $\phi_x = \Phi(x)$ is obtained from the feature mapping $\Phi\colon \mathcal{X} \to \mathcal{F}$. We assume the feature space $\mathcal{F}$ to be a Hilbert space equipped with the inner product $\langle \cdot, \cdot \rangle$ (Schölkopf and Smola, 2002). Because $\mathcal{F}$ can be of an infinite number of dimensions, SVM solvers usually work on the dual problem:

$$\begin{aligned} (P_2) \quad \min_{\lambda \in \mathbb{R}^N} \quad & \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}\lambda_i\lambda_j y_i y_j \mathcal{K}(x_i,x_j) - \sum_{i=1}^{N}\lambda_i \\ \text{s.t.} \quad & 0 \le \lambda_i \le C, \qquad \text{for } i = 1,2,\ldots,N, \\ & \sum_{i=1}^{N} y_i\lambda_i = 0. \end{aligned}$$

Here $\mathcal{K}$ is the kernel function defined as $\mathcal{K}(x,x') = \langle \phi_x, \phi_{x'} \rangle$. Then, the optimal classifier becomes

$$g(x) = \operatorname{sign}\left(\sum_{i=1}^{N} y_i\lambda_i \mathcal{K}(x_i,x) + b\right), \tag{1}$$

where b can be computed through the primal-dual relationship (Vapnik, 1998; Schölkopf and Smola, 2002).

The use of a kernel function $\mathcal{K}$ instead of computing the inner product directly in $\mathcal{F}$ is called the kernel trick, which works when $\mathcal{K}(\cdot,\cdot)$ can be computed efficiently (Schölkopf and Smola, 2002). Alternatively, we can begin with an arbitrary $\mathcal{K}$, and check whether there exists a space-mapping pair $(\mathcal{F},\Phi)$ such that $\mathcal{K}(\cdot,\cdot)$ is a valid inner product in $\mathcal{F}$. A key tool here is the *Mercer's condition*, which states that a symmetric $\mathcal{K}(\cdot,\cdot)$ is a valid inner product if and only if its Gram matrix K, defined by $K_{i,j} = \mathcal{K}(x_i,x_j)$, is always positive semi-definite (PSD) (Vapnik, 1998; Schölkopf and Smola, 2002).

The soft-margin SVM originates from the hard-margin SVM, which forces the margin violations ξ_i to be zero. When such a solution is feasible for (P_1), the corresponding dual solution can be obtained by setting C to ∞ in (P_2).

2.2 Adaptive Boosting and Linear Programming Boosting

The adaptive boosting (AdaBoost) algorithm (Freund and Schapire, 1996) is perhaps the most popular and successful approach for ensemble learning. For a given integer T and a hypothesis set $\mathcal{H}$, AdaBoost iteratively selects T hypotheses $h_t \in \mathcal{H}$ and weights $w_t \ge 0$ to construct an ensemble classifier

$$g_T(x) = \operatorname{sign}\left(\sum_{t=1}^{T} w_t h_t(x)\right).$$

The underlying algorithm for selecting $h_t \in \mathcal{H}$ is called a base learner. Under some assumptions (Rätsch et al., 2001), it is shown that when $T \to \infty$, AdaBoost asymptotically approximates an infinite ensemble classifier

$$g_\infty(x) = \operatorname{sign}\left(\sum_{t=1}^{\infty} w_t h_t(x)\right), \tag{2}$$

such that (w,h) is an optimal solution to

$$
\begin{aligned}
(P_3) \quad \min_{w_t\in\mathbb{R},h_t\in\mathcal{H}} \quad & \sum_{t=1}^{\infty} w_t \\
\text{s.t.} \quad & y_i\left(\sum_{t=1}^{\infty} w_t h_t(x_i)\right) \geq 1, && \text{for } i=1,2,\ldots,N, \\
& w_t \geq 0, && \text{for } t=1,2,\ldots,\infty.
\end{aligned}
$$

Note that there are infinitely many variables in (P_3). In order to approximate the optimal solution well with a fixed and finite T, AdaBoost resorts to two related properties of some of the optimal solutions for (P_3): finiteness and sparsity.

- **Finiteness:** When two hypotheses have the same prediction patterns on the training input vectors, they can be used interchangeably during the training time, and are thus *ambiguous*. Since there are at most 2^N prediction patterns on N training input vectors, we can partition $\mathcal{H}$ into at most 2^N groups, each of which contains mutually ambiguous hypotheses. Some optimal solutions of (P_3) only assign one or a few nonzero weights within each group (Demiriz et al., 2002). Thus, it is possible to work on a finite data-dependent subset of $\mathcal{H}$ instead of $\mathcal{H}$ itself without losing optimality.
- **Sparsity:** Minimizing the ℓ_1-norm $\|w\|_1 = \sum_{t=1}^{\infty} |w_t|$ often leads to sparse solutions (Meir and Rätsch, 2003; Rosset et al., 2007). That is, for hypotheses in the finite (but possibly still large) subset of $\mathcal{H}$, only a small number of weights needs to be nonzero. AdaBoost can be viewed as a stepwise greedy search algorithm that approximates such a finite and sparse ensemble (Rosset et al., 2004).

Another boosting approach, called the linear programming boosting (LPBoost), can solve (P_3) exactly. We will introduce the soft-margin LPBoost, which constructs an ensemble classifier like (2) with the optimal solution to

$$
\begin{aligned}
(P_4) \quad \min_{w_t\in\mathbb{R},h_t\in\mathcal{H}} \quad & \sum_{t=1}^{\infty} w_t + C\sum_{i=1}^{N} \xi_i \\
\text{s.t.} \quad & y_i\left(\sum_{t=1}^{\infty} w_t h_t(x_i)\right) \geq 1-\xi_i, && \text{for } i=1,2,\ldots,N, \\
& \xi_i \geq 0, && \text{for } i=1,2,\ldots,N, \\
& w_t \geq 0, && \text{for } t=1,2,\ldots,\infty.
\end{aligned}
$$

Demiriz et al. (2002) proposed to solve (P_4) with the column generating technique.[2] The algorithm works by adding one unambiguous h_t to the ensemble in each iteration. Because of the finiteness property, the algorithm is guaranteed to terminate within $T \leq 2^N$ iterations. The sparsity property can sometimes help speed up the convergence of the algorithm.

Rätsch et al. (2002) worked on a variant of (P_4) for regression problems, and discussed optimality conditions when $\mathcal{H}$ is of infinite size. Their results can be applied to (P_4) as well. In particular,

2. Demiriz et al. (2002) actually worked on an equivalent but slightly different formulation.

they showed that even without the finiteness property (e.g., when h_t outputs real values rather than binary values), (P_4) can still be solved using a finite subset of $\mathcal{H}$ that is associated with nonzero weights. The results justify the use of the column generating technique above, as well as a barrier, AdaBoost-like, approach that they proposed.

Recently, Rosset et al. (2007) studied the existence of a sparse solution when solving a generalized form of (P_4) with some $\mathcal{H}$ of infinite and possibly uncountable size. They showed that under some assumptions, there exists an optimal solution of (P_4) such that at most $N+1$ weights are nonzero. Thus, iterative algorithms that keep adding necessary hypotheses h_t to the ensemble, such as the proposed path-following approach (Rosset et al., 2007) or the column generating technique (Demiriz et al., 2002; Rätsch et al., 2002), could work by aiming towards such a sparse solution.

Note that even though the findings above indicate that it is possible to design good algorithms to return an optimal solution when $\mathcal{H}$ is infinitely large, the resulting ensemble relies on the sparsity property, and is effectively of only finite size. Nevertheless, it is not clear whether the performance could be improved if either or both the finiteness and the sparsity restrictions are removed.

2.3 Connecting Support Vector Machine to Ensemble Learning

The connection between AdaBoost, LPBoost, and SVM is well-known in literature (Freund and Schapire, 1999; Rätsch et al., 2001; Rätsch et al., 2002; Demiriz et al., 2002). Consider the feature transform

$$\Phi(x) = \big(h_1(x), h_2(x), \ldots\big). \tag{3}$$

We can see that the problem (P_1) with this feature transform is similar to (P_4). The elements of ϕ_x in SVM are similar to the hypotheses $h_t(x)$ in AdaBoost and LPBoost. They all work on linear combinations of these elements, though SVM deals with an additional intercept term b. SVM minimizes the ℓ_2-norm of the weights while AdaBoost and LPBoost work on the ℓ_1-norm. SVM and LPBoost introduce slack variables ξ_i and use the parameter C for regularization, while AdaBoost relies on the choice of the parameter T (Rosset et al., 2004). Note that AdaBoost and LPBoost require $w_t \geq 0$ for ensemble learning.

Several researchers developed interesting results based on the connection. For example, Rätsch et al. (2001) proposed to select the hypotheses h_t by AdaBoost and to obtain the weights w_t by solving an optimization problem similar to (P_1) in order to improve the robustness of AdaBoost. Another work by Rätsch et al. (2002) introduced a new density estimation algorithm based on the connection. Rosset et al. (2004) applied the similarity to compare SVM with boosting algorithms. Nevertheless, as limited as AdaBoost and LPBoost, their results could use only a finite subset of $\mathcal{H}$ when constructing the feature mapping (3). One reason is that the infinite number of variables w_t and constraints $w_t \geq 0$ are difficult to handle. We will show the remedies for these difficulties in the next section.

3. SVM-Based Framework for Infinite Ensemble Learning

Vapnik (1998) proposed a challenging task of designing an algorithm that actually generates an infinite ensemble classifier, that is, an ensemble classifier with infinitely many nonzero w_t. Traditional algorithms like AdaBoost or LPBoost cannot be directly generalized to solve the task, because they select the hypotheses in an iterative manner, and only run for a finite number of iterations.

We solved the challenge via another route: the connection between SVM and ensemble learning. The connection allows us to formulate a kernel that embodies all the hypotheses in $\mathcal{H}$. Then, the classifier (1) obtained from SVM with the kernel is a linear combination over $\mathcal{H}$ (with an intercept term). Nevertheless, there are still two main obstacles. One is to actually derive the kernel, and the other is to handle the constraints $w_t \geq 0$ to make (1) an ensemble classifier. In this section, we combine several ideas to deal with these obstacles, and conquer Vapnik's task with a novel SVM-based framework for infinite ensemble learning.

3.1 Embedding Hypotheses into the Kernel

We start by embedding the infinite number of hypotheses in $\mathcal{H}$ into an SVM kernel. We have shown in (3) that we could construct a feature mapping from $\mathcal{H}$. The idea is extended to a more general form for deriving a kernel in Definition 1.

Definition 1 *Assume that $\mathcal{H} = \{h_\alpha : \alpha \in \mathcal{C}\}$, where $\mathcal{C}$ is a measure space. The kernel that embodies $\mathcal{H}$ is defined as*

$$\mathcal{K}_{\mathcal{H},r}(x,x') = \int_{\mathcal{C}} \phi_x(\alpha)\phi_{x'}(\alpha)\, d\alpha, \tag{4}$$

where $\phi_x(\alpha) = r(\alpha)h_\alpha(x)$, and $r : \mathcal{C} \to \mathbb{R}^+$ is chosen such that the integral exists for all $x, x' \in \mathcal{X}$.

Here α is the parameter of the hypothesis h_α. Although two hypotheses with different α values may have the same input-output relation, we would treat them as different objects in our framework. We shall denote $\mathcal{K}_{\mathcal{H},r}$ by $\mathcal{K}_{\mathcal{H}}$ when r is clear from the context. The validity of the definition is formalized in the following theorem.

Theorem 2 *Consider the kernel $\mathcal{K}_{\mathcal{H}}$ in Definition 1.*

1. *The kernel is an inner product for ϕ_x and $\phi_{x'}$ in the Hilbert space $\mathcal{F} = \mathcal{L}_2(\mathcal{C})$, which contains functions $\varphi(\cdot) : \mathcal{C} \to \mathbb{R}$ that are square integrable.*

2. *For a set of input vectors $\{x_i\}_{i=1}^N \in \mathcal{X}^N$, the Gram matrix of $\mathcal{K}_{\mathcal{H}}$ is PSD.*

Proof The first part is known in mathematical analysis (Reed and Simon, 1980), and the second part follows Mercer's condition. ■

Constructing kernels from an integral inner product is a known technique in literature (Schölkopf and Smola, 2002). The framework adopts this technique for embedding the hypotheses, and thus could handle the situation even when $\mathcal{H}$ is uncountable. Note that when $r^2(\alpha)\, d\alpha$ is a "prior" on h_α, the kernel $\mathcal{K}_{\mathcal{H},r}(x,x')$ can be interpreted as a covariance function commonly used in Gaussian process (GP) models (Williams, 1998; Rasmussen and Williams, 2006). Some Bayesian explanations can then be derived from the connection between SVM and GP, but are beyond the scope of this paper.

3.2 Negation Completeness and Constant Hypotheses

When we use $\mathcal{K}_{\mathcal{H}}$ in (P_2), the primal problem (P_1) becomes

$$(P_5) \quad \min_{w\in\mathcal{L}_2(C),b\in\mathbb{R},\xi\in\mathbb{R}^N} \quad \frac{1}{2}\int_C w^2(\alpha)\,d\alpha + C\sum_{i=1}^{N}\xi_i$$
$$\text{s.t.} \quad y_i\left(\int_C w(\alpha)r(\alpha)h_\alpha(x_i)\,d\alpha + b\right) \geq 1-\xi_i, \qquad \text{for } i=1,2,\ldots,N,$$
$$\xi_i \geq 0, \qquad \text{for } i=1,2,\ldots,N.$$

In particular, the classifier obtained after solving (P_2) with $\mathcal{K}_{\mathcal{H}}$ is the same as the classifier obtained after solving (P_5):

$$g(x) = \text{sign}\left(\int_C w(\alpha)r(\alpha)h_\alpha(x)\,d\alpha + b\right). \tag{5}$$

When C is uncountable, it is possible that each hypothesis h_α only takes an infinitesimal weight $\big(w(\alpha)r(\alpha)\,d\alpha\big)$ in the ensemble. Thus, the classifier (5) is very different from those obtained with traditional ensemble learning, and will be discussed further in Subsection 4.2.

Note that the classifier (5) is not an ensemble classifier yet, because we do not have the constraints $w(\alpha)\geq 0$, and we have an additional term b. Next, we would explain that such a classifier is equivalent to an ensemble classifier under some reasonable assumptions.

We start from the constraints $w(\alpha)\geq 0$, which cannot be directly considered in (P_1). Vapnik (1998) showed that even if we add a countably infinite number of constraints to (P_1), infinitely many variables and constraints would be introduced to (P_2). Then, the latter problem would still be difficult to solve.

One remedy is to assume that $\mathcal{H}$ is negation complete, that is,[3]

$$h\in\mathcal{H} \Leftrightarrow (-h)\in\mathcal{H}.$$

Then, every linear combination over $\mathcal{H}$ has an equivalent linear combination with only nonnegative weights. Negation completeness is usually a mild assumption for a reasonable $\mathcal{H}$ (Rätsch et al., 2002). Following this assumption, the classifier (5) can be interpreted as an ensemble classifier over $\mathcal{H}$ with an intercept term b. Somehow b can be viewed as the weight on a constant hypothesis c, which always predicts $c(x)=1$ for all $x\in\mathcal{X}$. We shall further add a mild assumption that $\mathcal{H}$ contains both c and $(-c)$. Then, the classifier (5) or (1) is indeed equivalent to an ensemble classifier.

We summarize our framework in Algorithm 1. The framework shall generally inherit the profound performance of SVM. Most of the steps in the framework can be done by existing SVM implementations, and the hard part is mostly in obtaining the kernel $\mathcal{K}_{\mathcal{H}}$. In the next sections, we derive some concrete instances using different base hypothesis sets.

4. Stump Kernel

In this section, we present the stump kernel, which embodies infinitely many decision stumps. The decision stump $s_{q,d,\alpha}(x) = q\cdot\text{sign}\big((x)_d-\alpha\big)$ works on the d-th element of x, and classifies x according to $q\in\{-1,+1\}$ and the threshold α (Holte, 1993). It is widely used for ensemble learning because of its simplicity (Freund and Schapire, 1996).

3. We use $(-h)$ to denote the function $(-h)(\cdot) = -(h(\cdot))$.

1. Consider a training set $\{(x_i,y_i)\}_{i=1}^N$ and the hypothesis set $\mathcal{H}$, which is assumed to be negation complete and to contain a constant hypothesis.
2. Construct a kernel $\mathcal{K}_{\mathcal{H}}$ according to Definition 1 with a proper embedding function r.
3. Choose proper parameters, such as the soft-margin parameter C.
4. Solve (P_2) with $\mathcal{K}_{\mathcal{H}}$ and obtain Lagrange multipliers λ_i and the intercept term b.
5. Output the classifier
$$g(x) = \operatorname{sign}\left(\sum_{i=1}^N y_i\lambda_i \mathcal{K}_{\mathcal{H}}(x_i,x) + b\right),$$
which is equivalent to some ensemble classifier over $\mathcal{H}$.

Algorithm 1: SVM-based framework for infinite ensemble learning

4.1 Formulation and Properties

To construct the stump kernel, we consider the following set of decision stumps

$$\mathcal{S} = \left\{s_{q,d,\alpha_d} : q \in \{-1,+1\}, d \in \{1,\ldots,D\}, \alpha_d \in [L_d,R_d]\right\}.$$

We also assume $\mathcal{X} \subseteq (L_1,R_1)\times(L_2,R_2)\times\cdots\times(L_D,R_D)$. Thus, the set $\mathcal{S}$ is negation complete and contains $s_{+1,1,L_1}$ as a constant hypothesis. The stump kernel $\mathcal{K}_{\mathcal{S}}$ defined below can then be used in Algorithm 1 to obtain an infinite ensemble of decision stumps.

Definition 3 *The stump kernel is $\mathcal{K}_{\mathcal{S}}$ with $r(q,d,\alpha_d) = r_{\mathcal{S}} = \frac{1}{2}$,*

$$\mathcal{K}_{\mathcal{S}}(x,x') = \Delta_{\mathcal{S}} - \sum_{d=1}^D \left|(x)_d - (x')_d\right| = \Delta_{\mathcal{S}} - \left\|x-x'\right\|_1,$$

where $\Delta_{\mathcal{S}} = \frac{1}{2}\sum_{d=1}^D (R_d - L_d)$ is a constant.

Definition 3 is a concrete instance that follows Definition 1. The details of the derivation are shown in Appendix A. As we shall see further in Section 5, scaling $r_{\mathcal{S}}$ is equivalent to scaling the parameter C in SVM. Thus, without loss of generality, we use $r_{\mathcal{S}} = \frac{1}{2}$ to obtain a cosmetically cleaner kernel function.

The validity of the stump kernel follows directly from Theorem 2 of the general framework. That is, the stump kernel is an inner product in a Hilbert space of some square integrable functions $\varphi(q,d,\alpha_d)$, and it produces a PSD Gram matrix for any set of input vectors $\{x_i\}_{i=1}^N \in \mathcal{X}^N$. Given the ranges (L_d,R_d), the stump kernel is very simple to compute. Furthermore, the ranges are not even necessary in general, because dropping the constant $\Delta_{\mathcal{S}}$ does not affect the classifier obtained from SVM.

Theorem 4 *Solving (P_2) with the stump kernel $\mathcal{K}_{\mathcal{S}}$ is the same as solving (P_2) with the simplified stump kernel $\tilde{\mathcal{K}}_{\mathcal{S}}(x,x') = -\left\|x-x'\right\|_1$. That is, equivalent classifiers can be obtained from* (1)*.*

Proof We extend from the results of Berg et al. (1984) to show that $\tilde{\mathcal{K}}_{\mathcal{S}}(x,x')$ is conditionally PSD (CPSD). In addition, because of the constraint $\sum_{i=1}^{N} y_i\lambda_i = 0$, a CPSD kernel $\tilde{\mathcal{K}}(x,x')$ works exactly the same for (P_2) as any PSD kernel of the form $\tilde{\mathcal{K}}(x,x')+\Delta$, where Δ is a constant (Schölkopf and Smola, 2002). The proof follows with $\Delta = \Delta_{\mathcal{S}}$. ■

In fact, a kernel $\hat{\mathcal{K}}(x,x') = \tilde{\mathcal{K}}(x,x') + f(x) + f(x')$ with any mapping f is equivalent to $\tilde{\mathcal{K}}(x,x')$ for (P_2) because of the constraint $\sum_{i=1}^{N} y_i\lambda_i = 0$. Now consider another kernel

$$\hat{\mathcal{K}}_{\mathcal{S}}(x,x') = \tilde{\mathcal{K}}_{\mathcal{S}}(x,x') + \sum_{d=1}^{D}(x)_d + \sum_{d=1}^{D}(x')_d = 2\sum_{d=1}^{D}\min((x)_d,(x')_d).$$

We see that $\hat{\mathcal{K}}_{\mathcal{S}}$, $\tilde{\mathcal{K}}_{\mathcal{S}}$, and $\mathcal{K}_{\mathcal{S}}$ are equivalent for (P_2). The former is called the *histogram intersection kernel* (up to a scale of 2) when the elements $(x)_d$ represent generalized histogram counts, and has been successfully used in image recognition applications (Barla et al., 2003; Boughorbel et al., 2005; Grauman and Darrell, 2005). The equivalence demonstrates the usefulness of the stump kernel on histogram-based features, which would be further discussed in Subsection 6.4. A remark here is that our proof for the PSD-ness of $\mathcal{K}_{\mathcal{S}}$ comes directly from the framework, and hence is simpler and more straightforward than the proof of Boughorbel et al. (2005) for the PSD-ness of $\hat{\mathcal{K}}_{\mathcal{S}}$.

The simplified stump kernel is simple to compute, yet useful in the sense of dichotomizing the training set, which comes from the following positive definite (PD) property.

Theorem 5 *(Lin, 2005) Consider training input vectors $\{x_i\}_{i=1}^{N} \in \mathcal{X}^N$. If there exists a dimension d such that $(x_i)_d \neq (x_j)_d$ for all $i \neq j$, the Gram matrix of $\mathcal{K}_{\mathcal{S}}$ is PD.*

The PD-ness of the Gram matrix is directly connected to the classification capacity of the SVM classifiers. Chang and Lin (2001b) showed that when the Gram matrix of the kernel is PD, a hard-margin SVM with such a kernel can always dichotomize the training set perfectly. Keerthi and Lin (2003) then applied the result to show that SVM with the popular Gaussian-RBF kernel $\mathcal{K}(x,x') = \exp\left(-\gamma\|x-x'\|_2^2\right)$ can always dichotomize the training set when $C \to \infty$. We obtain a similar theorem for the stump kernel.

Theorem 6 *Under the assumption of Theorem 5, there exists some $C^* > 0$ such that for all $C \geq C^*$, SVM with $\mathcal{K}_{\mathcal{S}}$ can always dichotomize the training set $\{(x_i,y_i)\}_{i=1}^{N}$.*

We make two remarks here. First, although the assumption of Theorem 6 is mild in practice, there are still some data sets that do not have this property. An example is the famous XOR data set (Figure 1). We can see that every possible decision stump makes 50% of errors on the training input vectors. Thus, AdaBoost and LPBoost would terminate with one bad decision stump in the ensemble. Similarly, SVM with the stump kernel cannot dichotomize this training set perfectly, regardless of the choice of C. Such a problem is inherent in any ensemble model that combines decision stumps, because the model belongs to the family of generalized additive models (Hastie and Tibshirani, 1990; Hastie et al., 2001), and hence cannot approximate non-additive target functions well.

Second, although Theorem 6 indicates how the stump kernel can be used to dichotomize the training set perfectly, the classifier obtained usually overfits to noise (Keerthi and Lin, 2003). For

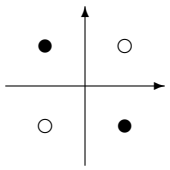

Figure 1: The XOR data set

the Gaussian-RBF kernel, it has been known that SVM with reasonable parameter selection provides suitable regularization and achieves good generalization performance even in the presence of noise (Keerthi and Lin, 2003; Hsu et al., 2003). We observe similar experimental results for the stump kernel (see Section 7).

4.2 Averaging Ambiguous Stumps

We have discussed in Subsection 2.2 that the set of hypotheses can be partitioned into groups and traditional ensemble learning algorithms can only pick a few representatives within each group. Our framework acts in a different way: the ℓ_2-norm objective function of SVM leads to an optimal solution that combines all the predictions within each group. This property is formalized in the following theorem.

Theorem 7 *Consider two ambiguous $h_\alpha, h_\beta \in \mathcal{H}$. If the kernel $\mathcal{K}_\mathcal{H}$ is used in Algorithm 1, the optimal w of (P_5) satisfies $\frac{w(\alpha)}{r(\alpha)} = \frac{w(\beta)}{r(\beta)}$.*

Proof The optimality condition between (P_1) and (P_2) leads to

$$\frac{w(\alpha)}{r(\alpha)} = \sum_{i=1}^{N} \lambda_i h_\alpha(x_i) = \sum_{i=1}^{N} \lambda_i h_\beta(x_i) = \frac{w(\beta)}{r(\beta)}. \qquad \blacksquare$$

If $w(\alpha)$ is nonzero, $w(\beta)$ would also be nonzero, which means both h_α and h_β are included in the ensemble. As a consequence, for each group of mutually ambiguous hypotheses, our framework considers the average prediction of all hypotheses as the consensus output.

The averaging process constructs a smooth representative for each group. In the following theorem, we demonstrate this behavior with the stump kernel, and show how the decision stumps group together in the final ensemble classifier.

Theorem 8 *Define $(\tilde{x})_{d,a}$ as the a-th smallest value in $\{(x_i)_d\}_{i=1}^N$, and A_d as the number of different $(\tilde{x})_{d,a}$. Let $(\tilde{x})_{d,0} = L_d$, $(\tilde{x})_{d,(A_d+1)} = R_d$, and*

$$\hat{s}_{q,d,a}(x) = q \cdot \begin{cases} +1, & \text{when } (x)_d \geq (\tilde{x})_{d,a+1}; \\ -1, & \text{when } (x)_d \leq (\tilde{x})_{d,a}; \\ \frac{2(x)_d - (\tilde{x})_{d,a} - (\tilde{x})_{d,a+1}}{(\tilde{x})_{d,a+1} - (\tilde{x})_{d,a}}, & \text{otherwise.} \end{cases}$$

Then, for $\hat{r}(q,d,a) = \frac{1}{2}\sqrt{(\tilde{x})_{d,a+1} - (\tilde{x})_{d,a}}$,

$$\mathcal{K}_\mathcal{S}(x_i, x) = \sum_{q \in \{-1,+1\}} \sum_{d=1}^{D} \sum_{a=0}^{A_d} \hat{r}^2(q,d,a) \hat{s}_{q,d,a}(x_i) \hat{s}_{q,d,a}(x).$$

Proof First, for any fixed q and d, a simple integration shows that

$$\int_{(\tilde{x})_{d,a}}^{(\tilde{x})_{d,a+1}} s_{q,d,\alpha}(x)\, d\alpha \quad = \quad \Big((\tilde{x})_{d,a+1} - (\tilde{x})_{d,a}\Big)\hat{s}_{q,d,a}(x).$$

In addition, note that for all $\alpha \in \Big((\tilde{x})_{d,a}, (\tilde{x})_{d,a+1}\Big)$, $\hat{s}_{q,d,a}(x_i) = s_{q,d,\alpha}(x_i)$. Thus,

$$\begin{aligned}
& \int_{L_d}^{R_d} \Big(r(q,d,\alpha) s_{q,d,\alpha}(x_i)\Big)\Big(r(q,d,\alpha) s_{q,d,\alpha}(x)\Big)\, d\alpha \\
= & \sum_{a=0}^{A_d} \int_{(\tilde{x})_{d,a}}^{(\tilde{x})_{d,a+1}} \left(\frac{1}{2} s_{q,d,\alpha}(x_i)\right)\left(\frac{1}{2} s_{q,d,\alpha}(x)\right) d\alpha \\
= & \sum_{a=0}^{A_d} \frac{1}{4} \hat{s}_{q,d,a}(x_i) \int_{(\tilde{x})_{d,a}}^{(\tilde{x})_{d,a+1}} s_{q,d,\alpha}(x)\, d\alpha \\
= & \sum_{a=0}^{A_d} \frac{1}{4} \Big((\tilde{x})_{d,a+1} - (\tilde{x})_{d,a}\Big) \hat{s}_{q,d,a}(x_i) \hat{s}_{q,d,a}(x).
\end{aligned}$$

The theorem can be proved by summing over all q and d. ■

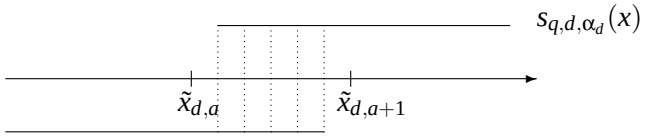
As shown in Figure 2, the function $\hat{s}_{q,d,a}$ is a smoother variant of the decision stump. Theorem 8 indicates that the infinite ensemble of decision stumps produced by our framework is equivalent to a finite ensemble of data-dependent and smoother variants. Another view of $\hat{s}_{q,d,a}$ is that they are continuous piecewise linear functions (order-2 splines) with knots defined on the training features (Hastie et al., 2001). Then, Theorem 8 indicates that an infinite ensemble of decision stumps can be obtained by fitting an additive model of finite size using these special splines as the bases. Note that although the fitting problem is of finite size, the number of possible splines can grow as large as $O(ND)$, which can sometimes be too large for iterative algorithms such as backfitting (Hastie et al., 2001). On the other hand, our SVM-based framework with the stump kernel can be thought as a route to solve this special spline fitting problem efficiently via the kernel trick.

As shown in the proof of Theorem 8, the averaged stump $\hat{s}_{q,d,a}$ represents the group of ambiguous decision stumps with $\alpha_d \in \Big((\tilde{x})_{d,a}, (\tilde{x})_{d,a+1}\Big)$. When the group is larger, $\hat{s}_{q,d,a}$ becomes smoother. Traditional ensemble learning algorithms like AdaBoost or LPBoost rely on a base learner to choose one decision stump as the only representative within each group, and the base learner usually returns the middle stump $m_{q,d,a}$. As shown in Figure 2, the threshold of the middle stump is at the mean of $(\tilde{x})_{d,a}$ and $(\tilde{x})_{d,a+1}$. Our framework, on the other hand, enjoys a smoother decision by averaging over more decision stumps. Even though each decision stump only has an infinitesimal hypothesis weight, the averaged stump $\hat{s}_{q,d,a}$ has a concrete weight in the ensemble.

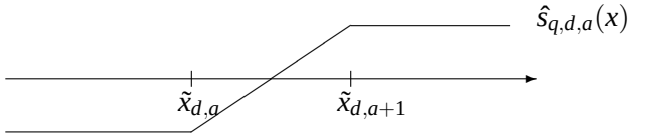
5. Perceptron Kernel

In this section, we extend the stump kernel to the perceptron kernel, which embodies infinitely many perceptrons. A perceptron is a linear threshold classifier of the form

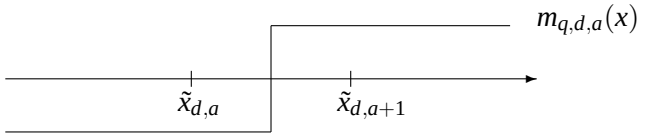
$$p_{\theta,\alpha}(x) = \mathrm{sign}\left(\theta^T x - \alpha\right).$$



(a) a group of ambiguous decision stumps s_{q,d,α_d} with $\alpha_d \in \left((\tilde{x})_{d,a}, (\tilde{x})_{d,a+1}\right)$



(b) SVM-based infinite ensemble learning uses the consensus: the averaged stump $\hat{s}_{q,d,a}$



(c) Base learners for AdaBoost and LPBoost usually only consider the middle stump $m_{q,d,a}$

Figure 2: The averaged stump and the middle stump

It is a basic theoretical model for a neuron, and is very important for building neural networks (Haykin, 1999).

To construct the perceptron kernel, we consider the following set of perceptrons

$$\mathcal{P} = \left\{ p_{\theta,\alpha} \colon \theta \in \mathbb{R}^D, \|\theta\|_2 = 1, \alpha \in [-R, R] \right\}.$$

We assume that $\mathcal{X}$ is within the interior of $\mathcal{B}(R)$, where $\mathcal{B}(R)$ is a ball of radius R centered at the origin in $\mathbb{R}^D$. Then, the set $\mathcal{P}$ is negation complete, and contains a constant hypothesis $p_{e_1,-R}$ where $e_1 = (1,0,\ldots,0)^T$. Thus, the perceptron kernel $\mathcal{K}_{\mathcal{P}}$ defined below can be used in Algorithm 1 to obtain an infinite ensemble of perceptrons.

Definition 9 *Let*

$$\Theta_D = \int_{\|\theta\|_2=1} d\theta, \quad \Xi_D = \int_{\|\theta\|_2=1} \left|\cos\left(\text{angle}\langle\theta, e_1\rangle\right)\right| d\theta,$$

where the operator angle$\langle\cdot,\cdot\rangle$ *is the angle between two vectors, and the integrals are calculated with uniform measure on the surface* $\|\theta\|_2 = 1$. *The perceptron kernel is* $\mathcal{K}_{\mathcal{P}}$ *with* $r(\theta,\alpha) = r_{\mathcal{P}}$,

$$\mathcal{K}_{\mathcal{P}}(x,x') = \Delta_{\mathcal{P}} - \left\|x - x'\right\|_2,$$

where the constants $r_{\mathcal{P}} = (2\Xi_D)^{-\frac{1}{2}}$ *and* $\Delta_{\mathcal{P}} = \Theta_D \Xi_D^{-1} R$.

The details are shown in Appendix A. With the perceptron kernel, we can construct an infinite ensemble of perceptrons. Such an ensemble is equivalent to a neural network with one hidden layer, infinitely many hidden neurons, and the hard-threshold activation functions. Williams (1998) built an infinite neural network with either the sigmoidal or the Gaussian activation function through computing the corresponding covariance function for GP models. Analogously, our approach returns an infinite neural network with hard-threshold activation functions (ensemble of perceptrons) through

computing the perceptron kernel for SVM. Williams (1998) mentioned that "*Paradoxically, it may be easier to carry out Bayesian prediction with infinite networks rather than finite ones.*" Similar claims can be made with ensemble learning.

The perceptron kernel shares many similar properties to the stump kernel. First, the constant $\Delta_{\mathcal{P}}$ can also be dropped, as formalized below.

Theorem 10 *Solving (P_2) with the simplified perceptron kernel $\tilde{\mathcal{K}}_{\mathcal{P}}(x,x') = -\|x-x'\|_2$ is the same as solving (P_2) with $\mathcal{K}_{\mathcal{P}}(x,x')$.*

Second, SVM with the perceptron kernel can also dichotomize the training set perfectly, which comes from the usefulness of the simplified perceptron kernel $\tilde{\mathcal{K}}_{\mathcal{P}}$ in interpolation.

Theorem 11 *(Micchelli, 1986) Consider input vectors $\{x_i\}_{i=1}^N \in \mathcal{X}^N$, and the perceptron kernel $\mathcal{K}_{\mathcal{P}}$ in Definition 9. If $x_i \neq x_j$ for all $i \neq j$, then the Gram matrix of $\mathcal{K}_{\mathcal{P}}$ is PD.*

Then, similar to Theorem 6, we get the following result.

Theorem 12 *If $x_i \neq x_j$ for all $i \neq j$, there exists some $C^* > 0$ such that for all $C \geq C^*$, SVM with $\mathcal{K}_{\mathcal{P}}$ can always dichotomize the training set $\{(x_i,y_i)\}_{i=1}^N$.*

Another important property, called *scale-invariance*, accompanies the simplified perceptron kernel, which was also named the *triangular kernel* by Fleuret and Sahbi (2003). They proved that when the kernel is used in the hard-margin SVM, scaling all training input vectors x_i by some positive γ does not change the optimal solution.

In fact, in the soft-margin SVM, a well-known result is that scaling the Gram matrix K by some $\gamma > 0$ is equivalent to scaling C by γ in (P_2). Because the simplified perceptron kernel $\tilde{\mathcal{K}}_{\mathcal{P}}$ satisfies $\gamma\tilde{\mathcal{K}}_{\mathcal{P}}(x,x') = \tilde{\mathcal{K}}_{\mathcal{P}}(\gamma x,\gamma x')$, the effect of scaling training examples can be equivalently performed with the parameter selection step on C. That is, when C is selected reasonably, there is no need to explicitly have a scaling parameter γ.

Recall that we construct the perceptron kernel (and the stump kernel) with an embedding constant $r_{\mathcal{P}}$ (and $r_{\mathcal{S}}$), and from Definition 1, multiplying the constant by $\sqrt{\gamma} > 0$ is equivalent to scaling the Gram matrix K by γ. Thus, when C is selected reasonably, there is also no need to explicitly try different $r_{\mathcal{P}}$ or $r_{\mathcal{S}}$ for these two kernels. We will further discuss the benefits of this property in Subsection 6.4.

6. Laplacian-RBF Kernel

In the previous sections, we applied Definition 1 on some simple base hypothesis sets. Next, we show how complex hypothesis sets can also be embedded in a kernel by suitably combining the kernels that embody simpler sets. We will introduce two useful tools: summation and multiplication. The tools would eventually allow us to embed infinitely many decision trees in a kernel. Interestingly, the kernel obtained is equivalent to the well-known Laplacian-RBF kernel in some parameters.

6.1 Summation: Embedding Multiple Sets of Hypotheses

Summation can be used to embed multiple sets of hypotheses altogether. For example, given kernels $\mathcal{K}_{\mathcal{H}_1}$ and $\mathcal{K}_{\mathcal{H}_2}$, their summation

$$\mathcal{K}(x,x') = \mathcal{K}_{\mathcal{H}_1}(x,x') + \mathcal{K}_{\mathcal{H}_2}(x,x')$$

embodies both $\mathcal{H}_1$ and $\mathcal{H}_2$. In other words, if we use $\mathcal{K}(x,x')$ in Algorithm 1, we could obtain an ensemble classifier over $\mathcal{H}_1 \cup \mathcal{H}_2$ when the union is negation complete and contains a constant hypothesis.

In traditional ensemble learning, when multiple sets of hypotheses are considered altogether, it is usually necessary to call a base learner for each set. On the other hand, our framework only requires a simple summation on the kernel evaluations. In fact, as shown in the next theorem, our framework can be applied to work with any countable sets of hypotheses, which may not be an easy task for traditional ensemble learning algorithms.

Theorem 13 *Assume that the kernels $\mathcal{K}_{\mathcal{H}_1}, \ldots, \mathcal{K}_{\mathcal{H}_J}$ are defined for some $J \in \mathbb{N} \bigcup \{\infty\}$ with sets of hypotheses $\mathcal{H}_1, \ldots, \mathcal{H}_J$, respectively. Then, let*

$$\mathcal{K}(x,x') = \sum_{j=1}^{J} \mathcal{K}_{\mathcal{H}_j}(x,x').$$

If $\mathcal{K}(x,x')$ exists for all $x,x' \in \mathcal{X}$, and $\mathcal{H} = \bigcup_{j=1}^{J} \mathcal{H}_j$ is negation complete and contains a constant hypothesis, Algorithm 1 using $\mathcal{K}(x,x')$ outputs an ensemble classifier over $\mathcal{H}$.

Proof The theorem comes from the following result in mathematical analysis: any countable direct sum over Hilbert spaces is a Hilbert space (Reed and Simon, 1980, Example 5). Lin (2005, Theorem 6) showed the details of the proof. ■

A remark on Theorem 13 is that we do not intend to define a kernel with $\mathcal{H}$ directly. Otherwise we need to choose suitable $\mathcal{C}$ and r first, which may not be an easy task for such a complex hypothesis set. Using the summation of the kernels, on the other hand, allow us to obtain an ensemble classifier over the full union with less efforts.

6.2 Multiplication: Performing Logical Combination of Hypotheses

It is known that we can combine two kernels by point-wise multiplication to form a new kernel (Schölkopf and Smola, 2002). When the two kernels are associated with base hypothesis sets, a natural question is: what hypothesis set is embedded in the new kernel?

Next, let output $+1$ represent logic TRUE and -1 represent logic FALSE. We show that multiplication can be used to perform common logical combinations on the hypotheses.

Theorem 14 *For two sets of hypotheses $\mathcal{H}_1 = \{h_\alpha : \alpha \in \mathcal{C}_1\}$ and $\mathcal{H}_2 = \{h_\beta : \beta \in \mathcal{C}_2\}$, define*

$$\mathcal{H} = \left\{h_{\alpha,\beta} : h_{\alpha,\beta}(x) = -h_\alpha(x) \cdot h_\beta(x), \alpha \in \mathcal{C}_1, \beta \in \mathcal{C}_2\right\}.$$

In addition, let $r(\alpha,\beta) = r_1(\alpha) r_2(\beta)$. Then,

$$\mathcal{K}_{\mathcal{H},r}(x,x') = \mathcal{K}_{\mathcal{H}_1,r_1}(x,x') \cdot \mathcal{K}_{\mathcal{H}_2,r_2}(x,x')$$

for all $x,x' \in \mathcal{X}$.

The proof simply follows from Definition 1. Note that when representing logic, the combined hypothesis $h_{\alpha,\beta}$ is the XOR operation on h_α and h_β. More complicated results about other operations can be introduced under a mild assumption called *neutrality*.

Definition 15 *A set of hypothesis $\mathcal{H} = \{h_\alpha : \alpha \in \mathcal{C}\}$ is neutral to $\mathcal{X}$ with a given r if and only if for all $x \in \mathcal{X}$, $\int_{\alpha\in\mathcal{C}} h_\alpha(x) r^2(\alpha)\, d\alpha = 0$.*

Note that for a negation complete set $\mathcal{H}$, neutrality is usually a mild assumption (e.g., by assigning the same r for h_α and $-h_\alpha$). We can easily verify that the set of decision stumps in Definition 3 and the set of perceptrons in Definition 9 are both neutral.

Theorem 16 *For two sets of hypotheses $\mathcal{H}_1 = \{h_\alpha : \alpha \in \mathcal{C}_1\}$ and $\mathcal{H}_2 = \{h_\beta : \beta \in \mathcal{C}_2\}$, define*

$$\mathcal{H} \quad = \quad \left\{h_{q,\alpha,\beta} : h_{q,\alpha,\beta}(x) = q \cdot \min\left(h_\alpha(x), h_\beta(x)\right), \alpha \in \mathcal{C}_1, \beta \in \mathcal{C}_2, q \in \{-1,+1\}\right\}.$$

Assume that $\mathcal{H}_1$ and $\mathcal{H}_2$ are neutral with r_1 and r_2, respectively, and both integrals

$$\Delta_1 = \int_{\alpha\in\mathcal{C}_1} r_1^2(\alpha)\, d\alpha,\ \Delta_2 = \int_{\beta\in\mathcal{C}_2} r_2^2(\beta)\, d\beta$$

are finite. In addition, let $r(q,\alpha,\beta) = \sqrt{2} r_1(\alpha) r_2(\beta)$. Then,

$$\mathcal{K}_{\mathcal{H},r}(x,x') = \left(\mathcal{K}_{\mathcal{H}_1,r_1}(x,x') + \Delta_1\right) \cdot \left(\mathcal{K}_{\mathcal{H}_2,r_2}(x,x') + \Delta_2\right)$$

for all $x, x' \in \mathcal{X}$. Furthermore, $\mathcal{H}$ is neutral to $\mathcal{X}$ with r.

Proof Because $h_\alpha(x), h_\beta(x) \in \{-1,+1\}$,

$$h_{+1,\alpha,\beta}(x) = \frac{1}{2}\left(h_\alpha(x)h_\beta(x) + h_\alpha(x) + h_\beta(x) - 1\right).$$

Then,

$$\begin{aligned}
& \mathcal{K}_{\mathcal{H},r}(x,x') \\
= \ & 2\int h_{+1,\alpha,\beta}(x) h_{+1,\alpha,\beta}(x') r^2(\alpha,\beta)\, d\beta\, d\alpha \\
= \ & \frac{1}{2}\int \left(h_\alpha(x)h_\beta(x) + h_\alpha(x) + h_\beta(x) - 1\right)\left(h_\alpha(x')h_\beta(x') + h_\alpha(x') + h_\beta(x') - 1\right) r^2(\alpha,\beta)\, d\beta\, d\alpha \\
= \ & \int \left(h_\alpha(x)h_\beta(x)h_\alpha(x')h_\beta(x') + h_\alpha(x)h_\alpha(x') + h_\beta(x)h_\beta(x') + 1\right) r_1^2(\alpha) r_2^2(\beta)\, d\beta\, d\alpha \qquad (6) \\
= \ & \left(\mathcal{K}_{\mathcal{H}_1,r_1}(x,x') + \Delta_1\right) \cdot \left(\mathcal{K}_{\mathcal{H}_2,r_2}(x,x') + \Delta_2\right).
\end{aligned}$$

Note that (6) comes from the neutrality assumption, which implies that during integration, the cross-terms like

$$\int h_\alpha(x) h_\beta(x') r_1^2(\alpha) r_2^2(\beta)\, d\alpha\, d\beta$$

are all 0. Neutrality of $\mathcal{H}$ follows from the symmetry in q. ■

The arithmetic operation $(+1 \cdot \min)$ is equivalent to the AND operation when the outputs represent logic, and hence $(-1 \cdot \min)$ represents the NAND operation. If $\mathcal{H}_1$ and $\mathcal{H}_2$ are negation complete, the NOT operation is implicit in the original sets, and hence OR can be equivalently performed through $\mathrm{OR}(a,b) = \mathrm{NAND}(\mathrm{NOT}(a), \mathrm{NOT}(b))$.

6.3 Stump Region Kernel, Decision Tree Kernel, and Laplacian-RBF Kernel

Next, we use the stump kernel to demonstrate the usefulness of summation and multiplication. When $\mathcal{H}_1 = \mathcal{H}_2 = \mathcal{S}$, the resulting $\mathcal{K}_{\mathcal{H}}$ from Theorem 16 embodies AND/OR combinations of two decision stumps in $\mathcal{S}$. Extending this concept, we get the following new kernels.

Definition 17 *The L-level stump region kernel $\mathcal{K}_{\mathcal{I}_L}$ is recursively defined by*

$$\begin{aligned} \mathcal{K}_{\mathcal{I}_1}(x,x') &= \mathcal{K}_{\mathcal{S}}(x,x') + \Delta_{\mathcal{S}},\ \Delta_1 = 2\Delta_{\mathcal{S}}, \\ \mathcal{K}_{\mathcal{I}_{L+1}}(x,x') &= \left(\mathcal{K}_{\mathcal{I}_L}(x,x') + \Delta_L\right)\left(\mathcal{K}_{\mathcal{S}}(x,x') + \Delta_{\mathcal{S}}\right),\ \Delta_{L+1} = 2\Delta_L\Delta_{\mathcal{S}} \text{ for } L \in \mathbb{N}. \end{aligned}$$

If we construct a kernel from $\{c,-c\}$ with $r = \sqrt{\frac{1}{2}\Delta_{\mathcal{S}}}$ on each hypothesis, we can see that the constant $\Delta_{\mathcal{S}}$ is also a neutral kernel. Since neutrality is preserved by summation, the kernel $\mathcal{K}_{\mathcal{I}_1}$ is neutral as well. By repeatedly applying Theorem 16 and maintaining Δ_L as the constant associated with $\mathcal{I}_L$, we see that $\mathcal{K}_{\mathcal{I}_L}$ embodies all possible AND/OR combinations of L decision stumps in $\mathcal{S}$. We call these hypotheses the *L-level stump regions*.

Note that we can solve the recurrence and get

$$\mathcal{K}_{\mathcal{I}_L}(x,x') = 2^L\Delta_{\mathcal{S}}^L \sum_{\ell=1}^{L} \left(\frac{\mathcal{K}_{\mathcal{S}}(x,x') + \Delta_{\mathcal{S}}}{2\Delta_{\mathcal{S}}}\right)^{\ell}, \text{ for } L \in \mathbb{N}.$$

Then, by applying Theorem 13, we obtain an ensemble classifier over stump regions of any level.

Theorem 18 *For $0 < \gamma < \frac{1}{\Delta_{\mathcal{S}}}$, the infinite stump region (decision tree) kernel*

$$\mathcal{K}_{\mathcal{I}}(x,x') = \exp\left(\gamma \cdot \left(\mathcal{K}_{\mathcal{S}}(x,x') + \Delta_{\mathcal{S}}\right)\right) - 1$$

can be applied to Algorithm 1 to obtain an ensemble classifier over $\mathcal{I} = \bigcup_{L=1}^{\infty} \mathcal{I}_L$.

Proof By Taylor's series expansion of $\exp(\varepsilon)$ near $\varepsilon = 0$, we get

$$\begin{aligned} \mathcal{K}_{\mathcal{I}}(x,x') &= \sum_{L=1}^{\infty} \frac{\gamma^L}{L!}\left(\mathcal{K}_{\mathcal{S}}(x,x') + \Delta_{\mathcal{S}}\right)^L \\ &= \gamma\mathcal{K}_{\mathcal{I}_1}(x,x') + \sum_{L=2}^{\infty} \frac{\gamma^L}{L!}\left(\mathcal{K}_{\mathcal{I}_L}(x,x') - 2\Delta_{\mathcal{S}}\,\mathcal{K}_{\mathcal{I}_{L-1}}(x,x')\right) \\ &= \sum_{L=1}^{\infty} \frac{\gamma^L}{L!}\mathcal{K}_{\mathcal{I}_L}(x,x') - \sum_{L=1}^{\infty} \frac{\gamma^{L+1}}{(L+1)!} 2\Delta_{\mathcal{S}}\,\mathcal{K}_{\mathcal{I}_L}(x,x') \\ &= \sum_{L=1}^{\infty} \left(\frac{\gamma^L}{L!} - \frac{\gamma^{L+1}2\Delta_{\mathcal{S}}}{(L+1)!}\right)\mathcal{K}_{\mathcal{I}_L}(x,x'). \end{aligned}$$

Note that $\tau_L = \frac{\gamma^L}{L!} - \frac{\gamma^{L+1}2\Delta_{\mathcal{S}}}{(L+1)!} > 0$ for all $L \geq 1$ if and only if $0 < \gamma < \frac{1}{\Delta_{\mathcal{S}}}$. The desired result simply follows Theorem 13 by scaling the r functions of each $\mathcal{K}_{\mathcal{I}_L}$ by $\sqrt{\tau_L}$. ■

The set of stump regions of any level contains all AND/OR combinations of decision stumps. It is not hard to see that every stump region can be represented by recursive axis-parallel partitions

that output $\{-1,+1\}$, that is, a decision tree (Quinlan, 1986; Hastie et al., 2001). In addition, we can view the nodes of a decision tree as logic operations:

$$\begin{aligned} & \mathsf{tree} \\ = \; & \mathrm{OR}(\mathrm{AND}(\text{root node condition}, \mathsf{left}), \mathrm{AND}(\mathrm{NOT}(\text{root node condition}), \mathsf{right})). \end{aligned}$$

By recursively replacing each root node condition with a decision stump, we see that every decision tree can be represented as a stump region hypothesis. Thus, the set $\mathcal{T}$ that contains stump regions of any level is the same as the set of all possible decision trees, which leads to the name *decision tree kernel*.[4]

Decision trees are popular for ensemble learning, but traditional algorithms can only deal with trees of finite levels (Breiman, 1999; Dietterich, 2000). On the other hand, when the decision tree kernel $\mathcal{K}_{\mathcal{T}}$ is plugged into our framework, it allows us to actually build an infinite ensemble over decision trees of arbitrary levels.

Note that the decision tree kernel $\mathcal{K}_{\mathcal{T}}(x,x')$ is of the form

$$\kappa_1 \exp\left(-\kappa_2 \left\|x-x'\right\|_1\right) + \kappa_3$$

where $\kappa_1, \kappa_2, \kappa_3$ are constants and κ_1, κ_2 are positive. We mentioned in Section 4 that scaling the kernel with κ_1 is equivalent to scaling the soft-margin parameter C in SVM, and in Theorem 4 that dropping κ_3 does not affect the solution obtained from SVM. Then, the kernel $\mathcal{K}_{\mathcal{T}}(x,x')$ is similar to the Laplacian-RBF kernel $\mathcal{K}_{\mathcal{L}}(x,x') = \exp(-\gamma\|x-x'\|_1)$. This result is a novel interpretation of the Laplacian-RBF kernel: under suitable parameters, SVM with the Laplacian-RBF kernel allows us to obtain an infinite ensemble classifier over decision trees of any level.[5]

Not surprisingly, when all training input vectors x_i are distinct (Micchelli, 1986; Baxter, 1991), the Gram matrix of $\mathcal{K}_{\mathcal{L}}$ (and hence $\mathcal{K}_{\mathcal{T}}$) is PD. Then, the Laplacian-RBF kernel and the decision tree kernel could be used to dichotomize the training set perfectly.

6.4 Discussion on Radial Basis Function Kernels

Note that the stump kernel, the perceptron kernel, the Laplacian-RBF kernel, and the Gaussian-RBF kernel are all radial basis functions. They can all be used to dichotomize the training set perfectly under mild conditions, while the first three connect to explanations from an ensemble perspective. Next, we compare two properties of these kernels, and discuss their use in SVM applications.

First, we can group these kernels by the distance metrics they use. The stump kernel and the Laplacian-RBF kernel deal with the ℓ_1-norm distance between input vectors, while the others work on the ℓ_2-norm distance. An interesting property of using the ℓ_2-norm distance is the invariance to rotations. From the construction of the perceptron kernel, we can see how the rotation invariance is obtained from an ensemble point-of-view. The transformation vectors θ in perceptrons represent the rotation, and rotation invariance comes from embedding all possible θ uniformly in the kernel.

4. We use the name decision tree kernel for $\mathcal{K}_{\mathcal{T}}$ in Theorem 18 because the kernel embodies an infinite number of decision tree "hypotheses" and can be used in our framework to construct an infinite ensemble of decision trees. As pointed out by a reviewer, however, the kernel is derived in a particular way, which makes the metric of the underlying feature space different from the metrics associated with common decision tree "algorithms."

5. Note that the techniques in Theorem 18 can be coupled with Theorem 14 to show that Laplacian-RBF kernel with any $\gamma > 0$ embodies XOR stump regions (a special type of decision tree) of any level. We emphasize on the AND-OR stump regions here to connect better to general decision trees.

Some applications, however, may not desire rotation invariance. For example, when representing an image with color histograms, rotation could mix up the information in each color component. Chapelle et al. (1999) showed some successful results with the Laplacian-RBF kernel on this application. In Subsection 4.1, we have also discussed some image recognition applications using the histogram intersection kernel, which is equivalent to the stump kernel, on histogram-based features. Gene expression analysis, as demonstrated by Lin and Li (2005b), is another area that the stump kernel could be helpful.

Second, we can group kernels by whether they are scale-invariant (see also Section 5). The simplified stump kernel and the simplified perceptron kernel are scale-invariant, which means that C is the only parameter that needs to be determined. On the other hand, different combinations of (γ, C) need to be considered for the Gaussian-RBF kernel or the Laplacian-RBF kernel during parameter selection (Keerthi and Lin, 2003). Thus, SVM with the simplified stump kernel or the simplified perceptron kernel enjoys an advantage on speed during parameter selection. As we will see in Section 7.2, experimentally they perform similarly to the Gaussian-RBF kernel on many data sets. Thus, SVM applications that consider speed as an important factor may benefit from using the simplified stump kernel or the simplified perceptron kernel.

7. Experiments

We first compare our SVM-based infinite ensemble learning framework with AdaBoost and LPBoost using decision stumps, perceptrons, or decision trees as the base hypothesis set. The simplified stump kernel (SVM-Stump), the simplified perceptron kernel (SVM-Perc), and the Laplacian-RBF kernel (SVM-Dec) are plugged into Algorithm 1 respectively. We also compare SVM-Stump, SVM-Perc, and SVM-Dec with SVM-Gauss, which is SVM with the Gaussian-RBF kernel.

The deterministic decision stump algorithm (Holte, 1993), the random coordinate descent perceptron algorithm (Li and Lin, 2007), and the C4.5 decision tree algorithm (Quinlan, 1986) are taken as base learners in AdaBoost and LPBoost for the corresponding base hypothesis set. For perceptrons, we use the RCD-bias setting with 200 epochs of training; for decision trees, we take the pruned tree with the default settings of C4.5. All base learners above have been shown to work reasonably well with boosting in literature (Freund and Schapire, 1996; Li and Lin, 2007).

We discussed in Subsection 4.2 that a common implementation of AdaBoost-Stump and LPBoost-Stump only chooses the middle stumps. For further comparison, we include all the middle stumps in a set $\mathcal{M}$, and construct a kernel $\mathcal{K}_{\mathcal{M}}$ with $r = \frac{1}{2}$ according to Definition 1. Because $\mathcal{M}$ is a finite set, the integral in (4) becomes a summation when computed with the counting measure. We test our framework with this kernel, and call it SVM-Mid.

LIBSVM 2.8 (Chang and Lin, 2001a) is adopted as the soft-margin SVM solver, with a suggested procedure that selects a suitable parameter with a five-fold cross validation on the training set (Hsu et al., 2003). For SVM-Stump, SVM-Mid, and SVM-Perc, the parameter $\log_2 C$ is searched within $\{-17, -15, \ldots, 3\}$, and for SVM-Dec and SVM-Gauss, the parameters $(\log_2 \gamma, \log_2 C)$ are searched within $\{-15, -13, \ldots, 3\} \times \{-5, -3, \ldots, 15\}$. We use different search ranges for $\log_2 C$ because the numerical ranges of the kernels could be quite different. After the parameter selection procedure, a new model is trained using the whole training set, and the generalization ability is evaluated on an unseen test set.

For boosting algorithms, we conduct the parameter selection procedure similarly. The parameter $\log_2 C$ of LPBoost is also searched within $\{-17, -15, \ldots, 3\}$. For AdaBoost, the parameter T

is searched within $\{10, 20, \ldots, 1500\}$. Note that because LPBoost can be slow when the ensemble size is too large (Demiriz et al., 2002), we set a stopping criterion to generate at most 1000 columns (hypotheses) in order to obtain an ensemble within a reasonable amount of time.

The three artificial data sets from Breiman (1999) (twonorm, threenorm, and ringnorm) are generated with training set size 300 and test set size 3000. We create three more data sets (twonorm-n, threenorm-n, ringnorm-n), which contain mislabeling noise on 10% of the training examples, to test the performance of the algorithms on noisy data. We also use eight real-world data sets from the UCI repository (Hettich et al., 1998): australian, breast, german, heart, ionosphere, pima, sonar, and votes84. Their feature elements are scaled to $[-1, 1]$. We randomly pick 60% of the examples for training, and the rest for testing. For the data sets above, we compute the means and the standard errors of the results over 100 runs. In addition, four larger real-world data sets are used to test the validity of the framework for large-scale learning. They are a1a (Hettich et al., 1998; Platt, 1999), splice (Hettich et al., 1998), svmguide1 (Hsu et al., 2003), and w1a (Platt, 1999).[6] Each of them comes with a benchmark test set, on which we report the results. Some information of the data sets used is summarized in Table 1.

6. These data sets are downloadable on tools page of LIBSVM (Chang and Lin, 2001a).

Table 4: Test error (%) of several ensemble learning algorithms using decision trees

7.1 Comparison of Ensemble Learning Algorithms

Tables 2, 3, and 4 show the test performance of several ensemble learning algorithms on different base hypothesis sets.[7] We can see that SVM-Stump, SVM-Perc, and SVM-Dec are usually better than AdaBoost and LPBoost with the same base hypothesis set, especially for the cases of decision stumps and perceptrons. In noisy data sets, SVM-based infinite ensemble learning always significantly outperforms AdaBoost and LPBoost. These results demonstrate that it is beneficial to go from a finite ensemble to an infinite one with suitable regularization. When comparing the two boosting approaches, LPBoost is at best comparable to AdaBoost on a small number of the data sets, which suggests that the success of AdaBoost may not be fully attributed to its connection to (P_3) or (P_4).

Note that SVM-Stump, SVM-Mid, AdaBoost-Stump, and LPBoost-Stump usually generate different kinds of ensembles: SVM-Stump produces infinite and nonsparse ones; SVM-Mid produces finite and nonsparse ones; AdaBoost-Stump produces finite and sparse ones; LPBoost-Stump produces finite and even sparser ones (since some of the selected h_t may end up having $w_t = 0$). In Table 2, we see that SVM-Stump often outperforms SVM-Mid, which is another evidence that an infinite ensemble could help. Interestingly, SVM-Mid often performs better than AdaBoost-Stump, which means that a nonsparse ensemble introduced by minimizing the ℓ_2-norm of w is better than a sparse one.

In Figure 3, we further illustrate the difference between the finite and infinite ensemble learning algorithms by a simplified experiment. We show the decision boundaries generated by the four algorithms on 300 training examples from the 2-D version of the twonorm data set. The Bayes-

7. For the first 14 rows of Tables 2, 3, 4, and 5, results that are as significant as the best ones are marked in bold; for the last 4 rows, the best results are marked in bold.

Figure 3: Decision boundaries of ensemble learning algorithms on a 2-D twonorm data set

optimal decision boundary is the line $(x)_1 + (x)_2 = 0$. We can see that SVM-Stump produces a decision boundary close to the optimal, SVM-Mid is slightly worse, while AdaBoost-Stump and LPBoost-Stump fail to generate a decent boundary. SVM-Stump obtains the smooth boundary by averaging over infinitely many decision stumps; SVM-Mid can also generate a smooth boundary by constructing a nonsparse ensemble over a finite number of decision stumps. Nevertheless, both LPBoost-Stump and AdaBoost-Stump, for which sparsity could be observed from the axis-parallel decision boundaries, do not have the ability to approximate the Bayes optimal boundary well. In addition, as can be seen near the origin point of Figure 3(c), AdaBoost-Stump could suffer from overfitting the noise.

Note that traditional ensemble learning and our SVM-based framework differ in the concept of sparsity. As illustrated in Subsection 2.2, traditional ensemble learning prefers sparse ensemble classifiers, that is, ensembles that include a small number of hypotheses. Our framework works with an infinite number of hypotheses, but results in a sparse classifier in the support vector domain. Both concepts can be justified with various generalization bounds (Freund and Schapire, 1997; Graepel et al., 2005). Nevertheless, our experimental results indicate that sparse ensemble classifiers are sometimes not sophisticated enough in practice, especially when the base hypothesis set is simple. For example, when using the decision stumps, a general data set may require many of them to describe a suitable decision boundary. Thus, AdaBoost-Stump and LPBoost-Stump could be limited by the finiteness and sparsity restrictions. The comparison between AdaBoost-Stump and SVM-Mid

indicates that the second restriction could be crucial. On the other hand, our framework (SVM-Stump), which suffers from neither restrictions, can perform better by averaging over an infinite number of hypotheses.

7.2 Comparison to Gaussian Kernel

In Table 5, we compare all the radial basis function kernels. We can see that SVM-Gauss, being the state-of-the-art setting (Hsu et al., 2003), usually performs well. Its superior performance on the artificial data sets is because they are generated from certain Gaussian distributions. Nevertheless, all SVM-Stump, SVM-Perc, and SVM-Dec outperform SVM-Gauss on some data sets, which demonstrates that they could achieve decent test performances as well.

Furthermore, SVM-Perc and SVM-Gauss share almost indistinguishable performance on the real-world data sets, which is possibly because they both use the ℓ_2-norm distance for measuring similarity. In addition, as discussed in Subsection 6.4, SVM-Perc enjoys the benefit of faster parameter selection. For example, in our experiments, SVM-Gauss involves solving 550 optimization problems, but SVM-Perc deals with only 55 problems. Table 6 shows the speed comparison.[8] We can qualitatively see that SVM-Stump and SVM-Perc are much faster than SVM-Dec and SVM-Gauss.

8. Solving each SVM optimization problem heavily depends on the condition number of the Gram matrix (which depends on the kernel) and the soft-margin parameter C. Thus, it is not easy to compare the training time between different kernels and the numbers here are meant to be interpreted qualitatively. Similar results are observed when using real-world data sets as well (Lin, 2005).

data set	SVM-Stump	SVM-Perc	SVM-Dec	SVM-Gauss
twonorm	1.34	1.44	19.5	23.1
threenorm	1.69	1.69	23.1	31.1
ringnorm	1.50	1.60	23.7	27.9

Table 6: Parameter selection time (sec.) on a dual 1.7 GHz Intel Xeon CPU machine

Since SVM-Perc and SVM-Gauss perform similarly on real-world data sets, the benefit of faster parameter selection makes SVM-Perc a favorable choice in practice. Furthermore, SVM-Stump, albeit slightly worse than SVM-Perc or SVM-Gauss, could still be a useful alternative in some applications where decision stump ensemble models are preferred, such as those described in Subsection 6.4.

8. Conclusion

We derived two novel kernels based on the infinite ensemble learning framework. The stump kernel embodies infinitely many decision stumps, and the perceptron kernel embodies infinitely many perceptrons. These kernels can be simply evaluated by the ℓ_1- or ℓ_2-norm distance between examples. We also explained that the Laplacian-RBF kernel embodies infinitely many decision trees. SVM equipped with the kernels can generate infinite and nonsparse ensembles, which are usually more robust than finite and sparse ones.

Experimental comparisons with AdaBoost and LPBoost showed that SVM with the kernels usually performs much better than boosting approaches with the same base hypothesis set, especially in the cases of decision stumps or perceptrons. Therefore, existing applications that use boosting with decision stumps, perceptrons, or decision trees may be improved by switching to SVM with the corresponding kernel.

In addition, we showed that the perceptron kernel shares similar performance to the Gaussian-RBF kernel, while the former benefits from faster parameter selection. This property makes the perceptron kernel favorable to the Gaussian-RBF kernel in practice.

Acknowledgments

Abstract

Classifiers favoring sparse solutions, such as support vector machines, relevance vector machines, LASSO-regression based classifiers, etc., provide competitive methods for classification problems in high dimensions. However, current algorithms for training sparse classifiers typically scale quite unfavorably with respect to the number of training examples. This paper proposes online and multi-pass algorithms for training sparse linear classifiers for high dimensional data. These algorithms have computational complexity and memory requirements that make learning on massive data sets feasible. The central idea that makes this possible is a straightforward quadratic approximation to the likelihood function.

Keywords: Laplace approximation, expectation propagation, LASSO

1. Introduction

We consider the problem of learning high-dimensional sparse linear classifiers from large numbers of training examples. A number of different applications from finance, text mining, and bioinformatics motivate this work. We concern ourselves specifically with binary classification and consider L_1-regularized logistic and probit regression models. Such models have provided excellent predictive accuracy in many applications (see, for example, Genkin et al., 2007; Figueiredo and Jain, 2001; Shevade and Keerthi, 2003) and attack overfitting and variable selection in a unified manner. L_1-regularization and a maximum *a posteriori* (MAP) Bayesian analysis with so-called Laplacian priors yield identical results (Tibshirani, 1996) and in order to streamline our presentation, we adopt the Bayesian approach. Many training algorithms now exist for L_1-logistic regression that can handle high-dimensional input vectors (Hastie et al., 2004; Shevade and Keerthi, 2003; Koh et al., 2007). However, these algorithms generally begin with a "load data into memory" step that precludes applications with large numbers of training examples. More precisely, consider a training data set that comprises t examples each of dimension d. Due to matrix multiplications on $t \times t$ or $d \times d$ matrices, typical computational time requirements are $O(t^3 + d^3)$, with memory requirements that are $O(td + d^2)$. In our target applications, both t and d can exceed 10^6 so standard algorithms become impractical.

This paper presents two basic algorithms for learning L_1-logistic and/or probit regression models. Both operate in the data streaming model, by which we mean that they scan the data sequentially, and never require storing processed observations. The first algorithm we present is an online algorithm which sequentially processes each observation only once. This algorithm is provably non-divergent and uses in the worst case $O(d^2)$ time and $O(d^2)$ space to assimilate each new training example (note that both costs are constant with respect to the number of observations, t). Further, if the input data are sparse, the practical computational cost can be significantly lower.

For massive data sets where t is constant, that is, when given a fixed training data set, we present a second algorithm that allows practitioners to trade-off computational time for improved accuracy. This multi-pass algorithm (the MP algorithm) also processes data sequentially but makes a small constant number of extra passes over the data set. Hence, this sequential algorithm provides results similar to those of batch algorithms for this problem. The MP algorithm's computational cost is a constant factor higher and memory costs are essentially the same as those of the online algorithm. Finally, we propose the RMMP (Reduced Memory MP) algorithm that has significantly lower worst case memory costs, $O(d+k^2)$ (where $k \ll d$) and the same computational costs as the MP algorithm (thus both computational and memory costs are essentially linear in t and d). We will comment on the similarities and differences of our technique to other learning algorithms, in particular other online algorithms, in the following sections.

2. Background and Notation

Throughout this manuscript, we concern ourselves with the task of binary classification, with class labels $y \in \{0,1\}$. The training data comprise t labeled training examples, that is, $D_t = \{(\mathbf{x}_i, y_i)\}_{i=1}^t$, with input vectors $\mathbf{x}_i = [x_{i1}, \ldots, x_{id}]^T$ in $\mathbb{R}^d$ and corresponding labels y_i, $i = 1, \ldots, t$. We consider probabilistic classifiers of the form:

$$p(y = 1|\mathbf{x}) = \Phi(\beta^T \mathbf{x})$$

where $\beta \in \mathbb{R}^d$ is a vector of regression parameters and $\Phi(\cdot)$ is a link function. We restrict our analytical results to the two most commonly used link functions, the probit $\Phi(z) = \int_{-\infty}^{z} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} dx$ and logistic $\Phi(z) = \frac{e^z}{1+e^z}$ link functions.

The machine learning problem is thus to estimate the parameters β, in the light of the training data D_t. We tailor our results towards high input dimension, that is, large d, and large numbers of training vectors, large t. Viewing the learning problem as one of Bayesian inference, we work with the posterior distribution of the parameters β conditioned on a labeled training data set D_t, given a prior distribution on the parameters β:

$$p(\beta|D_t) \propto \left(\prod_{i=1}^{t} p(y_i|\beta) \right) p(\beta). \tag{1}$$

The quantity on the left hand side of (1) is the required posterior distribution of β given the data set D_t, while the second term on the right hand side is the prior distribution on β, which we will specify momentarily. The first term on the right hand side is the likelihood:

$$\prod_{i=1}^{t} p(y_i|\beta) = \prod_{i=1}^{t} \left(y_i \Phi(\beta^T \mathbf{x}_i) + (1-y_i)(1-\Phi(\beta^T \mathbf{x}_i)) \right).$$

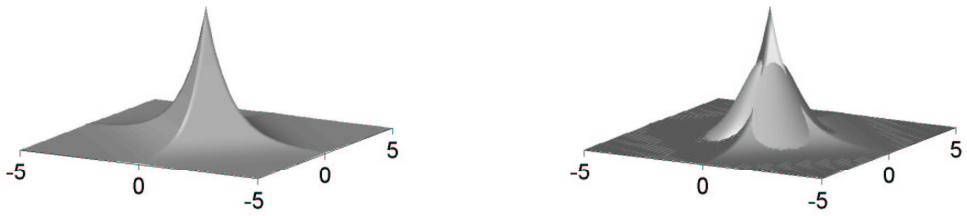
Finding the MAP β leads to the optimization problem we wish to solve (now on the log scale):

$$\begin{aligned} & \max_{\beta} \left(\log p(\beta|D_t)\right) \\ \equiv \quad & \max_{\beta} \left(\sum_{i=1}^{t} \log \left(y_i \Phi(\beta^T \mathbf{x}_i) + (1-y_i)(1-\Phi(\beta^T \mathbf{x}_i)\right) - \log p(\beta) \right). \end{aligned} \tag{2}$$

The prior distribution $p(\beta)$ we pick for the parameters is the LASSO prior (Tibshirani, 1996), a product of independent Laplacian or double-exponential prior distributions on each component β_j (with mean 0):

$$p(\beta_j|\gamma) = \frac{\gamma}{2} e^{-\gamma|\beta_j|}, \gamma > 0, j = 1, \ldots, d.$$

A prior of this form places high probability mass near zero and along individual component axes. It also has heavier tails than a Gaussian distribution—see Figure 1 for plots of the 2-dimensional distributions. It thus favors locations in parameter space with component magnitudes either exactly



(a) (b)

Figure 1: (a) A standard Laplacian distribution, $\gamma = 1$ (b) A superposition of standard (zero mean, unit variance) Gaussian distribution, and the Laplacian distribution showing both the higher probability mass the Laplacian assigns along the axes and at zero as well as its heavier tails.

zero, and hence pruned from our predictive model, or shrunk towards zero. With this prior distribution, (2) presents a convex optimization problem and yields the same solutions as the LASSO (Tibshirani, 1996) and Basis Pursuit (Chen et al., 1999):

$$\begin{aligned} & \max_{\beta} \left(\log p(\beta|D_t)\right) \\ \equiv \quad & \max_{\beta} \left(\sum_{i=1}^{t} \log \left(y_i \Phi(\beta^T \mathbf{x}_i) + (1-y_i)(1-\Phi(\beta^T \mathbf{x}_i)\right) - \gamma \|\beta\|_1 \right). \end{aligned} \tag{3}$$

The parameter γ in the above problem controls the amount of regularization. Figure 2 shows a 2-dimensional visualization of how the objective function of the optimization problem changes

as γ is varied. The choice of the regularization parameter is an important but separate question in itself (Efron et al., 2004; Hastie et al., 2004). Methods such as cross validation can be used to pick its value and algorithms also exist to find solutions for all values of the regularization parameter (commonly called regularization path algorithms). However, we do not address such issues in this manuscript, and we simply assume γ is some fixed, user-specified constant.

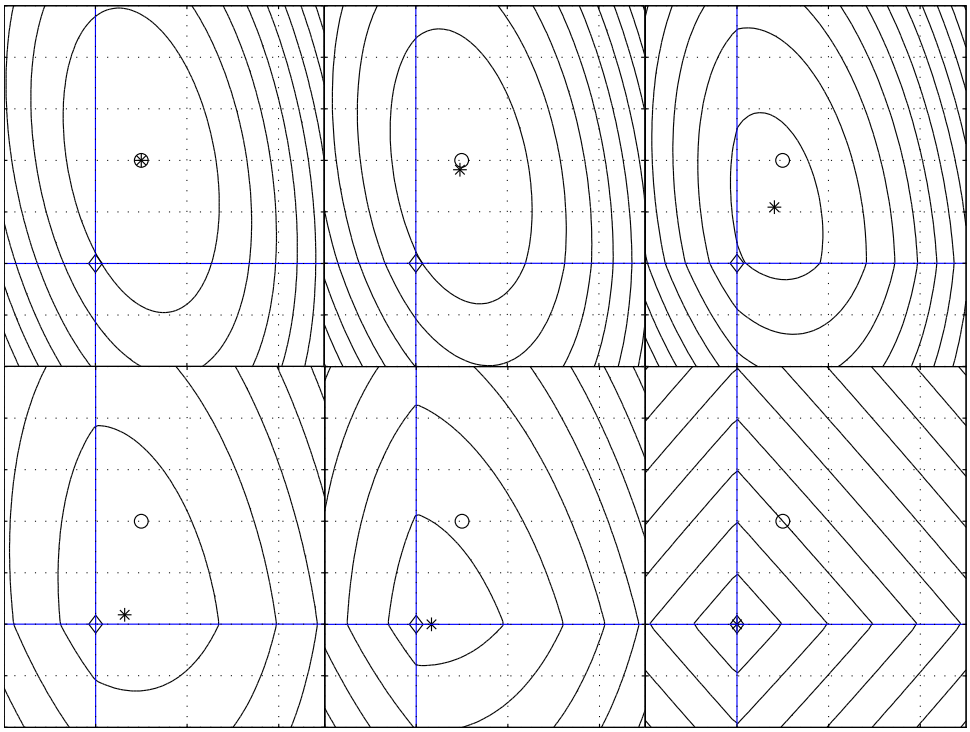


Figure 2: L_1-regularization in two dimensions (i.e., $d = 2$). The axes are the solid lines, the horizontal axis representing β_1 and the vertical axis representing β_2. The diamond represents the origin and the open circle represents the (non-regularized) maximum likelihood solution. The figure shows contours of the function in (3), the objective function, for increasing amounts of regularization (right to left and then top to bottom). The star shows the MAP location. The top row, left figure, shows negligible regularization; the MAP and maximum likelihood estimates coincide and the contours show no L_1-induced discontinuities. The top row, right figure, shows noticeable L_1 effects and the MAP and maximum likelihood solutions differ. The bottom row, middle panel shows enough L_1-regularization to set β_2 to zero (i.e., variable selection has occurred). The bottom row, right panel, shows extreme regularization, where both β_1 and β_2 are zero.

To the best of our knowledge, all existing algorithms solve the above convex optimization problem in the batch setting, that is, by storing the data set D_t in memory and iterating over it (Fu, 1998; Osborne et al., 2000; Zhang, 2002; Shevade and Keerthi, 2003; Genkin et al., 2007; Koh et al., 2007). Consequently, these algorithms cannot be used in the massive data/online scenario, where memory costs dependent on t represent a significant practical impediment. The approach we present

now attempts to overcome this limitation and thereby provide algorithms for training sparse linear classifiers without loading the entire data set into memory.

3. Approximating the Likelihood for Online Learning

The Bayesian paradigm supports online learning in a natural fashion; starting from the prior, the first training example produces a posterior distribution incorporating the evidence from the first example. This then becomes the prior distribution awaiting the arrival of the second example, and so on. In practice, however, except in those cases where the posterior distribution has the same mathematical form as the prior distribution, some form of approximation is required to carry out the sequential updating.

We want to avoid algorithms that begin with a "load data into memory" step and also avoid memory costs that increase with increasing amounts of data. In other words, we want memory costs independent of t. This requirement in turn, necessitates that we "forget" examples after processing them. We achieve this by maintaining the sufficient statistics of a quadratic approximation in β to the log-likelihood of the parameters after incorporating each observation.

We approximate the log-likelihood as:

$$\begin{aligned}\sum_{i=1}^{t}\log(p(y_i|\beta)) &= \sum_{i=1}^{t}\log\left(y_i\Phi(\beta^T\mathbf{x}_i)+(1-y_i)(1-\Phi(\beta^T\mathbf{x}_i)\right)\\ &\approx \sum_{i=1}^{t}\left(a_i(\beta^T\mathbf{x}_i)^2+b_i(\beta^T\mathbf{x}_i)+c_i\right),\end{aligned}$$

where $a_i(\beta^T\mathbf{x}_i)^2+b_i(\beta^T\mathbf{x}_i)+c_i$ approximates $\log\Phi(\beta^T\mathbf{x}_i)$ when $y_i=1$ and approximates $\log(1-\Phi(\beta^T\mathbf{x}_i))$ when $y_i=0$, $i=1,\ldots,t$. In either case the approximation uses a simple Taylor expansion around $\beta_{i-1}^T\mathbf{x}_i$, where β_{i-1} estimates the posterior mode given the first $i-1$ examples, D_{i-1} (Appendix A provides expressions for a_i, b_i for the probit and logistic link functions). We then have:

$$\begin{aligned}\sum_{i=1}^{t}\log(p(y_i|\beta)) &\approx \sum_{i=1}^{t}\left(a_i(\beta^T\mathbf{x}_i)^2+b_i(\beta^T\mathbf{x}_i)+c_i\right)\\ &= \sum_{i=1}^{t}a_i(\beta^T\mathbf{x}_i)(\mathbf{x}_i^T\beta)+\sum_{i=1}^{t}b_i(\beta^T\mathbf{x}_i)+\sum_{i=1}^{t}c_i\\ &= \beta^T\Psi_t\beta+\beta^T\theta_t+\sum_{i=1}^{t}c_i\end{aligned}$$

where:

$$\Psi_t=\sum_{i=1}^{t}a_i\mathbf{x}_i\mathbf{x}_i^T,\text{ and }\theta_t=\sum_{i=1}^{t}b_i\mathbf{x}_i.$$

We now substitute this approximation of the log-likelihood function into Equation (3) to obtain the modified (approximate) optimization problem:

$$\max_{\beta}\left(\log p(\beta|D_t)\right)\approx\max_{\beta}\left(\beta^T\Psi_t\beta+\beta^T\theta_t-\gamma\|\beta\|_1\right). \tag{4}$$

Note that we can ignore the term involving the c_i's, as it is not a function of β. Further, the fixed size $d \times d$ matrix Ψ and the $d \times 1$ vector θ can be updated in an online fashion as data accumulate:

$$\Psi_{t+1} = \Psi_t + a_{t+1}\mathbf{x}_{t+1}\mathbf{x}_{t+1}^T, \text{ and } \theta_{t+1} = \theta_t + b_{t+1}\mathbf{x}_{t+1}. \tag{5}$$

The size of the optimization problem in (4) doesn't depend on t, the size of the data set seen so far. Thus, solving a fixed (with respect to t) size optimization problem allows one to sequentially process labeled data items and march through the data set. In data streaming terminology, the matrix Ψ and the vector θ provide a constant size sketch or summary of the labeled observations seen so far.

A number of questions now present themselves: how good is this approximation? How do we solve the approximate optimization problem efficiently? How does this approach differ from other likelihood approximation schemes (some of which are also quadratic)? Also, the scheme as set up requires $O(d^2)$ memory in the worst case. Since we would like to use this approach for high dimensional data sets, can we reduce the memory requirements?

The remainder of this manuscript addresses these and other questions. First, we consider how to efficiently obtain the MAP solution of (4), the approximate optimization problem.

3.1 The Modified Shooting Algorithm

Recall that we need to find β that solves:

$$\max_{\beta} \left(\beta^T \Psi \beta + \beta^T \theta - \gamma \|\beta\|_1 \right). \tag{6}$$

In the above equation and following discussion, we drop the subscript t from Ψ, θ for notational convenience. This is a convex optimization problem and a number of efficient techniques exist to solve it. Newton's method and other Hessian-based algorithms may be prohibitively expensive as they need $O(d^3)$ computational time in order to construct the Hessian/invert $d \times d$ matrices. Other authors have described good results on the arguably tougher (non-approximate) optimization problem for logistic regression (essentially the terms in Equation 3, but with L_2 regularization of β) with techniques such as fixed memory BFGS (Minka, 2000), modified conjugate gradient (Komarek and Moore, 2005) and cyclic coordinate descent (Zhang and Oles, 2001; Genkin et al., 2007).

In this paper, we employ instead a slight modification of the Shooting algorithm (Fu, 1998), see Algorithm 1. Shooting is essentially a coordinate-wise gradient ascent algorithm, explicitly tailored for convex L_1-constrained regression problems (squared loss). Since our approximate optimization problem is also quadratic, the resulting modifications required are straightforward. The vector Ω in the algorithm is defined as $\Omega = 2\Psi'\beta + \theta$, where Ψ' is the matrix Ψ with its diagonal entries set to zero (see Appendix B for details). This vector is related to the gradient of the differentiable part of the objective function and consequently can be used for optimality checking. Minor variants of this algorithm have been independently proposed by Shevade and Keerthi (2003) and Krishnapuram et al. (2005). Although Fu originally derived the algorithm by taking the limit of a modified Newton-Raphson method, it can also be obtained by a subgradient analysis of the system (subgradients are necessary due to the non-differentiability that the L_1 constraints on β result in, see Appendix B for the derivation).

While one can think of numerous stopping criteria for the algorithm, in this paper we stop when successive iterates are sufficiently close to each other (relatively, and with respect to the L_2

  end
end

norm). More precisely, we declare convergence whenever $\|\beta_i - \beta_{i-1}\|_2 / \|\beta_{i-1}\|_2$ is less than some user specified tolerance. Note that β_i is the parameter vector at iteration i, which is obtained after cycling through and updating all d components once.

In the worst case, each iteration of Shooting requires $O(d^2)$ computational time. However, for reasonable amounts of regularization, where the final set of non-zero β values is small, the time requirements are much smaller. Indeed, the practical computational cost is perhaps better reflected by bounds in terms of the sparsity of MAP β. Let m denote the maximum number of non-zero components of β along the solution path to MAP β (hence $m \leq d$). Implemented carefully, Shooting requires $O(md)$ time per iteration (see Appendix B for details). Shooting can be initialized with $\beta_0 = 0$ if no information about the optimal β is known or to an appropriate "warm" starting point.

While coordinate-wise approaches are commonly regarded as slow in the literature (for example, Minka, 2001a), for sparse classifiers, they are much faster (see for example, Shevade and Keerthi, 2003). In our experiments, the Shooting algorithm has proven to be practical even for d in the hundreds of thousands.

4. An Online Algorithm

The quadratic approximation and the Shooting algorithm lead straightforwardly to an online algorithm. After initializing the sketch parameters Ψ_0, θ_0 and the initial parameter vector β_0, process the data set one observation at a time. Calculate the quadratic Taylor series approximation to each observation's log-likelihood at the current estimate of the posterior mode, β_{i-1}, thus finding parameters a_i, b_i. Use these parameters and the observation to update the sketches, Ψ, θ. Now run the modified Shooting algorithm to update the posterior mode, producing β_i and repeat for the next labelled observation—see Algorithm 2.

We show the performance of the online algorithm on a low dimensional simulated data set in Figure 3 (the data generating mechanism is a logistic regression model with $d = 11$, and $t = 100,000$. For details see the Experiments section of the manuscript). As we process greater numbers of observations, the online estimates (the solid lines) improve, that is, get closer to the batch

Algorithm 2: The Online algorithm.

Data: D_t, γ.
Result: For each i, produces β_i, an approximation to the MAP estimate of β for observations $(\mathbf{x}_1, y_1) \ldots (\mathbf{x}_i, y_i)$.
Initialize $\beta_0 = \theta_0 = 0$, $\Psi_0 = 0$, $i = 1$.
while $i < t$ **do**
  Get i'th observation $(\mathbf{x}_i, y_i)$.
  Obtain quadratic approximation to term likelihood at β_{i-1}, that is, obtain a_i, b_i.
  $\Psi_i \leftarrow \Psi_{i-1} + a_i \mathbf{x}_i \mathbf{x}_i^T$.
  $\theta_i \leftarrow \theta_{i-1} + b_i \mathbf{x}_i$.
  $\beta_i \leftarrow$ modified Shooting$(\Psi_i, \theta_i, \beta_{i-1}, \gamma)$
  $i \leftarrow i + 1$.
end

estimates (the dashed lines which we obtain using BBR, Genkin et al. 2007, publicly available software for batch L_1 penalized logistic regression). See Figure 3, where different colors represent different components of MAP β_i. Figure 4 shows individual plots of the online and batch estimates for four representative components of MAP β_i in blue. We also plot the absolute difference between the batch and online estimates in green (dotted line) on the same plot on the right (green) axis. As we expect, after the parameter estimates stabilize, this difference steadily tapers off with increasing amounts of data.

Table 1: Table with columns showing values of β_{true}, and the MAP estimates of β obtained by the batch algorithm and the online algorithm, for increasing amounts of data on the simulated data set. To aid assessing convergence of the online to the batch estimates, we show the value of the L_1 norm of the adjacent vectors (batch vs. online estimates) in the last row. For this example, $\gamma = 10$ (logistic link function).

In the worst case, the online algorithm requires $O(d^2)$ space and $O(d^2)$ computational time to compute the MAP β for each new observation. Note however, that if the input data has sparsity,

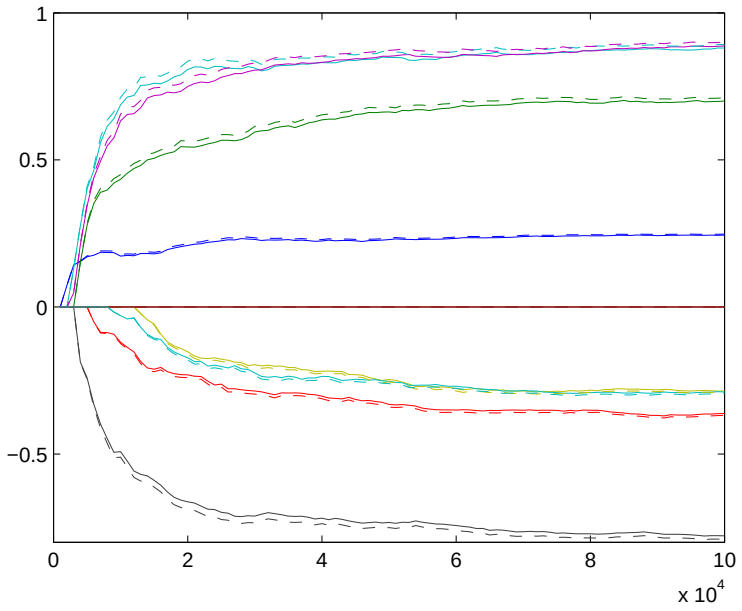

Figure 3: Performance of the online algorithm on a simulated data set, with regularization parameter $\gamma = 100$ (see text for details). The y-axis is the parameter value, the x-axis the number of observations processed, t.

which is true of text data for instance, the algorithm leverages this. Let the maximum number of non-zero components in any $\mathbf{x}$ be f and assume a constant number of iterations of the modified Shooting algorithm. In such case, the practical computational time requirement of the algorithm is $O(f^2 + md)$ per observation (we remind the reader that the md term, is for the cost of the Shooting algorithm—see 3.1). Although the practical memory costs of the algorithm will likely be less than $O(d^2)$, exactly how much less depends heavily on the data, since Ψ (the part of the sketch dominating the memory requirements) is a weighted sum of outer products of the $\mathbf{x}_i$'s. It is possible that even very sparse data may result in the full $O(d^2)$ memory requirement.

Here, we highlight the fact that the online algorithm is accurate and practical if the problem is of low to medium input dimension, but massive in terms of the number of observations. Appendix C proves non-divergence of the algorithm in the infinite data limit.

4.1 Heuristics for Improvement/Issues

While one can also obtain parameter estimates for fixed t (batch problems) using the online algorithm, multiple passes typically provide better estimates, albeit with increased computational cost. Denote by β_* the solution to the exact optimization problem (3) for some fixed t. Since the online algorithm typically initializes itself far from β_*, it is only after processing a sufficient number of examples that the online algorithm's term approximations will start being taken closer to β_*. The update formulae, (5), reveal that for values of $i < t$, both Ψ_i and θ_i are (comparatively) smaller in

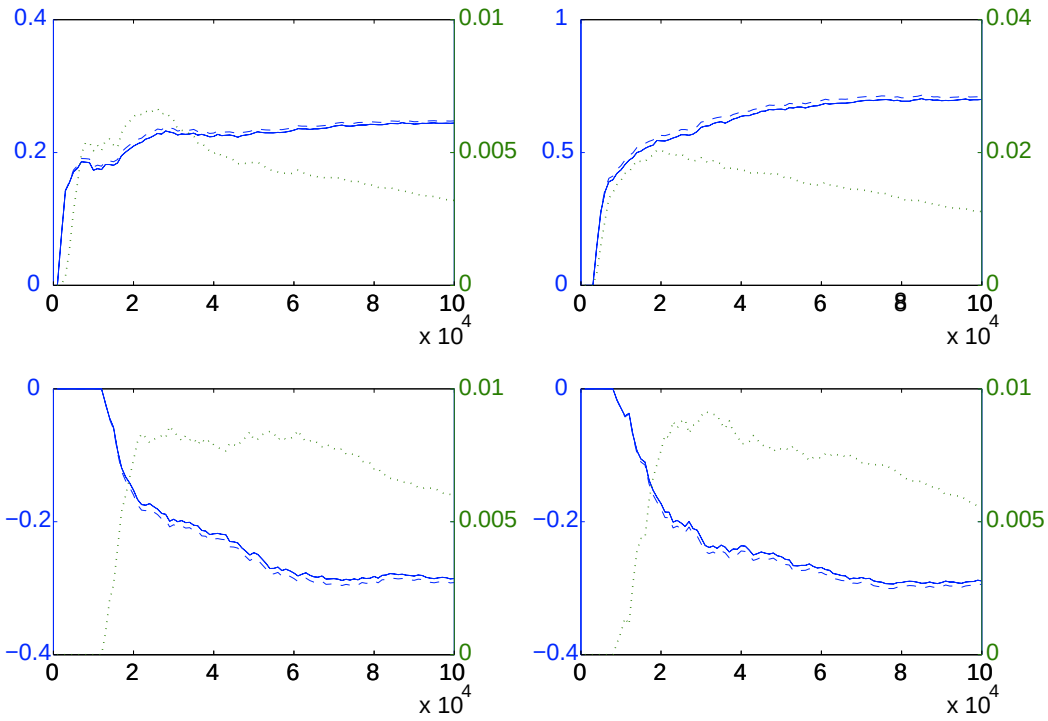

Figure 4: Slightly more detailed version of Figure 3. The panels show four representative parameters from that figure, also showing tapering L_1 loss (dotted green line) between the online and batch algorithm estimates on the right axis (in green). Simulated data set, $\gamma = 100$. Once again, the (left) y-axis is the parameter value and the x-axis the number of observations processed, t.

magnitude than their respective final values, Ψ_t, θ_t. However, the amount of regularization remains relatively fixed at $\gamma\|\beta\|_1$. Hence, if the online algorithm is initialized at $\beta_0 = 0$, for any $i < t$, the output MAP estimate β_i will be more shrunk towards zero than β_*. Figure 3 illustrates this for smaller values of t where the solid lines (approximate MAP estimates) are closer to zero than the dashed lines (exact batch estimates).

This suggests the following two heuristics to improve the quality of estimates from the online algorithm. The first is to increase the amount of regularization gradually as the algorithm processes observations sequentially (via a schedule, linearly say, $\propto t$ from zero initially to the specified value γ at the end of the data set[1]). Less regularization of the first few observations somewhat mitigates the effect of taking term approximations at shrunken parameter estimates.

The second heuristic is for the online algorithm to keep a block of observations in memory temporarily instead of immediately discarding each observation after processing it. The algorithm

1. While the choice of this regularization schedule in this setting is understudied in the literature, asymptotic consistency results for a slightly modified form of the problem may be of theoretical interest. We refer readers to Zou (2006), and the references therein.

then uses the value of the parameter estimates after having seen/processed all the observations in a block to update the sketches for the whole block. Note that this will involve keeping track of the corresponding updates to the sketches for the block (the block's contributions to Ψ and θ). In experiments not reported here, both of these heuristics improve the final online estimates somewhat.

One possibility for improving upon the $O(d^2)$ worst case computational requirement of the online algorithm is as follows. In the infinite data case, in order to obtain sparsity in parameter estimates, the amount of regularization must be allowed to increase as observations accumulate—an increasingly weighty likelihood term will inundate any fixed amount of regularization. In this setting (where we have the freedom to choose the amount of regularization), we can use exactly the same quadratic approximation machinery to pick the value of γ that maximizes the approximate one-step look ahead likelihood (although the expressions for this approximation would be slightly different). The resulting scheme has the flavor of predictive automatic relevance determination as presented in Qi et al. (2004).

The worst case $O(d^2)$ memory requirement of the online algorithm, however, presents a greater challenge. In the next section we outline a multi-pass algorithm based on the same sequential quadratic approximation that improves the accuracy of estimates when applied to finite data sets and also uses less memory than the online algorithm.

5. A Multi-pass Algorithm

The block heuristic of the previous section implies that taking *all* term approximations at the final online algorithm MAP β_t value would certainly produce better estimates of Ψ_t, θ_t. This in turn would lead to a better estimate of β_*.

Therefore, for fixed data sets where computational time restrictions still permit a few passes over the data set, this suggests the following algorithm, which we will refer to as the MP (Multi-Pass) algorithm: Initialize $\beta_0 = \theta_0 = 0$, $\Psi_0 = 0$, $z = 1$. The quantity z will count the number of passes through the data set. Compute Ψ_t, θ_t by the steps in Online Algorithm (Algorithm 2), except take *all* term approximations at the *fixed value* β_z. Note that consequently there is no need for the shooting algorithm during the pass through the data set. Once a pass through the data set is complete, compute a revised estimate of β_* by running modified Shooting, that is, set β_{z+1} =modified Shooting($\Psi_t, \theta_t, \beta_z, \gamma$). Iteratively loop over the data set, appropriately incrementing z.

For a constant number of passes, the MP algorithm has the worst case computational time requirement of $O(td^2)$ to do an equivalent batch MAP β estimation. Once again, if the data set is sparse, this cost is closer in practice to $O(tf^2 + md)$ (the first term is the cost of updating the sketches and the second md term is the cost of the Shooting algorithm).

The worst case memory requirement of the MP algorithm is $O(d^2)$, which is just a constant with respect to t. Expectation Propagation (Minka, 2001b) by contrast requires explicitly storing term approximations and thus has memory costs that scale linearly with t, that is, $O(t)$. The next subsection presents a modification of the MP algorithm that reduces this worst case memory requirement.

5.1 A Reduced Memory Multi-pass Algorithm

The key to reducing the memory requirements of the algorithm in the previous subsection is exploiting the sparsity of β_*. Towards this end, consider the modified Shooting algorithm upon convergence; say β_{MAP} is the sparse converged solution Shooting obtains with inputs Ψ, θ and γ. Now consider the smaller system obtained by only retaining those rows of the vectors, and also corre-

sponding columns for matrices, for which the components of β_{MAP} are nonzero (denoted with a $\tilde{}$). The important observation is that the solution to the reduced size system $\tilde{\beta}_{MAP}$, obtained using $\tilde{\Psi}, \tilde{\theta}$ and $\tilde{\Omega}$, has exactly the same nonzero components as β_{MAP} obtained for the full system.

We use this fact to derive the RMMP (Reduced Memory Multi-Pass) algorithm, Algorithm 3. The central idea is to use the optimality criteria for the Shooting algorithm to determine which components of β to keep track of. Call this set S, the active set, which is fixed during every iteration. Specifically, we set $S = \{j : |\Omega_j| \geq \gamma\}$. That is, the active set is the set of variables that are either nonzero and optimal or variables that violate optimality at the start of a pass (the corresponding nonzero elements of the vectors/matrices are denoted by their previous symbols but with a $\tilde{}$ above them). Now, during the pass we keep track of the much smaller matrix $\tilde{\Psi}$, while also keeping track of the unmodified/original full length vectors θ and Ω. The update for θ is unchanged and Appendix B shows how to perform the update for the full length vector Ω in small space. The algorithm continues by using $\tilde{\Psi}, \Omega$, and θ from the latest pass to re-estimate the active set, S and so on.

A desirable consequence of the setup is that no new approximation is introduced. The search for the optimal parameter values is slightly more involved though, now proceeding iteratively by first identifying candidate nonzero components of β_{MAP}, and then refining the estimates for these components. We can employ the same stopping criteria as for modified Shooting algorithm.

Algorithm 3: The RMMP algorithm.

Data: fixed data set D_t, γ.
Result: β_z, the MAP estimate of β that solves (3).
Initialize $\beta_0 = 0$, $S = \{\}, z = 1$.
while *not converged* **do**
  Set $\theta = 0$, $\tilde{\Psi} = 0$, $i = 1$.
  for $i = 1, 2, \ldots, t$ **do**
    Get i'th observation $(\mathbf{x}_i, y_i)$.
    Obtain quadratic approximation to term likelihood at β_{z-1}, that is, obtain a_i, b_i.
    $\tilde{\Psi} \leftarrow \tilde{\Psi} + a_i(\tilde{\mathbf{x}}_i \tilde{\mathbf{x}}_i^T)$.
    $\theta \leftarrow \theta + b_i \mathbf{x}_i$.
    Update Ω.
  end
  $\beta_z \leftarrow$ modified Shooting$(\tilde{\Psi}, \tilde{\theta}, \tilde{\beta}_{z-1}, \gamma)$.
  Obtain new active set $S = \{j : |\Omega_j| \geq \gamma\}$.
  $z \leftarrow z + 1$.
end

Note that memory requirements are now $O(d + k^2)$, where k is the number of variables in the largest active set. However, we can be even more stringent and set k to be a user specified constant provided k is bigger than the final number of nonzero components of β_*. Typically, setting k very close to this limit results in some loss of accuracy and the cost of a few more passes over the data for convergence. The worst case computational time requirements for a constant number of passes, are still $O(td^2)$ to do an equivalent batch MAP β estimation. Under the same sparsity assumptions as in previous sections, in practice this cost is better quantified as $O(t(k^2 + f^2) + kd)$ (again, the first term is the cost associated with updating the sketches and the second term is the cost of Shooting).

We now draw attention to a few practical considerations about the RMMP algorithm. The first is that although we consider initializing the parameter vector to zero, $\beta_0 = 0$, better guesses of β_0 (guesses closer to the MAP β) would likely result in fewer passes for convergence. Further, given we do initialize at zero, the first pass is completed very rapidly. This is because no outer products are computed, since the active set is initialized as the empty set; the first pass is used simply to determine the size and components of the active set and the parameter estimates for the next iteration are still zero, $\beta_1 = 0$. Typically, setting the reduced memory parameter k to be larger than this first active set size results in further RMMP iterations mimicking iterations of the MP algorithm. This is seen by observing two facts. One, for both algorithms, the only components that change in successive iterations are those in the active set (components that are either non-zero and optimal or not optimal). Two, in a typical search path for the MAP β, the size of the active set decreases (and finally stabilizes) as the MAP β is honed in on. Both of these observations together imply that if we start the RMMP algorithm with enough memory allotted to look at all possibly relevant β components, we will follow the MP search path (as a motivating example, consider that setting $k = d$ results in the MP algorithm exactly).

Another consideration is a very useful practical advantage of the proposed algorithm: knowledge of Ω implies the practitioner can confirm when convergence to β_* has/has not occurred. In practice, for numerical stability, slightly expanding the active set seems to be a good heuristic. In our experiments that follow, we do so only if we have extra space (if k is bigger than the number of variables in the current active set, for any iteration) in two ways: 1. We retain in the active set variables that were in the active set in the previous iteration and, 2. we add to the active set components that are *close to* violating optimality (close in terms of a threshold, $\tau < 1$. This amounts to replacing the rule in Algorithm 3 with $S = \{j : |\Omega_j| \geq \tau\gamma\}$).

In the next section, we place our work in the context of existing literature on similar problems.

6. Related Work

Although the Bayesian paradigm facilitates sequential updating of the posterior distribution (online learning) in a natural way, some form of approximation is almost always necessary for practical applications. Approximating the posterior distribution at every stage by a multivariate Gaussian distribution (which implies a quadratic approximation of the log posterior distribution) seems a natural first step backed by asymptotic Bayesian central limit results that imply this approximation will get better and better with the addition of data (Bernardo and Smith, 1994).

Indeed, approximating the log-likelihood function by a quadratic polynomial is a standard technique in Bayesian learning applications; see for example Laplace approximation (Kass and Raftery, 1995; MacKay, 1995), Assumed Density Filtering (ADF)/Expectation Propagation (EP) (Minka, 2001b), some variational approximation methods such as Jaakkola and Jordan (2000) and in Bayesian online learning (Opper, 1998). We would like to stress here that many of the above schemes are for the harder task of approximate inference—we are concerned only with the easier problem of approximate convex optimization. The similarities in the approaches are confined to the nature of the approximate (Gaussian) posterior.

The next sections describes results we obtained on some simulated as well as real examples using the proposed algorithms.

7. Experiments

We now present examples illustrating the application of the Online, MP and RMMP algorithms to simulated data sets, where we control the data generating mechanism, and some real data sets. We make logistic regression comparisons to results obtained using BBR (Genkin et al., 2007). BBR is publicly available software for Bayesian binary logistic regression that handles the Laplacian prior. We make probit regression comparisons to results obtained using a batch EM algorithm for Laplacian prior based probit regression (we implemented a slightly modified version of the algorithm in Figueiredo and Jain, 2001). We generally do not present prediction accuracy results here as our goal is to obtain accurate, that is, close to batch, parameter values. What we wish to accomplish with the experiments is demonstrate practical efficiency and applicability of the algorithms. In so doing and by obtaining essentially identical parameter estimates to batch algorithms, our predictive performance will mirror those of the batch algorithms. Several papers provide representative predictive performance results for L_1-regularized classifiers, for example, Genkin et al. (2007); Figueiredo and Jain (2001).

We carried out all the experiments on a standard Windows OS based 2Ghz processor machine with 1GB RAM. For all experiments we set the modified Shooting convergence tolerance to be 10^{-6}, and $\tau = 0.8$ (for experiments involving the RMMP algorithm).

We use the following data sets:

- Simulated data sets: d=11, t=10,000. The data generating mechanism is either a probit or logistic regression model with one intercept term and 10 model coefficients, for a total of 11 fixed parameters. Of the ten model variables, three are intentionally set as redundant variables (set with zero coefficients in the model). The data vectors $\mathbf{x}$, are draws from i.i.d. Gaussian distributions with mean zero and unit variance. For the experiments with the online algorithm (Figure 3, Table 1), we used the same model parameters as above, but with $t = 100,000$ and only a logistic regression model.
- ModApte training data set: $d = 21,989$, $t = 9,603$. This is a text data set, the ModApte split of Reuters-21578 (Lewis, 2004). We examine one particular category, "earn", to which we fit a logistic regression model.
- BIG-RCV data set: $d = 288,062$, $t = 421,816$, a data set constructed from the RCV1-v2 data set (Lewis et al., 2004). It consists of the training portion of the LYRL2004 split plus 2 parts of the test data (the test data is made publicly available in $4 \approx 350$ MB parts)—see Figure 5. We also use just the training portion of RCV1-v2 in some experiments. RCV1-v2 training data set : $d = 47,236$, $t = 23,149$ (the features in this data set are a particular subset of the features in BIG-RCV). Our results are for a single topic "ECAT", whether or not a document is related to economics.

7.1 Results

The low dimensional simulated data set highlights typical results we obtain with the Online algorithm and the MP algorithm (the RMMP algorithm is not of practical significance in this case). See Table 2. Each column in the table is an 11-dimensional vector which is the MAP β estimate of the parameter values (as a reminder, the true parameter values used to generate the data can be seen in Table 1). The parameter estimates from the Online algorithm are quite close to batch estimates, likely due to the relatively large data set size (t being large relative to d). Also, with very few passes over the data set, denoted as before by the variable z, we obtain parameter estimates practically identical to those obtained by the batch algorithm. The results in the table are typical for both link

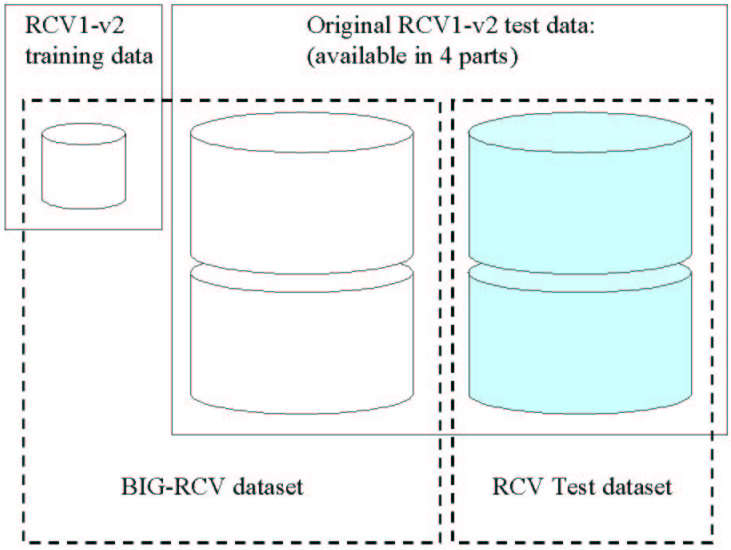

Figure 5: Schematic showing the construction of the various RCV1-v2 based data sets used in the experiments. The solid line bordered rectangles show the data as publicly available, the dashed-line bordered rectangles show the data sets we assembled. The shaded portion of the data is used only during testing.

functions and over a wide range of settings for the regularization parameter, γ. To show this, the tables report results for both too little regularization ($\gamma = 10$, probit link) and too much regularization ($\gamma = 100$, logistic link) for this particular data set. As a guide to assessing convergence in this and other tables that follow, we show the L_1 norm of the difference between the batch algorithm estimates (EM or BBR as appropriate) and the Online, MP or RMMP algorithm iterates (also as appropriate).

We next examine the first real data set, the training data for the ModApte split of Reuters-21578 (Lewis et al., 2004). This is a moderate dimensional ($d = 21989$ features) data set with $t = 9603$ labelled observations (we use the feature vectors that can be downloaded from the paper's appendix.). The features of this data set are weighted term occurrences and it is quite sparse, as is typical for text data. The batch EM algorithm for probit regression is prohibitively expensive on this data set as it involves inverting a high dimensional matrix, but we can run BBR to obtain batch logistic regression results. Hence we focus our results on logistic regression for this data set. We examine two reasonable settings for the regularization parameter, $\gamma = 10$ and $\gamma = 100$. For $\gamma = 10$, BBR returns 150 nonzero components and for $\gamma = 100$, the MAP β BBR returns has 31 non-zero components. Since the data set is sparse, and presents no memory limitations, we are able to apply the Online and MP algorithms in addition to the RMMP algorithm—see Tables 3 and 4.

For both amounts of regularization the Online parameter estimates aren't particularly good (although between the two settings, the parameter estimates with the higher amount of regularization are better). As discussed in Section 5, this is likely due to the relatively high dimensionality compared to the number of examples in the data set. The MP algorithm improves parameter estimates

Table 2: Table with columns showing values of the MAP estimates of β obtained by the batch algorithms (EM on the left half, for probit regression and BBR on the right half for logistic regression), the Online algorithm and three successive iterates of the MP algorithm applied to the simulated data set. The final row displays the L_1 norm of the difference between the batch algorithm estimates (EM or BBR as appropriate) and the Online/MP algorithm estimates. The results shown here are representative of those obtained for other values of γ as well.

as expected. For $\gamma = 100$, the MP algorithm converges in about $z = 6$ iterations to parameter values indistinguishable from BBR—see the left three columns in Table 3. We next applied the RMMP algorithm to this data set. Examining the size of the first active set reveals setting $k \approx 3000$, would give exactly the same results as the MP algorithm—see typical effects of changing k in Table 4 for $\gamma = 10$. We point out that this is a huge reduction in the worst case memory required, an approximately 98% reduction ($k = 3000$ vs. $d = 21989$ originally). Note also that the size of k should be compared relative to the nonzero components for MAP β (150 and 31 for $\gamma = 10$ and $\gamma = 100$ respectively).

We further test the limits of the algorithm, by running it with $k = 300$ for $\gamma = 100$. The RMMP algorithm performs very well, requiring about $z = 7$ passes (only two more than the MP algorithm) to converge to correct parameter values. For $\gamma = 10$, where $k = 300$ is small (only twice the number of non-zero components in the MAP β), once again the same kind of results hold, with the MP algorithm needing about 7 passes over the data set and the RMMP algorithm needing about 15 passes to converge to the batch β.

Finally, we present results of application of the algorithms to the RCV1-v2 data sets. For the RCV1-v2 training data ($d = 47,236$, $t = 23,149$), sparsity again enables application of BBR to obtain the batch MAP β parameter values, as well as the Online and MP algorithms, although this is quite cumbersome. See Table 5. Again, as expected (examining d vs. t for this data set), the Online estimates are not very good. The multi-pass algorithms have improved parameter estimates. For $\gamma = 10$ (a fairly high amount of regularization), we find essentially the same qualitative results as the ModApte data set—it takes about $z = 6$ passes through the data set to obtain indistinguishable

Table 5: RCV1-v2 results. Left portion RCV1-v2 training data set, right BIG-RCV data set.

parameter values as BBR (not shown in the table). The RMMP algorithm also gives excellent results in about 10 passes, see the left portion of Table 5 with $k = 1500$.

For the BIG-RCV data set ($d = 288,062$, $t = 421,816$) however, computational and memory limitations made it impossible to run the batch algorithms on this data set (also the Online and MP algorithm). It is precisely for cases like this that the RMMP algorithm is useful, and we were able to obtain parameter estimates for reasonable settings of regularization—see for example, the right portion of Table 5.

Does training on the entire BIG-RCV data set actually result in improved predictive performance? To address this, we conducted the following experiment. We obtained the best possible predictive parameters using 10-fold cross-validation on the RCV1-v2 training data set with a batch algorithm. This is an expensive computation, involving many repeated BBR runs for different values of the regularization parameter (we searched over $\gamma = 0.01, 0.1, 1, 10, 100$). The final cross-validation chosen β has 1010 non-zero parameters.

We then trained a separate sparse logistic classifier on the BIG-RCV data set using the RMMP algorithm with $k = 3000$ and $\gamma = 40$. Setting $\gamma = 40$ results in 1015 non-zero MAP β coefficients which is approximately the same number of non-zero coefficients as the cross-validation chosen β. Finally, we compare the predictive accuracy of both classifiers on the unused RCV test set (comprising the unused two portions of the original RCV1-v2 test data).

The results, shown in Table 6, demonstrate that using the information in extra examples, the "unsophisticated" classifier trained on the much larger data set outperforms the "optimized" classifier trained on a smaller data set.

8. Conclusions

In this paper we presented an asymptotically convergent online algorithm that builds sparse generalized linear models for massive data sets. We also presented efficient multi-pass algorithms that examine observations sequentially and thus enable learning on massive data sets. Both algorithms exploit sparsity of input data. We applied the algorithms to large, sparse data sets, for which state-

Table 6: This table shows confusion matrices for prediction results on the RCV Test data set. The CV β (trained on the RCV1-v2 training data set) results are on the left and the MAP β (trained on the BIG-RCV data set, with $\gamma = 30$, $k = 3000$) results are on the right. Also shown are recall and precision percentages in bold and brackets. There are approximately 383,000 examples in the test data set.

of-the-art batch algorithms are impractical/cumbersome, and our results show that examining such data sets in their entirety can lead to better classifier performance.

Some areas of further research that this work opens up are: extension of the algorithms for a hierarchical prior model so that the choice of regularization is less important, the possible application of our methods to kernel classifiers, and applications to multi-class classification problems.

Appendix A.

Here we show the Taylor expansions for the quadratic approximations to the log-likelihood function. To simplify notation, let $c(\beta) = \beta^T \mathbf{x}_i$ and $\hat{c} = \beta_{i-1}^T \mathbf{x}_i$. The link function (we will restrict analytical results to the logistic and probit link functions) is $\Phi(z)$ as before and we denote its first and second derivative, with respect to z, by $\Phi'(z)$ and $\Phi''(z)$ respectively.

Consider the case where $y_i = 1$:

$$\begin{aligned}
\log\Phi(c) &\approx \log\Phi(\hat{c}) + (c-\hat{c})\frac{\Phi'(\hat{c})}{\Phi(\hat{c})} + \frac{(c-\hat{c})^2}{2}\left(\frac{\Phi''(\hat{c})}{\Phi(\hat{c})} - \left(\frac{\Phi'(\hat{c})}{\Phi(\hat{c})}\right)^2\right) \\
&\propto \frac{\Phi'(\hat{c})}{\Phi(\hat{c})}c + \frac{1}{2}\left(\frac{\Phi''(\hat{c})}{\Phi(\hat{c})} - \left(\frac{\Phi'(\hat{c})}{\Phi(\hat{c})}\right)^2\right)c^2 - \hat{c}\left(\frac{\Phi''(\hat{c})}{\Phi(\hat{c})} - \left(\frac{\Phi'(\hat{c})}{\Phi(\hat{c})}\right)^2\right)c
\end{aligned}$$

so that:

$$a_i = \frac{1}{2}\left(\frac{\Phi''(\hat{c})}{\Phi(\hat{c})} - \left(\frac{\Phi'(\hat{c})}{\Phi(\hat{c})}\right)^2\right)$$

and

$$b_i = \frac{\Phi'(\hat{c})}{\Phi(\hat{c})} - \hat{c}\left(\frac{\Phi''(\hat{c})}{\Phi(\hat{c})} - \left(\frac{\Phi'(\hat{c})}{\Phi(\hat{c})}\right)^2\right).$$

Analogously, when $y_i = 0$:

$$\log(1-\Phi(c)) \approx \log(1-\Phi(\hat{c})) - (c-\hat{c})\frac{\Phi'(\hat{c})}{1-\Phi(\hat{c})} - \frac{(c-\hat{c})^2}{2}\left(\frac{\Phi''(\hat{c})}{1-\Phi(\hat{c})} + \left(\frac{\Phi'(\hat{c})}{1-\Phi(\hat{c})}\right)^2\right)$$

so that:

$$a_i = -\frac{1}{2}\left(\frac{\Phi''(\hat{c})}{1-\Phi(\hat{c})} + \left(\frac{\Phi'(\hat{c})}{1-\Phi(\hat{c})}\right)^2\right)$$

and

$$b_i = -\frac{\Phi'(\hat{c})}{1-\Phi(\hat{c})} + \hat{c}\left(\frac{\Phi''(\hat{c})}{1-\Phi(\hat{c})} + \left(\frac{\Phi'(\hat{c})}{1-\Phi(\hat{c})}\right)^2\right).$$

For the probit link function:

$$\begin{aligned}
\Phi(z) &= \int_{-\infty}^{z} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} dx \\
\Phi'(z) &= \frac{1}{\sqrt{2\pi}} e^{-z^2/2} \\
\Phi''(z) &= \frac{-z}{\sqrt{2\pi}} e^{-z^2/2},
\end{aligned}$$

whereas for the logistic link function:

$$\begin{aligned}
\Phi(z) &= \frac{e^z}{1+e^z} \\
\Phi'(z) &= \frac{e^z}{(1+e^z)^2} \\
\Phi''(z) &= \frac{(e^z)(1-e^z)}{(1+e^z)^3}.
\end{aligned}$$

These expressions then allow us to compute the a_i, b_i in the cases needed.

Appendix B.

In this appendix we derive the modified Shooting algorithm, Algorithm 1 and discuss its efficient implementation. We derive Shooting by analyzing the subdifferential of the system (Rockafellar, 1970). We need convex non-smooth analysis results because the regularization term is non-differentiable at zero. Reviewing concepts very briefly, the subgradient $\xi \in \mathbb{R}^{|x|}$, of a convex function f at x_0 is defined to be any vector satisfying:

$$f(x) \geq f(x_0) + \xi^T (x - x_0).$$

In words, any vector ξ, such that a plane through $(x, f(x))$ with slope ξ contains f in its upper half-space qualifies as a subgradient (equivalently, a tangent plane supporting the convex function

f). The subdifferential, ∂f, is just the set of all subgradients, ξ, at a particular point. This is a generalization of the gradient which collapses to the gradient, whenever f is differentiable. As a simple example, the subdifferential of $f(\beta) = |\beta|$, the absolute value function (which is non-differentiable at $\beta = 0$) is:

$$\partial f = \begin{cases} \{-1\}, & \beta < 0 \\ [-1,1], & \beta = 0 \\ \{1\}, & \beta > 0. \end{cases}$$

As one expects, analogous to optimality conditions resulting from setting the gradient of a differentiable function to zero, optimality conditions for non-differentiable functions result from restrictions on the subdifferential. In particular we appeal to the following result from non-smooth analysis (Rockafellar, 1970):

Theorem $\hat{\beta}$ *is a global minimizer of a convex function* $f(\beta)$ *if and only if* $0 \in \partial f(\hat{\beta})$.

Now to our particular problem. We need to find β that is a solution to:

$$\max_{\beta} \left(\beta^T \Psi \beta + \beta^T \theta - \gamma \|\beta\|_1 \right).$$

The convexity of the problem allows us to make incremental progress towards the maxima coordinate-wise. Starting from some parameter vector, we compute the jth component of the subdifferential of the function (keeping all other components fixed):

$$\begin{aligned} & \tfrac{\partial}{\partial \beta_j}(\beta^T \Psi \beta) + \tfrac{\partial}{\partial \beta_j}(\beta^T \theta) - \gamma \partial(\textstyle\sum_{j=1}^{d}(|\beta_j|) \\ = & \quad 2(\Psi\beta)_j + \theta_j - \gamma\partial(|\beta_j|) \\ = & \quad 2\Psi_{jj}\beta_j + 2(\Psi'\beta)_j + \theta_j - \gamma\partial(|\beta_j|) \end{aligned}$$

where $(\Psi'\beta)_j$ is the j'th component of the vector $\Psi'\beta$ and Ψ_{jj} refers to the (j,j)'th element of the matrix Ψ (Recall that Ψ' is defined to be the matrix Ψ with diagonal entries set to zero). The second equation follows from the first as the subdifferential of a univariate differentiable function is just its derivative and since matrix Ψ is symmetric (it is just a weighted sum of outer products). Now if we plug in the subdifferential of the non-differentiable absolute value function, and set $\Omega_j = 2(\Psi'\beta)_j + \theta_j$ (and thus define the vector Ω to be the gradient of the purely differentiable part of the objective function), we obtain the subdifferential of the objective function, whose j'th component we denote by ∂_{β_j} as:

$$\partial_{\beta_j} = \begin{cases} \{2\Psi_{jj}\beta_j + \Omega_j + \gamma\}, & \beta_j < 0 \\ [\Omega_j - \gamma, \Omega_j + \gamma], & \beta_j = 0 \\ \{2\Psi_{jj}\beta_j + \Omega_j - \gamma\}, & \beta_j > 0. \end{cases}$$

This is a piecewise linear function with fixed negative slope $2\Psi_{jj}$ and a constant jump of fixed size 2γ at $\beta_j = 0$ (Ψ_{jj} can be proven to always be negative by looking at the update formula for Ψ and using the fact that $\forall i, a_i < 0$). Using the optimality criteria (now for maximization since $-|\beta_j|$ is a concave function) naturally leads to the modified Shooting algorithm, illustrated in Figure 6.

Now to questions regarding the efficient implementation of the Shooting algorithm, used by the online, MP and RMMP algorithms. In the modified Shooting algorithm, after each component update (change in β_j) we need to modify Ω (the update Ω step in the algorithm). This can be implemented efficiently using the following result (similar to the trick detailed in Minka, 2001):

$$\Omega^{new} = \Omega^{old} + 2\Psi'_{(\cdot j)}(\Delta\beta_j)$$

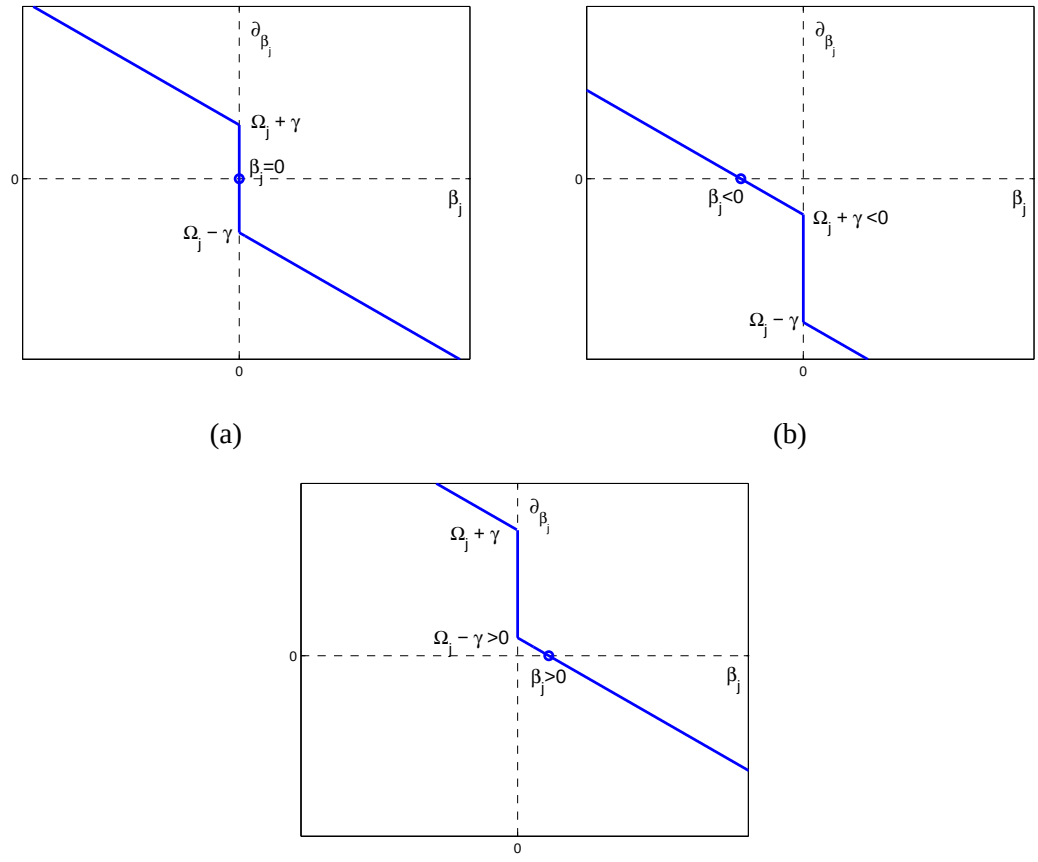

Figure 6: Illustration of cases occurring in the Shooting algorithm (a) If $|\Omega_j| \leq \gamma$ the constant portion of the subdifferential contains zero. In this case, set $\beta_j = 0$ (b) If instead, $\Omega_j < -\gamma$, the optimality conditions will be satisfied by setting $\beta_j = \frac{-\gamma - \Omega_j}{2\Psi_{jj}}$ (c) The case analogous to (b) but when $\Omega_j > \gamma$. Here the subdifferential is set equal to zero when $\beta_j = \frac{\gamma - \Omega_j}{2\Psi_{jj}}$.

where $\Delta\beta_j$ is the change in β_j and $\Psi'_{(.j)}$ is the j'th column of Ψ'. Thus each component update of Shooting can be done in $O(d)$ computational time. Now, if as before the maximum number of non-zero components of β along the solution path to MAP β is m, only m such updates will need to be made, giving a total time requirement per iteration of $O(md)$.

Finally we detail how to carry out the Ω updates efficiently for the RMMP algorithm, Algorithm 3. Recall that since we are discussing a multi-pass algorithm, the location where we take the quadratic approximation, β_{i-1}, is constant throughout the pass through the fixed data set, D_t. We exploit this fact to show that in this case, you don't explicitly need the matrix Ψ (or $\tilde{\Psi}$) to determine Ω. Indeed, after going through all the observations in the data set (pass z, say):

$$\Omega = 2\Psi'\beta_{z-1} + \theta = 2\left(\sum_{i=1}^{t} a_i\left(\mathbf{x}_i\mathbf{x}_i^T - \mathrm{diag}(\mathbf{x}_i^2)\right)\right)\beta_{z-1} + \sum_{i=1}^{t} b_i\mathbf{x}_i,$$

which follows from the definitions of Ω, θ and Ψ'. In the above equation, $\mathrm{diag}(\mathbf{x}_i^2)$ is a $d \times d$ matrix zero everywhere except the diagonal entries, which consists of the elements of the vector $\mathbf{x}_i$ squared component-wise. This leads to the following equation for Ω:

$$\Omega = 2\sum_{i=1}^{t} a_i(\beta_{z-1}^T\mathbf{x}_i)\mathbf{x}_i - 2\sum_{i=1}^{t} a_i(\mathbf{x}_i^2\beta_{z-1}) + \sum_{i=1}^{t} b_i\mathbf{x}_i,$$

where $(\mathbf{x}_i^2\beta_{z-1})$ is a vector whose entries are $\mathbf{x}_i^2$ multiplied by β_{z-1} component-wise. Note the first sum is just a weighted combination of the input data ($\beta_{z-1}^T\mathbf{x}_i$ is a scalar). Thus, our final update formula results:

$$\Omega^{new} = \Omega^{old} + (2a_i\beta_{z-1}^T\mathbf{x}_i + b_i)\mathbf{x}_i - 2a_i(\mathbf{x}_i^2\beta_{z-1}).$$

As can be seen, computing this update per observation takes time and space $O(d)$, and having restricted the number of non-zero components of β to k, a total computational cost per iteration of Shooting to $O(kd)$.

Appendix C.

We present a proof sketch for the convergence behavior of the online algorithm in the infinite data limit. The intuition for is as follows: as $t \to \infty$, the Bayesian central limit theorems dictate that the posterior distribution tends (in distribution) to a multivariate Gaussian with ever shrinking covariance, (Bernardo and Smith, 1994). Thus, less and less information is required to encode the posterior distribution as more and more data is added—to a point. Indeed, in the limit, only the vector of the maximum likelihood value of the parameters, β_{MLE}, is required to completely describe the posterior distribution.

Suppose now that the online algorithm converges to a particular fixed point. In the infinite data limit, an infinite number of term approximations are taken at this fixed point. Now, our Taylor polynomial based approximation preserves both the function value and its gradient, and an infinite number of approximations are jointly maximum at this fixed point. This implies the fixed point is an optima of the posterior distribution.

Thus, if the approximation converges to a fixed point, it is the correct optima location. The above is a modification of the fixed point Lemma in the paper on Laplace Propagation (Eskin et al., 2003). One can also prove unbiasedness which follows from our update rules and a minor modification of

a theorem in Opper (1998). Even though Opper derives his results based on a Gaussian prior on the parameters β (corresponding to L_2 regularization), the general format of Opper's theorem is still applicable in our case because, in the infinite data limit, the prior is inconsequential.

Abstract

We argue that when objects are characterized by many attributes, clustering them on the basis of a *random* subset of these attributes can capture information on the unobserved attributes as well. Moreover, we show that under mild technical conditions, clustering the objects on the basis of such a random subset performs almost as well as clustering with the full attribute set. We prove finite sample generalization theorems for this novel learning scheme that extends analogous results from the supervised learning setting. We use our framework to analyze generalization to unobserved features of two well-known clustering algorithms: *k*-means and the maximum likelihood multinomial mixture model. The scheme is demonstrated for collaborative filtering of users with movie ratings as attributes and document clustering with words as attributes.

Keywords: clustering, unobserved features, learning theory, generalization in clustering, information bottleneck

1. Introduction

Data clustering can be defined as unsupervised classification of objects into groups based on their similarity (see, for example, Jain et al., 1999). Often, it is desirable to have the clusters match some labels that are unknown to the clustering algorithm. In this context, good data clustering is expected to have homogeneous labels in each cluster, under some constraints on the number or complexity of the clusters. This can be quantified by mutual information (see, for example, Cover and Thomas, 1991) between the objects' cluster identity and their (unknown) labels, for a given complexity of clusters. However, since the clustering algorithm has no access to the labels, it is unclear how it can optimize the quality of the clustering. Even worse, the clustering quality depends on the specific choice of the unobserved labels. For example, good document clustering with respect to topics is very different from clustering with respect to authors.

In our setting, instead of attempting to cluster by some arbitrary labels, we try to predict unobserved features from observed ones. In this sense our target labels are simply other features that happened to be unobserved. For example, when clustering fruits based on their observed features such as shape, color and size, the target of clustering is to match unobserved features such as nutritional value or toxicity. When clustering users based on their movie ratings, the target of clustering is to match ratings of movies that were not rated, or not even created as yet.

In order to theoretically analyze and quantify this new learning scheme, we make the following assumptions. Consider a very large set of features, and assume that we observe only a *random*

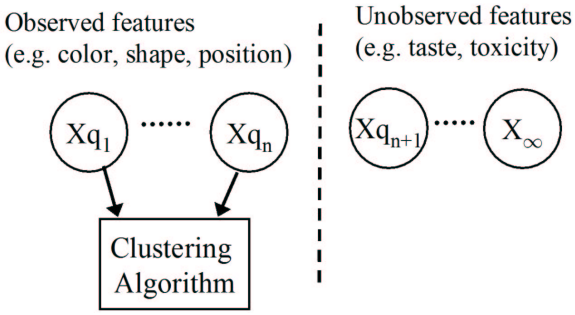

Figure 1: The learning scheme. The clustering algorithm has access to a random subset of features $(X_{q_1},...,X_{q_n})$ of m instances. The goal of the clustering algorithm is to assign a class label t_i to each instance, such that the expected mutual information between the class labels and a randomly selected *unobserved* feature is maximized.

subset of n features, called *observed features*. The other features are called *unobserved features*. We assume that the random selection of observed features is made from some unknown distribution $\mathcal{D}$ and each feature is selected independently.[1]

The clustering algorithm has access only to the observed features of m instances. After clustering, one of the *unobserved* features is randomly selected to be the target label. This selection is done using the same distribution, $\mathcal{D}$, of the observed feature selection. Clustering performance is measured with respect to this feature. Obviously, the clustering algorithm cannot be directly optimized for this specific feature.

The question is whether we can optimize the *expected* performance on the unobserved features, based only on the observed features. The expectation is over the *random* selection of the unobserved target features. In other words, can we find the clustering that is most likely to match a randomly selected unobserved feature? Perhaps surprisingly, for a large enough number of observed features, the answer is yes. We show that for any clustering algorithm, the average performance of the clustering with respect to the observed and unobserved features is similar. Hence we can indirectly optimize clustering performance with respect to unobserved features by analogy with generalization in supervised learning. These results are universal and do not require any additional assumptions such as an underlying model or a distribution that created the instances.

In order to quantify these results, we define two terms: the average observed information and the expected unobserved information. Let T be the variable which represents the cluster for each instance, and $\{X_1,...,X_L\}$ $(L \to \infty)$ the set of discrete random variables which denotes the features. The average observed information, denoted by I_{ob}, is the average mutual information between T and each of the observed features. In other words, if the observed features are $\{X_1,...,X_n\}$ then $I_{ob} = \frac{1}{n}\sum_{j=1}^{n} I(T;X_j)$. The expected unobserved information, denoted by I_{un}, is the *expected* value of the mutual information between T and a new *randomly* selected feature, that is, $E_{q\sim\mathcal{D}}\left\{I(T;X_q)\right\}$. We are interested in cases where this new selected feature is most likely to be one of the unobserved features, and therefore we use the term unobserved information. Note that whereas I_{ob} can be measured directly, this paper deals with the question of how to infer and maximize I_{un}.

1. For simplicity, we also assume that the probability of selecting the same feature more than once is near zero.

Our main results consist of two theorems. The first is a generalization theorem. It gives an upper bound on the probability of a large difference between I_{ob} and I_{un} for all possible partitions. It also states a *uniform convergence in probability* of $|I_{ob} - I_{un}|$ as the number of observed features increases. Conceptually, the average observed information, I_{ob}, is analogous to the training error in standard supervised learning (Vapnik, 1998), whereas the unobserved information, I_{un}, is similar to the generalization error.

The second theorem states that under constraints on the number of clusters, and a large enough number of observed features, one can achieve nearly the best possible performance, in terms of I_{un}. Analogous to the principle of Empirical Risk Minimization (ERM) in statistical learning theory (Vapnik, 1998), this is done by maximizing I_{ob}.

We use our framework to analyze clustering by the maximum likelihood of multinomial mixture model (also called Naive Bayes Mixture Model, see Figure 2 and Section 2.2). This clustering assumes a generative model of the data, where the *instances* are assumed to be sampled independently from a mixture of distributions, and for each such distribution all features are independent. These assumptions are quite different from our assumptions of fixed instances and randomly observed features.[2] Nevertheless, in Section 2.2 we show that this clustering achieves nearly the best possible clustering in terms of information on unobserved features.

In Section 3 we extend our framework to distance-based clustering. In this case the measure of the quality of clustering is based on some distance function instead of mutual information. We show that the *k*-means clustering algorithm (Lloyd, 1957; MacQueen, 1967) not only minimizes the observed intra-cluster variance, but also minimizes the unobserved intra-cluster variance, that is, the variance of unobserved features within each cluster.

Table 1 summarizes the similarities and differences of our setting to that of supervised learning. The key difference is that in supervised learning, the set of features is fixed and the training instances are assumed to be randomly drawn from some distribution. Hence, the generalization is to new instances. In our setting, the set of instances is fixed, but the set of observed features is assumed to be randomly selected. Hence, the generalization is to new features.

Our new theorems are evaluated empirically in Section 4, on two different data sets. The first is a movie ratings data set, where we cluster users based on their movie ratings. The second is a document data set, with words as features. Our main point in this paper, however, is the new conceptual framework and not a specific algorithm or experimental performance.

Section 5 discusses related work and Section 6 presents conclusions and ideas for future research. A notation table is available in Appendix B.

2. Feature Generalization of Information

In this section we analyze feature generalization in terms of mutual information between the clusters and the features. Consider a fixed set of m instances denoted by $\{\mathbf{x}[1],\ldots,\mathbf{x}[m]\}$. Each instance is represented by a vector of L features $\{x_1,\ldots,x_L\}$. The value of the qth feature of the jth instance is denoted by $x_q[j]$. Out of this set of features, n features are randomly and independently selected according to some distribution $\mathcal{D}$. The n randomly selected features are the *observed features* (variables) and their indices are denoted by $\tilde{\mathbf{q}} = (q_1,...,q_n)$, where $q_i \sim \mathcal{D}$. The ith observed feature of the jth instance is denoted by $x_{q_i}[j]$. After selecting the observed features, we also select *unobserved*

2. Note that in our framework, random independence refers to the *selection* of observed features, not to the feature values.

		Prediction of unobserved features	
	Supervised learning	Information	Distance-based
Training set	Randomly selected *instances*	*n* randomly selected features (observed features)	
Test set	Randomly selected *unlabeled instances*	Randomly selected *unobserved features*	
Hypothesis class	Class of functions from instances to labels	All possible partitions of *m* instances into *k* clusters	
Output of learning algorithm	Select hypothesis function	Cluster the *instances* into *k* clusters	
Goal	Minimize *expected* error on test set	Maximize *expected* information on *unobserved* features	Minimize *expected* intra-cluster variance of *unobserved* features
Assumption	Training and test instances are randomly and independently drawn from the same distribution	Observed and unobserved features are randomly and independently selected using the same distribution	
Strategy	Empirical Risk Minimization (ERM)	Observed Information Maximization (OIM)	Minimize observed intra-cluster variance
Related clustering algorithm		Maximum likelihood multinomial mixture model (Figure 2)	*k*-means
Good generalization	The training and test errors are similar	The observed and unobserved information are similar	The observed and unobserved intra-cluster variance are similar

Table 1: Analogy with supervised learning

features according to the same distribution $\mathcal{D}$. For simplicity, we assume that the total number of features, L, is large and the probability of selecting the same feature more than once is near zero (as in the case where $L \gg n^2$, where $\mathcal{D}$ is uniform distribution). This means that we can assume that a randomly selected unobserved feature is not one of the n observed features. It is important to emphasize that we have a fixed and finite set of instances; that is, we do not need to assume that the m instances were drawn from any distribution. Only the features are randomly selected.

We further assume that each of the features is a discrete variable with no more than s different values.[3] The clustering algorithm clusters the instances into k clusters. The clustering is denoted by the function $\mathbf{t} : [m] \to [k]$ that maps each of the m instances to one of the k clusters. The cluster label of the jth instance is denoted by $\mathbf{t}(j)$. Our measures for the quality of clustering are based on Shannon's mutual information. Let random variable Z denote a number chosen uniformly at random from $\{1,\ldots,m\}$. We define the quality of clustering with respect to a single feature, q, as $I(\mathbf{t}(Z); x_q[Z])$, that is, the empirical mutual information between the cluster labels and the feature.

Our measure of performance assumes that the number of clusters is predetermined. There is an obvious tradeoff between the preserved mutual information and the number of clusters. For example, one could put each instance in a different cluster, and thus get the maximum possible mutual information for all features. Obviously all clusters will be homogeneous with respect to all features but this clustering is pointless. Therefore, we need to have some constraints on the number of clusters.

Definition 1 *The **average observed information** of a clustering* $\mathbf{t}$ *and the observed features is denoted by* $I_{ob}(\mathbf{t}, \tilde{\mathbf{q}})$ *and defined by*

$$I_{ob}(\mathbf{t}, \tilde{\mathbf{q}}) = \frac{1}{n} \sum_{i=1}^{n} I(\mathbf{t}(Z); x_{q_i}[Z]).$$

*The **expected unobserved information** of a clustering is denoted by* $I_{un}(t)$ *and defined by*

$$I_{un}(\mathbf{t}) = \mathbf{E}_{q \sim \mathcal{D}} \left\{ I(\mathbf{t}(Z); x_q[Z]) \right\}.$$

In general, I_{ob} is higher when clusters are more coherent; that is, elements within each cluster have many identical observed features. I_{un} is high if there is a high probability that the clusters are informative on a randomly selected feature q (where $q \sim \mathcal{D}$). In the special case where the distribution $\mathcal{D}$ is uniform and $L \gg n^2$, I_{un} can also be written as the average mutual information between the cluster label and the unobserved features set; that is, $I_{un} \approx \frac{1}{L-n} \sum_{q \notin \{q_1,\ldots,q_n\}} I(\mathbf{t}(Z); x_q[Z])$. Recall that L is the total number of features, both observed and unobserved.

The goal of the clustering algorithm is to cluster the instances into k clusters that maximize the *unobserved* information, I_{un}. Before discussing how to maximize I_{un}, we first consider the problem of estimating it. Similar to the generalization error in supervised learning, I_{un} cannot be calculated directly in the learning algorithm, but we may be able to bound the difference between the observed information I_{ob}—our "training error"—and the unobserved information I_{un}—our "generalization error". To obtain generalization, this bound should be *uniform over all possible clusterings* with a high probability over the randomly selected features. The following lemma argues that *uniform convergence in probability* of I_{ob} to I_{un} always occurs.

3. Since we are exploring an empirical distribution of a finite set of instances, dealing with continuous features is not meaningful.

Lemma 2 *With the definitions above,*

$$\Pr_{\tilde{\mathbf{q}}=(q_1,\ldots,q_n)}\left\{\sup_{\mathbf{t}:[m]\to[k]}|I_{ob}(\mathbf{t},\tilde{\mathbf{q}})-I_{un}(\mathbf{t})|>\varepsilon\right\}\leq 2e^{-2n\varepsilon^2/(\log k)^2+m\log k},\quad\forall\varepsilon>0.$$

Proof For any q,

$$0\leq I(\mathbf{t}(Z);x_q[Z])\leq H(\mathbf{t}(Z))\leq\log k.$$

Using Hoeffding's inequality, for any specific (predetermined) clustering

$$\Pr_{\tilde{\mathbf{q}}=(q_1,\ldots,q_n)}\{|I_{ob}(\mathbf{t},\tilde{\mathbf{q}})-I_{un}(\mathbf{t})|>\varepsilon\}\leq 2e^{-2n\varepsilon^2/(\log k)^2}.$$

Since there are at most k^m possible partitions, the union bound is sufficient to prove Lemma 2.■

Note that for any $\varepsilon>0$, the probability that $|I_{ob}-I_{un}|>\varepsilon$ goes to zero, as $n\to\infty$. The convergence rate of I_{ob} to I_{un} is bounded by $O((\log k)/\sqrt{n})$. As expected, this upper bound decreases as the number of clusters, k, decreases.

Unlike the standard bounds in supervised learning, this bound increases with the number of instances (m), and decreases with increasing numbers of observed features (n). This is because in our scheme the training size is not the number of instances, but rather the number of observed features (see Table 1). However, in the next theorem we obtain an upper bound that is independent of m, and hence is tighter for large m.

Consider the case where n is fixed, and m increases infinitely. We can select a random subset of instances of size m'. For large enough m', the empirical distribution of this subset is similar to the distribution over all instances. By fixing m', we can get a bound which is independent of m. Using this observation, the next theorem gives a bound that is independent of m.

Theorem 3 ***(Information Generalization)*** *With the definitions above,*

$$\Pr_{\tilde{\mathbf{q}}=(q_1,\ldots,q_n)}\left\{\sup_{\mathbf{t}:[m]\to[k]}|I_{ob}(\mathbf{t},\tilde{\mathbf{q}})-I_{un}(\mathbf{t})|>\varepsilon\right\}\leq 8(\log k)e^{-n\varepsilon^2/\left(8(\log k)^2\right)+4sk\log k/\varepsilon-\log\varepsilon},\quad\forall\varepsilon>0.$$

The proof of this theorem is given in appendix A.1. In this theorem, the bound does not depend on the number of instances, but rather on s which is the maximum alphabet size of the features. The convergence rate here is bounded by $O((\log k)/\sqrt[3]{n})$. However, for relatively large n one can use the bound in Lemma 2, which converges faster.

As shown in Table 1, Theorem 3 is clearly analogous to the standard uniform convergence results in supervised learning theory (see, for example, Vapnik, 1998), where the random sample is replaced by our randomly selected features, the hypotheses are replaced by the clustering, and I_{ob} and I_{un} replace the empirical and expected risks, respectively. The complexity of the clustering (our hypothesis class) is controlled by the number of clusters, k.

We can now return to the problem of specifying a clustering that maximizes I_{un}, using only the observed features. For reference, we will first define I_{un} of the best possible clustering.

Definition 4 ***Maximally achievable unobserved information:*** *Let $I^*_{un,k}$ be the maximum value of I_{un} that can be achieved by any partition into k clusters,*

$$I^*_{un,k} = \sup_{\mathbf{t}:[m]\to[k]} I_{un}(\mathbf{t}).$$

The clustering that achieves this value is called ***the best clustering****. The average observed information of this clustering is denoted by $I^*_{ob,k}$.*

Definition 5 ***Observed information maximization algorithm:*** *Let* IobMax *be any clustering algorithm that, based on the values of the observed features, selects a clustering $\mathbf{t}^{opt,ob} : [m] \to [k]$ having the maximum possible value of I_{ob}, that is,*

$$\mathbf{t}^{opt,ob} = \arg\max_{\mathbf{t}:[m]\to[k]} I_{ob}(\mathbf{t}, \tilde{\mathbf{q}}).$$

Let $\tilde{I}_{ob,k}$ be the average observed information of this clustering and $\tilde{I}_{un,k}$ be the expected unobserved information of this clustering, that is,

$$\begin{aligned} \tilde{I}_{ob,k}(\tilde{\mathbf{q}}) &= I_{ob}\left(\mathbf{t}^{opt,ob}, \tilde{\mathbf{q}}\right), \\ \tilde{I}_{un,k}(\tilde{\mathbf{q}}) &= I_{un}\left(\mathbf{t}^{opt,ob}\right). \end{aligned}$$

The next theorem states that *IobMax* not only maximizes I_{ob}, but also maximizes I_{un}.

Theorem 6 ***(Achievability)*** *With the definitions above,*

$$\Pr_{\tilde{\mathbf{q}}=(q_1,\ldots,q_n)}\left\{\tilde{I}_{un,k}(\tilde{\mathbf{q}}) \le I^*_{un,k} - \varepsilon\right\} \le 8(\log k) e^{-n\varepsilon^2/\left(32(\log k)^2\right)+8sk\log k/\varepsilon-\log(\varepsilon/2)}, \quad \forall \varepsilon > 0. \qquad (1)$$

Proof We now define a *bad clustering* as a clustering whose expected unobserved information satisfies $I_{un} \le I^*_{un,k} - \varepsilon$. Using Theorem 3, the probability that $|I_{ob} - I_{un}| > \varepsilon/2$ for any of the clusterings is upper bounded by the right term of Equation 1. If for all clusterings $|I_{ob} - I_{un}| \le \varepsilon/2$, then surely $I^*_{ob,k} \ge I^*_{un,k} - \varepsilon/2$ (see Definition 4) and I_{ob} of all bad clusterings satisfies $I_{ob} \le I^*_{un,k} - \varepsilon/2$. Hence the probability that a bad clustering has a higher average observed information than the best clustering is upper bounded as in Theorem 6. ■

For small m, a tighter bound, similar to that of Lemma 2 can easily be formulated.

As a result of this theorem, when n is large enough, even an algorithm that knows the value of *all* features (observed and unobserved) cannot find a clustering which is significantly better than the clustering found by the *IobMax* algorithm. This is demonstrated empirically in Section 4.

Informally, this theorem means that for a large number of features we can find a clustering that is informative on unobserved features. For example, clustering users based on similar ratings of current movies are likely to match future movies as well (see Section 4).

In the generalization and achievability theorems (Theorems 3, 6) we assumed that we are dealing only with hard clustering. In Appendix A.2 we show that the generalization theorem is also applicable to soft clustering; that is, assigning a probability distribution among the clusters to each instance. Moreover, we show that soft clustering is not required to maximize I_{ob}, since its maximum value can be achieved by hard clustering.

2.1 Toy Examples

In the first two examples below, we assume that the instances are drawn from a given distribution (although this assumption is not necessary for the theorems above). We also assume that the number of instances is large, so the empirical and the actual distributions of the instances are about the same.

Example 1 *Let $X_1,...,X_\infty$ be Bernoulli($\frac{1}{2}$) random variables, such that all variables with an even index are equal to each other ($x_2 = x_4 = x_6 = ...$), and all variables with an odd index are independent of each other and of all other variables. If the number of randomly observed features is large enough we can find a clustering rule with two clusters such that $I_{ob} \cong \frac{1}{2}$. This is done by assigning the cluster labels based on the set of features that are correlated, for example, $\mathbf{t}(i) = x_2[i] + 1 \quad \forall i$, assuming that x_2 is one of the observed features. $I(\mathbf{t}(Z); x_i(Z))$ is one for even i, and zero for odd i. For large n, the number of randomly selected features with odd indices and even indices[4] is about the same (with high probability), and hence $I_{ob} \cong \frac{1}{2}$. For this clustering rule $I_{un} \cong \frac{1}{2}$, since half of the unobserved features match this clustering (all features with an even index).*

Example 2 *When $X_1,...,X_\infty$ are i.i.d. (independent and identically distributed) Bernoulli($\frac{1}{2}$) random variables, $I_{un} = 0$ for any clustering rule, regardless of the number of observed features. For a finite number of clusters, I_{ob} will necessarily approach zero as the number of observed features increases. More specifically, if we use two clusters, where the clustering is determined by one of the observed features (i.e., $\mathbf{t}(i) = x_j(i)$, where x_j is an observed feature), then $I_{ob} = \frac{1}{n}$ (because $I(\mathbf{t}(Z); x_j(Z)) = 1$ and $I(\mathbf{t}(Z); x_l(Z)) = 0$ for $l \neq j$).*

Example 3 *Clustering fruits based on the observed features (color, size, shape etc.) also matches many unobserved features. Indeed, people clustered fruits into oranges, bananas and others (by giving names in the language) long before vitamin C was discovered. Nevertheless, this clustering was very informative about the amount of vitamin C in fruits, that is, most oranges have similar amounts of vitamin C, which is different from the amount in bananas.*

Based on the generalization theorem, we now suggest a qualitative explanation of why clustering into bananas and oranges provides relatively high information on unobserved features, while clustering based on position (e.g., right/left in the field of view) does not. Clustering into bananas and oranges contains information on many observed features (size, shape, color, texture), and thus has relatively large I_{ob}. By the generalization theorem, this implies that it also has high I_{un}. By contrast, a clustering rule which puts all items that appeared in our right visual field in one cluster, and the others in a second cluster, has much smaller I_{ob} (since it does not match many observed features), and indeed it is not predictive about unobserved features.

Example 4 *As a negative example, if the type of observed features and the target unobserved features are very different, our assumptions do not hold. For example, when the observations are pixels of an image, and the target variable is the label of the image, we cannot generalize from information about the pixels to information about the label.*

2.2 Feature Generalization of Maximum Likelihood Multinomial Mixture Models

In the framework of Bayesian graphical models, the multinomial mixture model is commonly used. The assumption of this model is that all features are conditionally independent, given the value of

4. Note that the indices are arbitrary. The learning algorithm does not use the indices of the features.

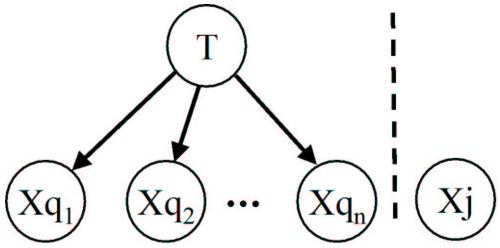

Figure 2: The Bayesian network (Pearl, 1988) of the multinomial mixture model. The observed random variables $\{X_{q_1},\ldots,X_{q_n}\}$ are statistically independent given the parent hidden random variable, T. This parent variable represents the cluster label. Although the basic assumptions of the multinomial mixture model are very different from ours, Theorem 7 tells us that this method of clustering generalizes well to unobserved features.

some hidden variable, that is,

$$\Pr(T=t,x_{q_1},\ldots,x_{q_n}) = \Pr(T=t)\prod_{r=1}^{n}\Pr(x_{q_r}|T=t),$$

where T denotes the hidden variable. The Bayesian network (Pearl, 1988) of this model is given in Figure 2. This standard model does not assume the existence of unobserved features, so we use the notation $x_{q_1},\ldots,x_{q_n}$ to denote the observed features which are used by the model. The set of instances are assumed to be drawn from such a distribution, with unknown parameters. Given the set of instances, the goal is to learn the distributions $\Pr(T=t)$ and $\Pr(x_{q_r}|T=t)$ that maximizes the probability of the observation, that is, values of the instances. This maximum-likelihood problem is typically solved using an EM algorithm (Dempster et al., 1977) with a fixed number of clusters (values of T). The output of this algorithm includes a soft clustering of all instances; that is, $P(T|Y)$, where Y denotes the index of the instance.

In the following theorem we analyze the feature generalization properties of soft clustering by the multinomial mixture model. We show that under some technical conditions, it pursues nearly the same goal as *IobMax* algorithm (Definition 5), that is, maximizing $\sum_j I\left(\mathbf{t}(Z);X_{q_j}(Z)\right)$.

Theorem 7 *Let $I_{ob,ML,k}$ be the observed information of clustering achieved by the maximum likelihood solution of a multinomial mixture model for k clusters. Then*

$$I_{ob,ML,k} \geq \tilde{I}_{ob,k} - \frac{2H(T)}{n},$$

where $\tilde{I}_{ob,k}$ is the observed information achieved by the IobMax clustering algorithm (Definition 5).

Proof

Elidan and Friedman (2003) showed that learning a hidden variable can be formulated as the multivariate information bottleneck (Friedman et al., 2001). Based on their work, in Appendix A.3 we show that maximizing the likelihood of observed variables is equivalent to maximizing $\sum_{j=1}^{n} I(T;X_{q_j}) - I(T;Y)$. Using our notations, this is equivalent to maximizing $I_{ob} - \frac{1}{n}I(T;Y)$. Since $I(T;Y) \leq H(T)$, the difference between maximizing I_{ob} and $I_{ob} - \frac{1}{n}I(T;Y)$ is at most $2H(T)/n$. ■

The meaning of Theorem 7 is that for large n, finding the maximum likelihood of mixture models is similar to finding the maximum unobserved information. Thus the standard EM-algorithm for maximum likelihood of mixture models can be viewed as a form of the *IobMax* algorithm.[5]

The standard mixture model assumes a generative model for generating the instances from some distribution, and finds the maximum likelihood of this model. This model does not assume anything about the selection of features or the existence of unobserved features. Our setup assumes that the instances are fixed and the observed features are randomly selected and we try to maximize information on unobserved features. Interestingly, while the initial assumptions are quite different, the results are nearly equivalent. We show that finding the maximum likelihood of the mixture model indirectly predicts unobserved features as well.

The maximum likelihood mixture model was used by Breese et al. (1998) to cluster users by their voting on movies. This clustering is used to predict the rating of new movies. Our analysis shows that for a large number of rated (observed) movies, it is nearly the best clustering method in terms of information on new movies.

The multinomial mixture model is also used for learning with labeled and unlabeled instances, and is considered a baseline method (see Section 2.3 in Seeger, 2002). The idea is to cluster the instances based on their features. Then, the prediction of a label for an unlabeled instance is estimated from the labels of other instances in the same cluster. From our analysis, this is nearly the best clustering method for preserving information on the label, assuming that the label is yet another feature that happened to be unobserved in some instances. This provides another interpretation regrading the hidden assumption of this clustering scheme for labeled and unlabeled data.

3. Distance-Based Clustering

In this section we extend the framework and include analysis of feature generalization bounds for distance-based clustering. We apply this to analyze feature generalization of the k-means clustering algorithm (See Table 1). The setup in this section is the same as the setup defined in Section 2 except as described below. We assume that we have a distance function, denoted by f, that measures the distance for every two values of any of the features. We assume that f has the following properties:

$$0 \leq f(x_q[j], x_q[l]) \leq c \quad \forall q, j, l, \tag{2}$$

$$f(a,a) = 0 \qquad \forall a, \tag{3}$$

$$f(a,b) = f(b,a) \qquad \forall a, b, \tag{4}$$

where c is some positive constant. An example of such a function is the square error, that is, $f(a,b) = (a-b)^2$, where we assume that the value of all features is bounded as follows $\left|x_q[j]\right| \leq \sqrt{c}/2$ ($\forall q, j$), for some constant c. The features themselves can be discrete or continuous. Although we do not directly use the function f in the definitions of the theorems in the following section, it is required for their proofs (Appendix A.4).

5. Ignoring the fact that achieving a global maximum is not guaranteed.

3.1 Generalization of Distance-Based Clustering

As in Section 2, we have a set of m fixed instances $\{\mathbf{x}[1],...,\mathbf{x}[m]\}$, and the clustering algorithm clusters these instances into k clusters. For better readability, in this section the partition is denoted by $\{C_1,...,C_k\}$. $|C_r|$ denotes the size of the rth cluster.

The standard objective of the k-means algorithm is to achieve minimum intra-cluster variance, that is, minimize the function

$$\sum_{r=1}^{k}\sum_{j\in C_r}|\mathbf{x}[j]-\mu_r|^2,$$

where μ_r is the mean point of all instances in the rth cluster.

In our setup, however, we assume that the clustering algorithm has access only to the *observed* features over the m instances. The goal of clustering is to achieve minimum intra-cluster variance of the *unobserved* features. To do so, we need to generalize from the observed to the unobserved intra-class variance. To formalize this type of generalization, let's first define these variances formally.

Definition 8 *The **observed intra-cluster variance** $D_{ob}\{C_1,...,C_k\}$ of a clustering $\{C_1,...,C_k\}$ is defined by*

$$D_{ob}\{C_1,...,C_k\}=\frac{1}{nm}\sum_{r=1}^{k}\sum_{j\in C_r}\sum_{i=1}^{n}\left(x_{q_i}[j]-\mu_{q_i}[r]\right)^2,$$

where $\mu_q[r]$ is the mean of feature q over all instances in cluster r, that is,

$$\mu_q[r]=\frac{1}{|C_r|}\sum_{l\in C_r}x_q[l].$$

In other words, D_{ob} is the average square distance of each observed feature from the mean of the value of the feature in its cluster. The average is over all observed features and instances. The k-means algorithm minimizes the observed intra-cluster variance.

Definition 9 *The **expected unobserved intra-cluster variance** $D_{un}\{C_1,...,C_k\}$ is defined by*

$$D_{un}\{C_1,...,C_k\}=\frac{1}{m}\sum_{r=1}^{k}\sum_{j\in C_r}\mathbf{E}_{q\sim\mathcal{D}}\left(x_q[j]-\mu_q[r]\right)^2.$$

D_{ob} and D_{un} are the distance-based variables analogous to I_{ob} and I_{un} defined in Section 2. In our setup, the goal of the clustering algorithm is to create clusters with minimal unobserved intra-class variance (D_{un}). As in the case of information-based clustering, we first consider the problem of estimating D_{un}. Before presenting the generalization theorem for distance-based clustering, we need the following definition.

Definition 10 *Let α be the ratio between the size of smallest cluster and the average cluster size, that is,*

$$\alpha(\{C_1,...,C_k\})=\frac{\min_r|C_r|}{m/k}.$$

Now we are ready for the generalization theorem for distance-based clustering.

Theorem 11 *With the above definitions, if* $\left|x_q[j]\right| \leq R$ *for every* q, j *then for every* $\alpha_c > 0$, $\varepsilon > 0$,

$$\Pr_{\{q_1,\ldots,q_n\}} \left\{ \sup_{\alpha(\{C_1,\ldots,C_k\})\geq\alpha_c} \left| D_{ob}\{C_1,\ldots,C_k\} - D_{un}\{C_1,\ldots,C_k\} \right| \leq \varepsilon \right\} \geq 1-\delta,$$

where

$$\delta = \frac{8k}{\alpha_c} e^{-n\varepsilon^2/8R^4 + \log\left(R^2/\varepsilon\right)}.$$

The proof of this theorem is given in Appendix A.4. Theorem 11 is a special case of a more general theorem (Theorem 14) that we present in the appendix. Theorem 14 can be applied to other distance-based metrics, beyond the intra-cluster variance defined in Definition 9.

Note that for any $\varepsilon > 0$, the probability that $|D_{ob} - D_{un}| \leq \varepsilon$ goes to one, as $n \to \infty$. The convergence rate of D_{ob} to D_{un} is bounded by $O(1/\sqrt{n})$. As expected, for a fixed value of δ the upper bound on $|D_{ob} - D_{un}|$ decreases as the number of clusters, k, decreases.

Theorem 11 bounds the difference between observed and unobserved variances. We now use it to find a clustering that minimizes the expected unobserved intra-cluster variance, using only the observed features.

Theorem 12 *Let* $\left\{C_1^{opt},\ldots,C_k^{opt}\right\}$ *be the clustering that achieves the minimum unobserved intra-cluster variance under the constraint* $\alpha(\{C_1,\ldots,C_k\}) \geq \alpha_c$ *for some constant* $0 < \alpha_c \leq 1$, *that is,*

$$\left\{C_1^{opt},\ldots,C_k^{opt}\right\} = \arg \min_{\{C_1,\ldots,C_k\}:\alpha\geq\alpha_c} D_{un}\{C_1,\ldots,C_k\},$$

and let D_{un}^{opt} *the best unobserved intra-cluster variance, be defined by* $D_{un}^{opt} = D_{un}\left\{C_1^{opt},\ldots,C_k^{opt}\right\}$.

Let $\left\{\hat{C}_1^{opt},\ldots,\hat{C}_k^{opt}\right\}$ *be the clustering with the minimum observed intra-cluster variance, under the same constraint on* $\alpha(\{C_1,\ldots,C_k\})$, *that is,*

$$\left\{\hat{C}_1^{opt},\ldots,\hat{C}_k^{opt}\right\} = \arg \min_{\alpha(\{C_1,\ldots,C_k\})\geq\alpha_c} D_{ob}\{C_1,\ldots,C_k\},$$

and let $\hat{D}_{un}^{opt}$ *be the unobserved intra-cluster variance of this clustering, that is,* $\hat{D}_{un}^{opt} = D_{un}\left\{\hat{C}_1^{opt},\ldots,\hat{C}_k^{opt}\right\}$.

For any $\varepsilon > 0$,

$$\Pr_{\{q_1,\ldots,q_n\}} \left\{\hat{D}_{un}^{opt} \leq D_{un}^{opt} + \varepsilon\right\} \geq 1-\delta,$$

where

$$\delta = \frac{16k}{\alpha_c} e^{-n\varepsilon^2/32R^4 + \log\left(R^2/\varepsilon\right)}. \tag{5}$$

Proof We now define a *bad clustering* as a clustering whose expected unobserved intra-cluster variance satisfies $D_{un} > D_{un}^{opt} + \varepsilon$. Using Theorem 11, the probability that $|D_{ob} - D_{un}| \leq \varepsilon/2$ for all possible clusterings (under the constraint on α) is at least $1-\delta$, where δ defined in Equation 5. If for all clusterings $|D_{ob} - D_{un}| \leq \varepsilon/2$, then surely $D_{ob}\left\{C_1^{opt},\ldots,C_k^{opt}\right\} \leq D_{un}^{opt} + \varepsilon/2$ and D_{ob} of all bad clusterings satisfies $D_{ob} > D_{un}^{opt} + \varepsilon/2$. Hence the probability that any of the bad clusterings has a lower observed intra-cluster variance than the best clustering is upper bounded by δ. Therefore, with a probability of at least $1-\delta$ none of the bad clusterings is selected by an algorithm that selects

the clustering with the minimum D_{ob}. ■

We cannot directly calculate the unobserved intra-cluster variance. However, Theorem 12 means that an algorithm that selects the clustering with the minimum observed intra-cluster variance indirectly finds the clustering with nearly minimum unobserved intra-cluster variance.

In general, minimizing observed intra-cluster variance is the optimization objective of *k*-means. Hence, *k*-means indirectly minimizes the unobserved intra-cluster variance. This means that in our context, *k*-means can be viewed as an analog to the empirical risk minimization (ERM) in the standard supervised learning context. We minimize the observed variance (training error) in order to indirectly minimize the expected unobserved variance (test error).

k-means is used in collaborative filtering such as movie rating predictions for grouping users based on similar ratings (see, for example, Marlin, 2004). After clustering, we can predict ratings of a new movie based on the ratings of a few users for this movie. If the intra-cluster variance of a new, previously unobserved movie is small, then we can estimate the rating of one user from the average ratings of other users in the same cluster.

An experimental illustration of the behavior of the observed and unobserved intra-cluster variances for *k*-means is available in Section 4.1.

4. Empirical Evaluation

In this section we test experimentally the generalization properties of *IobMax* and the *k*-means clustering algorithm for a finite number of features. For *IobMax* we examine the difference between I_{ob} and I_{un} as a function of the number of observed features, and number of clusters used. We also compare the value of I_{un} achieved by the *IobMax* algorithm to I^*_{un}, which is the maximum achievable I_{un} (see Definition 4). Similarly, for distance-based clustering we use *k*-means to examine the behavior of the observed and unobserved intra-cluster variances (see Definitions 8, 9).

The purpose of this section is *not* to suggest new algorithms for collaborative filtering or compare it to other methods, but simply to illustrate our new theorems on empirical data.

4.1 Collaborative Filtering

In this section, our evaluation uses a data set typically employed for collaborative filtering. Collaborative filtering refers to methods of making predictions about a user's preferences, by collecting the preferences of many users. For example, collaborative filtering for movie ratings can make predictions about the rating of movies by a user given a partial list of ratings from this user and many other users. Clustering methods are used for collaborative filtering by clustering users based on the similarity of their ratings (see, for example, Marlin, 2004; Ungar and Foster, 1998).

In our setting, each user is described as a vector of movie ratings. The rating of each movie is regarded as a feature. We cluster users based on the set of observed features, that is, rated movies. In our context, the goal of the clustering is to maximize the information between the clusters and unobserved features, that is, movies that have not yet been rated by any of the users. These can be movies that have not yet been made. By Theorem 6, given a large enough number of rated movies, we can achieve the best possible clustering of users with respect to unseen movies. In this region, no additional information (such as user age, taste, rating of more movies) beyond the observed features can improve the unobserved information, I_{un}, by more than some small ε.

For distance-based clustering, we cluster the users by the *k*-means algorithm based on a subset of features (movies). As we show in Section 3.1 the goal of *k*-means is to minimize the observed intra-cluster variance. From Theorem 12, this indirectly minimizes the unobserved intra-cluster variance as well. Here we empirically evaluate this type of generalization.

Data set. We use MovieLens (www.movielens.umn.edu), which is a movie rating data set. It was collected and distributed by GroupLens Research at the University of Minnesota. It contains approximately 1 million ratings of 3900 movies by 6040 users. Ratings are on a scale of 1 to 5. We use only a subset consisting of 2400 movies rated by 4000 users (or 2000 by 2000 for distance-based clustering). In our setting, each instance is a vector of ratings $(x_1,\ldots,x_{2400})$ by a specific user. Each movie is viewed as a feature, where the rating is the value of the feature.

Experimental Setup. We randomly split the 2400 movies into two groups, denoted by "A" and "B", of 1200 movies (features) each. We use a subset of the movies from group "A" as observed features and all movies from group "B" as the unobserved features. The experiment was repeated with 20 random splits and the results averaged. We estimate I_{un} by the mean information between the clusters and ratings of movies from group "B". We use a uniform distribution of feature selection ($\mathcal{D}$), and hence I_{un} can be estimated as the average information on the unobserved features, that is, $I_{un} = \frac{1}{1200}\sum_{j\in B} I(T;X_j)$. A similar setup is used for the distance-based clustering (with two groups of 1000 movies).

Handling Missing Values. In this data set, most of the values are missing (not rated). For information based-clustering, we handle this by defining the feature variable as 1,2,...,5 for the ratings and 0 for a missing value. We maximize the mutual information based on the empirical distribution of values that are present, and weight it by the probability of presence for this feature. Hence, $I_{ob} = \sum_{j=1}^{n} P(X_j \neq 0) I(T;X_j|X_j \neq 0)$ and $I_{un} = E_j\left\{P(X_j \neq 0) I(T;X_j|X_j \neq 0)\right\}$. The weighting prevents overfitting to movies with few ratings. Since the observed features are selected at random, the statistics of missing values of the observed and unobserved features are the same. Hence, all our theorems are applicable to these definitions of I_{ob} and I_{un} as well.

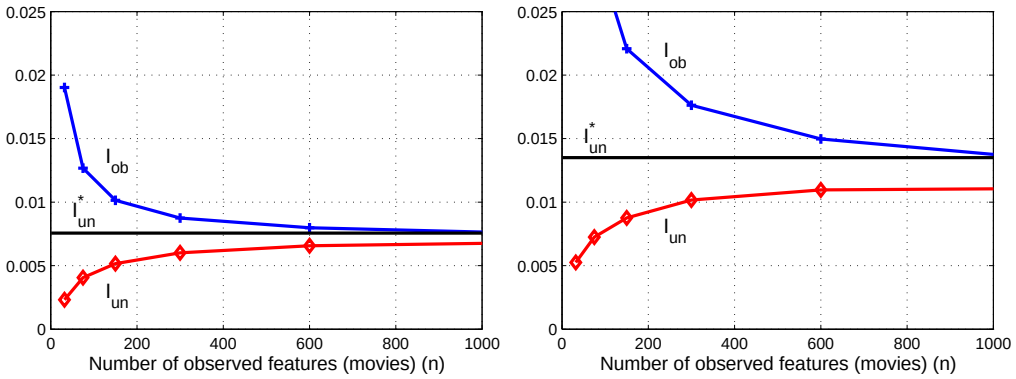
In order to verify that the estimated mutual information is not just an artifact of the finite sample size, we tested the mutual information after random permutation of ratings of each movie among users. Indeed, the resulting mutual information was significantly lower in the case of random permutation.

For the distance based clustering, we handle missing data by defining a default square distance between a feature and the cluster center where one (or two) of the values is missing. We select this default square distance to be the average variance of movie ratings (which is about 0.9).

4.2 Greedy *IobMax* Algorithm

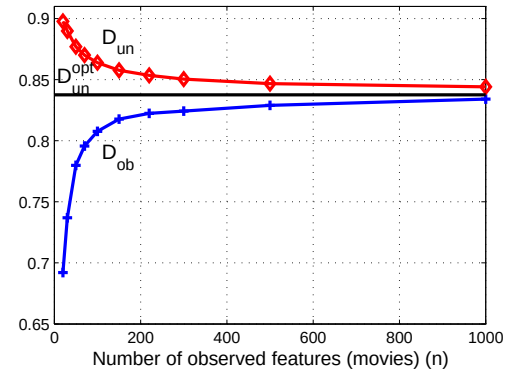
For information-based clustering, we cluster the users using a simple greedy clustering algorithm (see Algorithm 1). The input to the algorithm is all users, represented solely by the observed features. Since this algorithm can only find a local maximum of I_{ob}, we ran the algorithm 10 times (each used a different random initialization) and selected the results that had a maximum value of I_{ob}.

In our experiment, the number of observed features is large. Therefore, based on Theorem 7, the greedy *IobMax* can be replaced by the standard EM-algorithm which finds the maximum likelihood for multinomial mixture models. Although, in general, this algorithm finds soft clustering, in our

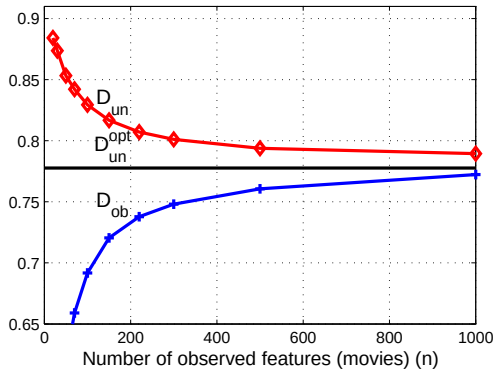


(a) 2 Clusters

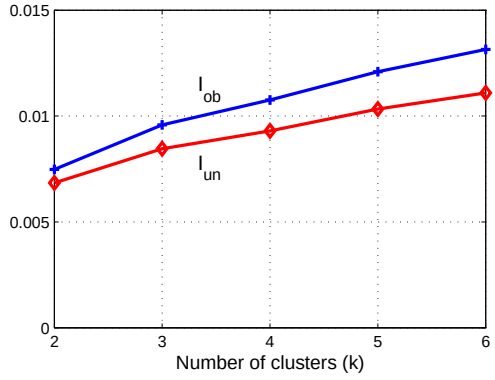
(b) 6 Clusters



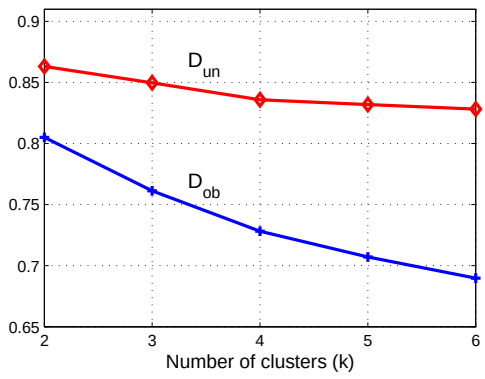
(c) 2 Clusters



(d) 6 Clusters



(e) Fixed number of features (n=1200)



(f) Fixed number of features (n=100)

Figure 3: Feature generalization as a function of the number of training features (movies) and the number of clusters. (a) (b) and (e) show the observed and unobserved information for various numbers of features and clusters (high is good). The overall mean information is low, since the rating matrix is sparse. (c) (d) and (f) shows the observed and unobserved intra-cluster variance (low is good). In these figures, the variance is only calculated on values which are not missing. Figures (e) and (f) show the effect of the number of clusters when the number of features is fixed.

case the empirical result clusterings are not soft, that is, one cluster is assigned to each instance (see Appendix A.2). As expected, the results of both algorithms are nearly the same.

Algorithm 1 A simple greedy *IobMax* algorithm

1. Assign a random cluster to each of the instances.
2. For $r = 1$ to R (where R is the upper limit on the number of iterations)
   (a) For each instance,
      i. Calculate I_{ob} for all possible clustering assignments of the current instance.
      ii. Choose the clustering that maximizes I_{ob}.
   (b) Exit if the clusters of all documents do not change.

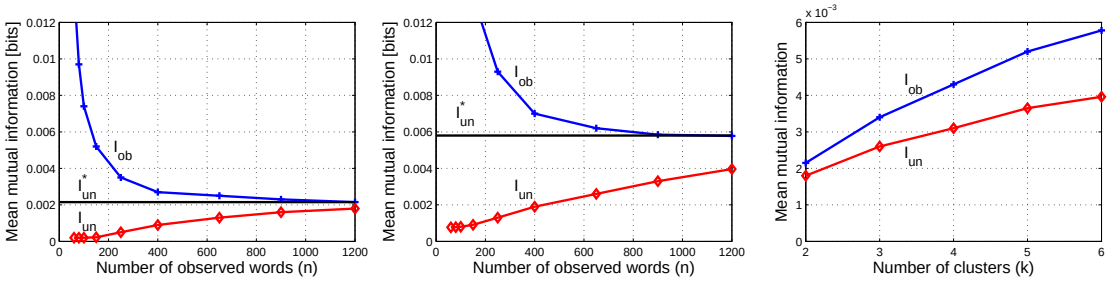
In order to estimate $I^*_{un,D}$ (see Definition 4), we also ran the same algorithm when all the features were available to the algorithm (i.e., also features from group "B"). In this case the algorithm tries directly to find the clustering that maximizes the mean mutual information on features from group "B".

4.3 Results

The results are shown in Figure 3. It is clear that as the number of observed features increases, I_{ob} decreases while I_{un} increases (see Figure 3(a,b)). When there is only one feature, two clusters can contain all the available information on this feature (e.g., by assigning $t(j) = x_{q_1}[j]$), so I_{ob} reaches its maximum value (which is $H(X_{q_1}[Z])$). As the number of observed features increases, we cannot preserve all the information on all the features in a few clusters, so the observed mutual information (I_{ob}) decreases. On the other hand, as the number of observed features increases, the cluster variable, $T = t(Z)$, captures the structure of the distribution (users' tastes), and hence contains more information on unobserved features. The generalization theorem (Theorem 3) tells us that the difference between I_{un} and I_{ob} will approach zero as the number of observed features increases. This is similar to the behavior of training and test errors in supervised learning. Informally, the achievability theorem (Theorem 6) tells as that for a large enough number of observed features, even though our clustering algorithm is based only on observed features, it can achieve nearly the best possible clustering, in terms of I_{un}. This can be seen in Figures 3 (a,b), where I_{un} approaches I^*_{un}, which is the unobserved information of the best clustering (Definition 4). As the number of clusters increases, both I_{ob}, I_{un} increase (Figure 3e), but the difference between them also increases.

Similar results were obtained for distance based clustering. The goal here is to minimize the unobserved intra-cluster variance (D_{un}), and this is done by minimizing the observed intra-cluster variance (D_{ob}). As discussed in Section 3.1, this can be achieved by k-means.[6] Again, for a small numbers of features (n) the clustering overfits the observed features, that is, the D_{ob} is relatively low but D_{un} is large. However, for large n, D_{un} and D_{ob} approach each other and both of them approach the unobserved intra-cluster variance of the best possible clustering (D^{opt}_{un}) as expected

6. Since k-means does not necessarily find the global optimum, we ran it 20 times with different initialization points, and chose the results with minimal observed intra-cluster variance. This does not guarantee a global optimum, but no other tractable algorithm is available today to achieve global optima.



(a) 2 Clusters (b) 6 Clusters (c) Fixed 1200 observed words

Figure 4: I_{ob}, I_{un} and I^*_{un} per number of training words and clusters. In (a) and (b) the number of words is variable, and the number of clusters is fixed. In (c) the number of observed words is fixed (1200), and the number of clusters is variable. The overall mean information is low, since a relatively small number of words contributes to the information (see Table 2)

from Theorem 12. When the number of clusters increases, both D_{ob} and D_{un} decrease, but the difference between them increases.

4.4 Words and Documents

In this section we repeat the information-based clustering experiment, but this time for document clustering with words as features. We show how clustering which is based on a subset of words (observed words) is also informative about the unobserved words. The obtained curves of information vs. number of features are similar to those in the previous section. However, in this section we also examine the resulting clustering (Table 2) to get a better intuition as to how this generalization occurs.

Data set. We use the 20-newsgroups (20NG) corpus, collected by Lang (1995). This collection contains about 20,000 messages from 20 Usenet discussion groups, some of which have similar topics.

Preprocessing. In order to prevent effects caused by different document lengths, we truncate each document to 100 words (by randomly selecting 100 words), and ignore documents which consist of fewer than 100 words. We use the "bag of words" representation: namely we convert each document into a binary vector $(x_1, x_2, \ldots)$, where each element in the vector represents a word, and equals one if the word appears in the document and zero otherwise. We select the 2400 words whose corresponding X_i has maximum entropy,[7] and remove all other words. After this preprocessing each document is represented by a vector $(x_1, \ldots, x_{2400})$.

Experimental setup. We randomly split the 2400 words into two groups of 1200 words (features) each. The groups were called "A" and "B". We use a variable number of words (1 to 1200) from group "A" as observed features. All the features from group "B" are used as the unobserved features. We repeat the test with 10 random splits and present the mean results.

7. In other words, the probability of the word appearing in a document is not near zero or near one.

	Word	t=1	t=2	t=3
Observed words	he	0.47	0.04	0.25
	game	0.23	0.01	0
	team	0.20	0	0
	x	0.01	0.15	0.01
	hockey	0.11	0	0
	jesus	0.01	0	0.09
	christian	0	0	0.08
	use	0.04	0.21	0.09
	file	0	0.08	0.01
Unobserved words	god	0.02	0.01	0.15
	players	0.13	0	0
	baseball	0.10	0	0
	window	0	0.10	0
	server	0	0.06	0

Table 2: Probability of a word appearing in a document from each cluster. Each column in the table represents a cluster (total of three clusters), and the numbers are the probabilities that a document from a cluster will contain the word (e.g., The word "he" appears in 47% of the documents from cluster 1). The results presented here are for learning from 1200 observed words, but only a few of the most informative words appear in the table.

4.5 Results

The results are shown in Figure 4 and Table 2. The qualitative explanation of the figure is the same as for collaborative filtering (see Section 4.1 and Figure 3). Table 2 presents a list of the most informative words, and their appearance in each cluster. This helps understand the way clustering learned from observed words matches unobserved words. We can see, for example, that although the word "player" is not part of the inputs to the clustering algorithm, it appears much more in the first cluster than in other clusters. Intuitively this can be explained as follows. The algorithm finds clusters that are informative on many observed words together, and thus matches the co-occurrence of words. This clustering reveals the hidden topics of the documents (sports, computers and religious), and these topics contain information on the unobserved words. We see that generalization to unobserved features can be explained from a standpoint of a generative model (a hidden variable which represents the topics of the documents) or from a statistical point of view (relationship between observed and unobserved information). In Section 6 we further discuss this dual view.

5. Related Work

In the framework of learning with labeled and unlabeled data (see, for example, Seeger, 2002), a fundamental issue is the link between the marginal distribution $P(\mathbf{x})$ over instances $\mathbf{x}$ and the conditional $P(y|\mathbf{x})$ for the label y (Szummer and Jaakkola, 2003). From this point of view our approach assumes that the label, y, is a feature in itself.

In the context of supervised learning, Ando and Zhang (2005) proposed an approach that regards features in the input data as labels in order to improve prediction in the target supervised problem. Their idea is to create many auxiliary problems that are related to the target supervised problem. They do this by masking some features in the input data, that is, making them unobserved features, and training classifiers to predict these unobserved features from the observed features. Then they transfer the knowledge acquired from these related classification tasks to the target supervised problem. A similar idea was used by Caruana and de Sa (1997) in supervised training of a neural net. The authors used some features as extra outputs of the neural net, rather than inputs, and show empirically that this can improve the classifier performance. In our framework, this could be interpreted as follows. We regard the label as a feature, and hence we can learn from prediction of these features to the prediction of the label. Loosely speaking, if we successfully predict many such features by the classifier, we expect to generalize better to the target feature (label).

The idea of an information tradeoff between complexity and information on target variables is similar to the idea of the information bottleneck (Tishby et al., 1999). But unlike the bottleneck method, here we are trying to maximize information on *unobserved* variables, using a finite sample.

In a recent paper, von Luxburg and Ben-David (2005) discuss the goal of clustering in two very different cases. The first is when we have complete knowledge about our data generating process, and the second is how to approximate an optimal clustering when we have incomplete knowledge about our data. In most current analyses of clustering methods, incomplete knowledge refers to getting a finite sample of instances rather than the distribution itself. Then, we can define the desired properties of a good clustering. An example of such a property is the stability of the clustering with respect to the sampling process, for example, the clusters do not change significantly if we add some data points to our sample. In our framework, even if the distribution of the instances is completely known, we assume that there are other features that we might not be aware of at the time of clustering. Another way to view this is that in our framework, incomplete knowledge refers to the existence of unobserved features rather than to an unknown distribution of the observed features. From this point of view, further research could concentrate on analyzing the feature stability of a clustering algorithm, for example, stability with respect to the adding of new features.

Another interesting work which addresses the difficulty of defining good clustering was presented by Kleinberg (2002). In this work the author states the desired properties a clustering algorithm should satisfy, such as scale invariances and richness of possible clusterings. Then he proves that it is impossible to construct a clustering that satisfies all the required properties. In his work the clustering depends on pairwise distances between data points. In our work, however, the analysis is feature oriented. We are interested in the information (or distance) per feature. Hence, our basic assumptions and analysis are very different.

The idea of generalization to unobserved features by clustering was first presented in a short version of this paper (Krupka and Tishby, 2005).

6. Discussion

We introduce a new learning paradigm: clustering based on observed features that generalizes to unobserved features. Our main results include two theorems that tell us how, without knowing the value of the unobserved features, one can estimate and maximize information between the clusters and the unobserved features. Using this framework we analyze feature generalization of the Maximum Likelihood Multinomial Mixture Model (Figure 2). The multinomial mixture model is a

generative probabilistic model which approximates the probability distribution of the observed data ($\mathbf{x}$), from a finite sample of instances. Our model does not assume any distribution that generated the instances, but instead assumes that the set of observed features is simply a random subset of features. Then, using statistical arguments we show that we can cluster by the unobserved features. Despite the very different assumptions of these models, we show that clustering by multinomial mixture models is nearly optimal in terms of maximizing information on unobserved features. However, to analyze and quantify this generalization our framework is required.

This dual view on the multinomial mixture model can also be applied to two different approaches that may explain our "natural clustering" of objects in the world (e.g., assigning object names in language). Let's return to our clustering of bananas and oranges (Example 3). From the generative point of view, we find a model with the cluster labels bananas and oranges as values of a hidden variable that created the distribution. This means that we have a mixture of two distributions, each related to one object type that is assigned to a different cluster. Since we have two types of objects (distributions), we expect that their unobserved features will correspond to these two types as well. However, the generative model does not quantify this expectation. In our framework, we view fruits in the world, and cluster them based on some kind of *IobMax* algorithm; that is, we find a representation (clustering) that contains significant information on as many observed features as possible, while still remaining simple. From our generalization theorem (Theorem 3), such a representation is expected to contain information on other rarely viewed salient features as well. Moreover, we expect this unobserved information to be similar to the information we have on the clustering on the observed features.

In addition to information-based clustering, we present similar generalization theorems for distance-based clustering, and use these to analyze generalization properties of *k*-means. Under some assumptions, *k*-means is also known as a solution for the maximum likelihood Gaussian mixture model. Analogous to what we show for information based clustering and multinomial mixture models, we show that this optimization goal of *k*-means is also optimal in terms of generalization to unobserved features.

The key assumption that enables us to prove these theorems is the *random independent selection* of the observed features. Note that a contrary assumption to random selection would be that given two instances $\{\mathbf{x}[1],\mathbf{x}[2]\}$, there is a correlation between the distance of a feature $\left|x_q[1]-x_q[2]\right|$ and the probability of observing this feature; for example, the probability of *observing* features that are similar is higher. If no such correlation exists, then the selection can be considered random in our context. Hence, we believe that in practice the random selection assumption is reasonable. However, in many cases, the assumption of complete independence in the selection of features is less natural. Therefore, we believe that further research on the effects of dependence in selection is required.

Another interpretation of the generalization theorem, without using the *random independence* assumption, might be combinatorial. The difference between the observed and unobserved information is large only for a small portion of all possible partitions into observed and unobserved features. This means that almost any arbitrary partition generalizes well.

The value of clustering which preserves information on unobserved features is that it enables us to learn new—previously unobserved—attributes from a small number of examples. Suppose that after clustering fruits based on their observed features (Example 3), we eat a chinaberry[8] and thus,

8. Chinaberries are the fruits of the Melia azedarach tree, and are poisonous.

we "observe" (by getting sick), the previously unobserved attribute of toxicity. Assuming that in each cluster, all fruits have similar unobserved attributes, we can conclude that all the fruits in the same cluster, that is, all chinaberries are likely to be poisonous.

Clustering is often used in scientific research, when collecting measurements on objects such as stars or neurons. In general, the quality of a theory in science is measured by its predictive power. Therefore, a reasonable measure of the quality of clustering, as used in scientific research, is its ability to predict unobserved features, or measurements. This is different from clustering that merely describes the observed measurements, and supports the rationale for defining the quality of clustering by its predictivity on unobserved features.

6.1 Further Research

Our clustering maximizes expected information on randomly selected features. Although on average this information may be high, there might be features the clustering has no information about. To address this problem, we could create more than one clustering, in such a way that each clustering contains information on other features. To achieve this, we want each new clustering to discover new information, that is, not to be redundant with previously created clusterings. This can be done based on the works of Gondek and Hofmann (2004) and Chechik and Tishby (2002) in the context of the Information Bottleneck. Another alternative is to represent each instance by a low dimensional vector, and then use this vector to predict unobserved features. Blitzer et al. (2005) represented words in a model called Distributed Binary Latent Variables, and used this representation to predict another word. Adopting this idea in our context, we can replace cluster labels by a vector of binary variables assigned to each instance, where each such variable encodes an independent aspect of the instance. Generalization in this case refers to the ability to predict unobserved features from these latent variables.

Our framework can also be extended beyond clustering by formulating a general question. Given the (empirical) marginal distribution of a random subset of features $P(X_{q_1},\ldots,X_{q_n})$, what can we say about the distribution of the full set $P(X_1,\ldots,X_L)$? In this paper we proposed a clustering based on a subset of features, and analyzed the information that the clustering yielded on features outside this subset. It would be useful to find more sophisticated representations than clustering, and analyze other theoretical aspects of the relationship between the distribution of the subset to that of the full set. This type of theoretical analysis can help in deriving prediction algorithms, where there are many instances for some of the variables (features), but other variables are rarely viewed, as in collaborative filtering. By relating the distribution of some variables to the distribution of others, we can also analyze and improve the estimation of $p(\mathbf{x})$ from a finite sample, even without assuming the existence of unobserved features. In a different context, Han (1978) analyzed the relationship between the average (per variable) entropy of random subsets of variables. He showed that the average entropy of a random subset of variables monotonically decreases with the size of the subset (see also Cover and Thomas, 1991). These results were developed in the context of information theory and compression, but may be applicable to learning theory as well.

In this paper, we assumed that we do not have additional prior information on the features. In practice, we often do have such information. For instance, in the movie ratings data set, we have some knowledge about each of the movies (genre, actors, year, etc.). This knowledge about the features can be regarded as meta-features. A possible extension of our framework is to use this knowledge to improve and analyze generalization as a function of the meta-features of the

unobserved features. The idea of learning along the features axis by using meta-features was implemented by Krupka et al. (submitted) for feature selection. They propose a method for learning to select features based on the meta-features. Using the meta-features we can learn what *types* of features are good, and predict the quality of unobserved features. They show that this is useful for feature selection out of a huge set of potentially extracted features; that is, features that are functions of the input variables. In this case all features can be observed, but in order to measure their quality we must calculate them for all instances, which might be computationally intractable. By predicting feature quality without calculating it, we can focus the search for good features on a small subset of the features. In a recent paper (Krupka and Tishby, 2007), we propose a method for learning the weights of a linear classifier based on meta-features. The idea is to learn weights as a function of the meta-features just as we learn labels as a function of features. Then, we can learn from feature to feature and not only from instance to instance. As shown empirically, this can significantly improve classification performance in the standard supervised learning setting.

In this work we focused on a new feature generalization analysis. Another research direction is to combine standard instance generalization with feature generalization. In problems like collaborative filtering or gene expression, there is an inherent symmetry between features and instances that have been used before in various ways (see, for example, Ungar and Foster, 1998). In the context of supervised learning, a recent work by Globerson and Roweis (2006) addresses the issue of handling differences in the set of observed features between training and test time. However, a general framework for generalization to both unobserved features and unobserved instances is still lacking.

Acknowledgments

We thank Aharon Bar-Hillel, Amir Globerson, Ran Bachrach, Amir Navot and Ohad Shamir for helpful discussions. We also thank the GroupLens Research Group at the University of Minnesota for use of the MovieLens data set. Our work is partly supported by the Center of Excellence grant from the Israeli Academy of Science and by the NATO SfP 982480 project.

Appendix A. Proofs

This appendix contains the proofs of Theorem 3 and Theorem 11. It also contains additional technical details that were used in the proof of Theorem 7.

A.1 Proof of Theorem 3

We start by introducing the following lemma, which is required for the proof of Theorem 3.

Lemma 13 *Consider a function g of two independent discrete random variables (U,V). We assume that $g(u,v) \leq c$, $\forall u,v$, where c is some constant. If $\Pr\{g(U,V) > \tilde{\varepsilon}\} \leq \delta$, then*

$$\Pr_V\{\mathbf{E}_u(g(u,V)) \geq \varepsilon\} \leq \frac{c-\tilde{\varepsilon}}{\varepsilon-\tilde{\varepsilon}}\delta, \quad \forall \varepsilon > \tilde{\varepsilon}.$$

Proof of lemma 13: Let $\mathcal{V}_L'$ be the set of values of V, such that for every $v' \in \mathcal{V}_L'$, $E_u(g(y,v')) \geq \varepsilon$. For every such v' we get,

$$\varepsilon \leq \mathbf{E}_u\left(g(u,v')\right) \leq c\Pr\left\{g(U,V) > \tilde{\varepsilon}|V=v'\right\} + \tilde{\varepsilon}\Pr\left\{g(U,V) \leq \tilde{\varepsilon}|V=v'\right\}.$$

Hence, $\Pr\{g(U,V) > \tilde{\varepsilon} | V = v'\} \geq \frac{\varepsilon - \tilde{\varepsilon}}{c - \tilde{\varepsilon}}$. From the complete probability formula,

$$\begin{aligned} \delta \geq \Pr\{g(U,V) > \tilde{\varepsilon}\} &= \sum_z \Pr\{g(U,V) > \tilde{\varepsilon} | V = v\} P(v) \\ &\geq \frac{\varepsilon - \tilde{\varepsilon}}{c - \tilde{\varepsilon}} \sum_{V : V \in V_L} P(v) \\ &= \frac{\varepsilon - \tilde{\varepsilon}}{c - \tilde{\varepsilon}} \Pr_V \{\mathbf{E}_u (g(u,V)) \geq \varepsilon\}. \end{aligned}$$

Lemma 13 follows directly from the last inequality. □

We first provide an outline of the proof of Theorem **3** and then provide a detailed proof.

Theorem 3—Proof outline: For the given m instances and any clustering $\mathbf{t}$, draw uniformly and independently m' instances (repeats allowed). For any feature index q, we can estimate $I(\mathbf{t}(Z); x_q[Z])$ from the empirical distribution of $(\mathbf{t}, x_q)$ over the m' instances. This empirical distribution is $p(\mathbf{t}(Z'), x_q[Z'])$ where Z' is a random variable denoting the index of instance chosen uniformly from the m' instances (defined formally below). The proof is built up from the following upper bounds, which are independent of m, but depend on the choice of m'. The first bound is on $\mathbf{E}\left\{\left|I(\mathbf{t}(Z); x_q[Z]) - I(\mathbf{t}(Z'); x_q[Z'])\right|\right\}$, where q is fixed and the expectation is over random selection of the m' *instances*. From this bound we derive an upper bound on $|I_{ob} - \mathbf{E}(\hat{I}_{ob})|$ and $|I_{un} - \mathbf{E}(\hat{I}_{un})|$, where $\hat{I}_{ob}$, $\hat{I}_{un}$ are the estimated values of I_{ob}, I_{un} based on the subset of m' instances, that is, the empirical distribution. The last required bound is on the probability that $\sup_{\mathbf{t}:[m]\to[k]} \left|\mathbf{E}\left(\hat{I}_{ob}\right) - \mathbf{E}\left(\hat{I}_{un}\right)\right| > \varepsilon_1$, for any $\varepsilon_1 > 0$. This bound is obtained from Lemmas 2 and 13. The choice of m' is independent of m. Its value should be large enough for the estimations $\hat{I}_{ob}$, $\hat{I}_{un}$ to be accurate, but not too large, so as to limit the number of possible clusterings over the m' instances.

Note that we do not assume the m instances are drawn from a distribution. The m' instances are drawn from the empirical distribution over the m instances. □

Theorem 3—Detailed proof: Let $\tilde{\mathbf{l}} = (l_1, \ldots, l_{m'})$ be indices of m' instances, where each index is selected randomly, uniformly and independently from $\{1, \ldots, m\}$. Let random variable Z' denote a number chosen uniformly at random from $\{1, \ldots, m'\}$. For any feature index q, we can estimate $I(\mathbf{t}(Z); x_q[Z])$ from $I(\mathbf{t}(l_{Z'}); x_q[l_{Z'}])$ as follows. The maximum likelihood estimation of entropy given a discrete empirical distribution $(\hat{p}_1, ..., \hat{p}_N)$, is defined as $\hat{H}_{MLE} = -\sum_{i=1}^{N} \hat{p}_i \log \hat{p}_i$. Note that N is the alphabet size of our discrete distribution. From Paninski (2003) (Proposition 1) the bias between the empirical and actual entropy $H(p)$ is bounded as follows:

$$-\log\left(1 + \frac{N-1}{m'}\right) \leq \mathbf{E}\left(\hat{H}_{MLE}(\hat{p})\right) - H(p) \leq 0.$$

where the empirical estimation $\hat{H}_{MLE}$ is based on m' instances drawn from the distribution p. The expectation is over random sampling of these m' instances. Since $I(\mathbf{t}(Z); x_q[Z]) = -H(\mathbf{t}(Z), x_q[Z]) + H(\mathbf{t}(Z)) + H(x_q(Z))$, we can upper bound the bias between the actual and the empirical estimation of the mutual information as follows:

$$\mathbf{E}_{\tilde{\mathbf{l}}=(l_1,\ldots,l_{m'})}\left\{\left|I(\mathbf{t}(Z); x_q[Z]) - I(\mathbf{t}(l_{Z'}); x_q[l_{Z'}])\right|\right\} \leq \log\left(1 + \frac{ks-1}{m'}\right) \leq \frac{ks}{m'}. \tag{6}$$

Recall that s is the upper bound on the alphabet size of x_q.

Let $\hat{I}_{ob}(\mathbf{t}, \tilde{\mathbf{q}}, \tilde{\mathbf{l}})$ and $\hat{I}_{un}\left(\mathbf{t}, \tilde{\mathbf{l}}\right)$ be the estimated values of $I_{ob}(\mathbf{t}, \tilde{\mathbf{q}})$, $I_{un}(\mathbf{t})$ based on $(l_1, \ldots, l_{m'})$, that is,

$$\hat{I}_{ob}\left(\mathbf{t}, \tilde{\mathbf{q}}, \tilde{\mathbf{l}}\right) = \frac{1}{n} \sum_{i=1}^{n} I\left(t(l_{z'}); x_{q_i}[l_{z'}]\right),$$

$$\hat{I}_{un}(\mathbf{t},\tilde{\mathbf{l}}) = \mathbf{E}_{q\sim\mathcal{D}}\left\{I\left(\mathbf{t}(l_{z'});x_q[l_{z'}]\right)\right\}.$$

From Equation 6 we obtain,

$$|I_{ob}(\mathbf{t},\tilde{\mathbf{q}}) - \mathbf{E}_{\tilde{\mathbf{l}}}\left(\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right)\right)|,\ |I_{un}(\mathbf{t}) - \mathbf{E}_{\tilde{\mathbf{l}}}\left(\hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right)| \le ks/m',$$

and hence,

$$\begin{aligned} |I_{ob}(\mathbf{t},\tilde{\mathbf{q}}) - I_{un}(\mathbf{t})| &\le \left|\mathbf{E}_{\tilde{\mathbf{l}}}\left(\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right)\right) - \mathbf{E}_{\tilde{\mathbf{l}}}\left(\hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right)\right| + 2ks/m' \\ &\le \mathbf{E}_{\tilde{\mathbf{l}}}\left(\left|\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right) - \hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right|\right) + 2ks/m'. \end{aligned} \tag{7}$$

Using Lemma 2 we have an upper bound on the probability that

$$\sup_{\mathbf{t}:[m]\to[k]} \left|\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right) - \hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right| > \varepsilon$$

over the random selection of *features*, as a function of m'. However, the upper bound we need is on the probability that

$$\sup_{\mathbf{t}:[m]\to[l]} \left\{\mathbf{E}_{\tilde{\mathbf{l}}}\left(\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right)\right) - \mathbf{E}_{\tilde{\mathbf{l}}}\left(\hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right)\right\} > \varepsilon_1.$$

Note that the expectations $\mathbf{E}_l(\hat{I}_{ob})$, $\mathbf{E}_l(\hat{I}_{un})$ are done over a random selection of the subset of m' *instances*, for a set of features that is randomly selected *once*. In order to link these two probabilities, we use Lemma 13.

From Lemmas 2 and 13 it is easy to show that

$$\Pr_{\tilde{\mathbf{q}}}\left\{\mathbf{E}_{\tilde{\mathbf{l}}}\left(\sup_{\mathbf{t}:[m]\to[k]}\left|\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right) - \hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right|\right) > \varepsilon_1\right\} \le \frac{4\log k}{\varepsilon_1} e^{-n\varepsilon_1^2/\left(2(\log k)^2\right)+m'\log k}. \tag{8}$$

Lemma 13 is used, where V represents the random selection of features, U represents the random selection of m' instances, $g(u,v) = \sup_{\mathbf{t}:[m]\to[k]}|\hat{I}_{ob} - \hat{I}_{un}|$, $c = \log k$, and $\tilde{\varepsilon} = \varepsilon_1/2$. Since

$$\mathbf{E}_{\tilde{\mathbf{l}}}\left(\sup_{\mathbf{t}:[m]\to[k]}\left|\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right) - \hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right|\right) \ge \sup_{\mathbf{t}:[m]\to[k]} \mathbf{E}_{\tilde{\mathbf{l}}}\left(\left|\hat{I}_{ob}\left(\mathbf{t},\tilde{\mathbf{q}},\tilde{\mathbf{l}}\right) - \hat{I}_{un}\left(\mathbf{t},\tilde{\mathbf{l}}\right)\right|\right),$$

and from Equations 7 and 8 we obtain

$$\Pr_{\tilde{\mathbf{q}}}\left\{\sup_{\mathbf{t}:[m]\to[k]}|I_{ob}(\mathbf{t},\tilde{\mathbf{q}}) - I_{un}(\mathbf{t})| > \varepsilon_1 + \frac{2ks}{m'}\right\} \le \frac{4\log k}{\varepsilon_1} e^{-n\varepsilon_1^2/\left(2(\log k)^2\right)+m'\log k}.$$

By selecting $\varepsilon_1 = \varepsilon/2$, $m' = 4ks/\varepsilon$, we obtain Theorem 3. □

Note that the selection of m' depends on s (maximum alphabet size of the features). This reflects the fact that in order to accurately estimate $I(\mathbf{t}(Z);x_q[Z])$, we need a number of instances, m', which is much larger than the product of k and the alphabet size of x_q.

A.2 Information Generalization for Soft Clustering

In Section 2 we assumed that we are dealing with hard clustering. Here we show that the generalization theorem (Theorem 3) is also applicable to soft clustering. Nevertheless, we also show that soft clustering is not required, since the maximum value of I_{ob} can be achieved by hard clustering. Hence, although *IobMax*, as appears in Definition 5, is a hard clustering algorithm, it also achieves maximum I_{ob} (and nearly maximum I_{un}) of all possible soft clusterings.

Theorem 3 is applicable to soft clustering from the following arguments. In terms of the distributions $P(\mathbf{t}(Z), x_q(Z))$, assigning a soft clustering to an instance can be approximated by a second empirical distribution, $\hat{P}$, achieved by duplicating each of the instances, and then using hard clustering. Consider, for example, a case where we create a new set of instances by duplicating each of the original instances by 100 identical instances. Using hard clustering on the $\times 100$ larger set of instances, can approximate any soft clustering of the original set with quantization of $P(T|\mathbf{X})$ in steps of $1/100$. Obviously, for any $\varepsilon > 0$ we can create $\hat{P}$ that satisfies $max\left|P - \hat{P}\right| < \varepsilon$.

Now we show that for any soft clustering of an instance, we can find a hard clustering of the same instance that has the same or a higher value of I_{ob} (without changing the cluster identity of other instances). This is enough to show that soft clustering is not required to achieve the maximum value of I_{ob}, since any soft clustering can be replaced by hard clustering instance by instance. Let $P_\lambda(T|X_{q_1},\ldots,X_{q_n})$ define the distribution of any soft clustering. It can be written as the weighted sum of k distributions as follows

$$P_\lambda(T|X_{q_1},\ldots,X_{q_n}) = \sum_{i=1}^{k} \lambda_i \tilde{P}_i^j(T|X_{q_1},\ldots,X_{q_n}), \quad 0 \le \lambda_i \le 1, \sum_{i=1}^{k} \lambda_i = 1.$$

where $\tilde{P}_i^j$ is created by keeping the same soft clustering of instances $\{1,\ldots,j-1,j+1,...,m\}$, and replacing the soft clustering of the jth instance by a hard clustering $\mathbf{t}(j) = i$. Since $I(T;X_q)$ is a convex function of $P(T|X_q)$ for a fixed $P(X_q)$ for any q (Cover and Thomas, 1991), we get

$$I_{P_\lambda}(T;X_q) \le \sum_{i=1}^{k} \lambda_i I_{\tilde{P}_i^j}(T;X_q).$$

Taking the sum over all observed features $(q_1,\ldots q_n)$, we get

$$\sum_q I_{P_\lambda}(T;X_q) \le \sum_{i=1}^{k} \lambda_i \sum_q I_{\tilde{P}_i^j}(T;X_q),$$

and hence at least one of the distributions $\tilde{P}_1^j,\ldots,\tilde{P}_k^j$ has the same or higher I_{ob} then P_λ. In other words, we can replace the soft clustering of any instance j by a hard clustering without decreasing I_{ob}.

A.3 Maximum Likelihood Mixture Model and IobMax

In the proof of Theorem 7 we claimed that maximizing the likelihood of observed variables is equivalent to maximizing $\sum_{j=1}^{n} I(T;X_j) - I(T;Y)$. In this section we show this based on the work of Elidan and Friedman (2003). For the purpose of better readability in the context of their paper, we use the same notations as in their paper, and review them briefly here. Let Y be a variable that denotes the instance identity, that is, $Y[i] = i$ where $i \in \{1,\ldots,m\}$. Let $Q(Y,\mathbf{X})$ be the empirical distribution

of the features $\mathbf{X}$ in the instances, augmented by the distribution of Y. Let $P(\mathbf{X},T)$ be the maximum likelihood mixture model of the joint distribution $Q(\mathbf{X})$, that is, $P(\mathbf{X},T) = P(T)\prod_j \Pr(x_j|T)$.

From Propositions 4.1, 4.3 in Elidan and Friedman (2003), finding local maxima of the likelihood function is equivalent to minimizing the following Lagrangian

$$\mathcal{L}_{EM} = I_Q(T;Y) - (\mathbf{E}_Q[\log P(\mathbf{X},T)] - \mathbf{E}_Q[\log Q(T)]),$$

as a function of $Q(T|Y)$ and $P(\mathbf{X},T)$. In the stationary point of the EM-algorithm (see Propositions 4.4 and 4.5 in Elidan and Friedman, 2003), $Q(x_j,T) = P(x_j,T)$. Minimizing $\mathcal{L}_{EM}$ is equivalent to minimizing $I(T;Y) - \sum I(T;X_j)$ as shown below:

$$\begin{aligned}
\mathcal{L}_{EM} &= I_Q(T;Y) - (\mathbf{E}_Q[\log P(\mathbf{X},T)] - \mathbf{E}_Q[\log Q(T)]) \\
&= I_Q(T;Y) - \sum_{X,T} Q(\mathbf{X},T)\log\left[P(T)\prod_j P(x_j|T)\right] - H(T) \\
&= I_Q(T;Y) + H(T) - \sum_j \sum_{T,x_j} Q(x_j,T)\log\frac{P(x_j,T)}{P(T)} - H(T) \\
&= I_Q(T;Y) - \sum_j \sum_{T,x_j} Q(x_j,T)\log\frac{P(x_j,T)}{P(x_j)P(T)} + \sum_j \sum_{T,x_j} Q(x_i,T)\log P(x_j) \\
&= I_Q(T;Y) - \sum_j I(T;X_j) + \sum_j H(X_j).
\end{aligned}$$

Since $\sum_j H(X_j)$ is independent of $Q(T|Y)$, and $P(T,Y) = Q(T,Y)$ minimizing $\mathcal{L}_{EM}$ is equivalent to maximizing

$$\sum_j I(T;X_j) - I(T;Y).$$

A.4 Proof of Theorem 11

Before proving Theorem 11, we write generalized definitions of D_{ob}, D_{un} and prove a generalization bound for these generalized definitions (Theorem 14). Then we show that Theorem 11 is a special case of Theorem 14.

The quality of the clustering with respect to a single variable, X_q, is defined by a (weighted) average distance of all pairs of instances within the same cluster (large distance means lower quality). This measure is denoted by D_q which is defined by

$$D_q\{C_1,...,C_k\} = \frac{1}{m}\sum_{r=1}^{k}\frac{1}{|C_r|}\sum_{j,l\in C_r} f(x_q[j],x_q[l]).$$

Using these definitions, we define a generalized observed intra-cluster variable, denoted by $\tilde{D}_{ob}$, as the average of D_q over the observed features within the cluster, that is,

$$\tilde{D}_{ob}\{C_1,...,C_k\} = \frac{1}{n}\sum_{i=1}^{n} D_{q_i}\{C_1,...,C_k\}.$$

When $f(a,b) = \frac{1}{2}(a-b)^2$, we get

$$\begin{aligned} D_{ob}\{C_1,...,C_k\} &= \frac{1}{nm}\sum_{r=1}^{k}\sum_{j\in C_r}\sum_{i=1}^{n}\left(x_{q_i}[j] - \frac{1}{|C_r|}\sum_{l\in C_r} x_{q_i}[l]\right)^2 \\ &= \frac{1}{nm}\sum_{i=1}^{n}\sum_{r=1}^{k}\frac{1}{2|C_r|}\sum_{j\in C_r}\sum_{l\in C_r}\left(x_{q_i}[j] - x_{q_i}[l]\right)^2 \\ &= \frac{1}{nm}\sum_{i=1}^{n}\sum_{r=1}^{k}\frac{1}{|C_r|}\sum_{j\in C_r}\sum_{l\in C_r} f\left(x_{q_i}[j], x_{q_i}[l]\right) \\ &= \frac{1}{n}\sum_{i=1}^{n} D_{q_i}\{C_1,...,C_k\} \\ &= \tilde{D}_{ob}\{C_1,...,C_k\}, \end{aligned} \tag{9}$$

which means that D_{ob} is a special case of $\tilde{D}_{ob}$.

Similarly we define the generalized unobserved intra-cluster variance, denoted by $\tilde{D}_{un}$, as follows:

$$\tilde{D}_{un}\{C_1,...,C_k\} = \mathbf{E}_{q\sim\mathcal{D}}\left\{D_q\{C_1,...,C_k\}\right\}.$$

Again, when $f(a,b) = \frac{1}{2}(a-b)^2$, we get

$$D_{un}\{C_1,...,C_k\} = \tilde{D}_{un}\{C_1,...,C_k\}. \tag{10}$$

Theorem 14 *With the above definitions, for every function, f satisfies Equations 2, 3 and 4 (see Section 3) and for every $\varepsilon > 0$,*

$$\Pr_{\{q_1,...,q_n\}}\left\{\sup_{\alpha(\{C_1,...,C_k\})\geq\alpha_c}\left|\tilde{D}_{ob}\{C_1,...,C_k\} - \tilde{D}_{un}\{C_1,...,C_k\}\right| > \varepsilon\right\} \leq \frac{2k}{\alpha_c}e^{-n\varepsilon^2/2c^2+\log\frac{c}{\varepsilon}},$$

where α is defined in Definition 10.

Before proving Theorem 14, we introduce the following lemma that is required for the proof.

Lemma 15 *Let $\{Z_1,...,Z_S\}$ be a set of jointly S distributed random binary variables, where $z_i \in \{0,1\}$. If $\Pr(z_i = 1) \leq \delta$ for every i then for any $N_b \geq 1$*

$$\Pr\left\{\sum_{i=1}^{S} z_i \geq N_b\right\} \leq \frac{S}{N_b}\delta.$$

Lemma 15 follows directly from Markov's inequality.

The proof of Theorem 14 (given below) is based on the observation that $\tilde{D}_{ob}$ and $\tilde{D}_{un}$ are the weighted average of distance functions over a subset of the pairs of instances. This subset includes only pairs that are within the same cluster. In other words, the calculated inter-cluster variances of a clustering is based on the weighted average of $\frac{1}{2}\sum_{r=1}^{k}|C_r|(|C_r|-1)$ pairs out of the $\frac{1}{2}m(m-1)$ pairs of instances. We define "bad pairs" as pairs of instances with a large difference between the observed and unobserved distances. We use Hoeffding's inequality and Lemma 15 to bound the

probability that we have a large number of "bad pairs". Then we show that if the number of "bad pairs" is small, all clusterings are "good", that is, $\left|\tilde{D}_{ob} - \tilde{D}_{un}\right| \leq \varepsilon$.

Proof of Theorem 14

For each pair of instances j,l $(l > j)$ we define a random variable d_{jl} as the difference between the average observed distance and the expected distance,

$$d_{jl} = \left| \frac{1}{n} \sum_{i=1}^{n} f\left(x_{q_i}[j], x_{q_i}[l]\right) - \mathbf{E}_q \left\{ f\left(x_q[j], x_q[l]\right) \right\} \right|.$$

We also define a binary random variable Z_{jl} $(l > j)$ by

$$z_{jl} = \begin{cases} 1 & \text{if } d_{jl} > \tilde{\varepsilon} \\ 0 & \text{otherwise} \end{cases}$$

where $\tilde{\varepsilon}$ is a positive constant. In other words, z_{jl} is one for "bad" pairs, that is, pairs that have a large difference between the average observed distance and the expected distance. From Hoeffding's inequality,

$$\Pr_{\{q_1,\ldots,q_n\}} \left(z_{jl} = 1\right) \leq \tilde{\delta}, \tag{11}$$

where

$$\tilde{\delta} = 2e^{-2n\tilde{\varepsilon}^2/c^2}. \tag{12}$$

We have $\frac{1}{2}m(m-1)$ of these random binary variables. Let N_{bad} be the number of "bad" pairs, that is, $N_{bad} = \sum_{j,l:l>j} z_{jl}$. First we calculate an upper bound on $\left|\tilde{D}_{ob} - \tilde{D}_{un}\right|$ as a function of N_{bad}, and later we prove an upper bound on the probability of large N_{bad}.

By definition of $\tilde{D}_{ob}, \tilde{D}_{un}, d_{jl}$ and the properties of f (Equations 3 and 4) we can bound the difference between $\tilde{D}_{ob}$ and $\tilde{D}_{un}$ (for any clustering) as follows

$$\begin{aligned} &\left|\tilde{D}_{ob}\left\{C_1,\ldots,C_k\right\} - \tilde{D}_{un}\left\{C_1,\ldots,C_k\right\}\right| \\ &= \left| \frac{1}{mn} \sum_{i=1}^{n} \sum_{r=1}^{k} \frac{1}{|C_r|} \sum_{j,l \in r} f\left(x_{q_i}[j], x_{q_i}[l]\right) - \frac{1}{m} \sum_{i=1}^{k} \frac{1}{|C_r|} \sum_{j,l \in C_r} \mathbf{E}_q \left\{ f\left(x_q[j], x_q[l]\right) \right\} \right| \\ &\leq \frac{2}{m} \sum_{r=1}^{k} \frac{1}{|C_r|} \sum_{j,l \in C_k : l > j} d_{jl}. \end{aligned}$$

By defining ε_d as the following function of the clustering

$$\varepsilon_d\left(\left\{C_1,\ldots,C_k\right\}\right) = \frac{2}{m} \sum_{r=1}^{k} \frac{1}{|C_r|} \sum_{j,l \in C_k : l > j} d_{jl},$$

we have

$$\left|\tilde{D}_{ob}\left\{C_1,\ldots,C_k\right\} - \tilde{D}_{un}\left\{C_1,\ldots,C_k\right\}\right| \leq \varepsilon_d. \tag{13}$$

Recall that r_t is the number of instances in cluster t. Now we calculate an upper bound on ε_d as a function of $\tilde{\varepsilon}$ and N_{bad}. The total number of pairs in the rth cluster is $\frac{1}{2}|C_r|\left(|C_r| - 1\right)$. We have N_{bad}

pairs with a difference above $\tilde{\varepsilon}$ (but not more than c, since f is bounded). The error of each of the other pairs is upper bounded by $\tilde{\varepsilon}$. Hence we get

$$\begin{aligned}\varepsilon_d &\leq \frac{2}{m}\sum_{r=1}^{k}\frac{1}{|C_r|}\sum_{j,l\in C_r:l>j}\left(\tilde{\varepsilon}+z_{jl}\left(c-\tilde{\varepsilon}\right)\right)\\ &\leq \frac{2}{m}\left(\frac{1}{2}\sum_{r=1}^{k}\frac{1}{|C_r|}|C_r|\left(|C_r|-1\right)\tilde{\varepsilon}+\frac{N_{bad}\left(c-\tilde{\varepsilon}\right)}{\min_r|C_r|}\right)\\ &\leq \frac{2}{m}\left(\frac{1}{2}\sum_{r=1}^{k}|C_r|\tilde{\varepsilon}+\frac{N_{bad}c}{\min_r|C_r|}\right).\end{aligned}$$

Note that $\sum_r |C_r| = m$ (the sum of the size of all clusters is m). Hence,

$$\varepsilon_d \leq \tilde{\varepsilon}+\frac{2N_{bad}}{m\min_r|C_r|}c. \tag{14}$$

Let N_b be defined as follows

$$N_b = \frac{m\min_r|C_r|\tilde{\varepsilon}}{2c}. \tag{15}$$

If $N_{bad} \leq N_b$ then $\varepsilon_d \leq 2\tilde{\varepsilon}$ (from Equations 14 and 15). Hence,

$$\Pr_{\{q_1,\ldots,q_n\}}\left\{\varepsilon_d > 2\tilde{\varepsilon}\right\} = \Pr_{\{q_1,\ldots,q_n\}}\left\{N_{bad} > N_b\right\}. \tag{16}$$

From Lemma 15 and Equation 11 for any $N_b \geq 1$

$$\Pr_{\{q_1,\ldots,q_n\}}\left\{N_{bad} \geq N_b\right\} \leq \frac{m(m-1)}{2N_b}\tilde{\delta} \leq \frac{m^2}{2N_b}\tilde{\delta}. \tag{17}$$

Combining Equations 15, 16, 17 and the definition of $\tilde{\delta}$ (Equation 12) we get

$$\Pr_{\{q_1,\ldots,q_n\}}\left\{\varepsilon_d > 2\tilde{\varepsilon}\right\} \leq \frac{mc}{\min_r|C_r|\tilde{\varepsilon}}\tilde{\delta} = \frac{2mc}{\min_r|C_r|\tilde{\varepsilon}}e^{-2n\tilde{\varepsilon}^2/c^2}. \tag{18}$$

By selecting $\varepsilon = \tilde{\varepsilon}/2$ and using Equation 13 and 18 we get

$$\Pr_{\{q_1,\ldots,q_n\}}\left\{\sup_{\alpha(\{C_1,\ldots,C_k\})\geq\alpha_c}\left|\tilde{D}_{ob}\left\{C_1,\ldots,C_k\right\}-\tilde{D}_{un}\left\{C_1,\ldots,C_k\right\}\right| > \varepsilon\right\} \leq 4\frac{m}{\min_r|C_r|}e^{-n\varepsilon^2/2c^2+\log\frac{c}{\varepsilon}}. \tag{19}$$

Using the definition of α we have $m/\min_r|C_r| \leq k/\alpha_c$. Together with Equation 19 we get Theorem 14.

■

Now we are ready to prove Theorem 11 by showing it is a special case of Theorem 14.

Proof of Theorem 11

Let $f(a,b) = \frac{1}{2}(a-b)^2$. In this case f satisfies Equation 2, 3 and 4 where $c = 2R^2$ (since $0 \leq f(x_q[j],x_q[l]) \leq 2R^2$ for all q, j, l). In addition, $\tilde{D}_{ob} = D_{ob}$ and $\tilde{D}_{un} = D_{un}$ (Equations 9 and 10). Therefore, Theorem 11 is a special case of Theorem 14.

■

Appendix B. Notation Table

The following table summaries the notation and definitions used in the paper for quick reference.

Notation	Short Description
m	Number of instances
L	Number of features (both observed and unobserved)
$\{X_1,\ldots,X_L\}$	Random variables (features)
n	Number of observed features
$\tilde{\mathbf{q}}=(q_1,\ldots,q_n)$	Indices of observed features
$\mathcal{D}$	Probability distribution of selecting features
$\{\mathbf{x}[1],\ldots,\mathbf{x}[m]\}$	Instances (each instance is a vector of L elements, where n are observed)
$x_q[j]$	The qth feature of the jth instance
$x_{q_i}[j]$	The ith observed feature of the jth instance
k	Number of clusters
$\mathbf{t}:[m]\rightarrow[k]$	Function that maps instances to clusters
$\{C_1,\ldots,C_k\}$	Clusters (C_r is the set of instances in the rth cluster)
$\lvert C_r\rvert$	Size of rth cluster
T	A variable that represents the cluster label
Z	A random variable taking values uniformly from $\{1,2,\ldots,m\}$ (Random selection of instance index)
s	Upper bound on the number of values a discrete feature can have
I_{ob}	Average observed information (Definition 1)
I_{un}	Expected unobserved information (Definition 1)
$I^*_{un,k}$	Maximum possible value of I_{un} for k clusters (Definition 4)
$I^*_{ob,k}$	Value of I_{ob} for clustering with maximum I_{un} (Definition 4)
$\tilde{I}_{un,k}$	Value of I_{un} for clustering that achieves $\tilde{I}_{ob,k}$ (Definition 5)
$\tilde{I}_{ob,k}$	Maximum possible value of I_{ob} for k clusters (Definition 5)
$f(\cdot,\cdot)$	Distance function between two feature values
c	Constant - upper bound on the distance function
$D_{ob}\{C_1,\ldots,C_k\}$	Observed intra-cluster variance (Definition 8)
$D_{un}\{C_1,\ldots,C_k\}$	Expected unobserved intra-cluster variance (Definition 9)
D^{opt}_{un}	Minimum possible intra-cluster variance (Theorem 12)
$\alpha(\{C_1,\ldots,C_k\})$	Ratio between smallest to average cluster size (Definition 10)

Abstract

Conformal prediction uses past experience to determine precise levels of confidence in new predictions. Given an error probability ε, together with a method that makes a prediction $\hat{y}$ of a label y, it produces a set of labels, typically containing $\hat{y}$, that also contains y with probability $1-\varepsilon$. Conformal prediction can be applied to any method for producing $\hat{y}$: a nearest-neighbor method, a support-vector machine, ridge regression, etc.

Conformal prediction is designed for an on-line setting in which labels are predicted successively, each one being revealed before the next is predicted. The most novel and valuable feature of conformal prediction is that if the successive examples are sampled independently from the same distribution, then the successive predictions will be right $1-\varepsilon$ of the time, even though they are based on an accumulating data set rather than on independent data sets.

In addition to the model under which successive examples are sampled independently, other on-line compression models can also use conformal prediction. The widely used Gaussian linear model is one of these.

This tutorial presents a self-contained account of the theory of conformal prediction and works through several numerical examples. A more comprehensive treatment of the topic is provided in *Algorithmic Learning in a Random World*, by Vladimir Vovk, Alex Gammerman, and Glenn Shafer (Springer, 2005).

Keywords: confidence, on-line compression modeling, on-line learning, prediction regions

1. Introduction

How good is your prediction $\hat{y}$? If you are predicting the label y of a new object, how confident are you that $y = \hat{y}$? If the label y is a number, how close do you think it is to $\hat{y}$? In machine learning, these questions are usually answered in a fairly rough way from past experience. We expect new predictions to fare about as well as past predictions.

Conformal prediction uses past experience to determine precise levels of confidence in predictions. Given a method for making a prediction $\hat{y}$, conformal prediction produces a 95% *prediction*

∗. Also at Computer Learning Research Centre, Royal Holloway.

region—a set $\Gamma^{0.05}$ that contains y with probability at least 95%. Typically $\Gamma^{0.05}$ also contains the prediction $\hat{y}$. We call $\hat{y}$ the *point prediction*, and we call $\Gamma^{0.05}$ the *region prediction*. In the case of regression, where y is a number, $\Gamma^{0.05}$ is typically an interval around $\hat{y}$. In the case of classification, where y has a limited number of possible values, $\Gamma^{0.05}$ may consist of a few of these values or, in the ideal case, just one.

Conformal prediction can be used with any method of point prediction for classification or regression, including support-vector machines, decision trees, boosting, neural networks, and Bayesian prediction. Starting from the method for point prediction, we construct a *nonconformity measure*, which measures how unusual an example looks relative to previous examples, and the *conformal algorithm* turns this nonconformity measure into prediction regions.

Given a nonconformity measure, the conformal algorithm produces a prediction region Γ^ε for every probability of error ε. The region Γ^ε is a $(1-\varepsilon)$-*prediction region*; it contains y with probability at least $1-\varepsilon$. The regions for different ε are nested: when $\varepsilon_1 \geq \varepsilon_2$, so that $1-\varepsilon_1$ is a lower level of confidence than $1-\varepsilon_2$, we have $\Gamma^{\varepsilon_1} \subseteq \Gamma^{\varepsilon_2}$. If Γ^ε contains only a single label (the ideal outcome in the case of classification), we may ask how small ε can be made before we must enlarge Γ^ε by adding a second label; the corresponding value of $1-\varepsilon$ is the confidence we assert in the predicted label.

As we explain in §4, the conformal algorithm is designed for an on-line setting, in which we predict the labels of objects successively, seeing each label after we have predicted it and before we predict the next one. Our prediction $\hat{y}_n$ of the nth label y_n may use observed features x_n of the nth object and the preceding examples $(x_1,y_1),\ldots,(x_{n-1},y_{n-1})$. The size of the prediction region Γ^ε may also depend on these details. Readers most interested in implementing the conformal algorithm may wish to look first at the elementary examples in §4.2.1 and §4.3.1 and then turn back to the earlier more general material as needed.

As we explain in §2, the on-line picture leads to a new concept of validity for prediction with confidence. Classically, a method for finding 95% prediction regions was considered valid if it had a 95% probability of containing the label predicted, because by the law of large numbers it would then be correct 95% of the time when repeatedly applied to independent data sets. But in the on-line picture, we repeatedly apply a method not to independent data sets but to an accumulating data set. After using $(x_1,y_1),\ldots,(x_{n-1},y_{n-1})$ and x_n to predict y_n, we use $(x_1,y_1),\ldots,(x_{n-1},y_{n-1}),(x_n,y_n)$ and x_{n+1} to predict y_{n+1}, and so on. For a 95% on-line method to be valid, 95% of these predictions must be correct. Under minimal assumptions, conformal prediction is valid in this new and powerful sense.

One setting where conformal prediction is valid in the new on-line sense is the one in which the examples (x_i,y_i) are sampled independently from a constant population—that is, from a fixed but unknown probability distribution Q. It is also valid under the slightly weaker assumption that the examples are probabilistically *exchangeable* (see §3) and under other on-line compression models, including the widely used Gaussian linear model (see §5). The validity of conformal prediction under these models is demonstrated in Appendix A.

In addition to the validity of a method for producing 95% prediction regions, we are also interested in its efficiency. It is efficient if the prediction region is usually relatively small and therefore informative. In classification, we would like to see a 95% prediction region so small that it contains only the single predicted label $\hat{y}_n$. In regression, we would like to see a very narrow interval around the predicted number $\hat{y}_n$.

The claim of 95% confidence for a 95% conformal prediction region is valid under exchangeability, no matter what the probability distribution the examples follow and no matter what nonconformity measure is used to construct the conformal prediction region. But the efficiency of conformal prediction will depend on the probability distribution and the nonconformity measure. If we think we know the probability distribution, we may choose a nonconformity measure that will be efficient if we are right. If we have prior probabilities for Q, we may use these prior probabilities to construct a point predictor $\hat{y}_n$ and a nonconformity measure. In the regression case, we might use as $\hat{y}_n$ the mean of the posterior distribution for y_n given the first $n-1$ examples and x_n; in the classification case, we might use the label with the greatest posterior probability. This strategy of first guaranteeing validity under a relatively weak assumption and then seeking efficiency under stronger assumptions conforms to advice long given by John Tukey and others (Tukey, 1986; Small et al., 2006).

Conformal prediction is studied in detail in *Algorithmic Learning in a Random World*, by Vovk, Gammerman, and Shafer (2005). A recent exposition by Gammerman and Vovk (2007) emphasizes connections with the theory of randomness, Bayesian methods, and induction. In this article we emphasize the on-line concept of validity, the meaning of exchangeability, and the generalization to other on-line compression models. We leave aside many important topics that are treated in *Algorithmic Learning in a Random World*, including extensions beyond the on-line picture.

2. Valid Prediction Regions

Our concept of validity is consistent with a tradition that can be traced back to Jerzy Neyman's introduction of confidence intervals for parameters (Neyman, 1937) and even to work by Laplace and others in the late 18th century. But the shift of emphasis to prediction (from estimation of parameters) and to the on-line setting (where our prediction rule is repeatedly updated) involves some rearrangement of the furniture.

The most important novelty in conformal prediction is that its successive errors are probabilistically independent. This allows us to interpret "being right 95% of the time" in an unusually direct way. In §2.1, we illustrate this point with a well-worn example, normally distributed random variables.

In §2.2, we contrast confidence with full-fledged conditional probability. This contrast has been the topic of endless debate between those who find confidence methods informative (classical statisticians) and those who insist that full-fledged probabilities based on all one's information are always preferable, even if the only available probabilities are very subjective (Bayesians). Because the debate usually focuses on estimating parameters rather than predicting future observations, and because some readers may be unaware of the debate, we take the time to explain that we find the concept of confidence useful for prediction in spite of its limitations.

2.1 An Example of Valid On-Line Prediction

A 95% prediction region is *valid* if it contains the truth 95% of the time. To make this more precise, we must specify the set of repetitions envisioned. In the on-line picture, these are successive predictions based on accumulating information. We make one prediction after another, always knowing the outcome of the preceding predictions.

To make clear what validity means and how it can be obtained in this on-line picture, we consider prediction under an assumption often made in a first course in statistics:

> Random variables $z_1, z_2, \ldots$ are independently drawn from a normal distribution with unknown mean and variance.

Prediction under this assumption was discussed in 1935 by R. A. Fisher, who explained how to give a 95% prediction interval for z_n based on $z_1, \ldots, z_{n-1}$ that is valid in our sense. We will state Fisher's prediction rule, illustrate its application to data, and explain why it is valid in the on-line setting.

As we will see, the predictions given by Fisher's rule are too weak to be interesting from a modern machine-learning perspective. This is not surprising, because we are predicting z_n based on old examples $z_1, \ldots, z_{n-1}$ alone. In general, more precise prediction is possible only in the more favorable but more complicated set-up where we know some features x_n of the new example and can use both x_n and the old examples to predict some other feature y_n. But the simplicity of the set-up where we predict z_n from $z_1, \ldots, z_{n-1}$ alone will help us make the logic of valid prediction clear.

2.1.1 FISHER'S PREDICTION INTERVAL

Suppose we observe the z_i in sequence. After observing z_1 and z_2, we start predicting; for $n = 3, 4, \ldots$, we predict z_n after having seen $z_1, \ldots, z_{n-1}$. The natural point predictor for z_n is the average so far:

$$\bar{z}_{n-1} := \frac{1}{n-1} \sum_{i=1}^{n-1} z_i,$$

but we want to give an interval that will contain z_n 95% of the time. How can we do this? Here is Fisher's answer (1935):

1. In addition to calculating the average $\bar{z}_{n-1}$, calculate

$$s_{n-1}^2 := \frac{1}{n-2} \sum_{i=1}^{n-1} (z_i - \bar{z}_{n-1})^2,$$

   which is sometimes called the sample variance. We can usually assume that it is non-zero.

2. In a table of percentiles for t-distributions, find $t_{n-2}^{0.025}$, the point that the t-distribution with $n-2$ degrees of freedom exceeds exactly 2.5% of the time.

3. Predict that z_n will be in the interval

$$\bar{z}_{n-1} \pm t_{n-2}^{0.025}\, s_{n-1} \sqrt{\frac{n}{n-1}}. \tag{1}$$

Fisher based this procedure on the fact that

$$\frac{z_n - \bar{z}_{n-1}}{s_{n-1}} \sqrt{\frac{n-1}{n}}$$

has the t-distribution with $n-2$ degrees of freedom, which is symmetric about 0. This implies that (1) will contain z_n with probability 95% regardless of the values of the mean and variance.

2.1.2 A NUMERICAL EXAMPLE

We can illustrate (1) using some numbers generated in 1900 by the students of Emanuel Czuber (1851–1925). These numbers are integers, but they theoretically have a binomial distribution and are therefore approximately normally distributed.[1]

Here are Czuber's first 19 numbers, $z_1, \ldots, z_{19}$:

$$17, 20, 10, 17, 12, 15, 19, 22, 17, 19, 14, 22, 18, 17, 13, 12, 18, 15, 17.$$

From them, we calculate

$$\bar{z}_{19} = 16.53, \qquad s_{19} = 3.31.$$

The upper 2.5% point for the t-distribution with 18 degrees of freedom, $t_{18}^{0.025}$, is 2.101. So the prediction interval (1) for z_{20} comes out to $[9.40, 24.13]$.

Taking into account our knowledge that z_{20} will be an integer, we can say that the 95% prediction is that z_{20} will be an integer between 10 and 24, inclusive. This prediction is correct; z_{20} is 16.

2.1.3 ON-LINE VALIDITY

Fisher did not have the on-line picture in mind. He probably had in mind a picture where the formula (1) is used repeatedly but in entirely separate problems. For example, we might conduct many separate experiments that each consists of drawing 100 random numbers from a normal distribution and then predicting a 101st draw using (1). Each experiment might involve a different normal distribution (a different mean and variance), but provided the experiments are independent from each other, the law of large numbers will apply. Each time the probability is 95% that z_{101} will be in the interval, and so this event will happen approximately 95% of the time.

The on-line story may seem more complicated, because the experiment involved in predicting z_{101} from $z_1, \ldots, z_{100}$ is not entirely independent of the experiment involved in predicting, say, z_{105} from $z_1, \ldots, z_{104}$. The 101 random numbers involved in the first experiment are all also involved in the second. But as a master of the analytical geometry of the normal distribution (Fisher, 1925; Efron, 1969), Fisher would have noticed, had he thought about it, that this overlap does not actually matter. As we show in Appendix A.3, the events

$$\bar{z}_{n-1} - t_{n-2}^{0.025}\, s_{n-1} \sqrt{\frac{n}{n-1}} \le z_n \le \bar{z}_{n-1} + t_{n-2}^{0.025}\, s_{n-1} \sqrt{\frac{n}{n-1}} \tag{2}$$

for successive n are probabilistically independent in spite of the overlap. Because of this independence, the law of large numbers again applies. Knowing each event has probability 95%, we can conclude that approximately 95% of them will happen. We call the events (2) *hits*.

The prediction interval (1) generalizes to linear regression with normally distributed errors, and on-line hits remain independent in this general setting. Even though formulas for these linear-regression prediction intervals appear in textbooks, the independence of their on-line hits was not noted prior to our work on conformal prediction. Like Fisher, the textbook authors did not have the

1. Czuber's students randomly drew balls from an urn containing six balls, numbered 1 to 6. Each time they drew a ball, they noted its label and put it back in the urn. After each 100 draws, they recorded the number of times that the ball labeled with a 1 was drawn (Czuber, 1914, pp. 329–335). This should have a binomial distribution with parameters 100 and $1/6$, and it is therefore approximately normal with mean $100/6 = 16.67$ and standard deviation $\sqrt{500/36} = 3.73$.

on-line setting in mind. They imagined just one prediction being made in each case where data is accumulated.

We will return to the generalization to linear regression in §5.3.2. There we will derive the textbook intervals as conformal prediction regions within the *on-line Gaussian linear model*, an on-line compression model that uses slightly weaker assumptions than the classical assumption of independent and normally distributed errors.

2.2 Confidence Says Less than Probability.

Neyman's notion of confidence looks at a procedure before observations are made. Before any of the z_i are observed, the event (2) involves multiple uncertainties: $\bar{z}_{n-1}$, s_{n-1}, and z_n are all uncertain. The probability that these three quantities will turn out so that (2) holds is 95%.

We might ask for more than this. It is after we observe the first $n-1$ examples that we calculate $\bar{z}_{n-1}$ and s_{n-1} and then calculate the interval (1), and we would like to be able to say at this point that there is still a 95% probability that z_n will be in (1). But this, it seems, is asking for too much. The assumptions we have made are insufficient to enable us to find a numerical probability for (2) that will be valid at this late date. In theory there is a conditional probability for (2) given $z_1,\ldots,z_{n-1}$, but it involves the unknown mean and variance of the normal distribution.

Perhaps the matter is best understood from the game-theoretic point of view. A probability can be thought of as an offer to bet. A 95% probability, for example, is an offer to take either side of a bet at 19 to 1 odds. The probability is valid if the offer does not put the person making it at a disadvantage, inasmuch as a long sequence of equally reasonable offers will not allow an opponent to multiply the capital he or she risks by a large factor (Shafer and Vovk, 2001). When we assume a probability model (such as the normal model we just used or the on-line compression models we will study later), we are assuming that the model's probabilities are valid in this sense before any examples are observed. Matters may be different afterwards.

In general, a 95% conformal predictor is a rule for using the preceding examples $(x_1,y_1),\ldots,(x_{n-1},y_{n-1})$ and a new object x_n to give a set, say

$$\Gamma^{0.05}((x_1,y_1),\ldots,(x_{n-1},y_{n-1}),x_n), \tag{3}$$

that we predict will contain y_n. If the predictor is valid, the prediction

$$y_n \in \Gamma^{0.05}((x_1,y_1),\ldots,(x_{n-1},y_{n-1}),x_n)$$

will have a 95% probability before any of the examples are observed, and it will be safe, at that point, to offer 19 to 1 odds on it. But after we observe $(x_1,y_1),\ldots,(x_{n-1},y_{n-1})$ and x_n and calculate the set (3), we may want to withdraw the offer.

Particularly striking instances of this phenomenon can arise in the case of classification, where there are only finitely many possible labels. We will see one such instance in §4.3.1, where we consider a classification problem in which there are only two possible labels, s and v. In this case, there are only four possibilities for the prediction region:

1. $\Gamma^{0.05}((x_1,y_1),\ldots,(x_{n-1},y_{n-1}),x_n)$ contains only s.
2. $\Gamma^{0.05}((x_1,y_1),\ldots,(x_{n-1},y_{n-1}),x_n)$ contains only v.
3. $\Gamma^{0.05}((x_1,y_1),\ldots,(x_{n-1},y_{n-1}),x_n)$ contains both s and v.

William S. Gossett
1876–1937

Ronald A. Fisher
1890–1962

Jerzy Neyman
1894–1981

Figure 1: **Three influential statisticians.** Gossett, who worked as a statistician for the Guinness brewery in Dublin, introduced the t-distribution to English-speaking statisticians (Student, 1908). Fisher, whose applied and theoretical work invigorated mathematical statistics in the 1920s and 1930s, refined, promoted, and extended Gossett's work. Neyman was one of the most influential leaders in the subsequent movement to use advanced probability theory to give statistics a firmer foundation and further extend its applications.

4. $\Gamma^{0.05}((x_1,y_1),\ldots,(x_{n-1},y_{n-1}),x_n)$ is empty.

The third and fourth cases can occur even though $\Gamma^{0.05}$ is valid. When the third case happens, the prediction, though uninformative, is certain to be correct. When the fourth case happens, the prediction is clearly wrong. These cases are consistent with the prediction being right 95% of the time. But when we see them arise, we know whether the particular value of n is one of the 95% where we are right or the one of the 5% where we are wrong, and so the 95% will not remain valid as a probability defining betting odds.

In the case of normally distributed examples, Fisher called the 95% probability for z_n being in the interval (1) a "fiducial probability," and he seems to have believed that it would not be susceptible to a gambling opponent who knows the first $n-1$ examples (see Fisher, 1973, pp. 119–125). But this turned out not to be the case (Robinson, 1975). For this and related reasons, most scientists who use Fisher's methods have adopted the interpretation offered by Neyman, who wrote about "confidence" rather than fiducial probability and emphasized that a confidence level is a full-fledged probability only before we acquire data. It is the procedure or method, not the interval or region it produces when applied to particular data, that has a 95% probability of being correct.

Neyman's concept of confidence has endured in spite of its shortcomings. It is widely taught and used in almost every branch of science. Perhaps it is especially useful in the on-line setting. It is useful to know that 95% of our predictions are correct even if we cannot assert a full-fledged 95% probability for each prediction when we make it.

3. Exchangeability

Consider variables $z_1,\ldots,z_N$. Suppose that for any collection of N values, the $N!$ different orderings are equally likely. Then we say that $z_1,\ldots,z_N$ are *exchangeable*. The assumption that $z_1,\ldots,z_N$ are exchangeable is slightly weaker than the more familiar assumption that they are drawn independently from a probability distribution.

In our book (Vovk et al., 2005), conformal prediction is first explained under the assumption that $z_1, \ldots, z_N$ are independently drawn from a probability distribution (or that they are "random," as we say there), and then it is pointed out that this assumption can be relaxed to the assumption that $z_1, \ldots, z_N$ are exchangeable. When we introduce conformal prediction in this article, in §4, we assume only exchangeability from the outset, hoping that this will make the logic of the method as clear as possible. Once this logic is clear, it is easy to see that it works not only for the exchangeability model but also for other on-line compression models (§5).

In this section we look at the relationship between exchangeability and independence and then give a backward-looking definition of exchangeability that can be understood game-theoretically. We conclude with a law of large numbers for exchangeable sequences, which will provide the basis for our confidence that our 95% prediction regions are right 95% of the time.

3.1 Exchangeability and Independence

Although the definition of exchangeability we just gave may be clear enough at an intuitive level, it has two technical problems that make it inadequate as a formal mathematical definition: (1) in the case of continuous distributions, any specific values for $z_1, \ldots, z_N$ will have probability zero, and (2) in the case of discrete distributions, two or more of the z_i might take the same value, and so a list of possible values $a_1, \ldots, a_N$ might contain fewer than n distinct values.

One way of avoiding these technicalities is to use the concept of a permutation, as follows:

> *Definition of exchangeability using permutations.* The variables $z_1, \ldots, z_N$ are exchangeable if for every permutation τ of the integers $1, \ldots, N$, the variables $w_1, \ldots, w_N$, where $w_i = z_{\tau(i)}$, have the same joint probability distribution as $z_1, \ldots, z_N$.

We can extend this to a definition of exchangeability for an infinite sequence of variables: $z_1, z_2, \ldots$ are exchangeable if $z_1, \ldots, z_N$ are exchangeable for every N.

This definition makes it easy to see that independent and identically distributed random variables are exchangeable. Suppose $z_1, \ldots, z_N$ all take values from the same example space $\mathbf{Z}$, all have the same probability distribution Q, and are independent. Then their joint distribution satisfies

$$\Pr(z_1 \in A_1 \ \& \ \ldots \ \& \ z_N \in A_N) = Q(A_1) \cdots Q(A_N)$$

for any[2] subsets $A_1, \ldots, A_N$ of $\mathbf{Z}$, where $Q(A)$ is the probability Q assigns to an example being in A. Because permuting the factors $Q(A_n)$ does not change their product, and because a joint probability distribution for $z_1, \ldots, z_N$ is determined by the probabilities it assigns to events of the form $\{z_1 \in A_1 \ \& \ \ldots \ \& \ z_N \in A_N\}$, this makes it clear that $z_1, \ldots, z_N$ are exchangeable.

Exchangeability implies that variables have the same distribution. On the other hand, exchangeable variables need not be independent. Indeed, when we average two or more distinct joint probability distributions under which variables are independent, we usually get a joint probability distribution under which they are exchangeable (averaging preserves exchangeability) but not independent (averaging usually does not preserve independence). According to a famous theorem by de Finetti, an exchangeable joint distribution for an infinite sequence of distinct variables is exchangeable only if it is a mixture of joint distributions under which the variables are independent (Hewitt and Savage, 1955). As Table 1 shows, the picture is more complicated in the finite case.

2. We leave aside technicalities involving measurability.

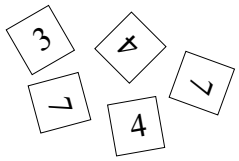
$\Pr(z_1 = \text{H} \,\&\, z_2 = \text{H})$	$\Pr(z_1 = \text{H} \,\&\, z_2 = \text{T})$
$\Pr(z_1 = \text{T} \,\&\, z_2 = \text{H})$	$\Pr(z_1 = \text{T} \,\&\, z_2 = \text{T})$

0.81	0.09
0.09	0.01

0.41	0.09
0.09	0.41

0.10	0.40
0.40	0.10

Table 1: **Examples of exchangeability.** We consider variables z_1 and z_2, each of which comes out H or T. Exchangeability requires only that $\Pr(z_1 = \text{H} \,\&\, z_2 = \text{T}) = \Pr(z_1 = \text{T} \,\&\, z_2 = \text{H})$. Three examples of distributions for z_1 and z_2 with this property are shown. On the left, z_1 and z_2 are independent and identically distributed; both come out H with probability 0.9. The middle example is obtained by averaging this distribution with the distribution in which the two variables are again independent and identically distributed but T's probability is 0.9. The distribution on the right, in contrast, cannot be obtained by averaging distributions under which the variables are independent and identically distributed. Examples of this last type disappear as we ask for a larger and larger number of variables to be exchangeable.



4	3	4	7	7

Figure 2: **Ordering the tiles.** Joe gives Bill a bag containing five tiles, and Bill arranges them to form the list 43477. Bill can calculate conditional probabilities for which z_i had which of the five values. His conditional probability for $z_5 = 4$, for example, is $2/5$. There are $(5!)/(2!)(2!) = 30$ ways of assigning the five values to the five variables; $(z_1, z_2, z_3, z_4, z_5) = (4, 3, 4, 7, 7)$ is one of these, and they all have the same probability, $1/30$.

3.2 Backward-Looking Definitions of Exchangeability

Another way of defining exchangeability looks backwards from a situation where we know the unordered values of $z_1, \ldots, z_N$.

Suppose Joe has observed $z_1, \ldots, z_N$. He writes each value on a tile resembling those used in Scrabble©, puts the N tiles in a bag, shakes the bag, and gives it to Bill to inspect. Bill sees the N values (some possibly equal to each other) without knowing their original order. Bill also knows the joint probability distribution for $z_1, \ldots, z_N$. So he obtains probabilities for the ordering of the tiles by conditioning this joint distribution on his knowledge of the bag. The joint distribution is exchangeable if and only if these conditional probabilities are the same as the probabilities for the result of ordering the tiles by successively drawing them at random from the bag without replacement.

To make this into a definition of exchangeability, we formalize the notion of a bag. A *bag* (or *multiset*, as it is sometimes called) is a collection of elements in which repetition is allowed. It is like a set inasmuch as its elements are unordered but like a list inasmuch as an element can occur more than once. We write $\wr a_1,\dots,a_N\int$ for the bag obtained from the list $a_1,\dots,a_N$ by removing information about the ordering.

Here are three equivalent conditions on the joint distribution of a sequence of random variables $z_1,\dots,z_N$, any of which can be taken as the definition of exchangeability.

1. For any bag B of size N, and for any examples $a_1,\dots,a_N$,

$$\Pr(z_1 = a_1 \,\&\, \dots \,\&\, z_N = a_N \mid \wr z_1,\dots,z_N\int = B)$$

   is equal to the probability that successive random drawings from the bag B without replacement produces first a_N, then a_{N-1}, and so on, until the last element remaining in the bag is a_1.

2. For any n, $1 \le n \le N$, z_n is independent of $z_{n+1},\dots,z_N$ given the bag $\wr z_1,\dots,z_n\int$ and for any bag B of size n,

$$\Pr(z_n = a \mid \wr z_1,\dots,z_n\int = B) = \frac{k}{n}, \tag{4}$$

   where k is the number of times a occurs in B.

3. For any bag B of size N, and for any examples $a_1,\dots,a_N$,

$$\Pr(z_1 = a_1 \,\&\, \dots \,\&\, z_N = a_N \mid \wr z_1,\dots,z_N\int = B) = \begin{cases} \frac{n_1!\cdots n_k!}{N!} & \text{if } B = \wr a_1,\dots,a_N\int \\ 0 & \text{if } B \neq \wr a_1,\dots,a_N\int, \end{cases} \tag{5}$$

   where k is the number of distinct values among the a_i, and $n_1,\dots,n_k$ are the respective numbers of times they occur. (If the a_i are all distinct, the expression $n_1!\cdots n_k!/(N!)$ reduces to $1/(N!)$.)

We leave it to the reader to verify that these three conditions are equivalent to each other. The second condition, which we will emphasize, is represented pictorially in Figure 3.

The backward-looking conditions are also equivalent to the definition of exchangeability using permutations given on p. 378. This equivalence is elementary in the case where every possible sequence of values $a_1,\dots,a_n$ has positive probability. But complications arise when this probability is zero, because the conditional probability on the left-hand side of (5) is then defined only with probability one by the joint distribution. We do not explore these complications here.

3.3 The Betting Interpretation of Exchangeability

The framework for probability developed in Shafer and Vovk (2001) formalizes classical results of probability theory, such as the law of large numbers, as theorems of game theory: a bettor can multiply the capital he risks by a large factor if these results do not hold. This allows us to express the empirical interpretation of given probabilities in terms of betting, using what we call *Cournot's principle*: the odds determined by the probabilities will not allow a bettor to multiply the capital he or she risks by a large factor (Shafer, 2007).

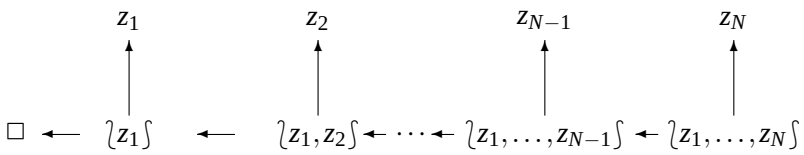


Figure 3: **Backward probabilities, step by step.** The two arrows backwards from each bag $\{z_1, \ldots, z_n\}$ symbolize drawing an example z_n out at random, leaving the smaller bag $\{z_1, \ldots, z_{n-1}\}$. The probabilities for the result of the drawing are given by (4). Readers familiar with Bayes nets (Cowell et al., 1999) will recognize this diagram as an example; conditional on each variable, a joint probability distribution is given for its children (the variables to which arrows from it point), and given the variable, its descendants are independent of its ancestors.

By applying this idea to the sequence of probabilities (4), we obtain a betting interpretation of exchangeability. Think of Joe and Bill as two players in a game that moves backwards from point N in Figure 3. At each step, Joe provides new information and Bill bets. Designate by $\mathcal{K}_N$ the total capital Bill risks. He begins with this capital at N, and at each step n he bets on what z_n will turn out to be. When he bets at step n, he cannot risk losing more than he has at that point (because he is not risking more than $\mathcal{K}_N$ in the whole game), but otherwise he can bet as much as he wants for or against each possible value a for z_n at the odds $(k/n) : (1-k/n)$, where k is the number of elements in the current bag equal to a.

For brevity, we write B_n for the bag $\{z_1, \ldots, z_n\}$, and for simplicity, we set the initial capital K_N equal to \$1. This gives the following protocol:

THE BACKWARD-LOOKING BETTING PROTOCOL

Players: Joe, Bill

$\mathcal{K}_N := 1$.
Joe announces a bag B_N of size N.
FOR $n = N, N-1, \ldots, 2, 1$
    Bill bets on z_n at odds set by (4).
    Joe announces $z_n \in B_n$.
    $\mathcal{K}_{n-1} := \mathcal{K}_n +$ Bill's net gain.
    $B_{n-1} := B_n \setminus \{z_n\}$.

Constraint: Bill must move so that his capital $\mathcal{K}_n$ will be nonnegative for all n no matter how Joe moves.

Our betting interpretation of exchangeability is that Bill will not multiply his initial capital $\mathcal{K}_N$ by a large factor in this game.

The permutation definition of exchangeability does not lead to an equally simple betting interpretation, because the probabilities for $z_1, \ldots, z_N$ to which the permutation definition refers are not determined by the mere assumption of exchangeability.

3.4 A Law of Large Numbers for Exchangeable Sequences

As we noted when we studied Fisher's prediction interval in §2.1.3, the validity of on-line prediction requires more than having a high probability of a hit for each individual prediction. We also need a law of large numbers, so that we can conclude that a high proportion of the high-probability predictions will be correct. As we show in §A.3, the successive hits in the case of Fisher's region predictor are independent, so that the usual law of large numbers applies. What can we say in the case of conformal prediction under exchangeability?

Suppose $z_1,\ldots,z_N$ are exchangeable, drawn from an example space $\mathbf{Z}$. In this context, we adopt the following definitions.

- An event E is an *n-event*, where $1 \le n \le N$, if its happening or failing is determined by the value of z_n and the value of the bag $\{\!|z_1,\ldots,z_{n-1}|\!\}$.
- An n-event E is ε-*rare* if
$$\Pr(E \mid \{\!|z_1,\ldots,z_n|\!\}) \le \varepsilon. \tag{6}$$

The left-hand side of the inequality (6) is a random variable, because the bag $\{\!|z_1,\ldots,z_n|\!\}$ is random. The inequality says that this random variable never exceeds ε.

As we will see in the next section, the successive errors for a conformal predictor are ε-rare n-events. So the validity of conformal prediction follows from the following informal proposition.

Informal Proposition 1 *Suppose N is large, and the variables $z_1,\ldots,z_N$ are exchangeable. Suppose E_n is an ε-rare n-event for $n = 1,\ldots,N$. Then the law of large numbers applies; with very high probability, no more than approximately the fraction ε of the events $E_1,\ldots,E_N$ will happen.*

In Appendix A, we formalize this proposition in two ways: classically and game-theoretically.

The classical approach appeals to the classical weak law of large numbers, which tells us that if $E_1,\ldots,E_N$ are mutually independent and each have probability exactly ε, and N is sufficiently large, then there is a very high probability that the fraction of the events that happen will be close to ε. We show in §A.1 that if (6) holds with equality, then E_n are mutually independent and each of them has unconditional probability ε. Having the inequality instead of equality means that the E_n are even less likely to happen, and this will not reverse the conclusion that few of them will happen.

The game-theoretic approach is more straightforward, because the game-theoretic version law of large numbers does not require independence or exact levels of probability. In the game-theoretic framework, the only question is whether the probabilities specified for successive events are rates at which a bettor can place successive bets. The Backward-Looking Betting Protocol says that this is the case for ε-rare n-events. As Bill moves through the protocol from N to 1, he is allowed to bet against each error E_n at a rate corresponding to its having probability ε or less. So the game-theoretic weak law of large numbers (Shafer and Vovk, 2001, pp. 124–126) applies directly. Because the game-theoretic framework is not well known, we state and prove this law of large numbers, specialized to the Backward-Looking Betting Protocol, in §A.2.

4. Conformal Prediction under Exchangeability

We are now in a position to state the conformal algorithm under exchangeability and explain why it produces valid nested prediction regions.

We distinguish two cases of on-line prediction. In both cases, we observe examples $z_1,\ldots,z_N$ one after the other and repeatedly predict what we will observe next. But in the second case we have more to go on when we make each prediction.

1. *Prediction from old examples alone.* Just before observing z_n, we predict it based on the previous examples, $z_1,\ldots,z_{n-1}$.

2. *Prediction using features of the new object.* Each example z_i consists of an object x_i and a label y_i. In symbols: $z_i = (x_i,y_i)$. We observe in sequence $x_1,y_1,\ldots,x_N,y_N$. Just before observing y_n, we predict it based on what we have observed so far, x_n and the previous examples $z_1,\ldots,z_{n-1}$.

Prediction from old examples may seem relatively uninteresting. It can be considered a special case of prediction using features x_n of new examples—the case in which the x_n provide no information, and this special case we may have too little information to make useful predictions. But its simplicity makes prediction with old examples alone advantageous as a setting for explaining the conformal algorithm, and as we will see, it is then straightforward to take account of the new information x_n.

Conformal prediction requires that we first choose a nonconformity measure, which measures how different a new example is from old examples. In §4.1, we explain how nonconformity measures can be obtained from methods of point prediction. In §4.2, we state and illustrate the conformal algorithm for predicting new examples from old examples alone. In §4.3, we generalize to prediction with the help of features of a new example. In §4.4, we explain why conformal prediction produces the best possible valid nested prediction regions under exchangeability. Finally, in §4.5 we discuss the implications of the failure of the assumption of exchangeability.

For some readers, the simplicity of the conformal algorithm may be obscured by its generality and the scope of our preliminary discussion of nonconformity measures. We encourage such readers to look first at §4.2.1, §4.3.1, and §4.3.2, which provide largely self-contained accounts of the algorithm as it applies to some small data sets.

4.1 Nonconformity Measures

The starting point for conformal prediction is what we call a *nonconformity measure*, a real-valued function $A(B,z)$ that measures how different an example z is from the examples in a bag B. The conformal algorithm assumes that a nonconformity measure has been chosen. The algorithm will produce valid nested prediction regions using any real-valued function $A(B,z)$ as the nonconformity measure. But the prediction regions will be efficient (small) only if $A(B,z)$ measures well how different z is from the examples in B.

A method $\hat{z}(B)$ for obtaining a point prediction $\hat{z}$ for a new example from a bag B of old examples usually leads naturally to a nonconformity measure A. In many cases, we only need to add a way of measuring the distance $d(z,z')$ between two examples. Then we define A by

$$A(B,z) := d(\hat{z}(B),z). \tag{7}$$

The prediction regions produced by the conformal algorithm do not change when the nonconformity measure A is transformed monotonically. If A is nonnegative, for example, replacing A with A^2 will make no difference. Consequently, the choice of the distance measure $d(z,z')$ is relatively unimportant. The important step in determining the nonconformity measure A is choosing the point predictor $\hat{z}(B)$.

To be more concrete, suppose the examples are real numbers, and write $\bar{z}_B$ for the average of the numbers in B. If we take this average as our point predictor $\hat{z}(B)$, and we measure the distance between two real numbers by the absolute value of their difference, then (7) becomes

$$A(B,z) := |\bar{z}_B - z|. \tag{8}$$

If we use the median of the numbers in B instead of their average as $\hat{z}(B)$, we get a different nonconformity measure, which will produce different prediction regions when we use the conformal algorithm. On the other hand, as we have already said, it will make no difference if we replace the absolute difference $d(z,z') = |z-z'|$ with the squared difference $d(z,z') = (z-z')^2$, thus squaring A.

We can also vary (8) by including the new example in the average:

$$A(B,z) := |(\text{average of } z \text{ and all the examples in } B) - z|. \tag{9}$$

This results in the same prediction regions as (8), because if B has n elements, then

$$|(\text{average of } z \text{ and all the examples in } B) - z| = \left| \frac{n\bar{z}_B + z}{n+1} - z \right| = \frac{n}{n+1}|\bar{z}_B - z|,$$

and as we have said, conformal prediction regions are not changed by a monotonic transformation of the nonconformity measure. In the numerical example that we give in §4.2.1 below, we use (9) as our nonconformity measure.

When we turn to the case where features of a new object help us predict a new label, we will consider, among others, the following two nonconformity measures:

Distance to the nearest neighbors for classification. Suppose $B = \lbag z_1, \ldots, z_{n-1} \rbag$, where each z_i consists of a number x_i and a nonnumerical label y_i. Again we observe x but not y for a new example $z = (x,y)$. The nearest-neighbor method finds the x_i closest to x and uses its label y_i as our prediction of y. If there are only two labels, or if there is no natural way to measure the distance between labels, we cannot measure how wrong the prediction is; it is simply right or wrong. But it is natural to measure the nonconformity of the new example (x,y) to the old examples (x_i,y_i) by comparing x's distance to old objects with the same label to its distance to old objects with a different label. For example, we can set

$$\begin{aligned} A(B,z) &:= \frac{\min\{|x_i - x| : 1 \le i \le n-1, y_i = y\}}{\min\{|x_i - x| : 1 \le i \le n-1, y_i \ne y\}} \\ &= \frac{\text{distance to } z\text{'s nearest neighbor in } B \text{ with the same label}}{\text{distance to } z\text{'s nearest neighbor in } B \text{ with a different label}}. \end{aligned} \tag{10}$$

Distance to a regression line. Suppose $B = \lbag (x_1,y_1), \ldots, (x_l,y_l) \rbag$, where the x_i and y_i are numbers. The most common way of fitting a line to such pairs of numbers is to calculate the averages

$$\bar{x}_l := \sum_{j=1}^{l} x_j \quad \text{and} \quad \bar{y}_l := \sum_{j=1}^{l} y_j,$$

and then the coefficients

$$b_l = \frac{\sum_{j=1}^{l}(x_j - \bar{x}_l)y_j}{\sum_{j=1}^{l}(x_j - \bar{x}_l)^2} \quad \text{and} \quad a_l = \bar{y}_l - b_l\bar{x}_l.$$

This gives the *least-squares line* $y = a_l + b_l x$. The coefficients a_l and b_l are not affected if we change the order of the z_i; they depend only on the bag B.

If we observe a bag $B = \{z_1, \ldots, z_{n-1}\}$ of examples of the form $z_i = (x_i, y_i)$ and also x but not y for a new example $z = (x, y)$, then the least-squares prediction of y is

$$\hat{y} = a_{n-1} + b_{n-1} x. \tag{11}$$

We can use the error in this prediction as a nonconformity measure:

$$A(B, z) := |y - \hat{y}| = |y - (a_{n-1} + b_{n-1} x)|.$$

We can obtain other nonconformity measures by using other methods to estimate a line.

Alternatively, we can include the new example as one of the examples used to estimate the least squares line or some other regression line. In this case, it is natural to write (x_n, y_n) for the new example. Then a_n and b_n designate the coefficients calculated from all n examples, and we can use

$$|y_i - (a_n + b_n x_i)| \tag{12}$$

to measure the nonconformity of each of the (x_i, y_i) with the others. In general, the inclusion of the new example simplifies the implementation or at least the explanation of the conformal algorithm. In the case of least squares, it does not change the prediction regions.

4.2 Conformal Prediction from Old Examples Alone

Suppose we have chosen a nonconformity measure A for our problem. Given A, and given the assumption that the z_i are exchangeable, we now define a valid prediction region

$$\gamma^{\varepsilon}(z_1, \ldots, z_{n-1}) \subseteq \mathbf{Z},$$

where $\mathbf{Z}$ is the example space. We do this by giving an algorithm for deciding, for each $z \in \mathbf{Z}$, whether z should be included in the region. For simplicity in stating this algorithm, we provisionally use the symbol z_n for z, as if we were assuming that z_n is in fact equal to z.

The Conformal Algorithm Using Old Examples Alone

Input: Nonconformity measure A, significance level ε, examples $z_1, \ldots, z_{n-1}$, example z,

Task: Decide whether to include z in $\gamma^{\varepsilon}(z_1, \ldots, z_{n-1})$.

Algorithm:

1. Provisionally set $z_n := z$.
2. For $i = 1, \ldots, n$, set $\alpha_i := A(\{z_1, \ldots, z_n\} \setminus \{z_i\}, z_i)$.
3. Set $p_z := \dfrac{\text{number of } i \text{ such that } 1 \le i \le n \text{ and } \alpha_i \ge \alpha_n}{n}$.
4. Include z in $\gamma^{\varepsilon}(z_1, \ldots, z_{n-1})$ if and only if $p_z > \varepsilon$.

If $\mathbf{Z}$ has only a few elements, this algorithm can be implemented in a brute-force way: calculate p_z for every $z \in \mathbf{Z}$. If $\mathbf{Z}$ has many elements, we will need some other way of identifying the z satisfying $p_z > \varepsilon$.

The number p_z is the fraction of the examples in $\wr z_1,\dots,z_{n-1},z\int$ that are at least as different from the others as z is, in the sense measured by A. So the algorithm tells us to form a prediction region consisting of the z that are not among the fraction ε most out of place when they are added to the bag of old examples.

The definition of $\gamma^\varepsilon(z_1,\dots,z_{n-1})$ can be framed as an application of the widely accepted Neyman-Pearson theory for hypothesis testing and confidence intervals (Lehmann, 1986). In the Neyman-Pearson theory, we test a hypothesis H using a random variable T that is likely to be large only if H is false. Once we observe $T=t$, we calculate $p_H := \Pr(T \geq t \,|\, H)$. We reject H at level ε if $p_H \leq \varepsilon$. Because this happens under H with probability no more than ε, we can declare $1-\varepsilon$ confidence that the true hypothesis H is among those not rejected. Our procedure makes these choices of H and T:

- The hypothesis H says the bag of the first n examples is $\wr z_1,\dots,z_{n-1},z\int$.
- The test statistic T is the random value of α_n.

Under H—that is, conditional on the bag $\wr z_1,\dots,z_{n-1},z\int$, T is equally likely to come out equal to any of the α_i. Its observed value is α_n. So

$$p_H = \Pr(T \geq \alpha_n \,|\, \wr z_1,\dots,z_{n-1},z\int) = p_z.$$

Since $z_1,\dots,z_{n-1}$ are known, rejecting the bag $\wr z_1,\dots,z_{n-1},z\int$ means rejecting $z_n = z$. So our $1-\varepsilon$ confidence is in the set of z for which $p_z > \varepsilon$.

The regions $\gamma^\varepsilon(z_1,\dots,z_{n-1})$ for successive n are based on overlapping sequences of examples rather than independent samples. But the successive errors are ε-rare n-events. The event that our nth prediction is an error, $z_n \notin \gamma^\varepsilon(z_1,\dots,z_{n-1})$, is the event $p_{z_n} \leq \varepsilon$. This is an n-event, because the value of p_{z_n} is determined by z_n and the bag $\wr z_1,\dots,z_{n-1}\int$. It is ε-rare because it is the event that α_n is among a fraction ε or fewer of the α_i that are strictly larger than all the other α_i, and this can have probability at most ε when the α_i are exchangeable. So it follows from Informal Proposition 1 (§3.4) that we can expect at least $1-\varepsilon$ of the $\gamma^\varepsilon(z_1,\dots,z_{n-1})$, $n=1,\dots,N$, to be correct.

4.2.1 EXAMPLE: PREDICTING A NUMBER WITH AN AVERAGE

In §2.1, we discussed Fisher's 95% prediction interval for z_n based on $z_1,\dots,z_{n-1}$, which is valid under the assumption that the z_i are independent and normally distributed. We used it to predict z_{20} when the first 19 z_i are

$$17,20,10,17,12,15,19,22,17,19,14,22,18,17,13,12,18,15,17.$$

Taking into account our knowledge that the z_i are all integers, we arrived at the 95% prediction that z_{20} is an integer between 10 to 24, inclusive.

What can we predict about z_{20} at the 95% level if we drop the assumption of normality and assume only exchangeability? To produce a 95% prediction interval valid under the exchangeability assumption alone, we reason as follows. To decide whether to include a particular value z in the interval, we consider twenty numbers that depend on z:

- First, the deviation of z from the average of it and the other 19 numbers. Because the sum of the 19 is 314, this is
$$\left|\frac{314+z}{20} - z\right| = \frac{1}{20}\,|314-19z|\,. \tag{13}$$

- Then, for $i = 1, \ldots, 19$, the deviation of z_i from this same average. This is

$$\left| \frac{314 + z}{20} - z_i \right| = \frac{1}{20} \left| 314 + z - 20 z_i \right|. \tag{14}$$

Under the hypothesis that z is the actual value of z_n, these 20 numbers are exchangeable. Each of them is as likely as the other to be the largest. So there is at least a 95% (19 in 20) chance that (13) will not exceed the largest of the 19 numbers in (14). The largest of the 19 z_is being 22 and the smallest 10, we can write this condition as

$$|314 - 19z| \leq \max \left\{ \left| 314 + z - (20 \times 22) \right|, \left| 314 + z - (20 \times 10) \right| \right\},$$

which reduces to

$$10 \leq z \leq \frac{214}{9} \approx 23.8.$$

Taking into account that z_{20} is an integer, our 95% prediction is that it will be an integer between 10 and 23, inclusive. This is nearly the same prediction we obtained by Fisher's method. We have lost nothing by weakening the assumption that the z_i are independent and normally distributed to the assumption that they are exchangeable. But we are still basing our prediction region on the average of old examples, which is an optimal estimator in various respects under the assumption of normality.

4.2.2 ARE WE COMPLICATING THE STORY UNNECESSARILY?

The reader may feel that we are vacillating about whether to include the new example in the bag with which we are comparing it. In our statement of the conformal algorithm, we define the nonconformity scores by

$$\alpha_i := A(\wr z_1, \ldots, z_n \int \setminus \wr z_i \int, z_i), \tag{15}$$

apparently signaling that we do not want to include z_i in the bag to which it is compared. But then we use the nonconformity measure

$$A(B, z) := \left| (\text{average of } z \text{ and all the examples in } B) - z \right|,$$

which seems to put z back in the bag, reducing (15) to

$$\alpha_i = \left| \frac{\sum_{j=1}^{n} z_j}{n} - z_i \right|.$$

We could have reached this point more easily by writing

$$\alpha_i := A(\wr z_1, \ldots, z_n \int, z_i) \tag{16}$$

in the conformal algorithm and using $A(B, z) := \left| \bar{z}_B - z \right|$.

The two ways of defining nonconformity scores, (15) and (16), are equivalent, inasmuch as whatever we can get with one of them we can get from the other by changing the nonconformity measure. In this case, (16) might be more convenient. But we will see other cases where (15) is more convenient. We also have another reason for using (15). It is the form that generalizes, as we will see in §5, to on-line compression models.

4.3 Conformal Prediction Using a New Object

Now we turn to the case where our example space $\mathbf{Z}$ is of the form $\mathbf{Z} = \mathbf{X} \times \mathbf{Y}$. We call $\mathbf{X}$ the *object space*, $\mathbf{Y}$ the *label space*. We observe in sequence examples $z_1, \ldots, z_N$, where $z_i = (x_i, y_i)$. At the point where we have observed

$$(z_1, \ldots, z_{n-1}, x_n) = ((x_1, y_1), \ldots, (x_{n-1}, y_{n-1}), x_n),$$

we want to predict y_n by giving a prediction region

$$\Gamma^\varepsilon(z_1, \ldots, z_{n-1}, x_n) \subseteq \mathbf{Y}$$

that is valid at the $(1-\varepsilon)$ level. As in the special case where the x_i are absent, we start with a nonconformity measure $A(B, z)$.

We define the prediction region by giving an algorithm for deciding, for each $y \in \mathbf{Y}$, whether y should be included in the region. For simplicity in stating this algorithm, we provisionally use the symbol z_n for (x_n, y), as if we were assuming that y_n is in fact equal to y.

The Conformal Algorithm

Input: Nonconformity measure A, significance level ε, examples $z_1, \ldots, z_{n-1}$, object x_n, label y

Task: Decide whether to include y in $\Gamma^\varepsilon(z_1, \ldots, z_{n-1}, x_n)$.

Algorithm:

1. Provisionally set $z_n := (x_n, y)$.
2. For $i = 1, \ldots, n$, set $\alpha_i := A(\{z_1, \ldots, z_n\} \setminus \{z_i\}, z_i)$.
3. Set $p_y := \dfrac{\#\{i = 1, \ldots, n \mid \alpha_i \geq \alpha_n\}}{n}$.
4. Include y in $\Gamma^\varepsilon(z_1, \ldots, z_{n-1}, x_n)$ if and only if $p_y > \varepsilon$.

This differs only slightly from the conformal algorithm using old examples alone (p. 385). Now we write p_y instead of p_z, and we say that we are including y in $\Gamma^\varepsilon(z_1, \ldots, z_{n-1}, x_n)$ instead of saying that we are including z in $\gamma^\varepsilon(z_1, \ldots, z_{n-1})$.

To see that this algorithm produces valid prediction regions, it suffices to see that it consists of the algorithm for old examples alone together with a further step that does not change the frequency of hits. We know that the region the old algorithm produces,

$$\gamma^\varepsilon(z_1, \ldots, z_{n-1}) \subseteq \mathbf{Z}, \tag{17}$$

contains the new example $z_n = (x_n, y_n)$ at least 95% of the time. Once we know x_n, we can rule out all $z = (x, y)$ in (17) with $x \neq x_n$. The y not ruled out, those such that (x_n, y) is in (17), are precisely those in the set

$$\Gamma^\varepsilon(z_1, \ldots, z_{n-1}, x_n) \subseteq \mathbf{Y} \tag{18}$$

produced by our new algorithm. Having (x_n, y_n) in (17) $1-\varepsilon$ of the time is equivalent to having y_n in (18) $1-\varepsilon$ of the time.

4.3.1 EXAMPLE: CLASSIFYING IRIS FLOWERS

In 1936, R. A. Fisher used discriminant analysis to distinguish different species of iris on the basis of measurements of their flowers. The data he used included measurements by Edgar Anderson of flowers from 50 plants each of two species, *iris setosa* and *iris versicolor*. Two of the measurements, sepal length and petal width, are plotted in Figure 4.

To illustrate how the conformal algorithm can be used for classification, we have randomly chosen 25 of the 100 plants. The sepal lengths and species for the first 24 of them are listed in Table 2 and plotted in Figure 5. The 25th plant in the sample has sepal length 6.8. On the basis of this information, would you classify it as *setosa* or *versicolor*, and how confident would you be in the classification? Because 6.8 is the longest sepal in the sample, nearly any reasonable method will classify the plant as *versicolor*, and this is in fact the correct answer. But the appropriate level of confidence is not so obvious.

We calculate conformal prediction regions using three different nonconformity measures: one based on distance to the nearest neighbors, one based on distance to the species average, and one based on a support-vector machine. Because our evidence is relatively weak, we do not achieve the high precision with high confidence that can be achieved in many applications of machine learning (see, for example, §4.5). But we get a clear view of the details of the calculations and the interpretation of the results.

Distance to the nearest neighbor belonging to each species. Here we use the nonconformity measure (10). The fourth and fifth columns of Table 2 (labeled NN for nearest neighbor) give nonconformity scores α_i obtained with $y_{25} = \mathrm{s}$ and $y_{25} = \mathrm{v}$, respectively. In both cases, these scores are given by

$$\begin{aligned} \alpha_i &= A(\{z_1, \ldots, z_{25}\} \setminus \{z_i\}, z_i) \\ &= \frac{\min\{|x_j - x_i| : 1 \le j \le 25 \;\&\; j \ne i \;\&\; y_j = y_i\}}{\min\{|x_j - x_i| : 1 \le j \le 25 \;\&\; j \ne i \;\&\; y_j \ne y_i\}}, \end{aligned} \tag{19}$$

but for the fourth column $z_{25} = (6.8, \mathrm{s})$, while for the fifth column $z_{25} = (6.8, \mathrm{v})$.

If both the numerator and the denominator in (19) are equal to zero, we take the ratio also to be zero. This happens in the case of the first plant, for example. It has the same sepal length, 5.0, as the 7th and 13th plants, which are *setosa*, and the 15th plant, which is *versicolor*.

Step 3 of the conformal algorithm yields $p_{\mathrm{s}} = 0.08$ and $p_{\mathrm{v}} = 0.32$. Step 4 tells us that

- s is in the $1 - \varepsilon$ prediction region when $1 - \varepsilon > 0.92$, and
- v is in the $1 - \varepsilon$ prediction region when $1 - \varepsilon > 0.68$.

Here are prediction regions for a few levels of ε.

- $\Gamma^{0.08} = \{\mathrm{v}\}$. With 92% confidence, we predict that $y_{25} = \mathrm{v}$.
- $\Gamma^{0.05} = \{\mathrm{s}, \mathrm{v}\}$. If we raise the confidence with which we want to predict y_{25} to 95%, the prediction is completely uninformative.
- $\Gamma^{1/3} = \emptyset$. If we lower the confidence to $2/3$, we get a prediction we know is false: y_{25} will be in the empty set.

	Data		Nonconformity scores					
			NN		Species Average		SVM	
	sepal length	species	α_i for $y_{25} = \text{s}$	α_i for $y_{25} = \text{v}$	α_i for $y_{25} = \text{s}$	α_i for $y_{25} = \text{v}$	α_i for $y_{25} = \text{s}$	α_i for $y_{25} = \text{v}$

p_v				0.32		0.08		1

Table 2: **Conformal prediction of iris species from sepal length, using three different nonconformity measures.** The data used are sepal length and species for a random sample of 25 of the 100 plants measured by Edgar Anderson. The second column gives x_i, the sepal length. The third column gives y_i, the species. The 25th plant has sepal length $x_{25} = 6.8$, and our task is to predict its species y_{25}. For each nonconformity measure, we calculate nonconformity scores under each hypothesis, $y_{25} = \text{s}$ and $y_{25} = \text{v}$. The p-value in each column is computed from the 25 nonconformity scores in that column; it is the fraction of them equal to or larger than the 25th. The results from the three nonconformity measures are consistent, inasmuch as the p-value for v is always larger than the p-value for s.

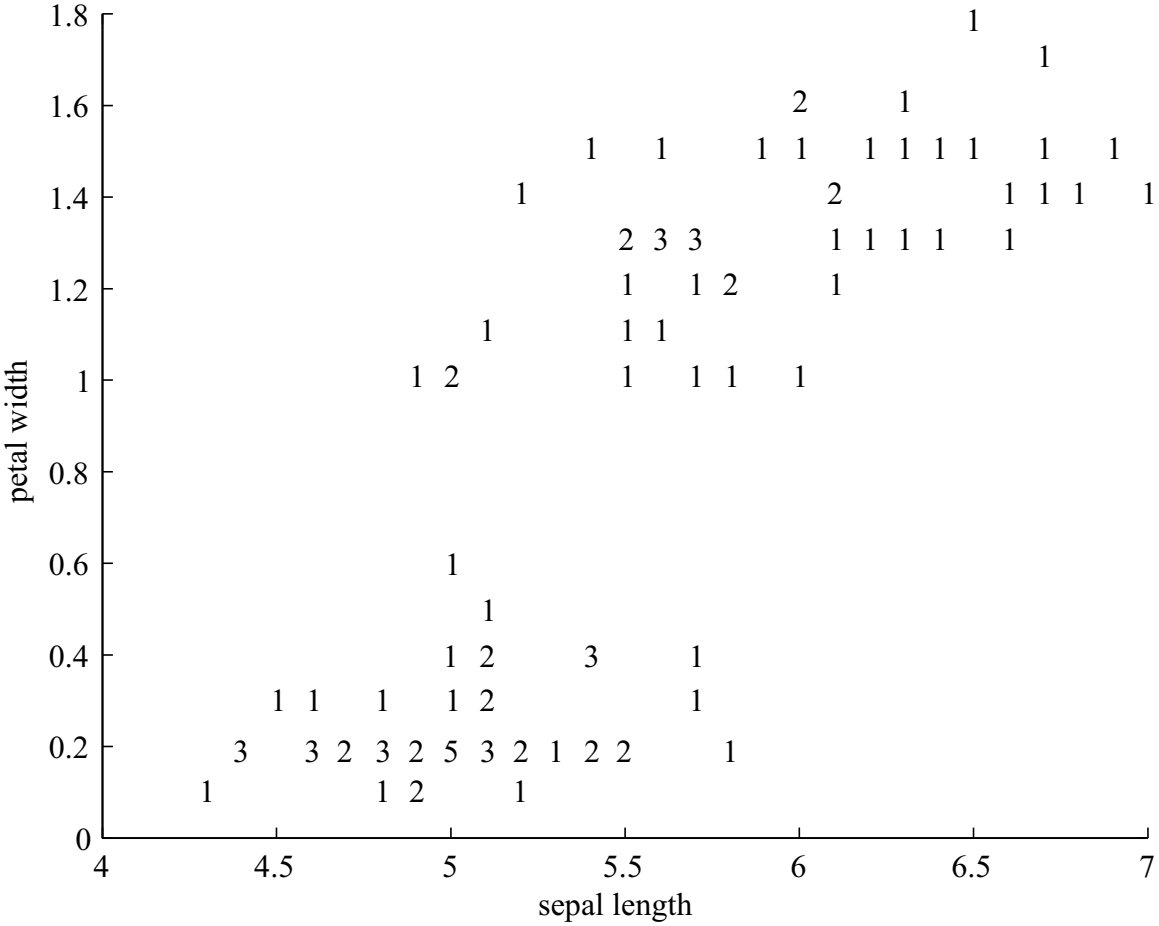

Figure 4: **Sepal length, petal width, and species for Edgar Anderson's** 100 **flowers.** The 50 *iris setosa* are clustered at the lower left, while the 50 *iris versicolor* are clustered at the upper right. The numbers indicate how many plants have exactly the same measurement; for example, there are 5 plants that have sepals 5 inches long and petals 0.2 inches wide. Petal width separates the two species perfectly; all 50 *versicolor* petals are 1 inch wide or wider, while all *setosa* petals are narrower than 1 inch. But there is substantial overlap in sepal length.

In fact, $y_{25} = \text{v}$. Our 92% prediction is correct.

The fact that we are making a known-to-be-false prediction with $2/3$ confidence is a signal that the 25th sepal length, 6.8, is unusual for either species. A close look at the nonconformity scores reveals that it is being perceived as unusual simply because $2/3$ of the plants have other plants in the sample with exactly the same sepal length, whereas there is no other plant with the sepal length 6.8.

In classification problems, it is natural to report the greatest $1-\varepsilon$ for which Γ^ε is a single label. In our example, this produces the statement that we are 92% confident that y_{25} is v. But in order

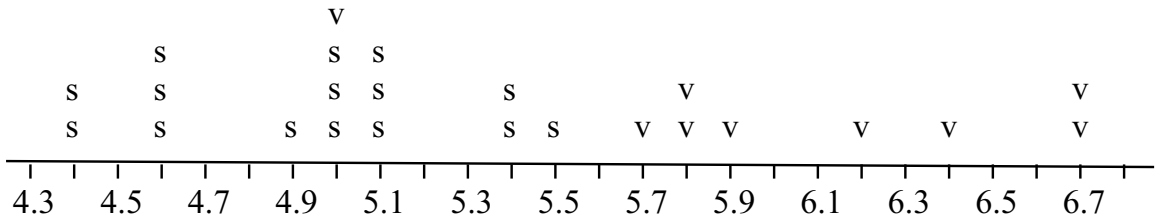

Figure 5: **Sepal length and species for the first** 24 **plants in our random sample of size** 25**.** Except for one *versicolor* with sepal length 5.0, the *versicolor* in this sample all have longer sepals than the *setosa*. This high degree of separation is an accident of the sampling.

to avoid overconfidence when the object x_n is unusual, it is wise to report also the largest ε for which Γ^ε is empty. We call this the *credibility* of the prediction (Vovk et al., 2005, p. 96).[3] In our example, the prediction that y_{25} will be v has credibility of only 32%, indicating that the example is somewhat unusual for the method that produces the prediction—so unusual that the method has 68% confidence in a prediction of y_{25} that we know is false before we observe y_{25} ($\Gamma^{0.68} = \emptyset$).

Distance to the average of each species. The nearest-neighbor nonconformity measure, because it considers only nearby sepal lengths, does not take full advantage of the fact that a *versicolor* flower typically has longer sepals than a *setosa* flower. We can expect to obtain a more efficient conformal predictor (one that produces smaller regions for a given level of confidence) if we use a nonconformity measure that takes account of average sepal length for the two species.

We use the nonconformity measure A defined by

$$A(B,(x,y)) = |\bar{x}_{B\cup\{(x,y)\},y} - x|, \tag{20}$$

where $\bar{x}_{B,y}$ denotes the average sepal length of all plants of species y in the bag B, and $B\cup\{z\}$ denotes the bag obtained by adding z to B. To test $y_{25} = \mathrm{s}$, we consider the bag consisting of the 24 old examples together with $(6.8,\mathrm{s})$, and we calculate the average sepal lengths for the two species in this bag: 5.06 for *setosa* and 6.02 for *versicolor*. Then we use (20) to calculate the nonconformity scores shown in the sixth column of Table 2:

$$\alpha_i = \begin{cases} |5.06 - x_i| & \text{if } y_i = \mathrm{s} \\ |6.02 - x_i| & \text{if } y_i = \mathrm{v} \end{cases}$$

for $i = 1,\ldots,25$, where we take y_{25} to be s. To test $y_{25} = \mathrm{v}$, we consider the bag consisting of the 24 old examples together with $(6.8,\mathrm{v})$, and we calculate the average sepal lengths for the two species in this bag: 4.94 for *setosa* and 6.1 for *versicolor*. Then we use (20) to calculate the nonconformity scores shown in the seventh column of Table 2:

$$\alpha_i = \begin{cases} |4.94 - x_i| & \text{if } y_i = \mathrm{s} \\ |6.1 - x_i| & \text{if } y_i = \mathrm{v} \end{cases}$$

for $i = 1,\ldots,25$, where we take y_{25} to be v.

We obtain $p_\mathrm{s} = 0.04$ and $p_\mathrm{v} = 0.08$, so that

3. This notion of credibility is one of the novelties of the theory of conformal prediction. It is not found in the prior literature on confidence and prediction regions.

- s is in the $1-\varepsilon$ prediction region when $1-\varepsilon > 0.96$, and
- v is in the $1-\varepsilon$ prediction region when $1-\varepsilon > 0.92$.

Here are the prediction regions for some different levels of ε.

- $\Gamma^{0.04} = \{\text{v}\}$. With 96% confidence, we predict that $y_{25} = \text{v}$.
- $\Gamma^{0.03} = \{\text{s}, \text{v}\}$. If we raise the confidence with which we want to predict y_{25} to 97%, the prediction is completely uninformative.
- $\Gamma^{0.08} = \emptyset$. If we lower the confidence to 92%, we get a prediction we know is false: y_{25} will be in the empty set.

In this case, we predict $y_{25} = \text{v}$ with confidence 96% but credibility only 8%. The credibility is lower with this nonconformity measure because it perceives 6.8 as being even more unusual than the nearest-neighbor measure did. It is unusually far from the average sepal lengths for both species.

A support-vector machine. As Vladimir Vapnik explains on pp. 408–410 of his *Statistical Learning Theory* (1998), support-vector machines grew out of the idea of separating two groups of examples with a hyperplane in a way that makes as few mistakes as possible—that is, puts as few examples as possible on the wrong side. This idea springs to mind when we look at Figure 5. In this one-dimensional picture, a hyperplane is a point. We are tempted to separate the *setosa* from the *versicolor* with a point between 5.5 and 5.7.

Vapnik proposed to separate two groups not with a single hyperplane but with a band: two hyperplanes with few or no examples between them that separate the two groups as well as possible. Examples on the wrong side of both hyperplanes would be considered very strange; those between the hyperplanes would also be considered strange but less so. In our one-dimensional example, the obvious separating band is the interval from 5.5 to 5.7. The only strange example is the *versicolor* with sepal length 5.0.

Here is one way of making Vapnik's idea into an algorithm for calculating nonconformity scores for all the examples in a bag $⦇(x_1,y_1),\ldots(x_n,y_n)⦈$. First plot all the examples as in Figure 5. Then find numbers a and b such that $a \le b$ and the interval $[a,b]$ separates the two groups with the fewest mistakes—that is, minimizes[4]

$$\#\{i \mid 1 \le i \le n, x_i < b, \text{ and } y_i = \text{v}\} + \#\{i \mid 1 \le i \le n, x_i > a, \text{ and } y_i = \text{s}\}.$$

There may be many intervals that minimize this count; choose one that is widest. Then give the ith example the score

$$\alpha_i = \begin{cases} \infty & \text{if } y_i = \text{v and } x_i < a \quad \text{or } y_i = \text{s and } b < x_i \\ 1 & \text{if } y_i = \text{v and } a \le x_i < b \quad \text{or } y_i = \text{s and } a < x_i \le b \\ 0 & \text{if } y_i = \text{v and } b \le x_i \quad \text{or } y_i = \text{s and } x_i \le a. \end{cases}$$

When applied to the bags in Figure 6, this algorithm gives the circled examples the score ∞ and all the others the score 0. These scores are listed in the last two columns of Table 2.

4. Here we are implicitly assuming that the *setosa* flowers will be on the left, with shorter sepal lengths. A general algorithm should also check the possibility of a separation with the *versicolor* flowers on the left.

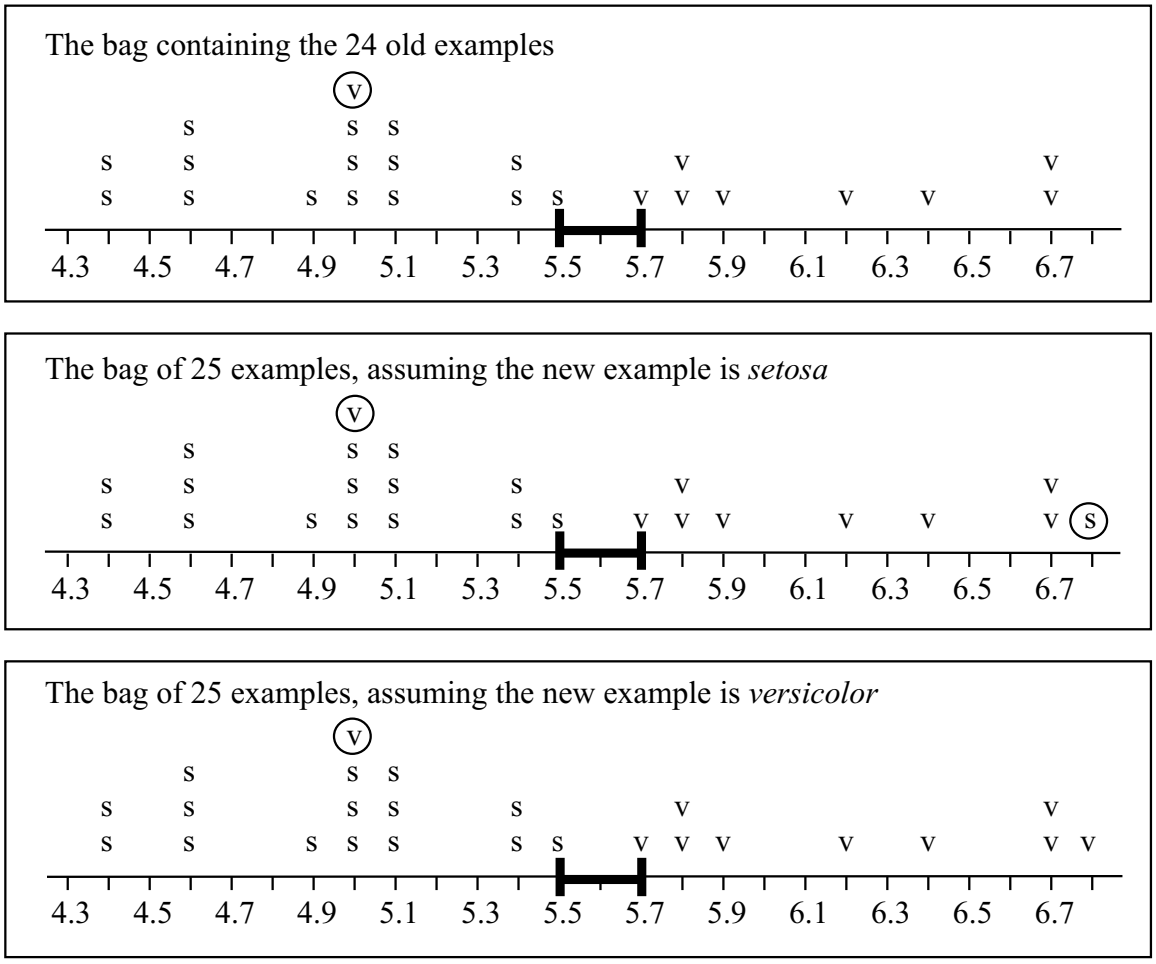

Figure 6: **Separation for three bags.** In each case, the separating band is the interval $[5.5, 5.7]$. Examples on the wrong side of the interval are considered strange and are circled.

As we see from the table, the resulting p-values are $p_{\text{s}} = 0.08$ and $p_{\text{v}} = 1$. So this time we obtain 92% confidence in $y_{25} = \text{v}$, with 100% credibility.

The algorithm just described is too complex to implement when there are thousands of examples. For this reason, Vapnik and his collaborators proposed instead a quadratic minimization that balances the width of the separating band against the number and size of the mistakes it makes. Support-vector machines of this type have been widely used. They usually solve the dual optimization problem, and the Lagrange multipliers they calculate can serve as nonconformity scores. Implementations sometimes fail to treat the old examples symmetrically because they make various uses of the order in which examples are presented, but this difficulty can be overcome by a preliminary randomization (Vovk et al., 2005, p. 58).

A systematic comparison. The random sample of 25 plants we have considered is odd in two ways: (1) except for the one *versicolor* with sepal length of only 5.0, the two species do not overlap

	NN	Species average	SVM
singleton hits	164	441	195
uncertain	795	477	762
total hits	959	918	957
empty	9	49	1
singleton errors	32	33	42
total errors	41	82	43
total examples	1000	1000	1000
% hits	96%	92%	96%
total singletons	196	474	237
% hits	84%	93%	82%
total errors	41	82	43
% empty	22%	60%	2%

Table 3: **Performance of** 92% **prediction regions based on three nonconformity measures.** For each nonconformity measure, we have found $1,000$ prediction regions at the 92% level, using each time a different random sample of 25 from Anderson's 100 flowers. The "uncertain" regions are those equal to the whole label space, $\mathbf{Y} = \{\mathrm{s}, \mathrm{v}\}$.

in sepal length, and (2) the flower whose species we are trying to predict has a sepal that is unusually long for either species.

In order to get a fuller picture of how the three nonconformity measures perform in general on the iris data, we have applied each of them to $1,000$ different samples of size 25 selected from the population of Anderson's 100 plants. The results are shown in Table 3.

The 92% regions based on the species average were correct about 92% of the time (918 times out of 1000), as advertised. The regions based on the other two measures were correct more often, about 96% of the time. The reason for this difference is visible in Table 2; the nonconformity scores based on the species average take a greater variety of values and therefore produce ties less often. The regions based on the species averages are also more efficient (smaller); 441 of its hits were informative, as opposed to fewer than 200 for each of the other two nonconformity measures. This efficiency also shows up in more empty regions among the errors. The species average produced an empty 92% prediction region for the random sample used in Table 2, and Table 3 shows that this happens 5% of the time.

As a practical matter, the uncertain prediction regions ($\Gamma^{0.08} = \{\mathrm{s}, \mathrm{v}\}$) and the empty ones ($\Gamma^{0.08} = \emptyset$) are equally uninformative. The only errors that mislead are the singletons that are wrong, and the three methods all produce these at about the same rate—3 or 4%.

4.3.2 EXAMPLE: PREDICTING PETAL WIDTH FROM SEPAL LENGTH

We now turn to the use of the conformal algorithm to predict a number. We use the same 25 plants, but now we use the data in the second and third columns of Table 4: the sepal length and petal width for the first 24 plants, and the sepal length for the 25th. Our task is to predict the petal width for the 25th.

	sepal length	petal width	Nearest neighbor	Linear regression
z_1	5.0	0.3	0.3	$\lvert 0.003y_{25} - 0.149\rvert$
z_2	4.4	0.2	0	$\lvert 0.069y_{25} + 0.050\rvert$
z_3	4.9	0.2	0.25	$\lvert 0.014y_{25} - 0.199\rvert$
z_4	4.4	0.2	0	$\lvert 0.069y_{25} + 0.050\rvert$
z_5	5.1	0.4	0.15	$\lvert 0.008y_{25} + 0.099\rvert$
z_6	5.9	1.5	0.3	$\lvert 0.096y_{25} - 0.603\rvert$
z_7	5.0	0.2	0.4	$\lvert 0.003y_{25} - 0.249\rvert$
z_8	6.4	1.3	0.2	$\lvert 0.151y_{25} - 0.154\rvert$
z_9	6.7	1.4	0.3	$\lvert 0.184y_{25} - 0.104\rvert$
z_{10}	6.2	1.5	0.2	$\lvert 0.129y_{25} - 0.453\rvert$
z_{11}	5.1	0.2	0.15	$\lvert 0.008y_{25} + 0.299\rvert$

Table 4: **Conformal prediction of petal width from sepal length.** We use the same random 25 plants that we used for predicting the species. The actual value of y_{25} is 1.4.

The most conventional way of analyzing this data is to calculate the least-squares line (11):

$$\hat{y} = a_{24} + b_{24}x = -2.96 + 0.68x.$$

The sepal length for the 25th plant being $x_{25} = 6.8$, the line predicts that y_{25} should be near $-2.96 + 0.68 \times 6.8 = 1.66$. Under the textbook assumption that the y_i are all independent and normally distributed with means on the line and a common variance, we estimate the common variance by

$$s_{24}^2 = \frac{\sum_{i=1}^{24}(y_i - (a_{24} + b_{24}x_i))^2}{22} = 0.0780.$$

The textbook $1-\varepsilon$ interval for y_{25} based on $\wr(x_1,y_1),\ldots,(x_{24},y_{24})\wr$ and x_{25} is

$$1.66 \pm t_{22}^{\varepsilon/2} s_{24} \sqrt{1 + \frac{1}{24} + \frac{(x_{25} - \bar{x}_{24})^2}{\sum_{j=1}^{24}(x_j - \bar{x}_{24})^2}} = 1.66 \pm 0.311 t_{22}^{\varepsilon/2} \tag{21}$$

(Draper and Smith 1998, p. 82; Ryan 1997, pp. 21–22; Seber and Lee 2003, p. 145). Taking into account the fact y_{25} is measured to only one decimal place, we obtain $[1.0, 2.3]$ for the 96% interval and $[1.1, 2.2]$ for the 92% interval.

The prediction interval (21) is analogous to Fisher's interval for a new example from the same normally distributed population as a bag of old examples (§2.1.1). In §5.3.2 we will review the general model of which both are special cases.

As we will now see, the conformal algorithm under exchangeability gives confidence intervals comparable to (21), without the assumption that the errors are normal. We use two different nonconformity measures: one based on the nearest neighbor, and one based on the least-squares line.

Conformal prediction using the nearest neighbor. Suppose B is a bag of old examples and (x,y) is a new example, for which we know the sepal length x but not the petal width y. We can predict y using the nearest neighbor in an obvious way: We find the $z' \in B$ for which the sepal length x' is closest to x, and we predict that y will be the same as the petal width y'. If there are several examples in the bag with sepal length equally close to x, then we take the median of their petal widths as our predictor $\hat{y}$. The associated nonconformity measure is $|y - \hat{y}|$.

The fourth column of Table 4 gives the nonconformity scores for our sample using this nonconformity measure. We see that $\alpha_{25} = |y_{25} - 1.55|$. The other nonconformity scores do not involve y_{25}; the largest is 0.75, and the second largest is 0.40. So we obtain these prediction regions y_{25}:

- The 96% prediction region consists of all the y for which $p_y > 0.04$, which requires that at least one of the other α_i be as large as α_{25}, or that $0.75 \geq |y - 1.55|$. This is the interval $[0.8, 2.3]$.

- The 92% prediction region consists of all the y for which $p_y > 0.08$, which requires that at least two of the other α_i be as large as α_{25}, or that $0.40 \geq |y - 1.55|$. This is the interval $[1.2, 1.9]$.

Conformal prediction using least-squares. Now we use the least-squares nonconformity measure with inclusion, given by (12). In our case, $n = 25$, so our nonconformity scores are

$$\begin{aligned}\alpha_i &= |y_i - (a_{25} + b_{25} x_i)| \\ &= \left| y_i - \frac{\sum_{j=1}^{25} y_j}{25} - \frac{\sum_{j=1}^{25} (x_j - \bar{x}_{25}) y_j}{\sum_{j=1}^{25} (x_j - \bar{x}_{25})^2} \left(x_i - \frac{\sum_{j=1}^{25} x_j}{25} \right) \right| .\end{aligned}$$

When we substitute values of $\sum_{j=1}^{24} y_j$, $\sum_{j=1}^{24} (x_j - \bar{x}_{25}) y_j$, $\sum_{j=1}^{25} (x_j - \bar{x}_{25})^2$, and $\sum_{j=1}^{25} x_j$ calculated from Table 4, this becomes

$$\alpha_i = |y_i + (0.553 - 0.110 x_i) y_{25} - 0.498 x_i + 2.04| .$$

For $i = 1, \ldots, 24$, we can further evaluate this by substituting the values of x_i and y_i. For $i = 25$, we can substitute 6.8 for x_{25}. These substitutions produce the expressions of the form $|c_i y_{25} + d_i|$ listed in the last column of Table 4. We have made sure that c_i is always positive by multiplying by -1 within the absolute value when need be.

Table 5 shows calculations required to find the conformal prediction region. The task is to identify, for $i = 1, \ldots, 24$, the y for which $|c_i y + d_i| \geq |0.805 y - 1.345|$. We first find the solutions of

the equation $|c_i y + d_i| = |0.805y - 1.345|$, which are

$$-\frac{d_i + 1.345}{c_i - 0.805} \qquad \text{and} \qquad -\frac{d_i - 1.345}{c_i + 0.805}.$$

As it happens, $c_i < 0.805$ for $i = 1, \ldots, 24$, and in this case the y satisfying $|c_i y + d_i| \geq |0.805 - 1.345|$ form the interval between these two points. This interval is shown in the last column of the table.

In order to be in the 96% interval, y must be in at least one of the 24 intervals in the table; in order to be in the 92% interval, it must be in at least two of them. So the 96% interval is $[1.0, 2.4]$, and the 92% interval is $[1.0, 2.3]$.

An algorithm for finding conformal prediction intervals using a least-squares or ridge-regression nonconformity measure with an object space of any finite dimension is spelled out on pp. 32–33 of our book (Vovk et al., 2005).

4.4 Optimality

The predictions produced by the conformal algorithm are invariant with respect to the old examples, correct with the advertised probability, and nested. As we now show, they are optimal among all region predictors with these properties.

Here is a more precise statement of the three properties:

1. *The predictions are invariant with respect to the ordering of the old examples.* Formally, this means that the predictor γ is a function of two variables, the significance level ε and the bag B of old examples. We write $\gamma^\varepsilon(B)$ for the prediction, which is a subset of the example space $\mathbf{Z}$.

2. *The probability of a hit is always at least the advertised confidence level.* For every positive integer n and every probability distribution under which $z_1, \ldots, z_n$ are exchangeable,

$$\Pr\{z_n \in \gamma^\varepsilon(\lbag z_1, \ldots, z_{n-1} \rbag)\} \geq 1 - \varepsilon.$$

3. *The prediction regions are nested.* If $\varepsilon_1 \geq \varepsilon_2$, then $\gamma^{\varepsilon_1}(B) \subseteq \gamma^{\varepsilon_2}(B)$.

Conformal predictors satisfy these three conditions. Other region predictors can also satisfy them. But as we now demonstrate, any γ satisfying them can be improved on by a conformal predictor: there always exists a nonconformity measure A such that the predictor γ_A constructed from A by the conformal algorithm satisfies $\gamma_A^\varepsilon(B) \subseteq \gamma^\varepsilon(B)$ for all B and ε.

The key to the demonstration is the following lemma:

Lemma 1 *Suppose γ is a region predictor satisfying the three conditions, $\lbag a_1, \ldots, a_n \rbag$ is a bag of examples, and $0 < \varepsilon \leq 1$. Then $n\varepsilon$ or fewer of the n elements of the bag satisfy*

$$a_i \notin \gamma^\varepsilon(\lbag a_1, \ldots, a_n \rbag \setminus \lbag a_i \rbag). \tag{22}$$

Proof Consider the unique exchangeable probability distribution for $z_1, \ldots, z_n$ that gives probability 1 to $\lbag z_1, \ldots, z_n \rbag = \lbag a_1, \ldots, a_n \rbag$. Under this distribution, each element of $\lbag a_1, \ldots, a_n \rbag$ has an equal probability of being z_n, and in this case, (22) is a mistake. By the second condition, the probability of a mistake is ε or less. So the fraction of the bag's elements for which (22) holds is ε or less. ■

	$\alpha_i = \lvert c_i y_{25} + d_i \rvert$	$-\frac{d_i + 1.345}{c_i - 0.805}$	$-\frac{d_i - 1.345}{c_i + 0.805}$	y satisfying $\lvert c_i y + d_i \rvert \geq \lvert 0.805 - 1.345 \rvert$

Table 5: **Calculations with least-squares nonconformity scores.** The column on the right gives the values of y for which the example's nonconformity score will exceed that of the 25th example.

Given the region predictor γ, what nonconformity measure will give us a conformal predictor that improves on it? If

$$z \notin \gamma^{\delta}(B), \tag{23}$$

then γ is asserting confidence $1-\delta$ that z should not appear next because it is so different from B. So the largest $1-\delta$ for which (23) holds is a natural nonconformity measure:

$$A(B,z) = \sup\{1-\delta \,|\, z \notin \gamma^{\delta}(B)\}.$$

	Least-squares prediction with normal errors	Conformal prediction with two different nonconformity measures	
		NN	Least squares
96%	$[1.0, 2.3]$	$[0.8, 2.3]$	$[1.0, 2.4]$
92%	$[1.1, 2.2]$	$[1.2, 1.9]$	$[1.0, 2.3]$

Table 6: **Prediction intervals for the 25th plant's petal width, calculated by three different methods.** The conformal prediction intervals using the least-squares nonconformity measure are quite close to the standard intervals based on least-squares with normal errors. All the intervals contain the actual value, 1.4.

The conformal predictor γ_A obtained from this nonconformity measure, though it agrees with γ on how to rank different z with respect to their nonconformity with B, may produce tighter prediction regions if γ is too conservative in the levels of confidence it asserts.

To show that $\gamma_A^\varepsilon(B) \subseteq \gamma^\varepsilon(B)$ for every ε and every B, we assume that

$$z \in \gamma_A^\varepsilon(\{z_1, \ldots, z_{n-1}\}) \tag{24}$$

and show that $z \in \gamma^\varepsilon(\{z_1, \ldots, z_{n-1}\})$. According to the conformal algorithm, (24) means that when we provisionally set z_n equal to z and calculate the nonconformity scores

$$\alpha_i = \sup\{1-\delta \,|\, z_i \notin \gamma^\delta(\{z_1, \ldots, z_n\} \setminus \{z_i\})\}$$

for $i = 1, \ldots, n$, we find that strictly more than $n\varepsilon$ of these scores are greater than or equal to α_n. Because γ's prediction regions are nested (condition 3), it follows that if $z_n \notin \gamma^\varepsilon(\{z_1, \ldots, z_{n-1}\})$, then $z_i \notin \gamma^\varepsilon(\{z_1, \ldots, z_n\} \setminus \{z_i\})$ for strictly more than $n\varepsilon$ of the z_i. But by Lemma 1, $n\varepsilon$ or fewer of the z_i can satisfy this condition. So $z_n \in \gamma^\varepsilon(\{z_1, \ldots, z_{n-1}\})$.

There are sensible reasons to use region predictors that are not invariant. We may want to exploit possible departures from exchangeability even while insisting on validity under exchangeability. Or it may simply be more practical to use a predictor that is not invariant. But invariance is a natural condition when we want to rely only on exchangeability, and in this case our optimality result is persuasive. For further discussion, see §2.4 of our book (Vovk et al., 2005).

4.5 Examples Are Seldom Exactly Exchangeable

Although the assumption of exchangeability is weak compared to the assumptions embodied in most statistical models, it is still an idealization, seldom matched exactly by what we see in the world. So we should not expect conclusions derived from this assumption to be exactly true. In particular, we should not be surprised if a 95% conformal predictor is wrong more than 5% of the time.

We can make this point with the USPS data set so often used to illustrate machine learning methods. This data set consists of 9298 examples of the form (x, y), where x is a 16×16 gray-scale matrix and y is one of the ten digits $0, 1, \ldots, 9$. It has been used in hundreds of books and articles. In our book (Vovk et al., 2005), it is used to illustrate conformal prediction with a number of different nonconformity measures. It is well known that the examples in this data set are not perfectly exchangeable. In particular, the first 7291 examples, which are often treated as a training

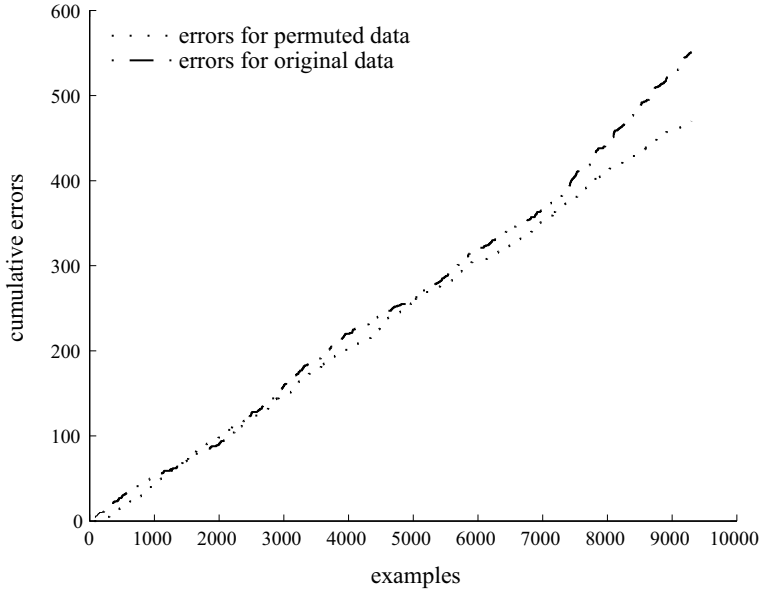

Figure 7: **Errors in** 95% **nearest-neighbor conformal prediction on the classical USPS data set.** When the 9298 examples are predicted in a randomly chosen order, so that the exchangeability assumption is satisfied for sure, the error rate is approximately 5% as advertised. When they are taken in their original order, first the 7291 in the training set, and then the 2007 in the test set, the error rate is higher, especially in the test set.

set, are systematically different in some respects from the remaining 2007 examples, which are usually treated as a test set.

Figure 7 illustrates how the non-exchangeability of the USPS data affects conformal prediction. The figure records the performance of the 95% conformal predictor using the nearest-neighbor nonconformity measure (10), applied to the USPS data in two ways. First we use the 9298 examples in the order in which they are given in the data set. (We ignore the distinction between training and test examples, but since the training examples are given first we do go through them first.) Working through the examples in this order, we predict each y_n using the previous examples and x_n. Second, we randomly permute all 9298 examples, thus producing an order with respect to which the examples are necessarily exchangeable. The law of large numbers works when we go through the examples in the permuted order: we make mistakes at a steady rate, about equal to the expected 5%. But when we go through the examples in the original order, the fraction of mistakes is less stable, and it worsens as we move into the test set. As Table 7 shows, the fraction of mistakes is 5%, as desired, in the first 7291 examples (the training set) but jumps to 8% in the last 2007 examples.

Non-exchangeability can be tested statistically, using conventional or game-theoretic methods (Vovk et al., 2005, §7.1). In the case of this data, any reasonable test will reject exchangeability decisively. Whether the deviation from exchangeability is of practical importance for prediction depends, of course, on circumstances. An error rate of 8% when 5% has been promised may or may not be acceptable.

	Original data			Permuted data		
	Training	Test	Total	Training	Test	Total

Table 7: **Details of the performance of** 95% **nearest-neighbor conformal prediction on the classical USPS data set.** Because there are 10 labels, the uncertain predictions, those containing more than one label, can be hits or errors.

5. On-Line Compression Models

In this section, we generalize conformal prediction from the exchangeability model to a whole class of models, which we call on-line compression models.

In the exchangeability model, we compress or summarize examples by omitting information about their order. We then look backwards from the summary (the bag of unordered examples) and give probabilities for the different orderings that could have produced it. The compression can be done on-line: each time we see a new example, we add it to the bag. The backward-looking probabilities can also be given step by step. Other on-line compression models compress more or less drastically but have a similar structure.

On-line compression models were studied in the 1970s and 1980s, under various names, by Per Martin-Löf (1974), Steffen Lauritzen (1988), and Eugene Asarin (1987; 1988). Different authors had different motivations. Lauritzen and Martin-Löf started from statistical mechanics, whereas Asarin started from Kolmogorov's thinking about the meaning of randomness. But the models they studied all summarize past examples using statistics that contain all the information useful for predicting future examples. The summary is updated each time one observes a new example, and the probabilistic content of the structure is expressed by Markov kernels that give probabilities for summarized examples conditional on the summaries.

In general, a Markov kernel is a mapping that specifies, as a function of one variable, a probability distribution for some other variable or variables. A Markov kernel for w given u, for example, gives a probability distribution for w for each value of u. It is conventional to write $P(w \mid u)$ for this

distribution. We are interested in Markov kernels of the form $P(z_1,\dots,z_n \mid \sigma_n)$, where σ_n summarizes the examples $z_1,\dots,z_n$. Such a kernel gives probabilities for the different $z_1,\dots,z_n$ that could have produced σ_n.

Martin-Löf, Lauritzen, and Asarin were interested in justifying widely used statistical models from principles that seem less arbitrary than the models themselves. On-line compression models offer an opportunity to do this, because they typically limit their use of probability to representing ignorance with a uniform distribution but lead to statistical models that seem to say something more. Suppose, for example, that Joe summarizes numbers $z_1,\dots,z_n$ by

$$\bar{z} = \frac{1}{n}\sum_{i=1}^{n} z_i \qquad \text{and} \qquad r^2 = \sum_{i=1}^{n} (z_i - \bar{z})^2$$

and gives these summaries to Bill, who does not know $z_1,\dots,z_n$. Bill might adopt a probability distribution for $z_1,\dots,z_n$ that is uniform over the possibilities, which form the $(n-1)$-dimensional sphere of radius r centered around $(\bar{z},\dots,\bar{z})$. As we will see in §5.3.2, this is an on-line compression model. It was shown, by Freedman and Smith (see Vovk et al., 2005, p. 217) and then by Lauritzen (1988, pp. 238–247), that if we assume this model is valid for all n, then the distribution of $z_1, z_2, \dots$ must be a mixture of distributions under which $z_1, z_2, \dots$ are independent and normal with a common mean and variance. This is analogous to de Finetti's theorem, which says that if $z_1,\dots,z_n$ are exchangeable for all n, then the distribution of $z_1, z_2, \dots$ must be a mixture of distributions under which $z_1, z_2, \dots$ are independent and identically distributed.

For our own part, we are interested in using an on-line compression model directly for prediction rather than as a step towards a model that specifies probabilities for examples more fully. We have already seen how the exchangeability model can be used directly for prediction: we establish a law of large numbers for backward-looking probabilities (§3.4), and we use it to justify confidence in conformal prediction regions (§4.2). The argument extends to on-line compression models in general.

For the exchangeability model, conformal prediction is optimal for obtaining prediction regions (§4.4). No such statement can be made for on-line compression models in general. In fact, there are other on-line compression models in which conformal prediction is very inefficient (Vovk et al., 2005, p. 220).

After developing the general theory of conformal prediction for on-line compression models (§5.1 and §5.2), we consider two examples: the exchangeability-within-label model (§5.3.1) and on-line Gaussian linear model (§5.3.2).

5.1 Definitions

A more formal look at the exchangeability model will suffice to bring the general notion of an on-line compression model into focus.

In the exchangeability model, we summarize examples simply by omitting information about their ordering; the ordered examples are summarized by a bag containing them. The backward-looking probabilities are equally simple; given the bag, the different possible orderings all have equal probability, as if the ordering resulted from drawing the examples successively at random from the bag without replacement. Although this picture is very simple, we can distinguish four distinct mathematical operations within it:

1. *Summarizing.* The examples $z_1,\dots,z_n$ are summarized by the bag $\wr z_1,\dots,z_n\int$. We can say that the summarization is accomplished by a *summarizing function* Σ_n that maps an n-tuple of examples $(z_1,\dots,z_n)$ to the bag containing these examples:

$$\Sigma_n(z_1,\dots,z_n) := \wr z_1,\dots,z_n\int.$$

   We write σ_n for the summary—that is, the bag $\wr z_1,\dots,z_n\int$.

2. *Updating.* The summary can be formed step by step as the examples are observed. Once you have the bag containing the first $n-1$ examples, you just add the nth. This defines an *updating function* $U_n(\sigma,z)$ that satisfies

$$\Sigma_n(z_1,\dots,z_n) = U_n(\Sigma_{n-1}(z_1,\dots,z_{n-1}),z_n).$$

   The top panel in Figure 8 depicts how the summary σ_n is built up step by step from $z_1,\dots,z_n$ using the updating functions $U_1,\dots,U_n$. First $\sigma_1 = U_1(\square,z_1)$, where $\square$ is the empty bag. Then $\sigma_2 = U_2(\sigma_1,z_2)$, and so on.

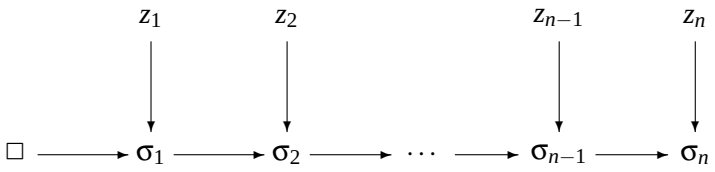
3. *Looking back all the way.* Given the bag σ_n, the $n!$ different orderings of the elements of the bag are equally likely, just as they would be if we ordered the contents of the bag randomly. As we learned in §3.2, we can say this with a formula that takes explicit account of the possibility of repetitions in the bag: the probability of the event $\{z_1 = a_1,\dots,z_n = a_n\}$ is

$$P_n(a_1,\dots,a_n \,|\, \sigma_n) = \begin{cases} \frac{n_1!\cdots n_k!}{n!} & \text{if } \wr a_1,\dots,a_n\int = \sigma_n \\ 0 & \text{if } \wr a_1,\dots,a_n\int \neq \sigma_n, \end{cases}$$

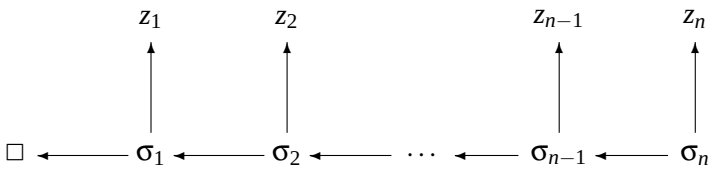
   where k is the number of distinct elements in σ_n, and $n_1,\dots,n_k$ are the numbers of times these distinct elements occur. We call $P_1,P_2,\dots$ the *full kernels*.

4. *Looking back one step.* We can also look back one step. Given the bag σ_n, what are the probabilities for z_n and σ_{n-1}? They are the same as if we drew z_n out of σ_n at random. In other words, for each z that appears in σ_n, there is a probability k/n, where k is the number of times z appears in σ_n, that (1) $z_n = z$ and (2) σ_{n-1} is the bag obtained by removing one instance of z from σ_n. The kernel defined in this way is represented by the two arrows backward from σ_n in the bottom panel of Figure 8. Let us designate it by R_n. We similarly obtain a kernel R_{n-1} backward from σ_{n-1} and so on. These are the *one-step kernels* for the model. We can obtain the full kernel P_n by combining the one-step kernels $R_n,R_{n-1},\dots,R_1$. This is most readily understood not in terms of formulas but in terms of a sequence of drawings whose outcomes have the probability distributions given by the kernels. The drawing from σ_n (which goes by the probabilities given by $R_n(\cdot\,|\,\sigma_n)$) gives us z_n and σ_{n-1}, the drawing from σ_{n-1} (which goes by the probabilities given by $R_{n-1}(\cdot\,|\,\sigma_{n-1})$) gives us z_{n-1} and σ_{n-2}, and so on; we finally obtain the whole random sequence $z_1,\dots,z_n$, which has the distribution $P_n(\cdot\,|\,\sigma_n)$. This is the meaning of the bottom panel in Figure 8.

All four operations are important. The second and fourth, updating and looking back one step, can be thought of as the most fundamental, because we can derive the other two from them. Summarization can be carried out by composing updates, and looking back all the way can be carried out by composing one-step look-backs. Moreover, the conformal algorithm uses the one-step back



Updating. We speak of "on-line" compression models because the summary can be updated with each new example. In the case of the exchangeability model, we obtain the bag σ_i by adding the new example z_i to the old bag σ_{i-1}.



Backward probabilities. The two arrows backwards from σ_i symbolize our probabilities, conditional on σ_i, for what example z_i and what previous summary σ_{i-1} were combined to produce σ_i. Like the diagram in Figure 3 that it generalizes, this diagram is a Bayes net.

Figure 8: **Elements of an on-line compression model.** The top diagram represents the updating functions $U_1,\ldots,U_n$. The bottom diagram represents the one-step kernels $R_1,\ldots,R_n$.

probabilities. But when we turn to particular on-line compression models, we will find it initially most convenient to describe them in terms of their summarizing functions and full kernels.

In general, an *on-line compression model* for an example space $\mathbf{Z}$ consists of a space $\mathbf{S}$, whose elements we call *summaries*, and two sequences of mappings:

- Updating functions $U_1, U_2, \ldots$. The function U_n maps a summary s and an example z to a new summary $U_n(s,z)$.

- One-step kernels $R_1, R_2, \ldots$. For each summary s, the kernel R_n gives a joint probability distribution $R_n(s', z \,|\, s)$ for an unknown summary s' and unknown example z. We require that $R_n(\cdot \,|\, s)$ give probability one to the set of pairs (s', z) such that $U_n(s', z) = s$.

We also require that the summary space $\mathbf{S}$ include the empty summary $\square$.

The recipes for constructing the summarizing functions $\Sigma_1, \Sigma_2, \ldots$ and the full kernels $P_1, P_2, \ldots$ are the same in general as in the exchangeability model:

- The summary $\sigma_n = \Sigma_n(z_1,\ldots,z_n)$ is built up step by step from $z_1,\ldots,z_n$ using the updating functions. First $\sigma_1 = U_1(\square, z_1)$, then $\sigma_2 = U_2(\sigma_1, z_2)$, and so on.

- We obtain the full kernel P_n by combining, backwards from σ_n, the random experiments represented by the one-step kernels $R_n, R_{n-1}, \ldots, R_1$. First we draw z_n and σ_{n-1} from $R_n(\cdot \mid \sigma_n)$, then we draw z_{n-1} and σ_{n-2} from $R_{n-1}(\cdot \mid \sigma_{n-1})$, and so on. The sequence $z_1, \ldots, z_n$ obtained in this way has the distribution $P_n(\cdot \mid \sigma_n)$.

On-line compression models are usually initially specified in terms of their summarizing functions Σ_n and their full kernels P_n, because these are usually easy to describe. One must then verify that these easily described objects do define an on-line compression model. This requires verifying two points:

1. $\Sigma_1, \Sigma_2, \ldots$ can be defined successively by means of updating functions:

$$\Sigma_n(z_1, \ldots, z_n) = U_n(\Sigma_{n-1}(z_1, \ldots, z_{n-1}), z_n).$$

   In words: σ_n depends on $z_1, \ldots, z_{n-1}$ only through the earlier summary σ_{n-1}.

2. Each P_n can be obtained as required using one-step kernels. One way to verify this is to exhibit the one-step kernels $R_1, \ldots, R_n$ and then to check that drawing z_n and σ_{n-1} from $R_n(\cdot \mid \sigma_n)$, then drawing z_{n-1} and σ_{n-2} from $R_{n-1}(\cdot \mid \sigma_{n-1})$, and so on produces a sequence $z_1, \ldots, z_n$ with the distribution $P_n(\cdot \mid \sigma_n)$. Another way to verify it, without necessarily exhibiting the one-step kernels, is to verify the conditional independence relations represented by Figure 8: z_n (and hence also σ_n) is probabilistically independent of $z_1, \ldots, z_{n-1}$ given σ_{n-1}.

5.2 Conformal Prediction

In the context of an on-line compression model, a *nonconformity measure* is an arbitrary real-valued function $A(\sigma, z)$, where σ is a summary and z is an example. We choose A so that $A(\sigma, z)$ is large when z seems very different from the examples that might be summarized by σ.

In order to state the conformal algorithm, we write $\tilde{\sigma}_{n-1}$ and $\tilde{z}_n$ for random variables with a joint probability distribution given by the one-step kernel $R(\cdot \mid \sigma_n)$. The algorithm using old examples alone can then be stated as follows:

The Conformal Algorithm Using Old Examples Alone

Input: Nonconformity measure A, significance level ε, examples $z_1, \ldots, z_{n-1}$, example z

Task: Decide whether to include z in $\gamma^\varepsilon(z_1, \ldots, z_{n-1})$.

Algorithm:

1. Provisionally set $z_n := z$.
2. Set $p_z := R_n(A(\tilde{\sigma}_{n-1}, \tilde{z}_n) \geq A(\sigma_{n-1}, z_n) \mid \sigma_n)$.
3. Include z in $\gamma^\varepsilon(z_1, \ldots, z_{n-1})$ if and only if $p_z > \varepsilon$.

To see that this reduces to the algorithm we gave for the exchangeability model on p. 385, recall that $\sigma_n = \wr z, \ldots, z_n \int$ and $\tilde{\sigma}_{n-1} = \wr z_1, \ldots, z_n \int \setminus \wr \tilde{z}_n \int$ in that model, so that

$$A(\tilde{\sigma}_{n-1}, \tilde{z}_n) = A(\wr z_1, \ldots, z_n \int \setminus \wr \tilde{z}_n \int, \tilde{z}_n) \tag{25}$$

and

$$A(\sigma_{n-1}, z_n) = A(\wr z_1, \ldots, z_{n-1} \int, z_n). \tag{26}$$

Under $R_n(\cdot \mid \{z_1,\dots,z_n\})$, the random variable $\tilde{z}_n$ has equal chances of being any of the z_i, so that the probability of (25) being greater than or equal to (26) is simply the fraction of the z_i for which

$$A(\{z_1,\dots,z_n\} \setminus \{z_i\}, z_i) \geq A(\{z_1,\dots,z_{n-1}\}, z_n),$$

and this is how p_z is defined on p. 385.

Our arguments for the validity of the regions $\gamma^\varepsilon(z_1,\dots,z_{n-1})$ in the exchangeability model generalize readily. The definitions of *n*-event and ε-rare generalize in an obvious way:

- An event E is an *n-event* if its happening or failing is determined by the value of z_n and the value of the summary σ_{n-1}.
- An *n*-event E is ε-*rare* if $R_n(E \mid \sigma_n) \leq \varepsilon$.

The event $z_n \notin \gamma^\varepsilon(z_1,\dots,z_{n-1})$ is an *n*-event, and it is ε-rare (the probability is ε or less that a random variable will take a value that it equals or exceeds with a probability of ε or less). So working backwards from the summary σ_N for a large value of N, Bill can still bet against the errors successively at rates corresponding to their probabilities under σ_n, which are always ε or less. This produces an exact analog to Informal Proposition 1:

Informal Proposition 2 *Suppose N is large, and the variables $z_1,\dots,z_N$ obey an on-line compression model. Suppose E_n is an ε-rare n-event for $n = 1,\dots,N$. Then the law of large numbers applies; with very high probability, no more than approximately the fraction ε of the events $E_1,\dots,E_N$ will happen.*

The conformal algorithm using features of the new example generalizes similarly:

The Conformal Algorithm

Input: Nonconformity measure A, significance level ε, examples $z_1,\dots,z_{n-1}$, object x_n, label y

Task: Decide whether to include y in $\Gamma^\varepsilon(z_1,\dots,z_{n-1},x_n)$.

Algorithm:

1. Provisionally set $z_n := (x_n, y)$.
2. Set $p_y := R_n(A(\tilde{\sigma}_{n-1}, \tilde{z}_n) \geq A(\sigma_{n-1}, z_n) \mid \sigma_n)$.
3. Include y in $\Gamma^\varepsilon(z_1,\dots,z_{n-1},x_n)$ if and only if $p_y > \varepsilon$.

The validity of this algorithm follows from the validity of the algorithm using old examples alone by the same argument as in the case of exchangeability.

5.3 Examples

We now look at two on-line compression models: the exchangeability-within-label model and the on-line Gaussian linear model.

The exchangeability-within-label model was first introduced in work leading up to our book (Vovk et al., 2005). It weakens the assumption of exchangeability.

The on-line Gaussian linear model, as we have already mentioned, has been widely studied. It overlaps the exchangeability model, in the sense that the assumptions for both of the models can

hold at the same time, but the assumptions for one of them can hold without the assumptions for the other holding. It is closely related to the classical Gaussian linear model. Conformal prediction in the on-line model leads to the same prediction regions that are usually used for the classical model. But the conformal prediction theory adds the new information that these intervals are valid in the sense of this article: they are right $1-\varepsilon$ of the time when used on accumulating data.

5.3.1 THE EXCHANGEABILITY-WITHIN-LABEL MODEL

The assumption of exchangeability can be weakened in many ways. In the case of classification, one interesting possibility is to assume only that the examples for each label are exchangeable with each other. For each label, the objects with that label are as likely to appear in one order as in another. This assumption leaves open the possibility that the appearance of one label might change the probabilities for the next label.

Suppose the label space has k elements, say $\mathbf{Y} = \{1,\dots,k\}$. Then we define the *exchangeability-within-label model* as follows:

Summarizing Functions The nth summarizing function is

$$\Sigma_n(z_1,\dots,z_n) := (y_1,\dots,y_n,B_1^n,\dots,B_k^n)\,,$$

where B_j^n is the bag consisting of the objects in the list $x_1,\dots,x_n$ that have the label j.

Full Kernels The full kernel $P_n(z_1,\dots,z_n \,|\, y_1,\dots,y_n,B_1^n,\dots,B_k^n)$ is most easily described in terms the random action for which it gives the probabilities: independently for each label j, distribute the objects in B_j^n randomly among the positions i for which y_i is equal to j.

To check that this is an on-line compression model, we exhibit the updating function and the one-step kernels:

Updating When (x_n,y_n) is observed, the summary

$$(y_1,\dots,y_{n-1},B_1^{n-1},\dots,B_k^{n-1})$$

is updated by inserting y_n after y_{n-1} and adding x_n to $B_{y_n}^{n-1}$.

One step back The one-step kernel R_n is given by

$$R_n(\text{summary},(x,y)\,|\,y_1,\dots,y_n,B_1^n,\dots,B_k^n) = \begin{cases} \frac{k}{|B_{y_n}^n|} & \text{if } y = y_n \\ 0 & \text{otherwise,} \end{cases}$$

where k is the number of xs in $B_{y_n}^n$. This is the same as the probability the one-step kernel for the exchangeability model would give for x on the basis of a bag of size $|B_{y_n}^n|$ that includes k xs.

Because the true labels are part of the summary, our imaginary bettor Bill can choose to bet just on those rounds of his game with Joe where the label has a particular value, and this implies that a 95% conformal predictor under the exchangeability-within-label model will make errors at no more than a 5% rate for examples with that label. This is not necessarily true for a 95% conformal predictor under the exchangeability model; although it can make errors no more than about 5% of

the time overall, its error rate may be higher for some labels and lower for others. As Figure 9 shows, this happens in the case of the USPS data set. The graph in the top panel of the figure shows the cumulative errors for examples with the label 5, which is particularly easy to confuse with other digits, when the nearest-neighbor conformal predictor is applied to that data in permuted form. The error rate for 5 is over 11%. The graph in the bottom panel shows the results of the exchangeability-within-label conformal predictor using the same nearest-neighbor nonconformity measure; here the error rate stays close to 5%. As this graph makes clear, the predictor holds the error rate down to 5% in this case by producing many prediction regions containing more than one label ("uncertain predictions").

As we explain in §4.5 and §8.4 of our book (Vovk et al., 2005), the exchangeability-within-label model is a *Mondrian model*. In general, a Mondrian model decomposes the space $\mathbf{Z} \times \mathbb{N}$, where $\mathbb{N}$ is set of the natural numbers, into non-overlapping rectangles, and it asks for exchangeability only within these rectangles. For each example z_i, it then records, as part of the summary, the rectangle into which (z_i, i) falls. Mondrian models can be useful when we need to weaken the assumption of exchangeability. They can also be attractive even if we are willing to assume exchangeability across the categories, because the conformal predictions they produce will be calibrated within categories.

5.3.2 THE ON-LINE GAUSSIAN LINEAR MODEL

Consider examples $z_1, \ldots, z_N$, of the form $z_n = (x_n, y_n)$, where y_n is a number and x_n is a row vector consisting of p numbers. For each n between 1 and N, set

$$X_n := \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix} \qquad \text{and} \qquad Y_n := \begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix}.$$

Thus X_n is an $n \times p$ matrix, and Y_n is a column vector of length n.

In this context, the *on-line Gaussian linear model* is the on-line compression model defined by the following summarizing functions and full kernels:

Summarizing Functions The nth summarizing function is

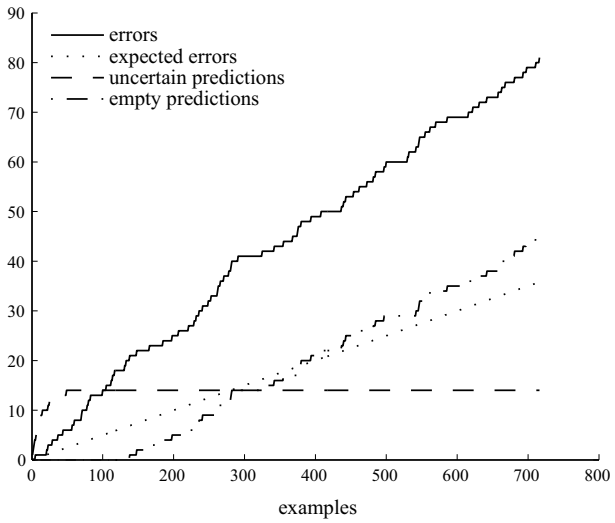
$$\begin{aligned} \Sigma_n(z_1, \ldots, z_n) &:= \left(x_1, \ldots, x_n, \sum_{i=1}^{n} y_i x_i, \sum_{i=1}^{n} y_i^2 \right) \\ &= \left(X_n, X_n' Y_n, Y_n' Y_n \right). \end{aligned}$$

Full Kernels The full kernel $P_n(z_1, \ldots, z_n \mid \sigma_n)$ distributes its probability uniformly over the set of vectors $(y_1, \ldots, y_n)$ consistent with the summary σ_n. (We consider probabilities only for $y_1, \ldots, y_n$, because $x_1, \ldots, x_n$ are fixed by σ_n.)

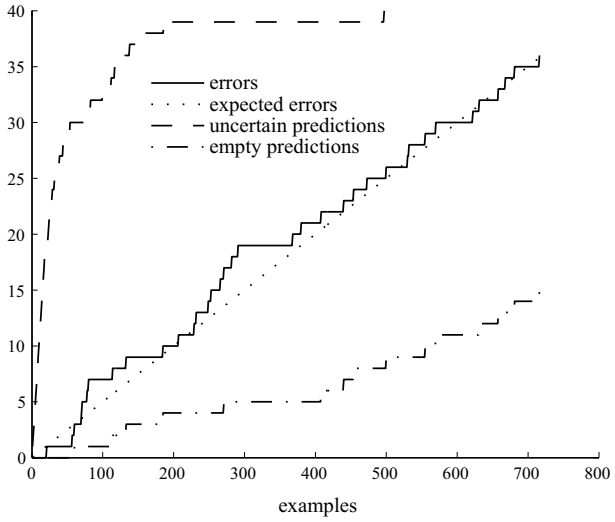
We can write $\sigma_n = (X_n, C, r^2)$, where C is a column vector of length p, and r is a nonnegative number. A vector $(y_1, \ldots, y_n)$ is consistent with σ_n if

$$\sum_{j=1}^{n} y_j x_j = C \qquad \text{and} \qquad \sum_{j=1}^{n} y_j^2 = r^2.$$

This is the intersection of a hyperplane with a sphere. Not being empty, the intersection is either a point (in the exceptional case where the hyperplane is tangent to the sphere) or a lower-dimensional



Exchangeability model



Exchangeability-within-label model

Figure 9: **Errors for** 95% **conformal prediction using nearest neighbors in the permuted USPS data when the true label is** 5**.** In both figures, the dotted line represents the overall expected error rate of 5%. The actual error rate for 5s with the exchangeability-within-label model tracks this line, but with the exchangeability model it is much higher. The exchangeability-within-label predictor keeps its error rate down by issuing more prediction regions containing more than one digit ("uncertain predictions").

sphere. (Imagine intersecting a plane and a 2-dimensional sphere; the result is a circle.) The kernel $P_n(\cdot \mid \sigma_n)$ puts all its probability on the point or distributes it uniformly over the the lower-dimensional sphere.

To see that the summarizing functions and full kernels define an on-line compression model, we must check that the summaries can be updated and that the full kernels have the required conditional independence property: conditioning $P_n(\cdot \mid \sigma_n)$ on $z_{i+1}, \ldots, z_n$ gives $P_i(\cdot \mid \sigma_i)$. (We do not condition on σ_i since it can be computed from $z_{i+1}, \ldots, z_n$ and σ_n.) Updating is straightforward; when we observe (x_n, y_n), we update the summary

$$\left(x_1, \ldots, x_{n-1}, \sum_{i=1}^{n-1} y_i x_i, \sum_{i=1}^{n-1} y_i^2 \right)$$

by inserting x_n after x_{n-1} and adding a term to each of the sums. To see that conditioning $P_n(\cdot \mid \sigma_n)$ on $z_{i+1}, \ldots, z_n$ gives $P_i(\cdot \mid \sigma_i)$, we note that conditioning the uniform distribution on a sphere on values $y_{i+1} = a_{i+1}, \ldots, y_n = a_n$ involves intersecting the sphere with the hyperplanes defined by these $n - i$ equations. This produces the uniform distribution on the possibly lower-dimensional sphere defined by

$$\sum_{j=1}^{i} y_j^2 = r^2 - \sum_{j=i+1}^{n} y_j^2 \qquad \text{and} \qquad \sum_{j=1}^{i} y_j x_j = C - \sum_{j=i+1}^{n} y_j x_j;$$

this is indeed $P_i(y_1, \ldots, y_i \mid \sigma_i)$.

The on-line Gaussian linear model is closely related to the *classical Gaussian linear model*. In the classical model,[5]

$$y_i = x_i \beta + e_i, \tag{27}$$

where the x_i are row vectors of known numbers, β is a column vector of unknown numbers (the regression coefficients), and the e_i are independent of each other and normally distributed with mean zero and a common variance. When $n - 1 > p$ and $\mathrm{Rank}(X_{n-1}) = p$, the theory of the classical model tells us the following:

- After observing examples $(x_1, y_1, \ldots, x_{n-1}, y_{n-1})$, estimate the vector of coefficients β by

  $$\hat{\beta}_{n-1} := (X'_{n-1} X_{n-1})^{-1} X'_{n-1} Y_{n-1}$$

  and after further observing x_n, predict y_n by

  $$\hat{y}_n := x_n \hat{\beta}_{n-1} = x_n (X'_{n-1} X_{n-1})^{-1} X'_{n-1} Y_{n-1}.$$

- Estimate the variance of the e_i by

  $$s_{n-1}^2 := \frac{Y'_{n-1} Y_{n-1} - \beta'_{n-1} X'_{n-1} Y_{n-1}}{n - p - 1}.$$

5. There are many names for the classical model. The name "classical Gaussian linear model" is used by Bickel and Doksum (2001, p. 366).

- The random variable

$$t_n := \frac{y_n - \hat{y}_n}{s_{n-1}\sqrt{1 + x_n'(X_{n-1}'X_{n-1})^{-1}x_n}} \tag{28}$$

has a t-distribution with $n-p-1$ degrees of freedom, and so

$$\hat{y}_n \pm t^{\varepsilon/2}_{n-p-1} s_{n-1}\sqrt{1 + x_n'(X_{n-1}'X_{n-1})^{-1}x_n} \tag{29}$$

has probability $1-\varepsilon$ of containing y_n (Ryan 1997, p. 127; Seber and Lee 2003, p. 132).

The assumption $\mathrm{Rank}(X_{n-1}) = p$ can be relaxed, at the price of complicating the formulas involving $(X_{n-1}'X_{n-1})^{-1}$. But the assumption $n-1 > \mathrm{Rank}(X_{n-1})$ is essential to finding a prediction interval of the type (29); when it fails there are values for the coefficients β such that $y_{n-1} = X_{n-1}\beta$, and consequently there is no residual variance with which to estimate the variance of the e_i.

We have already used two special cases of (29) in this article. Formula (1) in §2.1.1 is the special case with $p = 1$ and each x_i equal to 1, and formula (21) at the beginning of §4.3.2 is the special case with $p = 2$ and the first entry of each x_i equal to 1.

The relation between the classical and on-line models, fully understood in the theoretical literature since the 1980s, can be summarized as follows:

- If $z_1, \ldots, z_N$ satisfy the assumptions of the classical Gaussian linear model, then they satisfy the assumptions of the on-line Gaussian linear model. In other words, the assumption that the errors e_i in (27) are independent and normal with mean zero and a common variance implies that conditional on $X_n'Y_n = C$ and $Y_n'Y_n = r^2$, the vector Y_n is distributed uniformly over the sphere defined by C and r^2. This was already noted by R. A. Fisher in 1925.

- The assumption of the on-line Gaussian linear model, that conditional on $X_n'Y_n = C$ and $Y_n'Y_n = r^2$, the vector Y_n is distributed uniformly over the sphere defined by C and r^2, is sufficient to guarantee that (28) has the t-distribution with $n-p-1$ degrees of freedom (Dempster, 1969; Efron, 1969).

- Suppose $z_1, z_2, \ldots$ is an infinite sequence of random variables. Then $z_1, \ldots, z_N$ satisfy the assumptions of the on-line Gaussian linear model for every integer N if and only if the joint distribution of $z_1, z_2, \ldots$ is a mixture of distributions given by the classical Gaussian linear model, each model in the mixture possibly having a different β and a different variance for the e_i (Lauritzen, 1988).

A natural nonconformity measure A for the on-line Gaussian linear model is given, for $\sigma = (X, X'Y, Y'Y)$ and $z = (x, y)$, by

$$A(\sigma, z) := |y - \hat{y}|, \tag{30}$$

where $\hat{y} = x(X'X)^{-1}X'Y$.

Proposition 2 *When (30) is used as the nonconformity measure, the $1-\varepsilon$ conformal prediction region for y_n is (29), the interval given by the t-distribution in the classical theory.*

Proof When (30) is used as the nonconformity measure, the test statistic $A(\sigma_{n-1}, z_n)$ used in the conformal algorithm becomes $|y_n - \hat{y}_n|$. The conformal algorithm considers the distribution of this

statistic under $R_n(\cdot \mid \sigma_n)$. But when σ_n is fixed and t_n is given by (28), $|t_n|$ is a monotonically increasing function of $|y_n - \hat{y}_n|$ (see Vovk et al., 2005, pp. 202–203, for details). So the conformal prediction region is the interval of values of y_n for which $|t_n|$ does not take its most extreme values. Since t_n has the t-distribution with $n-p-1$ degrees of freedom under $R_n(\cdot \mid \sigma_n)$, this is the interval (29). ■

Together with Informal Proposition 2, Proposition 2 implies that when we use (29) for a large number of successive values of n, y_n will be in the interval $1-\varepsilon$ of the time. In fact, because the probability of error each time is exactly ε, we can say simply that the errors are independent and for this reason the classical law of large numbers applies.

In our example involving the prediction of petal width from sepal length, the exchangeability and Gaussian linear models gave roughly comparable results (see Table 6 in §4.3.2). This will often be the case. Each model makes an assumption, however, that the other does not make. The exchangeability model assumes that the *x*s, as well as the *y*s, are exchangeable. The Gaussian linear model assumes that given the *x*s, the *y*s are normally distributed.

Acknowledgments

This article is based on a tutorial lecture by Glenn Shafer at the Workshop on Information Theory and Applications at the University of California at San Diego on February 1, 2007. Glenn Shafer would like to thank Yoav Freund and Alon Orlitsky for the invitation to participate in this workshop. We thank Wei Wu for his assistance in computations. Many other intellectual debts are acknowledged in the preface of our book (Vovk et al., 2005).

Appendix A. Validity

The main purpose of this appendix is to formalize and prove the following informal proposition:

Informal Proposition 1 *Suppose N is large, and the variables $z_1, \ldots, z_N$ are exchangeable. Suppose E_n is an ε-rare n-event for $n = 1, \ldots, N$. Then the law of large numbers applies; with very high probability, no more than approximately the fraction ε of the events $E_1, \ldots, E_N$ will happen.*

We used this informal proposition in §3.4 to establish the validity of conformal prediction in the exchangeability model. As we promised then, we will discuss two different approaches to formalizing it: a classical approach and a game-theoretical approach. The classical approach shows that the E_n are mutually independent in the case where they are exactly ε-rare and then appeals to the classical weak law of large numbers for independent events. The game-theoretic approach appeals directly to the more flexible game-theoretic weak law of large numbers.

Our proofs will also establish the analogous Informal Proposition 2, which we used to establish the validity of conformal prediction in on-line compression models in general.

In §A.3, we return to R. A. Fisher's prediction interval for a normal random variable, which we discussed in §2.1.1. We show that this prediction interval's successive hits are independent, so that validity follows from the usual law of large numbers. Fisher's prediction interval is a special case of conformal prediction for the Gaussian linear model, and so it is covered by the general result

for on-line compression models. But the proof in §A.3, being self-contained and elementary and making no reference to conformal prediction, may be especially informative for many readers.

A.1 A Classical Argument for Independence

Recall the definitions we gave in §3.4 in the case where $z_1,\dots,z_N$ are exchangeable: An event E is an *n-event* if its happening or failing is determined by the value of z_n and the value of the bag $\{z_1,\dots,z_{n-1}\}$, and an n-event E is ε-*rare* if $\Pr(E \mid \{z_1,\dots,z_n\}) \le \varepsilon$. Let us further say that n-event E is *exactly* ε-*rare* if

$$\Pr(E \mid \{z_1,\dots,z_n\}) = \varepsilon. \tag{31}$$

The conditional probability in this equation is a random variable, depending on the random bag $\{z_1,\dots,z_n\}$, but the equation says that it is not really random, for it is always equal to ε. Its expected value, the unconditional probability of E, is therefore also equal to ε.

Proposition 3 *Suppose E_n is an exactly ε-rare n-event for $n = 1,\dots,N$. Then $E_1,\dots,E_N$ are mutually independent.*

Proof Consider (31) for $n = N-1$:

$$\Pr(E_{N-1} \mid \{z_1,\dots,z_{N-1}\}) = \varepsilon. \tag{32}$$

Given $\{z_1,\dots,z_{N-1}\}$, knowledge of z_N does not change the probabilities for z_{N-1} and $\{z_1,\dots,z_{N-2}\}$, and z_{N-1} and $\{z_1,\dots,z_{N-2}\}$ determine the $(N-1)$-event E_{N-1}. So adding knowledge of z_N will not change the probability in (32):

$$\Pr(E_{N-1} \mid \{z_1,\dots,z_{N-1}\} \ \&\ z_N) = \varepsilon.$$

Because E_N is determined by z_N once $\{z_1,\dots,z_{N-1}\}$ is given, it follows that

$$\Pr(E_{N-1} \mid \{z_1,\dots,z_{N-1}\} \ \&\ E_N) = \varepsilon,$$

and from this it follows that $\Pr(E_{N-1} \mid E_N) = \varepsilon$. The unconditional probability of E_{N-1} is also ε. So E_N and E_{N-1} are independent. Continuing the reasoning backwards to E_1, we find that the E_n are all mutually independent. ■

This proof generalizes immediately to the general case of on-line compression models (see p. 407); we simply replace $\{z_1,\dots,z_n\}$ with σ_n.

If N is sufficiently large, and E_n is an exactly ε-rare n-event for $n = 1,\dots,N$, then the law of large numbers applies; with very high probability, no more than approximately the fraction ε of the N events will happen. It is intuitively clear that this conclusion will also hold if we have an inequality instead of an equality in (31), because making the E_n even less likely to happen cannot reverse the conclusion that few of them will happen.

The preceding argument is less than rigorous on two counts. First, the proof of Proposition 3 does not consider the existence of the conditional probabilities it uses. Second, the argument from the case where (31) is an equality to that where it is merely an inequality, though entirely convincing, is only intuitive. A fully rigorous proof, which uses Doob's measure-theoretic framework to deal with the conditional probabilities and uses a randomization to bring the inequality up to an equality, is provided on pp. 211–213 of our book (Vovk et al., 2005).

A.2 A Game-theoretic Law of Large Numbers

As we explained in §3.3, the game-theoretic interpretation of exchangeability involves a backward-looking protocol, in which Bill observes first the bag $\{z_1,\dots,z_N\}$ and then successively z_N, z_{N-1}, and so on, finally observing z_1. Just before he observes z_n, he knows the bag $\{z_1,\dots,z_n\}$ and can bet on the value of z_n at odds corresponding to the probabilities the bag determines:

$$\Pr(z_n = a \mid \{z_1,\dots,z_n\} = B) = \frac{k}{n}, \tag{33}$$

where k is the number of times a occurs in B.

THE BACKWARD-LOOKING BETTING PROTOCOL
Players: Joe, Bill
$\mathcal{K}_N := 1$.
Joe announces a bag B_N of size N.
FOR $n = N, N-1, \dots, 2, 1$
Bill bets on z_n at odds set by (33).
Joe announces $z_n \in B_n$.
$\mathcal{K}_{n-1} := \mathcal{K}_n +$ Bill's net gain.
$B_{n-1} := B_n \setminus \{z_n\}$.

Bill's initial capital $\mathcal{K}_N$ is 1. His final capital is $\mathcal{K}_0$.

Given an event E, set

$$e := \begin{cases} 1 & \text{if } E \text{ happens} \\ 0 & \text{if } E \text{ fails.} \end{cases}$$

Given events $E_1,\dots,E_N$, set

$$\text{Freq}_N := \frac{1}{N}\sum_{j=1}^{N} e_j.$$

This is the fraction of the events that happen—the frequency with which they happen. Our game-theoretic law of large numbers will say that if each E_n is an ε-rare n-event, then it is very unlikely that Freq_N will substantially exceed ε.

In game-theoretic probability, what do we mean when we say an event E is "very unlikely"? We mean that the bettor, Bill in this protocol, has a betting strategy that guarantees

$$\mathcal{K}_0 \geq \begin{cases} C & \text{if } E \text{ happens} \\ 0 & \text{if } E \text{ fails,} \end{cases} \tag{34}$$

where C is a large positive number. Cournot's principle, which says that Bill will not multiply his initial unit capital by a large factor without risking bankruptcy, justifies our thinking E unlikely. The larger C, the more unlikely E. We call the quantity

$$\overline{\text{P}}E := \inf\left\{ \frac{1}{C} \;\middle|\; \text{Bill can guarantee (34)} \right\} \tag{35}$$

E's *upper probability*. An unlikely event is one with small upper probability.

Proposition 4 (Game-theoretic weak law of large numbers) *Suppose E_n is an ε-rare n-event, for $n = 1,\dots,N$. Suppose $\varepsilon < 1/2$, $\delta_1 > 0$, $\delta_2 > 0$, and $N \geq 1/\delta_1\delta_2^2$. Then*

$$\overline{\mathrm{P}}(\mathrm{Freq}_N \geq \varepsilon + \delta_2) \leq \delta_1.$$

In words: If N is sufficiently large, there is a small (less than δ_1) upper probability that the frequency will exceed ε substantially (by more than δ_2).

Readers familiar with game-theoretic probability will recognize Proposition 4 as a form of the game-theoretic weak law of large numbers (Shafer and Vovk, 2001, pp. 124–126). The bound it gives for the upper probability of the event $\mathrm{Freq}_N \geq \varepsilon + \delta_2$ is the same as the bound that Chebyshev's inequality gives for the probability of this event in classical probability theory when the E_n are independent and all have probability ε.

For the benefit of those not familiar with the concepts of game-theoretic probability used in the proof just cited, we now give an elementary and self-contained proof of Proposition 4.

Lemma 5 *Suppose, for $n = 1,\dots,N$, that E_n is an ε-rare n-event. Then Bill has a strategy that guarantees that his capital $\mathcal{K}_n$ will satisfy*

$$\mathcal{K}_n \geq \frac{n}{N} + \frac{1}{N}\left(\left(\sum_{j=n+1}^{N}(e_j - \varepsilon)\right)^+\right)^2 \tag{36}$$

for $n = 1,\dots,N$, where $t^+ := \max(t,0)$.

Proof When $n = N$, (36) reduces to $\mathcal{K}_N \geq 1$, and this certainly holds; Bill's initial capital $\mathcal{K}_N$ is equal to 1. So it suffices to show that if (36) hold for n, then Bill can bet on E_n in such a way that the corresponding inequality for $n-1$,

$$\mathcal{K}_{n-1} \geq \frac{n-1}{N} + \frac{1}{N}\left(\left(\sum_{j=n}^{N}(e_j - \varepsilon)\right)^+\right)^2, \tag{37}$$

also holds. Here is how Bill bets.

- If $\sum_{j=n+1}^{N}(e_j - \varepsilon) \geq \varepsilon$, then Bill buys $(2/N)\sum_{j=n+1}^{N}(e_j - \varepsilon)$ units of e_n. By assumption, he pays no more than ε for each unit. So we have a lower bound on his net gain, $\mathcal{K}_{n-1} - \mathcal{K}_n$:

$$\begin{aligned}
\mathcal{K}_{n-1} - \mathcal{K}_n &\geq \frac{2}{N}\left(\sum_{j=n+1}^{N}(e_j - \varepsilon)\right)(e_n - \varepsilon) \\
&\geq \frac{1}{N}\left(\sum_{j=n}^{N}(e_j - \varepsilon)\right)^2 - \frac{1}{N}\left(\sum_{j=n+1}^{N}(e_j - \varepsilon)\right)^2 - \frac{1}{N} \\
&\geq \frac{1}{N}\left(\left(\sum_{j=n}^{N}(e_j - \varepsilon)\right)^+\right)^2 - \frac{1}{N}\left(\left(\sum_{j=n+1}^{N}(e_j - \varepsilon)\right)^+\right)^2 - \frac{1}{N}.
\end{aligned} \tag{38}$$

Adding (38) and (36), we obtain (37).

- If $\sum_{j=n+1}^{N}(e_j-\varepsilon)<\varepsilon$, then Bill does not bet at all, and $\mathcal{K}_{n-1}=\mathcal{K}_n$. Because

$$\left(\left(\sum_{j=n}^{N}(e_j-\varepsilon)\right)^+\right)^2-\left(\left(\sum_{j=n+1}^{N}(e_j-\varepsilon)\right)^+\right)^2\le(\varepsilon+(e_n-\varepsilon))^2\le 1,$$

  we again obtain (37) from (36).

■

Proof of Proposition 4 The inequality $\mathrm{Freq}_N\ge\varepsilon+\delta_2$ is equivalent to

$$\frac{1}{N}\left(\left(\sum_{j=1}^{N}(e_j-\varepsilon)\right)^+\right)^2\ge N\delta_2^2. \tag{39}$$

Bill's strategy in Lemma 5 does not risk bankruptcy (it is obvious that $\mathcal{K}_n\ge 0$ for all n), and (36) says

$$\mathcal{K}_0\ge\frac{1}{N}\left(\left(\sum_{j=1}^{N}(e_j-\varepsilon)\right)^+\right)^2. \tag{40}$$

Combining (39) and (40) with the assumption that $N\ge 1/\delta_1\delta_2^2$, we see that when the event $\mathrm{Freq}_N\ge\varepsilon+\delta_2$ happens, $\mathcal{K}_0\ge 1/\delta_1$. So by (34) and (35), $\overline{\mathrm{P}}(\mathrm{Freq}_N\ge\varepsilon+\delta_2)\le\delta_1$. ■

A.3 The Independence of Hits for Fisher's Interval

Recall that if $z_1,\dots,z_n,z_{n+1}$ are independent normal random variables with mean 0 and standard deviation 1, the distribution of the ratio

$$\frac{z_{n+1}}{\sqrt{\sum_{i=1}^{n}z_i^2/n}} \tag{41}$$

is called the *t-distribution with n degrees of freedom*. The upper percentile points for this distribution, the points t_n^ε exceeded by (41) with probability exactly ε, are readily available from textbooks and standard computer programs.

Given a sequence of numbers $z_1,\dots,z_l$, where $l\ge 2$, we set

$$\bar{z}_l:=\frac{1}{l}\sum_{i=1}^{l}z_i\qquad\text{and}\qquad s_l^2:=\frac{1}{l-1}\sum_{i=1}^{l}(z_i-\bar{z}_l)^2.$$

As we recalled in §2.1.1, R. A. Fisher proved that if $n\ge 3$ and $z_1,\dots,z_n$ are independent and normal with a common mean and standard deviation, then the ratio t_n given by

$$t_n:=\frac{z_n-\bar{z}_{n-1}}{s_{n-1}}\sqrt{\frac{n-1}{n}} \tag{42}$$

has the t-distribution with $n-2$ degrees of freedom (Fisher, 1935). It follows that the event

$$\bar{z}_{n-1} - t_{n-2}^{\varepsilon/2}\, s_{n-1} \sqrt{\frac{n}{n-1}} \le z_n \le \bar{z}_{n-1} + t_{n-2}^{\varepsilon/2}\, s_{n-1} \sqrt{\frac{n}{n-1}} \tag{43}$$

has probability $1-\varepsilon$. We will now prove that the t_n for successive n are independent. This implies that the events (43) for successive values of n are independent, so that the law of large numbers applies: with very high probability approximately $1-\varepsilon$ of these events will happen. This independence was overlooked by Fisher and subsequent authors.

We begin with two purely arithmetic lemmas, which do not rely on any assumption about the probability distribution of $z_1, \dots, z_n$.

Lemma 6 *The ratio t_n given by (42) depends on $z_1, \dots, z_n$ only through the ratios among themselves of the differences*

$$z_1 - \bar{z}_n, \dots, z_n - \bar{z}_n.$$

Proof It is straightforward to verify that

$$z_n - \bar{z}_{n-1} = \frac{n}{n-1}\,(z_n - \bar{z}_n) \tag{44}$$

and

$$s_{n-1}^2 = \frac{(n-1)s_n^2}{n-2} - \frac{n(z_n-\bar{z}_n)^2}{(n-1)(n-2)}. \tag{45}$$

Substituting (44) and (45) in (42) produces

$$t_n = \frac{\sqrt{n(n-2)}(z_n-\bar{z}_n)}{\sqrt{(n-1)^2 s_n^2 - n(z_n-\bar{z}_n)^2}} \tag{46}$$

or

$$t_n = \frac{\sqrt{n(n-2)}(z_n-\bar{z}_n)}{\sqrt{(n-1)\sum_{i=1}^n (z_i-\bar{z}_n)^2 - n(z_n-\bar{z}_n)^2}}. \tag{47}$$

The value of (47) is unaffected if all the $z_i - \bar{z}_n$ are multiplied by a nonzero constant. ■

Lemma 7 *Suppose $\bar{z}_n$ and s_n are known. Then the following three additional items of information are equivalent, inasmuch as the other two can be calculated from any of the three:*

1. z_n
2. $\bar{z}_{n-1}$ *and* s_{n-1}
3. t_n

Proof Given z_n, we can calculate $\bar{z}_{n-1}$ and s_{n-1} from (44) and (45) and then calculate t_n from (42). Given $\bar{z}_{n-1}$ and s_{n-1}, we can calculate z_n from (44) or (45) and then t_n from (42). Given t_n, we can invert (46) to find z_n (when $\bar{z}_n$ and s_n are fixed, this equation expresses t_n as a monotonically increasing function of z_n) and then calculate $\bar{z}_{n-1}$ and s_{n-1} from (44) and (45). ■

Now we consider probability distributions for $z_1, \dots, z_n$.

Lemma 8 *If $z_1,\dots,z_n$ are independent and normal with a common mean and standard deviation, then conditional on $\bar{z}_n = w$ and $\sum_{i=1}^n (z_i - \bar{z}_n)^2 = r^2$, the vector $(z_1,\dots,z_n)$ is distributed uniformly over the $(n-2)$-dimensional sphere of vectors satisfying these conditions (the intersection of the hyperplane $\bar{z}_n = w$ with the $(n-1)$-dimensional sphere of radius r centered on the point $(w,\dots,w)$ in $\mathbb{R}^n$).*

Proof The logarithm of the joint density of $z_1,\dots,z_n$ is

$$-\frac{n}{2}\log(2\pi\sigma^2) - \frac{1}{2\sigma^2}\sum_{i=1}^n (z_i-\mu)^2 = -\frac{n}{2}\log(2\pi\sigma^2) - \frac{1}{2\sigma^2}\left(\sum_{i=1}^n (z_i-\bar{z}_n)^2 + n(\bar{z}_n-\mu)^2\right), \quad (48)$$

where μ and σ are the mean and standard deviation, respectively. Because this depends on $(z_1,\dots,z_n)$ only through $\bar{z}_n$ and $\sum_{i=1}^n (z_i-\bar{z}_n)^2$, the distribution of $(z_1,\dots,z_n)$ conditional on $\bar{z}_n = w$ and $\sum_{i=1}^n (z_i - \bar{z}_n)^2 = r^2$ is uniform over the set of vectors satisfying these conditions. ■

Lemma 9 *If the vector $(z_1,\dots,z_n)$ is distributed uniformly over the $(n-2)$-dimensional sphere defined by the conditions $\bar{z}_n = w$ and $\sum_{i=1}^n (z_i-\bar{z}_n)^2 = r^2$, then t_n has the t-distribution with $n-2$ degrees of freedom.*

Proof The distribution of t_n does not depend on w or r. This is because we can transform the uniform distribution over one $(n-2)$-dimensional sphere in $\mathbb{R}^n$ into a uniform distribution over another by adding a constant to all the z_i and then multiplying the differences $z_i - \bar{z}_n$ by a constant, and by Lemma 6, this will not change t_n.

Now suppose $z_1,\dots,z_n$ are independent and normal with a common mean and standard deviation. Lemma 8 says that conditional on $\bar{z}_n = w$ and $(n-1)s_n^2 = r^2$, the vector $(z_1,\dots,z_n)$ is distributed uniformly over the sphere of radius r centered on $w,\dots,w$. Since the resulting distribution for t_n does not depend on w or r, it must be the same as the unconditional distribution. ■

Lemma 10 *Suppose $(z_1,\dots,z_N)$ is distributed uniformly over the $N-2$-dimensional sphere defined by the conditions $\bar{z}_n = w$ and $\sum_{i=1}^n (z_i-\bar{z}_n)^2 = r^2$. Then $t_3,\dots,t_N$ are mutually independent.*

Proof It suffices to show that t_n still has the t-distribution with $n-2$ degrees of freedom conditional on $t_{n+1},\dots,t_N$. This will imply that t_n is independent of $t_{n+1},\dots,t_N$ and hence that all the t_n are mutually independent.

We start knowing $\bar{z}_N = r$ and $s_N = w$. So by Lemma 7, learning $t_{n+1},\dots,t_N$ is the same as learning $z_{n+1},\dots,z_N$. Geometrically, when we learn z_N we intersect our $(N-1)$-dimensional sphere in $\mathbb{R}^N$ with a hyperplane, reducing it to an $(N-2)$-dimensional sphere in $\mathbb{R}^{N-1}$. (Imagine, for example, intersecting a sphere in $\mathbb{R}^3$ with a plane: the result is a circle.) When we learn z_{N-1}, we reduce the dimension again, and so on. In each case, we obtain a uniform distribution on the lower-dimensional sphere for the remaining z_i. In the end, we find that $(z_1,\dots,z_n)$ is distributed uniformly over an $(n-1)$-dimensional sphere in $\mathbb{R}^n$, and so t_n has the t-distribution with $n-2$ degrees of freedom by Lemma 9. ■

Proposition 11 *Suppose $z_1, \ldots, z_N$ are independent and normal with a common mean and standard deviation. Then $t_3, \ldots, t_N$ are mutually independent.*

Proof By Lemma 10, $t_3, \ldots, t_N$ are mutually independent conditional on $\bar{z}_N = w$ and $s_N = r$, each t_n having the t-distribution with $n-2$ degrees of freedom. Because this joint distribution for $t_3, \ldots, t_N$ does not depend on w or r, it is also their unconditional joint distribution. ■

Abstract

This paper presents the dynamics of multiple learning agents from an evolutionary game theoretic perspective. We provide replicator dynamics models for cooperative coevolutionary algorithms and for traditional multiagent Q-learning, and we extend these differential equations to account for lenient learners: agents that forgive possible mismatched teammate actions that resulted in low rewards. We use these extended formal models to study the convergence guarantees for these algorithms, and also to visualize the basins of attraction to optimal and suboptimal solutions in two benchmark coordination problems. The paper demonstrates that lenience provides learners with more accurate information about the benefits of performing their actions, resulting in higher likelihood of convergence to the globally optimal solution. In addition, the analysis indicates that the choice of learning algorithm has an insignificant impact on the overall performance of multiagent learning algorithms; rather, the performance of these algorithms depends primarily on the level of lenience that the agents exhibit to one another. Finally, the research herein supports the strength and generality of evolutionary game theory as a backbone for multiagent learning.

Keywords: multiagent learning, reinforcement learning, cooperative coevolution, evolutionary game theory, formal models, visualization, basins of attraction

1. Introduction

Multiagent learning is a relatively new research area that has witnessed a significant research effort in the past decade. Work in this area is motivated by the wide-applicability of multiagent systems to a large set of complex real-world problem domains, as well as by the difficulty of hard-coding solutions for such distributed approaches (Panait and Luke, 2005a). Multiagent learning techniques have been successfully applied to domains such as multi-rover coordination (Tumer and Agogino, 2007; Knudson and Tumer, 2007), congestive games (Agogino and Tumer, 2006), air traffic control (Agogino and Tumer, 2007), and spacecraft power management (Airiau et al., 2006), to name but a few. Moreover, the formal analysis in Jansen and Wiegand (2003, 2004) demonstrated that these

techniques' strengths rely on the decomposition of the problem into simpler subproblems that can be explored separately, resulting at times in significant speedups over traditional learning algorithms. It is no surprise, then, that such techniques have also been successfully applied to problems outside of the multiagent systems realm, such as the discovery of cascade neural networks for classification tasks (Potter and Jong, 2000), the optimization of inventory control (Eriksson and Olsson, 1997), and the coevolution of neural networks for pole balancing (Gomez et al., 2006).

Multiagent learning is, however, a very challenging problem. Agents typically have limited knowledge of even which actions their teammates are currently performing, and must act not only in a constantly changing environment but one which may be actively *co-adapting* to the agents' actions, often in ways they cannot fully perceive (Panait and Luke, 2005a). Even when agents are notionally *cooperating* with one another, their limited perception capabilities can give rise to phenomena that hinder the agents' ability to coordinate effectively. Such dynamics are still not well understood formally.

Recent research has highlighted a tendency for multiagent learning algorithms to converge to suboptimal solutions, which is in marked contrast to the well-established convergence guarantees of their single-agent counterparts. For example, straightforward extensions of Q-learning to multi-agent systems fail to reach the optimal policy in fairly simple domains (Claus and Boutilier, 1998; Kapetanakis and Kudenko, 2002), despite Q-learning's convergence guarantees in single-agent domains (Sutton and Barto, 1998; Watkins and Dayan, 1992). Similarly, cooperative coevolutionary algorithms Potter and Jong (1994); Potter (1997) can not only converge but also be *attracted to* joint suboptima in the search space (Wiegand, 2004), despite traditional evolutionary algorithms being guaranteed to converge to the global optimum when given enough time and sufficient random exploration (Vose, 1999). Different reasons account for this: other agents are learning as well; the reinforcement an agent receives depends on the actions taken by the other agents; and not all information is observable. Such features make it very difficult to engineer learning algorithms capable of finding optimal solutions under these conditions.

This paper presents a theoretical foundation for multiagent learning in coordination games with no internal state; we only consider symmetric games where all agents receive equal reward. This foundation may be directly applied to two popular algorithms: cooperative coevolutionary algorithms (CCEAs) and multiagent Q-learning. These two techniques are representative of the two families (evolutionary algorithms and multiagent reinforcement learning) which form the bulk of the cooperative multiagent learning field (Panait and Luke, 2005a). In both of these algorithms it is common for an agent to base its assessment of a particular action on the expected reward received for that action. For example, a reinforcement learning agent usually updates its estimate for an action's utility every time[1] that action is performed in the environment, despite the dependence of the reward on the actions performed by the other agents. The formal analysis in this paper demonstrates that the reinforcement provided by the expected reward might be the primary cause for many observed problems with multiagent learning.

The paper applies a new theoretical framework to argue for a different approach to these problems, in which each agent tends to *ignore* lower rewards garnered by a particular action. We call this approach *lenience*: each agent shows lenience to its teammates by ignoring low rewards due to actions chosen by teammates that are poor matches to the agent's current action. For example, consider a simple scenario where agents A_1 and A_2 learn to play soccer together. Let's assume that they

1. This mechanism is essentially equivalent (over time) to using the expected reward.

do not have any *a priori* information about each other's skills. At some point, A_1 attempts a pass that should allow A_2 to receive the ball in a very favorable position (for example, alone with the goalie). However, A_2 is not able to receive the ball properly because he was not expecting the pass, or simply because A_2 has not learned the ball reception skill. Given the failure of their collaboration in this particular instance, should A_1 assume that the pass was bad in general and that it should be avoided in the future (due to the low reward the agents just received)? This is the approach usually taken by straightforward extensions of single-agent learning algorithms to multiagent domains. Alternatively, we argue that A_1 might benefit from showing lenience towards his teammate by completely ignoring the low reward observed following A_2's mistake, and only hope that A_2 will perform better once it learns to play better. In other words, A_1 might assume that the pass was good, and that the low reward is primarily due to A_2 not having learned the skill yet. With time, A_1 will be able to distinguish between good and bad passes based on A_2's future performance.

Lenience is particularly important early in the game, when the agents have not yet identified high-performing actions and so the average reward of a given action can be misleadingly low due to partnering with poor-performing joint actions. In previous work, we have demonstrated the efficacy of algorithms based on this notion: specifically, the Lenient Multiagent Q-learning algorithm (Panait et al., 2006) and the iCCEA algorithm (Panait and Luke, 2006). Here, we will establish a more formal justification for the effectiveness of lenience in multiagent learning, accompanied by an intuitive visualization of the impact that lenience has onto the tendency of these algorithms to converge to suboptimal solutions.

The remainder of this paper is structured as follows. Section 2 introduces basic formal models and background material, and describe the pathologies. In Section 3 we argue that lenience will benefit agents in overcoming such problems. Sections 4 and 5 present enhanced theoretical models of the multiagent learning paradigms. Finally, Section 6 concludes the paper and suggests directions for future research.

2. Background

This paper presents a formal analysis of two multiagent learning algorithms: cooperative coevolutionary algorithms and multiagent Q-learning. Sections 2.1.1 and 2.1.2 briefly describe each of them. Following, Sections 2.2.1 and 2.2.2 introduce the basics of the replicator equations both in discrete and continuous time. Sections 2.3.1 and 2.3.2 present two evolutionary game theory models that capture the dynamics of the two learning algorithms, that is, CCEA and multiagent Q-learning. These replicator dynamics (RD) models represent the foundation for our work and will be extended in Section 3 to account for lenience. More details on both models can be found in Wiegand (2004), Tuyls et al. (2006) and Tuyls et al. (2003).

2.1 Multiagent Learning Methods

This section provides a brief overview of two multiagent learning algorithms.

2.1.1 COOPERATIVE COEVOLUTIONARY ALGORITHMS

Evolutionary algorithms are beam search methods that employ and refine sets of candidate solutions to a given problem. The terminology in the field is borrowed from biology to reflect the main source of inspiration (Darwin's models for evolution) for these techniques; for example, candidate

solutions are termed *individuals*, sets of individuals are known as *populations*, and the creation of new solutions from previous ones is usually referred to as *breeding*.

An evolutionary algorithm begins with an initial population of random individuals. Each member of this population is then evaluated and assigned a *fitness* (a quality assessment). The algorithm then selects a set of fitter-than-average parents and alters them via *crossover* and *mutation* operations to produce a set of children, which are added to the population, replacing older, less fit individuals. One evaluation, selection, and breeding cycle is known as a *generation*. Successive generations continue to refine the population until time is exhausted, or until a sufficiently fit individual is discovered. For additional information, interested readers are referred to Jong (2006).

Coevolution is an intuitive extension of evolutionary algorithms for domains with multiple learning agents. Cooperative coevolutionary algorithms (CCEAs) are a popular approach for domains where agents succeed or fail together (Husbands and Mill, 1991; Potter and Jong, 1994). Here, each agent is given its own population[2] of individuals, each such individual representing a possible behavior for that agent. CCEAs usually assume that only the performance of the entire team can be assessed; as a consequence, one individual (behavior) for each of the team members is required for evaluation. Fitness assessment works as follows: for each individual i in an agent's population, one or more tuples are formed using i and individuals (termed *collaborators*) from the other agents' populations (either from the current generation, or from the previous one). These collaborators can be sampled randomly or selected based on performance (if the collaborators were evaluated in the previous generation, the better ones might be used preferentially). The fitness of i is then computed based on the performance obtained from evaluating the teams with the behaviors indicated by these tuples. As a consequence, the fitness assessment is context-sensitive and subjective. Aside from evaluation, the learning processes are independent of one another. The populations evolve concurrently (this is closer to the asynchronous nature of multiagent systems). Potter (1997), Potter and Jong (2000) and Wiegand (2004) provide comprehensive overviews of cooperative coevolutionary algorithms.

2.1.2 MULTIAGENT Q-LEARNING

Q-learning (Watkins, 1989; Sutton and Barto, 1998) is particularly useful in domains where reinforcement information (expressed as penalties or rewards) is stochastic and is observed after a sequence of actions has been performed. The algorithm associates a utility (or *Q*uality) Q with each (s,a) pair, where s is a state of the environment, and a is an action that the agent can perform when in state s. The agent updates the Q-values at each time step based on the reinforcement it has received. The update formula is

$$Q(s_t,a_t) \leftarrow Q(s_t,a_t) + \alpha\left(r_{t+1} + \gamma \max_a Q(s_{t+1},a) - Q(s_t,a_t)\right)$$

where the agent has just been in state s_t, has performed action a_t, has observed reward r_t, and has transitioned to the new (current) state s_{t+1}; α is the learning rate, and γ is a discount factor (bounded between 0 and 1) for incorporating future rewards into the utility estimate. Note that $Q(s_t,a_t)$ does not only depend on the immediate reward r_{t+1} observed by the agent, but also on future rewards (via the $\max_a Q(s_{t+1},a)$ term). The discount factor γ controls the impact of future versus immediate

2. Given this assumption that each agent has its own population, we sometimes use the term *population* instead of *agent* when the context deems it more appropriate.

rewards onto the *Q*uality terms: lower values of γ reduce the impact of future rewards onto the quality estimate for a state-action pair.

Action selection in Q-learning is usually based on a stochastic process; popular choices include ε-*greedy exploration* (select the best action with probability $1-\varepsilon$, or a random action otherwise) and *Boltzmann exploration* (the selection process further depends on a "temperature" parameter). As previously mentioned, Q-learning has certain guarantees of convergence under theoretical conditions, which include performing each action an infinite number of times in each state, as well as proper settings for the learning rate (Singh et al., 2000; Watkins and Dayan, 1992).

Multiagent Q-learning is a straightforward extension of Q-learning to domains involving multiple agents (Claus and Boutilier, 1998). Here, each agent is given its own Q-value function for (s,a) pairs. All agents choose their actions independently and concurrently, perform them in parallel, and observe the same reward associated with the joint action. In contrast to single-agent Q-learning, the information an agent observes depends on the actions chosen by other agents. The reward information is then used by each agent to update its Q-values. Agents usually cannot perceive which actions their teammates have chosen.

To simplify the theoretical analysis, we assume that agents choose actions by using the Boltzmann selection: an action a_k is chosen with probability

$$P(a_k) = \frac{e^{\frac{Q(s,a_k)}{\tau}}}{\sum_i e^{\frac{Q(s,a_i)}{\tau}}} \tag{1}$$

where τ is a temperature parameter used to balance exploration and exploitation (the agent tends to select actions associated with higher utilities when τ is low).

2.2 The Replicator Dynamics

John Maynard Smith introduced Evolutionary Game Theory (EGT) by applying traditional game theory to Biology (Smith, 1982; Maynard Smith and Price, 1973). EGT is particularly well-suited as a model of cooperative learning agents. In EGT, each agent holds a vector of proportions over possible actions, indicating the proportion of "individuals" or "replicators" in an infinite "population" (the agent) which have adopted a given action. EGT also commonly presumes one or more matrixes that represent the performance of actions in the context of actions of the other agents. Each timestep, the proportions of actions for each agent are changed based on the rewards in the matrix as well as on the current probabilities of other agents' choosing their actions.

Replicator dynamics (RD) is a key concept in EGT to express the adaptation of each population over time. RD can be represented either in discrete or continuous time. We elaborate on both forms of RD, starting with the discrete time version. In essence the replicator equations describe how a population of different actions evolves through time. An abstraction of an evolutionary process usually combines two basic elements: selection and mutation. Selection favors some population actions over others, while mutation provides variety in the population. The most basic form of RD only highlights the role of selection, that is, how the most fit actions in a population are selected.

2.2.1 DISCRETE TIME REPLICATOR DYNAMICS

Suppose there is a single population of actions (or replicators) and consider a discrete time process $t = 1,2,\ldots$. Let $A = (a_{ij})_{i,j=1}^{n}$ be the reward matrix ($a_{ij} \geq 0$ is the reward for the joint action (i,j),

and n is the total number of possible actions). Let us assume that the individuals in the population (considered infinite) represent different actions that the agent can perform. The state of the population can be described by a vector $x(t) = (x_1(t), ..., x_n(t))$, where $x_i(t)$ denotes the proportion of individual i in the population (it is also directly related to the probability that the agent will select action i).

At each time step t, the state $x(t)$ of the population changes according to the fitness values of the different individuals. More precisely, the expected number of offsprings for a single individual representing action i equals the ratio between the expected payoff for such an individual, $\sum_{j=1}^{n} a_{ij}x_j(t)$, and the average payoff $\sum_{k=1}^{n} x_k(t)\left(\sum_{j=1}^{n} a_{kj}x_j(t)\right)$ for all individuals in the population. Therefore, the ratio $x_i(t+1)$ of individuals representing action i at the next time step equals:

$$x_i(t+1) = x_i(t)\frac{\sum_{j=1}^{n} a_{ij}x_j(t)}{\sum_{k=1}^{n} x_k(t)\left(\sum_{j=1}^{n} a_{kj}x_j(t)\right)}.$$

Dividing both sides by $x_i(t)$ leads to:

$$\frac{x_i(t+1)}{x_i(t)} = \frac{\sum_{j=1}^{n} a_{ij}x_j(t)}{\sum_{k=1}^{n} x_k(t)\left(\sum_{j=1}^{n} a_{kj}x_j(t)\right)}.$$

A minor manipulation of the fractions leads to the general discrete time replicator dynamics:

$$\frac{\Delta x_i(t)}{x_i(t)} = \frac{\sum_{j=1}^{n} a_{ij}x_i(t) - x(t)Ax(t)}{x(t)Ax(t)}.$$

This system of equations expresses Darwinian selection as follows: the rate of change Δx_i of a particular action i is the difference between its average payoff, $\sum_{j=1}^{n} a_{ij}x_i(t)$, and the average payoffs for all actions, $x(t)Ax(t)$.

2.2.2 CONTINUOUS TIME REPLICATOR DYNAMICS

From a mathematical viewpoint, it is usually more convenient to work in continuous time. Therefore we now derive the continuous version of the above replicator equations. To do this we make time infinitesimal. More precisely, suppose that the amount of time that passes between two periods is given by δ with $\delta \in [0,1]$. We also assume that during a time period δ, only a fraction δ of the individuals die and generate offspring. Then the above equation can be rewritten as follows:

$$\frac{\Delta x_i(t)}{x_i(t)} = \frac{x_i(t+\delta) - x_i(t)}{x_i(t)} = \frac{\sum_{j=1}^{n} \delta a_{ij}x_i(t) - x(t)\delta Ax(t)}{x(t)\delta Ax(t) + (1-\delta)}.$$

Now, at the limit when δ approaches 0, the continuous replicator equations are:

$$\frac{dx_i}{dt} = \left[\sum_{j=1}^{n} a_{ij}x_i - x \cdot Ax\right] x_i$$

which can be rewritten as:

$$\frac{dx_i}{dt} = [(Ax)_i - x \cdot Ax]\, x_i. \tag{2}$$

In Equation 2, x_i represents the density of action i in the population, and A is the payoff matrix that describes the different payoff values that each individual replicator receives when interacting with other replicators in the population. The state x of the population can be described as a probability vector $x = (x_1, x_2, ..., x_n)$ which expresses the different densities of all the different types of replicators in the population. Hence $(Ax)_i$ is the payoff that replicator i receives in a population with state x and $x \cdot Ax$ describes the average payoff in the population. The growth rate $\frac{\frac{dx_i}{dt}}{x_i}$ of the proportion of action i in the population equals the difference between the action's current payoff and the average payoff in the population. Gintis (2001), Hofbauer and Sigmund (1998) and Weibull (1996) detail further information on this issues.

2.3 EGT Models for Multiagent Learning Algorithms

This paper is concerned with formal models of multiple agents that learn concurrently. For simplicity, the discussion focuses on only two such learning agents in a symmetric game (both agents receive the same payoff). As a result, we need two systems of differential equations, one for each agent. This setup corresponds to an RD for asymmetric games, where the available actions or strategies of the agents to belong to two different population. For example, consider the case of extending the continuous RD model to a multiagent learning scenario involving a two-player symmetric game with two agents, and consider that A^T is the payoff matrix that describes the reinforcements received by the second agent. Then, another equation similar to Equation 2 would emerge again to characterize the dynamics of the second learner.

This translates into the following replicator equations for the two populations:

$$\frac{dp_i}{dt} = [(Aq)_i - p \cdot Aq]p_i, \tag{3}$$

$$\frac{dq_i}{dt} = [(A^T p)_i - q \cdot A^T p]q_i. \tag{4}$$

Equations 3 and 4 indicate that the growth rate of the types in each population is additionally determined by the composition of the other population, in contrast to the single population (learner) case described by Equation 2.

Next, we present two EGT models for multiagent learning. First, Section 2.3.1 presents a model for cooperative coevolutionary algorithms, which is based on the discrete time RD model in Section 2.2.1. Then, Section 2.3.2 presents a model for multiagent Q-learning, which is based on the continuous time RD model in Section 2.2.2.

2.3.1 EGT MODEL FOR COOPERATIVE COEVOLUTIONARY ALGORITHMS

Wiegand (2004) describes an evolutionary game theoretic model for cooperative coevolutionary algorithms. The model applies to stateless domains involving only two agents, and where each agent has a finite set of actions to choose from. The two populations (one per agent) contain individuals, each of them representing an action that the agent might perform. The model further assumes that the two populations are infinite, and it computes the proportions of individuals in the populations at each generation. If the first agent has a finite number n of distinct actions to choose from, its population at each generation is an element of the set $\Delta^n = \{x \in [0,1]^n \mid \sum_{i=1}^n x_i = 1\}$. A higher proportion x_i indicates that the agent is more likely to choose action i. Given that the second agent might have a different set (of size m) of actions to choose from, its population is an element of the

set $\Delta^m = \left\{ y \in [0,1]^m \mid \sum_{j=1}^m y_j = 1 \right\}$. The fitness computation in the EGT model involves the game payoff matrix A, where the a_{ij} element represents the reward for the joint action (i, j). Assuming both agents are equally rewarded, A is used to compute the fitnesses in one population, and the transpose of A is used for the other population (as in Section 2.3). Equations 5–8 describe the EGT model for CCEAs, as expressed in Wiegand (2004):

$$u_i^{(t)} = \sum_{j=1}^{m} a_{ij} y_j^{(t)}, \tag{5}$$

$$w_j^{(t)} = \sum_{i=1}^{n} a_{ij} x_i^{(t)}, \tag{6}$$

$$x_i^{(t+1)} = \left(\frac{u_i^{(t)}}{\sum_{k=1}^{n} x_k^{(t)} u_k^{(t)}} \right) x_i^{(t)}, \tag{7}$$

$$y_j^{(t+1)} = \left(\frac{w_j^{(t)}}{\sum_{k=1}^{m} y_k^{(t)} w_k^{(t)}} \right) y_j^{(t)} \tag{8}$$

where $x^{(t)}$ and $y^{(t)}$ represent the proportions of genotypes (actions) in the two populations at generation t, and $x^{(t+1)}$ and $y^{(t+1)}$ represent the new proportions at the next generation $t+1$. For simplicity, the equations only model the dynamics of cooperative coevolutionary systems under the pressure of selection.

The EGT model can be separated into two phases. First, the fitness of each action is computed for the two populations (Equations 5 and 6). The fitness of action i is estimated as the mean payoff over pairwise collaborations with every action in the other population. Note that this computation uses the proportions of each action in the (infinite) populations. Second, the distributions of the two populations at the next generation are computed (Equations 7 and 8 model the effects of fitness proportional selection).

2.3.2 EGT MODEL FOR MULTIAGENT Q-LEARNING

This section introduces the RD model of Multiagent Q-learning. For a complete mathematical derivation of it, please refer to Tuyls et al. (2006, 2003). Basically, the derivation boils down to constructing a continuous time limit of the Q-learning model (in the same manner as when going from the discrete replicator equations to the continuous version), where Q-values are interpreted as Boltzmann probabilities for the action selection. For simplicity, we only consider games between two agents, and assume that the game is stateless: the reward that the agents receive depends solely on the actions they have currently performed in the environment. We admit up front that such scenarios are unrealistic for practical purposes, but they are complex enough to emphasize specific challenges for multiagent reinforcement learning algorithms. For this reason, several previous empirical investigations of these techniques have employed such domains (for example, by Claus and Boutilier 1998, Kapetanakis and Kudenko 2002 and Lauer and Riedmiller 2000).

Each agent has a probability vector over its action set, more precisely $x_1, \ldots, x_n$ over action set $a_1, \ldots, a_n$ for the first agent and $y_1, \ldots, y_m$ over $b_1, \ldots, b_m$ for the second agent. Equation 1 can also be rewritten as follows:

$$x_i(k) = \frac{e^{\frac{Qa_i(k)}{\tau}}}{\sum_{j=1}^{n} e^{\frac{Qa_j(k)}{\tau}}}$$

where $x_i(k)$ is the probability of playing action i at time step k and τ is the temperature. Now we can find an expression for, $x_i(k+1)$:

$$\begin{aligned}\frac{x_i(k+1)}{x_i(k)} &= \frac{e^{\frac{Qa_i(k+1)}{\tau}}\sum_j e^{\frac{Qa_j(k)}{\tau}}}{e^{\frac{Qa_i(k)}{\tau}}\sum_j e^{\frac{Qa_j(k+1)}{\tau}}} \\ &= \frac{e^{\frac{\Delta Qa_i(k)}{\tau}}}{\sum_j x_j(k) e^{\frac{\Delta Qa_j(k)}{\tau}}}\end{aligned}$$

from which follows that

$$x_i(k+1) = x_i(k)\frac{e^{\frac{\Delta Qa_i(k)}{\tau}}}{\sum_j x_j(k) e^{\frac{\Delta Qa_j(k)}{\tau}}}.$$

Considering the difference equation for x_i, we have that

$$\begin{aligned}x_i(k+1) - x_i(k) &= \frac{x_i(k) e^{\frac{\Delta Qa_i(k)}{\tau}}}{\sum_j x_j(k) e^{\frac{\Delta Qa_j(k)}{\tau}}} - x_i(k) \\ &= x_i(k)\left(\frac{e^{\frac{\Delta Qa_i(k)}{\tau}} - \sum_j x_j(k) e^{\frac{\Delta Qa_j(k)}{\tau}}}{\sum_j x_j(k) e^{\frac{\Delta Qa_j(k)}{\tau}}}\right).\end{aligned}$$

For the continuous time version, suppose that the amount of time that passes between two repetitions of the game is given by δ with $0 < \delta \leq 1$. The variable $x_i(k\delta)$ describes the x-values at time $k\delta = t$. Under these assumptions, it follows that

$$\begin{aligned}\frac{x_i(k\delta+\delta) - x_i(k\delta)}{\delta} &= \frac{x_i(k\delta)}{\delta\sum_j x_j(k\delta) e^{\frac{\Delta Qa_j(k\delta)}{\tau}}} \times \\ &\quad \left(e^{\frac{\Delta Qa_i(k\delta)}{\tau}} - \sum_j x_j(k\delta) e^{\frac{\Delta Qa_j(k\delta)}{\tau}}\right).\end{aligned}$$

We are interested in the limit with $\delta \to 0$. At a given time $t \geq 0$, the state of the limit process is computed by taking the limit of $x_i(k\delta)$ with $\delta \to 0$ and $k\delta \to t$.

$$\begin{aligned}\lim_{\delta\to 0}\frac{\Delta x_i(k\delta)}{\delta} &= \lim_{\delta\to 0}\frac{x_i(k\delta)}{\sum_j x_j(k\delta) e^{\frac{\Delta Qa_j(k\delta)}{\tau}}} \times \\ &\quad \lim_{\delta\to 0}\left(\frac{e^{\frac{\Delta Qa_i(k\delta)}{\tau}}}{\delta} - \frac{\sum_j x_j(k\delta) e^{\frac{\Delta Qa_j(k\delta)}{\tau}}}{\delta}\right). \qquad (9)\end{aligned}$$

The first limit equals $x_i(t)$ (or x_i for a shorter notation):

$$\lim_{\delta\to 0}\frac{x_i(k\delta)}{\sum_j x_j(k\delta) e^{\frac{\Delta Qa_j(k\delta)}{\tau}}} = x_i(t) \qquad (10)$$

because the exponent term becomes 1 ($\Delta Q_{a_j}(k\delta)$ becomes 0) and $\sum_j x_j(k\delta)$ equals 1(sum of all probabilities equals 1). Therefore,

$$\lim_{\delta\to 0}\frac{\Delta x_i(k\delta)}{\delta} = x_i \times \lim_{\delta\to 0}\left(\frac{e^{\frac{\Delta Q_{a_i}(k\delta)}{\tau}}}{\delta} - \frac{\sum_j x_j(k\delta)e^{\frac{\Delta Q_{a_j}(k\delta)}{\tau}}}{\delta}\right).$$

The second limit is undefined (this is a $\frac{0}{0}$ situation), which allows us to use L'Hôpital's rule. The second term now equals

$$\lim_{\delta\to 0}\left(\frac{e^{\frac{\Delta Q_{a_i}(k\delta)}{\tau}}}{\delta} - \frac{\sum_j x_j(k\delta)e^{\frac{\Delta Q_{a_j}(k\delta)}{\tau}}}{\delta}\right) = \frac{dQ_{a_i}(t)}{\tau dt} - \sum_j x_j(t)\frac{dQ_{a_j}(t)}{\tau dt}. \quad (11)$$

The total limit now becomes (by combining Equations 9 – 11),

$$\frac{\frac{dx_i}{dt}}{x_i} = \frac{1}{\tau}\left(\frac{dQ_{a_i}}{dt} - \sum_j \frac{dQ_{a_j}}{dt}x_j\right). \quad (12)$$

This completes the derivation of the continuous time model for the Q-learning process. As can be seen in Equation 12, we need an expression for $\frac{dQ_{a_i}(t)}{dt}$. This can be derived the differential equation for the Q-function by performing the following steps.

The Q-learning update rule for the first agent can be written as follows:

$$Q_{a_i}(k+1) = Q_{a_i}(k) + \alpha(r_{a_i}(k+1) + \gamma\max_{a_i} Q - Q_{a_i}(k))$$

which implies,

$$\Delta Q_{a_i}(k) = \alpha(r_{a_i}(k+1) + \gamma\max_{a_i} Q - Q_{a_i}(k)).$$

This expression is the difference equation for the Q-function. To make this equation infinitesimal, going from discrete steps to a continuous version, we suppose that the amount of time that passes between two repetitions of updates of the Q-values is given by δ with $0 < \delta \leq 1$. The variable $Q_{a_i}(k\delta)$ describes the Q-values at time $k\delta$. It follows that

$$\Delta Q_{a_i}(k\delta) = \alpha(r_{a_i}((k+1)\delta) + \gamma\max_{a_i} Q - Q_{a_i}(k\delta))((k+1)\delta - k\delta)$$

which is the same as writing

$$\Delta Q_{a_i}(k\delta) = \alpha(r_{a_i}((k+1)\delta) + \gamma\max_{a_i} Q - Q_{a_i}(k\delta))\delta.$$

We are interested in the limit $\delta \to 0$. The state of the limit process at some time $t \geq 0$ (which we keep fixed) can be computed by taking the limit of $Q_{a_i}(k\delta)$ with $\delta \to 0$ and $k\delta \to t$. Bringing δ to the left side, and taking the limit for $\delta \to 0$, it follows that

$$\frac{dQ_{a_i}}{dt} = \alpha(r_{a_i} + \gamma\max_{a_i} Q - Q_{a_i}). \quad (13)$$

Now, substituting Equation 13 in Equation 12 yields

$$\frac{\frac{dx_i}{dt}}{x_i} = \frac{1}{\tau}\alpha\left(r_{a_i} - \sum_j x_j r_{a_j} - Q_{a_i} + \sum_j Q_{a_j} x_j\right)$$

because $\sum_j x_j = 1$, this expression becomes

$$\frac{\frac{dx_i}{dt}}{x_i} = \frac{\alpha}{\tau}\left(r_{a_i} - \sum_j x_j r_{a_j} + \sum_j x_j (Q_{a_j} - Q_{a_i})\right).$$

Given that $\frac{x_j}{x_i}$ equals $\frac{e^{\frac{Q_{a_j}}{\tau}}}{e^{\frac{Q_{a_i}}{\tau}}}$, it follows that

$$\alpha \sum_j x_j ln \frac{x_j}{x_i} = \frac{\alpha}{\tau} \sum_j x_j (Q_{a_j} - Q_{a_i})$$

which gives us

$$\frac{\frac{dx_i}{dt}}{x_i} = \frac{\alpha}{\tau}\left(r_{a_i} - \sum_j x_j r_{a_j}\right) + \alpha \sum_j x_j ln\left(\frac{x_j}{x_i}\right).$$

Let us put this equation in the context of the two concurrent learning agents. For clarity, we use u_i (instead of r_{a_i}) to indicate the expected reward that the first agent expects for performing action i, and w_j to indicate the expected reward that the second agent expects for performing action j. Remember that the payoff matrix for the second agent is simply the transposed payoff matrix used by the first agent.

Thus $u_i = \sum_k a_{ik} y_k$ is the expected reward that would be observed by the first agent, given the other agent's current probabilities of selecting among its actions (and similarly $w_j = \sum_k a_{kj} x_k$). The RD model above therefore has the simpler form,

$$u_i = \sum_k a_{ik} y_k, \tag{14}$$

$$w_j = \sum_k a_{kj} x_k, \tag{15}$$

$$\frac{\frac{dx_i}{dt}}{x_i} = \frac{\alpha}{\tau}\left(u_i - \sum_k x_k u_k\right) + \alpha \sum_k x_k \ln \frac{x_k}{x_i}, \tag{16}$$

$$\frac{\frac{dy_j}{dt}}{y_j} = \frac{\alpha}{\tau}\left(w_j - \sum_k y_k w_k\right) + \alpha \sum_k y_k \ln \frac{y_k}{y_j}. \tag{17}$$

2.4 The Relative Overgeneralization Pathology

Wiegand et al. (2002) used the EGT model in Equations 5–8 to provide a formal analysis for the properties of cooperative coevolutionary algorithms. Note that the model described is deterministic: given the composition of the two populations, the model can be used to compute the precise distributions of genotypes in the populations at the next generation (the stochastic nature of evolutionary algorithms is compensated for by the use of infinite populations). Using this model, Wiegand et al.

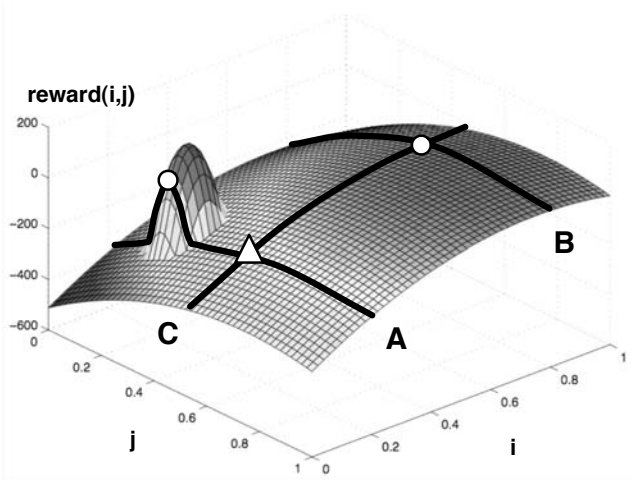

Figure 1: The relative generalization pathology in multiagent cooperative learning. The axes i and j are the various actions afforded to two different agents, and the axis $reward(i, j)$ is the reward received from a given joint action (higher is better).

(2002) showed that pure Nash equilibria are stable, attracting fixed points. This implies that starting from certain initial configurations and iterating the model until convergence may result in convergence to suboptimal Nash equilibria. A suboptimal Nash equilibrium is one that is Pareto-dominated by at least one other Nash equilibrium. This pathology, termed *relative overgeneralization* in Wiegand (2004), indicates that CCEAs have a tendency to move not to points of optimum reward, but rather to points which are "jacks of all trades but masters of none." This argument is taken further in Wiegand and Potter (2006) to suggest that cooperative coevolutionary algorithms might not necessarily search for solutions of high quality, but rather for robust solutions.

To illustrate how this can occur, consider a trivial scenario involving two agents, each with a set of actions. Both agents receive the same reward based on the joint action selected, and the objective of the two agents is to arrive on the joint action that optimizes their joint reward. Let i and j be the spaces of actions for the two agents. Figure 1 shows one possible joint space of actions $\langle i, j \rangle$ and their resulting reward. The optimum is at the top of the small peak; but it has been shown that a dynamical system such as in Equations 5 – 8 will tend to converge to the top of the broad suboptimal peak (Wiegand, 2004). The reason is as follows. Line A represents the possible rewards for the first population following action i_A when paired with various actions j from the other population. Some of these rewards are near the optimum; but most of them are below the suboptimal rewards that action i_B (line B) receives. If the utility of an action is based on *average reward*, the utility for i_B is higher that that of i_A, even though i_A has the potential to form better solutions (the circle on the higher peak in Figure 1). As a result, the system moves towards solutions more in line with i_B. This is the relative overgeneralization pathology.

Similar issues were reported in the multiagent Q-learning literature as well. For example, Fulda and Ventura (2007) attribute the convergence to suboptimal solutions to what they term *action shadowing*. Action i shadows action j if both of the following conditions apply. First, the rewards ob-

served by the agent upon performing action i over a period of time are higher than the ones observed for action j during the same period of time. This results in an expected higher utility for performing action i, as opposed to performing action j. Second, the reward obtained for j when the teammate selects a specific action k is higher than the reward obtain for i with any action selected by the teammate. For example, the domain illustrated in Figure 1 presents a scenario where action i_B shadows action i_A. This occurs because of low rewards received for i_A with poorly-matched actions (such as j_C) selected by the teammate. The circles represent how good actions i_A and i_B could be (when matched by specific actions of the teammate), while the triangle illustrates the low rewards due to action j_C that contribute to action shadowing (action shadowing is the result of many such actions).

Note informally that both relative overgeneralization and action shadowing might be solved by using the same approach: basing an action's utility on the *maximum* reward over some large number N of interactions with actions chosen by the other player. As N grows, the utility of an action approaches the joint reward it would produce were it paired with its optimum collaborating action; and thus each population could select from its actions knowing the true optimum potential of each.

This general notion of using the maximum is at the center of what we call *lenient learning*. The remainder of the paper demonstrates the advantages of being lenient in a multiagent learning system.

3. Lenient Learners

Lenient learning attempts to address the primary pathologies described in Section 2.4 by allowing agents to ignore the lower rewards received for a given action, notionally due to poorly-matched actions from the teammate, and instead concentrate on the higher rewards seen so far for that action.

Consider the Climb and Penalty domains introduced in Claus and Boutilier (1998) and used in previous investigations of multiagent Q-learning (Kapetanakis and Kudenko, 2002; Lauer and Riedmiller, 2000) and cooperative coevolution (Panait et al., 2003). The joint payoff matrices for these coordination games are defined as:

$$Climb: \begin{bmatrix} 11 & -30 & 0 \\ -30 & 7 & 6 \\ 0 & 0 & 5 \end{bmatrix}, \qquad Penalty: \begin{bmatrix} 10 & 0 & -10 \\ 0 & 2 & 0 \\ -10 & 0 & 10 \end{bmatrix}.$$

Observe that Climb has two Nash equilibria, the optimum $(1,1)$ (both agents play their first strategy: the indices of the matrix) and the suboptimum $(2,2)$ (both agents play their second strategy), and that it is strongly deceptive. Suboptimal meaning that $(2,2)$ is Pareto-dominated by $(1,1)$. Penalty has three Nash equilibria: $(1,1)$, $(2,2)$, and $(3,3)$. Of them, $(2,2)$ is suboptimal (Pareto-dominated), but is more forgiving if one or the other population deviates from the Nash equilibrium. This means that $(2,2)$ risk dominates $(1,1)$ and $(3,3)$, because playing action 2 will provide a higher expected payoff when an agent is uncertain about the other agent's action,.

Now consider two agents learning the Climb coordination game. Given that the agents have just started to learn and have no knowledge about the structure of the payoff matrix, we may assume that the agents choose their actions randomly. The expected reward for each action an agent might perform is:

$$\begin{aligned}
ExpectedReward(a_1) = &\quad 11*\tfrac{1}{3} - 30*\tfrac{1}{3} + 0*\tfrac{1}{3} &= -6.33\\
ExpectedReward(a_2) = &\quad -30*\tfrac{1}{3} + 7*\tfrac{1}{3} + 6*\tfrac{1}{3} &= -5.67\\
ExpectedReward(a_3) = &\quad 0*\tfrac{1}{3} + 0*\tfrac{1}{3} + 5*\tfrac{1}{3} &= 1.67
\end{aligned}$$

Observe that action a_1 has the lowest expected reward. The agent might thus become less likely to choose action a_1 due to the lower rewards it receives at early stages of learning. This is problematic, however, as a_1 corresponds to the optimal Nash equilibrium. The same applies to the Penalty coordination problem:

$$\begin{aligned}
ExpectedReward(a_1) = &\quad 10*\tfrac{1}{3} + 0*\tfrac{1}{3} - 10*\tfrac{1}{3} &= 0\\
ExpectedReward(a_2) = &\quad 0*\tfrac{1}{3} + 2*\tfrac{1}{3} + 0*\tfrac{1}{3} &= 0.67\\
ExpectedReward(a_3) = &\quad -10*\tfrac{1}{3} + 0*\tfrac{1}{3} + 10*\tfrac{1}{3} &= 0
\end{aligned}$$

One solution to remedy this problem is to allow agents to show lenience towards their teammates: the agents can *ignore* lower rewards observed upon performing their actions, and only update the utilities of actions based on the higher rewards. This can be achieved if the learners compare the observed reward with the estimated utility for an action, and update the utility only if it is lower than the reward. In some sense, such an approach changes the learning focus from performing as well as possible in the context of the current (likely mediocre) teammate, to performing as well as possible in the context of improved behaviors for its teammate (as the teammate learns, it likely will not choose those actions that resulted in lower rewards!).

Panait et al. (2006) presents evidence on the advantages of such an approach. The paper introduced a time-dependent degree of lenience: the agents start by ignoring most of the low rewards that they observe, but as learning progresses, agents tend to explore certain "better" actions and also ignore fewer low rewards. The paper also presented empirical evidence that several multiagent learning paradigms can significantly benefit from agents being lenient to one another. Similarly, cooperative coevolutionary algorithms often use agents that ignore lower rewards (for example, in Wiegand et al., 2001), and we previously demonstrated the advantages of a time-dependent degree of lenience for cooperative coevolution (Panait and Luke, 2005b). Although such algorithms have shown their strengths in empirical analysis, formal models of multiagent learning have always been one step behind.

This paper focuses on the mathematical foundations of a simpler approach to lenient learners: each agent collects the rewards it receives for performing actions. Upon observing N rewards for an action, only the maximum of these N rewards is used to update the utility associated with that action. The set of observed rewards for that action is cleared, and the learning process continues. In other words, the agents employ a fixed degree of lenience (which is determined by N) to their teammates. The more low rewards the agents ignore (the higher N is), the more lenient the agents can be said to be. Although this approach does not model any existing multiagent learning algorithm, its formal analysis has two major contributions. First, it provides a valuable addition to our set of tools to study such multiagent learning algorithms, and also strengthens evolutionary game theory as a primary framework for such analysis. Second, it adds to our understanding of the causes for multiagent learning algorithms drifting away from globally optimal solutions.

Next, we extend the EGT models from Section 2.3 such that each learner uses only the maximum of N rewards (it ignores the lower $N-1$ rewards) to improve its utility estimate. The following theorem establishes a key result for the formal model of lenient learners.

Theorem 1 *Let $(a_{ij})_{i,j=1}^{n}$ be the payoff matrix (a_{ij} is the payoff received by the agents when one performs action i and the other performs action j), and let $(p_j)_{j\in 1..n}$ be the probability that the teammate selects action j. The expected maximum payoff for i over N pairwise combinations with actions $j_1 \ldots j_N$ chosen with replacement according to $(p_j)_{j\in 1..n}$ is*

$$\sum_{j=1}^{n} a_{ij} \frac{p_j}{\sum_{k:a_{ik}=a_{ij}} p_k} \left(\left(\sum_{k:a_{ik}\leq a_{ij}} p_k \right)^N - \left(\sum_{k:a_{ik}<a_{ij}} p_k \right)^N \right).$$

Proof

The expected maximum reward of action i over N pairwise combinations can be expressed as a weighted sum of all possible rewards a_{ij} that action i can receive with different actions j for the teammate. The weight of each term a_{ij} equals the probability that a_{ij} is the maximum reward observed over N trials. This probability can be computed based on the difference between the probability of receiving N rewards that are no higher than a_{ij}, which equals $\left(\sum_{k:a_{ik}\leq a_{ij}} p_k\right)^N$, minus the probability of receiving N rewards that are strictly lower than a_{ij}, which equals $\left(\sum_{k:a_{ik}<a_{ij}} p_k\right)^N$. Observe that an action i might receive the same reward in combination with different actions of the teammate, and as a result, there is an extra weight $\frac{p_j}{\sum_{k:a_{ik}=a_{ij}} p_k}$ that computes the probability of observing the reward a_{ij} in combination with action j of the teammate, out of all the other actions the teammate might have selected and would have resulted in the same reward. ■

Using Theorem 1, let us compute the expected reward for a lenient learner that ignores the lower of two observed rewards for each of its actions. We assume again that the teammate selects actions at random. The expected rewards in the Climb coordination problem are:

$$\begin{aligned}
ExpectedReward(a_1) = &\quad 11*\tfrac{5}{9} - 30*\tfrac{1}{9} + 0*\tfrac{1}{3} &&= 2.78\\
ExpectedReward(a_2) = &\quad -30*\tfrac{1}{9} + 7*\tfrac{5}{9} + 6*\tfrac{1}{3} &&= 2.56\\
ExpectedReward(a_3) = &\quad 0*\tfrac{2}{9} + 0*\tfrac{2}{9} + 5*\tfrac{5}{9} &&= 2.78
\end{aligned}$$

Observe that a_1 has the highest reward (tied with that of a_3). Were the agent to be more lenient (for example, if it ignored the lower two of three observed rewards), the expected reward for a_1 would be significantly higher than those for a_2 and a_3. Similarly, the expected rewards in the Penalty domain (with learners ignoring the lower of every two rewards) are:

$$\begin{aligned}
ExpectedReward(a_1) = &\quad 10*\tfrac{5}{9} + 0*\tfrac{1}{3} - 10*\tfrac{1}{9} &&= 4.44\\
ExpectedReward(a_2) = &\quad 0*\tfrac{2}{9} + 2*\tfrac{5}{9} + 0*\tfrac{2}{9} &&= 1.11\\
ExpectedReward(a_3) = &\quad -10*\tfrac{1}{9} + 0*\tfrac{1}{3} + 10*\tfrac{5}{9} &&= 4.44
\end{aligned}$$

Note that the Penalty game has two global optima, and that the lenient agents might have difficulties choosing both the same optimum. As we will show in this paper, lenience can help multiagent learning algorithms converge to the global optimum in domains with a unique such global optimum, as well as in some domains with multiple optima.

The results above support the hypothesis that lenient learners might benefit from estimating the expected reward for an action based on how good that action might be once the teammate has learned a better behavior. However, the analysis so far relied on the assumption that the teammate only chooses random actions. The EGT frameworks for multiagent learning, as described in Section 2.3, clearly eliminate this assumption by explicitly keeping track of the agents' probabilities of selecting each action over time, and by using that information to describe the learning process of each agent. The paper continues with extensions of these models to account for lenience: Section 4 demonstrates the benefits of lenience for cooperative coevolutionary algorithms, while Section 5 presents evidence for the advantages of lenience in multiagent Q-learning algorithms.

4. Enhanced Evolutionary Game Theory Model for Cooperative Coevolutionary Algorithms

As described in Section 2.3.1, the EGT model for CCEAs updates the utility of an action based on the expected reward for that action in combination with all possible actions that the teammate might select (Equations 5 – 6). Next, we use Theorem 1 to enhance this model to account for lenient learners.

Assessing fitness as the maximum of multiple rewards has been used before in practical cooperative coevolutionary algorithms (for example, in Wiegand et al., 2001). The research here contributes a formal analysis of this approach, which has so far been lacking.

Definition 1 *The EGT model in Equations 18 – 21 represents a theoretical model for a cooperative coevolutionary algorithm where the fitness of an individual is computed as the maximum reward with N collaborators.*

$$u_i^{(t)} = \sum_{j=1}^{m} a_{ij} \frac{y_j^{(t)}}{\sum_{k:a_{ik}=a_{ij}} y_k^{(t)}} \left(\left(\sum_{k:a_{ik}\leq a_{ij}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{ik}<a_{ij}} y_k^{(t)} \right)^N \right), \tag{18}$$

$$w_j^{(t)} = \sum_{i=1}^{n} a_{ij} \frac{x_i^{(t)}}{\sum_{k:a_{kj}=a_{ij}} x_k^{(t)}} \left(\left(\sum_{k:a_{kj}\leq a_{ij}} x_k^{(t)} \right)^N - \left(\sum_{k:a_{kj}<a_{ij}} x_k^{(t)} \right)^N \right), \tag{19}$$

$$x_i^{(t+1)} = \left(\frac{u_i^{(t)}}{\sum_{k=1}^{n} x_k^{(t)} u_k^{(t)}} \right) x_i^{(t)}, \tag{20}$$

$$y_j^{(t+1)} = \left(\frac{w_j^{(t)}}{\sum_{k=1}^{m} y_k^{(t)} w_k^{(t)}} \right) y_j^{(t)}. \tag{21}$$

Note that the enhanced model is equivalent to Wiegand's standard EGT model in Equations 5 – 8 when a single collaborator is used ($N = 1$). As demonstrated next, CCEAs are expected to achieve better performance as N increases. The proof that is the case relies on the following lemmas which

establish bounds on the probabilities that the initial populations have extremely large or small proportions of certain genotypes.

Lemma 1 *Assume the populations for the EGT model are initialized at random based on a uniform distribution over all possible initial populations. Then, for any* $\varepsilon > 0$*, there exists* $\theta_\varepsilon > 0$ *such that*

$$P\left(\min_{i=1..n} x_i^{(0)} \leq \theta_\varepsilon\right) < \varepsilon, \tag{22}$$

$$P\left(\max_{i=1..n} x_i^{(0)} \geq 1-\theta_\varepsilon\right) < \varepsilon, \tag{23}$$

$$P\left(\min_{j=1..m} y_j^{(0)} \leq \theta_\varepsilon\right) < \varepsilon, \tag{24}$$

$$P\left(\max_{j=1..m} y_j^{(0)} \geq 1-\theta_\varepsilon\right) < \varepsilon. \tag{25}$$

Proof One method to sample the simplex Δ^n uniformly is described in Devroye (1986) (pages 568 – 569): take $n-1$ uniformly distributed numbers in $[0,1]$, then sort them, and finally use the differences between consecutive numbers (also, the difference between the smallest number and 0, and that between 1 and the largest number) as the coordinates for the point.

It follows that $\min_{i=1..n} x_i^{(0)}$ is the smallest distance between two such numbers (and possibly the boundaries 0 and 1). Similarly, $\max_{i=1..n} x_i^{(0)}$ is the largest distance between two numbers.

Suppose $\gamma > 0$ is a small number. We iterate over the $n-1$ uniformly-distributed random numbers that are needed to generate an initial population $\left(x_i^{(0)}\right)_{i=1..n}$. The probability that the first number is not within γ of the boundaries 0 and 1 is $1-2\gamma$. The probability that the second number is not within γ of the boundaries or of the first number is less than or equal to $1-4\gamma$. In general, the probability that the kth number is not within γ of the boundaries or of the first $k-1$ numbers is less than or equal to $1-2k\gamma$. Given that the numbers are generated independently of one another, the probability that the closest pair of points (considering the boundaries) is farther apart than γ is equal to

$$\begin{aligned} P\left(\min_{i=1..n} x_i^{(0)} \leq \gamma\right) &= 1 - P\left(\min_{i=1..n} x_i^{(0)} > \gamma\right) \\ &= 1 - \prod_{i=1}^{n-1} (1-2i\gamma) \quad \leq \quad 1-(1-2(n-1)\gamma)^{n-1}. \end{aligned}$$

Inequalities 22 and 24 are symmetric, and as such, the proof that

$$P\left(\min_{j=1..m} y_j^{(0)} \leq \gamma\right) \leq 1-(1-2(m-1)\gamma)^{m-1}$$

is very similar. Given that

$$\begin{aligned} \lim_{\gamma\to 0} 1-(1-2(n-1)\gamma)^{n-1} &= 0, \\ \lim_{\gamma\to 0} 1-(1-2(m-1)\gamma)^{m-1} &= 0 \end{aligned}$$

it follows that for any $\varepsilon > 0$ there exists $\theta_\varepsilon > 0$ such that $P\left(\min_{i=1..n} x_i^{(0)} \leq \theta_\varepsilon\right) < \varepsilon$ and $P\left(\min_{j=1..m} y_j^{(0)} \leq \theta_\varepsilon\right) < \varepsilon$.

To prove Inequality 23, consider that $\max_{i=1..n} x_i^{(0)} \geq 1-\theta_\varepsilon$ implies that all other x_i ratios except for the maximum are smaller to θ_ε, which, as proven above, occurs with probability smaller than ε. The proof for Inequality 25 is similar. ■

Lemma 1 basically proved that the probability that an agent starts with an extremely low or an extremely high probability of selecting an action is very low, given a random initialization of the multiagent learning process. Following, Lemma 2 derives a complementary result, namely that each agent should have a fair likelihood of selecting each of its actions when the learning process starts.

Lemma 2 *Assume the populations for the EGT model are initialized at random based on a uniform distribution over all possible initial populations. Then, for any* $\varepsilon > 0$*, there exists* $\eta_\varepsilon > 0$ *such that*

$$P\left(\min_{i=1..n} x_i^{(0)} > \eta_\varepsilon \wedge \max_{i=1..n} x_i^{(0)} < 1-\eta_\varepsilon \wedge \min_{j=1..m} y_j^{(0)} > \eta_\varepsilon \wedge \max_{j=1..m} y_j^{(0)} < 1-\eta_\varepsilon\right) \geq 1-\varepsilon.$$

Proof We apply Lemma 1 for $\frac{1-\sqrt{1-\varepsilon}}{2}$, which is greater than 0. The specific value of η_ε for this proof equals the value of $\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}$ from Lemma 1. It follows that:

$$\begin{aligned}
&P\left(\min_{i=1..n} x_i^{(0)} > \eta_\varepsilon \wedge \max_{i=1..n} x_i^{(0)} < 1-\eta_\varepsilon \wedge \min_{j=1..m} y_j^{(0)} > \eta_\varepsilon \wedge \max_{j=1..m} y_j^{(0)} < 1-\eta_\varepsilon\right) \\
&\quad = P\left(\min_{i=1..n} x_i^{(0)} > \theta_{\frac{1-\sqrt{1-\varepsilon}}{2}} \wedge \max_{i=1..n} x_i^{(0)} < 1-\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right) \times \\
&\qquad P\left(\min_{j=1..m} y_j^{(0)} > \theta_{\frac{1-\sqrt{1-\varepsilon}}{2}} \wedge \max_{j=1..m} y_j^{(0)} < 1-\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right) \\
&\quad = \left(1-P\left(\min_{i=1..n} x_i^{(0)} \leq \theta_{\frac{1-\sqrt{1-\varepsilon}}{2}} \vee \max_{i=1..n} x_i^{(0)} \geq 1-\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right)\right) \times \\
&\qquad \left(1-P\left(\min_{j=1..m} y_j^{(0)} \leq \theta_{\frac{1-\sqrt{1-\varepsilon}}{2}} \vee \max_{j=1..m} y_j^{(0)} \geq 1-\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right)\right) \\
&\quad \geq \left(1-\left(P\left(\min_{i=1..n} x_i^{(0)} \leq \theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right)+P\left(\max_{i=1..n} x_i^{(0)} \geq 1-\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right)\right)\right) \times \\
&\qquad \left(1-\left(P\left(\min_{j=1..m} y_j^{(0)} \leq \theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right)+P\left(\max_{j=1..m} y_j^{(0)} \geq 1-\theta_{\frac{1-\sqrt{1-\varepsilon}}{2}}\right)\right)\right) \\
&\quad \geq \left(1-2\frac{1-\sqrt{1-\varepsilon}}{2}\right) \times \left(1-2\frac{1-\sqrt{1-\varepsilon}}{2}\right) \\
&\quad = 1-\varepsilon.
\end{aligned}$$

■

Next, we prove that the revised EGT model described by Equations 18−21 converges to the global optimum with an arbitrarily-high probability.

Theorem 2 *Given a joint reward matrix A with a unique global optimum $a_{i^\star j^\star}$, for any $\varepsilon > 0$ there exists $N_\varepsilon \geq 1$ such that the theoretical CCEA model in Equations 18−21 converges to the global optimum with probability greater than $(1-\varepsilon)$ for any number of collaborators N such that $N \geq N_\varepsilon$.*

Proof

ε only serves as a guarantee for the worst case scenario for the proportions of individuals in the initial populations. From Lemma 2, it follows that there exists $\eta_\varepsilon > 0$ such that with probability at least $1-\varepsilon$, it is the case that $\eta_\varepsilon < x_i^{(0)} < 1-\eta_\varepsilon$ and $\eta_\varepsilon < y_j^{(0)} < 1-\eta_\varepsilon$ for $i, j \in \{1,2,3\}$. In other words, with probability ε, the initial populations will not have any proportion of individuals that cover more than $1-\eta_\varepsilon$, nor cover less than η_ε of the entire population.

We will prove that there exists $N_\varepsilon \geq 0$ such that the EGT model converges to the global optimum for any $N \geq N_\varepsilon$ and for all initial populations that satisfy $\eta_\varepsilon < x_{i^\star}^{(0)} < 1-\eta_\varepsilon$ and $\eta_\varepsilon < y_{j^\star}^{(0)} < 1-\eta_\varepsilon$. To this end, let α be the second highest element of the joint payoff matrix A ($\alpha < a_{i^\star j^\star}$). It follows that $u_i^{(t)} \leq \alpha$ for all $i \neq i^\star$, and similarly $w_j^{(t)} \leq \alpha$ for all $j \neq j^\star$. Given the symmetry, proving only the first (by refining Equation 18) is sufficient:

$$\begin{aligned} u_i^{(t)} &\leq \sum_{j=1}^{m} \alpha \frac{y_j^{(t)}}{\sum_{k:a_{ik}=a_{ij}} y_k^{(t)}} \left(\left(\sum_{k:a_{ik}\leq a_{ij}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{ik}<a_{ij}} y_k^{(t)} \right)^N \right) \\ &\leq \alpha \sum_{j=1}^{m} \left(\left(\sum_{k:a_{ik}\leq a_{ij}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{ik}<a_{ij}} y_k^{(t)} \right)^N \right) \leq \alpha. \end{aligned}$$

Next, we identify a lower bound for $u_{i^\star}^{(t)}$:

$$
\begin{aligned}
u_{i^\star}^{(t)} &= \sum_{j=1}^{m} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(\left(\sum_{k:a_{i^\star k}\le a_{i^\star j}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{i^\star k}< a_{i^\star j}} y_k^{(t)} \right)^N \right) \\
&= a_{i^\star j^\star} \left(1 - \left(1 - y_{j^\star}^{(t)} \right)^N \right) + \\
&\quad \sum_{j\neq j^\star} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(\left(\sum_{k:a_{i^\star k}\le a_{i^\star j}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{i^\star k}< a_{i^\star j}} y_k^{(t)} \right)^N \right) \\
&= a_{i^\star j^\star} \left(1 - \left(1 - y_{j^\star}^{(t)} \right)^N \right) + \\
&\quad \sum_{j\neq j^\star \wedge a_{i^\star j}\ge 0} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(\left(\sum_{k:a_{i^\star k}\le a_{i^\star j}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{i^\star k}< a_{i^\star j}} y_k^{(t)} \right)^N \right) + \\
&\quad \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(\left(\sum_{k:a_{i^\star k}\le a_{i^\star j}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{i^\star k}< a_{i^\star j}} y_k^{(t)} \right)^N \right) \\
&\ge a_{i^\star j^\star} \left(1 - \left(1 - y_{j^\star}^{(t)} \right)^N \right) + \\
&\quad \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(\left(\sum_{k:a_{i^\star k}\le a_{i^\star j}} y_k^{(t)} \right)^N - \left(\sum_{k:a_{i^\star k}< a_{i^\star j}} y_k^{(t)} \right)^N \right) \\
&\ge a_{i^\star j^\star} \left(1 - \left(1 - y_{j^\star}^{(t)} \right)^N \right) + \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(\sum_{k:a_{i^\star k}\le a_{i^\star j}} y_k^{(t)} \right)^N .
\end{aligned}
$$

Given that $\sum_{k=1}^{m} y_k^{(t)} = 1$, the previous inequality can be further refined:

$$
\begin{aligned}
u_{i^\star}^{(t)} &\ge a_{i^\star j^\star} \left(1 - \left(1 - y_{j^\star}^{(t)} \right)^N \right) + \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \frac{y_j^{(t)}}{\sum_{k:a_{i^\star k}=a_{i^\star j}} y_k^{(t)}} \left(1 - y_{j^\star}^{(t)} \right)^N \\
&\ge a_{i^\star j^\star} \left(1 - \left(1 - y_{j^\star}^{(t)} \right)^N \right) + \left(1 - y_{j^\star}^{(t)} \right)^N \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \\
&= a_{i^\star j^\star} - \left(1 - y_{j^\star}^{(t)} \right)^N \left(a_{i^\star j^\star} - \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \right). \qquad (26)
\end{aligned}
$$

The inequalities $\eta_\varepsilon < y_{j^\star}^{(0)} < 1-\eta_\varepsilon$ hold for the initial populations, as inferred earlier from Lemma 2. It follows from Equation 26 that

$$
u_{i^\star}^{(0)} \ge a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{j\neq j^\star \wedge a_{i^\star j}< 0} a_{i^\star j} \right). \qquad (27)
$$

However,

$$\lim_{N\to\infty} a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{j\neq j^\star \wedge a_{i^\star j}<0} a_{i^\star j} \right) \quad = \quad a_{i^\star j^\star} \tag{28}$$

Given that $a_{i^\star j^\star} > \alpha$, Equation 28 implies that there exists $N_1 \geq 1$ such that

$$a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{j\neq j^\star \wedge a_{i^\star j}<0} a_{i^\star j} \right) > \frac{a_{i^\star j^\star}}{2} + \frac{\alpha}{2} > \alpha \tag{29}$$

for all $N \geq N_1$. From Equations 26 and 29, it follows that

$$u_{i^\star}^{(0)} > \frac{a_{i^\star j^\star}}{2} + \frac{\alpha}{2} > \alpha \tag{30}$$

for all $N \geq N_1$. Observe that N_1 does not depend on the initial populations $x^{(0)}$ and $y^{(0)}$. Similarly, it is straightforward to prove that

$$w_{j^\star}^{(t)} \geq a_{i^\star j^\star} - \left(1 - x_{i^\star}^{(t)}\right)^N \left(a_{i^\star j^\star} - \sum_{i\neq i^\star \wedge a_{ij^\star}<0} a_{ij^\star} \right), \tag{31}$$

$$w_{j^\star}^{(0)} \geq a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{i\neq i^\star \wedge a_{ij^\star}<0} a_{ij^\star} \right) \tag{32}$$

and that there exists $N_2 \geq 1$ such that

$$a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{i\neq i^\star \wedge a_{ij^\star}<0} a_{ij^\star} \right) > \frac{a_{i^\star j^\star}}{2} + \frac{\alpha}{2} > \alpha$$

which implies that

$$w_{j^\star}^{(0)} > \frac{a_{i^\star j^\star}}{2} + \frac{\alpha}{2} > \alpha$$

for all $N \geq N_2$.

Let $N_\varepsilon = max(N_1, N_2)$, and let $N \geq N_\varepsilon$. Next, we show by induction by t (the number of iterations of the model, that is, the number of generations) that the following four inequalities hold (note that the last two imply a monotonic increase in the actions that comprise the global optimum):

$$u_{i^\star}^{(t)} \geq a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{j\neq j^\star \wedge a_{i^\star j}<0} a_{i^\star j} \right), \tag{33}$$

$$w_{j^\star}^{(t)} \geq a_{i^\star j^\star} - (1-\eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{i\neq i^\star \wedge a_{ij^\star}<0} a_{ij^\star} \right),$$

$$x_{i^\star}^{(t+1)} \geq x_{i^\star}^{(t)}, \tag{34}$$

$$y_{j^\star}^{(t+1)} \geq y_{j^\star}^{(t)}. \tag{35}$$

At the first generation ($t = 0$), the first two inequalities hold (Equations 27 and 32). Combining these with the definition of N, it follows that $u_{i^\star}^{(0)} > u_i^{(0)}$ for all $i \neq i^\star$ (and similarly, $w_{j^\star}^{(0)} > w_j^{(0)}$ for all $j \neq j^\star$). As a consequence, Equation 20 implies that

$$\begin{aligned} x_{i^\star}^{(1)} &= \left(\frac{u_{i^\star}^{(0)}}{\sum_{k=1}^{n} x_k^{(0)} u_k^{(0)}} \right) x_{i^\star}^{(0)} \\ &> \left(\frac{u_{i^\star}^{(0)}}{\sum_{k=1}^{n} x_k^{(0)} u_{i^\star}^{(0)}} \right) x_{i^\star}^{(0)} \\ &= x_{i^\star}^{(0)}. \end{aligned}$$

and Equation 21 similarly implies that

$$\begin{aligned} y_{j^\star}^{(1)} &= \left(\frac{w_{j^\star}^{(0)}}{\sum_{k=1}^{m} y_k^{(0)} w_k^{(0)}} \right) y_{j^\star}^{(0)} \\ &> \left(\frac{w_{j^\star}^{(0)}}{\sum_{k=1}^{m} y_k^{(0)} w_{j^\star}^{(0)}} \right) y_{j^\star}^{(0)} \\ &= y_{j^\star}^{(0)}. \end{aligned}$$

To prove the inductive step, it follows from Equation 26 and from the inductive hypothesis that

$$\begin{aligned} u_{i^\star}^{(t+1)} &\geq a_{i^\star j^\star} - \left(1 - y_{j^\star}^{(t+1)}\right)^N \left(a_{i^\star j^\star} - \sum_{j \neq j^\star \wedge a_{i^\star j} < 0} a_{i^\star j} \right) \\ &\geq a_{i^\star j^\star} - \left(1 - y_{j^\star}^{(t)}\right)^N \left(a_{i^\star j^\star} - \sum_{j \neq j^\star \wedge a_{i^\star j} < 0} a_{i^\star j} \right) \\ &\cdots \\ &\geq a_{i^\star j^\star} - \left(1 - y_{j^\star}^{(0)}\right)^N \left(a_{i^\star j^\star} - \sum_{j \neq j^\star \wedge a_{i^\star j} < 0} a_{i^\star j} \right) \\ &\geq a_{i^\star j^\star} - (1 - \eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{j \neq j^\star \wedge a_{i^\star j} < 0} a_{i^\star j} \right). \end{aligned}$$

Given the definitions of N and α, this also implies that $u_{i^\star}^{(t+1)} > \alpha > u_i^{(t+1)}$ for all $i \neq i^\star$. As a consequence,

$$\begin{aligned} x_{i^\star}^{(t+1)} &= \left(\frac{u_{i^\star}^{(t)}}{\sum_{k=1}^{n} x_k^{(t)} u_k^{(t)}}\right) x_{i^\star}^{(t)} \\ &> \left(\frac{u_{i^\star}^{(t)}}{\sum_{k=1}^{n} x_k^{(t)} u_{i^\star}^{(t)}}\right) x_{i^\star}^{(t)} \\ &= x_{i^\star}^{(t)}. \end{aligned}$$

Similarly, Equation 31 and the inductive hypothesis imply that

$$\begin{aligned} w_{j^\star}^{(t+1)} &\geq a_{i^\star j^\star} - \left(1 - x_{i^\star}^{(t+1)}\right)^N \left(a_{i^\star j^\star} - \sum_{i \neq i^\star \wedge a_{ij^\star} < 0} a_{ij^\star}\right) \\ &\geq a_{i^\star j^\star} - \left(1 - x_{i^\star}^{(t)}\right)^N \left(a_{i^\star j^\star} - \sum_{i \neq i^\star \wedge a_{ij^\star} < 0} a_{ij^\star}\right) \\ &\cdots \\ &\geq a_{i^\star j^\star} - (1 - \eta_\varepsilon)^N \left(a_{i^\star j^\star} - \sum_{i \neq i^\star \wedge a_{ij^\star} < 0} a_{ij^\star}\right). \end{aligned}$$

Again, given the definition of N and α, this implies $w_{j^\star}^{(t+1)} > \alpha > w_j^{(t+1)}$ for all $j \neq j^\star$. As a consequence,

$$\begin{aligned} y_{j^\star}^{(t+1)} &= \left(\frac{w_{j^\star}^{(t)}}{\sum_{k=1}^{m} y_k^{(t)} w_k^{(t)}}\right) y_{j^\star}^{(t)} \\ &> \left(\frac{w_{j^\star}^{(t)}}{\sum_{k=1}^{m} y_k^{(t)} w_{j^\star}^{(t)}}\right) y_{j^\star}^{(t)} \\ &= y_{j^\star}^{(t)} \end{aligned}$$

Having shown that both $\left(x_{i^\star}^{(t)}\right)_t$ and $\left(y_{j^\star}^{(t)}\right)_t$ are monotonically increasing (Equations 34–35), and given that they are bounded between 0 and 1, it follows that they converge to some value. Let $\bar{x} = \lim_{t\to\infty} x_{i^\star}^{(t)}$. We used Lemma 2 to define $\eta_\varepsilon > 0$ such that $\eta_\varepsilon < x_i^{(0)}$ (among other inequalities). This clearly implies $\bar{x} > 0$, as $\left(x_{i^\star}^{(t)}\right)_t$ is monotonically increasing. We also have that

$$\begin{aligned} \frac{x_{i^\star}^{(t+1)}}{x_{i^\star}^{(t)}} &= \frac{u_{i^\star}^{(t)}}{\sum_{k=1}^{n} u_k^{(t)} x_k^{(t)}} \\ &\geq \frac{u_{i^\star}^{(t)}}{u_{i^\star}^{(t)} x_{i^\star}^{(t)} + \alpha\left(1 - x_{i^\star}^{(t)}\right)} \\ &= 1 + \frac{\left(u_{i^\star}^{(t)} - \alpha\right)\left(1 - x_{i^\star}^{(t)}\right)}{u_{i^\star}^{(t)} x_{i^\star}^{(t)} + \alpha\left(1 - x_{i^\star}^{(t)}\right)}. \end{aligned}$$

But $\lim_{t\to\infty} \frac{x_{i^\star}^{(t+1)}}{x_{i^\star}^{(t)}} = 1$, and therefore

$$\lim_{t\to\infty} \frac{\left(u_{i^\star}^{(t)} - \alpha\right)\left(1 - x_{i^\star}^{(t)}\right)}{u_{i^\star}^{(t)} x_{i^\star}^{(t)} + \alpha\left(1 - x_{i^\star}^{(t)}\right)} = 0$$

which implies

$$\lim_{t\to\infty} \left(u_{i^\star}^{(t)} - \alpha\right)\left(1 - x_{i^\star}^{(t)}\right) = 0.$$

Finally, Equations 30 and 33 imply that $u_{i^\star}^{(t)} - \alpha > \frac{a_{i^\star j^\star}}{2} - \frac{\alpha}{2} > 0$. As a consequence $\lim_{t\to\infty} x_{i^\star}^{(t)} = 1$. The proof that $y_{j^\star}^{(t)}$ also converges to 1 is similar and is omitted for brevity. It follows that $x_i^{(t)}$ and $y_j^{(t)}$ converge to 0 for all $i \neq i^\star$ and for all $j \neq j^\star$. ■

Theorem 2 shows that CCEAs will converge to the global optimum in domains with a unique such optimum, if set appropriately and if given enough resources. This proves that the earlier claims of uncontrolled drift to suboptimal solutions, as reported in Wiegand (2004), were entirely due to the use of a formal model that employed a simplified fitness assessment mechanism. The term "enough" is used here to indicate two types of resources that CCEAs need: large populations to explore the space (the populations are in fact assumed to be infinite in our formal model, for simplicity), and large numbers of collaborators to provide accurate fitness estimates for all populations. This paper does not go into great depths with respect to the requirement for large populations. As for the second requirement, Section 4.1 analyzes the impact of the number of collaborators onto the performance of the CCEA.

Observe also that Theorem 2 does not cover domains with multiple optima, such as the Penalty domain discussed in Section 3. Next, we use a visualization technique to study the impact of lenience onto cooperative coevolutionary algorithms as applied to domains with one optimum, as well as to domains with multiple global optima.

4.1 Basins of Attraction due to Estimations

This section describes an intuitive way to visualize the impact of improved estimates on the performance of the system. Given specific initial populations, the EGT model is completely deterministic. As shown by Wiegand (2004), the populations are expected to converge to Nash equilibria in the payoff matrix. As a result, it is straightforward to provide two-dimensional visualizations of the basins of attraction for different Nash equilibria when each population contains only two genotypes: the two-dimensional location of a pixel uniquely encodes the initial ratios of one of the genotypes for each population, and the color of the pixel specifies the equilibrium to which the system converges after repeated iteration (see Panait et al., 2004, for details).

However, such simple problem domains present a limited range of challenges to cooperative coevolutionary algorithms. This section will instead illustrate the basins of attraction of Nash equilibria in two 3×3 coordination games: Climb and Penalty. This domains can stress the challenges posed by poor estimates of fitness, as discussed in Section 3.

Given that fitness proportional selection works properly only when all individuals have positive fitness, we add 30 to all values in the Climb payoff matrix, and we add 10 to all values in the Penalty

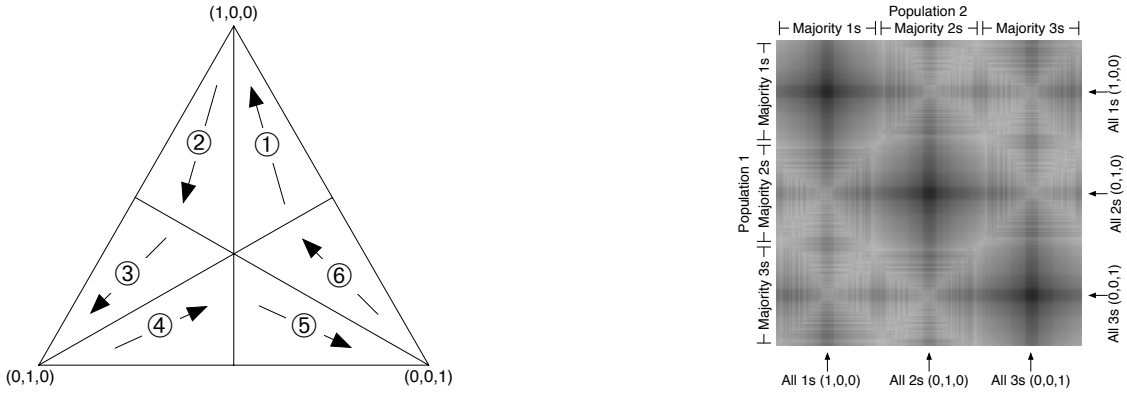

Figure 2: The projection of $\Delta^3 \times \Delta^3$ to $[0,1]^2$. (a): The projection divides the simplex Δ^3 into six equal-area triangles; arrows show the direction for sorting points in each area. (b): Visualization of the cartesian product of two simplexes.

payoff matrix. In contrast, in the next Section (Section 5), all experiments will employ the original payoff matrices.

We apply the EGT model in Equations $18-21$ to each of these two problem domains. The model is iterated for 100000 generations or until the proportion of one action in each population exceeds a threshold of $1-10^{-10}$. A specific color identifies each of the possible end results (Nash equilibria). For consistency, black dots always indicate convergence to a suboptimal solution, while white and grey dots indicate convergence to global optima. The projection of the $\Delta^3 \times \Delta^3$ is detailed next.

The search space (Δ^3) of the first population is projected along the vertical axis, while that of the second population is projected along the horizontal axis. The objective of this process is to group together regions of the space of initial populations that are expected to converge to the same Nash equilibrium. The projection of Δ^3 to one dimension starts by dividing it into six equal-area triangles, as shown in Figure 2a. Initial populations in areas $1-2$ have a majority of 1s in the population, and similarly areas $3-4$ and $5-6$ have majorities of 2s and 3s. If $i < j$, all initial populations in area i are projected before those in area j. Inside each area, initial populations are ordered lexicographically in the direction of the arrow. More specifically, in regions $1-2$, the sorting is done primarily on p_1, and secondarily on p_2; for $3-4$, p_2 and p_3; for $5-6$, p_3 and p_1. Even-numbered regions are sorted ascending and odd-numbered regions are sorted descending.

We sample 216 initial populations in the simplex: the six areas in Figure 2a are each divided into six triangles, and each of them is further divided into six more triangles. The center of each resulting triangle corresponds to an initial population. We add random noise distributed uniformly between -0.00005 and 0.00005 to reduce certain artifacts due to identical distributions of the two populations (see the discussion at the end of this section about the thin diagonal line in Figure 4). The sampling also does not cover initial populations on the edges or vertexes of the simplex, but the probability that an evolutionary algorithm starts from those initial populations is negligibly small.

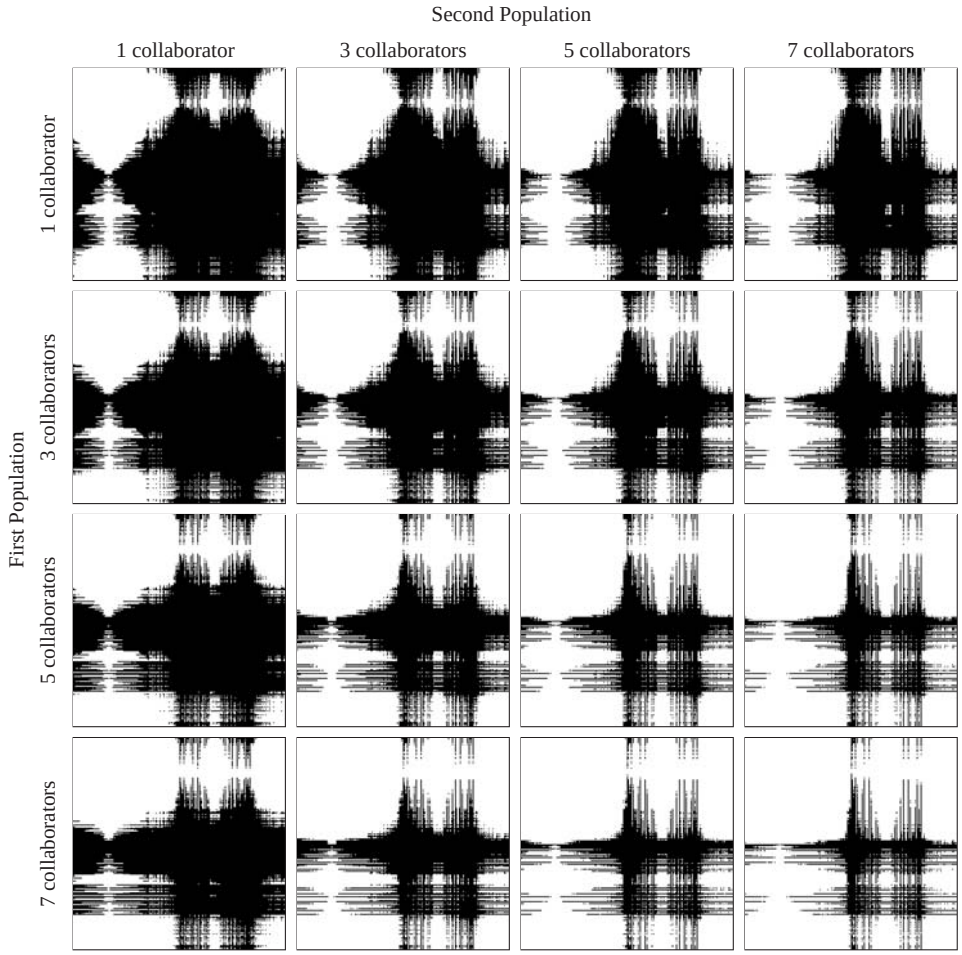

Figure 3: Basins of attraction for CCEA in the Climb problem domain for cooperative coevolution with 1, 3, 5 and 7 collaborators per population. White and black mark the basins of attraction for the (1,1) and (2,2) equilibria, respectively.

The right image in Figure 2 is an example of the resulting projection of $(\Delta^3)^2$ onto 2-D. Thanks to the sorting described above, certain regions reflect majority-1, majority-2, and majority-3 regions; and borders between those regions are the mixture of the two regions. Dark lines in this figure show locations that have high ratios of 1s, 2s, or 3s in one or the other population.

First, Figure 3 visualizes the impact of improved estimates due to increased numbers of collaborators for each population (to parallel Theorem 2). The images shows the basins of attraction in the Climb coordination game. Observe that the difficulty of the problem domain decreases as each population is provided with more accurate estimates for the fitness of individuals. When using a single collaborator, it appears that the coevolutionary search will find the optimum if at least one of the populations starts with a large number of 1s. Even in this case, the system is most likely to converge to the global optimum if the ratio of 2s is relatively low. As each population gets a

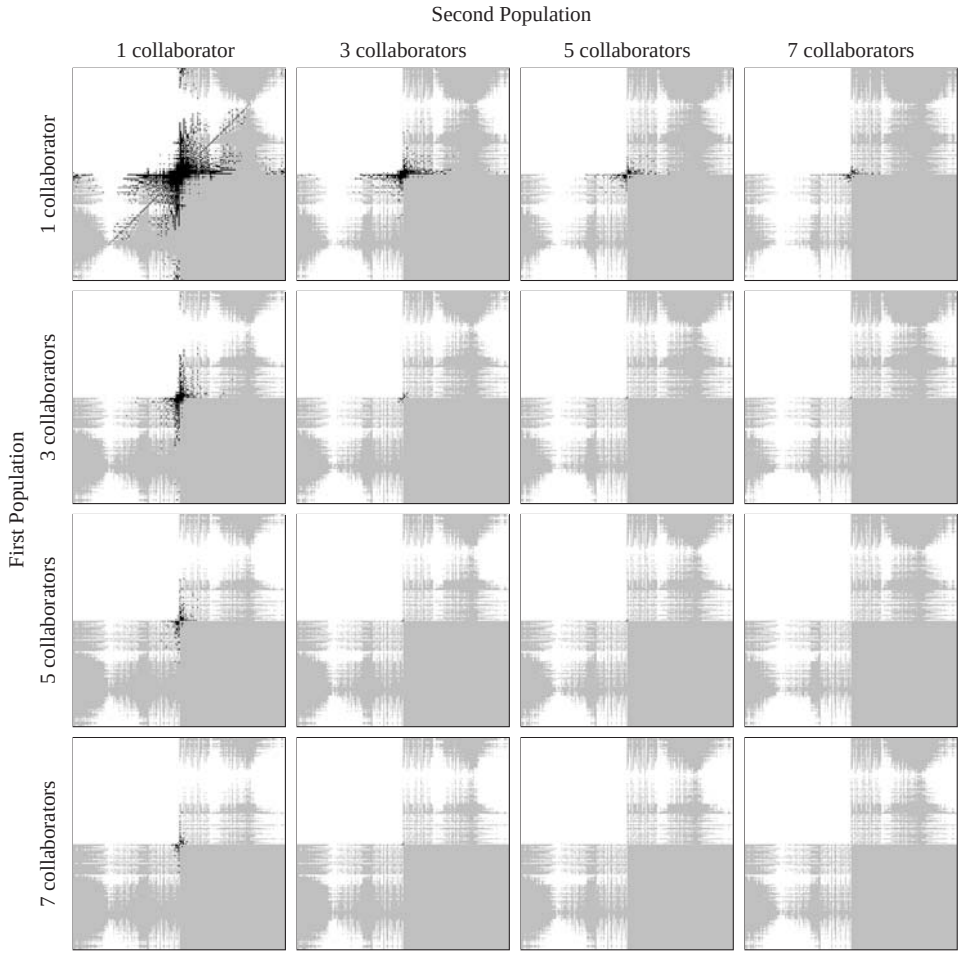

Figure 4: Basins of attraction for CCEA in the Penalty problem domain for cooperative coevolution with 1, 3, 5 and 7 collaborators per population. White, black, and light grey mark the basins of attraction for the (1,1), (2,2), and (3,3) equilibria, respectively.

better estimate of fitness (via an increased number of collaborators), the basin of attraction for the suboptimal equilibrium reduces to areas where at least one of the initial populations has a very large proportion of 2s or 3s: the more collaborators are used, the larger the proportion of 2s or 3s required to still converge to the sub-optimum.

Figure 4 presents the basins of attraction in the Penalty game. Note that the Penalty game has two global optima and thus does not fit the hypothesis of the formal proof in Theorem 2. The basins of attraction illustrated in Figure 4 indicate that lenient learners exhibit good performance in some games with multiple global optima as well. What precise characteristics of the coordination game pose difficulties to lenient learners is the focus of ongoing analysis.

Observe that the two global optima cover most of the space in Figure 4 even when a single collaborator is used; the suboptimal equilibria covers mainly areas where at least one of the pop-

ulation started with a high percentage of 2s, and the other population has the 1s and 3s equally distributed—this increases the percentage of miscoordinations. As the number of collaborators is increased, the basin of attraction for the (2,2) point reduces to only areas where *both* populations start with almost solely 2s. The visualization of the basins of attraction suggests that Penalty is a much easier coordination game than Climb. Note also the thin diagonal line in the top-left graph of Figure 4. Interestingly, this is due to the fact that if the proportion of 1s in one population is about equal to the proportion of 3s in the other population, there are frequent miscoordinations that impact on the expected reward for these actions as estimated by the learners, and the system converges to the suboptimal (2, 2) equilibrium.

The visualization of the basins of attraction to Nash equilibria provided an intuitive approach to grasping the impact that lenience has onto cooperative coevolutionary algorithms. Figures 3 – 4 showed that the number of trajectories for CCEAs that converge to suboptimal solutions decreases significantly across both problem domains, as the level of lenience increases. Next, we apply this visualization technique to show that lenience is not specific to only cooperative coevolution, but it can be used to improve the performance of other multiagent learning algorithms as well.

5. Evolutionary Game Theory Models for Lenient Multiagent Q-Learning

The RD model in Equations 14–17 assumes that the agent will update the utility of an action based on the average reward it expects to receive for that action. This approach is therefore similar to the one used by the EGT model of cooperative coevolutionary algorithms in Equations 5–8. As argued in Section 3 and demonstrated in Section 4 (for cooperative coevolutionary algorithms only), using the average reward usually results in poor estimates for the quality of actions, causing potential attraction to towards suboptimal solutions.

To remedy this situation, we extend the RD model such that each learner ignores lower rewards to improve its estimate. The key to this extension is in Theorem 1 in Section 3. The following RD model is a straightforward combination of these previous results:

$$u_i = \sum_{j=1}^{m} \frac{a_{ij} y_j \left(\left(\sum_{k:a_{ik} \leq a_{ij}} y_k \right)^N - \left(\sum_{k:a_{ik} < a_{ij}} y_k \right)^N \right)}{\sum_{k:a_{ik}=a_{ij}} y_k}, \tag{36}$$

$$w_j = \sum_{i=1}^{n} \frac{a_{ij} x_i \left(\left(\sum_{k:a_{kj} \leq a_{ij}} x_k \right)^N - \left(\sum_{k:a_{kj} < a_{ij}} x_k \right)^N \right)}{\sum_{k:a_{kj}=a_{ij}} x_k}, \tag{37}$$

$$\frac{\frac{dx_i}{dt}}{x_i} = \frac{\alpha}{\tau} \left(u_i - \sum_k x_k u_k \right) + \alpha \sum_k x_k \ln \frac{x_k}{x_i}, \tag{38}$$

$$\frac{\frac{dy_j}{dt}}{y_j} = \frac{\alpha}{\tau} \left(w_j - \sum_k y_k w_k \right) + \alpha \sum_k y_k \ln \frac{y_k}{y_j}. \tag{39}$$

Note that the two equations describing the update rule for the two learners have not changed. What has changed, however, is the expected reward that is used to update the utilities of actions Equations 36 and 37). As expected, observe that the two RD models described by Equations 14–17 and 36–39 are equivalent when $N = 1$ (that is, when the agents do not ignore any low rewards). For

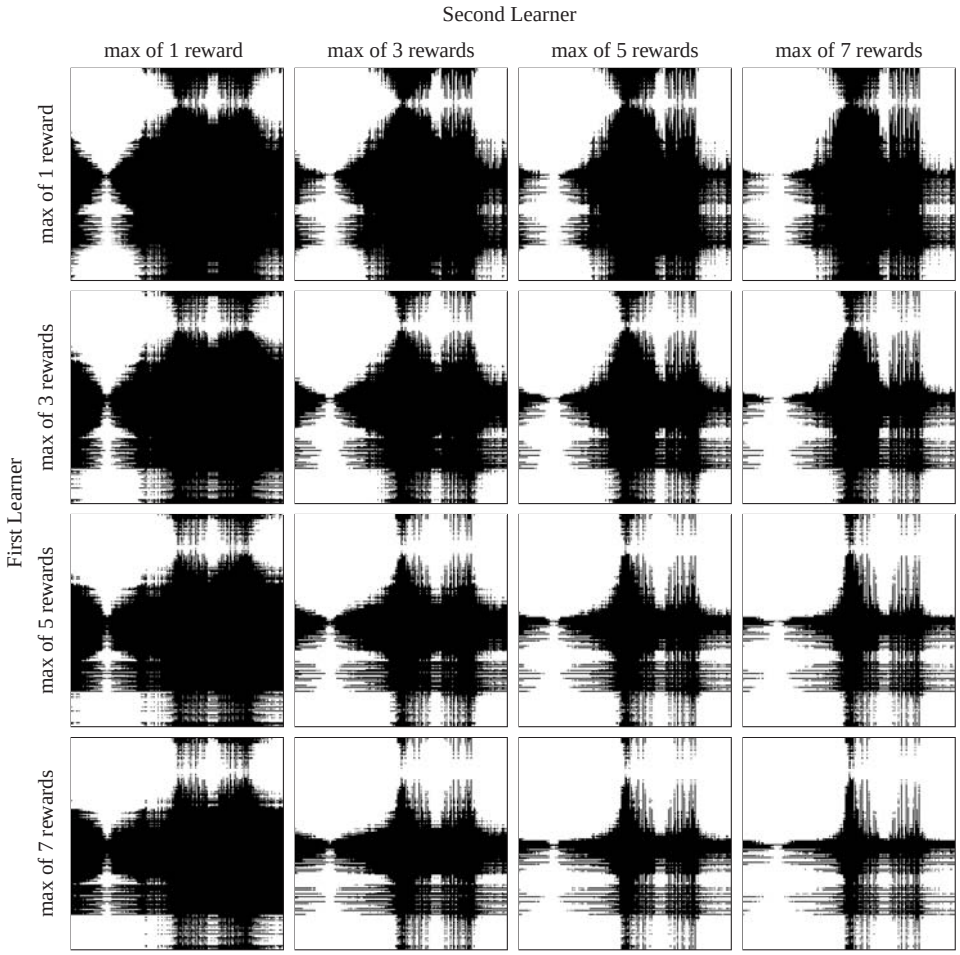

Figure 5: Basins of attraction in the Climb problem domain for multiagent Q-learning that updates the utility of an action based on the maximum of 1, 3, 5 and 7 of the rewards received when selecting that action. White and black mark the basins of attraction for the (1,1) and (2,2) equilibria.

this reason, the setting $N = 1$ constitutes a benchmark representing the formal model for traditional Q-learners.

5.1 Basins of Attraction to Nash Equilibria for Multiagent Q-Learning

Given that the RD model provides differential equations, the next state of the concurrent learning system can be approximated by assuming the variations in the derivative are small over short periods of time θ:

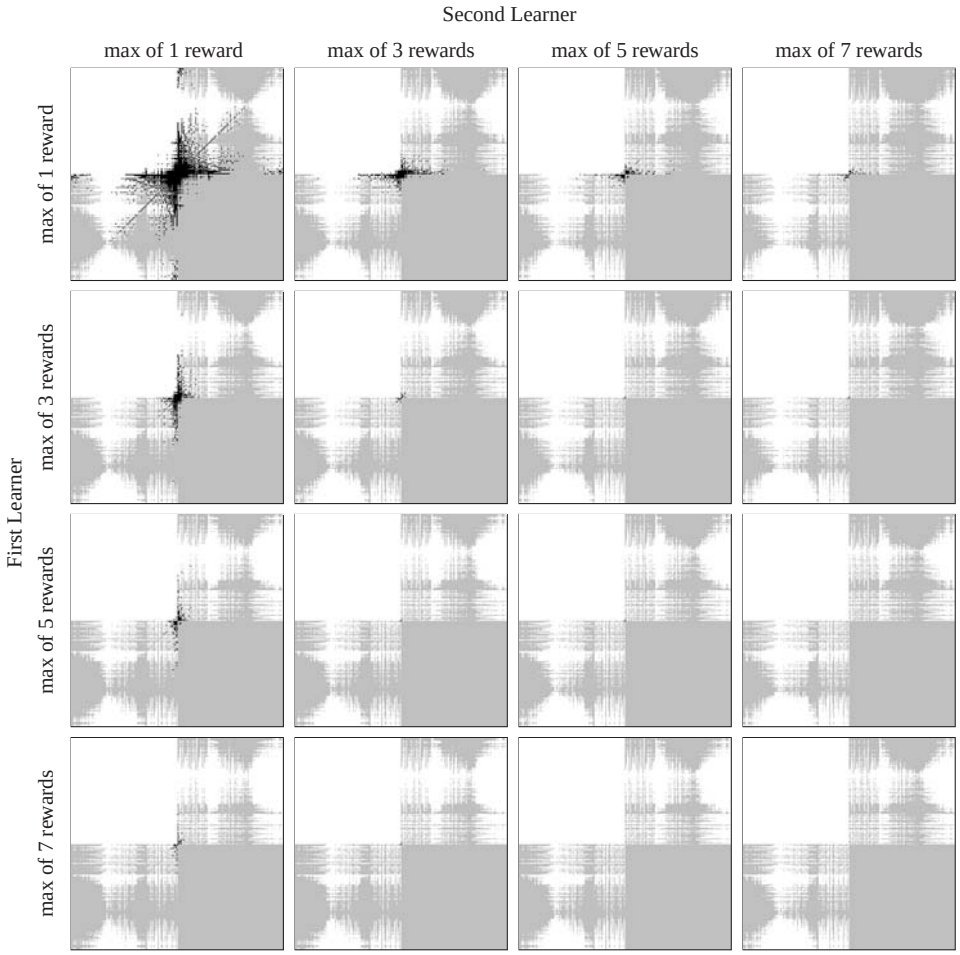

Figure 6: Basins of attraction in the Penalty problem domain for multiagent Q-learning that updates the utility of an action based on the maximum of 1, 3, 5 and 7 of the rewards received when selecting that action. White, black, and light grey mark the basins of attraction for the (1,1), (2,2), and (3,3) equilibria, respectively.

$$\begin{aligned} x_i' &= x_i + \theta \frac{dx_i}{dt}, \\ y_j' &= y_j + \theta \frac{dy_j}{dt}. \end{aligned}$$

Experiments used the following settings: $\theta = 0.001$, the learning rate $\alpha = 0.1$, and the exploration parameter $\tau = 0.01$. We iterate the RD model 100000 times, or until both agents have a probability exceeding $1 - 10^{-10}$ to select one of their actions over the other two.

The basins of attraction for the optimal $(1,1)$ (both play their first action) and suboptimal $(2,2)$ (both play their second action) equilibria in the Climb domain are visualized in Figure 5. Given

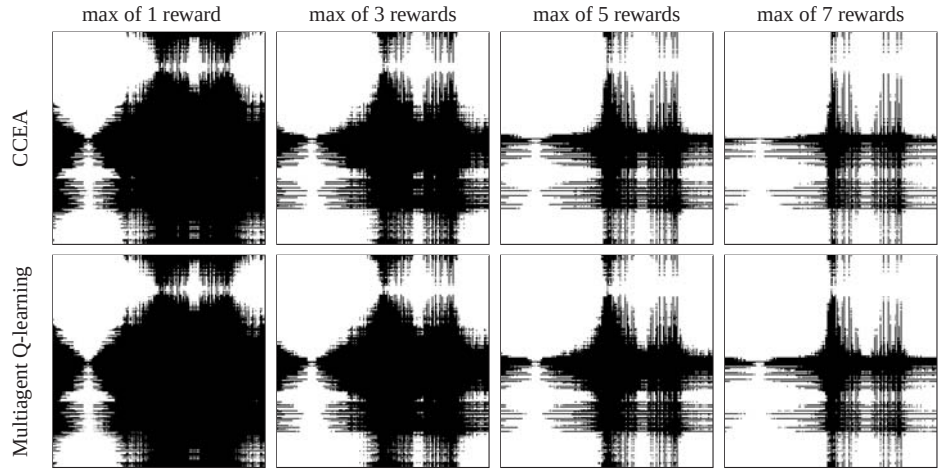

Figure 7: Basins of attraction in the Climb problem domain for cooperative coevolution and multiagent reinforcement learning, both ignoring all but the maximum of 1, 3, 5, and 7 rewards. White and black mark the basins of attraction for the (1,1) and (2,2) equilibria.

that the new RD model reduces to the one described in Tuyls et al. (2006) when $N = 1$, the basin of attraction in the top-left graph suggests that a straightforward extension of Q-learning to multiagent domains may converge to the suboptimal solution when started from many initial conditions. As the learners ignore more of the lower rewards, they improve their estimates for the quality of their actions, and are thus more likely to converge to the global optimum. The same behavior can be observed in the Penalty domain, as illustrated in Figure 6.

Note that multiagent Q-learning improves with more lenience in nearly an identical (but not *quite* identical) fashion to coevolution. Figure 5 shows the basins of attraction in the Climb coordination game. Once again, the images show that the difficulty of the problem domain decreases as each population is provided with more accurate estimates for the utilities of actions. Similarly, Figure 6 presents the basins of attraction in the Penalty game. As was the case for coevolution, increasing numbers of collaborators are able to essentially eliminate convergence to the suboptimal equilibrium. Also, Q-learning likewise has a thin diagonal line of suboptimal convergence in the top-left graph of Figure 6, which once again is due to one agent selecting action 1 in equal proportions to the second agent selecting action 3, and vice-versa.

6. Discussion and Conclusions

At first glance one would think that coevolution and multiagent Q-learning, being fairly different algorithms, with fairly different settings and aimed at different kinds of problems, would respond differently in these scenarios. However, not only do they perform nearly identically in the "classic" case (no lenience), but they also respond in nearly the same fashion when subjected to varying degrees of lenience as well. To highlight this similarity, Figures 7 and 8 sample the diagonal graphs in Figures 3 – 5 and Figures 4 – 6: these are the cases where both agents ignore the same number of lower rewards. This is not really that surprising however: as the theoretical analysis has shown,

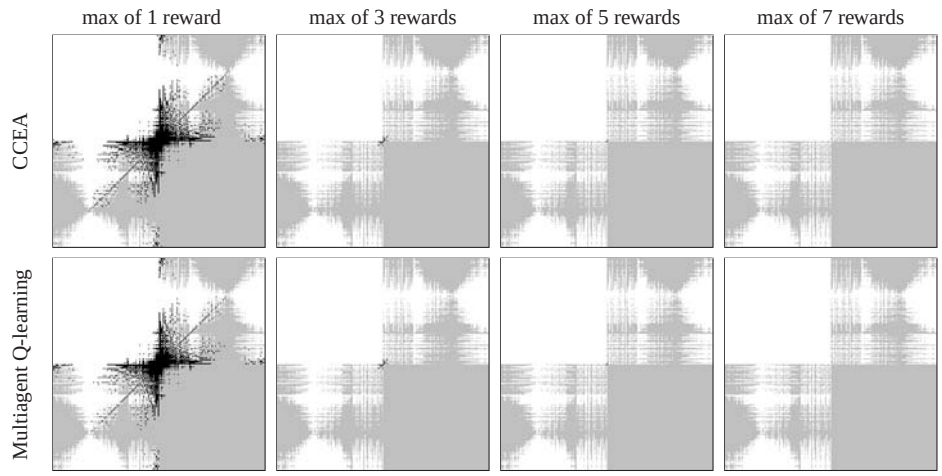

Figure 8: Basins of attraction in the Penalty problem domain for cooperative coevolution and multiagent reinforcement learning, both ignoring all but the maximum of 1, 3, 5, and 7 rewards. White, black, and light grey mark the basins of attraction for the (1,1), (2,2), and (3,3) equilibria, respectively.

the dynamics of these equations is quite similar; so much so, indeed, that each of these respective communities would do well to more closely examine the existing work of the other.

Keep in mind that both evolutionary algorithms and Q-learning are guaranteed to converge to the global optimum in single-agent scenarios, if properly set and if given enough resources. We have argued that the attraction of these algorithms towards suboptimal solutions is caused primarily by poor estimates, and that it can be dealt with if learners simply ignore lower rewards. Figures 7 and 8 suggest that if the multiagent learning algorithm is heading towards suboptimal solutions, it is usually caused by the estimation procedure for the quality of an action of the learning algorithm. These algorithms do not start to suffer from undesirable pathologies just because they are used in multiagent scenarios. Rather, poor estimates are the primary cause for the suboptimal solutions. Ignoring lower rewards improves the learners' estimate for the quality of their behaviors, resulting in an increased probability that the multiagent learning system will converge to the global optimum.

In summary, this paper presented an extended formal model for a new class of multiagent learning algorithms, namely those involving lenient agents that ignore low rewards observed upon performing actions in the environment. The paper also illustrated the basins of attraction to different optimal and suboptimal Nash equilibria, and showed how intuitive graphs might reveal valuable information about the properties of multiagent learning algorithms that was lacking in the summarizations of empirical results. The paper provided theoretical support for previous reports that lenience helps learners achieve higher rates of convergence to optimal solutions, and also proved that properly-set lenient learners are guaranteed to converge to the Pareto-optimal Nash equilibria in coordination games. Finally, the results strengthened the use of Evolutionary Game Theory to study the properties of multiagent reinforcement learning algorithms.

This work has also opened many avenues of future research. We plan to extend these formal models to help analyze the properties of multiagent learning algorithms in more complex domains,

such as those involving more actions and players, stochasticity, multiple states, and partial observability. We hope that this formal analysis will provide the foundation for new learning algorithms guaranteed to converge to optimal solutions.

Acknowledgments

The authors would like to thank R. Paul Wiegand, Dana Richards, Keith Sullivan, Dominic Mazzoni, and the anonymous reviewers for helpful discussions and suggestions.

Abstract

In this paper, we propose a recursive method for structural learning of directed acyclic graphs (DAGs), in which a problem of structural learning for a large DAG is first decomposed into two problems of structural learning for two small vertex subsets, each of which is then decomposed recursively into two problems of smaller subsets until none subset can be decomposed further. In our approach, search for separators of a pair of variables in a large DAG is localized to small subsets, and thus the approach can improve the efficiency of searches and the power of statistical tests for structural learning. We show how the recent advances in the learning of undirected graphical models can be employed to facilitate the decomposition. Simulations are given to demonstrate the performance of the proposed method.

Keywords: Bayesian network, conditional independence, decomposition, directed acyclic graph, structural learning

1. Introduction

Directed acyclic graphs (DAGs), also known as Bayesian networks, are frequently used to represent independencies, conditional independencies and causal relationships in a complex system with a large number of random variables (Lauritzen, 1996; Cowell et al., 1999; Pearl, 2000; Spirtes et al., 2000). Structural learning of DAGs from data is very important in applications to various fields, such as medicine, artificial intelligence and bioinformatics (Jordan, 2004; Engelhardt et al., 2006).

There have been two primary methods for learning the structures of DAGs from data. The search-and-score method defines a score for each possible structure based on the goodness-of-fit of the structure to data and the complexity of the structure, and then it tries to search the best structure over all possible structures (Cooper and Herskovits, 1992; Heckerman et al., 1995; Chickering, 2002; Friedman and Koller, 2003). The constraint-based method evaluates the presence or absence of an edge by testing conditional independencies among variables from data. The tests are usually done by using statistical or information-theoretic measures (Pearl, 2000; Spirtes et al., 2000; Cheng et al., 2002). There have also been hybrid methods. For example, Tsamardinos et al. (2006) takes advantage of both approaches. In a constraint-based method, search for separators of vertex pairs is a key issue for orientation of edges and for recovering DAG structures and causal relationships among variables. To recover structures of DAGs, Verma and Pearl (1990) presented the inductive causation (IC) algorithm which searches for a separator S of two variables, say u and v, from all possible

variable subsets such that u and v are independent conditionally on S. A systematic way of searching for separators in increasing order of cardinality was proposed by Spirtes and Glymour (1991). The PC algorithm limits possible separators to vertices that are adjacent to u and v (Pearl, 2000; Spirtes et al., 2000). Kalisch and Bühlmann (2007) showed that the PC algorithm is asymptotically consistent even when the number of vertices in a DAG grows at a certain rate as the sample size increases.

In this paper, we propose a recursive algorithm in which a problem of structural learning for a large DAG is split recursively into problems of structural learning for small vertex subsets. Our algorithm can be depicted as a binary tree whose top node is the full set of all vertices or variables and whose other nodes are proper subsets of the vertex set at its parent node. The algorithm mainly consists of two steps: the top-down step and the bottom-up step. First at the top-down step, the full set of all variables at the top is decomposed into two small subsets, each of which is decomposed recursively into two smaller subsets until each node cannot be decomposed further at the bottom of the tree. At each step, the decomposition is achieved by learning an undirected graph known as independence graph for a variable subset. Next at the bottom-up step, subgraphs (called skeletons) of leaf nodes are first constructed, and then a pair of child subgraphs are combined together into a large subgraph at their parent node until the entire graph is constructed at the top of the tree. In the algorithm, search for separators in a large graph is localized to small subgraphs. Statistical test is used to determine a skeleton as in the IC algorithm (Verma and Pearl, 1990) and the PC algorithm (Spirtes, 2000). By recursively decomposing the full variable set into small subsets, this algorithm can improve the efficiency of search for separators in structural learning, and it can also make statistical tests more powerful. We also discuss that several methods of learning undirected graphical models (Castelo and Roverato, 2006; Schmidt et al., 2007) can be used to facilitate the decomposition. Finally, we provide simulation results to show the performance of our method.

Section 2 gives notation and definitions. In Section 3, we first present the main theoretical results and then discuss the realization of the algorithm in detail, and we also introduce how the recent advances in various related fields can be used to improve the proposed method. In Section 4, we first use an example to illustrate our approach for learning the equivalence class of a DAG in detail, then we give numerical evaluations of its performance for several networks, and finally we discuss the computational complexity of our recursive algorithm. Conclusion is given in Section 5. The proofs of our main results are presented in Appendix.

2. Notation and Definitions

Let $\vec{G}_V = (V, \vec{E}_V)$ denote a DAG where $V = \{X_1, \ldots, X_n\}$ is the vertex set and $\vec{E}_V$ the set of directed edges. A directed edge from a vertex u to a vertex v is denoted by $\langle u, v \rangle$. We assume that there is no directed loop in $\vec{G}_V$. We say that u is a parent of v and v is a child of u if there is a directed edge $\langle u, v \rangle$, and denote the set of all parents of a vertex v by $pa(v)$ and the set of all children of v by $ch(v)$. We say that two vertices u and v are adjacent in $\vec{G}_V$ if there is an edge connecting them. A path l between two distinct vertices u and v is a sequence of distinct vertices in which the first vertex is u, the last one is v and two consecutive vertices are connected by an edge, that is, $l = (c_0 = u, c_1, \ldots, c_{m-1}, c_m = v)$ where $\langle c_{i-1}, c_i \rangle$ or $\langle c_i, c_{i-1} \rangle$ is contained in $\vec{E}_V$ for $i = 1, \ldots, m$ ($m \geq 1$), and $c_i \neq c_j$ for all $i \neq j$. We say that u is an ancestor of v and v is a descendant of u if there is a path between u and v in $\vec{G}_V$ and all edges on this path point at the direction toward v. The set of ancestors of v is denoted as $an(v)$, and we define $An(v) = an(v) \cup \{v\}$. A path l is said to be d-separated by a set of vertices Z if

(1) l contains a "chain": $u \to v \to w$ or a "fork" $u \leftarrow v \to w$ where v is in Z, or

(2) l contains a "collider" $u \to v \leftarrow w$ where v is not in Z and no descendant of v is in Z.

Two disjoint sets X and Y of vertices are d-separated by a set Z if Z d-separates every path from any vertex in X to any vertex in Y; We call Z a d-separator of X and Y. In $\vec{G}_V$, a collider $u \to v \leftarrow w$ is called a v-structure if u and w are non-adjacent in $\vec{G}_V$.

Let $\bar{G}_V = (V, \bar{E}_V)$ denote an undirected graph where $\bar{E}_V$ is a set of undirected edges. An undirected edge between two vertices u and v is denoted by (u,v). An undirected graph is called complete if any pair of vertices is connected by an edge. Define a moral graph $\bar{G}^m_V$ for a DAG $\vec{G}_V$ to be an undirected graph $\bar{G}^m_V = (V, \bar{E}_V)$ whose vertex set is V and whose edge set is constructed by marrying parents and dropping directions, that is, $\bar{E}_V = \{(u,v) : \langle u,v\rangle \text{ or } \langle v,u\rangle \in \vec{E}_V\} \cup \{(u,v) : (u,w,v) \text{ forms a } v\text{-structure}\}$ (Lauritzen, 1996). An undirected edge added for marrying parents is called a moral edge.

For an undirected graph, we say that vertices u and v are separated by a set of vertices Z if each path between u and v passes through Z. We say that two disjoint vertex sets X and Y are separated by Z if Z separates every pair of vertices u and v for any $u \in X$ and $v \in Y$. We call (A,B,C) a decomposition of $\bar{G}_V$ if

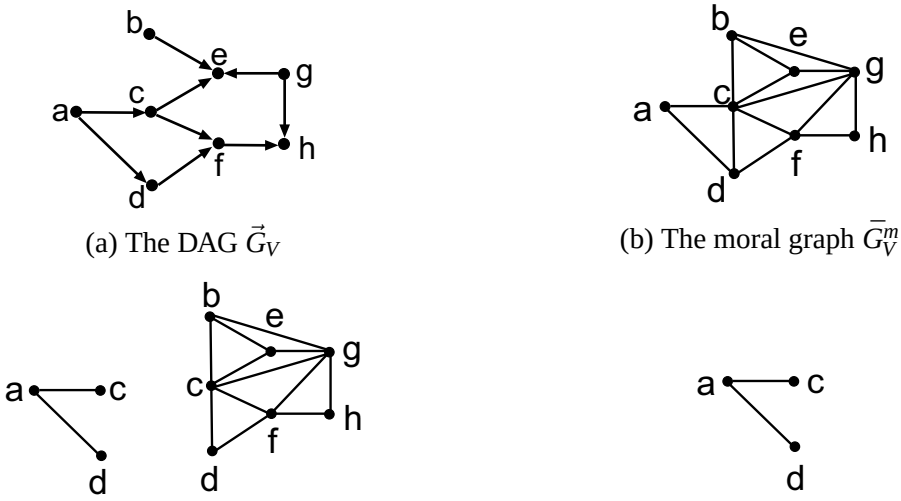
(1) $A \cup B \cup C = V$, and

(2) C separates A and B in $\bar{G}_V$.

Note that the above decomposition does not require that the separator C is complete, which is required for weak decomposition defined by Lauritzen (1996).

For a set $K \subseteq V$, we say that an undirected graph $\bar{G}_K$ is an undirected independence graph for a DAG $\vec{G}_V$ if that a set Z separates X and Y in $\bar{G}_K$ implies that Z d-separates X and Y in $\vec{G}_V$. An undirected independence graph is minimal if the proper subgraph obtained by deleting any edge is no longer an undirected independence graph. The moral graph $\bar{G}^m_V$ is the minimal undirected independence graph for $\vec{G}_V$ with $K = V$ (Lauritzen, 1996). It can also be obtained by connecting each vertex u with all vertices in its Markov blanket $Mb(u)$, which is the minimal set by which u are d-separated from the remaining set in V (that is, $V \setminus [Mb(u) \cup \{u\}]$). For a subset $K \subseteq V$, the Markov blanket for a vertex $u \in K$ can be defined similarly, that is, it is the minimum set that is contained in K and d-separates u from the remaining set in K. When $K = V$, it is easy to verify $Mb(u) = pa(u) \cup ch(u) \cup pa(ch(u))$. Define the local skeleton for a variable set $K \subseteq V$ with respect to $\vec{G}_V$ as an undirected graph $\bar{L}_K(K,E)$ where K is the vertex set and $E = \{(u,v) : \text{ no subset } S \text{ of } K \text{ } d\text{-separates } u \text{ and } v \text{ in } \vec{G}_V\}$ is the edge set. Note that though both minimal undirected independence graphs and local skeletons are undirected graphs and defined on the same vertex subset, they may be different. According to the definition of a minimal undirected independence graph, the absence or presence of an edge between u and v in the minimal undirected independence graph over $K \subseteq V$ depends on whether its two vertices are d-separated by the remaining set $K \setminus \{u,v\}$ in $\vec{G}_V$, while an edge between u and v in the local skeleton is determined by whether there exists a subset of K that can d-separate u and v in $\vec{G}_V$. Thus the edge set of the minimal undirected independence graph contains the edge set of the local skeleton.

The global skeleton is an undirected graph obtained by dropping the directions of the edges in a DAG, which coincides the local skeleton for $K = V$. Two DAGs over the same variable set



(a) The DAG $\vec{G}_V$

(b) The moral graph $\bar{G}_V^m$

(c) One decomposition based on $\bar{G}_V^m$

(d) A local skeleton

Figure 1: A directed graph, a moral graph, a decomposition and a local skeleton.

are called Markov equivalent if they induce the same conditional independence restrictions. Two DAGs are Markov equivalent if and only if they have the same global skeleton and the same set of *v*-structures (Verma and Pearl, 1990). An equivalence class of DAGs consists of all DAGs which are Markov equivalent, and it is represented as a partially directed graph (PDAG) where the directed edges represent arrows that are common to every DAG in the Markov equivalence class, while an undirected edge represents that the edge is oriented one way in some member of the Markov equivalence class, and is oriented the other way in some other member. Therefore the goal of structural learning is to construct a PDAG to represent the equivalence class.

Example 1. Consider the DAG in Figure 1 (a). $b \to e \leftarrow c$, $b \to e \leftarrow g$, $c \to f \leftarrow d$, $c \to e \leftarrow g$ and $f \to h \leftarrow g$ are *v*-structures. A path $l = (c,a,d)$ is d-separated by vertex a, while the path $l' = (c,f,h,g)$ is d-separated by an empty set. We have $an(e) = \{a,b,c,g\}$ and $An(e) = \{a,b,c,g,e\}$. The Markov blanket of c is $Mb(c) = \{a,b,d,e,f,g\}$, which d-separates c and the remaining set $\{h\}$. The moral graph $\bar{G}_V^m$ is given in Figure 1 (b), where edges (b,c), (b,g), (c,g), (c,d) and (f,g) are moral edges. Note that the set $\{c,d\}$ separates $\{a\}$ and $\{b,e,f,g,h\}$ in G_V^m, thus $(\{a\},\{b,e,f,g,h\},\{c,d\})$ forms a decomposition of the undirected graph G_V^m, the decomposed undirected independence subgraphs for $\{a,c,d\}$ and $\{b,c,d,e,f,g,h\}$ are shown in Figure 1 (c). The graph in Figure 1 (d) is the local skeleton $L_K(K,E)$ for $K = \{a,c,d\}$ because we have c and d are d-separated by $\{a\}$ in $\vec{G}_V$. Note that the minimal undirected independence graph for $\{a,c,d\}$ in Figure 1(c) coincides with its local skeleton in Figure 1 (d), which does not hold in general. For example, the local skeleton for $K = \{c,e,g\}$ does not have the edge (c,g), while the corresponding minimal undirected independence graph is complete.

Given a DAG $\vec{G}_V$, a joint distribution or density of variables $X_1,\ldots,X_N$ is

$$P(x_1,\cdots,x_N) = \prod_{i=1}^{N} P(x_i|pa_i),$$

where $P(x_i|pa_i)$ is the conditional probability or density of X_i given $pa(X_i) = pa_i$. The DAG $\vec{G}_V$ and the joint distribution P are said to be compatible (Pearl, 2000) and P obeys the global directed Markov property of $\vec{G}_V$ (Lauritzen, 1996). Let $X \perp\!\!\!\perp Y$ denote the independence of X and Y, and $X \perp\!\!\!\perp Y|Z$ the conditional independence of X and Y given Z. In this paper, we assume that all independencies of a probability distribution of variables in V can be checked by d-separations of $\vec{G}_V$, called the faithfulness assumption (Spirtes et al., 2000), which means that all independencies and conditional independencies among variables can be represented by $\vec{G}_V$. As a consequence, we also use $\perp\!\!\!\perp$ to denote the d-separation in DAGs.

3. A Recursive Method for Structural Learning of a DAG

In this section, we first present theoretical results in this paper and then we apply these results to structural learning of a DAG and show how the problem of searching for d-separators over the full set of all vertices can be recursively split into the problems of searching for d-separators over smaller subsets of vertices. We also discuss how to learn from data the undirected independence graphs which are used to achieve the recursive decomposition at each recursive step.

3.1 Theoretical Results and Recursive Algorithm for Structural Learning

Below we first give two theorems based on which we propose the recursive algorithm for structural learning of DAGs.

Theorem 1. Suppose that $A \perp\!\!\!\perp B|C$ in a DAG $\vec{G}_V$. Let $u \in A$ and $v \in A \cup C$. Then u and v are d-separated by a subset of $A \cup B \cup C$ if and only if they are d-separated by a subset of $A \cup C$.

According to Theorem 1, we can see that all edges falling in A or crossing A and C in the local skeleton $\overline{L}(K,E)$ with $K = A \cup C \cup B$ can be validly recovered from the marginal distribution of variables in $A \cup C$. Note that such a local skeleton over K can be used to recover the entire DAG over V even if there may not exist a marginalized DAG over K (Richardson and Spirtes, 2002).

Theorem 2. Suppose that $A \perp\!\!\!\perp B|C$ in a DAG $\vec{G}_V$. Let u and v be two vertices both of which are contained in the separator C. Then u and v are d-separated by a subset of $A \cup B \cup C$ if and only if they are d-separated by a subset of $A \cup C$ or by a subset of $B \cup C$.

According to Theorem 2, the existence of an edge falling into the separator C in the local skeleton $\overline{L}(K,E)$ with $K = A \cup C \cup B$ can be determined from the marginal distribution of $A \cup C$ or the marginal distribution of $B \cup C$.

Note that the union set $K = A \cup B \cup C$ in Theorems 1 and 2 may be a subset of the full set V (that is, $K \subseteq V$), and they are more general results than Theorem 1 presented in Xie et al. (2006), which requires that the union set K equals V (that is, $K = A \cup B \cup C = V$). These two theorems can guarantee that, for any partition (A,B,C) of a vertex set $K \subseteq V$ that satisfies $A \perp\!\!\!\perp B|C$, two non-adjacent vertices u and v in K are d-separated by a subset S of K in $\vec{G}_V$ if and only if they are d-separated by a subset S' of either $A \cup C$ or $B \cup C$ in $\vec{G}_V$. Therefore, we have the following result.

Theorem 3. Suppose that $A \perp\!\!\!\perp B|C$ in a DAG $\vec{G}_V$. Then the local skeleton $\overline{L}_K = (K, E_K)$ can be constructed by combining local skeletons $\overline{L}_{A\cup C} = (A \cup C, E_{A\cup C})$ and $\overline{L}_{B\cup C} = (B \cup C, E_{B\cup C})$ as follows:

(1) the vertex set $K = A \cup C \cup B$ and

(2) the edge set $E_K = (E_{A\cup C} \cup E_{B\cup C}) \setminus \{(u,v) : u,v \in C \text{ and } (u,v) \notin E_{A\cup C} \cap E_{B\cup C}\}$.

Based on these theorems, we propose a recursive algorithm for learning the structure of a DAG. Our algorithm has a series of operations on a binary tree. The top node of the tree is the full set of all variables, the leaves of the tree are subsets of variables which cannot be decomposed, and the variable set of each parent node in the binary tree is decomposed into two variable sets of its two children. Our algorithm consists of two steps: the top-down step for decomposing the full set of all variables into subsets as small as possible, and the bottom-up step for combining local skeletons into the global skeleton. At the top-down step, a variable set is decomposed into two subsets whenever a conditional independence $A \perp\!\!\!\perp B|C$ is found, and this decomposition is repeated until no new decomposition can be found. The decomposition at each step is done by learning an undirected independence graph over the vertex subset at the tree node, which will be discussed in Subsection 3.3. At the bottom-up step, two small skeletons are combined together to construct a larger skeleton, and the combination is repeated until the global skeleton is obtained. The entire process is formally described in the following algorithm.

Main Algorithm (*The recursive decomposition for structural learning of DAGs*)

1. Input: a target variable set V; observed data D.
2. Call DecompRecovery (V, $\bar{L}_V$) to get the global skeleton $\bar{L}_V$ and a separator list $\mathcal{S}$.
3. For each d-separator S_{uv} in the separator list $\mathcal{S}$, orient the local skeleton $u - w - v$ as a v-structure $u \rightarrow w \leftarrow v$ if $u - w - v$ (Note no edge between u and v) appears in the global skeleton and w is not contained in the separator S_{uv}.
4. Apply Meek's rule (Meek, 1995) to obtain a DAG in the Markov equivalence class: we orient other edges if each opposite of them creates either a directed cycle or a new v-structure. The Markov equivalence class can be obtained by collecting all possible DAGs.
5. Output: the equivalence class of DAGs.

PROCEDURE DecompRecovery (K, $\bar{L}_K$)

1. Construct an undirected independence graph $\bar{G}_K$;
2. If $\bar{G}_K$ has a decomposition (A, B, C)

   Then

   - For each pair (u, v) of $u \in A$ and $v \in B$, save $(u, v, S_{uv} = C)$ to the d-separator list $\mathcal{S}$;
   - DecompRecovery ($A \cup C$, $\bar{L}_{A\cup C}$);
   - DecompRecovery ($B \cup C$, $\bar{L}_{B\cup C}$);
   - Set $\bar{L}_K$ = CombineSubgraphs ($\bar{L}_{A\cup C}$, $\bar{L}_{B\cup C}$)

   Else

   - Construct the local skeleton $\bar{L}_K$ directly (such as using the IC algorithm):
     Start with a complete undirected graph over K.
     For any vertex pair (u, v) in the set K, if there exists a subset S_{uv} of $K \setminus \{u, v\}$ such that $u \perp\!\!\!\perp v|S_{uv}$, then delete the edge (u, v) and save (u, v, S_{uv}) to the d-separator list $\mathcal{S}$.

3. RETURN ($\bar{L}_K$).

FUNCTION CombineSubgraphs ($\bar{L}_U$, $\bar{L}_V$)

1. Combine $\bar{L}_U = (U, E_U)$ and $\bar{L}_V = (V, E_V)$ into an undirected graph $\bar{L}_{U\cup V} = (U \cup V, E_{U\cup V})$ where
$$E_{U\cup V} = (E_U \cup E_V) \setminus \{(u,v) : u,v \in U \cap V \text{ and } (u,v) \notin E_U \cap E_V\};$$
2. Return ($\bar{L}_{U\cup V}$).

As shown in the main algorithm, the equivalence class of $\vec{G}_V$ can be constructed by first calling DecompRecovery (V, $\bar{L}_V$) to get the skeleton, then recover all v-structures using the d-separator list $\mathcal{S}$ to orient the edges in $\bar{L}_V$, and finally orient other edges as much as possible using the rule in Meek (1995). Since a decomposition (A,B,C) of the undirected independence graph $\bar{G}_K$ implies $A \perp\!\!\!\perp B|C$, it is obvious by Theorems 1 and 2 that our algorithm is correct.

A binary decomposition tree is used in DecompRecovery to describe our algorithm simply and clearly. In our implementation, we use a junction tree to decompose a graph into several subgraphs simultaneously and to find the corresponding separators. It is known that the junction tree may not be unique, and thus we may have multiple decompositions. In theory, we prefer to use the junction tree with the minimum tree width. However, this is known to be an NP hard problem (Arnborg et al., 1987); therefore, we may use some sub-optimal method to consruct a junction tree for an undirected graph (Jensen and Jensen, 1994; Becker and Geiger, 2001). For example, two most well-known algorithms are the lexicographic search (Rose et al., 1976) and the maximum cardinality search (Tarjan and Yannakakis, 1984), whose computational expenses are $O(ne)$ and $O(n+e)$ respectively, where e is the number of edges in the graph. Especially, the latter method is used in our implementation. According to our experiences, the junction tree obtained by either method usually leads to very efficient decompositions.

In the recursive algorithm, statistical tests are used only at the top-down step but not at the bottom-up step. Thus the data sets used for statistical tests can be reduced into marginal data sets with decomposition of graphs. In this way, we only need to pass through small marginal data sets for statistical tests of subgraphs and need not pass through the full data set for every statistical test. Other algorithms (such as the PC algorithm) can be used to replace the IC algorithm to improve the performance of constructing the local skeleton $\bar{L}_K$ in DecompRecovery.

3.2 Tests of Conditional Independence

Conditional independence test of two variables u and v given a set C of variables is required at Step 1 and the 'Else' part of Step 2 of Procedure DecompRecovery to construct an undirected independence graph and a local skeleton respectively. Null hypothesis H_0 is $u \perp\!\!\!\perp v|C$ and alternative H_1 is that H_0 may not hold. Generally we can use the likelihood ratio test statistic

$$G^2 = -2\log \frac{\sup\{L(\theta|D) \text{ under } H_0\}}{\sup\{L(\theta|D) \text{ under } H_1\}},$$

where $L(\theta|D)$ is the likelihood function of parameter θ with observed data D. Under H_0, the statistic G^2 asymptotically follows the χ^2 distribution with df degrees of freedom being equal to the difference of the dimensions of parameters for the alternative and null hypothesis (Wilks, 1938).

Let $\mathbf{X}_k$ be a vector of variables and N be the sample size. For the case of a Gaussian distribution, the test statistic for testing $X_i \perp\!\!\!\perp X_j | \mathbf{X}_k$ can be simplified to

$$\begin{aligned} G^2 &= -N \times \log(1 - \text{corr}^2(X_i, X_j | \mathbf{X}_k)) \\ &= N \times \log \frac{\det(\hat{\Sigma}_{\{i,k\}\{i,k\}}) \det(\hat{\Sigma}_{\{j,k\}\{j,k\}})}{\det(\hat{\Sigma}_{\{i,j,k\}\{i,j,k\}}) \det(\hat{\Sigma}_{k,k})}, \end{aligned}$$

which has an asymptotic χ^2 distribution with $df = 1$. Actually, the exact null distribution or a better approximate distribution of G^2 can be obtained based on Bartlett decomposition, see Whittaker (1990) for more detailed discussion on this.

For the discrete case, let N_s^m be the observed frequency in a cell of $X_s = m$ where s is an index set of variables and m is a category of variables X_s. For example, N_{ijk}^{abc} denotes the frequency of $X_i = a$, $X_j = b$ and $\mathbf{X}_k = c$. The G^2 statistic for testing $X_i \perp\!\!\!\perp X_j | \mathbf{X}_k$ is then given by

$$G^2 = 2 \sum_{a,b,c} N_{ijk}^{abc} \log \frac{N_{ijk}^{abc} N_k^c}{N_{ik}^{ac} N_{jk}^{bc}},$$

which is asymptotically distributed as a χ^2 distribution under H_0 with degree of freedom

$$\text{df} = (\#(X_i) - 1)(\#(X_j) - 1) \prod_{X_l \in \mathbf{X}_k} \#(X_l),$$

where $\#(X)$ is the number of categories of variable X.

For discrete data, the size of conditional variable sets cannot be so large that independence tests become inefficient. Thus the algorithm restricts the cardinality of conditioning sets. There are many methods that can be used to find a small conditioning set, such as a forward selection of variables. With the recursive decomposition, independence tests are localized to smaller and smaller subsets of variables, and thus the recursive algorithm has higher power for statistical tests.

3.3 Constructing Undirected Independence Graphs

In this subsection, we discuss how to construct undirected independence graphs at Step 1 of Procedure DecompRecovery. At first we call DecompRecovery with the full set V as the input argument, and construct an undirected independence graph $\bar{G}_V$ at Step 1. Then at each recursive calling, to construct a local undirected independence graph $\bar{G}_K$ with a subset K (say $K = A \cup C$) as the input argument, we shall present a theoretical result based on which we only need to check edges over the separator C without need of testing conditional independencies between any pair of variables in A and between any pair of variables crossing A and C.

To construct an undirected independence graph $\bar{G}_V$, we start with a complete undirected graph, and then we check an edge between each pair of vertices u and v. The edge (u,v) is removed if u and v are independent conditionally on the set of all other variables. For linear Gaussian models, the undirected graph can be constructed by removing an edge (u,v) if and only if the corresponding entry in the inverse covariance matrix is zero (Dempster, 1972; Whittaker, 1990). After decomposing a graph $\bar{G}_{A \cup B \cup C}$ into two subsets $A \cup C$ and $B \cup C$, we need to construct a local undirected independence graph $\bar{G}_K$ (say $\bar{G}_{A \cup C}$) at Step 1 of Procedure DecompRecovery. We show in the following theoretical result that an initial $\bar{G}_{A \cup C}$ can be constructed by using all undirected edges contained

by $A \cup C$ in the previous graph $\bar{G}_{A \cup B \cup C}$ and then only pairs of vertices contained in C need to be checked via conditional independence tests.

Theorem 4. Suppose that the distribution of $V = A \cup B \cup C$ is positive and has the conditional independence $A \perp\!\!\!\perp B | C$. Then for any u in A and any v in $A \cup C$, we have that $u \perp\!\!\!\perp v | [(A \cup C) \setminus \{u, v\}]$ if and only if $u \perp\!\!\!\perp v | [(A \cup B \cup C) \setminus \{u, v\}]$.

Note that Theorems 1 and 4 are different. The former is used to determine an edge in a DAG, and the latter is used to determine an edge in an undirected independence graph. According to this theorem, there exists an edge (u, v) in the minimal undirected independence graph $\bar{G}_{A \cup C}$ for u in A and v in $A \cup C$ if and only if there exists an edge (u, v) in the minimal undirected independence graph $\bar{G}_{A \cup B \cup C}$. Thus given an undirected independence graph $\bar{G}_{A \cup B \cup C}$ obtained in the preceding step, an undirected independence graph $\bar{G}_{A \cup C}$ has the same set of edges as $\bar{G}_{A \cup B \cup C}$ each of which has at least one vertex in A, but all of possible edges within the separator C need to be checked for $\bar{G}_{A \cup C}$.

When there is a large number of variables and a small sample size, it is infeasible or statistically unstable to test an independence between two variables conditionally on all other variables, and this problem is more serious when variables are discrete. Many current methods for learning undirected graphical models can also be used in our algorithm. For example, procedures based on *limited-order partial correlations* (Wille and Bühlmann, 2004; Castelo and Roverato, 2006) are rather suitable and can be even used in the case where the number of variables is larger than the number of samples. Another way of learning undirected independence graphs is to apply current available Markov blanket learning algorithms. By connecting each vertex with those in its Markov blanket, an independence graph is then obtained. Indeed, it is neither new nor uncommon to learn the Markov blanket as either an initial step for learning a DAG or as a special problem of interest. Koller and Sahami (1996) developed a method for feature selection which employs the concept of Markov blanket. Margaritis and Thrun (1999) proposed a two-phase algorithm to first identify a Markov blanket for each variable and then obtain a DAG by connecting vertices in a maximally consistent way. Tsamardinos et al. (2003) proposed a method that can soundly identify all Markov blankets and scale-up to a graph with thousands of variables.

Another particular method for learning the undirected independence graph may use Lasso-type estimators (Tibshirani, 1996; Meinshausen and Bühlmann, 2006; Zhao and Yu, 2006; Wainwright et al., 2006). We can apply Lasso method to select a neighborhood set of a vertex which contains the Markov blanket of the vertex. Schmidt et al. (2007) developed a new method of learning structure of a DAG. Note that it is not necessary to learn neighborhoods exactly in our algorithm, and there may be extra edges in our undirected independence graph.

4. Illustration and Evaluation of the Recursive Algorithm

In this section, we first illustrate the recursive algorithm step by step via a concrete example and then show simulation results to evaluate its performance.

4.1 Illustration of the Recursive Algorithm

In this subsection, we illustrate our recursive algorithm using a concrete example. We suppose in the following example that conditional independencies can be implemented correctly, that is, each conditional independence is checked by using the underlying DAG. Therefore the purpose of the example is simply to illustrate the overall scheme of the recursive algorithm presented in Section 3.1. The performance of conditional independence tests is discussed in the next subsection. We

compare the recursive algorithm with the decomposition algorithm proposed in Xie et al. (2006), in which an entire undirected independence graph is first constructed and then it is decomposed into many small subgraphs at one step instead of recursive steps. We show that, in our algorithm, search for separators is localized to smaller vertex subsets than those obtained by using the decomposition algorithm.

Example 1. (Continued) Consider again the DAG $\vec{G}_V = (V, \vec{E}_V)$ in Figure 1 (a). We call Procedure DecompRecovery to construct the global skeleton over V. At the top-down step (that is, at the 'Then' part of Step 2 in DecompRecovery), we construct the binary tree shown in Figure 2. At the top of the binary tree, the first decomposition is done by splitting the full vertex set V in G_1 (that is, the moral graph) into two subsets $\{a,c,d\}$ and $\{b,c,\ldots,h\}$ with the separator $\{c,d\}$. Next we learn the undirected independence graphs G_2 and G_3 for the two subsets separately. To construct the subgraphs G_2 and G_3, by Theorem 5, we only need to check the edge (c,d) in the separator $\{c,d\}$, and other edges in G_2 and G_3 can be obtained directly from G_1. Repeat this procedure until no further decomposition is possible. Finally we get the entire binary tree T as shown in Figure 2, where each leaf node is a complete graph and cannot be decomposed further.

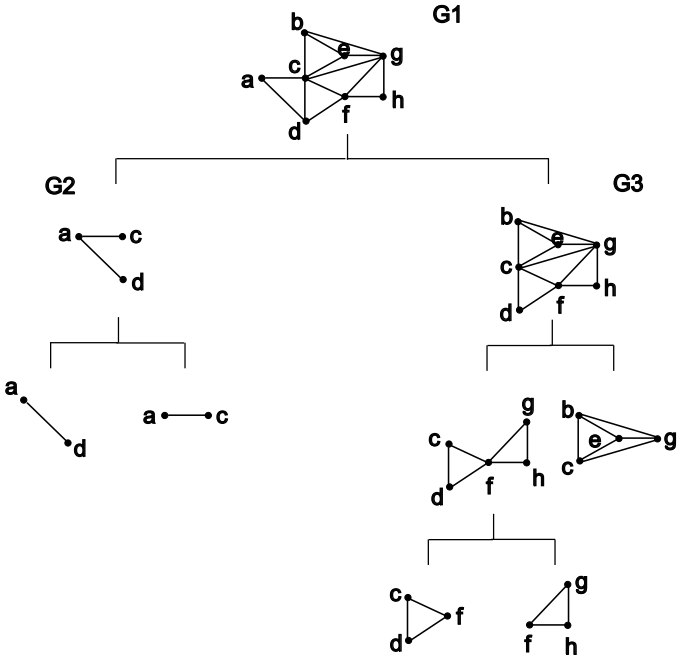


Figure 2: The binary tree T obtained at the top-down step (at 'Then' of Step 2).

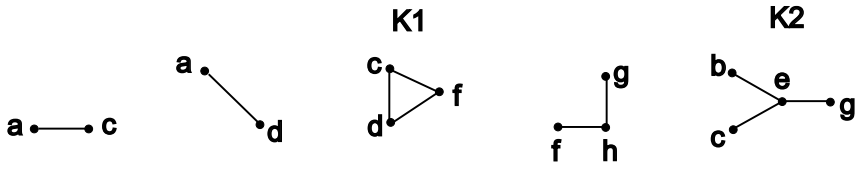

Figure 3: The local skeletons obtained at 'Else' of Step 2.

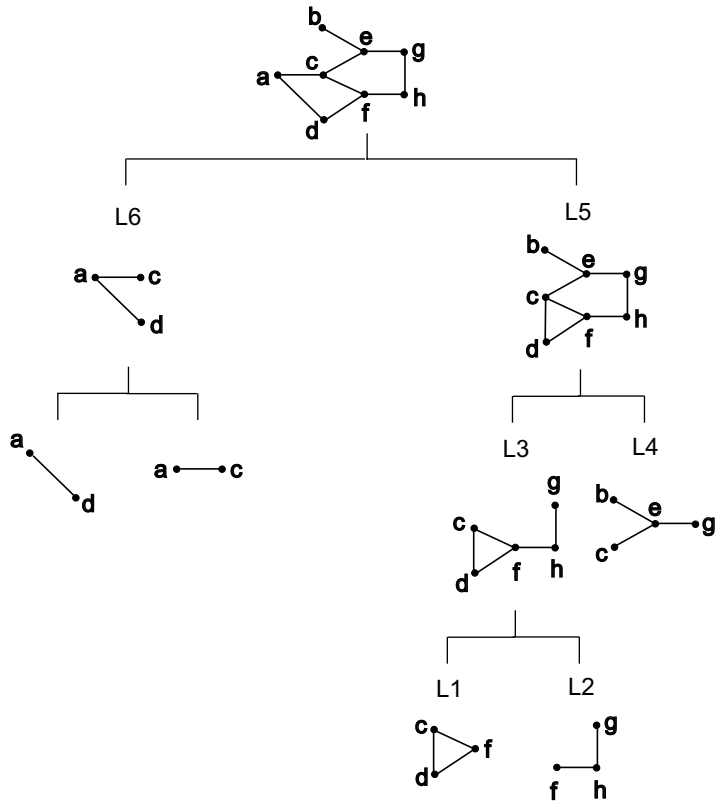

Figure 4: Combinations of local skeletons in Procedure CombineSubgraphs.

Before the bottom-up step (that is, the 'Else' part of Step 2 in Procedure DecompRecovery), for each leaf node K, we construct a local skeleton over K. For each vertex pair (u,v) in K, we search a separator set S_{uv} in all possible subsets of $K \setminus \{u,v\}$ to construct the local skeleton. All local skeletons of leaf nodes are shown in Figure 3. For example, the vertices c and d are adjacent in the local skeleton K_1 since no vertex set in K_1 d-separates them, whereas b and g are non-adjacent in the local skeleton K_2 since an empty set d-separates them in $\vec{G}_V$. At the bottom-up step, calling Function CombineSubgraphs, we combine the local skeletons from the leaf nodes to the root node to form the global skeleton, as shown in Figure 4. For example, local skeletons L_1 and L_2 are combined to L_3, and then L_3 and L_4 are combined to L_5, as shown in Figure 4. Similarly, we get the local skeleton L_6. At the last step, we combine L_5 and L_6 into the global skeleton. Note that the edge (c,d) in L_5 is deleted at Step 1 of Function CombineSubgraphs since the edge is not contained in L_6. After all the combinations are done, we get the global skeleton in Figure 5. We can see that the undirected independence graphs and the local skeletons are different as shown in Figure 2 and Figure 4 respectively and that the former has more edges than the latter.

At Step 2 of Procedure DecompRecovery, we save all separators to the d-separator list $\mathcal{S}$. At Step 3 of the main Algorithm, we use separators in the list $\mathcal{S}$ to recover all v-structures of the DAG. For example, there is a d-separator $\{a\}$ in $\mathcal{S}$ which d-separates c and d, and there is a structure $c - f - d$ in the global skeleton $\bar{L}_V$ where f is not contained in the separator $\{a\}$. Thus we can orient the structure $c - f - d$ as a v-structure $c \to f \leftarrow d$. Similarly, since an empty set d-separates

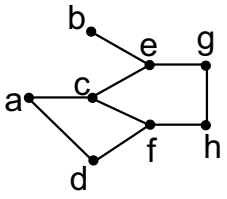

Figure 5: The global skeleton $\bar{L}_V$.

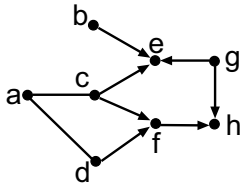

Figure 6: The recovered equivalence class.

b and g in $\vec{G}_V$, we can orient $b-e-g$ as $b \to e \leftarrow g$. After recovering all *v*-structures, we apply the orientation rule in Meek (1995) and get the desired equivalence class of $\vec{G}_V$ in Figure 6. In this equivalence class, the undirected edge (a,c) cannot be oriented uniquely because any of its orientation leads to a Markov equivalent DAG.

Below we compare the recursive algorithm with the decomposition algorithm proposed in Xie et al. (2006). We show that theoretically the recursive algorithm can decompose the entire graph into smaller subgraphs than the decomposition algorithm does because the decomposition in the decomposition algorithm is done only once, whereas the recursive algorithm tries to re-decompose undirected independence subgraphs at each recursive step. When there are a lot of *v*-structures in a DAG, many moral edges can be deleted in construction of a subgraph, and thus the recursive algorithm is more efficient than the decomposition algorithm. The following example illustrates the difference of decompositions obtained by these two algorithms.

Example 2. Consider the DAG in Figure 7. By using the decomposition algorithm proposed in Xie et al. (2006), a '*d*-separation tree' is built from an undirected independence graph (that is, the moral graph in this example), and the full variable set is decomposed into three subsets of variables at one time, see Figure 8 (a). By using the recursive algorithm proposed in this paper, we can decompose the graph into four subgraphs in Figure 8 (b), which have smaller subsets of variables. This is because the undirected independence graph over $\{a,b,c\}$ in Figure 8 (b) is re-constructed and the edge (b,c) is deleted for $b \perp\!\!\!\perp c|a$.

4.2 Simulation Studies

Below we give numerical examples to evaluate the performance of the recursive algorithm. We first present simulation results for the ALARM network, which is a medical diagnostic network and is shown in Figure 9 (Beinlich et al., 1989; Heckerman, 1998). It is a DAG with 37 vertices and 46 edges and it is often used to evaluate performance of learning algorithms. In the following two subsections, we use the ALARM network to do simulation for the Gaussian case and the discrete case separately. Next we show simulation results for several other networks in the final subsection.

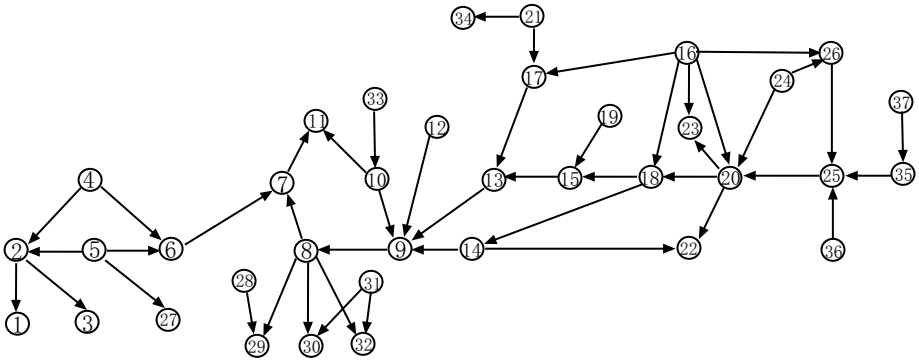

Figure 9: The ALARM network.

4.2.1 THE GAUSSIAN CASE

In this subsection, for the underlying DAG of the ALARM network, we generate a sample from a joint Gaussian distribution using a structural equation model of recursive linear regressions, whose coefficients are randomly generated from the uniform distribution in the interval $(-1.5,-0.5)\cup(0.5,1.5)$ and the residual variance is 1 for each linear regression. We apply the recursive algorithm to the generated sample to construct a DAG, and then we compare the underlying DAG with the

constructed DAG and record the number of extra edges, the number of missing edges and the structural hamming distance (SHD), where SHD is defined as the total number of operations to verify the constructed PDAG to the Markov equivalence class of the underlying DAG, and where the operations may be: add or delete an undirected edge, and add, remove or reverse an orientation of an edge (Tsamardinos et al., 2006). The likelihood ratio test introduced in Subsection 3.2 is used to test the partial correlation coefficient at the significance level $\alpha = 0.01$. We repeatedly draw $n = 1000$ sets of samples and obtain the average numbers of extra edges, missing edges and SHD from $n = 1000$ simulations. The first 3 simulation results are shown in Table 1 for different sample sizes 1000, 2000, 5000 and 10000. In Table 1, three values in a bracket denote the number of extra edges, the number of missing edges and SHD respectively. The column 'Ave' in Table 1 shows the averages of $n = 1000$ simulations. It can be seen that the algorithm performs better as the sample size increases. From the simulations, we found that most decompositions at the top-down step are correct, and we also found that when coefficients make the faithfulness assumption close to fail (that is, some of the edges only reflect weak or nearly zero associations), the learned PDAG from simulation may not be exactly the same as the underlying PDAG, and most of edge mistakes appear for these edges that represent rather weak associations.

Sample Size	1	2	3	Ave
1000	(2, 2, 13)	(0, 1, 6)	(2, 4, 10)	(1.20, 2.70, 12.8)
2000	(0, 1, 5)	(1, 0, 5)	(0, 1, 8)	(0.96, 1.77, 9.12)
5000	(1, 2, 5)	(0, 0, 2)	(1, 2, 4)	(0.85, 1.07, 6.18)
10000	(0, 1, 2)	(0, 0, 0)	(0, 2, 4)	(0.75, 0.77, 4.99)

Table 1: Extra edges, missing edges, and SHD for the first 3 simulations and averages from 1000 simulations.

Our implementation is based on the Bayesian network toolbox written by Murphy (2001) and the simulations run particularly fast. For a single simulation for all sample sizes $N = 1000$, 2000, 5000, 10000, when conditional independence tests are used to check edges, it costs only around 3 seconds in Matlab 7 on a laptop Intel 1.80GHz Pentium(R)M with 512 MByte RAM running Windows XP.

We also compare our methods with the PC algorithm (Spirtes and Glymour, 1991) and the Three Phaze Dependency Analysis (TPDA) algorithm (Cheng et al., 2002), which are readily available in the Causal Explorer System developed by Aliferis et al. (2003). The simulation is repeated 100 times for each of different network parameters and sample sizes. For each generated data set, the structure learned from each method is then compared with the true underlying structure. For each algorithm, we choose two different significance levels, that is, $\alpha = 0.01$ and 0.05. In the second row of Table 2, the underlined values in a bracket denote the number of extra edges, the number of missing edges and SHD respectively, and other rows give values relative to the second row,

Alg (Level α)	N = 1000	N = 2000	N = 5000	N = 10000	Ave Time
	(1.2, 2.4, 12)	(1.0, 1.5, 8.2)	(0.9, 0.9, 5.8)	(0.7, 0.6, 4.6)	2.55 sec
Rec(0.01)	(1.0, 1.0, 1.0)	(1.0, 1.0, 1.0)	(1.0, 1.0, 1.0)	(1.0 ,1.0, 1.0)	1.0
Rec(0.05)	(3.1, 1.0, 1.5)	(3.5, 1.1, 1.7)	(4.2, 1.1, 2.2)	(4.7, 1.2, 2.3)	1.5
PC(0.01)	(1.8, 4.5, 3.5)	(2.6, 6.3, 4.7)	(2.8, 8.0, 6.0)	(4.0, 9.7, 7.2)	21.2
PC(0.05)	(2.9, 4.0, 3.5)	(4.3, 3.5, 4.7)	(6.0, 4.0, 6.2)	(8.6, 5.1, 7.3)	24.8
TPDA(0.01)	(3.9, 4.1, 3.5)	(4.3, 5.7, 4.8)	(3.9, 7.5, 6.1)	(3.7, 8.5, 6.8)	73.6
TPDA(0.05)	(4.4, 3.7, 3.5)	(4.7, 5.1, 4.7)	(5.7, 4.3, 6.0)	(8.5, 4.8, 7.1)	88.3

Table 2: Results relative to the recursive algorithm with $\alpha = 0.01$ and $\alpha = 0.05$: extra edges, missing edges, and SHD

which are obtained by dividing their real values by the underlined values in the second row. A relative value larger than 1 denotes that its real value is larger than the corresponding value in the second row. For example, the third row labeled *Rec*(0.01) with all values equal to 1 shows that our algorithm with $\alpha = 0.01$ has the same results as the second row; the seventh row labeled PC(0.01) shows the relative results for the PC algorithm with $\alpha = 0.01$, where $(1.8, 4.5, 3.5)$ means the real values as $(1.8 \times 1.2, 4.5 \times 2.4, 3.5 \times 12)$. The last column labeled 'Ave Time' denotes average time cost for one simulation of all 4 sample sizes. In Table 2, all values are larger than 1, which means our algorithm Rec(0.01) has the least number of extra edges, the least number of missing edges and the least SHD, and further it costs the least times.

4.2.2 THE DISCRETE CASE

Now we show simulations of the ALARM network for the discrete case where these discrete variables have two to four levels. For every simulation, the conditional probability distribution of each variable X_i given its parents pa_i is draw randomly in the following way: for each fixed configuration pa_i of the parents, we first generate a sequence $\{r_1, \ldots, r_L\}$ of random numbers from the uniform distribution $U(0,1)$, where L is the number of levels of X_i; then let $P(X_i = j | pa_i) = r_j / \sum_k r_k$ as the distribution of X_i conditional on the fixed configuration pa_i of X_i's parents. Note that the joint distribution generated in this way may be unfaithful, which together with the problem of discreteness makes the learning task harder than that for the Gaussian case. We run 100 simulations for each sample size $N = 1000$, 2000, 5000 or 10000, and then we compare our method with several other algorithms by averages from 100 simulations. In addition to the PC algorithm and the TPDA algorithm used in the Gaussian case, we also compare our method with the Sparse Candidate (SC) algorithm (Friedman et al., 1999) and the MMHC algorithm (Tsamardinos et al., 2006). For the PC

algorithm, we set the parameter max-fan-in (that is, the maximum in-degree) to its true value so that the PC algorithm can run fast. We use the TPDA and the MMHC algorithms that are implemented in the Causal Explorer System (Aliferis et al., 2003) with the default setting. For all algorithms except the SC algorithm, we use two significance levels ($\alpha = 0.01$, $\alpha = 0.05$) in the simulations. For the SC algorithm, the most important parameter to be specified is the number of candidates (the maximum size of potential parent sets), which are set to 5 and 10 separately.

Alg (Level α)	N = 1000	N = 2000	N = 5000	N = 10000	Ave Time
	(1.3, 10, 33)	(1.2, 6.6, 23)	(0.8, 4.0, 16)	(0.7, 2.6, 11)	27 sec
Rec(0.01)	(1.0, 1.0, 1.0)	(1.0, 1.0, 1.0)	(1.0, 1.0, 1.0)	(1.0, 1.0, 1.0)	1.0
Rec(0.05)	(4.0, 0.8, 1.1)	(3.6, 0.8, 1.2)	(4.8, 0.8, 1.3)	(4.9, 0.8, 1.4)	1.3
PC(0.01)	(0.2, 1.5, 1.9)	(0.1, 1.5, 2.6)	(0.2, 1.6, 3.3)	(0.1, 1.8, 4.5)	1.7
PC(0.05)	(0.8, 1.2, 1.9)	(0.5, 1.3, 2.5)	(0.7, 1.3, 3.2)	(0.7, 1.5, 4.4)	1.9
TPDA(0.01)	(10.2, 1.2, 2.7)	(2.7, 1.6, 3.0)	(1.9, 2.7, 4.1)	(0.9, 4.1, 5.8)	0.9
TPDA(0.05)	(0.0, 2.5, 2.2)	(0.1, 3.9, 3.1)	(0.1, 6.5, 4.5)	(0.1, 9.9, 6.6)	0.2
SC(5)	(2.0, 0.8, 0.8)	(2.4, 0.8, 1.0)	(3.6, 0.9, 1.1)	(4.3, 0.9, 1.4)	4.7
SC(10)	(2.2, 0.8, 0.8)	(2.7, 0.9, 1.0)	(3.8, 0.8, 1.1)	(4.2, 0.7, 1.2)	6.6
MMHC(0.01)	(0.3, 1.3, 1.1)	(0.3, 1.4, 1.1)	(0.4, 1.5, 1.1)	(0.7, 1.5, 1.2)	1.1
MMHC(0.05)	(0.5, 1.2, 1.0)	(0.4, 1.3, 1.0)	(0.5, 1.3, 1.0)	(1.0, 1.3, 1.1)	1.4

Table 3: Results relative to the recursive algorithm with $\alpha = 0.01$ and $\alpha = 0.05$: extra edges, missing edges, and SHD

We summarize the simulation results in Table 3. In terms of SHD, our algorithm, the SC algorithm and the MMHC algorithm perform better than the PC and TPDA algorithms. It can also be seen that the performance difference between our method and the others becomes larger as the sample size increases. Although it can be seen from the last column labeled 'Ave Time' that the average CPU time cost for our algorithm is the second least, the fastest algorithm TPDA has the largest SHD among all algorithms. From the results in Tables 3, we can see that although the recursive algorithm seems to have a better performance in most cases, it is still not quite clear which one of these algorithms is superior in general. Their performance depends on preference of reducing the false positive error (including an edge that is not in the true DAG) or the false negative error

(excluding an edge that is in the true DAG). For example, the PC and MMHC algorithms have a smaller false positive error; the SC algorithm has a smaller false negative error; and the recursive algorithm has smaller SHD. We also found that choosing a good parameter is also important to achieve an optimal performance for each algorithm. The recursive algorithm seems to work better when we choose a significance level $\alpha = 0.01$, while for MMHC it is better to choose $\alpha = 0.05$.

The above comparison is based on results from randomly generated values of parameters of joint distributions. The results may change when different values of these parameters are used. The performance of an algorithm also depends on the structures of a network.

4.2.3 SIMULATIONS OF OTHER NETWORKS

In this subsection we show simulation results for other three networks: Insurance with 27 vertices and 52 edges (Binder et al., 1997), HailFinder with 56 vertices and 66 edges (Abramson et al., 1996) and Carpo with 61 vertices and 74 edges, all of which can be obtained through the online Bayesian network repository (http://www.cs.huji.ac.il/labs/compbio/ Repository). We compare the recursive algorithm with the SC and MMHC algorithms since these two have been extensively compared with many state-of-art algorithms and shown in general outperforming other algorithms by Tsamardinos et al. (2006). In our simulations, the parameter values of the joint distributions are set to the original values from the repository. For each network, 10 data sets are generated, and we give one better result in Table 4 for each algorithm with two criteria ($\alpha = 0.01$ and 0.05 for Rec and MMHC, the number of candidates = 5 and 10 for SC). From the last column 'Ave Time' of Table 4, it can be seen that the recursive algorithm is fastest in average CPU time and it also has a better performance in most cases for these networks.

4.3 Complexity Analysis

Below we discuss the complexity of the recursive algorithm proposed in this paper. We mainly focus on the number of conditional independence tests for constructing the equivalence class since decomposition of graphs is a computationally simple task compared to the conditional independence tests. In the recursive algorithm DecompRecovery, two steps (Step 1 for constructing an undirected independence graph $\bar{G}_K$ and the 'Else' part of Step 2 for constructing a local skeleton $\bar{L}_K$) involve conditional independence tests, where K is the vertex set of the subgraph. At Step 1, an undirected independence graph can be constructed by testing independence between any pair of variables conditionally on other variables, and thus the complexity is $O(|K|^2)$, where $|K|$ denotes the number of vertices in the set K. As discussed in Section 3.3, an undirected independence graph $\bar{G}_{A\cup C}$ can be constructed from the previous graph $\bar{G}_{A\cup B\cup C}$ by checking only all possible edges within the separator C. Thus the complexity for constructing an undirected independence graph can be reduced. At Step 2, we construct a local skeleton over a vertex subset K. Suppose that we use the IC algorithm. Then the complexity for constructing the local skeleton L_K is $O(|K|^2 2^{|K|-2})$. Below we consider the total expenses and suppose that the full vertex set V is recursively decomposed into H subsets $\{K_1,\ldots,K_H\}$, where $H \le n$ and $K_h \le n$ for all h. For each decomposition, we need to construct an undirected independence graph, and thus the total expenses for all decompositions is less than $O(Hn^2)$. The total expenses for constructing all skeletons is $O(\sum_h |K_h| 2^{|K_h|-2})$, which is less than $O(Hk_{max}2^{k_{max}-2})$, where $k_{\max} = \max\{|K_1|,\ldots,|K_H|\}$. The complexity for the IC algorithm is known to be $O(n^2 2^{n-2})$. Since $K_{\max}$ usually is much less than n, the recursive decomposition can greatly reduce the complexity of the IC algorithm. Of course, when no decomposition is available,

Alg (Level α)	N = 1000	N = 2000	N = 5000	N = 10000	Ave Time

Table 4: Results relative to the recursive algorithm for other networks: extra edges, missing edges, and SHD

the complexity of our algorithm becomes the same as the IC algorithm, which reflects the fact that structural learning of DAGs is an NP-hard problem (Chickering et al., 2004). Similarly, the recursive decomposition can also be used to improve the performance of the PC algorithm and other algorithms.

5. Conclusion

In this paper, we proposed a recursive algorithm for structural learning of DAGs. We first present its theoretical properties, then show its experimental results and compare it with other algorithms. In the recursive algorithm, a structural learning for a large DAG is first split recursively into those for small subgraphs until each subgraph cannot be decomposed further, then we perform local learning for these subgraphs which cannot be decomposed, finally we gradually combine these locally learned subgraphs into the entire DAG. The main problem for structural learning of a DAG is the search for d-separators, which becomes exponentially complicated with the number of vertices increases. In the recursive algorithm, all searches for d-separators are localized into subsets of vertices. Thus the efficiency of structural learning and the power of statistical tests can be improved by decomposition.

There are several works related to our recursive approach. Friedman et al. (1999) discussed how the idea of recursive decomposition can be used in accelerating their Sparse Candidate algorithm, Narasimhan and Bilmes (2005) discussed the application of this idea to find a sub-optimal graphical models by noticing the corresponding decomposition of the Kullback and Leibler divergence (Kullback and Leibler, 1951) with respect to the graph separation. Geng et al. (2005) and Xie et al. (2006) proposed the decomposition algorithms for structural learning of DAGs. However, the method proposed in Geng et al. (2005) requires that each separator has a complete undirected graph. Xie et al. (2006) removed the condition, but their algorithm performs decomposition only based on the entire undirected independence graph $\overline{G}_V$ of the full vertex set V and cannot perform decomposition of undirected independence subgraphs. Theorems 1, 2 and 3 in this paper relax this requirement, and they do not require the union set $K = A \cup B \cup C$ of a decomposition (A,B,C) to be equal to the full vertex set V. Thus the recursive algorithm can delete more edges in undirected independence subgraphs and further decompose them, see Example 2. Theorems 1, 2 and 3 are also useful properties for collapsibility of DAGs.

Now we discuss several potential utilities and further works of the recursive approach. This recursive decomposition approach can also be used to localize a learning problem of interest. Suppose that V is the full set of all observed variables, but we are interested only in a local structure over a variable subset A. Using the recursive approach, we can recursively decompose the variable sets into small sets, only focus on the subtrees that contain variables in A, and ignore other subtrees that are unrelated to A. In such a way, the local structure over A can be obtained without need of learning other structures that are unrelated to A. The recursive approach can also use a prior knowledge of independencies among variables to decompose structural learning.

Acknowledgments

We would like to thank the editor and the three referees for their helpful comments and suggestions that greatly improved the previous version of this paper. This research was supported by NSFC, NBRP 2003CB715900, 863 Project of China 2007AA01Z437 and MSRA. We would also like to thank Professor Rich Maclin, the publication editor, for his help with the revision.

Appendix A.

We first give some lemmas which will be used in proofs of theorems.

Lemma 1. A subset S of vertices separates u from v in $[\vec{G}_{An(\{u\}\cup\{v\}\cup S)}]^m$ if and only if $u \perp\!\!\!\perp v|S$.
Proof. The result can be obtained directly from Proposition 3.25 of Lauritzen (1996) and Theorem 1.2.4 of Pearl (2000). □

Lemma 2. Let S be a subset of V. Then two vertices u and v in S are d-separated by a subset of S if and only if they are d-separated by $an(\{u,v\}) \cap S$.
Proof. Define $S' = an(\{u,v\}) \cap S$. The necessity is obvious since $S \supseteq S'$. For sufficiency, suppose that u and v are not d-separated by S'. Since $An(\{u,v\} \cup S') = An(\{u,v\})$, we have from Lemma 1 that there is a path l connecting u and v in $[\vec{G}_{An(\{u,v\})}]^m$ which is not separated by S' in the moral graph, that is, the path l does not contain any vertex in S'. Since l is contained in $[\vec{G}_{An(\{u,v\})}]^m$ and $S' = an(\{u,v\}) \cap S$, we then have that l does not contain any vertex in $S \setminus \{u,v\}$. Now from the condition, suppose that u and v are d-separated by $S_0 \subseteq S$. Then we also have from $an(u,v) \cap S_0 \subseteq S'$ that l does not contain any vertex in $an(u,v) \cap S_0$. Thus we obtain that l is not separated by S_0 in $[\vec{G}_{An(u,v,S)}]^m$, which by Lemma 1 implies that u and v are not d-separated by S_0. However, this contradicts the condition that u and v are d-separated by $S_0 \subseteq S$, which concludes the proof for Lemma 2. □

Lemma 3. If four disjoint sets X, Y, Z and W satisfy $X \perp\!\!\!\perp Y \cup Z|W$, then we have $X \perp\!\!\!\perp Y|Z \cup W$.
Proof. This result is obvious. □

Under the faithfulness assumption, a conditional independence is equivalent to the corresponding d-separation, and thus d-separation also has the above property.

Lemma 4. Suppose that l is a path that connects two nonadjacent vertices u and v. If l is not contained completely in $An(u) \cup An(v)$, then l is d-separated by any subset S of $an(u) \cup an(v)$.
Proof. Since l is not completely contained in $An(u) \cup An(v)$, there exists vertices m and n in $l = (u,\ldots,m,x,\ldots,y,n,\ldots,v)$ such that both m and n are contained in $An(u) \cup An(v)$ and no vertices from x to y are contained in $An(u) \cup An(v)$ where x and y, u and m, n and v may be separately the same vertex. So we have that the arrows must be oriented as $\langle m,x\rangle$ and $\langle n,y\rangle$, and then there must be a collider between m and n on l. Let $s \to w \leftarrow t$ be the collider that is closest to m. Then we have that the sub-path of l from m to w is directed. Notice that $m \in An(u) \cup An(v)$ and $w \notin An(u) \cup An(v)$. Thus we obtain that S and its subset do not contain the middle vertex w or its descendants, which implies that l is d-separated by any subset of S at the collider $s \to w \leftarrow t$. □

Proof of Theorem 1: The necessity is obvious since $(A \cup B \cup C) \supseteq (A \cup C)$. For sufficiency, let a and d be two vertices in A and $A \cup C$ respectively that are d-separated by a subset of $A \cup B \cup C$. Define $W = (an(a) \cup an(d)) \cap (A \cup B \cup C)$. By Lemma 2, a and d must be d-separated by W. Define $S' = (an(a) \cup an(d)) \cap (A \cup C)$. Then we only need to show that S' ($\subseteq A \cup C$) can d-separate every path l connecting a and d in $\vec{G}_V$. We consider the following two cases separately:

(1) a path l is not contained completely in $An(a) \cup An(d)$, and

(2) a path l is contained completely in $An(a) \cup An(d)$.

For case (1), we get from Lemma 4 that l must be d-separated by S' since S' is a subset of $an(a) \cup an(d)$.

For case (2), we have from condition $A \perp\!\!\!\perp B|C$ that $[\{a\} \cup (S' \cap A)] \perp\!\!\!\perp b|C$ for any $b \in B$, which implies, by Lemma 3, $a \perp\!\!\!\perp b|(S' \cap A) \cup C$. Since $S' \subseteq (A \cup C)$, we get

$$a \perp\!\!\!\perp b|(S' \cup C).$$

By reduction to absurdity, suppose that there is a path l contained in $An(a) \cup An(d)$ connecting a and d which cannot be d-separated by S'. Because W $(\supseteq S')$ d-separates a and d and thus d-separates l but S' does not, there must exist at least one vertex on the path l which is contained in $W \setminus S'$ $(\subseteq B)$. Let b be such a vertex that is closest to a on the path l and define l' to be the sub-path of l from a to b. It is obvious that l' is d-connected by S'; otherwise l will be d-separated by S'. Since b is closest to a on l and $b \in B$, any of other vertices on l' is not in B. From $l' \subseteq l \subseteq (An(a) \cup An(d))$ and $S' = (an(a) \cup an(d)) \cap (A \cup C)$, we have that all vertices of l' except a and b are contained in S'. Since l' is d-connected by S', l' is also d-connected by $S' \cup C$, which contradicts (A.1). Thus we showed that every path in case (2) is also d-separated by S', which concludes our proof for Theorem 1. □

The following lemma, which is non-trivial due to the fact that a sequence can contain the same vertex more than once, indicates that the d-separation for a path can be made equivalent to that for a sequence.

Lemma 5. Two non-adjacent vertices u and v are d-separated by S in $\vec{G}_V$ if and only if for any sequence $l = (u, \ldots, v)$ connecting u and v

1. l contains a "chain" $i \to m \to j$ or a "fork" $i \leftarrow m \to j$ such that the middle vertex m is in S, or

2. l contains a "collider" $i \to m \leftarrow j$ such that the collision vertex m is not in S and no descendant of m is in S.

When a sequence $l = (u, \ldots, v)$ satisfies the above conditions 1 and 2, we also say that the sequence l is d-separated by S.

Proof. The sufficiency is obvious from definition of d-separation. For necessity, suppose there are sequences connecting u and v that satisfy neither condition 1 nor 2. Let $l = (z_0 = u, z_1 \ldots, z_{k-1}, z_k = v)$ be the shortest one of such sequences, it's easy to show that such a sequence is itself a path which contradicts with the condition that u and v are d-separated by S in $\vec{G}_V$. □

Proof of Theorem 2: The necessity is obvious since $(A \cup B \cup C) \supseteq (A \cup C)$. We show the sufficiency in a similar way to proof of Theorem 1. Let c and c' be two vertices in C that are d-separated by a subset of $A \cup B \cup C$. Thus from Lemma 2 they are also d-separated by $S = (an(c) \cup an(c')) \cap (A \cup B \cup C)$. Without loss of generality, suppose that c is not an ancestor of c'. Define $S_1 = (an(c) \cup an(c')) \cap (A \cup C)$ and $S_2 = (an(c) \cup an(c')) \cap (B \cup C)$. To prove that either S_1 $(\subseteq A \cup C)$ or S_2 $(\subseteq B \cup C)$ can d-separate c and c' in $\vec{G}_V$, it is sufficient to show that there will not exist a path l_1 in $A \cup C$ and a path l_2 in $B \cup C$ such that l_1 cannot be d-separated by S_1 and l_2 cannot be d-separated by S_2. To show this, we consider the following two cases separately:

(1) a path l_i is not completely contained in $An(c) \cup An(c')$, and

(2) both paths l_1 and l_2 are contained in $An(c) \cup An(c')$.

For case (1), since both S_1 and S_2 are subsets of $an(c) \cup an(c')$, we know from Lemma 4 that l must be d-separated both by S_1 and by S_2.

For case (2), by reduction to absurdity, we suppose that there are two paths l_1 and l_2 such that l_i cannot be d-separated by S_i for $i = 1$ and 2. Since every path l_i between c and c' is d-separated by S which equals $S_1 \cup S_2$, we have that for path l_i, there is at least one vertex contained in $S \setminus S_i$. Let d_1 and d_2 be such vertices that are closest to c on l_1 and l_2 respectively. We have $d_1 \in (S \setminus S_1)$ and thus $d_1 \in B$, and similarly $d_2 \in (S \setminus S_1)$ and thus $d_2 \in A$. Let l_1' denote the sub-path from c to d_1 of

l_1 and l_2' denote the sub-path from c to d_2 of l_2. Since l_i cannot be d-separated by S_i, we have that l_i' cannot be d-separated by S_i. Connecting l_1' and l_2' at c, we get a sequence l' from d_1 to d_2 through c. Note that l' may have the same vertices and thus it may not be a path. Below we show that l' is not d-separated by C, that is, the middle vertex of each collider or its descendant is in C but any of other vertices on l' is not in C.

For any vertex u which is not the middle vertex of a collider on l_1', since u is in $an(c) \cup an(c')$ and l_1 and l_1' is not d-separated by S_1, we have that $u \notin S_1$ and thus $u \notin C$. Similarly, we can show that C does not contain any vertex u which is not the middle vertex of a collider on l_2'. Thus we have shown that C does not contain any vertex which is not a middle vertex of colliders on l' except that vertex c has not yet been considered. Now we show that vertex c is a middle vertex of a collider on l'. Let v denote the neighbor of c on l_1'. Since v is in $an(c) \cup an(c')$ and it cannot be c', v is an ancestor of c or c'. If the edge between c and v is oriented as $c \to v$, then v must be an ancestor of c'. This contradicts the supposition that c is not an ancestor of c', and thus the edge between c and v must be oriented as $c \leftarrow v$. Similarly for the neighbor w of c on l_2', we can also show that the edge between c and w must be oriented as $c \leftarrow w$, which implies that the sequence (v, c, w) must form a collider on l'. Thus we have shown that C does not contain any vertex which is not a middle vertex of colliders on l'.

For any vertex u which is a middle vertex of a collider on l_i', u or its descendant must be in S_i, otherwise l_i' and so l_i are d-separated by S_i, which contradicts the supposition. Since u is contained in $an(c) \cup an(c')$, we have that c ($\in C$) or c' ($\in C$) is a descendant of u, and thus u or its descendant must be in C. For the collider $u \to c \leftarrow v$ on the sequence l', we also have that c is in C. Thus we have shown that the middle vertex of each collider on l' or its descendant is in C.

By the above result and Lemma 5, we have $d_2 \not\perp\!\!\!\perp d_1 | C$, where $d_2 \in A$ and $d_1 \in B$. This contradicts $A \perp\!\!\!\perp B | C$. Thus either S_1 or S_2 must d-separate c and c' in $\vec{G}_V$. □

Proof of Theorem 3: This is an immediate consequence of Theorems 1 and 2. □

Proof of Theorem 4: For necessity, since $A \perp\!\!\!\perp B | C$, we have from the property of conditional independence that $u \perp\!\!\!\perp B | A \cup C \setminus \{u\}$. This and the condition $u \perp\!\!\!\perp v | A \cup C \setminus \{u, v\}$ imply $u \perp\!\!\!\perp v \cup B | A \cup C \setminus \{u, v\}$. Again, from the property of conditional independence, we have $u \perp\!\!\!\perp v | A \cup B \cup C \setminus \{u, v\}$. For sufficiency, from $A \perp\!\!\!\perp B | C$, we get $u \perp\!\!\!\perp B | A \cup C \setminus \{u\}$. This and the condition $u \perp\!\!\!\perp v | A \cup B \cup C \setminus \{u, v\}$ imply $u \perp\!\!\!\perp B \cup \{v\} | A \cup C \setminus \{u, v\}$. Then we obtain $u \perp\!\!\!\perp v | A \cup C \setminus \{u, v\}$, and this completes our proof for the theorem. □

Abstract

We consider the problem of estimating the parameters of a Gaussian or binary distribution in such a way that the resulting undirected graphical model is sparse. Our approach is to solve a maximum likelihood problem with an added ℓ_1-norm penalty term. The problem as formulated is convex but the memory requirements and complexity of existing interior point methods are prohibitive for problems with more than tens of nodes. We present two new algorithms for solving problems with at least a thousand nodes in the Gaussian case. Our first algorithm uses block coordinate descent, and can be interpreted as recursive ℓ_1-norm penalized regression. Our second algorithm, based on Nesterov's first order method, yields a complexity estimate with a better dependence on problem size than existing interior point methods. Using a log determinant relaxation of the log partition function (Wainwright and Jordan, 2006), we show that these same algorithms can be used to solve an approximate sparse maximum likelihood problem for the binary case. We test our algorithms on synthetic data, as well as on gene expression and senate voting records data.

Keywords: model selection, maximum likelihood estimation, convex optimization, Gaussian graphical model, binary data

1. Introduction

Undirected graphical models offer a way to describe and explain the relationships among a set of variables, a central element of multivariate data analysis. The principle of parsimony dictates that we should select the simplest graphical model that adequately explains the data. In this paper we consider practical ways of implementing the following approach to finding such a model: given a set of data, we solve a maximum likelihood problem with an added ℓ_1-norm penalty to make the resulting graph as sparse as possible.

Many authors have studied a variety of related ideas. In the Gaussian case, model selection involves finding the pattern of zeros in the inverse covariance matrix, since these zeros correspond to conditional independencies among the variables. Traditionally, a greedy forward-backward search algorithm is used to determine the zero pattern (e.g., Lauritzen, 1996). However, this is computationally infeasible for data with even a moderate number of variables. Li and Gui (2005) introduce

a gradient descent algorithm in which they account for the sparsity of the inverse covariance matrix by defining a loss function that is the negative of the log likelihood function. Speed and Kiiveri (1986) and, more recently, Dahl et al. (Revised 2007) proposed a set of large scale methods for problems where a sparsity pattern for the inverse covariance is given and one must estimate the nonzero elements of the matrix.

Another way to estimate the graphical model is to find the set of neighbors of each node in the graph by regressing that variable against the remaining variables. In this vein, Dobra and West (2004) employ a stochastic algorithm to manage tens of thousands of variables. There has also been a great deal of interest in using ℓ_1-norm penalties in statistical applications. d'Aspremont et al. (2004) apply an ℓ_1 norm penalty to sparse principle component analysis. Directly related to our problem is the use of the Lasso of Tibshirani (1996) to obtain a very short list of neighbors for each node in the graph. Meinshausen and Bühlmann (2006) study this approach in detail, and show that the resulting estimator is consistent, even for high-dimensional graphs. A related approach is the graphical lasso, explored by Friedman et al. (2007).

Our objective here is to both estimate the sparsity pattern of the underlying graph and to obtain a regularized estimate of the covariance matrix. The difficulty of the problem formulation we consider lies in its computation. Although the problem is convex, it is non-smooth and has an unbounded constraint set. As we shall see, the resulting complexity for existing interior point methods is $O(p^6)$, where p is the number of variables in the distribution. In addition, interior point methods require that at each step we compute and store a Hessian of size $O(p^2)$. The memory requirements and complexity are thus prohibitive for $O(p)$ higher than the tens. Specialized algorithms are needed to handle larger problems.

The remainder of the paper is organized as follows. We begin by considering Gaussian data. In Section 2 we set up the problem, derive its dual, discuss properties of the solution and how heavily to weight the ℓ_1-norm penalty in our problem. In Section 3 we present a provably convergent block coordinate descent algorithm that can be interpreted a sequence of iterative ℓ_1-norm penalized regressions. In Section 4 we present a second, alternative algorithm based on Nesterov's recent work on non-smooth optimization, and give a rigorous complexity analysis with better dependence on problem size than interior point methods. In Section 5 we show that the algorithms we developed for the Gaussian case can also be used to solve an approximate sparse maximum likelihood problem for multivariate binary data, using a log determinant relaxation for the log partition function given by Wainwright and Jordan (2006). In Section 6, we test our methods on synthetic as well as gene expression and senate voting records data.

2. Problem Formulation

In this section we set up the sparse maximum likelihood problem for Gaussian data, derive its dual, and discuss some of its properties.

2.1 Problem Setup

Suppose we are given n samples independently drawn from a p-variate Gaussian distribution: $y^{(1)},\ldots,y^{(n)} \sim \mathcal{N}(\mu,\Sigma_p)$, where the covariance matrix Σ is to be estimated. Let S denote the second moment matrix about the mean:

$$S := \frac{1}{n}\sum_{k=1}^{n}(y^{(k)}-\mu)(y^{(k)}-\mu)^T.$$

Let $\hat{\Sigma}^{-1}$ denote our estimate of the inverse covariance matrix. Our estimator takes the form:

$$\hat{\Sigma}^{-1} = \arg\max_{X\succ 0} \log\det X - \mathrm{trace}(SX) - \lambda\|X\|_1. \tag{1}$$

Here, $\|X\|_1$ denotes the sum of the absolute values of the elements of the positive definite matrix X.

The scalar parameter λ controls the size of the penalty. The penalty term is a proxy for the number of nonzero elements in X, and is often used—albeit with vector, not matrix, variables—in regression techniques, such as the Lasso.

In the case where $S \succ 0$, the classical maximum likelihood estimate is recovered for $\lambda = 0$. However, when the number of samples n is small compared to the number of variables p, the second moment matrix may not be invertible. In such cases, for $\lambda > 0$, our estimator performs some regularization so that our estimate $\hat{\Sigma}$ is always invertible, no matter how small the ratio of samples to variables is.

Even in cases where we have enough samples so that $S \succ 0$, the inverse S^{-1} may not be sparse, even if there are many conditional independencies among the variables in the distribution. By trading off maximality of the log likelihood for sparsity, we hope to find a very sparse solution that still adequately explains the data. A larger value of λ corresponds to a sparser solution that fits the data less well. A smaller λ corresponds to a solution that fits the data well but is less sparse. The choice of λ is therefore an important issue that will be examined in detail in Section 2.3.

2.2 The Dual Problem and Bounds on the Solution

By expressing the ℓ_1 norm in (1) as

$$\|X\|_1 = \max_{\|U\|_\infty \le 1} \mathrm{trace}(XU),$$

where $\|U\|_\infty$ denotes the maximum absolute value element of the symmetric matrix U, we can write (1) as

$$\max_{X\succ 0}\min_{\|U\|_\infty\le\lambda} \log\det X - \mathrm{trace}(X, S+U).$$

This corresponds to seeking an estimate with the maximum worst-case log likelihood, over all additive perturbations of the second moment matrix S. A similar robustness interpretation can be made for a number of estimation problems, such as support vector machines for classification.

We can obtain the dual problem by exchanging the max and the min. The resulting inner problem in X can be solved analytically by setting the gradient of the objective to zero and solving for X. The result is

$$\min_{\|U\|_\infty\le\lambda} -\log\det(S+U) - p$$

where the primal and dual variables are related as: $X = (S+U)^{-1}$. Note that the log determinant function acts a log barrier, creating an implicit constraint that $S+U \succ 0$.

To write things neatly, let $W = S+U$. Then the dual of our sparse maximum likelihood problem is

$$\hat{\Sigma} := \max\{\log\det W : \|W-S\|_\infty \le \lambda\}. \tag{2}$$

Observe that the dual problem (2) estimates the covariance matrix while the primal problem estimates its inverse. We also observe that the diagonal elements of the solution are $\Sigma_{kk} = S_{kk} + \lambda$ for all k.

The following theorem shows that adding the ℓ_1-norm penalty regularizes the solution.

Theorem 1 *For every $\lambda > 0$, the optimal solution to (1) is unique, with bounded eigenvalues:*

$$\frac{p}{\lambda} \geq \|\hat{\Sigma}^{-1}\|_2 \geq (\|S\|_2 + \lambda p)^{-1}.$$

Here, $\|A\|_2$ denotes the maximum eigenvalue of a symmetric matrix A. The proof is contained in the appendix.

The dual problem (2) is smooth and convex, albeit with $p(p+1)/2$ variables. For small values of p, the problem can be solved by existing interior point methods (e.g., Vandenberghe et al., 1998). The complexity to compute an ε-suboptimal solution using such second-order methods, however, is $O(p^6 \log(1/\varepsilon))$, making them infeasible when p is larger than the tens.

A related problem, solved by Dahl et al. (Revised 2007), is to compute a maximum likelihood estimate of the covariance matrix when the sparsity structure of the inverse is known in advance. This is accomplished by adding constraints to (1) of the form: $X_{ij} = 0$ for all pairs (i, j) in some specified set. Our constraint set is unbounded as we hope to uncover the sparsity structure automatically, starting with a dense second moment matrix S.

2.3 Choice of Penalty Parameter

Consider the true, unknown graphical model for a given distribution. This graph has p nodes, and an edge between nodes k and j is missing if variables k and j are independent conditional on the rest of the variables. For a given node k, let C_k denote its connectivity component: the set of all nodes that are connected to node k through some chain of edges. In particular, if node $j \notin C_k$, then variables j and k are independent.

Meinshausen and Bühlmann (2006) show that the Lasso, when used to estimate the set of neighbors for each node, yields an estimate of the sparsity pattern of the graph in a way that is asymptotically consistent. Consistency, they show, hinges on the choice of the regularization parameter. In addition to asymptotic results, they prove a finite sample result: by choosing the regularization parameter in a particular way, the probability that two distinct connectivity components are falsely joined in the estimated graph can be controlled.

Following the methods used by Meinshausen and Bühlmann (2006), we can derive a corresponding choice for the regularization parameter. Let $\hat{C}_k^{\lambda}$ denote our estimate of the connectivity component of node k. In the context of our optimization problem, this corresponds to the entries of row k in $\hat{\Sigma}$ that are nonzero.

Let α be a given level in $[0, 1]$. Consider the following choice for the penalty parameter in (1):

$$\lambda(\alpha) := (\max_{i>j} \hat{\sigma}_i \hat{\sigma}_j) \frac{t_{n-2}(\alpha/2p^2)}{\sqrt{n-2+t_{n-2}^2(\alpha/2p^2)}} \tag{3}$$

where $t_{n-2}(\alpha)$ denotes the $(100-\alpha)\%$ point of the Student's t-distribution for $n-2$ degrees of freedom, and $\hat{\sigma}_i$ is the empirical variance of variable i. Then we can prove the following theorem:

Theorem 2 *Using $\lambda(\alpha)$ the penalty parameter in (1), for any fixed level α,*

$$P(\exists k \in \{1,\ldots,p\} : \hat{C}_k^{\lambda} \not\subseteq C_k) \leq \alpha.$$

Observe that, for a fixed problem size p, as the number of samples n increases to infinity, the penalty parameter $\lambda(\alpha)$ decreases to zero. Thus, asymptotically we recover the classical maximum likelihood estimate, S, which in turn converges in probability to the true covariance Σ.

Meinshausen and Bühlmann (2006) prove that Lasso recovers the underlying sparsity pattern consistently, in a scheme where the number of variables is allowed to grow with the number of samples: $p \in O(n^{\gamma})$. Although such an analysis is beyond the scope of this paper, a similar result seems to hold here provided we assume certain conditions on the true covariance matrix.

From the point of view of estimating the covariance matrix itself, when the number of variables is allowed to grow with the number of samples, it may be better to use estimates such as those described by Bickel and Levina (2008), which are shown to be consistent in the operator norm as long as $(\log p)^2/n \to 0$.

3. Block Coordinate Descent Algorithm

In this section we present an algorithm for solving (2) that uses block coordinate descent.

3.1 Algorithm Description

We begin by detailing the algorithm. For any symmetric matrix A, let $A_{\backslash k \backslash j}$ denote the matrix produced by removing column k and row j. Let A_j denote column j with the diagonal element A_{jj} removed. The plan is to optimize over one row and column of the variable matrix W at a time, and to repeatedly sweep through all columns until we achieve convergence.
Initialize: $W^{(0)} := S + \lambda I$
For $k \geq 0$

1. **For** $j = 1,\ldots,p$

   (a) Let $W^{(j-1)}$ denote the current iterate. Solve the quadratic program

   $$\hat{y} := \arg\min_y \{y^T (W^{(j-1)}_{\backslash j \backslash j})^{-1} y : \|y - S_j\|_\infty \leq \lambda\}. \tag{4}$$

   (b) Update rule: $W^{(j)}$ is $W^{(j-1)}$ with column/row W_j replaced by $\hat{y}$.

2. Let $\hat{W}^{(0)} := W^{(p)}$.

3. After each sweep through all columns, check the convergence condition. Convergence occurs when

   $$\text{trace}((\hat{W}^{(0)})^{-1} S) - p + \lambda \|(\hat{W}^{(0)})^{-1}\|_1 \leq \varepsilon.$$

3.2 Convergence and Property of Solution

Using Schur complements, we can prove convergence:

Theorem 3 *The block coordinate descent algorithm described above converges, achieving an* ε*-suboptimal solution to (2). In particular, the iterates produced by the algorithm are strictly positive definite: each time we sweep through the columns,* $W^{(j)} \succ 0$ *for all* j*.*

The proof of Theorem 3 sheds some interesting light on the solution to problem (1). In particular, we can use this method to show that the solution has the following property:

Theorem 4 *Fix any* $k \in \{1,\ldots,p\}$*. If* $\lambda \geq |S_{kj}|$ *for all* $j \neq k$*, then column and row* k *of the solution* $\hat{\Sigma}$ *to (2) are zero, excluding the diagonal element.*

This means that, for a given second moment matrix S, if λ is chosen such that the condition in Theorem 4 is met for some column k, then the sparse maximum likelihood method estimates variable k to be independent of all other variables in the distribution. In particular, Theorem 4 implies that if $\lambda \geq |S_{kj}|$ for all $k > j$, then (1) estimates all variables in the distribution to be pairwise independent.

Using the work of Luo and Tseng (1992), it may be possible to show that the local convergence rate of this method is at least linear. In practice we have found that a small number of sweeps through all columns, independent of problem size p, is sufficient to achieve convergence. In each iteration, we must solve one quadratic program (QP). In a standard primal-dual interior point method for solving QPs, the computational cost is dominated by the cost of finding a search direction, which involves inverting matrices of size p. The cost of each iteration is therefore $O(p^3)$. For a fixed number of K sweeps, the cost of the method is $O(Kp^4)$.

3.3 Interpretation as Iterative Penalized Regression

The dual of (4) is

$$\min_x x^T W_{\setminus j \setminus j}^{(j-1)} x - S_j^T x + \lambda \|x\|_1. \tag{5}$$

Strong duality obtains so that problems (5) and (4) are equivalent. If we let Q denote the square root of $W_{\setminus j \setminus j}^{(j-1)}$, and $b := \frac{1}{2} Q^{-1} S_j$, then we can write (5) as

$$\min_x \|Qx - b\|_2^2 + \lambda \|x\|_1. \tag{6}$$

The problem (6) is a penalized least-squares problems, known as the Lasso. If $W_{\setminus j \setminus j}^{(j-1)}$ were the j-th principal minor of the sample covariance S, then (6) would be equivalent to a penalized regression of variable j against all others. Thus, the approach is reminiscent of the approach explored by Meinshausen and Bühlmann (2006), but there are two differences. First, we begin by adding a multiple of the identity to the sample covariance matrix, so we can guarantee that each penalized regression problem has a unique solution, without requiring the data or solutions to satisfy any special conditions (see Osborne et al., 2000, for conditions that guarantee uniqueness of the Lasso). Second, and more importantly, we update the problem data after each regression: except at the very first update, $W_{\setminus j \setminus j}^{(j-1)}$ is never a minor of S. In this sense, the coordinate descent method can be interpreted as a sequence of iterative Lasso problems. The approach is pursued to great advantage by Friedman et al. (2007), who also provide a conceptual link to the approach of Meinshausen and Bühlmann (2006).

4. Nesterov's First Order Method

In this section we apply the recent results due to Nesterov (2005) to obtain a first order algorithm for solving (1) with lower memory requirements and a rigorous complexity estimate with a better dependence on problem size than those offered by interior point methods. Our purpose is not to obtain another algorithm, as we have found that the block coordinate descent is fairly efficient; rather, we seek to use Nesterov's formalism to derive a rigorous complexity estimate for the problem, improved over that offered by interior-point methods. In particular, although we have found in practice that a small, fixed number K of sweeps through all columns is sufficient to achieve convergence using the block coordinate descent method, we have not been able to compute a bound on K. In what follows, we compute a guaranteed theoretical upper bound on the complexity of solving (1).

As we will see, Nesterov's framework allows us to obtain an algorithm that has a complexity of $O(p^{4.5}/\varepsilon)$, where $\varepsilon > 0$ is the desired accuracy on the objective of problem (1). This is in contrast to the complexity of interior-point methods, $O(p^6 \log(1/\varepsilon))$. Thus, Nesterov's method provides a much better dependence on problem size and lower memory requirements at the expense of a degraded dependence on accuracy.

4.1 Idea of Nesterov's Method

Nesterov's method applies to a class of non-smooth, convex optimization problems of the form

$$\min_x \{ f(x) : x \in Q_1 \} \tag{7}$$

where the objective function can be written as

$$f(x) = \hat{f}(x) + \max_u \{ \langle Ax, u \rangle_2 : u \in Q_2 \}.$$

Here, Q_1 and Q_2 are bounded, closed, convex sets, $\hat{f}(x)$ is differentiable (with a Lipschitz-continuous gradient) and convex on Q_1, and A is a linear operator. The challenge is to write our problem in the appropriate form and choose associated functions and parameters in such a way as to obtain the best possible complexity estimate, by applying general results obtained by Nesterov (2005).

Observe that we can write (1) in the form (7) if we impose bounds on the eigenvalues of the solution, X. To this end, we let

$$Q_1 := \{x : aI \preceq X \preceq bI\},$$
$$Q_2 := \{u : \|u\|_\infty \leq \lambda\}$$

where the constants a, b are given such that $b > a > 0$. By Theorem 1, we know that such bounds always exist. We also define $\hat{f}(x) := -\log\det x + \langle S, x \rangle$, and $A := I$.

To Q_1 and Q_2, we associate norms and continuous, strongly convex functions, called prox-functions, $d_1(x)$ and $d_2(u)$. For Q_1 we choose the Frobenius norm, and a prox-function $d_1(x) = -\log\det x + p\log b$. For Q_2, we choose the Frobenius norm again, and a prox-function $d_2(x) = \|u\|_F^2/2$.

The method applies a smoothing technique to the non-smooth problem (7), which replaces the objective of the original problem, $f(x)$, by a penalized function involving the prox-function $d_2(u)$:

$$\tilde{f}(x) = \hat{f}(x) + \max_{u \in Q_2} \{ \langle Ax, u \rangle - \mu d_2(u) \}. \tag{8}$$

The above function turns out to be a smooth uniform approximation to f everywhere. It is differentiable, convex on Q_1, and a has a Lipschitz-continuous gradient, with a constant L that can be computed as detailed below. A specific gradient scheme is then applied to this smooth approximation, with convergence rate $O(L/\varepsilon)$.

4.2 Algorithm and Complexity Estimate

To detail the algorithm and compute the complexity, we must first calculate some parameters corresponding to our definitions and choices above. First, the strong convexity parameter for $d_1(x)$ on Q_1 is $\sigma_1 = 1/b^2$, in the sense that

$$\nabla^2 d_1(X)[H,H] = \mathrm{trace}(X^{-1}HX^{-1}H) \geq b^{-2}\|H\|_F^2$$

for every symmetric H. Furthermore, the center of the set Q_1 is $x_0 := \arg\min_{x\in Q_1} d_1(x) = bI$, and satisfies $d_1(x_0) = 0$. With our choice, we have $D_1 := \max_{x\in Q_1} d_1(x) = p\log(b/a)$.

Similarly, the strong convexity parameter for $d_2(u)$ on Q_2 is $\sigma_2 := 1$, and we have

$$D_2 := \max_{u\in Q_2} d_2(U) = p^2/2.$$

With this choice, the center of the set Q_2 is $u_0 := \arg\min_{u\in Q_2} d_2(u) = 0$.

For a desired accuracy ε, we set the smoothness parameter $\mu := \varepsilon/2D_2$, and set $x_0 = bI$. The algorithm proceeds as follows:

For $k \geq 0$ **do**

1. Compute $\nabla \tilde{f}(x_k) = -x^{-1} + S + u^*(x_k)$, where $u^*(x)$ solves (8).
2. Find $y_k = \arg\min_y \{\langle \nabla \tilde{f}(x_k), y - x_k\rangle + \frac{1}{2}L(\varepsilon)\|y - x_k\|_F^2 \ : \ y \in Q_1\}$.
3. Find $z_k = \arg\min_x \{\frac{L(\varepsilon)}{\sigma_1} d_1(X) + \sum_{i=0}^k \frac{i+1}{2}\langle \nabla \tilde{f}(x_i), x - x_i\rangle \ : \ x \in Q_1\}$.
4. Update $x_k = \frac{2}{k+3}z_k + \frac{k+1}{k+3}y_k$.

In our case, the Lipschitz constant for the gradient of our smooth approximation to the objective function is

$$L(\varepsilon) := M + D_2\|A\|^2/(2\sigma_2\varepsilon)$$

where $M := 1/a^2$ is the Lipschitz constant for the gradient of $\tilde{f}$, and the norm $\|A\|$ is induced by the Frobenius norm, and is equal to λ.

The algorithm is guaranteed to produce an ε-suboptimal solution after a number of steps not exceeding

$$\begin{aligned} &N(\varepsilon) := \\ &4\|A\|\sqrt{\frac{D_1 D_2}{\sigma_1\sigma_2}} \cdot \tfrac{1}{\varepsilon} + \sqrt{\tfrac{MD_1}{\sigma_1\varepsilon}} \\ &= (\kappa\sqrt{(\log\kappa)})(4p^{1.5}a\lambda/\sqrt{2} + \sqrt{\varepsilon p})/\varepsilon. \end{aligned} \tag{9}$$

where $\kappa = b/a$ is a bound on the condition number of the solution.

Now we are ready to estimate the complexity of the algorithm. For Step 1, the gradient of the smooth approximation is computed in closed form by taking the inverse of x. Step 2 essentially

amounts to projecting on Q_1, and requires that we solve an eigenvalue problem. The same is true for Step 3. In fact, each iteration costs $O(p^3)$. The number of iterations necessary to achieve an objective with absolute accuracy less than ε is given in (9) by $N(\varepsilon) = O(p^{1.5}/\varepsilon)$. Thus, if the condition number κ is fixed in advance, the complexity of the algorithm is $O(p^{4.5}/\varepsilon)$.

5. Binary Variables: Approximate Sparse Maximum Likelihood Estimation

In this section, we consider the problem of estimating an undirected graphical model for multivariate binary data. Recently, Wainwright et al. (2006) applied an ℓ_1-norm penalty to the logistic regression problem to obtain a binary version of the high-dimensional consistency results of Meinshausen and Bühlmann (2006). We apply the log determinant relaxation of Wainwright and Jordan (2006) to formulate an approximate sparse maximum likelihood (ASML) problem for estimating the parameters in a multivariate binary distribution. We show that the resulting problem is the same as the Gaussian sparse maximum likelihood (SML) problem, and that we can therefore apply our previously-developed algorithms to sparse model selection in a binary setting.

Consider a distribution made up of p binary random variables. Using n data samples, we wish to estimate the structure of the distribution. An Ising model for this distribution is

$$p(x;\theta) = \exp\{\sum_{i=1}^{p} \theta_i x_i + \sum_{i=1}^{p-1} \sum_{j=i+1}^{p} \theta_{ij} x_i x_j - A(\theta)\} \tag{10}$$

where

$$A(\theta) = \log \sum_{x \in \mathcal{X}^p} \exp\{\sum_{i=1}^{p} \theta_i x_i + \sum_{i=1}^{p-1} \sum_{j=i+1}^{p} \theta_{ij} x_i x_j\} \tag{11}$$

is the log partition function.

The sparse maximum likelihood problem in this case is to maximize (10) with an added ℓ_1-norm penalty on terms θ_{kj}. Specifically, in the undirected graphical model, an edge between nodes k and j is missing if $\theta_{kj} = 0$.

A well-known difficulty is that the log partition function has too many terms in its outer sum to compute. However, if we use the log determinant relaxation for the log partition function developed by Wainwright and Jordan (2006), we can obtain an approximate sparse maximum likelihood (ASML) estimate.

In their paper, Wainwright and Jordan (2006) consider the problem of computing marginal probabilities over subsets of nodes in a graphical model for a discrete-valued Markov random field. This problem is closely related to the one we examine here, and exactly solving the problem for general graphs is intractable. Wainwright and Jordan (2006) propose a relaxation by using a Gaussian bound on the log partition function (11) and a semidefinite outer bound on the polytope of marginal probabilities. In the next section, we use their results to obtain an approximate estimate of undirected graphical model for binary variables, and we show that, when using the simplest semidefinite outer bound on the constraint set, we obtain a problem that is almost exactly the same as that considered in previous sections, for the Gaussian case. In particular, this means that we can reuse the block coordinate descent or Nesterov algorithms to approximately estimate graphical models in the case of binary data.

5.1 Problem Formulation

Let's begin with some notation. Letting $d := p(p+1)/2$, define the map $R : \mathbf{R}^d \to S^{p+1}$ as follows:

$$R(\theta) = \begin{pmatrix} 0 & \theta_1 & \theta_2 & \dots & \theta_p \\ \theta_1 & 0 & \theta_{12} & \dots & \theta_{1p} \\ \vdots & & & & \\ \theta_p & \theta_{1p} & \theta_{2p} & \dots & 0 \end{pmatrix}$$

Suppose that our n samples are $z^{(1)}, \dots, z^{(n)} \in \{-1, +1\}^p$. Let $\overline{z_i}$ and $\overline{z_{ij}}$ denote sample mean and second moments. The sparse maximum likelihood problem is

$$\hat{\theta}_{\text{exact}} := \arg\max_{\theta} \frac{1}{2}\langle R(\theta), R(\overline{z})\rangle - A(\theta) - \lambda\|\theta\|_1. \tag{12}$$

Finally define the constant vector $m = (1, \frac{4}{3}, \dots, \frac{4}{3}) \in \mathbf{R}^{p+1}$. Wainwright and Jordan (2006) give an upper bound on the log partition function as the solution to the following variational problem:

$$\begin{array}{l} A(\theta) \leq \max_{\mu} \frac{1}{2}\log\det(R(\mu) + \operatorname{diag}(m)) + \langle\theta, \mu\rangle \\ = \frac{1}{2} \cdot \max_{\mu} \log\det(R(\mu) + \operatorname{diag}(m)) + \langle R(\theta), R(\mu)\rangle. \end{array} \tag{13}$$

If we use the bound (13) in our sparse maximum likelihood problem (12), we won't be able to extract an optimizing argument $\hat{\theta}$. Our first step, therefore, will be to rewrite the bound in a form that will allow this.

Lemma 5 *We can rewrite the bound (13) as*

$$A(\theta) \leq \frac{p}{2}\log(\frac{e\pi}{2}) - \frac{1}{2}(p+1) - \frac{1}{2} \cdot \{\max_{\nu} \nu^T m + \log\det(-(R(\theta) + diag(\nu))). \tag{14}$$

Using this version of the bound (13), we have the following theorem.

Theorem 6 *Using the upper bound on the log partition function given in (14), the approximate sparse maximum likelihood problem has the following solution:*

$$\begin{array}{l} \hat{\theta}_k = \overline{\mu_k} \\ \hat{\theta}_{kj} = -(\hat{\Gamma})^{-1}_{kj} \end{array} \tag{15}$$

where the matrix $\hat{\Gamma}$ is the solution to the following problem, related to (2):

$$\hat{\Gamma} := \arg\max\{\log\det W : W_{kk} = S_{kk} + \frac{1}{3},\ |W_{kj} - S_{kj}| \leq \lambda\}. \tag{16}$$

Here, S is defined as before:

$$S = \frac{1}{n}\sum_{k=1}^{n} (z^{(k)} - \overline{\mu})(z^{(k)} - \overline{\mu})^T$$

where $\overline{\mu}$ is the vector of sample means $\overline{z_i}$.

In particular, this means that we can reuse the algorithms developed in Sections 3 and 4 for problems with binary variables. The relaxation (13) is the simplest one offered by Wainwright and Jordan (2006). The relaxation can be tightened by adding linear constraints on the variable μ.

5.2 Penalty Parameter Choice for Binary Variables

For the choice of the penalty parameter λ, we can derive a formula analogous to (3). Consider the choice

$$\lambda(\alpha)_{\text{bin}} := \frac{(\chi^2(\alpha/2p^2,1))^{\frac{1}{2}}}{(\min_{i>j}\hat{\sigma}_i\hat{\sigma}_j)\sqrt{n}} \tag{17}$$

where $\chi^2(\alpha,1)$ is the $(100-\alpha)\%$ point of the chi-square distribution for one degree of freedom. Since our variables take on values in $\{-1,1\}$, the empirical variances are of the form:

$$\hat{\sigma}_i^2 = 1-\bar{\mu}_i^2.$$

Using (17), we have the following binary version of Theorem 2:

Theorem 7 *With (17) chosen as the penalty parameter in the approximate sparse maximum likelihood problem, for a fixed level α,*

$$P(\exists k \in \{1,\ldots,p\} : \hat{C}_k^{\lambda} \not\subseteq C_k) \leq \alpha.$$

6. Numerical Results

In this section we present the results of some numerical experiments, both on synthetic and real data. The synthetic experiments were performed on continuous data, and tests only the original problem formulation. Both continuous and discrete real data sets are used, however, testing the Gaussian and binary formulations respectively.

6.1 Synthetic Experiments

Synthetic experiments require that we generate underlying sparse inverse covariance matrices. To this end, we first randomly choose a diagonal matrix with positive diagonal entries. A given number of nonzeros are inserted in the matrix at random locations symmetrically. Positive definiteness is ensured by adding a multiple of the identity to the matrix if needed. The multiple is chosen to be only as large as necessary for inversion with no errors.

6.2 Sparsity and Thresholding

A very simple approach to obtaining a sparse estimate of the inverse covariance matrix would be to apply a threshold to the inverse empirical covariance matrix, S^{-1}. However, even when S is easily invertible, it can be difficult to select a threshold level. We solved a synthetic problem of size $p = 100$ where the true concentration matrix density was set to $\delta = 0.1$. Drawing $n = 200$ samples, we plot in Figure 1 the sorted absolute value elements of S^{-1} on the left and $\hat{\Sigma}^{-1}$, the solution to (1), on the right.

It is clearly easier to choose a threshold level for the sparse maximum likelihood estimate. Applying a threshold to either S^{-1} or $\hat{\Sigma}^{-1}$ would decrease the log likelihood of the estimate by an unknown amount. One way to compute the largest possible threshold t that preserves positive definiteness in S can be computed by solving the minimization problem:

$$t \leq \min_{\|v\|_1=1} v^T S^{-1} v.$$

The condition (6.2) is equivalent to the condition that $S^{-1}+L \succ 0$ for all matrices L such that $\|L\|_\infty \leq t$.

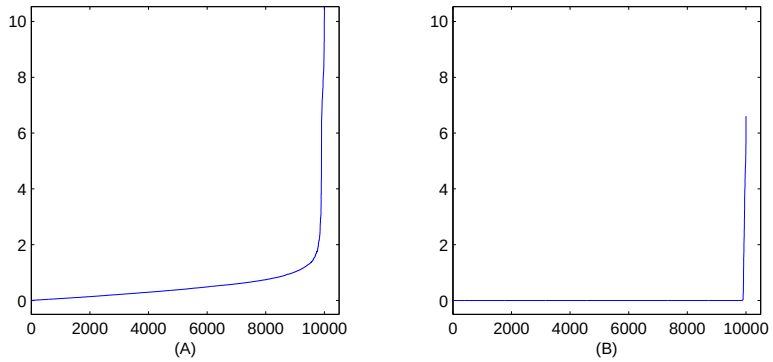

Figure 1: Sorted absolute value of elements of (A) S^{-1} and (B) $\hat{\Sigma}^{-1}$. The solution $\hat{\Sigma}^{-1}$ to (1) is un-thresholded.

6.3 Recovering Structure

We begin with a small experiment to test the ability of the method to recover the sparse structure of an underlying covariance matrix. Figure 2 (A) shows a sparse inverse covariance matrix of size $p = 30$. Figure 2 (B) displays a corresponding S^{-1}, using $n = 60$ samples. Figure 2 (C) displays the solution to (1) for $\lambda = 0.1$. The value of the penalty parameter here is chosen arbitrarily, and the solution is not thresholded. Nevertheless, we can still pick out features that were present in the true underlying inverse covariance matrix.

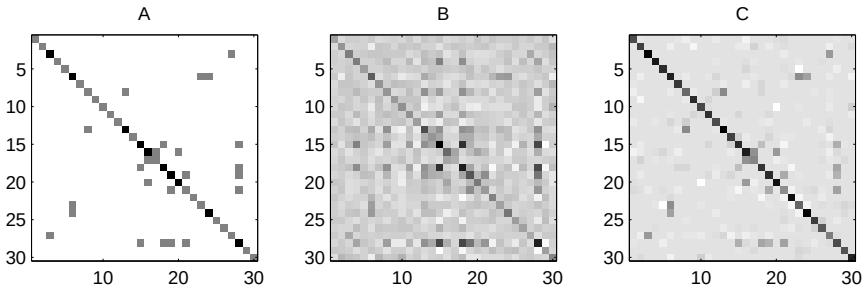

Figure 2: Recovering the sparsity pattern. We plot (A) the original inverse covariance matrix Σ^{-1}, (B) the noisy sample inverse S^{-1}, and (C) the solution to problem (1) for $\lambda = 0.1$.

Using the same underlying inverse covariance matrix, we repeat the experiment using smaller sample sizes. We solve (1) for $n = 30$ and $n = 20$ using the same arbitrarily chosen penalty parameter value $\lambda = 0.1$, and display the solutions in Figure 3. As expected, our ability to pick out features of the true inverse covariance matrix diminishes with the number of samples. This is an added reason to choose a larger value of λ when we have fewer samples, as in (3).

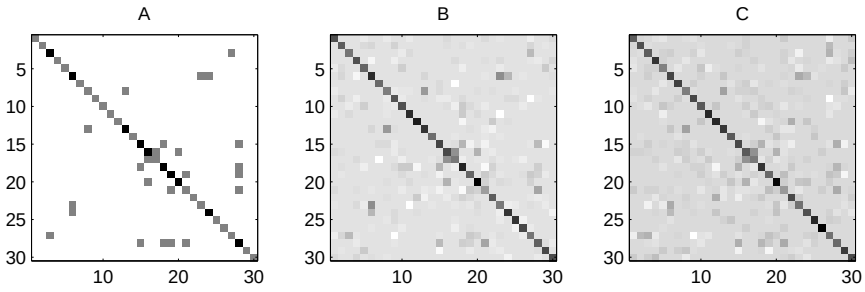

Figure 3: Recovering the sparsity pattern for small sample size. We plot (A) the original inverse covariance matrix Σ^{-1}, (B) the solution to problem (1) for $n = 30$ and (C) the solution for $n = 20$. A penalty parameter of $\lambda = 0.1$ is used for (B) and (C).

6.4 CPU Times Versus Problem Size

For a sense of the practical performance of the block coordinate descent method, we implemented it in Matlab, using Mosek to solve the quadratic program at each step. For problem sizes ranging from $p = 400$ to $p = 1000$, we solved the problem using $n = 2p$ samples. In all cases, one sweep through all the columns was sufficient to achieve an absolute accuracy of $\varepsilon = 1e-7$. The Nesterov algorithm, implemented in C, was found to have a comparable computation time provided one chooses a large value for the desired accuracy. Since the Nesterov algorithm aims for a lower accuracy and requires the setting of bounds a and b on the eigenvalues of the solution, it was not included in this experiment.

In Figure 4 we plot the average CPU time to achieve convergence, along with CPU times for the Lasso for comparision. CPU times were computed using an AMD Athlon 64 2.20Ghz processor with 1.96GB of RAM. Using this very simple implementation, the block coordinate descent method solves a problem of size $p = 1000$ in about an hour and a half. The computation time could possibly be cut down by using a fast Lasso implementation to solve the optimization problem, as described in Section 3.3, and by using a suitable method to compute the square root matrix Q from (6).

6.5 Path Following Experiments

Figure 6.5 shows two path following examples. We solve two randomly generated problems of size $p = 5$ and $n = 100$ samples. The red lines correspond to elements of the solution that are zero in the true underlying inverse covariance matrix. The blue lines correspond to true nonzeros. The vertical lines mark ranges of λ for which we recover the correct sparsity pattern exactly. Note that, by Theorem 4, for λ values greater than those shown, the solution will be diagonal.

On a related note, we observe that (1) also works well in recovering the sparsity pattern of a matrix masked by noise. The following experiment illustrates this observation. We generate a sparse inverse covariance matrix of size $p = 50$ as described above. Then, instead of using an empirical covariance S as input to (1), we use $S = (\Sigma^{-1} + V)^{-1}$, where V is a randomly generated uniform noise of size $\sigma = 0.1$. We then solve (1) for various values of the penalty parameter λ.

In Figure 6, for each value of λ shown, we randomly selected 10 sample covariance matrices S of size $p = 50$ and computed the number of misclassified zeros and nonzero elements in the solution

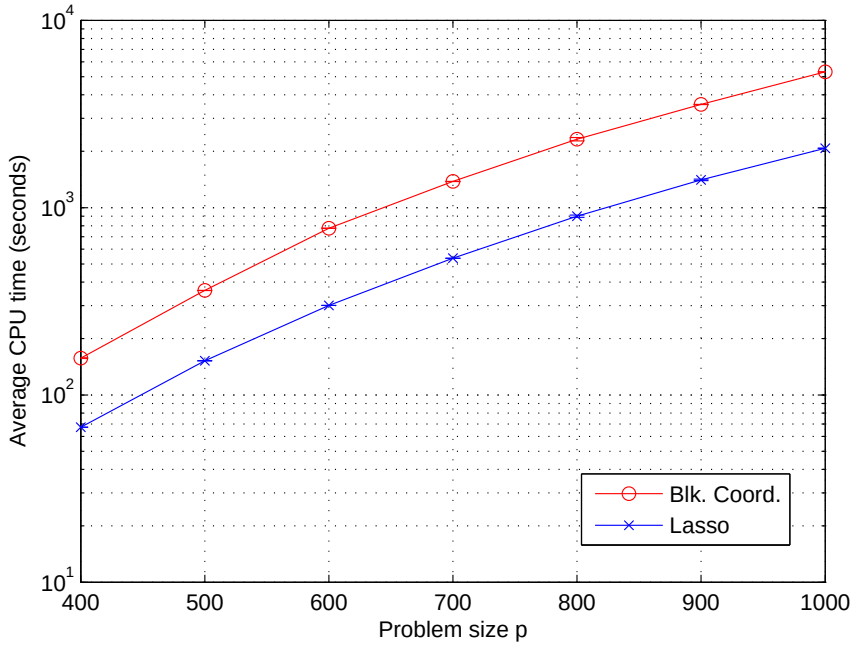

Figure 4: Average CPU times vs. problem size using block coordinate descent. We plot the average CPU time (in seconds) versus problem size. The standard deviations for the block coordinate descent method are: 0.6077, 0.2652, 0.1989, 1.0165, 48.0833, 2.7732, and 6.2314 seconds respectively. For the Lasso, the standard deviations are: 0.0221, 0.3646, 0.1878, 0.5966, 12.7279, 13.1257, and 0.6187 seconds respectively.

to (1). We plot the average percentage of errors (number of misclassified zeros plus misclassified nonzeros divided by p^2), as well as error bars corresponding to one standard deviation. As shown, the error rate is nearly zero on average when the penalty is set to equal the noise level σ.

6.6 Estimating the Stability of the Solution Using Cross-validation

Viewing our estimator as a machine that classifies elements of the concentration matrix as either zero or nonzero, we next turn to the question of the stability of the classification. Classifier instability is defined here as the probability that the classification of an arbitrary element of the matrix is changed by some small disturbance in the data. In other words, once we obtain a concentration graph by treating our estimated matrix $\hat{\Sigma}$ as an adjacency matrix, we would like to measure the stability of our results.

To empirically estimate the instability of our classifier, we can use the following simple procedure. First, we use all the available data to obtain an estimate of the concentration matrix $\hat{\Sigma}_0^{-1}$. Then we perform K-fold cross validation: randomly dividing the available data into K subsamples, we compute K different estimates $\hat{\Sigma}_i^{-1}$ by successively leaving out one subsample each time. After each estimate $\hat{\Sigma}_i^{-1}$ is computed, we count the number of matrix entries with classifications that are

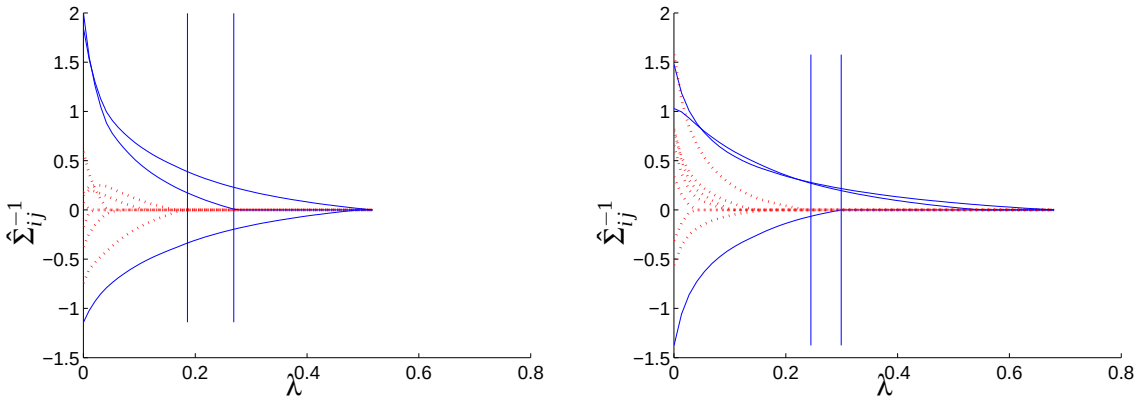

Figure 5: Path following: elements of solution to (1) as λ increases. Dashed lines correspond to elements that are zero in the true inverse covariance matrix; solid lines correspond to true nonzeros. Vertical lines mark a range of λ values using which we recover the sparsity pattern exactly.

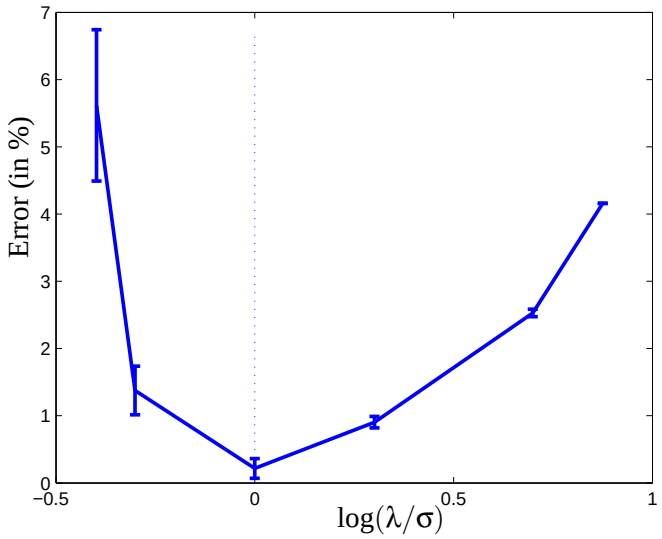

Figure 6: Recovering sparsity pattern in a matrix with added uniform noise of size $\sigma = 0.1$. We plot the average percentage or misclassified entries as a function of $\log(\lambda/\sigma)$.

different from those of $\hat{\Sigma}_0^{-1}$. Our estimate of the instability is then the average number of entries, taken over the K estimates, that were classified differently from those of $\hat{\Sigma}_0^{-1}$.

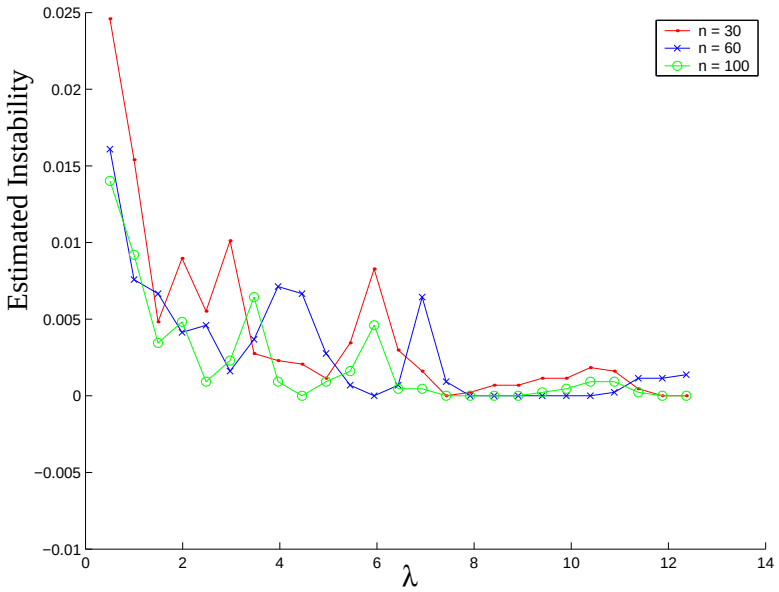

Figure 7: Estimating stability of the solution using cross validation. We plot estimated instability, the probability that the classification of an arbitrary element is changed by a small disturbance in the data, for a range of values of λ using data sets of size $n = 30, 60$, and 100 samples for a problem with $p = 30$ variables.

Below we show the results of some experiments using synthetic data. First, we randomly generated an underlying concentration matrix of size $p = 30$. Let $\delta = 0.25$ denote the fraction of nonzero elements in Σ^{-1}. Then, from the corresponding covariance matrix Σ, we generated three data sets of sizes $n = 30, 60$, and 100.

In Figure 7 we plot estimated instability versus a range of values for the penalty parameter λ, using 10-fold cross validation. We applied Theorem 4 to compute a maximum value of λ; beyond this value, the estimated graph is empty for all three data sets. As shown, even for a small number of samples, the estimated graph is fairly stable for all values of λ.

We can also see how our estimate of the instability changes as we divide the available data into a greater number of subsamples. In Figure 8 we repeat the experiment described above, this time fixing $\lambda = 0.2$ and instead varying the number of folds K in the cross validation. In these examples, for each value of n, dividing the available data into more subsamples for cross validation decreases our estimate of the instability.

6.7 Performance as a Binary Classifier

In this section we numerically examine the ability of the sparse maximum likelihood (SML) method to correctly classify elements of the inverse covariance matrix as zero or nonzero. For comparision, we will use the Lasso estimate of Meinshausen and Bühlmann (2006), which has been shown to perform extremely well. The Lasso regresses each variable against all others one at a time. Upon obtaining a solution $\theta^{(k)}$ for each variable k, one can estimate sparsity in one of two ways: either by

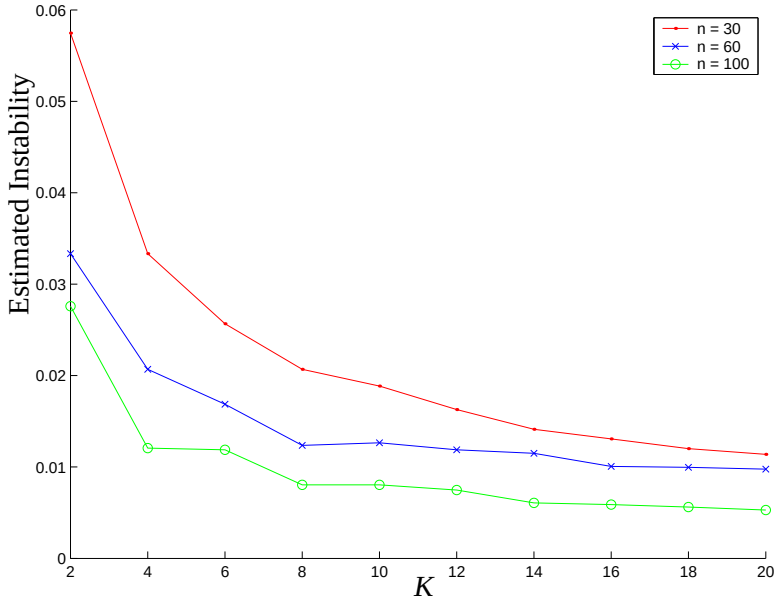

Figure 8: Estimating instability of the solution using cross validation. We plot the estimate of the instability obtained using K samples, for various values of K. Once again, we use data sets of size $n = 30, 60$, and 100 samples for a problem with $p = 30$ variables.

declaring an element $\hat{\Sigma}_{ij}$ nonzero if both $\theta_i^{(k)} \neq 0$ and $\theta_j^{(k)} \neq 0$ (Lasso-AND) or, less conservatively, if either of those quantities is nonzero (Lasso-OR).

As noted previously, Meinshausen and Bühlmann (2006) have also derived a formula for choosing their penalty parameter. Both the SML and Lasso penalty parameter formulas depend on a chosen level α, which is a bound on the same error probability for each method. For these experiments, we set $\alpha = 0.05$.

In the following experiments, we fixed the problem size p at 30 and generated sparse underlying inverse covariance matrices as described above. We varied the number of samples n from 10 to 310. For each value of n shown, we ran 30 trials in which we estimated the sparsity pattern of the inverse covariance matrix using the SML, Lasso-OR, and Lasso-AND methods. We then recorded the average number of nonzeros estimated by each method, and the average number of entries correctly identified as nonzero (true positives).

We show two sets of plots. Figure 6.7 corresponds to experiments where the true density was set to be low, $\delta = 0.05$. We plot the power (proportion of correctly identified nonzeros), positive predictive value (proportion of estimated nonzeros that are correct), and the density estimated by each method. Figure 6.7 corresponds to experiments where the true density was set to be high, $\delta = 0.40$, and we plot the same three quantities.

Meinshausen and Bühlmann (2006) report that, asymptotically, Lasso-AND and Lasso-OR yield the same estimate of the sparsity pattern of the inverse covariance matrix. At a finite number of samples, the SML method seems to fall in in between the two methods in terms of power, positive predictive value, and the density of the estimate. It typically offers, on average, the lowest total

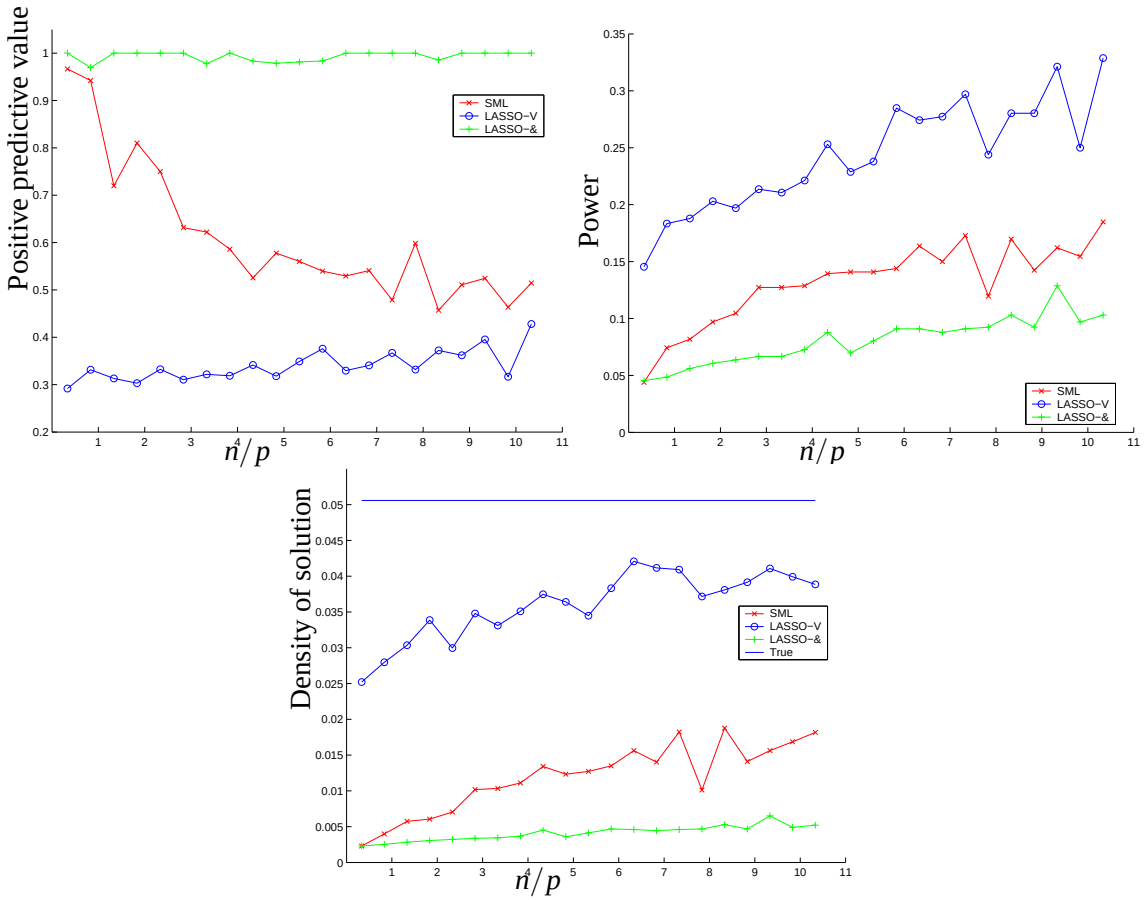

Figure 9: Classifying zeros and nonzeros for a true density of $\delta = 0.05$. We plot the positive predictive value, the power, and the estimated density using SML, Lasso-OR and Lasso-AND.

number of errors, tied with either Lasso-AND or Lasso-OR. Among the two Lasso methods, it would seem that if the true density is very low, it is slightly better to use the more conservative Lasso-AND. If the density is higher, it may be better to use Lasso-OR. When the true density is unknown, we can achieve an accuracy comparable to the better choice among the Lasso methods by computing the SML estimate. Figure 11 shows one example of sparsity pattern recovery when the true density is low.

The Lasso and SML methods have a comparable computational complexity. However, unlike the Lasso, the SML method is not parallelizable. Parallelization would render the Lasso a more computationally attractive choice, since each variable can regressed against all other separately, at an individual cost of $O(p^3)$. In exchange, SML can offer a more accurate estimate of the sparsity pattern, as well as a well-conditioned estimate of the covariance matrix itself.

6.8 Recovering Structure from Binary Data

Next we turn our attention to the binary version of the algorithm, as described in Section 5. For $p = 100$ variables, we randomly generated Ising models (10) such that the maximum degree of the

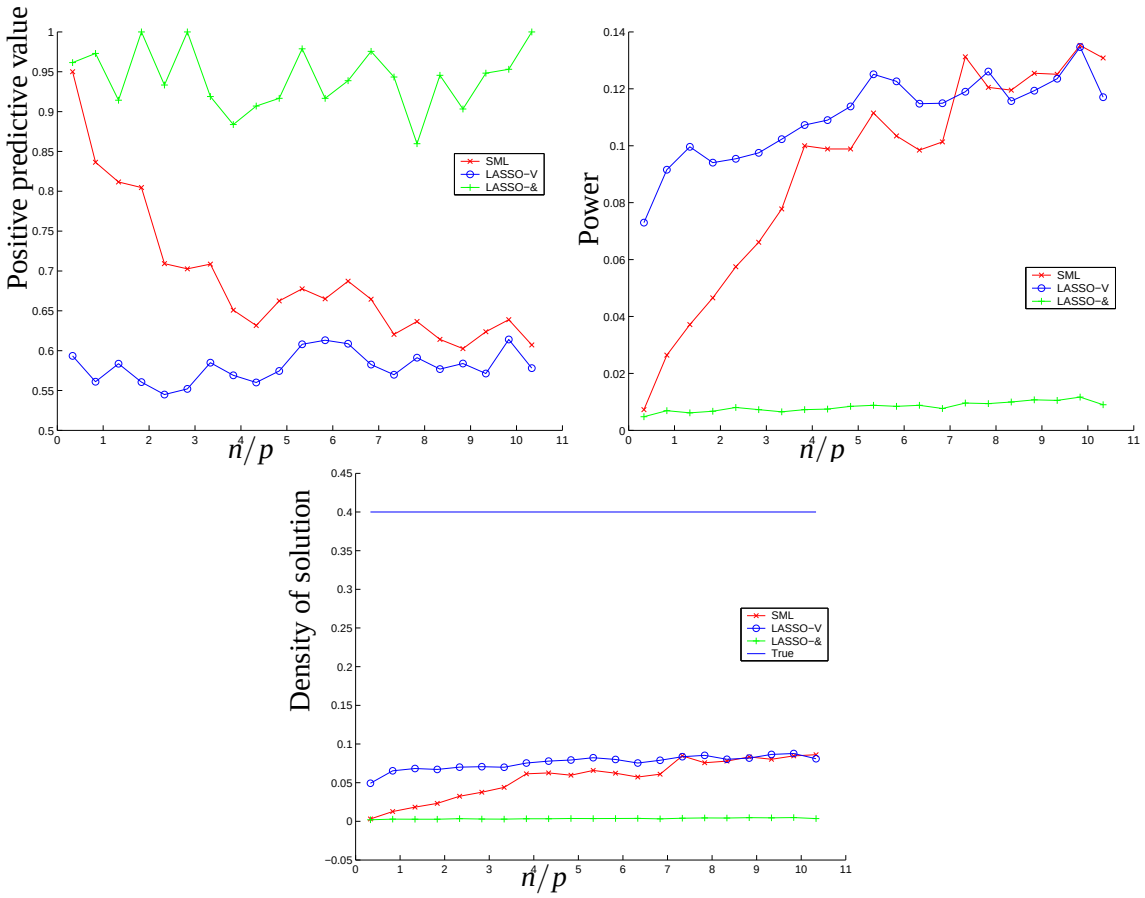

Figure 10: Classifying zeros and nonzeros for a true density of $\delta = 0.40$. We plot the positive predictive value, the power, and the estimated density using SML, Lasso-OR and Lasso-AND.

resulting graph was $d = 4$. We drew n i.i.d. samples and then attempted to recover the underlying sparsity pattern using both the approximate sparse maximum likelihood method and ℓ_1-norm penalized logistic regression as described by Wainwright et al. (2006).

In Figure 12 we plot the average sensitivity (the fraction of actual nonzeros that are correctly identified as nonzeros) as well as the average specificity (the fraction of actual zeros that are correctly identified as zeros) for a range of sample sizes. We used a significance level of $\alpha = 0.05$ for the approximate sparse maximum likelihood method, and a regularization parameter choice of $\lambda_n = 0.04 * (\log p)^3/\sqrt{n}$ for the penalized logistic regression AND method, as described by Wainwright et al. (2006).

7. Gene Expression and U.S. Senate Voting Records Data

We tested our algorithms on three sets of data: two gene expression data sets, as well as US Senate voting records. Gene expression data is often assumed to be approximately normally distributed,

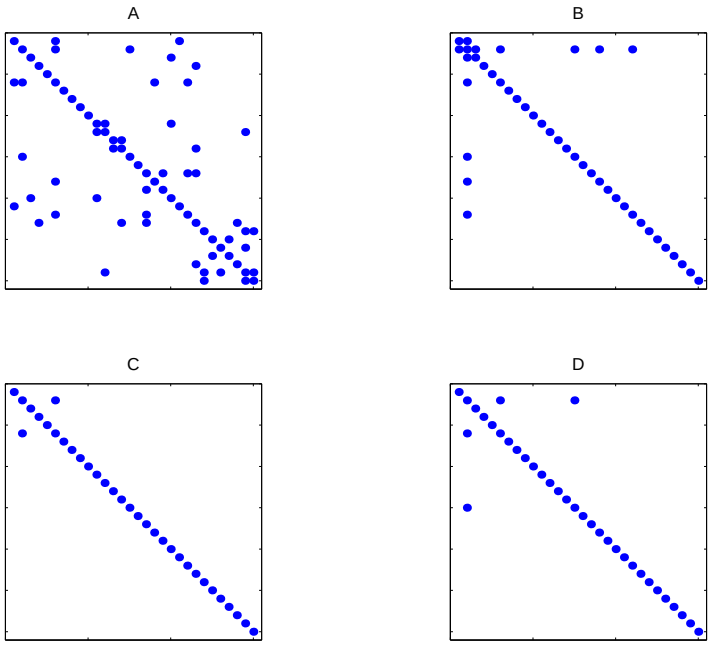

Figure 11: Comparing sparsity pattern recovery to the Lasso. (A) true covariance (B) Lasso-OR (C) Lasso-AND (D) SML.

while the voting records data is here considered binary. In this section we briefly explore their respective estimated graphical models.

7.1 Rosetta Inpharmatics Compendium

We applied our algorithms to the Rosetta Inpharmatics Compendium of gene expression profiles described by Hughes et al. (2000). The 300 experiment compendium contains $n = 253$ samples with $p = 6136$ variables. With a view towards obtaining a very sparse graph, we replaced $\alpha/2p^2$ in (3) by α, and set $\alpha = 0.05$. The resulting penalty parameter is $\lambda = 0.0313$.

This is a large penalty for this data set, and by applying Theorem 4 we find that all but 270 of the variables are estimated to be independent from all the rest, clearly a very conservative estimate. Figure 13 displays the resulting graph.

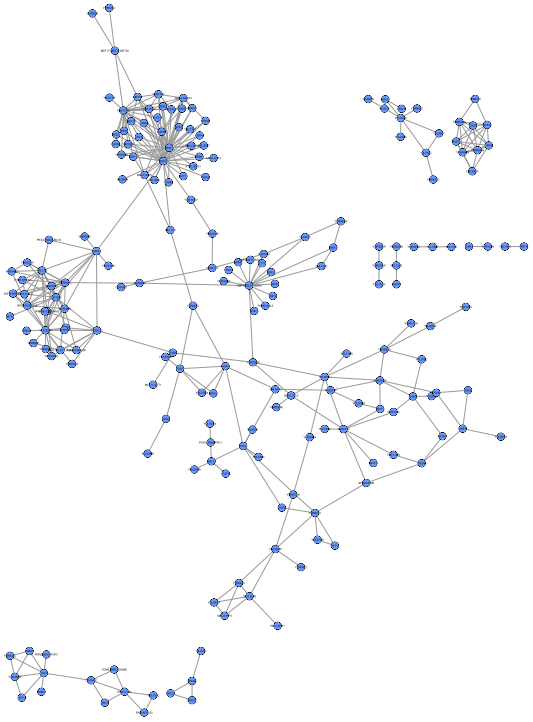

Figure 13: Application to Hughes compendium. The above graph results from solving (1) for this data set with a penalty parameter of $\lambda = 0.0313$.

Figure 14 focuses on a region of Figure 13, a cluster of genes that is unconnected to the remaining genes in this estimate. According to Gene Ontology (see Ashburner et al., 2000), these genes are associated with iron homeostasis. The probability that a gene has been false included in this cluster is at most 0.05.

As a second example, in Figure 15, we show a subgraph of genes associated with cellular membrane fusion. All three graphs were rendered using Cytoscape.

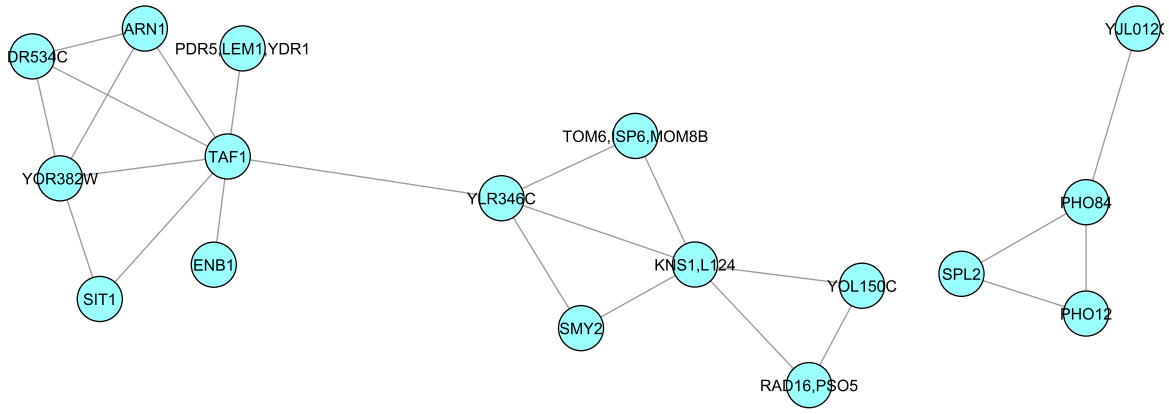

Figure 14: Application to Hughes data set (closeup of Figure 13). These genes are associated with iron homeostasis.

7.2 Iconix Microarray Data

Next we analyzed a subset of a $10,000$ gene microarray data set from 160 drug treated rat livers (Natsoulis et al., 2005). In this study, rats were treated with a variety of fibrate, statin, or estrogen receptor agonist compounds. Taking the 500 genes with the highest variance, we once again replaced $\alpha/2p^2$ in (3) by α, and set $\alpha = 0.05$. The resulting penalty parameter is $\lambda = 0.0853$.

By applying Theorem 4 we find that all but 339 of the variables are estimated to be independent from the rest. This estimate is less conservative than that obtained in the Hughes case since the ratio of samples to variables is 160 to 500 instead of 253 to 6136.

The first order neighbors of any node in a Gaussian graphical model form the set of predictors for that variable. In the estimated obtained by solving (1), we found that LDL receptor had one of the largest number of first-order neighbors in the Gaussian graphical model. The LDL receptor is believed to be one of the key mediators of the effect of both statins and estrogenic compounds on LDL cholesterol. Table 1 lists some of the first order neighbors of LDL receptor.

It is perhaps not surprising that several of these genes are directly involved in either lipid or steroid metabolism (K03249, AI411979, AI410548, NM_013200, Y00102). Other genes such as Cbp/p300 are known to be global transcriptional regulators. Finally, some are un-annotated ESTs. Their connection to the LDL receptor in this analysis may provide clues to their function.

7.3 Senate Voting Records Data

We conclude our numerical experiments by testing our approximate sparse maximum likelihood estimation method on binary data. The data set consists of US senate voting records data from the 109th congress (2004 - 2006). There are one hundred variables, corresponding to 100 senators.

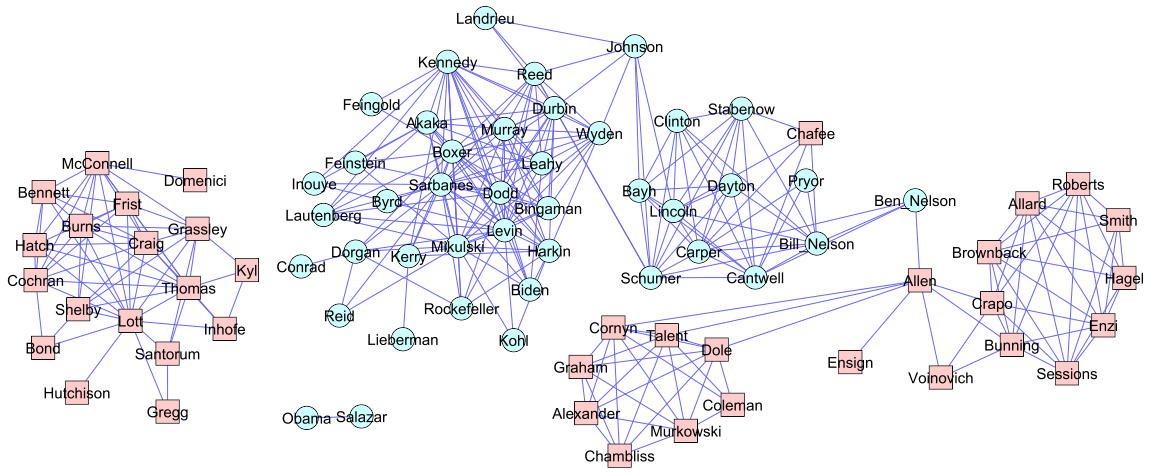

Figure 16: US Senate, 109th Congress (2004-2006). The graph displays the solution to (12) obtained using the log determinant relaxation to the log partition function of Wainwright and Jordan (2006). Democratic senators are represented by round nodes and Republican senators are represented by square nodes.

Each of the 542 samples is bill that was put to a vote. The votes are recorded as -1 for no and 1 for yes.

There are many missing values in this data set, corresponding to missed votes. Since our analysis depends on data values taken solely from $\{-1,1\}$, it was necessary to impute values to these. For this experiment, we replaced all missing votes with noes (-1). We chose the penalty parameter $\lambda(\alpha)$ according to (17), using a significance level of $\alpha = 0.05$. Figure 16 shows the resulting graphical model, rendered using Cytoscape. Red nodes correspond to Republican senators, and blue nodes correspond to Democratic senators.

We can make some tentative observations by browsing the network of senators. As neighbors most Democrats have only other Democrats and Republicans have only other Republicans. Senator Chafee (R, RI) has only Democrats as his neighbors, an observation that supports media statements made by and about Chafee during those years. Senator Allen (R, VA) unites two otherwise separate groups of Republicans and also provides a connection to the large cluster of Democrats through Ben Nelson (D, NE), which also supports media statements made about him prior to his 2006 re-election campaign. Thus, although we obtained this graphical model via a relaxation of the log partition function, the resulting picture is supported by conventional wisdom. Figure 17 shows a subgraph consisting of neighbors of degree three or lower of Senator Allen.

Finally, we estimated the instability of these results using 10-fold cross validation, as described in Section 6.6. The resulting estimate of the instability is 0.00376, suggesting that our estimate of the graphical model is fairly stable.

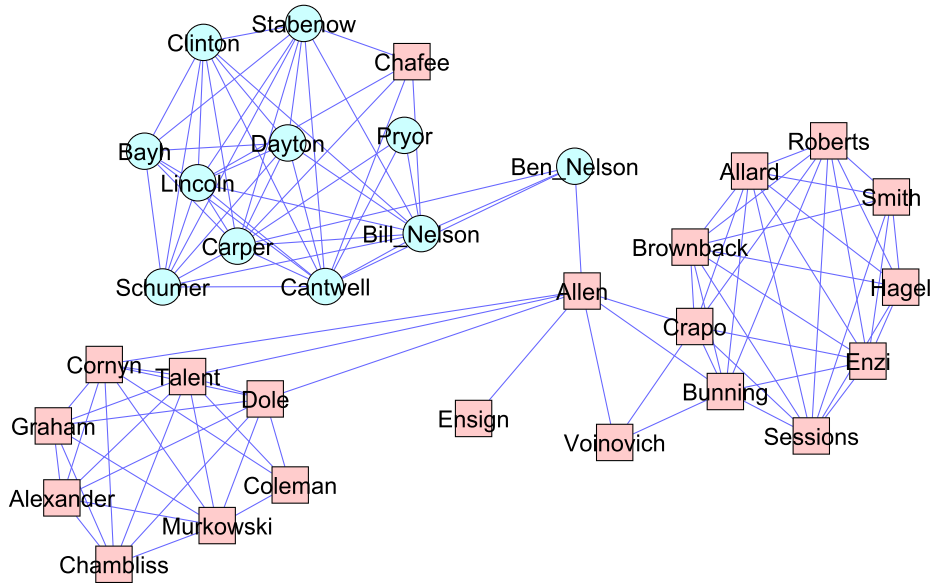

Figure 17: US Senate, 109th Congress. Neighbors of Senator Allen (degree three or lower).

Acknowledgments

We are indebted to Georges Natsoulis for his interpretation of the Iconix data set analysis and for gathering the senate voting records. We also thank Martin Wainwright, Bin Yu, Peter Bartlett, and Michael Jordan for many enlightening conversations.

Appendix A. Proof of Solution Properties and Block Coordinate Descent Convergence

In this section, we give short proofs of the two theorems on properties of the solution to (1), as well as the convergence of the block coordinate descent method.

Proof of Theorem 1:

Since $\hat{\Sigma}$ satisfies $\hat{\Sigma} = S + \hat{U}$, where $\|U\|_\infty \leq \lambda$, we have:

$$\begin{aligned}\|\hat{\Sigma}\|_2 &= \|S+\hat{U}\|_2 \\ &\leq \|S\|_2 + \|U\|_2 \leq \|S\|_2 + \|U\|_\infty \leq \|S\|_2 + \lambda p\end{aligned}$$

which yields the lower bound on $\|\hat{\Sigma}^{-1}\|_2$. Likewise, we can show that $\|\hat{\Sigma}^{-1}\|_2$ is bounded above. At the optimum, the primal dual gap is zero:

$$\begin{aligned}&-\log\det\hat{\Sigma}^{-1} + \mathrm{trace}(S\hat{\Sigma}^{-1}) + \lambda\|\hat{\Sigma}^{-1}\|_1 - \log\det\hat{\Sigma} - p \\ &= \mathrm{trace}(S\hat{\Sigma}^{-1}) + \lambda\|\hat{\Sigma}^{-1}\|_1 - p = 0\end{aligned}$$

We therefore have

$$\begin{aligned}&\|\hat{\Sigma}^{-1}\|_2 \leq \|\hat{\Sigma}^{-1}\|_F \leq \|\hat{\Sigma}^{-1}\|_1 \\ &= p/\lambda - \mathrm{trace}(S\hat{\Sigma}^{-1})/\lambda \leq p/\lambda\end{aligned}$$

where the last inequality follows from $\mathrm{trace}(S\hat{\Sigma}^{-1}) \geq 0$, since $S \succeq 0$ and $\hat{\Sigma}^{-1} \succ 0$. ■

Next we prove the convergence of block coordinate descent:

Proof of Theorem 3:

To see that optimizing over one row and column of W in (2) yields the quadratic program (4), let all but the last row and column of W be fixed. Since we know the diagonal entries of the solution, we can fix the remaining diagonal entry as well:

$$W = \begin{pmatrix} W_{\backslash p \backslash p} & w_p \\ w_p^T & W_{pp} \end{pmatrix}.$$

Then, using Schur complements, we have that

$$\det W = \det W_{\backslash p \backslash p} \cdot (W_{pp} - w_p^T (W_{\backslash p \backslash p})^{-1} w_p)$$

which gives rise to (4).

By general results on block coordinate descent algorithms (e.g., Bertsekas, 1998), the algorithms converges if (4) has a unique solution at each iteration. Thus it suffices to show that, at every sweep, $W^{(j)} \succ 0$ for all columns j. Prior to the first sweep, the initial value of the variable is positive definite: $W^{(0)} \succ 0$ since $W^{(0)} := S + \lambda I$, and we have $S \succeq 0$ and $\lambda > 0$ by assumption.

Now suppose that $W^{(j)} \succ 0$. This implies that the following Schur complement is positive:

$$w_{jj} - W_j^T (W_{\backslash j \backslash j}^{(j)})^{-1} W_j > 0$$

By the update rule we have that the corresponding Schur complement for $W^{(j+1)}$ is even greater:

$$w_{jj} - W_j^T (W_{\backslash j \backslash j}^{(j+1)})^{-1} W_j > w_{jj} - W_j^T (W_{\backslash j \backslash j}^{(j)})^{-1} W_j > 0$$

so that $W^{(j+1)} \succ 0$. ■

Finally, we apply Theorem 3 to prove the second property of the solution.

Proof of Theorem 4:

Suppose that column j of the second moment matrix satisfies $|S_{ij}| \leq \lambda$ for all $i \neq j$. This means that the zero vector is in the constraint set of (4) for that column. Each time we return to column j, the objective function will be different, but always of the form $y^T A y$ for $A \succ 0$. Since the constraint set will not change, the solution for column j will always be zero. By Theorem 3, the block coordinate descent algorithm converges to a solution, and so therefore the solution must have $\hat{\Sigma}_j = 0$. ■

Appendix B. Proof of Error Bounds

Next we shall show that the penalty parameter choice given in (3) yields the error probability bound of Theorem 2. The proof is nearly identical to that of (Meinshausen and Bühlmann, 2006, Theorem 3). The differences stem from a different objective function, and the fact that our variable is a matrix of size p rather than a vector of size p. Our proof is only an adaptation of their proof to our problem.

B.1 Preliminaries

Before we begin, consider problem (1), for a matrix S of any size:

$$\hat{X} = \arg\min -\log\det X + \mathrm{trace}(SX) + \lambda\|X\|_1$$

where we have dropped the constraint $X \succ 0$ since it is implicit, due to the log determinant function. Since the problem is unconstrained, the solution $\hat{X}$ must correspond to setting the subgradient of the objective to zero:

$$\begin{array}{ll} S_{ij} - X_{ij}^{-1} = -\lambda & \text{for } X_{ij} > 0, \\ S_{ij} - X_{ij}^{-1} = \lambda & \text{for } X_{ij} < 0, \\ |S_{ij} - X_{ij}^{-1}| \leq \lambda & \text{for } X_{ij} = 0. \end{array} \tag{18}$$

Recall that by Theorem 1, the solution is unique for λ positive.

B.2 Proof of Error Bound for Gaussian Data

Now we are ready to prove Theorem 2.

Proof of Theorem 2:

Sort columns of the covariance matrix so that variables in the same connectivity component are grouped together. The correct zero pattern for the covariance matrix is then block diagonal. Define

$$\Sigma^{\text{correct}} := \text{blk diag}(C_1, \ldots, C_\ell) \tag{19}$$

The inverse $(\Sigma^{\text{correct}})^{-1}$ must also be block diagonal, with possible additional zeros inside the blocks. If we constrain the solution to (1) to have this structure, then by the form of the objective, we can optimize over each block separately. For each block, the solution is characterized by (18).

Now, suppose that

$$\lambda > \max_{i \in N, j \in N \setminus C_i} |S_{ij} - \Sigma_{ij}^{\text{correct}}|. \tag{20}$$

Then, by the subgradient characterization of the solution noted above, and the fact that the solution is unique for $\lambda > 0$, it must be the case that $\hat{\Sigma} = \Sigma^{\text{correct}}$. By the definition of Σ^{correct}, this implies that, for $\hat{\Sigma}$, we have $\hat{C}_k = C_k$ for all $k \in N$.

Taking the contrapositive of this statement, we can write:

$$\begin{array}{l} P(\exists k \in N : \hat{C}_k \not\subseteq C_k) \\ \leq P(\max_{i \in N, j \in N \setminus C_i} |S_{ij} - \Sigma_{ij}^{\text{correct}}| \geq \lambda) \\ \leq p^2(n) \cdot \max_{i \in N, j \in N \setminus C_i} P(|S_{ij} - \Sigma_{ij}^{\text{correct}}| \geq \lambda) \\ = p^2(n) \cdot \max_{i \in N, j \in N \setminus C_i} P(|S_{ij}| \geq \lambda). \end{array} \tag{21}$$

The equality at the end follows since, by definition, $\Sigma_{ij}^{\text{correct}} = 0$ for $j \in N \setminus C_i$. It remains to bound $P(|S_{ij}| \geq \lambda)$.

The statement $|S_{kj}| \geq \lambda$ can be written as:

$$|R_{kj}|(1 - R_{kj}^2)^{-\frac{1}{2}} \geq \lambda(s_{kk}s_{jj} - \lambda^2)^{-\frac{1}{2}}$$

where R_{kj} is the correlation between variables k and j, since

$$|R_{kj}|(1 - R_{kj}^2)^{-\frac{1}{2}} = |S_{kj}|(S_{kk}S_{jj} - S_{kj}^2)^{-\frac{1}{2}}.$$

Furthermore, the condition $j \in N \backslash C_k$ is equivalent to saying that variables k and j are independent: $\Sigma_{kj} = 0$. Conditional on this, the statistic

$$R_{kj}(1-R_{kj}^2)^{-\frac{1}{2}}(n-2)^{\frac{1}{2}}$$

has a Student's t-distribution for $n-2$ degrees of freedom. Therefore, for all $j \in N \backslash C_k$,

$$\begin{aligned} &P(|S_{kj}| \geq \lambda | S_{kk} = s_{kk}, S_{jj} = s_{jj}) \\ &= 2P(T_{n-2} \geq \lambda (s_{kk}s_{jj} - \lambda^2)^{-\frac{1}{2}}(n-2)^{\frac{1}{2}} | S_{kk} = s_{kk}, S_{jj} = s_{jj}) \\ &\leq 2\tilde{F}_{n-2}(\lambda(\hat{\sigma}_k^2\hat{\sigma}_j^2 - \lambda^2)^{-\frac{1}{2}}(n-2)^{\frac{1}{2}}) \end{aligned} \tag{22}$$

where $\hat{\sigma}_k^2$ is the sample variance of variable k, and $\tilde{F}_{n-2} = 1 - F_{n-2}$ is the CDF of the Student's t-distribution with $n-2$ degree of freedom. This implies that, for all $j \in N \backslash C_k$,

$$P(|S_{kj}| \geq \lambda) \leq 2\tilde{F}_{n-2}(\lambda(\hat{\sigma}_k^2\hat{\sigma}_j^2 - \lambda^2)^{-\frac{1}{2}}(n-2)^{\frac{1}{2}})$$

since $P(A) = \int P(A|B)P(B)dB \leq K \int P(B)dB = K$. Putting the inequalities together, we have that:

$$\begin{aligned} &P(\exists k : \hat{C}_k^\lambda \not\subseteq C_k) \\ &\leq p^2 \cdot \max_{k, j \in N \backslash C_k} 2\tilde{F}_{n-2}(\lambda(\hat{\sigma}_k^2\hat{\sigma}_j^2 - \lambda^2)^{-\frac{1}{2}}(n-2)^{\frac{1}{2}}) \\ &= 2p^2\tilde{F}_{n-2}(\lambda((n-2)/((\max_{i>j}\hat{\sigma}_k\hat{\sigma}_j)^2 - \lambda^2))^{\frac{1}{2}}). \end{aligned}$$

For any fixed α, our required condition on λ is therefore

$$\tilde{F}_{n-2}(\lambda((n-2)/((\max_{i>j}\hat{\sigma}_k\hat{\sigma}_j)^2 - \lambda^2))^{\frac{1}{2}}) = \alpha/2p^2$$

which is satisfied by choosing λ according to (3). ■

B.3 Proof of Bound for Binary Data

We can reuse much of the previous proof to derive a corresponding formula for the binary case.

Proof of Theorem 7:

The proof of Theorem 7 is identical to the proof of Theorem 2, except that we have a different null distribution for $|S_{kj}|$. The null distribution of

$$nR_{kj}^2$$

is chi-squared with one degree of freedom. Analogous to (22), we have:

$$\begin{aligned} &P(|S_{kj}| \geq \lambda | S_{kk} = s_{kk}, S_{jj} = s_{jj}) \\ &= 2P(nR_{kj}^2 \geq n\lambda^2 s_{kk}s_{jj} | S_{kk} = s_{kk}, S_{jj} = s_{jj}) \\ &\leq 2\tilde{G}(n\lambda^2\hat{\sigma}_k^2\hat{\sigma}_j^2) \end{aligned}$$

where $\hat{\sigma}_k^2$ is the sample variance of variable k, and $\tilde{G} = 1 - G$ is the CDF of the chi-squared distribution with one degree of freedom. This implies that, for all $j \in N \backslash C_k$,

$$P(|S_{kj}| \geq \lambda) \leq 2\tilde{G}((\lambda\hat{\sigma}_k\hat{\sigma}_j\sqrt{n})^2).$$

Putting the inequalities together, we have that:

$$\begin{aligned} &P(\exists k : \hat{C}_k^{\lambda} \not\subseteq C_k) \\ &\leq p^2 \cdot \max_{k,j \in N \setminus C_k} 2\tilde{G}((\lambda \hat{\sigma}_k \hat{\sigma}_j \sqrt{n})^2) \\ &= 2p^2 \tilde{G}((\min_{i>j} \hat{\sigma}_k \hat{\sigma}_j)^2 n\lambda^2) \end{aligned}$$

so that, for any fixed α, we can achieve our desired bound by choosing $\lambda(\alpha)$ according to (17). ■

Appendix C. Proof of Connection Between Gaussian SML and Binary ASML

We end with a proof of Theorem 6, which connects the exact Gaussian sparse maximum likelihood problem with the approximate sparse maximum likelihood problem obtained by using the log determinant relaxation of Wainwright and Jordan (2006). First we must prove Lemma 5.

Proof of Lemma 5:

The conjugate function for the convex normalization $A(\theta)$ is defined as

$$A^*(\mu) := \sup_{\theta} \{\langle \mu, \theta \rangle - A(\theta)\}. \tag{23}$$

Wainwright and Jordan derive a lower bound on this conjugate function using an entropy bound:

$$A^*(\mu) \geq B^*(\mu). \tag{24}$$

Since our original variables are spin variables $x \{-1, +1\}$, the bound given in the paper is

$$B^*(\mu) := -\frac{1}{2} \log \det(R(\mu) + \mathrm{diag}(m)) - \frac{p}{2} \log(\frac{e\pi}{2}) \tag{25}$$

where $m := (1, \frac{4}{3}, \ldots, \frac{4}{3})$.

The dual of this lower bound is $B(\theta)$:

$$B^*(\mu) := \max_{\theta} \langle \theta, \mu \rangle - B(\theta) \leq \max_{\theta} \langle \theta, \mu \rangle - A(\theta) =: A^*(\mu). \tag{26}$$

This means that, for all μ, θ,

$$\langle \theta, \mu \rangle - B(\theta) \leq A^*(\mu) \tag{27}$$

or

$$B(\theta) \geq \langle \theta, \mu \rangle - A^*(\mu) \tag{28}$$

so that in particular

$$B(\theta) \geq \max_{\mu} \langle \theta, \mu \rangle - A^*(\mu) =: A(\theta) \tag{29}$$

Using the definition of $B(\theta)$ and its dual $B^*(\mu)$, we can write

$$\begin{aligned}
&B(\theta) := \max_\mu \langle \theta, \mu\rangle - B^*(\mu)\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) + \max_\mu \tfrac{1}{2}\langle R(\theta), R(\mu)\rangle + \tfrac{1}{2}\log\det(R(\mu)+\mathrm{diag}(m))\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) + \tfrac{1}{2}\cdot\max\{\langle R(\theta), X-\mathrm{diag}(m)\rangle + \log\det(X) : X \succ 0, \mathrm{diag}(X) = m\}\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) + \tfrac{1}{2}\cdot\{\max_{X\succ 0}\min_\nu \langle R(\theta), X-\mathrm{diag}(m)\rangle + \log\det(X) + \nu^T(\mathrm{diag}(X)-m)\}\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) + \tfrac{1}{2}\cdot\{\max_{X\succ 0}\min_\nu \langle R(\theta)+\mathrm{diag}(\nu), X\rangle + \log\det(X) - \nu^T m\}\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) + \tfrac{1}{2}\cdot\{\min_\nu -\nu^T m + \max_{X\succ 0}\langle R(\theta)+\mathrm{diag}(\nu), X\rangle + \log\det(X)\}\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) + \tfrac{1}{2}\cdot\{\min_\nu -\nu^T m - \log\det(-(R(\theta)+\mathrm{diag}(\nu))) - (p+1)\}\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) - \tfrac{1}{2}(p+1) + \tfrac{1}{2}\cdot\{\min_\nu -\nu^T m - \log\det(-(R(\theta)+\mathrm{diag}(\nu)))\}\\
&= \tfrac{p}{2}\log(\tfrac{e\pi}{2}) - \tfrac{1}{2}(p+1) - \tfrac{1}{2}\cdot\{\max_\nu \nu^T m + \log\det(-(R(\theta)+\mathrm{diag}(\nu\lambda)\}.
\end{aligned} \tag{30}$$

■

Now we use Lemma 5 to prove the main result of Section 5.1. Having expressed the upper bound on the log partition function as a constant minus a maximization problem will help when we formulate the sparse approximate maximum likelihood problem.

Proof of Theorem 6:

The approximate sparse maximum likelihood problem is obtained by replacing the log partition function $A(\theta)$ with its upper bound $B(\theta)$, as derived in Lemma 5:

$$\begin{aligned}
&n\cdot\{\max_\theta \tfrac{1}{2}\langle R(\theta), R(\overline{z})\rangle - B(\theta) - \lambda\|\theta\|_1\}\\
&= n\cdot\{\max_\theta \tfrac{1}{2}\langle R(\theta), R(\overline{z})\rangle - \lambda\|\theta\|_1 + \tfrac{1}{2}(p+1) - \tfrac{p}{2}\log(\tfrac{e\pi}{2})\\
&+\tfrac{1}{2}\cdot\{\max_\nu \nu^T m + \log\det(-(R(\theta)+\mathrm{diag}(\nu)))\}\}\\
&= \tfrac{n}{2}(p+1) - \tfrac{np}{2}\log(\tfrac{e\pi}{2}) + \tfrac{n}{2}\cdot\max_{\theta,\nu}\{\nu^T m + \langle R(\theta), R(\overline{z})\rangle\\
&+\log\det(-(R(\theta)+\mathrm{diag}(\nu))) - 2\lambda\|\theta\|_1\}.
\end{aligned} \tag{31}$$

We can collect the variables θ and ν into an unconstrained symmetric matrix variable $Y := -(R(\theta)+\mathrm{diag}(\nu))$.

Observe that

$$\begin{aligned}
\langle R(\theta), R(\overline{z})\rangle &= \langle -Y - \mathrm{diag}(\nu), R(\overline{z})\rangle\\
&= -\langle Y, R(\overline{z})\rangle - \langle \mathrm{diag}(\nu), R(\overline{z})\rangle = -\langle Y, R(\overline{z})\rangle
\end{aligned} \tag{32}$$

and that

$$\begin{aligned}
\nu^T m &= \langle \mathrm{diag}(\nu), \mathrm{diag}(\nu)\rangle = \langle -Y - R(\theta), \mathrm{diag}(m)\rangle\\
&= -\langle Y, \mathrm{diag}(m)\rangle - \langle R(\theta), \mathrm{diag}(m)\rangle = -\langle Y, \mathrm{diag}(m)\rangle.
\end{aligned} \tag{33}$$

The approximate sparse maximum likelihood problem can then be written in terms of Y:

$$\begin{aligned}
&\tfrac{n}{2}(p+1) - \tfrac{np}{2}\log(\tfrac{e\pi}{2}) + \tfrac{n}{2}\cdot\max_{\theta,\nu}\{\nu^T m + \langle R(\theta), R(\overline{z})\rangle\\
&+\log\det(-(R(\theta)+\mathrm{diag}(m))) - 2\lambda\|\theta\|_1\}\\
&= \tfrac{n}{2}(p+1) - \tfrac{np}{2}\log(\tfrac{e\pi}{2}) + \tfrac{n}{2}\cdot\max\{\log\det Y - \langle Y, R(\overline{z})+\mathrm{diag}(m)\rangle\\
&-2\lambda\textstyle\sum_{i=2}^{p}\sum_{j=i+1}^{p+1}|Y_{ij}|\}.
\end{aligned} \tag{34}$$

If we let $M := R(\overline{z}) + \mathrm{diag}(m)$, then:

$$M = \begin{pmatrix} 1 & \overline{\mu}^T \\ \overline{\mu} & Z + \frac{1}{3}I \end{pmatrix}$$

where $\bar{\mu}$ is the sample mean and

$$Z = \frac{1}{n}\sum_{k=1}^{n} z^{(k)}(z^{(k)})^T.$$

Due to the added $\frac{1}{3}I$ term, we have that $M \succ 0$ for any data set.

The problem can now be written as:

$$\hat{Y} := \arg\max\{\log\det Y - \langle Y, M\rangle - 2\lambda \sum_{i=2}^{p}\sum_{j=i+1}^{p+1} |Y_{ij}| : Y \succ 0\}. \tag{35}$$

Since we are only penalizing certain elements of the variable Y, the solution $\hat{X}$ of the dual problem to (35) will be of the form:

$$\hat{X} = \begin{pmatrix} 1 & \bar{\mu}^T \\ \bar{\mu} & \tilde{X} \end{pmatrix}$$

where

$$\tilde{X} := \arg\max\{\log\det V : V_{kk} = Z_{kk} + \frac{1}{3},\ |V_{kj} - Z_{kj}| \leq \lambda\}.$$

We can write an equivalent problem for estimating the covariance matrix. Define a new variable:

$$\Gamma = V - \bar{\mu}\bar{\mu}^T.$$

Using this variable, and the fact that the second moment matrix about the mean, defined as before, can be written

$$S = \frac{1}{n}\sum_{k=1}^{n} z^{(k)}(z^{(k)})^T - \bar{\mu}\bar{\mu}^T = Z - \bar{\mu}\bar{\mu}^T$$

we obtain the formulation (16). Using Schur complements, we see that our primal variable is of the form:

$$Y = \begin{pmatrix} * & * \\ * & \hat{\Gamma}^{-1} \end{pmatrix}.$$

From our definition of the variable Y, we see that the parameters we are estimating, $\hat{\theta}_{kj}$, are the negatives of the off-diagonal elements of $\hat{\Gamma}^{-1}$, which gives us (15). ■

Comments on the Complete Characterization of a Family of Solutions to a Generalized *Fisher* Criterion

Jieping Ye JIEPING.YE@ASU.EDU
Department of Computer Science and Engineering
Arizona State University
Tempe, AZ 85287, USA

Editor: Xiaotong Shen

Abstract

Loog (2007) provided a complete characterization of the family of solutions to a generalized *Fisher* criterion. We show that this characterization is essentially equivalent to the original characterization proposed in Ye (2005). The computational advantage of the original characterization over the new one is discussed, which justifies its practical use.

Keywords: linear discriminant analysis, dimension reduction, linear transformation

1. Generalized Fisher Criterion

For a given data set consisting of n data points $\{a_i\}_{i=1}^n$ in $\mathbb{R}^d$, a linear transformation $G \in \mathbb{R}^{d\times\ell}$ ($\ell < d$) maps each a_i for $1 \le i \le n$ in the d-dimensional space to a vector $\tilde{a}_i$ in the ℓ-dimensional space as follows:

$$G : a_i \in \mathbb{R}^d \to \tilde{a}_i = G^T a_i \in \mathbb{R}^\ell.$$

Assume that there are k classes in the data set. The within-class scatter matrix S_w, the between-class scatter matrix S_b, and the total scatter matrix S_t involved in linear discriminant analysis are defined as follows (Fukunaga, 1990):

$$\begin{aligned} S_w &= \sum_{i=1}^k (A_i - c_i e^T)(A_i - c_i e^T)^T, \\ S_b &= \sum_{i=1}^k n_i (c_i - c)(c_i - c)^T, \\ S_t &= \sum_{i=1}^k (A_i - ce^T)(A_i - ce^T)^T, \end{aligned}$$

where A_i denotes the data matrix of the i-th class, $c_i = A_i e/n_i$ is the centroid of the i-th class, n_i is the sample size of the i-th class, $c = Ae/n$ is the global centroid, and e is the vector of all ones with an appropriate length. It is easy to verify that $S_t = S_b + S_w$.

In Ye (2005), the optimal transformation G is computed by maximizing a generalized *Fisher* criterion as follows:

$$G = \arg\max_{G\in\mathbb{R}^{m\times\ell}} \operatorname{trace}\left(\left(G^T S_t G\right)^+ G^T S_b G\right), \tag{1}$$

where M^+ denotes the pseudo-inverse (Golub and Van Loan, 1996) of M and it is introduced to overcome the singularity problem when dealing with high-dimensional low-sample-size data.

1.1 Equivalent Transformation

Two linear transformations G_1 and G_2 can be considered equivalent if there is a vector v such that $G_1^T(a_i - v) = G_2^T(a_i - v)$, for $i = 1, \cdots, n$. Indeed, in this case, the difference between the projections by G_1 and G_2 is a mere shift.

Definition 1.1 *For a given data set $\{a_1, \cdots, a_n\}$, two transformations G_1 and G_2 are equivalent, if there is a vector v such that*

$$G_1^T(a_i - v) = G_2^T(a_i - v), \text{ for } i = 1, \cdots, n.$$

2. Characterization of Solutions to the Generalized *Fisher* Criterion

Let $S_t = U\Sigma U^T$ be the orthogonal eigendecomposition of S_t (note that S_t is symmetric and positive semi-definite), where $U \in \mathbb{R}^{d\times d}$ is orthogonal and $\Sigma \in \mathbb{R}^{d\times d}$ is diagonal with nonnegative diagonal entries sorted in nonincreasing order. Denote Σ_r as the r-th principal submatrix of Σ, where $r = \text{rank}(S_t)$. Partition U into two components as $U = [U_1, U_2]$, where $U_1 \in \mathbb{R}^{d\times r}$ and $U_2 \in \mathbb{R}^{d\times(d-r)}$. Note that $r \leq n$, and for high-dimensional low-sample-size data, U_1 is much smaller than U_2.

In Loog (2007), a complete family of solutions $\mathcal{S}$ to the maximization problem in Eq. (1) is given as (We correct the error in Loog (2007) by using U instead of U^T.)

$$\mathcal{S} = \left\{ U \begin{pmatrix} \Lambda Z \\ Y \end{pmatrix} \in \mathbb{R}^{d\times\ell} \;\middle|\; Z \in \mathbb{R}^{\ell\times\ell} \text{ is nonsingular }, \; Y \in \mathbb{R}^{(n-r)\times\ell} \right\},$$

where $\Lambda \in \mathbb{R}^{r\times\ell}$ maximizes the following objective function:

$$F_0(X) = \text{trace}\left(\left(X^T\Sigma_r X\right)^{-1} X^T (U_1^T S_b U_1) X \right).$$

In Ye (2005), a family of solutions $\tilde{\mathcal{S}}$ is given as

$$\tilde{\mathcal{S}} = \left\{ U \begin{pmatrix} \Lambda Z \\ 0 \end{pmatrix} \in \mathbb{R}^{d\times\ell} \;\middle|\; Z \in \mathbb{R}^{\ell\times\ell} \text{ is nonsingular } \right\}.$$

The only difference between these two characterizations of solutions is the matrix Y in $\mathcal{S}$, which is replaced by the zero matrix in $\tilde{\mathcal{S}}$. We show in the next section the equivalence relationship between these two characterizations.

3. Equivalent Solution Characterizations

Consider the following two transformations G_1 and G_2 from $\mathcal{S}$ and $\tilde{\mathcal{S}}$ respectively:

$$G_1 = U \begin{pmatrix} \Lambda Z \\ Y \end{pmatrix} \in \mathcal{S}, \quad G_2 = U \begin{pmatrix} \Lambda Z \\ 0 \end{pmatrix} \in \tilde{\mathcal{S}}.$$

Recall that $U = [U_1, U_2]$, where the columns of U_2 span the null space of S_t. Hence,

$$0 = U_2^T S_t U_2 = \sum_{i=1}^{n} U_2^T (a_i - c) \cdot (U_2^T (a_i - c))^T,$$

and $U_2^T (a_i - c) = 0$, for $i = 1, \cdots, n$, where c is the global centroid. It follows that

$$G_1^T (a_i - c) = Z^T \Lambda^T U_1^T (a_i - c) + Y^T U_2^T (a_i - c) = Z^T \Lambda^T U_1^T (a_i - c) = G_2^T (a_i - c),$$

for $i = 1, \cdots, n$. That is, G_1 and G_2 are equivalent transformations. Hence, the two solution characterizations $\mathcal{S}$ and $\tilde{\mathcal{S}}$ are essentially equivalent.

Remark 3.1 *The analysis above shows that the additional information contained in $\mathcal{S}$ is the null space, U_2, of S_t, which leads to an equivalent transformation. In $\tilde{\mathcal{S}}$, the null space U_2 is removed, which can be further justified as follows. Since $S_t = S_b + S_w$, we have*

$$0 = U_2^T S_t U_2 = U_2^T S_b U_2 + U_2^T S_w U_2.$$

It follows that $U_2^T S_b U_2 = 0$, as both S_b and S_w are positive semi-definite. Thus, the null space U_2 does not contain any discriminant information. This explains why the null space of S_t is removed in most discriminant analysis based algorithms proposed in the past.

4. Efficiency Comparison

In $\mathcal{S}$, the full matrix U is involved, whose computation may be expensive, especially for high-dimensional data. In contrast, only the first component $U_1 \in \mathbb{R}^{d \times r}$ of U is involved in $\tilde{\mathcal{S}}$, which can be computed efficiently for high-dimensional low-sample-size problem by directly working on the Gram matrix instead of the covariance matrix.

In summary, we show that $\mathcal{S}$ and $\tilde{\mathcal{S}}$ are equivalent characterizations of the solutions to the generalized *Fisher* criterion in Eq. (1). However, the latter one is preferred in practice due to its relative efficiency for high-dimensional low-sample-size data.

Abstract

Support vector machine (SVM) is one of the most popular and promising classification algorithms. After a classification rule is constructed via the SVM, it is essential to evaluate its prediction accuracy. In this paper, we develop procedures for obtaining both point and interval estimators for the prediction error. Under mild regularity conditions, we derive the consistency and asymptotic normality of the prediction error estimators for SVM with finite-dimensional kernels. A perturbation-resampling procedure is proposed to obtain interval estimates for the prediction error in practice. With numerical studies on simulated data and a benchmark repository, we recommend the use of interval estimates centered at the cross-validated point estimates for the prediction error. Further applications of the proposed procedure in model evaluation and feature selection are illustrated with two examples.

Keywords: *k*-fold cross-validation, model evaluation, perturbation-resampling, prediction errors, support vector machine

1. Introduction

As a state-of-the-art machine learning algorithm in classifying high-dimensional data, support vector machines (SVMs) developed by Vapnik and his colleagues (1995, 1998) have gained popularity due to many attractive features. The SVM has been used frequently in practice for developing prediction rules. After a prediction rule is constructed, the common practice is to provide a point estimate of the corresponding accuracy without accounting for the sampling variability in the estimated accuracy of the prediction rule. However, to ensure the reproducibility of the reported results, it is crucial to account for such sampling variability and provide interval estimates for the accuracy measures, especially when the sample size is not large relative to the number of unknown model parameters.

Various methods have been available to estimate the prediction error of classifiers based on the cross-validation and bootstrap methods (Efron, 1986; Efron and Tibshirani, 1997; Fu et al., 2005; Molinaro et al., 2005; Shao, 1996; Varma and Simon, 2006). When the sample size is not

sufficiently large, point estimates may be inadequate for choosing the classifier with optimized parameters or features (Reunanen, 2003; Varma and Simon, 2006). For example, in Table 1, we summarize the accuracies of SVM classifiers with different kernels based on on two artificial data sets that are generated as in Section 4.3. It appears that the polynomial kernel outperforms the linear kernel for both data sets with higher accuracy. However, it is unclear whether the difference in the higher accuracy is due to randomness. Due to its high generalization ability, the linear kernel may be preferred unless it results in significantly lower accuracy. As such, the point estimates of the accuracy measures may not provide sufficient evidence for determining which type of kernel should be used.

To adequately assess the accuracy and draw valid conclusions, it is important to account for the sampling variability in the estimated prediction error. Some studies have suggested performing hypothesis testing by considering the variability in the cross-validated estimator (Dietterich, 1998). Bengio and Grandvalet (2004) and Nadeau and Bengio (2003) pointed out that there exists no universally unbiased estimator of the variance of K-fold cross-validated estimator that is based only on the results of the cross-validation experiments. Therefore, the estimation of uncertainty around the prediction error estimators remains a theoretical, as well as practical problem.

Data Type	Sample Size	Linear Kernel Accuracy	Polynomial Kernel Accuracy
1	100	94%	95%
2	100	92%	96%

Table 1: Kernel selection in SVM classifiers based on the cross-validation point estimates for the prediction error.

To assess the predictive performance of SVM derived from data with finite sample size, probabilistic bounds such as VC-based bounds (Vapnik, 1998) and stability-based bounds (Kearns and Ron, 1999; Bousquet and Elisseeff, 2002) have been proposed. However, those theoretical bounds are too conservative to give an accurate estimation. In particular, they do not account for the sampling variability inherent in different types of data. In statistical literature, the bootstrap resampling procedure (Efron, 1979) and its variants (Efron, 1987; Wu, 1986; Liu, 1988; Hall and Mammen, 1994) provide a general framework for ascertaining variances and constructing confidence intervals, but limited effort has been made to study the distributional properties of the estimated prediction error (Efron and Tibshirani, 1995, Section 5).

In this article, we develop procedures to approximate the distribution of the estimated accuracy measures for SVM classifiers and construct confidence intervals for the accuracy measures. The proposed method, which may be linked to the weighted bootstrap resampling (Hall and Mammen, 1994; Hall and Maesono, 2000) and the Bayesian bootstrap method (Rubin, 1981), directly builds on the perturbation-resampling procedure considered in Park and Wei (2003) and Cai et al. (2005). The accuracy measure we consider is the expected absolute difference between the true and predicted responses for future subjects. For SVMs with finite-dimensional kernels, we show that the accuracy measure can be consistently estimated via cross-validation procedures, and the resulting estimators are asymptotically normal. A practical perturbation-resampling procedure is proposed to approximate the sampling distribution of the prediction error. This inference procedure is valid

without having to specify the true association between the response and the predictors. This is particularly appealing when it is difficult, if not impossible, to identify the *true* model under which the data are generated. Numerical studies based on simulated data and a benchmark repository suggest that both the variance estimator and the interval estimator centered at the cross-validated point estimator perform well. The proposed procedure is further illustrated with applications in kernel selection and in the genotypic testing for drug resistance.

2. Estimating the Prediction Error of SVM Classifiers

In this section, we provide a brief review on the construction of SVM classifiers and introduce point estimators of the accuracy measure used for evaluating the performance of SVM classifiers.

2.1 Basic Notations and Construction of SVM Classifiers

The SVM classifier is derived based on the hinge loss function:

$$L(Y, f(\mathbf{X})) = [1 - Y f(\mathbf{X})]_+ = \begin{cases} 0 & , \quad Y f(\mathbf{X}) > 1 \\ 1 - Y f(\mathbf{X}) & , \quad Y f(\mathbf{X}) \le 1 \end{cases},$$

where $\mathbf{X}$ is the input vector and $Y \in \{-1, 1\}$ is the output label, and $f(\mathbf{X})$ is the prediction function. Here, we first consider the case when $f(\mathbf{X})$ is a linear function, $f(\mathbf{X};\theta) = \mathbf{w}'\mathbf{X} + b$ (we use $\mathbf{V}'$ to denote the transpose of the vector $\mathbf{V}$ hereafter), where $\theta = (\mathbf{w}', b)'$ is the adjustable parameter. Based on $f(\cdot)$, we predict Y by the decision function $\hat{Y}(\mathbf{X},\theta) = \text{sign}\{f(\mathbf{X};\theta)\}$, where $\text{sign}(\cdot)$ denotes the sign of the function value.

To construct an optimal prediction rule, one may consider the prediction function $f(\mathbf{X};\theta)$ that minimizes the SVM risk function

$$Q(\theta) = E\{[1 - Y f(\mathbf{X};\theta)]_+\}.$$

To approximate the expected risk function $Q(\theta)$, one may consider its penalized empirical counterpart,

$$\hat{Q}_n(\theta) = \frac{1}{n}\sum_{i=1}^{n}[1 - Y_i f(\mathbf{X}_i;\theta)]_+ + \lambda_n \mathbf{w}'\mathbf{w}, \tag{1}$$

and obtain $\hat{\theta} = \text{argmin}_\theta \hat{Q}_n(\theta)$, where $\{(\mathbf{X}_i, Y_i); i = 1, \ldots, n\}$ are n independent realizations of $(\mathbf{X}, Y)$, and λ_n is the regularization parameter that controls the amount of penalty. Subsequently, the prediction of Y may be made based on $f(\mathbf{X};\hat{\theta})$.

In practice, the minimizer $\hat{\theta}$ may be ascertained through quadratic programming techniques since the minimization of $\hat{Q}_n(\theta)$ is equivalent to the minimization of

$$\min_\alpha \{\sum_{i=1}^{n}\alpha_i - \frac{1}{2}\sum_{i,j=1}^{n}\alpha_i Y_i (\mathbf{X}_i'\mathbf{X}_j) Y_j \alpha_j\}, \tag{2}$$

with linear constraints $0 \le \alpha_i \le C, i = 1, \ldots, n$ and $\sum_{i=1}^{n}\alpha_i Y_i = 0$, where $C = 1/(2\lambda_n n)$. Here, the constraint parameter $C = C(n)$ depends on the sample size n and typically satisfies $nC(n) \to \infty$, or equivalently $\lambda_n \to 0$, under which requirement SVM classifiers are universally consistent (Steinwart, 2002).

Note that the only way in which the input vectors appear in the minimizing problem (2) is in the form of inner products, $\mathbf{X}_i'\mathbf{X}_j$. If the input vectors are mapped to a so called "feature space" $\mathcal{H}$ via a mapping denoted by Φ, then the minimizing algorithm would only depend on the data through inner products in $\mathcal{H}$, that is, functions of the form $\Phi(\mathbf{X}_i)'\Phi(\mathbf{X}_j)$. Hence, if there is a *kernel function* $K(\cdot,\cdot)$ such that $K(\mathbf{X}_i,\mathbf{X}_j)=\Phi(\mathbf{X}_i)'\Phi(\mathbf{X}_j)$, one may carry out the minimization based on kernel function $K(\cdot,\cdot)$ only. For the simplest case when $K(\mathbf{X}_i,\mathbf{X}_j)=\mathbf{X}_i'\mathbf{X}_j$, we will refer to function $K(\cdot,\cdot)$ as the *linear kernel*. Other examples include the *polynomial kernel* $K(\mathbf{X}_i,\mathbf{X}_j)=(\gamma\mathbf{X}_i'\mathbf{X}_j+b)^d$, and the *RBF kernel* $K(\mathbf{X}_i,\mathbf{X}_j)=\exp\{-\|\mathbf{X}_i-\mathbf{X}_j\|^2/2\sigma^2\}$, with specified hyper-parameters γ, b, d and σ.

2.2 Point Estimators for the Prediction Error

To evaluate how well the trained SVM performs on a future, independent subject $(\mathbf{X}_0,Y_0)$ from the same population of $(\mathbf{X},Y)$, we consider the absolute prediction error D_0:

$$D_0 = E\left|Y_0-\hat{Y}(\mathbf{X}_0,\hat{\theta})\right|, \tag{3}$$

where $\hat{\theta}$ is the solution to minimizing function (1), and $\hat{Y}(\mathbf{X},\theta)$ is the decision function introduced in Section 2.1. Note that $\hat{\theta}$ is a function of random variables $\{(\mathbf{X}_i,Y_i);i=1,\ldots,n\}$, and the expectation E in (3) is with respect to $\{(\mathbf{X}_i,Y_i);i=1,\ldots,n\}$ and $(\mathbf{X}_0,Y_0)$. Thus, D_0 depends on sample size n and is sometimes referred to as the generalization error (see Nadeau and Bengio, 2003). To estimate D_0, we first consider the training error, which is also called apparent or re-substitution error in statistical literature, $\hat{D}=\hat{D}(\hat{\theta})$, where

$$\hat{D}(\theta) = n^{-1}\sum_{i=1}^{n}\left|Y_i-\hat{Y}(\mathbf{X}_i,\theta)\right|. \tag{4}$$

When the sample size n is small or moderate relative to the dimension of parameter θ, training error $\hat{D}(\hat{\theta})$ tends to be biased downward as an estimate of D_0. One remedy to reduce such a bias is to use the cross-validation procedure. Here we consider the commonly used K-fold cross-validation. Specifically, we randomly split the data into K disjoint subsets of about equal size and label them as $I_k, k=1,\ldots,K$. For each k, we use all observations which are not in I_k to obtain an estimate $\hat{\theta}_{(-k)}$ for θ via (1), and then compute the prediction error estimate $\hat{D}_{(k)}(\theta)$ via (4) based on observations in I_k. Then, the cross-validated prediction error estimator for D_0 is

$$\hat{\mathcal{D}} = K^{-1}\sum_{k=1}^{K}\hat{D}_{(k)}(\hat{\theta}_{(-k)}). \tag{5}$$

We show in the next section that the cross-validation estimator $\hat{\mathcal{D}}$ is consistent for estimating the prediction error of SVM classifiers under certain conditions. However, as we have mentioned above, point estimates are not adequate in drawing valid conclusions, and we need to further study the distributional properties of the estimated prediction error.

3. Interval Estimators for the Prediction Error

In this section, we provide large sample properties of the estimated prediction error. In particular, we discuss the consistency and asymptotic normality of the estimators. Based on these theoretical results, we present a simple perturbation-resampling procedure to obtain interval estimates for the prediction error. In addition, we provide inference procedures for comparing two competing models.

3.1 Large Sample Properties of Point Estimators

Suppose that the parameter θ belongs to a compact set Θ, and both the expectation $E(\mathbf{X})$ and the covariance matrix var$(\mathbf{X})$ of the input vector $\mathbf{X}$ are finite. To derive the asymptotic properties for $\hat{D}$, we first need to establish that $\hat{\theta}$ "stabilizes" as n increases, that is, $\hat{\theta}$ converges to a constant vector in probability, as $n \to \infty$. In **Theorem 1** of Appendix A, we show that under some regularity conditions, the limiting objective function $Q(\theta)$ is strictly convex with a unique minimizer θ_0, and thus for large n, there exists a unique minimizer, $\hat{\theta}$, of $\hat{Q}_n(\theta)$. Furthermore, as $n \to \infty$, $\hat{\theta} \to \theta_0$ and $\hat{D}(\hat{\theta}) \to D_0$ in probability.

To further study the large sample property of $\hat{D}$, we explore the distribution of

$$W = n^{1/2}\{\hat{D}(\hat{\theta}) - D_0\} \, . \tag{6}$$

Note that although $\hat{D}(\theta)$ is not differentiable with respect to θ, $E[\hat{D}(\theta)]$ is continuously differentiable at θ_0. In **Theorem 2** of Appendix B, we show that W is asymptotically equivalent to $n^{-1/2}\sum_{i=1}^{n}\eta_i$, and converges in distribution to a zero mean normal with variance $E(\eta_i^2)$, where η_i is defined in (14) of Appendix B. The variance of W can be approximated by

$$n^{-1}\sum_{i=1}^{n}\hat{\eta}_i^2 \, , \tag{7}$$

where $\hat{\eta}_i$ is obtained by replacing all the theoretical quantities in η_i by their empirical counterparts.

It is commonly known that the training error $\hat{D}$ is biased downward as an estimate of D_0 and hence should not be used without correction. To reduce such a bias, we consider the K-fold cross-validated estimator given in (5), where K is fixed and relatively small with respect to n. Using similar arguments as for the convergence of $\hat{D}(\hat{\theta})$, one may show that $\hat{\mathcal{D}}$ converges to D_0 in probability. Furthermore, we show in **Theorem 3** of Appendix C that

$$\mathcal{W} = n^{1/2}\{\hat{\mathcal{D}} - D_0\} \tag{8}$$

is asymptotically equivalent to W in (6) and thus $\mathcal{W}$ also converges in distribution to a zero mean normal with variance $E(\eta_i^2)$. This implies that the cross-validated estimator $\hat{\mathcal{D}}$, while potentially has less bias compared to the training error $\hat{D}$, is expected to have the same magnitude of variability as that of $\hat{D}$. Thus, we recommend to construct confidence intervals for D_0 by centering at $\hat{\mathcal{D}}$ with width determined by the variability in W. Although the proposed procedure is derived through large sample approximations, the results of numerical studies given below indicate that the distributions of W and $\mathcal{W}$ are reasonably close in finite samples.

3.2 Perturbation-Resampling Procedure for Estimating the Confidence Interval

Estimating the variance of $\mathcal{W}$ based on (7) may be difficult in practice with high-dimensional θ since it requires the estimation of the gradient of an unknown non-parametric function. To overcome such difficulties, we propose a computationally efficient perturbation-resampling procedure to approximate the distribution of $\mathcal{W}$. To be specific, let $\{G_i; i = 1, \ldots, n\}$ be a vector of independent and identically distributed *positive* random variables with unit mean and unit variance that are generated independent of the data. In practice, one may generate $\{G_i; i = 1, \ldots, n\}$ from an exponential

distribution. For any given set of $\{G_i; i = 1, \ldots, n\}$, we define

$$\hat{Q}_n^*(\theta) = \frac{1}{n}\sum_{i=1}^{n} G_i\{[1 - Y_i f(\mathbf{X}_i;\theta)]_+ + \lambda_n \mathbf{w}'\mathbf{w}\}\ , \tag{9}$$

and let θ^* be the minimizer of $\hat{Q}_n^*(\theta)$. Note that conditionally on the observed data, the only random quantities in $\hat{Q}_n^*(\theta)$ are the G's. Next, let

$$W^* = n^{-1/2}\sum_{i=1}^{n}\{|Y_i - \hat{Y}(\mathbf{X}_i, \theta^*)| - \hat{D}(\hat{\theta})\}G_i\ . \tag{10}$$

It follows from the arguments given in Appendix D that the distribution of $\mathcal{W}$ in (8) can be approximated well by the conditional distribution of W^* in (10) given the data $\{(\mathbf{X}_i, Y_i); i = 1, \ldots, n\}$. The random variables G_i used in (10) may be linked to the Bayesian bootstrap method (Rubin, 1981) with $G_i/(n^{-1}\sum_{i=1}^n G_i)$ being the weights instead.

To obtain θ^* numerically, one may solve the dual problem of (9),

$$\min_{\alpha}\{\sum_{i=1}^{n}\alpha_i - \frac{1}{2}\sum_{i,j=1}^{n}\alpha_i Y_i(\mathbf{X}_i'\mathbf{X}_j)Y_j\alpha_j\}\ , \tag{11}$$

under the constraints $\sum_{i=1}^n \alpha_i Y_i = 0$ and $0 \le \alpha_i \le CG_i$ for $i = 1, \ldots, n$. The solution of $\mathbf{w}$ is given by $\mathbf{w}^* = (\sum_{i=1}^n Y_i\alpha_i\mathbf{X}_i)/(n^{-1}\sum_{i=1}^n G_i)$. Note that the only difference between (2) and (11) is that there is a random multiplier on the upper bound of α_i in (11). For each generated set of $\{G_i; i = 1, \ldots, n\}$, we compute the corresponding W^* via (10). By repeatedly generating $\{G_i; i = 1, \ldots, n\}$, we may obtain a large number of realizations of W^* which may be used to approximate the distribution of $\mathcal{W}$ and construct confidence intervals for D_0. For example, a $100(1-\alpha)\%$ confidence interval for D_0 may be obtained as

$$[\hat{\mathcal{D}} - n^{-1/2}\hat{\xi}_{1-\alpha/2}, \hat{\mathcal{D}} - n^{-1/2}\hat{\xi}_{\alpha/2}],$$

where $\hat{\xi}_\alpha$ is the α^{th} percentile of W^*. The integrated procedure of perturbation-resampling is given in **Algorithm 1**, where N is the number of perturbations.

Algorithm 1 Perturbation-Resampling Procedure

1: Given data $\{(\mathbf{X}_i, Y_i); i = 1, \ldots, n\}$, a classifier is trained based on the SVM algorithm
2: Estimate the cross-validation error of the classifier by using (5)
3: **for** $r = 1 \to N$ **do**
4: Generate independent positive random variables $\{G_i; i = 1, \ldots, n\}$ from an exponential distribution with unit mean and unit variance
5: Solve the quadratic programming problem (11), and calculate W_r^* by using (10)
6: **end for**
7: Estimate the resampling distribution of W^* based on $\{W_r^*; r = 1, \ldots, N\}$, which approximates the distribution of W in (6), or asymptotically the distribution of $\mathcal{W}$ in (8)
8: Use the resampling distribution to estimate the confidence interval of the prediction error centered at the cross-validation error estimate
9: Statistical evaluation of different models can be further made based on the resampling distribution (see Section 3.3)

3.3 Comparing Models Based on Interval Estimates

Suppose there are two competing models, say, $f_j(\mathbf{X};\hat{\theta}_j), j = 1,2$, where the functions f_1 and f_2 could be different in the kernels or features used, and $\hat{\theta}_j$ is the solution via (1) with the function f_j and the data $\{(\mathbf{X}_i, Y_i); i = 1,\ldots,n\}$. The theoretical and empirical prediction errors D_{0j} and $\hat{D}_j(\theta_j)$ are defined by (3) and (4) accordingly, $j = 1,2$. We are interested in making inference about, for example, $\Delta = D_{02} - D_{01}$ to assess how much improvement Model 2 is over Model 1.

A consistent estimator for Δ is $\hat{\Delta} = \hat{D}_2(\hat{\theta}_2) - \hat{D}_1(\hat{\theta}_1)$. It follows from the argument presented in Section 3.1 that

$$W_\Delta = n^{1/2}\{\hat{\Delta} - \Delta\}$$

is asymptotically normal with mean zero. To approximate this normal distribution, one may use the perturbation-resampling technique discussed in Section 3.2. Specifically, let θ_j^* be the minimizer of $n^{-1}\sum_{i=1}^n G_i\{[1 - Y_i f_j(\mathbf{X}_i;\theta)]_+ + \lambda_n \mathbf{w}'\mathbf{w}\}$, $j = 1,2$. Also, let

$$W_j^* = n^{-1/2}\sum_{i=1}^n \{|Y_i - \hat{Y}_j(\mathbf{X}_i,\theta_j^*)| - \hat{D}_j(\hat{\theta}_j)\}G_i\ ,$$

where $\hat{Y}_j(\mathbf{X},\theta) = \text{sign}\{f_j(\mathbf{X};\theta)\}$. Then, the distribution of W_Δ can be approximated by the conditional distribution of $W_\Delta^* = W_2^* - W_1^*$. Confidence intervals for Δ can then be constructed.

Note that even if $\hat{\Delta}$ is a consistent estimator for the prediction gain Δ, it represents the fitting gain of using Model 2 and may lead to a wrong comparison between models with a large probability. By applying the cross-validation procedure, the overfitted model is likely to have a larger prediction error and one would choose the more parsimonious model. Thus, the K-fold cross-validated estimator $\hat{\mathcal{D}}_2 - \hat{\mathcal{D}}_1$, where $\hat{\mathcal{D}}_j$ is defined by (5) for Model $j, j = 1,2$, may be less biased than $\hat{\Delta}$ particularly in non-asymptotic situations. Let $\mathcal{W}_j$ be defined by (8) based on Model j. Again, the resampling distribution of $\mathcal{W}_2 - \mathcal{W}_1$ can be asymptotically approximated by W_Δ^*. Based on the results of our simulated experiments, this approximation performs quite well even with limited number of samples.

4. Numerical Studies and Examples

In this section, we examine the finite-sample performance of the proposed inference procedure via extensive numerical studies based on both simulated data and a benchmark repository. Furthermore, we illustrate the new procedure with examples in kernel and biomarker selections.

4.1 Simulation Studies

We first conduct simulation studies to examine how well the proposed inference procedure performs in finite samples. The data are generated as follows: (1) the response Y is generated from $\{-1,1\}$ with equal probabilities; (2) given Y, the input vector $\mathbf{X}$ are generated from d-dimensional multivariate normal with mean $\mathbf{1}_{d\times 1}I(Y=1) + (-\mathbf{1})_{d\times 1}I(Y=-1)$, where $\mathbf{1}_{d\times 1}$ is a d-dimensional vector of ones. We consider sample sizes $n = 50$ and 100, and dimensions $d = 10, 20$, and 30. For each configuration, we generate $1,000$ independent data sets. For each simulated data set, SVM classifiers are trained by using the LIBSVM program (Chang and Lin, 2001) with a linear kernel. For simplicity, we set the penalty parameter C equal to 1 here. We estimate the empirical absolute prediction

error via 5-fold cross-validation. The distribution of the empirical absolute prediction is obtained by using perturbation-resampling procedure with $1,000$ times of perturbations ($N = 1,000$ in **Algorithm 1**). Confidence interval with nominal level of 95% is then constructed based on empirical percentiles of the resampling distribution. To evaluate normal approximation and cross-validation procedures, we also construct confidence intervals based on normal assumption with both the estimated variance and the true variance calculated from the simulation parameters of the samples. For comparison, VC-based bounds (Vapnik, 1998) and stability-based bounds (Bousquet and Elisseeff, 2002) on the prediction error are also obtained with the same nominal level of 95%.

To evaluate these interval estimates, the true prediction errors of the trained SVM classifiers are calculated according to $10,000$ replications of simulated data sets for each setting. Confidence intervals are compared with the true prediction error, and their coverage accuracies are obtained by averaging on $1,000$ data sets. Coverage accuracy is defined as the frequency for true value to fall inside the estimated confidence interval, which measures the accuracy of interval estimates. In the ideal case, the coverage accuracy of an estimated interval should be equal or close to its level of confidence, and with its length as small as possible. In Table 2, we report the coverage accuracies and average lengths of 95% confidence intervals centered at 5-fold cross-validation errors for different procedures.

Sample Size	Dimension	Empirical Percentiles[1]		Normal Estimated[2]		Normal True[3]		VC Bound	Stability Bound
		CA	AL	CA	AL	CA	AL	CA	CA
50	10	94.7	0.20	93.9	0.19	94.8	0.20	100.0	100.0
	20	94.4	0.16	92.5	0.15	94.5	0.20	100.0	100.0
	30	93.8	0.12	90.4	0.14	94.2	0.17	100.0	100.0
100	10	95.1	0.15	94.8	0.14	95.2	0.16	100.0	100.0
	20	95.2	0.15	94.5	0.13	95.1	0.16	100.0	100.0
	30	94.6	0.12	93.2	0.12	95.1	0.15	100.0	100.0

Table 2: Coverage accuracies (CA) and average lengths (AL) of 95% confidence intervals obtained by using different procedures on simulated data.

As shown in Table 2, at sample size of $n = 100$, the empirical coverage levels for the 95% confidence intervals under normal approximation with the true variance range from 95.1% to 95.2%, which validates the accuracy of cross-validation and normal approximation. In practice, the true variance of the prediction error estimator is unknown and thus the perturbation-resampling procedure would be used to ascertain the variability of the estimator. From the results in Table 2, we can see that confidence intervals obtained by the empirical percentiles of the perturbed samples perform slightly better than those constructed via normal approximation with estimated variances, in a sense that intervals based on the empirical percentiles have larger coverage accuracies with comparable

1. Interval estimates are constructed by using empirical percentiles of the resampling distribution obtained by perturbation-resampling.
2. Interval estimates are constructed as $\hat{\mathcal{D}} \pm 1.96 n^{-1/2} \hat{\sigma}$ with $\hat{\sigma}^2$ being the conditional variance of W^* estimated by perturbation-resampling.
3. Interval estimates are constructed as $\hat{\mathcal{D}} \pm 1.96 n^{-1/2} \sigma$ with σ^2 calculated as the true variance of $\mathcal{W}$.

lengths. Although the proposed algorithm may fail when the dimension of the unknown parameters is equal to or larger than the sample size, the simulation results indicate that the procedure derived through large sample approximations performs well even when sample size is moderate relative to the dimension of the parameters. On the contrary, we note that confidence bounds based on VC dimension or stability are too conservative with relative small number of samples in this example. Since these bounds are proposed to provide general guides on the construction of classifiers, they may not be suitable to account for the sampling variability from a specific population.

4.2 Variance Estimation on Benchmark Repository

We further validate the ability of the proposed procedure in estimating the variance of the cross-validation estimator on the benchmark repository used in Mika et al. (1999) and Chang and Lin (2001). The benchmark repository consists of 10 artificial and real-world data sets from the UCI, DELVE and STATLOG benchmark repositories. These data sets are collected from a variety of research areas ranging from oncology and disease diagnosis to molecular biology, astronomy, banking and signal processing. Each data set is randomly divided into 100 partitions with equal size (50 partitions for the *flare-solar*, *image* and *titanic* data sets).

To evaluate the variance estimator obtained by the perturbation-resampling procedure, we estimate the standard deviation of 5-fold cross-validation error based *only* on the *first* partition of each data set. We also obtain the 5-fold cross-validation estimates of the SVM classifier on the rest 99 partitions, and the results are used to calculate the sample standard deviation of the cross-validation estimator, which is regarded as the true value. For comparison, we estimate the standard deviation based on two other methods proposed by Nadeau and Bengio (2003) using the first partition of each data set. The first approach is performed by randomly splitting data into two distinct sets (we name it "splitting" method here), and the second approach is based on the approximation of a so-called statistic ρ (we name it "ρ-based" method here). The description of the data sets, the standard deviations estimated by different methods, and their computational efficiencies are shown in Table 3. Computational time is tested on a PC with a Pentium 4 running at 2.8GHz and 512MB of RAM.

The results in Table 3 suggest that the perturbation-resampling based estimate of the standard deviation using *only* the first partition of each data set is rather close to the sample standard deviation estimated using the entire data set. To the contrary, the standard deviation estimated by splitting the data set tends to be biased upward, while the ρ-based method tends to underestimate the standard deviation of the cross-validation error. In the results shown above, $1,000$ times of randomly splitting or resampling are used in all the three methods, and as a result, the actual computational efficiencies of different methods are comparable. This study demonstrates that the proposed perturbation-resampling procedure can be an accurate and efficient way to estimate the variance of the cross-validation error.

4.3 Example in Kernel Selection

To illustrate the application of the proposed procedure in model comparison, we perform kernel selection for SVM classifiers on simulated data. Samples $\{(X_{1i}, X_{2i}); i = 1, \ldots, n\}$ are generated from a uniform distribution on two-dimensional area $[0,1] \times [0,1]$. For data type 1, two classes of samples are separated by the curve corresponding to a linear function, $X_1 + X_2 = 1$, with a few exceptions introduced as "noise". For data type 2, the separating curve corresponds to a cubic function $X_1^3 + X_2^3 = 1$. Intuitively, samples of data type 1 should be classified well by using the simple linear

kernel, while the cubic polynomial kernel might perform better when classifying samples from data type 2. We generate each type of data with sample size n equal to 100 and 200, respectively.

Polynomial kernels can be generalized as $K(\mathbf{X}_i, \mathbf{X}_j) = (\gamma \mathbf{X}_i' \mathbf{X}_j + b)^d$, where $\mathbf{X}_i$ and $\mathbf{X}_j$, $i, j = 1, \ldots, n$, are input vectors. In our study, we choose the hyper-parameters as $\gamma = 1/n$, $b = 0$, and $d = 3$. Then we apply the SVM algorithm by using the linear kernel and the polynomial kernel with optimal hyper-parameter C chosen by a cross-validation procedure, respectively. To make inference about the performances of different kernels, we use the model comparison procedure introduced in Section 3.3 to obtain 95% confidence intervals for the difference in cross-validation errors when using different kernels. We also compute the true prediction errors, together with the exact confidence intervals on the difference between their cross-validated estimates, based on the prediction results of $1,000$ replications of simulated data sets for each setting. In Table 4, we report the 10-fold cross-validation errors by using linear and polynomial kernels, the 95% confidence intervals on the difference between errors, and their respective true values.

For the first type of data, although the polynomial kernel could potentially lead to slightly lower error rates compared to the linear kernel, 95% confidence intervals for error difference are quite tight around zero. This suggests that the classifiers obtained based on these two types of kernels have similar accuracies as we expect. On the other hand, for the second type of data, 95% confidence intervals for error differences tend to deviate downward from zero, which indicates that the polynomial kernel indeed performs better than the linear kernel. (At the significant level of 0.05, $n = 100$ is not sufficient to conclude this, whereas $n = 200$ allows to make the above statement.) These

4. The true standard deviation (Sd) is calculated based on 5-fold cross-validation errors estimated on the rest 99 partitions of the data.
5. Standard deviation (Sd) and computation time (Time) are obtained by applying perturbation-resampling method on the first partition of the data.
6. Standard deviation (Sd) and computation time (Time) are obtained by applying splitting method (Nadeau and Bengio, 2003) on the first partition of the data.
7. Standard deviation (Sd) and computation time (Time) are obtained by applying ρ-based method (Nadeau and Bengio, 2003) on the first partition of the data.

Data Type	Sample Size	Linear Kernel Errors		Polynomial Kernel Errors		.95 Interval on Difference Between CV Errors

conclusions are consistent with the intuitions behind the data generating procedure. In particular, the predicted results are consistent with the true values of both point and interval estimates obtained by simulating a large number of data sets. This study serves as an example to demonstrate how to use the proposed model comparison procedure to choose an appropriate kernel in constructing SVM classifiers.

4.4 Example in the Genotypic Testing for Drug Resistance

In this section, we give an example to show how the proposed procedure can be used in selecting important markers in the genotypic testing for HIV protease inhibitor (PI) resistance on the HIV RT and Protease Sequence Database (Rhee et al., 2003). First, we divide the sample set into two classes by labeling each protease sequence sample with 99 amino acids as either "resistant" or "susceptible", depending on whether the resistance factor of the sample exceeds a certain drug-specific cutoff value or not (Beerenwinkel et al., 2002). Then, we predict the resistance to seven FDA-approved PIs using 10 sites on the substrate binding cleft or its flap that are reported to cause resistance by reducing the binding affinity between the inhibitor and the mutant protease enzyme. Aside from these mutations, mutation information at site 90, denoted by $X_{(90)}$, on the protease sequence has been reported to either contribute to or directly confer *in vitro* and *in vivo* resistance to each of the seven approved PIs, but the mechanism by which these mutations cause PI resistance is still not known. It is interesting to assess the incremental value of $X_{(90)}$ in predicting HIV drug resistance. To this end, we compare the prediction errors for the models with and without $X_{(90)}$ and evaluate the incremental value of $X_{(90)}$ based on the reduction in the prediction error, denoted by $\Delta_{X_{(90)}}$. We obtain the point and interval estimates of $\Delta_{X_{(90)}}$ based on the model comparison method discussed in Section 3.3 with 10-fold cross-validation. In both cases, the hyper-parameter C is chosen by using a cross-validation procedure, respectively.

The results in Table 5 show that the 95% confidence intervals for $\Delta_{X_{(90)}}$ are tight around zero for drugs APV, ATV, and LPV, which indicates that $X_{(90)}$ adds rather modest value, if any, on top of other variables, for predicting resistance to these drugs. On the other hand, by including information on $X_{(90)}$, the prediction of drug resistance to IDV and RTV can be significantly improved in a sense that

8. 10-fold cross-validation errors are computed.
9. The true errors are estimated based on the prediction results of $1,000$ replications of simulated data sets for each setting.
10. The exact confidence intervals are estimated based on the prediction results of $1,000$ replications of simulated data sets for each setting.

Drug Name	Sample Size	Resistant Fraction	Without Site 90 Error	Without Site 90 .95 Interval	With Site 90 Error	With Site 90 .95 Interval	.95 Interval for Difference
APV	577	38.1%	0.149	[0.130,0.202]	0.147	[0.129,0.198]	[-0.025,0.025]

LPV	253	74.7%	0.119	[0.090,0.236]	0.115	[0.078,0.167]	[-0.032,0.027]
NFV	617	64.0%	0.113	[0.093,0.147]	0.092	[0.076,0.130]	[-0.050,0.001]
RTV	510	50.2%	0.098	[0.069,0.123]	0.057	[0.039,0.090]	[-0.060,0.000]
SQV	598	43.6%	0.172	[0.146,0.211]	0.132	[0.113,0.166]	[-0.080,0.002]

Table 5: Interval estimates for the prediction errors and their difference in the genotypic testing for HIV drug resistance with or without mutation information at site 90 on the protease sequence.

the 95% confidence intervals for $\Delta_{X_{(90)}}$ tend to locate on the negative side of the zero point. These results are consistent with studies in literature (see Para et al., 2000; Shulman et al., 2002; Campo et al., 2003; Saah et al., 2003). Therefore, $X_{(90)}$ is an important marker for choosing antiretroviral drugs and therapies, and the roles played by $X_{(90)}$ in reducing the susceptibility of these two drugs need to be further studied.

5. Discussion

In this paper, we propose procedures for making inference about the prediction error of SVM classifiers based on cross-validated point estimators and their corresponding interval estimators. We establish large sample theory for the cross-validated estimators, and present a perturbation-resampling procedure to construct the confidence interval for prediction errors. The proposed interval estimates are obtained by approximating the spread of $\mathcal{W}$ with that of W. Alternatively, one may consider directly perturbing $\mathcal{W}$ to yield potentially better approximations. However, such a perturbation procedure may be computationally intensive since a K-fold cross-validation scheme has to be conducted for each realization of the resampling weights. Results from extensive simulation studies suggest that the proposed point and interval estimators perform well in finite samples. Furthermore, through numerical studies, we demonstrate that the interval estimates provide much more information about the true underlying prediction accuracy than the point estimates. Although it is unclear whether similar theoretical results hold for SVM classifier with the RBF kernel (see the discussion in Appendix B), the framework in this article is likely to be applicable to other inductive learning algorithms with different types of loss functions.

The proposed procedures also allow us to tackle the issue of model evaluation and selection by taking the uncertainty of estimators for the prediction error into account. We give several examples to illustrate some direct applications of the method, such as to provide confidence intervals around the estimated prediction error in kernel and biomarker selections. In addition to the examples outlined above, the proposed procedures may have other practical applications in model evaluation or variable selection.

Appendix A. Consistency of $\hat{\theta}$ and $\hat{D}$

In the following theorem, we will show that as $n \to \infty$, $\hat{\theta} \to \theta_0$ and the training error $\hat{D}(\hat{\theta})$ will converge to the absolute prediction error D_0 in probability. Without loss of generality, we assume that $g_0(\mathbf{X}) = P(Y = 1 \mid \mathbf{X})$ and the distribution function of $\mathbf{X}$ are continuously differentiable hereafter.

Theorem 1 Let $\theta_0 = (\mathbf{w}_0', b_0)' = \text{argmin}_{\theta \in \Theta} Q(\theta)$, Ω be the input vector space, and

$$\Lambda(Y, \theta_1) = \{\mathbf{X} \in \Omega \mid [1 - Y(\mathbf{w}_0'\mathbf{X} + b_0)][1 - Y(\mathbf{w}_1'\mathbf{X} + b_1)] < 0\}$$

for $\theta_1 = (\mathbf{w}_1', b_1)'$. Furthermore, we assume the following regularity condition:

$$P(Y = 1, \mathbf{X} \in \Lambda(1, \theta_1)) + P(Y = -1, \mathbf{X} \in \Lambda(-1, \theta_1)) > 0 \tag{12}$$

for any $\theta_1 \neq \theta_0$. Then, as $n \to \infty$, $\hat{\theta} \to \theta_0$ and $\hat{D}(\hat{\theta}) \to D_0$ in probability.

Proof. In view of Theorem 2.1 of Newey and McFadden (1994, Section 2), we can establish the convergence of $\hat{\theta} \to \theta_0$ by showing that (*a*) $Q(\theta)$ has a unique minimizer θ_0; and (*b*) $\hat{Q}_n(\theta)$ converges to $Q(\theta)$ in probability, uniformly in θ.

For (*a*), we note that since $Q(\theta)$ is continuous with respect to θ and Θ is compact, it must have a minimum within Θ. Furthermore, it is easy to verify that for any $a, b \in R$,

$$(a + b)_+ \leq a_+ + b_+ , \tag{13}$$

and a strict inequality holds if and only if $ab < 0$. As a result, under condition (12), $Q(\theta)$ is a strictly convex function at θ_0, and thus has a unique minimizer θ_0.

For (*b*), since $\hat{Q}_n(\theta)$ is also a convex function of θ because of (13), and $\hat{Q}_n(\theta)$ converges in probability to $Q(\theta)$ for each $\theta \in \Theta$, we have $\sup_{\theta \in \Theta} |\hat{Q}_n(\theta) - Q(\theta)|$ goes to zero in probability, a uniform convergence property for convex functions proved by Pollard (1991, Section 6). This concludes the proof for the convergence of $\hat{\theta}$ to θ_0 in probability.

It remains to show the consistency of $\hat{D}(\hat{\theta})$ for D_0. Since $g_0(\mathbf{X})$ is continuously differentiable, $E|Y_0 - \hat{Y}(\mathbf{X}_0, \theta)|$ is continuously differentiable in θ with bounded derivatives. Moreover, since $0 \leq E|Y_0 - \hat{Y}(\mathbf{X}_0, \theta)| \leq 2$, it follows from a uniform law of large numbers (Pollard, 1990, Chapter 8) that $\sup_{\theta \in \Theta} |\hat{D}(\theta) - E|Y_0 - \hat{Y}(\mathbf{X}_0, \theta)|| \to 0$ in probability. This, coupled with the convergence of $\hat{\theta}$ to θ_0, implies that $\hat{D}(\hat{\theta}) - D_0 \to 0$ in probability. ■

The regularity condition in (12) guarantees the existence and uniqueness of the minimizer to the objective function. This condition states that any deviation of the parameter θ from the minimizer θ_0 will always result in the change of output labels of certain samples. Given the continuous differentiability of both $g_0(\mathbf{X}) = P(Y = 1 \mid \mathbf{X})$ and the distribution function of $\mathbf{X}$, the condition can be satisfied if the probability density function of the input vector $\mathbf{X}$ is not equal to zero in some neighboring area of the optimal separating hyperplane.

Appendix B. Large Sample Distribution for $\hat{D}$

With the assumption that $g_0(\mathbf{X}) = P(Y = 1 \mid \mathbf{X})$ and the distribution function of $\mathbf{X}$ are continuously differentiable, we have $\nabla_{\theta=\theta_0} Q(\theta) = -E\{YI(Yf(\mathbf{X};\theta_0) < 1)(\mathbf{X}', 1)'\}$, which is also differentiable, almost everywhere $\theta \in \Theta$. Thus, $Q(\theta)$ is twice differentiable almost everywhere $\theta \in \Theta$. Let $\mathbf{H}$ be the Hessian matrix of $Q(\theta)$ at θ_0, $d(\theta) = E\{\hat{D}(\theta)\}$ and $\dot{d}(\theta) = \nabla d(\theta)$, we prove the following theorem:

Theorem 2 Under the regularity condition (12) in Theorem 1, the distribution of W is asymptotically equivalent to $n^{-1/2}\sum_{i=1}^n \eta_i$ and converges to a zero mean normal with variance $E(\eta_i^2)$, where

$$\eta_i = |Y_i - \hat{Y}(\mathbf{X}_i, \theta_0)| - D_0 - \dot{d}(\theta_0)\mathbf{H}^{-1}\mathbf{M}_i(\theta_0) \,, \tag{14}$$

and $\mathbf{M}_i(\theta_0) = -Y_i I(Y_i f(\mathbf{X}_i;\theta_0) < 1)(\mathbf{X}_i', 1)' + 2\lambda_n(\mathbf{w}_0', 0)'$.

Proof. Under the regularity condition, the limiting objective function $Q(\theta)$ is strictly convex at θ_0, and thus its Hessian matrix $\mathbf{H}$ at θ_0 is positive definite. To derive the asymptotic distribution theory for W, we first show that

$$\sqrt{n}(\hat{\theta} - \theta_0) = -n^{-1/2}\mathbf{H}^{-1}\sum_{i=1}^n \mathbf{M}_i(\theta_0) + o_p(1) \,, \tag{15}$$

where $\mathbf{M}_i(\theta_0) = -Y_i I(Y_i f(\mathbf{X}_i;\theta_0) < 1)(\mathbf{X}_i', 1)' + 2\lambda_n(\mathbf{w}_0', 0)'$.

To this end, let $\mathbf{Z} = (\mathbf{X}', Y)'$, $\mathbf{t} = (\mathbf{w}_t', b_t)'$, and write

$$[1 - Yf(\mathbf{X};\theta_0 + \mathbf{t})]_+ - [1 - Yf(\mathbf{X};\theta_0)]_+ = \mathbf{B}(\mathbf{Z})'\mathbf{t} + R(\mathbf{Z}, \mathbf{t}) \,, \tag{16}$$

where $\mathbf{B}(\mathbf{Z}) = -YI(Yf(\mathbf{X};\theta_0) < 1)(\mathbf{X}', 1)'$, and

$$R(\mathbf{Z}, \mathbf{t}) \;=\; \{1 - Yf(\mathbf{X};\theta_0 + \mathbf{t})\}[I\{Yf(\mathbf{X};\theta_0 + \mathbf{t}) < 1\} - I\{Yf(\mathbf{X};\theta_0) < 1\}] \,.$$

Noting that $R(\mathbf{Z}, \mathbf{0}) = 0$, and that the distribution function of $\mathbf{X}$ and the conditional probability mass function of Y given $\mathbf{X}$ are continuous differentiable, it is easy to verify that

$$ER(\mathbf{Z}, \mathbf{t}) = \frac{1}{2}\mathbf{t}'\mathbf{H}\mathbf{t} + o(\|\mathbf{t}\|^2) \text{ and } ER(\mathbf{Z}, \mathbf{t})^2 = O(\|\mathbf{t}\|^3) \,.$$

Furthermore, $E\mathbf{B}(\mathbf{Z})$ is just the first order derivative of $Q(\theta)$ at θ_0, thus $E\mathbf{B}(\mathbf{Z}) = 0$. Let $\mathbf{Z}_i = (\mathbf{X}_i', Y_i)'$, $\mathbf{s} = (\mathbf{w}_s', b_s)'$, and $A_n(\mathbf{s}) = \sum_{i=1}^n \{[1 - Y_i f(\mathbf{X}_i;\theta_0 + \mathbf{s}/\sqrt{n})]_+ + \lambda_n(\mathbf{w}_0 + \mathbf{w}_s/\sqrt{n})'(\mathbf{w}_0 + \mathbf{w}_s/\sqrt{n}) - [1 - Y_i f(\mathbf{X}_i;\theta_0)]_+ - \lambda_n \mathbf{w}_0'\mathbf{w}_0\}$. $A_n(\mathbf{s})$ is convex with respect to $\mathbf{s}$ because of (13), and it is minimized by $\sqrt{n}(\hat{\theta}_n - \theta_0)$. Note first that $nER(\mathbf{Z}, \mathbf{s}/\sqrt{n}) = \frac{1}{2}\mathbf{s}'\mathbf{H}\mathbf{s} + r_{n,0}(\mathbf{s})$, where $r_{n,0}(\mathbf{s}) = o(\|\mathbf{s}\|^2) \to 0$ for fixed $\mathbf{s}$. Accordingly, using (16),

$$\begin{aligned} A_n(\mathbf{s}) \;&=\; \sum_{i=1}^n \{[\mathbf{B}(\mathbf{Z}_i) + 2\lambda_n(\mathbf{w}_0', 0)']'\mathbf{s}/\sqrt{n} + R(\mathbf{Z}_i, \mathbf{s}/\sqrt{n}) - ER(\mathbf{Z}_i, \mathbf{s}/\sqrt{n})\} \\ &\quad + nER(\mathbf{Z}, \mathbf{s}/\sqrt{n}) + \lambda_n \mathbf{w}_s'\mathbf{w}_s \\ &=\; U_n'\mathbf{s} + \frac{1}{2}\mathbf{s}'\mathbf{H}\mathbf{s} + r_{n,0}(\mathbf{s}) + r_{n,1}(\mathbf{s}) + r_{n,2}(\mathbf{s}) \,, \end{aligned}$$

where $U_n = n^{-1/2}\sum_{i=1}^n \{\mathbf{B}(\mathbf{Z}_i) + 2\lambda_n(\mathbf{w}_0', 0)'\} = n^{-1/2}\sum_{i=1}^n \mathbf{M}_i(\theta_0)$, $r_{n,2}(\mathbf{s}) = \lambda_n \mathbf{w}_s'\mathbf{w}_s$, and $r_{n,1}(\mathbf{s}) = \sum_{i=1}^n \{R(\mathbf{Z}_i, \mathbf{s}/\sqrt{n}) - ER(\mathbf{Z}_i, \mathbf{s}/\sqrt{n})\}$. Now $r_{n,1}(\mathbf{s})$ tends to be zero in probability for each $\mathbf{s}$, since its

mean is zero and its variance is $\sum_{i=1}^{n} \mathrm{var}\{R(\mathbf{Z}_i, \mathbf{s}/\sqrt{n})\} = o(\|\mathbf{s}\|^2)$. Moreover, $r_{n,2}(\mathbf{s})$ also tends to be zero in probability when $\lambda_n \to 0$. Since $A_n(\mathbf{s})$ is a convex function, $\mathbf{H}$ is positive definite, and the covariance matrix $\mathrm{var}(\mathbf{X})$ is finite, it follows from the Basic Corollary of Hjort and Pollard (1993) that (15) holds.

Secondly, we show that the class of functions indexed by θ, $\Im = \{|Y - \hat{Y}(\mathbf{X}, \theta)| : \|\theta - \theta_0\| \le \delta\}$ is a Donsker class, where δ is a given positive number and $\hat{Y}(\mathbf{X}, \theta) = \mathrm{sign}(\mathbf{w}'\mathbf{X} + b)$. Both of the classes of function $\{1 + \hat{Y}(\mathbf{X}, \theta) : \|\theta - \theta_0\| \le \delta\}$ and $\{1 - \hat{Y}(\mathbf{X}, \theta) : \|\theta - \theta_0\| \le \delta\}$ are VC classes (van der Vaart and Wellner, 1996, Lemma 2.6.15), and hence are Donsker. Note that in this case $\Im = \{I(Y = -1)[1 + \hat{Y}(\mathbf{X}, \theta)] + I(Y = 1)[1 - \hat{Y}(\mathbf{X}, \theta)] : \|\theta - \theta_0\| \le \delta\}$, and therefore is a Donsker class. It follows that $n^{1/2}[\hat{D}(\theta) - d(\theta)]$, a process in θ, converges weakly to a zero mean Gaussian process and thus is stochastic equicontinuous at θ_0. This, coupled with (15), implies that $n^{1/2}\{\hat{D}(\hat{\theta}) - D_0\} = n^{1/2}[\hat{D}(\hat{\theta}) - \hat{D}(\theta_0)] + n^{1/2}[\hat{D}(\theta_0) - D_0]$ is asymptotically equivalent to

$$n^{1/2}\{\hat{D}(\theta_0) - D_0\} + \dot{d}(\theta_0) n^{1/2}(\hat{\theta} - \theta_0) \simeq n^{-1/2} \sum_{i=1}^{n} \eta_i \,,$$

where

$$\eta_i = |Y_i - \hat{Y}(\mathbf{X}_i, \theta_0)| - D_0 - \dot{d}(\theta_0)\mathbf{H}^{-1}\mathbf{M}_i(\theta_0) \,.$$

Here and in the sequel, we use the notation $a \simeq b$ to denote that $a = b + o_p(1)$. Thus, $W = n^{1/2}\{\hat{D}(\hat{\theta}) - D_0\}$ converges in distribution to a zero mean normal random variable. ■

Since the limiting variance of W is $\sigma^2 = E(\eta_i^2)$ and $n^{-1}\sum_{i=1}^{n} \eta_i^2$ converges to σ^2 in probability (based on the law of large numbers), one may estimate σ^2 by $n^{-1}\sum_{i=1}^{n} \eta_i^2$. Furthermore, it is not difficult to show that $n^{-1}\sum_{i=1}^{n}(\eta_i^2 - \hat{\eta}_i^2) \to 0$ since we expect that all the empirical estimates of the theoretical quantities in η_i are consistent. We note that although $n^{-1}\sum_{i=1}^{n} \hat{\eta}_i^2$ is a consistent estimator of σ^2, we approximate σ^2 based on the resampling method, not $n^{-1}\sum_{i=1}^{n} \hat{\eta}_i^2$.

For a more general case, when the prediction function $f(\mathbf{X})$ in (1) is not a linear function of the input vector $\mathbf{X}$, one can rewrite the prediction function in the form of $f(\mathbf{X}) = \mathbf{w}'\Phi(\mathbf{X}) + b$, where Φ is a mapping from the input vector space to a "feature space" $\mathcal{H}$. Given that the expectation $E\Phi(\mathbf{X})$, the covariance matrix $\mathrm{var}(\Phi(\mathbf{X}))$, and the VC dimension of $f(\mathbf{X})$ are all finite (for example, when Φ is a mapping corresponding to a polynomial kernel function), and coupled with the fact that a $\{0,1\}$-valued class of functions is a uniform Donsker class if and only if its VC dimension is finite (Dudley, 1999), one can prove all the results given above using similar arguments. Note that when it comes to construct SVM classifier using the RBF kernel, however, these conditions cannot be satisfied because of the infinite-dimensional feature space of the RBF kernel.

Appendix C. Large Sample Property of $\hat{\mathcal{D}}$

In this appendix, we will show that the distribution of $\mathcal{W}$ is asymptotically equivalent to that of W based on training error.

Theorem 3 $\mathcal{W}$ in (8) is asymptotically equivalent to W in (6).

Proof. For each partition I_k, $n^{-1/2}\{\hat{D}_{(k)}(\hat{\theta}_{(-k)}) - D_0\}$ is asymptotically equivalent to $n^{-1/2}K\sum_{i=1}^{n} I(\xi_i = k)\{|Y_i - \hat{Y}(\mathbf{X}_i, \hat{\theta}_{(-k)})| - D_0\}$, where $\{\xi_i; i = 1, \ldots, n\}$ are n exchangeable discrete random

variables uniformly distributed over $\{1,\ldots,K\}$, independent of the data, which satisfy $\sum_{i=1}^{n} I(\xi_i = k) \simeq n/K, k = 1,\ldots,K$. Conditionally on $\{\xi_i; i = 1,\ldots,n\}$, it follows from similar arguments in Appendix B that

$$\hat{\theta}_{(-k)} - \theta_0 = -\frac{K}{n(K-1)}\mathbf{H}^{-1}\sum_{i=1}^{n} I(\xi_i \neq k)\mathbf{M}_i(\theta_0) + o_p(n^{-1/2}) .$$

Then using the same argument as given for $n^{1/2}\{\hat{D}(\hat{\theta}) - D_0\}$, one can show that $n^{1/2}\{\hat{D}_{(k)}(\hat{\theta}_{(-k)}) - D_0\}$ is asymptotically equivalent to

$$n^{1/2}\{\hat{D}_{(k)}(\theta_0) - D_0\} + \dot{d}(\theta_0)n^{1/2}(\hat{\theta}_{(-k)} - \theta_0) \simeq n^{1/2}\sum_{i=1}^{n}\eta_{ki} ,$$

where

$$\eta_{ki} = I(\xi_i = k)K\{|Y_i - \hat{Y}(\mathbf{X}_i,\theta_0)| - D_0\} + I(\xi_i \neq k)\frac{K}{K-1}\dot{d}(\theta_0)\mathbf{H}^{-1}\mathbf{M}_i(\theta_0) .$$

It follows that $n^{1/2}(\hat{\mathcal{D}} - D_0) \simeq n^{-1/2}\sum_{i=1}^{n}(\sum_{k=1}^{K} K^{-1}\eta_{ki})$. Since $\sum_{k=1}^{K} I(\xi_i = k) = 1$ and $\sum_{k=1}^{K} I(\xi_i \neq k) = K-1$, it is straightforward to show that

$$\begin{aligned} n^{-1/2}\sum_{i=1}^{n}(\sum_{k=1}^{K} K^{-1}\eta_{ki}) &= n^{-1/2}\sum_{i=1}^{n}\left\{|Y_i - \hat{Y}(\mathbf{X}_i,\theta_0)| - D_0 + \dot{d}(\theta_0)\mathbf{H}^{-1}\mathbf{M}_i(\theta_0)\right\} \\ &= n^{-1/2}\sum_{i=1}^{n}\eta_i . \end{aligned}$$

■

Appendix D. Justification for the Perturbation-Resampling Procedure

Here, we give a brief justification for the perturbation-resampling approach presented in Section 3.2. For formal justification of the approach, please see similar but more rigorous derivations given in Park and Wei (2003) and Cai et al. (2005).

To justify the resampling method, we first note that it follows from the arguments in Appendix B that

$$\sqrt{n}(\hat{\theta} - \theta_0) = -n^{-1/2}\mathbf{H}^{-1}\sum_{i=1}^{n}\mathbf{M}_i(\theta_0) + o_p(1) ,$$

and that

$$\sqrt{n}(\theta^* - \theta_0) = -n^{-1/2}\mathbf{H}^{-1}\sum_{i=1}^{n} G_i\mathbf{M}_i(\theta_0) + o_p(1) ,$$

where $\mathbf{M}_i(\theta_0) = -Y_i I(Y_i f(\mathbf{X}_i;\theta_0) < 1)(\mathbf{X}_i', 1)' + 2\lambda_n(\mathbf{w}_0', 0)'$.

Then, consider the unconditional version of W^*. Let $D^*(\theta) = n^{-1}\sum_{i=1}^{n}\{|Y_i - \hat{Y}(\mathbf{X}_i,\theta)|G_i\}$, $\hat{D}(\theta) = n^{-1}\sum_{i=1}^{n}|Y_i - \hat{Y}(\mathbf{X}_i,\theta)|$, and $D_0 = E|Y_0 - \hat{Y}(\mathbf{X}_0,\hat{\theta})|$, where $(\mathbf{X}_0, Y_0)$ is an independent sample

from the same population of $(\mathbf{X}, Y)$, and the expectation E is with respect to $\{(\mathbf{X}_i, Y_i); i = 1, \ldots, n\}$ and $(\mathbf{X}_0, Y_0)$. As $\hat{\theta}$ converges to θ_0 and $\hat{D}(\hat{\theta})$ converges to D_0, it is straight forward to show that

$$\begin{aligned}
W^* &= n^{1/2}(D^*(\theta^*) - D^*(\theta_0)) - n^{1/2}(\hat{D}(\hat{\theta}) - \hat{D}(\theta_0)) \\
&\quad + n^{1/2}(D^*(\theta_0) - \hat{D}(\theta_0)) - n^{-1/2}\sum_{i=1}^{n} \hat{D}(\hat{\theta})(G_i - 1) \\
&\simeq \dot{d}(\theta_0)n^{1/2}(\theta^* - \theta_0) - \dot{d}(\theta_0)n^{1/2}(\hat{\theta} - \theta_0) \\
&\quad + n^{-1/2}\sum_{i=1}^{n} |Y_i - \hat{Y}(\mathbf{X}_i, \theta_0)|(G_i - 1) - n^{-1/2}\sum_{i=1}^{n} D_0(G_i - 1) \\
&\simeq n^{-1/2}\sum_{i=1}^{n} \{|Y_i - \hat{Y}(\mathbf{X}_i, \theta_0)| - D_0\}(G_i - 1) - \dot{d}(\theta_0)n^{-1/2}\mathbf{H}^{-1}\sum_{i=1}^{n} \mathbf{M}_i(\theta_0)(G_i - 1) \\
&= n^{-1/2}\sum_{i=1}^{n} \eta_i(G_i - 1)\ ,
\end{aligned}$$

where $\eta_i = |Y_i - \hat{Y}(\mathbf{X}_i, \theta_0)| - D_0 - \dot{d}(\theta_0)\mathbf{H}^{-1}\mathbf{M}_i(\theta_0)$.

Conditionally on the data, it follows from the Multiplier Central Limit Theorem (van der Vaart and Wellner, 1996, Chapter 2.9) that the conditional distribution of W^* converges to a normal with mean 0 and variance $n^{-1}\sum_{i=1}^{n} \eta_i^2$, which are the same as the unconditional distribution of W (or its cross-validation counterpart $\mathcal{W}$). This implies that for $\varepsilon > 0$, there exists an N_0 such that when $n > N_0$, the probability, with respect to samples $\mathcal{S} = \{(\mathbf{X}_i, Y_i); i = 1, \ldots, n\}$, of the event

$$\sup_{u \in \mathcal{R}} |P(W^* \leq u|\mathcal{S}) - P(W \leq u)| < \varepsilon\ ,$$

is at least $1 - \varepsilon$.

Abstract

Support vector machines for classification have the advantage that the curse of dimensionality is circumvented. It has been shown that a reduction of the dimension of the input space leads to even better results. For this purpose, we propose two information criteria which can be computed directly from the definition of the support vector machine. We assess the predictive performance of the models selected by our new criteria and compare them to existing variable selection techniques in a simulation study. The simulation results show that the new criteria are competitive in terms of generalization error rate while being much easier to compute. We arrive at the same findings for comparison on some real-world benchmark data sets.

Keywords: information criterion, supervised classification, support vector machine, variable selection

1. Introduction

We study classification using the support vector machine (SVM). We start from a training set $\{(x_i, y_i)\}$ containing n observations. Each p-dimensional observation $x_i = (x_{i1}, \ldots, x_{ip})$ has a class label y_i assigned to it, which is either $+1$ or -1. We wish to find a function $f(\cdot)$ such that for an observation x the predicted class $\hat{y} = +1$ if $f(x)$ is positive, and $\hat{y} = -1$ if $f(x)$ is negative. We want this function to assign the correct class labels to the training observations (low training error rate) and to accurately classify new observations (low generalization error rate). Working with a subset of the p variables $x_{i1}, \ldots, x_{ip}$ reduces variability of the class-label estimator and might lead to better out-of-sample predictions.

It is only true to some extent that variable selection would not be necessary in the support vector machine setting since it manages to circumvent the so-called "curse of dimensionality" (see, for example, Cristianini and Shawe-Taylor, 2000; Hastie et al., 2001; Schölkopf and Smola, 2002). While the SVM approach avoids fitting a number of parameters equal to the dimension of the input space, there remains the high probability of a perfect separation in high-dimensional problems. For example, if p is larger than the number of observations, it is always possible to perfectly separate the two classes of training data by a hyperplane. In general, the risk of overfitting will increases with the dimension for most data configurations. Hence, the risk of obtaining a decision rule with poor

generalization properties (high generalization error rate) cannot be avoided. Guyon et al. (2002) illustrate this and show that variable selection can further improve the SVM's performance.

Variable selection techniques can be divided into three categories. Filters select subsets of variables as a pre-processing step, independently of the prediction method. Wrappers use the classification method to score subsets of variables. Finally, embedded methods include variable selection into the construction of the classifier. In this paper we propose new information criteria for SVMs, yielding a wrapper method where we consider the SVM merely as a black box. We refer to Guyon and Elisseeff (2003) for an introduction to variable and feature selection in Machine Learning. Information criteria are a standard tool for model selection in traditional statistics. Information criteria for variable selection assign a numerical value to each subset of the variables under consideration. The subset with the lowest value of the information criterion is then selected. Examples are the Akaike information criterion (AIC, Akaike, 1973) and the Bayesian information criterion (BIC, Schwarz, 1978). Claeskens and Hjort (2008) survey and explain the use of common information criteria for statistical variable selection in likelihood-based models, we refer to there for more references.

For support vector machines only very few information criteria have been developed. The kernel regularisation information criterion (KRIC) of Kobayashi and Komaki (2006) was originally proposed for parameter tuning of the SVM. We apply it for variable selection. However, the KRIC has a complicated definition and is computationally expensive for large sample sizes. In this paper two new information criteria are proposed, one shares properties with AIC, the other with BIC. We want the new criteria to select a preferably compact subset of variables with good predictive properties. We will show that submodels selected by the new criteria are as performing as the ones chosen by the KRIC, while they incur substantially less computational overhead. We also make a comparison with using cross-validated error rate based criteria, as in Kearns et al. (1997). An important contribution of this paper is that our numerical comparisons show that the popular, but time consuming, cross-validation criteria are outperformed in generalization error by the new information criteria, where the latter are coming at almost no additional computational cost.

Alternative approaches perform variable selection in feature space instead of in input space (Shih and Cheng, 2005), or select a set of "maximally separating directions" in the input space (Fortuna and Capson, 2004). These methods, however, do not select a set of original input variables. Various other authors have suggested different formulations for the SVM such that variable selection is performed automatically. Examples of such embedded methods can be found in Bi et al. (2003), Zhu et al. (2004), Neumann et al. (2005), Lee et al. (2006), Wang et al. (2006), Zhang (2006), and Lin and Zhang (2006).

In Section 2 we define the support vector machine setting, we review existing information criteria and we describe ranking techniques to speed up the variable selection process. In Section 3, we define the new information criteria and highlight their advantages. Section 4 contains the results of a simulation study and in Section 5 we compare the different techniques on a few real-world benchmark data sets. Section 6 concludes and gives some directions for further research.

2. Problem Setting

In this Section we first review the definition of a support vector machine. Afterwards some existing variable selection techniques are discussed. Finally we present the ranking techniques that will be used in this paper.

2.1 The Support Vector Machine

We denote the training sample (x_i, y_i), $1 \leq i \leq n$, with x_i a p-dimensional vector of explicative variables, and $y_i \in \{-1, +1\}$ the class label. The goal is to estimate a target function $f(x)$ in the space of explicative variables such that $f(x_i) > 0$ for $y_i = +1$, and $f(x_i) < 0$ for $y_i = -1$.

We start with linear support vector machines, where $f(x)$ is of the form $f(x) = w'x + b$. For binary classification this function is obtained by solving the minimisation problem

$$\min_{w,b,\xi_i} \left\{ \frac{1}{2}\|w\|^2 + C\sum_{i=1}^{n} \xi_i \right\} \text{ subject to } \begin{cases} y_i(w'x_i + b) \geq 1 - \xi_i, \\ \xi_i \geq 0, i = 1, \ldots, n. \end{cases} \tag{1}$$

The ξ_i are slack margin variables, indicating how close a point x_i lies to the separating boundary (if $\xi_i < 1$), or how badly it is misclassified (if $\xi_i > 1$). The tuning parameter C controls how much weight is put on trying to achieve perfect separation.

The dual problem can be solved more easily, and has the following form:

$$\min_{\alpha} \{ \frac{1}{2}\alpha' Q\alpha - \sum_{i=1}^{n} \alpha_i \} \text{ subject to } \begin{cases} 0 \leq \alpha_i \leq C, \quad i = 1, \ldots, n, \\ \sum_{i=1}^{n} y_i \alpha_i = 0. \end{cases} \tag{2}$$

Here α_i is the weight given to the observation (x_i, y_i), and Q is a positive semi-definite matrix with entries $Q_{i,j} = y_i y_j x_i' x_j$. The vector w can be found from $w = \sum_{i=1}^{n} y_i \alpha_i x_i$. The negative intercept b is found by computing $b = 0.5(r_2 - r_1)$, where

$$r_1 = \frac{\sum_{0<y_i\alpha_i<C} (Q\alpha)_i - 1}{\sum_{0<y_i\alpha_i<C} 1} \text{ and } r_2 = \frac{\sum_{0>y_i\alpha_i>-C} (Q\alpha)_i - 1}{\sum_{0>y_i\alpha_i>-C} 1}.$$

If no i exist for which $0 < y_i\alpha_i < C$, then define

$$r_1 = \frac{1}{2}\Big(\min_{\alpha_i=0, y_i=1} (Q\alpha)_i - \max_{\alpha_i=C, y_i=1} (Q\alpha)_i \Big),$$

and analogously for r_2, with $y_i = -1$. Note that we can write $\xi_i = [1 - y_i a_i]_+$, where $[x]_+ = \max\{0, x\}$ and where $a_i = f(x_i)$.

The linear SVM can be extended towards more complex decision functions in a rather straightforward way. Therefore we replace the inner products $x_i' x_j$ in the definition of Q by a more general kernel function $K(x_i, x_j)$. See Cristianini and Shawe-Taylor (2000) for the properties that these kernel functions must have. This leads to a more general decision function

$$f(x) = \sum_{i=1}^{n} y_i \alpha_i K(x_i, x) + b. \tag{3}$$

Popular choices for the kernel function in (3) are the linear kernel, where the kernel function is $K(x,z) = x'z$, the polynomial kernel of the form $K(x,z) = (c_0 + \gamma x'z)^d$, and the radial basis kernel $K(x,z) = \exp(-\gamma\|x - z\|^2)$, where c_0, γ and d are regularization parameters that can be tuned for optimal performance of the classifier. In this more general setting, we have

$$\|w\|^2 = \sum_{i,j=1}^{n} y_i y_j \alpha_i \alpha_j K(x_i, x_j) = \alpha' Q\alpha$$

for the squared norm of the weight vector, where $Q_{i,j} = y_i y_j K(x_i, x_j)$.

2.2 Existing Variable Selection Techniques for SVM

We compare our new methods (Section 3) to variable selection based on (ten-fold) cross-validation (CV), guaranteed risk minimisation (GRM, Vapnik, 1982) and the kernel regularisation information criterion (KRIC) by Kobayashi and Komaki (2006). Each of these will be explained in more detail below.

Ten-fold cross-validation divides the training data in ten parts of roughly equal size. One part is left out, the other nine parts are the training data and are used to fit the SVM. This SVM is applied to the part that is left out to obtain an estimate of the error rate. This process is repeated ten times (each time a different part is left out) to obtain the CV generalization error rate $\hat{\varepsilon}(S)$ as the average of the ten separate error rates. We select the model with the lowest value of $\hat{\varepsilon}(S)$, where S ranges over all subsets of variables under consideration. Another common method is five-fold CV. The lower the number of folds, the less computing time is required, but the higher the variability of the estimates of the generalization error. Note that $n-$fold CV is the same as the computationally infeasible leave-one-out CV.

General risk minimisation (Vapnik, 1982) is derived from the estimated generalization error rate, using

$$GRM(S) = \hat{\varepsilon}(S) + \frac{|S|}{n}\big(1+\sqrt{1+\hat{\varepsilon}(S)(n/|S|)}\big). \tag{4}$$

Here, $|S|$ stands for the number of input variables in the set S and n is the number of observations in the training sample. We select the model with the lowest value of $GRM(S)$, where S ranges over all subsets of variables under consideration. Kearns et al. (1997) compare CV, GRM and minimum description length (Rissanen, 1989). Their experiments have demonstrated that none of the criteria is consistently better than the others. Note that the computational overhead for computing these measures can be immense, since we need to train ten support vector machines to estimate the generalization error rate for only one submodel.

We now define the KRIC of Kobayashi and Komaki (2006). This criterion was originally developed to tune the constant C in the SVM definition (1), and by extension to tune the kernel parameters. We use it without much adjustment for variable selection. Denote by $x_{i,S}$ the subvector of x_i, consisting of elements x_{ij} with $j \in S$, and similarly for other vectors. We estimate the SVM (1) using the observations $(x_{i,S}, y_i)$, yielding the vectors ω_S, b_S and ξ_S, where the subscript S refers to the subset of variables under consideration. In the dual problem (2), we have $\alpha_S = (\alpha_{S,1}, \ldots, \alpha_{S,n})$ and $[Q_S]_{i,k} = y_i y_k K(x_{i,S}, x_{k,S})$. The decision rule $f_S(x)$ is as in (3), and we set $a_{i,S} = f_S(x_{i,S})$. Next, we define vectors t_S and m_S of length n, with components

$$t_{S,i} = \eta^2 \frac{\exp(-\eta a_{i,S} y_i)}{(1+\exp(-\eta a_{i,S} y_i))^2} \quad \text{and} \quad m_{S,i} = -\eta \frac{y_i \exp(-\eta a_{i,S} y_i)}{1+\exp(-\eta a_{i,S} y_i)}, \;\; i = 1, \ldots, n.$$

Here we choose $\eta = \log(2)$ such that $\log(1+\exp(-\eta x))$ and $\eta[1-x]_+$ coincide for $x = 0$, see Kobayashi and Komaki (2006) for further motivation. With $\lambda = C^{-1}\log 2$ the KRIC for the logistic Bayesian model for SVMs is defined as

$$\begin{aligned} \mathrm{KRIC}(S) \;=\; & 2\Bigg[\sum_{i=1}^{n} \log\big(1+\exp(-\eta a_{i,S} y_i)\big) \\ & + \mathrm{trace}\big((Q_S \mathrm{diag}(t_S) + \lambda I_n)^{-1} Q_S (\mathrm{diag}(m_S)^2 - n^{-1} m_S m_S^t)\big)\Bigg]. \end{aligned} \tag{5}$$

Alternatively, Sollich's Bayesian model for SVMs (Sollich, 2002) leads to a KRIC with a similar form as the one in (5). Using

$$\nu(a_{i,S}) = (1+\exp(-2C))^{-1}(\exp(-C[1-a_{i,S}]_+)+\exp(-C[1+a_{i,S}]_+)),$$

the KRIC for the Sollich Bayesian model for SVMs is defined as

$$\mathrm{KRICS}(S) = \mathrm{KRIC}(S) - 2n\log\sum_{i=1}^{n}\nu(a_{i,S}). \tag{6}$$

The computation of the KRIC includes inverting an $n \times n$-matrix with only a few zeroes. Therefore, the computation is time-consuming if the sample size n is large. Both the CV error rate and the KRIC may require a prohibitive computing time when a large number of different models needs to be evaluated.

2.3 Ranking Techniques

A full subset search is computationally not feasible even not for problems with only a small number of dimensions ($p = 15$ for example). To dramatically reduce the number of models while still selecting a model that is "almost" the best model, Chen et al. (2005) use a genetic algorithm, while Peng et al. (2005) suggest a combined backward elimination/forward selection strategy. However, both of these techniques still suffer from the possibility that a large number of models needs to be checked before arriving at a solution.

Alternatively, variable ranking consists of assigning a "value of importance" to each variable and sorting the variables according to their importance. This results in a series of p stacked models, thus only p evaluations of the variable selection criterion are needed. The most commonly used algorithm is the SVM recursive feature elimination (SVM-RFE) technique from Guyon et al. (2002). For a linear SVM, the variables are ranked by w_j^2, with w_j the j-th component of the weight vector w. This technique assumes that the variables are standardized to have mean 0 and variance 1. The extension proposed by Rakotomamonjy (2003) allows application to SVMs with a non-linear kernel. We use the following SVM-RFE algorithm with variable influence

$$\Delta\|w_S\|^2_{(j)} = \left|\|w_S\|^2 - \|w_{S\setminus\{j\}}\|^2\right|$$

as suggested by Rakotomamonjy (2003).

Step 1: Initialise $S \leftarrow \{1,\ldots,p\}$, the subset of unranked features, and $r \leftarrow ()$, the vector of ranked features.

Step 2: Repeat the following steps until $S = \emptyset$.

(a) Train a SVM on $(x_{i,S}, y_i)$, and compute $\|w_S\|^2 = \alpha_S' Q_S \alpha_S$.

(b) For each $j \in S$, train a new SVM on $(x_{i,S\setminus\{j\}}, y_i)$. This gives a value $\|w_{S\setminus\{j\}}\|^2 = \alpha'_{S\setminus\{j\}} Q_{S\setminus\{j\}} \alpha_{S\setminus\{j\}}$ for each $j \in S$.

(c) Obtain $j_0 = \mathrm{argmin}_j \left|\|w_S\|^2 - \|w_{S\setminus(j)}\|^2\right|$ and set $S \leftarrow S\setminus\{j_0\}$ and $r \leftarrow (j_0, r)$.

The vector r contains the ranked variables, with the first element the most important one. A disadvantage of this method is that the number of SVMs to be trained is $O(p^2)$. This can be overcome by using α_S instead of $\alpha_{S\setminus\{j\}}$ in Step 2*b*, such that $\|w_{S\setminus\{j\}}\|^2 \approx \alpha_S' Q_{S\setminus\{j\}} \alpha_S$. Rakotomamonjy (2003) argues that this will not affect the ranking significantly, while still allowing a major reduction in computational time, bringing the number of SVMs to be estimated to $O(p)$. We employ this approximation in the simulation study in Section 4 and in the real data examples in Section 5.

The most easy way to rank the variables is by filtering methods. Zhang et al. (2006) propose using $s_j = |w_j(m_{j,+1} - m_{j,-1})|$ for ranking, where $m_{j,+1}$ and $m_{j,-1}$ are the within-class means of variable j. Shih and Cheng (2005) use the Fisher score

$$S_j = \frac{|m_{j,+1} - m_{j,-1}|}{\sqrt{\sigma^2_{j,+1} + \sigma^2_{j,-1}}}$$

for a linear SVM, where $\sigma^2_{j,+1}$ and $\sigma^2_{j,-1}$ are the within-class variances of variable j. The main advantage of using S_j is that it is not necessary to train any SVM to rank the variables. The Fisher score ranking is considered in Sections 4 and 5.

3. The New Information Criteria

As stated in the previous section, evaluating the CV error rate or the KRIC of a particular support vector machine model requires a high number of additional computations. For this reason, we propose two new criteria which use information already available in the SVM, without additional complicated computations. The criteria are based on how badly the SVM violates the margin constraints, which are written as $\sum_{i=1}^n \xi_{i,S}$, where $\xi_{i,S}$ is the margin slack of observation i in the support vector machine trained on the variables with indices in S, where S is a subset of $\{1,\ldots,p\}$. Alternatively, we can use the logarithm of this sum, analogous to Bai and Ng (2002) for selecting the number of factors in factor analysis. However, in the SVM setting this has the drawback that the value is undefined if the sum equals zero, which can happen if the data are perfectly separable. Also, Bai and Ng (2002) advise using a log-transform for scalar invariance reasons. Since we follow the advice to standardise the variables before training the SVM, for better ranking as explained in Section 2.3, we automatically have scalar invariance of the sum of the margin slacks. For these reasons, we choose not to take the log-transform.

Generally (but not always), $\sum_i \xi_{i,S}$ will decrease as more variables are added. Therefore we add a penalty term related to the number of included variables to ensure a tradeoff between accuracy and simplicity of the chosen model. We suggest adding a linear penalty term, such that we get an information criterion of the form

$$IC(S) = \sum_{i=1}^n \xi_i + C(n)|S|\,, \tag{7}$$

where S is the set of variables included in the model.

A first choice is to take $C(n)$ constant in (7). It is interesting to note that $IC(S)$ is then, up to constant factors, an easily computable approximation of the KRIC of Kobayashi and Komaki (2006), hereby providing a theoretical justification for its use. To better understand this, note first that $\log\left(1+\exp(-\eta a_{i,S} y_i)\right)$ is a continuous approximation of the hinge loss function

$\eta[1-y_i a_{i,S}]_+ = \eta\xi_{i,S}$ for all $1 \le i \le n$. Hence, the first term of the KRIC can be approximated, up to a constant factor, by $\sum_i \xi_{i,S}$. For the approximation of the second term in (5), rewrite

$$\begin{aligned} W &= (Q_S \mathrm{diag}(t_S) + \lambda I_n)^{-1} Q_S (\mathrm{diag}(m_S)^2 - n^{-1} m_S m_S^t) \\ &= V \mathrm{diag}(t_S)^{-1} (\mathrm{diag}(m_S)^2 - n^{-1} m_S m_S^t), \end{aligned}$$

with $V = (A + \lambda I_n)^{-1} A$ a symmetric, positive semi-definite matrix and $A = Q_S \mathrm{diag}(t_S)$. Denoting A^- the generalised inverse of A, and using a series expansion around $\lambda = 0$, gives that the leading term of $V = A^-(I + \lambda A^-)^{-1} A$ is equal to $A^- A$. This expansion converges as long as the eigenvalues of λA^- are strictly less than one, which can be obtained by taking λ small enough. We now use a singular value decomposition of both A and A^- and use the fact that the singular values of A^- are the reciprocals of the non-zero singular values of A, to obtain that the product $A^- A$ is a $n \times n$ diagonal matrix with on the diagonal $|S|$ ones and the remaining entries zero. Thus, the leading term of $\mathrm{trace}(W)$ equals the sum of $|S|$ diagonal entries of the matrix $\mathrm{diag}(t_S)^{-1}(\mathrm{diag}(m_S)^2 - n^{-1} m_S m_S^t))$. The i-th diagonal element of this matrix is equal to

$$\frac{n-1}{n} t_{S,i}^{-1} m_{S,i}^2 = \frac{n-1}{n} \exp(-\eta a_{i,S} y_i).$$

To further facilitate computations we replace this by 1, motivated by the fact that $\eta a_{i,S} y_i$ is often small. Although this approximation might be crude for a single term, we found empirically that it works well for the summation over the entire training set. Hence, we arrive at the approximation $\mathrm{trace}(W) \approx |S|$ which is the linear penalty term in (7).

Taking the constant value $C(n) = 2$, leads to our first new support vector machine information criterion (SVMIC):

$$\mathrm{SVMICa}(S) = \sum_{i=1}^{n} \xi_i + 2|S|. \tag{8}$$

The newly proposed criterion SVMICa for support vector machines shares the form of the penalty with the well-known Akaike (1973) information criterion. This AIC is defined as minus twice the value of the maximised log likelihood of the model, plus two times the number of parameters to be estimated (that is, $2|S|$). Because the penalty $2|S|$ is not dependent on the sample size n, we expect that both criteria share some properties, such as having the tendency to not select the most parsimonious model. For the AIC, Woodroofe (1982) has shown that in the limit for $n \to \infty$, the expected number of superfluous parameters is less than one.

To support the definition of SVMICa , we ran a simulation experiment and compared the values of KRIC and SVMICa for 100 models. The sample size is $n = 50$, with 10 variables of which only the first 4 variables are different from zero. A detailed description of the simulation setting can be found in Section 4. We used a linear kernel. Figure 1 reports these numerical results and shows a high correlation (0.975) between the values of the two criteria. Other simulation settings gave comparable correlation values.

Our second proposed criterion follows the spirit of Bayesian information criterion (BIC) by Schwarz (1978). This criterion is defined similarly as the AIC, but instead of the penalty $2|S|$, it uses $\log(n)|S|$. The BIC has been shown to be consistent (Haughton, 1988, 1989). This means that if the true model is contained in the search list, the criterion will (in the limit for $n \to \infty$) select this correct model. For a related construction for factor models, see Bai and Ng (2002). This motivates

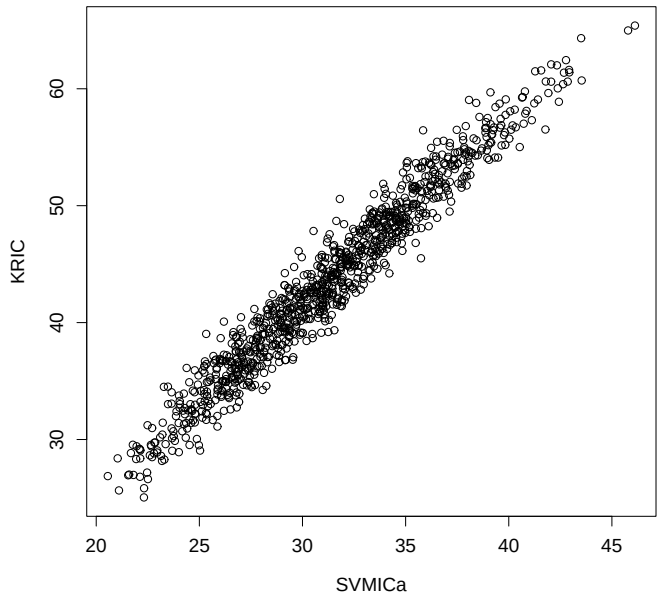

Figure 1: Values of KRIC and SVMICa in a simulation experiment, showing high correlation (0.975).

us to take $C(n) = \log(n)$, and we define our second criterion

$$\text{SVMICb}(S) = \sum_{i=1}^{n} \xi_i + \log(n)|S|. \tag{9}$$

It is immediate that the computational cost of both SVMICs is much lower than of the cross-validated error rate (10 more SVMs to train for 10-fold cross-validation) and of the kernel regularisation information criterion KRIC (which needs computations of the order $O(n^3)$ due to the matrix inversion). The best case is when the $\xi_{i,S}$ are directly available. Computing the SVMICs is only an $O(n)$ computation in that case, and usually even less when employing the property that

$$\xi_{i,S} \neq 0 \Leftrightarrow \alpha_{i,S} = 1.$$

When only α_S and Q_S are available, $\xi_{i,S}$ is computed using the relation

$$\xi_{i,S} = \Big[1 - y_i \sum_{\substack{j=1 \\ \alpha_{j,S}>0}}^{n} \alpha_{j,S}[Q_S]_{ij}\Big]_+.$$

This means that in the worst case, the computation time of the *SVMIC*s is $O(n^2)$, which is still faster than using either CV error rate or KRIC.

4. Simulation Results

We perform $M = 100$ simulation runs with the following settings. We generate $n \in \{25, 50, 100, 200\}$ independent observations x_i, $1 \leq i \leq n$ of dimension $p \in \{25, 50, 100, 200\}$, with distribution $\mathcal{N}(0, \sigma^2 I_p)$ where $\sigma^2 = 1$. For each observation we generate a class label $y_i \in \{-1, +1\}$, with $P(y_i = 1) = 1/2$. Finally, we let $\mu = (1/2, -1/2, -1/2, 1/2, 0, \ldots, 0)$ of dimension p, and set $x_i \leftarrow x_i + y_i \mu$ to separate the two classes to some extent. This implies that the optimal separating hyperplane is $x'\mu = 0$, such that $\hat{y} = +1$ if $x'\mu > 0$, resulting in a generalization error rate of $\Phi(-\|\mu\|_2/\sigma)$, with Φ the cumulative distribution function of a standard normal. In our example, with $\sigma = 1$ and $\|\mu\|_2 = 1$, we find an optimal generalization error rate of 0.159.

During each simulation run, we standardize the variables to improve the numerical performance of the SVM algorithm. The variables are ranked using either the Fisher score or based on the variable influence on w, as described in Section 2.3. For each of the nested models obtained in the variable ranking step, we compute (i) SVMICa and (ii) SVMICb as in (8) and (9). We compare their performance to (iii) ten-fold CV, (iv) Vapnik's GRM as in (4), (v) KRIC for the logistic Bayesian model for SVMs as in (5), and (vi) KRIC for the Sollich model for SVMs as in (6). An important remark is that for ten-fold CV, we employ the CV2 method, which includes the feature selection procedure in each cross-validation step, as suggested by Zhang et al. (2006). Computing the CV error rate in the usual way can lead to a (severely) biased estimate of the generalization error, and using CV2 reduces this bias.

The experiment is repeated with two different kernels (i) a linear kernel $K(x_1, x_2) = x_1' x_2$ leading to a linear decision rule (ii) a quadratic kernel $K(x_1, x_2) = (\gamma x_1' x_2 + 1)^2$, with $\gamma = 1/p$, the inverse of the number of variables, leading to a quadratic decision rule. The tuning parameter C in each SVM that we train is chosen to be $C = 1$, as we standardize the explicative variables a priori. This is also the standard setting for C for the `svm` procedure in the `R` software package. We experimented with other values of C in the range from 0.1 up to 10, and found only minor differences in the simulation outcomes. We test the accuracy of the classifiers computed from the selected input variables by estimating their generalization (out-of-sample) error rate from a test sample of 10000 new observations. These observations are generated in the same way as the training sample.

Table 1 reports the generalization error rates, obtained by averaging over the 100 simulation runs. An overall observation is that the error-rate based selection criteria (CV and GRM) have the worst performance. The performances of the KRICs and the new SVMICs are comparable. More precisely, we observe that the KRICs are better as a variable selection method for small sample sizes ($n = 25$), while the SVMICs give better results for larger sample sizes. This is especially apparent when the quadratic kernel is used. For a small number of observations compared to the number of variables, we also note that SVMICa slightly outperforms SVMICb in terms of generalization error rate, and that the opposite is true with many observations and fewer variables. The differences in generalization error rates become smaller as the number of variables grows. This is particularly true for CV, whose relative performance becomes better at large sample sizes. But SVMICa and SVMICb are still somewhat ahead, and have the advantage that they are much easier (and less time-intensive) to compute than the other criteria, included the KRICs having a computation time of order $O(n^3)$. Note that, as n grows, the generalization error rates of the models obtained by our two suggested criteria are converging towards the theoretically obtained minimal generalization error rate of 15.9%. Investigating which variable ranking criterion is better, results in case of linear

kernels to a strong preference for ranking with the Fisher score. For the quadratic kernel, it is slightly better to rank the variables based on variable influence on $\|w\|^2$.

Figure 2 presents the values of the 100 simulated generalization errors as boxplots, giving insight in the variability of the variable selection methods. For most of the cases it turns out that cross-validation is highly variable, while GRM has a small variability. This good property of GRM is, however, accompanied by a much higher average generalization error rate. Comparing the different information criteria shows that SVMICa is quite comparable to the KRICs. The SVMICb has a larger variability. In the setting with small sample size ($n = 25$) and relatively large number of variables (100), all methods, except for GRM, are comparable with respect to variability, but GRM has again the largest median error rate. Our main conclusion from this analysis is that SVMICa has a similar variability than the KRIC criteria, but SVMICb has a larger variability. Recall that the average error rates, as reported in Table 1, were of similar magnitude for all the four information criteria. Hence, when needing to choosing between the two newly proposed information criteria, we have a preference for SVMICa.

Given the variability of the generalization errors over the 100 simulation runs, see the boxplots in Figure 2, it is important to test whether the averages reported in Table 1 are also significantly different from each other. We performed standard t-tests, and most difference are indeed significant. For example, for the settings presented in Figure 1, we obtained that, at the 1% level, (a) all differences are significant, except between SVMICb and the 2 KRiCs (b) all differences are significant, except between SVMICa and the 2 KRICs (c) all differences are significant, except between SVMICb and the 2 KRICs (d) the differences with the GRM method are significant, the others not.

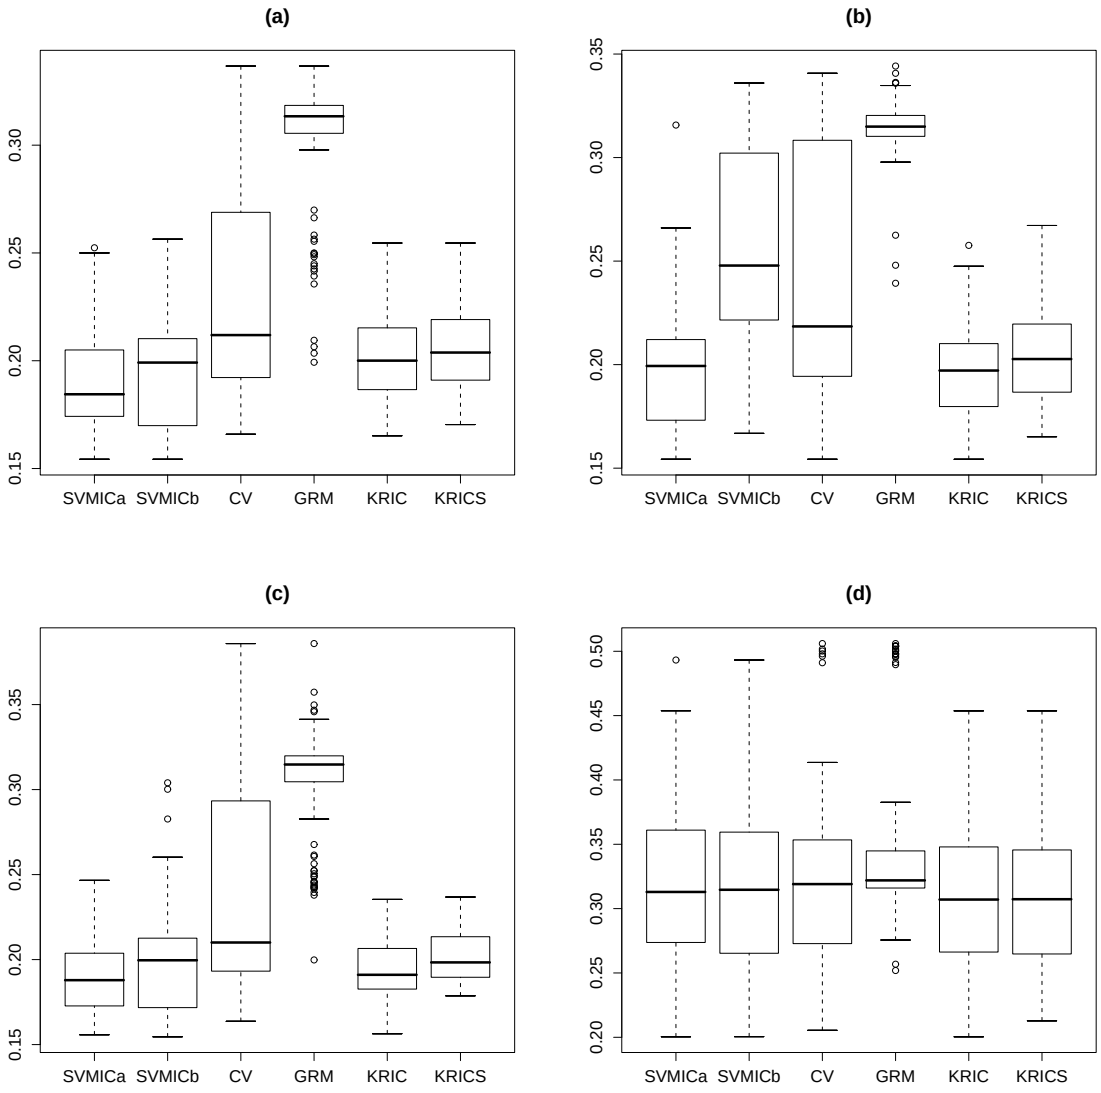

Figure 2: Generalization error rates for 100 simulation experiments, for $n = 100$, $p = 25$ (a) linear kernel, ranking with $\|w\|^2$, (b) linear kernel, ranking with Fisher score, (c) quadratic kernel, ranking with $\|w\|^2$, and for (d) $n = 25$, 100 variables, linear kernel and ranking with $\|w\|^2$.

Furthermore, we investigate which models are actually chosen by the different criteria. This information is reported in Table 2. For each setting, it shows how many times the correct subset of input variables, containing only the first four input variables, was chosen (C, correct). This table also shows how many times a too-sparse group of variables was selected (U, underfitting), and how many times a too-rich group of variables was chosen (O, overfitting). So an overfit means that all correct variables are selected, but in addition some superfluous ones, while an underfit selects a

subset of the important variables, but no irrelevant variables are included. The good performance of SVMICa and SVMICb might be due to the fact that these criteria seem to have the tendency to select a set of variables which includes all significant ones as the number of observations grows. The simulation results indicate that SVMICa behaves like AIC with its tendency to overfit. The SVMICb seems to share the property of BIC that it selects the correct model more often, if at least this true model is one of the possibilities to select from. The cross-validated error rate, and the general risk minimisation in particular, seem to have the tendency to ignore variables which nevertheless are important. As a consequence, the models that these criteria select are of poor predictive quality. The two KRICs of Kobayashi and Komaki (2006) share the overselection property exhibited by SVMICa, but the KRICs select excessive variables even more frequently than SVMICa. This can explain why these criteria perform somewhat worse when the number of observations is large, and why they outperform the proposed SVMICs when the number of observations is small, since the latter tend to underfit the model in the case of few observations.

This concludes the results for the case of two populations coming from an identical distribution, differing only in mean. Another case that we examined is where the variances of the two populations differ from each other. We performed a simulation study, in a similar way as the previous one, where the samples have been drawn from $\mathcal{N}(\mu, I_p)$ for class $+1$, and from $\mathcal{N}(-2\mu, 4I_p)$ for class -1.

The results of this simulation are summarized in Tables 3 and Table 4. We observe similar results as in the case where both populations had equal variance. Selection based on CV error rate and on GRM still perform rather poor. As before, the performances of the KRICs and SVMICs

are similar. More precisely, the SVMICs have an improved performance with respect to the KRICs when the sample size is large ($n \geq 50$) and the linear kernel is used, and the KRICs work slightly better for small sample sizes ($n = 25$). For the quadratic kernel, we notice a good performance of

the KRICs, which is only matched by SVMICa for larger sample sizes. From Table 4 we can again make the same observations as before when the linear kernel is used. For the quadratic kernel the SVMICs have more difficulty selecting all the relevant variables than the KRICs, which explains why the latter criteria have an improved performance here.

We also conducted a simulation experiment where the input variables were strongly correlated. First, the observations were generated as in the first simulation experiment. Then, we applied the transformation

$$x_{ij} = \rho x_{ik_j} + \varepsilon_{ij} \text{ with } \varepsilon_{ij} \sim \mathcal{N}(0, \rho^2) \text{ i.i.d.}$$

where $i = 1, \ldots, n$, k_j is chosen arbitrarily between 1 and 4, and $4 < j \leq p/2$, such that about half of the unimportant input variables are correlated with the four important ones. The parameter $|\rho| < 1$ controls the degree of correlation. We have chosen $\rho = 0.8$ and found similar results (not reported) as for the case where the variances of both class-population differ.

5. Tests on Real Data Sets

We compare the performance of the new methods with that of the other discussed criteria on several real-world data sets. We use some of the benchmark data sets used in Rakotomamonjy (2003), and in Rätsch et al. (2001). The data sets used are the Pima Indians Diabetes database (768 observations, 8 variables), the Statlog Cleveland Heart Disease database (303 observations, 14 variables), and Leo Breiman's ringnorm and twonorm data sets (both 7400 observations, 20 variables). These data sets are available from the UCI Machine Learning Repository (the first two), and the Delve Repository (last two). We perform 100 random splits of the data in a training sample and a test sample, where the size of the training sample is chosen as $\sqrt{2n}$, with n the total number of observations in the data set. We chose the size of the training set such that there is a sufficient amount of observations in the test sample to estimate the generalization (out-of-sample) error rate. The training sample size is relatively small, such that the computation time for the KRIC remains within bounds. For each of these partitions we perform variable selection on the training sample exactly as in the simulation study. We first rank the variables to retain p stacked subsets of input variables, and then use the information criteria to select the variables that best explain the training data. Then, we predict the class labels for the test sample, and use these predictions to estimate the generalization error rate. We use variable ranking based on variable influence on $\|w\|^2$ as well as on Fisher score, and we use a linear, quadratic and radial kernel.

The estimated generalization error rates are presented in Table 5 for each data set and estimation setting. We observe that the KRICs are the preferred choice of variable selection criterion in terms of generalization error rate for the 'twonorm' and 'heart' data sets. For the 'ringnorm' and 'diabetes' data sets the difference in performance between the KRICs and our newly proposed SVMICs is less pronounced. The predictive performance of the models selected by SVMICa are for most settings comparable to that of the KRIC, while being much faster to compute. These results are consistent across all settings. The CV error rate and especially the GRM have a poor performance, which is in line of the results obtained in the simulation.

From these results, and the results obtained in Section 4, we suggest to use either the SVMICa or the SVMICb if a preliminary analysis of the data or a priori knowledge indicates that the true decision function is almost linear. When it differs strongly from a linear function, the researcher has a choice between the ease of computation of the support vector machine information criteria, or the

	Ranking:	Variable influence on $\|\|w\|\|$			Fisher scores

Table 5: Generalization error rates (%) for variable selection applied to four data sets. Two variable ranking schemes and three types of kernel are used for each of the criteria.

somewhat improved predictive performance, though with higher computational cost, of the kernel regularization information criterion.

Finally, we applied the newly proposed information criteria for variable selection to two large data sets, the "Madelon" ($n = 2000, p = 500$) and "Arcene" data ($n = 100, p = 10000$). These data sets were part of the NIPS 2003 feature selection, and are described in detail in Guyon et al. (2006). Given the high dimensionality of these data, the variables were ranked according to the Fisher score. We used a linear kernel and computed balanced error rates (BER), that is the average of the error rate of the positive class and the error rate of the negative class. When using SVMICa we obtain a BER of 43.0% for the Madelon data, and 31.1% for the Arcene data. For SVMICb we get 37.3% and 31.1%, respectively. In Guyon et al. (2006, 2007) the BER of other feature selection methods is presented, and it turns out that several other methods yield much better performance on these data. A possible explication is that we used a standard SVM, without any optimal tuning of the regularization parameters.

6. Conclusions

In this paper we considered the problem of variable selection in support vector machines. We proposed two new information criteria, SVMICa and SVMICb, which allow us to evaluate the suitability of the selected subset of variables for predictive purposes, without much additional computational costs. We provided an argumentation for these criteria, linking SVMICa to the KRIC of Kobayashi and Komaki (2006), and justifying SVMICb with the need for a consistent selection criterion. We demonstrated the effectiveness of these criteria in a simulation study, where we compared their predictive performance to the KRIC, cross-validation and general risk minimization. Especially for decision functions which are close to an affine function, we found that SVMICa and SVMICb performed the best of all tested criteria, and were also the easiest to compute. For more complicated decision functions, we found that SVMICa still performs well for selecting models with good generalization properties. We repeated the experiment on several real data examples, and the result confirmed the good properties of these newly proposed criteria. In particular we showed that cross-validation criteria are outperformed in generalization error by the new information criteria, where the latter are coming at almost no additional computational cost.

The aim of our paper was to propose an information criterion for a standard SVM. We do not claim that the procedure is outperforming other very advanced feature selection methods, which are not relying on a standard SVM. Obtaining information criteria for other machine learners is an interesting topic for future research. Another research question is how suitable the information criteria are for optimal tuning of the regularization and other parameters of the SVM, without necessarily selecting a subset of input variables. Finally, it would be interesting to continue on the theoretical verification of the good performance of our two proposed criteria, and for example try to obtain consistency results for the SVM information criteria.

Acknowledgments

We thank the Editors, Professor Guyon and Professor Alamdari, and the reviewers for their constructive and insightful comments on the first submitted version of this paper.

Abstract

Closed sets have been proven successful in the context of compacted data representation for association rule learning. However, their use is mainly descriptive, dealing only with unlabeled data. This paper shows that when considering labeled data, closed sets can be adapted for classification and discrimination purposes by conveniently contrasting covering properties on positive and negative examples. We formally prove that these sets characterize the space of relevant combinations of features for discriminating the target class. In practice, identifying relevant/irrelevant combinations of features through closed sets is useful in many applications: to compact emerging patterns of typical descriptive mining applications, to reduce the number of essential rules in classification, and to efficiently learn subgroup descriptions, as demonstrated in real-life subgroup discovery experiments on a high dimensional microarray data set.

Keywords: rule relevancy, closed sets, ROC space, emerging patterns, essential rules, subgroup discovery

1. Introduction

Rule discovery in data mining mainly explores unlabeled data and the focus resides on finding itemsets that satisfy a minimum support constraint (namely frequent itemsets), and from them, constructing rules over a certain confidence. This is the case of the well-known Apriori algorithm of Agrawal et al. (1996), and its successors, for example, Brin et al. (1997), Han and Pei (2000) and Zaki (2000b) among others. From a different perspective, machine learning is mainly concerned with the analysis of class labeled data, mainly resulting in the induction of classification and prediction rules, and—more recently—also descriptive rules that aim at discovering insightful knowledge from the data (subgroup discovery, contrast set mining). Traditional rule learning algorithms for classification include CN2 (Clark and Niblett, 1989) and Ripper (Cohen, 1995). Other approaches have been proposed that are based on the association rule technology but applied to class labeled data, for example, a pioneer work towards this integration is Liu et al. (1998), and later followed by others, for example, the Apriori-C classifier by Jovanoski and Lavrač (2001), and the Essence algorithm for inducing "essential" classification rules based on the covering properties of frequent itemsets, by Baralis and Chiusano (2004).

Subgroup discovery is a learning task directed at finding subgroup descriptions that are characteristic for examples with a certain property (class) of interest. Special rule learning algorithms for subgroup discovery include Apriori-SD (Kavšek and Lavrač, 2006), CN2-SD (Lavrač et al., 2004) or SD (Gamberger and Lavrač, 2002). The goal of these descriptive mining algorithms is to find characteristic rules as combinations of features with high coverage. If there are several rules with the same coverage, most specific rules (with more features) are appropriate for description and explanation purposes. On the other hand, the closely related task of contrast set mining aims at capturing discriminating features that contrast instances between classes. Algorithms for contrast set mining are STUCCO (Bay and Pazzani, 2001), and also an innovative approach presented in the form of mining emerging patterns (Dong and Li, 1999). Basically, Emerging Patterns (EP) are sets of features in the data whose supports increase significantly from one class to another. Interestingly, also good classifiers can be constructed by using the discriminating power of the mined EPs, for example, see Li et al. (2000). A condensed representation of EPs, defined in terms of a support growth rate measure, has been studied in Soulet et al. (2004).

Indeed, we can see all these tasks on labeled data (learning classification rules, subgroup discovery, or contrast set mining) as a rule induction problem, that is, a process of searching a space of concept descriptions (hypotheses in the form of rule antecedents). Some descriptions in this hypothesis space may turn out to be more relevant than others for characterizing and/or discriminating the target class. The question of relevance has attracted much attention in the context of feature selection for propositional learning (Koller and Sahami, 1996; Liu and Motoda, 1998). This is an important problem since non-relevant features can be excluded from the learning process, thus facilitating the search for the final solution and increasing the quality of the final rules. Feature filtering can be applied during the learning process, or also, by pre-processing the set of training examples (Lavrač et al., 1999; Lavrač and Gamberger, 2005).

Searching for relevant descriptions for rule construction has been extensively addressed in descriptive data mining as well. A useful insight was provided by closure systems (Carpineto and Romano, 2004; Ganter and Wille, 1998), aimed at compacting the whole space of descriptions into a reduced system of relevant sets that formally conveys the same information as the complete space. The approach has successfully evolved towards mining closed itemsets (see, for example, Pasquier et al., 2001; Zaki, 2004). Intuitively, closed itemsets can be seen as maximal sets of items/features covering a maximal set of examples. Despite its success in the data mining community, the use of closed sets is mainly descriptive. For example, they can be used to limit the number of association rules produced without information loss (see, for example, how to characterize rules with respect to their antecedent in Crémilleux and Boulicaut, 2002).

To the best of our knowledge, the notion of closed sets has not yet been exported to labeled data, nor used in the learning tasks for labeled data described above. In this paper we show that raw closed sets can be adapted for discriminative purposes by conveniently contrasting covering properties on positive and negative examples. Moreover, by exploiting the structural properties and the feature relevancy theory of Lavrač et al. (1999) and Lavrač and Gamberger (2005), we formally justify that the obtained closed sets characterize the space of relevant combinations of features for discriminating the target class.

In practice, our notion of closed sets in the labeled context (described in Sections 3 and 4) can be naturally interpreted as non-redundant descriptive rules (discriminating the target class) in the ROC space (Section 5). We also show that finding closed sets in labeled data turns out to be very useful in many applications. We have applied our proposal to reduce the number of emerging

patterns (Section 6.1), to compress the number of essential rules (Section 6.2), and finally, to learn descriptions for subgroup discovery on potato microarray data (Section 6.3).[1]

2. Background

Features, used for describing the training examples, are logical variables representing attribute-value pairs (called items in the association rule learning framework of Agrawal et al., 1996). If $F = \{f_1, \ldots, f_n\}$ is a fixed set of features, we can represent a training example as a tuple of features $f \in F$ with an associated class label. For instance, Table 1 contains examples for the simplified problem of contact lens prescriptions (Witten and Frank, 2005). Patients are described by four attributes: Age, Spectacle prescription, Astigmatism and Tear production rate; and each tuple is labeled with a class label: none, soft or hard. Then, F is the set of all attribute-value pairs in the data, that is, $F = \{$Age=young, $\ldots$, Tear=normal$\}$ (the class label is not included in F), and each example (a patient) corresponds to a subset of features in F with an associated class label. This small data set will be used throughout the paper to ease the understanding of our proposals.

We consider two-class learning problems where the set of examples E is divided into positives (P, target-class examples identified by label $+$) and negatives (N, labeled by $-$), and $E = P \cup N$. Multi-class problems can be translated to a series of two-class learning problems: each class is once selected as the target class (positive examples), while examples of all the other classes are treated as non-target class examples (thus, negative examples). For instance, when class soft of Table 1 is the target class, all examples with label soft are considered as positive, as shown in Table 2, and all examples labeled none and hard are considered as negative.

Given a rule $X \rightarrow +$ formed from a set of features $X \subseteq F$, *true positives* (TP) are those positive examples covered by the rule, that is, $p \in P$ such that $X \subseteq p$; and *false positives* (FP) are those negative examples covered by the rule, that is, $n \in N$ such that $X \subseteq n$; reciprocally, *true negatives* (TN) are those negative examples not covered by X. Later, we will see that some combinations of features $X \subseteq F$ produce more relevant antecedents than others for the rules $X \rightarrow +$. Our study will focus specifically on the combinations of features from the universe F which best define the space of non-redundant rules for the target class. We will do it by integrating the notion of closed itemsets and the concept of feature relevancy proposed in previous works.

2.1 Closed Itemsets

From the practical point of view of data mining algorithms, closed itemsets are the largest sets (w.r.t. set-theoretic inclusion) among those other itemsets occurring in the same examples (Bastide et al., 2000a; Crémilleux and Boulicaut, 2002; Pasquier et al., 2001; Taouil et al., 2000; Zaki, 2000a, 2004; Zaki and Ogihara, 1998). Formally, let *support of itemset* $X \subseteq F$, denoted by $\mathrm{supp}(X)$, be the number of examples in the data where X is contained. Then: a set $X \subseteq F$ is said to be *closed* when there is no other set $Y \subseteq F$ such that $X \subset Y$ and $\mathrm{supp}(X) = \mathrm{supp}(Y)$.

In the example of Table 2, the itemset corresponding to $\{$Age=young$\}$ is not closed because it can be extended to the maximal set $\{$Age=young, Astigmatism=no, Tear=normal$\}$ that has the same support in this data. Notice that by treating positive examples separately, the positive label will be already implicit in the closed itemsets mined on the target class data. So, here we will work by

Table 2: The set of positive examples when class soft of the contact lens data of Table 1 is selected as the target class. These examples form the set P of positive examples, while instances of classes none and hard are considered non-target, thus treated together as negative examples N. Note that examples are represented here in a simplified tabular form instead of the feature set representation.

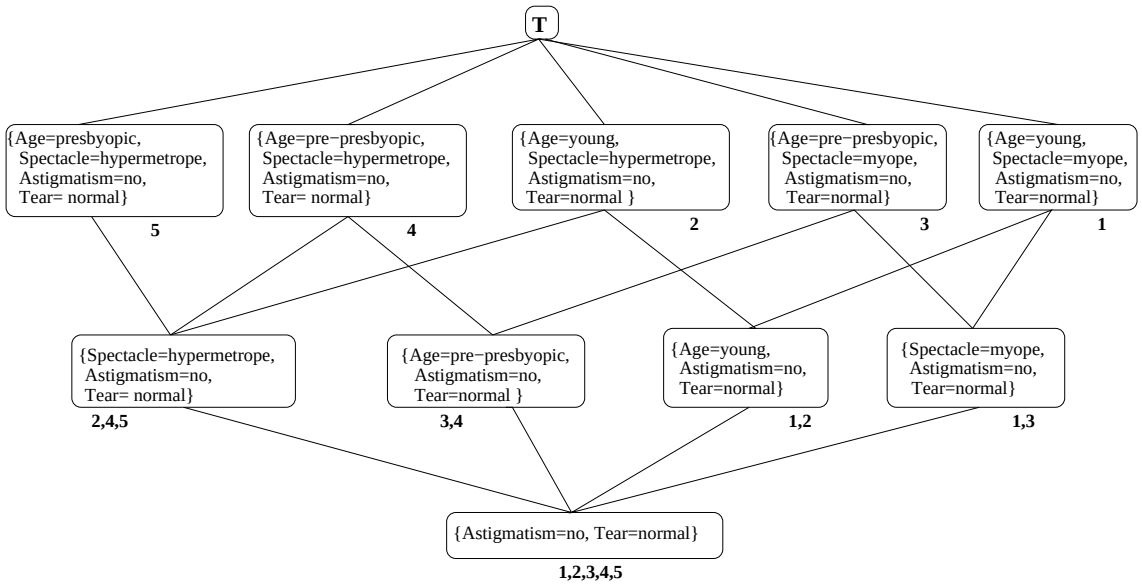

Figure 1: The lattice of closed itemsets for data in Table 2.

constructing the closure system of items on our positive examples and use this system to study the structural properties of the closed sets to discriminate the implicit label. Many efficient algorithms have been proposed for discovering closed itemsets over a certain minimum support threshold; see a compendium of them in Goethals and Zaki (2004).

The foundations of closed itemsets are based on the definition of a closure operator on a lattice of items (Carpineto and Romano, 2004; Ganter and Wille, 1998). The standard closure operator Γ for items acts as follows: the closure $\Gamma(X)$ of a set of items $X \subseteq F$ includes all items that are present in all examples having all items in X. According to the classical theory, operator Γ satisfies the following properties: Monotonicity: $X \subseteq X' \Rightarrow \Gamma(X) \subseteq \Gamma(X')$; Extensivity: $X \subseteq \Gamma(X)$; and Idempotency: $\Gamma(\Gamma(X)) = \Gamma(X)$.

From the formal point of view of Γ, closed sets are those coinciding with their closure, that is, for $X \subseteq F$, X is *closed* iff $\Gamma(X) = X$. Also, when $\Gamma(Y) = X$ for a set $Y \neq X$, it is said that Y is a *generator* of X. By extensivity of Γ we always have $Y \subseteq X$ for Y generator of X. Intensive work has focused on identifying which collection of generators is good to ensure that all closed sets can be produced. The named δ-free sets in Boulicaut et al. (2003) are minimal generators when $\delta = 0$, and these are equivalent to key patterns in Bastide et al. (2000b). Different properties of these δ-free sets generators in Boulicaut et al. (2003) have been studied for different values of δ.

Considering Table 2, we have the following $\Gamma(\{\text{Age=young}\}) = \{\text{Age=young, Astigmatism=no, Tear=normal}\}$. Then, $\{\text{Age=young}\}$ is a generator of this closed set. Note that for $\Gamma(Y) = X$, both Y and X are sets with exactly the same support in the data, but X being a largest set of items, that is, $Y \subset X$ for all Y such that $\Gamma(Y) = X$. This property is ensured by the extensivity of this operator. Moreover, closed sets formalized with operator Γ are exactly those sets obtained in closed set mining process and defined above, which present many advantages (see, for example, Balcázar and Baixeries, 2003; Crémilleux and Boulicaut, 2002).

Closed itemsets are lossless in the sense that they uniquely determine the set of all frequent itemsets and their exact support (cf. Pfaltz, 1996; Zaki and Ogihara, 1998, for more theoretical details). Closed sets of items can be graphically organized in a Hasse diagram, where each node corresponds to a closed itemset, and there is an edge between two nodes if and only if they are comparable (w.r.t. set-theoretic inclusion) and there is no other intermediate closed itemset in the lattice. In this partial order organization, ascending/descending paths represent the subset/superset relation. Typically, the top of this lattice is represented by a constant T corresponding to a set of items not included in any example.

Figure 1 shows the lattice of closed itemsets obtained from data from Table 2. Each node is depicted along with the set of example identifiers where the closed set occurs. Notice that all closed itemsets with the same support cover a different subset of transactions of the original data. In practice, such exponential lattices are not completely constructed, as only a list of closed itemsets over a certain minimum support suffices for practical purposes. Therefore, instead of closed sets one needs to talk about *frequent closed sets*, that is, those closed sets over the minimum support constraint given by the user. Also notice the difference of frequent closed sets from the popular concept of maximal frequent sets (see, for example, Tan et al., 2005), which refers to those sets for which none of their supersets are frequent.

Obviously, imposing a minimum support constraint will eliminate the largest closed sets whose support is typically very low. The impact of such constraint depends on the application. In general, there exists a trade-off between quality and speed up of the process. In the following we consider a theoretical framework with all closed sets; in practice though, we will need a minimum support constraint to consider only the frequent ones.

2.2 Relevant Features for Discrimination

The main aim of the theory of relevancy, described in Lavrač et al. (1999) and Lavrač and Gamberger (2005), is to reduce the hypothesis space by eliminating irrelevant features from F in the pre-processing phase. Other related work, such as Koller and Sahami (1996) and Liu and Motoda (1998), eliminate features in the model construction phase. However, here we concentrate on the elimination of irrelevant features in the preprocessing phase, as proposed by Lavrač and Gamberger (2005):

Definition 1 (Coverage of features) *Feature $f \in F$ covers another feature $f' \in F$ if and only if true positives of f' are a subset of true positives of f, and true negatives of f' are a subset of true negatives of f. In other words,* $\mathrm{TP}(f') \subseteq \mathrm{TP}(f)$ *and* $\mathrm{TN}(f') \subseteq \mathrm{TN}(f)$ *(or equivalently,* $\mathrm{TP}(f') \subseteq \mathrm{TP}(f)$ *and* $\mathrm{FP}(f) \subseteq \mathrm{FP}(f')$*).*

Using the definition of feature coverage, we further define that $f' \in F$ is *relatively irrelevant* if there exists another feature $f \in F$ such that f covers f'. To illustrate this notion we take the data of Table 1: if examples of class none form our positives and the rest of examples are considered negative, then the feature Tear=reduced covers Age=young, hence making this last feature irrelevant for the discrimination of the class none.

Other notions of irrelevancy described in Lavrač and Gamberger (2005) consider a minimum coverage constraint in the true positives or accordingly, on the true negatives.

3. Closed Sets on Target-class Data

Given a set of examples $E = P \cup N$ it is trivial to realize that for any rule $X \rightarrow +$ with a set of features $X \subseteq F$, the support of itemset X in P (target class examples) exactly corresponds to the number of true positives (TP) of the rule; reciprocally, the support of X in N (non-target class examples) is the number of false positives (FP) of the rule. Also, because of the anti-monotonicity property of support (i.e., $Y \subseteq X$ implies $\text{supp}(X) \leq \text{supp}(Y)$) the following useful property can be easily stated.

Proposition 2 *Let $X, Y \subseteq F$ such that $Y \subseteq X$, then* $\text{TP}(X) \subseteq \text{TP}(Y)$ *and* $\text{FP}(X) \subseteq \text{FP}(Y)$.

Proof The anti-monotonicity property of support on the set of positive examples ensures that $|\text{TP}(X)| \leq |\text{TP}(Y)|$. Since $Y \subseteq X$, we necessarily have $\text{TP}(X) \subseteq \text{TP}(Y)$. The same reasoning applies to the set of negative examples. ■

For convenience, let $\text{supp}^+(X)$ denote the support of the set X in the positive set of examples P, and $\text{supp}^-(X)$ the support in the negative set of examples N. Notice that for a rule $X \rightarrow +$ we indeed have that $\text{supp}^+(X) = |\text{TP}(X)|$ and $\text{supp}^-(X) = |\text{FP}(X)|$. In the following we will use one notation or the other according to the convenience of the context.

Following from the last proposition, the next property can be readily seen.

Lemma 3 *Feature $f \in F$ covers another feature $f' \in F$ (as in Definition 1), iff* $\text{supp}^+(\{f'\}) = \text{supp}^+(\{f, f'\})$ *and* $\text{supp}^-(\{f\}) = \text{supp}^-(\{f, f'\})$.

Proof That f covers f' can be formulated as $\text{TP}(f') \subseteq \text{TP}(f)$ and $\text{FP}(f) \subseteq \text{FP}(f')$. Because all the true positives of f' are also covered by f, it is true that $\text{TP}(f') = \text{TP}(f, f')$; similarly, because all the false positives of f are also covered by f' we have $\text{FP}(f) = \text{FP}(f, f')$. These two facts directly imply that $\text{supp}^+(\{f'\}) = \text{supp}^+(\{f, f'\})$ and $\text{supp}^-(\{f\}) = \text{supp}^-(\{f, f'\})$.

The other direction is proved as follows. The anti-monotonicity property of Proposition 2 applied over $\{f'\} \subseteq \{f, f'\}$ leads to $\text{TP}(f, f') \subseteq \text{TP}(f')$. Indeed, from $\text{supp}^+(\{f'\}) = \text{supp}^+(\{f, f'\})$ we have $|\text{TP}(f')| = |\text{TP}(f, f')|$, which along with $\text{TP}(f, f') \subseteq \text{TP}(f')$ implies an equivalence of true positives between these two sets: that is, $\text{TP}(f, f') = \text{TP}(f')$. From here we deduce $\text{TP}(f') \subseteq \text{TP}(f)$. Exactly the same reasoning applies to the negatives. Proposition 2 ensures that $\text{FP}(f, f') \subseteq \text{FP}(f)$ because $\{f\} \subseteq \{f, f'\}$. But from $\text{supp}^-(\{f\}) = \text{supp}^-(\{f, f'\})$ we have $|\text{FP}(f)| = |\text{FP}(f, f')|$, which together with $\text{FP}(f, f') \subseteq \text{FP}(f)$ leads to the equivalence of the false positives between these two sets: that is, $\text{FP}(f) = \text{FP}(f, f')$. Then, we deduce $\text{FP}(f) \subseteq \text{FP}(f')$. That is f covers f' as in Definition 1. ■

Indeed, this last result allows us to rewrite, within the data mining language, the definition of relevancy proposed by Lavrač et al. (1999) and Lavrač and Gamberger (2005): a feature f is *more relevant* than f' when $\text{supp}^+(\{f'\}) = \text{supp}^+(\{f, f'\})$ and $\text{supp}^-(\{f\}) = \text{supp}^-(\{f, f'\})$. For instance, the support of {Age=young} over the class none of data from Table 1 is equal to the support of {Age=young, Tear=reduced} in this same class none ; at the same time, the support of {Tear=reduced} is zero in the negatives (formed here by the classes soft and hard together), thus equal to the support in the negatives of {Age=young, Tear=reduced}. So, the feature Age=young is irrelevant with respect to Tear=reduced, as we identified in Section 2.1. In other words, f' is

irrelevant with respect to f if the occurrence of f' always implies the presence of f in the positives, and at the same time, f always implies the presence of f' in the negatives.

To the effect of our later arguments it will be useful to cast the result of Lemma 3 in terms of the formal closure operator Γ. This will provide the desired mapping from relevant sets of features to the lattice of closed itemsets constructed on target class examples. Again, because we need to formalize our arguments against positive and negative examples separately, we will use Γ^+ or Γ^- for the closure of itemsets on P or N respectively.

Lemma 4 *A feature f is more relevant than f' iff $\Gamma^+(\{f'\}) = \Gamma^+(\{f, f'\})$ and $\Gamma^-(\{f\}) = \Gamma^-(\{f, f'\})$.*

Proof It follows immediately from Lemma 3 and the formalization of operator Γ. A feature f is more relevant than f' when f covers f' according to Definition 1. Then, by Lemma 3 we have that $\text{supp}^+(\{f'\}) = \text{supp}^+(\{f, f'\})$ and $\text{supp}^-(\{f\}) = \text{supp}^-(\{f, f'\})$. By construction of Γ, this means that the sets $\{f'\}$ and $\{f, f'\}$ have the same closure on the positives, and the sets $\{f\}$ and $\{f, f'\}$ have the same closure on the negatives. That is: because Γ is an extensive operator, we can rewrite it as $\Gamma^+(\{f'\}) = \Gamma^+(\{f, f'\})$ and $\Gamma^-(\{f\}) = \Gamma^-(\{f, f'\})$. ■

Interestingly, operator Γ is formally defined for the universe of sets of items, so that these relevancy results on single features can be directly extended to sets of features. This provides a proper generalization, which we express in the following definition.

Definition 5 (Relevancy of feature sets) *Set of features $X \subseteq F$ is more relevant than set $Y \subseteq F$ iff $\Gamma^+(Y) = \Gamma^+(X \cup Y)$ and $\Gamma^-(X) = \Gamma^-(X \cup Y)$.*

To illustrate Definition 5 take the positive examples from Table 2, with negative data formed by classes none and hard together. Feature Spectacle=myope alone cannot be compared to feature Astigmatism=no alone with Definition 1 (because Astigmatism=no does not always imply Spectacle=myope in the negatives). For the same reason, Spectacle=myope cannot be compared to feature Tear=normal alone. However, when considering these two features together, then Spectacle=myope turns out to be irrelevant w.r.t. the set {Astigmatism=no, Tear=normal}. So, the new semantic notion of Definition 5 allows us to decide if a set of features is structurally more important than another for discriminating the target class. In the language of rules: rule $Y \rightarrow +$ is *irrelevant* if there exists another rule $X \rightarrow +$ satisfying two conditions: first, $\Gamma^+(Y) = \Gamma^+(X \cup Y)$; and second, $\Gamma^-(X) = \Gamma^-(X \cup Y)$. E.g., when soft is the target class: the rule Spectacle=myope $\rightarrow +$ is not relevant because at least the rule {Astigmatism=no, Tear=normal} $\rightarrow +$ will be more relevant.

Finally, from the structural properties of operator Γ and from Proposition 2, we can deduce that the semantics of relevant sets in Definition 5 is consistent.

Lemma 6 *A set of features $X \subseteq F$ is more relevant than set $Y \subseteq F$ (Definition 5) iff* $\text{TP}(Y) \subseteq \text{TP}(X)$ *and* $\text{FP}(X) \subseteq \text{FP}(Y)$.

Proof That X is more relevant than Y means $\Gamma^+(Y) = \Gamma^+(X \cup Y)$ and $\Gamma^-(X) = \Gamma^-(X \cup Y)$. Proposition 2 ensures that $\text{TP}(X \cup Y) \subseteq \text{TP}(Y)$ because $Y \subseteq X \cup Y$. Then, from $\Gamma^+(Y) = \Gamma^+(X \cup Y)$ we naturally have that $|\text{TP}(Y)| = |\text{TP}(X \cup Y)|$ (by formalization of Γ), which together with $\text{TP}(X \cup Y) \subseteq \text{TP}(Y)$ leads to the equality of the true positives between the following sets: $\text{TP}(X \cup Y) = \text{TP}(Y)$.

From here, $\mathrm{TP}(Y) \subseteq \mathrm{TP}(X)$. On the other hand, it is implied by the definition of relevancy that $Y \subseteq X$, thus directly from Proposition 2 we have that $\mathrm{FP}(X) \subseteq \mathrm{FP}(Y)$.

The other direction is proved as follows. Let X and Y be two sets such that $\mathrm{TP}(Y) \subseteq \mathrm{TP}(X)$ and $\mathrm{FP}(X) \subseteq \mathrm{FP}(Y)$. As all the true positives of Y are also covered by X, it is true that $\mathrm{TP}(Y) = \mathrm{TP}(X \cup Y)$; similarly, as all the false positives of X are also covered by Y we have that $\mathrm{FP}(X) = \mathrm{FP}(X \cup Y)$. This directly implies that $\mathrm{supp}^+(Y) = \mathrm{supp}^+(X \cup Y)$ and $\mathrm{supp}^-(X) = \mathrm{supp}^-(X \cup Y)$. By construction of Γ, this means we can directly rewrite this as $\Gamma^+(Y) = \Gamma^+(X \cup Y)$ and $\Gamma^-(X) = \Gamma^-(X \cup Y)$. That is: set X is more relevant than Y by Definition 5. ■

In the language of rules, Lemma 6 implies that when a set of features $X \subseteq F$ is more relevant than $Y \subseteq F$, then rule $Y \rightarrow +$ is less relevant than rule $X \rightarrow +$ for discriminating the target class. Moreover, Lemma 6 proves the consistency of Definition 5. If we consider $X = \{f\}$ and $Y = \{f'\}$, then the definition is simply reduced to the coverage of Definition 1. Yet, the interestingness of Definition 5 is that we can use this new concept to study the relevancy of itemsets (discovered in the mining process) for discrimination problems. Also, it can be immediately seen that if X is more relevant than Y in the positives, then Y will be more relevant than X in the negatives (by just reversing Definition 5).

Next subsection characterizes the role of closed itemsets to find relevant sets of features for discrimination. Notice that the first condition to consider a set X more relevant than Y in the discrimination of target class examples is that $\Gamma^+(Y) = \Gamma^+(X \cup Y)$. So, the closure system constructed on the positive examples will be proved to be structurally important for inducing target class rules.

3.1 Closed Sets for Discrimination

Together with the result of Lemma 6, it can be shown that only closed itemsets mined in the set of positive examples suffice for discrimination.

Theorem 7 *Let $Y \subseteq F$ be a set of features such that $\Gamma^+(Y) = X$ and $Y \neq X$. Then, set Y is less relevant than X (as in Definition 5).*[2]

Proof By the extensivity property of Γ we know $Y \subseteq X$. Then, Proposition 2 ensures that $\mathrm{TP}(X) \subseteq \mathrm{TP}(Y)$ and $\mathrm{FP}(X) \subseteq \mathrm{FP}(Y)$. However, by hypothesis we have $\Gamma^+(Y) = X$, which by construction ensures that $|\mathrm{TP}(Y)| = |\mathrm{TP}(X)|$; but because $Y \subseteq X$, it must be true that $\mathrm{TP}(Y) = \mathrm{TP}(X)$. In all, we obtained that $\mathrm{TP}(Y) = \mathrm{TP}(X)$ and $\mathrm{FP}(X) \subseteq \mathrm{FP}(Y)$, and from Lemma 6 we have that X is more relevant than Y. ■

Typically, in approaches such as Apriori-C (Jovanoski and Lavrač, 2001), Apriori-SD (Kavšek and Lavrač, 2006) or RLSD (Zhang et al., 2004), frequent itemsets with very small minimal support constraint are initially mined and subsequently post-processed in order to find the most suitable rules

2. We are aware that some generators Y of a closed set X might be exactly equivalent to X in terms of TP and FP, thus forming equivalence classes of rules (i.e., $Y \rightarrow +$ might be equivalent to $X \rightarrow +$). The result of this theorem characterizes closed sets in the positives as those representatives of relevant rules; so, any set which is not closed can be discarded, and thus, efficient closed mining algorithms can be employed for discrimination purposes. The next section will approach the notion of the shortest representation of a relevant rule, which will be conveyed by these mentioned equivalent generators.

for discrimination. The new result presented here states that not all frequent itemsets are necessary: as shown in Theorem 7 only the closed sets have the potential to be relevant.

To illustrate this result we use again data in Table 2, where $\Gamma^{+}(\{\text{Astigmatism=no}\}) = \{\text{Astigmatism=no, Tear=normal}\}$. Thus, rule Astigmatism=no $\rightarrow +$ can be discarded: it covers exactly the same positives as $\{$Astigmatism=no, Tear=normal$\}$, but more negatives. Thus, a rule whose antecedent is $\{$Astigmatism=no, Tear=normal$\}$ would be preferred for discriminating the class soft.

However, Theorem 7 simply states that those itemsets which are not closed in the set of positive examples cannot form a relevant rule to discriminate the target class, thus they do not correspond to a relevant combination of features. In other words, closed itemsets suffice but some of them might not be necessary to discriminate the target class. It might well be that a closed itemset is irrelevant with respect to another closed itemset in the system.

As illustrated above, when considering class soft as the target class (identified by $+$), we had that feature Spectacle=myope is irrelevant with respect to set $\{$Astigmatism=no, Tear=normal$\}$; yet, set $\{$Spectacle=myope, Astigmatism=no, Tear=normal$\}$ is closed in the system (see the lattice of Figure 1). Indeed, this latter closed set is still irrelevant in the system according to our Definition 5 and can be pruned away. The next section is dedicated to the task of reducing the closure system of itemsets to characterize the final space of relevant sets of features.

4. Characterizing the Space of Relevant Sets of Features

This section studies how the dual closure system on the negative examples is used to reduce the lattice of closed sets on the positives. This reduction will characterize a complete space of relevant sets of features for discriminating the target class. First of all, we raise the following two important remarks following from Proposition 2.

Remark 8 *Given two different closed sets on the positives X and X' such that $X \nsubseteq X'$ and $X' \nsubseteq X$ (i.e., there is no ascending/descending path between them in the lattice), then they cannot be compared in terms of relevancy, since they cover different positive examples.*

We exemplify Remark 8 with the lattice in Figure 1. The two closed sets: $\{$Age=young, Astigmatism=no, Tear=normal$\}$ and $\{$Spectacle=myope, Astigmatism=no, Tear=normal$\}$, are not comparable with subset relation: they cover different positive examples and they cannot be compared in terms of relevance.

Remark 9 *Given two closed sets on the positives X and X' with $X \subset X'$, we have by construction that* $\text{TP}(X') \subset \text{TP}(X)$ *and* $\text{FP}(X') \subseteq \text{FP}(X)$ *(from Proposition 2). Notice that because X and X' are different closed sets in the positives,* $\text{TP}(X')$ *is necessarily a proper subset of* $\text{TP}(X)$*; however, regarding the coverage of false positives, this inclusion is not necessarily proper.*

To illustrate Remark 9 we use the lattice of closed itemsets in Figure 1. By construction the closed set $\{$Spectacle=myope, Astigmatism=no, Tear=normal$\}$ from Figure 1 covers fewer positives than the proper predecessor $\{$Astigmatism=no, Tear=normal$\}$. However, both closed sets cover exactly one negative example. In this case $\{$Astigmatism=no, Tear= normal$\}$ is more relevant than $\{$Spectacle=myope, Astigmatism=no, Tear=normal$\}$.

Remark 9 points out that two different closed sets in the positives, yet being one included in the other, may end up covering exactly the same set of false positives. In this case, we would like

Transaction occurrence list	Closed Set
$1,2,3,4,5$	{Astigmatism=no, Tear=normal }
$2,4,5$	{Spectacle=hypermetrope, Astigmatism=no, Tear=normal }
$3,4$	{Age=pre-presbyopic, Astigmatism=no, Tear=normal }
$1,2$	{Age=young, Astigmatism=no, Tear=normal }

Table 3: The four closed sets corresponding to the space of relevant sets of features for data in Table 2.

to discard the closed set covering less true positives. Because of the anti-monotonicity property of support, the smaller one will be the most relevant.

From these two remarks we obtain the following result.

Theorem 10 *Let $X \subseteq F$ and $X' \subseteq F$ be two different closed sets in the positives such that $X \subset X'$. Then, we have that X' is less relevant than X (as in Definition 5) iff $\Gamma^-(X) = \Gamma^-(X')$.*

Proof That X' is less relevant than X is defined as: $\Gamma^+(X') = \Gamma^+(X' \cup X)$ and $\Gamma^-(X) = \Gamma^-(X' \cup X)$. Since $X \subset X'$ by hypothesis, we always have that $X' = X' \cup X$, so that the above two conditions can be rewritten as $\Gamma^+(X') = \Gamma^+(X')$ (always true) and $\Gamma^-(X) = \Gamma^-(X')$, as we wanted to prove.

In the backward direction we start from $\Gamma^-(X) = \Gamma^-(X')$, where $X \subset X'$ as stated by hypothesis of the theorem. Because $X \subset X'$ it is true that $X' = X' \cup X$. Then, we can rewrite $\Gamma^-(X) = \Gamma^-(X')$ as $\Gamma^-(X) = \Gamma^-(X' \cup X)$, thus satisfying already the first condition of Definition 5. Also, $\Gamma^+(X')$ is simply the same as $\Gamma^+(X') = \Gamma^+(X' \cup X)$, thus satisfying the second condition of Definition 5. ■

Thus, by Theorem 10 we can reduce the closure system constructed on the positives by discarding irrelevant nodes: if two closed itemsets are connected by an ascending/descending path on the lattice of positives (i.e., they are comparable by set inclusion $\subset$), yet they have the same closure on the negatives (i.e., they cover the same false positives, or equivalently, their support on the negatives is exactly the same), then just the shortest set is relevant.

Finally, after Theorem 7 and Theorem 10, we can characterize the space of relevant sets of features for discriminating the selected target class as follows.

Definition 11 (Space of relevant sets of features) *The space of relevant combinations of features for discriminating the target class is defined as those sets X for which it holds that: $\Gamma^+(X) = X$ and there is no other closed set $\Gamma^+(X') = X'$ such that $\Gamma^-(X') = \Gamma^-(X)$.*

It is trivial to see after Remarks 8 and 9, that by construction, any two sets in this space always cover a different set of positives and a different set of negatives. These final sets can be directly interpreted as antecedents of rules for classifying the target class (i.e., for each relevant $X \subseteq F$ in the space, we have a relevant rule $X \rightarrow +$ for classifying the positives).

The four closed sets forming the space of relevant sets of features for the class soft are shown in Table 3. It can be checked that the CN2 algorithm (Clark and Niblett, 1989) would output a single

rule whose antecedent corresponds to the closed set in the first row of Table 3. On the other hand, Ripper (Cohen, 1995) would obtain the most specific relevant rules, that is, those corresponding to the three last rows from Table 3. Finally, other algorithms such as Apriori-C would also output rules whose antecedents are not relevant as such, for example, Astigmatism=no $\rightarrow$ Lenses= soft.

To complete the example of the contact lenses database: the lattice of closed itemsets on the class hard contains a total of 7 nodes, which is reduced to only 3 relevant sets; on the other hand, the lattice of closed itemsets on the class none contains a total of 61 nodes, which is reduced to 19 relevant sets.

The space of relevant combinations defines exhaustively all the relevant antecedents for discriminating the target class. Not to generate this space completely, in large sets of data a minimum support threshold will be usually imposed (see more details in the experimental section). As expected, too large relevant sets will be naturally pruned by the minimum support constraint, which might have an undesired effect depending on the application. Still, it is known that very long closed sets, that is, too specific sets of features in our contribution, tend to overestimate when constructing a classifier or learning a discriminative model. In general, it will be up to the user to find a proper trade off between quality of the results and speed up of the process.

4.1 Shortest Representation of a Relevant Set

Based on Theorem 7 we know that generators Y of a closed set X are characterized to cover exactly the same positive examples, and at least the same negative examples. Because of this property, any generator will be redundant w.r.t. its closure. That is:

Remark 12 *Let Y be a generator of X in the closure system on the positives; then, $\Gamma^+(Y) = X$ always implies $\mathrm{TP}(Y) = \mathrm{TP}(X)$ and $\mathrm{FP}(X) \subseteq \mathrm{FP}(Y)$ (from Lemma 6 and Theorem 7). However, note that the inclusion between the set of false positives is not necessarily proper.*

However, we have $\mathrm{FP}(X) \subseteq \mathrm{FP}(Y)$ for Y generator of X; so, it might happen that some generators Y are equivalent to their closed set X in that they cover exactly the same true positives and also the same false positives.

Definition 13 (Equivalent generators) *Let $\Gamma^+(Y) = X$ and $Y \neq X$. We say that a generator Y is equivalent to its closure X iff $\mathrm{FP}(X) = \mathrm{FP}(Y)$.*

The equivalence between true positives of Y and X is guaranteed because $\Gamma^+(Y) = X$. Therefore, it would be only necessary to check if generators cover the same false positives than its closure to check equivalence. Generators will provide a more general representation of the relevant set (because $Y \subset X$ by construction). So, $Y \rightarrow +$ is shorter than the rule $X \rightarrow +$ and it is up to the user to choose the more meaningful to her or to the application. For example, this may depend on a minimum-length criterion of the final classification rules: a generator Y equivalent to a closed set X satisfies by construction that $Y \subset X$, so $Y \rightarrow +$ is shorter than the rule $X \rightarrow +$. Then, the minimal equivalent generators of a closed itemset X naturally correspond to the minimal representation of the relevant rule $X \rightarrow +$.

In terms of the closure operator of negatives, we have the following way of characterizing these equivalent generators.

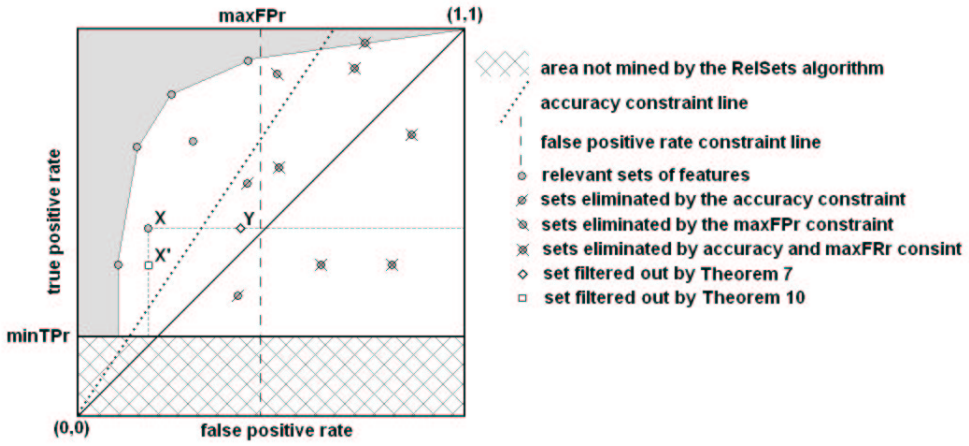

Figure 2: The evaluation of relevant combinations of features in the ROC space.

Proposition 14 *Let* $\Gamma^+(Y) = X$ *and* $Y \neq X$. *Then* Y *is an equivalent generator of* X *iff* $\Gamma^-(X) = \Gamma^-(Y)$.

Proof It is defined that the generator Y is equivalent to its closure X when $\mathrm{FP}(X) = \mathrm{FP}(Y)$, which directly implies $\Gamma^-(X) = \Gamma^-(Y)$ by construction of Γ. On the other direction: $\Gamma^-(X) = \Gamma^-(Y)$ implies $|\mathrm{FP}(Y)| = |\mathrm{FP}(X)|$, but because $Y \subseteq X$ by the extensivity of Γ, we necessarily have that $\mathrm{FP}(Y) = \mathrm{FP}(X)$. ■

It is well-known that minimal generators of a closed set X can be computed by traversing the hypergraph of differences between X and their proper predecessors in the system (see, for example, Pfaltz and Taylor, 2002). In practice, efficient algorithms have been designed for computing free sets and their generalizations (see, for example, Calders and Goethals, 2003).

5. Evaluation of Relevant Sets in the ROC Space

The ROC space (Provost and Fawcett, 2001) is a 2-dimensional space that shows a classifier (rule/ruleset) performance in terms of its *false positive rate* (also called 'false alarm'), $\mathrm{FPr} = \frac{|\mathrm{FP}|}{|\mathrm{TN}|+|\mathrm{FP}|} = \frac{|\mathrm{FP}|}{|N|}$ plotted on the X-axis, and *true positive rate* (also called 'sensitivity') $\mathrm{TPr} = \frac{|\mathrm{TP}|}{|\mathrm{TP}|+|\mathrm{FN}|} = \frac{|\mathrm{TP}|}{|P|}$ plotted on the Y-axis. The ROC space is appropriate for measuring the quality of rules since rules with the best covering properties are placed in the top left corner, while rules that have similar distribution of covered positives and negatives as the distribution in the entire data set are close to the main diagonal.

A set of features from Definition 5 can be interpreted as a condition part of a rule or also as a subgroup description. A set of relevant sets of features from Definition 11 can therefore be visualized and evaluated in the ROC space as a ruleset.

Relevant sets are induced with a minimum support constraint on the positives (as discussed in Section 4). This means that in the ROC space they all lie above the minimum true positive rate constraint line (in Figure 2 denoted as minTPr). Relevant sets are depicted in Figure 2 as circles.

Sometimes, depending on the application, additional filtering criteria are applied. In such cases a maximum false positive rate constraint can be imposed (in Figure 2 this constraint is represented by a dashed line, rules eliminated by this constraint are shown as circles with backslash), or we can apply a minimum confidence constraint (represented by a dotted line, rules eliminated by this constraint are shown as slashed circles in Figure 2). Alternatively we may simply select just the rules on the convex hull.

Let us interpret and visualize Theorems 7 and 10 in the ROC space. According to Theorem 7, sets of features Y, s.t. $Y \subset X$, that cover the same positives as X (i.e., $TP(Y) = TP(X)$), are filtered out. Since Y and X have the same true positive rate (i.e., $TPr(Y) = TPr(X)$), both lie on the same horizontal line in the ROC space. Since Y is a subset of X, which in rule learning terminology translates into "rule X is a specialization of rule Y", $FPr(X) \leq FPr(Y)$ so Y is located at the right hand side of X. In Figure 2, a sample feature set filtered out according to Theorem 7 is depicted as a diamond. Note that this captures exactly the notion of relevancy defined by Lavrač and Gamberger (2005) and Lavrač et al. (1999).

According to Theorem 10, sets of features X', s.t. $X \subset X'$, that cover the same negatives as X (i.e., $FP(X') = FP(X)$), are filtered out. Since X' and X have the same false positive rate (i.e., $FPr(X') = FPr(X)$), both lie on the same vertical line in the ROC space. Since X is a subset of X', which in rule learning terminology translates into "rule X' is a specialization of rule X ", $TPr(X) \geq TPr(X')$, therefore X is located above X' in the ROC space. In Figure 2, a sample feature set filtered out according to Theorem 10 is depicted as a square.

Note that the feature sets filtered out by the relevancy filter are never those on the ROC convex hull. Furthermore, it can be proved that there are no sets of features outside the convex hull (grey area on Figure 2 denotes an area without sets/rules).

6. Experimental Evaluation

The results presented above lead to the concept of closed sets in the context of labeled data. In practice, closed sets can be discovered from labeled data as follows.

1. First, mining the set $S = \{X_1, \ldots, X_n\}$ of frequent closed itemsets from the target class (Theorem 7). This requires a minimum support constraint on positives. For our experiments we will use the efficient LCM algorithm by Uno et al. (2004).

2. Second, reducing S to the space of relevant set of features by checking the coverage in the negatives (Theorem 10). Schematically, for any closed set $X_i \in S$, if there exists another closed set $X_j \in S$ such that both have the same support in the negatives and $X_j \subset X_i$, then X_i is removed.

The first step of this process usually requires a minimum support constraint on true positives, while the second step can be computed automatically without any constraints. However, depending on the purpose of the application we can apply an extra filtering criterion (such as forcing a maximum false positive constraint on the negatives, or a minimum accuracy constraint), or compute minimal equivalent generators of the relevant sets as described above. For short, we will name this computing process as *RelSets* (i.e., the process of discovering the Relevant Sets of features of Definition 5).

Table 4: Compression factor (CF% = $(1 - \frac{|RelSets|}{|EPs|}) \times 100$) of EPs in several UCI data sets. Note that we did not impose any minimum true positive threshold on any data set, except for Lymphography and Crx, where all EPs and RelSets were discovered with a 10% threshold on true positives.

As discussed above, the minimum support constraint on the first phase will tend to prune too long closed sets and this might have an impact in the application. In practice however, it is known that the longest sets of features are sometimes too specific, thus leading to overfitting problems. It is up to the user to trade off between the specificity of the closed sets and the speed up of the process. Also notice that the lowest the minimum support constraint, the largest the number of closed sets, and thus, the most expensive it becomes to compute the second phase of the approach. Our goal is not to present efficient algorithms but to illustrate the concept of relevancy.

Still we find important to point out that the notion of relevancy explored in the paper prefers typically the shortest closed sets. This is obvious by the second reduction phase shown in Theorem 10, where the shortest sets are always more relevant than the longest ones if they cover the same negative examples. Thus, finding a proper threshold level for the minimum support is not critical in our experiments as different minimum support thresholds lead to very similar results.

6.1 Emerging Patterns on UCI data

Emerging Patterns (EP) (Dong and Li, 1999; Li et al., 2000; Dong et al., 1999) are sets of features in the data whose supports change significantly from one class to another. More specifically, EPs are itemsets whose growth rates (the ratio of support from one class to the other, that is, $\frac{\text{TPr}}{\text{FPr}}$ of the pattern) are larger than a user-specified threshold. In this experimental setting we want to show that some of the EPs mined by these approaches are redundant, and that our relevant sets correspond to the notion of compacted data representation for labeled data. Indeed, EPs are a superset of the result returned by RelSets.

In our comparisons we calculate relevant sets over a certain growth rate threshold (1.5 and infinite), and we compare this with the number of EPs by using the same growth rate constraint. Numerical attributes in the data sets are discretized when necessary by using four equal frequency intervals. Although being a very simple discretization scheme, we want to point out that our goal in this experiment is to compare the number of EPs with our relevant sets, and thus, any preprocessing decision on the original data will affect in the same way the two methods we wish to compare.

Results are shown in Table 4. We observe that compression factor may vary according to the data set. When data is structurally redundant, compression factors are higher since many frequent sets are redundant with respect to the closed sets. However, in data sets where this structural redundancy does not exist (such as the Balance-scale data), the compression factor is zero, or close to zero.

A set of relevant properties of EPs have been studied in Soulet et al. (2004). This latter work also identifies condensed representations of EPs from closed sets mined in the whole database. Our approach is different in that we deal with pieces of the data for each class separately, and this allows for a reduction phase given by Theorem 10. Indeed, the amount of compression that this second phase provides in our approach depends on the distribution of the negative examples in the data, but at least, the number of relevant sets obtained by RelSets will be always smaller than the number of condensed EPs from Soulet et al. (2004).

6.2 Essential Rules on UCI Data

Essential rules were proposed by Baralis and Chiusano (2004) to reduce the number of association rules to those with nonredundant properties for classification purposes. Technically, they correspond to mining all frequent itemsets and removing those sets X such that there exists another frequent Y with $Y \subset X$ and having both the same support in positives and negatives. This differs from our proposal in the way of treating the positive class with closed sets. The compression factor achieved for these rules is shown in Table 5. Note that essential rules are not pruned by growth rate threshold, and this is why their number is usually higher than the number of emerging patterns shown in previous subsection.

6.3 Subgroup Discovery in Microarray Data Analysis

Microarray gene expression technology offers researchers the ability to simultaneously examine expression levels of hundreds or thousands of genes in a single experiment. Knowledge about gene regulation and expression can be gained by dividing samples into control samples (in our case mock infected plants), and treatment samples (in our case virus infected plants). Studying the differences between gene expression of the two groups (control and treatment) can provide useful insights into complex patterns of host relationships between plants and pathogens (Taiz and Zeiger, 1998).

Table 5: Compression factor (CF% = $(1 - \frac{|RelSets|}{|EPs|}) \times 100$) of essential rules in UCI data sets. Note that essential rules and RelSets are not pruned by any growth rate threshold.

Microarray data analysis problems are usually addressed by statistical and data mining/machine learning approaches (Speed, 2003; Causton et al., 2003; Parmigiani et al., 2003). State-of-the-art machine learning approaches to microarray data analysis include both supervised learning (learning from data with class labels) and unsupervised learning (such as conceptual clustering). A review of these various approaches can be found in Molla et al. (2004). It was shown by Gamberger et al. (2004) that microarray data analysis problems can be approached also through subgroup discovery, where the goal is to find a set of subgroup descriptions (a rule set) for the target class, that preferably has a low number of rules while each rule has high coverage and accuracy (Lavrač et al., 2004; Gamberger and Lavrač, 2002).

The goal of the real-life experiment addressed in this paper is to investigate the differences between virus sensitive and resistant transgenic potato lines. For this purpose, 48 potato samples were used, leading to 24 microarrays. The laboratory experiment was carried out at the National Institute of Biology, Ljubljana, Slovenia.

Our data set contains 12 examples. Each example is a pair of microarrays (8 and 12 hours after infection) from the same transgenic line. All the data was discretized by using expert background knowledge. Features of the form $|\textit{gene expression value}| > 0.3$ were generated and enumerated. Three groups of features were generated: first group corresponding to gene expression levels 8 hours after infection (feature numbers $\in [1, 12493]$); second group corresponding to gene expression levels 12 hours after infection (feature numbers $\in [12494, 24965]$); finally, a third group corresponding

Data set	Class	Num. of rules			AUC		Time	
		RelSets	RelSets-ROC	SD	RelSets	SD	RelSets	SD
potatoes	sensitive	1	1	20	100%	100%	<1s	>1h
	resistant	1	1	20	100%	91%	<1s	>1h

Table 6: Comparison of algorithms RelSets and SD on the potato microarray data. Column RelSets-ROC shows the number of RelSets rules on the ROC convex hull.

to the difference between gene expression levels 12 and 8 hours after infection (feature numbers $\in [24966, 37559]$).

We used the RelSets algorithm to analyze the differences between gene expression levels characteristic for virus sensitive potato transgenic lines, discriminating them from virus resistant potato transgenic lines and vice versa. We ran it twice: once the sensitive examples were considered positive and once the resistant ones were considered positive. In both cases the constraint of minimal true positive count was set to 4, and in the first phase the algorithm returned 22 closed sets on positives. Rule relevancy filtering according to Definition 5, filtered the rules to just one relevant rule with a 100% true positive rate and a 0% false positive rate for each class. The results gained are shown below, where features are represented by numbers.

Twelve features determine the virus sensitive class for the potato samples used:

$\{$*13031, 13066, 19130, 23462, 24794, 25509, 29938, 33795, 33829, 35003, 35190, 36266*$\}$ $\rightarrow$ *sensitive*

Sixteen features determine the virus resistant class for the potato samples used:

$\{$*16441, 20474, 20671, 24030, 25141, 29777, 30111, 32459, 33225, 33248, 33870, 34108, 34114, 34388, 37252, 37484*$\}$ $\rightarrow$ *resistant*

When comparing our results with the SD algorithm for subgroup discovery (Gamberger and Lavrač, 2002), we observe that the running time of SD degrades considerably due to the high dimensionality of this data set. Moreover, SD obtains a larger set of rules which are less interpretable and do not have the same quality as the rules obtained with RelSets. Table 6 shows the numbers of discovered rules, area under ROC curve and the running time of both algorithms.

The results obtained with RelSets were validated by the experts from the National Institute of Biology, Ljubljana, Slovenia, and evaluated as insightful. Based on the tested samples, the experts have observed that the response to the infection after 8 hours is not strong enough to distinguish between resistant transgenic lines and sensitive ones. None of the gene expression changes after 8 hours appeared significant for the RelSets algorithm. However, selected gene expression levels after 12 hours and the comparison of gene expression difference (12-8) characterize the resistance to the infection with potato virus for the transgenic lines tested.[3]

3. Details of this analysis are beyond the scope of this paper: first qualitative analysis results have appeared in Kralj et al. (2006), while a more thorough analysis is to appear in a biological journal.

7. Conclusions

We have presented a theoretical framework that, based on the covering properties of closed itemsets, characterizes those sets of features that are relevant for discrimination. We call them closed sets for labeled data, since they keep similar structural properties of classical closed sets, yet taking into account the positive and negative labels of examples. We show that these sets define a nonredundant set of rules in the ROC space.

This study extends previous results where the notion of relevancy was analyzed for single features (Lavrač and Gamberger, 2005; Lavrač et al., 1999), and it provides a new formal perspective for relevant rule induction. In practice the approach shows major advantages for compacting emerging patterns and essential rules and solving hard subgroup discovery problems. Thresholds on positives make the method tractable even for large databases with many features. The application to potato microarray data, where the goal was to find differences between virus resistant and virus sensitive potato transgenic lines, shows that our approach is not only fast, but also returns a small set of rules that are meaningful and easy to interpret by domain experts.

Future work will be devoted to adapting efficient algorithms of emerging patterns by Dong and Li (1999) for the discovery of the presented relevant sets.

Acknowledgments

This work was partially funded by the Pascal Network of Excellence through a visit of the first author to the Jožef Stefan Institute, Ljubljana, Slovenia, and the Slovenian Research Agency grant Knowledge Technologies (2004–2008). We wish to thank Ana Rotter, Nataša Toplak and Kristina Gruden from the National Institute of Biology, Ljubljana, Slovenia, for the biological data and the joint research on the application of closed sets in functional genomics.

Editor: Charles Elkan

Abstract

In this paper, the naive credal classifier, which is a set-valued counterpart of naive Bayes, is extended to a general and flexible treatment of incomplete data, yielding a new classifier called *naive credal classifier 2* (NCC2). The new classifier delivers classifications that are reliable even in the presence of small sample sizes and missing values. Extensive empirical evaluations show that, by issuing set-valued classifications, NCC2 is able to isolate and properly deal with instances that are hard to classify (on which naive Bayes accuracy drops considerably), and to perform as well as naive Bayes on the other instances. The experiments point to a general problem: they show that with missing values, empirical evaluations may not reliably estimate the accuracy of a traditional classifier, such as naive Bayes. This phenomenon adds even more value to the robust approach to classification implemented by NCC2.

Keywords: naive Bayes, naive credal classifier, imprecise probabilities, missing values, conservative inference rule, missing at random

1. Introduction

Is it possible to draw credible conclusions about a domain only looking at some data produced within the domain itself?

The answer to this question appears to be related to the problem of modeling *ignorance*.[1] In fact, there are at least two kinds of ignorance involved in the process of learning from data. The first is *prior ignorance* about the domain, as we are assuming that data are our only source of information. The second is ignorance arising from missing values, as data are often incomplete; in this case, ignorance is about the process that originates the missing values: that is, the *missingness process*. So, in principle, we should model both ignorances properly in order to deliver credible conclusions.

Let us consider *pattern classification*, which is the focus of this paper. Considering *Bayesian classifiers*, we see that prior ignorance is modeled in common practice by so-called non-informative *prior densities* (or just *priors*, for short). But such an approach can lead, especially when the learning set is *small*, to the known problem of prior-dependent classifications, whose reliability is

1. When we use the word "ignorance" in this paper, we actually mean a condition of *near-ignorance*. Indeed, full ignorance is not compatible with learning, as it is well known (e.g., see Section 7.3.7 of Walley, 1991, Section 2.3 of Zaffalon, 2005b).

questionable. This appears to indicate that non-informative priors do not model prior ignorance satisfactorily.

A more objective-minded[2] model of prior ignorance has been proposed through a classifier called *naive credal classifier* (NCC), see Zaffalon (2001), which is an extension of *naive Bayes classifier* (NBC) to *imprecise probabilities* (Walley, 1991). NCC models prior ignorance by a *set* of prior densities (also called prior *credal set*), which is turned into a set of posteriors by element-wise application of Bayes' rule. The classification is eventually issued by returning all the classes that are *non-dominated* by any other class according to the posterior credal set, where class c_i is said to dominate c_j if *for all* the posteriors it holds that the probability of c_i is larger than that of c_j. This makes NCC naturally issue *set-valued* classifications (i.e., classifications made by more than one class) when faced with instances that are hard to classify, due to a combination of prior ignorance and poor information *about those specific instances* in the learning set. The shift of paradigm based on set-valued classifications allows NCC to deliver robust classifications in spite of small learning sets. NCC has indeed shown excellent accuracy in real-world case studies (Zaffalon, 2005a; Zaffalon et al., 2003), thus demonstrating the usefulness, for classification purposes, of modeling prior ignorance via a credal set. In the following, set-valued classifications are also called *indeterminate*. *Determinate* classifications correspond instead to the set being a singleton, and hence to the case usually considered by more traditional classifiers. Similarly, we say that a classifier is determinate when it outputs a single class and indeterminate otherwise.

As for the ignorance arising from missing data, we can think of the missingness process (MP) as a process that takes in input the complete data, which we cannot usually observe, and outputs the incomplete data, which we do observe. If data are our only source of information, we are ignorant about the MP because it is usually not possible to learn how it operates, from the observed, incomplete data.

In common practice, missing values are often *ignored*; this entails the idea that the MP is non-selective in producing them, or, in other words, that it is a *missing at random* (MAR) process (Little and Rubin, 1987; Jaeger, 2005). However, if one is ignorant about the MP, assuming MAR cannot be regarded as an objective-minded approach, as is well documented, for instance, by Manski (2003).

In its original formulation, NCC introduced also an initial attempt to deal with ignorance about the MP. The idea was to model ignorance about it by using a set of *likelihoods*: a likelihood per each complete learning set consistent with the incomplete one. A similar avenue was also implemented by *robust Bayes classifier* (Ramoni and Sebastiani, 2001).[3] These approaches are indeed valuable, but have two problems: (i) they implicitly still assume MAR for the missing values in the instance to classify, thus creating a peculiar asymmetry between learning and test set that is not of general validity in applications; (ii) they may well be too conservative, because for some feature variables one might know that the missingness is MAR, and they do not allow this information to be incorporated in the model. Furthermore, their treatment of missing values rests on intuitive arguments rather than on a principled derivation.

2. Although we base our results on Walley's theory, which is a *subjective* theory of probability, we sometimes use the terminology "objective-minded." We do so to stress that using (very) weak assumptions leads to results that are much more determined by the data than by our prior beliefs (intended in a loose way, not only as prior probabilities), and in this sense are more objective. Yet, in the paper we deliberately avoid using the word "objective" alone, just because it is improper within the considered theory.
3. When used with the so-called *strong dominance score*.

By this paper we extend NCC to a very general and flexible treatment of incomplete data, both in learning and testing. We call the resulting classifier *naive credal classifier 2* (NCC2), in order to emphasize the advancement made to deal with incomplete data, while keeping the original benefits of NCC on the front of prior ignorance.

By NCC2, it is possible to declare that some (possibly all or none) of the feature variables are subject to a MAR process, and the remaining ones are automatically assumed to be subject to an MP that is unknown to us. Remarkably, the set of feature variables subject to a MAR MP can be chosen differently from the learning to the test set. This is a key characteristic of NCC2: in fact, if the MP is unknown, it may well change its behavior from unit to unit for all we know (i.e., it may not be *identically distributed*), and we should act accordingly.

The development of NCC2 is based on a recently derived so-called *conservative inference rule* (CIR) to compute (imprecise) conditional expectations with incomplete data (Zaffalon, 2005b). After giving some notation and briefly recalling CIR in Section 2, we derive NCC2 in Section 3 by specializing CIR to the case of naive classification. In the end we obtain procedures to learn NCC2 and to do classifications with it that do not involve approximations and are computationally fast. (The software which implements NCC2 is released as open source; more details are provided in Section 3.5.)

Next, we concentrate on empirical evaluations: in Section 4 we analyze the behavior of NCC2 from a number of angles and on a number of publicly available data sets. The analysis turns out to be particularly meaningful when we compare NCC2 with its precise-probability counterpart, that is, naive Bayes. We do this by evaluating the accuracy of NBC on the instances of the test set where NCC2 issues a determinate classification separately from those where it does not. In fact, NCC2 is indeterminate on an instance when it deems that there is not enough knowledge in the learning set to make a determinate classification reliably; NBC, on the other hand, issues a determinate classification on such an instance (as well as on any other). Therefore we expect NBC to have different behaviors on the two kinds of instances isolated by NCC2. And this is indeed the case: the experiments show that NBC undergoes a major drop in accuracy moving from the instances classified in a determinate way by NCC2 to the indeterminate ones. The drop is observed on every data set, with no exception.

It is important to realize that such a drop points out a key question: the usual way to measure the performance of a classifier, that is, its predictive accuracy, which is an average over all the instances of the test set, may not help uncover a possible bad performance of the classifier on a subset of the test instances. These instances are precisely those that are hard to classify and that NCC2 isolates by delivering set-valued classifications.

But set-valued classifications help NCC2 to do more than just isolating the hard instances, they enable it to cope effectively with them: in fact, we show that set-valued classifications are often informative, as they usually lead to drop some unlikely classes; and that the measured *set-based* accuracy of NCC2 (i.e., the proportion of times the true class is contained in the output set) is often similar to the accuracy obtained on the instances classified in a determinate way.

At this point we should say that the mentioned experiments have been carried out with a variety of settings, obtained considering both MAR processes and non-MAR ones, and the mentioned outcomes are been confirmed over all of them (although sometimes this is due more to prior ignorance and some others more to the missing data).

To make our results stronger, we have also investigated whether NBC could take advantage of the posterior probabilities it computes in order to deal more successfully with the hard instances.

We have considered such posterior probabilities again by separating the cases where NCC2 is determinate from the others, and by comparing those probabilities with the measured accuracy that NBC actually achieves on the data. What we show is that the NBC probabilities are (also very) unreliable on the instances that are hard to classify, as isolated by NCC2, and definitely more unreliable than on the remaining instances. In other words, we observe another kind of drop that now is related to the quality of the posterior probabilities computed by NBC.

Overall, we show that NBC may well be too optimistic in dealing with small data sets and missing data, thus yielding unreliable predictions. It is useful to recall that NBC is known to be very robust to missing data. Therefore, it is not unlikely that the optimism on the front of missing data is even greater with more complex classifiers. This point appears to be worth of serious consideration on its own.

At the same time, and in contrast with naive Bayes, our experiments show that NCC2 may sometimes be too pessimistic (i.e., conservative) especially when dealing with missing data. This happens because by construction NCC2 implicitly considers the worst possible MP to have acted on the non-MAR part of the data, and in some cases this hypothesis may be too far from the MP that has actually produced the missing values.

In most of our experiments, for instance, we have deliberately used very simple MPs, and this has favored some excess of caution to show up. Yet, we have also considered an illustrative example of a more elaborated MP, in Section 4.6. In this case we show that the indeterminacy of NCC2 is fully justified, the NBC being completely unreliable in the area of indeterminacy. Even more important, we show that such an unreliability *cannot be uncovered by making empirical evaluations*: despite the predictive accuracy of NBC on a certain instance is measured properly by cross-validation, the actual accuracy on new instances of the same type can be significantly worse. This highlights the fact that modeling ignorance properly is important, even if there are data available for empirical evaluations. Indeed, in such an experiment NCC2 does not decrease its performance, nor do its empirical evaluations fail.

This is not to say that one should abuse assuming ignorance about the MP: when there are many missing values, especially in the instance to classify, one would obtain conclusions much too weak. This is shown in a setup where missingness increases in Section 4.5. Our view is that information about the MP should be incorporated in a model when available. In fact, we regard as an important research avenue the definition of classification models able to flexibly incorporate MP-related knowledge, which is usually not conveyed by the data at hand. With NCC2, incorporating knowledge is done by declaring that some variables are subject to a MAR MP, and we actually recommend doing so whenever possible; this has the potential, shown also experimentally in the above section, to yield strong enough conclusions in many cases. Eventually, in Section 4.7 we analyze the results obtained on the eucalyptus data sets; in fact, such results are quite peculiar and therefore worthy of a separate investigation. The conclusion we achieve in this case is that the use of coarsened rather than missing observations is another very effective means to incorporate knowledge, in case there is no support for declaring some variables as subject to a MAR MP.

2. Setup

In this paper, the variables that refer to complete data, which are in general not observable, are called *latent*, while those referring to incomplete data, which are the ones to which we have usually access, are called *manifest*. A given manifest value is identical to the corresponding latent one, unless the

latent value has been turned into missing by the MP; in this case, the manifest value is actually the symbol of missing value. Therefore, in a case where the data at hand are complete, the instances of the latent and the manifest variables coincide.

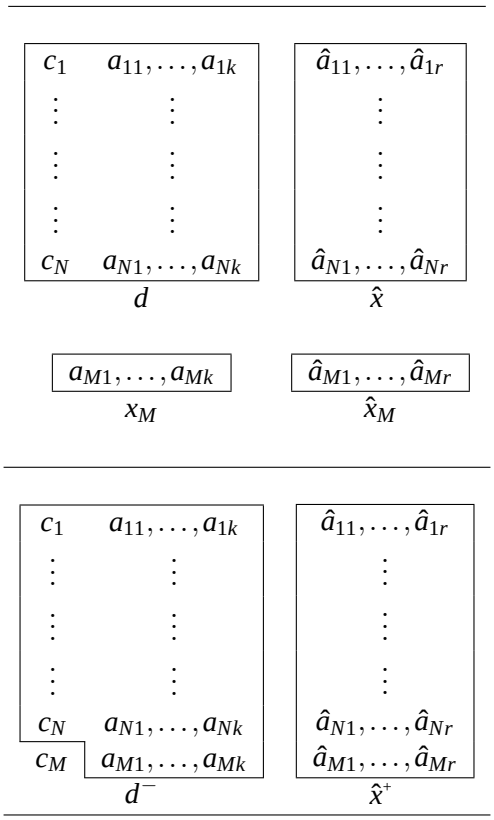

Figure 1: Graphical representation of some vectors of latent variables. Rows $1,\ldots,N$ constitute the training set, while the M-th unit is a new instance to be classified.

In the following, i indexes a given unit (i.e., a certain row) of the data set: the *learning set* (or *training set*) is made up of the units for which $1 \leq i \leq N$, while the unit to classify (not belonging to the learning set) is indexed by $M := N+1$. A set of units to classify is referred to as *test set*.

In a classification problem there are typically *class variables* and *attribute variables*. We denote: (i) the latent *class variable* as C_i, and we assume that it is always observed; (ii) the latent attribute variables affected by an unknown MP (i.e., to be conservatively modeled as non-MAR) as $A_{i1},\ldots,A_{ik}$; (iii) the latent attributes affected by a MAR MP as $\hat{A}_{i1}$, …, $\hat{A}_{ir}$. The two MPs are assumed to be independent of each other and their coarsening behavior is allowed to vary with different units, that is, they are *not* assumed to be identically distributed.[4]

For all i, C_i takes generic value c_i in the finite set $\mathcal{C}$, called *set of latent classes*, while A_{ij} ($\hat{A}_{il}$) take generic values a_j ($\hat{a}_l$) in the finite sets $\mathcal{A}_j$ ($\hat{\mathcal{A}}_l$), called *sets of latent attributes*.

We define the following groups of latent variables: $X_i := (A_{i1},\ldots,A_{ik})$, $D_i := (C_i, X_i)$, and $\hat{X}_i := (\hat{A}_{i1},\ldots,\hat{A}_{ir})$. We then extend such grouped variables to span the whole training set, instead than

4. See Zaffalon (2005b), Section 5, for a discussion about this point.

just the *i*-th unit, defining the vector $C := (C_1,\ldots,C_N)$ and the matrices $X := (X_1,\ldots,X_N)$, $\hat{X} := (\hat{X}_1,\ldots,\hat{X}_N)$, $D := (D_1,\ldots,D_N)$. The same grouped variables but with a "+" superscript, include also data of the M-th unit (i.e., the instance to be classified): $C^+ := (C_1,\ldots,C_M)$, $X^+ := (X_1,\ldots,X_M)$, $\hat{X}^+ := (\hat{X}_1,\ldots,\hat{X}_M)$,$D^+ := (D_1,\ldots,D_M)$. Let also define $D^- := (C,X^+)$.[5]

Observe that realizations of the random matrix $(D^+,\hat{X}^+)$ represent the possible complete data sets, which we cannot observe directly, and that realizations of $(D,\hat{X})$ represent the possible complete learning sets, while those of $(X_M,\hat{X}_M)$ represent the possible complete units to classify.

To complete the notation regarding latent variables, we assume that the generic latent unit $(d,\hat{x}) \in \mathcal{D}\times\hat{\mathcal{X}}$ is generated in *independently and identically distributed* (IID) way according to the *aleatory probability* (or *chance*) $\vartheta_{(d,\hat{x})}$. The vector of such chances is denoted by ϑ, which belongs to Θ, that is, a (non-empty) subset of the unitary $|\mathcal{D}\times\hat{\mathcal{X}}|$-dimensional simplex. Let θ denote the random variable of which ϑ is a generic value. Knowledge about θ is expressed by $p(\theta)$, which denotes an imprecise prior density for θ. This means that $p(\theta)$ is known to belong to a non-empty set $\mathcal{P}(\theta)$ of precise prior densities for θ. $\mathcal{P}(\theta)$ is referred to as *prior credal set*.

As for the manifest variables, we assume that we either observe a precise value, or we do not observe it at all. Manifest variables are denoted by the letter O followed by the latent variable they refer to, written as a subscript. We define hence the following manifest variables: $O := O_D = (O_1,\ldots,O_N)$, $O^+ := O_{D^+} = (O_1,\ldots,O_M)$, $O^- := O_{D^-} = (O_1,\ldots,O_N,X_M)$, $\hat{O} := O_{\hat{X}} = (\hat{O}_1,\ldots,\hat{O}_N)$, $\hat{O}^+ := O_{\hat{X}^+} = (\hat{O}_1,\ldots,\hat{O}_M)$.

2.1 Classification With Imprecise Probabilities and Conservative Inference Rule

The goal of classification is to predict the class of the M-th unit, given the previous units $(1,\ldots,N)$ and the values of the M-th attribute variables.

To this extent, a traditional probabilistic classifier outputs what it deems to be the optimal prediction: that is, the class with the highest probability (in the case of 0-1 loss function) on the basis of a uniquely computed posterior density. In the imprecise setting, however, the optimality criterion has to be extended to manage a set of posterior densities (derived from a set of priors and a set of likelihoods), instead of a single posterior; in particular, according to Section 3.9.2 of Walley (1991), the optimality criterion in the imprecise setting prescribes to return the *non-dominated* classes. The definition of dominance is as follows: class c_i dominates c_j if for all the computed posteriors densities, the posterior probability of c_i is greater than that of c_j; clearly, c_j is non-dominated if no class dominates c_j. The second procedure of Figure 2, based on pairwise comparison of classes, identifies the non-dominated classes. Observe that, as a result of the uncertainty arising from both prior specification and non-MAR missing values, there can be several non-dominated classes; in this case, the classifier returns an indeterminate (or set-valued) classification. Classifiers that issue set-valued classifications are called *credal classifiers* by Zaffalon (2002).

A key point is that non-dominated classes are *incomparable*;[6] this means that there is no information in the model that allows us to rank them. In other words, credal classifiers are models that allow us to drop the dominated classes, as sub-optimal, and to express our indecision about the optimal class by yielding the remaining set of non-dominated classes.

5. Since we assume the class variable to be always observed, C is a complete vector. Hence, it is possible to derive the NCC2 algorithms also by grouping C with $\hat{X}$.
6. If we exclude the classes that are non-dominated due to indifference rather than incomparability, and that constitute a very special case in the imprecise setting.

In the setup of this paper, the test of dominance can be re-written as follows: c'' is dominated by c' if and only if it holds that

$$1 < \min_{x_M \in o_M} \min_{d \in o} \inf_{p(\theta) \in \mathcal{P}(\theta)} \frac{p(c'_M | d^-, \hat{x}^+ \in \hat{o}^+)}{p(c''_M | d^-, \hat{x}^+ \in \hat{o}^+)}. \quad (1)$$

Actually, Equation (1) is the general form of the test of dominance for any classifier based on the conservative inference rule presented in Zaffalon (2005b); CIR is a conditioning rule (i.e., a rule for computing conditional expected values) that generalizes the traditional conditioning; it assumes that prior beliefs are dealt with via a credal set $\mathcal{P}(\theta)$ and it accounts for data sets in which the missingness process is MAR for some variables (the term $\hat{x}^+ \in \hat{o}^+$ refers indeed to the missing data of MAR feature variables in the training set), and unknown for some others. Moreover, CIR is able to manage variables whose MP is MAR in learning and unknown in testing, or vice versa. Equation (1) follows almost immediately from Theorem 4 in Zaffalon (2005b) after considering that for c'_M to dominate c''_M, it must hold that $p(c'_M | d^-, \hat{x}^+ \in \hat{o}^+) > p(c''_M | d^-, \hat{x}^+ \in \hat{o}^+)$ for all the possible posteriors, which we obtain considering any precise prior in the prior credal set, as well as any completion of the non-MAR missing values both in the sample and in the unit to classify.

CIR can be regarded as unifying two rules (Zaffalon, 2005b): a *conservative learning rule*, which prescribes how to learn the classifier from an incomplete training set, and a *conservative updating rule*, which prescribes how to classify a novel instance that contains missing values. Such a distinction is made clear by two distinct optimization loops of Equation (1); the middle optimization loop ($\min_{d \in o}$) realizes the conservative learning rule, by prescribing to loop on the completions of the non-MAR part of the learning set, that is, $d \in o$, while the outer minimum implements the conservative updating rule, prescribing to loop on the replacements for the non-MAR missing values of the unit to classify. The inner loop, which minimizes over the prior credal set, is common to both learning and updating rules.

NCC2 specializes the test of Equation (1) to the case of naive classification. In the following, we will move from the precise setting (corresponding in fact to naive Bayes) to NCC2 in four steps: in Section 3.1 we describe the precise setting (assuming hence that there is a single prior, and that there is a single likelihood as non-MAR data are complete); in Section 3.2 we extend the computation to manage a set of priors; in Sections 3.3 and 3.4 we finally relax the assumptions of completeness about non-MAR data in learning and testing respectively, thus managing a set of likelihoods and instances to classify.

3. Introducing NCC2

In this section, we introduce the NCC2 framework. In particular, we derive an expression that specializes the test of Equation (1) to the case of naive classification; such an expression realizes both the minimizations over possible priors and over possible unobserved values by distributing some pseudo-counts in a way that minimizes the ratio of the posterior probabilities of the two competing classes c'_M and c''_M.

Formal proofs of the findings derived in this section are provided in Appendix B.

3.1 Updating Precise Beliefs

In this section, we assume that a single prior is specified and that only the observations of the features affected by the MAR MP contain some missing data; the observations of the feature affected by the

unknown MP, instead, do not contain any missing data. In practice, this corresponds to the naive Bayes setting, with the difference that we explicitly separate variables affected by the MAR MP and the unknown MP. In our setting, the naive hypothesis (i.e, the assumption of mutual independence of the latent attribute variables $A_{i1}, \ldots, A_{ik}, \hat{A}_{i1}, \ldots, \hat{A}_{ir}$ conditional on the class variable C_i) can be formalized as follows:

$$\vartheta_{(d_i,\hat{x}_i)} = \vartheta_{c_i} \prod_{j=1}^{k} \vartheta_{a_{ij}|c_i} \prod_{l=1}^{r} \vartheta_{\hat{a}_{il}|c_i} \quad \forall (d_i,\hat{x}_i) \in \mathcal{D} \times \hat{\mathcal{X}}, \tag{2}$$

where ϑ_c denotes the chance of $(C_i = c_i)$; $\vartheta_{a_{ij}|c}$ and $\vartheta_{\hat{a}_{il}|c}$ denote the chances of $(A_{ij} = a_j | C_i = c_i)$ and $(\hat{A}_{il} = \hat{a}_l | C_i = c_i)$, respectively.

We focus on the precise probability $p(c_M | d^{\text{-}}, \hat{x}^{+} \in \hat{o}^{+})$. Let us consider the probability $p(c_M, d^{\text{-}}, \hat{x}^{+} \in \hat{o}^{+})$, which is proportional to the previous one. Write $p(c_M, d^{\text{-}}, \hat{x}^{+} \in \hat{o}^{+})$ as $\int_\Theta p(\vartheta) p(c_M, d^{\text{-}}, \hat{x}^{+} \in \hat{o}^{+} | \vartheta) d\vartheta$. Observe that $p(c_M, d^{\text{-}}, \hat{x}^{+} \in \hat{o}^{+} | \vartheta)$ is equal to $p(d, \hat{x} \in \hat{o} | \vartheta) p(c_M, x_M, \hat{x}_M \in \hat{o}_M | \vartheta)$ because of the IID assumption about the data generation mechanism. We obtain that

$$p(c_M | d^{\text{-}}, \hat{x}^{+} \in \hat{o}^{+}) \propto \int_\Theta p(\vartheta) p(d, \hat{x} \in \hat{o} | \vartheta) p(c_M, x_M, \hat{x}_M \in \hat{o}_M | \vartheta) d\vartheta. \tag{3}$$

The term $p(d, \hat{x} \in \hat{o} | \vartheta)$ in (3) is called *likelihood function*.

By sticking to the naive hypothesis, the likelihood can be expressed as follows:

Lemma 1
$p(d, \hat{x} \in \hat{o} | \vartheta) = \prod_{c \in \mathcal{C}} \{ \vartheta_c^{n(c)} [\prod_{j=1}^{k} \prod_{a_j \in \mathcal{A}_j} \vartheta_{a_j|c}^{n(a_j,c)}] [\prod_{l=1}^{r} \prod_{\hat{a}_l \in \hat{\mathcal{A}}_l} \vartheta_{\hat{a}_l|c}^{n(\hat{a}_l,c)}] \}$.

Here $n(c)$ resp. $n(a_j, c)$ denote the number of occurrences of c resp. of joint occurrences of (a_j, c) in d, and $n(\hat{a}_l, c)$ denotes the number of joint occurrences of $(\hat{a}_l, c)$ in the learning set after dropping the units with missing values of $\hat{A}_l$. Technically, the likelihood function of Lemma 1 has the same functional form as a product of Dirichlet densities; in particular, the frequencies $n(\cdot)$ correspond to the Dirichlet hyperparameters usually denoted as $\alpha(\cdot) - 1$.

With similar arguments to those used with Lemma 1, and assuming that the MAR attribute variables have been re-ordered so as to index the non-missing ones in the instance to classify from 1 to $r' \leq r$, we obtain:

Lemma 2 $p(c_M, x_M, \hat{x}_M \in \hat{o}_M | \vartheta) = \vartheta_{c_M} \prod_{j=1}^{k} \vartheta_{a_{Mj}|c_M} \prod_{l=1}^{r'} \vartheta_{\hat{a}_{Ml}|c_M}$.

Note that restricting the second product between $l = 1$ and $l = r'$ prevents the inclusion in the expression of the attributes that are missing in the unit to classify.

3.1.1 IMPRECISE PRIOR (PRIOR CREDAL SET)

The remaining term in (3) is $p(\vartheta)$, that is, the prior. We define it so as to be *conjugate* to the likelihood, according to the following expression:

$$p(\vartheta | s, t) d\vartheta \propto \prod_{c \in \mathcal{C}} \{ \vartheta_c^{st(c)-1} d\vartheta_C [\prod_{j=1}^{k} \prod_{a_j \in \mathcal{A}_j} \vartheta_{a_j|c}^{st(a_j,c)-1} d\vartheta_{A_j|c}] \cdot \cdot [\prod_{l=1}^{r} \prod_{\hat{a}_l \in \hat{\mathcal{A}}_l} \vartheta_{\hat{a}_l|c}^{st(\hat{a}_l,c)-1} d\vartheta_{\hat{A}_l|c}] \}, \tag{4}$$

which is a product of Dirichlet densities. The density is named $p(\vartheta|s,t)$, so as to make it explicitly the hyperparameters on which it depends (here t denotes the vector of $t(\cdot)$-hyperparameters). In other words, the prior is defined by an expression that is similar to the likelihood function except that the frequencies $n(\cdot)$ are replaced everywhere by $st(\cdot)-1$. The real hyperparameter s can be regarded as the size of the *hypothetical sample*, in the common interpretation of conjugate Bayesian priors as additional sample units; Walley (1996) gives arguments to choose s in the interval $[1,2]$, and we will adopt $s := 1$ for the empirical experiments of Section 4. The real hyperparameter $t(\cdot)$ can instead be regarded as the proportion of units in which the variables in question take certain values (e.g., $t(c)$ is the proportion of units where the class variable is equal to c) in the hypothetical sample.

Now, remember that we want the prior to be imprecise, that is, to be a set of priors. We define the set by imposing a system of constraints on the t-hyperparameters that resemble the structural constraints of the observed frequencies $n(\cdot)$: in particular, $\sum_{c\in\mathcal{C}} t(c) = 1$, $\sum_{a_j\in\mathcal{A}_j} t(a_j,c) = t(c)$, $\sum_{\hat{a}_l\in\hat{\mathcal{A}}_l} t(\hat{a}_l,c) = t(c)$. We moreover impose the conditions $t(a_j,c) > 0$, $t(\hat{a}_l,c) > 0$. The credal set $\mathcal{P}(\theta)$ is defined as the set of all the precise priors that satisfy these constraints. The construction of $\mathcal{P}(\theta)$ is similar to the approach implemented by Walleys' *imprecise Dirichlet model* (Walley, 1996).

Informally, one could interpret $\mathcal{P}(\theta)$ in the following way: say that any single, *precise* Dirichlet prior, is a possible state of information about the process generating (latent) data. Then, our ignorance about this process is modeled by considering the set of all the states of information about the process, that is, by considering that all of them are actually possible.[7]

3.1.2 PROBABILITY OF THE NEXT CLASS

The tools introduced so far lead us to the following result.

Theorem 3 *Consider Expression* (3)*. It holds that:*

$$p(c_M|d^{\cdot},\hat{x}^{+}\in\hat{o}^{+},s,t) = p(c_M|d,\hat{x}\in\hat{o},s,t)\prod_{j=1}^{k} p(a_{Mj}|c_M,d,\hat{x}\in\hat{o},s,t)\cdot \cdot\prod_{l=1}^{r'} p(\hat{a}_{Ml}|c_M,d,\hat{x}\in\hat{o},s,t), \tag{5}$$

where

- $p(c_M|d,\hat{x}\in\hat{o},s,t) := [n(c_M)+st(c_M)]/(N+s)$*;*
- $p(a_{Mj}|c_M,d,\hat{x}\in\hat{o},s,t) := [n(a_{Mj},c_M)+st(a_{Mj},c_M)]/[n(c_M)+st(c_M)]$ *($j=1,\ldots,k$);*
- $p(\hat{a}_{Ml}|c_M,d,\hat{x}\in\hat{o},s,t) := [n(\hat{a}_{Ml},c_M)+st(\hat{a}_{Ml},c_M)]/[n_l(c_M)+st(c_M)]$ *($l=1,\ldots,r'$);*
- $n_l(c_M) := \sum_{\hat{a}_l\in\hat{\mathcal{A}}_l} n(\hat{a}_l,c_M)$.

Note that MAR attributes that are missing in the unit to be classified do *not* affect the posterior probabilities of the class.

7. To be more precise, we do not consider all of them, only those with s fixed; this corresponds to fix the "strength" of our prior ignorance.

3.2 Credal Dominance Tests with an Imprecise Prior

Let us now address the computation of the inner optimization problem in (1), under the choice of the imprecise prior made in Section 3.1.1.

Lemma 4 *Consider the problem* $\inf_{p(\theta)\in\mathcal{P}(\theta)} p(c'_M|d^-,\hat{x}^+\in\hat{o}^+)/p(c''_M|d^-,\hat{x}^+\in\hat{o}^+)$*, with the set of prior densities described in Section 3.1.1, and the probabilities in the function to optimize (also called* objective function *in the following) defined as in* (5)*. Such a problem is equivalent to the following:*

$$\begin{aligned}&\inf_{0<t(c_{M''})<1}\{[\frac{n(c''_M)+st(c''_M)}{n(c'_M)+s-t(c''_M)}]^{k-1}\prod_{j=1}^{k}\frac{n(a_{Mj},c'_M)}{n(a_{Mj},c''_M)+st(c''_M)}\\&\cdot\prod_{l=1}^{r'}[\frac{n_l(c''_M)+st(c''_M)}{n_l(c'_M)+s-t(c''_M)}\cdot\frac{n(\hat{a}_{Ml},c'_M)}{n(\hat{a}_{Ml},c''_M)+st(c''_M)}]\}\\&=:\inf_{0<t(c_{M''})<1}h(t(c_{M''})).\end{aligned}\tag{6}$$

The problem of finding the prior $p(\theta)\in\mathcal{P}(\theta)$ that minimizes the ratio of the posterior probabilities $p(c'_M|d^-,\hat{x}^+\in\hat{o}^+)/p(c''_M|d^-,\hat{x}^+\in\hat{o}^+)$ can be hence be solved by finding the value $0<t(c_{M''})<1$ that minimizes $h(t(c_{M''}))$, as follows.

Theorem 5 *The infimum of* $h(t(c_{M''}))$ *over* $(0,1)$ *is determined by the following procedure:*

- *if there is* j *such that* $n(a_{Mj},c'_M)=0$ *or* l *such that* $n(\hat{a}_{Ml},c'_M)=0$*,* $\inf h(t(c_{M''}))=0$*;*
- *if* $k=0$ *and* $r'=0$*,* $\inf h(t(c_{M''}))=h(1)$*;*
- *otherwise,* $h(t(c_{M''}))$ *can be shown to be convex over* $(0,1)$*; hence, it can be minimized by a convex optimization procedure (detailed in the proofs).*

3.3 Credal Dominance Test with an Incomplete, Non-MAR, Learning Set

In case the learning data produced by the unknown MP are incomplete, the problem to be solved is

$$\min_{d\in o}\inf_{p(\theta)\in\mathcal{P}(\theta)} p(c'_M|d^-,\hat{x}^+\in\hat{o}^+)/p(c''_M|d^-,\hat{x}^+\in\hat{o}^+).\tag{7}$$

Theorem 6 *The procedure of Theorem 5 solves Problem* (7) *after renaming* $n(a_{Mj},c'_M):=\underline{n}(a_{Mj},c'_M)$ *and* $n(a_{Mj},c''_M):=\overline{n}(a_{Mj},c''_M)$*, where* $\underline{n}(a_{Mj},c'_M):=\min_{d\in o}n(a_{Mj},c'_M)$ *and* $\overline{n}(a_{Mj},c''_M):=\max_{d\in o}n(a_{Mj},c''_M)$*.*

In other words, to solve Problem (7) we have to select the realization of the non-MAR part of the learning set, among the possible realizations $d\in o$ consistent with our observations, which minimizes the probability ratio.

For a non-MAR feature variable A_j, one can prove that:

- the probability of class c'_M is minimized by assuming the value of $\mathcal{A}_j$ to be different from a'_{Mj} whenever A_j is missing and the class of the instance is c'_M; this is the meaning of the lower counts $\underline{n}(a_{Mj},c'_M)$;[8]

8. Note that, despite the different meaning, the counts $\underline{n}(a_j,c)$ for non-MAR feature variables are computed identically to the counts $n_l(a_j,c)$ for MAR ones.

- the probability of class c''_M is maximized by assuming the value of A_j to be a_{Mj} whenever A_j is missing and the class of the instance is c''_M; this is the meaning of the upper counts $\overline{n}(a_{Mj}, c''_M)$.

Once the realization of the non-MAR missing values is identified by upper and lower counts, the most unfavorable complete realization of the learning set has been chosen (i.e., the minimization over $d \in o$ has been accomplished), and we are in the case of Problem (6).

3.4 Credal Dominance Test with an Incomplete, Non-MAR, Unit to Classify

Finally, we consider the case when the unit to classify is missing some of the attributes subject to the unknown MP. We need to address the following problem:

$$\min_{x_M \in o_M} \min_{d \in o} \inf_{p(\theta) \in \mathcal{P}(\theta)} \frac{p(c'_M | d^-, \hat{x}^+ \in \hat{o}^+)}{p(c''_M | d^-, \hat{x}^+ \in \hat{o}^+)}. \tag{8}$$

Problem (8) can be trivially solved as follows: (i) considering all the possible realizations x_M of the non-MAR part of the instance (this is accomplished by considering all the possible replacements for the missing values); (ii) for each $x_M \in o_M$, assuming x_M to be the realization of the non-MAR part of the unit to classify, and then solving Problem (7); (iii) if the computed solution is smaller than or equal to 1, c''_M is not dominated by c'_M (and the computation can be interrupted); instead, if the solution is greater than 1 for each x_M, c''_M is dominated by c'_M.

Although this procedure leads to the exact solution, it takes exponential time due to the number of the replacements of missing values in the instance to classify. A more efficient polynomial-time procedure, which is still exact, can be designed to solve Problem (8) and is in fact given in Appendix A.

The underlying idea of such a procedure is to split the outer minimum in (8) in many minima, each one related to a different feature variable, and to distribute them at different places into the objective function. This makes is clear that the function to optimize is the lower envelope of a set of convex functions. In Appendix A we show that it is easy to compute the points where the function that determines the envelope changes, thus in fact obtaining a partition of the envelope function's domain with the property that in each of its elements the envelope function is convex. At that point, the function can be locally optimized efficiently on every element of the partition; and the global optimum is then just the minimum of the local optima so computed. The fact that the overall procedure is polynomial follows because the size of the partition is bounded by a polynomial.

A final remark is that, to make notation simpler, we refer to the possible realizations of the non-MAR variables in the instance to be classified as o_M; such a notation implies however that the non-MAR variables of the test set are the same of the training set. If instead the non-MAR variables of the test set are different from those of the training set, o_M should contain all the possible realizations of the variables which are non-MAR in the test set.

The NCC2 procedures are summarized in Fig. 2. Learning has linear complexity with respect to the number of attributes, while testing has roughly quadratic complexity, if the procedure carried out in Appendix A is adopted. Please refer to Appendix A also for the exact expression for the complexity.

3.5 Software Availability

The software JNCC2, implemented by the authors of this paper, implements the naive credal classifier 2. JNCC2 is open source, released under the GNU GPL license; it is hence freely available

LEARNING

- list the attributes affected by a MAR MP or by an unknown MP on the learning set;
- compute on the learning set the counts $n(\hat{a}_l, c)$, $n_l(c)$ for MAR attributes and the counts $\underline{n}(a_j, c)$, $\overline{n}(a_j, c)$, $n(c)$ for non-MAR attributes.

CLASSIFICATION OF AN INSTANCE

1. set NonDominatedClasses := $\mathcal{C}$;
2. for class $c' \in \mathcal{C}$
   - for class $c'' \in \mathcal{C}$, $c'' \neq c'$
     - if c'' is dominated by c' (to be assessed via the below procedure), drop c'' from NonDominatedClasses;
     - exit;
   - exit
3. return NonDominatedClasses.

DOMINANCE TEST BETWEEN TWO CLASSES (c', c'')

- list the attributes affected by a MAR MP or by an unknown MP in the instance;
- for each $x_M \in o_M$ (i.e., for each possible realizations of the non-MAR part of the unit to classify):
  - assume x_M to be the realization of the non-MAR part of the instance;
  - solve Problem (7) via Theorem 6;
  - if the computed solution is smaller than 1, c'' is not dominated by c'. STOP.
- if, after having tried every $x_M \in o_M$, no solution greater than 1 has been found, c' dominates c''.

/**alternatively to the above exhaustive procedure (for each $x_M \in o_M$) , the minimum can be computed more efficiently via the procedure presented in Appendix A.*/

Figure 2: Summary of NCC2 procedures.

together with user manual, sources and documentation. Being written in Java, it runs under any operating system; it has a command-line interface.

JNCC2 loads data stored in the ARFF format, which is a textual format (designed for classification problem), originally developed for WEKA (Witten and Frank, 2005), an open source software for data mining. Hence, the large public repositories of ARFF files can be used to extensively test NCC2.

For downloads and further information about JNCC2, see `www.idsia.ch/~giorgio/jncc2.html`.

4. Experiments

We consider 18 data sets from the UCI repository, and available in the ARFF format from the WEKA data sets page.[9] All the data sets are complete, that is, they do not contain any missing data.

We discretized the numerical features via MDL-based discretization (Fayyad and Irani, 1993), and then we split each data set into a training and a test set. Feature discretization is necessary, as NCC2 is designed to work with categorical variables. Discretizing the features on the entire data set introduces a slight optimistic bias in the evaluation of the classifiers accuracy (in principle, the discretization intervals should be computed on the training set, and then applied unchanged in the test set); yet, this is not a problem as our goal is to compare NBC and NCC2 in identical conditions, rather than to compare our findings with previous results obtained on the same data sets.

Also, since our goal is to fairly compare NBC and NCC2, and not to finely tune them for maximum performance, we did not perform feature selection (although, in fact, we remove numerical feature variables discretized into a single bin); yet, as both NBC and NCC2 are based on the naive hypothesis, redundant or mutually dependent feature variables might significantly bias the learning process; hence, in order to achieve maximum performance, one should consider selecting feature variables.

In the experiments presented in the following we generate artificial missingness on the original, complete data sets by using different MPs and then we compare NBC and NCC2 accuracy on the incomplete data sets.

4.1 Missingness Generation

We consider two different artificial MPs: (i) a MAR one, and (ii) a non-MAR, non-identically distributed one (nonMAR). The MPs we consider do not affect the class variable, as the class variable has been assumed to be always observed.

Note that we do not test mixed cases of MAR and non-MAR feature variables, which NCC2 is actually designed to treat. In fact, such settings would simply lead to results intermediate between those obtained under the MAR and the non-MAR settings. Yet, mixed settings are valuable and should be considered whenever possible when operating the classifier, as they allow for finely tuning the treatment of missing data to the characteristics of the MP.

The MAR MP turns into missing, with 5% probability, all the features of both the training and test sets. Such a missingness process actually meets not only the definition of MAR, but also the more restrictive definition called MCAR, that is, *missing completely at random*, see Little and Rubin (1987). We have taken into consideration also a non-MCAR, MAR MP; however, the results do not differ significantly from those obtained with the MAR MP (which satisfies also MCAR) described above.

The non-MAR MP works as follows : (i) it splits the categorical values of each feature variable into two halves; (ii) for each feature variable, it turns into missing, with probability 5%, the observations falling in the first half of values, on the training set; (ii) for each feature variable, it turns

9. The URL is `http://www.cs.waikato.ac.nz/ml/weka/`.

into missing, with probability 5%, the observations falling in the second half of values, in the test set. Such MP is not identically distributed, as it follows a different pattern from training to test set.

We split each data set into equally sized training and test subsets. Using this training/test split, for each data set and for each MP we generate artificial missingness 100 times, producing hence 100 different training and test sets. The results we present are obtained as an average over 100 runs for each data set-MP pair.

4.2 Performance Measures

The performance of NBC is measured by its *accuracy*, that is, the percentage of correct classifications, while the evaluation of NCC2 requires a larger number of indicators: *determinacy*, that is, the percentage of classifications having as output a unique class; *single accuracy*, that is, accuracy of NCC2 when it is determinate; *indeterminate output size*, that is, the average number of classes returned when NCC2 is indeterminate; *set-accuracy*, that is, the percentage of indeterminate classifications that contain the true class. Note that if a data set has two classes, the output size is necessarily 2 and set-accuracy 100%; therefore, such two indicators are meaningful on data sets with more than two classes only.

We consider three classifiers: (i) NBC (with standard Laplace prior); (ii) NCC2-MAR, that is, NCC2 which assumes all missing values to be generated by a MAR MP; (iii) NCC2-nonMAR, that is, NCC2 which assumes all missing values to be generated by an unknown MP. Indeterminate classifications of NCC2-MAR are in fact due to prior uncertainty only, while indeterminate classifications of NCC2-nonMAR are due to both the prior and the missing values.

We then consider an additional set of indicators, which refer to the NBC accuracy on specific subsets of instances (note that such indicators, referring to subsets of instances, are written in italic):

- *NCC2-MAR D* and *NCC2-MAR I*, as the NBC accuracies on the instances classified respectively in a determinate and indeterminate way by NCC2-MAR; such indicators point out the effects of the prior specification on NBC;

- *NCC2-nonMAR D* and *NCC2-nonMAR I*, as the NBC accuracies on the instances classified respectively in a determinate and indeterminate way by NCC2-nonMAR; such indicators point out the joint effect of prior specification and missing values on NBC;

- Δ*NCC2-nonMAR*, as the NBC accuracies on the instances over which NCC2-nonMAR outputs a larger number of classes than NCC2-MAR; such an indicator points out the effect of missing values on NBC.

It turns out however that *NCC2-MAR D* coincides with the single-accuracy of NCC2-MAR, and that *NCC2-nonMAR D* coincides with the single-accuracy of NCC2-nonMAR: in fact, when determinate, NCC2-MAR and NCC2-nonMAR return the same output as NBC.[10] In the following we will hence only mention *NCC-MAR D* and *NCC-nonMAR D*; it is understood that the single-accuracy of respectively NCC2-MAR and NCC2-nonMAR coincides with such values.

10. Differences might arise only in case that the NBC prior is not included in the credal set, and that such a prior leads to a classification which is different from the classification to which leads any single prior of the credal set. The frequency of such an event is however negligible and therefore the above indicators can be considered to be the same.

4.3 Overview of the Results

Table 1 reports the performance of NBC, NCC2-MAR and NCC2-nonMAR under the different MPs, averaged over all the data sets. The average of set-accuracy and indeterminate output size have been computed considering only data sets with more than two classes. The detailed results data set by data set are instead shown in Tables 6 and 7, which refer respectively to the MAR and non-MAR setting.

NBC achieves an average accuracy of about 80%; although its accuracy seems to be insensitive to the MP, we show later however, through a deeper analysis, that this is not the case.

The average determinacy of NCC2-MAR is about 91%, that is, NCC2-MAR yields set-valued classification in 9% of cases; this indicator is mainly influenced by the data set size and therefore it does not show great differences between the different MP settings. The point here is that when we declare all the feature variables to be MAR, imprecision in the probabilities is only originated by the imprecise prior density, as it follows from (1). Such a kind of imprecision strictly decreases with the size of the learning set because the prior, as in the precise Bayesian setting, counts less and less with more data.

The results detailed data set by data set (Tables 6 and 7) show that NCC2-MAR has considerably lower determinacy on the glass data set than on any other data set. This is a consequence of the low number of training instances (about 100) and high number of output classes (i.e., 7). In these conditions the prior has much weight and it originates more imprecision.

The determinacy of NCC2-nonMAR ranges from 33% under the MAR setting, to 50–55% under the non-MAR settings. The higher indeterminacy under the MAR setting for NCC2-nonMAR is due to the higher number of missing data: in fact, the MAR MP produces twice as many missing data as the non-MAR MPs, because it turns *all* the values of the feature variables into missing, with probability 5%, instead of half the values as the non-MAR MP does.

Looking at the results data set by data set, we can detect three factors that increase the indeterminacy of NCC2-nonMAR: (a) high prior uncertainty, that is, data sets over which NCC2-MAR is already quite indeterminate, and to which the uncertainty coming from missing data adds up; this is the case of glass; (b) high number of features variables (40–60), as in the case of kr-kp, optdigits, waveform, splice; in the case of the letter data set, the cause is instead (c) the high number of categories (10 on average) in which feature variables are discretized. Factors (b) and (c) increase the indeterminacy as they increase the number of complete data sets $d \in o$ consistent with the incomplete one. Increasing the number of the complete data sets makes it more likely to obtain lower values of the optimum in (1), eventually yielding a larger number of non-dominated classes. It is interesting to observe that the factors (a)–(c) above are the same that can lead NBC to overfitting. Hence, we can conjecture that classifiers based on precise and imprecise probability, respectively react in different ways to such critical characteristics of the data, the first ones by losing reliability, the second ones by becoming excessively cautious.

Let us focus now on the the size of the indeterminate output, which is the average number of classes in the set-valued classifications returned by NCC2 in a certain setting, and on set-accuracy, which denotes the percentage of times when set-valued classifications contain the actual class (we recall that the indeterminate output size and set-accuracy are measured only on data sets with more than two classes). The size of the indeterminate output should be compared with the (average) number of classes of the data sets under considerations, which is 8.8; hence, NCC2-MAR returns on average less than half the classes, and NCC2-nonMAR slightly more than half the classes. This

	MAR	non-MAR
	NBC	
Accuracy (%)	80.5	80.9
	NCC2-MAR	
Determinacy (%)	91.1	91.1
Set-Acc. (%)	84.0	84.3
Indeterminate Output Size	2.6	2.6
	NCC2-nonMAR	
Determinacy (%)	33.0	49.4
Set-Acc. (%)	97.9	96.6
Indeterminate Output Size	6.0	5.3
NBC accuracy (%) on subsets of instances		
	MAR	non-MAR
NCC2-MAR D	83.2	83.5
NCC2-MAR I	48.4	48.0
NCC2-nonMAR D	92.2	90.4
NCC2-nonMAR I	74.2	71.3
ΔNCC2-nonMAR	75.1	72.7

Table 1: Measured performance, averaged over all the 18 data sets. The average of set-accuracy and indeterminate output size has been computed considering only the data sets with more than two classes; the average number of classes of such data sets is 8.8.

shows that set-valued classifications are informative: they lead us to drop on average half of the classes, as sub-optimal, for the more doubtful instances, thus preventing an over-confident use of the issued judgment. Moreover, indeterminate classifications allow very high set-accuracy under any MP setting; about 85% for NCC2-MAR and about 96% for NCC2-nonMAR. Set-valued classifications appear then as a very effective way to maintain reliability while conveying informative content. This is especially appealing for contexts in which the classification outcome is very sensitive, such as, for instance, the medical area.

Probably the most interesting part of our results concerns the analysis of the accuracy of NBC made separately for the instances classified in a determinate way by NCC2 and for those whose classification is set-valued. Here the intuition is that we expect NBC to perform worse in the latter set of instances, as NCC2 deems that they are harder to classify. Indeed, by averaging over the two different MPs, we obtain that the accuracy of NBC drops of 33 points from *NCC2-MAR D* to *NCC2-MAR I*; of 20 points from *NCC2-nonMAR D* to *NCC2-nonMAR I* and of 19 points from *NCC2-nonMAR D* to Δ*NCC2-nonMAR*.

The overall performance of NBC can hence be regarded as the average of a good accuracy on the instances which are easier to classify, and a much lower accuracy on the instances which are harder, due to the fact that the available information about them is reduced with respect to the former ones. Such a reduction depends in part on the learning set, which in general contains different degrees of information in relationship with different units to classify; and in part on the number and type

of missing feature variables in those units, which contributes to determine the information that the classifier can exploit to classify them.

We regard the alternate good-bad performance of NBC on different units as an important finding, which should be brought to light and properly taken into account. In contrast, such a finding can well remain hidden if we only measure the predictive accuracy, as it is common with traditional classifiers, because it is an average over all the instances in the test set.[11] NCC2, instead, recognizes the more difficult instances and preserves its reliability by issuing indeterminate classifications. (NCC2-MAR does the same, but not with respect to the hardness originated by missing data, both in learning and test set.)

In fact, the following relationships hold on the average indicators, but also on *every* data set-MP pair:

- *NCC2-MAR D* $>$ *NCC2-MAR I*,
- *NCC-nonMAR D* $>$ *NCC2-nonMAR I*,
- Δ*NCC2-nonMAR* $>$ *NCC2-nonMAR I*.

The intuition behind these inequalities is, as before, that on the instances where NCC2 is indeterminate, there is a drop of accuracy of NBC compared to the remaining instances. This happens not only on every data set but also under every experimental setup that we considered. This enforces the idea that NCC2 truly isolates instances that are hard to classify and where, as a consequence, NBC is less reliable.

Despite the inequalities remain the same in the different settings, one should not overlook the fact that the amount of instances isolated by NCC2 may be also very different in the different cases. In particular, looking at Table 1, we see that NCC2-nonMAR may produce even 5–6 times as much indeterminacy as NCC2-MAR. This is not surprising as prior uncertainty tends to vanish with larger samples whereas this does not need to be the case for the uncertainty originated by missing values. We see then that the large majority of indeterminate classifications issued by NCC2-nonMAR are due to missing data rather than prior uncertainty.[12]

It is useful to remark also that the indeterminacy generated by NCC2-nonMAR may sometimes be greater than necessary, or, in other words, that NCC2-nonMAR may show an excess of caution. This makes the drop in NBC accuracy be usually smaller from *NCC2-MAR D* to *NCC2-MAR I*, than from *NCC2-nonMAR D* to Δ*NCC2-nonMAR*. The excess of caution appears because the MP acting on the data is simpler than what NCC2-nonMAR expects. One reason is that for the MP described in Section 4.1 only half the values contained in $\mathcal{A}_j$ are actually possible replacements. This information is not accessible to NCC2-nonMAR, which then considers all the values in $\mathcal{A}_j$ as possible replacement for the missing values of A_j. The other, more important, reason is that we have

11. There are some reasons why computing in addition the standard deviation of the predictive accuracy would not be very helpful either: (i) the standard deviation might be small simply because so is the subset of test-set instances on which the classifier performs badly; (ii) the standard deviation cannot be reliably estimated in the case of small samples; (iii) finally, even if computing the standard deviation might point to the problem, it would not help to isolate the critical instances, nor to know what to do with them, as opposed to what NCC2 makes it possible to do.
12. With respect to the variability of the empirical measures collected, we can observe that *NCC2-MAR I* has usually larger standard deviation than the others (see Tables 6 and 7); this is expected, as NCC2-MAR tends to generate indeterminacy on relatively few instances. Anyway, the difference between *NCC2-MAR D* and *NCC2-MAR I*, and between *NCC2-NonMAR D* and *NCC2-NonMAR I*, is much larger than the standard deviations of the estimate of then indicators (actually, is it well above twice the standard deviation in most cases).

deliberately designed the non-MAR MPs so as to make them act in quite a naive way. We have done so to show that even those MPs can lead to appreciable problems for NBC, as confirmed by the fact that for the large majority of data sets it holds that the NBC accuracy on the ΔNCC2-nonMAR area decreases, moving from the MAR to the non-MAR setting. And, finally, when we consider MPs that are not naive, as the one described in Sect. 4.6, we see that the caution of NCC2-nonMAR is fully justified, NBC being totally unreliable on the area of indeterminacy.

4.4 NBC Probabilities Vs. Set-valued Classifications

We have shown that, thanks to imprecise probabilities, NCC2 delivers set-valued classifications on hard-to-classify instances, over which the accuracy of NBC clearly drops. In the following, we further compare the predictions of NBC and NCC2 by taking into consideration also the posterior probabilities computed by NBC for the classes. To make things clearer we carry out the analysis in two steps.

The first step, described in the next two sections, focuses on a simplified setup that allows us to make a very detailed analysis: a single data set containing two classes, and subject only to a MAP MP. The focus in this case is on prior ignorance, as the only possible source of indeterminacy for NCC2; we can therefore understand how strong assumptions about the prior can affect the ability of NBC to compute posterior probabilities. Thanks to the restriction to the binary case (i.e., two classes), we can then also clearly see that there is a difference between the cases that are deemed doubtful by NBC (i.e., with probability close to 50%) and those that are deemed so by NCC2 (i.e., that lead it to indeterminacy).

The second step extends the analysis to all the data sets and to ignorance originated by non-MAR missing data. In this case there is necessarily less detail but we have the advantage of having the full comparison between NBC probabilities and NCC2 indeterminacy, and where we observe that the situation basically resembles the one observed in the first step. This is done in Section 4.4.3.

4.4.1 AN ILLUSTRATIVE EXAMPLE: THE SPECT DATA SET

We focus on the spect data set, which is made of 2 classes and 267 instances.

For the following analysis, we split the data set into training set of 67 instances and a test set of 200 instances. We choose a 25-75% split in this example because we want to clearly see the effect of the prior, which is well known to decrease with increasing sizes of the learning set.

We run the experimental framework of Section 4.3 with the MAR MP; that is, we generate 100 pairs of training and test sets (made artificially incomplete by the MP) from the original training/test split. The findings presented in the following are obtained by analyzing the predictions issued over the 100 test sets.

In particular, we consider four pieces of information for each classified instance: the actual class, the class returned by NBC and its associated probability, and whether or not the instance has been classified by NCC2 in a determinate way. The instances are then partitioned into subsets, according to the probability estimated by NBC for the returned class, that is, instances for which NBC estimates a probability in the range 50–55%, 55–60%, and so on (i.e., we use a step of 5% in probability to define the subsets). On each subset of instances, we measure: (a) the determinacy of NCC2-MAR; (b) the accuracy achieved by NBC on the instances classified determinately and (c) indeterminately by NCC2-MAR.

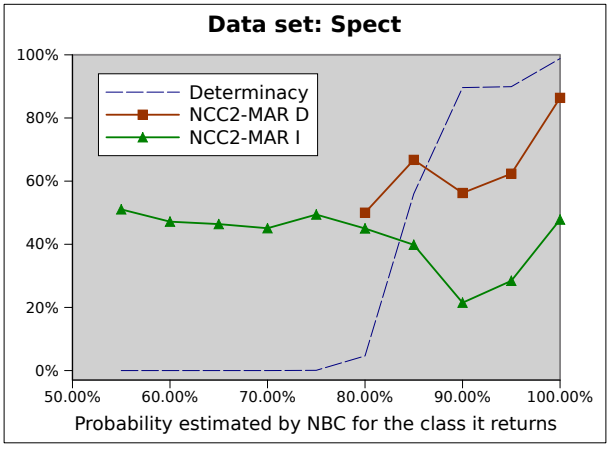

Figure 3: Relationship between the posterior probabilities computed by NBC and the output of NCC2-MAR on the spect data set.

The results are reported in Figure 3. The dashed line represents the percentage of instances in the subset (related to a certain range of probabilities) under consideration that is classified determinately by NCC2. We see then that there is a positive association between higher posterior probabilities computed by NBC and higher determinacy. This is a natural effect but it needs some words to be explained, and we postpone this task to the next section.

An interesting point is that the output of NCC2 is indeterminate for all the instances as long as the probability estimated by NBC for the returned class is lower than 75%. In other words, here NCC2 deems that there is very little information about those instances in the learning set and suspends the judgment. Remarkably, such caution is justified as on those instances NBC is just guessing (uniformly) at random, at is follows from the line for NCC2-MAR I. The point here is that NBC believes to be quite confident on a number of instances (assigning probabilities that go as up as 75%) but in practice it is not. Stated differently, it believes it knows but it does not. NCC2 simply knows not to know from the very beginning and this enables it to avoid losing credibility.

Moving on to greater probabilities, we see that the determinacy of NCC2 rises substantially when the probability estimated by NBC exceeds 80%; in this region NCC2 returns a mix of determinate and indeterminate classifications, and the drop of accuracy between *NCC2-MAR D* and *NCC2-MAR I* is large at any level of posterior probability. In fact, NCC2 returns indeterminate classification also on a non-negligible number of instances classified very confidently (for instance, with probability higher than 85%) by NBC, and over which the accuracy of NBC is bad indeed.

The last discussion points to an important question, which is useful to stress: that is, to the fact that NCC2 does not suspend the judgment only on instances that are deemed doubtful by NBC, that is, those whose probability is for instance less than 55%. Moreover, while on the spect data set NCC2 is fully indeterminate on the instances on which NBC is doubtful, this is not always the case. For instance, the same analysis performed on the spambase data set (2 classes, 1300 training instances) shows that about 40% of instances in the range 50–55% of probability are classified

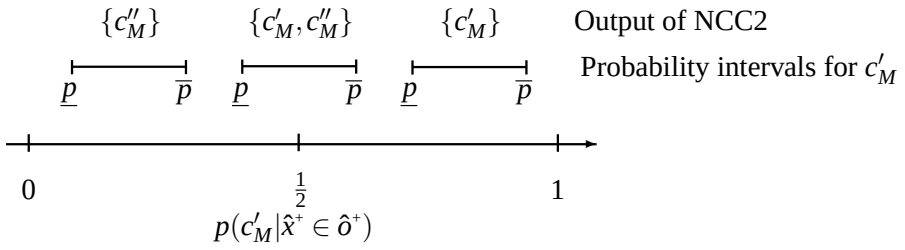

Figure 4: A graphical view of the test of dominance in the binary case. The output of the classifier is indeterminate if and only if the posterior probability interval for c'_M contains $\frac{1}{2}$.

determinately by NCC2 (while the behavior on the remaining ranges of probabilities followed a pattern similar to the one shown in Fig. 3).

4.4.2 ASSOCIATION BETWEEN NBC PROBABILITIES OF NCC2 DETERMINACY

In the following, we explain, with reference to a generic data set with two classes, why there is a positive association between increasing posterior probabilities computed by NBC and increasing determinacy of NCC2.

Re-consider the notation that we have introduced for the test of dominance in (1). Define the posterior *lower* and *upper probabilities* of class c'_M respectively as

$$\underline{p}(c'_M|\hat{x}^+ \in \hat{o}^+) := \inf_{p(\theta)\in\mathcal{P}(\theta)} p(c'_M|\hat{x}^+ \in \hat{o}^+)$$

and

$$\overline{p}(c'_M|\hat{x}^+ \in \hat{o}^+) := \sup_{p(\theta)\in\mathcal{P}(\theta)} p(c'_M|\hat{x}^+ \in \hat{o}^+).$$

Compared to (1), here we have removed the parts related to the non-MAR missingness process as in this moment we prefer to keep things simple by focusing on the MAR case, as in the previous section.

With the new definitions, the test of dominance (1) can be easily re-written in the case of a data set with two classes as a simple test that checks the position of the interval $[\underline{p}(c'_M|\hat{x}^+ \in \hat{o}^+), \overline{p}(c'_M|\hat{x}^+ \in \hat{o}^+)]$ relative to the probability value $\frac{1}{2}$. This is shown graphically in Fig. 4. Such a figure shows three possible positions of the posterior intervals, which are represented as segments. When the interval contains the value $\frac{1}{2}$, as in the middle case, then the output of the classifier is indeterminate: both classes are returned. Here we have complete indeterminacy because it is not possible to know if one of the two classes has posterior probability larger than the other (note that in this case the interval for c''_M contains $\frac{1}{2}$ as well). In the remaining two cases, the value $\frac{1}{2}$ is either greater or less than all the points in the interval and this allows the classifier to know that one of the two classes is dominated, thus returning a determinate classification, as shown above the intervals. Now, assume temporarily the width of the NCC2 interval to be constant across all the instances. By construction, the posterior interval computed by NCC2 is typically "close" to the posterior probability given by NBC.[13] Hence, the NBC probability and the NCC2 interval tend to move together; if the NBC

13. In our experiments the posterior probability is actually very often in the interval, but we cannot say this is always the case because the Laplace prior used for NBC is not contained in the prior credal set of NCC2.

probability grows, then the NCC2 interval reaches a point that makes it exclude the value $\frac{1}{2}$, leading to a determinate classification. This explains the basic mechanism behind the association between NBC probabilities and NCC2 determinacy.

Let us now move on to the realistic scenario that involves dropping the simplifying assumption about the width of the NCC2 interval to be constant.[14] In fact, it practice it happens that the length of the NCC2 interval varies from unit to unit, as it depends on the amount of information that the learning set contains about the *specific unit under consideration*: the less the information the wider the interval, and vice versa. The fact that the learning set contains different amounts of information for different units to classify should not be surprising: a unit to classify can be put in correspondence with the subset of the learning set characterized by the values taken by the feature variables for the unit under consideration; and these subsets have (also very) different sizes (remember that we are dealing only with the MAR case; in the non-MAR case, we should consider also the effect of missing data and the interpretation would be slightly more complicated, but still of a similar kind).

Therefore, it may well happen that for a certain unit to classify to which NBC assigns a high posterior probability, the width of the NCC2 interval dilates so much that $\frac{1}{2}$ gets included in the interval, leading to an indeterminate classification. In this case, NCC2 deems that there is little information in the learning set about the unit under consideration, and expresses this by a large width of the interval. NBC does not have such expressive means and, moreover, may generate such a high probability mostly because of its prior density, drawing then conclusions that are not supported by the data.

In any case, it is clear that increasing the NBC probability makes it less likely that the NCC2 interval is as large as to be able to contain the value $\frac{1}{2}$. This is the reason why we observe the, very natural at this point, association between increasing NBC probabilities and increasing NCC2 determinacy.

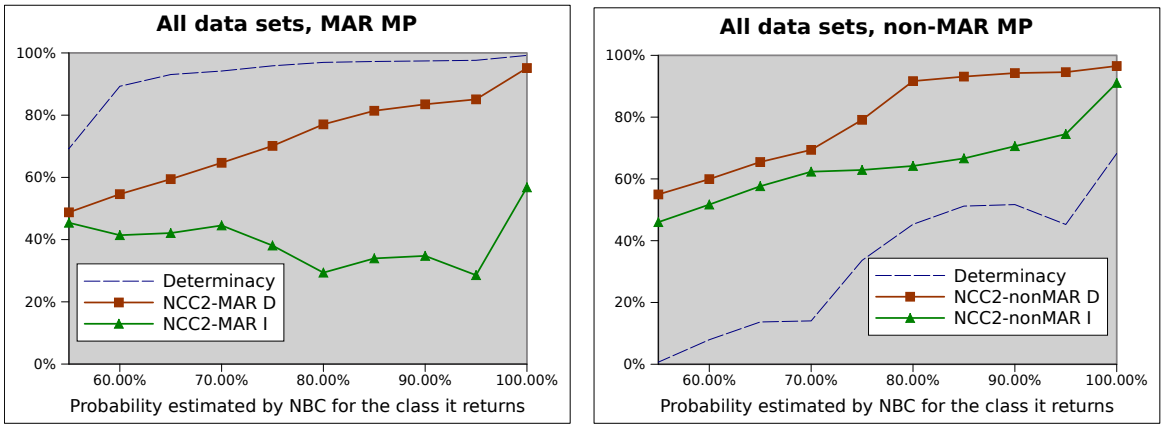
4.4.3 RESULTS ON ALL THE DATA SETS

In this section we consider all the usual 18 data sets with the same training/test splits of Section 4, that is, 50%-50%. We consider two settings: the first compares NBC and NCC2-MAR when the MP is MAR, and the second compares NBC and NCC2-nonMAR when the MP is non-MAR. We analyze jointly the predictions issued on all the data sets, respectively under the first (Figure 5a) and second setting (Figure 5b).

One point to consider is that in data sets with two classes, one can spot the instances doubtful for NBC looking at those with probability around 50% for the returned class. However, for data sets with more than two classes, the instances that are doubtful for NBC are not as easy to recognize as before; for instance, with four classes both the posterior mass functions [40%, 40.5%, 15%, 4.5%] and [24.5%, 25.5%, 25%, 25%], lead to doubtful classifications for NBC. For this reason, we only focus now on the case when NBC is confident, that is, on the instances with probability for the returned class greater than or equal to 55%.

Looking at the figures we see that the determinacy is much higher in the MAR setup than in the non-MAR; in fact, we have already seen that the non-MAR case leads in general to a much larger amount of instances that are isolated as difficult ones. Nevertheless, both Figures 5a and 5b show a clear drop of accuracy of NBC, for the same level of posterior probability of the predicted class, from

14. If it were really so, the behavior of NCC2 would be quite trivial, and could be reproduced by that of an NBC that uses a threshold larger that $\frac{1}{2}$ to decide when a class should be said to dominate the other.



(a) NBC, NCC2-MAR and MAR MP

(b) NBC, NCC2-nonMAR and non-MAR MP

Figure 5: Relationship between the posterior probabilities computed by NBC and the output of NCC2.

the instances classified in a determinate way by NCC2 to the others. The drop is especially striking on the instances classified confidently by NBC, when the computed probability is for instance larger than 70%. This is more evident in Fig. 5a; on the other hand, the drop observed in Fig. 5b applies to a much larger set of instances. In fact, NCC2-nonMAR suspends the judgment frequently also on the instances classified by NBC with probability greater than 80%; the reason is that a replacement for missing data especially unfavorable for the class predicted by NBC, can well change the outcome of the classification with respect to the output of NBC, which instead marginalizes out the missing feature variable.

The instances for which NBC returns a probability higher than 90% are of particular interest, also because they constitute 62% of the total instances. On this area, NCC2-MAR returns 1.5% of indeterminate classifications on which it achieves the following remarkable performance: *NCC2-MAR D*: 94%; *NCC2-MAR I*: 54%. The performance of NCC2-nonMAR in this area is as follows: determinacy 66%, *NCC2-NonMAR D*: 96%; *NCC2-NonMAR I*: 89%. The drop is in this case significant, yet smaller than under MAR: in fact, as already pointed out NCC2-nonMAR is more conservative than necessary under this setting.

Summing up, hence, uncertainty related to the choice of the prior manifest itself more evidently, but not only, on the instances in which NBC is less confident; yet, only part of such doubtful instances lead to indeterminate classifications. On the other hand, missing data treated as non-MAR can lead to many indeterminate classifications even if the probability computed by NBC for the returned class is high. This is clear by comparing the dashed lines in Figures 5a and 5b.

4.5 Results with Increasing Missingness

Next, we analyze how NCC2-nonMAR deals with very high levels of missingness. We adopt the non-MAR MP, with missingness rate at 15% per feature variable; given how the MP works, it will produce about 7.5% missing data on each feature. We focus on two data sets: segment-challenge

		NBC	NCC2-nonMAR				Subsets	
	MP rate (%)	Accuracy (%)	Determinacy (%)	Accuracy (%)	Set-Accuracy (%)	Output Size (%)	NCC2-nonMAR D	NCC2-nonMAR I
segment	5	91.6	54.8	97.7	99.4	5.5/7	97.7	84.1
segment	15	91.4	18.3	99.4	99.9	6/7	99.4	89.6
segment-pruned	5	93.8	77.8	98.0	99.7	4.6/7	98.0	79.1
segment-pruned	15	93.0	48.8	99.1	99.5	5.1/7	99.1	87.7

Table 2: *Segment-challenge* data set: impact of feature selection on the performance of NBC and NCC2-nonMAR. Standard deviation of the indicators is always smaller than 2%, that is, all indicators $\pm$ (at maximum) 2 percentage points.

(classes: 7; feature variables: 19; average number of bins per discretized feature variable: 5.6)[15] and waveform (classes: 3; feature variables: 40; average number of bins per feature variable: 8.4).[16]

Let us stress that in our intentions the results we present constitute a kind of worst-case analysis in terms of achieved determinacy, since (a) the amount of missing data generated by the MP is far higher than those usually found in real data sets; (b) NCC2-nonMAR treats all feature variables as non-MAR, both in training and testing (while usually, the investigator is able to isolate some MAR feature variables); (c) the considered data sets contain a high number of feature variables, classes and bins per feature variable, and these characteristics work together towards rising the indeterminacy of NCC2-nonMAR. Moreover, as already discussed, given how the non-MAR MP works, NCC2-nonMAR is more conservative than necessary under this setting.

Tables 2 and 3 report the results, displaying also the outcomes previously obtained with missingness rate 5%. In fact, while the performance of NBC is substantially insensitive to the amount of missing data, the determinacy of NCC2-nonMAR clearly decreases; with rate of missingness per feature variable equal to 15%, the determinacy of NCC2-nonMAR drops to about 1% on waveform and 18% on segment. As a side-effect, we see also that the indicator NCC2 I increases with the level of missingness; this is due to the fact that the number of instances on which NCC2 I is computed approaches the overall test set, so that NCC2 I approximates the average accuracy of NBC. Remarkably, however, even in such a difficult setting, there is a clear drop of accuracy (some 15 points), on both data sets, between NCC2 D and NCC2 I.

Is there a way to reduce the indeterminacy of NCC2-nonMAR? A first way to improve the situation is feature selection. On the one hand, feature selection is necessary if one wants to get maximum performance from NBC and NCC2, since redundant feature variables, which violate the naive assumption, might skew the learning process of both classifiers; on the other hand, reducing the set of feature variables reduces the amount of missing data, which is beneficial for the deter-

15. Two feature variables, out of the 19, are discretized into a single bin; they are not considered when computing the average number of bins.

16. Twenty feature variables, out of the 40, are discretized into a single bin; they are not considered when computing the average number of bins.

		NBC	NCC2-nonMAR				Subsets	
	MP rate (%)	Accuracy (%)	Determinacy (%)	Accuracy (%)	Set-Accuracy (%)	Output Size (%)	NCC2-nonMAR D	NCC2-nonMAR I
waveform	5	81.3	54.3	89.5	99.9	2.1/3	89.5	71.7
waveform	15	81.1	1.2	100	100	2.7/3	100	81.1
waveform-pruned	5	82.3	65.9	88.1	99.9	2.1/3	88.2	70.9
waveform-pruned	15	81.7	10.2	97.0	100	2.5/3	96.9	79.9

Table 3: *Waveform* data set: impact of feature selection on the performance of NBC and NCC2-nonMAR. Standard deviation of the indicators is always smaller than 2%, that is, all indicators $\pm$ (at maximum) 2 percentage points.

minacy of NCC2-nonMAR. We performed feature selection by cross-checking the suggestions of different methods implemented in WEKA (Witten and Frank, 2005); eventually, we selected 6 feature variables for segment-challenge and 14 for waveform.

In Table 2 and 3, the data sets after feature selection are referred to as *pruned*. The effectiveness of the feature selection we performed is demonstrated by a slight yet sensible improvement of NBC accuracy; as for NCC2-nonMAR, it achieves a satisfactory 50% of determinate classifications on segment-challenge, and a less satisfactory 10% on waveform. Still, it is remarkable that such a 10% of instances is naturally classified in a determinate way under such weak assumptions and with such an amount of missing data; this should make us quite confident about the reliability of the classification, and indeed the measured accuracy is 97%. The drop between NCC2 D and NCC2 I after feature selection does not show major changes compared to before feature selection.

So far the analysis in the most conservative possible conditions. Let us recall at this point that a strength of NCC2 is the possibility of declaring that some feature variables are MAR (possibly changing this from learning to test set). This is likely to be often possible to do in practice if we only consider that currently most classifiers take for granted that all the feature variables should be MAR. We considered then a new setup for waveform-pruned obtained by declaring that only half the feature variables are non-MAR both in training and testing; and the determinacy of NCC2 raised up to 58.5%.

4.6 A More Sophisticated MP

So far, we have considered a very simple MP, which in particular works independently on each feature variable. It is interesting at this point to consider a more complex MP, working for instance on the joint values of the feature variables. We show that this can have much bigger effects: in fact, it can lead not only to severe misclassifications, but also to erroneous empirical evaluations of the accuracy of classifiers which assume MAR.

We consider now the vote data set, also taken from the UCI repository. The data set contains information about the United States Congressional Voting; the classification task is to guess whether

a certain congressman is republican or democrat, by looking at his/her votes about some critical laws. The data set has 435 instances, 16 features variables and 2 classes; by feature selection, we reduce to 3 the number of features variables. The pruned data set is complete, that is, it does not contain any missing data. In the following, we denote by the symbol "*" a missing value generated by the non-MAR MP. Let us name as "type A" the instances with values (*n, y, n, class1*) and as "type B" the instances with values (*y, n, n, class0*). The data set contains about 26% type A and 26% type B instances.

The malicious MP that we consider turns the type A instances of the training set into (*, *, n, class1*), and the type B instances of the test set into (*, *, n, class0*); it hence affects about 26% of the training set and 26% of the test set.

We measured the following on the test set:

- NBC accuracy 71.4%;
- NCC2-MAR: determinacy 100%; single accuracy 71.4%;
- NCC2-nonMAR: determinacy 55.3%, single accuracy 99.2%.

Remarkably, in this case NCC2-MAR is always determinate, and therefore it behaves identically to NBC. With reference to the previous results on the same data set, obtained with a simpler MP, there is a major drop of accuracy (some 25 points) for NBC (and consequently for NCC2-MAR, too); on the other hand, NCC2-MAR becomes more indeterminate, but it preserves a high single-accuracy.

Going more deeply in the analysis, the accuracy of NBC and NCC2-MAR is 99.2% on the instances NCC2-nonMAR D, and 37.1 only (lower than random guessing!) on the instances NCC2-nonMAR I. Hence, this MP heavily deteriorates the reliability of the classifiers which assume MAR. NCC2-nonMAR, being based on CIR, behaves instead robustly even against such a malicious MP.

However, there is a further point of interest, concerning the failure of the empirical evaluations of classifiers that are always determinate, when data are made missing by a non-MAR MP. Let us assume that the only available data are the instances of the training set. Evaluating by cross-validation the classifiers on the instances of the training set, we measure:

- NBC accuracy 88.2%;
- NCC2-MAR: determinacy 89.9%; single accuracy 93.9%;
- NCC2-nonMAR: determinacy 49.5%, single accuracy 100%.

The evaluation of the accuracy of NBC and NCC2-MAR is hence heavily biased when compared against their actual performance on the test set. This phenomenon is discussed at some length in Section 6 of Zaffalon (2005b). On the other hand, NCC2-nonMAR is reliably evaluated.

Of course, this kind of "extreme" example heavily relies on the fact that the MP is not identically distributed. Yet, note that if one is ignorant about the MP, such a behavior should be considered as a possibility, which is just what NCC2 does. On the other hand, imposing the assumption that the MP is identically distributed should be done on a case-by-case basis, as doing it in general is questionable (unlike imposing the data generation process to be so, given that MPs are usually processes of a very different kind). Alternative assumptions, between the two extremes of assuming ignorance and assuming that the MP is identically distributed, are not so easy to envisage if we also require that they are widely applicable as one would like them to be in the field of data mining.

Algorithm	Determinacy (%)	Accuracy (%)	Output Size	Set-accuracy (%)
NBC	-	62.4 ± 5.1	-	-
NCC2-MAR	91.8 ± 3.3	64.2 ± 5.5	2.2 ± 0.2	83.9 ± 15.4
NCC2-nonMAR	65.1 ± 5.5	60.1 ± 7.7	3.3 ± 0.3	89.8 ± 5.7

Table 4: Results on the eucalyptus data set. Accuracy refers to determinate classifications only, while output size to indeterminate classifications only.

	Values of feature variable "vigour"						
Output class	*1*	*2*	*3*	*4*	*5*	*6*	*7*
c_1 ("*none*")	24	10	14	1	6	1	0
c_2 ("*low*")	0	3	24	17	8	2	0
c_3 ("*average*")	0	0	2	17	31	14	1
c_4 ("*good*")	0	0	0	6	28	57	16
c_5 ("*best*")	0	0	0	0	8	21	23

Table 5: Counts $n(a_j, c_k)$ for feature variable "vigour" in the eucalyptus data set.

In summary, we conclude that the conservative approach provided by NCC2 can be considered as a valuable avenue to reliably cope with situations where we miss substantial information about (part of) the MP. Such an approach might become even more effective by exploiting coarsened observations, as a way to insert knowledge about the MP. This is discussed in the next section.

4.7 The Eucalyptus Data Set: A Difficult One For NCC2-nonMAR

The *eucalyptus* data set is available from the Weka (Witten and Frank, 2005) repository[17] of public data sets. It contains 736 instances; there are 19 feature variables and 5 classes. After feature selection, there are 8 feature variables left; about 3% of the values in the data set are missing. NBC, NCC2-MAR and NCC2-nonMAR have been validated via 10 runs of 10 folds cross-validation; feature variables have been discretized via MDL-based discretization (Fayyad and Irani, 1993). Results are reported in Table 4.

Strikingly, NCC2-MAR has higher single-accuracy than NCC2-nonMAR. To investigate this issue, we split in a stratified way (i.e., keeping the proportion of the classes as close as possible between training and test set) the data set into a training and a test set; this enables us to detect a set of 35 critical instances, which are classified accurately and in a determinate way by NCC2-MAR, and in a totally indeterminate way by NCC-nonMAR, which returns five classes out of five.

17. The URL is `http://www.cs.waikato.ac.nz/ml/weka/index_datasets.html`.

A key point is that all these instances lack the value of feature variable vigour. The frequencies $n(a_j, c_k)$, reported in Table 5, show that, for any class c_k, there is at least a value $\tilde{a}_j$ such that $n(\tilde{a}_j, c_k)$=0. This is due to different reasons, such as the high number of classes in which the feature variable is discretized; the skew of the distribution of the counts $n(a_j, c_k)$, for any class c_k, towards certain values of the feature variable; the high number of output classes (i.e., 5), and also the relatively small size of the data set.

In fact, if the value of vigour is missing and the MP is supposed to be non-MAR, for any pair of classes (c_i, c_j) there exists a replacement $\tilde{a}_j$ for the missing value such that $n(\tilde{a}_j, c_i) = 0$, and hence $p(c'_M|d^-, \hat{x}^+ \in \hat{o}^+)/p(c''_M|d^-, \hat{x}^+ \in \hat{o}^+) = 0$, thus preventing the existence of any credal-dominance relationship between any two classes. In this condition, hence, NCC2-nonMAR has to output all the classes.

On the other hand, the conditional counts of the remaining feature variables, strongly skewed towards class c_1, allow NCC2-MAR (and NBC as well) for predicting all these instances accurately and in a determinate way. This phenomenon is the reason why NCC2-MAR is both more accurate and determinate than NCC2-nonMAR on the eucalyptus data set.

4.7.1 SOLUTION VIA COARSENING (OR SET-BASED OBSERVATIONS)

Yet, NCC2-nonMAR is processing correctly the eucalyptus instances: if the MP affecting the vigour feature variable is non-MAR, by definition all the possible replacements for the missing values should be taken into consideration. However, NCC2-nonMAR is unnecessarily cautious, as demonstrated by both NCC2-MAR and NBC, which are able to classify the critical instances both accurately and in a determinate way. It appears hence that some further knowledge should be put into the classifier, to mitigate its unnecessary caution; yet, we try to avoid assuming MAR. A step forward in this direction can be accomplished by introducing *set-based* (or *coarsened*) observations.

Up to now, we have assumed that manifest values are either equal to the latent ones, or set equal to the symbol of missing data. In the former case, the value is known exactly; in the latter, it is known in the most indeterminate way, that is, we only know that it belongs to the set of possible values of the feature variable. Coarsened observations represent an intermediate situation of knowledge, in which the observation, for instance referring to feature variable A_j, is known to belong to a set $\mathcal{A}'_j \subseteq \mathcal{A}_j$. The size and composition of $\mathcal{A}'_j$ can vary between different set-based observations of the same feature variable, thus allowing for a high degree of flexibility. Actually, the possible values of $\mathcal{A}'_j$ are all the possible non-empty subsets of $\mathcal{A}_j$.

If A_j is assumed to be affected by a non-MAR MP, set-based observations restrict the set of possible replacements from $\mathcal{A}_j$ to $\mathcal{A}'_j$ (we recall that $\mathcal{A}'_j$ will generally be different for each set-based observation). Therefore, set-based observations provide, without implying any strong assumption about the MP, a higher degree of knowledge than missing data, and they tend to generate less indeterminacy than missing data.

Remarkably, real MPs often produce set-based observations rather than missing data. For instance, let us consider a doctor that recommends a patient to go through exam B only if exam A is positive. In fact, the domain knowledge of the doctor makes it possible to conclude that if A is negative, the outcome of B will range within a restricted set of values, not influential for the diagnosis. On the contrary, if A is positive, the value of B cannot be predicted. However, when B is not performed because A is negative, we do have a set-based observation rather than a missing value.

In many cases, it is possible to provide coarsening sets rather than missing values at the time data are collected, by excluding unsuitable values from the set of the possible replacements.

Let us stress that using set-based observations and assuming MAR are two fundamentally different ways of inserting knowledge into the classifier. In fact, set-based observations incorporate specific domain knowledge (obtained at data collection or data validation time) into the data set and eventually into the classifier. On the other hand, MAR is an assumption typically done by the modeler, whose tenability is only rarely checked with domain experts.

What happens using set-based observations on the eucalyptus data set? On the 35 critical instances we tried to substitute the missing values of vigour with set-based observations, using a coarsening set $\mathcal{A}_j^{'} = \{1,2,3,4,5\}$, which contains 5 values out of the 7 possible. Using such set-based observations, NCC-nonMAR classifies 32/35 critical instances correctly and in a determinate way; on the remaining 3 instances, it outputs 4 classes, including the true one. In this way, the usual inequalities (*NCC-MAR D* $>$ *NCC-MAR I*, *NCC-nonMAR D* $>$ *NCC-nonMAR I*, Δ*NCC2-nonMAR* $>$ *NCC-nonMAR I*) hold also on the eucalyptus data set.

In our example, set-based observations constitute an effective way to insert knowledge about the MP into the classifier without assuming MAR; they appear hence as a promising approach for credal classifiers. It is useful to observe that coarsened observations have received considerable attention in the traditional literature of statistical inference from incomplete observations. A work of paramount importance on this topic is the popular coarse-data model of Heitjan and Rubin (1991), which generalizes the missing-data model of Rubin (1976). This appears to enforce the potential of coarsening for classification in general, and to make it worth of further investigation. From a practical viewpoint, the use of set-based observations would require some changes in the data archiving formats, which are usually designed to store precise observations only.

5. Conclusions

There are usually different amounts of information in the data that a classifier can exploit to classify different units. This depends in part of the fact that a learning set can be more informative about some units than some others, and in part on the type and amount of missing values in the units to classify. As a consequence, a classifier's predictions may be more uncertain on some units than on some others. But if we impose that the classifier is inferred using a single prior density and that it considers all the missing data as ignorable, we lose much of the capability to distinguish that some units are harder to classify than others: we cannot see anymore that some of the strong conclusions that we obtain are determined by our strong assumptions rather than the supposedly strong information in the data, and are hence actually fragile. Nor can help much in this respect the experimental evaluations of the classifier as they are, somewhat necessarily, designed to yield its average performance. And yet, we do care about distinguishing the hardness of different units in many real-world applications: in the case of medical diagnosis, for instance, we do not want a classifier to be good only *on average*; we want it to make reliable predictions on every single patient.

In this paper we have tried to pursue such a goal just by weakening the assumptions that are traditionally made by classifiers. We have modified the naive Bayes classifier so as to model prior ignorance in an objective-minded way by using a set of prior densities, and by giving the opportunity to treat some of the missing values as originated by a missingness process that we do not know (and the others by a MAR one). The resulting model, called naive credal classifier 2, departs from the more traditional classifiers in a number of ways, the more substantial one being the fact that NCC2

makes set-valued classifications in general: it issues a determinate classification (i.e., a singleton) only when it deems that there it has enough information to do so.

Extensive empirical evaluations have shown that NCC2 has high accuracy when it issues determinate classifications, and that when it is more cautious, it is very often justified: NBC is clearly shown to considerably decrease its classification accuracy on the instances classified in a set-valued way by NCC2, as well as its ability to compute predictive posterior probabilities. This indicates that set-valued classifications do indeed isolate the instances of the test set that are hard to classify. And they actually do more than just isolating them: they are in fact still informative, as unlikely classes are dropped anyway, and invite the domain expert (for instance, a doctor that has to issue the ultimate diagnosis) to avoid over-confident statements. We have also pointed out that in some extreme cases of missingness processes, the empirical evaluations made for naive Bayes can be completely biased, so that not even its average predictive accuracy can be evaluated reliably. In these cases, NCC2 was instead still reliably evaluated.

Dealing effectively with the hard instances is not an easy task in general, and we have shown that NBC fails on this a number of times by yielding unreliable classifications due to its inherent optimism. The way NCC2 sometimes fails on this is different, as it leads to an excess of caution; this is less critical although still not desirable. In these cases, the classifier is too pessimistic and the information used to build it up should be strengthened in order to obtain stronger conclusions. The more obvious way to do so with NCC2, and that—provided that one stays within the realm of tenable assumptions—is also what we recommend, is to minimize the number of missing values that are declared to be subject to an unknown missingness process. A less obvious but still very important way to do so is to simplify the model as much as possible, for example by doing feature selection. In fact we have conjectured that the same factors that can lead NBC to overfitting (e.g., high number of features or feature variables) can well result in excessive caution of NCC2. When also this is not enough, another approach may prove to be very helpful: using coarsened rather than missing values in data sets. Coarsened, or set-based, observations carry more information than missing ones in general because they naturally exclude some values as possible replacement for the missing information. Such extra information might be often available in real applications, and it seems to have the potential to lead to strong enough conclusions in a number of cases. It is also a kind of information that is typically provided by a domain expert rather than by the modeler (as opposed to MAR, for example) and as such it is a good candidate to be tenable.

More generally speaking, we regard the problem of providing a classifier with knowledge about the missingness process, which usually cannot be obtained from data, as a serious and an important topic of research. This seems to have much to do with identifying general and tenable assumptions about missingness processes of which classifiers could take advantage.

NCC2 can be regarded as the outcome of having made a first step in this direction. Doing such a step has led to a classifier that offers us a range of new opportunities to deal robustly with predictions in case of small or incomplete data sets: in particular, it allows us to check whether in very weak states of prior information we can draw strong enough conclusions for our aims, thus avoiding us to worry about doing mistaken assumptions; it lets us work incrementally towards stronger assumptions and conclusions; it enables us to uncover situations that otherwise could not be, not even experimentally. And it makes all of this possible by means of fast and exact computations.

Acknowledgments

We are grateful to all the reviewers for their constructive criticism, which has led us to expand and deepen the empirical analysis eventually making the paper gain insight, as well as to improve the paper at the level of presentation. Marco Zaffalon is also grateful to Peter Walley because of the joint work that led in 2001 to an inferential method for the naive credal classifier that was the starting point of the extension presented here. Work for this paper has been partially supported by the Swiss NSF grants 200021-113820/1 and 200020-116674/1, and by the Hasler Foundation (Hasler Stiftung) grant 2233.

Appendix A. A Polynomial-time Procedure for Incompleteness in the Instance to Classify

Although the procedure sketched in Section 3.4 solves Problem (8), a substantially more efficient procedure can be designed to solve the same problem. However, to avoid adding further complexity to the presentation of NCC2 carried out in the main body of the paper, we present it here, in Figure 6. The correctness of the procedure is stated by the following theorem, whose proof is in Appendix B.

Theorem 7 *The optimum of Problem* (8) *is obtained by the procedure in Figure 6.*

1. Build the set $\mathcal{U} := \{x_e = \frac{\overline{n}(a_{Me'},c''_M)\underline{n}(a_{Me''},c'_M)-\underline{n}(a_{Me'},c'_M)\overline{n}(a_{Me''},c''_M)}{s[\underline{n}(a_{Me'},c'_M)-\underline{n}(a_{Me''},c'_M)]} : e = 1,\dots,k', a_{Me'}, a_{Me''} \in \mathcal{A}_e, \underline{n}(a_{Me'},c'_M) \neq \underline{n}(a_{Me''},c'_M), x_e \in (0,1)\}$, where the lower and upper counts are defined as in Theorem 6.
2. Use the points in $\mathcal{U}$ to define a partition $\mathcal{J}$ of $(0,1)$.
3. For each interval $\mathcal{I} \in \mathcal{J}$, determine an associated tuple $(a^{\mathcal{I}}_{M1},\dots,a^{\mathcal{I}}_{Mk'}) \in \mathcal{A}_1 \times \cdots \times \mathcal{A}_{k'}$ by selecting, for each $e = 1,\dots,k'$ an element among those yielded by $\operatorname{argmin}_{a^{\mathcal{I}}_{Me} \in \mathcal{A}_e} \frac{\underline{n}(a^{\mathcal{I}}_{Me},c'_M)}{\overline{n}(a^{\mathcal{I}}_{Me},c''_M)+x^{\mathcal{I}}}$, where $x^{\mathcal{I}}$ denotes the middle point of the interval $\mathcal{I}$.
4. For each of the intervals in $\mathcal{J}$, minimize the function defined by the tuple associated with the interval, by applying of Theorem 6 with suitable changes to adapt it to $\mathcal{J}$.
5. Take the minimum of the values provided by the previous step.

Figure 6: The solution procedure for Problem (8).

The intuitive idea behind the procedure is presented in the following. Let us assume that among the k attribute variables there are k' ($1 \leq k' \leq k$) that are not observed in the instance to classify. Assume, without loss of generality, that they are indexed from 1 to k'. The objective function of the problem can be re-written as (let $x := st(c''_M)$):

$$\inf_{0<x<s}\{[\frac{n(c''_M)+x}{n(c'_M)+s-x)}]^{k-1}\prod_{e=1}^{k'}[\min_{a_{Me}\in\mathcal{A}_e}\frac{\underline{n}(a_{Me},c'_M)}{\overline{n}(a_{Me},c''_M)+x}]\cdot$$
$$\cdot\prod_{j=k'+1}^{k}\frac{\underline{n}(a_{Mj},c'_M)}{\overline{n}(a_{Mj},c''_M)+x}\prod_{l=1}^{r'}[\frac{n_l(c''_M)+x}{n_l(c'_M)+s-x}\cdot\frac{n(\hat{a}_{Ml},c'_M)}{n(\hat{a}_{Ml},c''_M)+x}]\}, \quad (9)$$

where the functions $\underline{n}(a_{Me}, c'_M)/[\overline{n}(a_{Me}, c''_M) + x]$ can be minimized, given x, separately over each a_{Me}, as shown by the minima over $a_{M1}, \cdots, a_{Mk'}$.
For variable A_e, the functions of this type obtained for each different value $a_{Me} \in \mathcal{A}_e$ are compared over the interval $[0, s]$; when the value a_{Me}, which minimizes them, changes, there is a so-called *partition point*. Now, let us consider the set $\mathcal{U}$, which collects the partition points of all the variables $A_1, \ldots, A_{k'}$: the tuple $\{a_1, \cdots a_{k'}\}$ which minimizes the first factor of Problem (9) changes over the interval $[0, s]$ at every point belonging to $\mathcal{U}$. Since the function is convex on each sub-interval, we can solve a minimization problem on each sub-interval; the global minimum is finally found by comparing the local minima obtained over each sub-interval.

Let us analyze briefly the computational complexity of the procedure. The procedure is based on the determination of the partition $\mathcal{J}$, whose size is at most $1 + \sum_{e=1}^{k'} (|\mathcal{A}_e|^2 - |\mathcal{A}_e|)/2$, which is also the number of minimizations in the worst case. Each minimization is done according to Theorem 6. This is based on the computation of the logarithmic derivatives of the function of interest. Each evaluation of the logarithmic derivative is a task linear in $k + r'$, where we recall that r' is the number of non-missing MAR variables in the instance to classify. If we regard the complexity of Newton-Raphson's method as a constant, which is reasonable as it is an extremely fast algorithm, we obtain that the procedure works in time $O([1 + \sum_{e=1}^{k'} (|\mathcal{A}_e|^2 - |\mathcal{A}_e|)/2](k + r'))$. To obtain a simpler expression, we can focus on an upper bound: $O(\overline{\mathcal{A}}^2 (k + r')^2)$, where $\overline{\mathcal{A}} := \operatorname{argmax}_{e=1}^{k'} |\mathcal{A}_e|$. The complexity is then roughly quadratic in the number of attribute variables and quadratic also in the worst-case number of attributes per variable.

Appendix B. Proofs

Proof [Lemma 1] The likelihood is easily re-written as $\prod_{i=1}^{N} \vartheta_{(d_i, \hat{x}_i \in \hat{o}_i)}$ thanks to the IID assumption, where $\vartheta_{(d_i, \hat{x}_i \in \hat{o}_i)} := \sum_{\hat{x}_i \in \hat{o}_i} \vartheta_{(d_i, \hat{x}_i)}$. By Assumption (2) we have that

$$
\begin{aligned}
p(d, \hat{x} \in \hat{o} | \vartheta) &= \prod_{i=1}^{N} [\sum_{\hat{x}_i \in \hat{o}_i} \vartheta_{(d_i, \hat{x}_i)}] \\
&= \prod_{i=1}^{N} (\sum_{\hat{a}_{i1} \in \hat{o}_{i1}} \cdots \sum_{\hat{a}_{ir} \in \hat{o}_{ir}} \vartheta_{c_i} \prod_{j=1}^{k} \vartheta_{a_{ij}|c_i} \prod_{l=1}^{r} \vartheta_{\hat{a}_{il}|c_i}) \\
&= \prod_{i=1}^{N} \{\vartheta_{c_i} [\prod_{j=1}^{k} \vartheta_{a_{ij}|c_i}] [\prod_{l=1}^{r} \sum_{\hat{a}_{il} \in \hat{o}_{il}} \vartheta_{\hat{a}_{il}|c_i}]\}.
\end{aligned}
$$

Let us focus on $\prod_{i=1}^{N} \vartheta_{c_i}$. By grouping the same chances over the N units, that expression can be re-written as $\prod_{c \in \mathcal{C}} \vartheta_c^{n(c)}$, where $n(c)$ denotes the number of occurrences of c in d. In the same way, we re-write $\prod_{i=1}^{N} \vartheta_{a_{ij}|c}$ for all j and a given c as $\prod_{a_j \in \mathcal{A}_j} \vartheta_{a_j|c}^{n(a_j, c)}$, where $n(a_j, c)$ denotes the number of joint occurrences (a_j, c) in d. Now consider $\sum_{\hat{a}_{il} \in \hat{o}_{il}} \vartheta_{\hat{a}_{il}|c}$, for a given c. Whenever $\hat{o}_{il}$ coincides with $\hat{\mathcal{A}}_l$, $\sum_{\hat{a}_{il} \in \hat{o}_{il}} \vartheta_{\hat{a}_{il}|c} = 1$; and in all the other cases the sum degenerates to a single term, as the observation of the variable value has been precise. Indeed, as clarified in Section 2, according to the definition of missing data we either observe a value exactly, or we do not observe it at all.

This means that we are allowed to drop the missing values from the learning set. In other words, $\prod_{i=1}^{N} (\sum_{\hat{a}_{il} \in \hat{o}_{il}} \vartheta_{\hat{a}_{il}|c})$ becomes, for all l, $\prod_{\hat{a}_l \in \hat{\mathcal{A}}_l} \vartheta_{\hat{a}_l|c}^{n(\hat{a}_l, c)}$, where $n(\hat{a}_l, c)$ denotes the number of joint occurrences $(\hat{a}_l, c)$ in the learning set after dropping the units with missing values of $\hat{A}_l$. ■

We skip the proof of Lemma 2 as it follows a pattern analogous (and easier) to that of the previous proof.

Proof [Theorem 3] Lemmas 1 and 2, together with the chosen prior in (4), allow us to re-write $p(c_M|d^-,\hat{x}^+ \in \hat{o}^+)$ in Equation (3), that is, $p(c_M|d^-,\hat{x}^+ \in \hat{o}^+,s,t)$, as follows:

$$
\begin{aligned}
&p(c_M|d^-,\hat{x}^+ \in \hat{o}^+,s,t) \propto \\
&\int_{\Theta_C} \vartheta_{c_M} \prod_{c\in\mathcal{C}} \vartheta_c^{n(c)+st(c)-1} d\vartheta_C \\
&\cdot \prod_{j=1}^{k} \int_{\Theta_{A_j|c_M}} \vartheta_{a_{Mj}|c_M} \prod_{a_j\in\mathcal{A}_j} \vartheta_{a_j|c_M}^{n(a_j,c_M)+st(a_j,c_M)-1} d\vartheta_{A_j|c_M} \\
&\cdot \prod_{\substack{l=1 \\ \hat{o}_{Ml}\neq\hat{\mathcal{A}}_l}}^{r} \int_{\Theta_{\hat{A}_l|c_M}} \vartheta_{\hat{a}_{Ml}|c_M} \prod_{\hat{a}_l\in\hat{\mathcal{A}}_l} \vartheta_{\hat{a}_l|c_M}^{n(\hat{a}_l,c_M)+st(\hat{a}_l,c_M)-1} d\vartheta_{\hat{A}_l|c_M}.
\end{aligned}
\tag{10}
$$

Expression (10) is obtained by the following steps: (i) substituting in (3) the expressions for the prior, the likelihood and the probability of the next class obtained in Section 3.1; (ii) observing that the Dirichlet densities involved in the integration are independent, so that they can be integrated separately; (iii) dropping the integrals related to classes different from c_M, as each of them equals 1 given that it is missing the term of which to take the expectation; and (iv), for similar reasons, dropping the integrals related to missing attribute values in the unit to classify. Observe that in (10) we have used the following notation: we have denoted by $\vartheta_C \in \Theta_C$ the vector of chances ϑ_c, $c \in \mathcal{C}$. Similarly, $\vartheta_{A_j|c_M} \in \Theta_{A_j|c_M}$ (for all $j = 1,\ldots,k$) resp. $\vartheta_{\hat{A}_l|c_M} \in \Theta_{\hat{A}_l|c_M}$ (for all $l = 1,\ldots,r$) denote the vector of chances $\vartheta_{a_j|c_M}$, $a_j \in \mathcal{A}_j$, resp. $\vartheta_{\hat{a}_l|c_M}$, $\hat{a}_l \in \hat{\mathcal{A}}_l$.

Each integral in (10) represents the expectation of a chance with respect to a Dirichlet density. It is well known that such a calculation can be solved exactly (Kotz et al., 2000, Chap. 49), leading to the statement of the theorem. ■

Proof [Lemma 4] Using (5) we first re-write the function to optimize as follows:

$$
\begin{aligned}
&\Big[\frac{n(c''_M)+st(c''_M)}{n(c'_M)+st(c'_M)}\Big]^{k-1} \prod_{j=1}^{k} \frac{n(a_{Mj},c'_M)+st(a_{Mj},c'_M)}{n(a_{Mj},c''_M)+st(a_{Mj},c''_M)} \cdot \\
&\cdot \prod_{l=1}^{r'} \Big[\frac{n_l(c''_M)+st(c''_M)}{n_l(c'_M)+st(c'_M)} \cdot \frac{n(\hat{a}_{Ml},c'_M)+st(\hat{a}_{Ml},c'_M)}{n(\hat{a}_{Ml},c''_M)+st(\hat{a}_{Ml},c''_M)}\Big].
\end{aligned}
$$

Then we simplify the optimization problem according to the following considerations.

- The objective function is only concerned with the r' non-missing MAR attribute variables.
- For each $j \in \{1,\ldots,k\}$ and $c \in \mathcal{C}$, the objective function contains only one term $t(a_j,c)$. We can choose its value freely in the interval $[0,t(c)]$, as the constraints of type $\sum_{a_j\in\mathcal{A}_j} t(a_j,c) = t(c)$ are always satisfied by assigning the value $[t(c)-t(a_j,c)]$ to any term $t(a_{j'},c)$ ($j' \in \{1,\ldots,r\}$, $j' \neq j$) that does not appear in the objective function, and zero to the others. It follows that constraints of type $\sum_{a_j\in\mathcal{A}_j} t(a_j,c) = t(c)$ can be re-written as $t(a_j,c) \leq t(c)$ for all $j \in \{1,\ldots,k\}$, $c \in \mathcal{C}$. Analogous considerations hold with constraints of type $\sum_{\hat{a}_l\in\hat{\mathcal{A}}_l} t(\hat{a}_l,c) = t(c)$.

- The optimum of the problem is obtained when all the terms $t(a_{Mj}, c'_M)$ and $t(\hat{a}_{Ml}, c'_M)$ go to zero, and all the terms $t(a_{Mj}, c''_M)$ and $t(\hat{a}_{Ml}, c''_M)$ go to $t(c''_M)$. This follows from the preceding observation and because the objective function is made of non-negative terms. Therefore, in the objective function we can replace the mentioned terms with the corresponding values at the optimum.

- Constraint $\sum_{c\in\mathcal{C}} t(c) = 1$ can be replaced by $t(c_{M'}) + t(c_{M''}) = 1$, because the objective function is only concerned with those two classes, as because such a constraint naturally holds at a global optimum. Suppose the last statement is false, that is, that $t(c_{M'}) + t(c_{M''}) < 1$ at a global optimum point. Then we might keep $t(c_{M''})$ fixed and increase $t(c_{M'})$ up to $1 - t(c_{M''})$ (making the $t(\cdot)$ terms of the remaining classes go to zero), so decreasing the optimum value.

These lead to the statement of the lemma once we also remove the variable $t(c'_M)$ from consideration. ■

Proof [Theorem 5] To demonstrate Theorem 5, it is necessary first to introduce two lemmas, whose proofs are given later.

Lemma 8 *Consider Problem* (6)*, assuming that the following two conditions hold: (i) there is no* j *such that* $n(a_{Mj}, c'_M) = 0$ *nor* l *such that* $n(\hat{a}_{Ml}, c'_M) = 0$*; and (ii)* $k + r' > 0$*. Then the objective function* $h(t(c_{M''}))$ *is (strictly) convex over* $(0,1)$*.*

Lemma 9 *Consider Problem* (6)*, and the same assumption used in Lemma 8. Then the logarithmic derivative of the objective function in* $t(c''_M) = 0$ *is* $-\infty$ *if and only if any of the following cases hold:* $n(c''_M) = 0$*; there is* $j \in \{1,\ldots,k\}$ *s.t.* $n(a_{Mj}, c''_M) = 0$*; there is* $l \in \{1,\ldots,r'\}$ *s.t.* $n(\hat{a}_{Ml}, c''_M) = 0$ *and* $n_l(c''_M) \neq 0$*.*

Having introduced Lemmas 8 and 9, we can now prove Theorem 5. The first two steps of the procedure deal with special cases. The first step is justified since in the stated conditions the objective function attains the value zero, and this is a global minimum because the function is non-negative. The second step considers a degenerate problem of classification, in which there are no attribute variables; in this case the minimum is at $t(c_{M''}) = 1$, as the objective function is strictly decreasing, as it can be shown by differentiating.

Otherwise, the function is convex and the local minimum is also the global minimum. The minimum is found by the following procedure:

1. If:

   - $n(c''_M) = 0$ or
   - there is $j \in \{1,\ldots,k\}$ s.t. $n(a_{Mj}, c''_M) = 0$ or
   - there is $l \in \{1,\ldots,r'\}$ s.t. $n(\hat{a}_{Ml}, c''_M) = 0$ and $n_l(c''_M) \neq 0$,

   then let $(\ln h(t(c''_M)))'|_{t(c''_M)=0} := -\infty$, else compute $(\ln h(t(c''_M)))'|_{t(c''_M)=0}$.

2. Compute $(\ln h(t(c''_M)))'|_{t(c''_M)=1}$.

3. If $(\ln h(t(c''_M)))'|_{t(c''_M)=0} \geq 0$, let $\inf_{0<t(c''_M)<1} h(t(c''_M)) := h(0)$. Stop.

4. If $(\ln h(t(c''_M)))'|_{t(c''_M)=1} \leq 0$, let $\inf_{0<t(c''_M)<1} h(t(c''_M)) := h(1)$). Stop.

5. If $(\ln h(t(c''_M)))'|_{t(c''_M)=0} < 0$ and $(\ln h(t(c''_M)))'|_{t(c''_M)=1} > 0$, approximate the minimum numerically by Newton-Raphson's algorithm as in p. 366 of Press et al. (1993).

The procedure is basically a test based on the values of the logarithmic derivative at the extremes of the interval $[0,1]$. If the function were bounded, the last three points would obviously identify the minimum. The preceding points allow the test to be extended to the case of $h(0)$ being unbounded.[18] This happens according to the conditions stated in Lemma 9. We account for these cases by introducing the value $-\infty$ for the derivative in the solution procedure, and treating it as one of the possible values.

As far as Newton-Raphson's method is concerned, it can be applied as the first and second derivatives are available. Note that if the Newton-Raphson is combined with bracketing as in the cited implementation, then its convergence is guaranteed. ■

Proof [Lemma 8] Consider the following definitions to simplify the notation: $\alpha_j := n(a_{Mj}, c'_M)$, $\beta_j := n(a_{Mj}, c''_M)$, $\tilde{\alpha} := n(c'_M)$, $\tilde{\beta} := n(c''_M)$, $\gamma_l := n(\hat{a}_{Ml}, c'_M)$, $\delta_l := n(\hat{a}_{Ml}, c''_M)$, $\tilde{\gamma}_l := n_l(c'_M)$, $\tilde{\delta}_l := n_l(c''_M)$, $x := st(c''_M)$. Re-write Problem (6) accordingly as

$$\begin{aligned}&\inf_{0<x<s} \left(\frac{\tilde{\beta}+x}{\tilde{\alpha}+s-x}\right)^{k-1} \prod_{j=1}^{k} \frac{\alpha_j}{\beta_j+x} \prod_{l=1}^{r'} \left(\frac{\tilde{\delta}_l+x}{\tilde{\gamma}_l+s-x} \cdot \frac{\gamma_l}{\delta_l+x}\right) \\ &= \inf_{0<x<s} h(x).\end{aligned}$$

The objective function is positive on the domain of definition, so we can compute the logarithmic derivative of $h(\cdot)$:

$$\begin{aligned}&\frac{d \ln h(x)}{dx} = \\ &= \frac{k-1}{\tilde{\beta}+x} + \frac{k-1}{\tilde{\alpha}+s-x} - \sum_{j=1}^{k} \frac{1}{\beta_j+x} + \sum_{l=1}^{r'} \frac{1}{\tilde{\delta}_l+x} + \\ &- \sum_{l=1}^{r'} \frac{1}{\delta_l+x} + \sum_{l=1}^{r'} \frac{1}{\tilde{\gamma}_l+s-x}.\end{aligned} \tag{11}$$

Another differentiation leads to the following expression:

$$\begin{aligned}&\frac{d^2 \ln h(x)}{dx^2} = \\ &= -\frac{k-1}{(\tilde{\beta}+x)^2} + \frac{k-1}{(\tilde{\alpha}+s-x)^2} + \sum_{j=1}^{k} \frac{1}{(\beta_j+x)^2} + \\ &- \sum_{l=1}^{r'} \frac{1}{(\tilde{\delta}_l+x)^2} + \sum_{l=1}^{r'} \frac{1}{(\delta_l+x)^2} + \sum_{l=1}^{r'} \frac{1}{(\tilde{\gamma}_l+s-x)^2}.\end{aligned} \tag{12}$$

18. Note that the function is always defined in $t(c_{M''}) = 1$ as the cases that arise when either $n(c'_M) = 0$ or when there is l such that $n_l(c'_M) = 0$, are ruled out by the initial assumption prescribing that there is neither j such that $n(a_{Mj}, c'_M) = 0$, nor l such that $n(\hat{a}_{Ml}, c'_M) = 0$.

There are three possible cases.

1. $k = 0$ and $r' > 0$. In Expression (12), the sum on j disappears, and the other terms are positive except for two of them: $-\frac{1}{(\tilde{\alpha}+s-x)^2}$ and $-\sum_{l=1}^{r'} \frac{1}{(\tilde{\delta}_l+x)^2}$.
   Consider the first one. By definition, $\tilde{\gamma}_l \leq \tilde{\alpha}$ for each l, so that $\frac{1}{(\tilde{\alpha}+s-x)^2} \leq \frac{1}{(\tilde{\gamma}_l+s-x)^2}$, whence $-\frac{1}{(\tilde{\alpha}+s-x)^2} + \sum_{l=1}^{r'} \frac{1}{(\tilde{\gamma}_l+s-x)^2} \geq 0$.
   Now consider the second negative term in Expression (12). By definition, it holds that $\delta_l \leq \tilde{\delta}_l$ for each l, whence $\sum_{l=1}^{r'} \frac{1}{(\tilde{\delta}_l+x)^2} \leq \sum_{l=1}^{r'} \frac{1}{(\delta_l+x)^2}$, or, in other words, $-\sum_{l=1}^{r'} \frac{1}{(\tilde{\delta}_l+x)^2} + \sum_{l=1}^{r'} \frac{1}{(\delta_l+x)^2} \geq 0$.
   This shows that the negative terms in Expression (12) together with the considered positive ones produce non-negative results. Since there are positive terms left in Expression (12), the overall expression is positive. In other words, the function $\ln h(\cdot)$ is (strictly) convex, and so is $h(\cdot)$ (by applying the exponential function).

2. $k > 0$ and $r' = 0$. In this case, there is only one negative term in Expression (12): $-\frac{k-1}{(\tilde{\beta}+x)^2}$. By definition, $\beta_j \leq \tilde{\beta}$ for each j, so that $-\frac{k-1}{(\tilde{\beta}+x)^2} + \sum_{j=1}^{k} \frac{1}{(\beta_j+x)^2} \geq 0$. Since there are positive terms left in Expression (12), the function $h(\cdot)$ is (strictly) convex.

3. $k > 0$ and $r' > 0$. In this case there are two negative terms in Expression (12) (the others being positive): $-\frac{k-1}{(\tilde{\beta}+x)^2}$ and $-\sum_{l=1}^{r'} \frac{1}{(\tilde{\delta}_l+x)^2}$. We have already shown in the two preceding cases that $-\sum_{l=1}^{r'} \frac{1}{(\tilde{\delta}_l+x)^2} + \sum_{l=1}^{r'} \frac{1}{(\delta_l+x)^2} \geq 0$ and that $-\frac{k-1}{(\tilde{\beta}+x)^2} + \sum_{j=1}^{k} \frac{1}{(\beta_j+x)^2} \geq 0$. As there are positive terms left in Expression (12), the overall expression is positive. Also in this case, the function $h(\cdot)$ is (strictly) convex.

■

Proof [Lemma 9] Consider Expression (11) for the logarithmic derivative, and the notation introduced there. Let us focus on the expression obtained from Expression (11) by dropping the terms that are bounded when x approaches zero:

$$\frac{k-1}{\tilde{\beta}+x} - \sum_{j=1}^{k} \frac{1}{\beta_j+x} + \sum_{l=1}^{r'} \frac{1}{\tilde{\delta}_l+x} - \sum_{l=1}^{r'} \frac{1}{\delta_l+x}. \tag{13}$$

Of course Expression (11) goes to $-\infty$ when x approaches zero if and only if Expression (13) does the same, so that we can concentrate on the latter.

($\Leftarrow$) Let us now show that if any of the conditions in the statement holds, Expression (13) goes to $-\infty$ with x approaching zero.

First, consider the case when $\tilde{\beta} = n(c''_M) = 0$, and suppose that $k = 0$. The first term in (13) becomes $-1/x$, the second disappears, and the last two terms sum up to zero. Indeed, when $\tilde{\beta} = 0$, $\tilde{\delta}_l = \delta_l = 0$. The expression becomes $-1/x$, and the implication is verified. In the case when $r' = 0$, it must be $k > 0$ and hence the first two terms in (13) yield $-1/x$ as $\beta_j = 0$ for all j when $\tilde{\beta} = 0$; and the last two terms disappear. Again, the expression becomes $-1/x$, and the implication is verified. The case when both $k > 0$ and $r' > 0$ is verified on the basis of the previous two cases.

Second, consider the case when there is $j \in \{1,\ldots,k\}$ s.t. $\beta_j = n(a_{Mj}, c''_M) = 0$. If also $\tilde{\beta} = 0$, we would fall in the previous case and the implication would be true, so we can assume that $\tilde{\beta} > 0$. In the case when $r' = 0$, the implication would follow immediately. Consider $r' > 0$. The only possibility for Expression (13) not to go to $-\infty$ with x going to zero, is that there is l s.t. $\tilde{\delta}_l = 0$. In this way the term $-1/(\beta_j + x) = -1/x$ would sum up to zero together with the term $1/(\tilde{\delta}_l + x) = 1/x$. But this is not possible: in fact, $\tilde{\delta}_l = 0$ implies $\delta_l = 0$, so that $1/(\tilde{\delta}_l + x) = 1/x$ cancels out together with $-1/(\delta_l + x) = -1/x$. The implication is true also in this case.

Finally, consider the case when there is $l \in \{1,\ldots,r'\}$ s.t. $\delta_l = n(\hat{a}_{Ml}, c''_M) = 0$ and $\tilde{\delta}_l = n_l(c''_M) \neq 0$. Observe that the term $-1/(\delta_l + x) = -1/x$ cannot cancel out because of other terms: in fact, with the l-th terms, we have that $\tilde{\delta}_l > 0$; if there is another l' s.t. $\tilde{\delta}_l = 0$, also $\delta_l = 0$ and the related two terms sum up to zero. The only remaining possibility to cancel $-1/(\delta_l + x) = -1/x$ out is that $\tilde{\beta} = 0$. But in this case we know that the implication must be true. It follows that also in this case the implication is verified.

($\Rightarrow$) Let us now consider the reverse implication. If Expression (13) goes to $-\infty$ with x going to zero, at least one of the terms in such an expression must do the same. By considering the terms one by one, the implication is proved in a trivial way. ■

Proof [Theorem 6]

Problem

$$\min_{d \in o} \inf_{p(\theta) \in \mathcal{P}(\theta)} p(c'_M | d^-, \hat{x}^+ \in \hat{o}^+) / p(c''_M | d^-, \hat{x}^+ \in \hat{o}^+),$$

where the set of prior densities is defined according to Expression (4), the constraints are those described in Section 3.1.1, and the probabilities in the function to optimize are defined as in (5), is equivalent to the following:

$$\min_{d \in o} \inf_{0 < t(c''_M) < 1} \{ [\frac{n(c''_M) + st(c''_M)}{n(c'_M) + s - st(c''_M)}]^{k-1} \prod_{j=1}^{k} \frac{n(a_{Mj}, c'_M)}{n(a_{Mj}, c''_M) + st(c''_M)} \cdot$$
$$\cdot \prod_{l=1}^{r'} [\frac{n_l(c''_M) + st(c''_M)}{n_l(c'_M) + s - st(c''_M)} \cdot \frac{n(\hat{a}_{Ml}, c'_M)}{n(\hat{a}_{Ml}, c''_M) + st(c''_M)}] \}.$$

The problem can be then re-written as follows:

$$\inf_{0 < t(c''_M) < 1} \min_{d \in o} \{ [\frac{n(c''_M) + st(c''_M)}{n(c'_M) + s - st(c''_M)}]^{k-1} \prod_{j=1}^{k} \frac{n(a_{Mj}, c'_M)}{n(a_{Mj}, c''_M) + st(c''_M)} \cdot$$
$$\cdot \prod_{l=1}^{r'} [\frac{n_l(c''_M) + st(c''_M)}{n_l(c'_M) + s - st(c''_M)} \cdot \frac{n(\hat{a}_{Ml}, c'_M)}{n(\hat{a}_{Ml}, c''_M) + st(c''_M)}] \}. \quad (14)$$

This is obtained by inverting the order of the optimizations and using Expression (6). Note that the inner minimization only affects the product over j in the objective function. Moreover, the counts in such a product attain the same value at the optimum for any choice of $t(c''_M)$, leading to the following product: $\prod_{j=1}^{k} \underline{n}(a_{Mj}, c'_M) / [\overline{n}(a_{Mj}, c''_M) + st(c''_M)]$. Note that the pairwise counts are optimized separately as they do not affect each other. These arguments enable us to reduce

Problem (14) as:

$$\inf_{0<t(c''_M)<1}\Big\{\left[\frac{n(c''_M)+st(c''_M)}{n(c'_M)+s-st(c''_M)}\right]^{k-1}\prod_{j=1}^{k}\frac{\underline{n}(a_{Mj},c'_M)}{\overline{n}(a_{Mj},c''_M)+st(c''_M)}\cdot \tag{15}$$
$$\cdot\prod_{l=1}^{r'}\left[\frac{n_l(c''_M)+st(c''_M)}{n_l(c'_M)+s-st(c''_M)}\cdot\frac{n(\hat{a}_{Ml},c'_M)}{n(\hat{a}_{Ml},c''_M)+st(c''_M)}\right]\Big\},$$

with $\underline{n}(a_{Mj},c'_M) := \min_{d\in o} n(a_{Mj},c'_M)$ and $\overline{n}(a_{Mj},c'_M) := \max_{d\in o} n(a_{Mj},c'_M)$. At this point, Problem (15) is an instance of Problem (6) obtained for a specific choice of a complete data set d in o. ■

Proof [Theorem 7] Let us focus the attention on the term $\min_{a_{Me}\in\mathcal{A}_e}\frac{\underline{n}(a_{Me},c'_M)}{\overline{n}(a_{Me},c''_M)+x}$. As a function of x, this is the lower envelope of the set of functions $\{\frac{\underline{n}(a_{Me},c'_M)}{\overline{n}(a_{Me},c''_M)+x} : a_{Me}\in\mathcal{A}_e\} =: \mathcal{F}_e$. Consider a value x such that the lower envelope coincides with two different functions in $\mathcal{F}_e$ before and after x. This implies that the two functions must cross at x, because the function that was over the other before x must be under it after x. In other words, the set of points where any two different functions in $\mathcal{F}_e$ cross (let us call them *partition points*), contains the points where the function matched by the lower envelope changes.

We can identify the partition points in the following way. Consider any two different functions in $\mathcal{F}_e$: $\underline{n}(a_{Me'},c'_M)/[\overline{n}(a_{Me'},c''_M)+x]$ and $\underline{n}(a_{Me''},c'_M)/[\overline{n}(a_{Me''},c''_M)+x]$. Assume that $\underline{n}(a_{Me'},c'_M)\neq\underline{n}(a_{Me''},c'_M)$: in the opposite case the only way for the two functions to cross would be that also $\overline{n}(a_{Me'},c''_M)=\overline{n}(a_{Me''},c''_M)$, but the two functions would be the same, which is excluded a priori. The two functions cross when $\underline{n}(a_{Me'},c'_M)/[\overline{n}(a_{Me'},c''_M)+x]=\underline{n}(a_{Me''},c'_M)/[\overline{n}(a_{Me''},c''_M)+x]$, and this happens if and only if

$$x=\frac{\overline{n}(a_{Me'},c''_M)\underline{n}(a_{Me''},c'_M)-\underline{n}(a_{Me'},c'_M)\overline{n}(a_{Me''},c''_M)}{\underline{n}(a_{Me'},c'_M)-\underline{n}(a_{Me''},c'_M)}. \tag{16}$$

In other words, there is at most one partition point for any two different functions,[19] and we can identify it easily by (16). The maximum number of partition points is also the number of distinct pairs of different functions in $\mathcal{F}_e$, which is at most $(|\mathcal{A}_e|^2-|\mathcal{A}_e|)/2$.[20]

The crucial observation here is that the lower envelope matches a single function of $\mathcal{F}_e$ in any sub-interval of $(0,s)$ that does not contain partition points; and we are always able to select an element of $\mathcal{A}_e$ that gives rise to the matched function. In other words, the partition points can be used to define a partition of $(0,s)$, in the sub-intervals of which the lower envelop matches a single function that we are able to characterize by an element of $\mathcal{A}_e$. This argument is easily extended to the entire product over e in (9): we compute the set of partition points for each term of the product, and take their union. The union defines a partition $\mathcal{J}$ of $(0,s)$, in which every sub-interval $\mathcal{I}$ is associated with a single tuple $(a^{\mathcal{I}}_{M1},\ldots,a^{\mathcal{I}}_{Mk'})\in\mathcal{A}_1\times\cdots\times\mathcal{A}_{k'}$, so that

$$\prod_{e=1}^{k'}[\min_{a_{Me}\in\mathcal{A}_e}\frac{\underline{n}(a_{Me},c'_M)}{\overline{n}(a_{Me},c''_M)+x}]=\prod_{e=1}^{k'}\frac{\underline{n}(a^{\mathcal{I}}_{Me},c'_M)}{\overline{n}(a^{\mathcal{I}}_{Me},c''_M)+x}.$$

19. Note that it could be outside $[0,s]$.

20. Note that some partition points may be such that the lower envelope does not change the matched function in $\mathcal{F}_e$, and so they could be discarded. As an example, assume that the value x identified by (16) is a partition point only for the two mentioned functions, and that there is a third function below the other two at x. In this case the former two functions are not involved in the determination of the lower envelope at x.

Problem (9) then becomes the following:

$$\min_{\mathcal{I}\in\mathcal{J}}\inf_{x\in\mathcal{I}}\{[\frac{n(c''_M)+x}{n(c'_M)+s-x)}]^{k-1}\prod_{e=1}^{k'}\frac{\underline{n}(a^{\mathcal{I}}_{Me},c'_M)}{\overline{n}(a^{\mathcal{I}}_{Me},c''_M)+x}\cdot$$
$$\cdot\prod_{j=k'+1}^{k}\frac{\underline{n}(a_{Mj},c'_M)}{\overline{n}(a_{Mj},c''_M)+x}\cdot$$
$$\cdot\prod_{l=1}^{r'}[\frac{n_l(c''_M)+x}{n_l(c'_M)+s-x}\cdot\frac{n(\hat{a}_{Ml},c'_M)}{n(\hat{a}_{Ml},c''_M)+x}]\},$$

where the inner optimization can be solved by the procedure given in Section (3.2), applying it to the interval $\mathcal{I}$ rather than $(0,s)$.

Now it is easy to show that the procedure in Fig. 6 solves Problem (8). The first step of the procedure builds the set of partition points for the functions in $\mathcal{F}_e$, and the next one defines the partition of $(0,s)$. Since the function is convex on each sub-interval, the remaining steps solve a minimization problem on each sub-interval; finally, the global minimum is selected. ■

Appendix C. Experimental Results Data Set by Data Set

Detailed results by data set are shown in Tables 6 and 7, which refer respectively to the MAR and non-MAR setting.

Abstract

In this paper we introduce an improved implementation of locally weighted projection regression (LWPR), a supervised learning algorithm that is capable of handling high-dimensional input data. As the key features, our code supports multi-threading, is available for multiple platforms, and provides wrappers for several programming languages.

Keywords: regression, local learning, online learning, C, C++, Matlab, Octave, Python

1. Introduction

Locally weighted projection regression (LWPR) is an algorithm that achieves nonlinear function approximation in high dimensional spaces even in the presence of redundant and irrelevant input dimensions (Vijayakumar et al., 2002). At its core, it uses locally linear models, spanned by a small number of univariate regressions in selected directions in input space. This nonparametric local learning system learns rapidly with second order learning methods based on incremental training, using statistically sound stochastic cross validation.

The implementation of LWPR we present in this work is written in low-level C, requires no additional libraries, and comes with convenient wrappers for C++, Matlab and Python. Together with documentation, tutorials and additional supporting materials, it is freely available for download from `http://www.ipab.inf.ed.ac.uk/slmc/software/lwpr`.

2. The LWPR Algorithm

The goal of LWPR is to learn a regression function from training data that incrementally arrive as input-output tuples $(\mathbf{x}_i, y_i)$, where we assume univariate output data for now. The LWPR regression function is constructed by blending local linear models $\psi_k(\mathbf{x})$ in the form

$$f(\mathbf{x}) = \frac{1}{W(\mathbf{x})} \sum_{k=1}^{K} w_k(\mathbf{x}) \psi_k(\mathbf{x}), \quad W(\mathbf{x}) = \sum_{k=1}^{K} w_k(\mathbf{x}). \tag{1}$$

Here, $w_k(\mathbf{x})$ is a locality kernel that defines the area of validity of the local models (also termed "receptive field"), which is usually modeled by a Gaussian

$$w_k(\mathbf{x}) = \exp\left(-\frac{1}{2}(\mathbf{x}-\mathbf{c}_k)^T\mathbf{D}_k(\mathbf{x}-\mathbf{c}_k)\right), \tag{2}$$

where $\mathbf{c}_k$ is the centre of the k^{th} linear model and $\mathbf{D}_k$ is its distance metric. During training, all updates to the local models are weighted by their activation $w_k(\mathbf{x})$, facilitating fully localised and inpedendent learning. If no existing local model yields an activation above a certain threshold (e.g., $w_{gen} = 0.1$), a new local model is created with its center $\mathbf{c}_k$ set to the input datum. Thus, the number K of local models is adapted automatically.

For learning the linear models $\psi_k(\mathbf{x})$ themselves, LWPR employs an online formulation of weighted partial least squares (PLS) regression. In particular, within each local model[1] the input data $\mathbf{x}$ is projected along selected directions $\mathbf{u}_i$, yielding "latent" variables s_i with

$$s_i = \mathbf{u}_i^T\mathbf{x}_{i-1}, \qquad \mathbf{x}_i = \mathbf{x}_{i-1} - s_i\mathbf{p}_i = \mathbf{x}_{i-1} - \mathbf{p}_i\mathbf{u}_i^T\mathbf{x}_{i-1}, \qquad \mathbf{x}_0 = \mathbf{x} - \bar{\mathbf{x}},$$

where the vectors $\mathbf{p}_i$ ensure orthogonality of the projections, and $\bar{\mathbf{x}}$ is the weighted mean of the input data (as seen through the receptive field). The output of the local model is then formed by a linear combination of the latent variables (also called PLS factor loadings)

$$\psi_k(\mathbf{x}) = \beta_0 + \sum_{i=1}^{R}\beta_i s_i. \tag{3}$$

The number R of regression directions is automatically adapted to the local dimensionality of the training data, and the parameters $\mathbf{u}_i$, $\mathbf{p}_i$, and β_i can be robustly estimated from accumulating certain statistics of the training set (for details please see Vijayakumar et al., 2005). In a similar fashion, the distance metrics $\mathbf{D}$ can be adapted using stochastic cross-validation, such that the input space is covered by wide receptive fields in regions of low curvature, and narrow receptive fields where the curvature is high. The initial distance metric assigned to a newly created receptive field is a rather critical open parameter. If available, one should use an estimate of the Hessian of the function that is to be approximated. As a valuable feature of the algorithm, LWPR can optionally yield confidence bounds for its predictions (Vijayakumar et al., 2005).

There are two possible choices with regard to handling multivariate output data: First, the local models itself could be made multivariate, in which case only one layer of receptive fields is needed. Alternately, one can learn all output dimensions independently, effectively using univariate PLS regression (see, e.g., Garthwaite, 1994) within the local models. In the present implementation we use the latter approach, which is computationally more costly for many output dimensions, but usually exhibits superior prediction performance.

LWPR is an algorithm that is particularly suited (and recommended) for regression problems with a sufficiently large number of training examples. For use in small data set scenarios, the data should be presented to the algorithm multiple times in random order.

3. Details of the Implementation

This section describes several important aspects of our implementation, all of which are related to execution speed.

1. For notational convenience we drop the index k of the local model.

3.1 Data Structures and Memory Allocation

On modern computers, the speed at which many algorithms run does not only depend on the processor, but also critically on the speed of memory access. We designed our library so that memory access is as continuous as possible, thus minimising the chance of cache misses. In our library, all variables[2] of each local model are allocated together in a contiguous piece of memory. Moreover, we allocate "workspaces" as part of the LWPR model for storing intermediate results, such that no further allocations are needed during the computations.

3.2 Multithreaded Updates and Predictions

Since the LWPR algorithm is designed to be parallelisable (the local models learn independently), and nowadays even off-the-shelf mainstream computers are equipped with multi-core processors, we constructed our LWPR library such that it is capable of running the computations in multiple threads. The library currently supports POSIX threads on Linux/Unix machines and native threads on the Windows platform. The desired number of threads has to be defined at compile time, and threading can be deactivated altogether.

In order to balance the overhead of creating threads with the expected reduction in computation time, we chose to implement two complimentary strategies for distributing the work. *Predictions* of the LWPR model are split up on a per-output-dimension level, which implies that LWPR models for one-dimensional output data will not be accelerated by using multiple threads. The more costly *update* operations, however, are distributed across multiple threads on the receptive field level, so even single-output models may benefit (see Fig. 1).

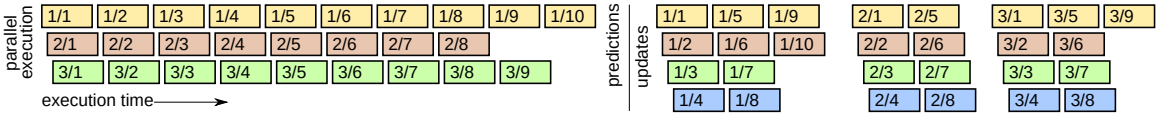

Figure 1: Illustration of our threading implementation for the case of (up to) 4 threads. The example LWPR model has 3 output dimensions with 10, 8, and 9 receptive fields, respectively. A label M/N denotes the N-th receptive field in the M-th output sub-model. For predictions, each thread handles a different output dimension. For updates, the workload of each output dimension is split up among threads, and outputs are handled one after another.

3.3 Fast Computation of Predictions and Their Gradients

For some applications of LWPR, it may be useful to compute analytic derivatives of the model, for example, to retrieve the Jacobian from a learned forward kinematics relation. The gradient of a single predicted output (1) is given by

$$\frac{\partial f(\mathbf{x})}{\partial \mathbf{x}} = \frac{1}{W}\sum_k \left(\frac{\partial w_k}{\partial \mathbf{x}}\psi_k + w_k \frac{\partial \psi_k}{\partial \mathbf{x}} \right) - \frac{1}{W^2}\sum_k w_k \psi_k \sum_l \frac{\partial w_l}{\partial \mathbf{x}},$$

2. Local models require no less than 27 variables, most of them vectors or matrices, for storing all the memory terms and sufficient statistics, etc.

where $\frac{\partial w_k}{\partial \mathbf{x}} = -w_k \mathbf{D}_k(\mathbf{x}-\mathbf{c}_k)$ for the Gaussian kernel (2). The local models $\psi_k(\mathbf{x})$ are computed by PLS recursions, and therefore also the gradients of (3) have to be calculated in this rather costly way:

$$\begin{aligned}\frac{\partial \psi}{\partial \mathbf{x}} &= \sum_{i=1}^{R} \beta_i \frac{\partial s_i}{\partial \mathbf{x}_0} = \sum_{i=1}^{R} \beta_i \left(\mathbf{u}_i^T \frac{\partial \mathbf{x}_{i-1}}{\partial \mathbf{x}_0} \right)^T = \sum_{i=1}^{R} \beta_i \left(\frac{\partial \mathbf{x}_{i-1}}{\partial \mathbf{x}_{i-2}} \cdots \frac{\partial \mathbf{x}_1}{\partial \mathbf{x}_0} \right)^T \mathbf{u}_i \\ &= \beta_1 \mathbf{u}_1 + \beta_2 (\mathbf{I} - \mathbf{u}_1 \mathbf{p}_1^T)\mathbf{u}_2 + \beta_3 (\mathbf{I} - \mathbf{u}_1 \mathbf{p}_1^T)(\mathbf{I} - \mathbf{u}_2 \mathbf{p}_2^T)\mathbf{u}_3 + \dots \ .\end{aligned}$$

However, between updates (for example, during prediction-only cycles) or after training has finished, the slopes $\frac{\partial \psi}{\partial \mathbf{x}}$ of the local models do not change. Our implementation exploits this by memorising the slopes once a gradient is calculated, and directly using these slopes for predictions without running through the PLS recursions.

3.4 Matlab Interface

Our library started its life as a Matlab-only implementation, and therefore the Matlab struct describing an LWPR model is practically identical to the data structure used within the C library. When calling the C functions from Matlab via MEX-wrappers, however, these data structures normally have to be converted back and forth, which is time-consuming. Therefore, we added a special storage mechanism to our MEX-wrappers, which allows us to transfer Matlab data to and from C-managed memory. Then, updates and predictions of an LWPR model can be computed by calling the "normal" MEX-functions, but passing a certain reference identifier instead of the complete Matlab struct. As an illustration of the performance gain, we trained an LWPR model on a 2D toy data set. For accomplishing 10,000 updates, the Matlab-only implementation took roughly 100 seconds, using the MEX wrappers alone took 11.3s, but with our storage mechanism the task is finished after only 0.8s. The Matlab implementation—including the MEX-wrappers and the storage scheme—is also compatible with recent versions of Octave.[3]

Abstract

Large-scale logistic regression arises in many applications such as document classification and natural language processing. In this paper, we apply a trust region Newton method to maximize the log-likelihood of the logistic regression model. The proposed method uses only approximate Newton steps in the beginning, but achieves fast convergence in the end. Experiments show that it is faster than the commonly used quasi Newton approach for logistic regression. We also extend the proposed method to large-scale L2-loss linear support vector machines (SVM).

Keywords: logistic regression, newton method, trust region, conjugate gradient, support vector machines

1. Introduction

The logistic regression model is useful for two-class classification. Given data $\mathbf{x}$ and weights $(\mathbf{w}, b)$, it assumes the following probability model

$$P(y = \pm 1|\mathbf{x}, \mathbf{w}) = \frac{1}{1 + \exp(-y(\mathbf{w}^T\mathbf{x} + b))},$$

where y is the class label. If training instances are $\mathbf{x}_i, i = 1, \ldots, l$ and labels are $y_i \in \{1, -1\}$, one estimates $(\mathbf{w}, b)$ by minimizing the negative log-likelihood:

$$\min_{\mathbf{w},b} \quad \sum_{i=1}^{l} \log(1 + e^{-y_i(\mathbf{w}^T\mathbf{x}_i + b)}).$$

There are numerous applications of logistic regression. It can be extended to a multi-class classification model, which is a special case of conditional random fields, and is also called the maximum entropy model in the natural language processing community.

To have a simpler derivation without considering the bias term b, one often augments each instance with an additional dimension:

$$\mathbf{x}_i^T \leftarrow [\mathbf{x}_i^T, 1] \qquad \mathbf{w}^T \leftarrow [\mathbf{w}^T, b]. \tag{1}$$

Moreover, to obtain good generalization abilities, one adds a regularization term $\mathbf{w}^T\mathbf{w}/2$, so in this paper we consider the following form of regularized logistic regression:

$$\min_{\mathbf{w}} f(\mathbf{w}) \equiv \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l}\log(1+e^{-y_i\mathbf{w}^T\mathbf{x}_i}), \tag{2}$$

where $C > 0$ is a parameter decided by users so that the two terms in (2) are balanced. One can easily check that (2) is twice continuously differentiable.

There are many methods for training logistic regression models. In fact, most unconstrained optimization techniques can be considered. Those which have been used in large-scale scenarios are, for example, iterative scaling (Darroch and Ratcliff, 1972; Pietra et al., 1997; Goodman, 2002; Jin et al., 2003), nonlinear conjugate gradient, quasi Newton (in particular, limited memory BFGS) (Liu and Nocedal, 1989; Benson and Moré, 2001), and truncated Newton (Komarek and Moore, 2005). All these optimization methods are iterative procedures, which generate a sequence $\{\mathbf{w}^k\}_{k=1}^{\infty}$ converging to the optimal solution of (2). One can distinguish them according to the following two extreme situations of optimization methods:

Low cost per iteration;	$\longleftrightarrow$	High cost per iteration;
slow convergence.		fast convergence.

For instance, iterative scaling updates one component of $\mathbf{w}$ at a time, so the cost per iteration is low but the number of iterations is high. In contrast, Newton method, which is expensive at each iteration, has very fast convergence rates. Many have attempted to compare these methods for logistic regression. Minka (2003) experiments with small data sets, and Malouf (2002) has done an extensive comparison for large-scale sets. Currently, most argue that the limited memory BFGS method is the most efficient and effective (e.g., Malouf, 2002; Sutton and McCallum, 2006) and references therein). In this article, we aim at situations for which both l (number of instances) and n (number of features) are very large. In addition, the data instances $\mathbf{x}_1, \ldots, \mathbf{x}_l$ are sparse (i.e., many feature values are zero). Many recent applications from document classification and computational linguistics are of this type.

Truncated Newton methods have been an effective approach for large-scale unconstrained optimization, but their use for logistic regression has not been fully exploited. Though Komarek and Moore (2005) have considered this type of methods, their implementation does not follow rigorous optimization derivations, and hence may not be guaranteed to obtain the minimum of the negative log-likelihood. In Section 2, we discuss an efficient and robust truncated Newton method for logistic regression. This approach, called trust region Newton method, uses only approximate Newton steps in the beginning, but takes full Newton directions in the end for fast convergence.

In Sections 3 and 4, we discuss some existing optimization methods for logistic regression and conduct comparisons. As Newton method uses the exact Hessian (second derivative), it has quadratic convergence near the optimum. Results indicate that our proposed method converges much faster than quasi-Newton methods, which use only an approximate Hessian. Section 5 investigates a variant of our proposed method by using preconditioned conjugate gradients in the trust region framework. In Section 6, we extend the proposed trust region method to solve L2-loss support vector machines. Finally, Section 7 gives conclusions.

A preliminary version of this work appears in a conference paper (Lin et al., 2007).

2. Trust Region Newton Methods

In this section, we briefly discuss Newton and truncated Newton methods. For large-scale logistic regression, we then propose a trust region Newton method, which is a type of truncated Newton approach.

2.1 Newton and Truncated Newton Methods

To discuss Newton methods, we need the gradient and Hessian of $f(\mathbf{w})$:

$$\nabla f(\mathbf{w}) = \mathbf{w} + C\sum_{i=1}^{l}(\sigma(y_i\mathbf{w}^T\mathbf{x}_i)-1)y_i\mathbf{x}_i, \tag{3}$$

$$\nabla^2 f(\mathbf{w}) = I + CX^T DX, \tag{4}$$

where I is the identity matrix,

$$\sigma(y_i\mathbf{w}^T\mathbf{x}_i) = (1+e^{-y_i\mathbf{w}^T\mathbf{x}_i})^{-1}.$$

D is a diagonal matrix with

$$D_{ii} = \sigma(y_i\mathbf{w}^T\mathbf{x}_i)(1-\sigma(y_i\mathbf{w}^T\mathbf{x}_i)), \text{ and } X = \begin{bmatrix}\mathbf{x}_1^T\\ \vdots \\ \mathbf{x}_l^T\end{bmatrix}$$

is an $l \times n$ matrix. The Hessian matrix $\nabla^2 f(\mathbf{w})$ is positive definite, so (2) is strictly convex. We can further prove the following theorem.

Theorem 1 (2) *attains a unique global optimal solution.*

The proof is in Appendix A.

Since $\nabla^2 f(\mathbf{w}^k)$ is invertible, the simplest Newton method updates $\mathbf{w}$ by the following way

$$\mathbf{w}^{k+1} = \mathbf{w}^k + \mathbf{s}^k, \tag{5}$$

where k is the iteration index and $\mathbf{s}^k$, the Newton direction, is the solution of the following linear system:

$$\nabla^2 f(\mathbf{w}^k)\mathbf{s}^k = -\nabla f(\mathbf{w}^k). \tag{6}$$

However, there are two issues in using this update rule:

1. The sequence $\{\mathbf{w}^k\}$ may not converge to an optimal solution. In fact, even the function value may not be guaranteed to decrease.

2. While we assume that the data matrix X is sparse, $X^T DX$ is much denser. The Hessian matrix is then too large to be stored. Thus, solving the linear system (6) is an issue that needs careful consideration.

Optimization researchers address the first issue by adjusting the length of the Newton direction. Two techniques are often used: line search and trust region.

For the second issue, there are two major types of methods for solving linear systems: direct methods (e.g., Gaussian elimination), and iterative methods (e.g., Jacobi and conjugate gradient). The main operation of certain iterative methods is the product between the Hessian matrix and a vector $\mathbf{s}$:

$$\begin{aligned} & \nabla^2 f(\mathbf{w})\mathbf{s} = (I + CX^T DX)\mathbf{s} \\ = \;& \mathbf{s} + C \cdot X^T (D(X\mathbf{s})). \end{aligned} \tag{7}$$

As we assume sparse X, (7) can be efficiently calculated without storing the Hessian matrix $\nabla^2 f(\mathbf{w}^k)$. Therefore, for large logistic regression, iterative methods are more suitable than direct methods, which require the whole Hessian matrix. Among iterative methods, currently conjugate gradients are the most used ones in Newton methods. The optimization procedure then has two layers of iterations: at each outer iteration an inner conjugate gradient procedure finds the Newton direction. Unfortunately, conjugate gradient methods may suffer from lengthy iterations in certain situations. To save time, one may use only an "approximate" Newton direction in the early stages of the outer iterations. Such a technique is called truncated Newton method (or inexact Newton method).

Komarek and Moore (2005) are among the first to apply truncated Newton methods for logistic regression.[1] They approximately solve (6) by conjugate gradient procedures and use (5) to update $\mathbf{w}^k$. They terminate the conjugate gradient procedure if the relative difference of log likelihoods between two consecutive conjugate gradient iterations is smaller than a threshold. However, they do not provide a convergence proof. In fact, when we tried their code, we found that $\|\nabla f(\mathbf{w}^k)\|$ may not approach zero and hence $\{\mathbf{w}^k\}$ may not converge to an optimum.

Optimization researchers have well addressed the above two issues together. They devise the procedure of outer iterations, and specify stopping conditions for the inner iterations. The overall framework guarantees the convergence to the global minimum. The truncation rule of the inner algorithm is important as one should stop after a sufficiently good direction has been found. A survey of truncated Newton methods is by Nash (2000). Some comparisons between limited memory quasi Newton and truncated Newton are by Nocedal and Nash (1991) and Zou et al. (1993).

2.2 A Trust Region Newton Method

We consider the trust region method (Lin and Moré, 1999), which is a truncated Newton method to deal with general bound-constrained optimization problems (i.e., variables are in certain intervals). We simplify the setting to unconstrained situations, so the algorithm is close to earlier work such as Bouaricha et al. (1997) and Steihaug (1983).

At each iteration of a trust region Newton method for minimizing $f(\mathbf{w})$, we have an iterate $\mathbf{w}^k$, a size Δ_k of the trust region, and a quadratic model

$$q_k(\mathbf{s}) = \nabla f(\mathbf{w}^k)^T \mathbf{s} + \frac{1}{2}\mathbf{s}^T \nabla^2 f(\mathbf{w}^k)\mathbf{s}$$

1. They minimize only the negative log likelihood without the regularization term $\mathbf{w}^T\mathbf{w}/2$.

Algorithm 1 A trust region algorithm for logistic regression

1. Given $\mathbf{w}^0$.
2. For $k = 0, 1, \ldots$ (outer iterations)
   - If $\nabla f(\mathbf{w}^k) = \mathbf{0}$, stop.
   - Find an approximate solution $\mathbf{s}^k$ of the trust region sub-problem
   $$\min_{\mathbf{s}} q_k(\mathbf{s}) \quad \text{subject to } \|\mathbf{s}\| \le \Delta_k. \tag{11}$$
   - Compute ρ_k via (8).
   - Update $\mathbf{w}^k$ to $\mathbf{w}^{k+1}$ according to (9).
   - Obtain Δ_{k+1} according to (10).

as the approximation of the value $f(\mathbf{w}^k + \mathbf{s}) - f(\mathbf{w}^k)$. Next, we find a step $\mathbf{s}^k$ to approximately minimize $q_k(\mathbf{s})$ subject to the constraint $\|\mathbf{s}\| \le \Delta_k$. We then update $\mathbf{w}^k$ and Δ_k by checking the ratio

$$\rho_k = \frac{f(\mathbf{w}^k + \mathbf{s}^k) - f(\mathbf{w}^k)}{q_k(\mathbf{s}^k)} \tag{8}$$

of the actual reduction in the function to the predicted reduction in the quadratic model. The direction is accepted if ρ_k is large enough:

$$\mathbf{w}^{k+1} = \begin{cases} \mathbf{w}^k + \mathbf{s}^k & \text{if } \rho_k > \eta_0, \\ \mathbf{w}^k & \text{if } \rho_k \le \eta_0, \end{cases} \tag{9}$$

where $\eta_0 > 0$ is a pre-specified value.

From Lin and Moré (1999), updating rules for Δ_k depend on positive constants η_1 and η_2 such that $\eta_1 < \eta_2 < 1$, while the rate at which Δ_k is updated relies on positive constants σ_1, σ_2, and σ_3 such that $\sigma_1 < \sigma_2 < 1 < \sigma_3$. The trust region bound Δ_k is updated by the rules

$$\begin{array}{lll} \Delta_{k+1} \in [\sigma_1 \min\{\|\mathbf{s}^k\|, \Delta_k\}, \sigma_2 \Delta_k] & \text{if} & \rho_k \le \eta_1, \\ \Delta_{k+1} \in [\sigma_1 \Delta_k, \sigma_3 \Delta_k] & \text{if} & \rho_k \in (\eta_1, \eta_2), \\ \Delta_{k+1} \in [\Delta_k, \sigma_3 \Delta_k] & \text{if} & \rho_k \ge \eta_2. \end{array} \tag{10}$$

Similar rules are used in most modern trust region methods. A description of our trust region algorithm is given in Algorithm 1. The main difference between our algorithm and those by Steihaug (1983) and Bouaricha et al. (1997) is on the rule (10) for updating Δ_k.

The conjugate gradient method to approximately solve the trust region sub-problem (11) is given in Algorithm 2. The main operation is the Hessian-vector product $\nabla^2 f(\mathbf{w}^k)\mathbf{d}^i$, which is implemented using the idea in Eq. (7). Note that only one Hessian-vector product is needed at each conjugate gradient iteration. Since

$$\mathbf{r}^i = -\nabla f(\mathbf{w}^k) - \nabla^2 f(\mathbf{w}^k)\bar{\mathbf{s}}^i,$$

the stopping condition (12) is the same as

$$\| -\nabla f(\mathbf{w}^k) - \nabla^2 f(\mathbf{w}^k)\bar{\mathbf{s}}^i\| \le \xi_k \|\nabla f(\mathbf{w}^k)\|,$$

Algorithm 2 Conjugate gradient procedure for approximately solving the trust region sub-problem (11)

1. Given $\xi_k < 1, \Delta_k > 0$. Let $\bar{\mathbf{s}}^0 = \mathbf{0}, \mathbf{r}^0 = -\nabla f(\mathbf{w}^k)$, and $\mathbf{d}^0 = \mathbf{r}^0$.
2. For $i = 0, 1, \ldots$ (inner iterations)
   - If
   $$\|\mathbf{r}^i\| \le \xi_k \|\nabla f(\mathbf{w}^k)\|, \tag{12}$$
   then output $\mathbf{s}^k = \bar{\mathbf{s}}^i$ and stop.
   - $\alpha_i = \|\mathbf{r}^i\|^2 / ((\mathbf{d}^i)^T \nabla^2 f(\mathbf{w}^k) \mathbf{d}^i)$.
   - $\bar{\mathbf{s}}^{i+1} = \bar{\mathbf{s}}^i + \alpha_i \mathbf{d}^i$.
   - If $\|\bar{\mathbf{s}}^{i+1}\| \ge \Delta_k$, compute τ such that
   $$\|\bar{\mathbf{s}}^i + \tau \mathbf{d}^i\| = \Delta_k, \tag{13}$$
   then output $\mathbf{s}^k = \bar{\mathbf{s}}^i + \tau \mathbf{d}^i$ and stop.
   - $\mathbf{r}^{i+1} = \mathbf{r}^i - \alpha_i \nabla^2 f(\mathbf{w}^k) \mathbf{d}^i$.
   - $\beta_i = \|\mathbf{r}^{i+1}\|^2 / \|\mathbf{r}^i\|^2$.
   - $\mathbf{d}^{i+1} = \mathbf{r}^{i+1} + \beta_i \mathbf{d}^i$.

which implies that $\bar{\mathbf{s}}^i$ is an approximate solution of the linear system (6). However, Algorithm 2 is different from standard conjugate gradient methods for linear systems as the constraint $\|\mathbf{s}\| \le \Delta$ must be taken care of. It is known that (Steihaug, 1983, Theorem 2.1) with $\bar{\mathbf{s}}^0 = \mathbf{0}$, we have

$$\|\bar{\mathbf{s}}^i\| < \|\bar{\mathbf{s}}^{i+1}\|, \forall i,$$

so in a finite number of conjugate gradient iterations, either (12) is satisfied or $\bar{\mathbf{s}}^{i+1}$ violates the trust region constraint. In the latter situation, (13) finds a point on the trust region boundary as

$$q_k(\bar{\mathbf{s}}^i + \tau \mathbf{d}^i) < q_k(\bar{\mathbf{s}}^i).$$

The whole procedure is a careful design to make sure that the approximate Newton direction is good enough and the trust region method converges.

Next, we discuss convergence properties of the trust region Newton method. Most results can be traced back to Steihaug (1983). However, here we follow Lin and Moré (1999) as our algorithmic settings are closer to it. For the sequence $\{\mathbf{w}^k\}$ to have at least one limit point,[2] since $f(\mathbf{w}^k)$ is decreasing, it suffices to show that the level set $\{\mathbf{w} \mid f(\mathbf{w}) \le f(\mathbf{w}^0)\}$ is closed and bounded. This result has been explained in the proof of Theorem 1. To have this limit point to be the minimum, Theorem 2.1 of Lin and Moré (1999) requires that $\nabla^2 f(\mathbf{w}^k)$ is uniformly bounded. We have this property as $\nabla^2 f(\mathbf{w})$ is continuous in this bounded level set.

Eq. (12) is a relative stopping condition in solving a linear system. The parameter ξ_k effectively controls the efforts associated with the inner iterations. The following theorem summarizes the convergence of Algorithm 1.

2. That is, the sequence $\{\mathbf{w}^k\}$ has at least one convergent sub-sequence.

Theorem 2 *The sequence $\{\mathbf{w}^k\}$ generated by Algorithm 1 globally converges to the unique minimum of* (2)*. If $\xi_k < 1$, then the trust region method Q-linearly converges:*

$$\lim_{k\to\infty} \frac{\|\mathbf{w}^{k+1} - \mathbf{w}^*\|}{\|\mathbf{w}^k - \mathbf{w}^*\|} < 1, \tag{14}$$

where $\mathbf{w}^*$ is the unique optimal solution of (2)*. If*

$$\xi_k \to 0 \text{ as } k \to \infty,$$

then the limit in (14) *becomes zero, so we have Q-superlinear convergence.*

We do not provide a proof here as it follows from Theorem 5.4 of Lin and Moré (1999). Since the Hessian matrix $\nabla^2 f(\mathbf{w})$ is continuously differentiable, $\nabla^2 f(\mathbf{w})$ is Lipschitz continuous around the optimal solution. Hence, as explained by Lin and Moré (1999),[3] if $\xi_k \le \kappa_0 \|\nabla f(\mathbf{w}^k)\|$ for a positive constant κ_0, then at final iterations, our algorithm has quadratic convergence:

$$\lim_{k\to\infty} \frac{\|\mathbf{w}^{k+1} - \mathbf{w}^*\|}{\|\mathbf{w}^k - \mathbf{w}^*\|^2} < 1.$$

Regarding the computational complexity, the cost per iteration is

$$\begin{aligned} & O(\text{nnz}) \text{ for 1 function and 0/1 gradient evaluations} \\ + \quad & O(\text{nnz}) \times \text{ number of conjugate gradient iterations,} \end{aligned} \tag{15}$$

where nnz is the number of nonzero elements in the sparse matrix X. Note that if $\mathbf{w}^k$ is not updated in (9), then the gradient is the same for the next iteration.

3. Related Methods and Implementation Issues

In this section, we discuss a general limited memory quasi Newton implementation (Liu and Nocedal, 1989). Many consider it to be very efficient for training logistic regression. We also discuss implementation issues of the proposed trust region Newton method.

3.1 Limited Memory Quasi Newton Method

We briefly introduce the approach by Liu and Nocedal (1989). Quasi Newton methods use certain techniques to obtain an approximate inverse Hessian H_k and can easily update it to H_{k+1}. One of the most popular updates is BFGS. The approach by Liu and Nocedal (1989) is almost the same as BFGS, but restricts the update to use only m vectors from the previous iterations. The matrix H_k is not formed explicitly and there is an efficient way to compute $H_k \nabla f(\mathbf{w}^k)$. This property is useful for large logistic regression as we cannot afford to store H_k. The procedure is sketched in Algorithm 3.

Regarding the convergence rate, Assumption 7.1 of Liu and Nocedal (1989) requires:

1. $f(\mathbf{w})$ is twice continuously differentiable.
2. The level set $\{\mathbf{w} \mid f(\mathbf{w}) \le f(\mathbf{w}^0)\}$ is bounded.

3. See the explanation given in that paper after the proof of Theorem 5.4.

Algorithm 3 Limited memory BFGS

1. Given $\mathbf{w}^0, H^0$ and a small integer m.
2. For $k = 0, 1, \ldots$
   - If $\nabla f(\mathbf{w}^k) = \mathbf{0}$, stop.
   - Using m vectors from previous iterations to calculate $H_k \nabla f(\mathbf{w}^k)$, where H_k is an approximate inverse Hessian.
   - Search α_k so that
     $$f(\mathbf{w}^k - \alpha H_k \nabla f(\mathbf{w}^k))$$
     satisfies certain sufficient decrease conditions.
   - Update H_k to H_{k+1}.

3. There are positive constants M_1 and M_2 such that
$$M_1 \|\mathbf{s}\|^2 \le \mathbf{s}^T \nabla^2 f(\mathbf{w}) \mathbf{s} \le M_2 \|\mathbf{s}\|^2, \quad \forall \mathbf{s}.$$

The function we are minimizing satisfies the first condition. The second condition follows from our proof of Theorem 1 (see Eq. 29). The third condition follows from choosing

$$M_1 = 1 \text{ and } M_2 = 1 + C\|X^T\|\|X\|.$$

Then Algorithm 3 is R-linearly convergent. That is, there is a constant $c < 1$ such that

$$f(\mathbf{w}^k) - f(\mathbf{w}^*) \le c^k (f(\mathbf{w}^0) - f(\mathbf{w}^*)), \tag{16}$$

where $\mathbf{w}^*$ is the unique optimal solution of (2). Note that (14) implies (16), so Algorithm 1 has a stronger convergence property than Algorithm 3. While truncated Newton methods find an approximate direction, they still use the exact Hessian matrix. In contrast, limited memory quasi Newton methods consider only approximate Hessian matrices, so we can expect that it has slower convergence.

The cost per iteration is

$$\begin{aligned} & O(\text{nnz}) \text{ for function/gradient evaluations in line search} \\ + \quad & O(nm) \text{ for } H_k \nabla f(\mathbf{w}^k) \text{ and updating } H_k \text{ to } H_{k+1}. \end{aligned} \tag{17}$$

As generally $nm <$ nnz, function/gradient evaluations take most computational time. Moreover, compared to (15), the cost per iteration is less than that for our trust region method. However, as we will show in experiments, LBFGS' total training time is longer due to its lengthy iterations.

In this paper, we use $m = 5$, which is the default choice in the LBFGS software (Liu and Nocedal, 1989).

3.2 Implementation Issues of Trust Region Newton Method

We give details of parameters in the proposed Algorithms 1 and 2. All settings are almost the same as the TRON software (Lin and Moré, 1999).

Problem	l	# Positive	# Negative	n	# nonzeros
a9a	32,561	7,841	24,720	123	451,592

yahoo-korea	460,554	145,831	314,723	3,052,939	156,436,656

Table 1: Data statistics: l is the number of instances and n is the number of features. # nonzeros indicates the number of nonzeros among $l \times n$ values.

We set the initial $\Delta_0 = \|\nabla f(\mathbf{w}^0)\|$ and take $\eta_0 = 10^{-4}$ in (9) to update $\mathbf{w}^k$. For changing Δ_k to Δ_{k+1}, we use

$$\eta_1 = 0.25, \eta_2 = 0.75,$$
$$\sigma_1 = 0.25, \sigma_2 = 0.5, \sigma_3 = 4.0.$$

As (10) specifies only the interval in which Δ_{k+1} should lie, there are many possible choices of the update rules. We use the same rules as given by Lin and Moré (1999). In the conjugate gradient procedure, we use $\xi_k = 0.1$ in the stopping condition (12). One may wonder how the above numbers are chosen. These choices are considered appropriate following the research on trust region methods in the past several decades. It is unclear yet if they are the best for logistic regression problems, but certainly we would like to try custom settings first.

4. Experiments

In this section, we compare our approach with a quasi Newton implementation for logistic regression. After describing data sets for experiments, we conduct detailed comparisons and discuss results.

4.1 Data Sets

We consider six data sets from various sources. Table 1 lists the numbers of instances (# positive, # negative), features, and nonzero feature values. Details of data sets are described below.

a9a: This set is compiled by Platt (1998) from the UCI "adult" data set (Asuncion and Newman, 2007). It is available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary/a9a`.

real-sim: This set is from the web site `http://people.cs.uchicago.edu/~vikass/datasets/lskm/svml/`. It, originally compiled by Andrew McCallum, includes Usenet articles from four discussion groups, for simulated auto racing, simulated aviation, real autos, and real aviation.

news20: This is a collection of news documents. We use the data processed by Keerthi and DeCoste (2005). They consider binary term frequencies and normalize each instance to unit length. This set is available at
`http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary/news20.binary.bz2`.

(f) yahoo-korea

Table 2: The comparison between TRON and LBFGS. Here time (in seconds) is the total training time in the CV procedure. As TRON and LBFGS minimize the same formulation and their CV accuracy values are almost the same, we present only the result of TRON. The number of CV folds is five for small problems, and is two for larger ones (yahoo-japan, rcv1, yahoo-korea). Note that the CV values do not increase using $C > 16$.

yahoo-japan: This set, obtained from Yahoo!, includes documents in hundreds of classes. We consider the class with the largest number of instances as positive and all remaining instances as negative. We use binary term frequencies and normalize each instance to unit length.

rcv1: This set (Lewis et al., 2004) is an archive of manually categorized newswire stories from Reuters Ltd. Each vector is a cosine normalization of a log transformed TF-IDF (term frequency, inverse document frequency) feature vector. The news documents are in a hierarchical structure of classes. We split the data to positive/negative by using the two branches in the first layer of the hierarchy. Data which are multi-labeled (i.e., in both branches) are not considered. The set used here can be found at
`http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary/rcv1_test.binary.bz2`.

yahoo-korea: This set, from Yahoo!, includes documents in a hierarchy of classes. We consider the largest branch from the root node (i.e., the branch including the largest number of classes) as positive, and all others as negative.

Clearly, except a9a, all other sets are from document classification. We find that normalizations are usually needed so that the length of each instance is not too large. Otherwise, when the number of features is large, $\mathbf{w}^T\mathbf{x}_i$ may be huge and cause difficulties in solving optimization problems (For good performance also, past experiences show that such normalizations are usually needed). After normalization, we include the bias term using (1).

All data sets are quite balanced. It is known that unbalanced sets usually lead to shorter training time. Therefore, problems used in this article are more challenging in terms of training time.

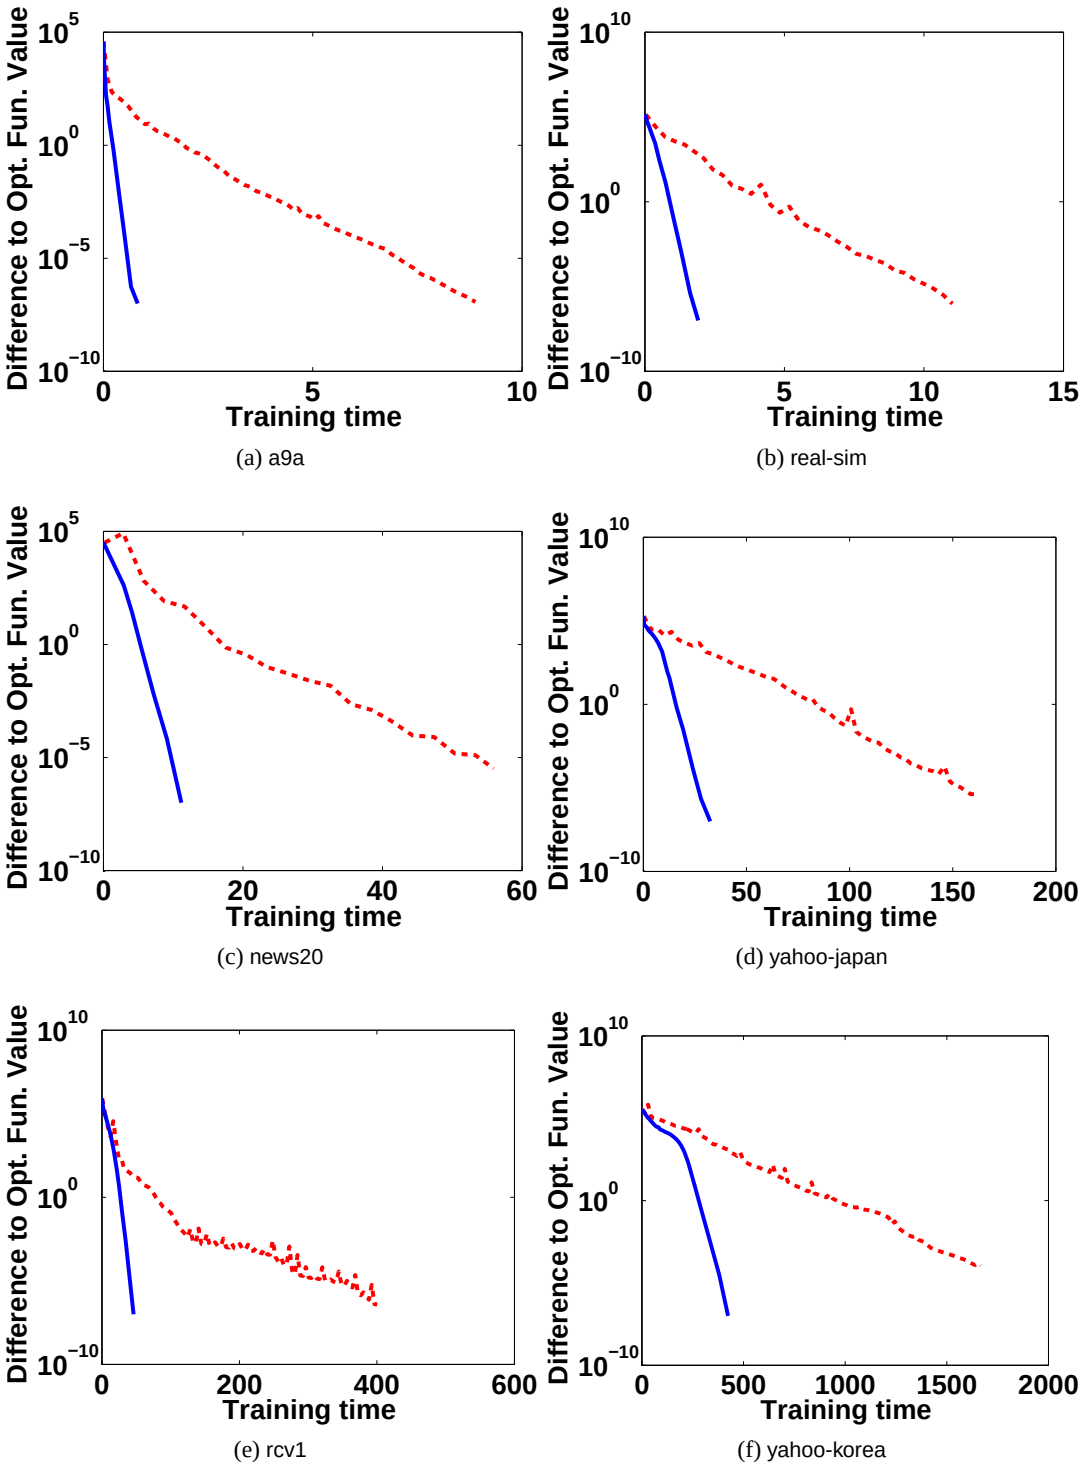

Figure 1: A comparison between TRON (blue solid line) and LBFGS (red dotted line). The y-axis shows the difference to the optimal function value. The x-axis (training time) is in seconds. We use the training set from the first training/validation split of the CV procedure and set $C = 4$.

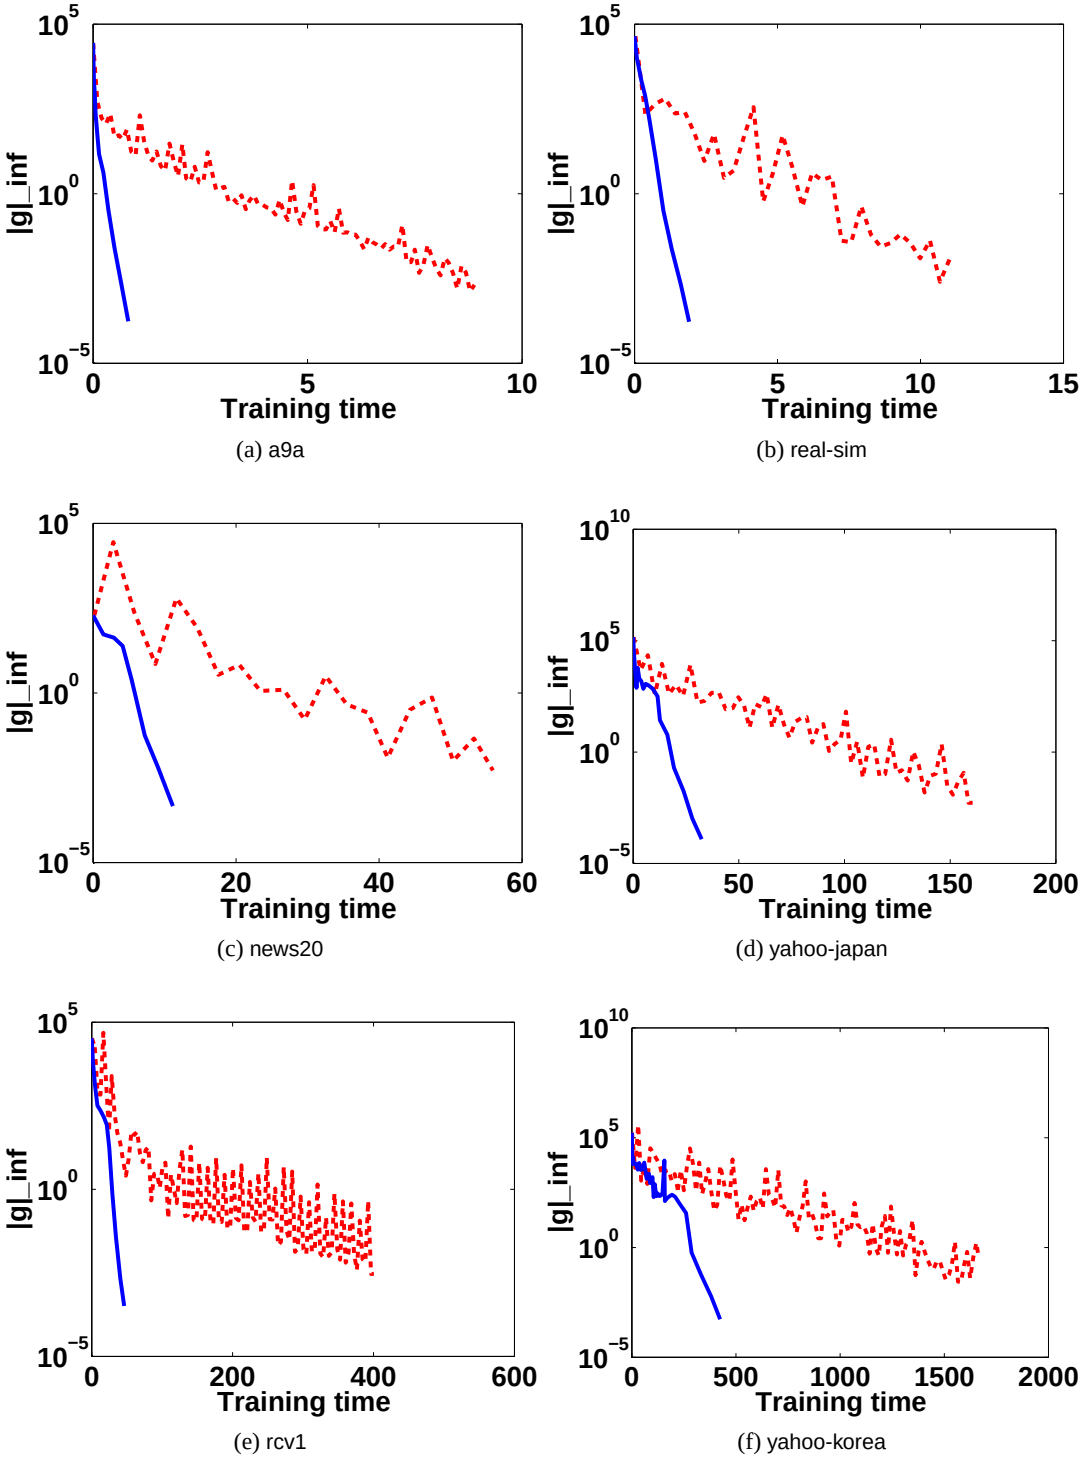

Figure 2: A comparison between TRON (blue solid line) and LBFGS (red dotted line). The y-axis shows $\|\nabla f(\mathbf{w})\|_\infty = \max_j |\nabla f(\mathbf{w})_j|$. The x-axis (training time) is in seconds. We use the training set from the first training/validation split of the CV procedure and set $C = 4$.

4.2 Comparisons

We compare two logistic regression implementations:

- TRON: the trust region Newton method discussed in Section 2.2.
- LBFGS: the limited memory quasi Newton implementation (Liu and Nocedal, 1989). See the discussion in Section 3.1. The source code is available online at

  `http://www.ece.northwestern.edu/~nocedal/lbfgs.html`.

We do not consider the code by Komarek and Moore (2005) because of two reasons. First, we have mentioned its convergence problems in Section 2.1. Second, for sparse data, it handles only problems with 0/1 feature values, but most our data have real-numbered features.

These methods are implemented in high-level languages such as C/C++ or FORTRAN. For easier experiments, we use their Matlab interfaces. Experiments are conducted on an Intel Core2 Quad (2.66GHz) computer with 8 GB RAM. All sources used for this comparison can be found at

`http://www.csie.ntu.edu.tw/~cjlin/liblinear`.

We set the initial $\mathbf{w}^0 = \mathbf{0}$.

We conduct two types of experiments. For the first one, we simulate the practical use of logistic regression by setting a stopping condition and checking the prediction ability. Most unconstrained optimization software use gradient information to terminate the iterative procedure, so we use

$$\|\nabla f(\mathbf{w}^k)\|_\infty \leq 10^{-3} \tag{18}$$

as the stopping condition. We then report cross-validation (CV) accuracy. For the larger sets (yahoo-japan, rcv1, and yahoo-korea), we use two-fold CV. For others, five-fold CV is conducted. We do not consider other measurements such as AUC (Area Under Curve) or F-measure as all problems are rather balanced, and CV accuracy is suitable. Moreover, different values of the regularization parameter C may affect the performance as well as training time. So we try four different C values: 0.25, 1, 4, and 16. Table 2 presents the result of comparisons. We show CV accuracy and the total training time in the CV procedure.

On training time, TRON is better than LBFGS, so truncated Newton methods are effective for training logistic regression. One may wonder if any implementation-specific details cause unfair timing comparisons. Indeed we have made the experimental environments as close as possible. For the methods compared here, we store the sparse matrix X by the same compressed row format. Section 4.3 discusses that different sparse formats may lead to dissimilar computational time. For LBFGS, one main cost is on function/gradient evaluations, which are provided by users. We implement the same code in TRON and LBFGS for function/gradient evaluations. Thus, our timing comparison is quite fair.

For $C \geq 16$, the CV accuracy does not improve. One can clearly see that the training time is higher as C increases. One reason is that the second term of (4) plays a more important role and hence the Hessian matrix is more ill-conditioned. Another reason is that (18) becomes a stricter condition. In (3), the second term of $f(\mathbf{w})$ is proportional to C. Hence, practically one may use a stopping condition relative to C.

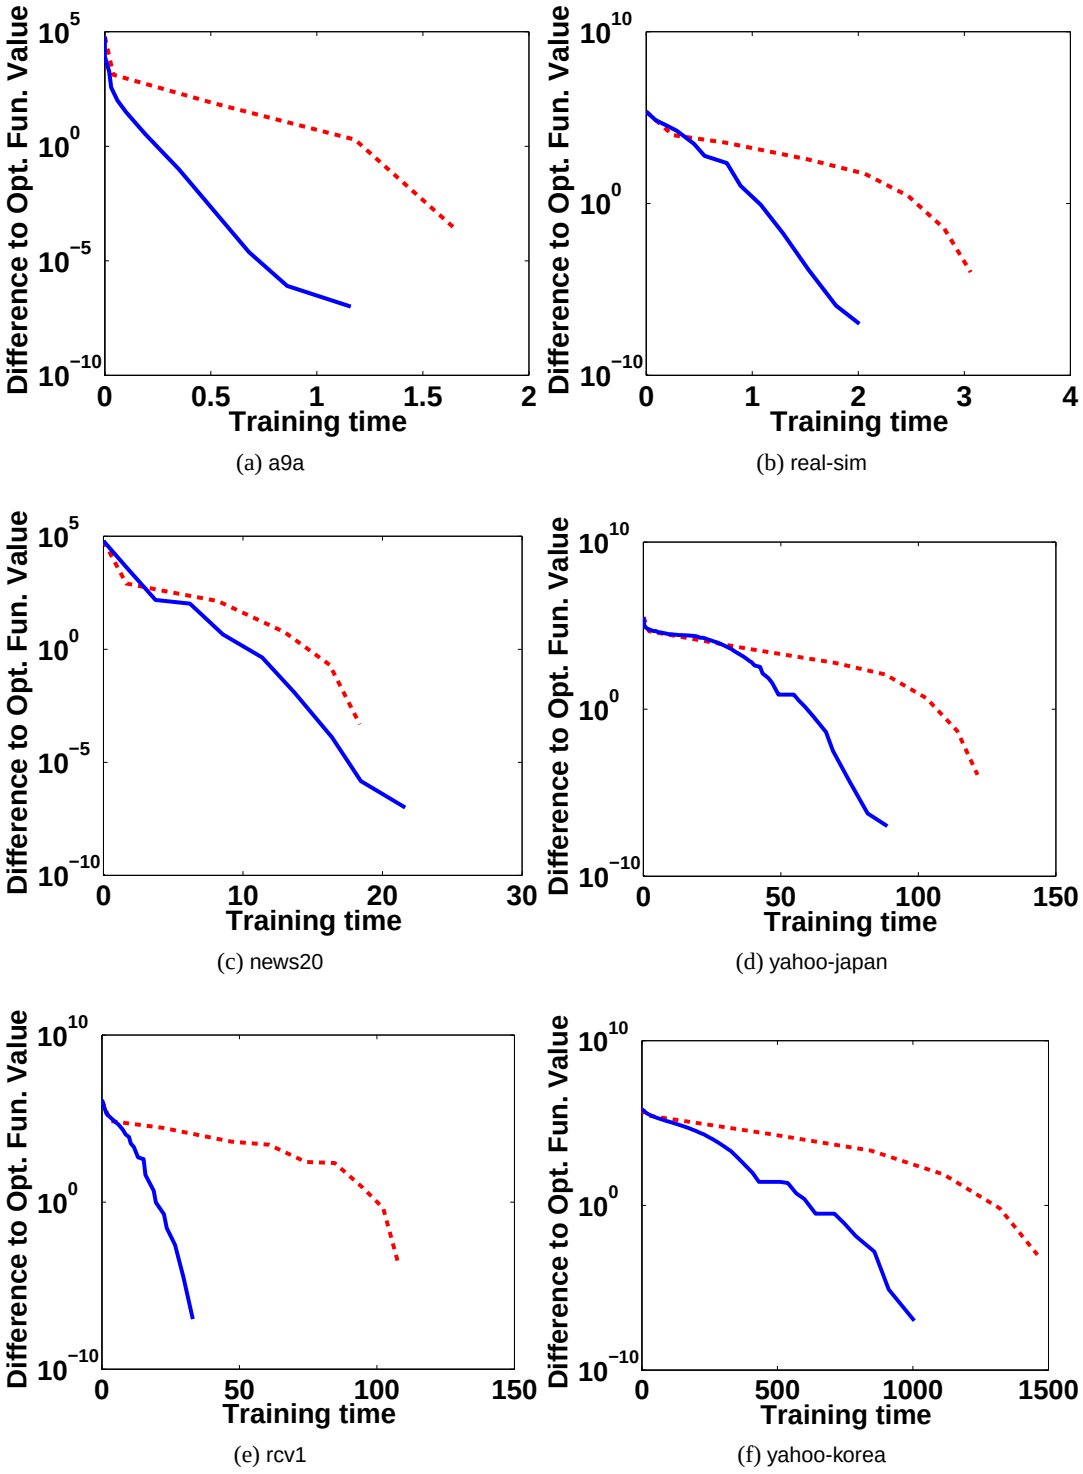

Figure 3: A comparison between TRON (blue solid line) and SVMlin (red dotted line) for L2-SVM. The *y*-axis shows the difference to the optimal function value. The *x*-axis (training time) is in seconds. We use the same training set as in Figure 1 and set $C = 4$.

For the second experiment, we check the convergence speed of both methods. Figure 1 presents the results of time versus the difference to the optimal function value. We use the training set from the first training/validation split of the CV procedure and set $C = 4$. In Figure 2, we check time against $\|\nabla f(\mathbf{w})\|_\infty$. Both figures indicate that TRON more quickly decreases the function as well as the gradient values than LBFGS. This result is consistent with the faster theoretical convergence rate of TRON.

4.3 Row and Column Formats in Storing X

A sparse matrix can be represented by many ways. Two commonly used ones are "compressed column" and "compressed row" formats (Duff et al., 1989). For example, if

$$X = \begin{bmatrix} -10 & 0 & -20 & 0 \\ 30 & 0 & 0 & 10 \end{bmatrix},$$

then its compressed column format is by three arrays:

$$\texttt{X\_val} = [-10, 30, -20, 10], \quad \texttt{X\_rowind} = [1, 2, 1, 2], \quad \texttt{X\_colptr} = [1, 3, 3, 4, 5],$$

where `rowind` means row indices and `colptr` means column pointers.[4] Alternatively, compress row format has

$$\texttt{X\_val} = [-10, -20, 30, 10], \quad \texttt{X\_colind} = [1, 3, 1, 4], \quad \texttt{X\_rowptr} = [1, 3, 5].$$

There are two important properties: First, X's column (row) format is X^T's row (column) format. Second, using the column (row) format for X leads to easy accesses of all values of one column (row). For data classification, the column (row) format thus lets us easily access any particular feature (any particular instance).

The main conjugate gradient operation (7) involves two matrix-vector products—one is with X^T, and the other is with X. In using the column format, there are ways so that for both operations, sequentially X's columns are accessed. Similarly, if using the row format, we only need to access X's rows. Thus, one may think that using the two (row and column) sparse formats does not cause many differences. Table 3 presents a comparison. Surprisingly, for some problems the difference is huge. One possible reason is the different number of nonzero entries per column and per row in X. During the matrix-vector product, as a column (or a row) is used at a time, its elements should be put in the higher level of the computer memory hierarchy. If the number of nonzeros in a column is significantly larger than those in a row, very likely a column cannot be fit into the same memory level as that for a row. We think that this situation occurs for rcv1, for which the number of instances is significantly larger than the number of features.

Of course the practical behavior depends on the computer architectures as well as how nonzero elements are distributed across rows and columns. We do not intend to fully address this issue here, but would like to point out the importance of implementation details in comparing learning algorithms. In Table 2, both methods are implemented using the row format. Without being careful on such details, very easily we may get misleading conclusions.

4. This way of using three arrays is common in FORTRAN programs, which did not support pointers. One can implement this format using pointers, where each pointer associates with values and indices of a row.

Problem	Row	Column

rcv1	118	226
yahoo-korea	1888	2060

Table 3: Total training time (in seconds) in the CV procedure by storing X in compress row and column formats. We use $C = 16$ and $\varepsilon = 0.001$.

5. Preconditioned Conjugate Gradient Methods

To reduce the number of conjugate gradient iterations, in the truncated Newton method one often uses preconditioned conjugate gradient procedures. Instead of solving the Newton linear system (6), we consider a preconditioner which approximately factorizes the Hessian matrix

$$\nabla^2 f(\mathbf{w}^k) \approx PP^T \tag{19}$$

and then solve a new linear system

$$(P^{-1}\nabla^2 f(\mathbf{w}^k)P^{-T})\hat{\mathbf{s}} = -P^{-1}\nabla f(\mathbf{w}^k),$$

where $\hat{\mathbf{s}} = P^T\mathbf{s}$. If the approximate factorization (19) is good enough, $P^{-1}\nabla^2 f(\mathbf{w}^k)P^{-T}$ is close to the identity and less conjugate gradient iterations are needed. However, as we need extra efforts to find P and the cost per conjugate iteration is higher, a smaller number of conjugate gradient iterations may not lead to shorter training time. Thus, finding suitable preconditioners is usually difficult. Popular preconditioners include, for example, diagonal matrix of the Hessian and incomplete Cholesky factorization.

Our situation differs from other unconstrained optimization applications in two aspects. First, lengthy conjugate gradient iterations often occur at final outer steps, but for machine learning applications the algorithm may stop before reaching such a stage. Thus we may not benefit from using preconditioners. Second, preconditioners are more easily obtained by assuming that the whole Hessian matrix $\nabla^2 f(\mathbf{w}^k)$ is available. As we never multiply $X^T DX$ out, $\nabla^2 f(\mathbf{w}^k)$ is not stored and the selection of preconditioners may be more restricted. In this section, we conduct experiments by using the simple diagonal preconditioner

$$P = P^T = \sqrt{\text{Diag}(\nabla^2 f(\mathbf{w}^k))}.$$

Since

$$\nabla^2 f(\mathbf{w}^k)_{ii} = 1 + C\sum_{j=1}^{l} X_{ji}^2 D_{jj},$$

one goes through all X's nonzero elements once for finding diagonal elements. The cost of obtaining the preconditioner is thus no more than that of one conjugate gradient iteration.

The trust region sub-problem needs to be adjusted. Here we follow the derivation of Lin and Moré (1999) by considering a scaled version

$$\min_{\mathbf{s}} \; q_k(\mathbf{s}) \quad \text{subject to } \|P^T\mathbf{s}\| \le \Delta_k. \tag{20}$$

Algorithm 4 Preconditioned conjugate gradient procedure for approximately solving the trust region sub-problem (21)

1. Given $\xi_k < 1, \Delta_k > 0$. Let $\hat{\mathbf{s}}^0 = \mathbf{0}, \mathbf{r}^0 = -\hat{\mathbf{g}}$, and $\mathbf{d}^0 = \mathbf{r}^0$.
2. For $i = 0, 1, \ldots$ (inner iterations)
   - If
   $$\|\mathbf{r}^i\| \le \xi_k \|\hat{\mathbf{g}}\|,$$
   then output $\mathbf{s}^k = P^{-T}\hat{\mathbf{s}}^i$ and stop.
   - $\alpha_i = \|\mathbf{r}^i\|^2 / ((\mathbf{d}^i)^T \hat{H}\mathbf{d}^i)$.
   - $\hat{\mathbf{s}}^{i+1} = \hat{\mathbf{s}}^i + \alpha_i \mathbf{d}^i$.
   - If $\|\hat{\mathbf{s}}^{i+1}\| \ge \Delta_k$, compute τ such that
   $$\|\hat{\mathbf{s}}^i + \tau \mathbf{d}^i\| = \Delta_k,$$
   then output $\mathbf{s}^k = P^{-T}(\hat{\mathbf{s}}^i + \tau \mathbf{d}^i)$ and stop.
   - $\mathbf{r}^{i+1} = \mathbf{r}^i - \alpha_i \hat{H}\mathbf{d}^i$.
   - $\beta_i = \|\mathbf{r}^{i+1}\|^2 / \|\mathbf{r}^i\|^2$.
   - $\mathbf{d}^{i+1} = \mathbf{r}^{i+1} + \beta_i \mathbf{d}^i$.

With $\hat{\mathbf{s}} = P^T \mathbf{s}$, we transform (20) to

$$\min_{\hat{\mathbf{s}}} \ \hat{q}_k(\hat{\mathbf{s}}) \quad \text{subject to } \|\hat{\mathbf{s}}\| \le \Delta_k, \tag{21}$$

where

$$\hat{q}_k(\hat{\mathbf{s}}) = \hat{\mathbf{g}}^T \hat{\mathbf{s}} + \frac{1}{2}\hat{\mathbf{s}}^T \hat{H}\hat{\mathbf{s}},$$

and

$$\hat{\mathbf{g}} = P^{-1}\nabla f(\mathbf{w}^k), \qquad \hat{H} = P^{-1}\nabla^2 f(\mathbf{w}^k)P^{-T}.$$

Eq. (21) is in the same form as (11), the sub-problem without using preconditioners, so the procedure to approximately solve (21) is almost the same as Algorithm 2. We give details in Algorithm 4. Note that in practical implementations we calculate $\hat{H}\mathbf{d}^i$ by a way similar to (7)

$$P^{-1}(P^{-T}\mathbf{d}^i + C(X^T(D(X(P^{-T}\mathbf{d}^i))))).$$

In Table 4, we present the average number of conjugate gradient iterations per fold in the CV procedure. The approach of using diagonal preconditioning reduces the number of iterations for only two problems. The number is increased for all other data sets. This experiment indicates the difficulty of doing preconditioning. Identifying effective preconditioners is thus a challenging future research issue.

Problem	CG	PCG
a9a	567	263
real-sim	104	160
news20	71	155
citeseer	113	115
yahoo-japan	278	326
rcv1	225	280
yahoo-korea	779	736

Table 4: Average number of conjugate gradient iterations per fold in the CV procedure. CG: without preconditioning. PCG: using diagonal preconditioning. We use $C = 16$ and the stopping condition $\|\nabla f(\mathbf{w}^k)\|_\infty \leq 0.001$.

6. Trust Region Method for L2-SVM

The second term in (2) can be considered as a loss function, so regularized logistic regression is related to other learning approaches such as Support Vector Machines (SVM) (Boser et al., 1992). L1-SVM solves the following optimization problem:

$$\min_{\mathbf{w}} f_1(\mathbf{w}) \equiv \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l} \max\left(0, 1 - y_i\mathbf{w}^T\mathbf{x}_i\right),$$

while L2-SVM solves

$$\min_{\mathbf{w}} f_2(\mathbf{w}) \equiv \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l} \left(\max(0, 1 - y_i\mathbf{w}^T\mathbf{x}_i)\right)^2. \tag{22}$$

SVM is often used with a nonlinear kernel, where data $\mathbf{x}_i$ are mapped to a high dimensional space. However, for document classification, past experiments show that with/without nonlinear mapping gives similar performances. For the case of no nonlinear mapping, we have the possibility of directly solving bigger optimization problems. We refer to such cases as *linear* SVM, and considerable efforts have been made on its fast training (e.g., Kao et al., 2004; Keerthi and DeCoste, 2005; Joachims, 2006; Shalev-Shwartz et al., 2007; Smola et al., 2008). L1-SVM is not differentiable, so our method cannot be applied. For L2-SVM, the training objection function (22) is differentiable but not twice differentiable (Mangasarian, 2002). In this section, we extend our trust region method for L2-SVM. We then compare it with an earlier Newton method for L2-SVM (Keerthi and DeCoste, 2005).

6.1 Trust Region Method

Let $f_2(\mathbf{w})$ be the L2-SVM function. It is strictly convex, so a proof similar to Theorem 1 shows that a unique global minimum exists. From Mangasarian (2002), $f_2(\mathbf{w})$ is continuously differentiable with the gradient

$$\nabla f_2(\mathbf{w}) = (I + 2CX_{I,:}^T X_{I,:})\mathbf{w} - 2CX_{I,:}^T \mathbf{y}_I,$$

where

$$I = \{i \mid 1 - y_i\mathbf{w}^T\mathbf{x}_i > 0\} \tag{23}$$

is an index set depending on $\mathbf{w}$ and $X_{I,:}$ includes X's rows corresponding to the set I. Unfortunately, L2-SVM is not twice differentiable, so one cannot use Newton directions. However, as shown by Mangasarian (2002), this function is almost twice differentiable. The gradient $\nabla f_2(\mathbf{w})$ is Lipschitz continuous, so one can define the *generalized* Hessian matrix

$$B(\mathbf{w}) = I + 2CX^T DX,$$

where

$$D_{ii} = \begin{cases} 1 & \text{if } 1 - y_i \mathbf{w}^T \mathbf{x}_i > 0, \\ \text{any element in } [0,1] & \text{if } 1 - y_i \mathbf{w}^T \mathbf{x}_i = 0, \\ 0 & \text{if } 1 - y_i \mathbf{w}^T \mathbf{x}_i < 0. \end{cases}$$

Then the trust region method (Lin and Moré, 1999) can be applied by replacing $\nabla^2 f(\mathbf{w})$ in Section 2.2 with $B(\mathbf{w})$. In other words, we use the generalized Hessian matrix $B(\mathbf{w})$ to obtain Newton-like directions. As $B(\mathbf{w})$ is uniformly bounded:

$$1 \le \|B(\mathbf{w})\| \le 1 + 2C\|X^T\|\|X\|, \quad \forall \mathbf{w},$$

Theorem 2.1 of Lin and Moré (1999) implies the global convergence. However, we cannot apply Theorem 5.4 of Lin and Moré (1999) to have quadratic convergence. This result requires the twice continuous differentiability.

For experiments here, we set $D_{ii} = 0$ if $1 - y_i \mathbf{w}^T \mathbf{x}_i = 0$. The Hessian-vector product in the conjugate gradient procedure is then

$$B(\mathbf{w})\mathbf{s} = \mathbf{s} + 2C \cdot X_{I,:}^T (D_{I,I}(X_{I,:}\mathbf{s})). \tag{24}$$

6.2 Modified Newton Method for L2-SVM

The method by Keerthi and DeCoste (2005) is currently one of the most efficient methods to train large-scale linear L2-SVM. Its key idea is that for any given index set $I \subset \{1, \ldots, l\}$, if the optimal solution $\mathbf{w}^*$ of the following problem

$$\min_{\mathbf{w}} \quad \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i \in I}(1 - y_i \mathbf{w}^T \mathbf{x}_i)^2 \tag{25}$$

satisfies

$$1 - y_i (\mathbf{w}^*)^T \mathbf{x}_i \begin{cases} > 0 & \text{if } i \in I, \\ \le 0 & \text{if } i \notin I, \end{cases}$$

then $\mathbf{w}^*$ is an optimal solution of the L2-SVM problem (22). Once I is fixed, (25) is a simple regularized least square problem and can be solved by the following linear system:

$$(I + 2CX_{I,:}^T X_{I,:})\mathbf{w} = 2CX_{I,:}^T \mathbf{y}_I. \tag{26}$$

One then guesses this set I by (23) and solves (26). The matrix in (26) is a generalized Hessian at $\mathbf{w}$, so (26) intends to obtain a Newton-like direction. Keerthi and DeCoste (2005) use conjugate gradient methods to solve (26), and the procedure is described in Algorithm 5. They prove that Algorithm 5 converges to the optimal solution of (22) in a finite number of iterations. This convergence result assumes that at each iteration, (26) is exactly solved. However, they use a relative stopping condition in practical implementations, so the convergence remains an issue. In contrast, the convergence of our trust region method holds when the conjugate gradient procedure only approximately minimizes the trust-region sub-problem.

Algorithm 5 Modified Newton Method for L2-SVM

1. Given $\mathbf{w}^0$.
2. For $k = 0, 1, \ldots$
   - If $\nabla f(\mathbf{w}^k) = \mathbf{0}$, stop.
   - Set up (26) using
     $$I_k = \{i \mid 1 - y_i (\mathbf{w}^k)^T \mathbf{x}_i > 0\}.$$
     Solve (26) by the conjugate gradient procedure and obtain $\bar{\mathbf{w}}^k$.
   - Let $\mathbf{s}^k = \bar{\mathbf{w}}^k - \mathbf{w}^k$.
     Find
     $$\alpha_k = \arg\min_{\alpha \geq 0} f(\mathbf{w}^k + \alpha \mathbf{s}^k),$$
     and set $\mathbf{w}^{k+1} = \mathbf{w}^k + \alpha_k \mathbf{s}^k$.

6.3 Comparisons

We compare our proposed trust region implementation (TRON) in Section 6.1 with SVMlin

`http://people.cs.uchicago.edu/~vikass/svmlin.html`,

an implementation of the method by Keerthi and DeCoste (2005). To solve (26), SVMlin considers a relative stopping condition for the conjugate gradient procedure. Following their convergence result, we modify SVMlin to quite accurately solve the linear system (26): Recall in Algorithm 5 that we sequentially obtain the following items:

$$\mathbf{w}^k \rightarrow I_k \rightarrow \bar{\mathbf{w}}^k.$$

We then use

$$\|(I + 2CX^T_{I_k,:} X_{I_k,:})\bar{\mathbf{w}}^k - 2CX^T_{I_k,:} \mathbf{y}_{I_k}\|_\infty \leq 10^{-3}$$

as the stopping condition of the conjugate gradient procedure in SVMlin.

Figure 3 presents the result of time versus the difference to the optimal function value. Both approaches spend most of their time on the operation (24) in the conjugate gradient procedure. Clearly, TRON more quickly reduces the function value. SVMlin is slower because it accurately solves (26) at early iterations. Hence, many conjugate gradient iterations are wasted. In contrast, trust region methods are effective on using only approximate directions in the early stage of the procedure.

7. Discussion and Conclusions

As logistic regression is a special case of maximum entropy models and conditional random fields, it is possible to extend the proposed approach for them. The main challenge is to derive the Hessian matrix and efficiently calculate the Hessian-vector product. This topic deserves a thorough investigation in the future.

One may use a different regularized term for logistic regression. For example, the two-norm $\|\mathbf{w}\|^2/2$ could be replaced by a one-norm term $\|\mathbf{w}\|_1$. Then (2) becomes

$$\min_{\mathbf{w}} \quad \|\mathbf{w}\|_1 + C\sum_{i=1}^{l}\log(1+e^{-y_i\mathbf{w}^T\mathbf{x}_i}). \tag{27}$$

This formula has been used for some applications. See (Balakrishnan and Madigan, 2005) and Koh et al. (2007) and references therein. Unfortunately, (27) is not differentiable on $\mathbf{w}$. We can transform it to a twice-differentiable bound-constrained problem by using $\mathbf{w} \equiv \mathbf{w}^+ - \mathbf{w}^-$:

$$\begin{aligned} \min_{\mathbf{w}^+,\mathbf{w}^-} \quad & \sum_{j=1}^{n} w_j^+ + \sum_{j=1}^{n} w_j^- + C\sum_{i=1}^{l}\log(1+e^{-y_i(\mathbf{w}^+-\mathbf{w}^-)^T\mathbf{x}_i}) \\ \text{subject to} \quad & w_j^+ \geq 0, w_j^- \geq 0, \quad j=1,\ldots,n. \end{aligned} \tag{28}$$

As the truncated Newton method by Lin and Moré (1999) exactly targets at such bound-constrained problems, we can thus extend the proposed approach for (28). A comparison to investigate if our method is better than existing ones is an interesting direction for future work.

In summary, we have shown that a trust region Newton method is effective for training large-scale logistic regression problems as well as L2-SVM. The method has nice optimization properties following past developments for large-scale unconstrained optimization. It is interesting that we do not need many special settings for logistic regression; a rather direct use of modern trust region techniques already yields excellent performances. From this situation, we feel that many useful optimization techniques have not been fully exploited for machine learning applications.

Appendix A. Proof of Theorem 1

Since $f(\mathbf{w})$ is strictly convex, a minimum attained is unique and global. The remaining issue is to check if a minimum exists (as strictly convex functions like e^x do not attain a minimum). It suffices to prove that the level set is bounded:

$$\{\mathbf{w} \mid f(\mathbf{w}) \leq f(\mathbf{w}^0)\}, \tag{29}$$

where $\mathbf{w}^0$ is any vector. If this property is wrong, there is a sequence $\{\mathbf{w}^k\}$ in the set (29) satisfying $\|\mathbf{w}^k\| \to \infty$. However,

$$f(\mathbf{w}^k) \geq \frac{1}{2}\|\mathbf{w}^k\|^2 \to \infty$$

contradicts the fact that $f(\mathbf{w}^k) \leq f(\mathbf{w}^0), \forall k$.

Abstract

In structured classification problems, there is a direct conflict between expressive models and efficient inference: while graphical models such as Markov random fields or factor graphs can represent arbitrary dependences among instance labels, the cost of inference via belief propagation in these models grows rapidly as the graph structure becomes more complicated. One important source of complexity in belief propagation is the need to marginalize large factors to compute messages. This operation takes time exponential in the number of variables in the factor, and can limit the expressiveness of the models we can use. In this paper, we study a new class of potential functions, which we call decomposable k-way potentials, and provide efficient algorithms for computing messages from these potentials during belief propagation. We believe these new potentials provide a good balance between expressive power and efficient inference in practical structured classification problems. We discuss three instances of decomposable potentials: the associative Markov network potential, the nested junction tree, and a new type of potential which we call the voting potential. We use these potentials to classify images of protein subcellular location patterns in groups of cells. Classifying subcellular location patterns can help us answer many important questions in computational biology, including questions about how various treatments affect the synthesis and behavior of proteins and networks of proteins within a cell. Our new representation and algorithm lead to substantial improvements in both inference speed and classification accuracy.

Keywords: factor graphs, approximate inference algorithms, structured classification, protein subcellular location patterns, location proteomics

1. Introduction

In standard supervised classification problems, the label of each test instance is independent of the labels of all other instances. In some problems, however, we may receive multiple test instances at a time, along with side information about dependences among the labels of these instances. For

example, if each instance is a handwritten character, the side information might be that the string of characters forms a common English word; or, if each instance is a microscope image of a cell with a certain protein tagged, the side information might be that several cells share the same tagged protein. To solve such a *structured classification problem* in practice, we need both an expressive way to represent our beliefs about the structure, as well as an efficient probabilistic inference algorithm for classifying new groups of instances.

Unfortunately, the goal of having an expressive language is in direct conflict with the goal of having an efficient inference algorithm: while Markov random fields or factor graphs can represent arbitrary dependences among instances, inference rapidly becomes intractable as the graph structure becomes more complicated (see, e.g., Koller and Friedman, 2007). Simple graphs such as pairwise links arranged in chains or trees lead to efficient inference, but these structures may not allow us to express our beliefs accurately or completely. On the other hand, if we try to couple large groups of labels (either directly, by specifying a factor that links to a large number of labels, or indirectly, by using a graph with large loops), the cost of inference grows exponentially.

To speed up inference, we can move to approximate algorithms such as loopy belief propagation (see, e.g., Koller and Friedman, 2007). Loopy belief propagation handles large loops efficiently, but it does nothing to speed up the task of working with single large factors. In fact, in practical problems, the operation of marginalizing a large factor can easily become the main bottleneck for inference, preventing us from using more-expressive models.

Therefore, in this paper, we study a new class of potential functions, which we call decomposable k-way potentials. Computing messages for these potentials is much more efficient than for general potentials, even though the new potentials can express distributions that cannot be represented by groups of smaller potentials. Accordingly, we believe these new potentials provide a better balance between expressive power and efficient inference than was previously available.

We discuss three instances of decomposable potentials: the associative Markov network potential, the nested junction tree, and a new type of potential which we call the voting potential. We use these potentials to classify images of protein subcellular location patterns in groups of cells. Classifying protein subcellular location patterns is important as a step in solving many practical computational biology problems, particularly in the area of systems biology: for example, it can help in designing high-throughput screening systems for drug discovery, or in conducting experiments to determine the effect of various treatments on the synthesis and behavior of proteins and networks of proteins within a cell. Our new representation and algorithm lead to substantial improvements in both inference speed and classification accuracy.

Preliminary versions of portions of this work have been presented previously (Chen and Murphy, 2006; Chen et al., 2006a,b). These papers describe applications of decomposable potentials and the corresponding fast inference algorithms for segmenting and classifying images of protein subcellular location patterns. But, none of these papers describe the idea of decomposable potentials of Section 4 or the nested inference algorithm of Section 5 in full generality. They also do not cover some of the instances of decomposable potentials described in Section 6; and, the experiments of Sections 8–9 have not been reported previously.

2. Factor Graphs

The factor graph representation of a probability distribution (Kschischang et al., 2001) describes the relationships among a set of variables x_i using local factors or potentials φ_j. Each factor depends

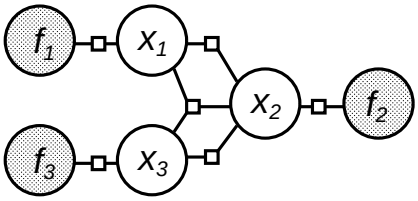

Figure 1: A probability distribution represented as a factor graph. Small squares denote potential functions; for example, this factor graph contains a potential which connects the variables x_1, x_2, and x_3, and another which connects x_1 and f_1.

on only a subset of the variables, and the overall probability distribution is the product of the local factors, together with a normalizing constant Z:

$$P(x) = \frac{1}{Z} \prod_{\text{factors } j} \varphi_j(x_{V(j)}).$$

Here $V(j)$ is the set of variables that are arguments to factor j; for example, if φ_j depends on x_1, x_3, and x_4, then $V(j) = \{1,3,4\}$ and $x_{V(j)} = (x_1, x_3, x_4)$.

Each variable x_i or factor φ_j corresponds to a node in the factor graph. Fig. 1 shows an example: the large nodes represent variables, with shaded circles for observed variables and open circles for unobserved ones. The small square nodes represent factors, and there is an edge between a variable x_i and a factor φ_j if and only if φ_j depends on x_i, that is, when $i \in V(j)$. (By convention the graph only shows factors with two or more arguments. Factors with just a single argument are not explicitly represented, but are implicitly allowed to be present at each variable node.)

The inference task in a factor graph is to combine the evidence from all of the factors to compute properties of the distribution over x represented by the graph. Naively, we can do inference by enumerating all possible values of x, multiplying together all of the factors, and summing to compute the normalizing constant. Unfortunately, the total number of terms in the sum is exponential in the number of random variables in the graph. So, usually, a better way to perform inference is via a message-passing algorithm called belief propagation (BP). Here we briefly review the basics of BP in factor graphs; for more details, see Kschischang et al. (2001).

The basic BP algorithm works on a factor graph which is tree-shaped (i.e., has no cycles). It sends messages from every variable to each of its neighboring factors, and from every factor to each of its neighboring variables. Messages to or from a variable x_i will be vectors whose length is equal to the number of values that x_i can take on.

For a variable x_i with neighboring factors $\varphi_1, \varphi_2, \ldots, \varphi_k$, suppose that x has received messages $m_{j \to i}(x_i)$ from its neighbors φ_j for $j \in \{1 \ldots (k-1)\}$. (To simplify notation, we have numbered x_i's neighbors consecutively starting from 1. This is not a loss of generality since we can always temporarily permute our factor indices to make it so.) Suppose also that x_i has local evidence represented by the one-argument factor $\varphi_i^{\text{loc}}(x_i)$. Then we can compute x_i's message to φ_k as

$$m_{i \to k}(x_i) = \varphi_i^{\text{loc}}(x_i) \prod_{j=1}^{k-1} m_{j \to i}(x_i). \tag{1}$$

That is, we take the componentwise product of all of the messages from factors $1 \ldots k-1$, multiply in the local evidence, and send the result to φ_k. The normalization of the message is arbitrary, so for convenience or numerical precision we may multiply each component of the message by an arbitrary constant.

Similarly, suppose that a factor φ_j has neighbors $x_1, x_2, \ldots, x_k$ (again numbered consecutively without loss of generality) and has received messages $m_{i \to j}(x_i)$ for $i \in \{1 \ldots (k-1)\}$. Then we can compute φ_j's message to x_k as

$$m_{j \to k}(x_k) = \sum_{x_1} \sum_{x_2} \cdots \sum_{x_{k-1}} \varphi_j(x_1, \ldots, x_k) \prod_{i=1}^{k-1} m_{i \to j}(x_i). \tag{2}$$

Unlike Equation 1, in Equation 2 we must marginalize out variables other than x_k by summing over their possible values.

BP works by picking an arbitrary node of the graph as root and then making two passes over the tree: first it passes messages inward from the leaves to the root, and then outward from the root to the leaves. When the message passing finishes, the posterior marginal probability of any random variable x_i is just the componentwise product of its local potential and all of its incoming messages:

$$P(x_i) = \varphi^{\text{loc}}(x_i) \prod_{\{j | i \in V(j)\}} m_{j \to i}(x_i). \tag{3}$$

2.1 Working with General Graphs

The above discussion assumed that our factor graph was tree-shaped. For graphs with loops, we have two alternatives: first, we can collapse groups of variable nodes together into combined nodes, which can turn our graph into a tree and allow us to run BP as above. Second, we can run an approximate inference algorithm that doesn't require a tree-shaped graph. We can also combine these alternatives if desired, grouping variable nodes to reduce the number of loops in the graph so that our approximate inference becomes more accurate.

When we combine a set of variable nodes, the new node represents all possible settings of all of the original nodes. E.g., if we collapse a variable x_1 that has settings T, F with a variable x_2 that has settings A, B, C, then the combined variable x_{12} has settings TA, TB, TC, FA, FB, FC. When we collapse a set of variables, we need to alter the neighboring factor nodes: any factor adjacent to any of the original nodes becomes a neighbor of the new combined node, and its list of arguments is extended if necessary to include all variables in the collapsed set.

The advantage of collapsing variable nodes is that it can allow us to simplify the structure of our graph: if in the collapsed graph there are two factor nodes with the same set of arguments, then we can combine them by multiplying their potentials elementwise. For example, Fig. 2 shows the result of collapsing x_1 and x_2 in the factor graph of Fig. 1. The potentials φ_{23} and φ_{123} from the original graph have the same set of neighbors in the new graph, and so can be combined into one factor node. Similarly, the local potentials φ_1^{loc} and φ_2^{loc} can be combined with the factor φ_{12} to form a new local potential at the collapsed node x_{12}. Notice that the new factor graph is tree-shaped, even though the original one had loops.

When removing loops from a factor graph, we may wish to include each original variable in more than one combined node. We are free to do so as long as we adjust our potentials to enforce the constraint that all copies of the variable must agree on its value. That is, when any two copies

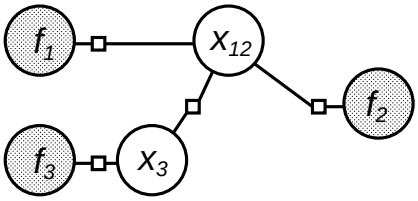

Figure 2: Another factor graph that can represent the same probability distribution as the graph of Fig. 1. The new graph was derived by collapsing together the nodes for variables x_1 and x_2 from Fig. 1.

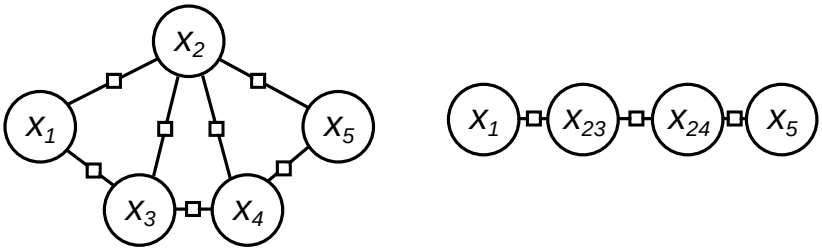

Figure 3: A factor graph with multiple loops (left) and a tree derived from the factor graph by collapsing pairs of nodes (right).

disagree, at least one potential must be zero. The cost of storing or working with such a hard-constraint potential depends only on the number of *distinct* variables in its argument list.

For example, in the graph of Fig. 3, we could form a tree by collapsing x_2, x_3, and x_4 into a single node. The resulting graph would have variables x_1, x_{234}, and x_5, and factors φ_{1234} and φ_{2345}. But, we can form a tree with smaller factors if we group x_2 with x_3 and also separately with x_4: the resulting graph has variables x_1, x_{23}, x_{24}, and x_5, and factors φ_{123}, φ_{234}, and φ_{245}. The potential φ_{234} encodes the constraint that the settings of x_{23} and x_{24} must agree on the assignment to x_2.

A factor graph that has been reduced to a tree is equivalent to a *junction tree*. A junction tree is a connected acyclic graph whose nodes are labeled with sets of variables in a way that satisfies the *running intersection property*: if a variable is present at two nodes A and B, it is also present at all nodes along the (unique) path connecting A and B in the tree. The factor nodes in a tree-shaped factor graph correspond to nodes of the junction tree, with labels equal to their argument sets. The collapsed variable nodes correspond to edges of the junction tree. The groups of original variables at each collapsed variable node (such as $\{x_2, x_4\}$ in the figure) are called *separators*, since conditioning on all of the variables in a separator is sufficient to separate the factor graph into two or more disconnected pieces. The running intersection property ensures that we can define potentials that constrain all copies of a variable to agree.

If we collapse our factor graph all the way to a tree, we can do inference with the exact BP algorithm from above. If we leave some loops, a similar BP algorithm can still work: we can initialize all messages to be uniform, then start at an arbitrary node and use the same formulas as before

for message calculation (Equations 1–2). However, we may have to update each message several times before the marginals converge. The version of the algorithm that updates messages repeatedly until convergence is called loopy BP, or LBP. Inference with LBP is approximate because it can double-count evidence: messages to a node i from two nodes j and k can both contain information from a common neighbor l of j and k. Several researchers have empirically demonstrated that when LBP converges, the posterior marginal probabilities from Equation 3 often approximate the true marginals well (Murphy et al., 1999; McEliece et al., 1998; Zhang and Chang, 2004). If LBP oscillates between some steady states and does not converge, we can stop the process after some number of iterations; in this case, the approximate posteriors will usually be inaccurate. Although oscillations can be avoided by using "momentum" (Murphy et al., 1999), which replaces the messages that were sent at time t with a weighted average of the messages at times t and $t-1$, in some cases the approximate posteriors are still inaccurate (Murphy et al., 1999). The convergence of LBP depends on the exact graph structure and on the type and strength of the factors involved (Pearl, 1988; Heskes, 2004). Recently, researchers have developed sufficient conditions for the convergence of LBP (Weiss, 2000; Tatikonda and Jordan, 2002; Ihler et al., 2005), and a measurement of message errors has been proposed (Ihler et al., 2005).

For either exact or loopy BP, the runtime for each pass over the factor graph is exponential in the number of distinct original variables included in the largest factor. So, inference can become prohibitively expensive if our factors are too large, either because they were too large in the original graph or because we merged too many variables.

3. Factor Graphs and Structured Classification

To use belief propagation to solve structured classification problems, we need two things: a local classifier for individual instances, and a factor graph which encodes our prior beliefs about likely arrangements of instance labels. The local classifier tells us the likelihood of individual test examples under each possible class assignment, while the factor graph tells us how to trade off evidence at one example against evidence at another. We can learn local classifiers in a number of ways; for the cell image classification experiments below, we use standard support vector machines, together with a post-processing step that allows us to interpret the SVM outputs as probabilities.

There are also a number of ways to construct factor graphs that encode our beliefs about likely label vectors. In our experiments below, we construct a factor graph in two steps: first we use domain-specific heuristics to identify pairs of examples whose labels are likely to be the same, and use these pairs to build a *similarity graph* with an edge between each such pair of examples. Then, we use this similarity graph to decide what potentials to add to our factor graph. (In the protein subcellular location pattern classification problem, the similarity graph edges come from either physical proximity or similarity in appearance.) Given the similarity graph, we compare factor graphs built from several different types of potentials; the following sections introduce these potentials and discuss their advantages and disadvantages.

3.1 The Potts Potential

The simplest potential function is the Potts potential. The Potts potential is a pairwise (i.e., two-argument) factor which encourages two nodes x_i and x_j to have the same label:

$$\varphi(x_i, x_j) = \begin{cases} \omega & x_i = x_j \\ 1 & \text{otherwise.} \end{cases} \tag{4}$$

Here $\omega > 1$ is an arbitrary parameter which expresses how strongly we believe that x_i and x_j have the same label. If we use one Potts potential for each edge in the similarity graph, the overall probability of a vector of labels x is

$$P(x) = \frac{1}{Z} \prod_{\text{nodes } i} P(x_i) \prod_{\text{edges } i,j} \varphi(x_i, x_j) \tag{5}$$

where we have written Z for a normalizing constant and $P(x_i)$ for the probability which the base classifier assigns to label x_i for node i. Equations 4–5 form what is known as a *Potts model*.

Unfortunately, the Potts model does not perfectly capture our desired intuition about inference from labels of neighboring cells. To see why, consider a two-class prediction problem where node x_i has k_A neighbors of class A and k_B neighbors of class B, and suppose that classes A and B have equal prior probability for x_i given the classifier output. In this situation the ratio of posterior probabilities for classes A and B will be $\omega^{k_A - k_B}$. So for example, if ω is 2, and if x_i has 1 neighbor of class A and 3 of class B, then the ratio of probabilities will be $2^{1-3} = 1/4$. So, class A will be 1/4 as likely as class B, and $P(x_i \text{ has label } A) = 0.2$.

However, if x_i has 7 neighbors of class A and 9 neighbors of class B, the posterior probability of class A will still be 0.2, even though our intuition tells us that the probability should be much closer to 0.5 in this case. The same will hold whenever there are 2 more neighbors of class B than class A, even if the counts are 107 and 109. Worse, as class B's majority gets larger, the ratio of probabilities will approach 0 exponentially fast. So, a sufficiently strong vote from x_i's neighbors will quickly overwhelm any evidence at x_i itself—an undesirable situation.

The source of this problem is that, in Equation 5, the evidence from separate potentials has to combine multiplicatively. So, as long as the evidence from different neighbors acts through separate potentials, we will see an exponential dependence between the number of neighbors of a given class and the probability of that class. We can reduce the severity of this problem by choosing ω to be only a little bit larger than 1. But, to fix the problem we need to move to potential functions that depend on $k > 2$ nodes. Our experimental results, below, will show that potentials that combine evidence additively can perform better than the Potts potential over a wider range of inference problems.

3.2 The Voting Potential

To capture the intuition that we should be less certain about nodes whose neighbors split relatively evenly, we propose a new potential which we call the *voting potential*. In the voting potential, a node's classification is influenced by the *proportion* of classes among its neighbors, rather than the difference in class counts as in the Potts model.

The voting potential has one distinguished argument, called the *center*; the remaining arguments are called *voters*. In the factor graphs for our cell classification experiments below, we use one voting potential per cell j; the center for the jth potential is cell j itself, and the voters are the cells that are adjacent to j in the similarity graph. We will write $N(j)$ for the set of similarity-graph neighbors of cell j, so that the jth potential depends on variables $V(j) = \{j\} \cup N(j)$.

x_1	x_2	x_3	φ
0	0	0	3/4
0	0	1	1/2
0	1	0	1/2
0	1	1	1/4
1	0	0	1/4
1	0	1	1/2
1	1	0	1/2
1	1	1	3/4

Table 1: An example of the voting potential with parameter $\lambda = 2$ for $n = 2$ classes. The center node x_1 has two neighbors, x_2 and x_3.

We define the voting potential as follows:

$$\varphi_j(x_{V(j)}) = \frac{\lambda/n + \sum_{i \in N(j)} I(x_i, x_j)}{|N(j)| + \lambda}. \tag{6}$$

Here n is the number of classes, λ is a smoothing parameter, and I is an indicator function:

$$I(x_i, x_j) = \begin{cases} 1 & \text{if } x_i = x_j \\ 0 & \text{otherwise.} \end{cases}$$

(The normalization constant in the denominator of Equation 6 is irrelevant to inference, and is included only for ease of interpretation.) An example of the voting potential is given in Table 1.

The voting potential function combines the evidence from all of node x_j's neighbors into a summary vote which then influences x's classification. The parameter λ controls how much weight we put on a vote from a small number of neighboring cells. We can interpret it as the size of an additional set of fictitious neighbors whose votes are distributed uniformly; this trick limits the influence of a vote from a small number of neighbors, and is called Laplace smoothing. For example, looking at the first and fifth rows of the table, we can see that when both of x_1's neighbors are 0, x_1 is 3 times as likely to be 0 as 1, since there are $2+1$ votes for $x_1 = 0$ and $0+1$ votes for $x_1 = 1$.

The behavior of the voting potential contrasts with that of the Potts potential described in Section 3.1, in which each neighbor separately influences the center node without reference to the other neighbors. In line with our intuition, we will see below that networks which use the voting potential can yield more accurate results than the Potts model for structured classification problems.

3.3 The AMN Potential

The associative Markov network (AMN) potential (Taskar et al., 2004) is defined to be

$$\varphi(x_1 \ldots x_k) = 1 + \sum_{y=1}^{n} (\omega_y - 1) I(x_1 = x_2 = \ldots = x_k = y) \tag{7}$$

for parameters $\omega_y > 1$, where $I(\text{predicate})$ is defined to be 1 if the predicate is true and 0 if it is false. So, the AMN potential is constant unless all of the variables $x_1 \ldots x_k$ are assigned to the same class y, in which case it is equal to ω_y.

The AMN potential reduces to the Potts potential when $k = 2$ and $\omega_y = \omega$ for all y. So, in this case it inherits the same problems that the Potts potential has. For any k, the AMN potential has no direct effect on a label vector's likelihood unless *all* of the k argument variables agree on the label y. (It affects all vectors' likelihoods indirectly through the normalizing constant.) As k gets larger, there are comparatively fewer label vectors where all k labels agree, and so the AMN potential may not have much influence on the overall posterior distribution over label vectors unless the cell-level classifiers already were very close to agreement. And in fact, our experiments below demonstrate that factor graphs based on the AMN potential perform best when the neighborhood size k is relatively small (but larger than 2).

4. Decomposable Potentials

While k-way factors can lead to more accurate inference, they can also slow down belief propagation. For a general k-way factor, it takes time exponential in k even to look at all of the entries. So, we cannot expect to find inference algorithms for general k-way potentials that take less than exponential time.

For specific k-way potentials, though, we can hope to take advantage of special structure to design a fast inference algorithm. In particular, for many interesting potential functions, we can write down an algorithm which efficiently performs sums of the form required for message computation:

$$\sum_{x_1} \sum_{x_2} \cdots \sum_{x_{k-1}} \varphi_j^*(x_1, \ldots, x_k), \tag{8}$$

$$\varphi_j^*(x_1, \ldots, x_k) = m_1(x_1) m_2(x_2) \ldots m_k(x_{k-1}) \varphi_j(x_1, \ldots, x_k). \tag{9}$$

Here $m_i(x_i)$ is the message to factor j from variable x_i. (If we removed loops in our factor graph by collapsing groups of variables, then Equation 9 may look instead like

$$\varphi_j^*(x_1, \ldots, x_k) = m_{12}(x_1, x_2) m_{245}(x_2, x_4, x_5) \ldots m_{k-1}(x_{k-1}) \varphi_j(x_1, \ldots, x_k).$$

That is, the argument sets of the messages may overlap with one another. The derivations below apply equally well to either expression for φ_j^*.)

For example, as we will see below, we can compute Equations 8–9 quickly if φ_j is a sum of terms $\sum_l \psi_{jl}$ where each term ψ_{jl} depends only on a small subset of its arguments $x_1 \ldots x_k$. Or, we can compute Equations 8–9 quickly if φ_j is constant except at a small number of input vectors $(x_1, \ldots, x_k)$. In the first case we will say that φ_j is a sum of *low-arity* terms ψ_{jl}, and in the second case we will say that φ_j is *sparse*.

More generally, suppose that φ_j^* in Equation 8 can be written as a sum of products of low-arity functions: writing ψ_{jl} for a generic term in the sum and ξ_{jlm} for a generic factor of ψ_{jl},

$$\varphi_j^*(x_1, \ldots, x_k) = \sum_{l=1}^{L_j} \psi_{jl}(x_1, \ldots, x_k) = \sum_{l=1}^{L_j} \prod_{m=1}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)}) \tag{10}$$

where the set of indices $V(j,l,m) \subseteq \{1 \ldots k\}$ tells us which variables ξ_{jlm} depends on. Also suppose that, for each term ψ_{jl} in the sum, the sets $V(j,l,m)$ can be arranged into a junction tree. That is, suppose that we can build a cycle-free graph on M_{jl} nodes, with one node labeled with $V(j,l,m)$ for each m, which satisfies the running intersection property.

If φ_j^* satisfies the above properties, and if L_j, M_{jl}, and $|V(j,l,m)|$ are small for all j, l, and m, then we will say that φ_j^* is *decomposable*. And, we will say that φ_j is a *decomposable potential* (in the context of this message computation). Decomposable potentials include the special cases mentioned above, namely sparse potentials and potentials that are sums of low-arity terms, as well as a wide variety of other examples which we will describe in more detail below. We will see below that we can evaluate Equations 8–9 quickly for a decomposable potential by using an algorithm very similar to belief propagation.

5. Belief Propagation with Decomposable Potentials

When we are running BP or loopy BP on a factor graph with decomposable potentials, we can accelerate the computation of the belief messages that would otherwise be slow to compute. There are two types of messages that we need for BP or loopy BP, shown in Equations 1 and 2.

Messages from a variable (or a separator, which we treat as a single large variable) to a factor are fast to compute in any case: we can calculate them from Equation 1 by looping over the incoming edges at node x_i and, for each edge, looping over the n possible classes we can assign to x_i. So, we do not need to accelerate the computation of these messages.

Messages from a factor to a variable (Equation 2) are slow to compute naïvely if the factor connects to many other variables. In this section we will show that we can calculate these messages efficiently for decomposable potentials of the form shown in Equation 10. So, this section shows that we can implement BP and loopy BP efficiently for decomposable potentials. The derivation of this section works with general decomposable potentials; below, in Sections 6.1 and 6.2, we will work out the formulas for specific cases including the voting potential and the associative Markov network potential.

The algorithm that we will use to compute the messages is essentially the same as the overall belief propagation algorithm. So, when we perform inference on a factor graph with decomposable potentials, we will be running two nested copies of belief propagation: the inner copy will act on a single decomposable potential, and will compute the messages which the outer copy needs to send from that potential.

Substituting Equations 8–10 into Equation 2 and rearranging terms tells us that the desired message is

$$\begin{aligned} m_{j\to k}(x_k) &= \sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}} \varphi_j(x_1,\ldots,x_k)\prod_{i=1}^{k-1} m_{i\to j}(x_i) \\ &= \sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}} \left(\sum_{l=1}^{L_j}\prod_{m=1}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)})\right) \\ &= \sum_{l=1}^{L_j}\sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}}\prod_{m=1}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)}). \end{aligned} \tag{11}$$

Now let us fix l temporarily, leaving a term of the form

$$\sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}}\prod_{m=1}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)}). \tag{12}$$

We have assumed that the sets $V(j,l,m)$ for $m \in \{1,\ldots,M_{jl}\}$ can be arranged into a junction tree. Pick a node of this junction tree whose label contains x_k, and call this node the root. Refer to each node by its index m, and write $\mathrm{par}(m)$ for the parent of node m.

Now pick an arbitrary leaf of the junction tree. Without loss of generality, say that this leaf has index $m = 1$. We can partition the variables in the set $V(j,l,1)$ into two subsets,

$$C(1) = V(j,l,1) \cap V(j,l,\mathrm{par}(1)) \quad \text{and} \quad D(1) = V(j,l,1) \setminus V(j,l,\mathrm{par}(1)).$$

$C(1)$ contains the variables that node 1 has in Common with its parent, while $D(1)$ contains the variables from node 1 that are Distinct from its parent's variables. The variables in $D(1)$ can only appear in $V(j,l,1)$: if any of them appeared in $V(j,l,m)$ for $m \neq 1$ it would violate the running intersection property, since any path from 1 to m has to pass through $\mathrm{par}(1)$.

Without loss of generality, suppose that the variables in $D(1)$ are numbered consecutively from 1, say $D(1) = \{1,2\}$. That means that the factor ξ_{jl1} depends on x_1 and x_2, but no other factor ξ_{jlm} for $m \neq 1$ depends on x_1 or x_2. So, by the distributive law, we can rearrange Equation 12 as follows:

$$\sum_{x_3} \cdots \sum_{x_{k-1}} \prod_{m=2}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)}) \cdot \left(\sum_{x_1} \sum_{x_2} \xi_{jl1}(x_{V(j,l,1)}) \right) \tag{13}$$

To get Equation 13 we have moved the x_1 and x_2 summations inward as far as possible.

We can think of the expression in parentheses in Equation 13 as a message which travels from node 1 to node $\mathrm{par}(1)$ of the junction tree: it depends only on the variables in the set $C(1)$, and it summarizes everything that node $\mathrm{par}(1)$ needs to know about node 1 in order to compute the term of Equation 12. We will write $\mu_{1 \to \mathrm{par}(1)}$ for this message, that is,

$$\mu_{1 \to \mathrm{par}(1)}(x_{C(1)}) = \sum_{x_1} \sum_{x_2} \xi_{jl1}(x_{V(j,l,1)}). \tag{14}$$

We can continue computing messages in this fashion from leaf nodes of the junction tree to their parents. After several steps our expression will look something like this:

$$\sum_{x_7} \cdots \sum_{x_{k-1}} \prod_{m=4}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)}) \prod_{m=1}^{3} \mu_{m \to \mathrm{par}(m)}(x_{C(m)}). \tag{15}$$

Here we have eliminated the variables x_1 through x_6 and computed the messages from nodes $m = 1,2,3$ to their parents. At this point suppose that node $m = 4$ is an internal node of the junction tree, and that it has as its only child node $m = 1$. Because we have already computed the message from node 1 to node 4, we can now compute the message from 4 to $\mathrm{par}(4)$. Suppose that $D(4) = \{7\}$; then we can rearrange Equation 15 as follows.

$$\begin{aligned} &\sum_{x_8} \cdots \sum_{x_{k-1}} \prod_{m=5}^{M_{jl}} \xi_{jlm}(x_{V(j,l,m)}) \times \\ &\qquad \prod_{m=2}^{3} \mu_{m \to \mathrm{par}(m)}(x_{C(m)}) \left(\sum_{x_7} \mu_{1 \to 4}(x_{C(1)}) \xi_{jl4}(x_{V(j,l,4)}) \right). \end{aligned} \tag{16}$$

Here we have used the distributive law to move the x_7 summation inward as far as possible. As above, none of the functions ξ_{jlm} for $m > 4$ can depend on x_7: if they did, then by the running

intersection property, 7 would have to be an element of $V(\text{par}(4))$ and couldn't be in $D(4)$. The message $\mu_{1\to 4}$ could depend on x_7, since 7 could be in $C(1)$. So, to be safe, we have left $\mu_{1\to 4}$ inside the x_7 summation. On the other hand, the messages $\mu_{2\to\text{par}(2)}$ and $\mu_{3\to\text{par}(3)}$ cannot depend on x_7: if one of them did, 7 would have to be in $V(j,l,\text{par}(2))$ or $V(j,l,\text{par}(3))$, which would again violate the running intersection property.

In a natural generalization of Equation 14, we will write $\mu_{4\to\text{par}(4)}(x_{C(4)})$ for the expression in parentheses in Equation 16. It should be clear at this point that we can compute a message from each node in the junction tree to its parent, so long as we work from the leaves upward; the message from a node m to its parent $\text{par}(m)$ will depend on the messages from m's children to m. Once we process all of the children of the root r, we will be left with an expression that contains summations only over variables in $V(j,l,r)$. (In fact, it will contain summations over exactly the variables in $V(j,l,r)\setminus\{k\}$.) We can perform these summations to find the desired term (Equation 12), which is a function only of x_k. We can then repeat the process for each l to get all of the terms in Equation 11.

The above algorithm computes the message from a factor φ_j to a single neighboring variable x_k. If we want the messages from φ_j to all of its variables we can run the above algorithm multiple times; however, the multiple runs will redundantly recompute many of the messages $\mu_{s\to t}$. Instead, as is usual for the belief propagation algorithm, we can combine all of the runs into a single computation which passes one message in each direction over each edge of the junction tree.

If we have merged groups of variables in constructing our outer junction tree, then there are two modifications needed for the above analysis. First, if the argument sets of the incoming messages at a given factor node overlap, we may need to build different inner junction trees to compute different outgoing messages. So, we may not be able to share computation as described in the previous paragraph. This loss of sharing may increase our runtime by a small factor. Second, and more importantly, if the desired outer message depends on several original variables, then there may be no node of our inner junction tree that contains all the needed variables. In this case we may condition on the possible values of some of the needed variables, and use several runs of inner message passing, each of which computes a slice of the desired outer message. In general, there may be several ways to decompose a potential, and several possible choices of which variables to condition on for a given decomposition. Each of these setups may lead to a different runtime for message computation. See Section 6.3 below and Kjærulff (1998) for more details.

6. Instances of Decomposable Potentials

Decomposable potentials are common and useful. In this section, we discuss the details and derivations of message passing with the voting potential, the associative Markov network potential, and the nested junction tree.

6.1 Decomposing the Voting Potential

The general BP-style algorithm of Section 5 is more complicated than we need when we are computing messages for the voting potential: since Equation 6 is a sum of low-arity functions rather than a sum of products of low-arity functions, the computation for each term in the sum is particularly simple. So, in this section we will derive efficient expressions for the necessary messages.

There are two types of messages we need to think about: those from a factor φ_j to the node x_k that φ_j is centered on, and those from a factor φ_j to some non-centered variable node x_i with $i\neq k$. To simplify notation, assume that $V(j)=\{1,\ldots,k\}$; also assume that we have normalized the

messages $m_{i\to j}(x_i)$ so that $\sum_{x_i} m_{i\to j}(x_i) = 1$. With these assumptions, the message from a factor φ_j to its center variable node x_k can be computed as follows:

$$\begin{aligned}
&(\lambda + |N(j)|)\, m_{j\to k}(x_k) \\
&= \sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}} \left(\lambda/n + \sum_{i=1}^{k-1} I(x_i, x_k)\right) \prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n}\sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}}\prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'}) + \\
&\quad \sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}}\sum_{i=1}^{k-1} I(x_i, x_k)\prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + \sum_{i=1}^{k-1}\sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}} I(x_i, x_k)\prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + \sum_{i=1}^{k-1}\sum_{x_1}\sum_{x_2}\cdots\sum_{x_{k-1}} I(x_i, x_k) m_{i\to j}(x_i) \prod_{i'=1, i'\neq i}^{k-1} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + \sum_{i=1}^{k-1}\sum_{x_i} I(x_i, x_k) m_{i\to j}(x_i) \\
&= \frac{\lambda}{n} + \sum_{i=1}^{k-1} m_{i\to j}(x_k).
\end{aligned}$$

The first equation above is the definition of the desired message. The second equation distributes multiplication over addition. The third equation uses the fact that all terms in the product $\prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'})$ are independent, along with our assumption $\sum_{x_{i'}} m_{i'\to j}(x_{i'}) = 1$, to compute the first summation. The fourth equation factors $m_{i\to j}$ out of the product. The fifth equation uses again the facts that all terms in the product are independent and $\sum_{x_{i'}} m_{i'\to j}(x_{i'}) = 1$. The last line uses the fact that $I(x_i, x_k)$ is nonzero iff $x_i = x_k$.

The message from a factor j to a non-centered variable can be computed similarly. Under the same assumptions as above, we will calculate the message $m_{j\to 1}$:

$$\begin{aligned}
&(\lambda + |N(j)|)\, m_{j\to 1}(x_1) \\
&= \sum_{x_2}\cdots\sum_{x_k} \left(\lambda/n + \sum_{i=1}^{k-1} I(x_i, x_k)\right) \prod_{i'=2}^{k} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + \sum_{x_2}\cdots\sum_{x_k}\sum_{i=1}^{k-1} I(x_i, x_k)\prod_{i'=2}^{k} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + \sum_{x_2}\cdots\sum_{x_k} I(x_1, x_k)\prod_{i'=2}^{k} m_{i'\to j}(x_{i'}) + \sum_{x_2}\cdots\sum_{x_k}\sum_{i=2}^{k-1} I(x_i, x_k)\prod_{i'=2}^{k} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + \sum_{x_k} I(x_1, x_k) m_{k\to j}(x_k) + \sum_{x_2}\cdots\sum_{x_k}\sum_{i=2}^{k-1} I(x_i, x_k)\prod_{i'=2}^{k} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + m_{k\to j}(x_1) + \sum_{x_2}\cdots\sum_{x_k}\sum_{i=2}^{k-1} I(x_i, x_k)\prod_{i'=2}^{k} m_{i'\to j}(x_{i'})
\end{aligned}$$

$$
\begin{aligned}
&= \frac{\lambda}{n} + m_{k\to j}(x_1) + \sum_{i=2}^{k-1} \sum_{x_2} \ldots \sum_{x_k} I(x_i, x_k) m_{i\to j}(x_i) m_{k\to j}(x_k) \prod_{i'=2, i'\neq i}^{k-1} m_{i'\to j}(x_{i'}) \\
&= \frac{\lambda}{n} + m_{k\to j}(x_1) + \sum_{i=2}^{k-1} \sum_{x_i} \sum_{x_k} I(x_i, x_k) m_{i\to j}(x_i) m_{k\to j}(x_k) \\
&= \frac{\lambda}{n} + m_{k\to j}(x_1) + \sum_{i=2}^{k-1} \sum_{x_k} m_{i\to j}(x_k) m_{k\to j}(x_k).
\end{aligned}
$$

The first equality above is the definition of the desired message. The second pulls the term λ/n out of the sums, using the facts that the terms in the product $\prod_{i'=2}^{k} m_{i'\to j}(x_{i'})$ are independent and $\sum_{x_{i'}} m_{i'\to j}(x_{i'}) = 1$. The third equality splits the sum over i into two pieces, one for $i = 1$ and the other for $i \geq 2$. The fourth equality uses the independence of the terms in the left-hand product to simplify away the summations over x_2 through x_{k-1}. The fifth uses the fact that $I(x_1, x_k) = 0$ when $x_1 \neq x_k$. The sixth equality pulls the terms $m_{i\to j}$ and $m_{k\to j}$ out of the remaining product. The seventh uses the independence of terms in the product to simplify away the summations over variables other than x_i and x_k. And the last equality uses the fact that $I(x_i, x_k) = 0$ when $x_i \neq x_k$.

Despite the fact that the variables $x_1, \ldots, x_k$ have exponentially many possible assignments, the above derivations show that we can compute the messages $m_{j\to k}$ and $m_{j\to 1}$ exactly and almost instantaneously. The message $m_{j\to k}$ is particularly easy to interpret: it is the (Laplace smoothed) average of the messages from $x_1, \ldots, x_{k-1}$.

6.2 Decomposing the AMN Potential

It is even easier to derive an efficient expression for the messages from an AMN potential than it was for the messages from a voting potential. As before, let us assume that $V(j) = \{1, \ldots, k\}$, that we desire the message $m_{j\to k}(x_k)$, and that we have normalized the messages $m_{i\to j}(x_i)$ to sum to 1 over x_i for each $i = 1, \ldots, k-1$. Since the AMN potential is symmetric in its arguments, there is only one type of message to calculate.

We can write Equation 7 in the form of Equation 10 by noting that

$$I(x_1 = x_2 = \ldots = x_k = y) = I(x_1 = y) I(x_2 = y) \ldots I(x_k = y)$$

and that each function $I(x_i = y)$ depends on only one variable x_i. Given this representation, the desired message is:

$$
\begin{aligned}
m_{j\to k}(x_k) &= \sum_{x_1} \sum_{x_2} \ldots \sum_{x_{k-1}} \left(1 + \sum_y (\omega_y - 1) \prod_{i=1}^{k} I(x_i, y) \right) \prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'}) \\
&= 1 + \sum_{x_1} \sum_{x_2} \ldots \sum_{x_{k-1}} \sum_y (\omega_y - 1) \prod_{i=1}^{k} I(x_i, y) \prod_{i'=1}^{k-1} m_{i'\to j}(x_{i'}) \\
&= 1 + \sum_y (\omega_y - 1) I(x_k, y) \sum_{x_1} \sum_{x_2} \ldots \sum_{x_{k-1}} \prod_{i=1}^{k-1} I(x_i, y) m_{i\to j}(x_i) \\
&= 1 + \sum_y (\omega_y - 1) I(x_k, y) \prod_{i=1}^{k-1} m_{i\to j}(y) \\
&= 1 + (\omega_{x_k} - 1) \prod_{i=1}^{k-1} m_{i\to j}(x_k).
\end{aligned}
$$

The first equality above is the definition of the desired message. The second pulls the constant 1 outside of the sums and uses the independence of terms in the product. The third rearranges the order of the sums and products. The fourth uses the fact that the product is zero unless $x_i = y$ for all $i \in \{1,\ldots,k-1\}$. The fifth uses the fact that $I(x_k,y)$ is 0 unless $x_k = y$.

6.3 The Nested Junction Tree

The nested junction tree method (Kjærulff, 1998) can speed up message propagation in the junction trees that arise when we remove loops from a factor graph. In particular, it helps compute messages from the large factors that arise when we merge groups of variables. It works by noticing that each of these messages is computed from the product of many smaller factors, which can sometimes be arranged into a nontrivial "inner" junction tree.

Unlike the previous two examples (the voting and AMN potentials), the nested junction tree method does not attempt to look inside the factors of the original factor graph. Instead, it keeps track of the variable merges during junction tree construction, and sometimes is able to "undo" some of these merges temporarily to provide computational savings.

For example, the factor graph of Fig. 4 can be collapsed into a junction tree by merging x_2 and x_3 as shown. The time and space costs of belief propagation on this junction tree are dominated by its largest potential, φ_{2345}. Consider the message from φ_{2345} to x_{23}:

$$m_{2345\to 23}(x_2,x_3) = \sum_{x_4}\sum_{x_5} \varphi_{2345}(x_2,x_3,x_4,x_5) m_{4\to 2345}(x_4) m_{5\to 2345}(x_5).$$

Standard belief propagation will first compute

$$\begin{aligned} \varphi^*_{2345}(x_2,x_3,x_4,x_5) &= \varphi_{2345}(x_2,x_3,x_4,x_5) m_{4\to 2345}(x_4) m_{5\to 2345}(x_5) \\ &= \varphi_{245}(x_2,x_4,x_5)\varphi_{345}(x_3,x_4,x_5) m_{4\to 2345}(x_4) m_{5\to 2345}(x_5) \end{aligned}$$

for all settings of (x_2,x_3,x_4,x_5), and then marginalize φ^*_{2345} to get $m_{2345\to 23}$.

If there are (for example) ten possible settings of each original variable, the space required for computing $m_{2345\to 23}$ with standard belief propagation is 10100 locations: 10^4 for storing φ^*_{2345}, and 10^2 for storing $m_{2345\to 23}$. And, the time cost is 39900 flops: for each of the 10^4 settings of (x_2,x_3,x_4,x_5) we must multiply together one element each from the tables φ_{245}, φ_{345}, $m_{4\to 2345}$, and $m_{5\to 2345}$, at a cost of 3 flops per iteration. Then, for each of the 10^2 elements of $m_{2345\to 23}$, we must sum 10^2 elements of φ^*_{2345} (using 10^2-1 flops), leading to a total cost of $3\times 10000 + 99\times 100$.

However, if we examine the message computations in more detail, it turns out that we can take advantage of the structure of φ^*_{2345} to save time and space. Since φ^*_{2345} was formed by multiplying together four smaller tables, and since the argument sets of these smaller tables form a junction tree, φ^*_{2345} is decomposable. (The inner junction tree is shown at the far right of Fig. 4.) Using this fact, we can find $m_{2345\to 23}$ by passing messages through the inner junction tree several times. In more detail, suppose we pick the factor φ_{345} as the root of the inner junction tree. This factor contains one of the message variables (x_3) but not the other one (x_2). So, we must condition on each value of x_2 in turn. For each value of x_2, we first compute the intermediate message

$$\varphi^{x_2}(x_4,x_5) = \varphi_{245}(x_2,x_4,x_5) m_{4\to 2345}(x_4) m_{5\to 2345}(x_5).$$

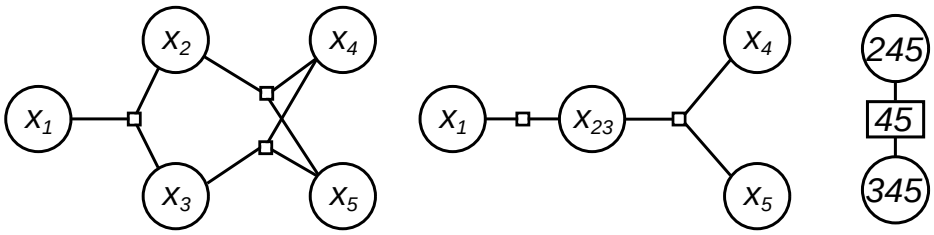

Figure 4: A factor graph for which the nested junction tree method can speed up belief propagation. Left: original factor graph. Middle: factor graph after merging x_2 and x_3. Right: inner junction tree for computing the message $m_{2345\to 23}$.

This message is associated with the separator $\{x_4, x_5\}$ in the inner junction tree. We can then incorporate this inner message into the factor $\{x_3, x_4, x_5\}$, and marginalize to get a slice of our desired (outer) message:

$$m_{2345\to 23}(x_2, x_3) = \sum_{x_4}\sum_{x_5} \varphi_{345}(x_3, x_4, x_5)\varphi^{x_2}(x_4, x_5).$$

Each pass through the inner junction tree keeps x_2 fixed, computing a slice $m_{2345\to 23}(x_2, \cdot)$ of the outer message. (By $m_{2345\to 23}(x_2, \cdot)$, we mean a table of the values of $m_{2345\to 23}$ for a fixed value of the first argument and all possible values of the second argument.)

The nested belief propagation algorithm for computing $m_{2345\to 23}$ saves us both space and time. For time, the cost to compute an element of one of the φ^{x_2} tables is 2 multiplications; there are 10^2 elements of each table, and 10 tables, so the total cost of this step is $2 \times 10 \times 100 = 2000$ flops. To compute $\varphi_{345}(x_3, x_4, x_5)\varphi^{x_2}(x_4, x_5)$ for fixed x_2 takes 1000 flops (one per table element), and to marginalize out (x_4, x_5) takes 99 flops for each of the 10 resulting elements, for a total of $1000 + 10 \times 99 = 1990$ per slice. Since there are 10 slices, we need 19900 flops for all of them. The grand total is therefore $19900 + 2000 = 21900$, a savings of approximately 45% compared to standard belief propagation.

The space savings are even greater: we can reuse a single array of size 10^2 for all of the φ^{x_2} tables, and a single array of size 10^3 for all of the products $\varphi_{345}(x_3, x_4, x_5)\varphi^{x_2}(x_4, x_5)$. Adding in the cost of storing the final message, we have a space cost of $100 + 1000 + 100 = 1200$ locations, a savings of about 88%.

An important limitation of the nested junction tree method is the following lemma, which provides a lower bound on inference time based on the number of variables in the largest node label (or clique):

Lemma 1 *In a junction tree T with binary variables, let C be the largest clique, and say that we wish to compute the posterior marginal for some variable x_q. So long as C is minimal, the nested junction tree method cannot reduce the time for this inference task to less than $\Omega(2^{|C|})$. (The time for non-binary variables is at least as large.)*

Proof Each edge (i, j) in clique C arises either because there is a potential that directly links variables x_i and x_j (this case includes so-called "moral edges"), or because we triangulated a chordless cycle that contains x_i and x_j (in which case some other clique sends C a message that links x_i with x_j). The nested junction tree method achieves its speedup by avoiding consideration of some of

these edges when computing outgoing messages from C: for a message M from C to some other clique D, we can ignore the corresponding incoming message N from D to C. Without N, we may be able to ignore as many as $\binom{|M|}{2}$ of the edges of C while calculating M, since each edge that connects two variables in M may be supported only by N.

Because we can ignore some of the edges of C, we can avoid building a single large table of size $2^{|C|}$, and instead run a nested copy of the message passing algorithm to find M. This inner message passing algorithm works on an inner junction tree T' built from the remaining edges of C. To compute M, we pick some clique C' of T' as root; then, for each possible setting of the variables in $M \setminus C'$, we pass messages from leaves to root in T' to find a slice of M. This slice corresponds to the fixed setting of $M \setminus C'$, and covers all possible settings of the variables in $M \cap C'$.

To calculate the total cost of these inner runs of message passing, we need to look at the structure of T'. In particular, we need to figure out the size of the largest clique of T'. For this purpose, we can divide the variables of T' into three sets: those in $M \setminus C'$ (which we hold fixed during each inner iteration), those in $M \cap C'$ (which form the resulting slice of M), and those in $C \setminus M$ (the rest of C). The variables in $M \cap C'$ are fully connected to one another, since they are all members of C'. And, the variables in $C \setminus M$ are fully connected to one another, since none of them are covered by the incoming message N. But, these two sets of variables are also fully connected to each another: no edge between $C \setminus M$ and $M \cap C'$ can be covered by N, since each such edge has one vertex in M and one outside of M. So, $C \setminus M$ and $M \cap C'$ together form a clique of T'.

Recapping, we have $2^{|M \setminus C'|}$ inner runs of message passing, each of which works with a junction tree containing a clique of size $|C \setminus M| + |M \cap C'|$. We will now prove by induction that inference takes time at least $k2^{|C|}$, where k is an implementation-dependent constant.

For the inductive step, our runtime for calculating M is at least

$$2^{|M \setminus C'|} \times k2^{|C \setminus M| + |M \cap C'|}$$

for $2^{|M \setminus C'|}$ runs of message passing, each of which costs $k2^{|C \setminus M| + |M \cap C'|}$ by the inductive hypothesis. Since $|M \setminus C'| + |C \setminus M| + |M \cap C'| = |C|$, our runtime is therefore at least $k2^{|C|}$, as claimed.

There are several possible base cases. The most obvious is when $|C| = 1$; in this case we can choose $k > 0$ so that the runtime is at least $2k$. The induction can also bottom out if the nested junction tree method becomes inapplicable at any step. There are two ways it can become inapplicable: first, if $M \setminus C' = \emptyset$, then the argument above means that the nested junction tree has only a single clique of size $|C|$, and the nested junction tree method therefore offers no speedup. In this case we need to build a table of size $2^{|C|}$ for inference. So, we can again choose $k > 0$ so that our runtime is at least $k2^{|C|}$.

Second, the nested junction tree method is inapplicable if clique C has no outgoing messages. C has no outgoing messages if and only if we select it as the root for message passing. In this case, C gets incoming messages from all of its neighbors, and the nested junction tree method again offers no speedup: to perform any inference task on C's fully-connected graph, we must again build a table of size $2^{|C|}$ and take time at least $k2^{|C|}$ for some $k > 0$.

So, by choosing $k > 0$ small enough to satisfy all of the above base cases, we have completed the induction. The only remaining detail is the question of non-binary variables. But, it should be obvious from the proof above that any non-binary variables can only increase the cost of inference. ■

Lemma 1 means that we cannot expect the nested junction tree method on its own to make it practical

to work with trees with very large cliques. This conclusion is borne out by the experimental results of Kjærulff (1998), Tables 1 and 2: the time savings shown there are never greater than about 60%. In contrast, the examples of the previous two sections show that decomposable potentials in general can lead to far greater savings: in these examples, the message calculation time goes from exponential to polynomial in the size of the clique, and Fig. 10 below shows that this change can easily result in speedups of multiple orders of magnitude.

7. Prior Updating

By calculating messages as described in Section 6.1, we can run loopy belief propagation on a factor graph that includes voting potentials. However, we might expect the messages from a factor φ_j to a non-centered variable x_i (where $i \neq c_j$) to be fairly weak: the overall vote of all of x_{c_j}'s neighbors will not be influenced very much by x_i's single vote, so there will not be a strong penalty if x_i votes the wrong way.

This observation suggests an even simpler algorithm for inference: we can run loopy BP but ignore all of the messages from factors to non-centered variables. (Ignoring a message means considering it to be uniform.) We will call this algorithm Prior Updating, or PU, since it works by using the current classifications of a node's neighbors to update the prior for the node's own classification. Our group proposed a version of Prior Updating for inference on graphs (Chen and Murphy, 2006) before the work described in the current paper, which explores its relationship to potential functions in loopy belief propagation.

We can expect that PU will be noticeably faster than loopy BP, since there will usually be many more non-centered variables than there are centered ones in each factor. We might also hope that PU could be more accurate than loopy BP, since it is less prone to double-count evidence: we have broken any loops which would allow a message that x_{c_j} sends to factor φ_j to return back and influence the classification of x_{c_j}. (As it turns out, we will see below that in our experiments PU is often slightly worse and sometimes slightly better than loopy BP on factor graphs with voting potentials.) We will examine the speed and classification performance of loopy BP, PU, and other inference methods in Section 9. PU can be seen as an approximation of LBP on factor graphs with voting potentials, and like LBP, is not guaranteed to converge. However, in our experiments, we never observed problems with convergence for PU or for LBP with the voting potential.

8. Experimental Materials and Methods

2D HeLa Image Set We applied our methods to the problem of classifying subcellular patterns in an image of many cells, a problem that we have formalized previously (Chen and Murphy, 2006). The starting point is a set of fluorescence microscope images of HeLa cells created by introducing antibodies and molecular probes against proteins in major subcellular organelles (Boland and Murphy, 2001). The data set contains 862 single-cell images from ten classes, with each class having between 73 and 98 images. The true class of each image is known with certainty since the fluorescent probe present in each slide is known.

Classifying protein subcellular patterns is important since it allows us to identify where a protein is located in cell organelles, which is required for it to carry out its specific function (Boland and Murphy, 2001). This knowledge is critical to understanding how that protein works in a cell, and to describing cell behaviors under different conditions.

In the past, the most common way to determine protein location patterns has been by human interpretation of fluorescence microscope images. In recent years, however, automated systems have been developed for consistent and objective interpretation of such images; the current paper's techniques are designed to help the accuracy of these automated systems (Chen et al., 2006c; Glory and Murphy, 2007). Automated systems, when available, can be preferable to human image annotation, since they can help avoid human biases and errors. They also make it possible to analyze images from high-throughput microscopy, which would otherwise be too numerous for humans to handle.

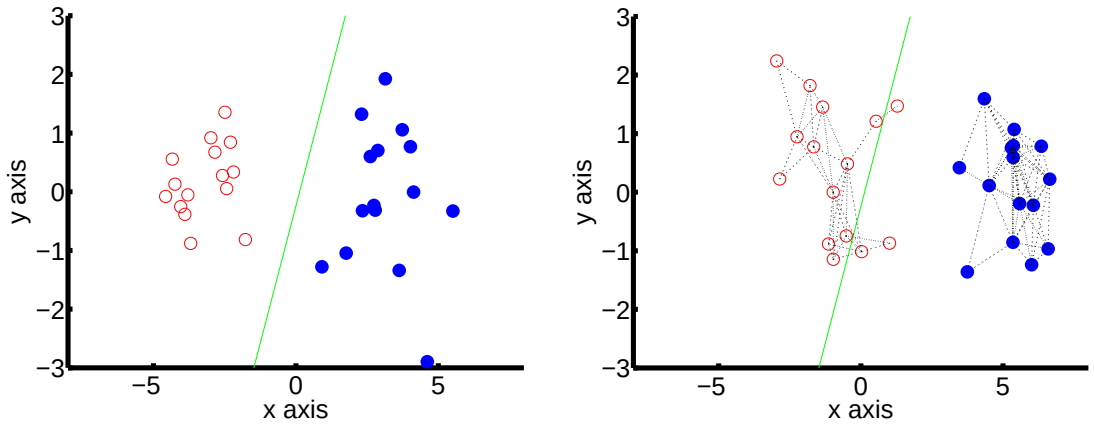
Subcellular Location Features Several sets of informative features have been developed to describe protein subcellular patterns (Boland and Murphy, 2001; Chen et al., 2006c; Glory and Murphy, 2007). These features, termed Subcellular Location Features (SLFs), are of several types, including Zernike moment features, Haralick texture features, morphological features and wavelet features. The details for different versions of SLFs are reviewed elsewhere (Huang and Murphy, 2004). The best single-cell classification results obtained to date with a single feature set for the 2D HeLa data set were with feature set SLF16 (Huang and Murphy, 2004), which we have therefore used in the work described here. In this feature set, each cell is represented by a feature vector f of length $d = 47$.

Support Vector Machine To determine the evidence for each individual cell we used Support Vector Machine classifiers (Cortes and Vapnik, 1995), as implemented in the LIBSVM library version 2.82 (Chang and Lin, 2001). To handle problems with $k > 2$ classes, we learned $k(k-1)/2$ binary SVM classifiers, one for each pair of classes. We then derived probability estimates by applying sigmoid functions to the decision values of these SVMs, in an improved implementation (Lin et al., 2003) of the Platt Scaling method (Platt, 2000).

Simulating Multi-Cell Images We are interested in the simultaneous classification of all of the cells in a multi-cell microscope image. Unfortunately, it is difficult to collect multi-cell images for which we know the ground truth classification of each cell: if we prepare a slide from a mixture of two or more types of cells, we do not have direct control over which type appears where. For this reason, we simulated the multi-cell problem by creating synthetic multi-cell images using multiple real single-cell HeLa images.[1] To generate a structured classification problem, we selected two of the ten classes at random; then we selected N_1 images from the first class and N_2 from the second, with $N_1 + N_2 = 12$. We then treated these images as if they were the output of a segmentation algorithm that was run on a multi-cell image.

Constructing the Similarity Graph As an intermediate step in the construction of our factor graph, we built a *similarity graph*: the nodes of this graph correspond to cells, and an edge between two cells means that we believe that they are likely to share the same label. The simplest approach to building the similarity graph is to include all possible edges. With a fully-connected similarity graph, all cells in the test image are considered equally similar to one another; such a graph expresses a prior belief that images containing a few groups of same-class cells are more likely than images containing cells of many different classes. Our experiments below show that even this modest amount of prior information can improve the accuracy of our classifier compared to the no-edges (independent classification) case; for example, in Figs. 7–9, the performance of LBVP is higher

1. We are in the process of analyzing true multi-cell images with known ground truth, which we collect by tagging one of the cell types with a fluorescent marker at a wavelength different from the one used to label the target protein.



(a) Training Stage

(b) Testing Stage

Figure 5: Classification of multiple examples using proximity in feature space. (a) At the training stage, a linear classifier separates two classes in a 2D feature space. (b) At the testing stage, we have added feature bias, causing 3 examples of one class to be misclassified. But, these examples can be classified correctly by constructing a similarity graph and running belief propagation on the corresponding factor graph.

when 100% of edges are present than it is when 0% of edges are present. But of course, if more-specific information is available, we will get better performance by using it to construct a more informative similarity graph with an intermediate number of edges.

One possible source of additional information is physical proximity between cells. Physical proximity is informative if we believe that nearby cells are likely to share an ancestor. However, we wanted to avoid having to simulate cell positions in our synthetic images, so in the current work we did not include edges based on physical proximity. In previous work (Chen and Murphy, 2006), we did evaluate graphs built using physical proximity, and they improved classification accuracy when applicable. So long as edges tend to connect cells that share the same class, the exact source of edges does not matter for our inference algorithms; so, the experimental results below should apply equally well to graphs that contain edges from physical proximity.

Instead, for our experiments below, we built the similarity graph according to feature-space proximity: we added edges between cells whose feature vectors were close to one another according to z-scored Euclidean distance. Using feature-space proximity in this way makes sense because minor experimental variations can perturb the features of a whole group of test cells in similar ways.

In more detail, minor differences in how cells were prepared (such as variations in plating time, exposure time, concentration of reagents, ambient temperature, etc.) can cause a noticeable bias in the computed features of a test group of cells compared to our training set. We do not generally have enough cells of enough different classes in a test group to estimate this bias accurately before classifying the cells. However, if there is a margin in feature space between classes, then building a similarity graph based on feature-space proximity is likely to connect each cell mostly to other cells

of the same class. So, as long as the feature bias is not so large that it causes most cells of a given class to be misclassified, we can hope to "rescue" cells that have been moved just across the class boundary, since they will be connected to other cells of the same class that are correctly classified. Fig. 5 justifies this intuition with a simple synthetic example.

In addition to the above reasons, feature-space proximity among test images could be informative if the training set wasn't large enough or the classifier wasn't flexible enough to learn the location classes well. In our experiments, we believe that the influence of this last effect is minimal.

To produce a variety of graphs with different edge densities, we introduced a parameter d_{cutoff}: we connected two nodes whenever their z-scored Euclidean distance in feature space was less than d_{cutoff}.[2] Large values of d_{cutoff} correspond to graphs with many edges, while small values correspond to graphs with few edges. We varied d_{cutoff} to produce graphs with edge densities ranging from 0% to 100% of the possible edges.

Constructing the Factor Graphs From each similarity graph we built several different factor graphs using different kinds of potentials. Each different factor graph corresponds to a different way to turn our qualitative similarity judgements into a precise probability distribution over label vectors.

The simplest factor graph was the Potts model. In the Potts model, we used one Potts potential for each edge in the similarity graph; each potential had parameter $\omega = 1.7$. The next type of factor graph was an associative Markov network. In this model we used one AMN potential for each node; this potential covered the node and all of its similarity-graph neighbors, and had $\omega_y = 2.9$ for all y. The last type of factor graph used the voting potential. In this graph there was one voting potential centered on each node; this potential covered the node and all of its similarity-graph neighbors, and had parameter $\lambda = 1.7$. For all three types of potential, we determined the above parameter values ahead of time by a coarse search.[3]

Synthetic Graphs Since the size of the 2D HeLa data set is limited, we performed additional experiments on automatically-generated inference problems. These experiments investigated the sensitivity of our method to the accuracy of the base classifier. We generated a synthetic graph by picking two of the ten classes at random and two numbers N_1 and N_2. We generated N_1 cells of the first class and N_2 cells of the second. For each cell we selected feature vectors of length $d = 2$ from a standard normal distribution; for one of the groups of cells we then displaced the feature vectors by a distance s. We chose $s = 3$ as a value which yielded a reasonable degree of overlap between classes. Finally, as above, we connected pairs of nodes whose feature-space distances were less than d_{cutoff}.

Synthetic Evidence To generate the evidence for a node in one of our synthetic graphs, we picked random scores for each class. The score for the true class was generated from a normal distribution

2. A reviewer of a previous version of this paper suggested that all edges should be present in the graph, and that we should adjust the weight of each edge based on the distance between the nodes. This is a reasonable suggestion; however, some of the potential functions we are evaluating do not have an obvious way to take edge weights into account. So, for the sake of an easier comparison, in this paper we work only with 0-1 weights.
3. As we examined the parameter space of the AMN potential, we discovered that results appear to be very sensitive to the strength parameter ω and the edge density of the graph. So, while we fixed a single compromise parameter for the AMN potentials in our experiments (so that our AMN results are comparable to our results for other potentials), we strongly recommend parameter learning for practical use of the AMN potential, for example, by the method described in (Taskar et al., 2004).

with mean $\mu > 0$ and unit variance, while the scores for other classes were generated from normal distributions with mean 0 and unit variance. Each score was then transformed by a sigmoid to produce the evidence for its corresponding class. Large values of μ result in a highly-accurate simulated base classifier, while small values yield a classifier that performs only a little better than chance. We show results for a range of values of μ that result in base accuracies from 50% to 90%.

9. Experimental Results

We conducted experiments to determine the effect of various potential functions and inference algorithms on overall classification accuracy in structured classification problems. In particular, we designed our experiments to compare the two-way Potts potential with the k-way AMN and voting potentials, and to compare our approximate inference algorithms to their exact counterparts. Our results support the following conclusions:

- We can achieve better classification accuracy by moving from the Potts model, with its two-way potentials, to models that contain k-way potentials for $k > 2$.
- Of the k-way potentials that we tested, the voting potential is the best for a range of problem types.
- For small networks where exact inference is feasible, our approximate inference algorithms yield results similar to exact inference at a fraction of the computational cost.
- For larger networks where exact inference becomes intractable, our approximate inference algorithms are still feasible, and structured classification with approximate inference lets us take advantage of the similarity graph to improve classification accuracy compared to the base (unstructured) classifier.

9.1 Synthetic Graphs

Our first experiment used small, synthetic graphs to compare the Potts, AMN, and voting potentials, and to compare exact and approximate inference. (Since we wanted a large number of test samples, and since we wanted to vary the accuracy of the base classifier over a wide range, it would not have been practical to conduct this experiment with the real HeLa data.) In this experiment, for each trial, we randomly generated a synthetic similarity graph with 10 nodes split between 2 classes (out of a list of 4 total classes), as described above. We used 50% graph edge density for the Potts and voting potentials and 40% graph edge density for the AMN potential, since these densities were approximately optimal according to our preliminary experiments. We also generated simulated classifier likelihoods at each node using values of μ that corresponded to base classifier accuracies ranging from 50% to 90%.

For each generated classification problem, we built three different factor graphs according to the methods described above: a Potts model, a model that used AMN potentials, and a model that used voting potentials. Finally, we computed posterior marginal class probabilities using seven different inference algorithms: exact inference on the Potts model (EIPP), loopy belief propagation on the Potts model (LBP), exact inference on the model with AMN potentials (EIAMN), loopy belief propagation on the model with AMN potentials (LBAMN), exact inference on the model with voting potentials (EIVP), loopy belief propagation on the model with voting potentials (LBVP), and

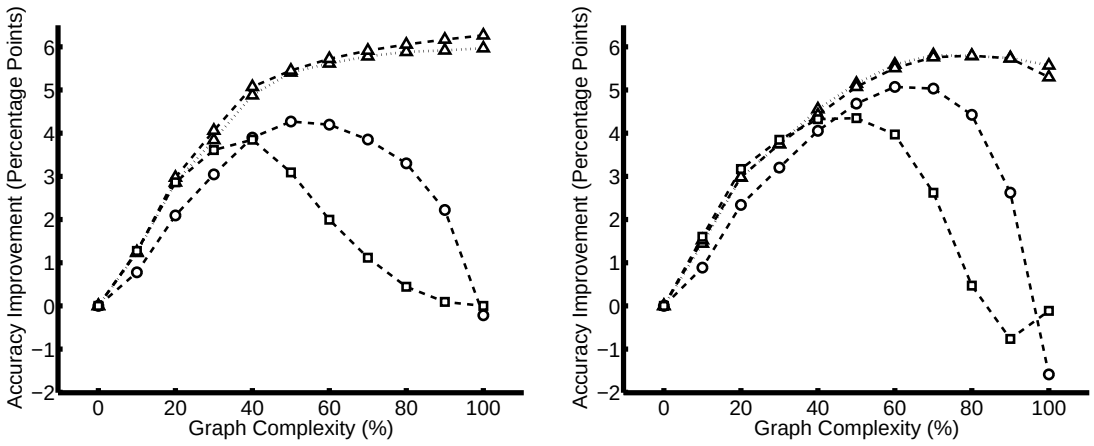
Figure 6: Accuracy Improvement vs. Base Accuracy with different inference methods on graphs with synthetic evidence: exact inference on the model with voting potentials (EIVP, $\triangle-$), loopy belief propagation on the model with voting potentials (LBVP, $\triangle--$), prior updating on the model with voting potentials (PU, $\triangle\cdots$), exact inference on the model with AMN potentials (EIAMN, $\square-$), loopy belief propagation on the model with AMN potentials (LBAMN, $\square--$), exact inference on the Potts model (EIPP, $\bigcirc-$) and loopy belief propagation on the Potts model (LBP, $\bigcirc--$). (a) Graphs with equal numbers of nodes from two classes, $(N_1, N_2) = (5,5)$. (b) Graphs with unequal numbers of nodes from two classes, $(N_1, N_2) = (2,8)$. 95% confidence bars (not shown) are smaller than the plot symbols.

prior updating on the model with voting potentials (PU). We evaluated each method by averaging its classification accuracy over all nodes in the graph, and then over 10,000 different graphs; the results are shown in Fig. 6.

As Fig. 6 illustrates, the methods using the voting potential (EIVP, LBVP, and PU) significantly outperformed the other potentials when the graph has an equal number of nodes from each class. For the unequal case, the voting potential had comparable performance to the Potts potential, and outperformed the AMN potential. In addition, the approximate methods (PU, LBVP, and LBP) did not differ substantially from their corresponding exact algorithms (EIVP, EIVP, and EIPP respectively), with the exception that LBAMN is substantially worse than EIAMN, and PU appears to be slightly worse than EIVP at lower base accuracies, and slightly better at higher base accuracies.

9.2 HeLa Data

Encouraged by the above results, we next considered classification accuracy for the real HeLa cell images. The factor graphs in this case are too large for exact inference, and therefore we cannot compare approximate and exact inference algorithms. Instead, we sought in our second experi-



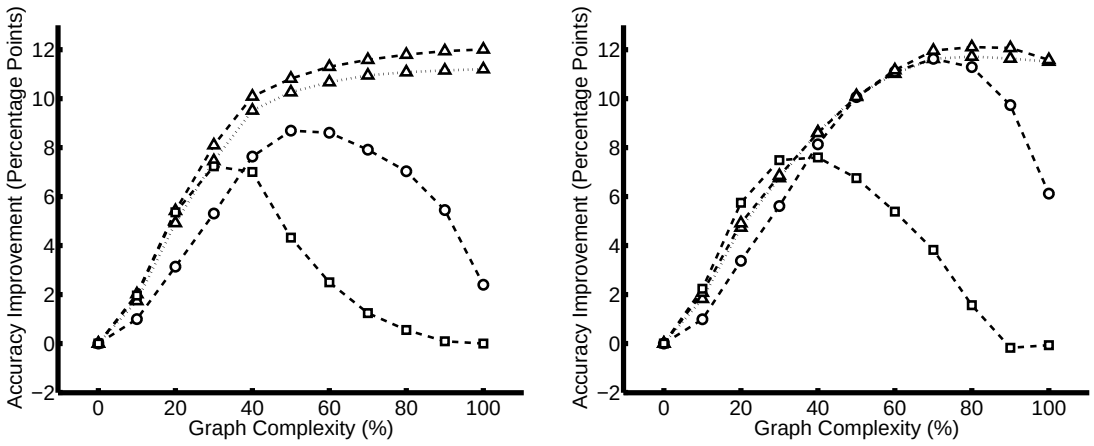
(a) (N_1,N_2)=(6,6) (b) (N_1,N_2)=(2,10)

Figure 7: Accuracy Improvement vs. Graph Complexity with different approximate inference methods on graphs with evidence from real data and base accuracy = 91.6%: loopy belief propagation on the model with voting potentials (LBVP, $\triangle--$), prior updating on the model with voting potentials (PU, $\triangle\cdots$), loopy belief propagation on the model with AMN potentials (LBAMN, $\square--$) and loopy belief propagation on the Potts model (LBP, $\bigcirc--$). (a) Graphs with equal numbers of nodes from two classes, $(N_1,N_2)=(6,6)$. (b) Graphs with unequal numbers of nodes from two classes, $(N_1,N_2)=(2,10)$. Confidence bars are not shown, since paired tests are more powerful for our experimental setup; see text for statistical comparisons.

ment to determine whether our approximate inference algorithms are able to improve classification accuracy substantially compared to our baseline SVM classifier.

For each trial in this experiment, we built a graph containing 12 cells in two classes. (We did not tell the classifier which two classes we used, so there were still 10 possible labels for each cell.) We assigned evidence to each cell using the SVM classifier described above; the base accuracy of this classifier was 91.6%. In order to evalute the inference performance on different base accuracies, we also selected the best 4 and 6 (out of 47) features to achieve the lower base accuracies of 70.6% and 83.1%, respectively. To test the algorithms' performance on a variety of problems, we adjusted d_{cutoff} to achieve levels of connectivity ranging from 0% to 100% of the possible edges; 0% graph complexity corresponds to a completely disconnected graph, in which each node's class is assigned using just the base classifier, while 100% means that the graph is fully connected.

We evaluated each algorithm's accuracy by 6-fold cross-validation: we trained the SVM using 5/6 of the images, used the other 1/6 of the images to construct testing networks, and recorded the improvement in classification accuracy compared to the base classifier in each testing network. We repeated this procedure 6 times so that every image appeared in the test partition once. Finally, we averaged the overall accuracy over 10 different splits into folds. The results in Fig. 7, Fig. 8, and Fig. 9 demonstrate that PU and LBVP can robustly achieve a good improvement in classification



(a) (N_1,N_2)=(6,6) (b) (N_1,N_2)=(2,10)

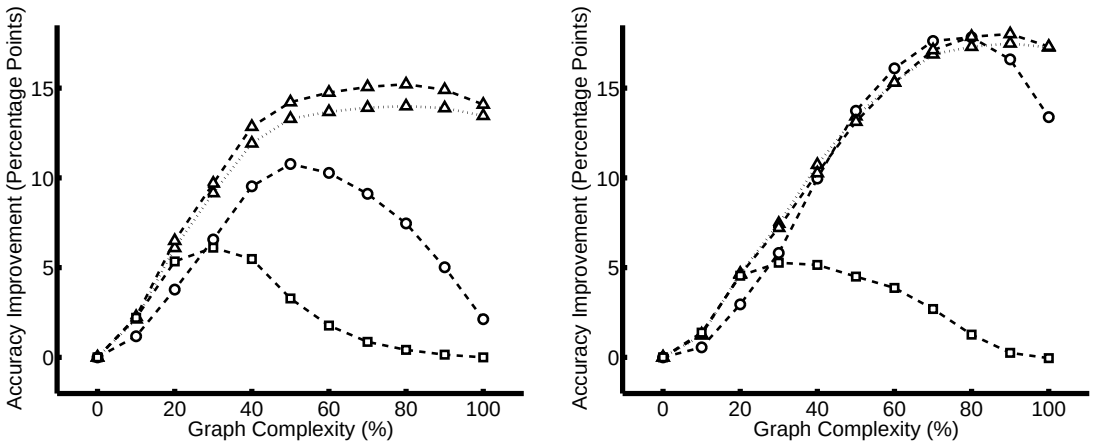
Figure 8: Accuracy Improvement vs. Graph Complexity with different approximate inference methods on graphs with evidence from real data and base accuracy = 83.1%: loopy belief propagation with voting potentials (LBVP, $\triangle --$), prior updating with voting potentials (PU, $\triangle \cdots$), loopy belief propagation with AMN potentials (LBAMN, $\square --$) and loopy belief propagation on the Potts model (LBP, $\bigcirc --$). (a) Graphs with equal numbers of nodes from two classes, $(N_1, N_2) = (6, 6)$. (b) Graphs with unequal numbers of nodes from two classes, $(N_1, N_2) = (2, 10)$. Confidence bars are not shown, since paired tests are more powerful for our experimental setup; see text for statistical comparisons.

accuracy on graphs with equal numbers of nodes from two classes, as compared to methods based on other potentials. (One-tailed paired t-test: $p = 0.0033, p = 0.0018, p = 0.0001$ for graphs with 91.6%, 83.1%, and 70.6% base accuracies, respectively. Tests were conducted at graph complexity 50%; p values are for comparison to closest competitor.)

On graphs with unequal class sizes, voting and Potts potentials achieved statistically comparable results when the graph complexity was tuned optimally. But, the performance of the voting-potential-based methods was more robust: their accuracy remained high for a wider range of graph complexities. (For example, one-tailed paired t-test for LBVP versus LBP: $p = 0.0036$ for graphs with 91.6% base accuracies at graph complexity 80%; $p = 0.0008$ for graphs with 83.1% base accuracies at graph complexity 90%; $p \leq 0.0001$ for graphs with 70.6% base accuracies at graph complexity 100%.)

9.3 Inference Speed

Our final experiment compares the computational efficiency of the different inference methods. Each point in Fig. 10 shows the average inference time per trial on different sizes of graphs with various algorithms (note the logarithmic time scale). Each graph has $N_1 = N_2$, uses four of the ten classes from the HeLa data set, and has 50% graph complexity. In this figure, we also included the processing time for loopy belief propagation with voting potentials using naive message com-



(a) (N_1,N_2)=(6,6) (b) (N_1,N_2)=(2,10)

Figure 9: Accuracy Improvement vs. Graph Complexity with different approximate inference methods on graphs with evidence from real data and base accuracy = 70.6%: loopy belief propagation on the model with voting potentials (LBVP, $\triangle--$), prior updating on the model with voting potentials (PU, $\triangle\cdots$), loopy belief propagation on the model with AMN potentials (LBAMN, $\square--$) and loopy belief propagation on the Potts model (LBP, $\bigcirc--$). (a) Graphs with equal numbers of nodes from two classes, $(N_1, N_2) = (6, 6)$. (b) Graphs with unequal numbers of nodes from two classes, $(N_1, N_2) = (2, 10)$. Confidence bars are not shown, since paired tests are more powerful for our experimental setup; see text for statistical comparisons.

putation (LBVPNC), which computes messages using ordinary marginalization rather than our new message computation algorithms. LBVPNC is expected to be faster then EIVP when the number of neighbors of one node is only a small fraction of the total number of nodes; otherwise LBVPNC could be much slower than EIVP, as is the case in this experiment.

The exact inference methods take time exponential in the size of the graph and are impractical to run for graphs of more than 12 nodes, while the processing times of PU, LBVP and LBP are much faster, and remain well under a second for the largest graphs tested. (With more than four classes, the exact inference times would rise even more quickly, and the graphs would have to be even smaller to allow exact inference.) The processing times for approximate inference methods are a combination of two factors: the number of iterations to converge and the time for each iteration. Fig. 11 shows the number of iterations needed for each method.

10. Related Work

The problem of how to quickly compute belief messages (or other similar quantities in an inference algorithm) is an important one, and several special cases of our decomposable structure have been previously described in the literature. One recent example is an algorithm for fast inference in

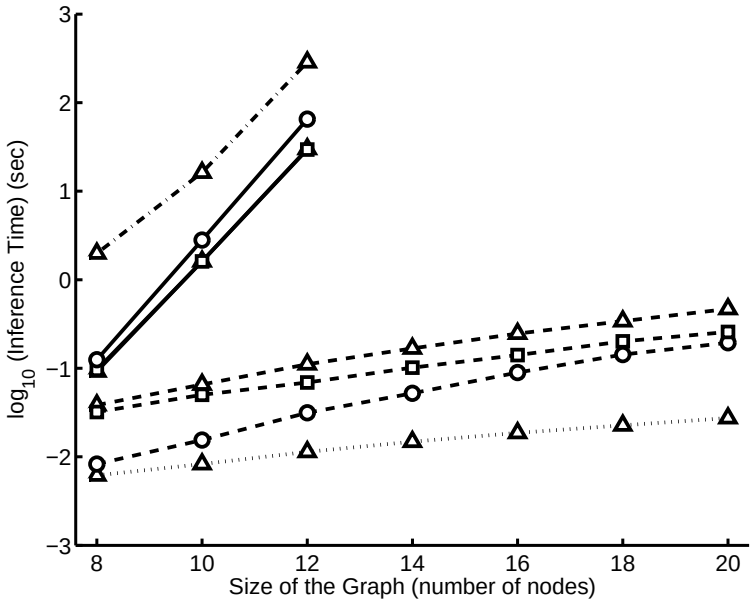


Figure 10: Dependence of inference time on graph size for different inference methods: exact inference on the model with voting potentials (EIVP, $\triangle-$), loopy belief propagation on the model with voting potentials (LBVP, $\triangle--$), loopy belief propagation on the model with voting potentials using naive message computation (LBVPNC, $\triangle\cdot-$), prior updating on the model with voting potentials (PU, $\triangle\cdots$), exact inference on the model with AMN potentials (EIAMN, $\square-$), loopy belief propagation on the model with AMN potentials (LBAMN, $\square--$), exact inference on the Potts model (EIPP, $\bigcirc-$) and loopy belief propagation on the Potts model (LBP, $\bigcirc--$). Values shown are times for one run of inference on the given graph, averaged over 12 trials.

hidden Markov models with structured transition matrices (Siddiqi and Moore, 2005). HMMs are a special case of chain-shaped factor graphs: there is one node representing the state x_t at each time step t, and there is a factor connecting the nodes x_t and x_{t+1} for each t. The potential functions for all factors are the same, and are equal to the transition matrix: $\varphi(x_t, x_{t+1}) = P(x_{t+1} \mid x_t)$.

The special structure for transition matrices proposed by Sidiqqi and Moore is called "Dense Mostly Constant," or DMC. In a DMC transition matrix for n states, each row contains k arbitrary entries in specified positions, and the other $n-k$ entries are all equal to a shared constant. The k arbitrary entries may be in different positions for each row, and the shared constant may also differ from row to row. Siddiqi and Moore show how to run the forward-backward, Viterbi, and Baum-Welsh algorithms quickly for HMMs with DMC transition matrices.

The DMC structure is a special case of our decomposable potential structure: any potential function corresponding to a DMC transition matrix can be written as a rank-one term plus a sparse term. More precisely,

$$\phi(x_t, x_{t+1}) = q(x_t) + \sum_{x,x' \in S} (w_{xx'} - q(x)) I(x_t, x) I(x_{t+1}, x').$$

Here $q(x_t)$ is the shared constant for the row corresponding to x_t, S is the set of transition matrix entries (x,x') which are allowed to differ from the shared constants, and $w_{xx'}$ is the value of the transition matrix entry at position (x,x'). The functions $q(x_t)$, $I(x_t,x)$, and $I(x_{t+1},x')$ each have arity 1; and, the set S is sparse, since it has at most $kn \ll n^2$ elements. Since DMC potentials are decomposable, our message calculation algorithm allows us to run belief propagation quickly; doing so is essentially equivalent to Sidiqqi and Moore's implementation of the forward-backward algorithm.

As we have pointed out above, the associative Markov network potential is also an example of our decomposable potential structure. The original paper on AMNs used an inference algorithm based on linear programming rather than on belief propagation (Taskar et al., 2004). However, the reason that their LP-based inference algorithm is tractable is exactly that they can take advantage of the AMN potential's special structure. There does not appear to be a simple way to extend their LP-based inference algorithm to the more general decomposable potential structure studied here, but this would be an interesting direction for future work. Another interesting direction for future work would be to extend their parameter-learning algorithm to handle more general structures like the decomposable potentials studied here.

In the context of a computer vision application, Felzenszwalb and Huttenlocher (2004) describe how to run loopy belief propagation quickly for a number of different pairwise potential functions. One that they consider is the Potts potential, and their algorithm for handling this potential takes advantage of the fact that it is a constant plus a sparse matrix, $1+(\omega-1)I$. They also consider pairwise potentials based on distance functions, which do not in general appear to be examples of our class of decomposable potential functions. On the other hand, they consider only potentials with up to two arguments.

In addition to the potentials studied in this paper, multiple examples of specific decomposable potentials exist in the literature. One of the most common forms is a potential used in directed graphical models (Bayes nets), in which the child's distribution depends on the sum of the parents' values (e.g., Frey and Kannan, 2000). Another good example is a potential used to represent probability distributions over graphs, in which a structure's probability depends on the degree of its nodes (Morris et al., 2003). All of these examples share a certain similarity to several of the special cases of decomposable potentials mentioned above, in that the speedup comes from accelerating the calculation of a single large sum within the message computation.

Another way to handle large sums is to build a sum tree: for example, the sum $x_1+x_2+x_3+x_4$ can be rewritten $[(x_1+x_2)+(x_3+x_4)]$. So, a potential with 4 arguments, $\varphi(x_1,x_2,x_3,x_4) = f(x_1+x_2+x_3+x_4)$, can be replaced by three smaller potentials and two new variables:

$$I(y_1 = x_1+x_2)\, I(y_2 = x_3+x_4)\, f(y_1+y_2).$$

Similarly, a potential that depends on a sum of n terms can be replaced by $n-1$ three-argument potentials and $n-2$ additional variables. See Liao et al. (2006) for an example of an algorithm based on this intuition. While this method works well for potentials that are functions of sums, it is not straightforward to extend it to more complicated potentials of the form we consider in this paper.

A final, and related, example of a tractable approximation to belief propagation is given by Barber (2001). Barber considers the directed version of the belief propagation algorithm, with conditional probability distribution functions of the form

$$P(x \mid \mathbf{s}) = f(\theta \cdot \mathbf{s}).$$

Here x is a node in the graph, $\mathbf{s}$ is the vector of parents of x, θ is a vector of fixed parameters, and f is a one-dimensional function with a tractable (approximate) Fourier expansion. This class of potentials is different from ours; perhaps an even larger class of potentials could be handled by combining the two techniques, arriving at a class of potentials that looked like

$$\varphi_j(x_1,\ldots,x_k) = \sum_i f_i\left(\sum_{l=1}^{L_j}\prod_{m=1}^{M_{jl}}\xi_{jlm}(x_{V(j,l,m)})\right)$$

where f_i is a basis function (e.g., a multiple of a sine wave if we are using Fourier expansions as above).

It is possible to find the most likely vector of labels for a Potts model using graph cuts when each variable x_i is binary. A related algorithm can be used for approximate inference with non-binary variables, and always finds a label vector within a factor of 2 of the most likely. (See Kleinberg and Tardos, 1999; Taskar et al., 2004, for a discussion.) It does not appear to be easily possible to extend this group of algorithms to k-way potentials such as the voting potential.

In our own previous work, we applied PU to image segmentation problems to identify cell regions (Chen et al., 2006b). In this case, the voting potential assumed that two sources of information were available: images of nuclear staining and of cell boundary locations, both of which were expected to be noisy. The nuclear staining provided an initial assignment of whether a pixel belongs to the background or to one of the cells, while the cell boundary image provided a probability estimate of whether two neighboring pixels should have the same label. The results indicated that PU provided efficient and accurate inference.

11. Conclusions and Future Work

We have examined the problem of classifying multiple dependent examples in a protein subcellular location pattern recognition task. We have compared several different graphical models and inference algorithms designed to solve this sort of structured classification problem, including one based on the novel voting potential function. The voting potential, like the previously studied Potts and AMN potentials, encodes the intuition that a variable is likely to have the same class as its neighbors. Our experiments show that the voting potential often does a better job of encoding this intuition than the Potts and AMN potentials do.

In addition to the new potential, we have presented new approximate inference algorithms: first, we have shown how to implement loopy belief propagation efficiently for networks with decomposable potentials, including the AMN and voting potentials. And second, we have suggested ignoring certain belief messages during LBP for the voting potential, resulting in an algorithm called Prior Updating. These fast algorithms enable us to use potentials like the voting potential on real data, where they would otherwise be impractical.

We believe that the voting potential function and the class of decomposable potentials will generalize to other graphs and other applications: for example, in image segmentation, it is common to use a potential which encourages nearby pixels to be part of the same object. With a potential similar to the voting potential described here, we could allow many neighboring pixels to vote on which object a particular pixel belongs to; and in fact, we have conducted initial experiments in this direction (Chen et al., 2006b). For another example, in regression and classification it is common to reject outliers to improve the robustness of the learned concept. In a given training set, multiple outliers may result from similar causes, such as being out of focus or in a different phase of the

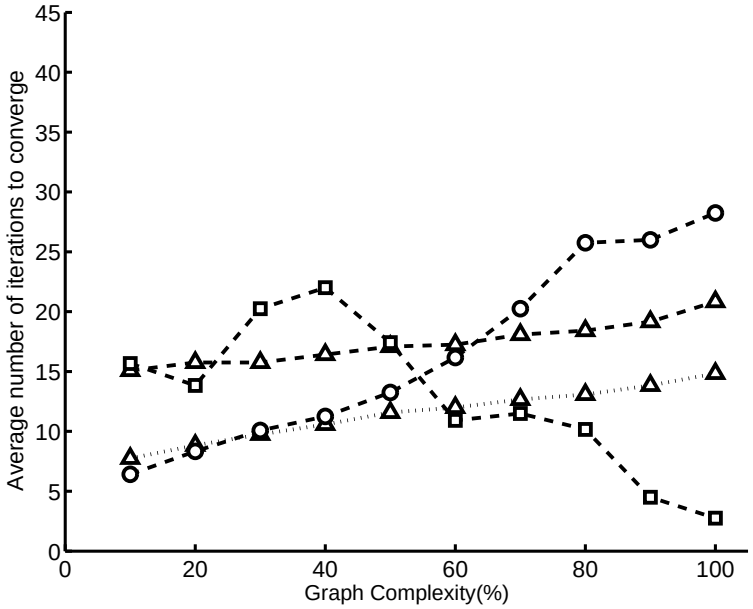

Figure 11: Dependence of number of iterations to converge on graph size for different inference methods: loopy belief propagation on the model with voting potentials (LBVP, $\triangle--$), prior updating on the model with voting potentials (PU, $\triangle\cdots$), loopy belief propagation on the model with AMN potentials (LBAMN, $\square--$) and loopy belief propagation on the Potts model (LBP, $\bigcirc--$). Values shown are numbers of iterations for one run of inference to converge on the given graph, averaged over 12 trials.

cell cycle. By using feature-space similarity to connect training examples in a graph, we can infer which types of outliers are present in the data and use this information to determine more accurately whether each point is an outlier.

In addition to the specific potentials we propose, our algorithms for calculating belief messages efficiently will also generalize to other domains. Whenever a graph contains a factor with a decomposable potential function, we can greatly reduce the time required to calculate belief messages from that factor. Our message calculation algorithm is exact; one might expect that further speed improvements would be possible if we are willing to accept approximate calculations. One promising avenue that we intend to explore is a "loopy" version of our message calculation algorithm. In such an algorithm, an inner loop of message passing would approximate the belief messages needed by the outer loop.

Abstract

A number of today's state-of-the-art planners are based on forward state-space search. The impressive performance can be attributed to progress in computing domain independent heuristics that perform well across many domains. However, it is easy to find domains where such heuristics provide poor guidance, leading to planning failure. Motivated by such failures, the focus of this paper is to investigate mechanisms for learning domain-specific knowledge to better control forward search in a given domain. While there has been a large body of work on inductive learning of control knowledge for AI planning, there is a void of work aimed at forward-state-space search. One reason for this may be that it is challenging to specify a knowledge representation for compactly representing important concepts across a wide range of domains. One of the main contributions of this work is to introduce a novel feature space for representing such control knowledge. The key idea is to define features in terms of information computed via relaxed plan extraction, which has been a major source of success for non-learning planners. This gives a new way of leveraging relaxed planning techniques in the context of learning. Using this feature space, we describe three forms of control knowledge—reactive policies (decision list rules and measures of progress) and linear heuristics—and show how to learn them and incorporate them into forward state-space search. Our empirical results show that our approaches are able to surpass state-of-the-art non-learning planners across a wide range of planning competition domains.

Keywords: planning, machine learning, knowledge representation, search

1. Introduction

In recent years, forward state-space search has become a popular approach in AI planning, leading to state-of-the-art performance in a variety of settings, including classical STRIPS planning (Hoffmann and Nebel, 2001; Vidal, 2004), optimal planning (Helmert et al., 2007), temporal-metric planning (Do and Kambhampati, 2003), nondeterministic planning (Bryce and Kambhampati, 2006), and oversubscribed planning (Benton et al., 2006), among others. Given that forward state-space search

is one of the oldest techniques available for planning, and many other search spaces and approaches have been developed, this state-of-the-art performance is somewhat surprising. One of the key reasons for the success is the development of powerful domain-independent heuristics that work well on many AI planning domains. Nevertheless, it is not hard to find domains where these heuristics do not work well, resulting in planning failure. We are motivated by these failures and in this study, we investigate machine learning techniques that find domain-specific control knowledge that can improve or speed-up forward state-space search in a non-optimal, or satisficing, planning setting.

As outlined in Section 3 there is a large body of work on learning search-control knowledge for AI planning domain. However, despite the significant effort, none of these approaches has been demonstrated to be competitive with state-of-the-art non-learning planners across a wide range of planning domains. There are at least two reasons for the performance gap between learning and non-learning planners. First, most prior work on learning control knowledge has been in the context of non-state-of-the-art planning approaches such as partial-order planning, means-ends analysis, among others. In fact, we are only aware of two recent efforts (Botea et al., 2005; Coles and Smith, 2007) that learn control knowledge for forward state-space search planners. Even these approaches have not demonstrated the ability to outperform the best non-learning planners as measured on planning competition domains. Second, it is a challenge to define a hypothesis space for representing control knowledge that is both rich enough for a wide variety of planning domains, yet compact enough to support efficient and reliable learning. Indeed, a common shortcoming of much of the prior work is that the hypothesis spaces, while adequate for the small number of domains investigated, were not rich enough for many other domains.

The primary goal of this work is to contribute toward reversing the performance gap between learning and non-learning planners. In this work, we do this by addressing each of the above two issues. First, our system is based on the framework of forward state-space search, in particular, being built upon the state-of-the-art planner FF (Hoffmann and Nebel, 2001). Second, we propose a novel hypothesis space for representing useful heuristic features of planning states. We show how to use this feature space as a basis for defining and learning several forms of control knowledge that can be incorporated into forward state-space search. The result is a learning-based planner that learns control knowledge for a planning domain from a small number of solved problems and is competitive with and often better than state-of-the-art non-learning planners across a substantial set of benchmark domains and problems.

A key novelty of our proposed feature space is that it leverages the computation of relaxed plans, which are at the core of the computation of modern forward-search heuristics (Bonet and Geffner, 2001; Hoffmann and Nebel, 2001). Relaxed plans are constructed by ignoring, to varying degrees, the delete/negative effects of actions and can be computed very efficiently. The length of these plans can then serve as an informative heuristic (typically non-admissible) for guiding state-space search. In addition to their length, relaxed plans contain much more information about a search state that is ignored by most forward-search planners.[1] Our proposed feature space gives one way of using this information by viewing the relaxed plan as a structure for defining potentially useful features of the current state. As an example of the utility of our feature space, note that the fact that relaxed planning ignores delete effects is the main reason that the length sometimes dramatically underestimates the true distance to goal, leading to poor heuristic guidance (note that relaxed-plan length can also overestimate the distance to goal). Our feature space is able to partially

1. One exception is Vidal (2004) where relaxed plans are also used to extract macro actions.

capture information about the delete effects ignored in a relaxed plan, which can be used to learn knowledge that partially compensates for the underestimation.

We use the relaxed-plan feature space to learn two forms of knowledge for controlling forward state-space planning. In each case, the knowledge is learned based on a set of training problems from a domain, each labeled by a solution. First, we consider learning knowledge in the form of linear heuristic functions. In particular, we learn heuristics that are linear combinations of relaxed-plan features, with one of those features being the relaxed-plan length. Thus, our heuristic learner can be viewed as an approach for automatically correcting deficiencies of the usual relaxed-plan length heuristic, by augmenting it with a weighted combination of additional features selected from the large space of possible relaxed-plan features.

As a second form of control knowledge, we investigate reactive policies. Learning reactive policies for planning domains has been studied by several researchers (Khardon, 1999; Martin and Geffner, 2000; Yoon et al., 2002, 2005). However, all of these studies have used the learned policies as stand-alone search-free planners that simply execute the linear sequence of actions selected by the policies. While this non-search approach is efficient and has been shown to work well in a number of domains, it often fails due to flaws in the policy that arise due to imperfect learning. Nevertheless, such policies capture substantial information about the planning domain, which we would like to exploit in a more robust way. In this work, we propose and evaluate a simple way of doing this by integrating learned policies into forward search. At each search node (i.e., state), we execute the learned policy for a fixed horizon and add all of the states encountered to the search queue. In this way, flaws in the policy can be overcome by search, while the search efficiency can be substantially improved by quickly uncovering good "deep states" that are found by the policy. We evaluate this idea using two representations for learned policies both of which make use of relaxed-plan features—decision lists of rules similar to Yoon et al. (2002) and measures of progress (Yoon et al., 2005)—both of which make use of relaxed-plan features.

In our experiments, we learned and evaluated both forms of control knowledge on benchmark problems from recent planning competitions. We learned on the first 15 problems in each domain and tested on the remaining problems. The results are very much positive. Forward state-space search with the learned control knowledge outperforms state-of-the-art planners, in most of the competition domains. We also demonstrate the utility of our relaxed-plan feature space by considering feature spaces that ignore parts of the relaxed-plan information, showing that using the relaxed-plan information leads to the best performance.

The remainder of the paper is structured as follows. In Section 2, we introduce the problem of learning domain-specific control knowledge for planning and in Section 3 we overview some of the prior work in this area. In Section 4, we describe the two general forms of control knowledge, heuristics and reactive policies, that we consider learning in this work and how we will use that knowledge to guide forward state-space search. In Section 5, we will describe a relaxed-plan feature space that will serve as our basis for representing both learned heuristics and policies. In Sections 6 and 7 we will describe specific representations for policies and heuristics, in terms of the relaxed-plan features, and give learning algorithms for these forms of control knowledge. In Section 8, we demonstrate the effectiveness of our proposal in this study through empirical results on benchmark planning domains. In Section 9, we summarize and discuss potential future extensions to this work.

2. Problem Setup

In this paper, we focus our attention on learning control knowledge for deterministic STRIPS planning domains. Below we first give a formal definition of the types of planning domains we consider and then describe the learning problem.

2.1 Planning Domains

A deterministic planning domain $\mathcal{D}$ defines a set of possible actions $\mathcal{A}$ and a set of states $\mathcal{S}$ in terms of a set of predicate symbols $\mathcal{P}$, action types Y, and objects O. Each state in $\mathcal{S}$ is a set of facts, where a fact is an application of a predicate symbol in $\mathcal{P}$ to the appropriate number of objects from O. There is an action in $\mathcal{A}$, for each way of applying the appropriate number of objects in O to an action type symbol in Y. Each action $a \in \mathcal{A}$ consists of: 1) an action name, which is an action type applied to the appropriate number of objects, 2) a set of precondition state facts $\text{Pre}(a)$, 3) two sets of state facts $\text{Add}(a)$ and $\text{Del}(a)$ representing the add and delete effects respectively. As usual, an action a is applicable to a state s iff $\text{Pre}(a) \subseteq s$, and the application of an (applicable) action a to s, denoted $a(s)$, results in the new state $a(s) = (s \setminus \text{Del}(a)) \cup \text{Add}(a)$.

Given a planning domain, a planning problem $\mathbb{P}$ from the domain is a tuple (s, A, g), where $A \subseteq \mathcal{A}$ is a set of applicable actions, $s \in \mathcal{S}$ is the initial state, and g is a set of state facts representing the goal. A solution plan for a planning problem is a sequence of actions $(a_1, \ldots, a_h)$, where the sequential application of the sequence starting in state s leads to a goal state s' where $g \subseteq s'$. Later in the paper, in Section 7, when discussing measures of progress, it will be useful to talk about reachability and deadlocks. We say that a planning problem (s, A, g) is reachable from problem (s_0, A, g) iff there is some action sequence in A^* that leads from s_0 to s. We say that a planning problem $\mathbb{P}$ is deadlock free iff all problems reachable from $\mathbb{P}$ are solvable.

2.2 Learning Control Knowledge from Solved Problems

The bi-annual International Planning Competition (IPC), has played a large role in the recent progress observed in AI planning. Typically the competition is organized around a set of planning domains, with each domain providing a sequence of planning problems, often in increasing order of difficulty. Despite the fact that the planners in these competitions experience many similar problems from the same domain, to our knowledge only one of them, Macro-FF (Botea et al., 2005), has made any attempt to learn from previous experience in a domain to improve performance on later problems.[2] Rather they solve each problem as if it were the first time the domain had been encountered. The ability to effectively transfer domain experience from one problem to the next would provide a tremendous advantage. Indeed, the potential benefit of learning domain-specific control knowledge can be seen by the impressive performance of planners such as TL Plan (Bacchus and Kabanza, 2000) and SHOP (Nau et al., 1999), where human-written control knowledge is provided for each domain. However, to date, most "learning to plan" systems have lagged behind the state-of-the-art non-learning domain-independent planners. One of the motivations and contributions of this work is to move toward reversing that trend.

The input to our learner will be a set of problems for a particular planning domain along with a solution plan to each problem. The solution plan might have been provided by a human or automat-

2. Macro-FF learned on training problems from each domain provided by the organizers before the competition, rather than learning during the actual competition itself.

ically computed using a domain-independent planner (for modestly sized problems). The goal is to analyze the training set to extract control knowledge that can be used to more effectively solve new problems from the domain. Ideally, the control knowledge allows for the solutions of large, difficult problems that could not be solved within a reasonable time limit before learning.

As a concrete example of this learning setup, in our experiments, we use the problem set from recent competition domains. We first use a domain-independent planner, in our case FF (Hoffmann and Nebel, 2001), to solve the low-numbered planning problems in the set (typically corresponding to the easier problems). The solutions are then used by our learner to induce control knowledge. The control knowledge is then used to solve the remaining, typically more difficult, problems in the set. Our objective here is to obtain fast, satisficing planning through learning. The whole process is domain independent, with knowledge transferring from easy to hard problems in a domain. Note that although learning times can be substantial, the learning cost can be amortized over all future problems encountered in the domain.

3. Prior Work

There has been a long history of work on learning-to-plan, originating at least back to the original STRIPS planner (Fikes et al., 1972), which learned triangle tables or macros that could later be exploited by the planner. For a collection and survey of work on learning in AI planning see Minton (1993) and Zimmerman and Kambhampati (2003).

A number of learning-to-plan systems have been based on the explanation-based learning (EBL) paradigm, for example, Minton et al. (1989) among many others. EBL is a deductive learning approach, in the sense that the learned knowledge is provably correct. Despite the relatively large effort invested in EBL research, the best approaches typically did not consistently lead to significant gains, and even hurt performance in many cases. A primary way that EBL can hurt performance is by learning too many, overly specific control rules, which results in the planner spending too much time simply evaluating the rules at the cost of reducing the number of search nodes considered. This problem is commonly referred to as the EBL utility problem (Minton, 1988).

Partly in response to the difficulties associated with EBL-based approaches, there have been a number of systems based on inductive learning, perhaps combined with EBL. The inductive approach involves applying statistical learning mechanisms in order to find common patterns that can distinguish between good and bad search decisions. Unlike EBL, the learned control knowledge does not have guarantees of correctness, however, the knowledge is typically more general and hence more effective in practice. Some representative examples of such systems include learning for partial-order planning (Estlin and Mooney, 1996), learning for planning as satisfiability (Huang et al., 2000), and learning for the Prodigy means-ends framework (Aler et al., 2002). While these systems typically showed better scalability than their EBL counterparts, the evaluations were typically conducted on only a small number of planning domains and/or small number of test problems. There is no empirical evidence that such systems are robust enough to compete against state-of-the-art non-learning planners across a wide range of domains.

More recently there have been several learning-to-plan systems based on the idea of learning reactive policies for planning domains (Khardon, 1999; Martin and Geffner, 2000; Yoon et al., 2002). These approaches use statistical learning techniques to learn policies, or functions, that map any state-goal pair from a given domain to an appropriate action. Given a good reactive policy for a domain, problems can be solved quickly, without search, by iterative application of the policy. Despite

its simplicity, this approach has demonstrated considerable success. However, these approaches have still not demonstrated the robustness necessary to outperform state-of-the-art non-learning planners across a wide range of domains.

Ideas from reinforcement learning have also been applied to learn control policies in AI planning domains. Relational reinforcement learning (RRL) (Dzeroski et al., 2001), used Q-learning with a relational function approximator, and demonstrated good empirical results in the Blocksworld. The Blocksworld problems they considered were complex from a traditional RL perspective due to the large state and action spaces, however, they were relatively simple from an AI planning perspective. This approach has not yet shown scalability to the large problems routinely tackled by today's planners. A related approach, used a more powerful form of reinforcement learning, known as approximate policy iteration, and demonstrated good results in a number of planning competition domains (Fern et al., 2006). Still the approach failed badly on a number of domains and overall does not yet appear to be competitive with state-of-the-art planners on a full set of competition benchmarks.

The most closely related approaches to ours are recent systems for learning in the context of forward state-space search. Macro-FF (Botea et al., 2005) and Marvin (Coles and Smith, 2007) learn macro action sequences that can then be used during forward search. Macro-FF learns macros from a set of training problems and then applies them to new problems. Rather, Marvin is an online learner in the sense that it acquires macros during search in a specific problem that are applied at later stages in the search. As evidenced in the recent planning competitions, however, neither system dominates the best non-learning planners.

Finally, we note that researchers have also investigated domain-analysis techniques, for example, Gerevini and Schubert (2000) and Fox and Long (1998), which attempt to uncover structure in the domain by analyzing the domain definition. These approaches have not yet demonstrated the ability to improve planning performance across a range of domains.

4. Control Knowledge for Forward State-Space Search

In this section, we describe the two general forms of control knowledge that we will study in this work: heuristic functions and reactive policies. For each, we describe how we will incorporate them into forward state-space search in order to improve planning performance. Later in the paper, in Sections 6 and 7, we will describe specific representations for heuristics and policies and give algorithms for learning them from training data.

4.1 Heuristic Functions

The first and most traditional forms of control knowledge we consider are heuristic functions. A heuristic function $H(s,A,g)$ is simply a function of a state s, action set A, and goal g that estimates the cost of achieving the goal from s using actions in A. If a heuristic is accurate enough, then greedy application of the heuristic will find the goal without search. However, when a heuristic is less accurate, it must be used in the context of a search procedure such as best-first search, where the accuracy of the heuristic impacts the search efficiency. In our experiments, we will use best-first search, which has often been demonstrated to be an effective, though sub-optimal, search strategy in forward state-space planning. Note that by best-first search, here we mean a search that is guided by only the heuristic value, rather than the path-cost plus heuristic value. This search is also called *greedy* best-first search. In this paper, when we use the term best-first search, it means greedy best-

first search and we will add *greedy* in front of best-first search to remind the readers, as necessary, in the following texts.

Recent progress in the development of domain-independent heuristic functions for planning has led to a new generation of state-of-the-art planners based on forward state-space heuristic search (Bonet and Geffner, 2001; Hoffmann and Nebel, 2001; Nguyen et al., 2002). However, in many domains these heuristics can still have low accuracy, for example, significantly underestimating the distance to goal, resulting in poor guidance during search. In this study, we will attempt to find regular pattern of heuristic inaccuracy (either due to over or under estimation) through machine learning and compensate the heuristic function accordingly.

We will focus our attention on linear heuristics that are represented as weighted linear combinations of features, that is, $H(s,A,g) = \Sigma_i w_i \cdot f_i(s,A,g)$, where the w_i are weights and the f_i are functions. In particular, for each domain we would like to learn a distinct set of features and their corresponding weights that lead to good planning performance in that domain. Note that some of the feature functions can correspond to existing domain-independent heuristics, allowing for our learned heuristics to exploit the useful information they already provide, while overcoming deficiencies by including additional features. The representation that we use for features is discussed in Section 5 and our approach to learning linear heuristics over those features is described in Section 6.

In all of our experiments, we use the learned heuristics to guide (greedy) best-first search when solving new problems.

4.2 Reactive Policies in Forward Search

The second general form of control knowledge that we consider in this study is of reactive policies. A reactive policy is a computationally efficient function $\pi(s,A,g)$, possibly stochastic, that maps a planning problem (s,A,g) to an action in A. Given an initial problem (s_0,A,g), we can use a reactive policy π to generate a *trajectory* of pairs of problems and actions $(((s_0,A,g),a_0),((s_1,A,g),a_1),((s_2,A,g),a_2)\ldots)$, where $a_i = \pi(s_i,A,g)$ and $s_{i+1} = a_i(s_i)$. Ideally, given an optimal or near-optimal policy for a planning domain, the trajectories represent high-quality solution plans. In this sense, reactive policies can be viewed as efficient domain-specific planners that avoid unconstrained search. Later in the paper, in Section 7, we will introduce two formal representations for policies: decision rule lists and measures of progress, and describe learning algorithms for each representation. Below we describe some of the prior approaches to using policies to guide forward search and the new approach that we propose in this work.

The simplest approach to using a reactive policy as control knowledge is to simply avoid search altogether and follow the trajectory suggested by the policy. There have been a number of studies (Khardon, 1999; Martin and Geffner, 2000; Yoon et al., 2002, 2005; Fern et al., 2006) that consider using learned policies in this way in AI planning context. While there have been some positive results, for many planning domains the results have been mostly negative. One reason for these failures is that inductive, or statistical, policy learning can result in imperfect policies, particularly with limited training data. Although these policies may select good actions in many states, the lack of search prevents them from overcoming the potentially numerous bad action choices.

In an attempt to overcome the brittleness of simply following imperfect reactive policies, previous researchers have considered more sophisticated methods of incorporating imperfect policies into search. Two such methods include discrepancy search (Harvey and Ginsberg, 1995) and policy

rollout (Bertsekas and Tsitsiklis, 1996). Unfortunately, our initial investigation showed that in many planning competition domains these techniques were not powerful enough to overcome the flaws in our learned polices. With this motivation we developed a novel approach that is easy to implement and has proven to be quite powerful.

The main idea is to use reactive policies during the node expansion process of a heuristic search, which in our work is greedy best-first search. Typically in best-first search, only the successors of the current node being expanded are added to the priority queue, where priority is measured by heuristic value. Rather, our approach first executes the reactive policy for h steps from the node being expanded and adds the nodes of the trajectory along with their neighbors to the queue. In all of our experiments, we used a value of $h = 50$, though we found that the results were quite stable across a range of h (we sampled a range from 30 to 200).

Note that when $h = 0$ we get standard (greedy) best-first search. In cases, where the policy can solve a given problem from the current node being expanded, this approach will solve the problem without further search provided that h is large enough. Otherwise, when the policy does not directly lead to the goal, it may still help the search process by putting heuristically better nodes in the search queue in a single node expansion. Without the policy (i.e., $h = 0$) such nodes would only appear in the queue after many node expansions. Intuitively, given a reasonably good heuristic, this approach is able to leverage the good choices made by a policy, while overcoming the flaws. While this technique for incorporating policies into search is simple, our empirical results, show that it is very effective, achieving better performance than either pure heuristic search or search-free policy execution.

5. A Relaxed-Plan Feature Space

A key challenge toward learning control knowledge in the form of heuristics and policies is to develop specific representations that are rich enough to capture important properties of search nodes. In this section, we describe a novel feature space for representing such properties. This feature space will be used as a basis for our policy and heuristic representations described in Sections 6 and 7. Note that throughout, for notational convenience we will describe each search node by its implicit planning problem (s,A,g), where s is the current state of the node, g is the goal, and A is the action set.

Each feature in our space is represented via an expression in taxonomic syntax, which as described in Section 5.4, provides a language for describing sets of objects with common properties. Given a search node (s,A,g) and a taxonomic expression C, the value of the corresponding feature is computed as follows. First, a database of atomic facts $D(s,A,g)$ is constructed, as described in Section 5.3, which specifies basic properties of the search node. Next, we evaluate the class expression C relative to $D(s,A,g)$, resulting in a class or set of objects. These sets, or features, can then be used as a basis for constructing control knowledge in various ways—for example, using the set cardinalities to define a numeric feature representation of search nodes.

Our feature space, is in the spirit of prior work (Martin and Geffner, 2000; Yoon et al., 2002; Fern et al., 2006) that also used taxonomic syntax to represent control knowledge. However, our approach is novel in that we construct databases $D(s,A,g)$ that contain not only facts about the current state and goal, but also facts derived via a bounded reasoning process known as relaxed planning. Prior work, considered only databases that included information about the current state and goal. By

defining features in terms of taxonomic expressions built from our extended databases, we are able to capture properties that are difficult to represent in terms of the state and goal predicates alone.

In the remainder of this section, we first review the idea of relaxed planning, which is central to our feature space. Next, we describe the construction of the database $D(s,A,g)$ for search nodes. Finally, we introduce taxonomic syntax, which is used to build complex features on top of the database.

5.1 Relaxed Plans

Given a planning problem (s,A,g), we define the corresponding relaxed planning problem to be the problem (s,A^+,g) where the new action set A^+ is created by copying A and then removing the delete list from each of the actions. Thus, a relaxed planning problem is a version of the original planning problem where it is not necessary to worry about delete effects of actions. A relaxed plan for a planning problem (s,A,g) is simply a plan that solves the relaxed planning problem.

Relaxed planning problems have two important characteristics. First, although a relaxed plan may not necessarily solve the original planning problem, the length of the shortest relaxed plan serves as an admissible heuristic for the original planning problem. This is because preconditions and goals are defined in terms of positive state facts, and hence removing delete lists can only make it easier to achieve the goal. Second, in general, it is computationally easier to find relaxed plans compared to solving general planning problems. In the worst case, this is apparent by noting that the problem of plan existence can be solved in polynomial time for relaxed planning problems, but is PSPACE-complete for general problems. However, it is still NP-hard to find minimum-length relaxed plans (Bylander, 1994). Nevertheless, practically speaking, there are very fast polynomial time algorithms that typically return short relaxed plans whenever they exist, and the lengths of these plans, while not admissible, often provide good heuristics.

The above observations have been used to realize a number of state-of-the-art planners based on heuristic search. HSP (Bonet and Geffner, 2001) uses forward state-space search guided by an admissible heuristic that estimates the length of the optimal relaxed plan. FF (Hoffmann and Nebel, 2001) also takes this approach, but unlike HSP, estimates the optimal relaxed-plan length by explicitly computing a relaxed plan. FF's style of relaxed plan computation is linear with the length of the relaxed plan, thus fast, but the resulting heuristics can be inadmissible. Our work builds on FF, using the same relaxed-plan construction technique, which we briefly describe below.

FF computes relaxed plans using a relaxed plan graph (RPG). An RPG is simply the usual plan graph created by Graphplan (Blum and Furst, 1995), but for the relaxed planning problem rather than the original problem. Since there are no delete lists in the relaxed plan, there will be no mutex relations in the plan graph. The RPG is a leveled graph alternating between action levels and state-fact levels, with the first level containing the state facts in the initial state. An action level is created by including any action whose preconditions are satisfied in the preceding state-fact level. A state-fact level is created by including any fact that is in the previous fact level or in the add list of an action in the preceding action level. RPG construction stops when a fixed point is reached or the goal facts are all contained in the most recent state-fact level. After constructing the RPG for a planning problem, FF starts at the last RPG level and uses a backtrack-free procedure that extracts a sequence of actions that correspond to a successful relaxed plan. All of this can be done very efficiently, allowing for fast heuristic computation.

While the length of FF's relaxed plan often serves as an effective heuristic, for a number of planning domains, ignoring delete effects leads to severe underestimates of the distance to a goal. The result is poor guidance and failure on all but the smallest problems. One way to overcome this problem would be to incorporate partial information about delete lists into relaxed plan computation, for example, by considering mutex relations. However, to date, this has not born out as a practical alternative. Another possibility is to use more information about the relaxed plan than just its length. For example, Vidal (2004) uses relaxed plans to construct macro actions, which help the planner overcome regions of the state space where the relaxed-plan length heuristic is flat. However, that work still uses length as the sole heuristic value. In this work, we give a novel approach to leveraging relaxed planning, in particular, we use relaxed plans as a source of information from which we can compute complex features that will be used to learn heuristic functions and policies. Interestingly, as we will see, this approach will allow for features that are sensitive to delete lists of actions in relaxed plans, which can be used to help correct for the fact that relaxed plans ignore delete effects.

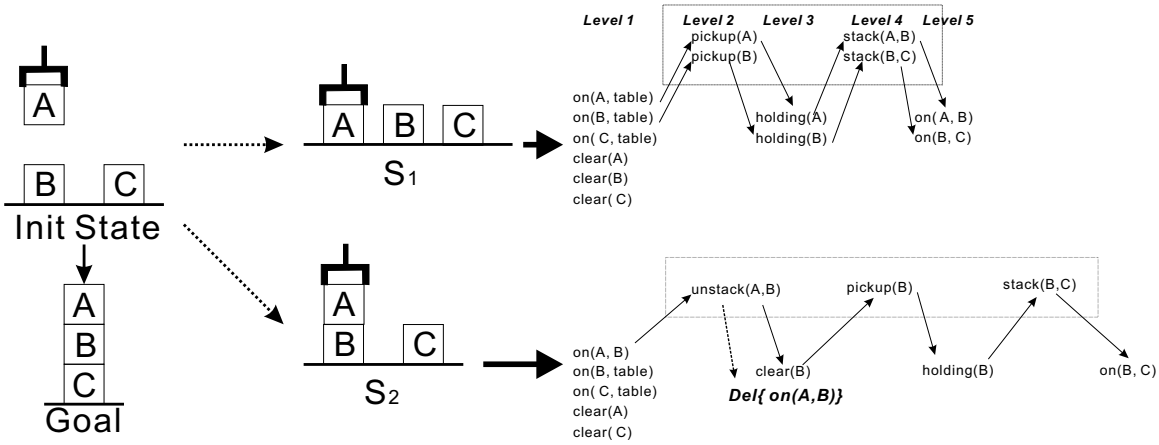

Figure 1: Blocksworld Example

5.2 Example of using Relaxed Plan Features for Learning Heuristics

As an example of how relaxed plans can be used to define useful features, consider a problem from the Blocksworld in Figure 1. Here, we show two states S_1 and S_2 that can be reached from the initial state by applying the actions putdown(A) and stack(A,B) respectively. From each of these states we show the optimal relaxed plans for achieving the goal. For these states, the relaxed-plan length heuristic is 3 for S_2 and 4 for S_1, suggesting that S_2 is the better state. However, it is clear that, in fact, S_1 is better.

Notice that in the relaxed plan for S_2, on(A,B) is in the delete list of the action unstack(A,B) and at the same time it is a goal fact. One can improve the heuristic estimation by adding together the relaxed-plan length and a term related to such deleted facts. In particular, suppose that we had a feature that computed the number of such "on" facts that were both in the delete list of some relaxed plan action and in the goal, giving a value of 0 for S_1 and 1 for S_2. We could then weight this feature by two and add it to the relaxed-plan length to get a new heuristic. This would assign a value of 4 for S_1 and 5 for S_2, correctly ranking the states. Using taxonomic syntax, one can define such a

feature as the cardinality of a certain class expression over a database of facts defined in the next section.

While this is an over-simplified example, it is suggestive as to the utility of features derived from relaxed plans. Below we describe a domain-independent feature space that can be instantiated for any planning domain. Our experiments show that these features are useful across a range of domains used in planning competitions.

5.3 Constructing Databases from Search Nodes

Recall that each feature in our feature space corresponds to a taxonomic syntax expression (see next section) built from the predicate symbols in databases of facts constructed for each search node encountered. We will denote the database for search node (s,A,g) as $D(s,A,g)$, which will simply contain a set of ground facts over some set of predicate symbols and objects derived from the search node. Whereas prior work defined $D(s,A,g)$ to include only facts about the goal g and state s, we will also include facts about the relaxed plan corresponding to problem (s,A,g), denoted by $(a_1,\ldots,a_n)$. Note that in this work we use the relaxed plan computed by FF's heuristic calculation.

Given any search node (s,A,g) we now define $D(s,A,g)$ to be the database that contains the following facts:

- All of the state facts in s.
- The name of each action a_i in the relaxed plan. Recall that each name is an action type Y from domain definition $\mathcal{D}$ applied to the appropriate number of objects, for example, unstack(A,B).
- For each state fact in the add list of some action a_i in the relaxed plan, add a fact to the database that is the result of prepending an **a** to the fact's predicate symbol. For example, in Figure 1, for state S_2 the fact holding(B) is in the add list of pickup(B), and thus we would add the fact **a**holding(B) to the database.
- Likewise for each state fact in the delete list of some a_i, we prepend a **d** to the predicate symbol and add the resulting fact to the database. For example, in Figure 1, for S_2, we would add the fact **d**on(A,B).
- For each state fact in the goal g, we prepend a **g** to the predicate symbol and add it to the database. For example, in Figure 1, we would add the facts **g**on(A,B) and **g**on(B,C).
- For each predicate symbol that appears in the goal, we prepend a **c** to the predicate symbol and add a corresponding fact to the database whenever it is true in the current state s and appears in the goal. For example, the predicate **c**on represents the relation "correctly on", and in Figure 1, for state S_2 we would add the fact **c**on(A,B) since A is currently on B and is supposed to be on B in the goal. The '**c**' predicates provide a useful mechanism for expressing concepts that relate the current state to the goal.

Figure 2, shows an example of the database that would be constructed for the state S_2 in Figure 1. Note that taxonomic syntax class expressions will be constructed from the predicates in this database which include the set of planning domain predicates and action types, along with a variant of each planning domain predicate prepended with an '**a**', '**d**', '**g**', or '**c**'. The database captures information about the state and goal using the planning domain predicates, the '**g**' predicates, and

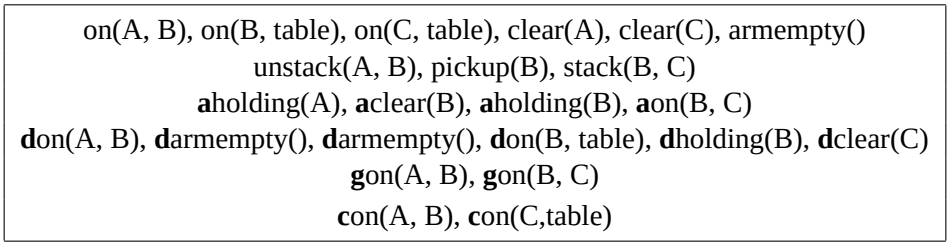

Figure 2: Database for state S_2 in Figure 1

'**c**' predicates. It captures information about the relaxed plan using the action type predicates and the '**a**' and '**d**' predicates. Notice that the database does not capture information about the temporal structure of the relaxed plan. Such temporal information may be useful for describing features, and is a natural extension of this work.

5.4 Defining Complex Features with Taxonomic Syntax

For a given search node (s,A,g) with database $D(s,A,g)$ we now wish to define more complex features of the search node. We will do this using taxonomic syntax (McAllester and Givan, 1993) which is a first-order language for writing class expressions C that are used to denote sets of objects. In particular, given a class expression C, the set of objects it represents relative to $D(s,A,g)$ will be denoted by $C[D(s,A,g)]$. Thus, each C can be viewed as defining a feature that for search node (s,A,g) takes the value $C[D(s,A,g)]$. Below we describe the syntax and semantics of the taxonomic syntax fragment we use in this paper.

Syntax. Taxonomic class expression are built from a set of predicates $\mathcal{P}$, where $n(P)$ will be used to denote the arity of predicate P. For example, in our application the set of predicates will include all predicates used to specify facts in database $D(s,A,g)$ as described above. The set of possible class expressions over $\mathcal{P}$ are given by the following grammar:

$$C := \textbf{a-thing} \mid P_1 \mid C \cap C \mid \neg C \mid (P\ C_1 \ldots C_{i-1}\ ?\ C_{i+1} \ldots C_{\mathrm{n}(P)})$$

where C and C_j are class expressions, P_1 is any arity one predicate, and P is any predicate symbol of arity two or greater. Given this syntax we see that the primitive class expressions are the special symbol **a-thing**, which will be used to denote the set of all objects, and single arity predicates, which will be used to denote the sets of objects for which the predicates are true. One can then obtain compound class expressions via complementation, intersection, or relational composition (the final rule). Before defining the formal semantics of class expressions, we introduce the concept of depth, which will be used in our learning procedures. We define the depth of a class expression C, denoted depth(C) as follows. The depth of **a-thing** or a single arity predicate is 0, depth$(C_1 \cap C_2) = 1 + \max(\text{depth}(C_1), \text{depth}(C_2))$, depth$(\neg C) = 1 + \text{depth}(C)$, and the depth of the expression $(P\ C_1 \ldots C_{i-1}\ ?\ C_{i+1} \ldots C_{\mathrm{n}(P)})$, is $1 + \max\big(\text{depth}(C_1), \ldots, \text{depth}(C_{\mathrm{n}(P)})\big)$. Note that the number of class expressions can be infinite. However, we can limit the number of class expressions under consideration by placing an upper bound on the allowed depth, which we will often do when learning.

Semantics. We now describe the semantics of class expressions, which are defined relative to a finite database D of ground facts over the set of predicates $\mathcal{P}$ and a finite set of constant symbols, or

objects. For example, D might correspond to one of the databases described in the previous section. One can simply view the database D as a finite first-order model, or Herbrand interpretation. Given a class expression C and a database D, we use $C[D]$ to denote the set of objects represented by C with respect to D. We also use $P[D]$ to denote the set of tuples of objects corresponding to predicate P in D, that is, the tuples that make P true.

If $C = \textbf{a-thing}$ then $C[D]$ denotes the set of all objects in D. For example, in a database constructed from a Blocksworld state, **a-thing** would correspond to the set of all blocks. If C is a single arity predicate symbol P, then $C[D]$ is the set of all objects in D for which P is true. For example, if D again corresponds to the Blocksworld then clear$[D]$ and ontable$[D]$ denote the sets of blocks that are clear and on the table respectively in D. If $C = C_1 \cap C_2$ then $C[D] = C_1[D] \cap C_2[D]$. For example, $(\text{clear} \cap \text{ontable})[D]$ denotes the set of blocks that are clear and on the table. If $C = \neg C'$ then $C[D] = \textbf{a-thing} - C'[D]$. Finally, for relational composition, if $C = (P\ \ C_1 \ldots C_{i-1}\ ?\ C_{i+1} \ldots C_{\text{n}(P)})$ then $C[D]$ is the set of all constants c such that there exists $c_j \in C_j[D]$ such that the tuple $(c_1, \ldots, c_{i-1}, c, c_{i+1}, \ldots, c_{\text{n}(R)})$ is in $P[D]$. For example, if D again contains facts about a Blocksworld problem, $(\text{on clear } ?)[D]$ is the set of all blocks that are directly under some clear block.

As some additional Blocksworld examples, $C = (\textbf{con}\ \ \textbf{a-thing}\ ?)$ describes the blocks that are currently directly under the block that they are supposed to be under in the goal. So if D corresponds to the database in Figure 2 then $C[D] = \{B, \text{table}\}$. Recall that as described in the previous section the predicate **con** is true of block pairs (x,y) that are correctly on each other, that is, x is currently on y and x should be on y in the goal. Likewise $(\textbf{con}\ ?\ \textbf{a-thing})$ is the set of blocks that are directly above the block they are supposed to be on in the goal and would be interpreted as the set $\{A, C\}$ in database D. Another useful concept is $\neg(\textbf{con}\ ?\ \textbf{a-thing})$ which denotes the set of blocks that are not currently on their final destination block and would be interpreted as $\{B, \text{table}\}$ with respect to D.

6. Learning Heuristic Functions

Given the relaxed plan feature space, we will now describe how to use that space to represent and learn heuristic functions for use as control knowledge in forward state-space search. Recall from Section 4.1 that we will use the learned heuristics to control (greedy) best-first search in our experiments. Below we first review our heuristic representation followed by a description of our learning algorithm. Recall that heuristic functions are just one of two general forms of control knowledge that we consider in this paper. Our second form, reactive policies, will be covered in the next section.

6.1 Heuristic Function Representation

Recall that a heuristic function $H(s, A, g)$ is simply a function of a state s, action set A, and goal g that estimates the cost of achieving the goal from s using actions in A. In this section, we will consider learning heuristic functions that are represented as weighted linear combinations of functions f_i, that is, $H(s, A, g) = \Sigma_i w_i \cdot f_i(s, A, g)$. In particular, for each planning domain we would like to learn a distinct set of functions f_i and their corresponding weights that lead to good planning performance in that domain when guided by the resulting linear heuristic function. In this work, each function will correspond to a class expression C_i defined over the relaxed-plan database as described in the previous section, and will be denoted by f_{C_i}. We will take the numeric value of f_{C_i} given a

search node (s,A,g) to be the cardinality of C_i with respect to $D(s,A,g)$—that is, $f_{C_i}(s,A,g) = |C_i[D(s,A,g)]|$.

6.2 Heuristic Function Learning

The input to our learning algorithm is a set of planning problems, each paired with an example solution plan, taken from a target planning domain. We do not assume that these solutions are optimal, though there is an implicit assumption that the solutions are reasonably good. Our learning objective is to learn a heuristic function that closely approximates the observed distance-to-goal for each state in the training solutions. To do this, we first create a derived training set $\mathbb{J}$ that contains a training example for each state in the solution set. In particular, for each training problem (s_0,A,g) and corresponding solution trajectory $(s_0,s_1,\ldots,s_n)$ we add to $\mathbb{J}$ a set of n examples $\{((s_i,A,g),n-i) \mid i=0,\ldots,n-1\}$, each example being a pair of a planning problem and the observed distance-to-goal in the training trajectory. Given the derived training set $\mathbb{J}$, we then attempt to learn a real valued function $\Delta(s,A,g)$ that closely approximates the difference between the distances recorded in $\mathbb{J}$ and the value of FF's relaxed-plan length (RPL) heuristic, $\mathrm{RPL}(s,A,g)$. We then take the final heuristic function to be $H(s,A,g) = \mathrm{RPL}(s,A,g) + \Delta(s,A,g)$.

We represent $\Delta(s,A,g)$ as a finite linear combination of functions f_{C_i} with the C_i selected from the relaxed plan feature space, that is, $\Delta(s,A,g) = \Sigma_i w_i \cdot f_{C_i}(s,A,g)$. Note that the overall representation for $H(s,A,g)$ is a linear combination of features, where the feature weight of $\mathrm{RPL}(s,A,g)$ has been clamped to one. Another design choice could have been to allow the weight of the RPL feature to also be learned, however, an initial exploration showed that constraining the value to be one and learning the residual $\Delta(s,A,g)$ gives moderately better performance in some domains.

Learning the above representation involves selecting a set of class expressions from the above infinite space defined in Section 5 and then assigning weights to the corresponding features. One approach to this problem would be to impose a depth bound on class expressions and then learn the weights (e.g., using least squares) for a linear combination that involves all features whose depths of class expression are within the bound. However, the number of such features is exponential in the depth bound, making this approach impractical for all but very small bounds. Such an approach will also have no chance of finding important features beyond the fixed depth bound. In addition, we would prefer to use the smallest possible number of features, since the time complexity of evaluating the learned heuristic grows in proportion to the number of selected features. Thus, we consider a greedy learning approach where we heuristically search through the space of features, without imposing apriori depth bounds. The procedure described below is a relatively generic approach that we found to work well, however, alternative more sophisticated search approaches are an important direction for future work.

Figure 3 gives our algorithm for learning $\Delta(s,A,g)$ from a derived training set $\mathbb{J}$. The main procedure **Learn-Delta** first creates a modified training set $\mathbb{J}'$ that is identical to $\mathbb{J}$ except that the distance-to-goal of each training example is changed to the difference between the distance-to-goal and FF's relaxed-plan length heuristic. Each iteration of **Learn-Delta** maintains a set of class expressions Φ, which represents the set of features that are currently under consideration. Initially Φ is equal to the set of expressions of depth 0 and 1. Each iteration of the loop has two main steps. First, we use the procedure **Learn-Approximation** (described below) to select a subset of class expressions from Φ and to compute their feature weights. Second, we create a new candidate feature set Φ that includes higher depth class expressions. This is done by using the selected features

as seeds and then calling the procedure **Expand-Features**. This results in a larger candidate feature set, including the seed features, which is again used by **Learn-Approximation** to find a possibly improved approximation. We continue alternating between feature space expansion and learning an approximation until the approximation accuracy does not improve. Here we measure the accuracy of the approximation by the R-square value, which is the fraction of the variance in the data that is explained by the linear approximation.

Learn-Approximation uses a simple greedy procedure. Starting with an empty feature set, on each iteration the feature from Φ that can most improve the R-square value of the current feature set is included in the approximation. This continues until the R-square value can no longer be improved. Given a current feature set, the quality of a newly considered feature is measured by calling the function *lm* from the statistics tool R, which outputs the R-square value and weights for a linear approximation that includes the new feature. After observing no improvement, the procedure returns the most recent set of selected features along with their weights, yielding a linear approximation of $\Delta(s,A,g)$.

The procedure **Expand-Features** creates a new set of class expressions that includes the seed set, along with new expressions generated from the seeds. There are many possible ways to generate an expanded set of features from a given seed C. Here we consider three such expansion functions that worked well in practice. The first function **Relational-Extension** takes a seed expression C and returns all expressions of the form $(P\ c_0 \ldots c_{j-1}\ C\ c_{j+1} \ldots c_{i-1}\ ?\ c_{i+1} \ldots c_{\mathrm{n}(P)})$, where P is a predicate symbol of arity larger than one, the c_i are all **a-thing**, and $i, j \leq \mathrm{n}(P)$. The result is all possible ways of constraining a single argument of a predicate by C and placing no other constraints on the predicate. For example in Blocksworld, a relational extension of the class expression, holding, is (**g**on holding ?). The extended expression describes the block in the goal state that should be under the block currently being held.

The second procedure for generating new expressions given a class expression C is **Specialize**. This procedure simply generates all class expressions that can be created by replacing a single depth zero or one sub-expression c' of C with the intersection of c' and another depth zero or one class expression. Note that all expressions that are produced by **Specialize** will be subsumed by C. That is, for any such expression C', we have that for any database D, $C'[D] \subseteq C[D]$. As an example, given the Blocksworld expression (on ? **a-thing**), one of the class expression generated by **Specialize** would be (on ? (**a-thing** $\cap$ **g**clear)). The input class expression describes all the blocks on some block, and the example output class expression describes the blocks that are currently on blocks that should be clear in the goal state. Finally, we add the complement of the seed classes into the expanded feature set. For example in Logisticsworld, for the input class expression (**c**in ? **a-thing**), the complement output is $\neg$(**c**in ? **a-thing**). The input describes packages that are already in the goal location, and the output describes packages that are not in the goal location.

7. Learning Reactive Policies

In this section, we present two representations and associated learning algorithms for reactive policies: taxonomic decision lists and measures of progress. Recall that Section 4.2 describes in detail our novel approach for using the resulting policies as search control knowledge.

Learn-Delta $(\mathbb{J}, \mathcal{D})$
// $\mathbb{J}$ is pairs of problem states and plan length from them
// $\mathcal{D}$ is domain definition to enumerate class expressions
$\mathbb{J}' \leftarrow \{((s,A,g), d - \text{RPL}(s,A,g)) \mid ((s,A,g),d) \in \mathbb{J}\}$
d is the plan length, the remaining states in the solution trajectories
$\Phi \leftarrow \{C \mid C$ is a class expression of depth 0 or 1$\}$
repeat until no R-square value improvement observed
$(\Phi', W) \leftarrow$ **Learn-Approximation($\mathbb{J}'$, Φ)**
// Φ' is newly selected features, W is the set of weights for Φ'
$\Phi \leftarrow$ **Expand-Features($\mathcal{D}$, Φ')**
Return Φ', W

Learn-Approximation $(\mathbb{J}, \Phi)$
$\Phi' \leftarrow \{\}$ *// return features*
repeat until no improvement in R-square value
$C \leftarrow \arg\max_{C \in \Phi}$ R-square$(\mathbb{J}, \Phi' \cup \{C\})$
// R-square is computed after linear approximation with the features
$\Phi' \leftarrow \Phi' \cup \{C\}$
$W \leftarrow lm(\mathbb{J}, \Phi')$
// lm, least square approximation, returns weights
Return Φ', W

Expand-Features $(\mathcal{D}, \Phi')$
$\Phi \leftarrow \Phi'$ *// return features*
for-each $C \in \Phi'$
$\Phi \leftarrow \Phi \cup$ **Relational-Extension**$(\mathcal{D}, C) \cup$ **Specialize**$(\mathcal{D}, C) \cup \{\neg C\}$
Return Φ

Figure 3: Pseudo-code for learning heuristics: The learning algorithm used to approximate the difference between the relaxed plan length heuristic and the observed plan lengths in the training data.

7.1 Taxonomic Decision Lists

We first consider representing and learning policies as taxonomic decision lists. Similar representations have been considered previously (Martin and Geffner, 2000; Yoon et al., 2002), though this is the first work that builds such lists from relaxed-plan-based features.

7.1.1 REPRESENTATION

A taxonomic decision list policy is a list of taxonomic *action-selection rules.* Each rule has the form

$$a(x_1, \ldots, x_k) : L_1, L_2, \ldots L_m$$

where a is a k-argument action type, the L_i are *literals,* and the x_i are action-argument variables. Each literal has the form $x \in C$, where C is a taxonomic syntax class expression and x is an action-argument variable.

Given a search node (s,A,g) and a list of action-argument objects $O = (o_1,\ldots,o_k)$, we say that a literal $x_i \in C$ is satisfied if $o_i \in C[D(s,A,g)]$, that is, object o_i satisfies the constraint imposed by the class expression C. We say that a rule $R = a(x_1,\ldots,x_k) : L_1,L_2,\ldots L_m$ *suggests* action $a(o_1,\ldots o_k)$ in (s,A,g) if each literal in the rule is true given (s,A,g) and O, and the preconditions of the action are satisfied in s. Note that if there are no literals in a rule for action type a, then all legal actions of type a are suggested by the rule. A rule can be viewed as placing mutual constraints on the tuples of objects that an action type can be applied to. Note that a single rule may suggest no action or many actions of one type. Given a decision list of such rules we say that an action is suggested by the list if it is suggested by some rule in the list, and no previous rule suggests any actions. Again, a decision list may suggest no action or multiple actions of one type.

A decision list $\mathbb{L}$ defines a deterministic policy $\pi[\mathbb{L}]$ as follows. If $\mathbb{L}$ suggests no action for node (s,A,g), then $\pi[\mathbb{L}](s,A,g)$ is the lexicographically least action in s, whose preconditions are satisfied; otherwise, $\pi[\mathbb{L}](s,A,g)$ is the least action suggested by $\mathbb{L}$. It is important to note that since $\pi[\mathbb{L}]$ only considers legal actions, as specified by action preconditions, the rules do not need to explicitly encode the preconditions, which allows for simpler rules and learning. In other words, we can think of each rule as implicitly containing the preconditions of its action type.

As an example of a taxonomic decision list policy, consider a simple Blocksworld domain where the goal is to place all of the blocks on the table. The following policy will solve any problem in the domain.

$$\begin{aligned} \text{putdown}(x_1) &: x_1 \in \text{holding}, \\ \text{pickup}(x_1) &: x_1 \in (\text{on ? (on ? } \textbf{a-thing})). \end{aligned}$$

The first rule will cause the agent to putdown any block that is being held. Otherwise, if no block is being held, then the second rule will pickup a block x_1 that is directly on top of a block that is directly on top of another object (either the table or another block). In particular, this will pickup a block at the top of a tower of height two or more, as desired.[3]

7.1.2 DECISION LIST LEARNING

Figure 4 depicts the learning algorithm we use for decision list policies. The training set $\mathbb{J}$ passed to the main procedure **Learn-Decision-List** is a multi-set that contains all pairs of search nodes and corresponding actions observed in the solution trajectories. The objective of the learning algorithm is to find a taxonomic decision list that for each search node in the training set suggests the corresponding action.

The algorithm takes a Rivest-style decision list learning approach (Rivest, 1987) where one rule is learned at a time, from highest to lowest priority, until the resulting rule set "covers" all of the training data. Here we say that a rule *covers* a training example if it suggests an action for the corresponding state. An ideal rule is one that suggests only actions that are in the training data.

The main procedure **Learn-Decision-List** initializes the rule list to () and then calls the procedure **Find-Best-Rule** in order to select a rule that covers many training examples and that correctly covers a high fraction of those examples—that is, a rule with high coverage and high precision. The resulting rule is then added to the tail of the current decision list, and at the same time the training examples that it covers are removed from the training set. The procedure then searches for another

3. If the second rule is changed to pickup$(x_1) : x_1 \in$ (on ? **a-thing**), then the decision rule list may find the loop, since it might try to pick up a block on the table that has just been put down.

Learn-Decision-List $(\mathbb{J}, d, b)$
// $\mathbb{J}$: set of training instances where each instance is a search node labeled by an action
// d: the depth limit for class expressions
// b: beam width, used in search for the rules
$\mathbb{L} \leftarrow ()$
while ($\mathbb{J} \neq \{\}$)
$\mathbb{R} \leftarrow$ **Find-Best-Rule** $(\mathbb{J}, d, b)$
$\mathbb{J} \leftarrow \mathbb{J} - \{j \in \mathbb{J} \mid \mathbb{R}$ suggests an action for $j\}$
$\mathbb{L} \leftarrow \mathbb{L} : \mathbb{R}$; *// append rule to end of current list*
Return $\mathbb{L}$

Find-Best-Rule$(\mathbb{J}, d, b)$
Hvalue-best-rule $\leftarrow -\infty$; $\mathbb{R} \leftarrow ()$
for-each action type a
$\mathbb{R}_a \leftarrow$**Beam-Search(**$a, \mathbb{J}, d, b$**)**
if $H(\mathbb{J}, \mathbb{R}_a) >$ **Hvalue-best-rule**
// $H(J, R_a)$ is learning heuristic function in Equation 2
$\mathbb{R} \leftarrow \mathbb{R}_a$
Hvalue-best-rule $\leftarrow H(\mathbb{J}, \mathbb{R}_a)$
Return $\mathbb{R}$

Beam-Search$(a, \mathbb{J}, d, b)$
$L_{set} \leftarrow \{(x_k \in C) | k \leq \mathbf{n}(a), \text{depth}(C) \leq d\}$
// the set of all possible literals involving class expressions of depth d or less
beam $\leftarrow \{a(x_1, \ldots, a_k)\}$ *// initial beam contains rule with empty rule body*
Hvalue-best $\leftarrow -\infty$; **Hvalue-best-new** $\leftarrow 0$
while (**Hvalue-best** $<$ **Hvalue-best-new**)
Hvalue-best $\leftarrow$ **Hvalue-best-new**
candidates $\leftarrow \{R, l | l \in L_{set}, R \in$ **beam**$\}$
// the set of all possible rules resulting from adding one literal to a rule in the beam
beam $\leftarrow$ set of b best rules in **candidates** according to heuristic H from Equation 2
Hvalue-best-new $\leftarrow H$ value of best rule in **beam**
Return best rule in **beam**

Figure 4: Pseudo-code for learning policy

rule with high coverage and high precision with respect to the reduced training set. The process of selecting good rules and reducing the training set continues until no training examples remain uncovered. Note that by removing the training examples covered by previous rules we force **Find-Best-Rule** to focus on only the training examples for which the current rule set does not suggest an action.

The key procedure in the algorithm is **Find-Best-Rule**, which at each iteration does a search through the exponentially large rule space for a good rule. Recall that each rule has the form

$$a(x_1, \ldots, x_k) : L_1, L_2, \ldots L_m$$

where a is one of the action types and the L_i are of the form $x \in C$. Since this rule space is exponentially large we use a greedy beam-search approach. In particular, the main loop of **Find-Best-Rule**

loops over each action type a and then uses a beam search to construct a set of literals for that particular a. The best of these rules, as measured by an evaluation heuristic, is then returned. It remains to describe the beam search over literal sets and our heuristic evaluation function.

The input to the procedure **Beam-Search** is the action type a, the current training set, a beam width b, and a depth bound d on the maximum size of class expressions that will be considered. The beam width and the depth bound are user specified parameters that bound the amount of search. We used $d = 2, b = 10$ in all of our experiments. The search is initialized so that the current beam contains only the empty rule, that is, a rule with head $a(x_1, \ldots, x_k)$ and no literals. On each iteration of the search a candidate rule set is constructed that contains one rule for each way of adding a new literal, with depth bound d, to one of the rules in the beam. If there are n possible literals of depth bound d this will resulting in a set of nb rules. Next the rule evaluation heuristic is used to select the best b of these rules which are kept in the beam for the next iteration, with all other candidates being discarded. The search continues until the search is unable to uncover an improved rule as measured by the heuristic.

Finally, our rule evaluation heuristic $H(\mathbb{J}, R)$ is shown in Equation 2, which evaluates a rule R with respect to a training set $\mathbb{J}$. There are many good choices for heuristics and this is just one that has shown good empirical performance in our experience. Intuitively this function will prefer rules that suggest correct actions for many search nodes in the training set, while at the same time minimizing the number of suggested actions that are not in the training data. We use $R(s,A,g)$ to represent the set of actions suggested by rule R in (s,A,g). Using this, Equation 1, evaluates the "benefit" of rule R on training instance $((s,A,g),a)$ as follows. If the training set action a is not suggested by R then the benefit is zero. Otherwise the benefit decreases with the size of $R(s,A,g)$. That is, the benefit decreases inversely with the number of actions other than a that are suggested. The overall heuristic H is simply the sum of the benefits across all training instances. In this way the heuristic will assign small heuristic values to rules that cover only a small number of examples and rules that cover many examples but suggest many actions outside of the training set.

$$\text{benefit}(((s,A,g),a),R) = \begin{cases} 0 & : \quad a \notin R(s,A,g) \\ \frac{1}{|R(s,A,g)|} & : \quad a \in R(s,A,g), \end{cases} \tag{1}$$

$$H(\mathbb{J}, R) = \sum_{j \in \mathbb{J}} \text{benefit}(j, R). \tag{2}$$

7.2 Measures of Progress

In this section, we describe the notion of measures of progress and how they can be used to define policies and learned from training data.

7.2.1 REPRESENTATION

Good plans can often be understood as seeking to achieve specific subgoals en route to the goal. In an object-oriented view, these subgoals, along with the goal itself, can be seen as properties of objects, where in each case we wish to increase the number of objects with the given property. Taking this view, we consider control knowledge in the form of compact descriptions of object classes (properties) that a controller is to select actions to enlarge. For example in Blocksworld, in an optimal trajectory, the number of blocks well placed from the table up never decreases, or in Logisticsworld the number of solved packages never decreases in an optimal plan.

Good trajectories also often exhibit locally monotonic properties: properties that increase monotonically for identifiable local periods, but not all the time during the trajectory. For example, in Blocksworld, consider a block "solvable" if its desired destination is clear and well placed from the table up. Then, in good trajectories, while the number of blocks well placed from the table up stays the same, the number of solvable blocks need never decrease locally; but, globally, the number of solvable blocks may decrease as the number of blocks well placed from the table up increases. Sequences of such properties can be used to define policies that select actions in order to improve the highest-priority property possible, while preserving higher-priority properties.

Previously, the idea of monotonic properties of planning domains have been identified by Parmar (2002) as "measures of progress" and we inherit the term and expand the idea to ensembles of measures where the monotonicity is provided via a prioritized list of functions. Let $F = (F_1, \ldots, F_n)$ be an ordered list where each F_i is a function from search nodes to integers. Given an F we define an ordering relation on search nodes (s,A,g) and (s',A,g) as $F(s,A,g) \succ F(s',A,g)$ if $F_i(s,A,g) > F_i(s',A,g)$ while $F_j(s,A,g) = F_j(s',A,g)$ for all $j < i$. F is a strong measure of progress for planning domain $\mathcal{D}$ iff for any reachable problem (s,A,g) of $\mathcal{D}$, either $g \subseteq s$ or there exists an action a such that $F(a(s),A,g) \succ F(s,A,g)$. This definition requires that for any state not satisfying the goal there must be an action that increases some component heuristic F_i while maintaining the preceding, higher-priority components. In this case we say that such an action has priority i. Note that we allow the lower priority heuristics that follow F_i to decrease so long as F_i increases. If an action is not able to increase some F_i, while maintaining all higher-priority components, we say that the action has null priority. In this work we represent our prioritized lists of functions $F = (F_1, \ldots, F_n)$ using a sequence of class expressions $\mathbb{C} = (C_1, \ldots, C_n)$ and just as was the case for our heuristic representation we take the function values to be the cardinalities of the corresponding sets of objects, that is, $F_i(s,A,g) = |C_i[D(s,A,g)]|$.

Given a prioritized list $\mathbb{C}$, we define the corresponding policy $\pi[\mathbb{C}]$ as follows. Given search node (s,A,g), if all legal actions in state s have null priority, then $\pi[\mathbb{C}](s,A,g)$ is just the lexicographically least legal action. Otherwise $\pi[\mathbb{C}](s,A,g)$ is the lexicographically least legal action that achieves highest priority among all other legal actions.

As a simple example, consider again a Blocksworld domain where the objective is to always place all the blocks on the table. A correct policy for this domain is obtained using a prioritized class expression list (C_1, C_2) where $C_1 = \neg(\text{on } ? \text{ (on } ? \textbf{ a-thing}))$ and $C_2 = \neg\text{holding}$. The first class expression causes the policy to prefer actions that are able to increase the set of objects that are *not* above at least two other objects (objects directly on the table are in this set). This expression can always be increased by picking up a block from a tower of height two or greater when the hand is empty. When the hand is not empty, it is not possible to increase C_1 and thus actions are preferred that increase the second expression while not decreasing C_1. The only way to do this is to putdown the block being held on the table, as desired.

7.2.2 LEARNING MEASURES OF PROGRESS

Figure 5 describes the learning algorithm for measures of progress. The overall algorithm is similar to our Rivest-style algorithm for learning decision lists. Again each training example is a pair $((s,A,g),a)$ of a search node and the corresponding action selected in that node. Each iteration of the main procedure **Learn-Prioritized-Measures** finds a new class expression, or measure, that is added to the tail of the prioritized list and then removes any newly "covered" examples from the

training set. Here we say that a measure C covers a training example $((s,A,g),a)$ if $|C(D[s,A,g])| \neq |C(D[a(s),A,g])|$. It covers the example positively, if $|C(D[s,A,g])| < |C(D[a(s),A,g])|$ and covers it negatively otherwise. Intuitively if a class expression positively covers an example then it increases across the state transition caused by the action of the example. Negative coverage corresponds to decreasing across the transition. We stop growing the prioritized list when we are unable to find a new measure with positive heuristic value.

The core of the algorithm is the procedure **Find-Best-Measure**, which is responsible for finding a new measure of progress that positively covers as many training instances as possible, while avoiding negative coverage. To make the search more tractable we restrict our attention to class expressions that are intersections of class expressions of depth d or less, where d is a user specified parameter. The search over this space of class expressions is conducted using a beam search of user specified width b which is initialized to a beam that contains only the universal class expression **a-thing**. We used $d = 2, b = 10$ in all of our experiments. Given the current beam of class expressions, the next set of candidates contains all expressions that can be formed by intersecting an element of the beam with a class expression of depth d or less. The next beam is then formed by selecting the best b candidates as measured by a heuristic. The search ends when it is unable to improve the heuristic value, upon which the best expression in the beam is returned.

To guide the search we use a common heuristic shown in Equation 3, which is known as weighted accuracy (Furnkranz and Flach, 2003). This heuristic evaluates an expression by taking a weighted difference between the number of positively covered examples and negatively covered examples. The weighting factor ω measures the relative importance of negative coverage versus positive coverage. In all of our experiments, we have used $\omega = 4$ which results in a positive value when the positive coverage is at least four times the negative coverage.

$$H_m(\mathbb{J},C,\omega) = |\{j|C \text{ covers positively } j \in \mathbb{J}\}| - \omega \times |\{j|C \text{ covers negatively } j \in \mathbb{J}\}|. \quad (3)$$

We note that one shortcoming of our current learning algorithm is that it can be fooled by properties that monotonically increase along all or many trajectories in a domain, even those that are not related to distinguishing between good and bad plans. For example, consider a domain with a class expression C, where $|C|$ never decrease and frequently increases along any trajectory. Our learner will likely output this class expression as a solution, although it does not in any way distinguish good from bad trajectories. In many of our experimental domains, such properties do not seem to exist, or at least are not selected by our learner. However, in PHILOSOPHER from IPC 4, this problem did appear to arise and hurt the performance of policies based on measures of progress.

There are a number of possible approaches for dealing with this pitfall. For example, one idea would be to generate a set of random (legal) trajectories and reward class expressions that can distinguish between the random and training trajectories.

8. Experiments

We evaluated our learning techniques on the traditional benchmark domain Blocksworld and then on a subset of the STRIPS/ADL domains from two recent international planning competitions (IPC3 and IPC4). We included all of the IPC3 and IPC4 domains where FF's RPL heuristic was sufficiently inaccurate on the training data, so as to afford our heuristic learner the opportunity to learn. That is, for domains where the FF heuristic is very accurate as measured in the first 15 training problems,

Learn-Prioritized-Measures $(\mathbb{J}, d, b, \omega)$
// $\mathbb{J}$: states and corresponding actions in the solution plan trajectories
// d: the depth limit of class expressions
// b is the beam width for the search for best measures
// ω is the weight used for the heuristic defined in Equation 3

$\mathbb{C} \leftarrow ()$ // $\mathbb{C}$ *is the list of prioritized measures*
while ($\mathbb{J} \neq \{\}$)
  $C \leftarrow$ **Find-Best-Measure** $(\mathbb{J}, d, b, \omega)$
  if $H_m(\mathbb{J}, C) \leq 0$ // *see Equation 3 for* H_m
    Return $\mathbb{C}$
  $\mathbb{J} \leftarrow \mathbb{J} - \{j \in \mathbb{J} \mid C \text{ covers } j\}$
  $\mathbb{C} \leftarrow \mathbb{C} : C$ // *append new expression to list*

Return $\mathbb{C}$

Find-Best-Measure$(\mathbb{J}, d, b, \omega)$

beam $\leftarrow \{$**a-thing**$\}$
Hvalue-best $\leftarrow -\infty$
Hvalue-best-new $\leftarrow 0$
while (**Hvalue-best-new** $>$ **Hvalue-best**)
  Hvalue-best $\leftarrow$ **Hvalue-best-new**
  candidates $\leftarrow \{C' \cap C | C \in$ **beam**$, \text{depth}(C') \leq d\}$
  beam $\leftarrow$ best b elements of **candidates** according to $H_m(J, C, \omega)$
  Hvalue-best-new $\leftarrow H_m$ value of best element of **beam**

Return best element of **beam**

Figure 5: Pseudo-code for learning measures of progress

our heuristic learning has nothing to learn since its training signal is the difference between the observed distance in the training set and FF's heuristic. Thus, we did not include such domains.

For each domain, we used 15 problems as training data, with the solutions being generated by FF. We then learned all three types of control knowledge (heuristics, taxonomic decision lists, and measures of progress) in each domain and used that knowledge to solve the remaining problems, which were typically more challenging than the training problems. We used each form of control knowledge as described in Section 4. For the case of the policy representations (taxonomic decision lists and measures of progress), we used FF's RPL heuristic as the heuristic function and used a fixed policy-execution horizon of 50.

To study the utility of our proposed relaxed-plan feature space, we also conducted separate experiments that removed the relaxed plan features from consideration. As the experiments will show, the relaxed-plan features were critical to achieving good performance in a number of domains. The time cutoff for each planning problem was set to 30 CPU minutes and a problem was considered unsolved after reaching the cutoff. For all of the experiments, we used a Linux box with 2 Gig RAM and 2.8 Ghz Intel Xeon CPU.

8.1 Table Mnemonics

Before we present our results, we first explain the mnemonics used in our data tables. We provide one table for each of our domains, each having the same structure, for example, Figure 6 gives our Blocksworld results. Each row corresponds to a distinct planning technique, some using learned control knowledge and some not. The mnemonics used for these planners are described below. These mnemonics are also used in the main text.

- **FF**: the planner FF (Hoffmann and Nebel, 2001). FF adds goal-ordering, enforced-hill climbing, and helpful action pruning on top of relaxed plan heuristic search. If all these fail, FF falls back on best first search guided by relaxed plan length.
- **RPL**: greedy best-first search using FF's RPL heuristic.
- **Best**: best performer of the corresponding domain during the competition (only available for IPC4).
- **DL**: greedy best-first search guided by RPL and *learned decision list policy* using the full relaxed-plan feature space, refer to Section 7 for the representation and learning algorithm and Section 4 for how to use the knowledge.
- **H**: greedy best-first search guided by a *learned heuristic function* using the full relaxed-plan feature space, refer to Section 6 for representation and learning.
- **MoP**: greedy best-first search guided by RPL and *learned measures-of-progress policy* using the full relaxed-plan feature space, refer to Section 7 for the representation and learning and to Section 4 for use of the knowledge to guide the search.
- **DL-noRP, H-noRP, MoP-noRP**: identical to **DL**, **H**, and **MoP** except that the control knowledge is learned from a feature space that does not include relaxed plan information. That is, the database construction described in Section 5.3 does not include any facts related to the relaxed plan into the search node databases. These experiments are conducted to check the usefulness of the relaxed plan information.

The columns of the results tables show various performance measures for the planners. In the following, we list mnemonics for the performance measures and their descriptions.

- **Solved** (n): gives the number of problems solved within 30 minutes out of n test problems.
- **Time**: the average CPU time in seconds consumed across all problems that were solved within the 30 minute cutoff.
- **Length**: average solution length of the problems solved within the 30 minute cutoff.
- **LTime**: the time used for learning (only applies to the learning systems). Unless followed by H, the number is in seconds.
- **Greedy**: number of problems solved using greedy execution of the decision list or measures-of-progress policies (only applies to systems that learn decision list rules and measures of progress). This allows us to observe the quality of the policy without the integration of heuristic search.

- **Evaluated**: the average number of states evaluated on the problems that were solved with the 30 minute cutoff.

8.2 Blocksworld Results

For Blocksworld, we have used the competition problems from track 1 of IPC2. There were 35 problems giving us 15 problems for training and 20 problems for testing. For this domain only, we included one additional predicate symbol "above" that is not part of the original domain definition. The above predicate is computed as the transitive closure of the "on" predicate and is true of tuple (x,y) if x is above y in a stack of towers. This is an important concept to be able to represent in the Blocksworld and is not expressible via the fragment of taxonomic syntax used in this work. Note that in prior work (Yoon et al., 2002; Fern et al., 2006), we included the Kleene-star operator into the taxonomic syntax, which allowed for concepts such as above to be expressed in terms of the primitive predicates. However, we have decided to not include Kleene star in this work as it did not appear necessary in most of the other domains and increases the size of the search space over taxonomic expressions and hence learning time.

Blocksworld (IPC2)						
Techniques	Solved (20)	Time	Length	LTime	Greedy	Evaluated
FF	16	0.64	38.12	-	-	15310
RPL	20	11.74	116	-	-	12932
DL	20	0.05	44	100	13	215
MoP	20	0.13	51.7	10	20	757
H	20	12.94	82.7	600	-	31940
DL-noRP	20	0.12	60.8	12	0	915
MoP-noRP	20	0.15	49.4	1	20	984
H-noRP	12	113.3	352	88	-	185808

Figure 6: Blocksworld (IPC2, Track 1) Results. For information on mnemonics, please refer sub-Section 8.1

Figure 6 shows Blocksworld results for various learning and non-learning systems. For this domain, **DL**, **H**, and **MoP** were all able to solve all of the problems. Note that greedy application of the learned decision list policy manages to solve only 13 of the 20 problems, indicating that the learned policy has a significant error rate. Despite this error rate, however, incorporating the policy into search as implemented in **DL** allows for all 20 problems to be solved. Furthermore, the incorporation of the policy into search significantly speeds up search, achieving an average search time of 0.05 seconds compared to a time of 11.74 seconds achieved by **RPL**, which uses the same RPL heuristic as **DL** but ignores the policy. The number of evaluated states partially shows why running policies in the best first search helps. The average number of evaluated states is significantly lower for **DL** compared to other techniques. Later in our discussion of the Depots domain we will give empirical evidence that one reason for this reduction in the amount of search is that the policies are able to quickly move through plateaus to find states with low heuristic values.

We see that for this domain the measures of progress are learned quite accurately, allowing for greedy search to solve all of the problems. Again, as for the decision-list policies we see that the incorporation of the measures of progress into search significantly speeds up planning time compared to **RPL**. The fact that measures of progress are learned more accurately is possibly due to the fact that the training data for decision-list policy learning is quite noisy. That is, all actions not in the training plans are treated as negative examples, while in fact many of those actions are just as good as the selected action, since there are often many good action choices in a state. The training data for learning measures of progress does not include such noisy negative examples. Note that prior work (Yoon et al., 2002) has learned highly accurate Blocksworld policies, however, there the training data contained the set of *all* optimal actions for each state, with all other actions labeled as negative. Thus, the training data was not nearly as noisy in that work.

Considering now the performance of the heuristic learner **H**, we see that overall its solution times were larger than for **RPL** and also considers more states than **RPL**. However, the heuristic learner **H** did find significantly better solutions than **RPL**, which used only the RPL heuristic, reducing the average length from 116 to 83. Thus, by attempting to learn a more accurate heuristic, **H** is able to find higher quality solutions at the expense of more search.

Overall we see that the learners **DL** and **MoP** are more effective in this domain. This is likely because it is possible to learn very good decision list rules and measure of progress in the Blocksworld, which guide the heuristic search to good solutions very quickly. Note that FF solves fewer problems than other systems, but the average solution length of FF is the best, noting that it is difficult to compare averages between planners that solve different sets of problems. Apparently enforced hill-climbing and the goal-ordering mechanisms of FF help facilitate shorter solutions when they are able to find solutions.

Our feature comparison results indicate that when the relaxed plan features are removed, decision-list and measures-of-progress learning still solve all of the problems, but the heuristic learner **H-noRP** only solves 12 problems. This indicates that the relaxed plan information is important to the heuristic learner in this domain. We note that previous work on learning Blocksworld decision list rules and measures did not use relaxed-plan features and also had reasonable success. Thus, for the Blocksworld it was not surprising that relaxed plan features were not critical for the policy learners.

The learning time for policies and measures are negligible for Blocksworld. As will be revealed later, the learning time for decision-list policies is quite significant in many other domains. For the Blocksworld domain, the number of predicates, the number of actions, and the arities of predicates and actions are all small, which greatly reduces the complexity of feature enumeration during learning, as described in Section 7. For many domains in the following experiments those numbers increase sharply, and accordingly so does the learning time. It is important to remember, however, that learning time is a price we pay once, and can then be amortized over all future problem solving.

8.3 IPC3 Results

IPC3 included 6 STRIPS domains: Zenotravel, Satellite, Rover, Depots, Driverlog, and FreeCell. FF's heuristic is very accurate for the first three domains, trivially solving the 15-training-problems and leaving little room for learning. Thus, here we report results on Depots, Driverlog, and FreeCell. Each domain includes 20 problems, and FF was able to generate training data for all 15 training problems. Figures 7, 8, 9 summarizes the results.

Depots (IPC3)						
Techniques	Solved (5)	Time	Length	LTime	Greedy	Evaluated
FF	5	4.32	54.2	-	-	1919
RPL	1	0.28	29	-	-	1106
DL	5	3.73	63.2	8H	0	2500
MoP	5	48.5	81.2	950	0	16699
H	5	174	68.4	325	-	71795
DL-noRP	2	0.83	30	8H	0	437
MoP-noRP	4	94.5	124.7	900	0	101965
H-noRP	3	5	61.7	258	-	4036

Figure 7: Depots results

Driverlog (IPC3)						
Techniques	Solved (5)	Time	Length	LTime	Greedy	Evaluated
FF	1	37.62	149	-	-	171105
RPL	1	1623	167	-	-	165454
DL	4	75.9	177	6H	0	15691
MoP	5	546	213	600	0	126638
H	3	199	402	274	-	98801
DL-noRP	3	86	142	8H	0	33791
MoP-noRP	3	583	177	900	0	253155
H-noRP	1	37	149	252	-	22164

Figure 8: Driverlog results

For Depots, FF performed the best, solving all of the problems. At the same time the average plan length was short. Clearly, the goal-ordering and the enforced hill climbing were key factors to this success since **RPL**, which carries out just the best-first search component of FF, only solved one problem. The learning systems **DL**, **MoP** and **H** were all able to solve all of the problems, showing that the learned knowledge was able to overcome the poor performance of **RPL**. However, the learning systems consumed more time than FF and/or resulted in longer plans. In the Driverlog domain, **MoP** was the only system able to solve all of the problems, with **H** and **DL** solving 4 and 3 problems respectively compared to the single solved problem of the non-learning systems. In FreeCell, both non-learning systems were able to outperform the learning systems in terms of problems solved and plan lengths. The learning system **DL** is close behind these systems, solving one less problem, with about the same average length. This domain is a clear example of how learned control knowledge can sometimes hurt performance. In practice, one might use a validation process to determine whether to use learned control knowledge or not, and also to select among various forms of control knowledge.

Aggregating the number of problems solved across the three domains in IPC3, the learning and planning systems **DL**, **MoP** and **H** all solved more problems than FF and **RPL**. Overall the learned control knowledge generally speeds up planning. The solution lengths are sometimes longer,

Freecell (IPC3)						
Techniques	Solved (5)	Time	Length	LTime	Greedy	Evaluated
FF	5	574	108	-	-	26344
RPL	5	442	109	-	-	25678
DL	4	217	108	6H	0	12139
MoP	3	371	192	1000	0	44283
H	5	89	145	4214	-	5096
DL-noRP	4	200	111	8H	0	11132
MoP-noRP	3	368	129	900	0	18299
H-noRP	2	29.87	85.5	3892	-	1521
