$$\begin{aligned}\mathbb{E}\left[\sum_{g\in\mathcal{G}} w_a^{(g)}\left(\overline{v}_a^{(g)}-\nu_a\right)\left(\overline{v}_a^{(g')}-\nu_a\right)\right] &= \mathbb{E}\left[\sum_{g\in\mathcal{G}} w_a^{(g)}\overline{\delta}_a^{(g)}\overline{\delta}_a^{(g')}\right] \\ &= \sum_{g\in\mathcal{G}} w_a^{(g)}\mathbb{E}\left[\overline{\delta}_a^{(g)}\overline{\delta}_a^{(g')}\right].\end{aligned} \tag{28}$$

Combining Equations 27 and 28 gives us Equation 8.

We now derive Equation 10. We assume that the bias error, $\overline{\mu}_a^{(g)}$, is uncorrelated with the random error, $\overline{\varepsilon}_a^{(g)}$. Using Equation 5, we obtain the relation,

$$\begin{aligned}\mathbb{E}\left[\overline{\delta}_a^{(g)}\overline{\delta}_a^{(g')}\right] &= \mathbb{E}\left[(\overline{\mu}_a^{(g)}+\overline{\varepsilon}_a^{(g)})(\overline{\mu}_a^{(g')}+\overline{\varepsilon}_a^{(g')})\right] \\ &= \mathbb{E}\left[\overline{\mu}_a^{(g)}\overline{\mu}_a^{(g')}+\overline{\mu}_a^{(g')}\overline{\varepsilon}_a^{(g)}+\overline{\mu}_a^{(g)}\overline{\varepsilon}_a^{(g')}+\overline{\varepsilon}_a^{(g)}\overline{\varepsilon}_a^{(g')}\right] \\ &= \mathbb{E}\left[\overline{\mu}_a^{(g)}\overline{\mu}_a^{(g')}\right]+\mathbb{E}\left[\overline{\mu}_a^{(g')}\overline{\varepsilon}_a^{(g)}\right]+\mathbb{E}\left[\overline{\mu}_a^{(g)}\overline{\varepsilon}_a^{(g')}\right]+\mathbb{E}\left[\overline{\varepsilon}_a^{(g)}\overline{\varepsilon}_a^{(g')}\right].\end{aligned} \tag{29}$$

We notice that, $\mathbb{E}\left[\overline{\mu}_a^{(g')}\overline{\varepsilon}_a^{(g)}\right]=\mathbb{E}\left[\overline{\mu}_a^{(g')}\right]\mathbb{E}\left[\overline{\varepsilon}_a^{(g)}\right]=0$. By a similar argument, $\mathbb{E}\left[\overline{\mu}_a^{(g)}\overline{\varepsilon}_a^{(g')}\right]=0$. This enables us to rewrite Equation 29 as,

$$\mathbb{E}\left[\overline{\delta}_a^{(g)}\overline{\delta}_a^{(g')}\right] = \mathbb{E}\left[\overline{\mu}_a^{(g)}\overline{\mu}_a^{(g')}\right]+\mathbb{E}\left[\overline{\varepsilon}_a^{(g)}\overline{\varepsilon}_a^{(g')}\right]. \tag{30}$$

Since $g'>g$, the stochastic error term at level g', $\overline{\varepsilon}_a^{(g')}$, can be expressed as a combination of $\overline{\varepsilon}_a^{(g)}$ and some terms that are independent of it:

$$\begin{aligned}\overline{\varepsilon}_a^{(g')} &= \frac{1}{N_a^{(g')}}\sum_{n\in\mathcal{N}_a^{(g')}}\varepsilon^n \\ &= \frac{1}{N_a^{(g')}}\left(\sum_{n\in\mathcal{N}_a^{(g)}}\varepsilon^n+\sum_{n\in\mathcal{N}_a^{(g')}\setminus\mathcal{N}_a^{(g)}}\varepsilon^n\right) \\ &= \frac{N_a^{(g)}}{N_a^{(g')}}\overline{\varepsilon}_a^{(g)}+\frac{1}{N_a^{(g')}}\sum_{n\in\mathcal{N}_a^{(g')}\setminus\mathcal{N}_a^{(g)}}\varepsilon^n.\end{aligned} \tag{31}$$

Using Equation 31, we can rewrite the second term on the right hand side of Equation 30 term as follows:

$$\mathbb{E}\left[\overline{\varepsilon}_a^{(g)}\overline{\varepsilon}_a^{(g')}\right] = \mathbb{E}\left[\overline{\varepsilon}_a^{(g)}\cdot\frac{N_a^{(g)}}{N_a^{(g')}}\overline{\varepsilon}_a^{(g)}\right]+\mathbb{E}\left[\overline{\varepsilon}_a^{(g)}\cdot\frac{1}{N_a^{(g')}}\sum_{n\in\mathcal{N}_a^{(g')}\setminus\mathcal{N}_a^{(g)}}\varepsilon^n\right]$$

$$= \frac{N_a^{(g)}}{N_a^{(g')}} \mathbb{E}\left[\bar{\varepsilon}_a^{(g)} \bar{\varepsilon}_a^{(g)}\right] + \frac{1}{N_a^{(g')}} \underbrace{\mathbb{E}\left[\bar{\varepsilon}_a^{(g)} \cdot \sum_{n \in \mathcal{N}_a^{(g')} \setminus \mathcal{N}_a^{(g)}} \varepsilon^n\right]}_{I}.$$

Since the individual observations are assumed to be independent, the term I can be further simplified as follows,

$$\begin{aligned}
\mathbb{E}\left[\bar{\varepsilon}_a^{(g)} \cdot \sum_{n \in \mathcal{N}_a^{(g')} \setminus \mathcal{N}_a^{(g)}} \varepsilon^n\right] &= \mathbb{E}\left[\bar{\varepsilon}_a^{(g)}\right] \mathbb{E}\left[\sum_{n \in \mathcal{N}_a^{(g')} \setminus \mathcal{N}_a^{(g)}} \varepsilon^n\right] \\
&= 0.
\end{aligned}$$

This implies that,

$$\begin{aligned}
\mathbb{E}\left[\bar{\varepsilon}_a^{(g)} \bar{\varepsilon}_a^{(g')}\right] &= \frac{N_a^{(g)}}{N_a^{(g')}} \mathbb{E}\left[\bar{\varepsilon}_a^{(g)^2}\right] \\
&= \frac{N_a^{(g)}}{N_a^{(g')}} \mathbf{Var}\left[\bar{\varepsilon}_a^{(g)}\right] \\
&= \frac{N_a^{(g)}}{N_a^{(g')}} \frac{1}{N_a^{(g)}} \mathbf{Var}\left[\varepsilon^n\right] \\
&= \frac{1}{N_a^{(g')}} \sigma_\varepsilon^2. \qquad (32)
\end{aligned}$$

Combining Equations (30 and 32 gives us the result in Equation 10. This results generalizes for all $g \in \mathcal{G}$, since g and g' can be interchanged when $g > g'$.

Abstract

Conditional random fields (CRFs) provide a flexible and powerful model for sequence labeling problems. However, existing learning algorithms are slow, particularly in problems with large numbers of potential input features and feature combinations. This paper describes a new algorithm for training CRFs via gradient tree boosting. In tree boosting, the CRF potential functions are represented as weighted sums of regression trees, which provide compact representations of feature interactions. So the algorithm does not explicitly consider the potentially large parameter space. As a result, gradient tree boosting scales linearly in the order of the Markov model and in the order of the feature interactions, rather than exponentially as in previous algorithms based on iterative scaling and gradient descent. Gradient tree boosting also makes it possible to use instance weighting (as in C4.5) and surrogate splitting (as in CART) to handle missing values. Experimental studies of the effectiveness of these two methods (as well as standard imputation and indicator feature methods) show that instance weighting is the best method in most cases when feature values are missing at random.

Keywords: sequential supervised learning, conditional random fields, functional gradient, gradient tree boosting, missing values

1. Introduction

Many applications of machine learning involve assigning labels collectively to sequences of objects. For example, in natural language processing, the task of part-of-speech (POS) tagging is to label each word in a sentence with a part of speech tag ("noun", "verb" etc.) (Ratnaparkhi, 1996). In computational biology, the task of protein secondary structure prediction is to assign a secondary structure class to each amino acid residue in the protein sequence (Qian and Sejnowski, 1988).

We call this class of problems *sequential supervised learning* (SSL), and it can be formulated as follows:

Given: A set of training examples of the form (X_i, Y_i), where each $X_i = (\mathbf{x}_{i,1}, \ldots, \mathbf{x}_{i,T_i})$ is a sequence of T_i feature vectors and each $Y_i = (y_{i,1}, \ldots, y_{i,T_i})$ is a corresponding sequence of class labels, where $y_{i,t} \in \{1, \ldots, K\}$.

Find: A classifier H that, given a new sequence X of feature vectors, predicts the corresponding sequence of class labels $Y = H(X)$ accurately.

Perhaps the most famous SSL problem is the NETtalk task of pronouncing English words by assigning a phoneme and stress to each letter of the word (Sejnowski and Rosenberg, 1987). Other applications of SSL arise in information extraction (McCallum et al., 2000) and handwritten word recognition (Taskar et al., 2004).

Early attempts to apply machine learning to SSL problems were based on *sliding windows*. To predict label y_t, a sliding window method uses features drawn from some "window" of the X sequence. For example, a 5-element window $w_t(X)$ would use the features $\mathbf{x}_{t-2}, \mathbf{x}_{t-1}, \mathbf{x}_t, \mathbf{x}_{t+1}, \mathbf{x}_{t+2}$. Sliding windows convert the SSL problem into a standard supervised learning problem to which any ordinary machine learning algorithm can be applied. However, in most SSL problems, there are correlations among successive class labels y_t. For example, in part-of-speech tagging, adjectives tend to be followed by nouns. In protein sequences, alpha helixes and beta structures always involve multiple adjacent residues. These correlations can be exploited to increase classification accuracy.

The best-known method for capturing the $y_{t-1} \leftrightarrow y_t$ correlation is the hidden Markov model (HMM) (Rabiner, 1989), which is a generative model of $P(X,Y)$, the joint distribution of the observation sequence and label sequence. In this model, the joint distribution is factored as $P(X,Y) = \prod_t P(y_t|y_{t-1})P(\mathbf{x}_t|y_t)$, and the observation distribution is further factored as $P(\mathbf{x}_t|y_t) = \prod_j P(\mathbf{x}_{t,j}|y_t)$. This assumption of independence of each input feature $\mathbf{x}_{t,j}$ conditioned on y_t makes HMMs unable to model arbitrary, non-independent input features, and this limits the accuracy and "engineerability" of HMMs.

Recent research has instead focused on discriminative models, in which arbitrary and non-independent observation features can be easily incorporated. Much machine learning research has shown that discriminative models tend to be more accurate and more robust to incorrect modeling assumptions (Ng and Jordan, 2002). McCallum and his collaborators introduced maximum entropy Markov models (MEMMs) (McCallum et al., 2000) and conditional random fields (CRFs) (Lafferty et al., 2001). MEMMs are directed graphical models of the form $P(Y|X) = \prod_t P(y_t|y_{t-1}, w_t(X))$, where $w_t(X)$ is a sliding window over the X sequence. They are easy to train, but they suffer from the *label bias problem* that results from the local normalization at each time step t. Conditional random fields are undirected models of the form $P(Y|X) = 1/Z(X) \exp \sum_t \Psi(y_t, y_{t-1}, w_t(X))$, where $Z(X)$ is a global normalizing term and $\Psi(y_t, y_{t-1}, w_t(X))$ is a potential function that scores the compatibility of y_t, y_{t-1}, and $w_t(X)$. The global normalization avoids the label bias problem but makes training much more computationally expensive. CRFs have been applied to many problems with excellent results including POS tagging (Lafferty et al., 2001) and noun-phrase chunking (Sha and Pereira, 2003).

Kernel-based methods have also been extended to the SSL case. The hidden Markov SVM (Altun et al., 2003; Tsochantaridis et al., 2004) and max-margin Markov networks (Taskar et al., 2004) learn a discriminant function $F(X,Y')$ that assigns a real valued score to each possible label sequence Y' to maximize the margin between the correct label sequence Y and all competing incorrect label sequences.

Training CRFs is difficult for several reasons. First, as with all collective classification problems, training requires performing inference. In particular, all algorithms must compute the conditional log likelihood $\log P(Y_i|X_i)$ for each training example (X_i, Y_i) in each iteration. This is expensive, and it dictates that training algorithms should try to minimize the number of iterations and maximize the amount of progress made in each iteration. Second, in many SSL applications, the space of potential

features for describing the arguments of ψ (i.e., y_t, y_{t-1}, and $w_t(X)$) is immense. Even in the simple case where ψ is represented as a simple linear function $W \cdot F(y_t, y_{t-1}, w_t(X))$, there can be millions of weights to learn in W. In POS tagging and semantic role labeling, for example, it is common to have one feature (and hence, one weight) for every combination of a word and a pair of class labels. Furthermore, in most applications, performance is improved if the algorithm can consider combinations of these basic features (e.g., word n-grams, feature conjunctions and disjunctions, etc.). If feature interactions are permitted, the number of parameters to be learned explodes. Finally, in some problems, feature values can be missing, and this is difficult for discriminative training algorithms to handle.

There has been steady progress in algorithms for training CRFs. The initial paper (Lafferty et al., 2001) introduced an iterative scaling algorithm, which was reported to be exceedingly slow. Several groups have implemented gradient ascent methods (such as Sha and Pereira, 2003), but naive implementations are also very slow. McCallum's Mallet system (McCallum, 2002) employs the BFGS algorithm, which is an approximate second order method, to speed up the training of CRFs and improve the prediction accuracy. More recently, Vishwanathan et al. (2006) proposed to use stochastic gradient method to train CRFs, and accelerate this process via the Stochastic Meta-Descent (SMD), which is a gain adaptation method. The resulting algorithm is much faster than the BFGS algorithm and scales well on large data sets.

In this paper, we introduce a different approach for training the potential functions based on Friedman's gradient tree boosting algorithm (Friedman, 2001). In this method, the potential functions are represented by sums of regression trees, which are grown stage-wise in the manner of Adaboost (Freund and Schapire, 1996). Because each iteration adds an entire regression tree to the potential function, each iteration can take a big step in parameter space, and hence, reduce the number of iterations needed. Tree boosting also addresses the problem of dealing with feature interactions. Each regression tree can be viewed as defining several new feature combinations—one corresponding to each path in the tree from the root to a leaf. The resulting potential functions still have the form of a linear combination of features, but the features can be quite complex. Another advantage of tree boosting is that it is able to handle missing values in the inputs using clever methods specific to regression trees, such as the instance weighting method of C4.5 (Quinlan, 1993) and the surrogate splitting method of CART (Breiman et al., 1984). Finally, the algorithm is fast and straightforward to implement. In addition, there may be some tendency to avoid overfitting because of the "ensemble effect" of combining multiple regression trees.

This paper describes the gradient tree boosting algorithm including methods for incorporating weight penalties into the procedure. It then compares training time and generalization performance against McCallum's Mallet system. The results show that our implementation of tree boosting is competitive with Mallet in both speed and accuracy and that additional improvements in our implementation of the forward-backward algorithm would likely produce a system that is faster than both systems. We also perform experiments to evaluate the effectiveness of four methods for handling missing values (instance weighting, surrogate splits, indicator features, and imputation). The results show that instance weighting works best, but that imputation also works surprisingly well.

This leads to two conclusions. First, for CRF models, instance weighting combined with gradient tree boosting can be recommended as a good algorithm for learning in the presence of missing values. Second, for all SSL methods, imputation can be employed to provide a reasonable missing values method.

2. Conditional Random Fields

Let (X,Y) be a sequential labeled training example, where $X = (\mathbf{x}_1,\ldots,\mathbf{x}_T)$ is the observation sequence and $Y = (y_1,\ldots,y_T)$ is the sequence of labels, where $y_t \in \{1,\ldots,K\}$ for all t. A conditional random field is a linear chain Markov random field (Geman and Geman, 1984) over the label sequence Y globally conditioned on the observation sequence X. The probability distribution can be written as

$$P(Y|X) = \frac{1}{Z(X)} \exp\left[\sum_t \Psi_t(y_t,X) + \Psi_{t-1,t}(y_{t-1},y_t,X)\right] \ ,$$

where $\Psi_t(y_t,X)$ and $\Psi_{t-1,t}(y_{t-1},y_t,X)$ are *potential functions* that capture (respectively) the degree to which y_t is compatible with X and the degree to which y_t is compatible with a transition from y_{t-1} and with X. These potential functions can be arbitrary real-valued functions. The exponential function ensures that $P(Y|X)$ is positive, and the normalizing constant $Z(X) = \sum_{Y'} \exp[\sum_t \Psi_t(y'_t,X) + \Psi_{t-1,t}(y'_{t-1},y'_t,X)]$ ensures that $P(Y|X)$ sums to 1. If given sufficiently rich potential functions, this model can represent any first-order Markov distribution $P(Y|X)$ subject to the assumption that $P(Y|X) > 0$ for all X and Y (Besag, 1974; Hammersley and Clifford, 1971). Normally, it is assumed that the potential functions do not depend on t, and we will adopt this assumption in this paper.

To apply a CRF to an SSL problem, we must choose a representation for the potential functions. Lafferty et al. (2001) studied potential functions that are weighted combinations of binary features:

$$\begin{aligned} \Psi_t(y_t,X) &= \sum_a \beta_a g_a(y_t,X) \ , \\ \Psi_{t-1,t}(y_{t-1},y_t,X) &= \sum_b \lambda_b f_b(y_{t-1},y_t,X) \ , \end{aligned}$$

where the β_a's and λ_b's are trainable weights, and the features g_a and f_b are boolean functions. In part-of-speech tagging, for example, $g_{234}(y_t,X)$ might be 1 when $\mathbf{x}_t$ is the word "bank" and y_t is the class "noun" (and 0 otherwise). As with sliding window methods, it is natural to define features that depend only on a sliding window $w_t(X)$ of X values. This linear parameterization can be seen as an extension of logistic regression to the sequential case.

CRFs can be trained by maximizing the log likelihood of the training data, possibly with a regularization penalty to prevent overfitting. Let $\Theta = \{\beta_1,\ldots,\lambda_1,\ldots\}$ denote all of the tunable parameters in the model. Then we seek to maximize the objective function

$$\begin{aligned} J(\Theta) &= \log \prod_i P(Y_i \mid X_i) \\ &= \sum_i \log \frac{1}{Z(X_i)} \exp\left[\sum_t \Psi_t(y_{i,t},X_i) + \Psi_{t-1,t}(y_{i,t-1},y_{i,t},X_i)\right] \\ &= \sum_i \sum_t \Psi_t(y_{i,t},X_i) + \Psi_{t-1,t}(y_{i,t-1},y_{i,t},X_i) - \log Z(X_i) \\ &= \sum_i \sum_t \sum_a \beta_a g_a(y_{i,t},X_i) + \sum_b \lambda_b f_b(y_{i,t-1},y_{i,t},X_i) - \log Z(X_i) \ . \end{aligned}$$

A drawback of this linear parameterization is that it assumes that each feature makes an independent contribution to the potential functions. Of course it is possible to define more features to capture combinations of the basic features, but this leads to a combinatorial explosion in the number

of features, and hence, in the dimensionality of the optimization problem. For example, in protein secondary structure prediction, Qian and Sejnowski (1988) found that a 13-residue sliding window gave best results for neural network methods. There are $3^2 \times 13 \times 20 = 2340$ basic f_b features that can be defined over this window. If we consider fourth-order conjunctions of such features, we obtain more than 10^{12} features. This is obviously infeasible.

McCallum's Mallet system (McCallum, 2002) implements standard CRFs and CRFs with feature induction (McCallum, 2003). When feature induction is turned on, the learner starts with a single constant feature and (every 8 iterations) introduces new feature conjunctions by taking conjunctions of the basic features with features already in the model. Candidate conjunctions are evaluated according to their incremental impact on the objective function. He demonstrates significant improvements in speed and classification accuracy compared to a CRF that only includes the basic features. In this paper, we employ the gradient tree boosting method (Friedman, 2001) to construct complex features from the basic features as part of a stage-wise construction of the potential functions. The regression trees grown at each step are compact representations of complex features.

3. Gradient Tree Boosting

Suppose we wish to solve a standard supervised learning problem where the training examples have the form $(\mathbf{x}_i, y_i)$, $i = 1, \ldots, N$ and $y_i \in \{1, \ldots, K\}$. We wish to fit a model of the form

$$P(y \mid \mathbf{x}) = \frac{\exp \Psi(y, \mathbf{x})}{\sum_{y'} \exp \Psi(y', \mathbf{x})} \ .$$

Gradient tree boosting is based on the idea of *functional gradient ascent*. In ordinary gradient ascent, we would parameterize Ψ in some way, for example, as a linear function,

$$\Psi(y, \mathbf{x}) = \sum_a \beta_a g_a(y, \mathbf{x}) \ .$$

Let $\Theta = \{\beta_1, \ldots\}$ represent all of the tunable parameters in this function. In gradient ascent, the fitted parameter vector after iteration m, Θ_m, is a sum of an initial parameter vector Θ_0 and a series of gradient ascent steps δ_m:

$$\Theta_m = \Theta_0 + \delta_1 + \cdots + \delta_m \ ,$$

where each δ_m is computed as a step in the direction of the gradient of the log likelihood function:

$$\delta_m = \eta_m \nabla_\Theta \sum_i \log P(y_i \mid \mathbf{x}_i; \Theta) \Big|_{\Theta_{m-1}} \ ,$$

and η_m is a parameter that controls the step size.

Functional gradient ascent is a more general approach. Instead of assuming a linear parameterization for Ψ, it just assumes that Ψ will be represented by a weighted sum of functions:

$$\Psi_m = \Psi_0 + \Delta_1 + \cdots + \Delta_m \ .$$

Each Δ_m is computed as a *functional gradient*:

$$\Delta_m = \eta_m \, E_{\mathbf{x},y} \left[\nabla_\Psi \log P(y \mid \mathbf{x}; \Psi)|_{\Psi_{m-1}} \right] \ .$$

The functional gradient indicates how we would like the function Ψ_{m-1} to change in order to increase the true log likelihood (i.e., on all possible points $(\mathbf{x},y)$). Unfortunately, we do not know the joint distribution $P(\mathbf{x},y)$, so we cannot evaluate the expectation $E_{\mathbf{x},y}[\cdot]$. We do have a set of training examples sampled from this joint distribution, so we can compute the value of the functional gradient at each of our training data points:

$$\Delta_m(y_i,\mathbf{x}_i) = \nabla_\Psi \sum_i \log P(y_i \mid \mathbf{x}_i;\Psi)\Big|_{\Psi_{m-1}} \quad .$$

We can then use these point-wise functional gradients to define a set of *functional gradient training examples*, $((\mathbf{x}_i,y_i),\Delta_m(y_i,\mathbf{x}_i))$, and then train a function $h_m(y,\mathbf{x})$ so that it approximates $\Delta_m(y_i,\mathbf{x}_i)$. Specifically, we can fit a regression tree h_m to minimize

$$\sum_i [h_m(y_i,\mathbf{x}_i) - \Delta_m(y_i,\mathbf{x}_i)]^2 \quad .$$

We can then take a step in the direction of this fitted function:

$$\Psi_m = \Psi_{m-1} + \eta h_m \quad .$$

Although the fitted function h_m is not exactly the same as the desired Δ_m, it will point in the same general direction (assuming there are enough training examples). So ascent in the direction of h_m will approximate true functional gradient ascent.

A key thing to note about this approach is that it replaces the difficult problem of maximizing the log likelihood of the data by the much simpler problem of minimizing squared error on a set of training examples. Friedman (2001) suggests growing h_m via a best-first version of the CART algorithm (Breiman et al., 1984; Friedman et al., 2000) and stopping when the regression tree reaches a pre-set number of leaves L. The pseudo-code of this algorithm is shown in Table 1. Overfitting is controlled by tuning L (e.g., by internal cross-validation).

In our experience, using L to control overfitting is a blunt tool that is hard to calibrate. In this paper, we instead introduce shrinkage into the algorithm for growing regression trees by adding a quadratic weight penalty. For each leaf in the regression tree h_m, the quantity that we minimize is the squared error of the examples $((\mathbf{x}_i,y_i),\Delta_m(y_i,\mathbf{x}_i))$ falling into this leaf plus a quadratic penalty:

$$\sum_i (\Delta_m(y_i,\mathbf{x}_i) - \hat{\delta})^2 + \lambda\hat{\delta}^2 \quad ,$$

where $\hat{\delta}$ is the output of this leaf and $\lambda > 0$ controls the strength of the penalty. Differentiating the above objective function with respect to $\hat{\delta}$ shows that the minimum is achieved at

$$\hat{\delta} = \frac{\sum_i \Delta_m(y_i,\mathbf{x}_i)}{\lambda + N} \quad , \tag{1}$$

where N is the total number of examples falling into this leaf. This has the nice interpretation that λ is an equivalent number of training examples with target values of 0. So this shrinks the leaf values (learned weights) toward zero. With this method, we can select a large number for L (the maximum number of leaves in the regression tree), and use λ to give fine control of overfitting. The algorithm shown in Table 1 can be adapted by using Equation 1 in the computation of function OUTPUT and function SQUAREDERROR. Experimental results show that this new algorithm works better and is more efficient than the original best-first version of the CART algorithm.

4. Training CRFs with Gradient Tree Boosting

In principle, it is straightforward to apply functional gradient ascent to train CRFs. All we need to do is to represent and train $\Psi(y_t, X)$ and $\Psi(y_{t-1}, y_t, X)$ as weighted sums of regression trees. Let

$$F^{y_t}(y_{t-1}, X) = \Psi(y_t, X) + \Psi(y_{t-1}, y_t, X)$$

be a function that computes the "desirability" of label y_t given values for label y_{t-1} and the input features X. There are K such functions F^k, one for each class label k. With this definition, the CRF has the form

$$P(Y|X) = \frac{1}{Z(X)} \exp \sum_t F^{y_t}(y_{t-1}, X) \ .$$

We now compute the functional gradient of $\log P(Y|X)$ with respect to $F^{y_t}(y_{t-1}, X)$. To simplify the computation, we replace X by $w_t(X)$, which is a window into the sequence X centered at $\mathbf{x}_t$. We will further assume, without loss of generality, that each window is unique, so there is only one occurrence of $w_t(X)$ in each sequence X.

Proposition 1 *The functional gradient of* $\log P(Y|X)$ *with respect to* $F^v(u, w_d(X))$ *is*

$$\frac{\partial \log P(Y|X)}{\partial F^v(u, w_d(X))} = I(y_{d-1} = u, y_d = v) - P(y_{d-1} = u, y_d = v \mid w_d(X)) \ ,$$

where $I(y_{d-1} = u, y_d = v)$ *is 1 if the transition* $u \to v$ *is observed from position* $d-1$ *to position* d *in the sequence* Y *and 0 otherwise, and where* $P(y_{d-1} = u, y_d = v \mid w_d(X))$ *is the predicted probability of this transition according to the current potential functions.*

To demonstrate this proposition, we must first introduce the forward-backward algorithm for computing the normalizing constant $Z(X)$. We will assume that y_t takes the value $\perp$ for $t < 1$. Define the forward recursion by

$$\begin{aligned} \alpha(k,1) &= \exp F^k(\perp, w_1(X)) \\ \alpha(k,t) &= \sum_{k'} \exp F^k(k', w_t(X)) \cdot \alpha(k', t-1) \ , \end{aligned}$$

and the backward recursion by

$$\begin{aligned} \beta(k,T) &= 1 \\ \beta(k,t) &= \sum_{k'} \exp F^{k'}(k, w_{t+1}(X)) \cdot \beta(k', t+1) \ . \end{aligned}$$

The variables k and k' iterate over the possible class labels. The normalizer $Z(X)$ can be computed at any position t as

$$Z(X) = \sum_k \alpha(k,t)\beta(k,t) \ .$$

If we unroll the α recursion one step, we can also write this as

$$Z(X) = \sum_k \left[\sum_{k'} \alpha(k', t-1) \cdot \left[\exp F^k(k', w_t(X)) \right] \right] \beta(k,t) \ .$$

Table 2 shows the derivation of the functional gradient. In Equation 2, exactly one of the $F^{y_t}(y_{t-1}, w_t(X))$ terms will match $F^v(u, w_d(X))$, because $w_d(X)$ is unique. This term will have a derivative of 1, so we represent this by the indicator function $I(y_{d-1} = u, y_d = v)$. In Equation 3, we expand $Z(X)$ at position d using the forward-backward algorithm. Again because $w_d(X)$ is unique, only the product where $k' = u$ and $k = v$ will give a non-zero derivative, so this gives us Equation 4. The right-hand expression in Equation 4 is precisely the joint probability that $y_{d-1} = u$ and $y_d = v$ given X. **Q.E.D.**

If $w_d(X)$ occurs more than once in X, each match contributes separately to the functional gradient.

This functional gradient has a very satisfying interpretation: It is our error on a probability scale. If the transition $u \to v$ is observed in the training example, then the predicted probability $P(u, v \mid X)$

$$
\begin{aligned}
&\frac{\partial \log P(Y|X)}{\partial F^v(u, w_d(X))} \\
&= \frac{\partial}{\partial F^v(u, w_d(X))} \sum_t F^{y_t}(y_{t-1}, w_t(X)) - \log Z(X) \\
&= I(y_{d-1} = u, y_d = v) - \frac{\partial \log Z(X)}{\partial F^v(u, w_d(X))} \qquad (2) \\
&= I(y_{d-1} = u, y_d = v) - \frac{1}{Z(X)} \frac{\partial Z(X)}{\partial F^v(u, w_d(X))} \\
&= I(y_{d-1} = u, y_d = v) - \frac{1}{Z(X)} \frac{\partial}{\partial F^v(u, w_d(X))} \sum_k \left[\sum_{k'} \left[\exp F^k(k', w_d(X)) \right] \cdot \alpha(k', d-1) \right] \beta(k, d) \qquad (3) \\
&= I(y_{d-1} = u, y_d = v) - \frac{1}{Z(X)} \left[\exp F^v(u, w_d(X)) \right] \alpha(u, d-1) \beta(v, d) \qquad (4) \\
&= I(y_{d-1} = u, y_d = v) - P(y_{d-1} = u, y_d = v \mid X)
\end{aligned}
$$

Table 2: Derivation of the functional gradient.

should be 1 in order to maximize the likelihood. If the transition is not observed, then the predicted probability should be 0. Functional gradient ascent simply involves fitting regression trees to these residuals.

The pseudo code for our gradient tree boosting algorithm is shown in Table 3. The potential function for each class k is initialized to zero. Then M iterations of boosting are executed. In each iteration, for each class k, a set $S(k)$ of functional gradient training examples is generated. Each example consists of a window $w_t(X_i)$ on the input sequence, a possible class label k' at time $t-1$, and the target Δ value. A regression tree having at most L leaves is fit to these training examples to produce the function $h_m(k)$. This function is then added to the previous potential function to produce the next function. In other words, we are setting the step size $\eta_m = 1$. We experimented with performing a line search at this point to optimize η_m, but this is very expensive. So we rely on the "self-correcting" property of tree boosting to correct any overshoot or undershoot on the next iteration.

The sets of generated examples $S(k)$ can become very large. For example, if we have 3 classes and 100 training sequences of length 200, then the number of training examples for each class k is $3 \times 100 \times 200 = 60,000$. Although regression tree algorithms are very fast, they still must consider all of the training examples! Friedman (2001) suggests two tricks for speeding up the computation: sampling and influence trimming. In sampling, a random sample of the training data is used for training. In influence trimming, data points with Δ values close to zero are ignored. We did not apply either of these techniques in our experiments.

The most related work to ours is the virtual evidence boosting (VEB) algorithm developed by Liao et al. (2007) for training CRFs. Both VEB and our approach use boosting for feature induction. However, VEB is a "soft" version of maximum pseudo-likelihood training, where the observed values of neighborhood labels are not used, but the probability distribution over neighborhood labels is used as virtual evidence. Our approach is a true maximum log likelihood method that does not depend on the pseudo-likelihood approximation. Another difference is that VEB only uses decision stumps to induce simple features, while our approach uses regression trees to induce more complex feature combinations.

TREEBOOST($Data, L$)

      $\Delta(k, k', i, t) := I(y_{i,t-1} = k', y_{i,t} = k) -$
        $P(y_{i,t-1} = k', y_{i,t} = k \mid X_i)$
      insert $((w_t(X_i), k'), \Delta(k, k', i, t))$ into S
    end
  end
end
return S
end GENERATEEXAMPLES

Table 3: Gradient tree boosting algorithm for CRFs.

5. Inference in CRFs

Once a CRF model has been trained, there are (at least) two possible ways to define a classifier $Y = H(X)$ for making predictions. First, we can predict the *entire sequence* Y that has the highest probability:

$$H(X) = \operatorname*{argmax}_Y P(Y|X) \ .$$

This makes sense in applications, such as part-of-speech tagging, where the goal is to make a coherent sequential prediction. This can be computed by the Viterbi algorithm (Rabiner, 1989), which has the advantage that it does not need to compute the normalizer $Z(X)$.

The second way to make predictions is to individually predict each y_t according to

$$H_t(X) = \operatorname*{argmax}_v P(y_t = v|X) \ ,$$

and then concatenate these individual predictions to obtain $H(X)$. This makes sense in applications where the goal is to maximize the number of individual y_t's correctly predicted, even if the resulting predicted sequence Y is incoherent. For example, a predicted sequence of parts of speech might not be grammatically legal, and yet it might maximize the number of individual words correctly classified. $P(y_t|X)$ can be computed by executing the forward-backward algorithm as

$$P(y_t|X) = \frac{\alpha(y_t,t)\beta(y_t,t)}{Z(X)} \ .$$

6. Handling Missing Values in CRFs with Gradient Tree Boosting

In some problem settings (e.g., activity recognition, sensor networks), the problem of missing values in the inputs can arise. The values of input features can be missing for a wide variety of reasons. Sensors may break or the sensor data feed may be lost or corrupted. Alternatively, input observations may not have been measured in all cases because, for example, they are expensive to obtain. Many methods for handling missing values have been developed for standard supervised learning, but many of them have not been tested on SSL problems. Recently, Sutton et al. (2006) used feature bagging method to deal with SSL problems where highly indicative features may be missing in the test data. A single CRF trained on all the features will be less robust, because the weights of weaker features will be undertrained. Feature bagging method divides all the original features into a collection of complementary and possibly overlapped feature subsets. Separate CRFs are trained on each subset and then combined.

With gradient tree boosting, a CRF is represented as a forest of regression trees. There exist very good methods for handing missing values when growing regression trees, which include instance weighting method of C4.5 (Quinlan, 1993) and surrogate splitting of CART (Breiman et al., 1984). An advantage of training CRFs with gradient tree boosting is that these missing values methods can be used directly in the process of generating regression trees over the functional gradient training examples.

6.1 Instance Weighting

The instance weighting method (Quinlan, 1993), also known as "proportional distribution", assigns a weight to each training example, and all splitting decisions are based on weighted statistics. Initially, each example has a weight of 1.0. When selecting a feature to split on, each boolean feature x_j is evaluated based on the expected weighted squared error of the split using only the training examples for which x_j is not missing. The best feature x_{j*} is chosen, and the training examples for which x_{j*} is not missing are sent to the appropriate child node. Suppose that n_{left} examples are sent to the left child and n_{right} examples are sent to the right child. The remaining training examples (i.e., those for which x_{j*} is missing) are sent to *both* children, but with reduced weight. The weight

of each example sent to the left child is multiplied by $n_{left}/(n_{left}+n_{right})$. Similarly, the weight of each example sent to the right child is multiplied by $n_{right}/(n_{left}+n_{right})$.

At test time, when the test example reaches the test on feature x_{j*}, if the feature value is present, then the example is routed left or right in the usual way. But if x_{j*} is missing, then the example is sent to both children (recursively). Let $\hat{y}_{left}$ be the predicted value computed by the left subtree and $\hat{y}_{right}$ be the predicted value computed by the right subtree. Then the value predicted by node $j*$ is the weighted average of these predictions:

$$\hat{y} = \frac{n_{left}\hat{y}_{left} + n_{right}\hat{y}_{right}}{n_{left}+n_{right}} \quad .$$

Instance weighting assumes that the training and test examples missing x_{j*} will on average behave exactly like the training examples for which x_{j*} is not missing.

6.2 Surrogate Splitting

The surrogate splitting method (Breiman et al., 1984) involves separate procedures during training and testing. During training, as the regression tree is being constructed (in the usual top-down, greedy way), the key step in the learning algorithm is to choose which feature to split on. Each boolean feature x_j is evaluated based only on the training examples that have non-missing values for that feature, and the best feature, x_{j*} is chosen. Each of the remaining features $j' \neq j*$ is then evaluated to determine how accurately it can predict the value of x_{j*}, and the features are sorted according to their predictive power. This sorted list of features, called the surrogate splits, is stored in the node.

At test time, when test example x is processed through the regression tree, if x_{j*} is not missing, then the example is processed as usual by sending it to the left child if x_{j*} is false and to the right child if x_{j*} is true. However if x_{j*} is missing, then surrogate split features are examined in order until a feature j' is found that is not missing. The value of this feature determines whether to branch left or right.

7. Experimental Results

We implemented gradient tree boosting algorithm for CRFs and compared it to McCallum's Mallet system (McCallum, 2002) on several data sets. We call our algorithm TREECRF. We use TREECRF-FB for the TREECRF with forward-backward predictions and TREECRF-V for the TREECRF with Viterbi predictions. MALLET denotes the Mallet package with McCallum's feature induction algorithm (McCallum, 2003) turned on. Similarly, we use MALLET-FB and MALLET-V for the MALLET with forward-backward predictions and Viterbi predictions respectively. We also used the Mallet package to train standard CRFs without feature induction. We call it BASELINE, which serves as the baseline method. As before, BASELINE-FB denotes BASELINE with forward-backward predictions and BASELINE-V denotes BASELINE with Viterbi predictions. Note that MALLET-FB algorithm and BASELINE-FB algorithm are not implemented in the original Mallet package. Instead we implemented them ourselves.

TREECRF, MALLET and BASELINE have parameters that must be set by the user. For all these algorithms, the user must set (a) the window size, (b) the order of the Markov model, which is set to be 1 in our experiments, and (c) the number of iterations to train. For TREECRF, the only

additional parameter is either the maximum number of leaves L in the regression trees using the best-first version of CART, or the regularization constant λ for the shrinkage alternative. For MALLET, the parameters are (a) the regularization penalty for squared weights (called the variance), (b) the number of iterations between feature inductions (kept constant at 8), (c) the number of features to add per feature induction (kept constant at 500), (d) the true label probability threshold (kept constant at 0.95), (e) the training proportions (kept constant at 0.2, 0.5, and 0.8). For BASELINE, the only additional parameter is the variance as in MALLET. Except for the variance, we kept all of MALLET's parameters fixed at the values recommended by Andrew McCallum (personal communication). We did not optimize the window size, but instead employed values that have been used in previous studies. The chosen sizes are given in the following section. To set the remaining parameters, we manually tried the following settings and chose the setting that gave the best internal cross-validation performance:

- Number of leaves in regression trees: 30, 50, 75, 100,
- TreeCRF regularization constant: 0, 5, 10, 20, 40, 80,
- Weight variance prior in Mallet package: 1, 5, 10, 20.

Throughout the experiments, we measured the performance by computing the prediction accuracy of individual labels, rather than individual sequences. McNemar's test is employed to assess the statistical significance of these results.

7.1 Data Sets

Protein Secondary Structure Benchmark (Qian and Sejnowski, 1988). Each observation sequence is a string of amino acid residues, and the corresponding output sequence is a string over the 3-letter alphabet $\{\alpha, \beta, \gamma\}$, where α indicates alpha helix, β indicates a beta sheet or beta turn, and γ indicates all other secondary structure types. There are 20 possible amino acid residues, and we represent each residue by a set of 20 indicator variables. There is a training set of 111 sequences and a test set of 17 sequences. An 11-residue sliding window is used in our experiments.

NETtalk Data Set. The original NETtalk task (Sejnowski and Rosenberg, 1987) is to assign a combination of phoneme and stress to each letter of the word so that the word is pronounced correctly. However, there are 140 legal phone-stress combinations, which gives a very large label space. Neither TREECRF nor MALLET is sufficient enough to work with such a large label space. Hence, we chose to study only the problem of assigning one of five possible stress labels to each letter. The labels are '2' (strong stress), '1' (medium stress), '0' (light stress), '$<$' (unstressed consonant, center of syllable to the left), and '$>$' (unstressed consonant, center of syllable to the right).

Each input sequence is an English word, a string of letters over the 26 letter alphabet. Each input observation is represented by 26 boolean indicator variables. There are 1000 training words and 1000 test words in our standard training and test sets. We employed a window size of 13 (window width of 6).

Hyphenation Data Set. The hyphenation task is to insert hyphens into words at points where it is legal to break a word for a new line. This problem appears widely in many word processing programs. The input sequences are English words, encoded as for the NETtalk task. The output class label has only two values to indicate whether or not a hyphen may legally follow the current

	TREECRF-FB		TREECRF-V

Table 4: Performance comparison of TREECRF with different regression tree fitting algorithms. Entries marked with one or more stars are statistically significantly better than the alternative method. Specifically, * means $p < 0.025$, ** means $p < 0.005$ and *** means $p < 0.001$ according to McNemar's test.

letter. We manually constructed a training set of 1951 words and a test set of 908 words. The input window size is set to be 6 (i.e., 3 letters on either side of the potential hyphen location).

Usenet FAQs Data Sets. Each of the FAQ data sets consists of Frequently Asked Questions files for a Usenet newsgroup (McCallum et al., 2000). The FAQs for each newsgroup are divided in separate files: ai-general has 7 files, ai-neural has 7 files, and aix has 5 files. Every line of an FAQ file is labeled as either part of the header, a question, an answer, or part of the tail. Hence, each $\mathbf{x}_t$ consists of a line in the FAQ file, and the corresponding $y_t \in \{\text{header, question, answer, tail}\}$. The measure of accuracy is the number of individual lines correctly classified. McCallum provided us with the definitions of 20 features for each line $\mathbf{x}_t$. We made a slight correction to one of the features, so our results are not directly comparable to his. The size of the sliding window used here is 1. For each newsgroup, performance was measured by leave-1-out cross-validation: the CRF was trained on all-but-one of the files and tested on the remaining file. This was repeated with each file, and the results averaged.

7.2 Performance of Shrinkage in Regression Tree Generation

To evaluate the effectiveness of shrinkage in the regression tree fitting algorithm, we fixed L, the maximum number of leaves in regression trees, to be 100, and applied internal cross-validation to choose the best regularization constant λ. For purposes of comparison, we also implemented the original best-first regression tree generation algorithm. Internal cross-validation was employed to select the best value for L.

We ran these two implementations of TREECRF on each data set. The best performance of both forward-backward predictions and Viterbi predictions are reported as percentages, as shown in Table 4. There are 12 pairs of comparisons (6 data sets with 2 prediction algorithms). In six of them, TREECRF with shrinkage does statistically better than TreeCRF without shrinkage. In five of them, the performance of these two versions of TREECRF is statistically indistinguishable. In only one of them, TREECRF without shrinkage does statistically better than TREECRF with shrinkage. Based on the results of these experiments, we decided to only employ TREECRF with shrinkage in the remaining experiments.

		Protein	NETtalk	Hyphen	FAQ ai-general	FAQ ai-neural	FAQ aix
Accuracy (%)	TREECRF	64.52*	85.20**	92.20**	**95.65** **	99.20**	95.26**

Table 5: Performance of TREECRF, MALLET, and BASELINE on each data set. Entries marked with one or more stars are statistically significant than BASELINE. Specifically, * means $p < 0.005$, ** means $p < 0.001$ according to McNemar's test. Bolded numbers indicate the statistically better prediction accuracy between TREECRF and MALLET. The BASELINE method stops training if the optimization of loss functions converges. So for each FAQ data set, different training set may have different number of training iterations. Here we gave out the range of number of training iterations for each FAQ data set.

7.3 Comparison between TREECRF and MALLET

TREECRF and MALLET are the two leading CRF training methods that have feature induction capability. Here we compare the prediction accuracy and training speed of these two methods on each available data set. We also compare TREECRF and MALLET with the BASELINE method. For each method, internal cross-validation is applied to select the parameters that give the best performance of both forward-backward predictions and Viterbi predictions. The results reported here for each method are based on the prediction algorithm that gives higher prediction accuracy. All experiments were run on machines with 2.4 GHz Intel Xeon processors, 512KB cache, and 4GB memory.

Prediction Accuracy. Table 5 summarizes the prediction accuracy of TREECRF, MALLET, and BASELINE on each data set. McNemar's tests show that on four of the data sets, that is, protein, hyphen, FAQ ai-neural and FAQ aix, the difference between the prediction accuracy of TREECRF and MALLET is not statistically significant. On the FAQ ai-general data set, the prediction accuracy of TREECRF is statistically better than that of MALLET($p < 0.001$). Only on the NETtalk data set is the prediction accuracy of MALLET statistically better than that of TREECRF ($p < 0.05$). In comparison with the baseline method, the prediction accuracy of TREECRF and MALLET is statistically better than that of BASELINE in most cases. On the FAQ ai-general data set, the difference between MALLET and BASELINE is not statistically significant. Only on the FAQ ai-neural data set is the prediction accuracy of BASELINE statistically better than that of both TREECRF and MALLET.

Figure 1 plots the prediction accuracy of TREECRF, MALLET and BASELINE as a function of the number of training iterations. One worrying aspect of MALLET is that the performance curve exhibits a high degree of fluctuation, which is clearly shown on Figure 1a, 1d, 1e and 1f. This is presumably due to the effect of introducing new features. But it also suggests that it will be difficult to find the optimal stopping points for avoiding overfitting.

Training Speed. It is difficult to directly compare the CPU time of these two methods, because TREECRF is written in C++ while MALLET is written in Java. However, comparing the CPU time

Table 6: Comparison of average CPU seconds spent per iteration on forward-backward algorithm and feature induction algorithm in TREECRF and MALLET for each data set.

on different data sets can still give us some insight into the properties of these two methods. Figure 2 shows the number of cumulative CPU seconds consumed by these two methods on each data set. First, we can see that TREECRF scales linearly in the number of training iterations, because the cumulative CPU time has a constant slope. This makes sense, because for each potential function, only one regression tree is generated in each training iteration. Regression tree evaluations from previous iterations are cached so that they do not need to be re-evaluated. Without caching, the cumulative CPU curves for TREECRF would rise quadratically. Second, as shown in Figure 2a, 2b and 2c, TREECRF runs faster than MALLET on protein, NETtalk and hyphen data sets. But it is much slower than MALLET on FAQ data sets as shown in Figure 2d, 2e and 2f. The actual time required for each method to reach its peak performance on each data set is given in Table 5. Again we see that on the protein, NETtalk, and hyphen data sets, the time required for MALLET to reach its peak performance is about twice that of TREECRF. However, on the FAQ data sets, the time required for TREECRF to reach its peak performance is about 10-20 times more than for MALLET. BASELINE is faster than both TREECRF and MALLET as shown in Figure 2 and Table 5.

Analysis and Discussion. We can explain the training speed difference between TREECRF and MALLET by examining the details of these two methods. In both of them, most of the CPU time is spent on two major computations: forward-backward inference and feature induction/tree growing. The relative proportion of these two computations varies from problem to problem. To measure this, we instrumented both TREECRF and MALLET to track the amount of CPU time spent on each of these two computations. Table 6 shows that on domains with short sequences (Protein, NETtalk, and Hyphen), the time spent by both algorithms on forward-backward inference is about the same. But for domains with very long sequences, TREECRF consumes much more CPU time in forward-backward inference. Conversely, in domains with a small number of basic features (the FAQ data sets), the two methods consume roughly the same amount of CPU time in feature induction. But in domains with a large number of basic features, TREECRF is much more efficient than MALLET.

Why would the forward-backward cost of TREECRF be larger than for MALLET? TREECRF and MALLET use almost the same implementation of forward-backward algorithm except that in TREECRF the values of the potential functions at each position of the sequences are computed by evaluating the gradient regression trees generated in the current training iteration, while in MALLET those values are obtained by computing dot products of vectors, which is faster than tree evaluation. We hypothesize that the regression trees are more expensive to evaluate, not only because dot prod-

ucts are easier to compute than tree evaluations, but also possibly because of the reduced memory locality of regression trees.

Why would feature induction be more expensive in MALLET? In each feature induction iteration, MALLET considers conjoining all of the basic features to each of the existing compound features. Hence, if there are n basic features and C compound features, this costs nC. Furthermore, C grows over time, so the cost of feature induction gradually increases. In the cumulative CPU time plots of Figure 2, the "steps' in the "staircase" correspond to the feature induction iterations. In TREECRF, the cost of feature induction is the cost of growing a regression tree, which depends on the number of basic features n and the number of internal nodes in the tree L. This cost is nL, which remains constant across the iterations.

To verify our conjectures about the computational complexity of TREECRF and MALLET, we generated synthetic training data sets using a hidden Markov model (HMM) with 3 labels $\{l_1, l_2, l_3\}$ and 24 possible observations $\{o_1, \ldots, o_{24}\}$. To specify the observation distribution, for each label l_i, we randomly draw an observation from the set $\{o_{i*8-7}, \ldots, o_{i*8}\}$ with probability 0.6 and randomly draw an observation from the complement of this set with probability 0.4. The transition distribution is defined as $P(y_t = l_i \mid y_{t-1} = l_i) = 0.6$ and $P(y_t = l_j \mid y_{t-1} = l_i) = 0.2$ if $i \neq j$.

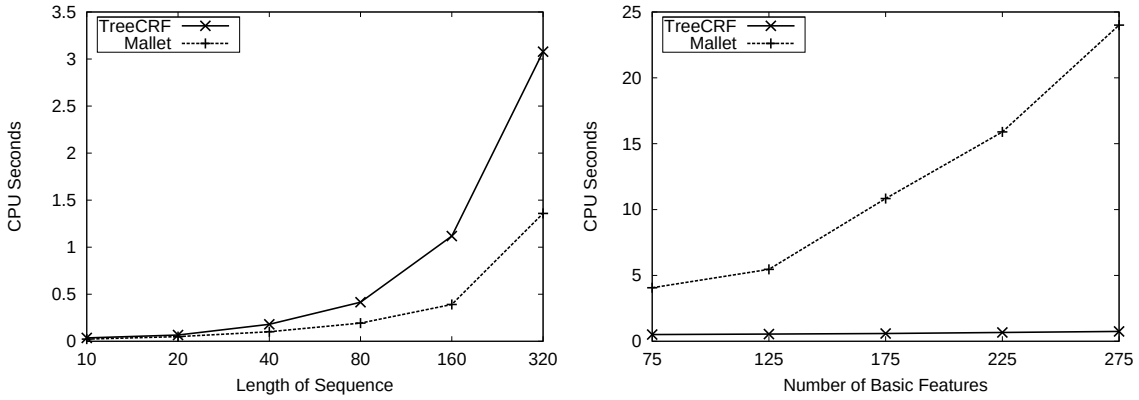
In order to measure the complexity of the forward-backward algorithm, we tried sequence lengths of 10, 20, 40, 80, 160 and 320. For each sequence length, we generated a training data set with 100 sequences and employed a sliding window of size 3. TREECRF and MALLET are run on each of these training data sets. Figure 3a shows the average CPU seconds spent per iteration on the forward-backward algorithm by these two methods. We see that the forward-backward algorithm in TREECRF implementation scales faster than that in MALLET implementation as the length of sequence increases.

In order to measure the complexity of the feature induction algorithms, we generated a training data set with 100 sequences. The length of each sequences is 100. We tried sliding window sizes of 3, 5, 7, 9 and 11, so that the number of input features at each sequence position takes the values of 75, 125, 175, 225 and 275 (because each input observation is represented by 25 boolean indicator variables). TREECRF and MALLET are run for each sliding window size. Figure 3b shows the average CPU seconds spent per iteration on the feature induction algorithm by these two methods. It is clear that the feature induction algorithm in MALLET spends more and more CPU time than that in TREECRF as the number of basic features increases. In all the experiments on synthetic data sets, TREECRF uses regression trees of maximum 100 leaves and shrinkage constant 40. MALLET uses weight variance prior 20.

This analysis suggests that the performance of TREECRF could be improved by "flattening" the ensemble of regression trees to compute the corresponding vector of features and vector of weights. Then the cost of potential function evaluations would be similar to that of MALLET, and we would have a method that was faster than both the current TREECRF and MALLET implementations.

7.4 Experimental Studies of Missing Values in TREECRF

We performed a series of experiments to evaluate the effectiveness of methods for handling missing values in TREECRF algorithm. In addition to the instance weighting and surrogate splitting methods described above, we also studied two simpler methods: imputation and indicator features. Let $x_{tj}, j = 1, \ldots, n$ be the input features describing a particular input observation $\mathbf{x}_t$. Imputation and indicator features are defined as follows:



(a) Forward-backward algorithm (b) Feature induction algorithm

Figure 3: Comparison of average CPU seconds spent per iteration on forward-backward algorithms and feature induction algorithms by TREECRF and MALLET.

Imputation: when a feature value x_{tj} is missing, it is replaced with the most common value for x_j in the training data among those feature values that are not missing. This strategy can be viewed as substituting the most likely value of x_j a priori or alternatively as substituting the value of x_j least likely to be informative.

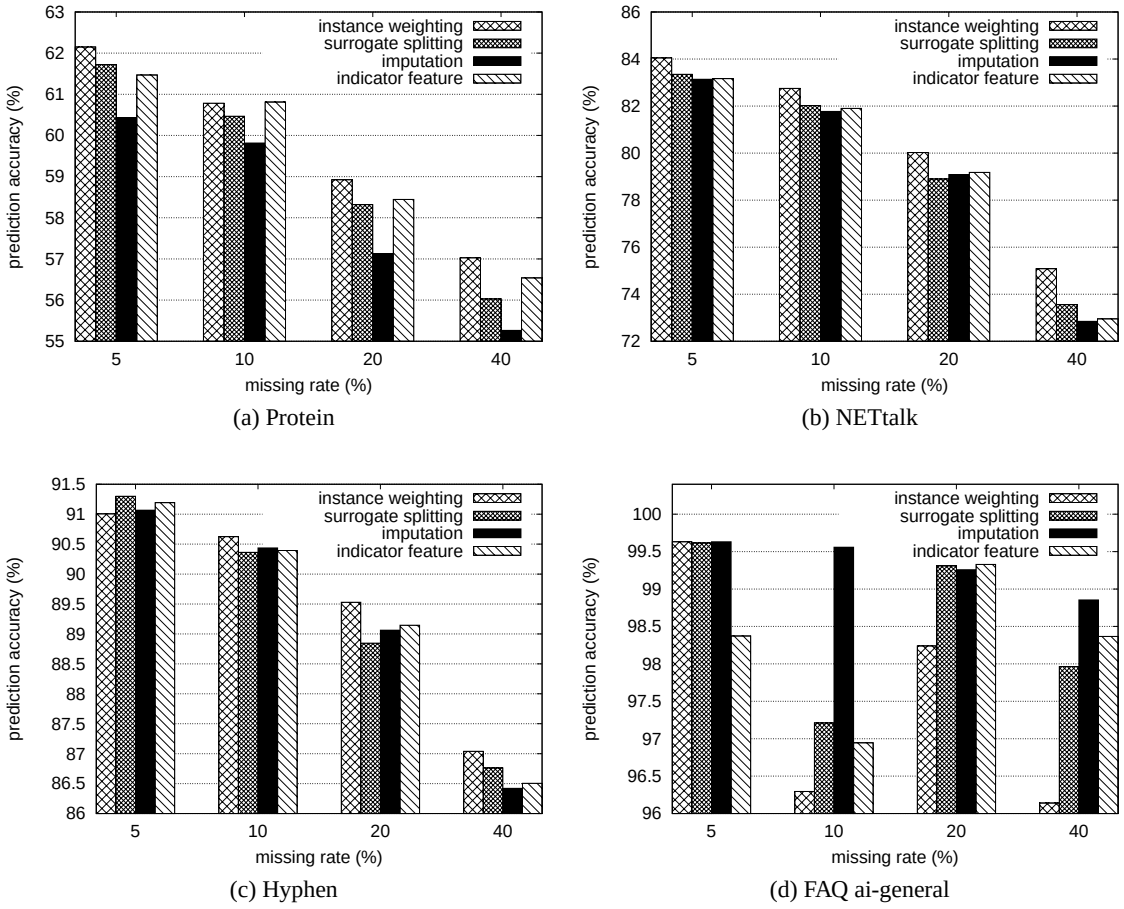
Indicator Features: a boolean feature $\tilde{x}_{tj}$ is introduced for each feature x_{tj} such that if x_{tj} is present, $\tilde{x}_{tj}$ is false. But if x_{tj} is missing, then $\tilde{x}_{tj}$ is true and x_{tj} is set to a fixed chosen value, typically 0. Indicator features make sense when the fact that a value is missing is itself informative. For example, if x_{tj} represents a temperature reading, it may be that extremely cold temperature values tend to be missing because of sensor failure.

We adopted a first-order Markov model in all the following experiments and employed an internal hold-out method to set the other parameters: Two-thirds of the original training set was used as sub-training set and the other one third was used as development set to choose parameter values. Final training was performed using the entire training set.

For each learning problem, we took the chosen training and test sets and inject missing values at rates of 5%, 10%, 20% and 40%. For a given missing rate, we generate five versions of the training set and five versions of the test set. A CRF is then trained on each of the training sets and evaluated on each of the test sets (for a total of 5 CRFs and 25 evaluations per missing rate). The label sequences are predicted by the forward-backward algorithm (i.e., we compute $\hat{y}_t = \text{argmax}_{y_t} P(y_t|X)$ for each t separately). Prediction accuracy is based on the number of individual labels correctly predicted in the label sequences. The final prediction accuracy is the average of all 25 cases.

To test the statistical significance of the differences among the four methods, we performed an analysis of deviance based on the generalized linear model discussed by Agresti (1996). We fit a logistic regression model

$$\log \frac{P(y_t = \hat{y}_t)}{1 - P(y_t = \hat{y}_t)} = \delta_1 m_1 + \delta_2 m_2 + \delta_3 m_3 + \sum_\ell \sigma_\ell S_\ell \ ,$$



(a) Protein (b) NETtalk

(c) Hyphen (d) FAQ ai-general

Figure 4: Performance of missing values methods for different missing rates.

where m_1, m_2, and m_3 are boolean indicator variables that specify which missing values method we are using and the S_ℓ's are indicator variables that specify which of the five training sets we are using. If $m_1 = m_2 = m_3 = 0$, then we are using instance weighting, which serves as our baseline method. If $m_1 = 1$, this indicates surrogate splitting, $m_2 = 1$ indicates imputation, and $m_3 = 1$ indicates the indicator feature method. Consequently, the fitted coefficients δ_1, δ_2, and δ_3 indicate the change in log odds (relative to the baseline) resulting from using each of these missing values methods. We can then test the hypothesis $\delta_i \neq 0$ against the null hypothesis $\delta_i = 0$ to determine whether missing values method i is different from the baseline method.

This statistical approach controls for variability due to the choice of the training set (through the σ_ℓ's) and variability due to the size of the test set.

Protein Secondary Structure Prediction. Figure 4a shows that instance weighting achieves the best prediction accuracy for each of the different missing rates. Table 7a shows that the base line missing values method, instance weighting, is statistically better than the other three missing values methods in most cases. In other cases, it is as good as other methods.

(d) FAQ ai-general

Table 7: Estimation of the coefficients corresponding to different missing values methods and statistical test results. In FAQ ai-general problem, imputation was the baseline method, so the coefficient values give the log odds of the change in accuracy relative to imputation. * means that the parameter value is statistically significantly different from zero ($p < 0.05$).

NETtalk Stress Prediction. In Figure 4b, we see that instance weighting does better than the other three missing values methods for all the different missing rates. The statistical tests reported in Table 7b show that the baseline method, instance weighting, is statistically better than each of the other missing value methods in all cases.

Hyphenation. Figure 4c shows that instance weighting is the best missing values method except for a missing rate of 5%. Statistical tests shown in Table 7c tell us that for missing rate of 5%, surrogate splitting is the best missing values method and the other three methods are not statistically significantly different from each other. For a missing rate of 10%, instance weighting and imputation are statistically better than the other two methods (and indistinguishable from each other). For missing rates of 20% and 40%, instance weighting is statistically better than the other three methods.

FAQ Document Segmentation. This task is based on the ai-general Usenet FAQ data set as we discussed before. We treat the first 6 files as the training set and the seventh file as the test set. The input window contains only the features corresponding to a single line in the file (window half-width of 0). Unlike in the previous data sets, instance weighting is no longer the best missing values method, as shown in Figure 4d. Instead, imputation performs very well for various missing value rates. Table 7d shows that imputation is statistically the best missing values method. For missing rates of 10% and 40%, it is statistically better than the other three methods. For a missing rate of 5%, it does as well as instance weighting and surrogate splitting. For a missing rate of 20%, it does as well as surrogate splitting and indicator features.

Analysis and Discussion. The four missing values methods are based on different assumptions about the input data. Imputation assumes that the most frequent value of a feature is the least informative and therefore presents the lowest risk of introducing errors into the learning process. Missing values are injected prior to converting the input features to binary. Hence, in the protein data set, missing values are introduced by choosing an amino acid residue position in the observa-

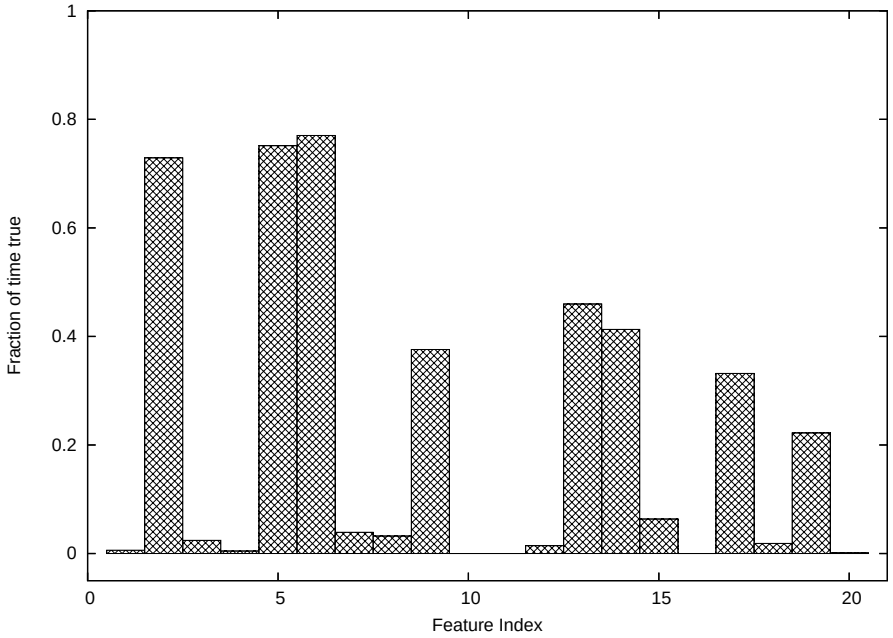

Figure 5: Fraction of the time that each FAQ feature is true (versus false). Features 1, 3, 4, 7, 8, 10, 11, 12, 16, 18, and 20 are rarely true.

tion sequence and setting all 20 boolean indicator features that represent that position to missing. Similarly, in the NETtalk and hyphenation problems, a letter is made to be missing by setting all 26 indicator features for that letter to missing. Similarly, imputation is computed at the amino acid or letter level, not at the level of boolean features. However, in the Usenet FAQ data set, since the binary features are not exclusive, imputation is computed at the level of boolean features. In the case of protein sequences, imputation will replace missing values with the most frequently-occurring amino acid, which is alanine, code 'A'. Alanine tends to form alpha helices, so this may cause the learning algorithms to over-predict the helix class, which may explain why imputation performed worst on the protein data set. In the case of English words, the most common letter is 'E', and it does not carry much information either about pronunciation or about hyphenation, so this may explain why imputation worked well in the NETtalk and hyphenation problems. Finally, in the ai-general FAQ data set, most of the features exhibit a highly skewed distribution, so that one feature value is much more common than another, as shown in Figure 5. Hence, in most cases, imputation with the most common feature value will supply the correct missing value. This may be why it worked best on that data set.

The indicator feature approach is based on the assumption that the presence or absence of a feature is meaningful (e.g., in medicine, a feature could be missing because a physician explicitly chose not to measure it). Because features were marked as missing completely at random, this is not true, so the indicator feature carries no positive information about the class label. However, in cases where imputation causes problems, the indicator feature approach may help prevent those problems by being more neutral. The learning algorithm can learn that if the indicator feature is set, then the actual feature value should be ignored. This may explain why the indicator feature method works slightly better in most cases than the imputation method.

The surrogate splitting method assumes that the input features are correlated with one another, so that if one feature is missing, its value can be computed from another feature. The protein, NETtalk, and hyphenation data sets have a single input feature for each amino acid or letter. Hence, if this input feature is missing, then there is no information about that position in the sequence. The only exception to this would be if there were strong correlations between successive amino acids or letters. However, such strong correlations do not exist much either in protein sequences or in English, with the possible exception of the letter 'q', which is always followed by 'u'. Note that the converse is not true: 'u' is not always preceded by 'q'. Based on these considerations, we would not expect surrogate splitting to work well in these domains, and it does not.

In the FAQ data set, each line is described by 20 features computed from the words in that line. In the experiment, each of these 20 features could be independently marked as missing, which is a bit unrealistic, since presumably the real missing values would involve some loss or corruption of the words making up the line, and this would affect multiple features. The 20 features do have some redundancy, so we would expect that surrogate splitting should work well, and it does for 5% and 20% missing rates.

The instance weighting method assumes that the feature values are missing at random and that the other features provide no redundant information, so the most sensible thing to do is to marginalize away the uncertainty about the missing values. Our experiments show that this is a very good strategy in all cases except for the FAQ data set, where the features are somewhat redundant.

8. Conclusions

In this paper, we presented TREECRF, a novel method for training conditional random fields based on gradient tree boosting. TREECRF has the ability to construct very complex feature conjunctions from basic features and scales much better than methods based on iterative scaling and simple gradient descent. It appears to match the L-BFGS algorithm implemented in MALLET, which also gives dramatic speedups when there are many potential features. In our experiments, TREECRF is as accurate as MALLET on four data sets, more accurate on one data set and less accurate on one data set. Its feature induction method is faster than that of MALLET for problems with a large number of features. But its forward-backward implementation is slower than that of MALLET for really long sequences. In addition, TREECRF is easier to implement and tune. It introduces only one tunable parameter (either the maximum number of leaves permitted in each regression tree or the regularization constant), whereas MALLET has many more parameters to consider. It is easier for the TREECRF to find the optimal stopping point to avoid overfitting, since its performance improves smoothly, while that of MALLET fluctuates wildly. Combining the benefit of these two methods will be a promising direction to pursue.

TREECRF also provides us with extra ability to handle missing data with instance weighting and surrogate splitting methods, which are not available in MALLET and other CRF training algorithms. The experiments suggest that when the feature values are missing at random, the instance weighting approach works very well. In the one domain where instance weighting did not work well, imputation was the best method. The indicator feature method was also very robust. The method of surrogate splitting was the most expensive method to run and the least accurate. Hence, we do not recommend using surrogate splits with conditional random fields. The good performance of the indicator features and imputation methods is encouraging, because these methods can be applied with all known methods for sequential supervised learning, not only with gradient tree

boosting. Since there is no one best method for handling missing values, as with many other aspects of machine learning, preliminary experiments on subsets of the training data are required to select the most appropriate method.

Abstract

We replaced the conditional probability tables of Bayesian network nodes whose parents have high cardinality with a multilevel empirical hierarchical Bayesian model called hierarchical pattern Bayes (HPB).[1] The resulting Bayesian networks achieved significant performance improvements over Bayesian networks with the same structure and traditional conditional probability tables, over Bayesian networks with simpler structures like naïve Bayes and tree augmented naïve Bayes, over Bayesian networks where traditional conditional probability tables were substituted by noisy-OR gates, default tables, decision trees and decision graphs and over Bayesian networks constructed after a cardinality reduction preprocessing phase using the agglomerative information bottleneck method. Our main tests took place in important fraud detection domains, which are characterized by the presence of high cardinality attributes and by the existence of relevant interactions among them. Other tests, over UCI data sets, show that HPB may have a quite wide applicability.

Keywords: probabilistic reasoning, Bayesian networks, smoothing, hierarchical Bayes, empirical Bayes

1. Introduction

In most countries, imported goods must be declared by the importer to belong to one of large set of classes (customs codes). It is important that each good is correctly classified, because each of the customs codes implies not only different customs duties but also different administrative, sanitary, and safety requirements. The original goal of this work was to develop a tool that, considering four explanatory attributes: *declared custom code* (DCC), *importer* (IMP), *country of production* (CP) and *entry point in the receiving country* (EPR), will estimate, for each new example, the probability that it involves a misclassification. Such estimates will be used later by a larger system that allocates human resources for different types of anti-fraud operations.

Our main study data set contains 682226 examples of correct classification (which we will call negative examples) and 6460 examples of misclassification (positive examples). In this data set, the

1. This paper is a an extended version of a conference paper (Jambeiro Filho and Wainer, 2007).

first attribute assumes 7608 distinct values, the second, 18846 values, the third, 161 values, and the fourth 80 values. Thus, the domain is characterized by the presence of high cardinality attributes.

The data set is imbalanced, with only 0.93% of positive examples. This is usually handled with different resampling strategies (Chawla et al., 2002). However, resampling requires retraining the classifiers for each different assignment of costs for *false positives* and *false negatives*. In our context, such costs are not known in advance (priorities change according to other anti-fraud demands) and they vary from example to example (not all false negatives cost the same). These facts make the use of resampling techniques unattractive.

On the other hand, if we can produce reliable probability estimates directly from the original data set, the work of the human resource allocation system becomes much easier. It can at any time, define a selection rate that matches the available human resources for the specific task of detecting wrong customs codes considering all other anti-fraud demands at the moment. If the selection rate is, for example, 10%, the examples to be verified will naturally be the 10% that are most likely to involve a misclassification according to the calculated probability estimates. The allocation system may also combine the probability estimates with costs that may vary from example to example without any retraining. Thus, we decided to concentrate on Bayesian techniques.

Domain specialists claim that there are combinations of attribute values (some involving all of them) that make the probability of an instance being positive significantly higher then it could be expected looking at each value separately. They call such combinations *critical patterns*. To benefit from critical patterns we would like to use the Bayesian network (BN) (Pearl, 1988) presented in Figure 1, where all explanatory attributes are parents of the class attribute. We call a structure of this kind a *direct BN structure*.

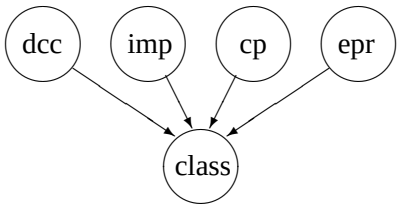

Figure 1: Direct BN structure for misclassification detection

In a BN, considering that x_{ji} is a possible value for node X_j and π_{jk} is a complete combination of values for Π_j, the set of parents of node X_j, the vector, θ_{jk}, such that $\theta_{jki} = P(x_{ji}|\pi_{jk})$ is stored in a table that is called conditional probability table (CPT) of node X_j and is assessed from the frequencies of the values of X_j among the training instances where $\Pi_j = \pi_{jk}$. The distributions of X_j given any two different combinations of values for its parents are assumed to be independent and a Dirichlet prior probability distribution for θ_{jk} is usually adopted. Applying Bayes rule and integrating over all possible values for θ_{jk} it is found that

$$E(\theta_{jki}) = P(x_{ji}|\pi_{jk}) = \frac{N_{jki} + \alpha_{jki}}{N_{jk} + \alpha_{jk}}, \tag{1}$$

where N_{jki} is the number of simultaneous observations of x_{ji} and π_{jk} in the training set, $N_{jk} = \sum_{\forall i} N_{jki}$, α_{jki} is the value of one of the parameters of the Dirichlet prior probability distribution and $\alpha_{jk} = \sum_{\forall i} \alpha_{jki}$, the equivalent sample size of the prior probability distribution.

The Dirichlet prior probability distribution is usually assumed to be noninformative, thus

$$P(x_{ji}|\pi_{jk}) = \frac{N_{jki} + \lambda}{N_{jk} + \lambda M_j}, \tag{2}$$

where all parameters of the Dirichlet distribution are equal to a small smoothing constant λ, and M_j is the number of possible values for node X_j. We call this *direct estimation* (DE). DE is sometimes called Lidstone estimate and if $\lambda = 1$ it is called Laplace estimate.

The conditional probability table of the class node of a BN with the structure in Figure 1 contains more than 1.8×10^{12} parameters. It is clear that for rarely seen combinations of attributes the choice of such structure and Equation (2) tends to produce unreliable probabilities whose calculation is dominated by the noninformative prior probability distribution.

Instead of the structure in Figure 1, we can choose a network structure that does not lead to too large tables. This can be achieved limiting the number of parents for a network node. Naïve Bayes(Duda and Hart, 1973) is an extreme example where the maximum number of parents is limited to one (the class node is the only parent of any other node). Tree augmented naïve Bayes (TAN) (Friedman et al., 1997) adds a tree to the structure of naïve Bayes connecting the explanatory attributes and limits the maximum number of parent nodes to two. However, limiting the maximum number of parents also limits the representational power of the Bayesian network(Boullé, 2005) and, thus, limits our ability to capture interactions among attributes and benefit from critical patterns. Therefore, we would prefer not to do it.

Since the high cardinality of our attributes is creating trouble, it is a reasonable idea to preprocess the data, reducing the cardinality of the attributes. We can use, for example, the agglomerative information bottleneck (AIBN) method (Slonim and Tishby, 1999) for this task. However, the process of reducing the cardinality of one attribute is blind with respect to the others (except for the class attribute) (Slonim and Tishby, 1999; Boullé, 2005; Micci-Barreca, 2001), and thus it is unlikely that cardinality reduction will result in any significant improvement in the ability to capture critical patterns, which always depend on more than one attribute.

When the number of probabilities to be estimated is too large if compared to the size of the training set and we cannot fill the traditional conditional probability tables satisfactorily, Pearl (1988) recommends the adoption of a model that resorts to causal independence assumptions like the noisy-OR gate. Using noisy-OR, the number of parameters required to represent the conditional probability distribution (CPD) of a node given its parents, instead of being proportional to the product of the cardinality of all parents attributes, becomes proportional to the sum of their cardinality. However, causal independence assumptions are incompatible with our goal of capturing critical patterns.

It is possible to use more flexible representations for the conditional probability distributions of a node given its parents, like default tables (DFs) (Friedman and Goldszmidt, 1996b), decision trees (DTs) (Friedman and Goldszmidt, 1996b) and decision graphs (DGs) (Chickering et al., 1997). According to Friedman and Goldszmidt (1996b), using such representations together with adequate learning procedures induces models that better emulate the real complexity of the interactions present in the data and the resulting network structures tend to be more complex (in terms of arcs) but require fewer parameters. Fewer parameters may result in more reliable probability estimates.

Using traditional CPTs, we assume that the probability distributions for a node given any two combinations of values for the parents are independent. If some of these distributions are actually identical, DTs, DFs and DGs, can reflect it and represent the CPD using a variable number of parameters that is only proportional to the number of actually different distributions.

On the other hand, using DTs, DFs or DGs to represent the conditional probability distributions of a node given its parents, we assume that the probability distribution of the node given two different combinations of values for the parents may be either identical or completely independent. It is possible that neither of the two assumptions hold.

Gelman et al. (2003) assert that modeling hierarchical data nonhierarchically leads to poor results. With few parameters, nonhierarchical models cannot fit the data accurately. With many parameters they fit the existing data well but lead to inferior predictions for new data. In other words they overfit the training set. In contrast, hierarchical models can fit the data well without overfitting. They can reflect similarities among distributions without assuming equality.

The slight modification in Equation (2) used by Friedman et al. (1997) in the definition of a smoothing schema for TAN shows that we can treat the data that is used to estimate a CPT as hierarchical:

$$P(x_{ji}|\pi_{jk}) = \frac{N_{jki} + S \cdot P(x_{ji})}{N_{jk} + S},$$

where S is a constant that defines the equivalent sample size of the prior probability distribution. We call this *almost direct estimation* (ADE). ADE is the consequence of adopting an informative Dirichlet prior probability distribution where $\alpha_{jki} \propto P(x_{ji})$, where $P(x_{ji})$ is the unconditional probability of x_{ji} (for the meaning of α_{jki}, see Equation 1). ADE uses the probability distribution assessed in a wider population (the whole training set) to build an informative prior probability distribution for a narrower population and so it has a hierarchical nature. In the sense of Gelman et al. (2003) ADE is an empirical hierarchical Bayesian model, not a full hierarchical Bayesian model. Probability estimation methods which use such empirical models are popularly known as empirical Bayes (EB) methods. ADE is also considered a m-estimation method (Cestnik, 1990; Zadrozny and Elkan, 2001).

We believe that ADE can get closer to the true probability distribution, but not that its discrimination power can be significantly better than DE's. It is a linear combination of two factors N_{jki}/N_{jk} and $P(x_{ji})$. The second factor is closer to the true probability distribution than its constant counterpart in *direct estimation* but it is still equal for any combination of values of Π_j and thus has no discrimination power.

ADE jumps from a very specific population (the set of training examples where $\Pi_j = \pi_{jk}$) to a very general population (the whole training set). In contrast, we present a model, that we call hierarchical pattern Bayes (HPB), which moves slowly from smaller populations to larger ones benefiting from the discrimination power available at each level.

2. Hierarchical Pattern Bayes

HPB is an empirical Bayes method that generalizes ADE into an aggressive multilevel smoothing strategy. Its name comes from the fact that it explores an hierarchy of patterns intensively, though it is not a full hierarchical Bayesian model.

Given a pattern W and a training set, D, of pairs (U_t, C_t), where U_t is the t^{th} instance in D and C_t is the class label of U_t, HPB calculates $P(C_r|W)$ for any class C_r, where a pattern is as defined below:

Definition 1 *A pattern is a set of pairs of the form* $(Attribute = Value)$*, where any attribute can appear at most once.*

An attribute that is not in the set is said to be undefined or missing. Before presenting HPB details we need a few more definitions:

Definition 2 *An instance* U *is a pair* $(iid, Pat(U))$ *where* $Pat(U)$ *is a pattern and iid is an identifier that makes each instance unique.*

Definition 3 *A pattern* Y *is more generic than a pattern* W *if and only if* $Y \subseteq W$

If Y is more generic than W, we say that W satisfies Y. If an instance U_t is such that $W = Pat(U_t)$ and W satisfies Y, we also say that U_t satisfies Y. It is worth noting that, if $Y \subseteq W$ then $S_Y \supseteq S_W$ where S_Y is the set of instances satisfying Y and S_W is the set of instances satisfying W.

Definition 4 *The level of a pattern* W*,* $level(W)$*, is the number of attributes defined in* W*.*

Definition 5 $g(W)$ *is the set of all patterns more generic than a pattern* W *whose elements have level equal to* $level(W) - 1$*.*

For example, if W is $\{A = a, B = b, C = c\}$, $g(W)$ is

$$\{\ \{B = b, C = c\}, \{A = a, C = c\}, \{A = a, B = b\}\ \}.$$

2.1 The Hierarchical Model

HPB calculates the posterior probability $P(C_r|W)$, using a strategy that is similar to almost direct estimation, but the prior probabilities are considered to be given by $P(C_r|g(W))$.

The parameters of the Dirichlet prior probability distribution used by HPB are given by $\alpha_r = S \cdot P(C_r|g(W))$, where S is a smoothing coefficient. Consequently,

$$P(C_r|W) = \frac{N_{wr} + S \cdot P(C_r|g(W))}{N_w + S}, \tag{3}$$

where N_w is the number of instances in the training set satisfying the pattern W and N_{wr} is the number of instances in the training set satisfying the pattern W whose class label is C_r.

Given Equation (3), the problem becomes to calculate $P(C_r|g(W))$. Our basic idea is to write $P(C_r|g(W))$ as a function of the various $P(C_r|W_j)$ where the W_j are patterns belonging to $g(W)$ and calculate each $P(C_r|W_j)$ recursively, using Equation (3).

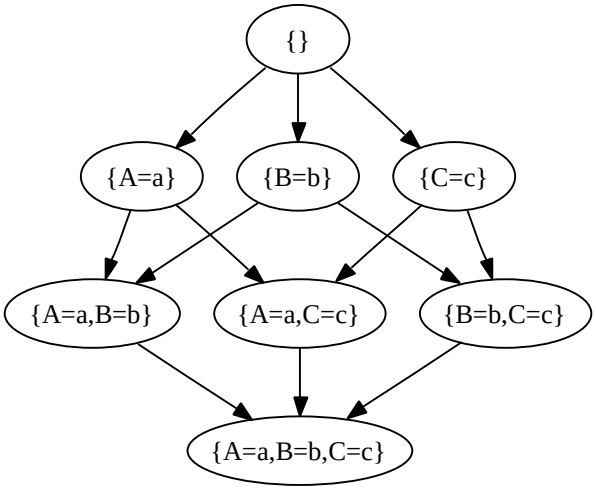

Figure 2: Example of HPB structure

Figure 2 shows a pattern hierarchy,[2] where A, B and C are the attributes. Each pattern is represented by a node and the set of parents of a pattern W in the DAG presented in Figure 2 is $g(W)$. HPB combines the posterior predictive probability distributions, $P(C_r|W_j)$, of the class given each parent, W_j, of a pattern W, to build the prior predictive probability distribution for the class given W, $P(C_r|g(W))$.

The first step to write $P(C_r|g(W))$ as a function of all the $P(C_r|W_j)$ is to apply Bayes theorem:

$$\begin{aligned} P(C_r|g(W)) &= \frac{P(g(W)|C_r)P(C_r)}{P(g(W))} \\ &\propto P(W_1, W_2, \ldots, W_L|C_r)P(C_r), \end{aligned}$$

where W_1,W_2,...,W_L are the elements of $g(W)$. Then we approximate the joint probability $P(W_1, W_2, \ldots, W_L|C_r)$ by the product of the marginal probabilities:

$$P'(C_r|g(W)) \propto P(C_r)\prod_{j=1}^{L} P(W_j|C_r), \tag{4}$$

Note that we do not assume any kind of independence when using Equation (3) to calculate posterior predictive probabilities, but we do assume independence in a naïve Bayes fashion when calculating the prior probabilities using Equation (4). Naïve Bayes is known to perform well with regard to classification error (Domingos and Pazzani, 1997) and ranking (Zhang and Su, 2004), even when its independence suppositions are violated. Assuming independence among overlapping patterns, as Equation (4) does, is equivalent to assuming independence among attributes which are known to be highly correlated, what may appear to be strange. However, naïve Bayes has been reported to perform better when attributes are highly correlated than when correlation is moderate (Rish et al., 2001).

2. Note that the DAG in Figure 2 is not a Bayesian network and the dependencies among its nodes do not follow BN conventions.

On the other hand, naïve Bayes is known to produce extreme probabilities (Domingos and Pazzani, 1997), thus we apply a calibration mechanism (Bennett, 2000; Zadrozny, 2001), which is expressed in Equation (5):

$$P''(C_r|g(W)) = (1-A)\cdot P'(C_r|g(W)) + A\cdot P(C_r), \tag{5}$$

where $A = B/(1+B)$ and B is a calibration coefficient. We discuss this calibration mechanism in Section 2.2. $P''(C_r|g(W))$ is our best estimate for $P(C_r|g(W))$ and it is used in Equation (3) as if it were the true value of $P(C_r|g(W))$.

Given Equations (4) and (5) we need to calculate $P(W_j|C_r)$. Applying Bayes theorem again,

$$P(W_j|C_r) = \frac{P(C_r|W_j)P(W_j)}{P(C_r)}. \tag{6}$$

We can estimate $P(C_r)$ is using the maximum likelihood approach: $P(C_r) = N_r/N$, where N_r is the number of examples in the training set whose class label is C_r, and N is the total number of examples in the training set. If the class variable is binary, this strategy works well, but if the class node has high cardinality it is better to employ a noninformative prior probability distribution:

$$P(C_r) = \frac{N_r + S^{NI}/M_c}{N + S^{NI}},$$

where M_c is the number of classes and S^{NI} is the smoothing constant that defines the equivalent sample size of the noninformative distribution.

When we substitute $P(W_j|C_r)$ by the right side of Equation (6) into Equation (4) we are able to clear out the factor $P(W_j)$ because it is identical for all classes:

$$\begin{aligned} P'(C_r|g(W)) &\propto P(C_r)\prod_{j=1}^{L} P(W_j|C_r) \\ &\propto P(C_r)\prod_{j=1}^{L} \frac{P(C_r|W_j)P(W_j)}{P(C_r)} \\ &\propto P(C_r)\prod_{j=1}^{L} \frac{P(C_r|W_j)}{P(C_r)}, \end{aligned}$$

so we do not need to worry about it.

Since W_j is a pattern, the estimation of $P(C_r|W_j)$ can be done recursively, using Equation (3). The recursion ends when $g(W)$ contains only the empty pattern. In this case $P(C_r|g(W)) = P(C_r|\{\{\}\}) = P(C_r)$.

2.2 Calibration Mechanism

Naïve Bayes is known to perform well in what regards to classification error (Domingos and Pazzani, 1997) and ranking (Zhang and Su, 2004), even when its independence suppositions are violated. However, naïve Bayes is also known to produce unbalanced probability estimates that are typically too "extreme" in the sense that they are too close to zero or too close to one.

The reason why naïve Bayes produces extreme probabilities is that it treats each attribute value in a pattern as if it were new information. Since attributes are not really independent, a new attribute

value is not 100% new information, treating it as if it were completely new reinforces the previous beliefs of naïve Bayes towards either zero or one. This reuse of information is explained by Bennett (2000) in the context of text classification.

In order to obtain better posterior probability distributions, calibration mechanisms which try to compensate the overly confident predictions of naïve Bayes have been proposed (Bennett, 2000; Zadrozny, 2001).

Naïve Bayes assumes that attributes are independent given the class. Equation (4) assumes that some aggregations of attributes are independent given the class. Since many of these aggregations have attributes in common, the use of Equation (4) is equivalent to assuming independence among attributes which are known to be highly correlated. Naïve Bayes has been reported to perform better when attributes are highly correlated than when correlation is moderate (Rish et al., 2001), but it is quite obvious that we are reusing a lot of information and that we can expect very extreme probability estimates. Therefore, we need to use a calibration mechanism.

Our mechanism is simpler than the ones presented by Bennett (2000) and by Zadrozny and Elkan (2002) and is unsupervised. This makes it very fast and easy to employ within each step of HPB.

We just made a linear combination of the result of Equation (4) and $P(C_r)$. We did that considering that if the estimates are more extreme than the true probabilities both near zero and near one they must match the true probabilities at some point in the middle. We believe that this point is somewhere near $P(C_r)$.

Extreme probabilities are produced when evidence in favor or against a class is reused. $P(C_r)$ is a point where either there is no evidence or there is evidence in conflicting directions in such way that the effect is null. Thus, such a point cannot be considered extreme. Our calibration mechanism attenuates the probabilities when they are extreme without affecting them in the point $P(C_r)$, where, we believe, they are already correct.

In Figure 3 we show the effect of the calibration mechanism.

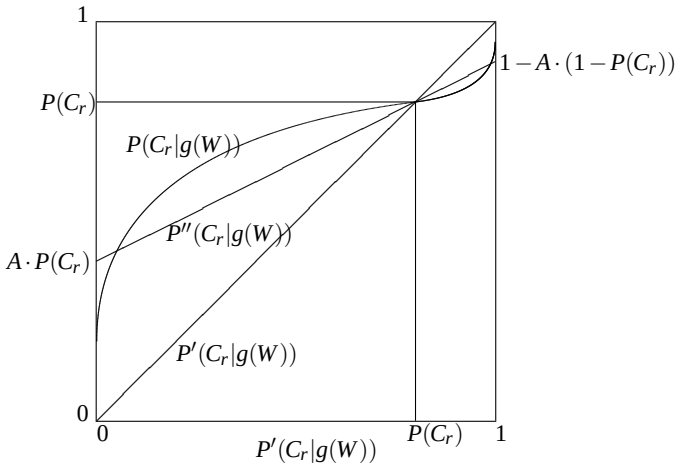

Figure 3: Effect of linear calibration over extreme probabilities

In the horizontal axis the non calibrated estimation $P'(C_r|g(W))$ is represented. The curved line represents the true probability, $P(C_r|g(W))$, as a function of $P'(C_r|g(W))$. Since all informa-

tion about $P'(C_r|g(W))$ comes from a finite data set such function never hits one or zero. When $P'(C_r|g(W))$ is near zero, $P(C_r|g(W))$ is not as near. The same happens when $P(C_r|g(W))$ is near one.

The 45^o straight line represents what would be our final estimation if we did not do any calibration, that is, $P'(C_r|g(W))$ itself. The other oblique straight line is the result of our calibration mechanism, $P''(C_r|g(W))$. It is still a linear approximation but it is much closer from $P(C_r|g(W))$ than $P'(C_r|g(W))$.

2.3 Analyzing HPB

HPB tries to explore the training set as much as possible. If there are L attributes, HPB starts its work capturing the influence of patterns of level L. At this level, all interactions among attributes may be captured as long as there are enough training instances. However, no training set is so large that we can expect that all level L patterns are well represented. Actually, if there are high cardinality attributes, it is more likely that only a minority of them are represented well. For this minority, level L dominates Equation (3) and prior probabilities are not very important. On the other hand, prior probabilities are critical for the vast majority of cases where level L patterns are not well represented in the training set. Then, HPB moves to level $L-1$. At this level, a greater fraction of patterns are well represented and it is still possible to capture the majority of attribute interactions. Many patterns of level $L-1$, however, are still not well represented and it is necessary to resort to lower level patterns. The lower are the level of the patterns the weaker is HPB's capacity to capture interactions, but less common are problems with small sample sizes.

Equation (3) combines the influence of different level patterns in a way that the most specific patterns always dominate if they are well represented. Equation (4) combines patterns in an naïve Bayes fashion, in spite of the fact that they are highly correlated. This results in extreme probability estimates that are attenuated by the calibration mechanism in Equation (5).

Since the population of instances (both in the training and in the test set) satisfying a pattern W is a subpopulation of the population of instances satisfying $W_j, \forall W_j \in g(W)$, we can say that HPB uses results previously assessed in a wider population to build informative prior probability distributions for narrower populations. Therefore, HPB is a an empirical Bayesian model, not a full hierarchical Bayesian model.

In the work of Gelman et al. (2003); Andreassen et al. (2003); Stewart et al. (2003) full hierarchical Bayesian models are presented, but they have only two levels. HPB deals with a multi level hierarchy recursively and also handles the fact that each subpopulation is contained by several overlapping superpopulations and not only by one superpopulation. These facts make it more difficult to build a full model that allows the calculation of all involved probability distributions at once considering all available evidence.

2.4 HPB as a Replacement for conditional probability tables

HPB's original goal was to be a stand alone classifier well suited a to particular domain, but it is much more relevant as a replacement for conditional probability tables.

HPB's use of space and time is exponential in the number of attributes. Thus, in domains with many attributes, it is not possible to use HPB directly. However, since the number of parents of any node in a Bayesian network is usually small because the size of a CPT is exponential in the number

of parent nodes, HPB may be used as a replacement for Bayesian networks conditional probability tables in almost any domain.

Space and time are frequently not the limiting factor for the number of parents of a BN node. More parents usually mean less reliable probabilities (Keogh and Pazzani, 1999) and it is not uncommon to limit their number to two (Friedman and Goldszmidt, 1996a; Keogh and Pazzani, 1999; Hamine and Helman, 2004). So, if HPB produces better probability estimates, it will actually allow for the addition of more parent nodes.

If the BN structure is given, the use of HPB as a replacement of the CPT of any node, X_j, is straightforward. To calculate, $P(x_{jk}|\pi_{ji})$ it is just a matter of acting as if $C_r = x_{jk}$ and $W = \pi_{ji}$, ignoring all other attributes and using HPB to calculate $P(C_r|W)$.

If the BN structure needs to be learned from data, it is necessary to choose a scoring metric that can work together with HPB in the task of choosing among the possible BN structures. We propose the use of the log-likelihood evaluated using leave-one-out cross validation:

$$LLLOO = \sum_t \log P(U_t|S, D - \{U_t\}) = \sum_t \sum_j \log P(x_{jt}|\pi_{jt}^S, D - \{U_t\}),$$

where D is the training set, U_t is the t^{th} instance of D, S is the BN structure being scored, x_{jt} is the value assumed by attribute X_j in the instance U_t, π_{jt}^S is the set of values assumed, in U_t, by the parents of X_j in S and $P(x_{jt}|\pi_{jt}^S, D - \{U_t\})$ is the value calculated by HPB for $P(x_{jt}|\pi_{jt}^S)$ using $D - \{U_t\}$ as the training set.

HPB uses the training set only through the frequencies N_{wr} and N_w in Equation (3). For fast computation of *LLLOO*, we can assess these frequencies in D and rely on the relations:

$$N_w^{D-\{U_t\}} = \begin{cases} N_w^D - 1 & \text{if } W \subset \pi_{jt}^S; \\ N_w^D & \text{otherwise;} \end{cases}$$

$$N_{wr}^{D-\{U_t\}} = \begin{cases} N_{wr}^D - 1 & \text{if } W \subset \pi_{jt}^S \wedge x_{jr} = x_{jt}; \\ N_{wr}^D & \text{otherwise.} \end{cases}$$

2.5 Selecting HPB Coefficients

Equations (3) and (5) require respectively the specifications of coefficients S and B. In the classification of a single instance, these equations are applied by HPB in the calculation of $P(C_r|W)$ for several different patterns, W. The optimal values of S and B can be different for each pattern.

In the case of the B coefficients, we use a heuristic motivated by the fact that the level of any pattern in $g(W)$ is $level(W) - 1$. The higher such level is, the more attributes in common the aggregations have, the more extreme probability estimates are and the stronger must be the effect of the calibration mechanism. Thus, we made the coefficient B in Equation (5) equal to $b(level(W) - 1)$, where b is an experimental constant.

In the case of the S coefficients, we can employ a greedy optimization approach, or, for faster training, simply define S to be a constant.

The optimization process we propose uses the area under the hit curve(Zhu, 2004) as a scoring metric. The hit curve of a classifier C over a data set D is a function, $h_{C,D}(r)$, where r is a selection rate (a real number in the interval $[0,1]$). The classifier is used to assign to each example, U_t in D the probability that U_t is a positive instance. The value of $h_{C,D}(r)$ is the number of positive instances among the $r \cdot |D|$ instances that were considered the most likely to be positive by the classifier.

We employed hit curves, instead of the more popular *Receiver Operating Characteristic Curves* (ROC) (Egan, 1975), because they match the interests of the user of a fraud detection system directly. Given a selection rate that reflects the available human resources, he/she wants to maximize the number of detected frauds.

Since the concept of a positive instance only makes sense for binary class variables, the optimization process only works for binary class problems.

When applicable, the process starts from the most general pattern family and moves toward the more specific ones, where a pattern family is the set containing all patterns that define exactly the same attributes (possibly with different values).

Assuming that the S coefficients have already been fixed for all pattern families that are more generic than a family F, there is a single S coefficient that needs to be specified to allow the use of Equation (3) to calculate $P(C_r|W)$, where W is any pattern belonging to F.

This coefficient is selected in order to maximize the area under the hit curve that is induced when, using leave-one-out cross validation, we calculate $P(C_0|W)$ for all training patterns, W, in F, where C_0 is the class that is defined to be the *positive* class.

Calculating $P(C_0|W)$ using leave-one-out cross validation, means, as explained in Section 2.4, simply subtracting one from some frequencies used by Equation (3).

2.6 Computational Complexity

The training phase of the version of HPB where constant smoothing coefficients are employed consists solely in assessing the frequencies used by Equation (3). It is easy to see that each instance, U, such that $W = Pat(U)$, in the training set, D, requires that exactly 2^L frequencies are incremented, where L is the number of parent attributes. Thus, HPB training time is

$$O(N_{tr} \cdot 2^L),$$

where N_{tr} in the number of training instances.

The test (or application) phase of HPB requires that, for each test instance, U, such that $W = Pat(U)$, the probability distribution for the class is computed given 2^L patterns. Since each computation is proportional to the number of classes, HPB test time is

$$O(N_{ts} \cdot M_c \cdot 2^L),$$

where N_{ts} in the number of test instances and M_c is the number of classes.

Note that, in both cases, HPB running time is exponential in the number of parent attributes, linear in the number of instances and independent of the cardinality of the parent attributes.

When the S coefficients are chosen by the optimization process described in Section 2.5, HPB test time does not change, but training requires that, for each pattern family, several S candidates are tested. There are 2^L pattern families and each test requires applying HPB to all training instances. Thus, HPB training time becomes

$$O(N_{tr} \cdot 2^L + N_{cand} \cdot 2^L \cdot N_{tr} \cdot M_c \cdot 2^L) = O(N_{cand} \cdot N_{tr} \cdot M_c \cdot 2^{2L}),$$

where N_{cand} is the number of candidates considered to choose a single S coefficient, which depends on the search algorithm.

HPB needs to save, for each training pattern, less than 2^L frequencies. Thus HPB use of space is

$$O(N_{tr} \cdot 2^L).$$

3. Experimental Results

We evaluated HPB in three different contexts:

- *misclassification detection*: HPB's motivation problem, an important classification problem for Brazil's Federal Revenue, where four high cardinality attributes which are supposed to have relevant interactions are used to predict a binary class attribute;
- *prediction of joint behavior*: another problem originated from Brazil's Federal Revenue where two high cardinality attributes are used to predict a third high cardinality attribute;
- *HPB as a general replacement for CPTs of Bayesian Networks*: tests over several UCI data sets comparing HPB to CPTs and other representations of the conditional probability distribution of a BN node given its parents.

In all cases the classification methods were tested using the Weka Experimenter tool (Witten and Frank, 1999) with five-fold cross validation. The machine used in the tests was an Intel Core 2 Duo 6300 with 2 GB of primary memory.

3.1 Misclassification Detection

This is the motivation problem for HPB. Considering four explanatory attributes: *declared custom code* (DCC), *importer* (IMP), *country of production* (CP) and *entry point in the receiving country* (EPR), we need to estimate, for each new example, the probability that it involves a misclassification, that is, the probability that the DCC is not the correct custom code for the goods being traded.

Our data set has 682226 examples of correct classification (which we will call negative examples) and 6460 examples of misclassification (positive examples). In this data set, the first attribute assumed 7608 distinct values, the second, 18846 values, the third, 161 values, and the fourth 80 values. There are no missing values.

We compared classifiers built using the following methods:

- *HPB-OPT*: BN with the *direct BN structure* (Figure 1), where the CPT of the class node was replaced by HPB with selection of *S* coefficients by the optimization process described in Section 2.5.
- *HPB*: BN with the *direct BN structure* (Figure 1), where the CPT of the class node was replaced by HPB with fixed *S* coefficients;
- *NB*: naïve Bayes;
- *Noisy-OR*: BN with the *direct BN structure* (Figure 1) using a noisy-OR gate instead of a CPT;
- *TAN*: Smoothed version of tree augmented naïve Bayes as described by Friedman et al. (1997) ;
- *ADE*: *almost direct estimation*. BN with the *direct BN structure*, traditional CPTs and the smoothing schema described by Friedman et al. (1997);
- *DE*: *direct estimation*. BN with the *direct BN structure* (Figure 1) and traditional CPTs;
- *DG*: Decision Graph constructed following Chickering et al. (1997). In this larger experiment, deviating from what was proposed by Chickering et al. (1997), we did not use DGs within BNs, but as standalone classification methods.

- *BN-HC-DT*: BN with decision trees learned using hill climbing (HC) and MDL as the scoring metric as described by Friedman and Goldszmidt (1996b);
- *BN-HC-DF*: BN with default tables learned using HC and MDL as described by Friedman and Goldszmidt (1996b);
- *PRIOR*: Trivial classifier that assigns the prior probability to every instance.

We were unable to build BNs with DGs replacing CPTs following Chickering et al. (1997) because it took too long (more than one day without completing a single fold). We found that the construction of a DG becomes very slow when the BN node in question has high cardinality and its parents also have high cardinality. High cardinality parents imply many possible split/merge operations to compare in each step of the learning algorithm and a high cardinality child implies that each comparison requires a lot of calculation.

In some experiments in the same domain, with BNs with DGs applied over smaller data sets, we found that in the global BN structures chosen by the search algorithm described by Chickering et al. (1997), all four explanatory attributes were parents of the class attribute. This means that if we had used a decision graph as a standalone classification method we would have had exactly the same results. Thus we concluded that it was worth to test a DG as a standalone classification method over our large data set. Since our class variable is binary the running time becomes acceptable.

We tried different parameterizations for each method and chose the parameter set that provided the best results in the five-fold cross-validation process, where best results mean best area under the hit curve up to 20% of selection rate. We ignored the area under the curve for selection rates above 20%, because all selection rates of interest are below this threshold.

Besides using the hit curve, we compared the probability distributions estimated by the models with the distribution actually found in the test set using two measures: root mean squared error (RMSE) and mean cross entropy (MCE):

$$RMSE = \sqrt{\frac{\sum_{t=1}^{N}\sum_{r=1}^{M}(P'(C_{rt}) - P(C_{rt}))^2}{MN}}, \quad MCE = \frac{\sum_{i=1}^{N}\sum_{t=1}^{M} -P(C_{rt})\log_2 P'(C_{rt})}{MN},$$

where N is the number of instances in the test set, M is the number of classes, $P'(C_{jt})$ is the estimated probability that the t^{th} instance belongs to class C_r and $P(C_{tr})$ is the true probability that t^{th} instance belongs to class C_r. $P(C_r)$ is always either 0 or 1.

Many of the methods tested require the specification of parameters and many of them are real constants. We used a common strategy to chose such constants:

1. Based on experience, decide on a search interval, $SI = [beg, end]$, within which we believe the ideal constant is;
2. Build a search enumeration SE containing all powers of 10, all halves of powers of 10 and quarters of powers of 10 within SI;
3. Try all constants in SE. If the method requires more than one constant try all possible combinations exhaustively;
4. If the optimal constant, C is in the middle of SE take C as the final constant;

5. If the optimal constant, C is one of the extreme values of SE expand SE adding one more value to it and try again. The value to be added is the real number that is the nearest to the current optimal value that was not in SE and is a power of 10, a half of a power 10 or a quarter of a power of 10.

By restricting ourselves to powers of 10, halves of powers of 10 and quarters of powers of 10 we try different orders of magnitude for the constants and avoid fine tuning them.

The smoothing coefficients employed by HPB-OPT are all automatically selected. The selection involves a leave-one-out cross validation that takes place within the current training set (the five-fold cross validation varies the current training set). The B coefficients are defined by the heuristic described in Section 2.5 and by the constant b. The choice of b was done starting with $SI = [0.5, 2.5]$. The value of S^{NI} was set to zero.

HPB requires the specification of the S constant, which is used directly and the b constant which defines the B coefficients through the heuristic in Section 2.5. The choice of b was done starting with $SI = [0.5, 2.5]$. To choose S we defined $s = S/NumClasses = S/2$ and chose s starting from $SI = [1.0, 10.0]$. The reason to introduce the constant s is just to follow the way Weka usually handles smoothing constants. Again, the value of S^{NI} was set to zero.

DGs have four parameters: the smoothing constant and three boolean parameters defining the activation state of each of the possible operations, which are complete splits, binary splits and merges. The smoothing constant was chosen starting from $SI = [0.01, 1.0]$. We always kept complete splits enabled and tried the variations resulted from enabling/disabling binary splits and merges exhaustively for each smoothing constant.

Noisy-OR and PRIOR have no parameters. The optimization of all other methods involves only the smoothing constant, which, in all cases, was chosen starting from $SI = [0.01, 2.5]$.

Below we report the optimal parameters for each method:

- *HPB-OPT*: $b = 1.0$;
- *HPB*: $s = 5.0$ and $b = 1.0$;
- *NB*: $s = 0.1$;
- *TAN*: $s = 0.25$;
- *ADE*: $s = 0.01$;
- *DE*: $s = 2.5$;
- *DG CBM*: $s = 0.05$, complete splits, binary splits and merges enabled;
- *BN-HC-DT*: $s = 0.01$;
- *BN-HC-DF*: $s = 0.025$;

In Figure 4, we show the hit curves produced by each classification method. We chose to represent the $Recall = N_{TruePositives}/N_{Positives}$, in the vertical axis, instead of the absolute number of hits, because this does not change the form of the curve and makes interpretation easier. We represented the selection rate in log scale to emphasize the beginning of the curves. In Table 2 we show the recall values for different selection rates.

In Table 1, we show the area under the hit curve (AUC), the area under the hit curve up to 20% of selection rate (AUC20), the root mean squared error (RMSE), the mean cross entropy (MCE),[3] the training time (TR) and the test time (TS) of each method. The presence of the symbol *!* before any result means that it is significantly worse than its counterpart in the first row of the table using a 95% confidence t-test. Since HPB is in the first row, we can see that HPB is significantly better than all other classifiers with regard to AUC, AUC20 and MCE. With regard to RMSE, HPB was not better than BN-HC-DT, BN-HC-DF and PRIOR.

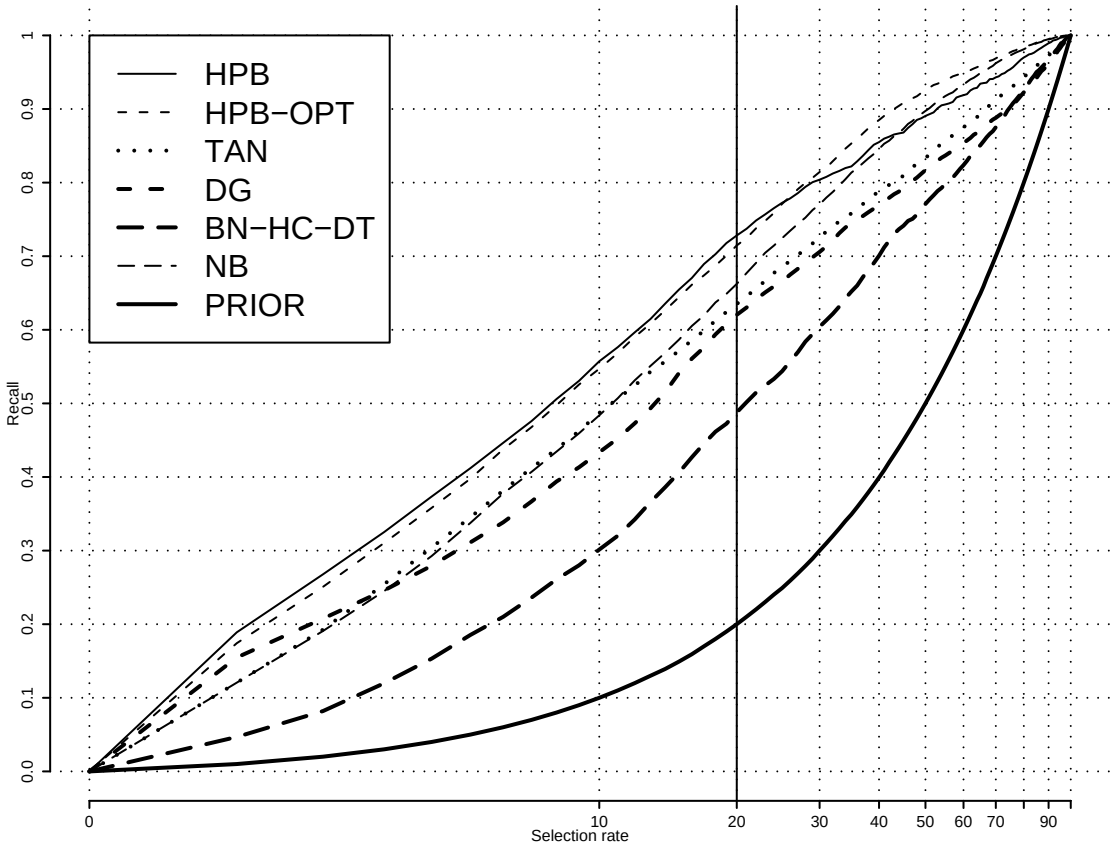

Figure 4: Misclassification detection - hit curves (to avoid pollution we only present curves related to a subset of the tested methods)

3. For better visualization of the RMSE values, MCE values and their deviations, all RMSE and MCE values presented in this paper were multiplied by 10^4.

Table 2: Misclassification detection - recall at different selection rates

The PRIOR method is very conservative, assigning the prior probability to every instance. In this data set, such strategy results in a good MCE and a good RMSE. On the other hand, the PRIOR method has absolutely no discrimination power, considering all instances to be equally likely to be positive. In Figure 4 and Table 2, we can see that this results in random selection, just checking that recall is always approximately equal to the selection rate.

BN-HC-DT and BN-HC-DF produced similar hit curves as can be seen in Table 2. In Figure 4 BN-HC-DT is the second worse method. The reason is that the construction of DTs and DFs presented by Friedman and Goldszmidt (1996b) turned out to be very conservative, tending to prefer simple structures: DFs with few rows and DTs with few splits. Observing the PRIOR method

results, it is not surprising that this conservative behavior results in a good MCE, a good RMSE and an unsatisfactory hit curve in comparison to other methods.

At a selection rate of 1%, ADE performs better than NB, noisy-OR and TAN, but for higher selection rates it is worse by a very significant margin. The reason is that critical patterns involving all attributes are decisive in the very beginning of the curves. ADE treats all attributes at once and thus can benefit from their presence, but soon ADE is forced to choose among test patterns for which there are no identical training patterns. At this point it starts to choose at random (in the average, 17% of the positive test instances are identical to at least one training instance).

Using Decision Graphs (with binary splits enabled), the most critical patterns were separated from the others and that resulted in a significant improvement in the beginning of the hit curve in comparison to methods like NB, noisy-OR or TAN, which cannot capture the influence of many attributes at once. However, the other patterns were clustered into few leaves in the graph. Within a leaf all patterns are considered equally likely to be positive. This resulted in loss of discrimination power for selection rates above 5%.

HPB (in both versions) benefits from critical patterns involving many or even all attributes, but also considers the influence of less specific patterns. As a consequence, it performs well for any selection rate. The version of HPB that uses a fixed value for the S coefficients is worse than NB for selection rates above 45%, but at this point, recall is already of 87% for both methods and the differences between them are never significant. Except for its non-optimized version, HPB-OPT is better than any other method for all selection rates, but the optimization process makes it fifty times slower than the simpler HPB.

It is worth noting that even the slower version of HPB is faster than the methods involving decision graphs, decision trees and default tables.

Since the cardinality of the attributes is a problem in this domain, we decided to also test all classification methods on a transformed data set where the cardinality of all attributes were reduced by the agglomerative information bottleneck method (AIBN). To prevent AIBN from using information from the test sets, we implemented a Weka meta classifier that applies AIBN immediately before training the real classifier and after each training set was separated from its associated test set in the five-fold cross validation process.

AIBN reduces the cardinality of an attribute by successively executing the merge of two values that results in minimum mutual information lost. The process can continue till a single value lasts, but can be stopped at any convenient point. We chose to limit the loss of mutual information to $1e-4$, a very low value. In spite of this, the cardinality reduction was accentuated. Table 3 shows the cardinality of the attributes before and after reduction.

Attribute	Original Cardinality	Final Cardinality
DCC	7608	101
IMP	18846	84
CP	161	50
EPR	80	28

Table 3: Cardinality reduction using AIBN

Because of the lower cardinality of the resulting attributes, it was possible to test BNs with DGs instead of standalone DGs. Results are in Table 4, Figure 5 and Table 5.

	1%	2%	5%	10%	20%

PRIOR	1.00±0.00	2.00±0.00	5.00±0.00	10.00±0.00	20.00±0.00

Table 4: Misclassification detection with cardinality reduction - recall at different selection rates

HPB and HPB-OPT are still the best methods but they lose much of their ability to explore critical patterns, and, at a selection rate of 1%, they do not perform nearly as well as they did over the original data set. The reason is that AIBN joins attribute values looking at each attribute separately and thus ignoring any interaction among them. In this case, relevant interactions were lost.

BNs with DGs lost much of their ability to explore critical patterns too, which also resulted in a much worse performance at a selection rate of 1%.

3.2 Prediction of Joint Behavior

In some problems of interest for Brazil's Federal Revenue it is important to answer the following question: what do two or more actors tend to do when they act together? When BNs are used to model such problems, their structure tend to follow the sketch in Figure 6.

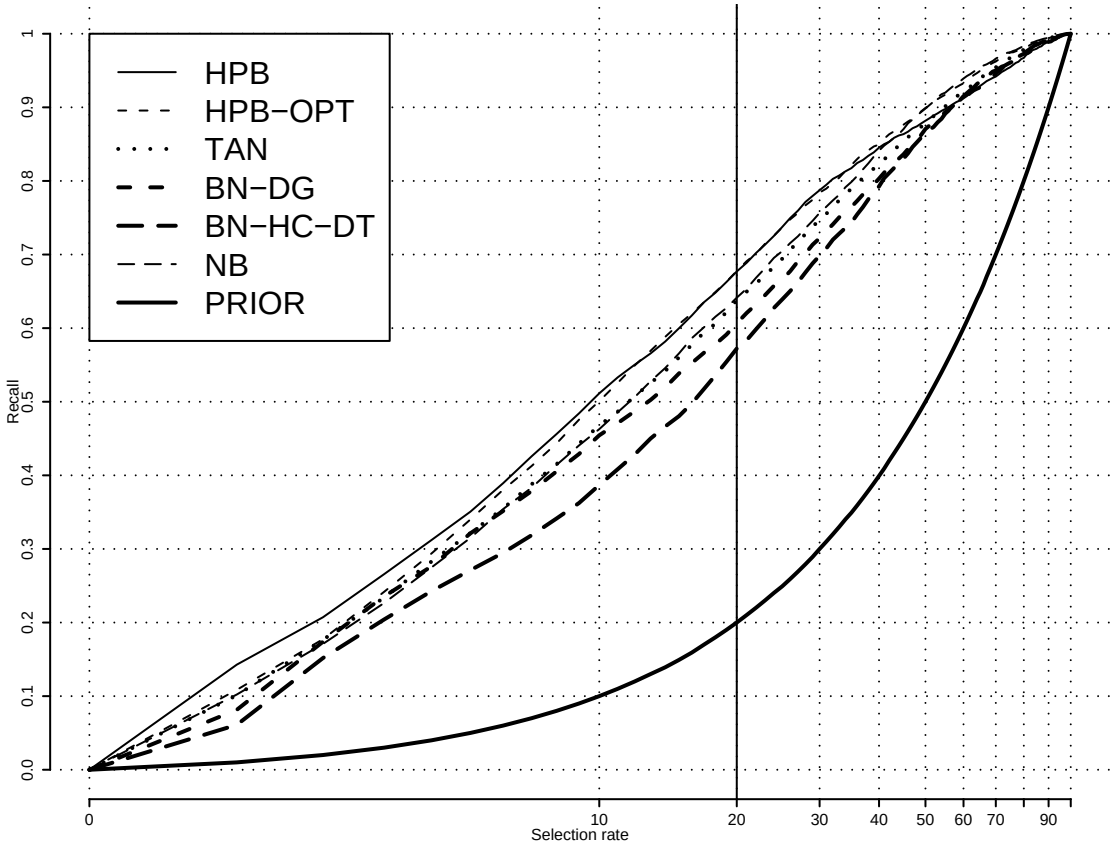

Figure 5: Misclassification detection with cardinality reduction - hit curves (to avoid pollution we only present curves related to a subset of the tested methods)

Table 5: Misclassification detection with cardinality reduction - other measures

Since the number of possible actors can be very big, but the number of roles is usually small, it seems reasonable to replace the CPT of the *Action* node in Figure 6 with HPB. However, in Section 3.1, HPB was used to predict a binary class. The number of possible actions can be high, so we have a different challenge for HPB.

In this section, we present the performance of HPB in a standalone classification problem which was built to resemble the problem of calculating the prior probability distribution of the *Action* node in Figure 6. We used two high cardinality explanatory attributes: the *importer* (IMP) and the *exporter* (EXP)[4] to predict another high cardinality variable, the *declared custom code* (DCC). Note that we are not predicting if there is a misclassification or not, but the DCC itself.

The importer attribute can assume 18846 values, the exporter attribute can assume 43880 values and the declared custom code can assume 7608 values. There are no missing values.

The tested methods were:

- *HPB*: BN with a *direct BN structure* and HPB with fixed *S* coefficients;
- *NB*: naïve Bayes;
- *ADE*: *almost direct estimation*. BN with a *direct BN structure* and the smoothing schema described by Friedman et al. (1997);
- *DE*: *direct estimation*. BN with a *direct BN structure* and traditional CPTs;
- *DE Imp*: *direct estimation*, ignoring the exporter attribute;
- *DE Exp*: *direct estimation*, ignoring the importer attribute.

HPB-OPT was not tested because its optimization process requires a binary class variable. We did not test DGs, DFs and DTs because the combination of high cardinality parents and a high cardinality child makes them too slow.

4. The *exporter* attribute was not available when we ran the tests in Section 3.1, so we did not use it there.

The parameters for each method were chosen as in Section 3.1, but MCE was used as the selection criterion. Below we present the initial search intervals and the optimal constants ($s = S/NumClasses = S/7608$):

- *HPB*: The *SI* for the *s* constant was $[1e-4, 1e-03]$ and the optimal value for *s* was equal to $1e-3$. The SI for the *b* constant was $[0.5, 2.5]$ and the optimal value for *b* was equal to 1.0. S^{NI} was always set to be equal to *S*;
- *NB*: $SI = [1e-3, 2.5]$, $s = 0.05$;
- *ADE*: $SI = [1e-3, 2.5]$, $s = 1e-3$;
- *DE*: $SI = [1e-3, 2.5]$, $s = 1e-3$;
- *DE Imp*: $SI = [1e-3, 2.5]$, $s = 1e-3$;
- *DE Exp*: $SI = [1e-3, 2.5]$, $s = 2.5e-3$;

Table 6 shows that HPB is the best method with regard to RMSE, MCE and number of correct predictions (NC). The difference is significant with the exception that HPB was not significantly better than NB with respect to number of correct assignments.

	RMSE($\times 10^4$)	MCE($\times 10^4$)	NC	PC(%)	TR(s)	TS(s)

Table 6: Prediction of joint behavior

3.3 HPB as a General Replacement for CPTs of Bayesian Networks

In this section we test HPB over UCI data sets. Our goal is to observe its performance in domains whose characteristics are different from the ones which inspired its design. We evaluated the performance of Bayesian networks where the usual CPTs were replaced with HPB models. For comparison we also evaluated BNs using other representations for the conditional probability distribution (CPD) of a node given its parents . Below we list all tested CPD representations:

- *HPB*: HPB as described in Section 2.4;
- *DE*: direct estimation, that is, traditional CPTs;
- *ADE*: almost direct estimation. Also CPTs but using the smoothing strategy presented by Friedman et al. (1997);
- *DG*: decision graphs as presented by Chickering et al. (1997);
- *DT*: decision trees as presented by Friedman et al. (1997);
- *DF*: default tables as presented by Friedman et al. (1997).

In all cases, we learned the global BN structure using the hill climbing search algorithm implemented in Weka 3.4.2 and used NB as the starting point. To guarantee that we would not have excessively long execution times we limited the maximum number of parents to 10 and because HPB does not handle continuous attributes we removed them all. We also removed all instances with missing attributes.

Depending on the chosen representation for the CPDs, we employed different scoring metrics in the BN structure search. Below we list our choices:

- HPB: log-likelihood evaluated using leave-one-out cross validation;
- DE: MDL;
- ADE: MDL;
- DGs: Bayesian Dirichlet scoring metric as presented by Chickering et al. (1997);
- DTs: MDL as presented by Friedman and Goldszmidt (1996b);
- DFs: MDL as presented by Friedman and Goldszmidt (1996b).

The tested data sets were: *anneal*, *audiology*, *autos*, *breast-cancer*, *horse-colic*, *credit-rating*, *german-credit*, *cleveland-14-heart-disease*, *hungarian-14-heart-disease*, *hepatitis*, *hypothyroid*, *kr-vs-kp*, *labor*, *lymphography*, *mushroom*, *primary-tumor*, *sick*, *soybean*, *vote* and *zoo*.

Before building a BN we decided on fixed equivalent sample size for the prior probability distributions (this means a fixed S constant) and used it for all HPB's instances inside the BN. Fortunately, the optimal values for the equivalent sample sizes tend to be similar.

We chose S starting from $SI = [1.0, 25.0]$ and, forced the S^{NI} be identical to the S. The b constant was chosen starting from $SI = [0.5, 2.5]$.

We chose the s constant ($s = S/NumClasses$) for DGs starting from $SI = [0.01, 2.5]$. We always kept complete splits enabled and exhaustively varied the activation state of binary splits and merges. We chose the s constant for the other methods starting from $SI = [0.01, 2.5]$.

In contrast to Sections 3.1 and 3.2 we did not expand the initial search intervals if the optimal value for a constant turned out to be in one of its extreme points.

We compared the results using three criteria: number of correct classifications (NC), mean cross entropy (MCE) and root mean squared error (RMSE). To save space we present only the numbers of times where each method resulted in the best average performance. Since selecting the best parameterization for each method using a criterion and comparing the methods using only the same criterion would possibly not provide the reader enough information, we selected parameterizations using all three criteria and compared the methods using also all the three criteria in exhaustive combinations. In some cases, two or more classifiers resulted in exactly the same value for NC. In these cases, if NC was the comparison criterion, we used MCE to decide who was the winner. Results are in Table 7. Details are available in appendix A.

Sel.Crit.	Comp.Crit.	HPB	DG	DF	DT	ADE	DE
NC	NC	9	6	2	1	1	1
NC	MCE	9	5	2	1	2	1
NC	RMSE	7	6	4	1	1	1
MCE	NC	9	5	2	0	3	1
MCE	MCE	10	5	2	1	0	2
MCE	RMSE	8	6	4	0	1	1
RMSE	NC	7	7	4	0	1	1
RMSE	MCE	9	5	2	1	1	2
RMSE	RMSE	8	6	4	0	1	1

Table 7: Number of winning results in UCI data sets

HPB	DG	DF	DT	ADE	DE
3.18	3.79	1.49	1.56	1.0	1.0

Table 8: Proportions among the number of arcs of BN structures

In Table 8 we show the average proportions between the number of arcs in the BN structures learned using each CPD representation and the BN structures learned using direct estimation (traditional CPTs). We can see that, as predicted by Friedman and Goldszmidt (1996b), the use of structures like DFs, DTs and DGs does result in BNs with more arcs. The use of HPB has a similar effect.

As shown in Section 3.1, HPB is much faster than DGs, DTs and DFs in the task of handling a small set of high cardinality explanatory attributes. However, in UCI tests, many BN structures involved sets of low cardinality parents. This makes HPB comparatively slow. HPB was, in all cases, the slowest method and in some of them more than 10 times slower than the second slowest method.

Moreover, the advantage of HPB in all three criteria (MCE, RMSE and NC) was rarely statistically significant. Thus, we cannot recommend HPB as a general replacement for CPTs.

However, the vast majority of variables in the tested data sets have low cardinality (the highest cardinality variable among all data sets is the audiology class variable with 24 possible values) and many of them are binary. In spite of this, HPB's are clearly the best results in Table 7 showing that good prior probability distributions, can, many times, improve the quality of predictions.

We can say that a BN where CPDs are represented using HPB has a quite high probability of producing better classification predictions than BNs employing other CPD representations. The only explanation we found for this fact is that HPB represents some CPDs better than its alternatives and that such better representations result in BNs with better classification predictions, even when the characteristics of the attributes are opposite to the ones that inspired HPB.

This suggests that it should not be difficult to find problems where, if a BN is employed, there will be one or more BN nodes where it will be worth using HPB.

4. Conclusions

We presented HPB a novel multilevel empirical hierarchical Bayesian model, which is intended to replace conditional probability tables of Bayesian network nodes whose parents have high cardinality.

We presented HPB in two versions. The first version involves an optimization process to choose the best smoothing coefficients for each family of patterns, while the second and simpler version employs a fixed smoothing coefficient. We prefer the simpler version because it is much faster and can handle non binary child nodes.

We evaluated HPB in the domain of preselection of imported goods for human verification using hit curves, RMSE and MCE. In this domain, interactions among attributes have a great influence over the probability of finding a positive instance of misclassification, but due to the high cardinality of the attributes in this domain, exploiting such interactions is challenging.

Even the simpler version of HPB was shown capable of capturing the influence of interactions among high cardinality attributes and achieved performance improvements over standard Bayesian network methods like naïve Bayes and tree augmented naïve Bayes, over Bayesian networks where traditional conditional probability tables were substituted by noisy-OR gates, default tables, decision trees and decision graphs, and over Bayesian networks constructed after a cardinality reduction preprocessing phase using the agglomerative information bottleneck method.

HPB's execution time is exponential in the number of parents of a BN node but independent of their cardinality. Since the number of parents of a BN node is almost always small, for nodes whose parents have high cardinality, HPB, at least when its smoothing coefficients are fixed, is much faster than default tables, decision trees or decision graphs when employed to represent the conditional probability distribution of the node given its parents. This version of HPB uses the training set only through frequencies, thus data can be added dynamically without any retraining procedures other than some frequency increments.

We tested HPB in another classification problem: the prediction of the behavior of two actors when they act together. As a subproblem, this prediction is relevant in several fraud detection domains and, if the general problem is modeled as a BN, generally appears as the the task of representing the CPD of a particular node given its parents. The results, again, favored HPB.

We also provide experimental results over UCI data sets, where Bayesian network classifiers with different CPD representations are compared. Despite the fact that these data sets do not include high cardinality attributes, HPB was the representation that resulted in more winnings than any other representation in three comparison measures. The comparatively large execution times and the fact that most differences in comparison measures were not significant, do not allow us to propose HPB as a general replacement for CPTs. However, we can still conclude that BN nodes whose CPDs given their parents are better represented by HPB than by other methods are not rare. This fact indicates that HPB may have a quite wide applicability.

HPB can be very useful in practice. If specialists are handcrafting a Bayesian network structure, they want it to reflect the structure of the target problem. If this results in a node with high cardinality parents, they can just use HPB as a plug-in replacement for the CPT of the node and keep the structure they want. Without a method like HPB the high cardinality parents could easily result in unreliable probability estimates that could compromise the whole model. The specialists would have to accept a BN structure that would not reflect the target problem as closely as the original one, but which would avoid the use of high cardinality nodes as parents of the same node.

Full hierarchical Bayesian models have been widely used in the marketing community under the name of Hierarchical Bayes (Allenby et al., 1999; Lenk et al., 1996). These models have also been used in medical domains (Andreassen et al., 2003) and robotics (Stewart et al., 2003). However, we are not aware of any hierarchical Bayesian model that can replace conditional probability tables of Bayesian network nodes whose parents have high cardinality. Moreover, HPB deals with a multi level hierarchy recursively and also handles the fact that the population of instances associated to each pattern is contained by several overlapping superpopulations and not by a single one. It would be very difficult to build a full hierarchical Bayesian model that can do the same.

As future work we leave the development of better mechanisms to select HPB coefficients. Both optimization processes and heuristics should be considered. The first for the most reliable predictions and the last for fast and acceptable ones.

The pattern hierarchy employed by HPB is fixed, symmetrical (all attributes are treated the same way) and complete (all subsets of each pattern of interest are considered in the calculation of the probability of a class given the pattern). It is possible that there exists an incomplete, possibly asymmetrical hierarchy that would lead to better results. Developing an algorithm to search for such hierarchy is also left as future work.

We compared HPB against algorithms which employ the best default tables, decision trees and decision graphs chosen using some criterion. If instead of this we employed mixtures of probability tables (Fujimoto and Murata, 2006) where default tables, decision trees or decision graphs were used as category integration tables, results could be better. As a final future work we leave the development of an algorithm that can build such a mixture model and the comparison of its results to HPB's ones.

Appendix A. Detailed Results over UCI Data Sets

In this appendix we detail the results of our tests over UCI data sets (see Section 3.3). To save space we only present results where the number of correct classifications (NC) was used to select the best parameterization for each method. The methods appear in the tables in decreasing order of NC. In some cases, two or more classifiers resulted in exactly the same value for NC. In these cases, we used MCE to decide the order. Results are in Table 9, Table 10 and Table 11.

Abstract

The success of support vector machines in binary classification relies on the fact that hinge loss employed in the risk minimization targets the Bayes rule. Recent research explores some extensions of this large margin based method to the multicategory case. We show a moment bound for the so-called multi-hinge loss minimizers based on two kinds of complexity constraints: entropy with bracketing and empirical entropy. Obtaining such a result based on the latter is harder than finding one based on the former. We obtain fast rates of convergence that adapt to the unknown margin.

Keywords: multi-hinge classification, all-at-once, moment bound, fast rate, entropy

1. Introduction

We consider multicategory classification with equal cost. Let $Y \in \{1,\ldots,m\}$ denote one of the m possible categories, and let $X \in \mathbb{R}^d$ be a feature. We study the classification problem, where the goal is to predict Y given X with small error. Let $\{(X_i,Y_i)\}_{i=1}^n$ be an independent and identically distributed sample from (X,Y). In the binary case ($m=2$) a classifier $f : \mathbb{R}^d \to \mathbb{R}$ can be obtained by minimizing the empirical hinge loss

$$\frac{1}{n}\sum_{i=1}^{n}(1-Y_i f(X_i))_+ \tag{1}$$

over a given class of candidate classifiers $f \in \mathcal{F}$, where $(1-Yf(X))_+ := \max(0,1-Yf(X))$ with $Y \in \{\pm 1\}$. Hinge loss in combination with a reproducing kernel Hilbert space (RKHS) regularization penalty is called the support vector machine (SVM). See, for example, Evgeniou, Pontil, and Poggio (2000). In this paper, we examine the generalization of (1) to the multicategory case ($m > 2$). We refer to this classifier as the *multi-hinge*, although, instead of RKHS-regularization we will assume a given model class $\mathcal{F}$ satisfying a complexity constraint. We show a moment bound for the excess multi-hinge risk based on two kinds of complexity constraints: entropy with bracketing and empirical entropy. Obtaining such a result based on the latter is harder than finding one based on the former. We obtain fast rates of convergence that adapt to the unknown margin.

There are two strategies to generalize the binary SVM to the multicategory SVM. One strategy is by solving a series of binary problems; the other is by considering all of the categories at once. For the first strategy, some popular methods are the one-versus-rest method and the one-versus-one method. The one-versus-rest method constructs m binary SVM classifiers. The j-th classifier f_j is trained taking the examples from class j as positive and the examples from all other categories

as negative. A new example x is assigned to the category with the largest values of $f_j(x)$. The one-versus-one method constructs one binary SVM classifier for every pair of distinct categories, that is, all together $m(m-1)/2$ binary SVM classifiers are constructed. The classifier f_{ij} is trained taking the examples from category i as positive and the examples from category j as negative. For a new example x, if f_{ij} classifies x into category i then the vote for category i is increased by one. Otherwise the vote for category j is increased by one. After each of the $m(m-1)/2$ classifiers makes its vote, x is assigned to the category with the largest number of votes. See Duan and Keerthi (2005) and the references therein for an empirical study of the performance of these methods and its variants.

An all-at-once strategy for SVM loss has been proposed by some authors. For examples, see Vapnik (2000), Weston and Watkins (1999), Crammer and Singer (2000, 2001), and Guermeur (2002). Roughly speaking, the idea is similar to the one-versus-rest approach but all the m classifiers are obtained by solving one problem. (See Hsu and Lin, 2002, for details of the formulations.) Lee, Lin, and Wahba (2004) (see also Lee, 2002) show that the relationship of the formulations of the approaches above to the Bayes' rule is not clear from the literature and that they do not always implement the Bayes' rule. They propose a new approach that has good theoretical properties. That is, the defined loss is Bayes consistent and it provides a unifying framework for both equal and unequal misclassification costs.

We consider the equal misclassification cost where a correct classification costs 0 and an incorrect classification costs 1. The target function $f : \mathbb{R}^d \to \mathbb{R}^m$ is defined as an m-tuple of separating functions with zero-sum constraint $\sum_{j=1}^m f_j(x) = 0$, for any $x \in \mathbb{R}^d$. Hence, the classifier induced by $f(\cdot)$ is

$$g(\cdot) = \arg\max_{j=1,\ldots,m} f_j(\cdot)\ . \tag{2}$$

Analogous to the binary case, when applying RKHS-regularization, each component $f_j(x)$ is considered as an element of a RKHS $\overline{\mathcal{H}}_K = \{1\} + \mathcal{H}_K$, for all $j = 1,\ldots,m$. That is, $f_j(x)$ is expressed as $h_j(x) + b_j$ with $h_j \in \mathcal{H}_K$ and b_j some constant. To find $f(\cdot) = (f_1(\cdot),\ldots,f_m(\cdot)) \in \Pi_{j=1}^m \overline{\mathcal{H}}_K$ with the zero-sum constraint, the extension of SVM methodology is to minimize

$$\frac{1}{n}\sum_{i=1}^n \sum_{j=1, j\neq Y_i}^m (f_j(X_i) + \frac{1}{m-1})_+ \ + \ \frac{\lambda}{2}\sum_{j=1}^m ||h_j||^2_{\mathcal{H}_K}\ . \tag{3}$$

Based on (3), the multi-hinge loss is now defined as

$$l(Y, f(X)) := \sum_{j=1, j\neq Y}^m (f_j(X) + \frac{1}{m-1})_+\ . \tag{4}$$

The binary SVM loss (1) is a special case by taking $m = 2$. When $Y = 1$, $l(1, f(X)) = (f_2(X) + 1)_+ = (1 - f_1(X))_+$. Similarly, when $Y = -1$, $l(-1, f(X)) = (1 + f_1(X))_+$. Thus, (4) is identical with the binary SVM loss $(1 - Y f(X))_+$, where f_1 plays the same role as f.

Using a classifier g defined as in (2), a misclassification occurs whenever $g(X) \neq Y$. Let P be the unknown underlying measure of (X,Y). The prediction error of g is $P(g(X) \neq Y)$. Let $p_j(x)$ denote the conditional probability of category j given $x \in \mathbb{R}^d$, $j = 1,\ldots,m$. The prediction error is minimized by the Bayes classifier $g^* = \arg\max_{j=1,\ldots,m} p_j$, and the smallest prediction error is $P(g^*(X) \neq Y)$.

The theoretical multi-hinge risk is the expectation of the empirical multi-hinge loss with respect to the measure P and is denoted by

$$R(f) := \int l(y, f(x))\, dP(x,y)\ , \tag{5}$$

with $l(Y, f(X))$ defined as in (4). In this setting, Bayes' rule f^* is then an m-tuple separating functions with 1 in the kth coordinate and $-1/(m-1)$ elsewhere, whenever $k = \arg\max_{j=1,\ldots,m} p_j(x)$, $x \in \mathbb{R}^d$. Lemma 1 below shows that multi-hinge loss (4) is Bayes consistent. That is, f^* minimizes multi-hinge risk (5) over all possible classifiers. We write $R^* = R(f^*)$, the smallest possible multi-hinge risk. Lemma 1 is an extension of Bayes consistency of the binary SVM that has been shown by, for example, Lin (2002), Zhang (2004a) and Bartlett, Jordan, and McAuliffe (2006).

Lemma 1. *Bayes classifier f^* minimizes the multi-hinge risk $R(f)$.*

This lemma can be found in Lee, Lin, and Wahba (2004), Zhang (2004b,c), Tewari and Bartlett (2005) and Zou, Zhu, and Hastie (2006). We give a self-contained proof in Appendix for completeness. They establish the conditions needed to achieve the consistency for a general family of multicategory loss functions extended from various large margin binary classifiers. They also show that the SVM-type losses proposed by Weston and Watkins (1999) and Crammer and Singer (2001) are not Bayes consistent. Tewari and Bartlett (2005) and Zhang (2004b,c) also show that the convergence to zero (in probability) of the excess multi-hinge risk $R(f) - R^*$ implies the convergence to zero with the same rate (in probability) of the excess prediction error $P(g(f(X)) \neq Y) - P(g(f^*(X)) \neq Y)$.

The RKHS-regularization (3) has attracted some interest. For example, Lee and Cui (2006) study an algorithm of fitting the entire regularization path and Wang and Shen (2007) study the use of l_1 penalty in place of the l_2 penalty. In this paper, we will not study the RKHS-regularization but we take the minimization of the empirical multi-hinge loss over a given class of candidate classifiers $\mathcal{F}$ satisfying a complexity constraint. That is, we do not invoke a penalization technique.

Let $\mathcal{F}$ be a model class of candidate classifiers. For $j = 1, \ldots, m$, we assume that each f_j is a member of the same class $\mathcal{F}_o = \{h : \mathbb{R}^d \to \mathbb{R}, h \in L_2(Q)\}$, with Q the unknown marginal distribution of X. That is,

$$\mathcal{F} = \{f = (f_1, \ldots, f_m) : \sum_{j=1}^{m} f_j = 0,\ f_j \in \mathcal{F}_o\}\ . \tag{6}$$

Let P_n be the empirical distribution of (X,Y) based on the observations $\{(X_i, Y_i)\}_{i=1}^n$ and Q_n the corresponding empirical distribution of X based on $X_1, \ldots, X_n$. We endow $\mathcal{F}$ with the following squared semi-metrics

$$\begin{aligned} \|f - \tilde{f}\|_{2,Q}^2 &:= \sum_{j=1}^{m} \int |f_j - \tilde{f}_j|^2\, dQ\ , \text{ and} \\ \|f - \tilde{f}\|_{2,Q_n}^2 &:= \sum_{j=1}^{m} \frac{1}{n} \sum_{i=1}^{n} |f_j(X_i) - \tilde{f}_j(X_i)|^2\ , \end{aligned}$$

for all $f, \tilde{f} \in \mathcal{F}$. We impose a complexity constraint on the class $\mathcal{F}_o$ in term of either the entropy with bracketing or the empirical entropy. Below we give the definitions of the entropies.

Definition of entropy. *Let $\mathcal{G}$ be a subset of a metric space (Λ, d). Let*

$$H(\varepsilon, \mathcal{G}, d) := \log N(\varepsilon, \mathcal{G}, d) \text{ , for all } \varepsilon > 0 \text{ ,}$$

where $N(\varepsilon, \mathcal{G}, d)$ is the smallest value of N for which there exist functions $g_1, \ldots, g_N$ in $\mathcal{G}$, such that for each $g \in \mathcal{G}$, there is a $j = j(g) \in \{1, \ldots, N\}$, such that

$$d(g, g_j) \leq \varepsilon \text{ .}$$

Then $N(\varepsilon, \mathcal{G}, d)$ is called the ε-covering number *of $\mathcal{G}$ and $H(\varepsilon, \mathcal{G}, d)$ is called the* ε-entropy *of $\mathcal{G}$ (for the d-metric).*

Definition of entropy with bracketing. *Let $\mathcal{G}$ be a subset of a metric space (Λ, d) of real-valued functions. Let*

$$H_B(\varepsilon, \mathcal{G}, d) := \log N_B(\varepsilon, \mathcal{G}, d) \text{ , for all } \varepsilon > 0 \text{ ,}$$

where $N_B(\varepsilon, \mathcal{G}, d)$ is the smallest value of N for which there exist pairs of functions $\{[g_1^L, g_1^U], \ldots, [g_N^L, g_N^U]\}$ such that $d(g_j^L, g_j^U) \leq \varepsilon$ for all $j = 1, \ldots, N$, and such that for each $g \in \mathcal{G}$, there is a $j = j(g) \in \{1, \ldots, N\}$ such that

$$g_j^L \leq g \leq g_j^U \text{ .}$$

Then $N_B(\varepsilon, \mathcal{G}, d)$ is called the ε-covering number with bracketing *of $\mathcal{G}$ and $H_B(\varepsilon, \mathcal{G}, d)$ is called the* ε-entropy with bracketing *of $\mathcal{G}$ (for the d-metric).*

Let $H_B(\varepsilon, \mathcal{F}_o, L_2(Q))$ and $H(\varepsilon, \mathcal{F}_o, L_2(Q_n))$ denote the ε-entropy with bracketing and the empirical ε-entropy of the class $\mathcal{F}_o$, respectively. The complexity of a model class can be summarized in a complexity parameter $\rho \in (0, 1)$. Let A be some positive constant. We consider classes $\mathcal{F}_o$ satisfying one of the following complexity constraints:

$$\begin{aligned} H_B(\varepsilon, \mathcal{F}_o, L_2(Q)) &\leq A\varepsilon^{-2\rho} \text{ , for all } \varepsilon > 0 \text{ , or} \\ H(\varepsilon, \mathcal{F}_o, L_2(Q_n)) &\leq A\varepsilon^{-2\rho} \text{ , for all } \varepsilon > 0 \text{ , a.s. for all } n \geq 1 \text{ .} \end{aligned}$$

It is straightforward to show that for all $\varepsilon > 0$:

$$\begin{aligned} H_B(\varepsilon, \mathcal{F}, \|\cdot\|_{2,Q}) &\leq (m-1)\, H_B(\varepsilon(m-1)^{-1/2},\ \mathcal{F}_o,\ L_2(Q)) \text{ ,} \\ H(\varepsilon, \mathcal{F}, \|\cdot\|_{2,Q_n}) &\leq (m-1)\, H(\varepsilon(2(m-1))^{-1/2},\ \mathcal{F}_o,\ L_2(Q_n)) \text{ .} \end{aligned}$$

We define the minimizer of the empirical multi-hinge loss (without penalty)

$$\hat{f}_n := \arg\min_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1, j \neq Y_i}^{m} (f_j(X_i) + \frac{1}{m-1})_+ \text{ ,} \tag{7}$$

where the model class $\mathcal{F}$ defined as in (6) satisfies either an entropy with bracketing constraint or an empirical entropy constraint described above.

Besides the model class complexity, the rate of convergence also depends on the so-called margin condition (see Condition A below) that quantifies the identifiability of the Bayes rule and is summarized in a margin parameter (or noise level) $\kappa \geq 1$. In Tarigan and van de Geer (2006), a

probability inequality has been obtained for l_1-penalized excess hinge risk in the binary case that adapts to the unknown parameters. In this paper, we show a moment bound for the excess multi-hinge risk $R(\hat{f}_n) - R^*$ of $\hat{f}_n$ over the model class $\mathcal{F}$ with rate of convergence $n^{-\kappa/(2\kappa-1+\rho)}$, which is faster than $n^{-1/2}$.

In Section 2 we present our main result based on the margin and complexity conditions. The proof of the main result is given in Section 3, together with our supporting lemmas. For the sake of completeness and to avoid distraction, we place the proof of some supporting lemmas in the Appendix.

2. A Moment Bound for Multi-hinge Classifiers

We first state the margin and the complexity conditions.

Condition A (Margin condition)**.** *There exist constants $\sigma > 0$ and $\kappa \geq 1$ such that for all $f \in \mathcal{F}$,*

$$R(f) - R^* \;\geq\; \frac{1}{\sigma^\kappa}\Big(\sum_{j=1}^{m} \int |f_j - f_j^*| \, dQ\Big)^\kappa .$$

Condition B1 (Complexity constraint under ε-entropy with bracketing)**.** *Let $0 < \rho < 1$ and let A be a positive constant. The ε-entropy with bracketing satisfies the inequality*

$$H_B(\varepsilon, \mathcal{F}_o, L_2(Q)) \leq A\varepsilon^{-2\rho} \;, \;\; \textit{for all } \varepsilon > 0 \, .$$

Condition B2 (Complexity constraint under empirical ε-entropy)**.** *Let $0 < \rho < 1$ and let A be a positive constant. The empirical ε-entropy, almost surely for all $n \geq 1$, satisfies the inequality*

$$H(\varepsilon, \mathcal{F}_o, L_2(Q_n)) \leq A\varepsilon^{-2\rho} \;, \;\; \textit{for all } \varepsilon > 0 \, .$$

Now we come to the main result.

Theorem 2. *Assume Condition A is met and that $|f_j - f_j^*| \leq M$ for all $j = 1, \ldots, m$, and all $f = (f_1, \ldots, f_m) \in \mathcal{F}$. Let $\hat{f}_n$ be the multi-hinge loss minimizer defined in (7). Suppose that either Condition B1 or Condition B2 holds. Then for small values of $\delta > 0$,*

$$\mathbb{E}[R(\hat{f}_n) - R^*] \leq \frac{1+\delta}{1-\delta} \, \inf\Big\{ R(f) - R^* + C_0 \, n^{-\frac{\kappa}{2\kappa-1+\rho}} \;:\; f \in \mathcal{F} \Big\}$$

with C_0 some constant depending only on m, M, κ, σ, A and ρ.

Condition A follows from the condition on the behaviour of the conditional probabilities p_j. We formulate this in Condition AA below. We require that, for a fixed $x \in \mathbb{R}^d$, there is no pair of categories having the same conditional probabilities each of which stays away from 1. Originally

the terminology "margin condition" comes from the binary case of the prediction error considered in the work of Mammen and Tsybakov (1999) and Tsybakov (2004), where the behaviour of p_1, the conditional probability of category 1, is restricted near $\{x : p_1(x) = 1/2\}$. The "margin" set $\{x : p_1(x) = 1/2\}$ identifies the Bayes predictor which assigns a new x to class 1 if $p_1(x) > 1/2$ and class 2 otherwise. The margin condition is also called the *condition on the noise level*, and it is summarized in a margin parameter κ. Boucheron, Bousquet, and Lugosi (2005, Section 5.2) discuss the noise condition and its equivalent variants, corresponding to the fast rates of convergence, in the binary case. Thus, Condition AA is a natural extension for the multicategory case wrt. hinge loss. Lemma 3 below gives the connection between Condition A and Condition AA. We provide the proof in the Appendix. For $x \in \mathcal{X}$, let $p_k(x) = \max_{j\in\{1,\ldots,m\}} p_j(x)$ and define

$$\tau(x) := \min_{j\neq k}\{|p_j(x) - p_k(x)|, 1 - p_k(x)\}\ , \tag{8}$$

where j and k take values in $\{1,2,\ldots,m\}$.

Condition AA. *Let τ be defined in (8). There exist constants $C \geq 1$ and $\gamma \geq 0$ such that $\forall z > 0$,*

$$Q(\{\tau \leq z\}) \leq (Cz)^{1/\gamma}\ .$$

[Here we use the convention $(Cz)^{1/\gamma} = \mathbb{1}\{z \geq 1/C\}$ for $\gamma = 0$.]

Lemma 3. *Suppose Condition AA is met. Then for all $f \in \mathcal{F}$ with $|f_j - f_j^*| \leq M$ for all $j = 1,\ldots,m$,*

$$R(f) - R^* \geq \frac{1}{\sigma_M}\Big(\sum_{j=1}^m \int |f_j - f_j^*|\, dQ\Big)^{1+\gamma}\ ,$$

where $\sigma_M = C\,(mM(1/\gamma+1))^{\gamma}(1+\gamma)$. That is, Condition A holds with $\sigma = (\sigma_M)^{1/\kappa}$ and $\kappa = 1+\gamma$.

Remark. In the definition of τ we have the extra piece $1 - p_k$. It is needed for technical reason. It forces that nowhere in the input space one class can clearly dominate. We refer to the work of Bartlett and Wegkamp (2006, Section 4) and Tarigan and van de Geer (2006, Section 3.3.1) for some ideas how to get around this difficulty.

The complexity constraints B1 and B2 cover some interesting classes, including Vapnik-Chervonenkis (VC) subgraph classes and VC convex hull classes. See, for example, van der Vaart and Wellner (1996, Section 2.7), van de Geer (2000, Sections 2.4, 3.7, 7.4, 10.1 and 10.3) and Song and Wellner (2002). In the situation when the approximation error $\inf_{f\in\mathcal{F}} R(f) - R^*$ is zero (the model class $\mathcal{F}$ contains the Bayes classifier), Steinwart and Scovel (2005) obtain the same rate of convergence for the excess hinge risk under the margin condition A and the complexity condition B2. They consider the RKHS-regularization setting for the binary case instead.

We do not explore the behaviour of the approximation error $\inf_{f\in\mathcal{F}} R(f) - R^*$. This problem is still open and very hard to solve even in the binary case.

3. Proof of Theorem 2

Let $f^o := \arg\min_{f\in\mathcal{F}} R(f)$, the minimizer of the theoretical risk in the model class $\mathcal{F}$. As shorthand notation we write for the loss $l_f = l_f(X,Y) = l(Y, f(X))$. We also write $\nu_n(l_f) = \sqrt{n}\,(R_n(f) - R(f))$.

Since $R_n(\hat{f}_n) - R_n(f) \leq 0$ for all $f \in \mathcal{F}$, we have

$$\begin{aligned} R(\hat{f}_n) - R^* &\leq -[R_n(\hat{f}_n) - R(\hat{f}_n)] + [R_n(f^o) - R(f^o)] + R(f^o) - R^* \\ &\leq |\nu_n(l_{\hat{f}_n}) - \nu_n(l_{f^o})|/\sqrt{n} + R(f^o) - R^* \ . \end{aligned} \tag{9}$$

We call inequality (9) a basic-inequality, following van de Geer (2000). This upper bound enables us to work with the increments of the empirical process $\{\nu_n(l_f) - \nu_n(l_{f^o}) \ : \ l_f \in \mathcal{L}\}$ indexed by the multi-hinge loss $l_f \in \mathcal{L}$, where $\mathcal{L} = \{l_f : f \in \mathcal{F}\}$.

The procedure of the proof is based on the proof of Lemma 2.1 in del Barrio et al. (2007), page 206. We write

$$Z_n(l_f) := \frac{|\nu_n(l_f) - \nu_n(l_{f^o})|}{\left(\|l_f - l_{f^o}\|_{2,P} \vee n^{-\frac{1}{2+2\rho}}\right)^{1-\rho}} \ , \ l_f \in \mathcal{L} \ ,$$

where $(a \vee b) := \max\{a,b\}$, $\|l_f\|_{2,P}^2 := \int l_f^2(x,y)\, dP(x,y)$ and ρ is from either Condition B1 or B2. For short hand of notation, we also write $Z_n = Z_n(l_{\hat{f}_n})$. Then

$$R(\hat{f}_n) - R^* \leq (Z_n/\sqrt{n}) \ (\ \|l_{\hat{f}_n} - l_{f^o}\|_{2,P}^{1-\rho} \vee n^{-\frac{1-\rho}{2+2\rho}}) \ + \ R(f^o) - R^* \ . \tag{10}$$

Applying the triangular inequality and Lemma 4 below gives

$$\|l_{\hat{f}_n} - l_{f^o}\|_{2,P}^{1-\rho} \leq (m-1)^{(1-\rho)/2} \ \left(\|\hat{f}_n - f^*\|_{2,Q}^{1-\rho} + \|f^o - f^*\|_{2,Q}^{1-\rho}\right) .$$

Observe that for any $f \in \mathcal{F}$ with $|f_j - f_j^*| \leq M$, and for all j, Condition A gives $\|f - f^*\|_{2,Q}^2 \leq M\sigma \ (R(f) - R^*)^{1/\kappa}$. Thus,

$$\|l_{\hat{f}_n} - l_{f^o}\|_{2,P}^{1-\rho} \leq C_1 \left\{[R(\hat{f}_n) - R^*]^{(1-\rho)/2\kappa} + [R(f^o) - R^*]^{(1-\rho)/2\kappa}\right\} ,$$

with $C_1 = ((m-1)M\sigma)^{(1-\rho)/2}$. Denote by $\mathcal{R}$ the right hand side of the above inequality. Hence, from (10) we have

$$R(\hat{f}_n) - R^* \leq (Z_n/\sqrt{n}) \ (\mathcal{R} \vee n^{-\frac{1-\rho}{2+2\rho}}) + R(f^o) - R^* \ .$$

We consider first the case $(\mathcal{R} \vee n^{-\frac{1-\rho}{2+2\rho}}) = \mathcal{R}$. That is,

$$R(\hat{f}_n) - R^* \leq \frac{Z_n}{\sqrt{n}} C_1 \left\{[R(\hat{f}_n) - R^*]^{(1-\rho)/2\kappa} + [R(f^o) - R(f^*)]^{(1-\rho)/2\kappa}\right\} + R(f^o) - R^* \ .$$

Two applications of Lemma 5 below yield for all $0 < \delta < 1$,

$$\begin{aligned} R(\hat{f}_n) - R^* &\leq \delta(R(\hat{f}_n) - R^*) + (1+\delta)(R(f^o) - R^*) + 2\left(C_1 \ Z_n/\sqrt{n}\right)^{\frac{2\kappa}{2\kappa-1+\rho}} \ \delta^{-\frac{1-\rho}{2\kappa-1+\rho}} \\ &\leq \delta(R(\hat{f}_n) - R^*) \ + (1+\delta)\left(R(f^o) - R^* + C_2 \ Z_n^r \ n^{-\frac{\kappa}{2\kappa-1+\rho}}\right) , \end{aligned}$$

with $C_2 = 2 \ C_1^r \ \delta^{-\frac{1-\rho}{2\kappa-1+\rho}}$ and $r = 2\kappa/(2\kappa-1+\rho)$. Now it is left to show that $\mathbb{E}[Z_n^r]$ is bounded, say by some constant C_3. Then, $C_0 = C_2 C_3$ in Theorem 2.

To show that $\mathbb{E}[Z_n^r]$ is bounded, we use an exponential tail probability of the supremum of the weighted empirical process

$$\{Z_n(l_f) \ : \ l_f \in \mathcal{L}\} \ . \tag{11}$$

We recall that $H_B(\varepsilon, \mathcal{F}, \|\cdot\|_{2,Q}) \leq (m-1)H_B(\varepsilon(m-1)^{-1/2}, \mathcal{F}_o, L_2(Q))$. A key observation is that

$$H_B(\varepsilon, \mathcal{L}, L_2(P)) \leq (m-1)\, H_B(\varepsilon(m-1)^{-1/2}, \mathcal{F}, \|\cdot\|_{2,Q})\,,$$

by Lemma 4. It gives an upper bound for the ε-entropy with bracketing of the model class $\mathcal{L}$: $H_B(\varepsilon, \mathcal{L}, L_2(P)) \leq A_o\varepsilon^{-2\rho}$, for all $\varepsilon > 0$, with $A_o = A(m-1)^{2+2\rho}$. Under Condition B1, an application of Lemma 5.14 in van de Geer (2000), presented below in Lemma 6, gives the desired exponential tail probability. Hence, for some positive constant c,

$$\begin{aligned}\mathbb{E}[Z_n^r] &= \int_0^c \mathbb{P}(Z_n \geq t^{1/r})\, dt \,+\, \int_c^\infty \mathbb{P}(Z_n \geq t^{1/r})\, dt \\ &\leq c \,+\, \int_0^\infty c\, \exp(-\frac{t^{1/r}}{c^2})\, dt \,= c + rc^{2r+1}\Gamma(r)\,.\end{aligned}$$

For the case $\mathcal{R} \leq n^{-(1-\rho)/(2+2\rho)}$, we have

$$R(\hat{f}_n) - R^* \leq Z_n\, n^{-1/(1+\rho)} \,+\, R(f^o) - R^*\,.$$

We conclude by noting that $n^{-1/(1+\rho)} \leq n^{-\kappa/(2\kappa-1+\rho)}$, where $\kappa \geq 1$ and $0 < \rho < 1$.

Now we consider the case where Condition B2 holds instead of B1. By virtue of the proof above, we need only to verify an exponential probability of the supremum of the process (11) under Condition B2 instead of B1. This is done by employing Lemmas 7–9 below. Again, a key observation is that Lemma 4 and Condition B2 give us $H(\varepsilon, \mathcal{L}, L_2(P_n)) \leq A(m-1)^{2+2\rho}\varepsilon^{-2\rho}$. ■

Lemma 4 gives an upper bound of the squared $L_2(P)$-metric of the excess loss in terms of $\|\cdot\|_{2,Q}$-metric.

Lemma 4. $\mathbb{E}[(l_f(X,Y) - l_{f^*}(X,Y))^2] \leq (m-1)\sum_{j=1}^m \int |f_j - f_j^*|^2\, dQ\,.$

Proof. We write $\Delta(f, f^*) = \mathbb{E}_{Y|X}[(l_f(X,Y) - l_{f^*}(X,Y))^2 | X = x]$ and recall that $p_j(x) = P(Y = j | X = x)$, for all $j = 1, \ldots, m$. We fix an arbitrary $x \in \mathbb{R}^d$. Definition of the loss gives

$$\begin{aligned}\Delta(f, f^*) &= \sum_{j=1}^m p_j \Big(\sum_{i\neq j}(f_i + \frac{1}{m-1})_+ - (f_i^* + \frac{1}{m-1})_+\Big)^2 \\ &= \sum_{j=1}^m p_j \Big(\sum_{i\in I^+(j)}(f_i - f_i^*) + \sum_{i\in I^-(j)}(-\frac{1}{m-1} - f_i^*)\Big)^2\,,\end{aligned}$$

where $I^+(j) = \{i \neq j \;:\; f_i \geq -1/(m-1),\ i = 1, \ldots, m\}$ and $I^-(j) = \{i \neq j \;:\; f_i < -1/(m-1),\ i = 1, \ldots, m\}$. Use the facts that $(\sum_{i=1}^n a_i)^2 \leq n\sum_{i=1}^n a_i^2$ for all $n \in \mathbb{N}$ and $a_i \in \mathbb{R}$, and that $\max\{|I^+(j)|, |I^-(j)|\} \leq m-1$, to obtain

$$\Delta(f, f^*) \leq (m-1)\sum_{j=1}^m p_j \Big(\sum_{i\in I^+(j)}(f_i - f_i^*)^2 \,+\, \sum_{i\in I^-(j)}(-\frac{1}{m-1} - f_i^*)^2\Big)\,.$$

Clearly, $|-1/(m-1) - f_i^*| \leq |f_i - f_i^*|$ for all $i \in I^-(j)$. Hence,

$$\Delta(f, f^*) \leq (m-1)\sum_{j=1}^m p_j\, (\sum_{i\neq j}|f_i - f_i^*|^2) = (m-1)\sum_{j=1}^m (1-p_j)|f_j - f_j^*|^2\,,$$

where the last equality is obtained using $\sum_{j=1}^{m} p_j = 1$. We conclude the proof by bounding $1 - p_j$ with 1 for all j and integrating over all $x \in \mathbb{R}^d$ wrt. the marginal distribution Q. ■

The technical lemma below is an immediate consequence of Young's inequality (see, for example, Hardy, Littlewood, and Pólya, 1988, Chapter 8.3), using some straightforward bounds to simplify the expressions.

Lemma 5 (Technical Lemma)**.** *For all positive* ν, t, δ *and* $\kappa > \beta$*:*

$$\nu t^{\beta/\kappa} \;\leq\; \delta t \;+\; \nu^{\frac{\kappa}{\kappa-\beta}}\, \delta^{\frac{-\beta}{\kappa-\beta}} \;.$$

To ease the exposition, throughout Lemma 6 and Lemma 7 we write $\|\cdot\| = \|\cdot\|_{2,Q}$ and $\|\cdot\|_n = \|\cdot\|_{2,Q_n}$ for the $L_2(Q)$-norm and the $L_2(Q_n)$-norm, respectively.

Lemma 6 (van de Geer, 2000, Lemma 5.14)**.** *For a probability measure Q, let $\mathcal{H}$ be a class of uniformly bounded functions h in $L_2(Q)$, say $\sup_{h\in\mathcal{H}} |h - h^o|_\infty < 1$, where h^o is a fixed but arbitrary function in $\mathcal{H}$. Suppose that*

$$H_B(\varepsilon, \mathcal{H}, L_2(Q)) \leq A_o \varepsilon^{-2\rho} \;,\; \textit{for all } \varepsilon > 0 \;,$$

with $0 < \rho < 1$ and $A_o > 0$. Then for some positive constants c and n_o depending only on ρ and A_o,

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}} \frac{|\nu_n(h) - \nu_n(h^o)|}{\Big(\|h - h^o\| \vee n^{-\frac{1}{2+2\rho}} \Big)^{1-\rho}} \geq t \Big) \leq c\, \exp(-t/c^2) \;,$$

for all $t > c$ and $n > n_o$.

Lemma 7. *For a probability measure Q on $(\mathcal{Z}, \mathcal{A})$, let $\mathcal{H}$ be a class of uniformly bounded functions h in $L_2(Q)$, say $\sup_{h\in\mathcal{H}} |h - h^o|_\infty < 1$, where h^o is a fixed but arbitrary element in $\mathcal{H}$. Suppose that*

$$H(\varepsilon, \mathcal{H}, L_2(Q_n)) \leq A_o \varepsilon^{-2\rho} \;,\; \textit{for all } \varepsilon > 0 \;,$$

with $0 < \rho < 1$ and $A_o > 0$. Then for some positive constants c and n_o depending on ρ and A_o,

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}} \frac{|\nu_n(h) - \nu_n(h^o)|}{\Big(\|h - h^o\| \vee n^{-\frac{1}{2+2\rho}} \Big)^{1-\rho}} \geq t \Big) \leq c\, \exp(-t/c^2) \;,$$

for all $t > c$ and $n > n_o$.

Proof. For $n \geq (t^2/8)^{1+\rho/(1-\rho)}$, Chebyshev's inequality and a symmetrization technique (see, for example, van de Geer, 2000, page 32) give

$$\mathbb{P}\left(\sup_{h\in\mathcal{H}} \frac{|\nu_n(h) - \nu_n(h^o)|}{\Big(\|h - h^o\| \vee n^{-1/(2+2\rho)} \Big)^{1-\rho}} \geq t \right)$$

$$\leq 4\mathbb{P}\left(\sup_{h\in\mathcal{H}}\frac{|\nu_n^\varepsilon(h)-\nu_n^\varepsilon(h^o)|}{\left(\|h-h^o\|_n\vee n^{-1/(2+2\rho)}\right)^{1-\rho}}\geq\sqrt{t}/4\right) \tag{12}$$

$$+\,4\mathbb{P}\left(\sup_{h\in\mathcal{H}}\frac{\|h-h^o\|_n^{1-\rho}}{\left(\|h-h^o\|\vee n^{-1/(2+2\rho)}\right)^{1-\rho}}\geq\sqrt{t}/4\right), \tag{13}$$

where $\nu_n^\varepsilon(h)$ is the symmetrized version of the $\nu_n(h)$. That is, $\nu_n^\varepsilon(h)=(1/\sqrt{n})\sum_{i=1}^n\varepsilon_i h(Z_i)$, where $\{\varepsilon_i\}_{i=1}^n$ are independent random variables, independent of $\{Z_i\}_{i=1}^n$, with $\mathbb{P}(\varepsilon_i=1)=\mathbb{P}(\varepsilon_i=-1)=1/2$ for all $i=1,\ldots,n$.

To handle (12), we divide the class $\mathcal{H}$ into two disjoint classes where the empirical distance $\|h-h^o\|_n$ is smaller or larger than $n^{-1/(2+2\rho)}$. Write $\mathcal{H}_n=\{h\in\mathcal{H}:\ \|h-h^o\|_n\leq n^{-1/(2+2\rho)}\}$. By Lemma 5.1 in van de Geer (2000), stated below in Lemma 8, for some positive constant c_1,

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}_n}\frac{|\nu_n^\varepsilon(h)-\nu_n^\varepsilon(h^o)|}{n^{-(1-\rho)/(2+2\rho)}}\geq\sqrt{t}/4\Big)\leq c_1\exp\Big(-\frac{t\,n^{1/(1+\rho)}}{64\,c_1^2}\Big)\,.$$

Let $J=\min\{j>1:2^{-j}<n^{-1/(2+2\rho)}\}$. We apply the peeling device on the set $\{h\in\mathcal{H}:2^{-j}\leq\|h-h^o\|_n\leq 2^{-j+1},\ j=1,\ldots,J\}$ to obtain that, for all $t>1$,

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}_n^c}\frac{|\nu_n^\varepsilon(h)-\nu_n^\varepsilon(h^o)|}{\|h-h^o\|_n^{1-\rho}}\geq\sqrt{t}/4\ \Big|\ Z_1,\ldots,Z_n\Big)$$

$$\leq\sum_{j=1}^J\mathbb{P}\Big(\sup_{\substack{h\in\mathcal{H}\\ \|h-h^o\|_n\leq 2^{-j+1}}}|\nu_n^\varepsilon(h)-\nu_n^\varepsilon(h^o)|\geq\frac{\sqrt{t}}{4}\,2^{-j(1-\rho)}\mid Z_1,\ldots,Z_n\Big)$$

$$\leq\sum_{j=1}^J c_2\exp(-\frac{t\,2^{2\rho j}}{216\,c_2^2})\ \leq c\ \exp(-t/c^2)\,.$$

To handle (13), we use a modification of Lemma 5.6 in van de Geer (2000), stated below in Lemma 9, where we take t such that $(\sqrt{t}/4)^{1/(1-\rho)}\geq 14u$. ■

Lemma 8 (van de Geer, 2000, Lemma 5.1)**.** *Let $Z_1,\ldots,Z_n,\ldots$ be i.i.d. with distribution Q on $(\mathcal{Z},\mathcal{A})$. Let $\{\varepsilon_i\}_{i=1}^n$ be independent random variables, independent of $\{Z_i\}_{i=1}^n$, with $\mathbb{P}(\varepsilon_i=1)=\mathbb{P}(\varepsilon_i=-1)=1/2$ for all $i=1,\ldots,n$. Let $\mathcal{H}\subset L_2(Q)$ be a class of functions on $\mathcal{Z}$. Write $\nu_n^\varepsilon(h):=\frac{1}{\sqrt{n}}\sum_{i=1}^n\varepsilon_i h(Z_i)$, with $h\in\mathcal{H}$. Let*

$$\mathcal{H}(\delta):=\{h\in\mathcal{H}:\|h-h^o\|_{2,Q}\leq\delta\}\,,\quad\hat{\delta}_n:=\sup_{h\in\mathcal{H}(\delta)}\|h-h^o\|_{2,Q_n}\,,$$

where h^o is a fixed but arbitrary function in $\mathcal{H}$ and Q_n is the corresponding empirical distribution of Z based on $\{Z_i\}_{i=1}^n$. For $a\geq 8C\left(\int_{a/(32\sqrt{n})}^{\hat{\delta}_n}H^{1/2}(u,\mathcal{H},Q_n)du\ \vee\ \hat{\delta}_n\right)$, where C is some positive constant, we have

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}(\delta)}|\nu_n^\varepsilon(h)-\nu_n^\varepsilon(h^o)|\geq\frac{a}{4}\Big|Z_1,\ldots,Z_n\Big)\leq C\exp(-\frac{a^2}{64C^2\hat{\delta}_n^2})\,.$$

The following lemma is a modification of Lemma 5.6 in van de Geer (2000).

Lemma 9. *For a probability measure S on $(\mathcal{Z},\mathcal{A})$, let $\mathcal{H}$ be a class of uniformly bounded functions independent of n with $\sup_{h\in\mathcal{H}}|h|_\infty \le 1$. Suppose that almost surely for all $n \ge 1$,*

$$H(\varepsilon,\mathcal{H},L_2(S_n)) \le A_o\varepsilon^{-2\rho}, \text{ for all } \varepsilon > 0 ,$$

with $0<\rho<1$ and $A_o>0$. Then, for all n,

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}} \frac{\|h\|_{2,S_n}}{\|h\|_{2,S}\vee n^{-\frac{1}{2+2\rho}}} \ge 14u\Big) \le 4\,\exp(-u^2\, n^{\frac{\rho}{1+\rho}}) ,$$

for all $u \ge 1$.

Proof. Let $\{\delta_n\}$ be a sequence with $\delta_n\to 0$, $n\delta_n^2\to\infty$, $n\delta_n^2 \ge 2A_oH(\delta_n)$ for all n with $H(\delta_n)=\delta_n^{-2\rho}$. We apply the randomization device in Pollard (1984, page 32), as follows. Let $Z_{n+1},\dots,Z_{2n}$ be an independent copy of $Z_1,\dots,Z_n$. Let $\omega_1,\dots,\omega_n$ be independent random variables, independent of $Z_1,\dots,Z_{2n}$, with $\mathbb{P}(\omega_i=1)=\mathbb{P}(\omega_i=0)=1/2$ for all $i=1,\dots,n$. Set $Z_i{}' = Z_{2i-1+\omega_i}$ and $Z_i{}'' = Z_{2i-\omega_i}$, $i=1,\dots,n$, and $S_n{}' = (1/n)\sum_{i=1}^n \delta_{Z_i'}$, $S_n{}'' = (1/n)\sum_{i=1}^n \delta_{Z_i''}$, and $\bar{S}_{2n} = (S_n{}' + S_n{}'')/2$. Since the class is uniformly bounded by 1, an application of Chebyshev's inequality gives that for each h in $\mathcal{H}$,

$$\mathbb{P}\Big(\frac{\|h\|_{2,S_n}}{\|h\|_{2,S}\vee\delta_n} \le 2u\Big) \ge 1-\frac{1}{4u^2} \ge 3/4,$$

for all $u\ge 1$. Use a symmetrization lemma of Pollard (1984, Lemma II.3.8), see Appendix, to obtain

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}}\frac{\|h\|_{2,S_n}}{\|h\|_{2,S}\vee\delta_n}\ge 14u\Big) \le 2\mathbb{P}\Big(\sup_{h\in\mathcal{H}}\frac{|\|h\|_{2,S_n'}-\|h\|_{2,S_n''}|}{\|h\|_{2,S}\vee\delta_n}\ge 12u\Big) .$$

The peeling device on the set

$$\{h\in\mathcal{H} : (2u)^{j-1}\delta_n \le \|h\|_{2,S} \le (2u)^j\delta_n\ , j=1,2,\dots\}$$

and the inequality in Pollard (1984, page 33) give

$$\mathbb{P}\Big(\sup_{h\in\mathcal{H}}\frac{|\|h\|_{2,S_n'}-\|h\|_{2,S_n''}|}{\|h\|_{2,S}\vee\delta_n}\ge 12u \;\Big|\; Z_1,\dots,Z_n\Big)$$

$$\le \sum_{j=1}^\infty \mathbb{P}\Big(\sup_{\substack{h\in\mathcal{H}\\ \|h\|_{2,S}\le(2u)^j\delta_n}} |\|h\|_{S_n'}-\|h\|_{S_n''}| \ge 6(2u)^j\delta_n \mid Z_1,\dots,Z_n\Big)$$

$$\le \sum_{j=1}^\infty 2\exp\Big(H(\sqrt{2}(2u)^j\delta_n,\mathcal{H},\bar{S}_{2n}) - 2n(2u)^{2j}\delta_n^2\Big)$$

$$\le \sum_{j=1}^\infty 2\exp\Big(H((2u)^j\delta_n,\mathcal{H},S_n{}') + H((2u)^j\delta_n,\mathcal{H},S_n{}'') - 2n(2u)^{2j}\delta_n^2\Big)$$

$$\leq \sum_{j=1}^{\infty} 2\exp\Big(-n(2u)^{2j}\delta_n^2\Big)\,, \tag{14}$$

where the last inequality is obtained using that since $n\delta_n^2 \geq 2A_oH(\delta_n)$, also $nt^2 \geq 2A_oH(t)$ for all $t \geq \delta_n$ (here $t = (2u)^j\delta_n$). Observe that, since $(2u)^{2j} \geq (2u)^2 j > u^2 j$ for all $u \geq 1$ and $j \geq 1$, we have

$$\sum_{j=1}^{\infty} \exp(-n(2u)^{2j}\delta_n^2) \leq 2\exp(-u^2 n\delta_n^2)\,, \tag{15}$$

whenever $n\delta_n^2 > \log 2$. We finish the proof by combining (14) and (15), and taking $\delta_n = n^{-\frac{1}{2+2\rho}}$. ■

Appendix A.

Proof of Lemma 1. We write $L(f(x)) = \mathbb{E}_{Y|X}[l(Y, f(X))|X = x]$ and recall that $p_j(x) = P(Y = j|X = x)$ for all $j = 1,\ldots,m$, and that $f = (f_1,\ldots,f_m)$ with $\sum_{j=1}^m f_j = 0$. Definition (4) of the loss and the fact that $\sum_{j=1}^m p_j = 1$ give

$$L(f) = \sum_{j=1}^m p_j\Big(\sum_{k=1,\,k\neq j}^m (f_k + \frac{1}{m-1})_+\Big) = \sum_{j=1}^m (1-p_j)(f_j + \frac{1}{m-1})_+\,.$$

Let $p_k = \max_{j\in\{1,\ldots,m\}} p_j$. Here $f_j^* = -1/(m-1)$ for all $j \neq k$, and $f_k^* = 1$. Let $J^+(k) = \{j \neq k\,:\, f_j \geq -1/(m-1)\,,\ j = 1,\ldots,m\}$ and $J^-(k) = \{j \neq k\,:\, f_j < -1/(m-1)\,,\ j = 1,\ldots,m\}$. Write

$$\begin{aligned}\Delta(f) &:= L(f) - L(f^*)\\ &= \sum_{j\neq k}(1-p_j)(f_j + \frac{1}{m-1})_+ \,+\, (1-p_k)(f_k + \frac{1}{m-1})_+ \,-\, (1-p_k)(1+\frac{1}{m-1})\,.\end{aligned}$$

We first consider the case $f_k \geq -1/(m-1)$. Here,

$$\Delta(f) = (1-p_k)(f_k - 1) \,+\, \sum_{j\neq k}(1-p_j)(f_j + \frac{1}{m-1})_+\,.$$

The zero-sum constraint $\sum_{j=1}^m f_j = 0$ simply implies $f_k - 1 = -\sum_{j\neq k}(f_j + \frac{1}{m-1})$. Divide the sum into the sets $J^+(k)$ and $J^-(k)$ to obtain

$$\Delta(f) = \sum_{j\in J^+(k)} (p_k - p_j)\,(f_j + \frac{1}{m-1}) \,+\, (1-p_k)\sum_{j\in J^-(k)} |f_j + \frac{1}{m-1}|\,.$$

For the case $f_k < -1/(m-1)$, observe that

$$\frac{m}{m-1} \;=\; \sum_{j\neq k}(f_j + \frac{1}{m-1}) + f_k + \frac{1}{m-1} \;<\; \sum_{j\neq k}(f_j + \frac{1}{m-1})$$

to obtain

$$\begin{aligned}\Delta(f) &= (1-p_k)\,(-\frac{m}{m-1}) + \sum_{j\neq k}(1-p_j)(f_j + \frac{1}{m-1})_+\\ &> (p_k - 1)\sum_{j\neq k}(f_j + \frac{1}{m-1}) + \sum_{j\neq k}(1-p_j)(f_j + \frac{1}{m-1})_+\\ &= \sum_{j\in J^+(k)} (p_k - p_j)\,(f_j + \frac{1}{m-1}) \,+\, (1-p_k)\sum_{j\in J^-(k)} |f_j + \frac{1}{m-1}|\,.\end{aligned}$$

In both cases clearly $L(f)-L(f^*)$ is always non-negative since $p_k - p_j$ is non-negative for all $j \neq k$. It follows that

$$R(f)-R(f^*) = \sum_{k=1}^{m} \int (L(f)-L(f^*))\ \mathbb{1}(p_k = \max_{j=1,\ldots,m} p_j)\ dQ$$

is always non-negative, with Q the unknown marginal distribution of X. ■

Proof of Lemma 3. Let τ be defined as in (8). We write $L(f(x)) = \mathbb{E}_{Y|X}[l(Y, f(X))|X = x]$ and recall that $p_j(x) = P(Y = j|X = x)$ for all $j = 1,\ldots,m$, and that $f = (f_1,\ldots,f_m)$ with $\sum_{j=1}^m f_j = 0$. From the proof of Lemma 1, clearly

$$(L(f)-L(f^*))\ \mathbb{1}(p_k = \max_{j=1,\ldots,m} p_j) \geq \tau \sum_{j\neq k} |f_j - f_j^*| \geq \frac{\tau}{2} \sum_{j=1}^{m} |f_j - f_j^*|\ ,$$

where the second inequality is obtained from the fact that $|f_k - f_k^*| \leq \sum_{j\neq k} |f_j - f_j^*|$. That is, the excess risk is lower bounded by

$$\frac{1}{2} \sum_{j=1}^{m} \int \tau |f_j - f_j^*| dQ\ .$$

It implies that, for all $z > 0$,

$$R(f) - R^* \geq \frac{z}{2} \sum_{j=1}^{m} \left[\int |f_j - f_j^*| dQ - \int_{\tau \leq z} |f_j - f_j^*| dQ \right]\ .$$

Since $|f_j - f_j^*| \leq M$ for all j, and by Condition AA, the second integral in the inequality above can be upper bounded by $M(Cz)^{1/\gamma}$. Thus, for all $z > 0$,

$$R(f) - R^* \geq \frac{z}{2} \sum_{j=1}^{m} \int |f_j - f_j^*| dQ\ -\ \frac{z}{2} m M (Cz)^{1/\gamma}\ .$$

We take $z = \left(\sum_{j=1}^m \int |f_j - f_j^*| dQ \right)^\gamma / \left(mMC^{1/\gamma}(1+\gamma^{-1}) \right)^\gamma$ when $\gamma > 0$, and $z \uparrow 1/C$ when $\gamma = 0$. ■

Symmetrization lemma (Pollard, 1984, Lemma II.3.8)**.** *Let $\{Z(t) : t \in T\}$ and $\{Z'(t) : t \in T\}$ be independent stochastic process sharing an index set T. Suppose there exist constants $\beta > 0$ and $\alpha > 0$ such that $\mathbb{P}(|Z(t)| \leq \alpha) \geq \beta$ for every $t \in T$. Then*

$$\mathbb{P}\left(\sup_t |Z(t)| > \varepsilon \right) \leq \beta^{-1} \mathbb{P}\left(\sup_t\ |Z(t) - Z'(t)| > \varepsilon - \alpha \right)\ .$$

Abstract

This paper proposes new approaches to rank individuals from their group comparison results. Many real-world problems are of this type. For example, ranking players from team comparisons is important in some sports. In machine learning, a closely related application is classification using coding matrices. Group comparison results are usually in two types: binary indicator outcomes (wins/losses) or measured outcomes (scores). For each type of results, we propose new models for estimating individuals' abilities, and hence a ranking of individuals. The estimation is carried out by solving convex minimization problems, for which we develop easy and efficient solution procedures. Experiments on real bridge records and multi-class classification demonstrate the viability of the proposed models.

Keywords: ranking, group comparison, binary/scored outcomes, Bradley-Terry model, multi-class classification

1. Introduction

We address an interesting problem of estimating individuals' abilities from their group comparison results. This problem arises in some sports. One can evaluate a basketball player by his/her average points, but this criterion may be unfair as it ignores opponents' abilities. Comparison results in some sports, such as bridge, even do not reveal any direct information related to individuals' abilities. In a bridge match two partnerships form a team to compete with another two. The match record fairly reflects which two partnerships are better, but a partnership's raw score, depending on different boards, does not indicate its ability. Finding reasonable individual rankings using all group comparison records is thus a challenging task. Another application in machine learning/statistics is multi-class classification by coding matrices (Dietterich and Bakiri, 1995; Allwein et al., 2001). This technique decomposes a multi-class problem into several two-class problems, each of which is considered as the comparison between two disjoint subsets of class labels. The label with the greatest ability then serves as the prediction.

This line of research stems from the study of paired comparisons (David, 1988), in which one group/team consists of only one individual, and individuals' abilities are estimated from paired comparison results. Several models have been proposed, among which the most popular one is the

Bradley-Terry model (Bradley and Terry, 1952): suppose there are k individuals whose abilities are indicated by a non-negative vector $\mathbf{p} = [p_1\ p_2\ \ldots\ p_k]^T$. They proposed that

$$P(\text{individual } i \text{ beats } j) = \frac{p_i}{p_i + p_j}. \tag{1}$$

If comparisons are independent, then the maximum likelihood estimate of $\mathbf{p}$ is obtained by solving

$$\begin{aligned} \min_{\mathbf{p}} \quad & -\sum_{i \neq j} n_{ij} \log \frac{p_i}{p_i + p_j} \\ \text{subject to} \quad & \sum_{j=1}^{k} p_j = 1, \quad p_j \geq 0, j = 1, \ldots, k, \end{aligned} \tag{2}$$

where n_{ij} is the number of times individual i beats j. The normalizing constraint in (2) is imposed because the objective function is scale-invariant. The solution to (2) can be found via a simple iterative procedure, which converges to the unique global minimum under mild conditions. Detailed discussions are in, for example, Hunter (2004).

Going from paired to group comparisons, we consider k individuals $\{1, \ldots, k\}$ having m comparisons. The ith comparison setting involves a subset I_i, which is separated as two disjoint teams, I_i^+ and I_i^-. They have $n_i = n_i^+ + n_i^-$ comparisons, among which I_i^+ and I_i^- win n_i^+ and n_i^- times, respectively. Before seeking sophisticated models, an intuitive way to estimate the sth individual's ability is by the number of its winning comparisons normalized by the total number it involves:

$$\frac{\sum_{i:s \in I_i^+} n_i^+ + \sum_{i:s \in I_i^-} n_i^-}{\sum_{i:s \in I_i} n_i}. \tag{3}$$

In the case of paired comparisons, several authors (David, 1988; Hastie and Tibshirani, 1998) have shown that if

$$n_{si} > 0,\ n_{is} > 0, \text{ and } n_{si} + n_{is} = \text{constant}, \forall s, i, \tag{4}$$

then the ranking by (3) is identical to that by the solution of (2). Note that under (4), the denominator of (3) is the same over all s, so the calculation is simplified to

$$\sum_{i:i \neq s} n_{si},$$

Although the above property may provide some support of (3), this approach has several problems. Firstly, (4) may not hold in most applications of paired comparisons. Secondly, (3) does not consider teammates' abilities, so strong players and weak ones receive the same credits. Because of these deficiencies, we use (3) as a baseline in experiments in Section 4 to demonstrate the need for more advanced methods. We refer to this approach as AVG.

As a direct extension of (1), Huang et al. (2006b) proposed a generalized Bradley-Terry model for group comparisons:

$$P(I_i^+ \text{ beats } I_i^-) = \frac{\sum_{j:j \in I_i^+} p_j}{\sum_{j:j \in I_i} p_j}, \tag{5}$$

which assumes that a team's ability is the sum of its members'. Under the assumption that comparisons are independent, individuals' abilities can be estimated by minimizing the negative log-likelihood of (5):

$$\begin{aligned} \min_{\mathbf{p}} \quad & -\sum_{i=1}^{m} \left(n_i^+ \log \frac{\sum_{j:j\in I_i^+} p_j}{\sum_{j:j\in I_i} p_j} + n_i^- \log \frac{\sum_{j:j\in I_i^-} p_j}{\sum_{j:j\in I_i} p_j} \right) \\ \text{subject to} \quad & \sum_{j=1}^{k} p_j = 1, \quad p_j \geq 0, j = 1,\ldots,k. \end{aligned} \tag{6}$$

Huang et al. (2006b) pointed out that (6) may not be a convex optimization problem, so global minima are not easy to obtain. Zadrozny (2002) was the first attempt to solve (6) by an iterative procedure, which, however, may fail to converge to a stationary point (Huang et al., 2006b). The algorithm of Huang et al. (2006b) converges to a stationary point under certain conditions. We refer to this approach as GBT.ML (Generalized Bradley-Terry Model using Maximum Likelihood).

Both models (1) and (6) consider comparisons' "binary" outcomes, that is, wins and losses. However, in many comparisons, results are also quantities reflecting opponents' performances/strengths, such as points in basketball or soccer games. Some work use these "measured" outcomes for paired comparisons; an example is Glickman (1993): instead of modeling the probability that one individual beats another, he considers the difference in two individuals' abilities as a random variable, whose realization is the difference in two scores. Individuals' abilities are then estimated via maximizing the likelihood.

In this paper we focus on the *batch* setting, under which individuals' abilities are not estimated until all comparisons are finished. This setting is suitable for annual sports events, such as the Bermuda Bowl for bridge considered in Section 4, where the goal is to rank participants according to their performances in the event. However, in some applications, competitions continue to take place without a clear end and a real-time ranking is required. An example is online gaming, where players make teams to compete against one another anytime they wish and expect a real-time update of their ranking right after a game is over. Several work deal with such an *online* scenario. For example, Herbrich and Graepel (2007) proposed the TrueSkill$^{\text{TM}}$ system, which generalizes the Elo system used in Chess (Elo, 1986). The system follows a Bayesian framework and obtains real-time rankings by an online learning scheme called *Gaussian density filtering* (Minka, 2001). Menke and Martinez (2007) re-parameterized the Bradley-Terry model (2) as a single-layer artificial neural network (ANN) and extended it for group competitions. Individuals' abilities are estimated by training the ANN with the delta rule, a typical online or incremental learning technique.

We managed to advance the state of the art in two directions. On the one hand, for comparisons with binary outcomes, we propose a new exponential model in Section 2. The main advantage over Huang et al. (2006b) is that one can estimate individuals' abilities by minimizing unconstrained convex formulations. Hence global minima are easily obtained. On the other hand, we propose in Section 3 two models for comparisons with measured outcomes, which we call scored outcomes. The induced optimization problems are also unconstrained and convex; simple solution procedures are presented. This section may be the first study on finding individuals' abilities from *scored* group comparisons. Section 4 ranks partnerships in real bridge matches with the proposed approaches. Properties of different methods and their relations are studied in Section 5, which helps to explain experimental results. Section 6 demonstrates applications in multi-class classification. Section 7 concludes the work and discusses possible future directions.

Part of this work appears in a conference paper (Huang et al., 2006a).

2. Comparisons with Binary Outcomes

We denote individuals' abilities as a vector $\mathbf{v} \in R^k$, $-\infty < v_s < \infty$, $s = 1, \ldots, k$. Unlike $\mathbf{p}$ used in (5), $\mathbf{v}$ may have negative values. A team's ability is then defined as the sum of its members': for I_i^+ and I_i^-, their abilities are respectively

$$T_i^+ \equiv \sum_{s:s\in I_i^+} v_s \qquad \text{and} \qquad T_i^- \equiv \sum_{s:s\in I_i^-} v_s. \tag{7}$$

We consider teams' actual performances as random variables Y_i^+ and Y_i^-, $1 \le i \le m$ and define

$$P(I_i^+ \text{ beats } I_i^-) \equiv P(Y_i^+ - Y_i^- > 0). \tag{8}$$

The distribution of Y_i^+ and Y_i^- is generally unknown, but a reasonable choice should place the mode (the value at which the density function is maximized) around T_i^+ and T_i^-. To derive a computationally simple form for (8), we assume that Y_i^+ (and similarly Y_i^-) has a doubly-exponential extreme value distribution with

$$P(Y_i^+ \le y) = \exp(-e^{-(y-T_i^+)}), \tag{9}$$

whose mode is exactly T_i^+. Suppose Y_i^+ is independent of Y_i^-, from (8) and (9) we have

$$P(I_i^+ \text{ beats } I_i^-) = \frac{e^{T_i^+}}{e^{T_i^+} + e^{T_i^-}}. \tag{10}$$

The derivation is in Appendix A. One may assume other distributions (e.g., normal) in (9), but the resulting model is more complicated than (10). Such differences already occur for paired comparisons, where David (1988) gave some discussion. Thus (10) is our proposed model for binary outcomes.

For paired comparisons (i.e., each individual forms a team), (10) reduces to

$$P(\text{individual } i \text{ beats individual } j) = \frac{e^{v_i}}{e^{v_i} + e^{v_j}},$$

which is an equivalent re-parameterization (David, 1988; Hunter, 2004) of the Bradley-Terry model (1) by

$$p_i \equiv \frac{e^{v_i}}{\sum_{j=1}^k e^{v_j}}.$$

Therefore, our model (10) can also be considered as a generalized Bradley-Terry model. This re-parameterization however does not extend to the case of group comparisons, so (10) and (5) are different. Interestingly, (10) is a conditional exponential model or a *maximum entropy* model (Jaynes, 1957a,b), which is commonly used in the computational linguistic community (Berger et al., 1996). Thus we can use existing properties of this type of models.

Following the proposed model (10), we estimate $\mathbf{v}$ by using available comparison results. The following two sub-sections give two approaches: one minimizes a regularized least square formula, and the other minimizes the negative log-likelihood. Both are unconstrained convex optimization problems. Their differences are discussed in Section 5.

2.1 Regularized Least Square (Ext-B.RLS)

Recall that n_i^+ and n_i^- are respectively the number of comparisons teams I_i^+ and I_i^- win. From (10), we have

$$\frac{e^{T_i^+}}{e^{T_i^+}+e^{T_i^-}} \approx \frac{n_i^+}{n_i^+ + n_i^-},$$

and therefore

$$e^{T_i^+ - T_i^-} = \frac{e^{T_i^+}}{e^{T_i^-}} \approx \frac{n_i^+}{n_i^-}.$$

If $n_i^+ \neq 0$ and $n_i^- \neq 0$, one can solve

$$\min_{\mathbf{v}} \qquad \sum_{i=1}^{m} \left((T_i^+ - T_i^-) - \log \frac{n_i^+}{n_i^-} \right)^2 \tag{11}$$

to estimate the vector $\mathbf{v}$ of individuals' abilities. In case of $n_i^+ = 0$ or $n_i^- = 0$, a simple solution is adding a small number to all n_i^+ and n_i^-. This technique is widely used in the computational linguistic community, known as the "add-one smoothing" for dealing with the zero-frequency problem. To represent (11) in a simpler form, we define a vector $\mathbf{d} \in R^m$ with

$$d_i \equiv \log \frac{n_i^+}{n_i^-},$$

and a "comparison setting matrix" $G \in R^{m \times k}$ with

$$G_{ij} \equiv \begin{cases} 1 & \text{if individual } j \in I_i^+, \\ -1 & \text{if individual } j \in I_i^-, \\ 0 & \text{if individual } j \notin I_i. \end{cases} \tag{12}$$

Take bridge in teams of four as an example. An individual stands for a partnership, so G's jth column records the jth partnership's team memberships in all m matches. Since a match is played by four partnerships from two teams, each row of G has two 1's, two -1's and $k-4$ 0's. Thus, G may look like

$$\begin{bmatrix} 1 & 1 & -1 & -1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & -1 & -1 & 0 & 0 \\ -1 & -1 & 0 & 0 & 0 & 0 & 1 & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix}, \tag{13}$$

read as "The first match: the 1st, 2nd partnerships versus the 3rd, 4th; the second match: the 1st, 2nd versus the 5th, 6th; ...."

With the help of $\mathbf{d}$ and G, we rewrite (11) as

$$\min_{\mathbf{v}} \qquad (G\mathbf{v} - \mathbf{d})^T (G\mathbf{v} - \mathbf{d}), \tag{14}$$

which is equivalent to solving the following linear system:

$$G^T G\mathbf{v} = G^T \mathbf{d}. \tag{15}$$

If $G^T G$ is not invertible, the linear system (15) may have multiple solutions, which lead to possibly multiple rankings. To see when $G^T G$ is invertible, we prove the following result:

Theorem 1 *G^TG is invertible if and only if rank$(G) = k$.*

The proof is in Appendix B. This result shows that teams' members should change frequently across comparisons (as indicated by *rank*$(G) = k$) so that individuals' abilities are uniquely determined. To see how multiple rankings occur, consider an extreme case where several players always belong to the same team. Under the model (10), they can be merged as a single virtual player. After solving (14), their respective abilities can take any values but still remain optimal as long as the total ability is equal to the virtual player's. To handle such situations, we add a regularization term $\mu\mathbf{v}^T\mathbf{v}$ to (14):

$$\min_{\mathbf{v}} \qquad (G\mathbf{v}-\mathbf{d})^T(G\mathbf{v}-\mathbf{d})+\mu\mathbf{v}^T\mathbf{v},$$

where μ is a small positive number. Then a unique solution exists:

$$\left(G^TG+\mu I\right)^{-1}G^T\mathbf{d}. \tag{16}$$

The rationale of the regularization is that individuals have equal abilities before having comparisons. We refer to this approach as Ext-B.RLS (Extreme value model for Binary outcomes using Regularized Least Square).

2.2 Maximum Likelihood (Ext-B.ML)

Under the assumption that comparisons are independent, the negative log-likelihood function is

$$l(\mathbf{v}) \equiv -\sum_{i=1}^{m}\left(n_i^+\log\frac{e^{T_i^+}}{e^{T_i^+}+e^{T_i^-}}+n_i^-\log\frac{e^{T_i^-}}{e^{T_i^+}+e^{T_i^-}}\right), \tag{17}$$

and we may estimate $\mathbf{v}$ by

$$\arg\min_{\mathbf{v}} l(\mathbf{v}).$$

It is well known that the log-likelihood of a conditional exponential model is concave, and hence $l(\mathbf{v})$ is convex. However, if $l(\mathbf{v})$ is not strictly convex, multiple global minima may result in multiple rankings. The following theorem gives the sufficient and necessary condition for strict convexity:

Theorem 2 *$l(\mathbf{v})$ is strictly convex if and only if rank$(G) = k$.*

The proof is in Appendix C. As discussed in Section 2.1, the condition may not hold, and a regularization term is usually added to ensure the uniqueness of the optimal solution. Here we consider a special one

$$\mu\sum_{s=1}^{k}(e^{v_s}+e^{-v_s}), \tag{18}$$

which is strictly convex and has unique minimum at $v_s = 0, s = 1,\ldots,k$. Later we will see that this function helps to derive a simple algorithm for maximizing the likelihood.

The modified negative log-likelihood is as the following:

$$l(\mathbf{v}) \equiv -\sum_{i=1}^{m}\left(n_i^+\log\frac{e^{T_i^+}}{e^{T_i^+}+e^{T_i^-}}+n_i^-\log\frac{e^{T_i^-}}{e^{T_i^+}+e^{T_i^-}}\right)+\mu\sum_{s=1}^{k}(e^{v_s}+e^{-v_s}), \tag{19}$$

where μ is a small positive number. We estimate individuals' abilities by the unique global minimum

$$\arg\min_{\mathbf{v}} l(\mathbf{v}), \tag{20}$$

which satisfies the optimality condition:

$$\begin{aligned}\frac{\partial l(\mathbf{v})}{\partial v_s} &= -\Big(\sum_{i:s\in I_i^+} n_i^+ + \sum_{i:s\in I_i^-} n_i^-\Big) + \sum_{i:s\in I_i^+} \frac{n_i e^{T_i^+}}{e^{T_i^+}+e^{T_i^-}} + \sum_{i:s\in I_i^-} \frac{n_i e^{T_i^-}}{e^{T_i^+}+e^{T_i^-}} + \mu(e^{v_s}-e^{-v_s}) \\ &= 0,\ \ s=1,\ldots,k.\end{aligned}$$

Note that the strict convexity of (19) may not guarantee (20) to be attainable; we address this issue later in Theorem 3. Since μ is small,

$$\sum_{i:s\in I_i^+} n_i^+ + \sum_{i:s\in I_i^-} n_i^- \approx \sum_{i:s\in I_i^+} \frac{n_i e^{T_i^+}}{e^{T_i^+}+e^{T_i^-}} + \sum_{i:s\in I_i^-} \frac{n_i e^{T_i^-}}{e^{T_i^+}+e^{T_i^-}}, \tag{21}$$

which is a reasonable condition that the total number of observed wins of individual s is nearly the expected number by the assumed model. Meanwhile, the last term in $\partial l(\mathbf{v})/\partial v_s$ restricts the value of v_s from extremity, and thereby brings some robustness against huge n_i^+ or n_i^-.

Standard optimization methods (e.g., gradient or Newton's method) can be used to find a solution of (19). For conditional exponential models, an alternative technique to maximize the likelihood is the generalized iterative scaling by Darroch and Ratcliff (1972), which generates a sequence of iterations $\{\mathbf{v}^t\}_{t=0}^{\infty}$. The improved iterative scaling (Pietra et al., 1997) speeds up the convergence, but its update from $\mathbf{v}^t$ to $\mathbf{v}^{t+1}$ requires the solution of k one-variable minimization problems, which, however, usually do not have closed-form solutions. Goodman (2002) proposed the sequential conditional generalized iterative scaling, which changes only one variable at a time with a closed-form update rule. All the above techniques, however, need to be modified for solving (19) due to the regularization term (18). In the following we propose an iterative method that modifies one component of $\mathbf{v}$ at a time. Let $\delta \equiv [0,\ldots,0,\delta_s,0,\ldots,0]^T$ indicate the change of the sth component. Using the inequality $\log x \le x-1,\ \forall x>0$,

$$\begin{aligned}& l(\mathbf{v}+\delta)-l(\mathbf{v}) \\ =& -\left(\sum_{i:s\in I_i^+} n_i^+ + \sum_{i:s\in I_i^-} n_i^-\right)\delta_s + \sum_{i:s\in I_i^+} n_i \log\left(\frac{e^{T_i^+}+e^{\delta_s}+e^{T_i^-}}{e^{T_i^+}+e^{T_i^-}}\right) \\ &+ \sum_{i:s\in I_i^-} n_i \log\left(\frac{e^{T_i^+}+e^{T_i^-+\delta_s}}{e^{T_i^+}+e^{T_i^-}}\right) + \mu e^{v_s}(e^{\delta_s}-1) + \mu e^{-v_s}(e^{-\delta_s}-1) \\ \le& -\left(\sum_{i:s\in I_i^+} n_i^+ + \sum_{i:s\in I_i^-} n_i^-\right)\delta_s + \left(\sum_{i:s\in I_i^+} \frac{n_i e^{T_i^+}}{e^{T_i^+}+e^{T_i^-}} + \sum_{i:s\in I_i^-} \frac{n_i e^{T_i^-}}{e^{T_i^+}+e^{T_i^-}}\right)(e^{\delta_s}-1) \\ &+ \mu e^{v_s}(e^{\delta_s}-1) + \mu e^{-v_s}(e^{-\delta_s}-1).\end{aligned} \tag{22}$$

If $\delta_s = 0$, (22) $= 0$. We then minimize (22) to obtain the largest reduction. It is easy to see that (22) is strictly convex. Taking the derivative with respect to δ_s to be zero, we find the root for a

second-order polynomial of e^{δ_s}, so the update rule is:

$$v_s \leftarrow v_s + \log \frac{B_s + \sqrt{B_s^2 + 4\mu A_s e^{-v_s}}}{2A_s}, \tag{23}$$

where

$$\begin{aligned} A_s &\equiv \mu e^{v_s} + \sum_{i:s\in I_i^+} \frac{n_i e^{T_i^+}}{e^{T_i^+} + e^{T_i^-}} + \sum_{i:s\in I_i^-} \frac{n_i e^{T_i^-}}{e^{T_i^+} + e^{T_i^-}}, \\ B_s &\equiv \sum_{i:s\in I_i^+} n_i^+ + \sum_{i:s\in I_i^-} n_i^-. \end{aligned} \tag{24}$$

If using other regularization terms, minimizing (22) may not lead to a closed-form solution of δ_s. The algorithm is as the following:

Algorithm 1

1. Start with $\mathbf{v}^0$ and obtain $T_i^{0,+}, T_i^{0,-}, i = 1,\ldots,m$.
2. Repeat ($t = 0, 1, \ldots$)
   (a) Let $s = (t+1) \mod k$. Change the sth element of $\mathbf{v}^t$ by (23) to obtain $\mathbf{v}^{t+1}$.
   (b) Calculate $T_i^{t+1,+}, T_i^{t+1,-}, i = 1,\ldots,m$.

   until $\partial l(\mathbf{v}^t)/\partial v_j = 0,\ j = 1,\ldots,k$ are satisfied.

Next we address the convergence issue. As $A_s > 0$, (23) is always well-defined. A formal proof of Algorithm 1's convergence is in the following theorem:

Theorem 3 *The modified negative log-likelihood $l(\mathbf{v})$ defined in* (19) *attains a unique global minimum, and the sequence $\{\mathbf{v}^t\}$ generated by Algorithm 1 converges to it.*

The proof is in Appendix D. In Huang et al. (2006b), some assumptions are needed to ensure their update rule to be well-defined as well as the convergence. In contrast, Algorithm 1 does not require any assumption since the regularization term provides very nice properties. We refer to the approach of minimizing (19) as Ext-B.ML (Extreme value distribution model for Binary outcomes using Maximum Likelihood).

3. Comparisons with Scored Outcomes

This section proposes estimating individuals' abilities based on measured outcomes, such as points in basketball or soccer games. We still use random variables Y_i^+ and Y_i^- for team performances, but give n_i^+ and n_i^- different meanings: they now denote scores of I_i^+ and I_i^-. Our idea is to view $n_i^+ - n_i^-$ as a realization of $Y_i^+ - Y_i^-$ and maximize the resulting likelihood. Note that we model *difference* in scores instead of the score itself. We propose two approaches in the following subsections. One assumes normal distributions for Y_i^+ and Y_i^-, while the other assumes the same extreme value distribution (9). Individuals' abilities are estimated by maximizing the likelihood of score differences. Properties of the two approaches are investigated in Section 5.

3.1 Normal Distribution Model (NM-S.ML)

As mentioned in Section 2, using normal distributions for comparisons with binary outcomes is computationally more difficult due to a complicated form of $P(I_i^+ \text{ beats } I_i^-)$. However, for scored paired comparisons, Glickman (1993) successfully applied normal distributions. He considers individuals' performances as normally distributed random variables

$$Y_i \sim N(v_i, \sigma^2),\ i = 1, \ldots, k,$$

and view the score difference of individuals i and j as a realization of $Y_i - Y_j$. By assuming Y_i and Y_j are independent for all individuals,

$$Y_i - Y_j \sim N(v_i - v_j, 2\sigma^2), \tag{25}$$

and individuals' abilities are estimated by maximizing the likelihood. We extend this approach to group comparisons. Recall that Y_i^+ and Y_i^- are random variables for two teams' performances. With the same assumption of independent normal distributions, we have

$$Y_i^+ \sim N(T_i^+, \sigma^2), \quad Y_i^- \sim N(T_i^-, \sigma^2).$$

and

$$Y_i^+ - Y_i^- \sim N(T_i^+ - T_i^-, 2\sigma^2).$$

Assuming comparisons are independent and defining a vector $\mathbf{b}$ with

$$b_i \equiv n_i^+ - n_i^-,$$

the negative log-likelihood then is

$$\begin{aligned} l(\mathbf{v}, \sigma) &= \log\sigma + \frac{1}{4\sigma^2} \sum_{i=1}^{m} \left(T_i^+ - T_i^- - (n_i^+ - n_i^-)\right)^2 \\ &= \log\sigma + \frac{(G\mathbf{v} - \mathbf{b})^T (G\mathbf{v} - \mathbf{b})}{4\sigma^2}, \end{aligned} \tag{26}$$

where G is the comparison setting matrix defined in (12). The maximum likelihood estimate of $\mathbf{v}$ is obtained by solving $\partial l(\mathbf{v}, \sigma)/\partial v_s = 0\ \forall s$, which is the following linear system:

$$G^T G\mathbf{v} = G^T \mathbf{b}. \tag{27}$$

Similar to (14), (27) may have multiple solutions if $G^T G$ is not invertible. To overcome this problem, we add a regularization term and solve

$$\min_{\mathbf{v}} \quad l(\mathbf{v}, \sigma) + \frac{\mu}{4\sigma^2} \mathbf{v}^T \mathbf{v}, \tag{28}$$

where μ is small positive number. The unique solution of (28) then is

$$\bar{\mathbf{v}} \equiv (G^T G + \mu I)^{-1} G^T \mathbf{b}. \tag{29}$$

In addition, we also obtain an estimate of the variance by solving

$$\frac{\partial \left(l(\mathbf{v}, \sigma^2) + \frac{\mu}{4\sigma^2} \mathbf{v}^T \mathbf{v}\right)}{\partial \sigma} = 0,$$

which leads to

$$\bar{\sigma}^2 \equiv \frac{(G\bar{\mathbf{v}} - \mathbf{b})^T (G\bar{\mathbf{v}} - \mathbf{b}) + \mu \bar{\mathbf{v}}^T \bar{\mathbf{v}}}{2}.$$

We refer to this method as NM-S.ML (Normal distribution-based Model for Scored outcomes using Maximum Likelihood).

3.2 Extreme Value Distribution Model (Ext-S.ML)

Instead of the normal distribution in (25), we now consider that $Y_i^+ - Y_i^-$ is under the extreme value distribution for binary outcomes. Appendix A shows that

$$P(Y_i^+ - Y_i^- \le y) = \frac{e^{T_i^-}}{e^{T_i^+ - y} + e^{T_i^-}}, \tag{30}$$

and hence the density function is

$$f_{Y_i^+ - Y_i^-}(y) = \frac{e^{T_i^- + T_i^+ - y}}{(e^{T_i^+ - y} + e^{T_i^-})^2}.$$

The negative log-likelihood function is

$$-\sum_{i=1}^{m} \log \frac{e^{T_i^+ + T_i^- - (n_i^+ - n_i^-)}}{\left(e^{T_i^+ - (n_i^+ - n_i^-)} + e^{T_i^-}\right)^2}. \tag{31}$$

A similar proof to Theorem 2's shows that (31) is convex and shares the same condition for strict convexity in Section 2.2. Therefore, the problem of multiple solutions may also occur. We thus adopt the same regularization term as in Section 2.2 and solve

$$\min_{\mathbf{v}} \quad l(\mathbf{v}) \equiv -\sum_{i=1}^{m} \log \frac{e^{T_i^+ + T_i^- - (n_i^+ - n_i^-)}}{\left(e^{T_i^+ - (n_i^+ - n_i^-)} + e^{T_i^-}\right)^2} + \mu \sum_{s=1}^{k} (e^{v_s} + e^{-v_s}). \tag{32}$$

The unique global minimum satisfies for $s = 1, \ldots, k$,

$$\begin{aligned} \frac{\partial l(\mathbf{v})}{\partial v_s} &= -m_s + 2\left(\sum_{i:s \in I_i^+} \frac{e^{T_i^+ + n_i^-}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} + \sum_{i:s \in I_i^-} \frac{e^{T_i^- + n_i^+}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} \right) + \mu(e^{v_s} - e^{-v_s}) \\ &= 0, \end{aligned} \tag{33}$$

where

$$m_s \equiv \sum_{i:s \in I_i} 1.$$

From (30),

$$P(Y_i^+ - Y_i^- \ge T_i^+ - T_i^-) = \frac{1}{2},\ i = 1, \ldots, m. \tag{34}$$

Since μ is small, (33) and (34) imply that for $s = 1, \ldots, k$,

$$\begin{aligned} &\sum_{i:s \in I_i^+} P(Y_i^+ - Y_i^- \ge n_i^+ - n_i^-) + \sum_{i:s \in I_i^-} P(Y_i^- - Y_i^+ \ge n_i^- - n_i^+) \\ \approx \frac{m}{2} &= \sum_{i:s \in I_i^+} P(Y_i^+ - Y_i^- \ge T_i^+ - T_i^-) + \sum_{i:s \in I_i^-} P(Y_i^- - Y_i^+ \ge T_i^- - T_i^+). \end{aligned}$$

As (21) in Section 2.2, the above condition also indicates that models should be consistent with observations. To solve (32), we use Algorithm 1 with a different update rule, which is in the form of (23) but with

$$\begin{aligned} A_s &\equiv \mu e^{v_s} + 2\left(\sum_{i:s \in I_i^+} \frac{e^{T_i^+ + n_i^-}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} + \sum_{i:s \in I_i^-} \frac{e^{T_i^- + n_i^+}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} \right), \\ B_s &\equiv m_s. \end{aligned}$$

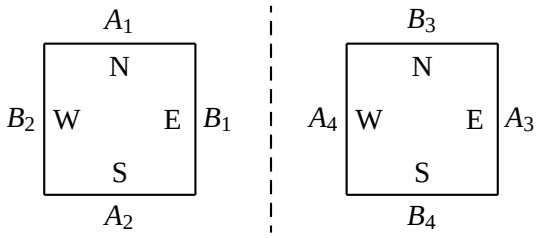

Figure 1: A typical bridge match setting. N, S, E and W stand for north, south, east, and west, respectively.

The derivation is similar to (23)'s: let $\delta \equiv [0,\ldots,0,\delta_s,0,\ldots,0]^T$. Then

$$\begin{aligned}
& l(\mathbf{v}+\delta) - l(\mathbf{v}) \\
=& -m_s\delta_s + 2\left(\sum_{i:s\in I_i^+} \log \frac{e^{T_i^+ + n_i^- + \delta_s} + e^{T_i^- + n_i^+}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} + \sum_{i:s\in I_i^-} \log \frac{e^{T_i^- + n_i^+ + \delta_s} + e^{T_i^+ + n_i^-}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} \right) \\
& + \mu e^{v_s}(e^{\delta_s} - 1) + \mu e^{-v_s}(e^{-\delta_s} - 1) \\
\leq& -m_s\delta_s + 2\left(\sum_{i:s\in I_i^+} \frac{e^{T_i^+ + n_i^-}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} + \sum_{i:s\in I_i^-} \frac{e^{T_i^- + n_i^+}}{e^{T_i^+ + n_i^-} + e^{T_i^- + n_i^+}} \right)(e^{\delta_s} - 1) \\
& + \mu e^{v_s}(e^{\delta_s} - 1) + \mu e^{-v_s}(e^{-\delta_s} - 1). \qquad (35)
\end{aligned}$$

Minimizing (35) leads to the update rule. Global convergence can be proved in a similar way to Theorem 3. We refer to this approach as Ext-S.ML (Extreme value distribution model for Scored outcomes using Maximum Likelihood).

4. Ranking Partnerships from Real Bridge Records

This section presents a real application: ranking partnerships from match records of Bermuda Bowl 2005,[1] which is the most prestigious bridge event. In a match two partnerships (four players) from a team compete with two from another team. The rules require mutual understanding within a partnership, so partnerships are typically fixed while a team can send different partnerships for different matches. To rank partnerships using our model, an individual stands for a partnership, and every T_i^+ (or T_i^-) consists of two individuals. We caution the use of the term "team" here. Earlier we refer to each T_i^+ as a team and in bridge the two partnerships (or four players) of T_i^+ are really called a team. However, these four players are from a (super)-team (usually a country), which often has six members. We use "team" in both situations, which are easily distinguishable.

4.1 Experimental Settings

We discuss why a partnership's ability is not directly available from match results, and explain why our model is applicable here. Figure 1 illustrates the match setting. A_1, A_2, A_3, A_4 and B_1, B_2, B_3, B_4

1. All match records are available at `http://www.worldbridge.org/tourn/Estoril.05/Estoril.htm`. The subset used here is available at `http://www.csie.ntu.edu.tw/~cjlin/papers/genBTexp/Data.zip`.

Board	Table I		Table II		IMPs	
	NS	EW	NS	EW	IN	PT
1		1510		1510		
2	100		650			11
3		630		630		
4		650		660		
5	690		690			
6	420			50	10	
7	140		600			10
8		420		100		8
9	460		400		2	
10		110		140	1	

Table 1: Records of the first ten boards between India (IN) and Portugal (PT). India: NS at Table I and EW at Table II. The four columns in the middle are boards' raw scores, and only winners get points. For example, in the second board IN's NS partnership won at Table I and got 100 points while PT's NS got 650 at Table II. Since PT got more points than IN, it obtained IMPs.

are four players of Team *A* and Team *B*, sitting at two tables as depicted. A match consists of several boards, each of which is played at both tables. An important feature is that a board's four hands are at identical positions of two tables, but a team's two partnerships sit at complementary positions. In Figure 1, A_1 and A_2 sit at the north (N) and the south (S) sides of one table, so A_3 and A_4 must sit at the east (E) and the west (W) sides of the other table. This setting reduces the effect of uneven hands.

On each board winning partnerships receive raw scores. Depending on the difference in two teams' total scores, the winning team gains International Match Points (IMPs). For example, Table 1 shows records of the first ten boards of the match between two Indian partnerships and two Portuguese partnerships. We can see that a larger difference in raw scores results in more IMPs for the winner. IMPs are then converted to Victory Points (VP) for the team ranking.[2] A quick look at Table 1 may motivate the following straightforward approach: a partnership's score in a match is the sum of raw scores over all boards, and its ability is the average over the matches it plays. However, this estimate is unfair due to raw scores' dependency on boards and opponents. Summing a partnership's raw scores favors those who get better hands or play against weak opponents. Moreover, since boards are different across rounds and partnerships play in different rounds, the sum of raw scores can be more unfair. The above analysis indicates that a partnership's ability cannot be obtained directly from group comparison results. Hence the proposed models can be helpful.

We consider qualifying games: 22 teams from all over the world had a round robin tournament, which consisted of $\binom{22}{2} = 231$ matches and each team played 21. Most teams had six players in three fixed partnerships, and there were 69 partnerships in total. In order to obtain reasonable rankings, each partnership should play enough matches. The last column of Table 3 shows each partnership's

2. The IMP-to-VP conversion for Bermuda Bowl 2005 is on page 32, http://www.worldbridge.org/departments/rules/GeneralConditionsOfContest2005.pdf.

number of matches. Most played 13 to 15 matches, which are close to the average (14=21×2/3) of a team with three fixed partnerships. Thus these match records are reasonable for further analysis.

To use our model, the comparison setting matrix G defined in (12) is of size 231×69; as shown in (13) each row records a match setting and has exactly two 1's (two partnerships from one team), two -1's (two partnerships from another team) and 65 0's (the remaining partnerships). The sum of two rival teams' scores (VPs) is generally 30, but occasionally between 25 to 30 as a team's maximal VP is 25. We use two rival teams' VPs as n_i^+ and n_i^-, respectively. Several matches have zero scores; we add one to all n_i^+ and n_i^- for Ext-B.RLS to avoid the numerical difficulties caused by $\log(n_i^+/n_i^-)$.

4.2 Evaluation and Results

In sport events, rankings serve two main purposes. On the one hand, they summarize the relative performances of players or teams based on outcomes in the event, so that people may easily distinguish outstanding ones from poor ones. On the other hand, rankings in past events may indicate the outcomes of future events, and can therefore become a basis for designing future event schedules. Interestingly, we may connect these two purposes with two basic concepts in machine learning: minimizing the empirical error and minimizing the generalization error. For the first purpose, a good ranking must be consistent with available outcomes of the event, which relates to minimizing errors on training data, while for the second, a good ranking must predict well on the outcomes of future events, which is about minimizing errors on unseen data. We thus adopt these two principles to evaluate the proposed approaches, and in the context of bridge matches, they translate into the following evaluation criteria:

- **Empirical Performance**: How well do the estimated abilities and rankings fit the available match records?
- **Generalization Performance**: How well do the estimated abilities and rankings predict the outcomes of unseen matches?

Here we distinguish individuals' abilities from their ranking: Abilities give a ranking, but not vice versa. When we only have a ranking of individuals, groups' strengths are not directly available since the relation of individuals' ranks to those of groups is unclear. In contrast, if individuals' abilities are available, a group's ability can be the sum of its members'. We thus propose different error measures for abilities and rankings. Let $\{(I_1^+, I_1^-, n_1^+, n_1^-), \ldots, (I_m^+, I_m^-, n_m^+, n_m^-)\}$ be the group comparisons of interest and their outcomes. For a vector $\mathbf{v} \in R^k$ of individuals' abilities, we define the

- **Group Comparison Error**:

$$GCE(\mathbf{v}) \quad \equiv \quad \frac{\sum_{i=1}^{m} I\left\{(n_i^+ - n_i^-)(T_i^+ - T_i^-) \leq 0\right\}}{m},$$

where $I\{\cdot\}$ is the indicator function; T_i^+ and T_i^- are predicted group abilities of I_i^+ and I_i^-, as defined in (7). The GCE is essentially the proportion of wrongly predicted comparisons by the ability vector $\mathbf{v}$ to the m comparisons.

In the error measure for rankings, we use $\mathbf{r}$, a permutation of the k individuals, to denote a ranking, where r_s is the rank of individual s. Then we define the

- **Group Rank Error**:

$$GRE(\mathbf{r}) \equiv \frac{\sum_{i=1}^{m}\left(I\left\{n_i^+ > n_i^- \text{ and } U_i^+ > L_i^-\right\} + I\left\{n_i^+ < n_i^- \text{ and } L_i^+ < U_i^-\right\}\right)}{\sum_{i=1}^{m}\left(I\left\{U_i^+ > L_i^-\right\} + I\left\{L_i^+ < U_i^-\right\}\right)}, \quad (36)$$

in which

$$U_i^+ \equiv \min_{j\in I_i^+} r_j, \qquad L_i^+ \equiv \max_{j\in I_i^+} r_j,$$
$$U_i^- \equiv \min_{j\in I_i^-} r_j, \qquad L_i^- \equiv \max_{j\in I_i^-} r_j.$$

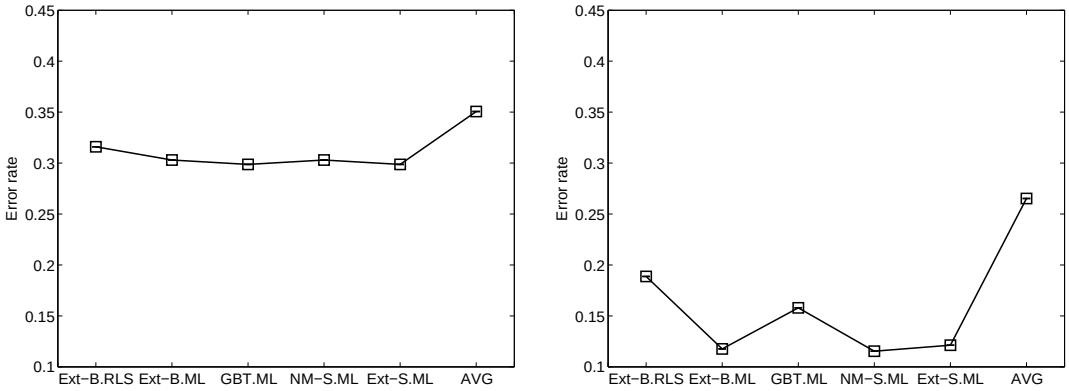
Since a smaller rank indicates more strength, the U_i^+ and L_i^+ defined above represent the best and the weakest in I_i^+, respectively. The denominator in (36) is thus the number of comparisons where one group's members are all ranked higher (or lower) than the members of the competing group, and the numerator in (36) counts the number of wrong predictions, that is, comparisons in which members of the winning group are all ranked lower than those of the defeated group. In other words, GRE computes the error only on comparisons in which relative strengths of the participating groups can be clearly determined by their members' ranks, whereas GCE considers the error on all of the comparisons. From this point of view, GRE is a more conservative error measure.

Combining the two error measures with the two evaluation criteria, we conducted four sets of experiments: Empirical GCE, Empirical GRE, Generalization GCE, and Generalization GRE. We compared six approaches, including the newly proposed Ext-B.RLS, Ext-B.ML, NM-S.ML, and Ext-S.ML; the generalized Bradley-Terry model GBT.ML (Huang et al., 2006b), and AVG, the simple approach (3) of summing individuals' scores, which serves as a baseline.[3] In the empirical part, we applied each approach on the entire 231 matches to estimate partnerships' abilities, and computed the two errors. Since the goal in the empirical part is to fit available records well, we set the regularization parameter μ for all approaches[4] except AVG to a small value 10^{-3}. In the generalization part, we randomly split the entire set as a training set of 162 matches and a testing set of 69 matches for 50 times. For each split, we searched for μ in $[2^5, 2^4, \ldots, 2^{-8}, 2^{-9}]$ by the Leave-One-Out (LOO) validation on the training set, estimated partnerships' abilities with the best μ, and then computed GCE and GRE on the testing set.

Results are in Figures 2 and 3 for empirical and generalization performances, respectively. In the empirical part, the four proposed approaches and GBT.ML perform obviously better than AVG, and the improvement in GRE is very significant. In particular, Ext-B.ML, NM-S.ML, and Ext-S.ML cause very small GREs, to the order of 10^{-1}. These results show that the proposed approaches are effective in fitting the available bridge match records. However, in the generalization part, all of the approaches result in poor GCEs, nearly as large as a random predictor does, and the proposed approaches did not improve over AVG. For GREs, values are smaller, but the improvements over

3. AVG gives individuals' abilities. We then use the same summation assumption to obtain groups' abilities for computing GCEs.

4. In order to ensure the convergence of their algorithm, Huang et al. (2006b) added to the objective function (5) what they called a "barrier term," which is also controlled by a small positive number μ (See Eq. (14) in Huang et al. 2006b). Here we simply refer to it as a regularization parameter.



(a) Group Comparison Error (b) Group Rank Error

Table 2: Empirical Group Rank Errors in fraction.

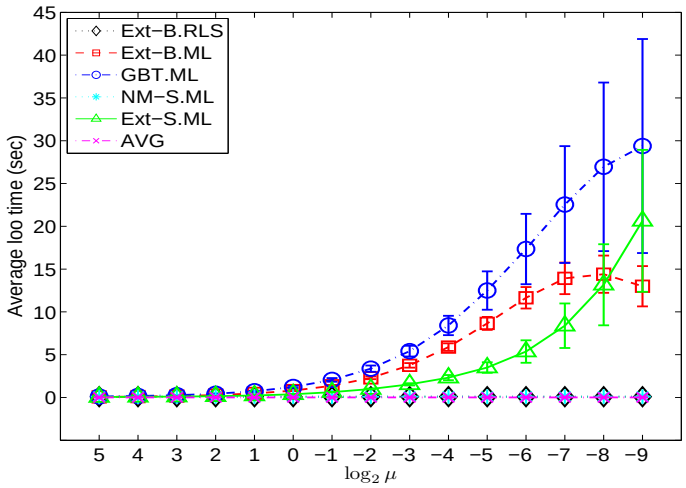

Figure 4: Average LOO time (sec) over 50 training/testing splits. Vertical bars indicate standard deviations.

AVG are rather marginal. In the following we give some accounts of the poor generalization performances. As mentioned in Section 4.1, each match setting can be viewed as a vector in $\{1,0,-1\}^{69}$, in which only two dimensions have 1's, and another two have -1's. Moreover, we are using records in the qualifying stage, a round-robin tournament in which every two teams (countries) played exactly one match. Consequently, when a match is removed from the training set, the four competing partnerships of that match have no chance to meet directly during the training stage. Indirect comparisons may only be marginally useful in predicting those partnerships' competition outcomes due to the lack of transitivity. In conclusion, the outcome of a match in this bridge data set may not be well indicated by outcomes of the other matches, and therefore all of the approaches failed to generalize well.

To further study the rankings by the six approaches, we show in Table 2 their empirical GREs. Since GRE only looks at the subset of matches in which group members' ranks clearly decide groups' relative strengths, the size of this subset, that is, the denominator in GRE, may also be a performance indicator of each approach. We thus present GREs in fraction. It is clear that the ranking by AVG is able to determine the outcomes of more matches, but at the same time causes more errors. Similar results are also found in the generalization experiments. We may therefore say that the proposed approaches and GBT.ML lead to rankings with more "precision," in the sense that they may not be able to decide groups' relative performances in the majority of comparisons, but once they do, their decisions are accurate.

In addition to the efficacy of the six approaches, we also reported their efficiency. Figure 4 shows the average LOO time over the 50 training/testing splits under different values of μ. We obtained these timing results on an Intel® Core™2 Quad CPU (2.66GHz) machine with 8G main

memory; the linear systems of Ext-B.RLS and NM-S.ML were solved by Gaussian Elimination. AVG,[5] Ext-B.RLS, and NM-S.ML finished LOO almost instantly under all values of μ, while Ext-B.ML, GBT.ML, and Ext-S.ML, the three approaches using iterative algorithms, took more time as μ decreased. However, for large-scale problems with a huge k or m, traditional linear system solvers may encounter memory or computational difficulties, and the efficiency of the proposed approaches requires a more thorough study.

Finally, we list the top ten partnerships ranked by Ext-B.ML in Appendix F. Most of them are famous bridge players.

5. Properties of Different Approaches

Although we distinguish binary comparisons from scored ones, they are similar in some situations. On the one hand, if two teams had a series of comparisons, the number of victories can be viewed as a team's score in a super-game. On the other hand, scores in a game might be the sum of binary outcomes; for example, scores in soccer games are total numbers of successful shots. It is therefore interesting to study the properties of different methods and their relation. Table 3 lists partnership rankings obtained by applying the six approaches to the entire set of match records. We first investigate the similarity between these rankings by Kendall's tau, a standard correlation coefficient that quantifies the consistency between two rankings. We computed Kendall's tau for every pair of the six rankings and present them in Table 4, which indicates roughly three groups: Ext-B.RLS, Ext-B.ML, GBT.ML and NM-S.ML give similar rankings; the one by Ext-S.ML is quite different, while AVG seems to be uncorrelated with the others. We then measure the distance between two groups of rankings $g1$ and $g2$: For each partnership,

$$\begin{aligned} & d(\text{ranks by } g1, \text{ranks by } g2) \\ \equiv & \begin{cases} \min(\text{ranks by } g2) - \max(\text{ranks by } g1) & \text{if ranks by } g1 \text{ are all smaller,} \\ \min(\text{ranks by } g1) - \max(\text{ranks by } g2) & \text{if ranks by } g2 \text{ are all smaller,} \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \tag{37}$$

For example, from Table 3 the second partnership of U.S.A.2 is ranked 67th/65th/67th/65th by Ext-B.RLS/Ext-B.ML/GBT.ML/NM-S.ML and 25th by AVG. Therefore,

$$d(\{67,65,67,65\},25) = \min(67,65,67,65) - 25 = 40.$$

Checking all 69 partnerships' ranks gives

$$|d(\{\text{Ext-B.RLS,Ext-B.ML,GBT.ML,NM-S.ML}\}, \text{Ext-S.ML}) \geq 20| = 6, \tag{38}$$

$$|d(\{\text{Ext-B.RLS,Ext-B.ML,GBT.ML,NM-S.ML}\}, \text{AVG}) \geq 20| = 11. \tag{39}$$

In Table 3 we respectively underline and boldface partnerships satisfying (38) and (39). The eleven ranks satisfying (39) shows that AVG's ranking is closer to the team ranking:[6] Partnerships satisfying (39) have higher ranks than those by the others when the team ranks are high, but have the opposite when the team ranks are low. This observation indicates that AVG may fail to identify weak (strong) individuals from strong (weak) groups.

5. Apparently there is no need to run LOO for AVG, which is independent of μ; we do it here only for timing comparisons.

6. Recall that in the beginning of Section 4, we mentioned that all teams, after the qualifying stage was over, were ranked according to their total VPs gained in the tournament.

Table 3: Partnerships' rankings. A partnership corresponds to the same position in columns. For example, Italy's second partnership is ranked 18th, 14th, 12th, 18th, 4th and 4th by Ext-B.RLS, Ext-B.ML, GBT.ML, NM-S.ML, Ext-S.ML and AVG, respectively, and it plays 14 matches. Rankings satisfying (38) and (39) are underlined and boldfaced, respectively.

	Ext-B.RLS	Ext-B.ML	GBT.ML	NM-S.ML	Ext-S.ML	AVG
Ext-B.RLS	1.00	0.84	0.79	0.82	0.50	0.44
Ext-B.ML	0.84	1.00	0.87	0.97	0.61	0.49
GBT.ML	0.79	0.87	1.00	0.86	0.62	0.53
NM-S.ML	0.82	0.97	0.86	1.00	0.60	0.49
Ext-S.ML	0.50	0.61	0.62	0.60	1.00	0.50
AVG	0.44	0.49	0.53	0.49	0.50	1.00

Table 4: Kendall's tau (correlation coefficients).

The above results suggest that approaches based on different types of comparisons may produce similar rankings, such as Ext-B.ML and NM-S.ML, while those based on the same type of outcomes may lead to diverse results, such as NM-S.ML and Ext-S.ML. Therefore, in the next two subsections we study their formulations and obtain the following results:

- When all n_i's are equal, that is, the number of games or the total score in every group comparison is the same, and estimated group abilities are approximately even, Ext-B.ML and NM-S.ML give similar rankings.
- When all n_i's are equal, Ext-B.RLS is more sensitive than Ext-B.ML and NM-S.ML to extreme outcomes ($n_i^+ \approx 0$ or $n_i^+ \approx n_i$).
- For the two scored-outcome approaches, extreme outcomes have a greater impact on NM-S.ML than on Ext-S.ML.

5.1 Comparing Binary- and Scored-outcome Approaches

Experimental results in Section 4 show that the binary-outcome approach Ext-B.ML and the scored-outcome approach NM-S.ML give very similar rankings. By analyzing their optimization problems, we find that

Claim 1 *If all n_i's are equal and the optimal* **v** *for Ext-B.ML satisfies*

$$T_i^+ \approx T_i^- \quad \forall i,$$

then Ext-B.ML and NM-S.ML give very close rankings.

The proof is in Appendix E. For the bridge data used in Section 4, n_i's are two rival teams' total VPs and are mostly 30; the average $|T_i^+ - T_i^-|$ from the optimal **v** for Ext-B.ML is 0.3983.

However, in applications where n_i's are unequal, these two approaches may give different results. Clearly, they use different approximations:

$$\frac{e^{T_i^+}}{e^{T_i^-}} \approx \frac{n_i^+}{n_i^-} \qquad \text{and} \qquad T_i^+ - T_i^- \approx n_i^+ - n_i^-. \tag{40}$$

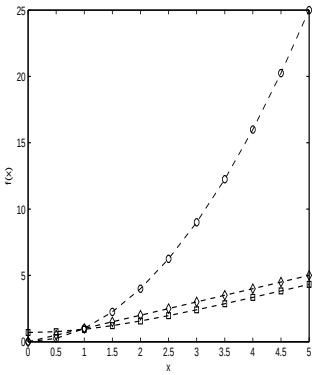
One considers the ratio, which is independent from the values of n_i's, but the other considers the difference, whose value scales with those of n_i's. Therefore, the estimate by NM-S.ML may be more biased than Ext-B.ML to fit comparison outcomes with large n_i.

Another issue is the small but perceivable dissimilarity of the ranking by Ext-B.RLS from those by Ext-B.ML and NM-S.ML, as revealed in the empirical GREs in Table 2 and the Kendall's tau in Table 4. Investigating them more carefully, we find that

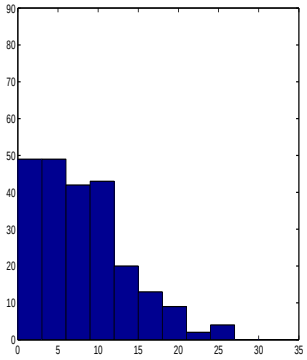
$$|d(\text{Ext-B.RLS}, \{\text{Ext-B.ML, NM-S.ML}\}) \geq 10| = 8, \tag{41}$$

where the distance is defined in (37). Interestingly, five of these eight partnerships played matches where weak teams beat strong teams by an extreme amount, such as Netherlands beating U.S.A.2 by 25:0, and Ext-B.RLS ranks them higher than Ext-B.ML and NM-S.ML do. This result suggests that Ext-B.RLS is vulnerable to even only few extreme outcomes so as to change the overall ranking. We verify this property by comparing the estimates by Ext-B.RLS and NM-S.ML. Suppose $n_i = n \; \forall i$ (which is the case here), and then according to (16), the ability estimate of individual s by Ext-B.RLS is

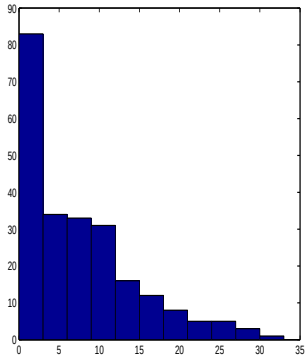
$$v_s = \sum_{i=1}^{m} A_{si}\big(\log n_i^+ - \log n_i^-\big) = \sum_{i=1}^{m} A_{si}\big(\log n_i^+ - \log(n - n_i^+)\big),$$



(a) Loss function curves. Circles: x^2. Diamonds: x. Squares: $\log(1+\cosh(x))$.



(b) Error histogram for NM-S.ML



(c) Error histogram for Ext-S.ML

Figure 5: Error function curves and histograms. The x-axis of histograms is $|T_i^+ - T_i^- - (n_i^+ - n_i^-)|$.

where $A = \left(G^T G + \mu I\right)^{-1} G^T$. To check the sensitivity of v_s with respect to the change of n_i^+, we calculate

$$\frac{\partial v_s}{\partial n_i^+} = A_{si}\left(\frac{1}{n_i^+} + \frac{1}{n - n_i^+}\right) = \frac{nA_{si}}{n_i^+(n - n_i^+)}.$$

Clearly, the estimate v_s is more sensitive to extreme values of n_i^+, that is, $n_i^+ \approx 0$ or $n_i^+ \approx n$. However, for NM-S.ML we have

$$v_s = \sum_{i=1}^{m} A_{si}(n_i^+ - n_i^-) = \sum_{i=1}^{m} A_{si}(2n_i^+ - n)$$

and

$$\frac{\partial v_s}{\partial n_i^+} = 2A_{si}.$$

That is, different values of n_i^+ have equal impact on the estimate by NM-S.ML.

In conclusion, when n_i remains a constant and the estimates by Ext-B.ML have $T_i^+ \approx T_i^- \ \forall i$, NM-S.ML and Ext-B.ML give similar estimates, which are less sensitive than that by Ext-B.RLS to extreme outcomes. When n_i's are unequal, the discussion in (40) indicates that NM-S.ML is more affected than Ext-B.ML.

5.2 Comparing the Two Scored-outcome Approaches

As shown in (38), the ranking by Ext-S.ML is rather diverse from those by Ext-B.RLS, Ext-B.ML, and NM-S.ML. We explore this issue by first re-writing the objective functions of NM-S.ML and Ext-S.ML respectively as

$$\min_{\mathbf{v}} \quad \sum_{i=1}^{m}\left(T_i^+ - T_i^- - (n_i^+ - n_i^-)\right)^2 + \mu\sum_{s=1}^{k} v_s^2$$

and

$$\min_{\mathbf{v}} \quad \sum_{i=1}^{m} \log\left(1+\cosh\left(T_i^+ - T_i^- - (n_i^+ - n_i^-)\right)\right) + \mu \sum_{s=1}^{k} (e^{v_s} + e^{-v_s}),$$

where cosh is the *hyperbolic cosine* function. Although these two formulations are derived to maximize the likelihood, they can be viewed as minimizing estimation errors

$$\left|T_i^+ - T_i^- - (n_i^+ - n_i^-)\right|$$

with two different loss functions. As μ is small, we ignore the effect of the regularization term. It is easy to show that as $\left|T_i^+ - T_i^- - (n_i^+ - n_i^-)\right| \to \infty$,

$$\frac{\log\left(1+\cosh\left(T_i^+ - T_i^- - (n_i^+ - n_i^-)\right)\right)}{\left|T_i^+ - T_i^- - (n_i^+ - n_i^-)\right|} \to 1.$$

To show the behaviors of the three functions: x^2, x and $\log(1+\cosh(x))$, we plot their curves in Figure 5(a). One can see that $\log(1+\cosh(x))$ increases almost linearly with x. In the machine learning community, it is well known that quadratic loss functions may lead to a very different estimation from linear ones. The reason is that quadratic loss functions penalize large errors more severely than linear ones do; estimations are thus dominated by even only few extreme observations, and as a side effect, may cause quite a few moderate errors. In contrast, estimations under linear loss functions may allow several large errors in order to make most errors small. Figures 5(b) and 5(c) are histograms of $\left|T_i^+ - T_i^- - (n_i^+ - n_i^-)\right|$ for NM-S.ML and Ext-S.ML, respectively; we see clearly the aforementioned two error patterns: Compared with NM-S.ML, Ext-S.ML has a lot more errors in the first bin and also some in the last two. In addition, we find that the empirical GRE of Ext-S.ML in Section 4.2 is highly related to its error pattern: Among the 24 correct rank predictions[7] produced by Ext-S.ML but not by NM-S.ML, twelve have $\left|T_i^+ - T_i^- - (n_i^+ - n_i^-)\right|$ smaller than 3 (the first bin of histograms); NM-S.ML has no $\left|T_i^+ - T_i^- - (n_i^+ - n_i^-)\right|$ larger than 27 (the last two bins of histograms) while Ext-S.ML has four, among which the partnerships satisfying (38) participate in three. Interestingly, the two types of loss functions seem to reflect two different ranking criteria: one focuses more on performances against extreme opponents, so wins over strong opponents and losses to weak opponents greatly influence the ranking; the other is less sensitive to extreme outcomes and treat comparisons more evenly. Consequently, deciding which loss function, and hence which approach to use may eventually be contingent on game-specific factors and subjective preferences.

6. Multi-class Classification

Multi-class classification using coding matrices (Dietterich and Bakiri, 1995; Allwein et al., 2001) is a general scheme to decompose a problem into several two-class problems. The widely-used methods "one-against-one" and "one-against-the rest" are special cases of this framework. The decomposition is usually specified by a coding matrix $G \in \{1,0,-1\}^{m\times k}$, where k is the number of classes and m is the number of two-class problems. Each row of G describes how the k classes are separated to two groups: those with 1 are in one group while those with -1 are in the other; those with 0 are not used in this two-class problem. The coding matrix in Table 5 illustrates four common types of codes: one-against-one, one-against-all, dense, and sparse; their definitions are

7. Correct rank predictions are the denominator of GRE minus its numerator.

One-against-one	$\begin{bmatrix} 0 & 0 & 1 & 0 & 0 & -1 & 0 & 0 \\ -1 & -1 & -1 & 1 & -1 & -1 & -1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & 0 & 0 & 1 & 0 & 0 & -1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix}$
One-against-the rest	
Dense	
Sparse	
$\vdots$	

Table 5: A coding matrix ($k = 8$). The four rows illustrate four types of codes.

given by Items 1 to 4 on Page 2210. At the training stage, m binary classifiers are trained for the m two-class problems. For an unlabeled instance, its label is predicted by combining results of the m binary classifiers.

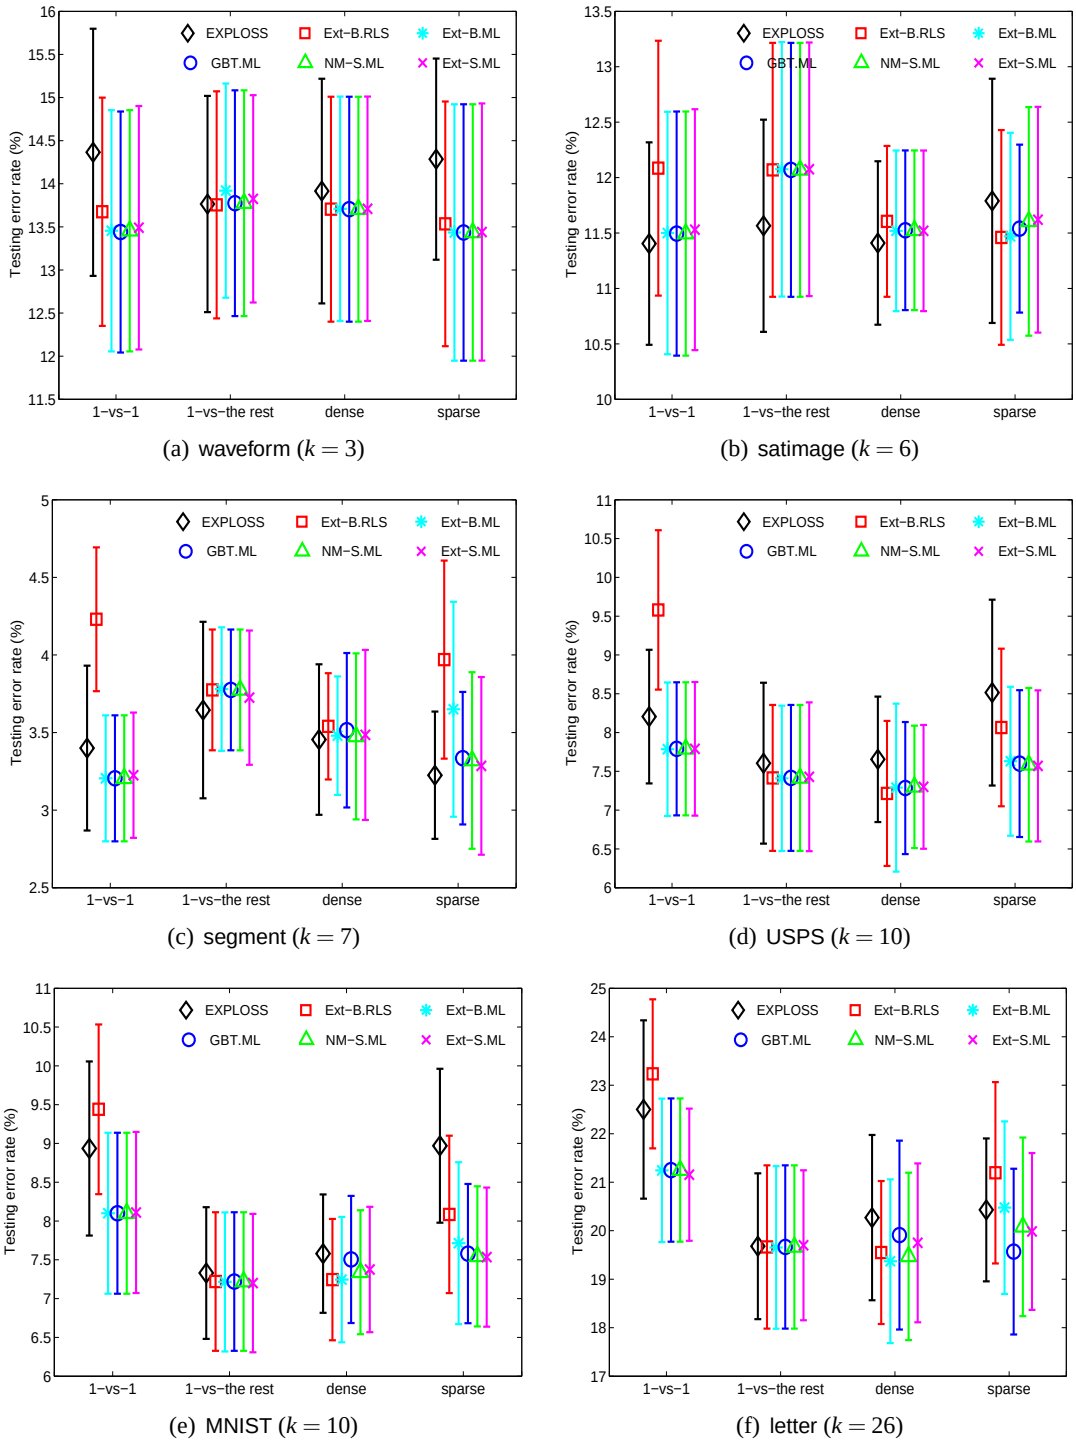
There are several schemes for deciding the final prediction. Dietterich and Bakiri (1995) proposed choosing the class whose column in G has the smallest distance to the m binary decisions on the instance. This method can correct errors made by some decision rules, and thus is called *error-correcting output codes* (ECOC). Allwein et al. (2001) proposed a more general framework, the *loss-based decoding*, which exploits not only binary decisions, but also *decision values* of binary classifiers. In particular, they adopted the *exponential loss-based decoding* (EXPLOSS): let $\hat{f}_i$ be the decision function of the ith binary classifier, and $\hat{f}_i(\mathbf{x}) > 0$ (< 0) specifies that an instance $\mathbf{x}$ to be in classes of I_i^+ (I_i^-). Then,

$$\text{predicted label } \equiv \arg\min_s \Big(\sum_{i=1}^{m} e^{-G_{is}\hat{f}_i} \Big).$$

If $G_{is} = 1$ and $\hat{f}_i(\mathbf{x})$ says $s \in I_i^+$, then $e^{-G_{is}\hat{f}_i}$ gives a small loss. By using decision values, the loss-based decoding incorporates the confidence of each binary prediction in making the final decision.

Table 5 is in the same format as our "comparison setting matrix" G defined in (12) and (13). Huang et al. (2006b) (GBT.ML) thus consider classes as individuals and two-class problems as group comparisons; the 1's and -1's in the ith row of G correspond to I_i^+ and I_i^-, respectively. The group competition results n_i^+ and n_i^- are assumed to be available from two-class classifiers. For an unlabeled instance, classes are ranked according to their estimated "abilities" and the highest one (with the largest ability) serves as the prediction. All of our newly proposed models can be applied in the same way, but there are two minor issues. Firstly, all of our proposed methods except Ext-B.RLS assume that group comparisons are independent. This property does not hold for multi-class classification since two-class classifiers involving the same classes share training data. Huang et al. (2006b) pointed out that GBT.ML can be interpreted as minimizing the Kullback-Leibler distance between the model and the observations. It is easy to see that their argument also applies to Ext-B.ML but not to NM-S.ML nor Ext-S.ML. Secondly, the n_i^+ and n_i^- given by two-class classifiers are real values, for which the binary-outcome approaches, according to their definition, may not be suitable. Despite of these minor issues, as we will show, our proposed methods perform quite well in practice.

We compare our methods with EXPLOSS and GBT.ML on six real data sets: waveform, satimage, segment, USPS, MNIST, and letter; numbers of classes range from 3 to 26. The settings of



(a) waveform ($k = 3$) (b) satimage ($k = 6$)

(c) segment ($k = 7$) (d) USPS ($k = 10$)

(e) MNIST ($k = 10$) (f) letter ($k = 26$)

Figure 6: Testing error rates on the 800-training-1000-testing data sets by six approaches under four codes: one-against-one (1-vs-1), one-against-the rest (1-vs-the rest), dense, and sparse. Vertical bars indicate standard deviations.

experiments are the same as those in Huang et al. (2006b). We use the 20 subsets of 800 training and 1,000 testing instances[8] and consider the same four types of coding matrices:

1. One-against-one: $|I_i^+| = |I_i^-| = 1,\ i = 1,\ldots,k(k-1)/2$.
2. One-against-all: $|I_i^+| = 1,\ |I_i^-| = k-1,\ i = 1,\ldots,k$.
3. Dense: $|I_i^+| = |I_i^-| = k/2,\ \forall i;\ m = [10\log_2 k]$.
4. Sparse: $E(|I_i^+|) = E(|I_i^-|) = k/4,\ \forall i;\ m = [15\log_2 k]$.

$[x]$ rounds a real number x to its nearest integer. We choose support vector machines (SVM) (Boser et al., 1992) with the RBF (Radial Basis Function) kernel $e^{-\gamma\|\mathbf{x}_i-\mathbf{x}_j\|^2}$ as the two-class classifier, where $\mathbf{x}_i$ and $\mathbf{x}_j$ are two training instances. An improved version (Lin et al., 2007) of Platt (2000) generates n_i^+ and $n_i^- = 1 - n_i^+$ from SVM decision values. We implement our methods by modifying LIBSVM (Chang and Lin, 2001). For all of the 20 subsets, we select SVM parameters by cross validation before testing. Figures 6(a)-6(f) report the average testing error rates and standard deviations of the six methods: EXPLOSS, Ext-B.RLS, Ext-B.ML, GBT.ML, NM-S.ML and Ext-S.ML. Each figure summarizes the results on one data set by six groups of colored error bars, which represent the error rates of the six methods under the four types of codes. We can see that EXPLOSS (black diamond) and Ext-B.RLS (red square) perform worse than the others under the one-against-one and the sparse codes as k becomes large, while GBT.ML, Ext-B.ML, NM-S.ML and Ext-S.ML are almost equally good. Regarding the performances of the four types of codes, one-against-one and sparse are less effective for large values of k, an observation consistent with the results in (Huang et al., 2006b). Recall that in Section 4.2 Ext-S.ML behaves differently from the others, but here its predictions are similar to those of NM-S.ML and Ext-B.ML. The reason is that the n_i^+ and n_i^- produced by (Lin et al., 2007) are probabilities satisfying $n_i^+ + n_i^- = 1$, so values of $|T_i^+ - T_i^- - (n_i^+ - n_i^-)|$ are mostly small and the difference between quadratic and linear loss functions is negligible. Results here suggest that the proposed methods are useful for multi-class classification with coding matrices.

7. Conclusions

We propose new and useful methods to rank individuals from group comparisons. For comparisons with binary outcomes, earlier work solves non-convex problems, but here convex formulations with easy solution procedures are developed. For scored outcomes, our formulations are probably the first for this type of problems. Experiments show that the proposed approaches give reasonable partnership rankings from bridge records and perform effectively in multi-class classification. We give theoretical accounts for behaviors of proposed approaches, which demonstrate how different models reflect diverse ranking criteria. We also develop techniques to evaluate different rankings, which may be used in other ranking tasks.

Appendix A. Derivation of (10) from (8)

$$P(Y_i^+ - Y_i^- > 0) \equiv \int_{-\infty}^{\infty}\int_{y^-}^{\infty} de^{-e^{-(y^+-T_i^+)}} de^{-e^{-(y^--T_i^-)}}. \tag{42}$$

8. Available at http://www.csie.ntu.edu.tw/~cjlin/papers/svmprob/data.

Let

$$x^+ \equiv e^{-(y^+ - T_i^+)} \text{ and } x^- \equiv e^{-(y^- - T_i^-)}.$$

Consequently,

$$de^{-e^{-(y^+ - T_i^+)}} = -e^{-x^+}dx^+ \text{ and } de^{-e^{-(y^- - T_i^-)}} = -e^{-x^-}dx^-.$$

Then,

$$\begin{aligned} (42) &= \int_0^\infty -e^{-x^-} \int_0^{x^- e^{T_i^+ - T_i^-}} -e^{-x^+}dx^+dx^- \\ &= \frac{e^{T_i^+}}{e^{T_i^+} + e^{T_i^-}}. \end{aligned}$$

Appendix B. Proof of Theorem 1

If $rank(G) < k$, G^TG is obviously not invertible; if $rank(G) = k$, the Singular Value Decomposition of G can be written as

$$G = U\Lambda V^T,$$

where $U \in R^{m\times k}$ and $V \in R^{k\times k}$ are orthonormal and $\Lambda \in R^{k\times k}$ is diagonal with

$$\Lambda_{ii} \neq 0,\ i = 1,\ldots,k.$$

Therefore,

$$G^TG = V\Lambda U^TU\Lambda V^T = V\Lambda^2V^T$$

is invertible.

Appendix C. Proof of Theorem 2

We first rewrite $l(\mathbf{v})$ as

$$l(\mathbf{v}) = -\sum_{i=1}^m (n_i^+T_i^+ + n_i^-T_i^-) + \sum_{i=1}^m n_i \log(e^{T_i^+} + e^{T_i^-}).$$

The first summation is obviously convex. For the second summation, by using Hölder's inequality we have

$$\begin{aligned} & \sum_{i=1}^m n_i \log\left(e^{\lambda T_i^+ + (1-\lambda)\tilde{T}_i^+} + e^{\lambda T_i^- + (1-\lambda)\tilde{T}_i^-}\right) \\ = & \sum_{i=1}^m n_i \log\left((e^{T_i^+})^\lambda (e^{\tilde{T}_i^+})^{1-\lambda} + (e^{T_i^-})^\lambda (e^{\tilde{T}_i^-})^{1-\lambda}\right) \\ \leq & \sum_{i=1}^m n_i \log\left(e^{T_i^+} + e^{T_i^-}\right)^\lambda \left(e^{\tilde{T}_i^+} + e^{\tilde{T}_i^-}\right)^{1-\lambda} \\ = & \sum_{i=1}^m n_i\lambda \log\left(e^{T_i^+} + e^{T_i^-}\right) + \\ & \sum_{i=1}^m n_i(1-\lambda) \log\left(e^{\tilde{T}_i^+} + e^{\tilde{T}_i^-}\right) \end{aligned} \quad (43)$$

for any $\mathbf{v}, \tilde{\mathbf{v}}$ and $\lambda \in (0,1)$, and the equality holds if and only if

$$T_i^+ - T_i^- = \tilde{T}_i^+ - \tilde{T}_i^- \ \forall i,$$

which can be re-written as

$$G(\mathbf{v} - \tilde{\mathbf{v}}) = \mathbf{0}. \tag{44}$$

If $rank(G) = k$, then (44) holds if and only if $\mathbf{v} = \tilde{\mathbf{v}}$, so $l(\mathbf{v})$ is strictly convex. If $l(\mathbf{v})$ is strictly convex, then the equality in (43) holds if and only if $\mathbf{v} = \tilde{\mathbf{v}}$, so

$$G(\mathbf{v} - \tilde{\mathbf{v}}) = \mathbf{0} \Leftrightarrow \mathbf{v} = \tilde{\mathbf{v}},$$

which implies $rank(G) = k$.

Appendix D. Proof of Theorem 3

It is easy to verify that the level sets of $l(\mathbf{v})$ are bounded. Since $l(\mathbf{v})$ is strictly convex, it then attains a unique global minimum. To prove the convergence of Algorithm 1, we first show that if $\partial l(\mathbf{v})/\partial v_s \neq 0$, then minimizing (22) leads to

$$l(\mathbf{v} + \delta) < l(\mathbf{v}). \tag{45}$$

From (23), if the optimal δ_s for (22) is zero, then

$$\frac{B_s + \sqrt{B_s^2 + 4\mu A_s e^{-v_s}}}{2A_s} = 1,$$

which implies

$$4A_s(\mu e^{-v_s} - A_s + B_s) = -4A_s \frac{\partial l(\mathbf{v})}{\partial v_s} = 0. \tag{46}$$

Since $A_s \neq 0$ throughout iterations, (46) implies $\partial l(\mathbf{v})/\partial v_s = 0$. Thus if $\partial l(\mathbf{v})/\partial v_s \neq 0$, the optimal $\delta_s \neq 0$. With (22) $= 0$ if $\delta_s = 0$, (45) follows.

Next we show that the sequence $\{\mathbf{v}^t\}$ generated by Algorithm 1 is bounded. If not, there must exist j such that $|v_j^t| \to \infty$. Then

$$\begin{aligned} l(\mathbf{v}^t) &\geq \mu \sum_{s=1}^{k} (e^{v_s^t} + e^{-v_s^t}) \\ &= \mu \sum_{s=1}^{k} (e^{|v_s^t|} + e^{-|v_s^t|}) \\ &\geq \mu e^{|v_j^t|} + e^{-|v_j^t|} \\ &\to \infty, \end{aligned}$$

which contradicts the fact that

$$l(\mathbf{v}^0) > l(\mathbf{v}^t) \ \forall t.$$

Since $\{\mathbf{v}^t\}$ is bounded, it has limit points. For any limit point $\mathbf{v}^*$, there is an infinite set $\bar{N}$ such that

$$\lim_{t \in \bar{N}, t \to \infty} \mathbf{v}^t = \mathbf{v}^*.$$

Since $\mathbf{v}$ is finite dimensional, there is one component s updated in an infinite set $N \subset \bar{N}$:

$$(t \bmod k) + 1 = s \text{ for } t \in N.$$

Because $l(\mathbf{v})$ is convex, to prove that $\mathbf{v}^*$ is a global minimum, it suffices to show that

$$\frac{\partial l(\mathbf{v}^*)}{\partial v_s} = 0 \text{ for } s = 1, \ldots, k. \tag{47}$$

Suppose the contrary is true, then among $s, s+1, \ldots, k, 1, \ldots, s-1$, there is $\bar{s}$ such that

$$\frac{\partial l(\mathbf{v}^*)}{\partial v_s} = \cdots = \frac{\partial l(\mathbf{v}^*)}{\partial v_{\bar{s}-1}} = 0, \ \frac{\partial l(\mathbf{v}^*)}{\partial v_{\bar{s}}} \neq 0. \tag{48}$$

From (45), updating $v_{\bar{s}}^*$ by (23) yields $\mathbf{v}^{*+1} \neq \mathbf{v}^*$ and

$$l(\mathbf{v}^{*+1}) < l(\mathbf{v}^*).$$

We have that $\partial l(\mathbf{v}^*)/\partial v_s = 0$ implies

$$\frac{B_s + \sqrt{B_s^2 + 4\mu A_s^* e^{-v_s^*}}}{2A_s^*} = 1,$$

where A_s^* is defined according to (24) and B_s is a constant independent of $\mathbf{v}$. Therefore,

$$\begin{aligned} \lim_{\substack{t \in N, \\ t \to \infty}} v_s^{t+1} &= \lim_{\substack{t \in N, \\ t \to \infty}} \left(v_s^t + \log \frac{B_s + \sqrt{B_s^2 + 4\mu A_s^t e^{-v_s^t}}}{2A_s^t} \right) \\ &= v_s^* + \log \frac{B_s + \sqrt{B_s^2 + 4\mu A_s^* e^{-v_s^*}}}{2A_s^*} \\ &= v_s^*, \end{aligned} \tag{49}$$

and

$$\lim_{t \in N, t \to \infty} \mathbf{v}^{t+1} = \lim_{t \in N, t \to \infty} \mathbf{v}^t = \mathbf{v}^*. \tag{50}$$

Let $\bar{t}$ be the iteration corresponding to $\bar{s}$. Using (48), a similar derivation to (49) and (50) shows that

$$\lim_{\substack{t \in N, \\ t \to \infty}} \mathbf{v}^{t+1} = \cdots = \lim_{\substack{t \in N, \\ t \to \infty}} \mathbf{v}^{\bar{t}} = \mathbf{v}^* \text{ and } \lim_{\substack{t \in N, \\ t \to \infty}} \mathbf{v}^{\bar{t}+1} = \mathbf{v}^{*+1};$$

consequently,

$$\lim_{t \in N, t \to \infty} l(\mathbf{v}^{\bar{t}+1}) = l(\mathbf{v}^{*+1}) < l(\mathbf{v}^*),$$

which contradicts the fact that

$$l(\mathbf{v}^*) \leq \cdots \leq l(\mathbf{v}^{t+1}) \leq l(\mathbf{v}^t).$$

Thus (47) holds for all limit points. Since $l(\mathbf{v})$ is strictly convex, every limit point is the unique global minimum. Moreover, the sequence $\{\mathbf{v}^t\}$ is bounded, so it globally converges to the global minimum.

Appendix E. Proof of Claim 1

From (29) it is clear that the ranking by NM-S.ML is invariant to the scale of n_i; we thus assume

$$n_i^+ + n_i^- = 2, \forall i.$$

Then (26) can be rewritten as

$$\min_{\mathbf{v}} \sum_{i=1}^{m} \left((T_i^+ - T_i^-)^2 - (4n_i^+ - 4)(T_i^+ - T_i^-) \right).$$

For Ext-B.ML, as μ is small and can be ignored, we consider the objective function in (17), which can be re-written as

$$\sum_{i=1}^{m} -n_i^+ (T_i^+ - T_i^-) + n_i \log(e^{T_i^+ - T_i^-} + 1) \tag{51}$$

$$= \sum_{i=1}^{m} -n_i^+ (T_i^+ - T_i^-) + 2\Big(\log 2 + \frac{1}{2}(T_i^+ - T_i^-) + \frac{1}{8}(T_i^+ - T_i^-)^2 + O\big((T_i^+ - T_i^-)^3\big) \Big) \tag{52}$$

$$\approx \frac{1}{8} \sum_{i=1}^{m} \left((T_i^+ - T_i^-)^2 - (4n_i^+ - 4)(T_i^+ - T_i^-) \right).$$

From (51) to (52) we use the Taylor expansion of the function $\log(e^x + 1)$ at $x = 0$ and the assumption that $T_i^+ \approx T_i^- \ \forall i$. Therefore, the rankings by NM-S.ML and Ext-B.ML are similar.

Abstract

Web sites must forecast Web page views in order to plan computer resource allocation and estimate upcoming revenue and advertising growth. In this paper, we focus on extracting trends and seasonal patterns from page view series, two dominant factors in the variation of such series. We investigate the Holt-Winters procedure and a state space model for making relatively short-term prediction. It is found that Web page views exhibit strong impulsive changes occasionally. The impulses cause large prediction errors long after their occurrences. A method is developed to identify impulses and to alleviate their damage on prediction. We also develop a long-range trend and season extraction method, namely the *Elastic Smooth Season Fitting (ESSF)* algorithm, to compute scalable and smooth yearly seasons. ESSF derives the yearly season by minimizing the residual sum of squares under smoothness regularization, a quadratic optimization problem. It is shown that for long-term prediction, ESSF improves accuracy significantly over other methods that ignore the yearly seasonality.

Keywords: web page views, forecast, Holt-Winters, Kalman filtering, elastic smooth season fitting

1. Introduction

This is a machine learning application paper about a prediction task that is rapidly growing in importance: predicting the number of visitors to a Web site or page over the coming weeks or months. There are three reasons for this growth in importance. First, hardware and network bandwidth need to be provisioned if a site is growing. Second, any revenue-generating site needs to predict its revenue. Third, sites that sell advertising space need to estimate how many page views will be available before they can commit to a contract from an advertising agency.

1.1 Background on Time Series Modeling

Time series are commonly decomposed into "trend", "season", and "noise":

$$X_t = L_t + I_t + N_t \ , \tag{1}$$

∗. Also, Associate Professor, Department of Statistics, The Pennsylvania State University.

where L_t is trend, I_t is season, and N_t is noise. For some prediction methods, L_t is more than a global growth pattern, in which case it will be referred to as "level" to distinguish from the global pattern often called trend. These components of a time series need to be treated quite differently. The noise N_t is often modeled by stationary ARMA (autoregressive moving average) process (Brockwell and Davis, 2002; Wei, 2006). Before modeling the noise, the series needs to be "detrended" and "deseasoned". There are multiple approaches to trend and season removal (Brockwell and Davis, 2002). In the well-known Box-Jenkins ARIMA (autoregressive integrated moving average) model (Box and Jenkins, 1970), the difference between adjacent lags (i.e., time units) is taken as noise. The differencing can be applied several times. The emphasis of ARIMA is still to predict noise. The trend is handled in a rather rigid manner (i.e., by differencing). In some cases, however, trend and season may be the dominant factors in prediction and require methods devoted to their extraction. A more sophisticated approach to compute trend is by smoothing, for instance, global polynomial fitting, local polynomial fitting, kernel smoothing, and exponential smoothing. Exponential smoothing is generalized by the Holt-Winters (HW) procedure to include seasonality. Chatfield (2004) provides practical accounts on when ARIMA model or methods aimed at capturing trend and seasonality should be used.

Another type of model that offers the flexibility of handling trend, season, and noise together is the state space model (SSM) (Durbin and Koopman, 2001). The ARIMA model can be cast into an SSM, but SSM includes much broader non-stationary processes. SSM and its computational method—the Kalman filter were developed in control theory and signal processing (Kalman, 1960; Sage and Melsa, 1971; Anderson and Moore, 1979). For Web page view series, experiments suggest that trend and seasonality are more important than the noise part for prediction. We thus investigate the HW procedure and an SSM emphasizing trend and seasonality. Despite its computational simplicity, HW has been successful in some scenarios (Chatfield, 2004). The main advantages of SSM over HW are (a) some parameters in the model are estimated based on the series, and hence the prediction formula is adapted to the series; (b) if one wants to modify the model, the general framework of SSM and the related computational methods apply the same way, while HW is a relatively specific static solution.

1.2 Web Page View Prediction

Web page view series exhibit seasonality at multiple time scales. For daily page view series, there is usually a weekly season and sometimes a long-range yearly season. Both HW and SSM can effectively extract the weekly season, but not the yearly season for several reasons elaborated in Section 4. For this task, we develop the Elastic Smooth Season Fitting (ESSF) method. It is observed that instead of being a periodic sequence, the yearly seasonality often emerges as a yearly pattern that may scale differently across the years. ESSF takes into consideration the scaling phenomenon and only requires two years of data to compute the yearly season. Experiments show that the prediction accuracy can be improved remarkably based on the yearly season computed by ESSF, especially for forecasting distant future.

To our best knowledge, existing work on forecasting Internet access data is mostly for network traffic load. For short-term traffic, it is reasonable to assume that the random process is stationary, and thus prediction relies on extracting the serial statistical dependence in the seemingly noisy series. Stationary ARMA models are well suited for such series and have been exploited (Basu et al., 1996; You and Chandra, 1999). A systematic study of the predictability of network traffic based

on stationary traffic models has been conducted by Sang and Li (2001). For long-term prediction of large-scale traffic, because trends often dominate, prediction centers around extracting trends. Depending on the characteristics of trends, different methods may be used. In some cases, trends are well captured by growth rate and the main concern is to accurately estimate the growth rate, for instance, that of the overall Internet traffic (Odlyzko, 2003). Self-similarity is found to exist at multiple time scales of network traffic, and is exploited for prediction (Grossglauser and Bolot, 1999). Multiscale wavelet decomposition has been used to predict one-minute-ahead Web traffic (Aussem and Murtagh, 2001), as well as Internet backbone traffic months ahead (Papagiannaki et al., 2005). Neural networks have also been applied to predict short-term Internet traffic (Khotanzad and Sadek, 2003). An extensive collection of work on modeling self-similar network traffic has been edited by Park and Willinger (2000).

We believe Web page view series, although closely related to network traffic data, have particular characteristics worthy of a focused study. The contribution of the paper is summarized as follows.

1. We investigate short-term prediction by HW and SSM. The advantages and disadvantages of the two approaches in various scenarios are analyzed. It is also found that seasonality exists at multiple time scales and is important for forecasting Web page view series.

2. Methods are developed to detect sudden massive impulses in the Web traffic and to remedy their detrimental impact on prediction.

3. For long-term prediction several months ahead, we develop the ESSF algorithm to extract global trends and scalable yearly seasonal effects after separating the weekly season using HW.

1.3 Application Scope

The prediction methods in this paper focus on extracting trend and season at several scales, and are not suitable for modeling stationary stochastic processes. The ARMA model, for which mature off-the-shelf software is available, is mostly used for such processes. The trend extracted by HM or SSM is the noise-removed non-season portion of a time series. If a series can be compactly described by a growth rate, it is likely better to directly estimate the growth rate. However, HW and SSM are more flexible in the sense of not assuming specific functional form for the trend on the observed series. HW and SSM are limited for making long-term prediction. By HW, the predicted level term of the page view at a future time is assumed to be the current level added by a linear function of the time interval, or simply the current level if linear growth is removed, as in some reduced form of HW. If a specifically parameterized function can be reliably assumed, it is better to estimate parameters in the function and apply extrapolation accordingly. However, in the applications we investigated, there is little base for choosing any particular function. The yearly season extraction by ESSF is found to improve long-term prediction. The basic assumption of ESSF is that the time series exhibits a yearly pattern, possibly scaled differently across the years. It is not intended to capture event driven pattern. For instance, the search volume for `Batman` surges around the release of every new Batman movie, but shows no clear yearly pattern.

In particular, we have studied two types of Web page view series: (a) small to moderate scale Web sites; (b) dynamic Web pages generated by Google for given search queries. Due to the fast changing pace of the Internet, page view series available for small to moderate scale Web sites are usually short (e.g., shorter than two years). Therefore, the series are insufficient for exploiting

yearly seasonality in prediction. The most dramatic changes in those series are often the news-driven surges. Without side information, such surges cannot be predicted from the page view series alone. It is difficult for us to acquire page view data from Web sites with long history and very high access volume because of privacy constraints. We expect the page views of large-scale Web sites to be less impulsive in a relative sense because of their high base access. Moreover, large Web sites are more likely to have existed long enough to form long-term, for example, yearly, access patterns. Such characteristics are also possessed by the world-wide volume data of search queries, which we use in our experiments.

The rest of the paper is organized as follows. In Section 2, the Holt-Winters procedure is introduced. The effect of impulses on the prediction by HW is analyzed, based on which methods of detection and correction are developed. In Section 3, we present the state space model and discuss the computational issues encountered. Both HW and SSM aim at short-term prediction. The ESSF algorithm for long-term prediction is described in Section 4. Experimental results are provided in Section 5. We discuss predicting the noise part of the series by AR (autoregressive) models and finally conclude in Section 6.

2. The Holt-Winters Procedure

Let the time series be $\{x_1, x_2, ..., x_n\}$. The Holt-Winters (HW) procedure (Chatfield, 2004) decomposes the series into level L_t, season I_t, and noise. The variation of the level after one lag is assumed to be captured by a local linear growth term T_t. Let the period of the season be d. The HW procedure updates L_t, I_t, and T_t simultaneously by a recursion:

$$\begin{aligned} L_t &= \zeta(x_t - I_{t-d}) + (1-\zeta)(L_{t-1} + T_{t-1}), && (2)\\ T_t &= \kappa(L_t - L_{t-1}) + (1-\kappa)T_{t-1}, && (3)\\ I_t &= \delta(x_t - L_t) + (1-\delta)I_{t-d} && (4) \end{aligned}$$

where the pre-selected parameters $0 \le \zeta \le 1$, $0 \le \kappa \le 1$, and $0 \le \delta \le 1$ control the smoothness of updating. This is a stochastic approximation method in which the current level is an exponentially weighted running average of recent season-adjusted observations. To better see this, let us assume the season and linear growth terms are absent. Then Eq. (2) reduces to

$$\begin{aligned} L_t &= \zeta x_t + (1-\zeta)L_{t-1} && (5)\\ &= \zeta x_t + (1-\zeta)\zeta x_{t-1} + (1-\zeta)^2 L_{t-2}\\ &\;\;\vdots\\ &= \zeta x_t + (1-\zeta)\zeta x_{t-1} + (1-\zeta)^2\zeta x_{t-2} + \cdots + (1-\zeta)^{t-1}\zeta x_1 + (1-\zeta)^t L_0. \end{aligned}$$

Suppose L_0 is initialized to zero, the above equation is an on the fly exponential smoothing of the time series, that is, a weighted average with the weights attenuating exponentially into the past. We can also view L_t in Eq. (5) as a convex combination of the level indicated by the current observation x_t and the level suggested by the past estimation L_{t-1}. When the season is added, x_t subtracted by the estimated season at t becomes the part of L_t indicated by current information. At this point of recursion, the most up-to-date estimation for the season at t is I_{t-d} under period d. When the linear growth is added, the past level L_{t-1} is expected to become $L_{t-1} + T_{t-1}$ at t. Following the same scheme of convex combination, Eq. (5) evolves into (2). Similar rationale applies to the update

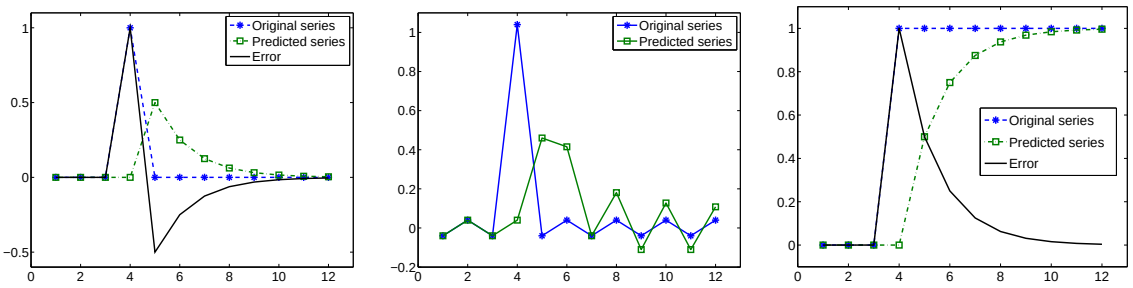

Figure 1: Holt-Winters prediction for time series with abrupt changes. (a) Impulse effect on a leveled signal: slow decaying tail; (b) Impulse effect on a periodic signal: ripple effect; (c) Response to a step signal.

of T_t and I_t in Eqs. (3) and (4). Based on past information, T_t and I_t are expected to be T_{t-1} and I_{t-d} under the implicit assumption of constant linear growth and fixed season. On the other hand, the current x_t and the newly computed L_t suggest T_t to be $L_t - L_{t-1}$, and I_t to be $x_t - L_t$. Applying convex combination leveraging past and current information, we obtain Eqs. (3) and (4).

To start the recursion in the HW procedure at time t, initial values are needed for L_{t-1}, T_{t-1}, and $I_{t-\tau}$, $\tau = 1,2,...,d$. We use the first period of data $\{x_1, x_2, ..., x_d\}$ for initialization, and start the recursion at $t = d+1$. Specifically, linear regression is conducted for $\{x_1, x_2, ..., x_d\}$ versus the time grid $\{1,2,...,d\}$. That is, x_τ and τ, $\tau = 1,...,d$, are treated as dependent variable and independent variable respectively. Suppose the regression function obtained is $b_1\tau + b_2$. We initialize by setting $L_\tau = b_1\tau + b_2$, $T_\tau = 0$, and $I_\tau = x_\tau - L_\tau$, $\tau = 1,2,...,d$.

The forecasting of h time units forward at t, that is, the prediction of x_{t+h} based on $\{x_1, x_2, ..., x_t\}$, is

$$\hat{x}_{t+h} = L_t + hT_t + I_{t-d+h \bmod d} ,$$

where *mod* is the modulo operation. The linear function of h, $L_t + hT_t$, with slope given by the most updated linear growth T_t, can be regarded as an estimation for L_{t+h}; while $I_{t-d+h \bmod d}$, the most updated season at the same cyclic position as $t+h$, which is already available at t, is the estimation for I_{t+h}.

Experiments using the HW procedure show that the local linear growth term, T_t, helps little in prediction. In fact, for relatively distant future, the linear growth term degrades performance. This is because for the Web page view series, we rarely see any linear trends visible over a time scale from which the gradient can be estimated by HW. We can remove the term T_t in HW conveniently by initializing it with zero and setting the corresponding smoothing parameter $\kappa = 0$.

Web page view series sometimes exhibit impulsive surges or dips. Such impulsive changes last a short period of time and often bring the level of page views to a magnitude one or several orders higher than the normal range. For instance, in Figure 5(a), the amount of page views for an example Web site jumps tremendously at the 404th day and returns to normal one day later. Impulses are triggered by external forces which are unpredictable based on the time series alone. One such common external force is a news launch related to the Web site. Because it is extremely difficult if possible at all to predict the occurrence of an impulse, we focus on preventing its after effect.

The influence of an impulse on the prediction by the HW procedure is elaborated in Figure 1. In Figure 1(a), a flat leveled series with an impulse is processed by HW. The predicted series attempts to catch up with the impulse after one lag. Although the impulse is over after one lag, the predicted series attenuates slowly, causing large errors several lags later. The stronger the impulse is, the slower the predicted series returns close to the original one. The prediction error consumes a positive value and then a negative one, both of large magnitudes. Apparently, a negative impulse will result in a reversed error pattern. Figure 1(b) shows the response of HW to an impulse added to a periodic series. The prediction error still yields the pattern of switching signs and large magnitudes. To reduce the influence of an impulse, it is important that we differentiate an impulse from a sudden step-wise change in the series. When a significant step appears, we want the predicted series to catch up with the change as fast as possible rather than hindering the strong response. Figure 1(c) shows the prediction by HW for a series with a sudden positive step change. The prediction error takes a large positive value and reduces gradually to zero without crossing into the negative side.

Based on the above observations, we detect an impulse by examining the co-existence of errors with large magnitudes and opposite signs within a short window of time. In our experiments, the window size is $s_1 = 10$. The extremity of the prediction error is measured relatively with respect to the standard deviation of prediction errors in the most recent past of a pre-selected length. In the current experiment, this length is $s_2 = 50$. The time units of s_1 and s_2 are the same as that of the time series in consideration. Currently, we manually set the values of $s_{1,2}$. The rationale for choosing these values is that s_1 implies the maximum length of an impulse; and s_2 balances accurate estimation of the noise variance and swift adaptation to the change of the variance over time. We avoid setting s_1 too high to ensure that a detected impulse is a short-lived, strong, and abrupt change. If a time series undergoes a real sudden rising or falling trend, the prediction algorithm will capture the trend but with a certain amount of delay, as shown by the response of HW to a step signal in Figure 1(c). In a special scenario when an impulse locates right at the boundary of a large rising trend, the measure taken to treat the impulse will further slow down the response to, but not prevent the eventual catch-up of the rise.

At time t, let the prediction for x_t based on the past series up to $t-1$ be $\hat{x}_t$, and the prediction error be $e_t = x_t - \hat{x}_t$. We check whether an impulse has started at t', $t - s_1 + 1 \le t' \le t - 1$, and ended at t by the following steps.

1. Compute the standard deviation with removed outliers, σ_{t-1}, for the prediction errors $\{e_{t-s_2}, e_{t-s_2+1}, ..., e_{t-1}\}$, which are known by time t. The motivation for removing the outliers is that at any time an impulse exists, the prediction error will be unusually large, and hence bias the estimated average amount of variation. In our experiments, 10% of the errors are removed as outliers.

2. Compute the relative magnitude of e_t by $\theta_t = \frac{|e_t|}{\sigma_{t-1}}$.

3. Examine $\theta_{t'}$ in the window $t' \in [t - s_1 + 1, t]$. If there is a t', $t - s_1 + 1 \le t' \le t - 1$, such that $\theta_{t'} > \Delta_1$ and $\theta_t > \Delta_2$ and $sign(e_{t'}) \neq sign(e_t)$, the segment $[t', t]$ is marked as an impulse. If $e_{t'}$ is positive while e_t negative, the impulse is a surge; the reverse is a dip. The two thresholds Δ_1 and Δ_2 determine the sensitivity to impulses and are chosen around 2.5.

If impulse is not detected, the HW recursion is applied at the next time unit $t+1$. Otherwise, L_t, T_t, and $I_{t'}$ for $t' \in [t - s_1 + 1, t]$, are revised as follows to reduce the effect of the impulse on the future L_τ, T_τ, and I_τ, $\tau > t$. Once the revision is completed, the HW recursion resumes at $t+1$.

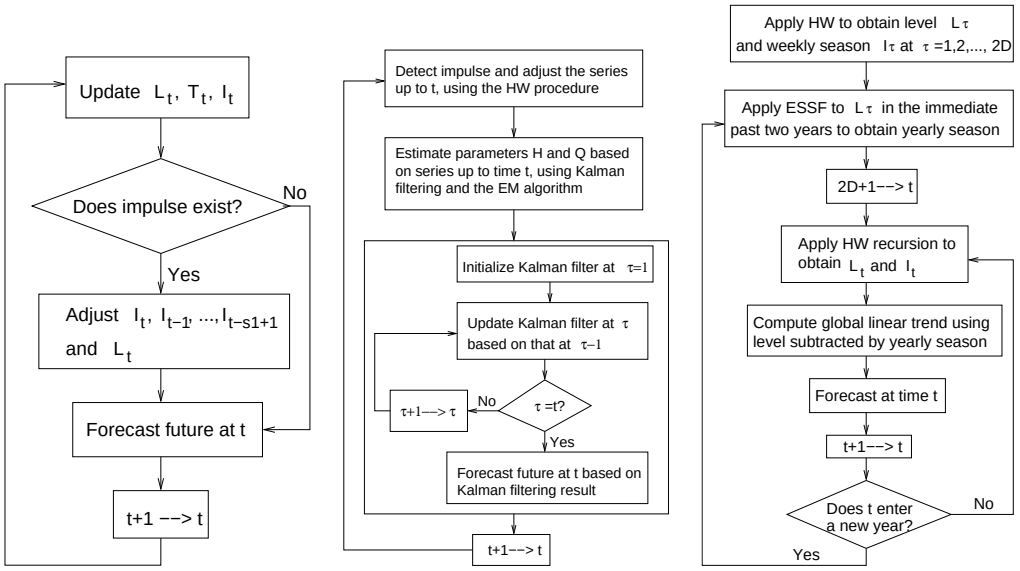

Figure 2: The schematic diagrams for the forecasting algorithms: (a) Holt-Winters with impulse detection; (b) GLS; (c) ESSF.

1. For $t' = t - s_1 + 1, \ldots, t$, set $I_{t'} = I_{t'-d}$ sequentially. This is equivalent to discarding the season computed during the impulse segment and using the most recent season right before the impulse.

2. Let $L_t = \frac{1}{2} L_{t-s_1} + \frac{1}{2}(x_t - I_t)$, where L_{t-s_1} is the level before the impulse and I_t is the already revised season at t.

3. Let $T_t = 0$.

In this paper, we constrain our interest to reducing the adverse effect of an impulse on later prediction after it has occurred and been detected. Predicting the arrival of impulses in advance using side information, for instance, scheduled events impacting Web visits, is expected to be beneficial, but is beyond our study here. A schematic diagram of the HW procedure is illustrated in Figure 2(a).

Holt-Winters and our impulse-resistant modification have the merit of being very cheap to update and predict, requiring only a handful of additions and multiples. This may be useful in some extremely high throughput situations, such as network routers. But in more conventional settings, it leads to the question: can we do better with more extensive model estimation at each time step?

3. State Space Model

A state space model (SSM) assumes that there is an underlying state process for the series $\{x_1, \ldots, x_n\}$. The states are characterized by a Markov process, and x_t is a linear combination of the states added

with Gaussian noise. In general, an SSM can be represented in the following matrix form:

$$\begin{aligned} x_t &= \mathbf{Z}_t\alpha_t + \varepsilon_t\,, \qquad \varepsilon_t \sim N(0,\mathbf{H}_t), \\ \alpha_{t+1} &= \mathbf{T}_t\alpha_t + \mathbf{R}_t\eta_t\,, \quad \eta_t \sim N(0,\mathbf{Q}_t)\,, \quad t = 1,...,n, \\ &\qquad\qquad \alpha_1 \sim N(a_1,\mathbf{P}_1) \end{aligned} \tag{6}$$

where $\{\alpha_1,\alpha_2,...,\alpha_n\}$ is the state process. Each state is an m-dimensional column vector. Although in our work, the observed series x_t is univariate, SSM treats generally p-dimensional series. The noise terms ε_t and η_t follow Gaussian distributions with zero mean and covariance matrices $\mathbf{H}_t$ and $\mathbf{Q}_t$ respectively. For clarity, we list the dimension of the matrices and vectors in (6) below.

observation	x_t	$p\times 1$	$\mathbf{Z}_t$	$p\times m$
state	α_t	$m\times 1$	$\mathbf{T}_t$	$m\times m$
noise	ε_t	$p\times 1$	$\mathbf{H}_t$	$p\times p$
noise	η_t	$r\times 1$	$\mathbf{R}_t$	$m\times r$
			$\mathbf{Q}_t$	$r\times r$
initial state mean	a_1	$m\times 1$	$\mathbf{P}_1$	$m\times m$

We restrict our interest to time invariant SSM where the subscript t can be dropped for $\mathbf{Z}$, $\mathbf{T}$, $\mathbf{R}$, $\mathbf{H}$, and $\mathbf{Q}$. Matrices $\mathbf{Z}$, $\mathbf{T}$ and $\mathbf{R}$ characterize the intrinsic relationship between the state and the observed series, as well as the transition between states. They are determined once we decide upon a model. The covariance matrices $\mathbf{H}$ and $\mathbf{Q}$ are estimated based on the time series using the Maximum Likelihood (ML) criterion.

Next, we describe the *Level with Season (LS)* model, which decomposes x_t in the same way as the HW procedure in Eq. (2)$\sim$(4), with the linear growth term removed. We discard the growth term because, as mentioned previously, this term does not contribute in the HW procedure under our experiments. However, if necessary, it would be easy to modify the SSM to include this term. We then describe the *Generalized Level with Season (GLS)* model that can explicitly control the smoothness of the level.

3.1 The Level with Season Model

Denote the level at t by μ_t and the season with period d by i_t. The LS model assumes

$$\begin{aligned} x_t &= \mu_t + i_t + \varepsilon_t, \\ i_t &= -\sum_{j=1}^{d-1} i_{t-j} + \eta_{1,t}, \\ \mu_t &= \mu_{t-1} + \eta_{2,t} \end{aligned} \tag{7}$$

where ε_t and $\eta_{j,t}$, $j = 1,2$, are the Gaussian noises.

Comparing with the HW recursion equations (2)$\sim$(4), Eq. (7) is merely a model specifying the statistical dependence of x_t on μ_t and i_t, both of which are unobservable random processes. The Kalman filter for this model, playing a similar role as Eqs. (2)-(4) for HW, will be computed recursively to estimate μ_t, i_t, and to predict future. Details on the Kalman filter are provided in Appendix A. In its simplest form, with both the linear growth and season term removed, HW reduces to exponential smoothing with recursion $L_t = \zeta x_t + (1-\zeta)L_{t-1}$. It can be shown that if we let $L_t = E(\mu_t \mid x_1,...,x_{t-1})$, the recursion for L_t in HW is the same as that derived from the Kalman

filter for the LS model without season. The smoothing parameter ζ is determined by the parameters of the noise distributions in LS. When season is added, there is no complete match between the recursion of HW and that of the Kalman filter. In the LS model, it is assumed that $\sum_{\tau=1}^{d} i_{t+\tau} = 0$ up to white noise, but HW does not enforce the zero sum of one period of the season terms. The decomposition of x_t into level μ_t and season i_t by LS is however similar to that assumed by HW.

We can cast the LS model into a time invariant SSM following the notation of (6). The matrix expansion according to (6) leads to the same set of equations in (7):

$$\alpha_t = \begin{pmatrix} i_t \\ i_{t-1} \\ \vdots \\ i_{t-d+2} \\ \mu_t \end{pmatrix}, \quad \eta_t = \begin{pmatrix} \eta_{1,t} \\ \eta_{2,t} \end{pmatrix},$$

$$\underset{d\times 1}{\mathbf{Z} = \quad (1,0,0,\cdots,0,1)}, \quad \underset{d\times 3}{\mathbf{R} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \\ 0 & 1 \end{pmatrix}}, \quad \underset{d\times d}{\mathbf{T} = \begin{pmatrix} -1 & -1 & -1 & \cdots & -1 & 0 \\ 1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 & 1 \end{pmatrix}}.$$

3.2 Generalized Level with Season Model

We generalize the above LS model by imposing different extent of smoothness on the level term μ_t. Specifically, let

$$\begin{aligned} x_t &= \mu_t + i_t + \varepsilon_t, \\ i_t &= -\sum_{j=1}^{s-1} i_{t-j} + \eta_{1,t}, \\ \mu_t &= \frac{1}{q}\sum_{j=1}^{q} \mu_{t-j} + \eta_{2,t}\ . \end{aligned} \tag{8}$$

Here $q \geq 1$ controls the extent of smoothness. The higher the q, the smoother the level $\{\mu_1, \mu_2, ..., \mu_n\}$. We experiment with $q = 1, 3, 7, 14$.

Again, we cast the model into an SSM. The dimension of the state vector is $m = d - 1 + q$.

$$\alpha_t = \begin{pmatrix} i_t \\ \vdots \\ i_{t-d+2} \\ \mu_t \\ \vdots \\ \mu_{t-q+1} \end{pmatrix}, \quad \eta_t = \begin{pmatrix} \eta_{1,t} \\ \eta_{2,t} \end{pmatrix}.$$

We describe **Z**, **R**, **T** by the sparse matrix format. Denote the (i, j)th element of a matrix, for example, **T**, by $\mathbf{T}(i, j)$ (one index for vectors). An element is zero unless specified.

$$\begin{aligned}
&\mathbf{Z} = [\mathbf{Z}(i,j)]_{1\times m}, && \mathbf{Z}(1) = 1,\ \mathbf{Z}(d) = 1,\\
&\mathbf{R} = [\mathbf{R}(i,j)]_{m\times 2}, && \mathbf{R}(1,1) = 1,\ \mathbf{R}(d,2) = 1,\\
&\mathbf{T} = [\mathbf{T}(i,j)]_{m\times m}, && \mathbf{T}(1,j) = -1,\ j = 1,2,...,d-1,\\
& && \mathbf{T}(1+j,j) = 1,\ j = 1,2,...,d-2,\\
& && \mathbf{T}(d,d-1+j) = \frac{1}{q},\ j = 1,...,q,\\
& && \mathbf{T}(d+j,d-1+j) = 1, j = 1,2,...,q-1, \text{ if } q > 1.
\end{aligned}$$

We compare the LS and GLS models in Section 5 by experiments. It is shown that for distant prediction, imposing smoothness on the level can improve performance.

In practice, the prediction of a future x_{t+h} based on $\{x_1, x_2, ..., x_t\}$ comprises two steps:

1. Estimate **H** and **Q** in GLS (or SSM in general) using the past series $\{x_1, ..., x_t\}$.

2. Estimate x_{t+h} by the conditional expectation $E(x_{t+h} \mid x_1, x_2, ..., x_t)$ under the estimated model.

We may not need to re-estimate the model with every new coming x_t, but update the model once every batch of data. We estimate the model by the ML criterion using the EM algorithm. The Kalman filter and smoother, which involve forward and backward recursion respectively, are the core of the EM algorithm for SSM. Given an estimated model, the Kalman filter is used again to compute $E(x_{t+h} \mid x_1, x_2, ..., x_t)$, as well as the variance $Var(x_{t+h} \mid x_1, x_2, ..., x_t)$: a useful indication for the prediction accuracy. Details on the algorithms for estimating SSM and making prediction based on SSM are provided in the Appendix. A thorough coverage on the theories of SSM and related computational methods is referred to Durbin and Koopman (2001).

Because treating impulses improves prediction, as demonstrated by the experiments in Section 5, it is conducted for the GLS approach. In particular, we invoke the impulse detection embedded in HW. For any segment of time where an impulse is marked, the observed data x_t are replaced by $L_t + I_t$ computed by HW. This modified series is then input to the GLS estimation and prediction algorithms. The schematic diagram for forecasting using GLS is shown in Figure 2(b).

4. Long-range Trend and Seasonality

Web page views sometimes show long-range trend and seasonality. In Figure 7(a), three time series over a period of four years are shown. Detailed description of the series is provided in Section 5. Each time series demonstrates apparently a global trend and yearly seasonality. For instance, the first series, namely `amazon`, grows in general over the years and peaks sharply every year around December. Such long-range patterns can be exploited for forecasting, especially for distant future. To effectively extract long-range trend and season, several needs ought to be addressed:

1. Assume the period of the long-range season is a year. Because the Internet is highly dynamic, it is necessary to derive the yearly season using past data over recent periods and usually only a few (e.g., two) are available.

2. A mechanism to control the smoothness of the long-range season is needed. By enforcing smoothness, the extracted season tends to be more robust, a valuable feature especially when given limited past data.

3. The magnitude of the yearly season may vary across the years. As shown in Figure 7(a), although the series over different years show similar patterns, the patterns may be amplified or shrunk over time. The yearly season thus should be allowed to scale.

The HW and GLS approaches fall short of meeting the above requirements. They exploit mainly the local statistical dependence in the time series. Because HW (and similarly GLS) performs essentially exponential smoothing on the level and linear growth terms, the effect of historic data further away attenuates fast. HW is not designed to extract a global trend over multiple years. Furthermore, HW requires a relatively large number of periods to settle to the intended season; and importantly, HW assumes a fixed season over the years. Although HW is capable of adjusting with a slowly changing season when given enough periods of data, it does not directly treat the scaling of the season, and hence is vulnerable to the scaling phenomenon.

In our study, we adopt a linear regression approach to extract the long-range trend. We inject elasticity into the yearly season and allow it to scale from a certain yearly pattern. The algorithm developed is called *Elastic Smooth Season Fitting (ESSF)*. The time unit of the series is supposed to be a day.

4.1 Elastic Smooth Season Fitting

Before extracting long-range trend and season, we apply HW with impulse detection to obtain the weekly season and the smoothed level series L_t, $t = 1,...,n$. Recall that the HW prediction for the level L_{t+h} at time t is L_t, assuming no linear growth term in our experiments. We want to exploit the global trend and yearly season existing in the level series to better predict L_{t+h} based on $\{L_1, L_2, ..., L_t\}$.

We decompose the level series L_t, $t = 1,...,n$, into a yearly season, y_t, a global linear trend u_t, and a volatility part n_t:

$$L_t = u_t + y_t + n_t \ , \quad t = 1,2,...,n \ .$$

Thus the original series x_t is decomposed into:

$$x_t = u_t + y_t + n_t + I_t + N_t \ , \tag{9}$$

where I_t and N_t are the season and noise terms from HW. Let $\mathbf{u} = \{u_1, u_2, ..., u_n\}$ and $\mathbf{y} = \{y_1, y_2, ..., y_n\}$. They are solved by the following iterative procedure. At this moment, we assume the ESSF algorithm, to be described shortly, is available. We start by setting $\mathbf{y}^{(0)} = 0$. At iteration p, update $\mathbf{y}^{(p)}$ and $\mathbf{u}^{(p)}$ by

1. Let $g_t = L_t - y_t^{(p-1)}$, $t = 1,...,n$. Note g_t is the global trend combined with noise, taking out the current additive estimate of the yearly season.

2. Perform linear regression of $\mathbf{g} = \{g_1, ..., g_n\}$ on the time grid $\{1,2,...,n\}$. Let the regressed value at t be $u_t^{(p)}$, $t = 1,2,...,n$. Thus for some scalars $b_1^{(p)}$ and $b_2^{(p)}$, $u_t^{(p)} = b_1^{(p)} t + b_2^{(p)}$.

3. Let $z_t = L_t - u_t^{(p)}$, $t = 1, ..., n$. Here z_t is the yearly season combined with noise, taking out the current estimate of the global trend. Apply ESSF to $\mathbf{z} = \{z_1, z_2, ..., z_n\}$. Let the yearly season derived by ESSF be $\mathbf{y}^{(p)}$.

It is analytically difficult to prove the convergence of the above procedure. Experiments based on three series show that the difference in $\mathbf{y}^{(p)}$ reduces very fast. At iteration p, $p \geq 2$, we measure the relative change from $\mathbf{y}^{(p-1)}$ to $\mathbf{y}^{(p)}$ by

$$\frac{||\mathbf{y}^{(p)} - \mathbf{y}^{(p-1)}||}{||\mathbf{y}^{(p-1)}||}, \tag{10}$$

where $||\cdot||$ is the L_2 norm. Detailed results are provided in Section 5. Because ESSF always has to be coupled with global trend extraction, for brevity, we also refer to the entire procedure above as ESSF when the context is clear, particularly, in Section 4.2 and Section 5.

We now present the ESSF algorithm for computing the yearly season based on the trend removed $\mathbf{z}$. For notational brevity, we re-index day t by double indices (k, j), which indicates day t is the jth day in the kth year. Denote the residue $z_t = L_t - u_t$ by $z_{k,j}$, the yearly season y_t by $y_{k,j}$ (we abuse the notation here and assume the meaning is clear from the context), and the noise term n_t by $n_{k,j}$. Suppose there are a total of K years and each contains D days. Because leap years contain one more day, we take out the extra day from the series before applying the algorithm.

We call the yearly season pattern $\bar{\mathbf{y}} = \{\bar{y}_1, \bar{y}_2, ..., \bar{y}_D\}$ the *season template*. Since we allow the yearly season $y_{k,j}$ to scale over time, it relates to the season template by

$$y_{k,j} = \alpha_{k,j}\bar{y}_j, \quad k = 1, 2, ..., K, \ j = 1, ..., D,$$

where $\alpha_{k,j}$ is the scaling factor. One choice for $\alpha_{k,j}$ is to let $\alpha_{k,j} = c_k$, that is, a constant within any given year. We call this scheme step-wise constant scaling since $\alpha_{k,j}$ is a step function if single indexed by time t. One issue with the step-wise constant scaling factor is that $y_{k,j}$ inevitably jumps when entering a new year. To alleviate the problem, we instead use a piece-wise linear function for $\alpha_{k,j}$. Let $c_0 = 1$. Then

$$\alpha_{k,j} = \frac{j-1}{D}c_k + \frac{D-j+1}{D}c_{k-1}, \quad k = 1, 2, ..., K, \ j = 1, ..., D. \tag{11}$$

The number of scaling factors c_k to be determined is still K. Let $\mathbf{c} = \{c_1, ..., c_K\}$. At the first day of each year, $\alpha_{k,1} = c_{k-1}$. We optimize over both the season template $\bar{y}_j$, $j = 1, ..., D$, and the scaling factors c_k, $k = 1, ..., K$.

We now have

$$z_{k,j} = \alpha_{k,j}\bar{y}_j + n_{k,j},$$

where $z_{k,j}$'s are given, while c_k, $\bar{y}_j$, and $n_{k,j}$, $k = 1, ..., K$, $j = 1, ..., D$, are to be solved. A natural optimization criterion is to minimize the sum of squared residues:

$$\min_{\bar{\mathbf{y}}, \mathbf{c}} \sum_k \sum_j n_{k,j}^2 = \min_{\bar{\mathbf{y}}, \mathbf{c}} \sum_k \sum_j (z_{k,j} - \alpha_{k,j}\bar{y}_j)^2 .$$

If the number of years K is small, $\bar{\mathbf{y}}$ obtained by the above optimization can be too wiggly. We add a penalty term to ensure the smoothness of $\bar{\mathbf{y}}$. The discrete version of the second order derivative for $\bar{y}_j$ is

$$\ddot{\bar{y}}_j = \bar{y}_{j+1} + \bar{y}_{j-1} - 2\bar{y}_j ,$$

and $\sum_j \ddot{\bar{y}}_j^2$ is used as the smoothness penalty. Since $\bar{\mathbf{y}}$ is one period of the yearly season, when j' is out of the range $[1,D]$, $\bar{y}_{j'}$ is understood as $\bar{y}_{j' \bmod D}$. For instance, $\bar{y}_0 = \bar{y}_D$, $\bar{y}_{D+1} = \bar{y}_1$. We form the following optimization criterion with a pre-selected regularization parameter λ:

$$\min_{\bar{\mathbf{y}},\mathbf{c}} G(\bar{\mathbf{y}},\mathbf{c}) = \min_{\bar{\mathbf{y}},\mathbf{c}} \sum_k \sum_j (z_{k,j} - \alpha_{k,j}\bar{y}_j)^2 + \lambda \sum_j (\bar{y}_{j+1} + \bar{y}_{j-1} - 2\bar{y}_j)^2 \,. \tag{12}$$

To solve (12), we alternate the optimization of $\bar{\mathbf{y}}$ and $\mathbf{c}$. With either fixed, $G(\bar{\mathbf{y}},\mathbf{c})$ is a convex quadratic function. Hence a unique minimum exists and can be solved by a multivariable linear equation. The algorithm is presented in details in Appendix B.

Experiments show that allowing scalable yearly season improves prediction accuracy, so does the smoothness regularization of the yearly season. As long as λ is not too small, the prediction performance varies marginally for a wide range of values. The sensitivity of prediction accuracy to λ is studied in Section 5.

A more ad-hoc approach to enforce smoothness is to apply moving average to the yearly season extracted without smoothness regularization. We can further simplify the optimization criterion in (12) by employing step-wise constant scaling factor, that is, let $\alpha_{k,j} = c_k$, $k = 1,...,K$. The jump effect caused by the abrupt change of the scaling factor is reduced by the moving average as well. Specifically, the optimization criterion becomes

$$\min_{\bar{\mathbf{y}},\mathbf{c}} \tilde{G}(\bar{\mathbf{y}},\mathbf{c}) = \min_{\bar{\mathbf{y}},\mathbf{c}} \sum_k \sum_j (z_{k,j} - c_k\bar{y}_j)^2 \,. \tag{13}$$

The above minimization is solved again by alternating the optimization of $\bar{\mathbf{y}}$ and $\mathbf{c}$. See Appendix B for details. Comparing with Eq. (12), the optimization for (13) reduces computation significantly. After acquiring $\bar{\mathbf{y}}$, we apply a double sided moving average. We call the optimization algorithm for (13) combined with the post operation of moving average the fast version of ESSF. Experiments in Section 5 show that ESSF Fast performs similarly to ESSF.

4.2 Prediction

We note again that ESSF is for better prediction of the level L_t obtained by HW. To predict x_t, the weekly season extracted by HW should be added to the level L_t. The complete process of prediction is summarized below. We assume that prediction starts on the 3rd year since the first two years have to serve as past data for computing the yearly season.

1. Apply HW to obtain the weekly season I_t, and the level L_t, $t = 1,2,...,n$.

2. At the beginning of each year k, $k = 3,4,...$, take the series of L_t's in the past two years (year $k-2$ and $k-1$) and apply ESSF to this series to solve the yearly season template $\bar{\mathbf{y}}$ and the scaling factors, c_1 and c_2 for year $k-2$ and $k-1$ respectively. Predict the yearly season for future years $k' \geq k$ by $c_2\bar{\mathbf{y}}$. Denote the predicted yearly season at time t in any year $k' \geq k$ by $Y_{t,k}$, where the second subscript clarifies that only the series before year k is used by ESSF.

3. Denote the year in which day t lies by $\nu(t)$. Let the yearly season removed level be $\tilde{L}_t = L_t - Y_{t,\nu(t)}$. At every t, apply linear regression to $\{\tilde{L}_{t-2D+1},...,\tilde{L}_t\}$ over the time grid $\{1,2,...,2D\}$. The slope of the regressed line is taken as the long-range growth term $\tilde{T}_t$.

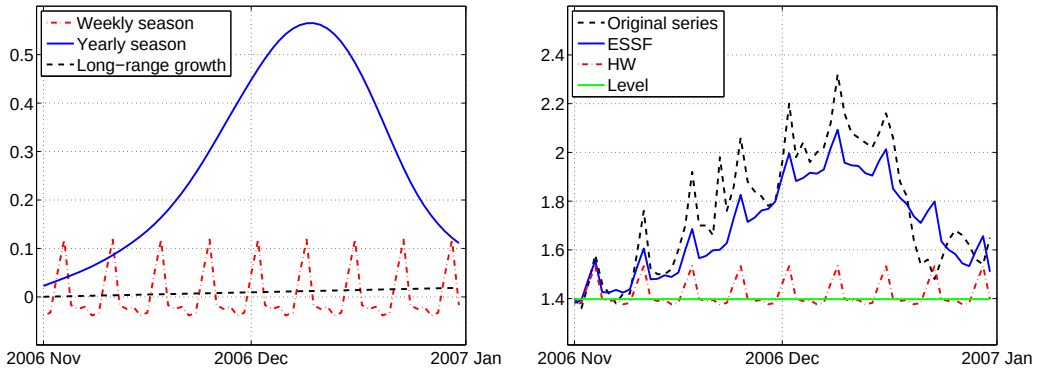

Figure 3: Decomposition of the prediction terms for the amazon series in November and December of 2006 based on data up to October 31, 2006: (a) The weekly season, yearly season, and long-range linear growth terms in the prediction; (b) Comparison of the predicted series by HW and ESSF.

Suppose at the end of day t (or beginning of day $t+1$), we predict for the hth day ahead of t. Let the prediction be $\hat{x}_{t+h}$. Also let $r(t+h)$ be the smallest integer such that $t+h-r(t+h)\cdot d \le t$ (d is the weekly period). Then,

$$\hat{x}_{t+h} = \tilde{L}_t + h\tilde{T}_t + Y_{t+h,\nu(t)} + I_{t+h-r(t+h)\cdot d}\ . \tag{14}$$

Drawing a comparison between Eqs. (14) and (9), we see that $\tilde{L}_t + h\tilde{T}_t$ is essentially the prediction for the global linear trend term u_{t+h}, $Y_{t+h,\nu(t)}$ the prediction for the yearly season y_{t+h}, and $I_{t+h-r(t+h)\cdot d}$ the prediction for the weekly season I_{t+h}. The schematic diagram for forecasting by ESSF is shown in Figure 2(c).

If day $t+h$ is in the same year as t, $Y_{t+h,\nu(t)} = Y_{t+h,\nu(t+h)}$ is the freshest possible prediction for the yearly season at $t+h$. If instead $\nu(t) < \nu(t+h)$, the yearly season at $t+h$ is predicted based on data more than one year ago. One might have noticed that we use only two years of data to extract the yearly season regardless of the available amount of past data. This is purely an individual choice due to our preference of using recent data. Experiments based on the series described in Section 5 show that whether all the available past data are used by ESSF causes negligible difference in prediction performance.

To illustrate the roles of the terms in the prediction formula (14), we plot them separately in Figure 3(a) for the amazon series. The series up to October 31, 2006 is assumed to have been observed, and the prediction is for November and December of 2006. Figure 3(a) shows that during these two months, the predicted yearly season is much more prominent than the weekly season and the slight linear growth. Figure 3(b) compares the prediction by ESSF and HW respectively. The series predicted by HW is weekly periodic with a flat level, while that by ESSF incorporates the yearly seasonal variation and is much closer to the original series, as one might have expected.

5. Experiments

We conduct experiments using twenty six time series. As a study of the characteristics of Web page views, we examine the significance of the seasonal as well as impulsive variations. Three relatively short series are used to assess the performance of short-term prediction by the HW and GLS approaches. The other twenty three series are used to test the ESSF algorithm for long-term prediction. In addition to comparing the different forecasting methods, we also present results to validate the algorithmic choices made in ESSF.

5.1 Data Sets

We conduct experiments based on the time series described below.

1. The `Auton` series records the daily page views of the Auton Lab, headed by Andrew Moore, in the Robotics Institute at the Carnegie Mellon University (*http://www.autonlab.org*). This series spans from August 14, 2005 to May 1, 2007, a total of 626 days.

2. The `Wang` series records the daily page views of the Web site for the research group headed by James Wang at the Pennsylvania State University (*http://wang.ist.psu.edu*). This series spans from January 1, 2006 to February 1, 2008, a total of 762 days.

3. The `citeseer` series records the hourly page views to citeseer, an academic literature search engine currently located at *http://citeseer.ist.psu.edu*. This series spans from 19 : 00 on September 6, 2005 to 4 : 00 on September 25, 2005, a total of 442 hours.

4. We acquired 23 relatively long time series from the site *http://www.google.com/trends*. This Web site provides search volumes for user specified phrases. We treat the search volumes as an indication of the page views to dynamically generated Web pages by Google. The series record daily volumes from Jan, 2004 to December 30, 2007 (roughly four full years), a total of 1460 days. The volumes for each phrase are normalized with respect to the average daily volume of that phrase in the month of January 2004. The normalization will not affect the prediction accuracy, which is measured relatively with respect to the average level of the series. We also call the series collectively the `g-trends` series.

5.2 Evaluation

Let the prediction for x_t be $\hat{x}_t$. Suppose prediction is provided for a segment of the series, $\{x_{t_0+1}, x_{t_0+2}, \ldots, x_{t_0+J}\}$, where $0 \le t_0 < n$. We measure the prediction accuracy by the error rate defined as

$$R_e = \sqrt{\frac{RSS}{SSS}}$$

where *RSS*, the *residual sum of squares* is

$$RSS = \sum_{t=t_0+1}^{t_0+J} (\hat{x}_t - x_t)^2 \tag{15}$$

and *SSS*, the *series sum of squares* is

$$SSS = \sum_{t=t_0+1}^{t_0+J} x_t^2 \,. \tag{16}$$

We call R_e the prediction error rate. It is the reciprocal of the square root of the signal to noise ratio (SNR), a measure commonly used in signal processing. We can also evaluate the effectiveness of a prediction method by comparing *RSS* to *SPV*, the *sum of predictive variation*:

$$SPV = \sum_{t=t_0+1}^{t_0+J} (x_t - \bar{x}_t)^2, \quad \bar{x}_t = \frac{\sum_{\tau=1}^{t-1} x_\tau}{t-1}.$$

We can consider $\bar{x}_t$, the mean up to time $t-1$, as the simplest prediction of x_t using past data. We call this scheme of prediction Mean of Past (MP). *SPV* is essentially the *RSS* corresponding to the MP method. The R_e of MP is $\sqrt{SPV/SSS}$. We denote the ratio between the R_e of a prediction method and that of MP by $Q_e = \sqrt{RSS/SPV}$, referred to as the error ratio. As a measure on the amount of error, in practice, R_e is more pertinent than Q_e for users concerned with employing the prediction in subsequent tasks. We thus use R_e as the major performance measure in all the experimental results. For comparison with baseline prediction methods, we also show R_e of MP as well as that of the Moving Average (MA). In the MA approach, considering the weekly seasonality, we treat Monday to Sunday separately. Specifically, if a day to be predicted is a Monday, we forecast by the average of the series on the past 4 Mondays. Similarly for the other days of a week. For the hourly page view series with daily seasonality, MA predicts by the mean of the same hours in the past 4 days.

As discussed previously, Web page views exhibit impulsive changes. The prediction error during an impulse is extraordinarily large, skewing the average error rate significantly even if impulses only exist on a small fraction of the series. The bias caused by the outlier errors is especially strong when the usual amount of page views is low. We reduce the effect of outliers by removing a small percentage of large errors, in particular, 5% in our experiments. Without loss of generality, suppose the largest (in magnitude) 5% errors are $\hat{x}_t - x_t$ at $t_0 + 1 \le t \le t_1$. We adjust RSS and SSS by using only $\hat{x}_t - x_t$ at $t > t_1$ and compute the corresponding R_e. Specifically,

$$RSS_{adj} = \sum_{t=t_1+1}^{t_0+J} (\hat{x}_t - x_t)^2, \; SSS_{adj} = \sum_{t=t_1+1}^{t_0+J} x_t^2, \; R_e^{adj} = \sqrt{\frac{RSS_{adj}}{SSS_{adj}}}.$$

We report both R_e and R_e^{adj} to measure the prediction accuracy for the series `Auton`, `Wang`, and `citeseer`. For the twenty three `g-trends` series, because there is no clear impulse, we use only R_e.

Because the beginning portion of the series with a certain length is needed for initialization in HW, SSM, or ESSF, we usually start prediction after observing $t_0 > 0$ time units. Moreover, we may predict several time units ahead for the sum of the series over a run of multiple units. The ground truth at t is not necessarily x_t. In general, suppose prediction starts after t_0 and is always for a stretch of w time units that starts h time units ahead. We call w the *window size* of prediction and h the *unit ahead*.

Let the whole series be $\{x_1, x_2, ..., x_n\}$. In the special case when $h = 1$ and $w = 1$, after observing the series up to $t-1$, we predict for x_t, $t = t_0 + 1, ..., n$. The ground truth at t is x_t. If $h \ge 1$, $w = 1$, we predict for x_t, $t = t_0 + h, ..., n$, after observing the series up to $t - h$. Let the predicted value be $\hat{x}_{t,-h}$, where the subscript $-h$ emphasizes that only data h time units ago are used. If $h \ge 1$, $w \ge 1$, we predict for

$$\tilde{x}_t = \sum_{\tau=t}^{t+w-1} x_\tau, \quad t = t_0 + h, ..., n - w + 1,$$

after observing the series up to $t-h$. The predicted value at t is

$$\hat{\tilde{x}}_t = \sum_{\tau=t}^{t+w-1} \hat{x}_{\tau,-h}\,.$$

To compute the error rate R_e, we adjust *RSS* and *SSS* in Eq. (15) and (16) according to the ground truth:

$$RSS = \sum_{t=t_0+h}^{n-w+1} (\hat{\tilde{x}}_t - \tilde{x}_t)^2\,, \quad SSS = \sum_{t=t_0+h}^{n-w+1} \tilde{x}_t^2\,.$$

For the series `Auton`, `Wang`, and `citeseer`, $t_0 = 4d$, where d is the season period. The segment $\{x_1,...,x_{4d}\}$ is used for initialization by both HW and SSM. For the `g-trends` series, $t_0 = 731$. That is, the first two years of data are used for initialization. Two years of past data are needed because the ESSF algorithm requires at least two years of data to operate.

5.3 Results

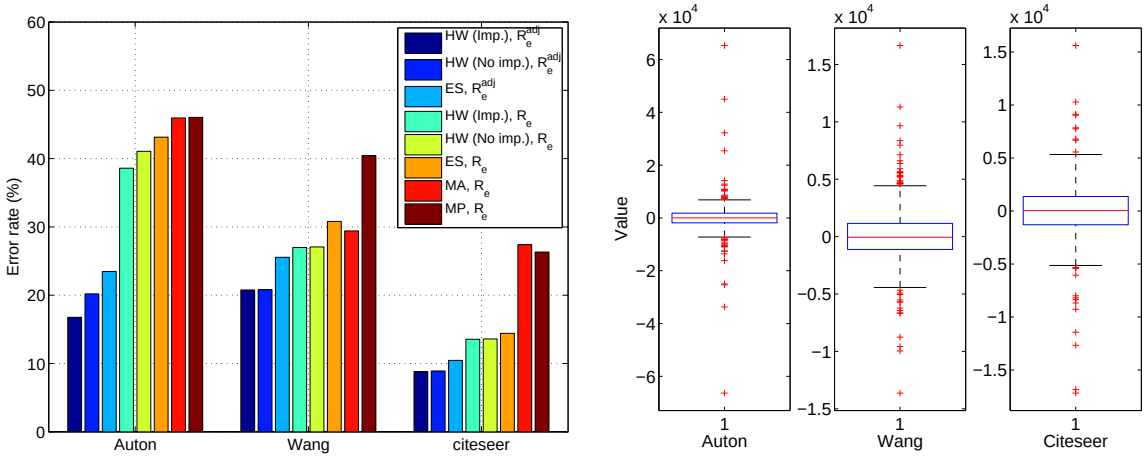
For the series `Auton`, `Wang`, and `citeseer`, we focus on short-term prediction no greater than 30 time units ahead. Because the series are not long enough for extracting long-range trend and season by the ESSF algorithm, we only test the HW procedure with or without impulse detection and the GLS approach. For the twenty three `g-trends` series, we compare ESSF with HW for prediction up to half a year ahead.

5.3.1 SHORT-TERM PREDICTION

Web page views often demonstrate seasonal variation, sometimes at multiple scales. The HW procedure given by Eq. (2)∼(4) and the GLS model specified in Eq. (8) both assume a season term with period d. In our experiments, for the daily page view series `Auton` and `Wang`, $d = 7$ (a week), while for the hourly series `citeseer`, $d = 24$ (a day). As mentioned previously, the local linear growth term in Eq. (3) is removed in our experiments because it is found not helpful. The smoothing parameters for the level and the season terms in Eq. (2) and (4) are set to $\zeta = 0.5$ and $\delta = 0.25$. Because HW has no embedded mechanism to select these parameters, we do not aggressively tune them and use the same values for all the experiments reported here.

To assess the importance of weekly (or daily) seasonality for forecasting, we compare HW and and its reduced form without the season term. Similarly as the linear growth term, the season term can be deleted by initializing it to zero and setting its corresponding smoothing parameter δ in Eq. (4) to zero. The reduced HW procedure without the local linear growth and season terms is essentially Exponential Smoothing (ES) (Chatfield, 2004). Figure 4(a) compares the prediction performance in terms of R_e and R_e^{adj} for the three series by HW and ES. Results for two versions of HW, with and without treating impulses, are provided. The comparison of the two versions will be discussed shortly. Results obtained from the two baseline methods MA and MP are also shown. For each of the three series, HW (both versions), which models seasonality, consistently outperforms ES, reflecting the significance of seasonality in these series. We also note that for the `auton` series, R_e is almost twice as large as R_e^{adj} although only 5% of outliers are removed. This dramatic skew of the error rate is caused by the short but strong impulses occurred in this series.

To evaluate the impulse-resistant measure, described in Section 2, we compare HW with and without impulse detection in Figure 4(a). Substantial improvement is achieved for the `Auton` series.



(a) (b)

Figure 4: Compare the prediction performance in terms of R_e^{adj} and R_e on the three series `Auton`, `Wang`, and `citeseer` using different methods: HW with or without impulse detection, ES without season, MA, and MP. (a) The error rates. (b) The box plots for the differences of page views at adjacent time units.

The decrease in error rate for the other two series is small, a result of the fact there is no strong impulse in them. To directly demonstrate the magnitude of the impulses, we compute the differences in page view between adjacent time units, $\{x_2 - x_1, x_3 - x_2, ..., x_n - x_{n-1}\}$, and show the box plots for their distributions in Figure 4(b). The stronger impulses in `Auton` are evident from the box plots. Comparing with the other two series, the middle half of the `Auton` data (between the first and third quartiles), indicated by the box in the plot, is much narrower relative to the overall range of the data. In another word, the outliers deviate more severely from the majority mass of the data.

To illustrate the gain from treating impulses, we also show the predicted series for `Auton` in Figure 5(a). For clarity of the plot, only a segment of the series around an impulse is shown. The predicted series by HW with impulse detection returns close to the original series shortly after the impulse, while that without ripples with large errors over several periods afterward. In the sequel, for both HW and GLS, impulse detection is included by default.

Table 1 lists the error rates for the three series using different methods and under different pairs of (h,w), where h is the unit ahead and w is the window size of prediction. We provide the error rate R_e^{adj} in addition to R_e to show the performance on impulse excluded portion of the series. For `Auton` and `Wang`, $(h,w) = (1,1),(1,7),(1,28)$. For `citeseer`, $(h,w) = (1,1),(1,12),(1,24)$. For the GLS model, a range of values for the smooth parameter q are tested. As shown by the table, when $(h,w) = (1,1)$, the performance of HW and that of GLS at the best q are close. When predicting multiple time units, for example, $w = 7,28$ or $w = 12,24$, GLS with $q > 1$ achieves better accuracy. For `Wang` and `citeseer`, at every increased w, the lowest error rates are obtained by GLS with an increased q. This supports the heuristic that when predicting for a more distant time, smoother prediction is preferred to reduce the influence of local fluctuations.

We compare the predicted series for `Auton` by GLS with $q = 1$ and $q = 7$ in Figure 5(b). Here, the unit ahead $h = 1$, and the window size $w = 7$. The fluctuation of the predicted series obtained

Table 1: The prediction error rates R_e and R_e^{adj} for the three series Auton, Wang, and citeseer obtained by several methods. The window size of prediction takes multiple values, while the unit ahead is always 1. HW and the GLS model with several values of q are compared.

by $q = 1$ is more volatile than that by $q = 7$. The volatility of the predicted series by $q = 7$ is much closer to that of the true series. As shown in Table 1, the error rate R_e^{adj} achieved by $q = 7$ is 12.94%, while that by $q = 1$ is 15.63%.

Based on the GLS model, the variance of x_t conditioned on the past $\{x_1, ..., x_{t-1}\}$ can be computed. The equations for the conditional mean $E(x_t \mid x_1, ..., x_{t-1})$ (i.e., the predicted value) and variance $Var(x_t \mid x_1, ..., x_{t-1})$ are given in (19). Since the conditional distribution of x_t is Gaussian, we can thus calculate a confidence band for the predicted series, which may be desired in certain applications to assess the potential deviation of the true values. Figure 6 shows the 95% confidence band for citeseer with $(h, w) = (1, 1)$. The confidence band covers nearly the entire original series.

GLS is more costly in computation than HW. We conduct the experiments using Matlab codes on 2.4GHz Dell computer with Linux OS. At $(h, w) = (1, 28)$ for Auton and Wang, and $(h, w) = (1, 24)$ for citeseer, the average user running time for sequential prediction along the whole series is respectively 0.51, 56.38, 65.87, 72.10, and 86.76 seconds for HW, and GLS at $q = 1, 3, 7, 14$. In our experiments, the GLS models are re-estimated after every $4d$ units, where d is the period. The computation in GLS is mainly spent on estimating the models and varies negligibly for different pairs of (h, w).

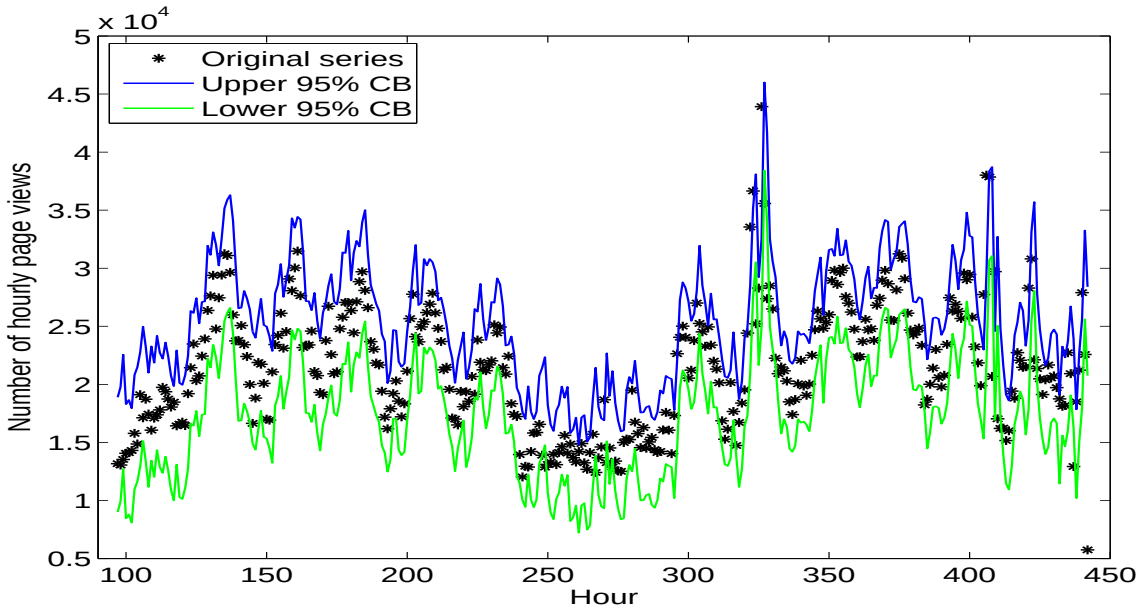

Figure 6: The predicted 95% confidence band for `citeseer` obtained by GLS with $q = 1$. The unit ahead h and window size w are 1.

5.3.2 LONG-TERM PREDICTION—A COMPREHENSIVE STUDY

We now examine the performance of ESSF based on the `g-trends` series. The first three series are acquired by the search phrases `amazon`, `Renoir` (French impressionism artist), and `greenhouse effect`, which will be used as the names for the series in the sequel. A comprehensive study with detailed results is first presented using these three series. Then, we expand the experiments to twenty additional `g-trends` series and present results on prediction accuracy and computational speed.

The original series of `amazon`, `Renoir`, and `greenhouse effect` averaged weekly are shown in Figure 7(a). Due to the weekly season, without averaging, the original series are too wiggly for clear presentation. Figure 7(c) and (d) show the yearly season templates extracted by ESSF from year 2004 and 2005 with smoothing parameter $\lambda = 0$, 1000 respectively. As expected, at $\lambda = 1000$, the yearly seasons are much smoother than those obtained at $\lambda = 0$, especially for the series `Renoir` and `greenhouse effect`. Figure 7(b) shows the scaling factors of the yearly seasons obtained by applying ESSF to the entire four years.

We compare the prediction obtained by ESSF with HW and the MA approach as a baseline. For ESSF, we test both $\lambda = 0$ and 1000, and its fast version with moving average window size 15. Prediction error rates are computed for the unit ahead h ranging from 1 to 180 days. We fix the prediction window size $w = 1$.

The error rates R_e obtained by the methods are compared in Figure 8(a), (b), (c) for `amazon`, `Renoir`, `greenhouse effect` respectively. Comparing with the other methods, the difference in the performance of HW and MA is marginal. When the unit ahead h is small, HW outperforms MA, but the advantage diminishes when h is large. For `Renoir` and `greenhouse effect`, HW becomes even inferior to MA when h is roughly above 60. ESSF with $\lambda = 1000$ and ESSF Fast perform

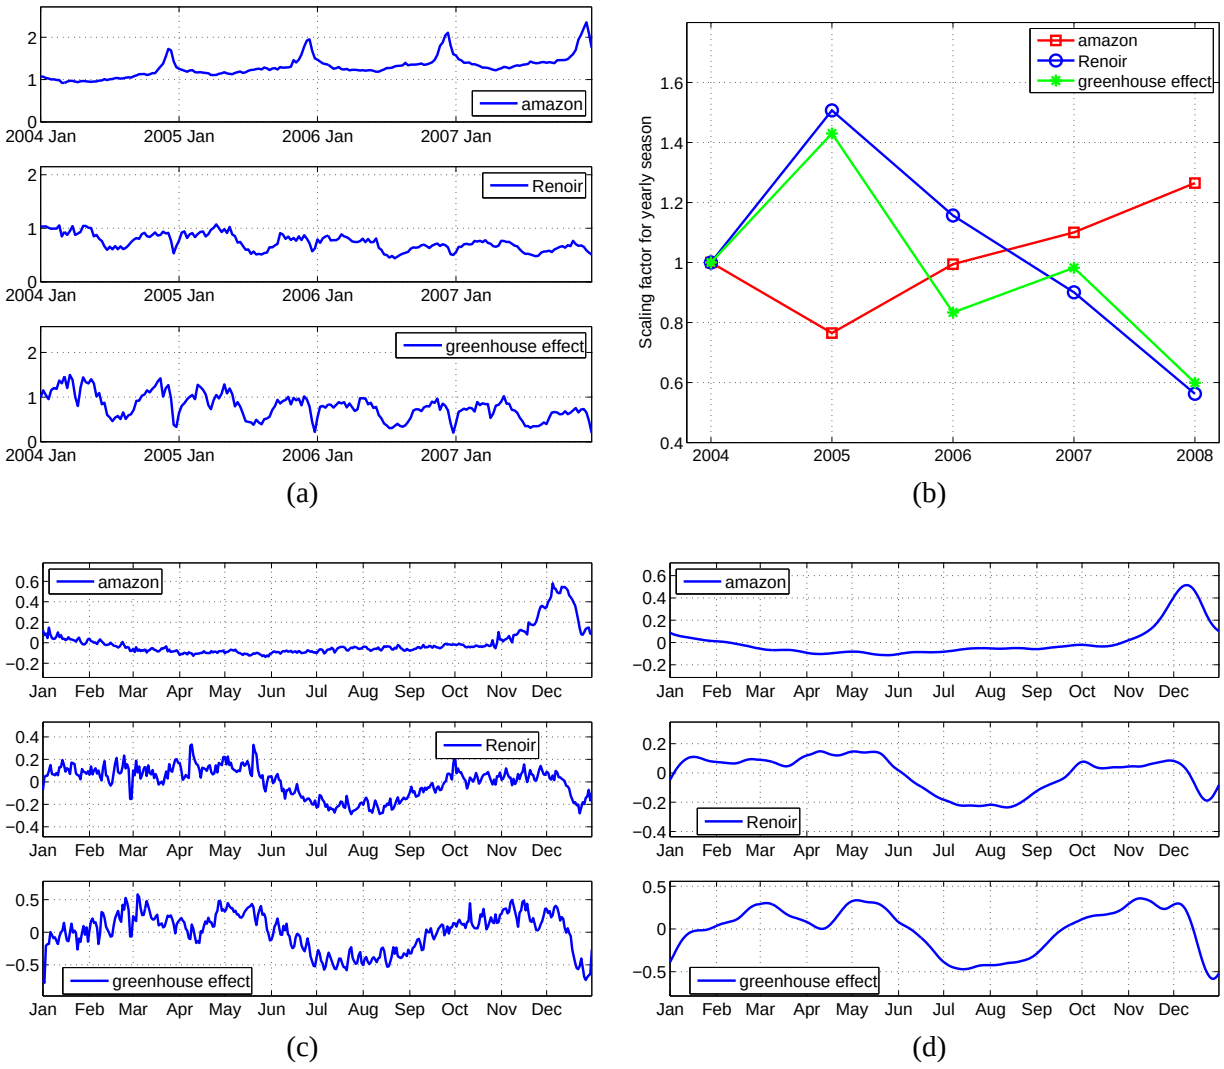

Figure 7: Extract the yearly seasons by ESSF for the `g-trends` series `amazon`, `Renoir`, and `greenhouse effect`: (a) The weekly averaged original series; (b) The scaling factor for the yearly season; (c) The yearly season extracted without smoothing at $\lambda = 0$; (d) The yearly season extracted with smoothing at $\lambda = 1000$.

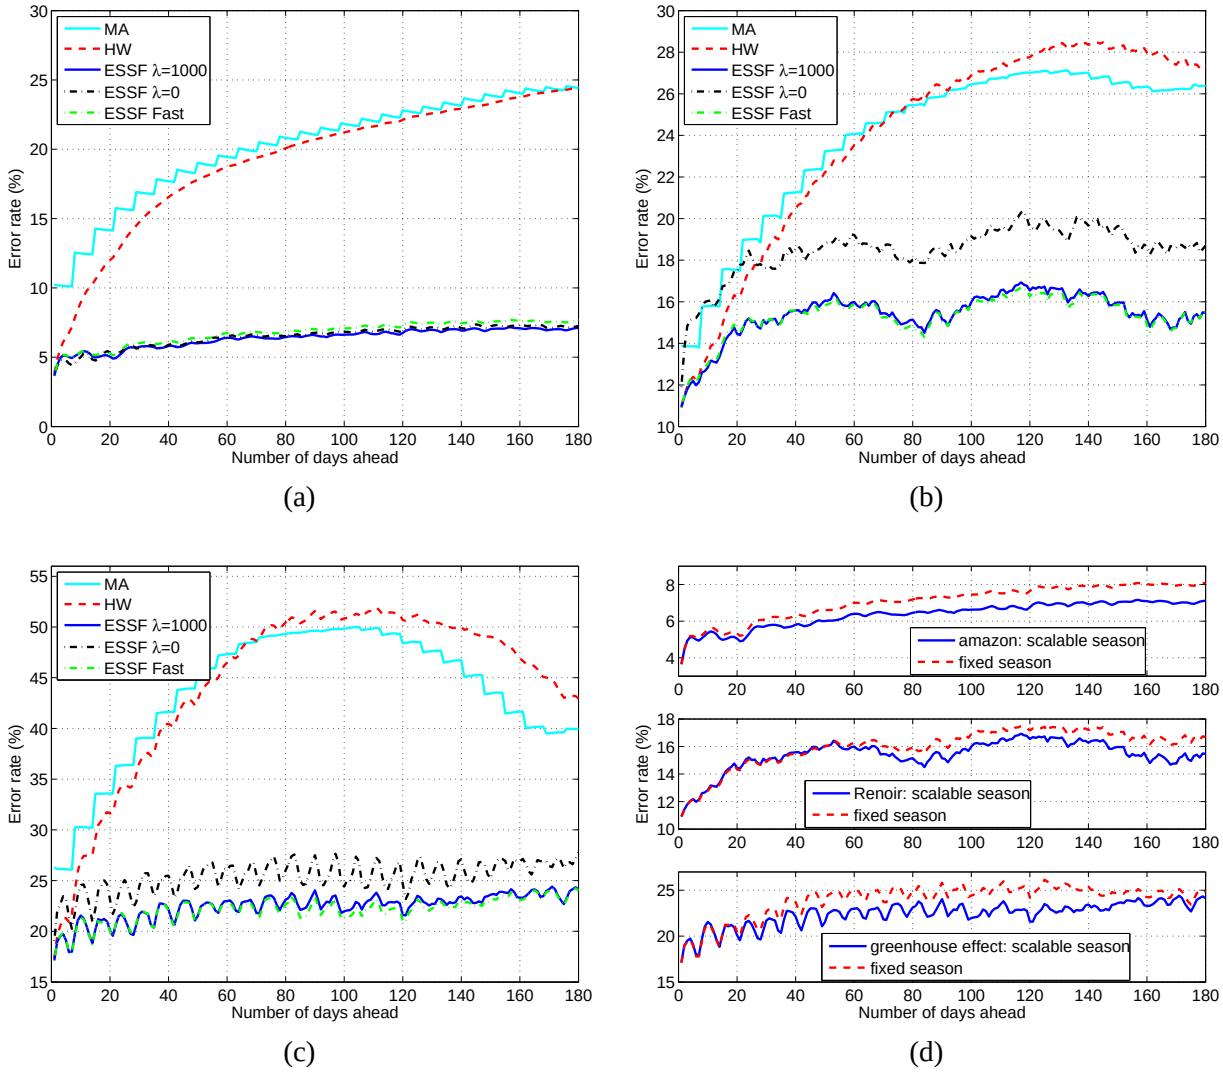

Figure 8: Compare prediction error rates R_e for three `g-trends` series using several methods. Prediction is performed for the unit ahead h ranging from 1 to 180, and a fixed the window size $w = 1$. Error rates obtained by MA, HW, ESSF with $\lambda = 1000$, 0, and the fast version of ESSF with moving average window size 15, are shown for the three series (a) `amazon`, (b) `Renoir`, (c) `greenhouse effect` respectively. The yearly season in ESSF is scalable. (d) Error rates obtained for the three series by ESSF, with $\lambda = 1000$, assuming a scalable yearly season versus fixed season.

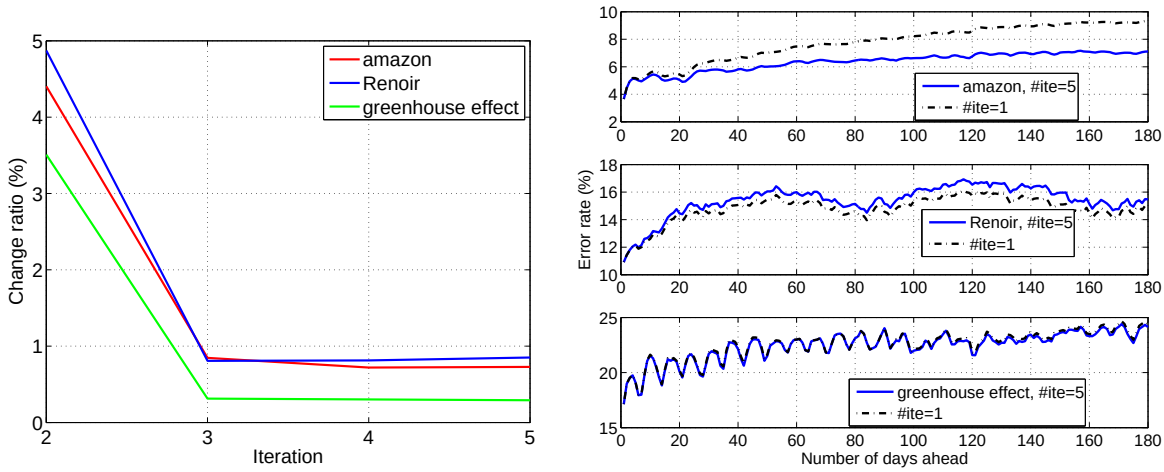

(a) (b)

Figure 9: The effect of the number of iterations in the ESSF algorithm: (a) The change ratio in the extracted yearly season over the iterations; (b) Compare the error rates R_e obtained by ESSF with 1 iteration and 5 iterations respectively.

nearly the same, both achieving error rates consistently lower than those by HW. The gap between the error rates of ESSF and HW widens quickly with an increasing h. In general, when h increases, the prediction is harder, and hence the error rate tends to increase. The increase is substantially slower for ESSF than HW and MA. ESSF with $\lambda = 0$ performs considerably worse than $\lambda = 1000$ for `Renoir` and `greenhouse effect`, and closely for `amazon`. This demonstrates the advantage of imposing smoothness on the yearly season. We will study more thoroughly the effect of λ on prediction accuracy shortly.

Next, we experiment with ESSF under various setups and demonstrate the advantages of several algorithmic choices. First, recall that the fitting of the yearly season and the long-range trend is repeated multiple times, as described in Section 4.1. To study the effect of the number of iterations, we plot in Figure 9(a) the ratio of change in the yearly season after each iteration, as given by Eq. (10). For all the three series, the most prominent change occurs between iteration 1 and 2 and falls below 1% for any later iterations. We also compare the prediction error rates for $h = 1, \ldots, 180$ achieved by using only 1 iteration (essentially no iteration) versus 5 iterations. The results for the three series are plotted in Figure 9(b). The most obvious difference is with `amazon` for large h. At $h = 180$, the error rate obtained by 5 iterations is about 2% lower than by 1 iteration. On the other hand, even with only 1 iteration, the error rate at $h = 180$ is below 10%, much lower than the nearly 25% error rate obtained by HW or MA. For `greenhouse effect`, the difference is almost imperceptible.

In ESSF, the yearly season is not assumed simply as a periodic series. Instead, it can scale differently over the years based on the season template. To evaluate the gain, we compare ESSF with scalable yearly seasons versus fixed seasons. Here, the fixed season can be thought of as a special case of the scalable season with all the scaling parameters set to 1, or equivalently, the yearly season is the plain repeat of the season template. Figure 8(d) compares the error rates under

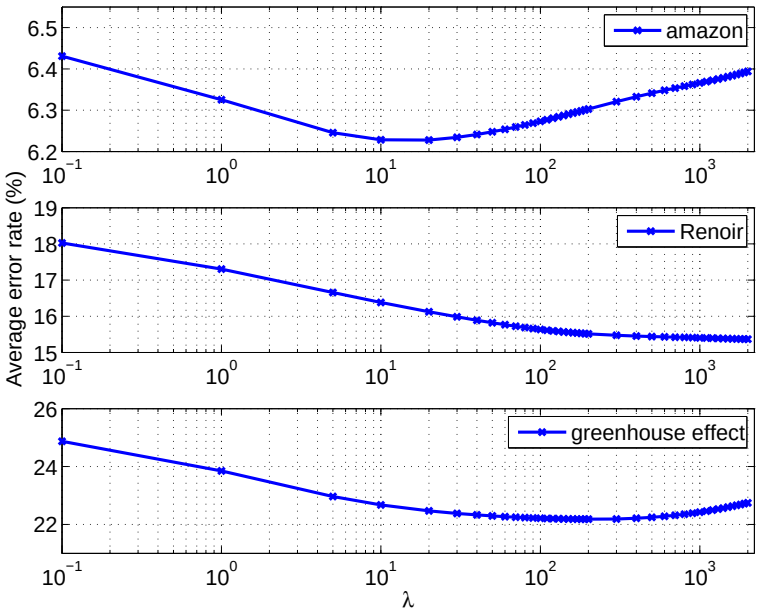

Figure 10: The effect of the smoothing parameter λ in ESSF on prediction accuracy. At each λ, the average of error rates R_e across the unit ahead $h = 1, ..., 180$ are shown.

the two schemes for the three series. Better performance is achieved by allowing scalable yearly seasons for all the three series. The advantage is more substantial when predicting the distant future.

To examine the sensitivity of the prediction accuracy to the smoothing parameter λ, we vary λ from 0.1 to 2000, and compute the error rates for $h = 1, ..., 180$. For concise illustration, we present the average of the error rates across h. Note that the results of $\lambda = 0, 1000$ at every h are shown in Figure 8, where $\lambda = 0$ is inferior. The variation of the average error rates with respect to λ (in log scale) is shown in Figure 10. For `amazon`, the error rates with different λ's lie in the narrow range of $[6.2\%, 6.45\%]$, while for `Renoir` and `greenhouse effect`, the range is wider, roughly $[15\%, 18\%]$ and $[22\%, 25\%]$ respectively. For all the three series, the decrease of the error rate is most steep when λ increases from 0.1 to 10. For $\lambda > 10$ and as large as 2000, the change in error rate is minor, indicating that the prediction performance is not sensitive to λ as long as it is not too small.

5.3.3 LONG-TERM PREDICTION—EXTENDED STUDY ON TWENTY TREND SERIES

We collect another twenty `g-trends` series with query phrases and corresponding series ID listed in Table 2. The error rates R_e achieved by the four methods: MA, HW, ESSF with $\lambda = 1000$, and ESSF Fast, over the twenty series are compared in Figure 11. The four plots in this figure each show results for predicting a single day in advance of h days, with $h = 1, 30, 60, 90$ respectively. For most series, MA is inferior to HW at every h. However, when h increases, the margin of HW over MA decreases. At $h = 1$, HW performs similarly as ESSF and ESSF Fast. At $h = 30, 60, 90$, both versions of ESSF, which achieve similar error rates between themselves, outperform HW.

To assess the predictability of the series, we compute the variation rates at $h = 1, 30, 60, 90$, shown in Figure 12(a). The variation rate at h is defined as $\sqrt{Var(x_{t+h} - x_t)} / \sqrt{Var(x_t)}$, where

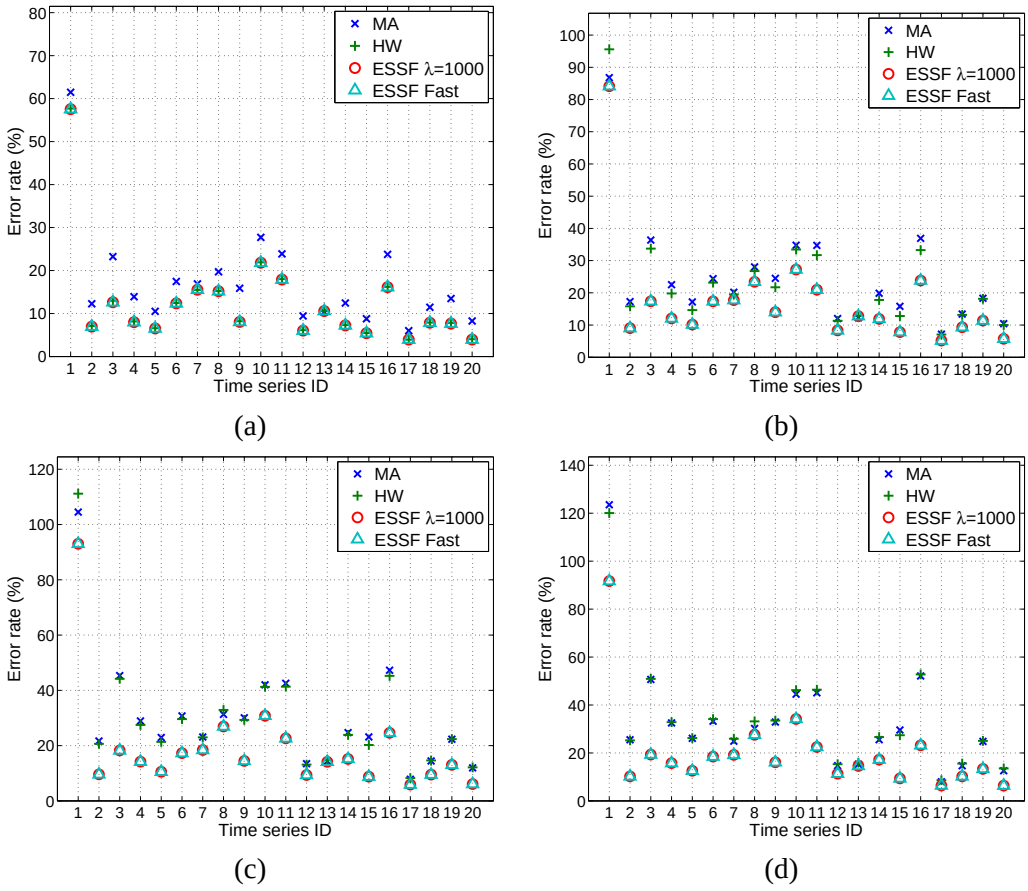

Figure 11: Compare the error rates by MA, HW, ESSF with $\lambda = 1000$, and ESSF Fast for twenty `g-trends` series. (a)-(d): The unit ahead $h = 1, 30, 60, 90$.

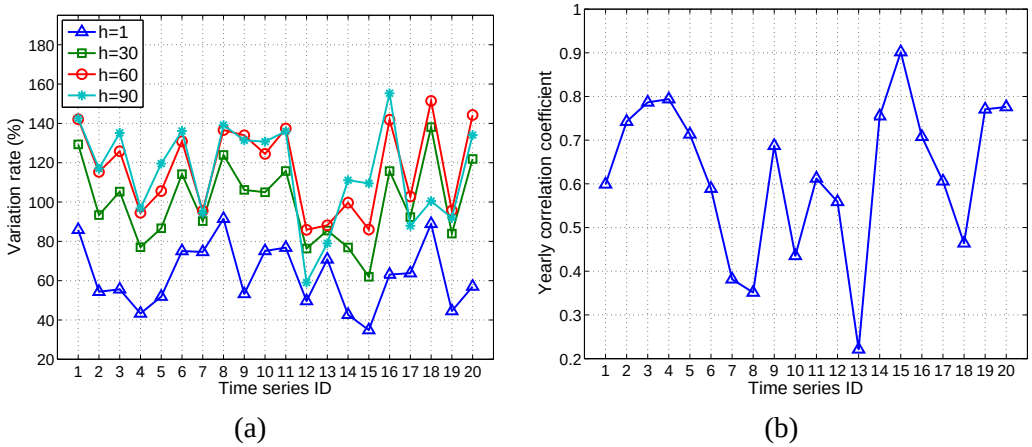

Figure 12: Predictability of twenty `g-trends` series. (a) The variation rates at $h = 1, 30, 60, 90$; (b) The average serial correlation coefficient between adjacent years.

ID	Query phrase	ID	Query phrase
1	American idol	11	human population
2	Anthropology	12	information technology
3	Aristotle	13	martial art
4	Art history	14	Monet
5	Beethoven	15	National park
6	Confucius	16	NBA
7	Cosmology	17	photography
8	cure cancer	18	public health
9	democracy	19	Shakespeare
10	financial crisis	20	Yoga

Table 2: The query phrases for twenty g-trends series and their IDs.

$Var(\cdot)$ denotes the serial variance. This rate is the ratio between the standard deviation of the change in page view h time units apart and that of the original series. A low variation rate indicates the series is less volatile and hence likely to be easier to predict. For example, Art history (ID 4) and National park (ID 15) have the lowest variation rates at $h = 1$, and they both yield relatively low prediction error rates, as shown by Figure 11. We also compute the variation rates for the page views of Web sites Auton, Wang, and citeseer at $h = 1$. They are respectively 100.0%, 88.1%, and 48.2%. This shows that the volatility of page views at these Web sites is in a similar range as that of the g-trends series.

In addition to the variation rate, the yearly correlation of the time series also indicates the potential for accurate prediction. For each of the twenty g-trends series, we compute the average of the correlation coefficients between segments of the series in adjacent years (i.e., 2004/05, 05/06, 06/07). Figure 12(b) shows the results. A series with high yearly correlation tends to benefit more in prediction from the yearly season extraction of ESSF. For instance, martial art (ID 13) has relatively low yearly correlation. The four prediction methods perform nearly the same for this series. In contrast, for NBA (ID 16) and democracy (ID 9), which have high yearly correlation, ESSF achieves substantially better prediction accuracy than HW and MA at all the values of h.

To compare the computational load of the prediction algorithms, we acquire the average user running time over the twenty g-trends series for one day ahead ($h = 1$) prediction at all the days in the last two years, 2006 and 2007. Again, we use Matlab codes on 2.4GHz Dell computer with Linux OS. The average time is respectively 0.11, 0.32, 0.59, and 3.77 seconds for MA, HW, ESSF Fast, and ESSF with $\lambda = 1000$.

6. Discussion and Conclusions

We have so far focused on extracting the trend and season parts of a time series using either HW or GLS, and have not considered predicting the noise part, as given in Eq. (1). We have argued that the variation in Web page view series is dominated by that of the trend and season. To quantitatively assess the potential gain from modeling and predicting the noise term in HW, we fit AR models to the noise. Specifically, we compute the level L_t and the season I_t by HW and let the noise $N_t = x_t - L_t - I_t$. We then fit AR models of order p to the noise series using the Yule-Walker estimation (Brockwell and Davis, 2002). We let p range from 1 to 10 and select an order p by the large-sample

motivated method described in Brockwell and Davis (1991, 2002). The fitted AR models are used to predict the noise, and the predicted noise is added to the forecasting value by HW. Suppose we want to predict x_{t+1} based on $\{x_1, x_2, ..., x_t\}$. The formula given by HW is $\hat{x}_{t+1} = L_t + I_{t+1-d}$. The predicted noise at $t+1$ given by the AR model is $\hat{N}_{t+1} = \hat{\phi}_1 N_t + \hat{\phi}_2 N_{t-1} + \cdots + \hat{\phi}_p N_{t-p+1}$, where $\hat{\phi}_j$, $j = 1, ..., p$, are estimated parameters in the AR model. We then adjust the prediction of HW by $\hat{x}_{t+1} = L_t + I_{t+1-d} + \hat{N}_{t+1}$.

In our experiments, the order of the AR model chosen for each of the three series `Auton`, `Wang`, and `citeseer` is 5, 6, 9 respectively. The error rates R_e^{adj} obtained for `Auton`, `Wang`, and `citeseer` are 17.16%, 20.30%, and 8.45%. As listed in Table 1, the error rates obtained by HW are 16.76%, 20.77%, and 8.80%. We see that the error rates for `Wang` and `citeseer` are improved via noise prediction, but that for `Auton` is degraded. For every series, the difference is insignificant. This shows that the gain from predicting the noise series is minor if positive at all. It is out of the scope of this paper to investigate more sophisticated models for the noise series. We consider it an interesting direction for future work.

To conclude, we have examined multiple approaches to Web page view forecasting. For short-term prediction, the HW procedure and the GLS state space model are investigated. It is shown that seasonal effect is important for page view forecasting. We developed a method to identify impulses and to reduce the decrease in prediction accuracy caused by them. The HW procedure, although computationally simple, performs closely to the GLS approach for predicting a small number of time units ahead. For predicting moderately distant future, the GLS model with smoother level terms tends to perform better. We developed the ESSF algorithm to extract global trend and scalable long-range season with smoothness regularization. It is shown that for predicting the distant future, ESSF outperforms HW significantly.

Acknowledgments

We thank Michael Baysek, C. Lee Giles, and James Wang for providing the logs of the Auton Lab, citeseer, and the Wang Lab. We also thank Artem Boytsov and Eyal Molad for helping us access the Google trends series, Robbie Sedgewick for suggestions on writing, and the reviewers for many insightful and constructive comments.

Appendix A. Algorithms for the State Space Model

Several major issues can be studied under the state space model:

1. Filtering: obtain the conditional distribution of α_{t+1} given X_t for $t = 1, ..., n$ where $X_t = \{x_1, ..., x_t\}$. If we consider α_t as the "true" signal, filtering is to discover the signal on the fly.

2. State smoothing: estimate α_t, $t = 1, ..., n$, given the entire series $\{x_1, ..., x_n\}$. This is to discover the signal in a batch mode.

3. Disturbance smoothing: estimate the disturbances $\hat{\varepsilon}_t = E(\varepsilon_t | y_1, ..., y_n)$, $\hat{\eta}_t = E(\eta_t | y_1, ..., y_n)$. The estimation can be used to estimate the covariance matrices of the disturbances.

4. Forecasting: given $\{x_1, ..., x_n\}$, forecast x_{n+j} for $j = 1, ..., J$.

5. Perform the Maximum Likelihood (ML) estimation for the parameters based on $\{x_1, ..., x_n\}$.

The computation methods involved in the above problems are tightly related. Filtering is conducted by forward recursion, while state smoothing is achieved by combining the forward recursion with a backward recursion. Disturbance smoothing can be easily performed based on the results of filtering and smoothing. ML estimation in turn relies on the result of disturbance smoothing. Next, we present the algorithms to solve the above problems.

A.1 Filtering and Smoothing

Recall the SSM described by Eq. (6)

$$\begin{aligned} x_t &= \mathbf{Z}_t\alpha_t + \varepsilon_t\,, \qquad \varepsilon_t \sim N(0,\mathbf{H}_t), \\ \alpha_{t+1} &= \mathbf{T}_t\alpha_t + \mathbf{R}_t\eta_t\,, \quad \eta_t \sim N(0,\mathbf{Q}_t)\,, \quad t = 1,\ldots,n, \\ &\qquad\qquad \alpha_1 \sim N(a_1,\mathbf{P}_1). \end{aligned}$$

Suppose the goal is filtering, that is, to obtain the conditional distribution of α_{t+1} given X_t for $t = 1,\ldots,n$ where $X_t = \{x_1,\ldots,x_t\}$. Since the joint distribution is Gaussian, the conditional distribution is also Gaussian and hence is uniquely determined by the mean and covariance matrix. Moreover, note that x_{t+1} is conditionally independent of X_t given α_{t+1}. Let $a_t = E(\alpha_t \mid X_{t-1})$ and $\mathbf{P}_t = Var(\alpha_t \mid X_{t-1})$. Then $\alpha_t \mid X_{t-1} \sim N(a_t,\mathbf{P}_t)$. It can be shown that a_{t+1} and $\mathbf{P}_{t+1}$ can be computed recursively from a_t, $\mathbf{P}_t$.

Let the one-step forecast error of x_t given X_{t-1} be v_t and the variance of v_t be $\mathbf{F}_t$:

$$\begin{aligned} v_t &= x_t - E(x_t \mid X_{t-1}) = x_t - \mathbf{Z}_t a_t, \\ \mathbf{F}_t &= Var(v_t) = \mathbf{Z}_t\mathbf{P}_t\mathbf{Z}_t^t + \mathbf{H}_t. \end{aligned}$$

For clarity, also define

$$\begin{aligned} \mathbf{K}_t &= \mathbf{T}_t\mathbf{P}_t\mathbf{Z}_t^t\mathbf{F}_t^{-1}, \\ \mathbf{L}_t &= \mathbf{T}_t - \mathbf{K}_t\mathbf{Z}_t. \end{aligned}$$

Then a_t, $\mathbf{P}_t$, $t = 2,\ldots,n+1$ can be computed recursively by updating v_t, $\mathbf{F}_t$, $\mathbf{K}_t$, $\mathbf{L}_t$, a_{t+1}, $\mathbf{P}_{t+1}$ as follows. It is assumed that a_1 and $\mathbf{P}_1$ are part of the model specification, and hence are known or provided by initialization. Details on initialization are referred to Durbin and Koopman (2001). For $t = 1,2,\ldots,n$,

$$\begin{aligned} v_t &= x_t - \mathbf{Z}_t a_t, \\ \mathbf{F}_t &= \mathbf{Z}_t\mathbf{P}_t\mathbf{Z}_t^t + \mathbf{H}_t, \\ \mathbf{K}_t &= \mathbf{T}_t\mathbf{P}_t\mathbf{Z}_t^t\mathbf{F}_t^{-1}, \\ \mathbf{L}_t &= \mathbf{T}_t - \mathbf{K}_t\mathbf{Z}_t, \\ a_{t+1} &= \mathbf{T}_t a_t + \mathbf{K}_t v_t, \\ \mathbf{P}_{t+1} &= \mathbf{T}_t\mathbf{P}_t\mathbf{L}_t^t + \mathbf{R}_t\mathbf{Q}_t\mathbf{R}_t^t. \end{aligned} \tag{17}$$

The above recursion is called *Kalman filter*. The dimensions for the above matrices are:

$$\begin{array}{ll} v_t & p \times 1\ , \\ \mathbf{F}_t & p \times p\ , \\ \mathbf{K}_t & m \times p\ , \\ \mathbf{L}_t & m \times m\ , \\ a_t & m \times 1\ , \\ \mathbf{P}_t & m \times m\ . \end{array}$$

We are concerned with univariate forecasting here with $p = 1$.

We now consider the *smooth estimation* $\hat{\alpha}_t = E(\alpha_t \mid x_1, x_2, ..., x_{t-1}, x_t, ..., x_n)$. Note its difference from the forward estimation $a_t = E(\alpha_t \mid x_1, x_2, ..., x_{t-1})$. The smooth estimation takes into consideration the series after t. Let the variance of the smooth estimation be $\mathbf{V}_t = Var(\alpha_t \mid x_1, x_2, ..., x_{t-1}, x_t, ..., x_n)$.

We can compute $\hat{\alpha}_t$ and $\mathbf{V}_t$ by the *backwards recursion* specified below. At $t = n$, set $\gamma_n = [0]_{m\times 1}$ and $\mathbf{N}_n = [0]_{m\times m}$. For $t = n, n-1, ..., 1$,

$$\begin{aligned} \gamma_{t-1} &= \mathbf{Z}_t^t \mathbf{F}_t^{-1} v_t + \mathbf{L}_t^t \gamma_t\ , \\ \mathbf{N}_{t-1} &= \mathbf{Z}_t^t \mathbf{F}_t^{-1} \mathbf{Z}_t + \mathbf{L}_t^t \mathbf{N}_t \mathbf{L}_t, \\ \hat{\alpha}_t &= a_t + \mathbf{P}_t \gamma_{t-1}, \\ \mathbf{V}_t &= \mathbf{P}_t - \mathbf{P}_t \mathbf{N}_{t-1} \mathbf{P}_t. \end{aligned} \tag{18}$$

Note that $\mathbf{Z}_t$, $\mathbf{F}_t$, $\mathbf{L}_t$, and $\mathbf{P}_t$ are already acquired by the Kalman filter (17). Eq. (17) and (18) are referred to as *Kalman filter and smoother*. The Kalman filter only involves forward recursion, while the smoother involves both forward and backward recursions.

A.2 Disturbance Smoothing

Let the smoothed disturbances be $\hat{\varepsilon}_t = E(\varepsilon_t | x_1, x_2, ..., x_n)$, $\hat{\eta}_t = E(\eta_t | x_1, x_2, ..., x_n)$. Suppose $\mathbf{F}_t$, $\mathbf{K}_t$, $\mathbf{L}_t$, $t = 1, ..., n$, have been obtained by the Kalman filter, and γ_t, $\mathbf{N}_t$ have been obtained by the Kalman smoother. Then we have

$$\begin{aligned} \hat{\varepsilon}_t &= \mathbf{H}_t(\mathbf{F}_t^{-1} v_t - \mathbf{K}_t^t \gamma_t), \\ Var(\varepsilon_t | x_1, x_2, ..., x_n) &= \mathbf{H}_t - \mathbf{H}_t(\mathbf{F}_t^{-1} + \mathbf{K}_t^t \mathbf{N}_t \mathbf{K}_t)\mathbf{H}_t, \\ \hat{\eta}_t &= \mathbf{Q}_t \mathbf{R}_t^t \gamma_t, \\ Var(\eta_t | x_1, x_2, ..., x_n) &= \mathbf{Q}_t - \mathbf{Q}_t \mathbf{R}_t^t \mathbf{N}_t \mathbf{R}_t \mathbf{Q}_t. \end{aligned}$$

A.3 Forecasting

Now suppose we want to forecast x_{n+j}, $j = 1, ..., J$, given $\{x_1, ..., x_n\}$. Let

$$\begin{aligned} \overline{x}_{n+j} &= E(x_{n+j} \mid x_1, x_2, ..., x_n), \\ \overline{\mathbf{F}}_{n+j} &= Var(x_{n+j} \mid x_1, x_2, ..., x_n)\ . \end{aligned}$$

First, we compute $\overline{a}_{n+j}$ and $\overline{P}_{n+j}$, $j = 1, ..., J$, by forward recursion similar to the Kalman filter in Eq. (17). The slight difference is that when $j = 1, ..., J-1$, set $v_{n+j} = 0$ and $\mathbf{K}_{n+j} = 0$. Specifically, set $\overline{a}_{n+1} = a_{n+1}$, $\overline{P}_{n+1} = \mathbf{P}_{n+1}$. The recursion for $\overline{a}_{n+j+1}$ and $\overline{P}_{n+j+1}$ for $j = 1, ..., J-1$ is:

$$\begin{aligned} \overline{a}_{n+j+1} &= \mathbf{T}_{n+j} \overline{a}_{n+j}, \\ \overline{\mathbf{P}}_{n+j+1} &= \mathbf{T}_{n+j} \overline{\mathbf{P}}_{n+j} \mathbf{T}_{n+j}^t + \mathbf{R}_{n+j} \mathbf{Q}_{n+j} \mathbf{R}_{n+j}^t\ . \end{aligned}$$

Then we forecast

$$\begin{aligned}\overline{x}_{n+j} &= \mathbf{Z}_{n+j}\overline{a}_{n+j},\\ \overline{\mathbf{F}}_{n+j} &= \mathbf{Z}_{n+j}\overline{\mathbf{P}}_{n+j}\mathbf{Z}_{n+j}^{t}+\mathbf{H}_{n+j}\,.\end{aligned}$$

A.4 Maximum Likelihood Estimation

The parameters to be estimated in the SSM are $\mathbf{H}_t$ and $\mathbf{Q}_t$, $t=1,2,...,n$. The EM algorithm is used to obtain the ML estimation. The missing data in EM in this case are the unobservable states α_t, $t=1,...,n$. Denote the parameters to be estimated collectively by ψ and the parameters obtained from the previous iteration by $\tilde{\psi}$. Let $\alpha=\{\alpha_1,\alpha_2,...,\alpha_n\}$ and $X_n=\{x_1,x_2,...,x_n\}$. The update of the EM algorithm comprises two steps:

1. Compute the expectation
$$E_{\tilde{\psi},X_n}[\log p(\alpha,X_n|\psi)]\,.$$

2. Maximize over ψ the above expectation.

It can be shown that

$$\begin{aligned}E_{\tilde{\psi},X_n}[\log p(\alpha,X_n|\psi)] &= \text{constant}-\frac{1}{2}\sum_{t=1}^{n}[\log|\mathbf{H}_t|+\log|\mathbf{Q}_{t-1}|+\\ &\quad tr[(\hat{\varepsilon}_t\hat{\varepsilon}_t^t+Var(\varepsilon_t|X_n))\mathbf{H}_t^{-1}]+\\ &\quad tr[(\hat{\eta}_{t-1}\hat{\eta}_{t-1}^t+Var(\eta_{t-1}|X_n))\mathbf{Q}_{t-1}^{-1}]\mid\psi]\end{aligned}$$

where $\hat{\varepsilon}_t$, $\hat{\eta}_{t-1}$, $Var(\varepsilon_t|X_n)$, and $Var(\eta_{t-1}|X_n)$ are computed by disturbance smoothing under parameter $\tilde{\psi}$. In the special case, when $\mathbf{H}_t=\mathbf{H}$, $\mathbf{Q}_t=\mathbf{Q}$, the maximization can be solved analytically:

$$\begin{aligned}\mathbf{H} &= \frac{\sum_{t=1}^{n}[\hat{\varepsilon}_t\hat{\varepsilon}_t^t+Var(\varepsilon_t|X_n)]}{n},\\ \mathbf{Q} &= \frac{\sum_{t=2}^{n}[\hat{\eta}_{t-1}\hat{\eta}_{t-1}^t+Var(\eta_{t-1}|X_n)]}{n-1}.\end{aligned}$$

The formula can be further simplified if $\mathbf{H}$ and $\mathbf{Q}$ are assumed diagonal. Suppose

$$\begin{aligned}\mathbf{H} &= diag(\sigma_{\varepsilon,1}^2,\sigma_{\varepsilon,2}^2,...,\sigma_{\varepsilon,p}^2),\\ \mathbf{Q} &= diag(\sigma_{\eta,1}^2,\sigma_{\eta,2}^2,...,\sigma_{\eta,r}^2)\,.\end{aligned}$$

Then

$$\begin{aligned}\sigma_{\varepsilon,j}^2 &= \frac{\sum_{t=1}^{n}[\hat{\varepsilon}_{t,j}^2+Var(\varepsilon_{t,j}|X_n)]}{n},\quad j=1,...,p,\\ \sigma_{\eta,j}^2 &= \frac{\sum_{t=2}^{n}[\hat{\eta}_{t-1,j}^2+Var(\eta_{t-1,j}|X_n)]}{n-1},\quad j=1,...,r\,.\end{aligned}$$

Appendix B. The ESSF Algorithm and Its Fast Version

To solve $\min_{\bar{\mathbf{y}},\mathbf{c}} G(\bar{\mathbf{y}},\mathbf{c})$ in Eq. (12), we iteratively optimize over $\bar{\mathbf{y}}$ and $\mathbf{c}$. Given $\mathbf{c}$, $\bar{\mathbf{y}}$ is solved by

$$\mathbf{A}_y \bar{\mathbf{y}} = \mathbf{b}_y$$

where $\mathbf{A}_y$ is a $D \times D$ matrix with non-zero entries:

$$\begin{aligned}
\mathbf{A}_y(j,j) &= \sum_k \alpha_{k,j}^2 + 6\lambda, \quad j = 1,2,...,D, \\
\mathbf{A}_y(j,j-1) &= \mathbf{A}_y(j,j+1) = -4\lambda, \quad j = 1,2,...,D, \\
\mathbf{A}_y(j,j-2) &= \mathbf{A}_y(j,j+2) = \lambda, \quad j = 1,2,...,D,
\end{aligned}$$

and the column vector $\mathbf{b}_y = (\sum_k \alpha_{k,j} z_{k,j})_j$. Recall that $\alpha_{k,j}$ is computed from $\mathbf{c}$ by Eq. (11).

Given $\mathbf{y}$, $\mathbf{c}$ is solved by

$$\mathbf{A}_c \mathbf{c} = \mathbf{b}_c$$

where $\mathbf{A}_c$ is a $K \times K$ matrix. Define $\mathbf{w}_1 = (0, \frac{1}{D}, \frac{2}{D}, ..., \frac{D-1}{D})^t$ and $\mathbf{w}_2 = (1, \frac{D-1}{D}, \frac{D-2}{D}, ..., \frac{1}{D})^t$. Let diagonal matrices $\mathbf{W}_1 = diag(\mathbf{w}_1)$, $\mathbf{W}_2 = diag(\mathbf{w}_2)$. Also define $\mathbf{z}_k = (z_{k,1}, z_{k,2}, ..., z_{k,D})^t$. The non-zero entries of $\mathbf{A}_c$ are:

$$\begin{aligned}
\mathbf{A}_c(k,k) &= (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{W}_1 \bar{\mathbf{y}} + (\mathbf{W}_2\bar{\mathbf{y}})^t \mathbf{W}_2 \bar{\mathbf{y}}, \quad k = 1,2,...,K-1, \\
\mathbf{A}_c(K,K) &= (\mathbf{W}_2\bar{\mathbf{y}})^t \mathbf{W}_2 \bar{\mathbf{y}}, \\
\mathbf{A}_c(k,k-1) &= (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{W}_2 \bar{\mathbf{y}}, \quad k = 2,3,...,K, \\
\mathbf{A}_c(k,k+1) &= (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{W}_2 \bar{\mathbf{y}}, \quad k = 1,2,...,K-1,
\end{aligned}$$

and the column vector $\mathbf{b}_c$ is given by:

$$\begin{aligned}
\mathbf{b}_c(1) &= (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{z}_1 + (\mathbf{W}_2\bar{\mathbf{y}})^t \mathbf{z}_2 - (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{W}_2 \bar{\mathbf{y}}, \\
\mathbf{b}_c(k) &= (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{z}_k + (\mathbf{W}_2\bar{\mathbf{y}})^t \mathbf{z}_{k+1}, \quad k = 2,3,...,K-1, \\
\mathbf{b}_c(K) &= (\mathbf{W}_1\bar{\mathbf{y}})^t \mathbf{z}_1.
\end{aligned}$$

In summary, the ESSF algorithm iterates the following two steps with initialization $\mathbf{c}^{(0)} = \mathbf{1}$. At iteration $p \geq 1$:

1. Given $\mathbf{c}^{(p-1)}$, compute $\mathbf{A}_y$ and $\mathbf{b}_y$. Let $\bar{\mathbf{y}}^{(p)} = \mathbf{A}_y^{-1}\mathbf{b}_y$.
2. Given $\bar{\mathbf{y}}^{(p)}$, compute $\mathbf{A}_c$ and $\mathbf{b}_c$. Let $\mathbf{c}^{(p)} = \mathbf{A}_c^{-1}\mathbf{b}_c$.

For the fast version of ESSF, we need to solve $\min_{\bar{\mathbf{y}},\mathbf{c}} \tilde{G}(\bar{\mathbf{y}},\mathbf{c})$ in Eq. (13). We start with $\mathbf{c}^{(0)} = \mathbf{1}$. Without loss of generality, we fix $c_1 = 1$. At iteration $p \geq 1$:

1. Given $\mathbf{c}^{(p-1)}$, compute
$$\bar{y}_j^{(p)} = \frac{\sum_k c_k^{(p-1)} z_{k,j}}{\| \mathbf{c}^{(p-1)} \|^2}, \quad j = 1,...,D.$$
2. Given $\bar{\mathbf{y}}^{(p)}$, compute
$$c_k^{(p)} = \frac{\sum_j z_{k,j} \bar{y}_j^{(p)}}{\| \bar{\mathbf{y}}^{(p)} \|^2}, \quad k = 1,...,K.$$

Abstract

Classical approaches used to learn Bayesian network structure from data have disadvantages in terms of complexity and lower accuracy of their results. However, a recent empirical study has shown that a hybrid algorithm improves sensitively accuracy and speed: it learns a skeleton with an independency test (IT) approach and constrains on the directed acyclic graphs (DAG) considered during the search-and-score phase. Subsequently, we theorize the structural constraint by introducing the concept of super-structure S, which is an undirected graph that restricts the search to networks whose skeleton is a subgraph of S. We develop a super-structure constrained optimal search (COS): its time complexity is upper bounded by $O(\gamma_m{}^n)$, where $\gamma_m < 2$ depends on the maximal degree m of S. Empirically, complexity depends on the average degree $\tilde{m}$ and sparse structures allow larger graphs to be calculated. Our algorithm is faster than an optimal search by several orders and even finds more accurate results when given a sound super-structure. Practically, S can be approximated by IT approaches; significance level of the tests controls its sparseness, enabling to control the trade-off between speed and accuracy. For incomplete super-structures, a greedily post-processed version (COS+) still enables to significantly outperform other heuristic searches.

Keywords: Bayesian networks, structure learning, optimal search, super-structure, connected subset

1. Introduction

It is impossible to understand large raw sets of data obtained from a huge number of correlated variables. Therefore, in order to simplify the comprehension of the system, various graphical models have been developed to summarize interactions between such variables in a synoptic graph. Among the existing models, Bayesian networks have been widely employed for decades in various domains including artificial intelligence (Glymour, 2001), medicine (Cowell et al., 1999), bioinformatics (Friedman et al., 2000), and even economy (Segal et al., 2005) and sociology (Heckerman, 1996). Bayesian networks compactly represent a joint probability distribution P over the set of variables, using DAG to encode conditional independencies between them (Pearl, 1988). The popularity of this model is primarily due to its high expressive power, enabling the simultaneous investigation of complex relationships between many variables of a heterogeneous nature (discrete or continuous). Further, for Bayesian network model inference from data is comparatively simpler; incomplete or noisy data are also usable and prior knowledge can be incorporated. When the DAG or structure of

the model is known, the parameters of the conditional probability distributions can be easily fit to the data; thus, the bottleneck of modeling an unknown system is to infer its structure.

Over the previous decades, various research directions have been explored through a numerous literature to deal with structure learning, which let us propose the following observations. Maximizing a score function over the space of DAGs is a promising approach towards learning structure from data. A search strategy called optimal search (OS) have been developed to find the graphs having the highest score (or global optima) in exponential time. However, since it is feasible only for small networks (containing up to thirty nodes), in practice heuristic searches are used. The resulting graphs are local optima and their accuracy strongly depends on the heuristic search strategy. In general, given no prior knowledge, the best strategy is still a basic greedy hill climbing search (HC). In addition, Tsamardinos et al. (2006) proposed to constrain the search space by learning a skeleton using an IT-based technique before proceeding to a restricted search. By combining this method with a HC search, they developed a hybrid algorithm called max-min hill-climbing (MMHC) that is faster and usually more accurate.

In the present study we are interested in OS since the optimal graphs will converge to the true model in the sample limit. We aim to improve the speed of OS in order to apply it to larger networks; for this, a structural constraint could be of a valuable help. In order to keep the asymptotic correctness of OS, the constraint has to authorize at least the edges of the true network, but it can contain also extra edges. Following this minimal condition that should respect a constraint on the skeletons to be sound, we formalize a flexible structural constraint over DAGs by defining the concept of a super-structure. This is an undirected graph that is assumed to contain the skeleton of the true graph (i.e., the true skeleton). In other word, the search space is the set of DAGs that have a subgraph of the given super-structure as a skeleton. A sound super-structure (that effectively contains the true skeleton) could be provided by prior knowledge or learned from data much more easily (with a higher probability) than the true skeleton itself. Subsequently, we consider the problem of maximizing a score function given a super-structure, and we derive a constrained optimal search, COS, that finds a global optimum over the restricted search space. Not surprisingly, our algorithm is faster than OS since the search space is smaller; more precisely, its computational complexity is proportional to the number of connected subsets of the super-structure. An upper bound is derived theoretically and average complexity is experimentally showed to depend on the average degree of the super-structure. Concretely, for sparse structures our algorithm can be applied to larger networks than OS (with an average degree around 2.1, graphs having 1.6 times more nodes could be considered). Moreover, for a sound super-structure, learned graphs are more accurate than unconstrained optima: this is because, some incorrect edges are forbidden, even if their addition to the graph improves the score.

Since the sparseness directly affects the speed, and therefore the feasibility of our search, it remains to propose efficient methods to learn a sound and sparse super-structures without prior knowledge. This is out of the scope of this present paper where we focus on the enunciation of our constraint, its application to optimal search and optimizations of its implementation. Nevertheless, in order to demonstrate our algorithm in practice, we propose a first basic strategy to approximate a super-structure from data. The idea is to use "relaxed" independency testing to obtain an undirected graph that may contain the true skeleton with a high probability, while yet being sparse. In that case, we can consider the significance level of the independency tests, α, as a tool to choose between accuracy (high values return dense but probably sound structures) and speed (low values give sparse but incomplete structures). We tested our proposition on MMPC, the IT-based strategy

used by Tsamardinos et al. (2006) in MMHC; our choice was motivated by the good results of their algorithm that we also include in our comparative study. MMPC appears to be a good method to learn robust and relatively sparse skeletons; unfortunately, soundness is achieved only for high significance levels, $\alpha > 0.9$, implying a long calculation and a denser structure. Practically, when the constraint is learned with $\alpha = 0.05$, in terms of accuracy, COS is worse than OS since the super-structure is usually incomplete; still, COS outperforms most of the time greedy searches, although it finds graphs of lower scores. Resulting graphs can be quickly improved by applying to them a post-processing unconstrained hill-climbing (COS+). During that final phase, scores are strictly improved, and usually accuracy also. Interestingly, even for really low significance levels ($\alpha \approx 10^{-5}$), COS+ returns graphs more accurate and of a higher score than both MMHC and HC. COS+ can be seen as a bridge between HC (when α tends to 0) and OS (when α tends to 1) and can be applied up to a hundred nodes by selecting a low enough significance level.

This paper is organized as follows. In Section 2, we discuss the existing literature on structure learning. We clarify our notation in Section 3.1 and reintroduce OS in Section 3.2. Then, in Section 4, the core of this paper, we define super-structures and present our algorithm, proofs of its complexity and practical information for implementation. Section 5 details our experimental procedures and presents the results. Section 5.1.4 briefly recalls MMPC, the method we used during experiments to learn the super-structures from data. Finally, in Section 6, we conclude and outline our future works.

2. Related Works

The algorithms for learning the Bayesian network structure that have been proposed until now can be regrouped into two different approaches, which are described below.

2.1 IT Approach

This approach includes IC algorithm (inductive causation) (Pearl, 1988), PC algorithm (after its authors, Peter and Clark) (Spirtes et al., 2000), GS algorithm (grow and shrink) (Margaritis and Thrun, 2000), and TPDA algorithm (three-phase dependency analysis) (Cheng et al., 2002). All of them build the structure to be consistent with the conditional independencies among the variables that are evaluated with a statistical test (G-square, partial correlation). Usually, algorithms start by learning the skeleton of the graph (by propagating constraints on the neighborhood of each variable) and then edges are oriented to cope with dependencies revealed from data. Finally, one network is retained from the equivalent class consistent with the series of tests. Under the faithful condition of *P*, such strategies have been proven to build a graph converging to the true network as the size of the data approaches infinity. Moreover, their complexity is polynomial, assuming that the maximal degree of the network, that is, the maximal size of nodes neighborhood, is bounded (Kalisch and Bühlmann, 2007). However, in practice, the results are mixed because of the tests sensitivity to noise: since these algorithms base their decisions on a single or few tests, they are prone to accumulate errors (Margaritis and Thrun, 2000). Worse, they can obtain a set of conditional independencies that is contradictory, or that cannot be faithfully encoded by a DAG, leading to a failure of the algorithm. Moreover, except for sparse graphs, their execution time is generally longer than that of algorithms from the scoring criteria-based approach (Tsamardinos et al., 2006).

2.2 Scoring Criteria-Based Approach

Search-and-score methods are favored in practice and considered as a more promising research direction. This second family of algorithms uses a scoring criterion, such as the posterior probability of the network given the data, in order to evaluate how well a given DAG fits empirical results, and returns the one that maximized the scoring function during the search. Since the search space is known to be of a super exponential size on the number of nodes n, that is, $O(n!2^{\binom{n}{2}})$ (Robinson, 1973), an exhaustive search is practically infeasible, implying that various greedy strategies have been proposed to browse DAG space, sometimes requiring some prior knowledge.

Among them, the state-of-the-art greedy hill climbing (HC) strategy, although it is simple and will find only a locally optimal network, remains one of the most employed method in practice, especially with larger networks. There exist various implementations using different empirical tricks to improve the score of the results, such as TABU list, restarting, simulated annealing, or searching with different orderings of the variables (Chickering et al., 1995; Bouckaert, 1995). However a traditional and basic algorithm will process in the following manner:

- Start the search from a given DAG, usually the empty one.
- Then, from a list of possible transformations containing at least addition, withdrawal or reversal of an edge, select and apply the transformation that improves the score most while also ensuring that graph remains acyclic.
- Finally repeat previous step until strict improvements to the score can no longer be found.

More details about our implementation of HC are given in Section 5.1.3. Such an algorithm can be used even for large systems, and if the number of variables is really high, it can be adapted by reducing the set of transformations considered, or by learning parents of each node successively. In any case, this algorithm finds a local optimum DAG but without any assertion about its accuracy (besides its score). Further, the result is probably far from a global optimal structure, especially when number of nodes increases. However, optimized forms of this algorithm obtained by using one or more tricks have been considered to be the best search strategies in practice until recently.

Other greedy strategies have also been developed in order to improve either the speed or accuracy of HC one: sparse candidate (SC, Friedman et al., 1999) that limits the maximal number of parents and estimate candidate parents for each node before the search, greedy equivalent search (GES, Chickering, 2002b) that searches into the space of equivalence classes (PDAGs), and optimal reinsertion (OR, Moore and Wong, 2003) that greedily applies an optimal reinsertion transformation repeatedly on the graph.

SC was one of the first to propose a reduction in the search space, thereby sensitively improving the score of resulting networks without increasing the complexity too much if candidate parents are correctly selected. However, it has the disadvantage of a lack of flexibility, since imposing a constant number of candidate parents to every node could be excessive or restrictive. Furthermore, the methods and measures proposed to select the candidates, despite their intuitive interest, have not been proved to include at least the true or optimal parents for each node.

GES has the benefit that it exploits a theoretically justified direction. Main scoring functions have been proved to be score equivalent (Chickering, 1995), that is, two equivalent DAGs (representing the same set of independencies among variables) have the same score. Thus they define

equivalent classes over networks that can be uniquely represented by CPDAGs. Therefore, searching into the space of equivalent classes reduces the number of cases that have to be considered, since one CPDAG represents several DAGs. Further, by using usual sets of transformations adapted to CPDAGs, the space browsed during a greedy search becomes more connected, increasing the chances of finding a better local maximum. Unfortunately, the space of equivalent classes seems to be of the same size order than that of DAGs, and an evaluation of the transformations for CPDAGs is more time consuming. Thus, GES is several times slower than HC, and it returns similar results. Interestingly, following the comparative study of Tsamardinos et al. (2006), if structural errors rather than scores are considered as a measure of the quality of the results, GES is better than a basic HC.

In the case of OR, the algorithm had the advantage to consider a new transformation that globally affects the graph structure at each step: this somehow enables the search to escape readily from local optima. Moreover, the authors developed efficient data-structures to rationalize score evaluations and retrieve easily evaluation of their operators. Thus, it is one of the best greedy methods proposed; however, with increasing data, the algorithm will collapse due to memory shortage.

Another proposed direction was using the K2 algorithm (Cooper and Herskovits, 1992), which constraints the causal ordering of variables. Such ordering can be seen to be a topological ordering of the true graph, provided that such a graph is acyclic. Based on this, the authors proposed a strategy to find an optimal graph by selecting the best parent set of a node among the subsets of nodes preceding it. The resulting graph can be the global optimal DAG if it accepts the same topological ordering. Therefore, given an optimal ordering, K2 can be seen as an optimal algorithm with a time and space complexity of $O(2^n)$. Moreover, for some scoring functions, branch-pruning can be used while looking for the best parent set of a node (Suzuki, 1998), thereby improving the complexity. However, in practice, a greedy search that considers adding and withdrawing a parent is applied to select a locally optimal parent set. In addition, the results are strongly depending on the quality of the ordering. Some investigations have been made to select better orderings (Teyssier and Koller, 2005) with promising results.

2.3 Recent Progress

One can wonder about the feasibility of finding a globally optimal graph without having to explicitly check every possible graph, since nothing can be asserted with respect to the structural accuracy of the local maxima found by previous algorithms. In a general case, learning Bayesian network from data is an NP-hard problem (Chickering, 1996), and thus for large networks, only such greedy algorithms are used. However, recently, algorithms for global optimization or exact Bayesian inference have been proposed (Ott et al., 2004; Koivisto and Sood, 2004; Singh and Moore, 2005; Silander and Myllymäki, 2006) and can be applied up to a few tens of nodes. Since they all principally share the same strategy that we will introduce in detail subsequently, we will refer to it as optimal search (OS). Even if such a method cannot be of a great use in practice, it could validate empirically the search-and-score approach by letting us study how a global maximum converges to the true graph when the data size increases; Also, it could be a meaningful gold standard to judge the performances of greedy algorithms.

Finally, a recent noteworthy step was performed with the min-max hill climbing algorithm (MMHC, Tsamardinos et al., 2006), since it was empirically proved to be the fastest and the best method in terms of structural error based on the structural hamming distance. This algorithm can be considered as a hybrid of the two approaches. It first learns an approximation of the skeleton of

the true graph by using an IT strategy. It is based on a subroutine called min-max-parents-children (MMPC) that reconstructs the neighborhood of each node; G-square tests are used to evaluate conditional independencies. The algorithm subsequently proceeds to a HC search to build a DAG limiting edge additions to the one present in the retrieved skeleton. As a result, it follows a similar technique than that of SC, except that the number of candidate parents is tuned adaptively for each node, and that the chosen candidates are sound in the sample limit. It is worth to notice that the skeleton learned in the first phase can differ from the one of the final DAG, since all edges will not be for sure added during the greedy search. However, it will be certainly a cover of the resulting graph skeleton.

3. Definitions and Preliminaries

In this section, after explaining our notations and recalling some important definitions and results, we discuss structure constraining and define the concept of a super-structure. Section 3.3 is dedicated to OS.

3.1 Notation and Results for Bayesian Networks

In the rest of the paper, we will use upper-case letters to denote random variables (e.g., X_i, V_i) and lower-case letters for the state or value of the corresponding variables (e.g., x_i, v_i). Bold-face will be used for sets of variables (e.g., $\mathbf{Pa}_i$) or values (e.g., $\mathbf{pa}_i$). We will deal only with discrete probability distributions and complete data sets for simplicity, although a continuous distribution case could also be considered using our method.

Given a set $\mathbf{X}$ of n random variables, we would like to study their probability distribution P_0. To model this system, we will use Bayesian networks:

Definition 1. (Pearl, 1988; Spirtes et al., 2000; Neapolitan, 2003) *Let P be a discrete joint probability distribution of the random variables in some set* $\mathbf{V}$*, and* $G = (\mathbf{V}, \mathbf{E})$ *be a directed acyclic graph (DAG). We call* (G, P) *a* Bayesian network (BN) *if it satisfies the Markov condition, that is, each variable is independent of any subset of its non-descendant variables conditioned on its parents.*

We will denote the set of the parents of a variable V_i in a graph G by $\mathbf{Pa}_i$, and by using the Markov condition, we can prove that for any BN (G, P), the distribution P can be factored as follows:

$$P(\mathbf{V}) = P(V_1, \cdots, V_p) = \prod_{V_i \in \mathbf{V}} P(V_i | \mathbf{Pa}_i).$$

Therefore, to represent a BN, the graph G and the joint probability distribution have to be encoded; for the latter, every probability $P(V_i = v_i | \mathbf{Pa}_i = \mathbf{pa}_i)$ should be specified. G directly encodes some of the independencies of P and entails others (Neapolitan, 2003). More precisely, all independencies entailed in a graph G are summarized by its skeleton and by its v-structures (Pearl, 1988). Consequently, two DAGs having the same skeleton and v-structures entail the same set of independencies; they are said to be *equivalent* (Neapolitan, 2003). This equivalence relation defines *equivalent classes* over space of DAGs that are unambiguously represented by *completed partially directed acyclic graphs (CPDAG)* (Chickering, 2002b). Finally, if all and only the conditional independencies true in a distribution P are entailed by the Markov condition applied to a DAG G, we say that the Bayesian Network (G, P) is *faithful* (Spirtes et al., 2000).

In our case, we will assume that the probability distribution P_0 over the set of random variables $\mathbf{X}$ is faithful, that is, that there exists a graph G_0, such that (G_0, P_0) is a faithful Bayesian network. Although there are distributions P that do not admit a faithful BN (for example the case when parents are connected to a node via a parity or XOR structure), such cases are regarded as "rare" (Meek, 1995), which justifies our hypothesis.

To study $\mathbf{X}$, we are given a set of data $\mathbf{D}$ following the distribution P_0, and we try to learn a graph G, such that (G, P_0) is a faithful Bayesian network. The graph we are looking for is probably not unique because any member of its equivalent class will also be correct; however, the corresponding CPDAG is unique. Since there may be numerous graphs G to which P_0 is faithful, several definitions are possible for the problem of learning a BN. We choose as Neapolitan (2003):

Definition 2. *Let P_0 be a faithful distribution and* $\mathbf{D}$ *be a statistical sample following it. The problem of learning the structure of a Bayesian network given* $\mathbf{D}$ *is to* induce a graph G so that (G, P_0) is a faithful BN, *that is, G and G_0 are on the same equivalent class, and both are called the true structure of the system studied.*

In every IT-based or constraint-based algorithm, the following theorem is useful to identify the skeleton of G_0:

Theorem 1. (Spirtes et al., 2000) *In a faithful BN (G, P) on variables* $\mathbf{V}$*, there is an edge between the pair of nodes X and Y if and only if X depends on Y conditioning on every subset* $\mathbf{Z}$ *included in* $\mathbf{V} \setminus \{X, Y\}$.

Thus, from the data, we can estimate the skeleton of G_0 by performing conditional independency tests (Glymour and Cooper, 1999; Cheng et al., 2002). We will return to this point in Section 4.1 since higher significance levels for the test could be used to obtain a cover of the skeleton of the true graph.

3.2 General Optimal Search

Before presenting our algorithm, we should review the functioning of an OS. Among the few articles on optimal search (Ott et al., 2004; Koivisto and Sood, 2004; Singh and Moore, 2005; Silander and Myllymäki, 2006), Ott and Miyano (2003) are to our knowledge the first to have published an exact algorithm. In this section we present the algorithm of Ott et al. (2004) for summarizing the main idea of OS. While investigating the problem of exact model averaging, Koivisto and Sood (2004) independently proposed another algorithm that also learn optimal graphs proceeding on a similar way. As for Singh and Moore (2005), they presented a recursive implementation that is less efficient in terms of calculation; however, it has the advantage that potential branch-pruning rules can be applied. Finally, Silander and Myllymäki (2006) detailed a practically efficient implementation of the search: the main advantage of their algorithm is to calculate efficiently the scores by using contingency tables (still computational complexity remains the same). They empirically demonstrated that optimal graphs could be learned up to $n = 29$.

To understand how OS finds global optima in $O(n2^n)$ without having to explicitly check every DAG possible, we must first explain how a score function is defined. Various scoring criteria for graphs have been defined, including Bayesian Dirichlet (specifically BDe with uniform priors, BDeu) (Heckerman et al., 1995), Bayesian information criterion (BIC) (Schwartz, 1978), Akaike information criterion (AIC) (Akaike, 1974), minimum description length (MDL) (Rissanen, 1978),

and Bayesian network and nonparametric regression criterion (BNRC) (Imoto et al., 2002). They are usually costly to evaluate; however, due to the Markov condition, they can be evaluated locally:

$$Score(G,\mathbf{D}) = \sum_{i=1}^{n} score(X_i, \mathbf{Pa}_i, \mathbf{D}).$$

This property is essential to enable efficient calculation, particularly with large graphs, and is usually supposed while defining an algorithm. Another classical attribute is score equivalence, which means that two equivalent graphs will have the same score. It was proved to be the case for BDe, BIC, AIC, and MDL (Chickering, 1995). In our study, we will use BIC, thereby our score is local and equivalent, and our task will be to find a DAG over $\mathbf{X}$ that maximizes the score given the data $\mathbf{D}$. Exploiting score locality, Ott et al. (2004) defined for every node X_i and every candidate parent set $\mathbf{A} \subseteq \mathbf{X} \setminus \{X_i\}$:

- The best local score on X_i: $F_s(X_i,\mathbf{A}) = \max_{\mathbf{B}\subseteq\mathbf{A}} score(X_i,\mathbf{B},\mathbf{D})$;
- The best parent set for X_i: $F_p(X_i,\mathbf{A}) = \operatorname{argmax}_{\mathbf{B}\subseteq\mathbf{A}} score(X_i,\mathbf{B},\mathbf{D})$.

From now we omit writing $\mathbf{D}$ when referring to the score function. F_s can be calculated recursively on the size of $\mathbf{A}$ using the following formulas:

$$F_s(X_i,\emptyset) = score(X_i,\emptyset), \quad (1)$$
$$F_s(X_i,\mathbf{A}) = \max(score(X_i,\mathbf{A}), \max_{X_j\in\mathbf{A}}(F_s(X_i,\mathbf{A}\backslash\{X_j\})). \quad (2)$$

Calculation of F_p directly follows; we will sometimes use F as a shorthand to refer to these two functions. Noticing that we can dynamically evaluate F, one can think that it is thus directly possible to find the best DAG. However, it is also essential to verify that the graph obtained is acyclic and hence, that there exists a topological ordering over the variables.

Definition 3. *Let w be an ordering defined on $\mathbf{A} \subseteq \mathbf{X}$ and $H = (\mathbf{A},\mathbf{E})$ be a DAG. We say that H is* w-linear *if and only if $w(X_i) < w(X_j)$ for every directed edge $(X_i,X_j) \in \mathbf{E}$.*

By using F_p and given an ordering w on $\mathbf{A}$ we derive the best w-linear graph G^*_w as:

$$G^*_w = (\mathbf{A},\mathbf{E}^*_w), \text{ with } (X_j,X_i) \in \mathbf{E}^*_w \text{ if and only if } X_j \in F_p(X_i, \mathbf{Pred}_w(X_i)). \quad (3)$$

Here, G^*_w is directly obtained by selecting for each variable $X_i \in \mathbf{A}$ its best parents among the nodes preceding X_i in the ordering w referred as $\mathbf{Pred}_w(X_i) = \{X_j \text{ with } w(X_j) < w(X_i)\}$. Therefore, to achieve OS, we need to find an optimal w^*, that is, a topological ordering of an optimal DAG. With this end, we define for every subset $\mathbf{A} \subseteq \mathbf{X}$ not empty:

- The best score of graphs G on $\mathbf{A}$: $M_s(\mathbf{A}) = \max_G Score(G)$
- The last node of an optimal ordering on $\mathbf{A}$: $M_l(\mathbf{A})$

Another way to interpret $M_l(\mathbf{A})$ is as a sink of an optimal graph on $\mathbf{A}$, that is, a node that has no children. M_s and M_l are simply initialized by:

$$\begin{aligned} \forall X_i \in \mathbf{X}: \;\; & M_s(\{X_i\}) = score(X_i, \emptyset), \\ & M_l(\{X_i\}) = X_i. \end{aligned} \tag{4}$$

When $|\mathbf{A}| = k > 1$, we consider an optimal graph G^* on that subset and w^* one of its topological ordering. The parents of the last element X_{i^*} are for sure $F_p(X_{i^*}, \mathbf{B}_{i^*})$, where $\mathbf{B}_j = \mathbf{A} \setminus \{X_j\}$; thus its local score is $F_s(X_{i^*}, \mathbf{B}_{i^*})$. Moreover, the subgraph of G^* induced when removing X_{i^*} must be optimal for $\mathbf{B}_{i^*}$; thus, its score is $M_s(\mathbf{B}_{i^*})$. Therefore, we can derive a formula to define M_l recursively:

$$M_l(\mathbf{A}) = X_{i^*} = \underset{X_j \in \mathbf{A}}{\operatorname{argmax}}(F_s(X_j, \mathbf{B}_j) + M_s(\mathbf{B}_j)). \tag{5}$$

This also enables us to calculate M_s directly. We will use M to refer to both M_s and M_l. M can be computed dynamically and M_l enables us to build quickly an optimal ordering w^*; elements are find in reverse order:

$$\begin{aligned} & \mathbf{T} = \mathbf{X} \\ & \text{While } \mathbf{T} \neq \emptyset \\ & \qquad w^*(M_l(\mathbf{T})) = |\mathbf{T}| \\ & \qquad \mathbf{T} = \mathbf{T} \setminus M_l(\mathbf{T}) \end{aligned} \tag{6}$$

Therefore, the OS algorithm is summarized by:

Algorithm 1 (OS). (Ott et al., 2004)

(a) Initialize $\forall X_i \in \mathbf{X}$, $F_s(X_i, \emptyset)$ and $F_p(X_i, \emptyset)$ with (1)

(b) For each $X_i \in \mathbf{X}$ and each $\mathbf{A} \subseteq \mathbf{X} \setminus \{X_i\}$:
Calculate $F_s(X_i, \mathbf{A})$ and $F_p(X_i, \mathbf{A})$ using (2)

(c) Initialize $\forall X_i$, $M_s(\{X_i\})$ and $M_l(\{X_i\})$ using (4)

(d) For each $\mathbf{A} \subseteq \mathbf{X}$ with $|\mathbf{A}| > 1$:
Calculate $M_s(\mathbf{A})$ and $M_l(\mathbf{A})$ using (5)

(e) Build an optimal ordering w^* using (6)

(f) Return the best w^*-linear graph $G^*_{w^*}$ using (3)

Note that in steps (b) and (d) subsets $\mathbf{A}$ are implicitly considered by increasing size to enable formulae (2) and (5). With respect to computational complexity, in steps (a) and (b) F is calculated for $n2^{n-1}$ pairs of variable and parent candidate set. In each case, one score exactly is computed. Then, M is computed over the 2^n subsets of $\mathbf{X}$ (step (c) and (d)). w^* and G^*_w are both build in $O(n)$ time at step (e) and (f); thus, the algorithm has a total time complexity of $O(n2^n)$ and evaluates $n2^{n-1}$ scores. Here, time complexity refers to the number of times that the formulae (2) or (5) are computed; however, it should be pointed out that these formulae require at least $O(n)$ basic operations.

As proposed (Ott et al., 2004), OS can be speed up by constraining with a constant c the maximal size of parent sets. This limitation is easily justifiable, as graphs having many parents for a node are usually strongly penalized by score functions. In that case, the computational complexity remains the same; only formulas (2) is constrained, and $score(X_i, \mathbf{A})$ is not calculated when $|\mathbf{A}| > c$. Consequently, the total number of score evaluated is reduced to $O(n^{c+1})$, which is a decisive improvement since computing a score is costly.

The space complexity of Algorithm 1 can be slightly reduced by recycling memory as mentioned (Ott et al., 2004). In fact, when calculating functions F and M for subsets $\mathbf{A}$ of size k, only values for subsets of size $k-1$ are required. Therefore, by computing simultaneously these two functions, when values for subsets of a given size have been computed, the memory used for smaller set can be reused. However, to be able to access G^*_w, we should redefine M_l to store optimal graphs instead of optimal sinks. The worst memory usage corresponds to $k = \lfloor \frac{n}{2} \rfloor + 1$ when we have to consider approximately $O(\frac{2^n}{\sqrt{n}})$ sets: this approximation comes from Stirling formula applied to the binomial coefficient of n and $\lfloor \frac{n}{2} \rfloor$ ($\lfloor x \rfloor$ is the highest integer less than or equal to x). At that time, $O(\sqrt{n}2^n)$ best parent sets are stored by F, and $O(\frac{2^n}{\sqrt{n}})$ graphs by M. Since a parent set requires $O(n)$ space and a graph $O(n^2)$, we derive that the maximal memory usage with recycling is $O(n^{\frac{3}{2}}2^n)$, while total memory usage of F in Algorithm 1 was $O(n^2 2^n)$. Actually, since Algorithm 1 is feasible only for small n, we can consider that a set requires $O(1)$ space (represented by less than k integers on a x-bit CPU if $n < kx$): in that case also, the memory storage is divided by a factor $\sqrt{n}$ with recycling.

Ott et al. (2005) also adapted their algorithm to list as many suboptimal graphs as desired. Such capacity is precious in order to find which structural similarities are shared by highly probable graphs, particularly when the score criteria used is not equivalent. However, for an equivalent score, since the listed graphs will be mainly on the same equivalent classes, they will probably not bring more information than the CPDAG of an optimal graph.

4. Super-Structure Constrained Optimal Search

Compare to a brute force algorithm that would browse all search space, OS achieved a considerable improvement. Graphs of around thirty nodes are still hardly computed, and many small real networks such as the classical ALARM network (Beinlich et al., 1989) with 37 variables are not feasible at all. The question of an optimal algorithm with a lower complexity is still open. In our case, we focus on structural constraint to reduce the search space and develop a faster algorithm.

4.1 Super-Structure

To keep the property that the result of OS converges to the true graph in the sample limit, the constraint should at least authorize the true skeleton. Since knowing the true skeleton is a strong assumption and learning it with high confidence from finite data is a hard task, we propose to consider a more flexible constraint than fixing the skeleton. To this end, we introduce a super-structure as:

Definition 4. *An undirected graph $S = (\mathbf{V}, \mathbf{E}_S)$ is said to be a* super-structure *of a DAG $G = (\mathbf{V}, \mathbf{E}_G)$, if the skeleton of G, $G' = (\mathbf{V}, \mathbf{E}_{G'})$ is a subgraph of S (i.e., $\mathbf{E}_{G'} \subseteq \mathbf{E}_S$). We say that S* contains *the skeleton of G.*

Considering a structure learning task, a super-structure S is said to be true or *sound* if it contains the true skeleton; otherwise it is said *incomplete*. Finally we propose to study the problem of model

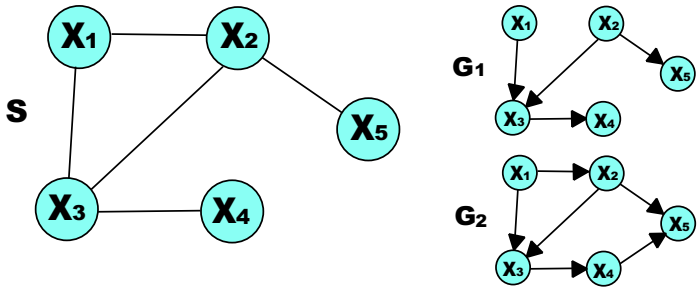

Figure 1: In a search constrained by S, G_1 could be considered but not G_2 because $\langle X_4, X_5 \rangle \notin \mathbf{E}_S$.

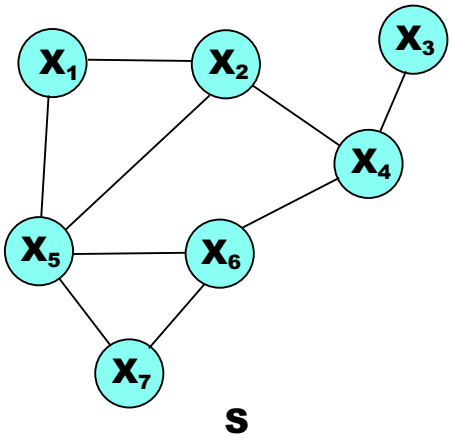
inference from data given a super-structure S: S is assumed to be sound, and the search space is restricted to DAGs whose skeletons are contained in S as illustrated in Figure 1. Actually, the "skeleton" learned by MMPC is used as a super-structure in MMHC. In fact, the skeleton of the graph returned by MMHC is not proven to be the same than the learned one; some edges can be missing. It is the same for the candidate parents in SC. Thus, the idea of super-structure already existed, but we define it explicitly, which has several advantages.

First, a dedicated terminology enables to emphasize two successive and independent phases in structure learning problem: on one hand, learning with high probability a sound super-structure S (sparse if possible); on the other hand, given such structure, searching efficiently the restricted space and returning the best optimum found (global optimum if possible). This problem cutting enables to make clearer the role and effect of each part. For example, since SC and MMHC use the same search, comparing their results allow us directly to evaluate their super-structure learning approach. Moreover, while conceiving a search strategy, it could be of a great use to consider a super-structure given. This way, instead of starting from a general intractable case, we have some framework to assist reasoning: we give some possible directions in our future work. Finally, this manner to apprehend the problem already integrates the idea that the true skeleton will not be given by an IT approach; hence, it could be better to learn a bit denser super-structure to reduce missing edges, which should improve accuracy.

Finally, we should explain how practically a sound super-structure S can be inferred. Even without knowledge about causality, a quick analysis of the system could generate a rough draft by determining which interactions are impossible; localization, nature or temporality of variables often forbid evidently many edges. In addition, for any IT-based technique to learn the skeleton, the neighborhood of variables or their Markov blanket could be used to get a super-structure. This one should become sound while increasing the significance level of the tests: this is because we only need to reduce false negative discovery. Although the method used in PC algorithm could be a good candidate to learn a not sparse but sound super-structure, we illustrate our idea with MMPC in Section 5.1.

4.2 Constraining and Optimizing

From now on, we will assume that we are given a super-structure $S = (\mathbf{X}, \mathbf{E}_S)$ over $\mathbf{X}$. We refer to the neighborhood of a variable X_i in S by $\mathbf{N}(X_i)$, that is, the set of nodes connected to X_i in S (i.e., $\{X_j \mid \langle X_i, X_j \rangle \in \mathbf{E}_S\}$); m is the maximal degree of S, that is, $m = \max_{X_i \in \mathbf{X}} |\mathbf{N}(X_i)|$. Our task is to globally maximize the score function over our reduced search space.



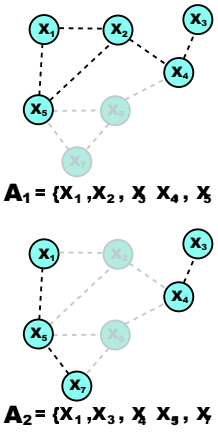


Figure 2: $\mathbf{A}_1$ is in $Con(S)$, but not $\mathbf{A}_2$ because in $S_{\mathbf{A}_2}$, X_7 and X_4 are not connected.

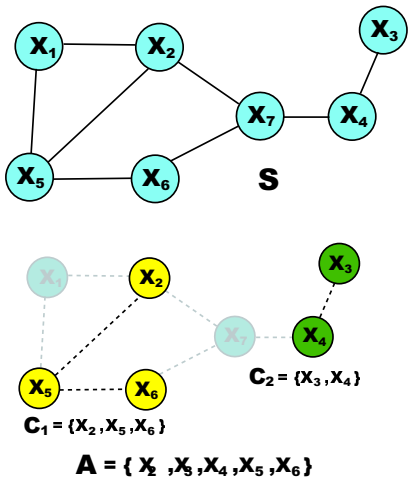

Figure 3: The maximal connected subsets of $\mathbf{A}$: $\mathbf{C}_1$ and $\mathbf{C}_2$.

Since the parents of every X_i are constrained to be included in $\mathbf{N}(X_i)$, the function F has to be defined only for $\forall \mathbf{A} \subseteq \mathbf{N}(X_i)$. Consequently, computation of F in step (b) becomes:

(b*) For each $X_i \in \mathbf{X}$ and each $\mathbf{A} \subseteq \mathbf{N}(X_i)$
Calculate $F_s(X_i, \mathbf{A})$ and $F_p(X_i, \mathbf{A})$ using (2)

Only the underlined part has been modified; clearly, F still can be computed recursively since $\forall X_j \in \mathbf{A}$, the subset $\mathbf{A} \backslash \{X_j\}$ is also included in $\mathbf{N}(X_i)$, and its F value is already known. With this slight modification, the time complexity of computing F becomes $O(n2^m)$, which is a decisive improvement opening many perspectives; more details are given at the end of this section. However, to keep formulae (5) and (3) correct, $F(X_i, \mathbf{A})$ for any subset $\mathbf{A}$ has to be replaced by $F(X_i, \mathbf{A} \cap \mathbf{N}(X_i))$. Before simplifying the calculation of M, it is necessary to introduce the notion of *connectivity*:

Definition 5. *Given an undirected graph $S = (\mathbf{X}, \mathbf{E}_S)$, a subset $\mathbf{A} \subseteq \mathbf{X}$ is said to be* connected *if $\mathbf{A} \neq \emptyset$ and the subgraph of S induced by $\mathbf{A}$, $S_{\mathbf{A}}$, is connected (cf. Figure 2).*

In our study, connectivity will always refer to the connectivity in the super-structure S. $Con(S)$ will refer to the set of connected subsets of $\mathbf{X}$. In addition, each not empty subset of $\mathbf{X}$ can be broken down uniquely into the following family of connected subsets:

Definition 6. *Given an undirected graph $S = (\mathbf{X}, \mathbf{E}_S)$ and a subset $\mathbf{A} \subseteq \mathbf{X}$, let $S_1 = (\mathbf{C}_1, \mathbf{E}_1), \cdots, S_p = (\mathbf{C}_p, \mathbf{E}_p)$ be the connected components of the induced subgraph $S_{\mathbf{A}}$. The subsets $\mathbf{C}_1, \cdots, \mathbf{C}_p$ are called the* maximal connected subsets *of $\mathbf{A}$ (cf. Figure 3).*

The most important property of the maximal connected subsets $\mathbf{C}_1, \cdots, \mathbf{C}_p$ of a subset $\mathbf{A}$ is that, when $p > 1$ (i.e., when $\mathbf{A} \notin Con(S)$) for any pair $\mathbf{C}_i$, $\mathbf{C}_j$ with $i \neq j$, $\mathbf{C}_i \cap \mathbf{C}_j = \emptyset$ and there is no edges in S between nodes of $\mathbf{C}_i$ and nodes of $\mathbf{C}_j$. Next we show that the value of M for subsets that are unconnected do not have to be explicitly calculated, which is the second and last modification

of Algorithm 1. The validity of our algorithm is simultaneously proved.

Theorem 2. *A constrained optimal graph can be found by computing M only over Con*(S).
Proof: First, let consider a subset $\mathbf{A} \notin Con(S)$, its maximal connected subsets $\mathbf{C}_1, \cdots, \mathbf{C}_p$ ($p > 1$), and an optimal constrained DAG $G^* = (\mathbf{A}, \mathbf{E}^*)$. Since G^* is constrained by the super-structure, and following the definition of the maximal connected subsets, there cannot be edges in G^* between any element in $\mathbf{C}_i$ and any element in $\mathbf{C}_j$ if $i \neq j$. Therefore, the edges of G^* can be divided in p sets $\mathbf{E} = \mathbf{E}_1 \cup \cdots \cup \mathbf{E}_p$ with $G_i = (\mathbf{C}_i, \mathbf{E}_i)$ a DAG over every $\mathbf{C}_i$. Moreover, all G_i are optimal constrained graphs otherwise G^* would not be. Consequently, we can derive the two following formulas:

$$M_s(\mathbf{A}) = \sum_{i=1}^{p} M_s(\mathbf{C}_i), \tag{7}$$

$$M_l(\mathbf{A}) = M_l(\mathbf{C}_1). \tag{8}$$

Formula (7) directly follows our previous considerations that maximizing the score over $\mathbf{A}$ is equivalent to maximizing it over each $\mathbf{C}_i$ independently, since they cannot affect each other. Actually, any $M_l(\mathbf{C}_i)$ is an optimal sink and could be selected in (8); we chose $M_l(\mathbf{C}_1)$ since it is accessed faster when using the data structure proposed in Section 4.3 for M. By using (7) and (8) the value of M for unconnected subsets can be directly computed if needed from the values of smaller connected subsets. Therefore, we propose to compute M only for connected subsets by replacing step (d) with (d*) in Algorithm 2 described below. Since each singleton $\{X_i\}$ is connected, step (c) is not raising a problem. In step (d*) we consider $\mathbf{A} \in Con(S)$ and apply formula (5), if there is $X_j \in \mathbf{A}$ such that $\mathbf{B}_j = \mathbf{A} \backslash \{X_j\}$ is not connected, we then can directly calculate $M_s(\mathbf{B}_j)$ by applying (7). the values of M_s for the maximal connected subsets of $\mathbf{B}_j$ are already computed since these subsets are of smaller sizes than $\mathbf{A}$. Therefore, $M_l(\mathbf{A})$ and $M_s(\mathbf{A})$ can be computed. Finally, it is also possible to retrieve w^* from (6) by using (8) if $\mathbf{T}$ is not connected, which conclude the proof of this Theorem. ■

We can now formulate our optimized version of Algorithm 1 for optimal DAG search conditioned by a super-structure S:

Algorithm 2.

(a*) Initialize $\forall X_i \in \mathbf{X}$, $F_s(X_i, \emptyset)$ and $F_p(X_i, \emptyset)$ with (1)

(b*) For each $X_i \in \mathbf{X}$ and each $\mathbf{A} \subseteq \mathbf{N}(X_i)$
Calculate $F_s(X_i, \mathbf{A})$ and $F_p(X_i, \mathbf{A})$ using (2)

(c*) Initialize $\forall X_i$, $M_s(\{X_i\})$ and $M_l(\{X_i\})$ using (4)

(d*) For each $\mathbf{A} \in Con(S)$ with $|\mathbf{A}| > 1$
Calculate $M_s(\mathbf{A})$ and $M_l(\mathbf{A})$ using (5) and (7)

(e*) Build an optimal ordering w^* using (6) and (8)

(f*) Return the best w^*-linear graph $G^*_{w^*}$ using (3)

The underlined parts of Algorithm 2 are the modifications introduced in Algorithm 1. Computational complexity and correctness of (b*) has already been presented. With Theorem 2, validity of our algorithm is assured and since in (c*) and (d*) every element of $Con(S)$ are considered only

once, the total computational complexity is in $O(n2^m + |Con(S)|)$; here again complexity refers to the number of times formulae (2) or (5) are computed. We will describe in the next Section a method to consider only connected subsets, and come over the number of connected subsets of S in Section 4.4. Although set operators are used heavily in our algorithm, such operations can be efficiently implemented and considered of a negligible cost as compared to other operations, such as score calculations. Concerning the complexity of calculating F, $O(n2^m)$ is in fact a large upper bound. Still, since it depends only linearly on the size of the graphs, F can be computed for graphs of any size if their maximal degree is less than around thirty. This enables usage of this function in new search strategies for many real systems that could not be considered without constraint. We should remark that some cases of interest still cannot be studied since this upper limitation on m constrains also the maximal number of children of every variables. However, this difficulty concerns also many IT-approaches since their complexity also depends exponentially on m (see Tsamardinos et al. 2006 for MMPC and Kalisch and Bühlmann 2007 for PC). Finally, like in Algorithm 1, the number of scores calculated can be reduced to $O(nm^c)$ by constraining on the number of parents.

Although the number of M and F values calculated is strictly reduced, a potential drawback of Algorithm 2 is that memory cannot be recycled anymore. First, when (5) is used during step (d*), now $F_s(X_i, \mathbf{B}_j \cap \mathbf{N}(X_i))$ is required, and nothing can be said about $|\mathbf{B}_j \cap \mathbf{N}(X_i)|$ implying that we should store every value of F_s computed before. Similar arguments hold for F_p in case M_l is used to store optimal graphs, and for M_s and M_l because (7) and (8) could have to be used anytime during (d*) and (e*) respectively. However, since space complexity of F is $O(n2^m)$ and the one of M is $O(|Con(S)|)$ (cf. next section), if m is bounded Algorithm 2 should use less memory than Algorithm 1 even when recycling memory (i.e., $O(\sqrt{n}2^n)$ assuming that a set takes $O(1)$ space). This soften the significance of recycling memory in our case.

Finally, since our presentation of Algorithm 2 is mainly formal, we should detail how it is practically possible to browse efficiently only the connected subsets of $\mathbf{X}$. For this, we present in the next section a simple data structure to store values of M and a method to build it.

4.3 Representation of $Con(S)$

For every $\mathbf{A} \in Con(S)$ we define $\mathbf{N}(\mathbf{A}) = \left(\bigcup_{X_i \in \mathbf{A}} \mathbf{N}(X_i)\right) \setminus \mathbf{A}$, that is the set of variables neighboring $\mathbf{A}$ in S. For every $X_i \notin \mathbf{A}$, we note $\mathbf{A}_i^+ = \mathbf{A} \cup \{X_i\}$, it is connected if and only if $X_i \in \mathbf{N}(\mathbf{A})$. Finally, for a subset $\mathbf{A}$ not empty, let $min(\mathbf{A})$ be the smallest index in $\mathbf{A}$, that is, $min(\mathbf{A}) = i$ means that $X_i \in \mathbf{A}$ and $\forall X_j \in \mathbf{A}$, $j \geq i$; by convention, $min(\emptyset) = 0$. Now we introduce an auxiliary directed graph $G^\star = (Con(S)^\star, \mathbf{E}^\star)$, where $Con(S)^\star = Con(S) \cup \{\emptyset\}$ and the set of directed edges $\mathbf{E}^\star$ is such that there is an edge from $\mathbf{A}$ to $\mathbf{B}$ if and only if $\mathbf{A} \subset \mathbf{B}$ and $|\mathbf{B}| = |\mathbf{A}| + 1$. In other words, with the convention that $\mathbf{N}(\emptyset) = \mathbf{X}$, $\mathbf{E}^\star = \{(\mathbf{A}, \mathbf{A}_i^+), \forall \mathbf{A} \in Con(S)^\star \text{ and } \forall X_i \in \mathbf{N}(\mathbf{A})\}$. Actually, $G^\star$ is trivially a DAG since arcs always go from smaller to bigger subsets. Finally, let define H as being the spanning tree obtained from the following depth-first-search (DFS) on $G^\star$:

- The search starts from $\emptyset$.
- While visiting $\mathbf{A} \in Con(S)^\star$: for all $X_{k_i} \in \mathbf{N}(\mathbf{A})$ considered by increasing indices (i.e., such that $k_1 < \cdots < k_p$, where $p = |\mathbf{N}(\mathbf{A})|$) visit the child $\mathbf{A}_{k_i}^+$ if it was not yet done. When all children are done, the search backtracks.

Since there is a path from the empty set to every connected subset in $G^\star$, the nodes of the tree H represent unambiguously $Con(S)^\star$. We use H as a data structure to store the values of M in

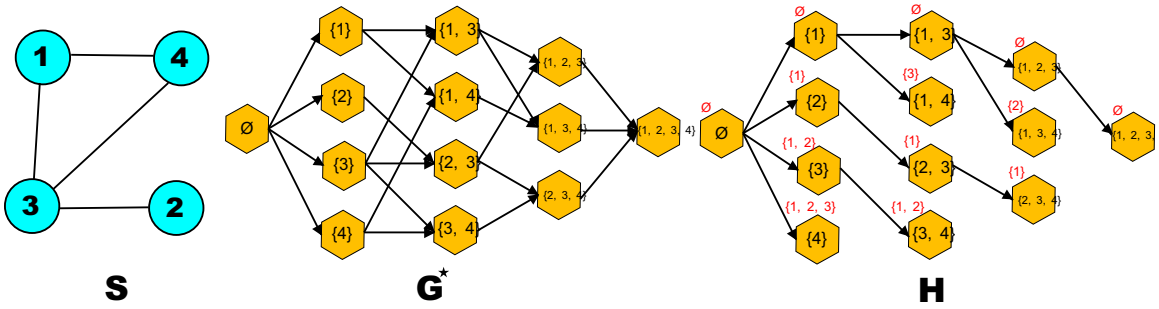

Figure 4: $G^\star$ and H for a given S. $\mathbf{Fb}(\mathbf{A})$ is indicated in red above each node in H.

Algorithm 2; this structure is illustrated by an example in Figure 4. Further, we propose a method to build H directly from S without having to build $G^\star$ explicitly. First, we notice that after visiting $\mathbf{A}$, every $\mathbf{B} \in Con(S)$ such that $\mathbf{B} \supset \mathbf{A}$ have been visited for sure. When visiting $\mathbf{A}$, we should consider only the children of $\mathbf{A}$ that were not yet visited. For this, we define:

- $\mathbf{Fb}(\mathbf{A})$ is the set of forbidden variables of $\mathbf{A}$, that is: for every $\mathbf{B} \in Con(S)$ with $\mathbf{B} \supset \mathbf{A}$, $\mathbf{B}$ has been already visited if and only if $\mathbf{B} \supseteq \mathbf{A}^+_j$ with $X_j \in \mathbf{Fb}(\mathbf{A})$.

By defining recursively this forbidden set for every child of $\mathbf{A}$ that has not yet been visited, we derive the following method to build H:

Method 1.
1: Create the root of H (i.e., $\emptyset$), and initialize $\mathbf{Fb}(\emptyset) = \emptyset$.
2: For i from 0 to $n-1$, and for all $\mathbf{A}$ in H such that $|\mathbf{A}| = i$
3: Set $\mathbf{Fb}^* = \mathbf{Fb}(\mathbf{A})$,
4: For every $X_{k_j} \in \mathbf{N}(\mathbf{A}) \backslash \mathbf{Fb}(\mathbf{A})$ considered by increasing indices
5: Add to $\mathbf{A}$ the child $\mathbf{A}^+_{k_j}$ in H and define $\mathbf{Fb}(\mathbf{A}^+_{k_j}) = \mathbf{Fb}^*$
6: Update $\mathbf{Fb}^* = \mathbf{Fb}^{*+}_{k_j}$

The correctness of Method 1 is proven in the next Theorem. In order to derive the time complexity of step (d*) in terms of basic operations, while using Method 1 in Algorithm 2, let consider that the calculation takes place on a x-bit machine and that n is at maximum few times greater than x. Thus, subsets requires $O(1)$ space, and any operations on subsets are done in $O(1)$ time, except $min(\mathbf{A})$ (in $O(\log(n))$ time).

Theorem 3. *The function M can be computed in time and space proportional to $O(|Con(S)|)$, up to some polynomial factors. With Method 1, M is computed in $O(\log(n)n^2|Con(S)|)$ time and requires $O(|Con(S)|)$ space.*

Proof: First, to prove correctness of Method 1, we show that if $\mathbf{Fb}(\mathbf{A})$ is correctly defined in regard to our DFS, the search from $\mathbf{A}$ proceeds as expected and that before back tracking every connected superset of $\mathbf{A}$ has been visited. The case when all the variables neighboring $\mathbf{A}$ are forbidden being trivial, we directly consider all the elements $X_{k_1}, \cdots, X_{k_p}$ of $\mathbf{N}(\mathbf{A}) \backslash \mathbf{Fb}(\mathbf{A})$ by increasing indices like in DFS (with $p \geq 1$). Then, $\mathbf{A}^+_{k_1}$ should be visited first, and $\mathbf{Fb}(\mathbf{A}^+_{k_1}) = \mathbf{Fb}(\mathbf{A})$ because $\forall X_j \in$

$\mathbf{Fb}(\mathbf{A})$ among the supersets of $\mathbf{A}_j^+$ there is also the supersets of $\mathbf{A}_{k_1,j}^{++}$. Now let suppose that the forbidden sets were correctly defined and that the visits correctly proceeded until $\mathbf{A}_{k_i}^+$: if $i = p$ by hypothesis we explored every connected supersets of the children of $\mathbf{A}$ and the search back track correctly. Otherwise, we should define $\mathbf{Fb}(\mathbf{A}_{k_{i+1}}^+) = \mathbf{Fb}(\mathbf{A}) \cup \{X_{k_1}\} \cup \cdots \cup \{X_{k_i}\} = \mathbf{Fb}(\mathbf{A}_{k_i}^+)_{k_i}^+$ to take into account all supersets visited during the previous recursive searches. Although Method 1 does not proceed recursively (to follow the definition of M), since it uses the same formulae to define the forbidden sets, and since $\mathbf{Fb}(\emptyset)$ is correctly initialized, H is built as expected.

To be able to access easily $M(\mathbf{A})$, we keep for every node an auxiliary set defined by $\mathbf{Nb}(\mathbf{A}) = \mathbf{N}(\mathbf{A}) \setminus \mathbf{Fb}(\mathbf{A})$ that is easily computed as processing Method 1. Since there is $O(|Con(S)|)$ nodes in H, each storing a value of M and two subsets requiring $O(1)$ space, the assertion about space complexity is correct.

Finally, building a node requires $O(1)$ set operations. To access $M(\mathbf{A})$ even for an unconnected subset, we proceed on the following manner: we start from the root, and define $\mathbf{T} = \mathbf{A}$. Then, when we rushed the node $\mathbf{B} \subseteq \mathbf{A}$, with $i = min(\mathbf{Nb}(\mathbf{B}) \cap \mathbf{T})$, we withdraw X_i from $\mathbf{T}$, and go down to the i^{th} child of $\mathbf{B}$. If $i = 0$ then if $\mathbf{T} = \emptyset$ we found the node of $\mathbf{A}$; otherwise we rushed the first maximal connected component of $\mathbf{A}$, that is, $\mathbf{C}_1$ of which we can accumulate the M value in order to apply (7) or (8). In that case, we continue the search by restarting from the root with the variables remaining in $\mathbf{T}$. In any cases, at maximum *min* is used $O(n)$ times to find $M(\mathbf{A})$, implying a time complexity of $O(\log(n)n^2)$ for formula (5). ■

It is interesting to notice that, even without memoization, the values of M can be calculated in different order. For example, by calling H_i the subtree of H starting from $\{X_i\}$, only values of M over H_j such that $j \geq i$ are required. Then it is feasible to calculate M from H_n to H_1, which could be used to apply some branch-pruning rules based on known values of M or to apply different strategies depending on the topology of the connected subset; these are only suppositions.

More practically, other approach could be proposed to build a spanning tree of $G^\star$ and Method 1 is presented here only to complete our implementation and illustrate Theorem 3. We should note that one can also implement the calculation of M over $Con(S)$ in a top-down fashion using memoization and an auxiliary function to list maximal connected components of a subset. However, such implementations will be less efficient both in space and time complexity. Even without considering the cost of recursive programming, listing connected components is in $O(nm)$. Then, in order to not waste an exponential factor of memory, self balanced trees should be used to store the memorized values of M: it would require $O(n)$ time to access a value and up to $O(n^2)$ if (7) is used. This should be repeated $O(n)$ times to apply (5), which implies a complexity of around $O(n^3|Con(S)|)$. Consequently, we believe that Method 1 is a competitive implementation of step (d*).

4.4 Counting Connected Subsets of a Graph

To understand the complexity of Algorithm 2, the asymptotic behavior of $|Con(S)|$ should be derived, depending on some attributes of S. Comparing the trivial cases of a linear graph (i.e., $m \leq 2$) where $|Con(S)| = O(n^2)$ and a star graph (i.e., one node is the neighbor of all others) where $|Con(S)| = 2^{n-1} + n - 1$ clearly indicates that $|Con(S)|$ depends strongly on the degrees of Srather than on the number of edges or number of cycles. One important result from Björklund et al. (2008) is that $|Con(S)| = O(\beta_m^n)$ with $\beta_m = (2^{m+1} - 1)^{\frac{1}{m+1}}$ a coefficient that only depends on the maximal degree m of S.

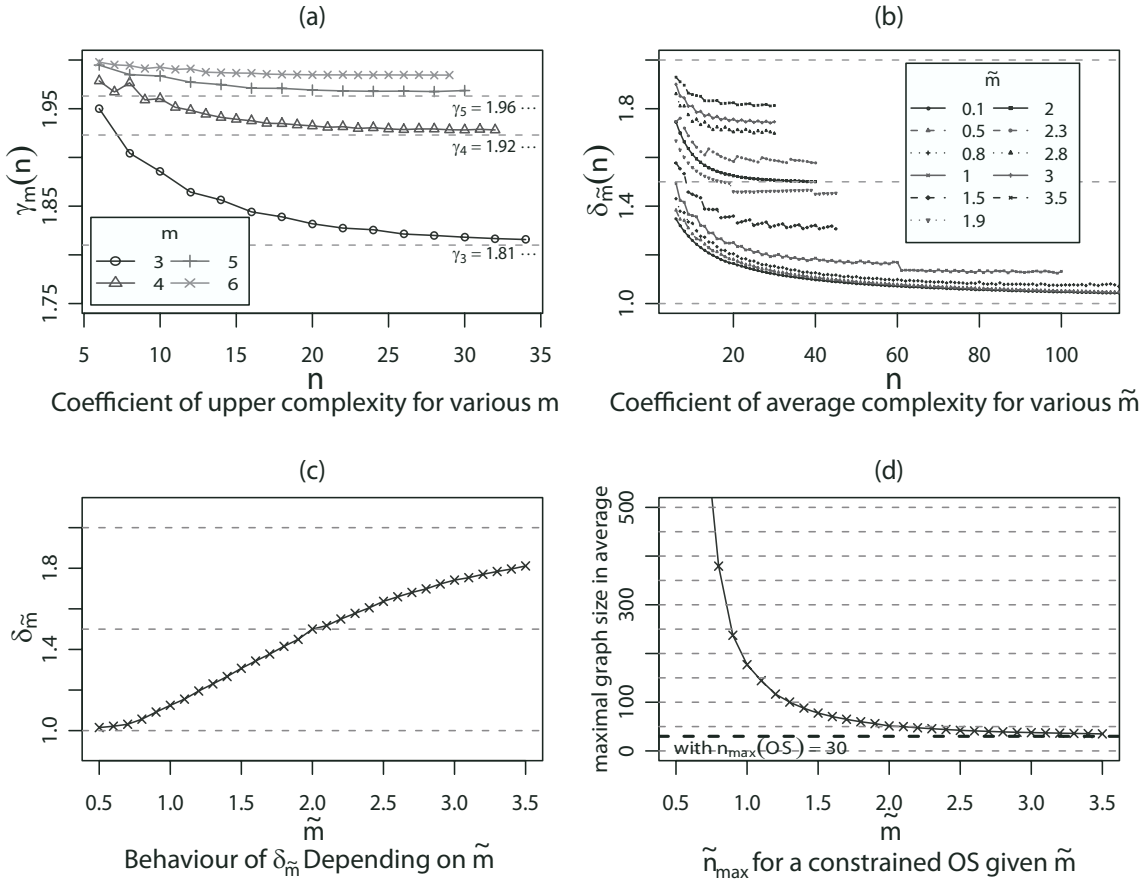

Figure 5: Experimental derivation of γ_m, $\delta_{\tilde{m}}$ and $\tilde{n}_{\max_2}(\tilde{m})$.

Still, since this upper bound is probably over-estimated, we tried to evaluate a better one experimentally. For every pair (m,n) of parameters considered , we randomly generated 500 undirected graphs S pushing their structures towards a maximization of the number of connected subsets. For this, all the nodes had exactly m neighbors and S should at least be connected. Then, since after a first series of experiments the most complex structures appeared to be similar to full $(m-1)$-trees, with a root having m children and leaves being connected to each other, only such structures were considered during a second series of experiments. Finally, for each pair (m,n), from the maximal number $R_{n,m}$ of connected subsets found, we calculated $\exp(\frac{\ln(R_{n,m})}{n})$ in order to search for an exponential behavior as shown in Figure 5(a).

Results 1. *Our experimental measures led us to propose that* $|Con(S)| = O({\gamma_m}^n)$ *(cf. Figure 5(a)).*

The weak point of our strategy is that more graphs should be consider while increasing n, since the number of possible graphs also increases. Unfortunately, this is hardly feasible in practice since counting gets longer with larger graphs. Nevertheless, Results 1 were confirmed during a more detailed study of the case $m = 3$ using 10 times more graphs and up to $n = 30$. In addition, even this estimated upper bound is practically of a limited interest since it still dramatically overestimates $|Con(S)|$ for real networks. Real networks are not, in general, as regular and as dense graphs as

Complexity	Algorithm 1 (OS)	Algorithm 2 (COS)
Time (steps)	$O(n2^n)$	$O(\|Con(S)\|)$
in details	$O(n^2 2^n)$	$O(\log(n)n^2\|Con(S)\|)$
scores computed	$n2^n$	$O(n2^m)$
if $\|\mathbf{Pa}_i\| < c$	$O(n^{c+1})$	$O(nm^c)$
Space	$O(\sqrt{(}n)2^n)$	$O(\|Con(S)\|)$

Table 1: Improvement achieved by COS.

S	$\|Con(S)\|$	some values
Tree-like	$O(\alpha_m^n)$	$\alpha_3 \approx 1.58$, $\alpha_4 \approx 1.65$, $\alpha_5 \approx 1.707$
General	$O(\beta_m^n)$	$\beta_3 \approx 1.968$, $\beta_4 \approx 1.987$, $\beta_5 \approx 1.995$
Measured	$O(\gamma_m^n)$	$\gamma_3 \approx 1.81$, $\gamma_4 \approx 1.92$, $\gamma_5 \approx 1.96$
In average	$O(\delta_{\tilde{m}}^n)$	$\delta_{1.5} \approx 1.3$, $\delta_2 \approx 1.5$, $\delta_{2.5} \approx 1.63$, $\delta_3 \approx 1.74$

Table 2: Results on $|Con(S)|$

the ones used in previous experiments. To illustrate that $O({\gamma_m}^n)$ is a pessimistic upper bound, we derived the theoretical upper bound of $|Con(S)|$ for tree-like structures of maximal degree m. This is given as an example, although it might help estimation of $|Con(S)|$ for structures having a bounded number of cycles. The proof is deferred to the Appendix.

Proposition 1. *If S is a forest, then $|Con(S)| = O(\alpha_m^n)$ with $\alpha_m = (\frac{2^{m-1}+1}{2})^{\frac{1}{m-1}}$.*

Finally, we studied the average size of $|Con(S)|$ for a large range of average degrees $\tilde{m}$. For each pair $(n,\tilde{m})$ considered, we generated 10000 random graphs and averaged the number of connected subsets to obtain $R_{n,\tilde{m}}$. No constraint was imposed on m, since graphs were generated by randomly adding edges until $\lfloor \frac{n\tilde{m}}{2} \rfloor$. In each case, we calculated $\exp(\frac{\ln(R_{n,\tilde{m}})}{n}))$ to search for an asymptotic behavior on $\tilde{m}$.

Results 2. *On average, for super-structures having an average degree of $\tilde{m}$, $|Con(S)|$ increases asymptotically as $O({\delta_{\tilde{m}}}^n)$, see Figure 5(b) and (c) for more details.*

Based on the assumption that Algorithm 1 is feasible at maximum for graphs of size $n_{\max_1} = 30$ (Silander and Myllymäki, 2006), we calculated $\tilde{n}_{\max_2}(\tilde{m}) = n_{\max_1}\frac{\ln(2)}{\ln(\delta_{\tilde{m}})}$ that can be interpreted as an estimation of the maximal size of graphs that can be considered by Algorithm 2 depending on $\tilde{m}$. As shown in Figure 5(d), on average, it should be feasible to consider graphs having up to 50 nodes with Algorithm 2 if $\tilde{m} = 2$. Moreover, since $\lim_{\tilde{m}\to 0} \delta_{\tilde{m}} = 1$, our algorithm can be applied to graphs of any sizes if they are enough sparse. Unfortunately, the case when $\tilde{m} < 2$ is not really interesting since it implies that networks are mainly unconnected.

To conclude, we summarize and compare the time and space complexities of both Algorithms in Table 1, using the same hypothesis on the size of a subset as Section 4.3. We neglected the complexity due to F in our algorithm, which is justified if m is not huge. Concerning the space complexity of Algorithm 1, the maximal space needed while recycling memory is used. Results on $O(|Con(S)|)$ are listed in Table 2. If super-structures S are relatively sparse and have a bounded maximal degree, the speed improvement of Algorithm 2 over Algorithm 1 should increase expo-

nentially with n. Moreover, our algorithm can be applied to some small real networks that are not feasible for Algorithm 1.

5. Experimental Evaluation

Although the demonstrations concerning correctness and complexity of Algorithm 2 enable us to anticipate results obtained experimentally, some essential points remain to be studied. Among them, we should demonstrate practically that, in the absence of prior knowledge, it is feasible to learn a sound super-structure with a relaxed IT approach. We choose to test our proposition on MMPC (Tsamardinos et al., 2006) in Section 5.2; the details of this algorithm are briefly reintroduced in Section 5.1.4. Secondly, we compare COS to OS to confirm the speed improvement of our method and study the effect of using a sound constraint in Section 5.3. We also should evaluate the worsening in terms of accuracy due to the incompleteness of an approximated super-structure. In this case we propose and evaluate a greedy method, COS+, to improve substantially the results of COS. In Section 5.4, we compare our methods to other greedy algorithms to show that, even with an incomplete super-structure, COS, and especially COS+, are competitive algorithms to study small networks. Finally we illustrate this point by studying the ALARM Network (Beinlich et al., 1989) in Section 5.5, a benchmark of structure learning algorithm for which OS is not feasible.

5.1 Experimental Approach

Except in the last real experiment, we are interested in comparing methods or algorithms for various set of parameters, such as: the size of the networks n, their average degree $\tilde{m}$ (to measure effect of sparseness on Algorithm 2), the size of data considered d and the significance level α used to learn the super-structure.

5.1.1 NETWORKS AND DATA CONSIDERED

Due to the size limitation imposed by Algorithm 1, only small networks can be learned. Further, since there it is hardly feasible to find many real networks for every pair $(n,\tilde{m})$ of interest, we randomly generated the networks to which we apply structure learning. Given a pair $(n,\tilde{m})$, DAGs of size n are generated by adding randomly $\lfloor \frac{n\tilde{m}}{2} \rfloor$ edges while assuring that cycles are not created.

For simplicity, we considered only Boolean variables; therefore, Bayesian networks are obtained from each DAG by generating conditional probabilities $P(X_i = 0|\mathbf{Pa}_i = \mathbf{pa}_i^k)$ for all X_i and all possible $\mathbf{pa}_i^k$ by choosing a random real number in $]0,1[$. Then, d data are artificially generated from such Bayesian networks, by following their entailed probability distribution.

Finally, the data are used to learn a network with every algorithm and some criteria are measured. In order to generalize our results, we repeat g times the previous steps for each quadruplet $(n,\tilde{m},\alpha,d)$. The values of each criterion of comparison for every algorithm are averaged on the g learned graphs.

5.1.2 COMPARISON CRITERIA

While learning Bayesian networks, we evaluate the performances of every algorithm on three criteria. Since the learning task consists in the maximization of the score function, a natural criterion to evaluate the quality of the learned network is its score. In our experiments we use BIC because of its speed of evaluation. Since we are interested in comparing results in terms of score depending on

n or $\tilde{m}$ in a diagram, we do not directly represent scores (their values change radically for different parameters) but use a score ratio to the optimal score: $\frac{Score(G_{OS})}{Score(G_{\text{Other}})}$, where the label of the graph indicates which Algorithm was used. The better is the score obtained by an algorithm, the closer to 1 is its score ratio. We preferred to use the best score rather than the score of the true network, because the true network is rarely optimal; its score is even strongly penalized if its structure is dense and data sets are small. Therefore, it is not convenient to use it as a reference in terms of score.

The second criterion is a measure of the complexity estimated by the execution time of each algorithm, referred as *Time*. Of course, this is not the most reliable way to estimate complexity, but since calculations are done on the same machine, and since measures are averaged on few similar calculations, execution time should approximate correctly the complexity. To avoid bias of this criterion, common routines are shared among algorithms (such as the score function, the structure learning method and the hill climbing search).

Finally, since our aim is to learn a true network, we use a structural hamming distance that compares the learned graph with the original one. As proposed in Tsamardinos et al. (2006), to take into consideration equivalence classes, the CPDAGs of both original and learned DAGs are built and compared. This defines the structural error ratio SER of a learned graph, which is the number of extra, missing, and wrongly oriented edges divided by the total number of edges in the original graph. In our case, we penalize wrongly oriented edges only by half, because we consider that errors in the skeleton are more "grave" than those in edges orientation. The reason is not only visual: a missing edge, or an extra edge, implies more mistakes in terms of conditional independencies in general than wrongly oriented ones. Moreover, in CPDAGs, the fact that an edge is not correctly oriented is often caused by extra or missing edges. Furthermore, such a modification does not intrinsically change the results, since it benefits every algorithm on the same manner.

5.1.3 HILL CLIMBING

Although hill climbing searches are used by different algorithms, we implemented only one search that is used in all cases. This search can consider a structural constraint S, and is given a graph G_{init} from which to start the search. Then it processes as summarized in Section 2.2, selecting at each step the best transformation among all edge withdrawals, edge reversals and edge additions according to the structure constraint. The search stops as soons as the score cannot be strictly improved anymore. If several transformations involve the same increase of the score, the first transformation encountered is applyed. This implies that the results will depend on the ordering of the variables; however, since the graphs considered are randomly generated, their topological ordering is also random, and in average the results found by our search should not be biased.

5.1.4 RECALL ON MMPC

In Section 5.3 a true super-structure is given as a prior knowledge; otherwise we should use an IT-approach to approximate the structural constraint S from data. Since MMHC algorithm is included in our experiments, we decided to illustrate our idea of relaxed independency testing on MMPC strategy (Tsamardinos et al., 2006).

In MMPC, the following independency test is used to infer independencies among variables. Given two variables X_i and X_j, it is possible to measure if they are independent conditioning on a subsets of variables $\mathbf{A} \subseteq \mathbf{X} \backslash \{X_i, X_j\}$ by using the G^2 statistic (Spirtes et al., 2000), under the null hypothesis of conditional independency holding. Referring by $N^{ab\mathbf{c}}$ to the number of times that

$X_i = a$, $X_j = b$ and $\mathbf{A} = \mathbf{c}$ simultaneously in the data, G^2 is defined by:

$$G^2 = 2 \sum_{a,b,\mathbf{c}} N^{ab\mathbf{c}} \ln \left(\frac{N^{ab\mathbf{c}} N^{\mathbf{c}}}{N^{a\mathbf{c}} N^{b\mathbf{c}}} \right).$$

The G^2 statistic is asymptotically distributed as χ^2 under the null hypothesis. The χ^2 test returns a p-value, $P_{IT}(X_i, X_j|\mathbf{A})$, that corresponds to the probability of falsely rejecting the null hypothesis given it is true; in MMPC, the effective number of parameters defined in Steck and Jaakkola (2002) is used as degree of freedom. Thus given a significance level α, if $P_{IT} \leq \alpha$ null hypothesis is rejected, that is, X_i and X_j are considered as conditionally dependent. Otherwise, the hypothesis is accepted (abusing somehow of the meaning of the test), and variables are declared conditionally independent. The main idea of MMPC is: given a conditioning set $\mathbf{A}$, instead of considering only $P_{IT}(X_i, X_j|\mathbf{A})$ to decide dependency, it is more robust to consider $\max_{\mathbf{B} \subseteq \mathbf{A}} P_{IT}(X_i, X_j|\mathbf{B})$; that way, the decision is based on more tests; p-values already computed are cached and reused to calculate this maximal p-value. Finally, MMPC build the neighborhood of each variable X_i (called the set of parents and children, or **PC**) by adding successively potential neighbors of X_i from a temporary set $\mathbf{T}$. While conditioning on the actual neighborhood **PC**, the variable $X_k \in \mathbf{T}$ that minimizes the maximal p-value defined before is selected because it is the variable the most related to X_i. During this phase, every variable that appears independent of X_i is not considered anymore and withdrawn from $\mathbf{T}$. Then when X_k is added to **PC**, we test if all neighbors are always conditionally dependent: if some are not, they are withdrawn from **PC** and not considered anymore. This process ends when $\mathbf{T}$ becomes empty.

We present further the details of our implementation of MMPC, referred as Method 2; it is slightly different from the original presentation of MMPC, but the main steps of the algorithm are the same. One can prove by using Theorem 1 that if the independencies are correctly estimated, this Method should return the true skeleton, which should be the case in the sample limit. About computational complexity, one can derive that MMPC should calculate around $O(n^2 2^m)$ tests in average. However, nothing can be said in practice about the maximal size of **PC**, especially if many false dependencies occurs. Therefore, the time complexity of MMPC can be in the worst case $O(n^2 2^n)$.

Method 2 (MMPC). (Tsamardinos et al., 2006)

1: For $\forall X_i \in \mathbf{X}$
2: Initialize $\mathbf{PC} = \emptyset$ and $\mathbf{T} = \mathbf{X} \setminus \{X_i\}$
3: While $\mathbf{T} \neq \emptyset$
4: For $\forall X_j \in \mathbf{T}$, if $\max_{\mathbf{B} \subseteq \mathbf{PC}} P_{IT}(X_i, X_j|\mathbf{B}) > \alpha$ then $\mathbf{T} = \mathbf{T} \setminus \{X_j\}$
5: Define $X_k = \min_{X_j \in \mathbf{T}} \max_{\mathbf{B} \subseteq \mathbf{PC}} P_{IT}(X_i, X_j|\mathbf{B})$ and $\mathbf{PC} = \mathbf{PC} \cup \{X_k\}$
6: For $\forall X_j \in \mathbf{PC} \setminus \{X_k\}$, if $\max_{\mathbf{B} \subseteq \mathbf{PC} \setminus \{X_j\}} P_{IT}(X_i, X_j|\mathbf{B}) > \alpha$ Then $\mathbf{PC} = \mathbf{PC} \setminus \{X_j\}$
7: $\mathbf{N}(X_i) = \mathbf{PC}$
8: For $\forall X_i \in \mathbf{X}$ and $\forall X_j \in \mathbf{N}(X_i)$
9: If $X_i \notin \mathbf{N}(X_j)$ Then $\mathbf{N}(X_i) = \mathbf{N}(X_i) \setminus \{X_j\}$

5.2 Learning a Super-structure with MMPC

To emphasize the feasibility of learning a super-structure from data, we study how changes the skeleton learned by MMPC while α increases, considering various cases of $(n, \tilde{m}, d)$. As proposed

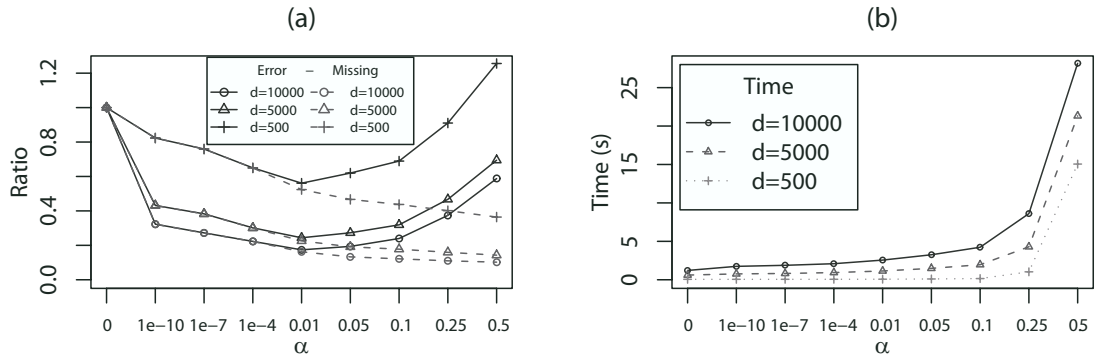

Figure 6: Effects of d and α on the results of Method 2.

before, we average our criteria of interest over $g = 50$ different graphs for every set of parameters. In the present case our criteria are: the time of execution *Time*, the ratio of wrong edges (missing and extra) $Error$, and the ratio of missing edges *Miss* of the learned skeleton. Here again, these ratios are defined while comparing to the true skeleton and dividing by its total number of edges $\lfloor \frac{n\tilde{m}}{2} \rfloor$. While learning a skeleton, $Error$ should be minimized; however in the case of learning a super-structure, *Miss* is the criterion to minimize.

Results 3 $\lim_{\alpha \to 1} Miss(\alpha) = 0$, *which validates our proposition of using higher* α *to learn super-structures (cf. Figure 6(a)). Of course, we obtain the same results with increasing data,* $\lim_{d \to \infty} Miss(\alpha) = 0$. *However, since when* $\alpha \to 1$, $Time(\alpha) \approx O(n^2 2^{n-2})$, *high values of* α *can be practically infeasible (cf. Figure 6(b)). Therefore, to escape a time-consuming structure-learning phase,* α *should be kept under* 0.25 *if using MMPC.*

In Figure 6(a), one can also notice that $Error$ is minimized for $\alpha \approx 0.01$, that is why such values are used while learning a skeleton. Next, we summarize the effect of n and $\tilde{m}$ on the criteria:

Results 4 *Increasing* α *improves uniformly the ration of missing edges independently of n and* $\tilde{m}$ *(cf. Figure 7(c) and (d)).* $Miss(\alpha)$ *is not strongly affected by increasing n but it is by increasing* $\tilde{m}$*; thus for dense graphs, the super-structures approximated by MMPC will probably not be sound.*

Previous statement could be explained by the fact that when $\tilde{m}$ increases, the size of conditional probability tables of each node increases enormously. Thus, the probability of creating weak or nearly unfaithful dependencies between a node and some of its parents also increases. Therefore, the proportion of edges that are difficult to learn increases as well. To complete analysis of Figure 7, we can notice as expected that *Time* increases on a polynomial manner with n (cf. Figure 7 (e)), which penalizes especially the usage of high α. $Error(\alpha)$ is minimized in general for $\alpha = 0.01$ or $\alpha = 0.05$ depending on n and $\tilde{m}$: for a given $\tilde{m}$, lower α (such as $\alpha = 0.01$) are better choices when n increases (cf. Figure 7(a)); conversely, if $\tilde{m}$ increases for a fixed n, higher α (such as $\alpha = 0.05$) are favored (Figure 7(b)). This can be justified, since if $\tilde{m}$ is relatively high, higher α that are more permissive in terms of dependencies will miss less edges, as opposed to lower ones with finite set of data.

In conclusion, although $\alpha \approx 0.01$ is preferable while learning a skeleton with MMPC, higher significance leves can be used to reduce the number of missing edges, and approximate a super-structure. Still, in this case, due to the exponential time complexity of MMPC if α is too high,

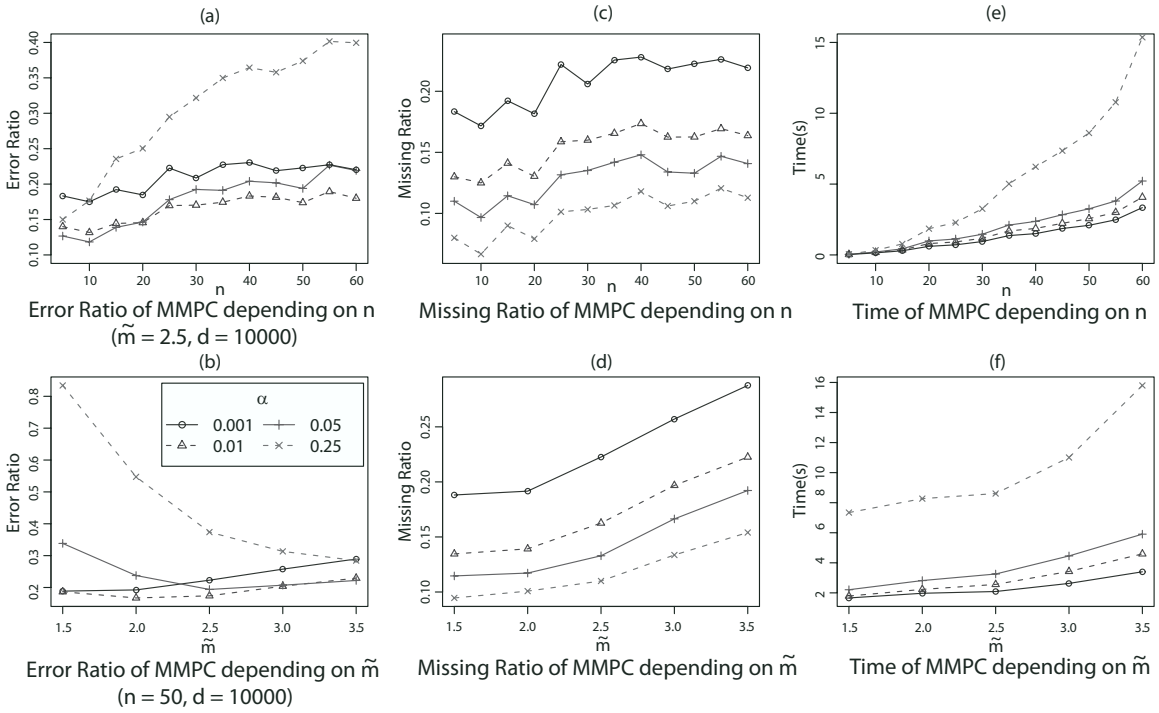

Figure 7: The criteria depending on $\tilde{m}$ and n, for α in $[0.001, 0.01, 0.05, 0.25]$.

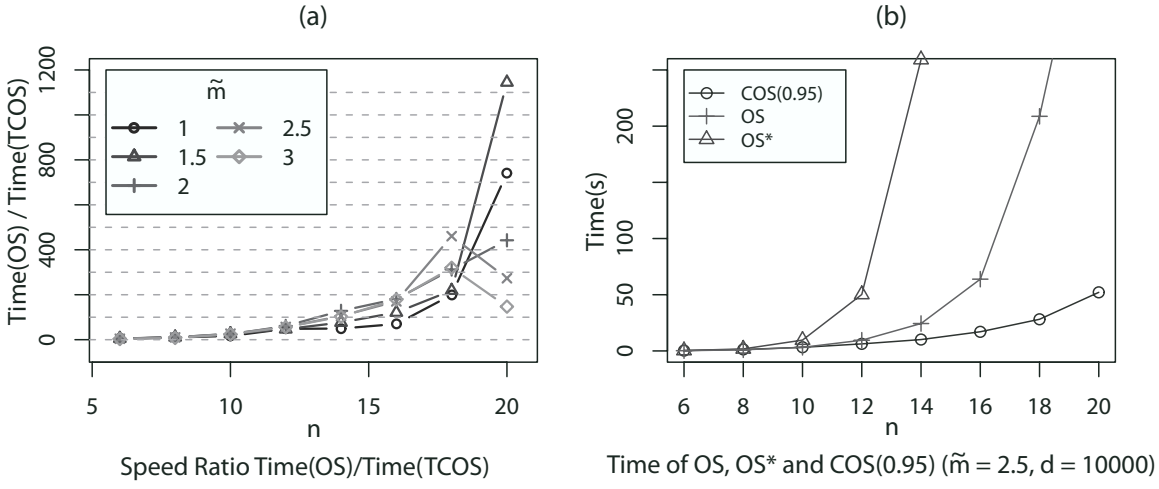

Figure 8: Comparing time complexity of OS, TCOS, and COS(α)

values of α should be selected to compromise between time complexity and ratio of missing edges. Except for $n < 30$ with $\tilde{m} < 2.5$ where $\alpha = 0.25$ is feasible and gives good results, the learned super-structure will be probably incomplete, especially if the original graph is dense: consequently, COS will not perform as well as OS when S is approximated with MMPC.

5.3 Comparison of OS and COS

In this second series of experiment, we compare Algorithm 1 and Algorithm 2 over a large sampling of graphs, for confirming and evaluating results presented in Table 1. Algorithm 1, referred as OS, is always given the true maximal number of parents c for each structure learning: this way, its execution time is considerably reduced, and we could conduct our experiments in a reasonable time. Still, to emphasize that this prior knowledge is considerably improving the speed of OS, we also considered another version of Algorithm 1 that uses in all cases a standard maximal number of parents equal to 10: it is referred as OS*. Regarding Algorithm 2, two cases are took into consideration:

- TCOS: a sound super-structure is given to the algorithm; we use the true skeleton.
- COS(α): S is learned from the data by using MMPC and a significance level α: a wide range of values are tested.

However, we know from previous section that MMPC will probably learn an incomplete super-structure, and that $G_{\mathrm{COS}(\alpha)}$ will be penalized both in its score and accuracy. Therefore, we check the effect of applying a post-processing unconstrained hill climbing search starting from $G_{\mathrm{COS}(\alpha)}$. In fact, $G_{\mathrm{COS}(\alpha)}$ might not be a local optimum if the super-structure constraint is removed; further, it could be a good starting point for a hill climbing search. The post processed version of COS is referred as COS+. Finally we compare all those algorithms for every $n \in [6,8,\cdots,20]$, $\tilde{m} \in [1,1.5,\cdots,3]$, $d \in [500,1000,\cdots,10000]$ while averaging the criteria of interest over $g = 30$ graphs: in total 4800 random graphs were used. Since there was no relevant differences depending on d, only the results for $d = 10000$ are reported here.

Results 5 *As expected, TCOS and COS(α) proceed exponentially faster than OS, even with $\alpha \approx 1$ (cf. Figures 8 (a) and (b)).*

Interestingly, the speed factor in Figure 8(a), is not purely exponential, especially for higher $\tilde{m}$. This is because, the complexity of OS is due to the costly $O(n^c)$ score calculations (here $c = O(\tilde{m})$) and the $O(2^n)$ steps (b) and (d) that dominate the complexity only for large n. As for TCOS, it only calculates $O(n)$ scores and needs around $O(\delta_{\tilde{m}}^n)$ steps. Thus, the speed factor starts by increasing fast with n because of the $O(n^c)$ scores of OS, before decreasing to behave asymptotically as $O(\left(\frac{2}{\delta_{\tilde{m}}}\right)^n)$. In Figure 8(b), the complexity of OS* is also represented: without limitation on the number of parents, the speed ratio would be purely exponential.

To evaluate the quality of the graphs learned depending on the algorithm used, for $n = 12$ and $\tilde{m} = 2$ we compare the SER and the score ratio of $G_{\mathrm{COS}(\alpha)}$ and $G_{\mathrm{COS}(\alpha)+}$ depending on α with the ones of G_{OS} and G_{TCOS} in Figure 9. Then in Figure 10, the criteria are represented depending on n (with $\tilde{m} = 2.5$), and on $\tilde{m}$ (with $n = 16$) for every algorithms: here, just three different values of α are considered (0.001, 0.05 and 0.75).

Results 6 *In average, G_{TCOS} has a slightly lower score than G_{OS} (cf. Figure 9 (b)), but it is more accurate (cf. Figure 9 (c), Figures 10 (c) and (d)): it implies that global optima contain in general extra edges. Hence, Algorithm 2 is preferable if a sound constraint is known.*

This important result emphasizes again that the optima of a score function with finite data are not the true networks usually: some false edges improve the score of a graph. Therefore, struc-

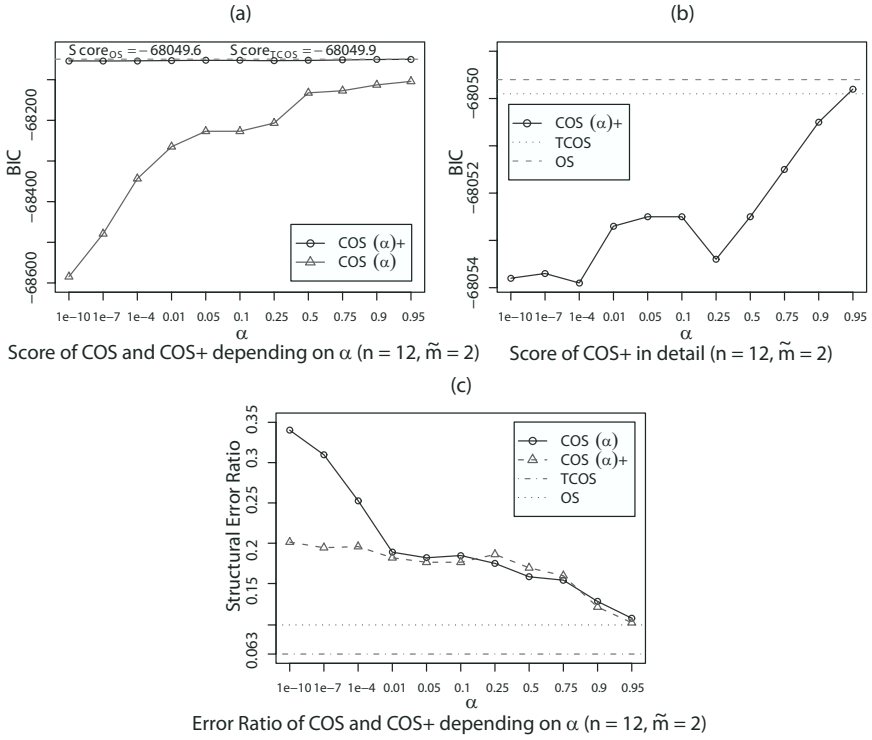

Figure 9: Score and SER for COS(α) and COS(α)+

tural constraint should be generalized whenever a sound super-structure is known: by doing so, the resulting graphs although having a lower score can be more accurate. It is the case for TCOS.

Results 7 *Although* $Score(G_{\mathrm{COS}(\alpha)})$ *converges to* $Score(G_{\mathrm{OS}})$ *when* α *increases (cf. Figure 9(a)), it is usually far lower, and worsen with larger networks or denser networks (cf. Figures 10 (a) and (b)). However,* $SER(G_{\mathrm{COS}(\alpha)})$ *is converging faster to* $SER(G_{\mathrm{OS}})$ *when* α *increases, which enables to find relatively accurate results for* $\alpha \geq 0.01$ *(cf. Figure 9(c)). In addition, n does not affect sensitively* $SER(G_{\mathrm{COS}(\alpha)})$ *(cf. Figure 10 (c)), neither does* $\tilde{m}$ *if* α *is enough high, that is,* $\alpha \geq 0.05$ *(cf. Figure 10 (d)).*

At first sight, these results sound really negative with regard to COS algorithm, or more exactly, with regard to the super-structure learned by MMPC. However, although $Score(G_{\mathrm{COS}(\alpha)})$ is disappointingly low, $SER(G_{\mathrm{COS}(\alpha)})$ is still relatively good: while $SER(G_{\mathrm{OS}}) \approx 0.1$, $SER(G_{\mathrm{COS}}) \approx 0.2$ for α as small as 0.01 in Figure 9 (c). Of course, following Results 6, we could think that for enough high α, $SER(G_{\mathrm{COS}(\alpha)}) \leq SER(G_{\mathrm{OS}})$, but it seems to be hardly feasible while using MMPC: in this case, when IT are relaxed (i.e., $\alpha \to 1$), false edges that improve the score are learned faster than the true ones missing. Still, as it appears in Figures 10 (c) and (d), for $\alpha = 0.75$, COS finds graphs nearly as accurate as the optimal ones. Therefore, when OS is not feasible, COS could be an alternative to greedy searches (such situation is studied in following Sections). Interestingly, our assumption about the potential interest of a hill climbing starting from $G_{\mathrm{COS}(\alpha)}$ are encouraged since $G_{\mathrm{COS}(\alpha)}$ has a low score while being relatively accurate. Next, we focus on COS+.

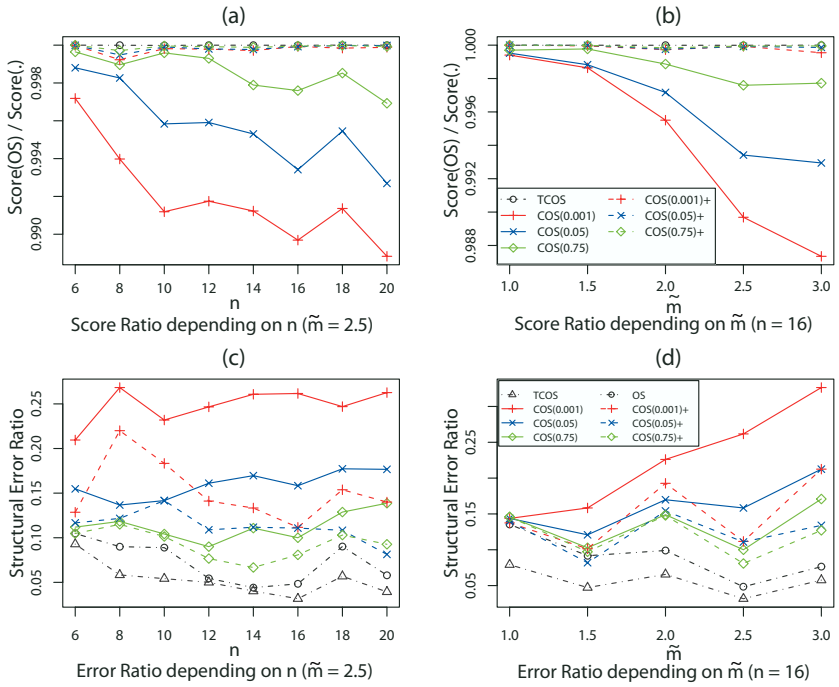

Figure 10: Evolution of Score and SER for every algorithm depending on n and $\tilde{m}$.

Results 8 *For any* α*, after post-processing Score*$(G_{\mathrm{COS}(\alpha)+})$ *is nearly as good as Score*(G_{OS}) *(cf. Figure 9 (a), Figures 10 (a) and (b)).* $G_{\mathrm{COS}(\alpha)+}$ *is in general more accurate than* $G_{\mathrm{COS}(\alpha)}$ *(cf. Figures 10 (c) and (d)), but it is not always the case. Still, SER is clearly improved for* $\alpha < 0.01$ *(cf. Figure 9 (c)): COS+ could be feasible on larger networks while giving interesting results if sufficiently small* α *are used.*

As expected, $G_{\mathrm{COS}(\alpha)}$ is not a local optima, and is at least a good starting point to maximize the score. Figure 9 (b) presents a detailed view of *Score*$(G_{\mathrm{COS}(\alpha)+})$: with post processing, we cannot be sure that *Score*$(G_{\mathrm{COS}(\alpha)+})$ increases strictly with α because of the greedy nature of hill climbing. For the same reasons, previous results concerning the SER are true only in average. To complete Results 8, we should remark that post-processing also appears to improve SER for dense graphs (cf. Figure 10 (d)). This is probably due to the fact that MMPC misses many true edges when the structure is dense: the greedy search would add more true edges missing than false ones, improving consequently the SER.

To summarize this section, TCOS is superior to OS in terms of structure accuracy, while performing faster. However, when S is learned from data, COS cannot perform as well as OS. One efficient strategy to improve both score and accuracy of G_{COS} is to proceed to a post-processing unconstrained hill climbing search. With such an improvement, both score and accuracy of $G_{\mathrm{COS}(\alpha)+}$ become similar for any α used, despite a relative superiority for higher significance levels. Consequently, it would be interesting to compare COS and COS+ to greedy searches, to see if they enable to learn efficiently more accurate graphs than other methods, while being given incomplete super-structures.

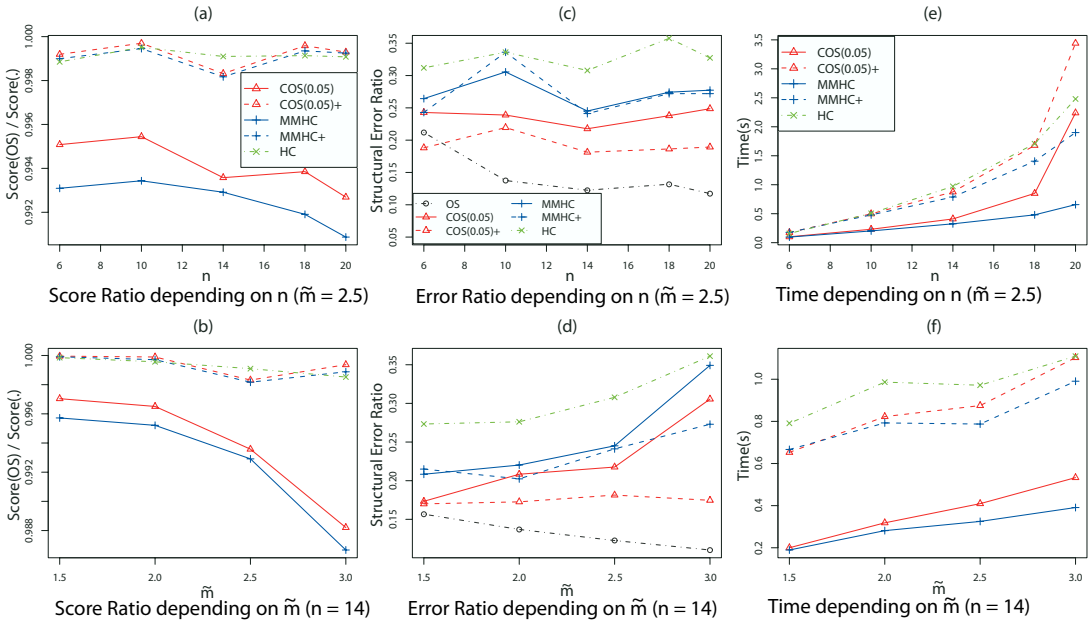

Figure 11: Score, SER and time of every algorithm depending on n and $\tilde{m}$.

5.4 COS and COS+ Compared to Heuristic Searches

In this last series of experiment, we compare COS and COS+ to other greedy searches. The structural constraint is learned with MMPC and $\alpha = 0.05$, it is used by COS and also by a constrained hill climbing search (MMHC). Like COS+, G_{MMHC} is used to start an unconstrained hill climbing (MMHC+). Finally, a classic hill climbing search from the empty graph is also considered (HC). Actually, OS is also performed, but it is not directly referred in this section. Every $n \in [6,10,14,18,20]$, $\tilde{m} \in [1,1.5,2,2.5,3]$, $d \in [500,1000,5000,10000]$ are considered and criteria are averaged over $g = 30$ graphs: in total 3000 graphs are used.

Figure 11 presents the three criteria in function of n and $\tilde{m}$; here $d = 5000$. Synoptic results are presented in Figures 12 and 13, and summarized in Tables 3 and 4. To obtain these tables, we ordered algorithms by score for all the 100 triplets $(n,\tilde{m},d)$ (the scores after averaging over the g graphs were used). Subsequently, we counted the number of times each algorithm was at a given rank: If two algorithms had equal results, they were given the same rank (cf. Table 3). We then performed a similar ranking by comparing SER; the first ranked algorithm being the one that minimized SER (cf. Table 4). In Figures 12 and 13 ranks are represented by colors and all algorithms can be directly compared for every triplet $(n,\tilde{m},d)$. However, while considering the impact of these results, one should take the fact that criteria are compared after averaging into account since it accentuates the contrast between algorithms.

Results 9 *In general,* $Score(G_{\text{COS+}}) \geq Score(G_{\text{MMHC+}}) \geq Score(G_{\text{HC}}) \geq Score(G_{\text{COS}}) \geq Score(G_{\text{MMHC}})$ *(cf. Figures 11 (a), (b), 12 and Table 3). In other words, the super-structure penalizes the score in comparison with HC; however, starting a greedy search from a constrained optimal graph enables to find better scores than HC.*

Many of these inequalities are naturally following the definition of the algorithms; another part comes from the fact that S is incomplete and penalizes the score of the results. Moreover, our

Algorithm	1st	2nd	3rd	4th	5th
COS+	84	8	8	0	0
MMHC+	12	70	18	0	0
HC	7	28	65	0	0
COS	0	1	8	91	0
MMHC	0	0	1	8	91

Table 3: Classification by score.

Algorithm	1st	2nd	3rd	4th	5th
COS+	85	9	6	0	0
COS	14	52	22	12	0
MMHC+	6	29	28	35	2
MMHC	0	12	34	31	23
HC	1	2	17	24	56

Table 4: Classification by SER.

experiments confirm that in nearly every case $Score(G_{\text{COS+}}) > Score(G_{\text{MMHC+}}) > Score(G_{\text{HC}})$; A reason could be that both constrained algorithms find good constrained optima, which are not locally optimal when withdrawing the constraint. Then, since G_{COS} is better than G_{MMHC}, it leads to better local optima when applying the HC post-processing.

Results 10 *In general,* $SER(G_{\text{COS+}}) \leq SER(G_{\text{COS}}) \leq SER(G_{\text{MMHC+}}) \leq SER(G_{\text{MMHC}}) \leq SER(G_{\text{HC}})$ *(cf. Figures 11 (c), (d), 13 and Table 4). The superiority of COS and COS+ is particularly clear with larger data sets (cf. Figure 13).*

Previous results are experimentally more confused than Results 9 since there are no theoretical evidences about SER while comparing algorithms, especially as regards to MMHC+ and MMHC. However, COS+ is clearly demonstrated to be in general the most accurate search. Interestingly, COS+ can be viewed as a bridge between OS (when $\alpha = 1$) and HC (when $\alpha = 0$). Of course, as long as OS is feasible, and without a sound constraint, COS+ is not really needed. However, it is of a certain interest for $n > 30$. Its superiority as compared to HC comes from the fact that some parent sets are optimally learned by COS even with the constraint. Such parent sets could not be learned by the greedy strategy of HC in any cases: as for example in the case of a XOR structure or any configurations for which HC should add several parents in the same time to obtain a score improvement. That way, a HC starting from G_{COS} would benefit from such correct parent sets and find more accurate graphs than a HC starting from the empty graph.

Although for the small networks considered here ($n \leq 20$) our algorithms are as fast as other greedy approaches (cf. Figures 11 (e) and (f)), of course their exponential complexity keeps us from applying them to really large networks without decreasing α. Therefore, COS is restricted to be used only for small networks or sparse ones (Figure 5 (d) gives an idea of what kind of graphs can be considered). COS+ could be used for larger graphs by using lower α as we will see in the next experiment.

5.5 A Real Case: The ALARM Network

In this last experiment, we illustrate a practical usage of COS and COS+ by studying a well-known Bayesian network example, the ALARM network (Beinlich et al., 1989). This graph has $n = 37$ discrete variables having from 2 to 4 states: it is too large to be learned by OS. The maximal in-degree is $c = 4$, the maximal neighborhood is $m = 6$, and the structure is relatively dense since $\tilde{m} \approx 2.5$. Incidentally, the true skeleton entails $86818458 \approx 2^{26}$ connected subsets: if it was given as a prior knowledge, Algorithm 2 could be applied. However, as in previous experiments, S is learned by using MMPC. Nevertheless, α should be enough small so that the super-structure is sparse enough to let execute COS.

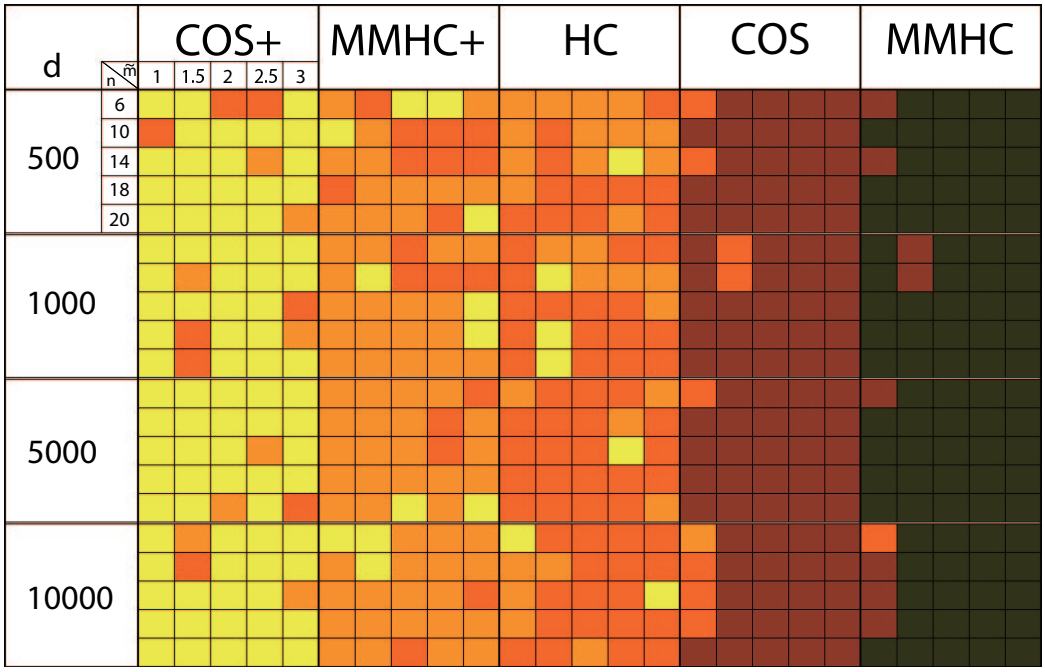

Figure 12: Comparison by score: for every $(n, \tilde{m}, d)$, the worse is the rank of an algorithm (i.e., the lower is the score), the darker is the box.

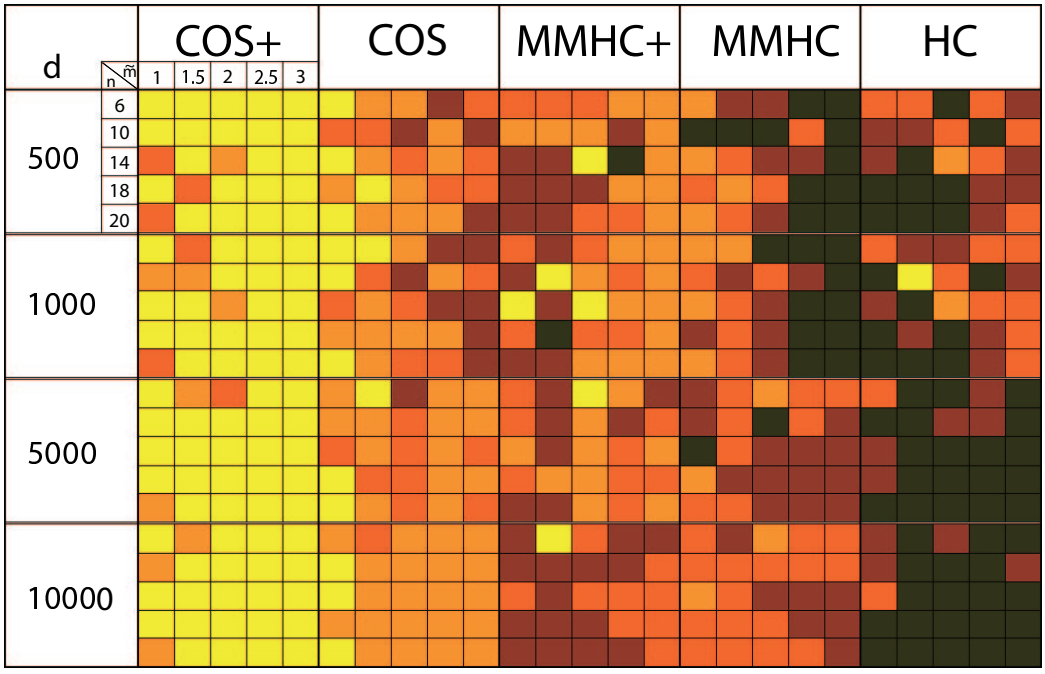

Figure 13: Comparison by SER: for every $(n, \tilde{m}, d)$, the worse is the rank of an algorithm (i.e., the higher is the SER), the darker is the box.

Table 5: Averaged criteria for some pairs (d, α) considered.

We consider the same algorithms than in Section 5.4, apart from OS. The significance level used to learn the skeleton of MMHC is always set to 0.01, while various small values of α are tested when learning the super-structure used by COS. For every $d \in [3000, 5000, 10000]$, we start by learning S with MMPC(α) to run COS afterwards. Since, the execution time of COS can be huge depending on S, COS is stopped if its execution exceeds 20 seconds (on a cluster of 96 CPUs of 1050 MHz each, with a total memory of 288GB). In that case, the experience is restarted on a new set of data. If COS finishes on time, all other algorithms are also applied. Previous steps are repeated 20 times for every pair (d, α). We also count the number t of times that COS had to be restarted. Finally, the criteria are averaged over the 20 learned graphs as in the previous Sections.

In all cases results were sensibly the same: Table 5 presents the results obtained with the minimal and maximal values of d and α considered. With larger data sets, smaller significant levels are required in order to obtain an enough sparse S since true edges are learned more confidently. This is why, we can observe that t decreases with smaller α and increases with larger d (cf. Table 5). Therefore, for $d = 10000$ we tried values of $\alpha \in [10^{-7}, \cdots, 10^{-10}]$, while for other data sets $\alpha \in [10^{-4}, \cdots, 10^{-7}]$. In Figures 14 (a) and (b), box plot is used to layout the SER and score of every algorithm over the 20 repetitions of structure learning for $d = 5000$ and $\alpha = 10^{-7}$. Figures 14 (c) and (d) represent the SER of COS and COS+ depending on d and α, respectively.

Results 11 *COS+ is the best algorithm in terms of score, followed by MMHC+ (cf. Table 4 and Figure 14 (a)), while COS+ and COS learn the most accurate networks (cf. Table 4 and Figure 14 (b)). Accuracy of these algorithms is not markedly modified by smaller α (cf. Figure (d)) and slightly improves with bigger data sets (cf. Figure 14 (c)).*

In other words, the present results are in total agreement with the ones derived from smaller and random networks in the previous section. Actually, with ALARM network the contrast between algorithms is even clearer. This is probably because random networks are harder to learn than real ones since the parameters randomly selected can entail nearly unfaithful probability distributions. Interestingly, even with the smallest α used (i.e., $\alpha = 10^{-10}$ in the case of $d = 10000$), only around

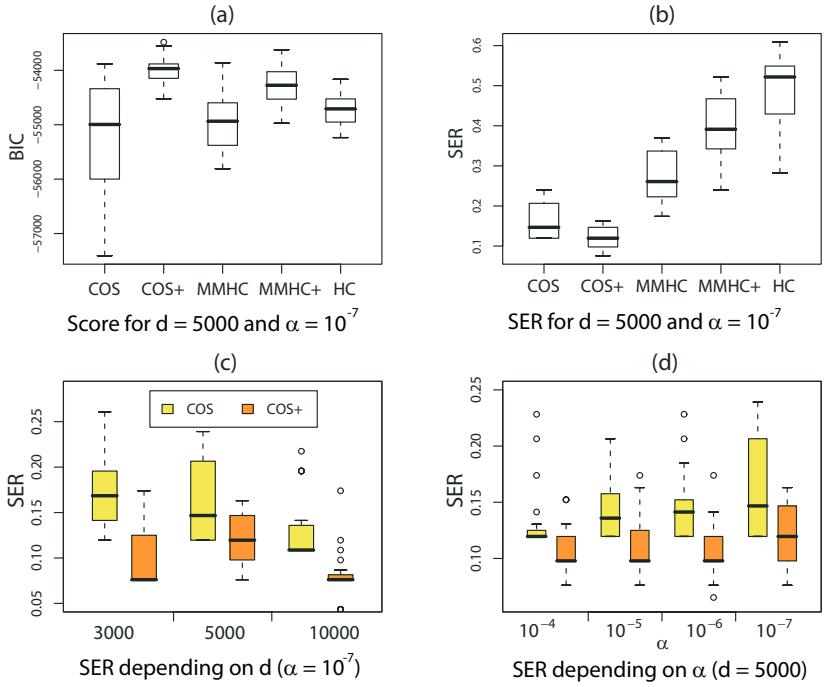

Figure 14: Some detailed results on ALARM network.

6 edges were missing to S in order to be sound. Besides, although COS ran in few seconds for some S, one extra edge in the same super-structure could lead to drastically longer computations. Such a problem is easily understood in terms of the number of connected subsets and underline the fact that some edges contribute particularly to the increase of $|Con(S)|$. Therefore it could be interesting to develop a method to select and withdraw some edges from a learned super-structure, to enable COS+ for larger networks: this way, extremely small α would not be required anymore.

6. Discussion and Conclusion

To conclude our discussion, we would like to recall and summarize the main results of our actual research. First, it is possible to reduce the complexity of an optimal search of an exponential factor by using a structural constraint such as a super-structure. It is then possible to consider larger networks having a sparse skeleton. Moreover, if this super-structure is sound, the accuracy of the resulting graph is improved. Consequently, more attention should be paid to learning sound super-structures rather than true skeleton from data. This should be an easier task and it might improve both speed and accuracy of other search strategies as well, except greedy HC. Next, we outline bellow some strategies that could benefit from a sound super-structure.

In addition, current IT methods that learn a skeleton can be used for approximating a super-structure by relaxing the independency testing. However, as revealed our experiments with MMPC, sound super-structures are rarely learned except for high values of α that implies denser structures and especially a long computation. Although some other IT approaches, such as the randomized version of GS (Margaritis and Thrun, 2000), could solve the problem of complexity, they would probably face the same difficulty to learn efficiently at least every true edge. Indeed, they were de-

signed from the viewpoint of learning the true skeleton, and thereby they should also reject potential extra edges. Learning sound and sparse super-structures is a problem that requires to be considered as a whole, which is not our main concern in the present paper. Therefore, to offset the incompleteness of the super-structures learned with MMPC that weakens the results of our algorithm COS, we developed a greedy post processed search COS+. This algorithm enables to balance between speed and accuracy as it sets up a bridge between optimal search and hill climbing search. In practice, COS+ is demonstrated with success on the ALARM network. It is theoretically feasible for graphs of any sizes but leads to a problem for selecting the significance level; further, we expect that the larger is the graph, the less COS+ should improve over HC.

Therefore, our future research will concentrate on an elaboration of new greedy strategies that benefit from super-structure constraint. As shown in Section 4.2, if S is not having a very high maximal degree (i.e., $m < 20$), F can be calculated even for large networks. Then, by using formula (3) of Section 3.2 we can build in linear time the best constrained graph of a given ordering. This way a fast greedy search over topological orderings is efficiently feasible. With a good set of greedy operations, a constrained optimal graph could be quickly approached using a hill climbing over orderings, without having to calculate M values. Moreover, even for higher m, by fixing a limited number of parents c, we could also manage to calculate F. Consequently, such ordering-based strategy is theoretically feasible for any network size and only need to be evaluated experimentally.

Our second idea concerns only constrained optimal searches. When looking for an optimal graph on $\mathbf{A} \in Con(S)$, if there exists $X_i \in \mathbf{A}$ such that $\mathbf{A}\backslash\{X_i\}$ is unconnected, an optimal graph can be found on another manner. We just need to consider every candidate parent set on the neighborhood of X_i, and search for each of them separately an optimal graph on each connected component of $\mathbf{A}\backslash\{X_i\}$. Thus, if S is a tree, it would be feasible to find an optimal graph in polynomial time with this different strategy. Then, we could develop an algorithm that would change S into a tree, learn an optimal graph that would be post-processed greedily to add missing edges.

Besides, as illustrated in Section 4.4, COS can be used for large graphs, if S is sufficiently sparse. Alternatively, when learning a super-structure, a "score" could be given to every edge that would evaluate the "strength" of the dependency represented. For example, the highest p-value encountered while learning the super-structure with an IT approach could be used. Thus, COS could be used sequentially: the subset of the strongest edges would be considered first, while learning a temporary optimal graph that would be used as a prior knowledge for a second search, this time optimally "adding" a second set of edges. Therefore, by considering successively all the edges of S by a sufficient number of sparse layers, we might be able to approximate accurately an optimal graph. This strategy is potentially interesting since it always assumes the graph as a whole, although the layer of edges should be mainly unconnected to allow COS to be applied to large networks. However, other strategies such as rebuilding optimally the structure locally before merging results could also be developed.

Finally if any of these algorithms were giving convincing empirical proofs of their capacities to learn accurately large networks, we also would like to design strategies for learning sparse and sound super-structures.

Acknowledgments

We would like to thank the reviewers and the associate editor who helped us considerably to improve the quality of this paper, and gave us many valuable suggestions. We should also thank the Super Computer System, Human Genome Center, Institute of Medical Science, University of Tokyo, for letting us use their super computer with which we realized our experiments. We also acknowledge the Japanese Ministry of Education, Culture, Sports, Science and Technology for its financial support.

Appendix A.

Proof of Proposition 1. The complete proof we found is long, complex, and not of the greatest theoretical interest. Hence we will only present the main steps of the demonstration here without explicitly developing every step.

- We start by considering any binary tree, which can be generated by successively applying the following operation to the tree reduced to one leaf: Select a leaf, and change it to a node with two leaves. Then, for the set of trees that have been generated by applying this transformation t times, we define $U(t)$ as the maximum number of sub-trees in these trees, and $V(t)$ as the maximum number of sub-trees that include a given leaf. Given such a tree T, we apply the transformation to a leaf L_i. This generates a node N_i' and two leaves L_{i1}' and L_{i2}', where the prime indicates that we refer to the elements of the newly generated tree T'. By calling $Sub(L)$ the set of sub-trees that contain L, we have: since $|Sub(L_i)| \leq V(t)$, $|Sub(L_{i1}')| \leq 1+2V(t)$. If L_i had a brother L_j, we can show that $|Sub(L_j')| \leq \frac{5}{2}V(t)$ since only half the sub-trees of $Sub(L_j)$ contain L_i. Then, for leaves L_k at agreater distance from L_i than L_j, since the proportion of sub-trees of $Sub(L_k)$ that also contain L_i is decreasing, $Sub(L_k')$ is less increased. Thus, we can conclude that $V(t+1) < \frac{5}{2}V(t)$, and that $V(t) < U(t) < O((\frac{5}{2})^t)$. Finally, since $n = 2t-1$, we derive that $|Con(S)| < O({\alpha_3}^n)$ with $\alpha_3 = \sqrt{\frac{5}{2}}$.
- Hereafter, we can apply the same reasoning to any k-tree, and find that $|Con(S)| < O({\alpha_{k+1}}^n)$ with $\alpha_{k+1} = (\frac{2^k+1}{2})^{\frac{1}{k}}$.
- Then, start the fastidious part of the demonstration by considering a connected forest S of maximal degree m. The idea of the demonstration is to first show that when we consider two nodes of the tree, we can transfer from one node to the other every sub-rooted trees while only increasing the number of connected subsets (actually it is possible to express exactly the variation in the number of connected subsets depending on the unique path between the two nodes and sub-rooted trees of the nodes in this path). Then, by selecting one of the nodes of degree m from S, and fixing it as the root R_0, we can sequentially build a nearly m-1-tree S', except for the root, and maybe for one node R_i, while increasing the number of connected subsets. We do this by considering depth by depth descendants of R_0 and transferring sub-rooted trees from one to the other until all of them at a given depth have $m-1$ or 0 children, taking sub-rooted trees deeper if necessary. Then, if the sons of R_i are not all leaves, we can continue to apply transformations between it and its descendants until obtaining a nearly m-1-tree S" except for its root, and one of its nodes that contain only p leaves. Since $p \leq m-1$, we add $m-p$ leaves to this node, and we select as the root of this final tree S_f one of the

leaves; S_f is like a m-1-tree except for the root that has only one son. In such a case, we can use the results found for such structures, neither the root will sensitively affect the number of connected subsets, nor the nodes that we added at the end; because they can be put in the constant of $O(\alpha_m{}^n)$, which is an upper bound since we built S_f always taking care to increase the number of connected subsets. ■

Editor: John Shawe-Taylor

Abstract

We design an online algorithm for Principal Component Analysis. In each trial the current instance is centered and projected into a probabilistically chosen low dimensional subspace. The regret of our online algorithm, that is, the total expected quadratic compression loss of the online algorithm minus the total quadratic compression loss of the batch algorithm, is bounded by a term whose dependence on the dimension of the instances is only logarithmic.

We first develop our methodology in the expert setting of online learning by giving an algorithm for learning as well as the best subset of experts of a certain size. This algorithm is then lifted to the matrix setting where the subsets of experts correspond to subspaces. The algorithm represents the uncertainty over the best subspace as a density matrix whose eigenvalues are bounded. The running time is $O(n^2)$ per trial, where n is the dimension of the instances.

Keywords: principal component analysis, online learning, density matrix, expert setting, quantum Bayes rule

1. Introduction

In Principal Component Analysis (PCA) the n-dimensional data instances are projected into a k-dimensional subspace ($k < n$) so that the total quadratic compression loss is minimized. After centering the data, the problem is equivalent to finding the eigenvectors of the k largest eigenvalues of the data covariance matrix. The variance along an eigendirection is always equal to the corresponding eigenvalue and the subspace defined by the eigenvectors corresponding to the k largest eigenvalues is the subspace that captures the largest total variance and this is equivalent to minimizing the total quadratic compression loss.

We develop a probabilistic online version of PCA: in each trial the algorithm chooses a center m^{t-1} and a k-dimensional projection matrix P^{t-1} based on some internal parameter (which summarizes the information obtained from the previous $t-1$ trials); then an instance x^t is received and the algorithm incurs compression loss $\|(x^t - m^{t-1}) - P^{t-1}(x^t - m^{t-1})\|_2^2$; finally, the internal parameters are updated. The goal is to obtain online algorithms whose total compression loss in all trials is close to the total compression loss $\min_{m,P} \sum_{t=1}^{T} \|(x^t - m) - P(x^t - m)\|_2^2$ of the batch algorithm which can choose its center and k-dimensional subspace in hindsight based on all T instances. Specifically,

*. Supported by NSF grant IIS 0325363. A preliminary version of this paper appeared in Warmuth and Kuzmin (2006b).

in this paper we obtain randomized online algorithms with bounded *regret*. Here we define regret as the difference between the total expected compression loss of the randomized online algorithm and the compression loss of the best mean and subspace of rank k chosen offline. In other words the regret is essentially the expected additional compression loss incurred by the online algorithm compared to normal batch PCA. The expectation is over the internal randomization of the algorithm.

We begin by developing our online PCA algorithm for the uncentered case, that is, all $m^t = 0$ and the compression loss of the offline comparator is simplified to $\min_P \sum_{t=1}^{T} \|x^t - Px^t\|_2^2$. In this simpler case our algorithm is motivated by a related problem in the expert setting of online learning, where our goal is to perform as well as the best size k subset of experts. The algorithm maintains a mixture vector over the n experts. At the beginning of trial t the algorithm chooses a subset P^{t-1} of k experts based on the current mixture vector w^{t-1} that summarizes the previous $t-1$ trials. It then receives a loss vector $\ell^t \in [0,1]^n$. Now the subset P^{t-1} corresponds to the subspace onto which we "compress" or "project" the data. The algorithm incurs no loss on the k components of P^{t-1} and its compression loss equals the sum of the remaining $n-k$ components of the loss vector, that is, $\sum_{i \in \{1,\ldots,n\} - P^{t-1}} \ell_i^t$. Finally it updates its mixture vector to w^t.

The key insight is to maintain a mixture vector w^{t-1} as a parameter with the additional constraint that $w_i^{t-1} \leq \frac{1}{n-k}$. We will show that this "capped" mixture vector represents an implicit mixture over all subsets of experts of size $n-k$, and given w^{t-1} we can efficiently sample a subset of size $n-k$ from the implicit mixture and choose P^{t-1} as the complementary subset of size k. This gives an online algorithm whose total loss over all trials is close to the smallest $n-k$ components of the total loss vector $\sum_{t=1}^{T} \ell^t$. We will show how this algorithm generalizes to an online PCA algorithm when the mixture vector w^{t-1} is replaced by a density matrix W^{t-1} whose eigenvalues are capped by $\frac{1}{n-k}$. Now the constrained density matrix W^{t-1} represents an implicit mixture of $(n-k)$-dimensional subspaces. Again, we can efficiently sample from this mixture, and the complementary k-dimensional subspace P^{t-1} is used for projecting the current instance x_t at trial t.

A simple way to construct an online algorithm is to run the offline or batch algorithm on all data received so far and use the resulting hypothesis on the next data instance. This is called the "Incremental Offline Algorithm" (Azoury and Warmuth, 2001). When the offline algorithm just minimizes the loss on the past instances, then this algorithm is also called the "Follow the Leader (FL) Algorithm" (Kalai and Vempala, 2005). For uncentered PCA we can easily construct a sequence of instances for which the total online compression loss of FL is $\frac{n}{n-k}$ times larger than the total compression loss of batch PCA. However, in this paper we have a more stringent goal. We design randomized online algorithms whose total expected compression loss is at most one times the compression loss of batch PCA plus an additional lower order term which we optimize. In other words, we are seeking online algorithms with bounded *regret*. Our regret bounds are worst-case in that they hold for arbitrary sequences of instances.

Simple online algorithms such as the Generalized Hebbian Algorithm (Sanger, 1989) have been investigated previously that provably converge to the best offline solution. No worst-case regret bounds have been proven for these algorithms. More recently, the online PCA problem was also addressed in Crammer (2006). However, that paper does not fully capture the PCA problem because the presented algorithm uses a full-rank matrix as its hypothesis in each trial, whereas we use a probabilistically chosen projection matrix of the desired rank k. Furthermore, that paper proves bounds on the filtering loss, which are typically easier to obtain, and it is not clear how the filtering loss relates to the more standard regret bounds for the compression loss proven in this paper.

Our algorithm is unique in that we can prove a regret bound for it that is linear in the target dimension k of the subspace but logarithmic in the dimension of the instance space. The key methodology is to use a density matrix as the parameter and employ the quantum relative entropy as a regularizer and measure of progress. This was first done in Tsuda et al. (2005) for a generalization of linear regression to the case when the parameter matrix is a density matrix. Our update of the density matrix can be seen as a "soft" version of computing the top k eigenvectors and eigenvalues of the covariance matrix. It involves matrix logarithms and exponentials which are seemingly more complicated than the FL Algorithm which simply picks the top k directions. Actually, the most expensive step in both algorithms is to update the eigendecomposition of the covariance matrix after each new instance, and this costs $O(n^2)$ time (see, e.g., Gu and Eisenstat, 1994).

The paper is organized as follows. We begin by introducing some basics about batch and online PCA (Section 2) as well as the Hedge Algorithm from the expert setting of online learning (Section 3). We then develop a version of this algorithm that learns as well as the best subset of experts of fixed size (Section 4). When lifted to the matrix setting, this algorithm does uncentered PCA online (Section 5). Surprisingly, the regret bound for the matrix setting stays the same and this is an example of a phenomenon that has been dubbed the "free matrix lunch" (Warmuth, 2007b). We briefly discuss the merits of various alternate algorithms in sections 4.1 and 5.1.

Our online algorithm for centered online PCA is more involved since it has to learn the center as well (Section 6). After motivating the updates to the parameters (Section 6.1) we generalize our regret bound to the centered case (Section 6.2). We then briefly describe how to construct batch PCA algorithms from our online algorithms via standard conversion techniques (Section 6.3). Surprisingly, the bounds obtained this way are competitive with the best known batch PCA bounds. Lower bounds are discussed in Section 7. A brief experimental evaluation is given in Section 8 and we conclude with an overview of online algorithms for matrix parameters and discuss a number of open problems (Section 9).

2. Setup of Batch PCA and Online PCA

Given a set (or batch) of instance vectors $\{x^1, \ldots, x^T\}$, the goal of *batch PCA* is to find a low-dimensional approximation of this data that minimizes the quadratic compression loss. Specifically, we want to find a center vector $m \in \mathbb{R}^n$ and a rank k projection matrix[1] P such that the following loss function is minimized:

$$\text{comp}(P, m) = \sum_{t=1}^{T} \|(x^t - m) - P(x^t - m)\|_2^2. \tag{1}$$

Differentiating and solving for m gives us $m^* = \bar{x}$, where $\bar{x}$ is the data mean. Substituting this optimal center m^* into loss (1) we obtain

$$\begin{aligned} \text{comp}(P) &= \sum_{t=1}^{T} \|(I-P)(x^t - \bar{x})\|_2^2 = \sum_{t=1}^{T} (x^t - \bar{x})^\top (I-P)^2 (x^t - \bar{x}) \\ &= \text{tr}\Big((I-P)^2 \underbrace{\sum_{t=1}^{T} (x^t - \bar{x})(x^t - \bar{x})^\top}_{C} \Big). \end{aligned}$$

1. Projection matrices are symmetric matrices P with eigenvalues in $\{0, 1\}$. Note that $P^2 = P$.

The sum of outer products in the above trace is called the data covariance matrix C. Since $I-P$ is a projection matrix, $(I-P)^2 = I-P$, and

$$\mathrm{comp}(P) = \mathrm{tr}((\underbrace{I-P}_{\text{rank } n-k})C) = \mathrm{tr}(C) - \mathrm{tr}(\underbrace{P}_{\text{rank } k}C).$$

We call the above loss the *compression loss of P* or the *loss of subspace $I-P$*. We now give a justification for this choice of terminology. Observe that $\mathrm{tr}(C)$ equals $\mathrm{tr}(CP)+\mathrm{tr}(C(I-P))$, the sum of the losses of the complementary subspaces. However, we project the data into subspace P and the projected parts of the data are perfectly reconstructed. We charge the subspace P with the parts that are missed, that is, $\mathrm{tr}((I-P)C)$, and therefore call this the compression loss of P.

We now show that $\mathrm{tr}(PC)$ is maximized (or $\mathrm{tr}((I-P)C)$ minimized) if P consists of the k eigendirections of C with the largest eigenvalues. This proof might seem a digression, but elements of it will appear throughout the paper. By rewriting C in terms of its eigendecomposition, that is, $C = \sum_{i=1}^n \gamma_i\, c_i c_i^\top$, we can upper bound $\mathrm{tr}(PC)$ as follows:

$$\mathrm{tr}(PC) = \sum_{i=1}^n \gamma_i\, \mathrm{tr}(P\, c_i c_i^\top) = \sum_{i=1}^n \gamma_i\, c_i^\top P c_i \leq \max_{0\leq\delta_i\leq 1, \sum_i \delta_i = k} \sum_{i=1}^n \gamma_i\, \delta_i.$$

We can replace the scalars $c_i^\top P c_i$ in the ending inequality by the constrained δ_i's because of the following facts:

$$c_i^\top P c_i \leq 1, \text{ for } 1\leq i\leq n, \text{ and } \sum_{i=1}^n c_i^\top P c_i = \mathrm{tr}(P\underbrace{\sum_{i=1}^n c_i c_i^\top}_{I}) = \mathrm{tr}(P) = k,$$

since the eigenvectors c_i of C are an orthogonal set of n directions. A linear function is maximized at one of the vertices of its polytope of feasible solutions. The vertices of this polytope defined by the constraints $0\leq\delta_i\leq 1$ and $\sum_i \delta_i = k$ are those δ vectors with exactly k ones and $n-k$ zeros. Thus the vertices of the polytope correspond to sets of size k and

$$\mathrm{tr}(PC) \;\leq\; \max_{1\leq i_1<i_2<\ldots<i_k\leq n} \sum_{j=1}^k \gamma_{i_j}.$$

Clearly the set that gives the maximum upper bound corresponds to the largest k eigenvalues of C and $\mathrm{tr}(P^*C)$ equals the above upper bound when P^* consists of the eigenvectors corresponding to the set of k largest eigenvalues.

In the online setting, learning proceeds in trials. At trial t the algorithm chooses a center m^{t-1} and a rank k projection matrix P^{t-1}. It then receives an instance x^t and incurs loss

$$\|(x^t - m^{t-1}) - P^{t-1}(x^t - m^{t-1})\|_2^2 = \mathrm{tr}((I-P^{t-1})\,(x^t-m^{t-1})(x^t-m^{t-1})^\top).$$

Note that this is the compression loss of the center m^{t-1} and subspace P^{t-1} on the instance x^t. Our goal is to obtain an algorithm whose total online compression loss over the entire sequence of T trials $\sum_{t=1}^T \mathrm{tr}((I-P^{t-1})\,(x^t-m^{t-1})(x^t-m^{t-1})^\top)$ is close to the total compression loss (1) of the best center m^* and best rank k projection matrix P^* chosen in hindsight by the batch algorithm.

3. Learning as Well as the Best Expert with the Hedge Algorithm

The following setup and algorithm will be the basis of this paper. The algorithm maintains a probability distribution w^{t-1} over n experts. At the beginning of trial t it chooses an expert probabilistically according to the probability vector w^{t-1}, that is, expert i is chosen with probability w_i^{t-1}. Then a loss vector $\ell^t \in [0,1]^n$ is received, where ℓ_i^t specifies the loss of expert i incurred in trial t. The expected loss of the algorithm will be $w^{t-1} \cdot \ell^t$, since the expert was chosen probabilistically. At the end of the trial, the probability distribution is updated to w^t using exponential update factors (See Algorithm 1). This is essentially the Hedge Algorithm of Freund and Schapire (1997). In the

Algorithm 1 Hedge Algorithm

input: Initial n-dimensional probability vector w^0
for $t = 1$ to T **do**
  Draw an expert i with probability w_i^{t-1}
  Receive loss vector ℓ^t
  Incur loss ℓ_i^t
    and expected loss $w^{t-1} \cdot \ell^t$
  $w_i^t = \frac{w_i^{t-1} \exp(-\eta \ell_i^t)}{\sum_{j=1}^n w_j^{t-1} \exp(-\eta \ell_j^t)}$
end for

original version the algorithm proposes a distribution w^{t-1} at trial t and incurs loss $w^{t-1} \cdot \ell^t$ (instead of drawing an expert from w^{t-1} and incurring expected loss $w^{t-1} \cdot \ell^t$).

It is easy to prove the following bound on the total expected loss. Here $d(u,w)$ denotes the relative entropy between two probability vectors $d(u,w) = \sum_{i=1}^n u_i \log \frac{u_i}{w_i}$ and log is the natural logarithm.

Theorem 1 *For an arbitrary sequence of loss vectors $\ell^1, \ldots, \ell^T \in [0,1]^n$, the total expected loss of Algorithm 1 is bounded as follows:*

$$\sum_{t=1}^T w^{t-1} \cdot \ell^t \leq \frac{\eta \sum_{t=1}^T u \cdot \ell^t + \big(d(u,w^0) - d(u,w^T)\big)}{1 - \exp(-\eta)},$$

for any learning rate $\eta > 0$ and comparison vector u in the n dimensional probability simplex.

Proof The update for w^t in Algorithm 1 is essentially the update of the Continuous Weighted Majority Algorithm where the absolute loss of expert i is replaced by ℓ_i^t. Since $\ell_i^t \in [0,1]$, we have $\exp(-\eta \ell_i^t) \leq 1 - (1 - \exp(-\eta))\ell_i^t$ and this implies (essentially Littlestone and Warmuth 1994, Lemma 5.2, or Freund and Schapire 1997):

$$-\log \sum_{i=1}^n w_i^{t-1} \exp(-\eta \ell_i^t) \geq -\log(1 - (1 - \exp(-\eta)) w^{t-1} \cdot \ell^t) \geq w^{t-1} \cdot \ell^t (1 - \exp(-\eta)).$$

The above can be reexpressed with relative entropies as follows (Kivinen and Warmuth, 1999):

$$\begin{aligned} d(u,w^{t-1}) - d(u,w^t) &= -\eta\, u \cdot \ell^t - \log \sum_{i=1}^n w_i^{t-1} \exp(-\eta \ell_i^t) \\ &\geq -\eta\, u \cdot \ell^t + w^{t-1} \cdot \ell^t (1 - \exp(-\eta)). \end{aligned} \tag{2}$$

The bound of theorem can now be obtained by summing over trials. ■

The original Weighted Majority algorithms were described for the absolute loss (Littlestone and Warmuth, 1994). The idea of using loss vectors instead was introduced in Freund and Schapire (1997). The latter paper also shows that when $\sum_t u \cdot \ell^t \leq L$ and $d(u,w^0) - d(u,w^T) \leq D \leq \log n$, then with $\eta = \log(1+\sqrt{2D/L})$, we get the bound

$$\sum_t w^{t-1} \cdot \ell^t \leq \sum_t u \cdot \ell^t + \sqrt{2LD} + d(u,w_0) - d(u,w^T). \tag{3}$$

By setting u to be the vector with a single one identifying the best expert, we get the following bound on the regret of the algorithm (Again log denotes the natural logarithm.):

$$\text{total loss of alg.} - \text{total loss of best expert} \leq \sqrt{2\,(\text{total loss of best expert})\,\log n} + \log n.$$

4. Learning as Well as the Best Subset of Experts

Recall that projection matrices are symmetric positive definite matrices with eigenvalues in $\{0,1\}$. Thus a rank k projection matrix can be written as $P = \sum_{i=1}^{k} p_i p_i^\top$, where the p_i are the k orthonormal vectors forming the basis of the subspace. Assume for the moment that the eigenvectors are restricted to be standard basis vectors. Now a projection matrix becomes a diagonal matrix with k ones in the diagonal and $n-k$ zeros. Also, the trace of a product of such a diagonal projection matrix and any symmetric matrix specifying the loss becomes a dot product between the diagonals of both matrices. The diagonal of the symmetric matrix may be seen as a loss vector ℓ^t. Thus, in this simplified diagonal setting, our goal is to develop online algorithms whose total loss is close to the sum of the lowest $n-k$ components of total loss vector $\sum_{t=1}^{T} \ell^t$. Equivalently, we want to find the highest k components of the total loss vector and per our nomenclature the loss of the lowest $n-k$ components is the compression loss of the complementary highest k components.

For this problem, we will encode the subsets of size $n-k$ as probability vectors: we call $r \in [0,1]^n$ an $(n-k)$-*corner* if it has $n-k$ components fixed to $\frac{1}{n-k}$ and the remaining k components fixed to zero. The algorithm maintains a probability vector w^t as its parameter. At trial t it probabilistically chooses an $(n-k)$-corner r based on the current probability vector w^{t-1} (Details of how this is done will be given shortly). The set of k components missed by r is the set P^{t-1} that we compress with at trial t. The algorithm then receives a loss vector ℓ^t and incurs compression loss $(n-k)\,r \cdot \ell^t = \sum_{i \in \{1,\ldots,n\} - P^{t-1}} \ell_i^t$. Finally the weight vector w^{t-1} is updated to w^t.

We now describe how the corner is chosen: The current probability vector is decomposed into a mixture of n corners and then one of the n corners is chosen probabilistically based on the mixture coefficients. In the description of the decomposition algorithm we use $d = n-k$ for convenience. Let A_d^n denote the convex hull of the $\binom{n}{d}$ corners of size d (where $1 \leq d < n$). Clearly, any component w_i of a vector w in the convex hull is at most $\frac{1}{d}$ because it is a convex combination of numbers in $\{0, \frac{1}{d}\}$. Therefore $A_d^n \subseteq B_d^n$, where B_d^n is the capped probability simplex, that is, the set of n-dimensional vectors w for which $|w| = \sum_i w_i = 1$ and $0 \leq w_i \leq \frac{1}{d}$, for all i. Figure 1 depicts the capped probability simplex for case $d = 2$ and $n = 3, 4$. The following theorem shows that the convex hull of the corners is exactly the capped probability simplex, that is, $A_d^n = B_d^n$. It shows this by expressing any probability vector in the capped simplex B_d^n as a convex combination of at most n $d-$corners. For example, when $d = 2$ and $n = 4$, B_d^n is an octahedron (which has 6 vertices). However, each point in this octahedron is contained in a tetrahedron which is the hull of only 4 of the 6 total vertices.

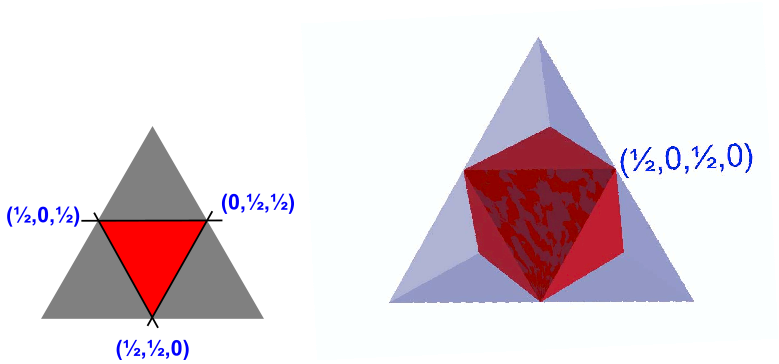

Figure 1: The capped probability simplex B_d^n, for $d = 2$ and $n = 3, 4$. This simplex is the intersection of n halfspaces (one per capped dimension) and its vertices are the $\binom{n}{d}$ d-corners.

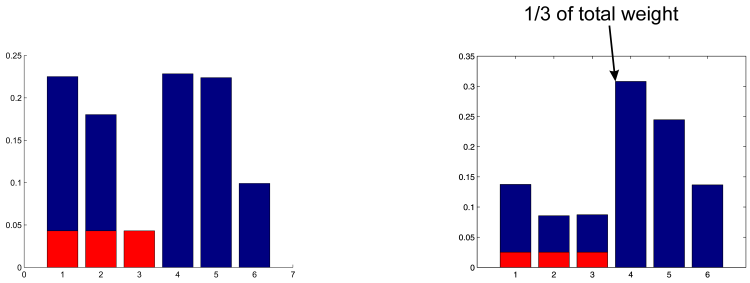

Figure 2: A step of the Mixture Decomposition Algorithm 2, $n = 6$ and $k = 3$. When a corner is removed, then at least one more component is set to zero or raised to a d-th fraction of the total weight. The left picture shows the case where a component inside the corner gets set to zero and the right one depicts the case where a component outside the picked corner gets d-th fraction of the total weight.

Theorem 2 *Algorithm 2 decomposes any probability vector w in the capped probability simplex B_d^n into a convex combination*[2] *of at most n d-corners.*

Proof Let $b(w)$ be the number of *boundary* components in w, that is, $b(w) = |\{i : w_i \text{ is } 0 \text{ or } \frac{|w|}{d}\}|$. Let $\widetilde{B}_d^n$ be all vectors w such that $0 \le w_i \le \frac{|w|}{d}$, for all i. If $b(w) = n$, then w is either a corner or 0. The loop stops when $w = 0$. If w is a corner then it takes one more iteration to arrive at 0. We show that if $w \in \widetilde{B}_d^n$ and w is neither a corner nor 0, then the successor $\widehat{w}$ lies in $\widetilde{B}_d^n$ and $b(\widehat{w}) > b(w)$. Clearly, $\widehat{w} \ge 0$, because the amount that is subtracted in the d components of the corner is at most as large as the corresponding components of w. We next show that $\widehat{w}_i \le \frac{|\widehat{w}|}{d}$. If i belongs to the corner that was chosen then $\widehat{w}_i = w_i - \frac{p}{d} \le \frac{|w|-p}{d} = \frac{|\widehat{w}|}{d}$. Otherwise $\widehat{w}_i = w_i \le l$, and $l \le \frac{|\widehat{w}|}{d}$ follows from the fact that $p \le |w| - d\,l$. This proves that $\widehat{w} \in \widetilde{B}_d^n$.

2. The existence of a convex combination of at most n corners is implied by Carathéodory's theorem (Rockafellar, 1970), but Algorithm 2 gives an effective construction.

input $1 \leq d < n$ and $w \in B_d^n$
repeat
Let r be a corner for a subset of d non-zero components of w
that includes all components of w equal to $\frac{|w|}{d}$
Let s be the smallest of the d chosen components of r
and l be the largest value of the remaining $n-d$ components
$w := w - \underbrace{\min(d\,s, |w| - d\,l)}_{p}\, r$ and **output** $p\,r$
until $w = 0$

For showing that $b(\widehat{w}) > b(w)$ first observe that all boundary components in w remain boundary components in $\widehat{w}$: zeros stay zeros and if $w_i = \frac{|w|}{d}$ then i is included in the corner and $\widehat{w}_i = \frac{|w|-p}{d} = \frac{|\widehat{w}|}{d}$. However, the number of boundary components is increased at least by one because the components corresponding to s and l are both non-boundary components in w and at least one of them becomes a boundary point in $\widehat{w}$: if $p = d\,s$ then the component corresponding to s in w is $s - \frac{p}{d} = 0$ in $\widehat{w}$, and if $p = |w| - d\,l$ then the component corresponding to l in w is $l = \frac{|w|-p}{d} = \frac{|\widehat{w}|}{d}$. It follows that it may take up to n iterations to arrive at a corner which has n boundary components and one more iteration to arrive at 0. Finally note that there is no weight vector $w \in \widetilde{B}_d^n$ s.t. $b(w) = n-1$ and therefore the size of the produced linear combination is at most n. More precisely, the size is at most $n - b(w)$ if $n - b(w) \leq n-2$ and one if w is a corner.

The algorithm produces a linear combination of $(n-k)$-corners, that is, $w = \sum_j p_j r_j$. Since $p_j \geq 0$ and all $|r_j| = 1$, $\sum_j p_j = 1$ and we actually have a convex combination. ■

It is easy to implement the Mixture Decomposition Algorithm in $O(n^2)$ time: simply sort w and spend $O(n)$ per loop.

The batch algorithm for the set problem simply picks the best set in a greedy fashion.

Fact 1 *For any loss vector ℓ, the following corner has the smallest loss of any convex combination of corners in $A_d^n = B_d^n$: Greedily pick the component of minimum loss (d times).*

How can we use the above mixture decomposition and fact to construct an online algorithm? It seems too hard to maintain information about all $\binom{n}{n-k}$ corners of size $n-k$. However, the best corner is also the best convex combination of corners, that is, the best from the set A_{n-k}^n where each member of this set is given by $\binom{n}{n-k}$ coefficients. Luckily, this set of convex combinations equals the capped probability simplex B_{n-k}^n and it takes only n coefficients to specify a member in B_{n-k}^n. Therefore we can maintain a parameter vector in B_{n-k}^n and for any such capped vector w, Algorithm 2 decomposes it into a convex combination of at most n many $(n-k)$-corners. This means that any algorithm producing a hypothesis vector in B_{n-k}^n can be converted to an efficient algorithm that probabilistically chooses an $(n-k)$-corner.

Algorithm 3 spells out the details for this approach. The algorithm chooses a corner probabilistically and $(n-k)\,w^{t-1} \cdot \ell^t$ is the expected loss at trial t. After updating the weight vector w^{t-1} by multiplying with the factors $\exp(-\eta \ell_i^t)$ and renormalizing, the resulting weight vector $\widehat{w}^t$ might lie outside of the capped probability simplex B_{n-k}^n. We then use a Bregman projection with the relative

entropy as the divergence to project the intermediate vector $\widehat{w}^t$ back into B^n_{n-k}:

$$w^t = \operatorname*{argmin}_{w \in B^n_{n-k}} d(w, \widehat{w}^t).$$

This projection can be achieved as follows (Herbster and Warmuth, 2001): find the smallest i s.t. capping the largest i components to $\frac{1}{n-k}$ and rescaling the remaining $n-i$ weights to total weight $1 - \frac{i}{n-k}$ makes none of the rescaled weights go above $\frac{1}{n-k}$. The simplest algorithm starts with sorting the weights and then searches for i (see Algorithm 4). However, a linear time algorithm is given in Herbster and Warmuth (2001)[3] that recursively uses the median.

3. The linear time algorithm of Figure 3 of that paper bounds the weights from below. It is easy to adapt this algorithm to the case of bounding the weights from above (as needed here).

When $k = n-1$ and $d = n-k = 1$, B_1^n is the entire probability simplex. In this case the call to Algorithm 2 and the projection onto B_1^n are vacuous and we get the standard Hedge Algorithm (Algorithm 1) as a degenerate case. Note that $(n-k)\sum_{t=1}^T u \cdot \ell^t$ is the total compression loss of comparator vector u. When u is an $(n-k)$-corner, that is, the uniform distribution on a set of size $n-k$, then $(n-k)\sum_{t=1}^T u \cdot \ell^t$ is the total loss of this set.

Theorem 3 *For an arbitrary sequence of loss vectors $\ell^1, \ldots, \ell^T \in [0,1]^n$, the total expected compression loss of Algorithm 3 is bounded as follows:*

$$(n-k)\sum_{t=1}^T w^{t-1} \cdot \ell^t \leq \frac{\eta(n-k)\sum_{t=1}^T u \cdot \ell^t + (n-k)(d(u,w^0) - d(u,w^T))}{1-\exp(-\eta)},$$

for any learning rate $\eta > 0$ and comparison vector $u \in B_{n-k}^n$.

Proof The update for $\widehat{w}^t$ in Algorithm 3 is the same as update for w^t in Algorithm 1. Therefore we can use inequality (2):

$$d(u,w^{t-1}) - d(u,\widehat{w}^t) \geq -\eta\, u \cdot \ell^t + w^{t-1} \cdot \ell^t (1-\exp(-\eta)).$$

Since the relative entropy is a Bregman divergence (Bregman, 1967; Censor and Lent, 1981), the weight vector w^t is a Bregman projection of vector $\widehat{w}^t$ onto the convex set B_{n-k}^n. For such projections the Generalized Pythagorean Theorem holds (see, e.g., Herbster and Warmuth, 2001, for details):

$$d(u,\widehat{w}^t) \geq d(u,w^t) + d(w^t,\widehat{w}^t).$$

Since Bregman divergences are non-negative, we can drop the $d(w^t,\widehat{w}^t)$ term and get the following inequality:

$$d(u,\widehat{w}^t) - d(u,w^t) \geq 0, \text{ for } u \in B_{n-k}^n.$$

Adding this to the previous inequality we get:

$$d(u,w^{t-1}) - d(u,w^t) \geq -\eta\, u \cdot \ell^t + w^{t-1} \cdot \ell^t (1-\exp(-\eta)).$$

By summing over t, multiplying by $n-k$, and dividing by $1-\exp(-\eta)$, the bound follows. ■

It is easy to see that $(n-k)(d(u,w^0) - d(u,w^T)) \leq (n-k)\log\frac{n}{n-k}$ and this is bounded by $k\log\frac{n}{k}$ when $k \leq n/2$. By tuning η as in (3), we get the following regret bound:

$$\begin{aligned}&\text{(expected total compression loss of alg.) - (total compression loss of best } k\text{-subset)}\\ &\overset{k\leq n/2}{\leq} \sqrt{2(\text{total compression loss of best } k\text{-subset})\,k\log\frac{n}{k}} + k\log\frac{n}{k}. \qquad (4)\end{aligned}$$

The last inequality follows from the fact that $(n-k)\log\frac{n}{n-k} \leq k\log\frac{n}{k}$ when $k \leq n/2$. Note that the dependence on k in the last regret bound is essentially linear and dependence on n is logarithmic.

4.1 Alternate Algorithms for Learning as Well as the Best Subset

The question is whether projections onto the capped probability simplex are really needed. We could simply have one expert for each set of $n-k$ components and run Hedge on the $\binom{n}{n-k}$ set experts, where the loss of a set expert is always the sum of the $n-k$ component losses. The set expert $\{i_1,\ldots,i_{n-k}\}$ receives weight proportional to $\exp(-\sum_{j=1}^{n-k}\ell_{i_j}^{<t}) = \prod_{j=1}^{n-k}\exp(-\ell_{i_j}^{<t})$, where $\ell_q^{<t} = \sum_{p=1}^{t}\ell_q^p$. These product weights can be maintained implicitly: keep one weight per component where the ith component receives weight $\exp(-\ell_i^{<t})$, and use dynamic programming for summing the produced weights over the $\binom{n}{n-k}$ sets and for choosing a random set expert based on the product weights. See, for example, Takimoto and Warmuth (2003) for this type of method. While this dynamic programming algorithm can be made reasonably efficient ($O(n^2(n-k))$ per trial), the range of the losses of the set experts is now $[0,\mathbf{n}-\mathbf{k}]$ and this introduces factors of $\mathbf{n}-\mathbf{k}$ into the tuned regret bound:

$$\sqrt{2(\text{total compression loss of best } k\text{-subset})\,(\mathbf{n}-\mathbf{k})\,k\log\frac{n}{k}} + (\mathbf{n}-\mathbf{k})\,k\log\frac{n}{k}. \tag{5}$$

Curiously enough our new capping trick avoids these additional factors in the regret bound by using only the original n experts whose loss is in [0,1]. We do not know whether the improved regret bound (4) (i.e., no additional $n-k$ factors) also holds for the sketched dynamic programming algorithm. However, the following example shows that the two algorithms produce qualitatively different distributions on the sets.

Assume $n=3$ and $k=1$ and the update factors $\exp(-\eta\ell_i^{<t})$ for experts 1, 2 and 3 are proportional to 1, 2, and 4, respectively, which results in the normalized weight vector $(\frac{1}{7},\frac{2}{7},\frac{4}{7})$. Capping the weights at $\frac{1}{n-k}=\frac{1}{2}$ with Algorithm 4 produces the following vector which is then decomposed via Algorithm 2:

$$(\frac{1}{6},\frac{1}{3},\frac{1}{2}) \;= \frac{1}{3}\underbrace{(\frac{1}{2},0,\frac{1}{2})}_{\text{set }\{1,3\}} + \frac{2}{3}\underbrace{(0,\frac{1}{2},\frac{1}{2})}_{\text{set }\{2,3\}}. \tag{6}$$

On the other hand the product weights $\exp(-\eta\ell_i^{<t})*\exp(-\eta\ell_j^{<t})$ of the dynamic programming algorithm for the three sets $\{1,2\}$, $\{1,3\}$ and $\{2,3\}$ of size 2 are $1*2$, $1*4$, and $2*4$, respectively. That is, the dynamic programming algorithm gives (normalized) probability $\frac{1}{7}$, $\frac{2}{7}$ and $\frac{4}{7}$ to the three sets. Notice that Capped Hedge gives expert 3 probability 1 (since it is included in all corners of the decomposition (6)) and the dynamic programming algorithm gives expert 3 probability $\frac{6}{7}$, the total probability it has assigned to the two sets $\{1,3\}$ and $\{2,3\}$ that contain expert 3.

A second alternate is the Follow the Perturbed Leader (FPL) Algorithm (Kalai and Vempala, 2005). This algorithm adds random perturbations to the losses of the individual experts and then selects the set of minimum perturbed loss as its hypothesis. The algorithm is very efficient since it only has to find the set with minimum perturbed loss. However its regret bound has additional factors in addition to the $\mathbf{n}-\mathbf{k}$ factors appearing in the above bound (5) for the dynamic programming algorithm. For the original Randomized Hedge setting with just n experts (Section 3), a distribution of perturbations was found for which FPL simulates the Hedge exactly (Kalai, 2005; Kuzmin and Warmuth, 2005) and therefore the additional factors can be avoided. However we don't know whether there is a distribution of additive perturbations for which FPL simulates Hedge with set experts.

5. Uncentered Online PCA

We create an online PCA algorithm by lifting our new algorithm for sets of experts based on capped weight vector to the matrix case. Now *matrix corners* are density matrices[4] with d eigenvalues equal to $\frac{1}{d}$ and the rest are 0. Such matrix corners are just rank d projection matrices scaled by $\frac{1}{d}$. (Notice that the number of matrix corners is uncountably infinite.) We define the set $\mathcal{A}_d^n$ as the convex hull of all matrix corners. The maximum eigenvalue of a convex combination of symmetric matrices is at most as large as the maximum eigenvalue of any of the individual matrices (see, e.g., Bhatia, 1997, Corollary III.2.2). Therefore each convex combination of corners is a density matrix whose eigenvalues are bounded by $\frac{1}{d}$ and $\mathcal{A}_d^n \subseteq \mathcal{B}_d^n$, where $\mathcal{B}_d^n$ consists of all density matrices whose maximum eigenvalue is at most $\frac{1}{d}$. Assume we have some density matrix $W \in \mathcal{B}_d^n$ with eigendecomposition $\mathcal{W}\,\mathrm{diag}(\omega)\mathcal{W}^\top$. Algorithm 2 can be applied to the vector of eigenvalues ω of this density matrix. The algorithm decomposes ω into at most n diagonal corners r_j: $\omega = \sum_j p_j r_j$. This convex combination can be turned into a convex combination of matrix corners that decomposes the density matrix: $W = \sum_j p_j \mathcal{W}\,\mathrm{diag}(r_j)\mathcal{W}^\top$. It follows that $\mathcal{A}_d^n = \mathcal{B}_d^n$, as in the diagonal case.

As discussed before, losses can always be viewed in two different ways: the loss of the algorithm at trial t is the compression loss of the chosen projection matrix P^{t-1} or the loss of the complementary subspace $I - P^{t-1}$, that is,

$$\|\underbrace{P^{t-1}}_{\text{rank } k} x^t - x^t\|_2^2 = \mathrm{tr}(\underbrace{(I - P^{t-1})}_{\text{rank } n-k} x^t (x^t)^\top).$$

Our online PCA Algorithm 5 has uncertainty about which subspace of rank $n-k$ is best and it represents this uncertainty by a density matrix $W^{t-1} \in \mathcal{A}_{n-k}^n$, that is, a mixture of $(n-k)$-dimensional matrix corners. The algorithm efficiently samples a subspace of rank $n-k$ from this mixture and uses the complementary subspace P^{t-1} of rank k for compression. The expected compression loss of algorithm will be $(n-k)\mathrm{tr}(W^{t-1}xx^\top)$.

The following lemma shows how to pick the best matrix corner. When $S = \sum_{t=1}^T x^t (x^t)^\top$, then this lemma justifies the choice of the batch PCA algorithm.

Theorem 4 *For any symmetric matrix S, $\min_{W \in \mathcal{B}_d^n} \mathrm{tr}(WS)$ attains its minimum at the matrix corner formed by choosing d orthogonal eigenvectors of S of minimum eigenvalue.*

Proof Let $\lambda^\downarrow(W)$ denote the vector of eigenvalues of W in descending order and let $\lambda^\uparrow(S)$ be the same vector of S but in ascending order. Since both matrices are symmetric, $\mathrm{tr}(WS) \geq \lambda^\downarrow(W) \cdot \lambda^\uparrow(S)$ (Marshall and Olkin 1979, Fact H.1.h of Chapter 9, we will sketch a proof below). Since $\lambda^\downarrow(W) \in B_d^n$, the dot product is minimized and the inequality is tight when W is a d-corner (on the n-dimensional probability simplex) corresponding to the d smallest eigenvalues of S. Also the greedy algorithm finds the solution (see Fact 1 of this paper).

For the sake of completeness, we will sketch a proof of the inequality $\mathrm{tr}(WS) \geq \lambda^\downarrow(W) \cdot \lambda^\uparrow(S)$. We begin by rewriting the trace using an eigendecomposition of both matrices:

$$\mathrm{tr}(WS) = \mathrm{tr}(\sum_i \omega_i w_i w_i^\top \sum_j \sigma_j s_j s_j^\top) = \sum_{i,j} \omega_i \sigma_j \underbrace{(w_i \cdot s_j)^2}_{:=M_{i,j}}.$$

4. Density matrix is a symmetric positive definite matrix of trace 1, that is, they are symmetric matrices whose eigenvalues form a probability vector

The matrix M is *doubly stochastic*, that is, its entries are nonnegative and its rows and columns sum to 1. By Birkhoff's Theorem (see, e.g., Bhatia, 1997), such matrices are the convex combinations of permutations matrices (matrices with a single one in each row and column). Therefore the minimum of this linear function occurs at a permutation, and by a swapping argument one can show that the permutation which minimizes the linear function is the one that matches the ith smallest eigenvalue of W with the $(n-i)$th largest eigenvalue of S. ■

We obtain our algorithm for online PCA (Algorithm 5) by lifting Algorithm 3 for set experts to the matrix setting. The exponential factors used in the updates of the expert setting are replaced by the corresponding matrix version which employs the matrix exponential and matrix logarithm (Warmuth and Kuzmin, 2006a).[5] For any symmetric matrix A with eigendecomposition $\sum_{i=1}^{n} \alpha_i a_i a_i^\top$, the matrix exponential $\mathbf{exp}(A)$ is defined as the symmetric matrix $\sum_{i=1}^{n} \exp(\alpha_i) a_i a_i^\top$. Observe that the matrix exponential $\exp(A)$ (and analogously the matrix logarithm $\mathbf{log}(A)$ for symmetric positive definite A) affects only the eigenvalues and not the eigenvectors of A.

The following theorem shows that for the Bregman projection we can keep the eigensystem fixed. Here the quantum relative entropy $\Delta(U,W) = \mathrm{tr}(U(\mathbf{log}\,U - \mathbf{log}\,W))$ is used as the Bregman divergence.

Theorem 5 *Projecting a density matrix onto $\mathcal{B}_d^n$ w.r.t. the quantum relative entropy is equivalent to projecting the vector of eigenvalues w.r.t. the "normal" relative entropy: If W has the eigendecomposition $\mathcal{W}\,\mathrm{diag}(\omega)\,\mathcal{W}^\top$, then*

$$\operatorname*{argmin}_{U \in \mathcal{B}_d^n} \Delta(U,W) \;=\; \mathcal{W} u^* \mathcal{W}^\top, \text{ where } u^* = \operatorname*{argmin}_{u \in B_d^n} d(u,\omega).$$

Proof The quantum relative entropy can be rewritten as follows:

$$\Delta(U,W) = \mathrm{tr}(U\,\mathbf{log}\,U) - \mathrm{tr}(U\,\mathbf{log}\,W) = \lambda(U)\cdot\log(\lambda(U)) - \mathrm{tr}(U\,\mathbf{log}\,W),$$

where $\lambda(U)$ denotes the vector of eigenvalues of U and log is the componentwise logarithm of a vector. For any symmetric matrices S and T, $\mathrm{tr}(ST) \le \lambda^{\downarrow}(S)\cdot\lambda^{\downarrow}(T)$ (Marshall and Olkin 1979, Fact H.1.g of Chapter 9; also see proof sketch of a similar fact given in previous theorem). This implies that

$$\Delta(U,W) \ge \lambda(U)\cdot\log(\lambda(U)) - \lambda^{\downarrow}(U)\cdot\lambda^{\downarrow}(\mathbf{log}(W)) = \lambda(U)\cdot\log(\lambda(U)) - \lambda^{\downarrow}(U)\cdot\log\lambda^{\downarrow}(W).$$

Therefore $\min_{U \in \mathcal{B}_d^n} \Delta(U,W) \ge \min_{u \in B_d^n} d(u,\omega)$, and if u^* minimizes the r.h.s. then $\mathcal{W}\,\mathrm{diag}(u^*)\,\mathcal{W}^\top$ minimizes the l.h.s. because $\Delta(\mathcal{W}\,\mathrm{diag}(u^*)\,\mathcal{W}, W) = d(u^*,\omega)$. ■

The lemma means that the projection of a density matrix onto $\mathcal{B}_{n-k}^n$ is achieved by applying Algorithm 4 to the vector of eigenvalues of the density matrix.

We are now ready to prove a worst-case loss bound for Algorithm 5 for the uncentered case of online PCA. Note that the expected loss in trial t of this algorithm is $(n-k)\mathrm{tr}(W^{t-1}x^t(x^t)^\top)$. When U is a matrix corner then $(n-k)\sum_{t=1}^{T}\mathrm{tr}(Ux^t(x^t)^\top)$ is the total loss of the corresponding subspace.

5. This update step is a special case of the Matrix Exponentiated Gradient update for the the linear loss $\mathrm{tr}(Wx^t(x^t)^\top)$ (Tsuda et al., 2005).

Algorithm 5 Uncentered online PCA algorithm

  Incur compression loss $\|x^t - P^{t-1}x^t\|_2^2 = \mathrm{tr}((I - P^{t-1})\,x^t(x^t)^\top)$
    and expected compression loss $(n-k)\mathrm{tr}(W^{t-1}x^t(x^t)^\top)$
  Update: $\widehat{W}^t = \dfrac{\mathbf{exp}(\mathbf{log}\,W^{t-1} - \eta\,x^t(x^t)^\top)}{\mathrm{tr}(\mathbf{exp}(\mathbf{log}\,W^{t-1} - \eta\,x^t(x^t)^\top))}$
    $W^t = \mathrm{cap}_{n-k}(\widehat{W}^t)$,
      where $\mathrm{cap}_{n-k}(A)$ applies Algorithm 4 to the vector of eigenvalues of A
end for

Theorem 6 *For an arbitrary sequence of data instances $x^1, \ldots, x^T$ of 2-norm at most one, the total expected compression loss of the algorithm is bounded as follows:*

$$\sum_{t=1}^{T}(n-k)\mathrm{tr}(W^{t-1}x^t(x^t)^\top) \leq \frac{\eta(n-k)\sum_{t=1}^{T}\mathrm{tr}(Ux^t(x^t)^\top) + (n-k)(\Delta(U,W^0) - \Delta(U,W^T))}{1-\exp(-\eta)},$$

for any learning rate $\eta > 0$ and comparator density matrix $U \in \mathcal{B}^n_{n-k}$.

Proof The update for $\widehat{W}^t$ is a density matrix version of the Hedge update which was used for variance minimization along a single direction (i.e., $k = n-1$) in Warmuth and Kuzmin (2006a). The basic inequality (2) for that update becomes:

$$\Delta(U,W^{t-1}) - \Delta(U,\widehat{W}^t) \geq -\eta\,\mathrm{tr}(Ux^t(x^t)^\top) + \mathrm{tr}(W^{t-1}x^t(x^t)^\top)(1-\exp(-\eta)).$$

As in the proof of Theorem 3 of this paper, the Generalized Pythagorean Theorem applies and dropping one term we get the following inequality:

$$\Delta(U,\widehat{W}^t) - \Delta(U,W^t) \geq 0, \text{ for } U \in \mathcal{B}^n_{n-k}.$$

Adding this to the previous inequality we get:

$$\Delta(U,W^{t-1}) - \Delta(U,W^t) \geq -\eta\,\mathrm{tr}(Ux^t(x^t)^\top) + \mathrm{tr}(W^{t-1}x^t(x^t)^\top)(1-\exp(-\eta)).$$

By summing over t, multiplying by $n-k$, and dividing by $1-\exp(-\eta)$, the bound follows. ■

It is easy to see that $(n-k)(\Delta(U,W^0)-\Delta(U,W^T)) \leq (n-k)\log\frac{n}{n-k}$ and this is bounded by $k\log\frac{n}{k}$ when $k \leq n/2$. By tuning η as in (3), we can get regret bounds of the form:

$$\begin{aligned}&\text{(expected total compression loss of alg.) - (total compression loss of best } k\text{-subspace)}\\ &\overset{k\leq n/2}{\leq} \sqrt{2(\text{total compression loss of best } k\text{-subspace})\,k\log\frac{n}{k}} + k\log\frac{n}{k}. \end{aligned} \tag{7}$$

Let us complete this section by discussing the minimal assumptions on the loss functions needed for proving the regret bounds obtained so far. Recall that in the regret bounds for experts as well as set experts we always assumed that the loss vector ℓ^t received at trial t lies in $[0,1]^n$. In the case of uncentered PCA, the loss at trial t is specified by an instance vector x^t that has 2-norm at most one. In other words, the single eigenvalue of the instance matrix $x^t(x^t)^\top$ must be bounded by 1. However, it is easy to see that the regret bound of the previous theorem still holds if at trial t the instance matrix $x^t(x^t)^\top$ is replaced by any symmetric instance matrix S^t whose vector of eigenvalues lies in $[0,1]^n$.

5.1 Alternate Algorithms for Uncentered Online PCA

We conjecture that the following algorithm has the regret bound (7) as well: run the dynamic programming algorithm for the set experts sketched in Section 4 on the vector of eigenvalues of the current covariance matrix. The produced set for size k is converted to a projection matrix of rank k by replacing it with the k outer products of the corresponding eigenvectors. We are not elaborating on this approach since the algorithm inherits the additional $n-k$ factors contained in the regret bound (5) for set experts. If these factors in the regret bound for set experts can be eliminated then this approach might lead to a competitive algorithm.

Versions of FPL might also be used to design an online PCA algorithm for compressing with a k dimensional subspace. Such an algorithm would be particularly useful if the same regret bound (7) could be proven for it as for our online PCA algorithm. The question is whether there exists a distribution of additive perturbations of the covariance matrix for which the loss of the subspace formed by the eigenvectors of the $n-k$ smallest eigenvalues simulates a matrix version of Hedge on subspaces of rank $n-k$ and whether this algorithm does not have the $n-k$ factors in its bound. Note that extracting the subspace formed by the eigenvectors of the $n-k$ smallest (or k largest) eigenvalues might be more efficient than performing a full eigendecomposition.

6. Centered Online PCA

In this section we extend our online PCA algorithm to also estimate the data center online. Under the extended protocol, the algorithm needs to produce both a rank k projection matrix P^{t-1} and a data center m^{t-1} at trial t. It then receives a data point x^t and incurs compression loss $\|(x^t-m^{t-1})-P^{t-1}(x^t-m^{t-1})\|_2^2$. As for uncentered online PCA, we will use a capped density matrix W^{t-1} to represent the algorithm's uncertainty about the hidden subspace.

6.1 Motivation of the Updates

We begin by motivating the updates of all the algorithms analyzed so far. We follow Kivinen and Warmuth (1997) and motivate the updates by minimizing a tradeoff between a parameter divergence and a loss function. Here we also have the linear capping constraints. Since our loss is linear, the

tradeoff minimization problem can be solved exactly instead of using approximations as is done in Kivinen and Warmuth (1997) for non-linear losses. Updates motivated by exact solution of tradeoff minimization problems involving non-linear loss functions are sometimes called *implicit* updates since they typically do not have a closed form (Kivinen et al., 2005). Even though the loss function used here is linear, the additional capping constraints are responsible for the fact that there is again no closed form for the updates. Nevertheless our algorithms are always able to compute the optimal solutions of the tradeoff minimization problems defining the updates.

We begin our discussion of motivations of updates with the set expert case. Consider the following two updates:

$$w^t = \text{arginf}_{w \in B^n_{n-k}} \left(\eta^{-1} d(w, w^{t-1}) + w \cdot \ell^t \right), \tag{8}$$

$$w^t = \text{arginf}_{w \in B^n_{n-k}} \left(\eta^{-1} d(w, w^0) + \sum_{q=1}^{t} w \cdot \ell^q \right). \tag{9}$$

In the motivations of all our updates, the divergences are always versions of relative entropies which are special cases of Bregman divergences. Here d denotes the standard relative entropy between probability vectors. The first update above trades off the divergence to the last parameter vector with the loss in the last trial. The second update trades off the divergence to the initial parameter with the total loss in all past trials. In both cases the minimization is over B^n_{n-k} which as we recall is the n-dimensional probability simplex with the components capped at $\frac{1}{n-k}$. One can show that the combined two update steps of the Capped Hedge Algorithm 3 coincide with the first update (8) above. The solution to (8) has the following exponential form:

$$w^t_i = \frac{w^{t-1}_i \exp(-\eta \ell^t_i + \gamma^t_i)}{\sum_{j=1}^n w^{t-1}_j \exp(-\eta \ell^t_j + \gamma^t_j)},$$

where γ^t_i is the Lagrangian coefficient that enforces the cap on the weight w^t_i. The non-negativity constraints don't have to be explicitly enforced because the relative entropy is undefined on vectors with negative elements and thus acts as a barrier function. Because of the capping constraints, the two updates (8) and (9) given above are typically not the same. However when $k = n-1$, then $B^n_{n-k} = B^n_1$ is the entire probability simplex and the γ^t_i coefficients disappear. In that case both updates agree and motivate the update of vanilla Hedge (Algorithm 1) (See Kivinen and Warmuth, 1999).

Furthermore, the above update (8) can be split into two steps as is done in Algorithm 3: the first update step uses exponential factors to update the probability vector and the second step performs a relative entropy projection of the intermediate vector onto the capped probability simplex. Here we give the sequence of two optimization problems that motivate the two update steps of Algorithm 3:

$$\widehat{w}^t = \text{arginf}_{w_i \geq 0,\, \sum w_i = 1} \left(\eta^{-1} d(w, w^{t-1}) + w \cdot \ell^t \right),$$

$$w_t = \text{arginf}_{w \in B^n_{n-k}} d(w, \widehat{w}^t).$$

For the motivation of the uncentered online PCA update (Algorithm 5), we replace the relative entropy $d(w, w^{t-1})$ between probability vectors in (8) by the Quantum Relative Entropy $\Delta(W, W^{t-1}) = \text{tr}(W(\mathbf{log}\, W - \mathbf{log}\, W^{t-1}))$ between density matrices. Furthermore, we change the loss function from a dot product to a trace:

$$W^t = \text{arginf}_{W \in \mathcal{D}^n_{n-k}} \left(\eta^{-1} \Delta(W, W^{t-1}) + \text{tr}(W x^t (x^t)^\top) \right).$$

Recall that $\mathcal{B}^n_{n-k}$ is the set of all $n \times n$ density matrices whose maximum eigenvalue is at most $\frac{1}{n-k}$. Note that in Algorithm 5, this update is again split into two steps.

The case of centered online PCA, which we will address now, is the most interesting because now we have two parameters. We use the following update which uses a divergence to the initial parameters (as in (9)):

$$(W^t, m^t) \;=\; \operatorname*{arginf}_{W \in \mathcal{B}^n_{n-k},\, m \in \mathbb{R}^n} \quad \Big(\eta^{-1}\Delta(W, W^0) + \widetilde{\eta}^{-1}(m-m^0)^\top W (m-m^0)\Big) + \sum_{q=1}^{t} \operatorname{tr}(W(x^q-m)(x^q-m)^\top). \tag{10}$$

Notice that we have two learning rates: η for the density matrix parameter and $\widetilde{\eta}$ for the center parameter. The above update may be viewed as a maximum a posteriori estimator since the divergences act as priors or initial examples and the inverse learning rates that multiply the divergences determine the importance of the priors (See, e.g., Azoury and Warmuth, 2001, for a discussion). When $\eta^{-1} = \widetilde{\eta}^{-1} = 0$, then there are no priors and the update become the Maximum Likelihood estimator or Follow the Leader (FL) Algorithm. If $\widetilde{\eta}^{-1} \to \infty$, then m^t is clamped to the fixed center m^0. If further $m^0 = 0$, then the above motivation becomes a motivation for an uncentered update with a divergence to the initial density matrix W^0 (analogous to (9)). Similarly, when $\eta^{-1} \to \infty$, then W^t is clamped to the fixed density matrix W^0 and the resulting optimization problem motivates the Incremental Off-line Algorithm for Gaussian density estimation with a fixed covariance matrix (Azoury and Warmuth, 2001).

As in Kuzmin and Warmuth (2007), we analyze this update for centered PCA by rewriting its optimization problem (10) as the dual maximization problem. The constraint $W \in \mathcal{B}^n_{n-k}$ in equation (10) is equivalent to having constraints $\operatorname{tr}(W) = 1$ and $W \preceq \frac{1}{n-k} I$. The constraint $W \succeq 0$ is automatically enforced since the quantum relative entropy acts as a barrier. With this in mind, we write down the Lagrangian function, where $U^t(W, m)$ is the objective function of our optimization problem (10) that includes data points from t trials, δ is the dual variable for the trace constraint and the symmetric positive definite matrix Γ is the dual variable for the capping constraint:

$$L^t(W, m, \Gamma, \delta) \;=\; U^t(W, m) + \delta(\operatorname{tr}(W) - 1) + \operatorname{tr}\Big((W - \frac{1}{n-k} I)\Gamma\Big).$$

The optimization over m is unconstrained, giving the solution for m^t:

$$m^t = \frac{\widetilde{\eta}^{-1} m^0 + \sum_{q=1}^t x^q}{\widetilde{\eta}^{-1} + t}. \tag{11}$$

This is essentially the normal mean of an extended sample, where we added $\widetilde{\eta}^{-1}$ copies of m^0 to $x^1, \ldots, x^t$. To write down the form of the solution for W^t compactly we will introduce the following matrix:

$$C^t = \widetilde{\eta}^{-1}(m^0 - m^t)(m^0 - m^t)^\top + \sum_{q=1}^{t} (x^q - m^t)(x^q - m^t)^\top. \tag{12}$$

This can be seen as the extended sample covariance matrix where we added $\widetilde{\eta}^{-1}$ copies of instance m^0.

Setting the derivatives to zero and solving (see Tsuda et al. 2005 for similar derivation), we obtain the following form of W^t in terms of the dual variables $\delta' = \eta\delta$ and Γ:

$$W^t(\delta', \Gamma) = \mathbf{exp}(\mathbf{log} W^0 - \eta C^t - \delta' I - \eta\Gamma).$$

The constraint $\mathrm{tr}(W) = 1$ is enforced by choosing $\delta' = \log \mathrm{tr}(\mathbf{exp}(\mathbf{log} W_1 - \eta C^t - \Gamma))$. By substituting $W^t(\delta', \Gamma)$ and the formula for m^t into the Lagrangian L^t and simplifying, we obtain the following dual problem:

$$\max_{\Gamma \succeq 0} \widehat{L}^t(\Gamma), \text{ where } \widehat{L}^t(\Gamma) = -\eta^{-1} \log \mathrm{tr}(\mathbf{exp}(\mathbf{log} W^0 - \eta C^t - \eta\Gamma)) - \frac{\mathrm{tr}(\Gamma)}{n-k}. \tag{13}$$

Let Γ^t be the optimal solution of the dual problem above and let $\mathrm{cap}_d(W)$ be the density matrix obtained when the capping Algorithm 4 is applied to the vector of eigenvalues of W and capping parameter d. This lets us express W^t as:

$$W^t = \frac{\mathbf{exp}(\mathbf{log} W^0 - \eta C^t - \eta\Gamma^t)}{\mathrm{tr}(\mathbf{exp}(\mathbf{log} W^0 - \eta C^t - \eta\Gamma^t))} = \mathrm{cap}_{n-k}\Big(\frac{\mathbf{exp}(\mathbf{log} W^0 - \eta C^t)}{\mathrm{tr}(\mathbf{exp}(\mathbf{log} W^0 - \eta C^t))}\Big). \tag{14}$$

For the analysis we express m^t and C^t as online updates:

Lemma 7 *The estimates of mean and covariance can be updated as follows:*

$$m^t = \frac{(\widetilde{\eta}^{-1} + t - 1)m^{t-1} + x^t}{\widetilde{\eta}^{-1} + t} = m^{t-1} - \frac{1}{\widetilde{\eta}^{-1} + t}(m^{t-1} - x^t),$$

$$C^t = C^{t-1} + \frac{\widetilde{\eta}^{-1} + t - 1}{\widetilde{\eta}^{-1} + t}(x^t - m^{t-1})(x^t - m^{t-1})^\top$$

Proof The update rule for m^t is easy to verify. For the update of C^t, we start by expanding the expression (12) for C^{t-1}:

$$\begin{aligned} C^{t-1} &= \widetilde{\eta}^{-1}(m^0(m^0)^\top - m^0(m^{t-1})^\top - m^{t-1}(m^0)^\top + m^{t-1}(m^{t-1})^\top) \\ &\quad + \sum_{q=1}^{t-1}(m^{t-1}(m^{t-1})^\top - x^q(m^{t-1})^\top - m^{t-1}(x^q)^\top + x^q(x^q)^\top) \\ &= \sum_{q=1}^{t-1} x^q(x^q)^\top + (\widetilde{\eta}^{-1} + t - 1)m^{t-1}(m^{t-1})^\top \\ &\quad - (\widetilde{\eta}^{-1}m^0 + \sum_{q=1}^{t-1} x^q)(m^{t-1})^\top - m^{t-1}(\widetilde{\eta}^{-1}m^0 + \sum_{q=1}^{t-1} x^q)^\top + \widetilde{\eta}^{-1}m^0(m^0)^\top. \end{aligned}$$

By substituting

$$\widetilde{\eta}^{-1}m^0 + \sum_{q=1}^{t-1} x^q = (\widetilde{\eta}^{-1} + t - 1)m^{t-1}$$

we get the following:

$$C^{t-1} = \sum_{q=1}^{t-1} x^q(x^q)^\top - (\widetilde{\eta}^{-1} + t - 1)m^{t-1}(m^{t-1})^\top + \widetilde{\eta}^{-1}m^0(m^0)^\top.$$

Algorithm 6 Centered Online PCA Algorithm

input: $1 \leq k < n$ and an initial offset m^0, initial density matrix $W^0 \in \mathcal{B}^n_{n-k}$, $C^0 = 0$
for $t = 1$ to T **do**
Perform eigendecomposition $W^{t-1} = \mathcal{W}\omega\mathcal{W}^\top$
Decompose ω into a convex combination $\sum_j p_j r_j$ of at most n corners r_j
by applying Algorithm 2 with $d = n-k$
Draw corner $r = r_j$ with probability p_j
Form a matrix corner $R = \mathcal{W}\,\mathrm{diag}(r)\,\mathcal{W}^\top$
Form a rank k projection matrix $P^{t-1} = I - (n-k)R$
Receive data instance vector x^t
Incur compression loss
$\|(x^t - m^{t-1}) - P^{t-1}(x^t - m^{t-1})\|_2^2 = \mathrm{tr}((I - P^{t-1})(x^t - m^{t-1})(x^t - m^{t-1})^\top)$
and expected compression loss $(n-k)\mathrm{tr}(W^{t-1}(x^t - m^{t-1})(x^t - m^{t-1})^\top)$
Update:

$$m^t = m^{t-1} - \frac{1}{\widetilde{\eta}^{-1} + t}(m^{t-1} - x^t) \tag{15}$$

$$C^t = C^{t-1} + \frac{\widetilde{\eta}^{-1} + t - 1}{\widetilde{\eta}^{-1} + t}(x^t - m^{t-1})(x^t - m^{t-1})^\top \tag{16}$$

$$\widehat{W}^t = \frac{\mathbf{exp}(\mathbf{log}\, W^0 - \eta C^t)}{\mathrm{tr}(\mathbf{exp}(\mathbf{log}\, W^0 - \eta C^t))}$$

$$W^t = \mathrm{cap}_{n-k}(\widehat{W}^t),$$

where $\mathrm{cap}_{n-k}(A)$ applies Algorithm 4 to the vector of eigenvalues of A
end for

Now the update for C can be written as:

$$C^t = C^{t-1} + (\widetilde{\eta}^{-1} + t - 1)m^{t-1}(m^{t-1})^\top + x^t(x^t)^\top - (\widetilde{\eta}^{-1} + t)m^t(m^t)^\top.$$

Substituting the left update for m^t from the statement of the lemma and simplifying gives the desired online update for C^t. ■

: All the steps for the Centered Online PCA Algorithm are summarized as Algorithm 6. We already reasoned that the capping and decomposition steps are $O(n^2)$. The remaining expensive step is maintaining the eigendecomposition of the covariance matrix for computing the matrix exponential. Using standard rank one update techniques for the eigendecomposition of a symmetric matrix, this costs $O(n^2)$ per trial (see, e.g., Gu and Eisenstat, 1994).

6.2 Regret Bound for Centered PCA

The following theorem proves a regret bound for our Centered Online PCA Algorithm.

Theorem 8 *For any data sequence $x^1,\ldots,x^T$, initial center value m^0 such that $\|x^t - m^0\|_2 \le \frac{1}{2}$, any density matrix $U \in \mathcal{B}^n_{n-k}$ and any center vector m, the following bound holds:*

$$comp_{alg} \le \frac{\eta\, comp_{U,m} + \Delta(U,W^0) + \eta\widetilde{\eta}^{-1}(m-m^0)^\top U(m-m^0)}{1-\exp(-\eta)} + 1 + \log\big(1+\frac{T-1}{\widetilde{\eta}^{-1}+1}\big)$$

where

$$comp_{alg} = \sum_{i=1}^{T} \mathrm{tr}(W^{t-1}(x^t - m^{t-1})(x^t - m^{t-1})^\top)$$

is the overall expected compression loss of the centered online PCA Algorithm 6 and

$$comp_{U,m} = \sum_{i=1}^{T} \mathrm{tr}(U(x^t - m)(x^t - m)^\top)$$

is the total compression loss of comparison parameters (U,m).

Proof There are two main proof methods for the expert setting. The first is based on Bregman projections and was used so far in this paper. The second uses the value of the optimization problem defining the update as a potential and then shows that the drop of this value (Kivinen and Warmuth, 1999; Cesa-Bianchiand and Lugosi, 2006) is lower bounded by a constant times the per trial loss of the algorithm. Here we use a refinement of the second method that expresses the value of the optimization problem in terms of its dual. These variations of the second method were developed in the context of boosting (Warmuth et al., 2006; Liao, 2007) and in the conference paper (Kuzmin and Warmuth, 2007) where we enhanced the Uncentered Online PCA Algorithm of this paper with a kernel.

For our problem the value[6] of optimization problem (10) is $v^t = U^t(W^t, m^t)$ and this equals the value of the dual problem $\widehat{L}^t(\Gamma^t)$ where Γ^t maximizes the dual problem (13).

We want to establish the following key inequality:

$$v^t - v^{t-1} \;\ge\; \eta^{-1}(1-e^{-\eta})\Big(\mathrm{tr}(W^{t-1}(x^t - m^{t-1})(x^t - m^{t-1})^\top) - \frac{1}{\widetilde{\eta}^{-1}+t}\Big). \tag{17}$$

Since Γ^t optimizes the dual function $\widehat{L}^t$ and Γ^{t-1} is a non-optimal choice, $\widehat{L}^t(\Gamma^t) \ge \widehat{L}^t(\Gamma^{t-1})$ and therefore

$$v^t - v^{t-1} \;=\; \widehat{L}^t(\Gamma^t) - \widehat{L}^{t-1}(\Gamma^{t-1}) \;\ge\; \widehat{L}^t(\Gamma^{t-1}) - \widehat{L}^{t-1}(\Gamma^{t-1}) \tag{18}$$

Substituting $\widehat{L}^t$ and $\widehat{L}^{t-1}$ from (13) into the right hand side of this inequality gives the following:

$$\begin{aligned}
&\widehat{L}^t(\Gamma^{t-1}) - \widehat{L}^{t-1}(\Gamma^{t-1}) \\
&\quad = -\eta^{-1}\log\mathrm{tr}(\mathbf{exp}(\mathbf{log}\,W^0 - \eta C^t - \eta\Gamma^{t-1})) + \eta^{-1}\log\mathrm{tr}(\mathbf{exp}(\mathbf{log}\,W^0 - \eta C^{t-1} - \eta\Gamma^{t-1})) \\
&\quad = -\eta^{-1}\log\mathrm{tr}(\mathbf{exp}(\mathbf{log}\,W^0 - \eta C^t - \eta\Gamma^{t-1} - \log\mathrm{tr}(\mathbf{exp}(\mathbf{log}\,W^0 - \eta C^{t-1} - \eta\Gamma^{t-1}))).
\end{aligned}$$

Now we expand C^t and use the covariance matrix update from Lemma 7:

$$\begin{aligned}
\widehat{L}^t(\Gamma^{t-1}) - \widehat{L}^{t-1}(\Gamma^{t-1}) = -\eta^{-1}\log\mathrm{tr}(\mathbf{exp}(&\log W^0 - \eta C^{t-1} - \eta\Gamma^{t-1} \\
&- \log\mathrm{tr}(\mathbf{exp}(\mathbf{log}\,W^0 - \eta C^{t-1} - \eta\Gamma^{t-1})) - \eta\frac{\widetilde{\eta}^{-1}+t-1}{\widetilde{\eta}^{-1}+t}(x^t - m^{t-1})(x^t - m^{t-1})^\top)).
\end{aligned}$$

6. Optimization problem (10) minimizes a convex function subject to linear cone constraint. Since this problem has a strictly feasible solution, strong duality is implied by a generalized Slater condition (Boyd and Vandenberghe, 2004).

The first four terms under the matrix exponential form $\log W^{t-1}$, which can be seen from the first expression for W^{t-1} from (14):

$$\widehat{L}^t(\Gamma^{t-1}) - \widehat{L}^{t-1}(\Gamma^{t-1}) = -\eta^{-1}\log \mathrm{tr}\Big(\mathbf{exp}(\mathbf{log}\, W^{t-1} - \eta\frac{\widetilde{\eta}^{-1}+t-1}{\widetilde{\eta}^{-1}+t}(x^t-m^{t-1})(x^t-m^{t-1})^\top)\Big).$$

Going back to (18) we get the inequality:

$$v^t - v^{t-1} \geq -\eta^{-1}\log \mathrm{tr}\Big(\mathbf{exp}(\mathbf{log}\, W^{t-1} - \eta\frac{\widetilde{\eta}^{-1}+t-1}{\widetilde{\eta}^{-1}+t}(x^t-m^{t-1})(x^t-m^{t-1})^\top)\Big).$$

This expression for the drop of the value is essentially the same expression that is normally bounded in the proof of online variance minimization algorithm in Warmuth and Kuzmin (2006a). Using those techniques (assumption in the theorem implies that that $\|x^t - m^{t-1}\|_2^2 \leq 1$ and all the necessary inequalities hold) we get the following inequality:

$$-\eta^{-1}\log \mathrm{tr}\Big(\mathbf{exp}(\mathbf{log}\, W^{t-1} - \eta\frac{\widetilde{\eta}^{-1}+t-1}{\widetilde{\eta}^{-1}+t}(x^t-m^{t-1})(x^t-m^{t-1})^\top)\Big) \geq \eta^{-1}\frac{\widetilde{\eta}^{-1}+t-1}{\widetilde{\eta}^{-1}+t}(1-e^{-\eta})\mathrm{tr}(W^{t-1}(x^t-m^{t-1})(x^t-m^{t-1})^\top).$$

W^{t-1} is a density matrix and its eigenvalues are at most 1. And by assumption, norm of $x^t - m^{t-1}$ is at most 1. Therefore, the loss $\mathrm{tr}(W^{t-1}(x^t-m^{t-1})(x^t-m^{t-1})^\top)$ is also at most 1. We split the factor in front of the loss as $\frac{\widetilde{\eta}^{-1}+t-1}{\widetilde{\eta}^{-1}+t} = 1 - \frac{1}{\widetilde{\eta}^{-1}+t}$, upper bounding the loss by 1 for the second part and leaving it as is for the first. With this (17) is obtained.

Note that the trace in the inequality (17) is the loss of the algorithm at trial t. Summation over t and telescoping gives us:

$$v^T - v^0 \geq \eta^{-1}(1-e^{-\eta})\Big(\mathrm{comp}_{\mathrm{alg}} - \sum_{t=1}^{T}\frac{1}{\widetilde{\eta}^{-1}+t}\Big).$$

We consider the left side first: v^0 is equal to zero, and v^T is a minimum of optimization problem (10), thus we can make it bigger by substituting arbitrary non-optimal values U and m. Index T means the optimization problem is defined with respect to the entire data sequence, therefore the loss term becomes the loss of the comparator. On the right side we use the following bound on the sum of generalized harmonic series: $\sum_{t=1}^{T}\frac{1}{\widetilde{\eta}^{-1}+t} \leq 1 + \log\Big(1+\frac{T-1}{\widetilde{\eta}^{-1}+1}\Big)$. Overall, we get:

$$\eta^{-1}\Delta(U,W^0) + \widetilde{\eta}^{-1}(m-m^0)^\top U(m-m^0) + \mathrm{comp}_{U,m} \geq \eta^{-1}(1-e^{-\eta})\left(\mathrm{comp}_{\mathrm{alg}} - \Big(1+\log\big(1+\frac{T-1}{\widetilde{\eta}^{-1}+1}\big)\Big)\right).$$

Moving things over and dividing results in the bound of the theorem. ■

As discussed before, when $\eta^{-1} = \widetilde{\eta}^{-1} = 0$, then the algorithm becomes the FL Algorithm. When $\widetilde{\eta}^{-1} \to \infty$, then m^t is clamped to m^0, that is, the update for the center (11,15) becomes $m^t = m^0$ and

is vacuous. Also in that case the term $\eta\widetilde{\eta}^{-1}(m-m^0)^\top U(m-m^0)$ in the upper bound of Theorem 8 is infinity unless the comparison center m is m^0 as well. If $m^0=0$ in addition to $\widetilde{\eta}^{-1}\to\infty$, then we call this the *uncentered version of Algorithm 6*: this version simply ignores step (15) and in (16) uses $m^{t-1}=0$. Our original Algorithm 5 for uncentered PCA as well as the uncentered version of Algorithm 6 have the same regret bound[7] of Theorem 6. Recall however that the two algorithms were motivated differently: Algorithm 5 trades off divergence to the last parameter with the loss in the last trial, whereas Algorithm 6 trades off a divergence to the initial parameter matrix with the total loss in all past trials. If all constraints are equality constraints, then the two algorithms are the same. However, capping introduces inequality constraints and therefore the two algorithms are decidedly not the same. Both algorithm can behave quite differently experimentally (Section 8). The difference between the two algorithms will become important in the followup paper (Kuzmin and Warmuth, 2007), where we were only able to use a kernel with the algorithm that trades off a divergence to the initial parameter matrix with the total loss in all past trials.

Similarly, when $\eta^{-1}\to\infty$, then W^t is clamped to W^0 and the algorithm degenerates to a previously analyzed algorithm, the Incremental Off-line Algorithm for Gaussian density estimation with fixed covariance matrix (Azoury and Warmuth, 2001). For this restricted density estimation problem, improved regret bounds were proven for the Forward Algorithm which further shrinks the estimate of the mean towards the initial mean. So far we were not able to improve our regret bound for uncentered PCA using additional shrinkage towards the initial mean.

The statement of the theorem requires strong initial knowledge about the center of the data sequence we are about to observe: the condition of the theorem says that our data sequence has to be contained in a ball of radius $\frac{1}{2}$ around m^0. This can be relaxed by using $m^0=0$ and $\widetilde{\eta}^{-1}=0$, which corresponds to using standard empirical mean for m^t. Now it suffices to assume that data is contained in some ball, but we are not required to know where exactly that ball is. The appropriate assumption and the change to the bound are detailed in the following corollary.

Corollary 9 *For any data sequence $x^1,\ldots,x^T$ that can be covered by a ball of radius $\frac{1}{2}$, that is, $\|x^{t_1}-x^{t_2}\|_2\le 1$ and that also has the bound on the norm of instances $\|x^t\|_2\le R$, any density matrix $U\in\mathcal{B}^n_{n-k}$ and any center vector m, the total expected loss of centered online PCA Algorithm 6 being used with parameters $\widetilde{\eta}^{-1}=0$ and $m^0=0$ is bounded as follows:*

$$comp_{alg}\le\frac{\eta\, comp_{U,m}+\Delta(U,W^0)}{1-e^{-\eta}}+\log T+R^2,$$

Proof The ball assumption means that the empirical mean m^{t-1} and any element of the data sequence are not too far from each other: $\|m^{t-1}-x^t\|_2\le 1$. Thus we can still use the Inequality (17), for all trials but the first one, where we haven't seen any data points yet. Summing the drops of the value starting from $t=1$ we get:

$$v^T-v^1\ge\eta^{-1}(1-e^{-\eta})\left(\sum_{t=2}^{T}\mathrm{tr}(W^{t-1}(x^t-m^{t-1})(x^t-m^{t-1})^\top)-\sum_{t=2}^{T}\frac{1}{t}\right).$$

7. The remaining $+1$ is an artifact of our bound on the harmonic sum.

We now add the loss of the first trial into the sum and rearrange terms:

$$\overbrace{\sum_{t=1}^{T} \mathrm{tr}(W^{t-1}(x^t - m^{t-1})(x^t - m^{t-1})^\top)}^{\mathrm{comp}_{\mathrm{alg}}}$$
$$\leq \frac{\eta(v^T - \overbrace{v^1}^{\geq 0})}{1-e^{-\eta}} + \overbrace{\sum_{t=2}^{T} \frac{1}{t}}^{\leq \log T} + \overbrace{\mathrm{tr}(W^0(x^1 - m^0)(x^1 - m^0)^\top)}^{\leq R^2}.$$

Finally, from the definition of v^T it follows that $v^T \leq \eta^{-1}\Delta(U, W^0) + \mathrm{comp}_{U,m}$, for any comparator U and m, and this gives the bound of the theorem. ■

Tuning η as in (3), Corollary 9 gives the following regret bound for our centered online PCA Algorithm 6 (when $k \leq \frac{n}{2}$):

(expected total compression loss of alg.) - (total comp. loss of best centered k-subspace)
$$\leq \sqrt{2(\text{total comp. loss of best centered } k\text{-subspace})\, k \log \frac{n}{k}} + k \log \frac{n}{k} + R^2 + \log T.$$

6.3 Converting the Online PCA Algorithms to Batch PCA Algorithms

In the online learning community a number of conversion techniques have been developed that allow one to construct a hypothesis with good generalization bounds in the batch setting from the hypotheses produced by a run of the online learning algorithm over the given batch of examples.

For example, using the standard conversion techniques developed for the expert setting based on the leave-one-out loss (Cesa-Bianchi et al., 1997), we obtain algorithms with good expected regret bounds in the following model: The algorithm is given $T-1$ instances drawn from a fixed but unknown distribution and produces a k-dimensional subspace based on those instances; it then receives a new instance from the same distribution. We can bound the expected loss on the new instance (under the usual norm less than one assumption on instances):

(expected compression loss of alg.) - (expected compression loss best k-space)
$$= O\Big(\sqrt{\frac{(\text{expected compression loss of best } k\text{-subspace})\, k \log \frac{n}{k}}{T}} + \frac{k \log \frac{n}{k}}{T}\Big).$$

The expected loss of the algorithm is taken as expectation over both the internal randomization of the algorithm and fixed distribution over the instances. The expected loss of the best subspace just averages over the distribution of the instances. The best subspace itself will be determined by the covariance matrix of this distribution.

Additionally, there also exist very general conversion methods that allow us to state bounds that say that the generalization error will be big with small probability (Cesa-Bianchi and Gentile, 2005). These bounds are more complicated and therefore we don't state them here. The conversion algorithms however, are pretty simple: for example, one can use the average density matrix of all density matrices produced by the online algorithm while doing one pass through the batch of instances. Perhaps surprisingly, the generalization bounds for batch PCA obtained via the online-to-batch conversions are competitive with the best bounds for batch PCA that we are aware of Shawe-Taylor et al. (2005).

7. Lower Bounds

We first prove some lower bounds for the simplest online algorithm that just predicts with the model that has incurred minimum loss so far (the Follow the Leader (FL) Algorithm). After that we give a lower bound for uncentered PCA that shows that the algorithm presented in this paper is optimal in a very strong sense.

Our first lower bound is in the standard expert setting. We assume that there is a deterministic tie-breaking rule, because by adding small perturbations, ties can always be avoided in this construction. It is easy to see that the following adversary strategy forces FL to have loss n times larger than the loss of the best expert chosen in hindsight: in each trial have the expert chosen by FL incur one unit of loss. Note that the algorithm incurs loss one in each trial, whereas the loss of the best expert is $\lfloor \frac{T}{n} \rfloor$ after T trials. We conclude that the loss of FL can be by a factor of n larger than the loss of the best expert.

We next show that for the set expert case, FL can be forced to have loss at least $\frac{n}{d}$ times the loss of the best set of size d. In this case FL chooses a set of size d of minimum loss and the adversary forces the lowest loss expert in the set chosen by FL to incur one unit of loss. The algorithm again incurs loss one in each trial, but the loss of the best set lies in the range $d\,[\lfloor \frac{T}{n} \rfloor, \lceil \frac{T}{n} \rceil]$. Thus in this case the loss of FL can be by a factor of $\frac{n}{d}$ larger than the loss of the best set of size d.

When rephrased i.t.o. compression losses, FL picks a set of size $n-d$ whose complementary set of size d has minimum compression loss. We just showed that the total compression loss of FL can be at least $\frac{n}{d}$ times the compression loss of the best subset of size $n-d$.

We can lift the above lower bound for sets to the case of uncentered PCA. Now $d = n-k$ and k is the rank of the subspace we want to compress onto. To simplify the argument, we let the first n instances be small multiples of the standard basis vectors. More precisely, $x_t = t\varepsilon\, e^t$, for $1 \leq t \leq n$ and small real ε. These instances cause the uncentered data covariance matrix $\sum_{t=1}^{n} x_t x_t^\top$ to be a diagonal matrix. Also, if ε is small enough then the loss in the first n trials is negligible. From now on FL always chooses a unique set of $d = n-k$ standard basis vectors of minimum loss and the adversary chooses a standard basis vector with the lowest loss in the set as the next instance. So the lower bound argument essentially reduces to the set case, and FL can be forced to have compression loss $\frac{n}{n-k}$ times the loss of the compression loss of the best k dimensional subspace.

So far we have shown that our online algorithms are better than the simplistic FL Algorithm since their compression losses are at most one times the loss of the best plus essentially a square root term. We now show that the constant in front of the square root term is rather tight as well. For the expert setting ($d = 1$) this was already done:

Theorem 10 *(Theorem C.3. of the journal version Helmbold and Warmuth 2008 of the conference paper Helmbold and Warmuth 2007.) For all $\varepsilon > 0$ there exists n_ε such that for any number of experts $n \geq n_\varepsilon$, there exists a $T_{\varepsilon,n}$ where for any number of trials $T \geq T_{\varepsilon,n}$ the following holds for any algorithm in the expert setting: there is a sequence of T trials with n experts for which the loss of the best expert is at most $T/2$ and the regret of the algorithm is at least $(1-\varepsilon)\sqrt{(T/2)\log n}$.*

In the expert model used in this paper, we follow Freund and Schapire (1997) and assume that the losses of the experts in each trial are specified by a loss vector in $[0,1]^N$. There is a related model (studied earlier), where the experts produce predictions in each trial. After receiving those predictions the algorithm produces its own prediction and receives a label. The loss of the experts

and algorithm is the absolute value of the difference between the predictions and the label, respectively (Littlestone and Warmuth, 1994). The above theorem actually holds for this model of online learning with the absolute loss (when all predictions are in $[0,1]$ and the labels are in $\{0,1\}$), and the model used in this paper may be seen as the special case where the prediction of the algorithm is formed by simply averaging the predictions of the experts (Freund and Schapire, 1997). Therefore any lower bound for the described expert model with absolute loss immediately holds for the expert model where the loss is specified by a loss vector.

Note that the regret bounds for the Hedge Algorithm discussed at the end of Section 3 have an additional factor of 2 in the square root term. By choosing a prediction function other than the weighted average, the factor of 2 can be avoided in the expert model with the absolute loss, and the upper and lower bounds for the regret have the same constant in front of the square root term (provided that N and T are large enough) (Cesa-Bianchi et al., 1997; Cesa-Bianchiand and Lugosi, 2006).

The above lower bound theorem immediately generalizes to the case of set experts. Partition the experts into d blocks of size $\frac{n}{d}$ (assume d divides n). For any algorithm and block, construct a sequence of length T as before. During the sequence for one block, the experts for all the other blocks have loss zero. The loss of the best set of size d on the whole sequence of length Td is at most $Td/2$ and the regret, that is, the loss of the algorithm on the sequence minus the loss of the best set of size d, is lower bounded by

$$(1-\varepsilon)d\sqrt{\frac{T}{2}\log\frac{n}{d}} = (1-\varepsilon)\sqrt{\frac{dT}{2}d\log\frac{n}{d}}.$$

Rewritten in terms of compression losses for compression sets of size k (i.e., $d = n-k$), the lower bound on the compression loss regret becomes

$$(1-\varepsilon)\sqrt{\text{compression loss of best } k\text{-subset } (n-k)\log\frac{n}{n-k}}. \tag{19}$$

Note that the upper bound (4) obtained by our algorithm for learning as well as the best subset is essentially a factor of $\sqrt{2}$ larger than this lower bound.

Finally, we lift the above lower bound for subsets to a lower bound for uncentered PCA. In the setup for uncentered PCA, the instance matrix at trial t is $S^t = x^t(x^t)^\top$, where x^t has 2-norm at most 1. For the lower bound we need the instance matrix S^t to be an arbitrary symmetric matrix with eigenvalues in $[0,1]$. As discussed before Section 5.1, the upper bound for uncentered PCA still holds for these more general instance matrices.

To lift the lower bound for subsets to uncentered PCA, we simply replace the loss vector ℓ^t by the instance matrix $S^t = \operatorname{diag}(\ell^t)$. At trial t, the PCA algorithm uses the density matrix W^{t-1} and incurs expected loss $\operatorname{tr}(W^{t-1}\operatorname{diag}(\ell^t)) = \operatorname{diag}(W^{t-1})\cdot\ell^t$. Note that the diagonal vector $\operatorname{diag}(W^{t-1})$ is a probability vector. Thus the PCA algorithm doesn't have any advantage from using non-diagonal density matrices and the lower bound reduces to the set case. We conclude that the lower bound (19) also holds for the compression loss regret of uncentered PCA algorithms when the instance matrices are allowed to be symmetric matrices with eigenvalues in $[0,1]$. Again the corresponding upper bound (7) is essentially a factor of $\sqrt{2}$ larger.

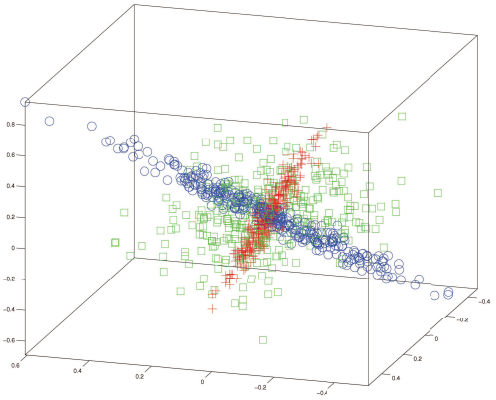

Figure 3: The data sequence used for the first experiment switches between three different subspaces. It is split into three segments. Within each segment, the data is drawn from a different 20-dimensional Gaussian with a rank 2 covariance matrix. We plot the first three coordinates of each data point. Different colors/symbols denote the data points that came from the three different subspaces.

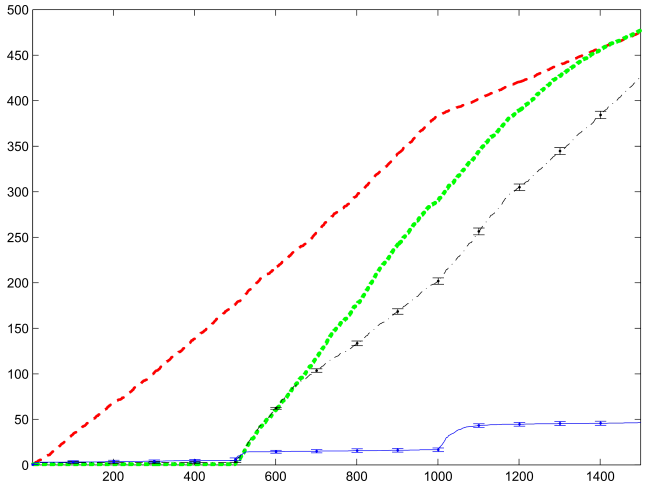

Figure 4: The blue/solid curve is the total loss of uncentered online PCA Algorithm 5 for the data sequence described in Figure 3 (with $n = 20, k = 2$ and $\eta = 1$). The algorithm uses internal randomization for choosing a subspace and therefore the curve is actually the average total loss over 50 runs for the same data sequence. The error bars (one standard deviation) indicate the variance of the algorithm. The black/dash-dotted curve plots the same for the uncentered version of Algorithm 6 (again $\eta = 1$). The visible bumps in the curves correspond to places in the data sequence where it shifts from one subspace to another. The red/dashed curve is the total loss of the best projection matrix determined in hindsight (i.e., loss of batch uncentered PCA). The green/dotted curve is the total loss of the Follow the Leader Algorithm.

8. Simple Experiments

The regret bounds we prove for our online PCA algorithms hold for arbitrary sequences of instances. In other words, they hold even if the instances are produced by an adversary which aims to make the algorithm have large regret. In many cases, natural data does not have a strong adversarial nature and even the simple Follow the Leader Algorithm might have small regret against the best subspace chosen in hindsight. However, natural data commonly shifts with time. It is on such time-changing data sets that online algorithms have an advantage. In this section we present some simple experiments that bring out the ability of our online algorithms to adapt to data that shifts with time.

For our first experiment we constructed a simple synthetic data set of time-changing nature. The data sequence is divided into three equal intervals, of 500 points each. Within each interval data points are picked at random from a multivariate Gaussian distribution on $\mathbb{R}^{20}$ with zero mean.

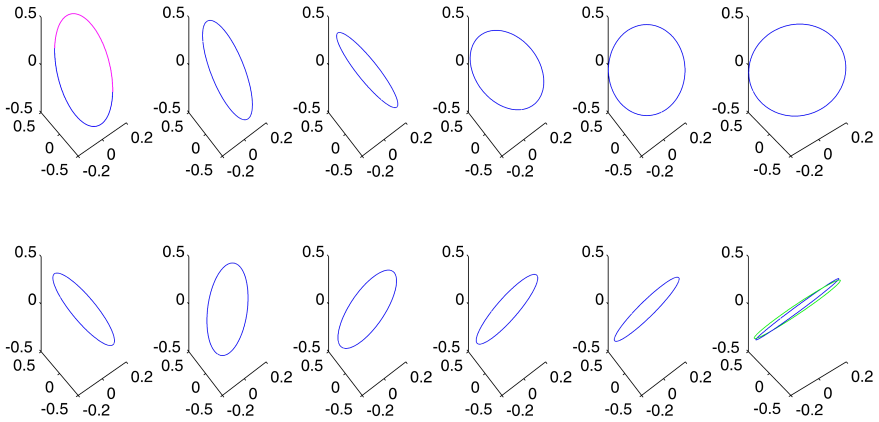

Figure 5: Behavior of the Uncentered Online PCA Algorithm 5 when data shifts from one subspace to another. First shift for one of the runs in Figure 4 is shown. We show the projection matrices that have the highest probability of being picked by the algorithm in a given trial. Since $k = 2$, each such matrix P^t can be seen as a 2-dimensional ellipse in $\mathbb{R}^{20}$: the ellipse is formed by points $P^t x$ for all $\|x\|_2 = 1$. We plot the first three coordinates of this ellipse. The transition sequence starts with the algorithm focused on the optimal projection matrix for the first subset of data and ends with essentially the optimal matrix for the second subset. The depicted transition takes about 60 trials and only every $5th$ trial is plotted.

The covariance matrices for the Gaussians were picked at random but constrained to rank 2, thus ensuring that the generated points lie in some 2-dimensional subspace. The generated points with norm bigger than one were normalized to 1. The data set is graphically represented in Figure 3, which plots the first three dimensions of each one of the data points. Different colors/symbols indicate data points that came from the three different subspaces.

In Figure 4 we plot the total compression loss for some of the algorithms introduced in this paper. For the sake of simplicity we restrict ourselves to uncentered PCA. Here the data dimension n is 20 and the subspace dimension k is 2. We plot the total loss of the following algorithms as a function of the trial number: the FL Algorithm, the original uncentered PCA Algorithm 5 and the uncentered version of Algorithm 6. For the latter two algorithms we need to select a learning rate. One possibility is to choose the learning rate that optimizes our upper bound on the regret of the algorithms (3). Since the bound is the same for both algorithms this choice of η is also the same: the choice depends on an upper bound on the compression loss of the batch algorithm. Plugging in the actual compression loss of the batch algorithm gives $\eta = 0.12$. In practice, heuristics can be used to tune η. For the experiment of Figure 4 we simply chose $\eta = 1$. Recall that our online PCA algorithms decompose their density matrix parameter W^t into a convex combination of projection matrices using the deterministic Algorithm 2. However, the PCA algorithms then randomly select one of the k dimensional projection matrices in the convex combination with probability equal to its coefficient. This introduces randomness into the execution of the algorithm even when run on a fixed data sequence. We run the algorithms 50 times and plot the average total loss as a function

of t for the fixed data sequence depicted in Figure 3. We also indicate the variance of this total loss with error bars of one standard deviation. Note again that the average and variance is w.r.t. internal randomization of the algorithm. The bumps in the loss curves of Figure 4 correspond to the places in the data sequence where it shifts from one subspace to another. When the loss curve of an algorithm flattens out then the algorithm has learned the correct subspace for the current segment. For example, Figure 5 depicts how the density matrix of the uncentered PCA Algorithm 5 ($\eta = 1$) transitions around a segment boundary.

The FL Algorithm (which coincides with the uncentered version of Algorithm 10 when $\eta \to \infty$) learns the first segment really quickly, but it does not recover during the later segments. The original uncentered PCA Algorithm 5 (with $\eta = 1$) recovers in each segment, whereas the uncentered version of Algorithm 6 (with $\eta = 1$) does not recover as quickly and has higher total loss on this data sequence. Recall that both online algorithms for uncentered PCA have the same regret bound against the best fixed offline comparator.

In Figure 4 we also plot the compression loss of the best subspace selected in hindsight by running batch uncentered PCA (dashed/red line). The data set we generated is not well approximated by a single 2-dimensional subspace, since it consists of three different 2-dimensional subspaces. As a result, the overall loss of the fixed subspace is higher than the loss of both of our uncentered online PCA algorithms that to a varying extent were able to switch between the different 2-dimensional subspaces.

There are many heuristics for detecting switches of the data. For example one could simply check for a performance loss of any algorithm in a suitably chosen final segment. However, such algorithms are often unwieldy and are hard to tune when the data in difference segments are not drastically different. Note that for the Uncentered Online PCA Algorithm presented in this paper we only have provable good regret bounds against the best fixed subspace chosen offline (based on the entire data sequence). (In Figure 4 both of our online algorithms beat the offline comparator and thus have negative regret against this simple comparator.) Ideally we would like measure regret against stronger offline comparators that can exploit the shifting nature of the data. In the expert setting there is a long line of research where the offline algorithm is allowed to partition the data sequence into s segments and pick the best subspace for each of the s segments. There are simple modifications of the online algorithm in the experts setting that have good regret bounds against the best partition of size s (see, e.g., Herbster and Warmuth, 1998). Naturally, the regret bounds grow with the number of segments s. The modifications that are needed to achieve these regret bounds are simple: insert an additional update step at the end of each trial that mixes a little bit of the uniform distribution into the weight vector. In the context of uncentered PCA this amounts to adding the following update at the end of each trial:

$$W^t = (1-\alpha)W^t + \alpha\frac{I}{n}.$$

We claim that it is easy to again lift the techniques developed in the expert setting to PCA and prove the analogous regret bounds against the best partition.

The following subtle modification of the mixing rule leads to algorithms with even more interesting properties. If the algorithm mixes in a little bit of the average of all past weight vectors instead of the uniform vector, then it is able to switch quickly to experts that have been good at some time in the past. This has been called the "long-term memory" property of such algorithms. In the context of uncentered PCA, this amounts the following additional update step for the density

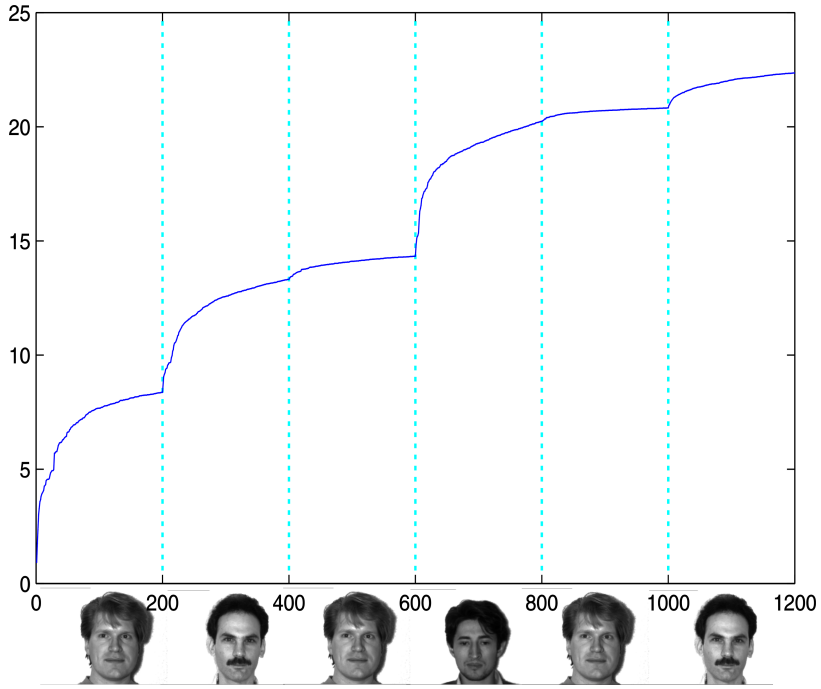

Figure 6: Long term memory effect when mixing in past average is added to the uncentered online PCA Algorithm 5. The data sequence is comprised of several segments, each one of two hundred randomly sampled images of the same person but with different facial expressions and lighting conditions. These segments are indicated with dotted lines and are labeled with the face of the person that was used to generate the segment. The plot depicts the regret of the uncentered online PCA Algorithm 5 ($\eta = 1$) with added mixing update (20) ($\alpha = .001$). The regret is w.r.t. the indicated partition of size six.

matrix:

$$W^t = (1-\alpha)W^t + \alpha\frac{\sum_{q=0}^{t-1} W^q}{t}. \tag{20}$$

We performed another experiment that demonstrates this "long-term memory" effect by adding update (20) to the uncentered online PCA Algorithm 5: For this experiment we used face image data from Yale-B data set. A segmented data sequence was constructed by sampling the face images, where each segment contained images of the same person, but with different facial expressions, lighting conditions, etc. Figure 6 plots the regret of our uncentered online PCA Algorithm 5 against the best partition of size 6 chosen offline ($\eta = 1, \alpha = .001$). In the picture the segment boundaries are indicated with dotted lines and the face below each segment shows the person who's pictures were sampled during that section. Note that our online algorithm doesn't have knowledge of segment boundaries. The first segment shows the typical behavior of online algorithms: the regret grows initially, but then flattens out once the algorithm converges to the best solution for that segment. Thus the "bump" in the regret curve is due to the fact that the algorithm has to learn a new segment of pictures from a different person. By comparing the bumps of different segments we see that they are significantly smaller in segments where the algorithm encounters pictures from a person that it

has previously seen: the algorithm "remembers" subspaces that were good in the past. These small bumps can be seen in segments 3,5 and 6 in our data set. For additional plots of long-term memory effects in the expert setting see Bousquet and Warmuth (2002). Our experiments are preliminary and we did not formally prove regret bounds for shifting comparators in PCA setting, but such bounds are straightforwardly obtained using the methodology from this paper and Bousquet and Warmuth (2002).

9. Conclusions

We developed a new set of techniques for learning as well as a low dimensional subspace. We first developed the algorithms in the expert case and then lifted these algorithms and bounds to the matrix case as essentially done in Tsuda et al. (2005); Warmuth and Kuzmin (2006a). The new insight is to represent our uncertainty over the subspace as a density matrix with capped eigenvalues. We show how to decompose such a matrix into a mixture of n subspaces of the desired rank. In the case of PCA the seemingly quadratic compression loss can be rewritten as a linear loss of our matrix parameter. Therefore a random subspace chosen from the mixture has the same expected loss as the loss of the parameter matrix.

Similar techniques (albeit not capping) have been used recently for learning permutations (Helmbold and Warmuth, 2008): Instead of maintaining a probability vector over the $n!$ permutations, the parameter used in that paper is a convex combination of permutation matrices which is an $n \times n$ doubly stochastic matrix. This matrix can be efficiently decomposed into a mixture of $O(n^2)$ permutation matrices. If the loss is linear, then a random permutation chosen from the mixture has the same expected loss as the loss of the doubly stochastic parameter matrix.

When the loss is convex and not linear (as for example the quadratic loss in the generalization of linear regression to matrix parameters Tsuda et al. 2005), then our new capping trick can still be applied to the density matrix parameter. In this case, the online loss of the capped density matrix can be shown to be close to the loss of the best low dimensional subspace. However the quadratic loss of the capped density matrix (which is a convex combination of subspaces) can be much smaller than the convex combination of the losses of the subspaces. The bounds of that paper only hold for the smaller loss of the capped density matrix and not for the expected loss of the subspace sampled from the convex combination represented by the capped density matrix.

Our new capping technique is interesting in its own right. Whereas the vanilla multiplicative update on n experts with exponential factors is prone to be unstable because it tends to go into a corner of the simplex (by putting all weight on the currently best expert), the technique of capping the weight at $\frac{1}{d}$ keeps a set of at least d experts alive. In some sense the capping has the same effect as a "super predator" has on a biological system: such a predator specializes on the most frequent species of prey, preventing the dominance of any particular species and thus preserving variety. See Warmuth (2007a) for a discussion of the relationships of our updates to biological systems.

Following Kivinen and Warmuth (1997); Helmbold et al. (1999), we motivate our updates by trading off a parameter divergence against a loss divergence. In our case, the parameter divergence is always a capped relative entropy and the loss divergence is simply linear. It would be interesting to apply the capping trick to the logistic loss used in logistic regression. The logistic loss can be seen as a relative entropy between the desired probabilities of the outcomes and the predicted probabilities of the outcomes obtained by applying a sigmoid function to the linear activations (Kivinen and Warmuth, 2001). For "capped logistic regression", linear constraints would be added to the op-

timization problem defining the updates that cap the predicted probabilities of the outcomes. This would lead to versions of logistic regression where the loss favors a small set of outcomes instead of a single outcome.

The algorithms of this paper belong to the family of multiplicative updates, that is, the parameters are updated by multiplicative factors of exponentials. In the matrix case the updates make use of the matrix log and matrix exponential. There is a second family of updates that does additive parameter updates. In particular, there are additive online updates for PCA (Crammer, 2006). The latter update family has the key advantage that they can be easily used with kernels. However, in a recent conference paper (Kuzmin and Warmuth, 2007) we also were able to give a special case where the multiplicative updates could be enhanced with a kernel. In this case the instance matrices are outer products $x^t(x^t)^\top$ and are replaced by $\phi(x)^t(\phi(x^t))^\top$. In particular, the online PCA algorithms of this paper can be "kernelized" this way.

In PCA the instance matrices are *symmetric* matrices $x^t(x^t)^\top$ and we seek a low rank *symmetric* subspace that approximates the instances well. In a recent conference paper we showed in a slightly different context how to generalize our methods to the case of "asymmetric" matrices of arbitrary shape. Using those techniques, the online PCA algorithms of this paper can be generalized to the asymmetric case: now the instance matrices are rank one $n \times m$ matrices of the form $x^t(\widetilde{x}^t)^\top$, where x and $\widetilde{x}$ are vectors of dimension n and m, respectively. In the asymmetric case, the underlying decomposition is the SVD decomposition instead of the eigendecomposition.

There are two technical open problems that arise in this paper. We gave a number of dynamic programming algorithms, such as the one given for the set expert problem. If the loss range for the individual experts is [0,1] then the loss range for the set experts is $[0,d]$ when d is the size of the set. The straightforward application of results for the Hedge Algorithm leads to extra factors of d in the regret bounds for set experts. We avoided these factors using our capping trick. However, the question is whether the same bounds (without the d factors) hold for the dynamic programming algorithm as well. There is a different fundamental algorithmic technique for dealing with structural domains: the Follow the Perturbed Leader Algorithm (Kalai and Vempala, 2005). The second open problem is how to adapt this algorithm to online PCA and prove bounds for it that don't contain the extra d factors.

Finally, independent of what theoretical progress might have been achieved in this paper, we still have to find a convincing experimental setting where our new online PCA algorithms are indispensable. The update time of our algorithms is $O(n^2)$ and further time improvements via approximations or lazy evaluation might be needed to make the algorithms widely applicable.

Abstract

In this paper we use the methodology introduced by Dhurandhar and Dobra (2009) for analyzing the error of classifiers and the model selection measures, to analyze decision tree algorithms. The methodology consists of obtaining parametric expressions for the moments of the generalization error (GE) for the classification model of interest, followed by plotting these expressions for interpretability. The major challenge in applying the methodology to decision trees, the main theme of this work, is customizing the generic expressions for the moments of GE to this particular classification algorithm. The specific contributions we make in this paper are: (a) we primarily characterize a subclass of decision trees namely, Random decision trees, (b) we discuss how the analysis extends to other decision tree algorithms and (c) in order to extend the analysis to certain model selection measures, we generalize the relationships between the moments of GE and moments of the model selection measures given in (Dhurandhar and Dobra, 2009) to randomized classification algorithms. An empirical comparison of the proposed method with Monte Carlo and distribution free bounds obtained using Breiman's formula, depicts the advantages of the method in terms of running time and accuracy. It thus showcases the use of the deployed methodology as an exploratory tool to study learning algorithms.

Keywords: moments, generalization error, decision trees

1. Introduction

Consider the problem of estimating how a given classification algorithm (rather than a particular classifier) performs on a given joint distribution over the input-output space ($X \times Y$). As opposed to the general setup in machine learning where the distribution is unknown and only independent and identically distributed (i.i.d.) samples are available, in this scenario, *in principle*, the behavior of classification algorithm can be accurately studied. If this problem be solved efficiently, it offers an alternative line of study for classification algorithms and potentially unique insights into the *non-asymptotic* behavior of learning algorithms.

While the problem of estimating classification algorithm performance on a given distribution might look simple, solving it efficiently poses significant technical hurdles. The most natural way of studying a classification algorithm would be to sample N datapoints from the given distribution, train the algorithm to produce a classifier, test the classifier on a few sampled test sets and report the average error computed over these test sets. A shortcoming of the above approach is that based on just one single instance of the algorithm (since the algorithm was trained on a single data set of size N) we conclude about its general behavior. A straightforward extension of the above approach

to make the results more relevant in studying the algorithm would be to sample multiple data sets of size N, train on each of them to produce different classifiers, compute the test error for each of the classifiers and calculate the average and variance of the obtained test errors. This procedure would be a better indicator of the behavior of the algorithm than the previous case since we study multiple instances of the algorithm than just an isolated instance. Ideally, we would want to study the behavior of the algorithm by training it on all possible data sets of size N producing a variety of classifiers and then evaluating the expected value and variance of the generalization error (GE) of each of these classifiers. The GE of a classifier ζ is given by,

$$\begin{aligned} GE(\zeta) &= E\left[\lambda(\zeta(x),y)\right] \\ &= P\left[\zeta(x) \neq y\right] \end{aligned}$$

where $\lambda(.,.)$ is a 0-1 loss function, x is an input and y is an output and the expectation is over the input-output space $X \times Y$. The expected value and variance of GE over all possible classifiers[1] are denoted by,

$$E_{\mathcal{Z}(N)}\left[GE(\zeta)\right],$$

$$Var(GE(\zeta)) = E_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[GE(\zeta)GE(\zeta')\right] - E_{\mathcal{Z}(N)}\left[GE(\zeta)\right]^2$$

where $\mathcal{Z}(N)$ represents the space of all possible classifiers produced by training the classification algorithm on all data sets of size N (denoted by $D(N)$), drawn from the joint distribution. With this we have shown that the moments provide a natural and informative avenue for studying classification algorithms. The question that now arises is, can we compute them efficiently. In our previous work (Dhurandhar and Dobra, 2009), we presented a general framework for computing these quantities for an arbitrary classification algorithm efficiently. By extensive use of the linearity of expectation and change of the order of sums (and integrals), the moments of GE can be expressed in terms of the behavior of the classification algorithm on specific inputs rather than on the whole space, thus reducing the complexity from an exponential in the size of the input space to linear for the computation of the first moment and quadratic for the second moment. As part of this prior work, the generic expressions to compute the moments were customized for the Naive Bayes Classification algorithm. In the present work we customize the generic expressions to compute moments of the generalization error for a more popular classification algorithm: Random decision trees.

The specific contributions we make are: We develop a characterization for a subclass of decision trees. In particular, we characterize Random decision trees which are an interesting variant with respect to three popular stopping criteria namely; fixed height, purity and scarcity (i.e., fewer than some threshold number of points in a portion of the tree). The analysis directly applies to categorical as well as continuous attributes with split points predetermined for each attribute. Moreover, the analysis in Section 3.3 is applicable to even other deterministic attribute selection methods based on information gain, gini gain etc. These and other extensions of the analysis to continuous attributes with dynamically chosen split points is discussed in Section 5. In the experiments that ensue the theory, we compare the accuracy of the derived expressions with direct Monte Carlo (i.e., hold-out-set estimation) and Breiman's strength and correlation based bounds (Breiman, 2001) on synthetic

1. Expectations over $\mathcal{Z}(N)$ are more general than over $D(N)$ since the classification algorithm can be randomized.

distributions as well as on distributions built on real data. Notice that using the expressions, the moments can be computed without explicitly building the tree. We also extend the relationships between the moments of GE and moments of cross validation error (CE), leave-one-out error (LE) and hold-out-set error (HE) given in Dhurandhar and Dobra (2009) which were applicable only to deterministic classification algorithms, to be made applicable to randomized classification algorithms.

2. Preliminaries

Model selection for classification is one of the major challenges in Machine Learning and Datamining. Given an i.i.d. sample from the underlying probability distribution, the classification model selection problem consists in building a classifier by selecting among competing models. Ideally the model selected minimizes GE. Since GE cannot be directly computed, part of the sample is used to estimate GE through measures such as cross validation, hold-out-set, leave-one-out, etc. Though certain rules of thumb are followed by practitioners w.r.t. training size and other parameters specific to the validation measures in evaluating models through empirical studies (Kohavi, 1995; Blum et al., 1999) and certain asymptotic results exist (Vapnik, 1998; Shao, 1993), the fact remains that most of these models and model selection measures are not well understood in real life (non-asymptotic) scenarios (e.g., what fraction should be test and training, what should be the value k in k-fold cross validation etc.). This lack of deep understanding limits our ability of using the models most effectively and maybe more importantly trusting the models to perform well in a particular application.

Recently, a novel methodology was proposed in Dhurandhar and Dobra (2009) to study the behavior of models and model selection measures. Since the methodology is at the core of the current work, we briefly describe it together with the motivation for using this type of analysis for classification in general and decision trees in particular.

2.1 *What* is the Methodology?

The methodology for studying classification models consists of studying the behavior of the first two central moments of the GE of the classification algorithm studied. The moments are taken over the space of all possible classifiers produced by the classification algorithm, by training it over all possible data sets sampled i.i.d. from some distribution. The first two moments give enough information about the statistical behavior of the classification algorithm to allow interesting observations about the behavior/trends of the classification algorithm w.r.t. any chosen data distribution.

2.2 *Why* have such a Methodology?

The answers to the following questions shed light on why the methodology is necessary if tight statistical characterization is to be provided for classification algorithms.

1. *Why study GE ?* The biggest danger of learning is *overfitting* the training data. The main idea in using GE as a measure of success of learning instead on the empirical error on a given data set is to provide a mechanism to avoid this pitfall. Implicitly, by analyzing GE all the input is considered.

2. *Why study the moments instead of the distribution of GE ?* Ideally, we would study the distribution of GE instead of moments in order to get a complete picture of what is its behavior.

Studying the distribution of discrete random variables, except for very simple cases, turns out to be very hard. The difficulty comes from the fact that even computing the probability of a single point is intractable since all combinations of random choices that result in the same value for GE have to be enumerated. On the other hand, the first two central moments coupled with distribution independent bounds such as Chebychev and Chernoff give guarantees about the worst possible behavior that are not too far from the actual behavior (small constant factor). Interestingly, it is possible to compute the moments of a random variable like GE without ever explicitly writing or making use of the formula for the cumulative distribution function. What makes such an endeavor possible is extensive use of the linearity of expectation.

3. *Why characterize a class of classifiers instead of a single classifier ?* While the use of GE as the success measure is standard practice in Machine Learning, characterizing classes of classifiers instead of the particular classifier produced on a given data set is not. From the point of view of the analysis, without large testing data sets it is not possible to evaluate directly GE for a particular classifier. By considering classes of classifiers to which a classifier belongs, an indirect characterization is obtained for the particular classifier. This is precisely what Statistical Learning Theory (SLT) does; there the class of classifiers consists in all classifiers with the same VC dimension. The main problem with SLT results is that classes based on VC dimension are too large, thus results tend to be pessimistic. In our methodology, the class of classifiers consists only of the classifiers that are produced by the given classification algorithm from data sets of fixed size from the underlying distribution. This is the probabilistic smallest class in which the particular classifier produced on a given data set can be placed in.

2.3 *How* do we Implement the Methodology ?

One way of approximately estimating the moments of GE over all possible classifiers for a particular classification algorithm is by directly using Monte Carlo. If we use Monte Carlo directly, we first need to produce a classifier on a sampled data set then test on a number of test sets sampled from the same distribution acquiring an estimate of the GE of this classifier. Repeating this entire procedure a few times we would acquire estimates of GE for different classifiers. Then by averaging the error of these multiple classifiers we would get an estimate of the first moment of GE. The variance of GE can also be similarly estimated. The problem with this procedure is that the space of all possible data sets can be huge. For instance, if we have d attributes each taking m values then the number of possible data sets of size N is $N^{m^d} - 1$. Even for any reasonable assignment to N (say, 100), m (say 2) and d (say 3) the number of experiments that need to be performed to guarantee accurate (if not exact) estimation of the moments seems unreasonable.

Another way of estimating the moments of GE, is by obtaining parametric expressions for them. If this can be accomplished the moments can be computed exactly. Moreover, by dexterously observing the manner in which expressions are derived for a particular classification algorithm, insights can be gained into analyzing other algorithms of interest. Though deriving the expressions may be a tedious task, using them we obtain highly accurate estimates of the moments. In this paper, we propose this second alternative for analyzing a subclass of decision trees. The key to the analysis is focusing on the learning phase of the algorithm. In cases where the parametric expressions are computationally intensive to compute directly, we show that approximating individual terms using Monte Carlo we obtain accurate estimates of the moments when compared to directly using Monte Carlo (first alternative) for the same computational cost.

If the moments are to be studied on synthetic data then the distribution is anyway assumed and the parametric expressions can be directly used. If we have real data an empirical distribution can be built on the data set and then the parametric expressions can be used.

2.4 Applications of the Methodology

It is important to note that the methodology is not aimed towards providing a way of estimating bounds for GE of a classifier on a given data set (i.e., finding distribution free bounds). The primary goal is creating an avenue in which learning algorithms can be studied precisely, that is, studying the statistical behavior of a particular algorithm w.r.t. a chosen/built distribution. Below, we discuss the two most important perspectives in which the methodology can be applied.

2.4.1 ALGORITHMIC PERSPECTIVE

If a researcher/practitioner designs a new classification algorithm, he/she needs to validate it. Standard practice is to validate the algorithm on a relatively small (5-20) number of data sets and to report the performance. By observing the behavior of only a few instances of the algorithm the designer infers its quality. Moreover, if the algorithm under performs on some data sets, it can be sometimes difficult to pinpoint the precise reason for its failure. If instead he/she is able to derive parametric expressions for the moments of GE, the test results would be more relevant to the particular classification algorithm, since the moments are over all possible data sets of a particular size drawn i.i.d. from some chosen/built distribution. Testing individually on all these data sets is an impossible task. Thus, by computing the moments using the parametric expressions the algorithm would be tested on a plethora of data sets with the results being highly accurate. Moreover, since the testing is done in a controlled environment, that is, all the parameters are known to the designer while testing, he/she can precisely pinpoint the conditions under which the algorithm performs well and the conditions under which the algorithm under performs.

2.4.2 DATA SET PERSPECTIVE

If an algorithm designer validates his/her algorithm by computing moments as mentioned earlier, it can instill greater confidence in the practitioner searching for an appropriate algorithm for his/her data set. The reason for this being, if the practitioner has a data set which has a similar structure or is from a similar source as the test data set on which an empirical distribution was built and favorable results reported by the designer, then this would mean that the results apply not only to that particular test data set, but to other similar type of data sets and since the practitioner's data set belongs to this similar collection, the results would also apply to his. Note that a distribution is just a weighting of different data sets and this perspective is used in the above exposition.

3. Computing Moments

In this section we first provide the necessary technical groundwork, followed by customization of the expressions for decision trees. We now introduce some notation that is used primarily in this section. X is a random vector modeling input whose domain is denoted by $\mathcal{X}$. Y is a random variable modeling output whose domain is denoted by $\mathcal{Y}$ (set of class labels). $Y(x)$ is a random variable modeling output for input x. ζ represents a particular classifier with its GE denoted by

$GE(\zeta)$. $\mathcal{Z}(N)$ denotes a set of classifiers obtained by application of a classification algorithm to different samples of size N.

3.1 Technical Framework

The basic idea in the generic characterization of the moments of GE, is to define a class of classifiers induced by a classification algorithm and an i.i.d. sample of a particular size from an underlying distribution. Each classifier in this class and its GE act as random variables, since the process of obtaining the sample is randomized. Since $GE(\zeta)$ is a random variable, it has a distribution. Quite often though, characterizing a finite subset of moments turns out to be a more viable option than characterizing the entire distribution. Based on these facts, we revisit the expressions for the first two moments around zero of the GE of a classifier,

$$E_{\mathcal{Z}(N)}\left[GE(\zeta)\right] = \sum_{x\in\mathcal{X}} P\left[X=x\right] \sum_{y\in\mathcal{Y}} P_{\mathcal{Z}(N)}\left[\zeta(x)=y\right] P\left[Y(x)\neq y\right],$$

$$E_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[GE(\zeta)GE(\zeta')\right] = \sum_{x\in\mathcal{X}}\sum_{x'\in\mathcal{X}} P\left[X=x\right] P\left[X=x'\right] \cdot \sum_{y\in\mathcal{Y}}\sum_{y'\in\mathcal{Y}} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[\zeta(x)=y \wedge \zeta'(x')=y'\right] \cdot P\left[Y(x)\neq y\right] P\left[Y(x')\neq y'\right]$$

From the above equations we observe that for the first moment we have to characterize the behavior of the classifier on each input separately while for the second moment we need to observe its behavior on pairs of inputs. In particular, to derive expressions for the moments of any classification algorithm we need to characterize $P_{\mathcal{Z}(N)}\left[\zeta(x)=y\right]$ for the first moment and $P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[\zeta(x)=y\wedge\zeta'(x')=y']$ for the second moment.[2] The values for the other terms denote the error of the classifier for the first moment and errors of two classifiers for the second moment which are obtained directly from the underlying joint distribution. For example, if we have data with a class prior p for class 1 and *1-p* for class 2. Then the error of a classifier classifying data into class 1 is *1-p* and the error of a classifier classifying data into class 2 is given by p. We now focus our attention on relating the above two probabilities, to probabilities that can be computed using the joint distribution and the classification model viz. Decision Trees.

In the subsections that follow we assume the following setup. We consider the dimensionality of the input space to be d. $A_1, A_2, ..., A_d$ are the corresponding discrete attributes or continuous attributes with predetermined split points. $a_1, a_2, ..., a_d$ are the number of attribute values/the number of splits of the attributes $A_1, A_2, ..., A_d$ respectively. m_{ij} is the i^{th} attribute value/split of the j^{th} attribute, where $i \leq a_j$ and $j \leq d$. Let $C_1, C_2, ..., C_k$ be the class labels representing k classes and N the sample size.

2. These probabilities and $P\left[Y(x)\neq y\right]$ are conditioned on x. We omit explicitly writing the conditional since it improves readability and is obvious from the context.

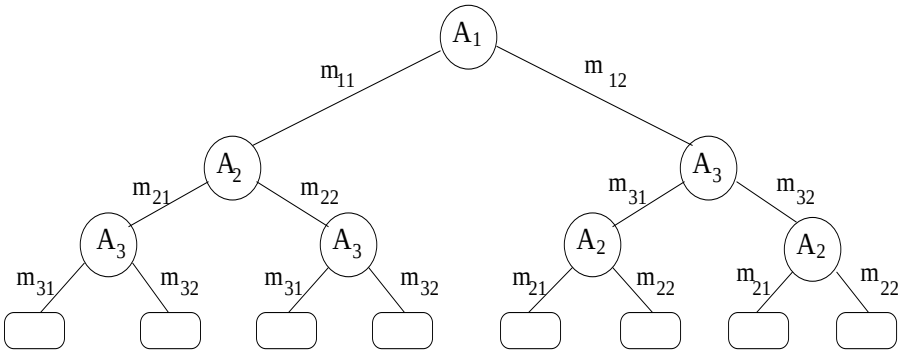

Figure 1: The all attribute tree with 3 attributes $A_1,\ A_2,\ A_3$, each having 2 values.

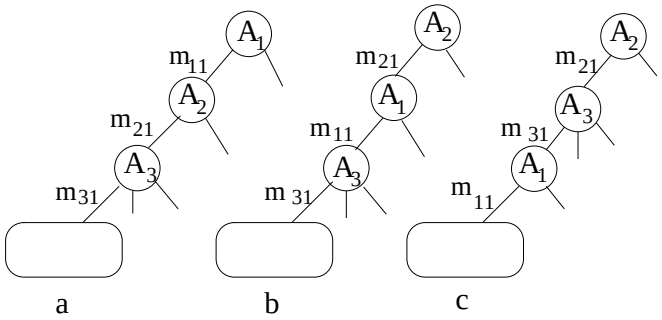

Figure 2: Given 3 attributes $A_1,\ A_2,\ A_3$, the path $m_{11}m_{21}m_{31}$ is formed irrespective of the ordering of the attributes. Three such permutations are shown in the above figure.

3.2 All Attribute Decision Trees (ATT)

Let us consider a decision tree algorithm whose only stopping criterion is that no attributes remain when building any part of the tree. In other words, every path in the tree from root to leaf has all the attributes. An example of such a tree is shown in Figure 1. It can be seen that irrespective of the split attribute selection method (e.g., information gain, gini gain, randomized selection, etc.) the above stopping criteria yields trees with the same leaf nodes. Thus although a particular path in one tree has an ordering of attributes that might be different from a corresponding path in other trees, the leaf nodes will represent the same region in space or the same set of datapoints. This is seen in Figure 2. Moreover, since predictions are made using data in the leaf nodes, any deterministic way of prediction would lead to these trees resulting in the same classifier for a given sample and thus having the same GE. Usually, prediction in the leaves is performed by choosing the most numerous class as the class label for the corresponding datapoint. With this we arrive at the expressions for computing the aforementioned probabilities,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)}\left[\zeta(x)=C_i\right]= \\
&\quad P_{\mathcal{Z}(N)}[ct(m_{p1}m_{q2}...m_{rd}C_i)>ct(m_{p1}m_{q2}...m_{rd}C_j), \\
&\qquad \forall j\neq i,\ i,j\in[1,...,k]]
\end{aligned}
$$

where $x = m_{p1}m_{q2}...m_{rd}$ denotes a datapoint which is also a path from root to leaf in the tree. We refer to this path as a cell sometimes since it represents a rectangular region in a d dimensional space. $ct(m_{p1}m_{q2}...m_{rd}C_i)$ is the count of the datapoints in the cell $m_{p1}m_{q2}...m_{rd}C_i$. Henceforth, when using the word "path" we will strictly imply path from root to leaf. By computing the above probability $\forall\ i$ and $\forall\ x$ we can compute the first moment of the GE for this classification algorithm.

Similarly, for the second moment we compute cumulative joint probabilities of the following form:

$$\begin{aligned} &P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[\zeta(x)=C_i \wedge \zeta'(x')=C_v\right] = \\ &\quad P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(m_{p1}...m_{rd}C_i) > ct(m_{p1}...m_{rd}C_j), \\ &\qquad ct(m_{f1}...m_{hd}C_v) > ct(m_{f1}...m_{hd}C_w), \\ &\qquad \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]] \end{aligned}$$

where the terms have similar connotation as before. These probabilities can be computed exactly or by using fast approximation techniques proposed in Dhurandhar and Dobra (2009).

3.3 Decision Trees with Non-trivial Stopping Criteria

We just considered decision trees which are grown until all attributes are exhausted. In real life though we seldom build such trees. The main reasons for this could be any of the following: we wish to build small decision trees to save space; certain path counts (i.e., number of datapoints in the leaves) are extremely low and hence we want to avoid splitting further, as the predictions can get arbitrarily bad; we have split on a certain subset of attributes and all the datapoints in that path belong to the same class (purity based criteria); we want to grow trees to a fixed height (or depth). These stopping measures would lead to paths in the tree that contain a subset of the entire set of attributes. Thus from a classification point of view we cannot simply compare the counts in two cells as we did previously. The reason for this being that the corresponding path may not be present in the tree. Hence, we need to check that the path exists and then compare cell counts. Given the classification algorithm, since the $P_{\mathcal{Z}(N)}\left[\zeta(x)=C_i\right]$ is the probability of all possible ways in which an input x can be classified into class C_i for a decision tree it equates to finding the following kind of probability for the first moment,

$$\begin{aligned} &P_{\mathcal{Z}(N)}\left[\zeta(x)=C_i\right] = \\ &\quad \sum_p P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), path_p exists, \\ &\qquad \forall j \neq i,\ i,j \in [1,...,k]] \end{aligned} \tag{1}$$

where p indexes all allowed paths by the tree algorithm in classifying input x. After the summation, the right hand side term above is the probability that the cell $path_pC_i$ has the greatest count, with the path "$path_p$" being present in the tree. This will become clearer when we discuss different stopping criteria. Notice that the characterization for the ATT is just a special case of this more generic characterization.

The probability that we need to find for the second moment is,

$$\begin{aligned} &P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[\zeta(x)=C_i \wedge \zeta'(x')=C_v\right] = \\ &\sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), path_pexists, \\ &\qquad ct(path_qC_v) > ct(path_qC_w), path_qexists, \\ &\qquad \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]] \end{aligned} \tag{2}$$

where p and q index all allowed paths by the tree algorithm in classifying input x and x' respectively. The above two equations are generic in analyzing any decision tree algorithm which classifies inputs into the most numerous class in the corresponding leaf. It is not difficult to generalize it further when the decision in leaves is some other measure than majority. In that case we would just include that measure in the probability in place of the inequality.

3.3.1 CHARACTERIZING *Path Exists* FOR THREE STOPPING CRITERIA

It follows from above that to compute the moments of the GE for a decision tree algorithm we need to characterize conditions under which particular paths are present. This characterization depends on the stopping criteria and split attribute selection method in a decision tree algorithm. We now look at three popular stopping criteria, namely a) Fixed height based, b) Purity (i.e., entropy 0 or gini index 0 etc.) based and c) Scarcity (i.e., too few datapoints) based. We consider conditions under which certain paths are present for each stopping criteria. Similar conditions can be enumerated for any reasonable stopping criteria. We then choose a split attribute selection method, thereby fully characterizing the above two probabilities and hence the moments.

1. **Fixed Height:** This stopping criteria is basically that every path in the tree should be of length exactly h, where $h \in [1,...,d]$. If $h = 1$ we classify based on just one attribute. If $h = d$ then we have the all attribute tree.
   In general, a path $m_{i1}m_{j2}...m_{lh}$ is present in the tree iff the attributes $A_1,\ A_2,...,\ A_h$ are chosen in any order to form the path for a tree construction during the split attribute selection phase. Thus, for any path of length h to be present we bi-conditionally imply that the corresponding attributes are chosen.

2. **Purity:** This stopping criteria implies that we stop growing the tree from a particular split of a particular attribute if all datapoints lying in that split belong to the same class. We call such a path pure else we call it impure. In this scenario, we could have paths of length 1 to d depending on when we encounter purity (assuming all datapoints don't lie in 1 class). Thus, we have the following two separate checks for paths of length d and less than d respectively.

   a) Path $m_{i1}m_{j2}...m_{ld}$ present iff the path $m_{i1}m_{j2}...m_{l(d-1)}$ is impure and attributes $A_1,\ A_2,...,\ A_{d-1}$ are chosen above A_d, or $m_{i1}m_{j2}...m_{s(d-2)}m_{ld}$ is impure and attributes $A_1,\ A_2,...,\ A_{d-2},\ A_d$ are chosen above A_{d-1}, or ... or $m_{j2}...m_{ld}$ is impure and attributes $A_2,...,\ A_d$ are chosen above A_1.
   This means that if a certain set of $d-1$ attributes are present in a path in the tree then we split on the d^{th} attribute iff the current path is not pure, finally resulting in a path of length d.

   b) Path $m_{i1}m_{j2}...m_{lh}$ present where $h < d$ iff the path $m_{i1}m_{j2}...m_{lh}$ is pure and attributes $A_1,\ A_2,...,\ A_{h-1}$ are chosen above A_h and $m_{i1}m_{j2}...m_{l(h-1)}$ is impure or the path $m_{i1}m_{j2}...m_{lh}$

is pure and attributes A_1, A_2,..., A_{h-2}, A_h are chosen above A_{h-1} and $m_{i1}m_{j2}...m_{l(h-2)}m_{lh}$ is impure or ... or the path $m_{j2}...m_{lh}$ is pure and attributes A_2,..., A_h are chosen above A_1 and $m_{j2}...m_{lh}$ is impure.
This means that if a certain set of $h-1$ attributes are present in a path in the tree then we split on some h^{th} attribute iff the current path is not pure and the resulting path is pure.

The above conditions suffice for "path present" since the purity property is anti-monotone and the impurity property is monotone.

3. **Scarcity:** This stopping criteria implies that we stop growing the tree from a particular split of a certain attribute if its count is less than or equal to some pre-specified pruning bound. Let us denote this number by pb. As before, we have the following two separate checks for paths of length d and less than d respectively.

   a) Path $m_{i1}m_{j2}...m_{ld}$ present iff the attributes $A_1,...,A_{d-1}$ are chosen above A_d and $ct(m_{i1}m_{j2}...m_{l(d-1)}) > pb$ or the attributes $A_1,...,A_{d-2},A_d$ are chosen above A_{d-1} and $ct(m_{i1}m_{j2}...m_{l(d-2)}m_{nd}) > pb$ or ... or the attributes $A_2,...,A_d$ are chosen above A_1 and $ct(m_{i2}m_{j3}...m_{ld}) > pb$.

   b) Path $m_{i1}m_{j2}...m_{lh}$ present where $h < d$ iff the attributes $A_1,...,A_{h-1}$ are chosen above A_h and $ct(m_{i1}m_{j2}...m_{l(h-1)}) > pb$ and $ct(m_{i1}m_{j2}...m_{lh}) \leq pb$ or the attributes $A_1,...,A_{h-2},A_h$ are chosen above A_{h-1} and $ct(m_{i1}m_{j2}...m_{l(h-2)}m_{nh}) > pb$ and $ct(m_{i1}m_{j2}...m_{nh}) \leq pb$ or ... or the attributes $A_2,...,A_h$ are chosen above A_1 and $ct(m_{i2}m_{j3}...m_{lh}) > pb$ and $ct(m_{i1}m_{j2}...m_{lh}) \leq pb$.
   This means that we stop growing the tree under a node once we find that the next chosen attribute produces a path with occupancy $\leq pb$.

   The above conditions suffice for "path present" since the occupancy property is monotone.

We observe from the above checks that we have two types of conditions that need to be evaluated for a path being present namely, i) those that depend on the sample viz. $m_{i1}m_{j2}...m_{l(d-1)}$ is impure or $ct(m_{i1}m_{j2}...m_{lh}) > pb$ and ii) those that depend split attribute selection method viz. A_1, A_2,..., A_h are chosen. The former depends on the data distribution which we have specified to be a multinomial. The latter we discuss in the next subsection. Note that checks for a combination of the above stopping criteria can be obtained by appropriately combining the individual checks.

3.4 Split Attribute Selection

In decision tree construction algorithms, at each iteration we have to decide the attribute variable on which the data should be split. Numerous measures have been developed (Hall and Holmes, 2003). Some of the most popular ones aim to increase the purity of a set of datapoints that lie in the region formed by that split. The purer the region, the better the prediction and lower the error of the classifier. Measures such as, i) Information Gain (IG) (Quinlan, 1986), ii) Gini Gain (GG) (Breiman et al., 1984), iii) Gain Ratio (GR) (Quinlan, 1986), iv) Chi-square test (CS) (Shao, 2003) etc. aim at realizing this intuition. Other measures using Principal Component Analysis (Smith, 2002), Correlation-based measures (Hall, 1998) have also been developed. Another interesting yet non-intuitive measure in terms of its utility is the Random attribute selection measure. According to this measure we randomly choose the split attribute from available set. The decision tree that this algorithm produces is called a Random decision tree (RDT). Surprisingly enough, a collection of RDTs quite often outperform their seemingly more powerful counterparts (Liu et al., 2005). In this

paper we study this interesting variant. We do this by first presenting a probabilistic characterization in selecting a particular attribute/set of attributes, followed by simulation studies. Characterizations for the other measures can be developed in similar vein by focusing on the working of each measure. As an example, for the deterministic purity based measures mentioned above the split attribute selection is just a function of the sample and thus by appropriately conditioning on the sample we can find the relevant probabilities and hence the moments.

Before presenting the expression for the probability of selecting a split attribute/attributes in constructing a RDT we extend the results in Dhurandhar and Dobra (2009) where relationships were drawn between the moments of HE, CE, LE (just a special case of cross validation) and GE, to be applicable to randomized classification algorithms. The random process is assumed to be independent of the sampling process. This result is required since the results in Dhurandhar and Dobra (2009) are applicable to deterministic classification algorithms and we would be analyzing RDT's. With this we have the following lemma.

Lemma 1 *Let D and T be independent discrete random variables, with some distribution defined on each of them. Let $\mathcal{D}$ and $\mathcal{T}$ denote the domains of the random variables. Let $f(d,t)$ and $g(d,t)$ be two functions such that $\forall t \in \mathcal{T}\ E_{\mathcal{D}}[f(d,t)] = E_{\mathcal{D}}[g(d,t)]$ and $d \in \mathcal{D}$. Then, $E_{\mathcal{T}\times\mathcal{D}}[f(d,t)] = E_{\mathcal{T}\times\mathcal{D}}[g(d,t)]$*

Proof

$$\begin{aligned} E_{\mathcal{T}\times\mathcal{D}}[f(d,t)] &= \sum_{t\in\mathcal{T}}\sum_{d\in\mathcal{D}} f(d,t)P[T=t,D=d] \\ &= \sum_{t\in\mathcal{T}}\sum_{d\in\mathcal{D}} f(d,t)P[D=d]P[T=t] \\ &= \sum_{t\in\mathcal{T}} E_{\mathcal{D}}[g(d,t)]P[T=t] \\ &= E_{\mathcal{T}\times\mathcal{D}}[g(d,t)]. \end{aligned}$$

■

The result is valid even when D and T are continuous, but considering the scope of this paper we are mainly interested in the discrete case. This result implies that all the relationships and expressions in Dhurandhar and Dobra (2009) hold with an extra expectation over the $t's$, for randomized classification algorithms where the random process is independent of the sampling process.

3.5 Random Decision Trees

In this subsection we explain the randomized process used for split attribute selection and provide the expression for the probability of choosing an attribute/a set of attributes. The attribute selection method we use is as follows. We assume a uniform probability distribution in selecting the attribute variables, that is, attributes which have already not been chosen in a particular branch, have an equal chance of being chosen for the next level. The random process involved in attribute selection is independent of the sample and hence the lemma 1 applies. We now give the expression for the probability of selecting a subset of attributes from the given set for a path. This expression is required in the computation of the above mentioned probabilities used in computing the moments.

For the first moment we need to find the following probability. Given d attributes A_1, A_2,..., A_d the probability of choosing a set of h attributes where $h \in \{1,2,...,d\}$ is,

$$P[h \text{ attributes chosen}] = \frac{1}{\left(\begin{array}{c} d \\ h \end{array} \right)}$$

since choosing without replacement is equivalent to simultaneously choosing a subset of attributes from the given set.

For the second moment when the trees are different (required in the finding of variance of CE since, the training sets in the various runs in cross validation are different, that is, for finding $E_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[GE(\zeta)GE(\zeta')]$), the probability of choosing l_1 attributes for path in one tree and l_2 attributes for path in another tree where $l_1, l_2 \leq d$ is given by,

$$P[l_1 \text{ attribute path in tree } 1,\ l_2 \text{ attribute path in tree } 2] = \frac{1}{\left(\begin{array}{c} d \\ l_1 \end{array} \right)\left(\begin{array}{c} d \\ l_2 \end{array} \right)}$$

since the process of choosing one set of attributes for a path in one tree is independent of the process of choosing another set of attributes for a path in a different tree.

For the second moment when the tree is the same (required in the finding of variance of GE and HE, that is, for finding $E_{\mathcal{Z}(N)}\left[GE(\zeta)^2\right]$), the probability of choosing two sets of attributes such that the two distinct paths resulting from them co-exist in a single tree is given by the following. Assume we have d attributes A_1, A_2,..., A_d. Let the lengths of the two paths (or cardinality of the two sets) be l_1 and l_2 respectively, where $l_1, l_2 \leq d$. Without loss of generality assume $l_1 \leq l_2$. Let p be the number of attributes common to both paths. Notice that $p \geq 1$ is one of the necessary conditions for the two paths to co-exist. Let $v \leq p$ be those attributes among the total p that have same values for both paths. Thus $p - v$ attributes are common to both paths but have different values. At one of these attributes in a given tree the two paths will bifurcate. The probability that the two paths co-exist given our randomized attribute selection method is computed by finding out all possible ways in which the two paths can co-exist in a tree and then multiplying the number of each kind of way by the probability of having that way. A detailed proof is given in the Appendix A. The expression for the probability based on the attribute selection method is,

$$P[l_1 \text{ and } l_2 \text{ length paths co} - \text{exist}] =$$
$$\sum_{i=0}^{v} vPr_i (l_1 - i - 1)!(l_2 - i - 1)!(p - v) prob_i$$

where $vPr_i = \frac{v!}{(v-i)!}$ denotes permutation and $prob_i = \frac{1}{d(d-1)...(d-i)(d-i-1)^2...(d-l_1+1)^2(d-l_1)...(d-l_2+1)}$ is the probability of the i^{th} possible way. For fixed height trees of height h, $(l_1 - i - 1)!(l_2 - i - 1)!$ becomes $(h - i - 1)!^2$ and $prob_i = \frac{1}{d(d-1)...(d-i)(d-i-1)^2...(d-h+1)^2}$.

3.6 Putting Things Together

We now have all the ingredients that are required for the computation of the moments of GE. In this subsection we combine the results derived in the previous subsections to obtain expressions for

$P_{\mathcal{Z}(N)}[\zeta(x)=C_i]$ and $P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[\zeta(x)=C_i \wedge \zeta'(x')=C_v]$ which are vital in the computation of the moments.

Let *s.c.c.s.* be an abbreviation for stopping criteria conditions that are sample dependent. Conversely, *s.c.c.i.* be an abbreviation for stopping criteria conditions that are dependent on the attribute selection method. We now provide expressions for the above probabilities categorized by the 3 stopping criteria.

3.6.1 FIXED HEIGHT

The conditions for "path exists" for fixed height trees depend only on the attribute selection method as seen in Section 3.3.1. Hence the probability used in finding the first moment is given by,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)}[\zeta(x)=C_i] \\
&= \sum_p P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), path_p exists,\ \forall j \neq i,\ i,j \in [1,...,k]] \\
&= \sum_p P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), s.c.c.i.,\ \forall j \neq i,\ i,j \in [1,...,k]] \\
&= \sum_p P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j),\ \forall j \neq i,\ i,j \in [1,...,k]] P_{\mathcal{Z}(N)}[s.c.c.i.] \\
&= \sum_p \frac{P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j),\ \forall j \neq i,\ i,j \in [1,...,k]]}{\binom{d}{h}}
\end{aligned}
$$

where h is the length of the paths or the height of the tree. The probability in the last step of the above derivation can be computed from the underlying joint distribution. The probability for the second moment when the trees are different is given by,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[\zeta(x)=C_i \wedge \zeta'(x')=C_v\right] \\
&= \sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), path_p exists, ct(path_qC_v) > ct(path_qC_w), \\
&\quad path_q exists, \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]] \\
&= \sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), ct(path_qC_v) > ct(path_qC_w), \forall j \neq i, \\
&\quad \forall w \neq v,\ i,j,v,w \in [1,...,k]] \cdot P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[s.c.c.i.] \\
&= \frac{1}{\binom{d}{h}^2} \Big(\sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), ct(path_qC_v) > ct(path_qC_w), \\
&\qquad \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]]\Big).
\end{aligned}
$$

The probability for the second moment when the trees are the same is given by,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)}\left[\zeta(x)=C_i \wedge \zeta(x')=C_v\right] \\
&=\sum_{p,q} P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), path_p exists, ct(path_qC_v)>ct(path_qC_w), \\
&\quad path_q exists, \forall j\neq i,\ \forall w\neq v,\ i,j,v,w\in[1,...,k]] \\
&=\sum_{p,q} P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), ct(path_qC_v)>ct(path_qC_w), \forall j\neq i,\ \forall w\neq v,\ i,j, \\
&\quad v,w\in[1,...,k]]\cdot P_{\mathcal{Z}(N)}[s.c.c.i.] \\
&=\sum_{p,q}\sum_{t=0}^{b} bPr_t(h-t-1)!^2(r-v)prob_t P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), \\
&\qquad ct(path_qC_v)>ct(path_qC_w), \forall j\neq i,\ \forall w\neq v,\ i,j,v,w\in[1,...,k]]
\end{aligned}
$$

where r is the number of attributes that are common in the 2 paths, b is the number of attributes that have the same value in the 2 paths, h is the length of the paths and $prob_t = \frac{1}{d(d-1)...(d-t)(d-t-1)^2...(d-h+1)^2}$. As before, the probability comparing counts can be computed from the underlying joint distribution.

3.6.2 PURITY AND SCARCITY

The conditions for "path exists" in the case of purity and scarcity depend on both the sample and the attribute selection method as can be seen in 3.3.1. The probability used in finding the first moment is given by,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)}\left[\zeta(x)=C_i\right] \\
&=\sum_{p} P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), path_p exists,\ \forall j\neq i,\ i,j\in[1,...,k]] \\
&=\sum_{p} P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), s.c.c.i, s.c.c.s.,\ \forall j\neq i,\ i,j\in[1,...,k]] \\
&=\sum_{p} P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), s.c.c.s.,\ \forall j\neq i,\ i,j\in[1,...,k]]P_{\mathcal{Z}(N)}[s.c.c.i.] \\
&=\sum_{p} \frac{P_{\mathcal{Z}(N)}[ct(path_pC_i)>ct(path_pC_j), s.c.c.s.,\ \forall j\neq i,\ i,j\in[1,...,k]]}{dC_{h_p-1}(d-h_p+1)}
\end{aligned}
$$

where h_p is the length of the path indexed by p. The joint probability of comparing counts and $s.c.c.s.$ can be computed from the underlying joint distribution. The probability for the second moment when the trees are different is given by,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}\left[\zeta(x)=C_i \wedge \zeta'(x')=C_v\right] \\
&= \sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), path_pexists, ct(path_qC_v) > ct(path_qC_w), \\
&\quad path_qexists, \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]] \\
&= \sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), ct(path_qC_v) > ct(path_qC_w), s.c.c.s., \forall j \neq i, \\
&\quad \forall w \neq v,\ i,j,v,w \in [1,...,k]] \cdot P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[s.c.c.i.] \\
&= \frac{1}{dC_{h_p-1}dC_{h_q-1}(d-h_p+1)(d-h_q+1)}(\sum_{p,q} P_{\mathcal{Z}(N)\times\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), \\
&\quad ct(path_qC_v) > ct(path_qC_w), s.c.c.s., \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]])
\end{aligned}
$$

where h_p and h_q are the lengths of the paths indexed by p and q. The probability for the second moment when the trees are the same is given by,

$$
\begin{aligned}
&P_{\mathcal{Z}(N)}\left[\zeta(x)=C_i \wedge \zeta(x')=C_v\right] \\
&= \sum_{p,q} P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), path_pexists, ct(path_qC_v) > ct(path_qC_w), path_qexists, \\
&\quad \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]] \\
&= \sum_{p,q} P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), ct(path_qC_v) > ct(path_qC_w), s.c.c.s., \forall j \neq i,\ \forall w \neq v, \\
&\quad i,j,v,w \in [1,...,k]] P_{\mathcal{Z}(N)}[s.c.c.i.] \\
&= \sum_{p,q}\sum_{t=0}^{b} \frac{bPr_t(h_p-t-2)!(h_q-t-2)!(r-v)prob_t}{(d-h_p+1)(d-h_q+1)} P_{\mathcal{Z}(N)}[ct(path_pC_i) > ct(path_pC_j), \\
&\quad ct(path_qC_v) > ct(path_qC_w), s.c.c.s., \forall j \neq i,\ \forall w \neq v,\ i,j,v,w \in [1,...,k]]
\end{aligned}
$$

where r is the number of attributes that are common in the 2 paths sparing the attributes chosen as leaves, b is the number of attributes that have the same value, h_p and h_q are the lengths of the 2 paths and without loss of generality assuming $h_p \leq h_q$ $prob_t = \frac{1}{d(d-1)...(d-t)(d-t-1)^2...(d-h_p)^2(d-h_p-1)...(d-h_q)}$. As before, the probability of comparing counts and s.c.c.s. can be computed from the underlying joint distribution.

Using the expressions for the above probabilities the moments of GE can be computed. In next section we perform experiments on synthetic as well as distributions built on real data to portray the efficacy of the derived expressions.

4. Experiments

To exactly compute the probabilities for each path the time complexity for fixed height trees is $O(N^2)$ and for purity and scarcity based trees it is $O(N^3)$. Hence, computing exactly the probabilities and consequently the moments is practical for small values of N. For larger values of N, we propose computing the individual probabilities using Monte Carlo. In the empirical studies we report, we initially set N to small value and compute the error (i.e., expected value + standard deviation) exactly, using the derived expressions (which is thus the golden standard) and compare it

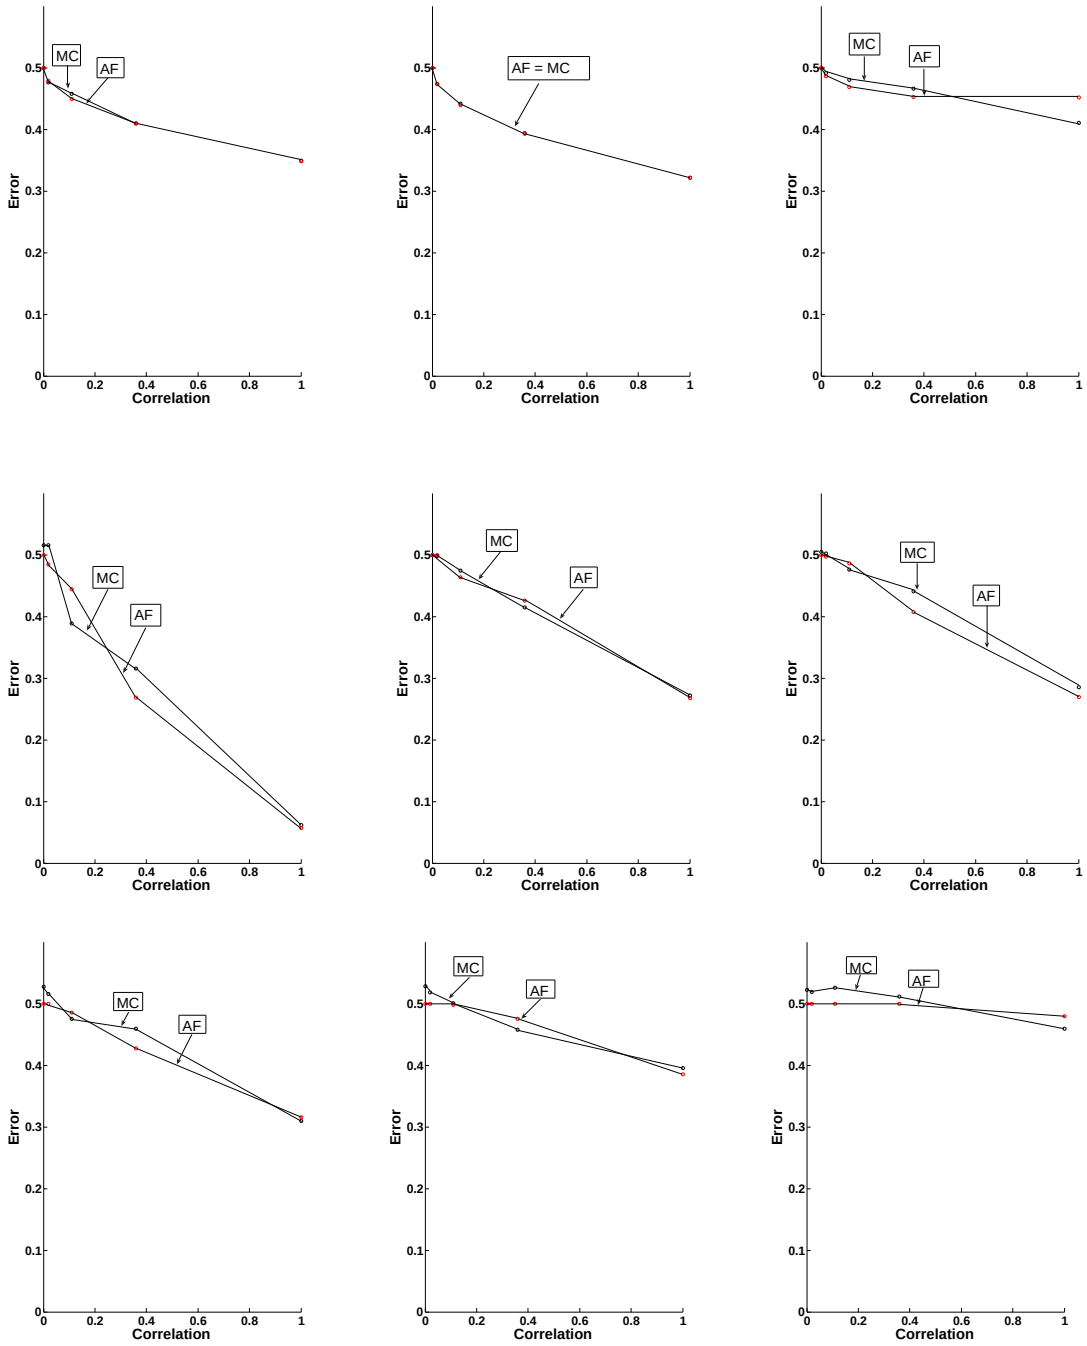

Figure 3: Errors of Fixed height trees (top row figures), Purity trees (center row figures) and Scarcity trees (bottom row figures) with $N = 100$ are shown. The leftmost figures are for $d = 5$ and binary splits, the center figures are for $d = 5$ and ternary splits and the rightmost figures are for $d = 8$ and binary splits. $h = 3$ for Fixed height trees and $pb = \frac{N}{10}$ for Scarcity based trees.

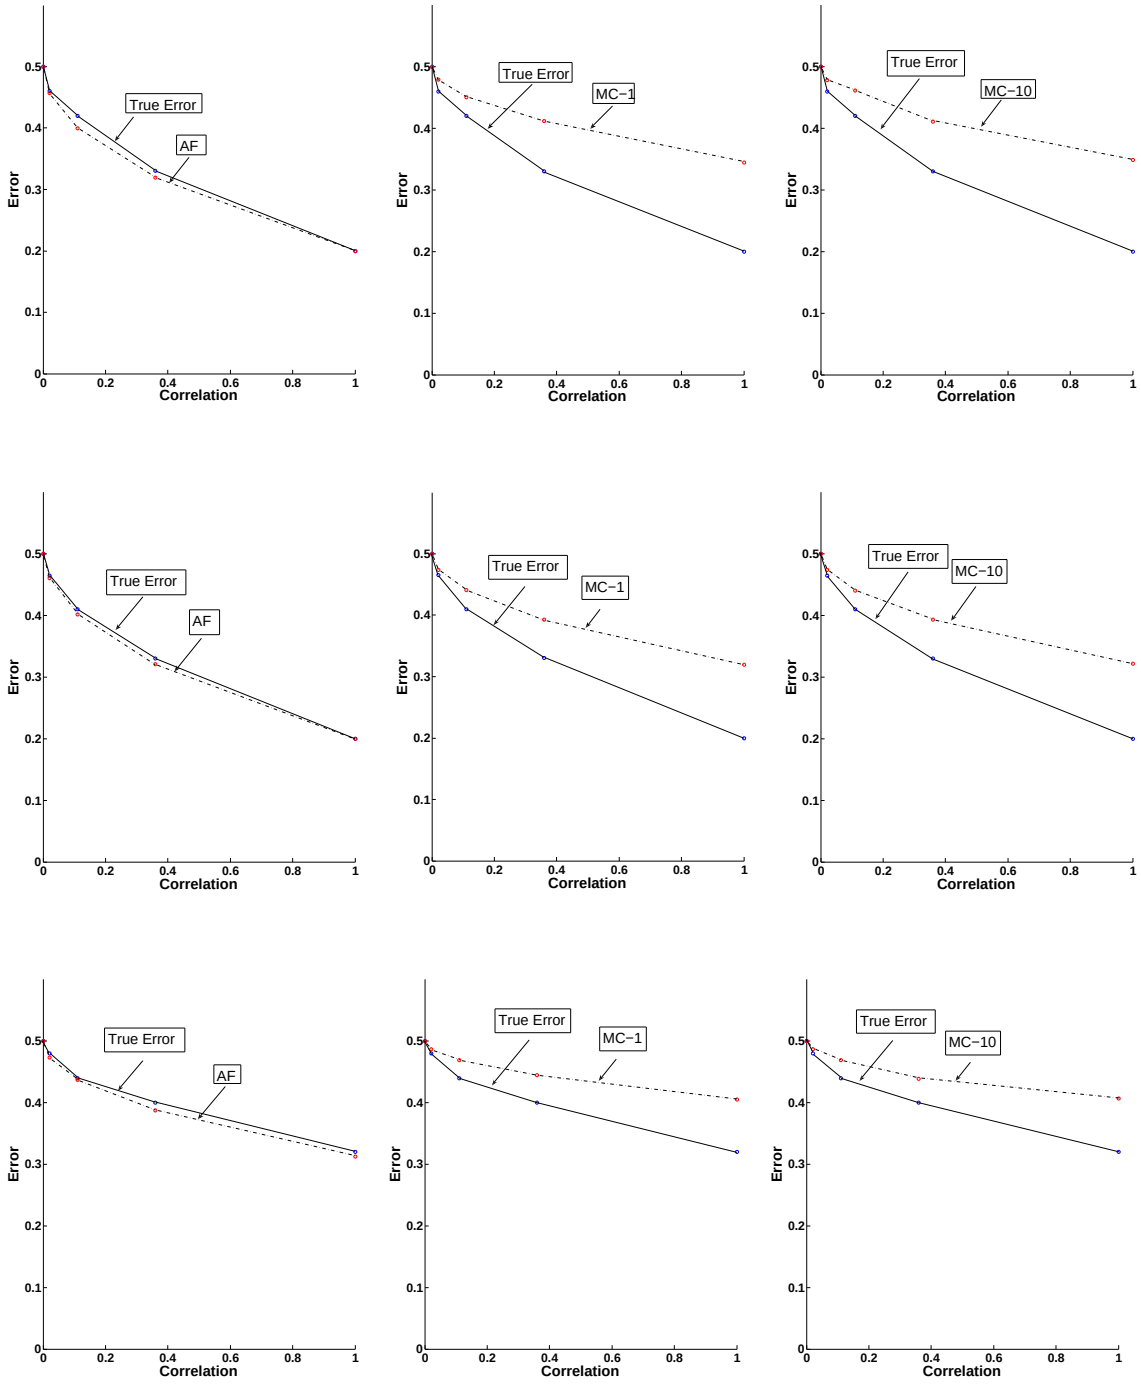

Figure 4: Errors of Fixed height trees with $N = 10000$ and $h = 3$ are shown. In the top row $d = 5$ and splits are binary, in the center row $d = 5$ and splits are ternary and in the last row $d = 8$ and splits are binary.

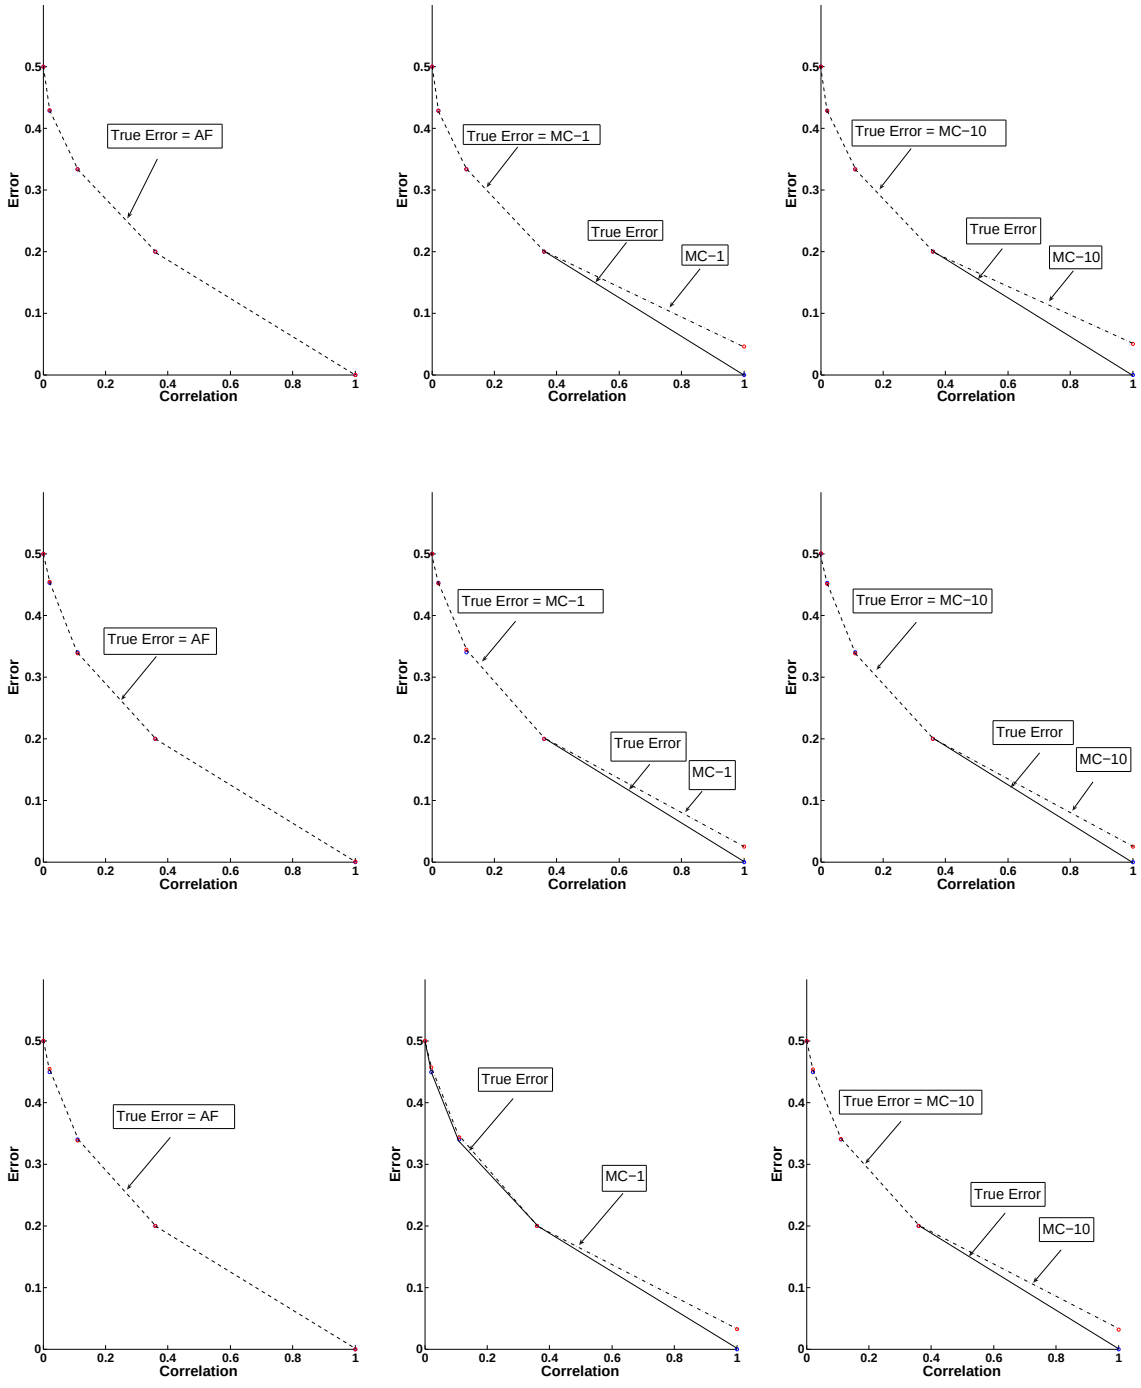

Figure 5: Errors of Purity trees with $N = 10000$ are shown. In the top row $d = 5$ and splits are binary, in the center row $d = 5$ and splits are ternary and in the last row $d = 8$ and splits are binary.

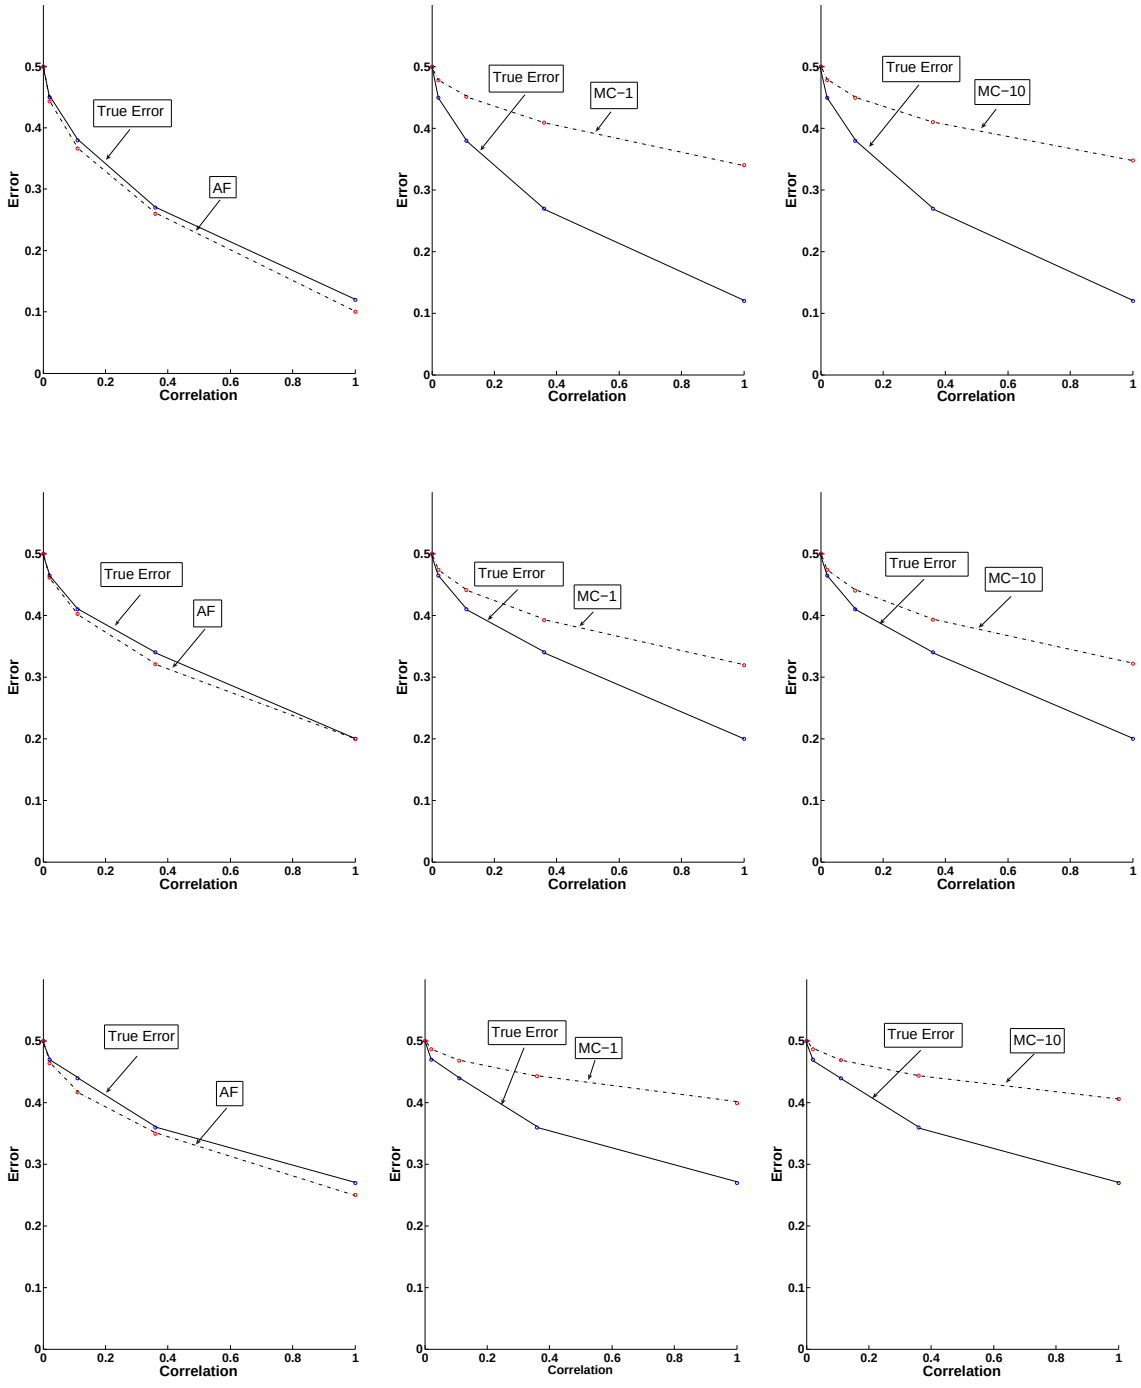

Figure 6: Errors of Scarcity trees with $N = 10000$ and $pb = \frac{N}{10}$ are shown. In the top row $d = 5$ and splits are binary, in the center row $d = 5$ and splits are ternary and in the last row $d = 8$ and splits are binary.

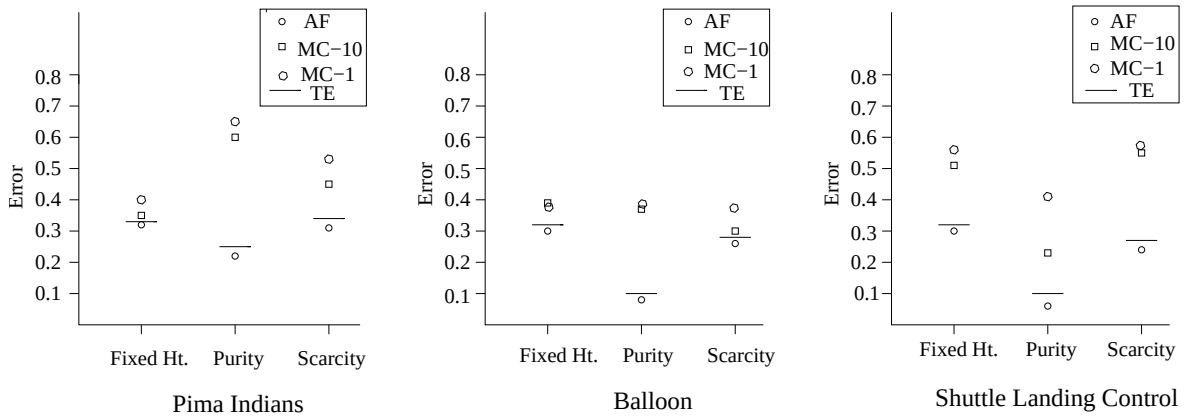

Figure 7: Comparison between AF and MC on three UCI data sets for trees prunned based on fixed height ($h = 3$), purity and scarcity ($pb = \frac{N}{10}$).

Table 1: The above table shows the upper bounds on $E_{\mathcal{Z}(N)}[GE(\zeta)]$ for different levels of correlation (ρ) between the attributes and class labels obtained using Breiman's formula.

Stopping Criteria	Pima Indians	Balloon	Shuttle Landing Control
Fixed Height	151.58	51.84	1.91
Purity	98.97	50.56	2.74
Scarcity	180.93	41.67	2.32

Table 2: The above table shows the upper bounds on $E_{\mathcal{Z}(N)}[GE(\zeta)]$ for 3 UCI data sets obtained using Breiman's formula.

with MC (i.e., hold-out-set estimation)[3] for the same computational cost. We then choose a larger N and show that the accuracy in estimating the error by using our expressions with Monte Carlo is always greater than by directly using MC for the same computational cost. In fact, the accuracy of using the expressions is never worse than MC even when MC is executed for 10 times the number of iterations as those of our expressions. The true error or the golden standard against which we compare the accuracy of these estimators in this scenario, (since the expressions are also approximated) is MC that is run for around 200 times the number of iterations as those of the expressions. Moreover, in Tables 1 and 2 we depict the upper bounds on the error as computed using Breiman's strength and correlation based upper bound formula (Breiman, 2001).

4.1 Notation

In the experiments, AF refers to the estimates obtained by using the expressions in conjunction with Monte Carlo. MC-i refers to simple Monte Carlo being executed for i times the number of iterations as those of the expressions. Writing just MC denotes MC-1. The term True Error or TE refers to the golden standard against which we compare AF and MC-i. This is relevant only for large N in experiments on synthetic data and experiments on real data, since AF is itself the golden standard for synthetic data experiments with a small N.

4.2 General Setup

We perform empirical studies on synthetic as well as real data. The experimental setup for synthetic data is as follows: In our initial experiments we fix N to a 100 and then increase it to 10000. The number of classes is fixed to two. We observe the behavior of the error for the three kinds of trees with the number of attributes fixed to $d = 5$ and each attribute having 2 attribute values. We then increase the number of attribute values to 3, to observe the effect that increasing the number of split points has on the performance of the estimators. We also increase the number of attributes to $d = 8$ to study the effect that increasing the number of attributes has on the performance. With this we have a $d+1$ dimensional contingency table whose d dimensions are the attributes and the $(d+1)^{th}$ dimension represents the class labels. When each attribute has two values the total number of cells in the table is $c = 2^{d+1}$ and with three values the total number of cells is $c = 3^d \times 2$. If we fix the probability of observing a datapoint in cell i to be p_i such that $\sum_{i=1}^{c} p_i = 1$ and the sample size to N the distribution that perfectly models this scenario is a multinomial distribution

3. In hold-out set we build a tree, find the test error by averaging over multiple test sets. Perform this procedure multiple times to obtain multiple test errors and find the average and variance of these test errors.

with parameters N and the set $\{p_1, p_2, ..., p_c\}$. In fact, irrespective of the value of d and the number of attribute values for each attribute the scenario can be modeled by a multinomial distribution. In the studies that follow the p_i's are varied and the amount of dependence between the attributes and the class labels is computed for each set of p_i's using the Chi-square test (Connor-Linton, 2003). More precisely, we sum over all i the squares of the difference of each p_i with the product of its corresponding marginals, with each squared difference being divided by this product, that is, correlation $= \sum_i \frac{(p_i - p_{im})^2}{p_{im}}$, where p_{im} is the product of the marginals for the i^{th} cell. The behavior of the error for trees with the three aforementioned stopping criteria is seen for different correlation values and for a class prior of 0.5.

In case of real data, we perform experiments on distributions built on three UCI data sets. We split the continuous attributes at the mean of the given data. We thus can form a contingency table representing each of the data sets. The counts in the individual cells divided by the data set size provide us with empirical estimates for the individual cell probabilities (p_i's). Thus, with the knowledge of N (data set size) and the individual p_i's we have a multinomial distribution. Using this distribution we observe the behavior of the error for the three kinds of trees with results being applicable to other data sets that are similar to the original.

In Tables 1 and 2 we see the upper bounds computed using Breiman's formula (Breiman, 2001): $\kappa \frac{(1-s^2)}{s^2}$ where κ is the correlation between the random decision trees in an ensemble and s is the strength of the resultant classifier.[4] Since, we consider only single random decision trees in this paper and not random forests $\kappa = 1$. To compute s we build a tree and calculate the necessary probabilities. Knowing κ and s we find the upper bound on the GE for the particular classifier. Since, we need an estimate of $E_{\mathcal{Z}(N)}[GE(\zeta)]$, we perform the above procedure multiple times thus building multiple trees and computing an upper bound on GE for each. We then average the upper bounds that we have computed and report the result as an estimate of the upper bound on $E_{\mathcal{Z}(N)}[GE(\zeta)]$.

4.3 Observations

In Figure 3 we observe the behavior of MC vs AF (the golden standard) for $N = 100$. We observe that the estimates provided by MC are reasonable but not as accurate as AF for the same computational cost. The behavior of MC becomes worse as we increase the data set size (N) to 10000 as we discuss now. Figure 4 depicts the error of Fixed height trees for different dimensionalities (5 and 8) and for different number of splits (binary and ternary). We observe here that AF is significantly more accurate than both MC-1 and MC-10. In fact the performance of the 3 estimators namely, AF, MC-1 and MC-10 remains more or less unaltered even with changes in the number of attributes and in the number of splits per attribute. A similar trend is seen for both purity based trees Figure 5 as well as scarcity based trees 6. Though in the case of purity based trees the performance of both MC-1 and MC-10 is much superior as compared with their performance on the other two kinds of trees, especially at low correlations. The reason for this being that, at low correlations the probability in each cell of the multinomial is non-negligible and with $N = 10000$ the event that every cell contains at least a single datapoint is highly likely. Hence, the trees we obtain with high probability using the purity based stopping criteria are all ATT's. Since in an ATT all the leaves are identical irrespective of the ordering of the attributes in any path, the randomness in the classifiers produced, is only due to the randomness in the data generation process and not because of the random attribute selection method. Thus, the space of classifiers over which the error is computed reduces and MC performs

4. For further details refer to Breiman (2001) and Buttrey and Kobayashi (2003).

well even for a relatively fewer number of iterations. At higher correlations and for the other two kinds of trees the probability of smaller trees is reasonable and hence MC has to account for a larger space of classifiers induced by not only the randomness in the data but also by the randomness in the attribute selection method.

In case of real data too Figure 7, the performance of the expressions is significantly superior as compared with MC-1 and MC-10. The performance of MC-1 and MC-10 for the purity based trees is not as impressive here since the data set sizes are much smaller (in the tens or hundreds) compared to 10000 and hence the probability of having an empty cell are not particularly low. Moreover, the correlations are reasonably high (above 0.6).

By inspecting Tables 1 and 2 it is immediately apparent that the bound in Breiman (2001) when applied to a single tree is ineffective in most situations—the prediction for the GE is larger than 1. For this formula to provide reasonable predictions, a large number of mostly uncorrelated trees needs to be used so that the constant κ balances the influence of s.

4.4 Reasons for Superior Performance of Expressions

With simple MC, trees have to be built while performing the experiments. Since, the expectations are over all possible classifiers, that is, over all possible data sets and all possible randomizations in the attribute selection phase, the exhaustive space over which direct MC has to run is huge. No tree has to be explicitly built when using the expressions. Moreover, the probabilities for each path can be computed parallelly. Another reason as to why calculating the moments using expressions works better is that the portion of the probabilities for each path that depend on the attribute selection method are computed *exactly* (i.e., with no error) by the given expressions and the inaccuracies in the estimates only occur due to the sample dependent portion in the probabilities.

5. Discussion

In the previous sections we derived the analytical expressions for the moments of the GE of decision trees and depicted interesting behavior of RDT's built under the 3 stopping criteria. It is clear that using the expressions we obtain highly accurate estimates of the moments of errors for situations of interest. In this section we discuss issues related to extension of the analysis to other attribute selection methods and issues related to computational complexity of algorithm.

5.1 Extension

The conditions presented for the 3 stopping criteria namely, fixed height, purity and scarcity are applicable irrespective of the attribute selection method. Commonly used deterministic attribute selection methods include those based on Information Gain (IG), Gini Gain (GG), Gain ratio (GR) etc. Given a sample the above metrics can be computed for each attribute. Hence, the above metrics can be implemented as corresponding functions of the sample. For example, in the case of IG we compute the loss in entropy ($qlogq$ where the q's are computed from the sample) by the addition of an attribute as we build the tree. We then compare the loss in entropy of all attributes not already chosen in the path and choose the attribute for which the loss in entropy is maximum. Following this procedure we build the path and hence the tree. To compute the probability of *path exists*, we add these sample dependent conditions in the corresponding probabilities. These conditions account for a particular set of attributes being chosen, in the 3 stopping criteria. In other words, these conditions

quantify the conditions in the 3 stopping criteria that are attribute selection method dependent. Similar conditions can be derived for the other attribute selection methods (attribute with maximum gini gain for GG, attribute with maximum gain ratio for GR) from which the relevant probabilities and hence the moments can be computed. Thus, while computing the probabilities given in Equations 1 and 2 the conditions for *path exists* for these attribute selection methods depend totally on the sample. This is unlike what we observed for the randomized attribute selection criterion where the conditions for *path exists* depending on this randomized criterion, were sample independent while the other conditions in purity and scarcity were sample dependent. Characterizing these probabilities enables us in computing the moments of GE for these other attribute selection methods.

In the analysis that we presented, we assumed that the split points for continuous attributes were determined apriori to tree construction. If the split point selection algorithm is dynamic, that is, the split points are selected while building the tree, then in the *path exists* conditions of the 3 stopping criteria we would have to append an extra condition namely, the split occurs at "this" particular attribute value. In reality, the value of "this" is determined by the values that the samples attain for the specific attribute in the particular data set, which is finite (since data set is finite). Hence, while analyzing we can choose a set of allowed values for "this" for each continuous attribute. Using these updated set of conditions for the 3 stopping criteria the moments of GE can be computed.

Another interesting extension to the current work, in which we customized expressions for RDT's is to extend the analysis to Random Forests. Random Forests are essentially an ensemble of RDT's and the decision to classify a datapoint is based on a majority vote taken from this ensemble. Hence, in the analysis to compute $P_{Z(N)}[\zeta(x)=y]$ (which is the key ingredient in finding the moments), we would have to compute the probability of the event that more than half of the trees classify the input x into class y. The precise details as to how this might be accomplished efficiently is a part of future research.

5.2 Scalability

The time complexity of implementing the analysis is proportional to the product of the size of the input/output space[5] and the number of paths that are possible in the tree while classifying a particular input. To this end, it should be noted that if a stopping criterion is not carefully chosen and applied, then the number of possible trees and hence the number of allowed paths can become exponential in the dimensionality. In such scenarios, studying small or at best medium size trees is feasible. For studying larger trees the practitioner should combine stopping criteria (e.g., pruning bound and fixed height or scarcity and fixed height), that is, combine the conditions given for each individual stopping criteria or choose a stopping criterion that limits the number of paths (e.g., fixed height). Keeping these simple facts in mind and on appropriate usage, the expressions can assist in delving into the statistical behavior of the errors for decision tree classifiers. Further speedup w/o compromising much on accuracy is a challenge for the future.

5.3 Strengths and Limitations of the Applied Methodology

We now discuss the primary advantage and weakness of the approach taken by Statistical Learning Theory (SLT) and our methodology from the point of view of studying classification algorithms. SLT categorizes classification algorithms (actually the more general learning algorithms) into dif-

5. In case of continuous attributes the size of the input/output space is the size after discretization.

ferent classes called Concept Classes. The concept class of a classification algorithm is determined by its Vapnik-Chervonenkis (VC) dimension which is related to the shattering capability of the algorithm. Distribution free bounds on the generalization error of a classifier built using a particular classification algorithm belonging to a concept class are derived in SLT. The bounds are functions of the VC dimension, the sample size and the training error. The strength of this technique is that by finding the VC dimension of an algorithm we can derive error bounds for the classifiers built using this algorithm without ever referring to the underlying distribution. A consequence of the fact that the characterization is general is that the bounds are usually loose (Boucheron et al., 2005; Williamson, 2001) which in turn results in making statements about any particular classifier and hence classification algorithm weak.

The idea behind the methodology pursued in this paper was to define a class of classifiers induced by a given learning algorithm and i.i.d. data of a given size. As a consequence, this class of classifiers is much smaller than the classes considered in SLT. Hence, the characterization of this class is strongly connected to the behavior of the classifiers and hence the classification algorithm (as seen in this paper for RDT's). The downside of our method is the fact that we loose the strength to make generalized statements to the extent that SLT makes, that is, bounds that are distribution independent. While the process of characterizing classification algorithms employing the deployed methodology might be tedious, we believe that it leads to a more precise study of individual learning algorithms.

6. Conclusion

In this paper we have developed a general characterization for computing the moments of the GE for decision trees. In particular we have specifically characterized RDT's for three stopping criteria namely, fixed height, purity and scarcity. Being able to compute moments of GE, allows us to compute the moments of the various validation measures and observe their relative behavior. Using the general characterization, characterizations for specific attribute selection measures (e.g., IG, GG etc.) other than randomized can be developed as described before. As a technical result, we have extended the theory in Dhurandhar and Dobra (2009) to be applicable to randomized classification algorithms; this is necessary if the theory is to be applied to random decisions trees as we did in this paper. The experiments reported in Section 4 had two purposes: (a) portray the manner in which the expressions can be used as an exploratory tool to gain a better understanding of decision tree classifiers, and (b) show that the methodology in Dhurandhar and Dobra (2009) together with the developments in this paper provide can prove to be a superior analysis tool when compared with other techniques such as Monte Carlo and distribution free bounds.

More work needs to be done to explore the possibilities and test the limits of the kind of analysis that we have performed. However, if learning algorithms are analyzed in the manner that we have shown, it would aid us in studying them more precisely, leading to better understanding and improved decision-making in the practice of model selection.

Appendix A.

The probability that two paths of lengths l_1 and l_2 ($l_2 \geq l_1$) co-exist in a tree based on the randomized attribute selection method is given by,

$$P[l_1 \textit{ and } l_2 \textit{ length paths co} - \textit{exist}] = \sum_{i=0}^{v} vPr_i (l_1 - i - 1)!(l_2 - i - 1)!(r - v) prob_i$$

where r is the number of attributes common in the two paths, v is the number attributes with the same values in the two paths, $vPr_i = \frac{v!}{(v-i)!}$ denotes permutation and $prob_i = \frac{1}{d(d-1)\ldots(d-i)(d-i-1)^2\ldots(d-l_1+1)^2(d-l_1)\ldots(d-l_2+1)}$.

We now prove the above result. The derivation of the above result will become clearer through the following example. Consider the total number of attributes to be d as usual. Let A_1, A_2 and A_3 be three attributes that are common to both paths and also having the same attribute values. Let A_4 and A_5 be common to both paths but have different attribute values for each of them. Let A_6 belong to only the first path and A_7, A_8 to only the second path. Thus, in our example $l_1 = 6$, $l_2 = 7$, $r = 5$ and $v = 3$. For the two paths to co-exist notice that atleast one of A_4 or A_5 has to be at a lower depth than the non-common attributes A_6, A_7, A_8. This has to be true since, if a non-common attribute say A_6 is higher than A_4 and A_5 in a path of the tree then the other path cannot exist. Hence, in all the possible ways that the two paths can co-exist, one of the attributes A_4 or A_5 has to occur at a maximum depth of $v+1$, that is, 4 in this example. Figure 8a depicts this case. In the successive tree structures, that is, Figure 8b, Figure 8c the common attribute with distinct attribute values (A_4) rises higher up in the tree (to lower depths) until in Figure 8d it becomes the root. To find the probability that the two paths co-exist we sum up the probabilities of such arrangements/tree structures. The probability

of the subtree shown in Figure 8a is $\frac{1}{d(d-1)(d-2)(d-3)(d-4)^2(d-5)^2(d-6)}$ considering that we choose attributes w/o replacement for a particular path. Thus the probability of choosing the root is $\frac{1}{d}$, the next attribute is $\frac{1}{d-1}$ and so on till the subtree splits into two paths at depth 5. After the split at depth 5 the probability of choosing the respective attributes for the two paths is $\frac{1}{(d-4)^2}$, since repetitions are allowed in two separate paths. Finally, the first path ends at depth 6 and only one attribute has to be chosen at depth 7 for the second path which is chosen with a probability of $\frac{1}{d-6}$. We now find the total number of subtrees with such an arrangement where the highest common attribute with different values is at depth of 4. We observe that A_1, A_2 and A_3 can be permuted in whichever way w/o altering the tree structure. The total number of ways of doing this is 3!, that is, $3Pr_3$. The attributes below A_4 can also be permuted in 2!3! w/o changing the tree structure. Moreover, A_4 can be replaced by A_5. Thus, the total number of ways the two paths can co-exist with this arrangement is $3Pr_3 2!3!2$. The probability of the arrangement is hence given by, $\frac{3Pr_3 2!3!2}{d(d-1)(d-2)(d-3)(d-4)^2(d-5)^2(d-6)}$. Similarly, we find the probability of the arrangement in Figure 8b where the common attribute with different values is at depth 3 then at depth 2 and finally at the root. The probabilities for the successive arrangements are $\frac{3Pr_2 3!4!2}{d(d-1)(d-2)(d-3)^2(d-4)^2(d-5)^2(d-6)}$, $\frac{3Pr_1 4!5!2}{d(d-1)(d-2)^2(d-3)^2(d-4)^2(d-5)^2(d-6)}$ and $\frac{3Pr_0 5!6!2}{d(d-1)^2(d-2)^2(d-3)^2(d-4)^2(d-5)^2(d-6)}$ respectively. The total probability for the paths to co-exist is given by the sum of the probabilities of these individual arrangements.

In the general case, where we have v attributes with the same values the number of arrangements possible is $v+1$. This is because the depth at which the two paths separate out lowers from $v+1$ to 1. When the bifurcation occurs at $v+1$ the total number of subtrees is $vPr_v(l_1-v-1)!(l_2-v-1)!(r-v)$ with this arrangement. vPr_v is the permutations of the common attributes with same values. $(l_1-v-1)!$ and $(l_2-v-1)!$ are the total permutations of the attributes in path 1 and 2 respectively after the split. $r-v$ is the number of choices for the split attribute. The probability of any one of the subtrees is $\frac{1}{d(d-1)...(d-v)(d-v-1)^2...(d-l_1+1)^2(d-l_1)...(d-l_2+1)}$ since until a depth of $v+1$ the two paths are the same and then from $v+2$ the two paths separate out. The probability of the first arrangement is thus, $\frac{vPr_v(l_1-v-1)!(l_2-v-1)!(r-v)}{d(d-1)...(d-v)(d-v-1)^2...(d-l_1+1)^2(d-l_1)...(d-l_2+1)}$. For the second arrangement with the bifurcation occurring at a depth of v, the number of subtrees is $vPr_{v-1}(l_1-v)!(l_2-v)!(r-v)$ and the probability of any one of them is $\frac{1}{d(d-1)...(d-v+1)(d-v)^2...(d-l_1+1)^2(d-l_1)...(d-l_2+1)}$. The probability of the arrangement is thus $\frac{vPr_{v-1}(l_1-v)!(l_2-v)!(r-v)}{d(d-1)...(d-v+1)(d-v)^2...(d-l_1+1)^2(d-l_1)...(d-l_2+1)}$. Similarly, the probabilities of the other arrangements can be derived. Hence the total probability for the two paths to co-exist which is the sum of the probabilities of the individual arrangements is given by,

$$P[l_1 \textit{ and } l_2 \textit{ length paths co}-\textit{exist}] = \sum_{i=0}^{v} \frac{vPr_i(l_1-i-1)!(l_2-i-1)!(r-v)}{d(d-1)...(d-i)(d-i-1)^2...(d-l_1+1)^2(d-l_1)...(d-l_2+1)}.$$

Abstract

Feature selection is the task of choosing a small subset of features that is sufficient to predict the target labels well. Here, instead of trying to directly determine which features are better, we attempt to learn the properties of good features. For this purpose we assume that each feature is represented by a set of properties, referred to as *meta-features*. This approach enables prediction of the quality of features without measuring their value on the training instances. We use this ability to devise new selection algorithms that can efficiently search for new good features in the presence of a huge number of features, and to dramatically reduce the number of feature measurements needed. We demonstrate our algorithms on a handwritten digit recognition problem and a visual object category recognition problem. In addition, we show how this novel viewpoint enables derivation of better generalization bounds for the joint learning problem of selection and classification, and how it contributes to a better understanding of the problem. Specifically, in the context of object recognition, previous works showed that it is possible to find one set of features which fits most object categories (aka a *universal dictionary*). Here we use our framework to analyze one such universal dictionary and find that the quality of features in this dictionary can be predicted accurately by its meta-features.

Keywords: feature selection, unobserved features, meta-features

1. Introduction

In many supervised learning tasks the input is represented by a very large number of features, many of which are not needed for predicting the labels. *Feature selection* is the task of choosing a small subset of features that is sufficient to predict the target labels well. The main motivations for feature selection are computational complexity, reducing the cost of measuring features, improved classification accuracy and problem understanding. Feature selection is also a crucial component in the context of *feature extraction*. In feature extraction the original input features (for example, pixels) are used to generate new, more complicated features (for example logical AND of sets of 3 binary pixels). Feature extraction is a very useful tool for producing sophisticated classification rules using simple classifiers. One main problem here is that the potential number of additional features one can extract is huge, and the learner needs to decide which of them to include in the model.

In the most common selection paradigm an evaluation function is used to assign scores to subsets of features and a search algorithm is used to search for a subset with a high score. The evaluation

function can be based on the performance of a specific predictor (*wrapper* model) or on some general (typically cheaper to compute) relevance measure of the features to the prediction (*filter* model) (Kohavi and John, 1997). In any case, an exhaustive search over all feature sets is generally intractable due to the exponentially large number of possible sets. Therefore, search methods apply a variety of heuristics, such as hill climbing and genetic algorithms. Other methods simply rank individual features, assigning a score to each feature independently. These methods ignore redundancy and inevitably fail in situations where only a combined set of features is predictive of the target function. However, they are usually very fast, and are very useful in most real-world problems, at least for an initial stage of filtering out useless features. One very common such method is *Infogain* (Quinlan, 1990), which ranks features according to the mutual information[1] between each feature and the labels. Another selection method which we refer to in the following is Recursive Feature Elimination (RFE, Guyon et al., 2002). SVM-RFE is a wrapper selection methods for linear Support Vector Machine (SVM). In each round it measures the quality of the candidate features by training SVM and eliminates the features with the lowest weights. See Guyon and Elisseeff (2003) for a comprehensive overview of feature selection.

In this paper we present a novel approach to the task of feature selection. Classical methods of feature selection tell us which features are better. However, they do not tell us what *characterizes* these features or how to judge new features which were not measured in the training data. We claim that in many cases it is natural to represent each feature by a set of properties, which we call *meta-features*. As a simple example, in image-related tasks where the features are gray-levels of pixels, the (x,y) position of each pixel can be the meta-features. The value of the meta-features is fixed per feature; in other words it is not dependent on the instances. Therefore, we refer to the meta-features as prior knowledge. We use the training set to learn the relation between the meta-feature values and feature usefulness. This in turn enables us to predict the quality of unseen features. This ability is an asset particularly when there are a large number of potential features and it is expensive to measure the value of each feature. For this scenario we suggest a new algorithm called Meta-Feature based Predictive Feature Selection (MF-PFS) which is an alternative to RFE. The MF-PFS algorithm uses predicted quality to select new good features, while eliminating many low-quality features without measuring them. We apply this algorithm to a visual object recognition task and show that it outperforms standard RFE. In the context of object recognition there is an advantage in finding one set of features (referred to as *a universal dictionary*) that is sufficient for recognition of most kinds of objects. Serre et al. (2005) found that such a dictionary can be built by random selection of patches from natural images. Here we show what characterizes good universal features and demonstrate that their quality can be predicted accurately by their meta-features.

The ability to predict feature quality is also a very valuable tool for feature extraction, where the learner has to decide which potential complex features have a good chance of being the most useful. For this task we derive a selection algorithm (called *Mufasa*) that uses meta-features to explore a huge number of candidate features efficiently. We demonstrate the Mufasa algorithm on a handwritten digit recognition problem. We derive generalization bounds for the joint problem of feature selection (or extraction) and classification, when the selection uses meta-features. We show that these bounds are better than those obtained by direct selection.

The paper is organized as follows: we provide a formal definition of the framework and define some notations in Section 2. In Sections 3 and 4 we show how to use this framework to predict the

1. Recall that the mutual information between two random variables X and Y is $I(X;Y) = \sum_{\{x,y\}} p(x,y) \log \frac{p(x,y)}{p(x)p(y)}$.

quality of individual unseen features and how this ability can be combined with RFE. In Section 5 we apply MF-PFS to an object recognition task. In Section 6 we show how the use of meta-features can be extended to sets of features, and present our algorithm for guiding feature extraction. We illustrate its abilities on the problem of handwritten digit recognition. Our theoretical results are presented in Section 7. We discuss how to choose meta-features wisely in Section 8. Finally we conclude with some further research directions in Section 9. A Matlab code running the algorithms and experiments presented in this paper is available upon request from the authors.

1.1 Related Work

Incorporating prior knowledge about the representation of objects has long been known to profoundly influence the effectiveness of learning. This has been demonstrated by many authors using various heuristics such as specially engineered architectures or distance measures (see, for example, LeCun et al., 1998; Simard et al., 1993). In the context of support vector machines (SVM) a variety of successful methods to incorporate prior knowledge have been published over the last ten years (see, for example, Decoste and Schölkopf 2002 and a recent review by Lauer and Bloch 2006). Krupka and Tishby (2007) proposed a framework that incorporates prior knowledge on features, which is represented by meta-features, into learning. They assume that a weight is assigned to each feature, as in linear discrimination, and they use the meta-features to define a prior on the weights. This prior is based on a Gaussian process and the weights are assumed to be a smooth *function* of the meta-features. While in their work meta-features are used for learning a better classifier, in this work meta-features are used for feature selection.

Taskar et al. (2003) used meta-features of words for text classification when there are features (words) that are unseen in the training set, but appear in the test set. In their work the features are words and the meta-features are words in the neighborhood of each word. They used the meta-features to predict the role of words that are unseen in the training set. Generalization from observed (training) features to unobserved features is discussed by Krupka and Tishby (2008). Their approach involves clustering the instances based on the observed features. What these works and ours have in common is that they all extend learning from the standard instance-label framework to learning in the feature space. Our formulation here, however, is different and allows a mapping of the feature learning problem onto the standard supervised learning framework (see Table 1). Another related model is *Budget Learning* (Lizotte et al., 2003; Greiner, 2005), that explores the issue of deciding which is the most valuable feature to measure next under a limited budget. Other ideas using feature properties to produce or select good features can be found in the literature and have been employed in various applications. For instance, Levi et al. (2004) used this rationale in the context of inductive transfer for object recognition. Raina et al. (2006) also used this approach in the same context for text classification. They use a property of pairs of words which indicates whether they are synonyms or not for the task of estimating the words' covariance matrix. Recently, Lee et al. (2007) used meta-features for feature selection in related tasks. They assume that the meta-features are informative on the relevance of the features. Using a related task they model feature relevance as a function of the meta-features. Kadous and Sammut (2005) used property-based clustering of features for handwritten Chinese recognition and other applications. Our formulation encompasses a more general framework and suggests a systematic way to use the properties as well as derive algorithms and generalization bounds for the combined process of feature selection and classification.

Training set	Features described by meta-features

Table 1: Feature learning by meta-features as a form of standard supervised learning

2. Framework and Notation

In supervised (classification) learning it is assumed that we have a training set $S^m = \left\{x^i, y^i\right\}_{i=1}^m$, $x^i \in \mathbb{R}^N$ and $y^i = c\left(x^i\right)$ where c is an unknown classification rule. The task is to find a mapping h from $\mathbb{R}^N$ to the label set with a small chance of erring on a new unseen instance, $x \in \mathbb{R}^N$, that was drawn according to the same probability function as the training instances. The N coordinates are called *features*. The standard task of feature selection is to select a subset of features that enables good prediction of the label. This is done by looking for features which are more useful than the others. We can also consider the instances as *abstract entities* in space $\mathcal{S}$ and think of the features as *measurements* on the instances. Thus each feature f can be considered as a function from $\mathcal{S}$ to $\mathbb{R}$; that is, $f : \mathcal{S} \to \mathbb{R}$. We denote the set of all the features by $\{f_j\}_{j=1}^N$. We use the term *feature* to describe both raw input variables (for example, pixels in an image) and variables constructed from the original input variables using some function (for example, product of 3 pixels in the image). We also use F to denote a set of features and S_F^m to denote the training set restricted to F; that is, each instance is described only by the features in F.

Here we assume that each feature is described by a set of k properties $\mathbf{u}(\cdot) = \{u_r(\cdot)\}_{r=1}^k$ which we call *meta-features*. Formally, each $u_r(\cdot)$ is a function from the space of possible measurements to $\mathbb{R}$. Thus each feature f is described by a vector $\mathbf{u}(f) = (u_1(f), \ldots, u_k(f)) \in \mathbb{R}^k$. Note that the meta-features are not dependent on the instances. As already mentioned, and will be described in detail later, this enables a few interesting applications. We also denote a general point in the image of $\mathbf{u}(\cdot)$ by $\mathbf{u}$. log is the base 2 logarithm while ln denotes the natural logarithm. A table that summarizes the above notations and additional notations that will be introduced later appears in Appendix B.

3. Predicting the Quality of Features

In this section we show how meta-features can be used to predict the quality of unseen features. The ability to predict the quality of features without measuring them is advantageous for many applications. In the next section we demonstrate its usage for efficient feature selection for SVM (Vapnik, 1995), when it is very expensive to measure each feature.

We assume that we observe only a subset of the N features; that is in the training set we only see the value of some of the features. We can directly measure the quality (that is, usefulness) of these features using the training set. Based on the quality of these features, our goal is to predict the quality of all features, including features that were not part of the training set. Thus we can think of the training set not only as a "training set of instances", but also as a "training set of features".

More formally, our goal is to use the training set S^m and the set of meta-features to learn a mapping $\hat{Q} : \mathbb{R}^k \longrightarrow \mathbb{R}$ that predicts the quality of a feature using the values of its meta-features.

Algorithm 1 $\hat{Q}$ =quality_map(S^m, featquality, regalg)

1. measure the feature quality vector: $Y_{MF} = \text{featquality}(S^m)$
2. calculate the $N \times k$ meta-features matrix X_{MF}
3. use the regression alg. to learn a mapping from meta-feature value to quality: $\hat{Q} = \text{regalg}(X_{MF}, Y_{MF})$

The quality can be based on any kind of standard evaluation function that uses the labeled training set to evaluate features (for example, Infogain or the square weights assigned by linear SVM). Y_{MF} denotes the vector of measured qualities; that is $Y_{MF}(j)$ is the measured quality of the j's feature in the training set. Now we have a new supervised learning problem, with the **original features** as **instances**, the **meta-features** as **features** and Y_{MF} as the (continuous) target **label**. The analogy to the standard supervised problem is summarized in Table 1. Thus we can use any standard regression learning algorithm to find the required mapping from meta-features to quality. The above procedure is summarized in Algorithm 1. Note that this procedure uses a standard regression learning procedure. That is, the generalization ability to new features can be derived using standard generalization bounds for regression learning. In the next section we give a specific choice for featquality and regalg (see step 2(b) of algorithm 2).

4. Efficient Feature Selection for SVM

Support Vector Machine (SVM) (Vapnik, 1995), is one of the most prominent learning algorithms of the last decade. Many feature selection algorithms for SVM have been suggested (see, for example, Weston et al. 2000). One of the popular methods for linear SVM is Recursive Feature Elimination (Guyon et al., 2002). In SVM-RFE you start by training SVM using all the features, then eliminate the ones with the smallest square weights in the result linear classifier and repeat the same procedure with the remaining features until the set of selected features is small enough. The reason that features are eliminated iteratively and not in one step is that the weights given by SVM to a feature depend on the set of features that was used for training. Thus eliminating only a small number of the worst features in each stage minimizes the unwanted effect of this phenomenon.

The main drawback of SVM-RFE is that all the candidate features have to be measured. This is infeasible when measuring each feature is computationally expensive. We suggest an alternative version of SVM-RFE using meta-features that obviates the need to measure all the features. This algorithm is called Meta-Features based Predictive Feature Selection (MF-PFS). The main idea is to run SVM on only a small (random) subset of the features, and then use the assigned weights for these features to predict the quality of all candidate features using their meta-features (Algorithm 1). Based on this prediction we exclude a group of low quality features, and repeat the process with a smaller set of candidate features. The exact procedure is summarized in Algorithm 2. The suggested algorithm considers all the features while calculating only a small fraction of the them. Thus, it is extremely valuable in a situation where there are a large number of candidate features and the cost of measuring each feature is very high. In the next section we demonstrate MF-PFS on such a data set, and show that it achieves results equivalent to those obtained through standard RFE with an order of magnitude less computation time.

Algorithm 2 $\hat{Q}$ =MF-PFS($S^m, n, t,$ featquality, regalg)

(The algorithm selects n features out of the full set of N)

1. Initialize the set of selected features $F = \left\{ f_j \right\}_{j=1}^{N}$ (all the features).
2. while $|F| > n$,
   (a) Select a set F_0 of random αn features out of F, measure them and produce a training set of features $S^m_{F_0}$.
   (b) Use Algorithm 1 to produce a map $\hat{Q}$ from meta-features values to quality:

$$\hat{Q} = \text{quality\_map}(S^m_{F_0}, \text{featquality}, \text{regalg})$$

   where featquality trains linear SVM and uses the resulting square weights as a measure of quality (Y_{MF} in Algorithm 1). regalg is based on k-Nearest-Neighbor Regression (Navot et al., 2006).
   (c) Use $\hat{Q}$ to estimate the quality of all the features in F.
   (d) Eliminate from F $\min(t|F|, |F| - n)$ features with the lowest estimated quality.

The number of measured features can be further reduced by the following method. The relative number of features we measure in each round (α in step 2(a) of the algorithm) does not have to be fixed; for example, we can start with a small value, since a gross estimation of the quality is enough to eliminate the very worst features, and then increase it in the last stages, where we fine-tune the selected feature set. This way we can save on extra feature measurements without compromising on the performance. Typical values for α might be around 0.5 in the first iteration and slightly above 1 in the last iteration. For the same reason, in step 2(d), it makes sense to decrease the number of features we drop along the iterations. Hence, we adopted the approach that is commonly used in SVM-RFE that drops a constant fraction, $t \in (0,1)$ of the remaining features, where a typical value of t is 0.5. An example of specific choice of parameter values is given in the next section.

5. Experiments with Object Recognition

In this section we use the Caltech-101 data set and adopt the setting in Serre et al. (2005). The data set contains natural images of objects belonging to 101 different categories. The label of each image specifies which object appears in the image, but does not specify the location of the object in the image. Examples of the images are shown in Figure 1. Serre et al. (2007) built a classification system for the above task using linear SVM on a sophisticated representation of the images. In their setting an image is represented by features inspired by the current model of the visual cortex. They show how the features can be built using a hierarchical feedforward system, where each layer mimics the behavior of the relevant layer in the cortex. The interested reader should consult their original paper for all the details on how the features are constructed. Here we simply summarize the description of the features they use, which is sufficient for our needs. First, original images are converted into a representation where the original pixels are replaced by the response to Gabor filters

(Gabor, 1946) of 4 different orientations and 16 different scales, followed by a local maximum of the absolute value over the location, two adjacent scales and decimation (sub-sampling). Thus, each image is replaced by 8 quadruplets of lower resolution images. Each quadruplet corresponds to one scale, and includes all 4 orientations. The following description is over this complex representation. Each feature is defined by a specific patch *prototype.* The prototype is one such quadruplet of a given size (4x4, 8x8, 12x12 or 16x16). The value of the feature on a new image is calculated as follows:

1. The image is converted to the above complex representation.

2. The Euclidean distance of the prototype from every possible patch (that is, at all locations and the 8 scales) of the same size in the image representation is calculated. The minimal distance (over all possible locations and scales) is denoted by d.

3. The value of the feature is $e^{-\beta d^2}$, where β is a parameter.

Step 2 is very computationally costly, and takes by far more resources than any other step in the process. This means that calculating the feature value on all images takes a very long time. Since each feature is defined by a prototype, the feature selection is done by selecting a set of prototypes. In Serre's paper the features are selected randomly by choosing random patches from a data set of natural images (or the training set itself). Namely, to select a prototype you chose an image randomly, convert it to the above representation, then randomly select a patch from it. In Serre's paper, after this random selection, the feature set is fixed, that is no other selection algorithm is used. One method to improve the selected set of features is to use SVM-RFE to select the best features from a larger set of randomly selected candidate features. However, since SVM-RFE requires calculating all the feature values, this option is very expensive to compute. Therefore we suggest choosing the features using meta-features by MF-PFS. The meta-features we use are:

1. The size of the patch (4, 8, 12 or 16).

2. The DC of the patch (average over the patch values).

3. The standard deviation of the patch.

4. The peak value of the patch.

5. Quantiles 0.3 and 0.7 of the values of the patch.

In the following we show that by using these meta-features we can predict the quality of new features with high accuracy, and hence we can drop bad features without measuring their values on the images. This significantly reduces feature selection time. Alternatively, it can improve the classification accuracy since we are able to select from a large set of features in a reasonable training time (using feature selection by MF-PFS). In addition, we draw some interesting observations about the properties of more or less useful features.

Figure 1: Excerpts from the Caltech-101 data-set

5.1 Predicting the Quality of New Features

Since the entire discussion here relies on the assumption that we can predict the quality of a feature from its meta-feature values, we first need to test whether this assumption holds. We need to prove that we can indeed predict the quality of a patch using the above meta-features; that is, from its size, DC, std, peak value and quantile values. We measure feature quality by SVM square weights of multi-class SVM (Shalev-Shwartz and Singer, 2006). Based on this quality definition, Figure 2 presents an example of prototypes of "good" and "bad" features of different sizes. In Figure 3 we explore the quality of features as a function of two meta-features: the patch size and the standard deviation (std). We can see that for small patches (4x4), more details are better, for large patches (16x16) fewer details are better and for medium size patches (for example, 8x8) an intermediate level of complexity is optimal. In other words, the larger the patch, the smaller the optimal complexity. This suggests that by using the size of the patch together with certain measurements of its "complexity" (for example, std) we should be able to predict its quality. In the following experiment we show that such a prediction is indeed possible.

We use Algorithm 1 with the sum square of SVM weights as the direct measure for patch quality and a weighted version of k-Nearest-Neighbor Regression (Navot et al., 2006) as a regressor. To solve the SVM, we use the Shalev-Shwartz and Singer (2006) online algorithm. This algorithm has the advantage of a built-in ability to deal with multi-class problems. We use 500 features as training features. Then we use the map returned by Algorithm 1 to predict the quality of another 500 features. The results presented in Figure 4 show that the prediction is very accurate. The correlation coefficient between measured and predicted quality (on the test set of 500 features) is 0.94. We also assessed the contribution of each meta-feature, by omitting one meta-feature each time and measuring the drop in the correlation coefficient. The meta-features which contributed most to the prediction are size, mean (DC) and std.

The interesting point in the above result is that we show that feature quality can be predicted by its meta-feature values, which represent general statistical properties of the prototype. This observation is notable since it explains the existence of a universal set of features (prototypes) that enables recognition of most objects, regardless of whether the prototypes were taken from pictures that contain the relevant objects or not. Indeed, Serre et al. (2005) found that a set of features (prototypes) which consists of prototypes taken randomly from any natural images constitute such a universal set; however, they did not characterize which features are good. Ullman et al. (2002) also analyzed the properties of good features, where they use a simpler representation of patches (for example, without a Gabor filter). Their conclusion was that intermediate complex features are

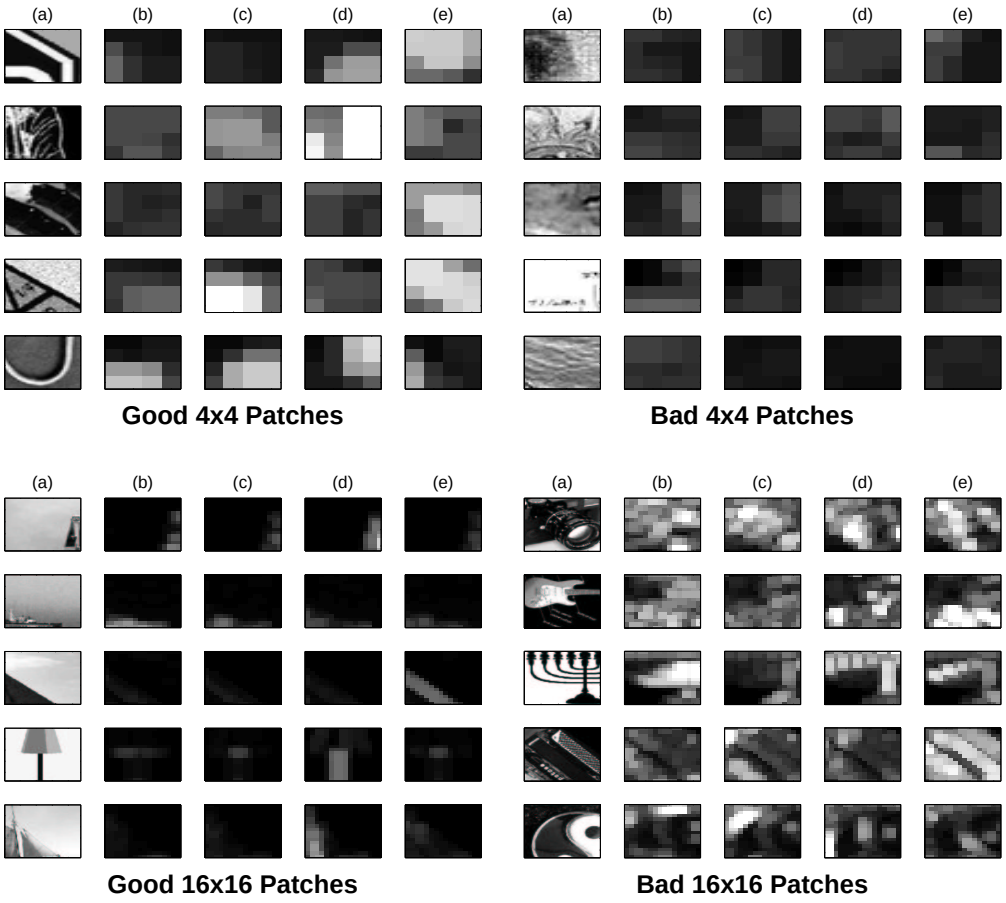

Figure 2: Examples of "good" and "bad" patch prototypes of different sizes. Each row represents one patch. The left column (a) is the image from which the patch was extracted and the other 4 columns (b,c,d,e) correspond to the 4 different orientations (– / | \, respectively). Good small patches are rich in details whereas good large patches are relatively uniform.

the most useful features. However, in their work the features are object fragments, and hence their quality is dependent on the specific training set and not on general statistical properties as we found in this work.

5.2 Applying MF-PFS to Object Recognition

After showing that we are able to predict patches quality, we have a reason to believe that by using MF-PFS (see Section 4) we can obtain an efficient feature selection in Serre et al. (2005) setting. The features in this setting are very expensive to compute and thus a standard selection methods cannot consider many candidate features. MF-PFS on the other hand, allows us to explore a large set of features while measuring only a few of them. In this section we show that MF-PFS (with the above meta-features) indeed succeeds in selecting good features while keeping the computational cost low. Now we turn to present the experimental setup in details. Readers may also skip directly to the results.

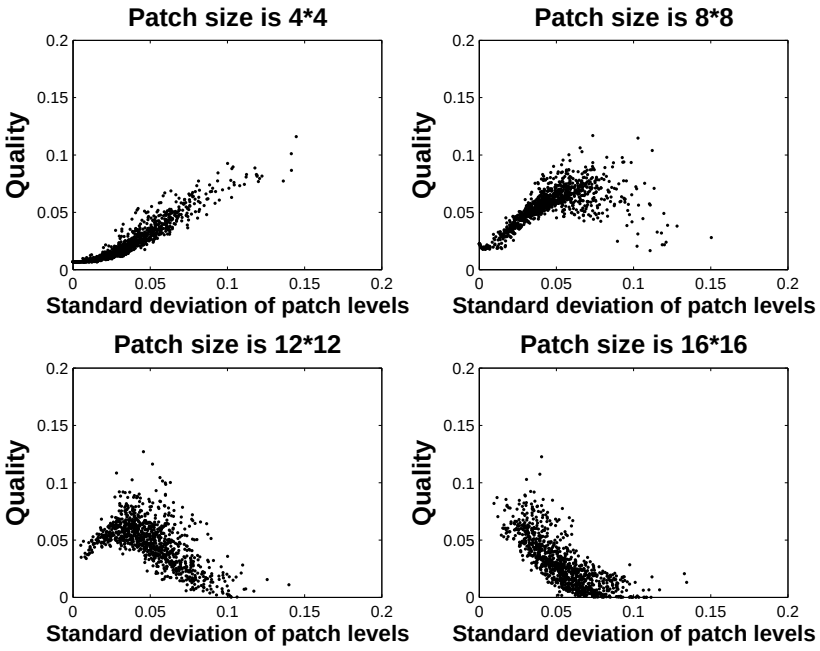

Figure 3: Quality as function of the standard deviation of the meta-feature. Good small patches are "complex" whereas good large patches are "simple".

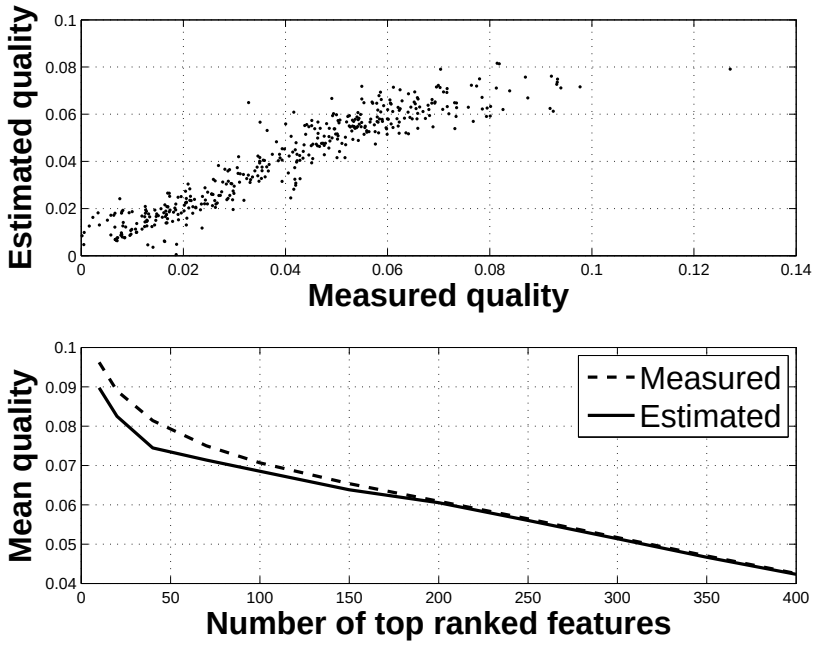

Figure 4: Predicting the quality of patches. top: Scatter plot of the predicted vs. measured quality. The correlation coefficient is 0.94. bottom: The mean quality of the k top ranked features, for different values of k. Ranking using the predicted quality gives (almost) the same mean as ranking by the measured quality.

We use Algorithm 2, with multi-class SVM (Shalev-Shwartz and Singer, 2006) as a classifier and the square of weights as a measure of feature quality. The regression algorithm for quality prediction is based on a weighted version of the *k*-Nearest-Neighbor regression (Navot et al., 2006). Since the number of potential features is virtually infinite, we have to select the initial set of N features.[2] We always start with $N = 10n$ that were selected randomly from natural images in the same manner as in Serre et al. (2005). We use 4 elimination steps (follows from $t = 0.5$, see Algorithm 2). We start with $\alpha = 0.4$ (see step 2(a) of the algorithm) and increase it during the iterations up to $\alpha = 1.2$ in the last step (values in the 2nd and 3rd iteration are 0.8 and 1 respectively). The exact values may seem arbitrary; however the algorithm is not sensitive to small changes in these values. This can be shown as follows. First note that increasing α can only improve the accuracy. Now, note also that the accuracy is bounded by the one achieved by *RFEall*. Thus, since the accuracy we achieve is very close to the accuracy of *RFEall* (see Figure 5), there is a wide range of α selection that hardly affects the accuracy. For example, our initial tests were with $alpha = 0.6, 0.8, 1, 1.2$ which yielded the same accuracy, while measuring almost 10% more features. General guidelines for selecting α are discussed in Section 4. For the above selected value of α, the algorithm measures only about $2.1n$ features out of the $10n$ candidates.

We compared MF-PFS to three different feature selection algorithms. The first was a standard RFE which starts with all the $N = 10n$ features and selects n features using 6 elimination steps (referred to as *RFEall*). The second method was also a standard RFE, but this time it started with $2.1n$ features that were selected randomly from the $N = 10n$ features (referred to as *RFEsmall*). The rationale for this is to compare the performance of our algorithm to standard RFE that measures the same number of features. Since standard RFE does not predict the quality of unseen features, it has to select the initial set randomly. As a baseline we also compared it to random selection of the n features as done in Serre et al. (2005) (referred to as *Baseline*). Note that RFEall considers all the features MF-PFS does, but makes many more measurements (with costs that become infeasible in many cases).[3] On the other hand RFEsmall uses the same number of measurements as MF-PFS, but it considers about one-fifth of the potential features. Finally, in order to estimate the statistical significance of the results we repeated the whole experiment 20 times, with different splits into train instances and test instances.

Results. The results are presented in Figure 5. MF-PFS is nearly as accurate as RFEall, but uses many fewer feature measurements. When RFE measures the same number of features (RFEsmall), it needs to select twice the number of selected features (n) to achieve the same classification accuracy as MF-PFS. Recall that in this setting, as Serre et al. (2005) mentioned, measuring each feature is very expensive; thus these results represent a significant improvement.

6. Guided Feature Extraction

In the previous section we demonstrated the usefulness of meta-features in a scenario where the measurement of each feature is very costly. Here we show how the low dimensional representation of features by a relatively small number of meta-features enables efficient selection even when the number of potential features is very large or even infinite and the evaluation function is expensive (for example, the wrapper model). This is highly relevant to the feature extraction scenario. Note

2. In Section 6 we show that meta-features can be used to explore a space of an infinite number of potential features.
3. It took days on dozens of computers to measure the N=10,000 features on Caltech-101 required for *RFEall*. This is by far the most demanding computational part of the training.

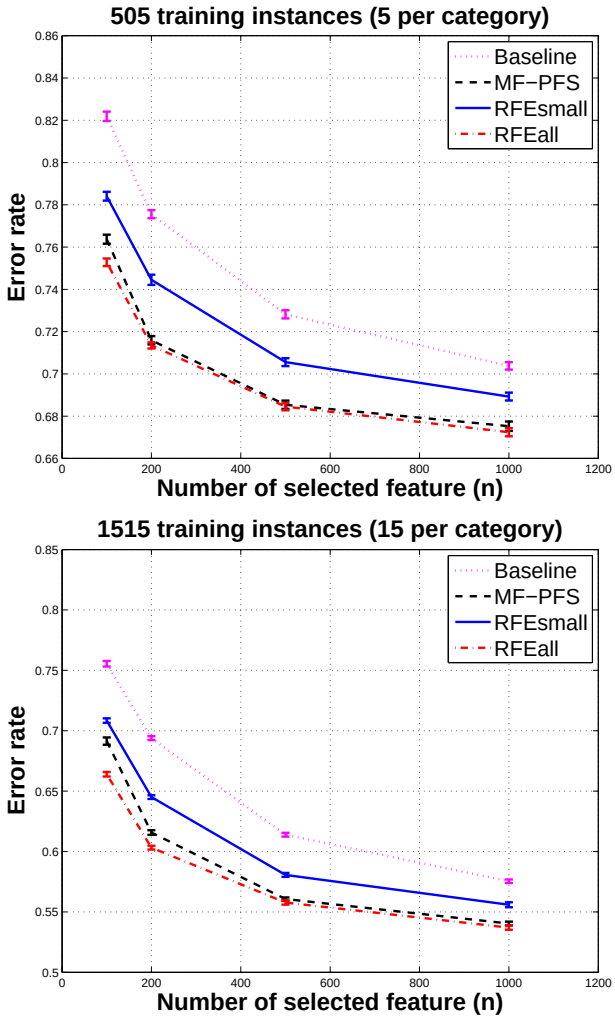

Figure 5: Applying SVM with different feature selection methods for object recognition. When the number of selected features (n) is not too small, our meta-feature based selection (MF-PFS) achieves the same accuracy as RFEall which measures 5 times more features at training time. MF-PFS significantly outperforms RFEsmall which measures the same number of features at training time. To get the same classification accuracy RFEsmall needs about twice the number of features that MF-PFS needs. The results of the baseline algorithm that uses random selection are also presented (Baseline). Error bars show 1-std of the mean performance over the 20 runs.

that an algorithm such as MF-PFS that was presented in the previous sections is not adequate for this scenario, because we need to consider a huge (or even infinite) number of potentially extracted features, and thus even a fast prediction of the quality of all of them is not feasible. Thus we take another approach: a direct search in the meta-feature space, guided by an evaluation of only a subset of representative features.

Algorithm 3 F_{best} =Mufasa(n, J)

1. Initialization: $q_{best} = maxreal,\ \mathbf{u}_0$ is the initial guess of $\mathbf{u}$ (In our experiments we use uniform random).
2. For $j = 1 \ldots J$
   (a) Select (or generate) a new set F_j of n random features according to $p(v|\mathbf{u}_{j-1})$. See Sections 6.1 and 6.2 for details.
   (b) $q_j =$ quality (F_j). (Any measure of quality, In our experiment we use cross-validation classification accuracy of SVM)
   (c) If $q_j \geq q_{best}$
   $F_{best} = F_j,\ \mathbf{u}_{best} = \mathbf{u}_{j-1},\ q_{best} = q_j$
   (d) Randomly select new $\mathbf{u}_j$ which is near $\mathbf{u}_{best}$. For example, in our experiments we add Gaussian random noise to each coordinate of $\mathbf{u}_{best}$, followed by round to the nearest valid value.
3. return F_{best}

6.1 Meta-features Based Search

Assume that we want to select (or extract) a set of n features out of large number of N potential features. We define a stochastic mapping from values of meta-features to selection (or extraction) of features. More formally, let V be a random variable that indicates which feature is selected. We assume that each point $\mathbf{u}$ in the meta-feature space induces density $p(v|\mathbf{u})$ over the features. Our goal is to find a point $\mathbf{u}$ in the meta-feature space such that drawing n features (independently) according to $p(v|\mathbf{u})$ has a high probability of giving us a good set of n features. For this purpose we suggest the *Mufasa* (for Meta-Features Aided Search Algorithm) (Algorithm 3) which implements a stochastic local search in the meta-feature space.

Note that *Mufasa* does not use explicit prediction of the quality of unseen features as we did in MF-PFS, but it is clear that it cannot work unless the meta-features are informative on the quality. Namely, *Mufasa* can only work if the likelihood of drawing a good set of features from $p(v|\mathbf{u})$ is some continuous function of $\mathbf{u}$; that is, a small change in $\mathbf{u}$ results in a small change in the chance of drawing a good set of features. If, in addition, the meta-feature space is "simple"[4] we expect it to find a good point in a small number of steps J. In practice, we can stop when no notable improvement is achieved in a few iterations in a row. The theoretical analysis we present later suggests that overfitting is not a main consideration in the choice of J, since the generalization bound depends on J only logarithmically.

Like any local search over a non-convex target function, convergence to a global optimum is not guaranteed, and the result may depend on the starting point $\mathbf{u}_0$. Note that the random noise added to $\mathbf{u}$ (step 2d in Algorithm 3) may help avoid local maxima. However, other standard techniques to avoid local maxima can also be used (for example, *simulated annealing*). In practice we found, at least in our experiments, that the results are not sensitive to the choice of $\mathbf{u}_0$, though it may affect

4. We elaborate on the meaning of "simple" in Sections 7 and 8.

the number of iterations, J, required to achieve good results. The choice of $p(v|\mathbf{u})$ is application-dependent. In the next section we show how it is done for a specific example of feature generation. For feature selection it is possible to cluster the features based on the similarity of meta-features, and then randomly select features per cluster. Another issue is how to choose the next meta-features point (step 2(d)). Standard techniques for optimizing the step size, such as gradually reducing it, can be used. However, in our experiment we simply added an independent Gaussian noise to each meta-feature.

In Section 6.2 we demonstrate the ability of *Mufasa* to efficiently select good features in the presence of a huge number of candidate (extracted) features on a handwritten digit recognition problem. In Section 7.1 we present a theoretical analysis of *Mufasa*.

6.2 Illustration on a Digit Recognition Task

In this section we use a handwritten digit recognition problem to demonstrate how *Mufasa* works for feature extraction. We used the MNIST (LeCun et al., 1998) data set which contains images of 28×28 pixels of centered digits $(0 \ldots 9)$. We converted the pixels from gray-scale to binary by thresholding. We use extracted features of the following form: logical AND of 1 to 8 pixels (or their negation), which are referred to as *inputs*. This creates intermediate AND-based features which are determined by their input locations. The features we use are calculated by logical OR over a set of such AND-features that are shifted in position in a *shiftInfLen*shiftInvLen* square. For example, assume that an AND-based feature has two inputs in positions (x_1, y_1) and (x_2, y_2), *shiftInvLen=2* and both inputs are taken without negation. Thus the feature value is calculated by OR over 2*2 AND-based features as follows:

$$(Im(x_1,y_1) \wedge Im(x_2,y_2)) \vee (Im(x_1,y_1+1) \wedge Im(x_2,y_2+1)) \vee$$
$$(Im(x_1+1,y_1) \wedge Im(x_2+1,y_2)) \vee (Im(x_1+1,y_1+1) \wedge Im(x_2+1,y_2+1))$$

where $Im(x,y)$ denotes the value of the image in location (x,y). This way we obtain features which are not sensitive to the exact position of curves in the image.

Thus a feature is defined by specifying the set of *inputs*, which inputs are negated, and the value of *shiftInvLen*. Similar features have already been used by Kussul et al. (2001) on the MNIST data set, but with a fixed number of inputs and without shift invariance. The idea of using shift invariance for digit recognition is also not new, and was used, for example, by Simard et al. (1996). It is clear that there are a huge number of such features; thus we have no practical way to measure or use all of them. Therefore we need some guidance for the extraction process, and this is the point where the meta-features framework comes in. We use the following four meta-features:

1. *numInputs*: the number of inputs (1-8).
2. *percentPos*: percent of logic positive pixels (0-100, rounded).
3. *shiftInvLen*: maximum allowed shift value (1-8).
4. *scatter*: average distance of the inputs from their center of gravity (COG) (1-3.5).

In order to find a good value for the meta-features we use *Mufasa* (Algorithm 3) and compare it to some alternatives. A standard method of comparison is to look on the graph of *test error* vs. *the number of selected features* (as done in Figure 5). Here, however, we use a variant of this graph which replaces *the number of selected features* by the total cost of computing the selected features. This modification is required since features with large *shiftInvLen* are significantly more

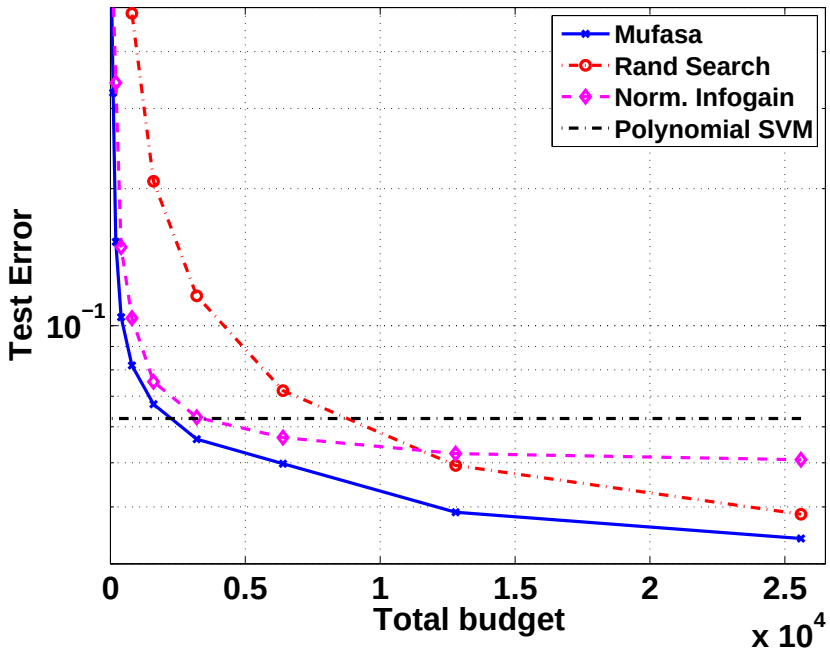

Figure 6: Guided feature extraction for digit recognition. The generalization error rate as a function of the available budget for features, using different selection methods. The number of training instances is 2000 (randomly selected from the MNIST training set). Error bars show a one standard deviation confidence interval. SVM is not limited by the budget, and always implicitly uses all the products of features. We only present the results of SVM with a polynomial kernel of degree 2, the value that gave the best results in this case.

computationally expensive. Thus a selection algorithm is restricted by a *budget* which the total cost of the selected set of features cannot be exceeded, rather than by an allowed number of selected features. We defined the cost of measuring (calculating) a feature as $0.5\left(1+a^2\right)$, where a is the *shiftInvLen* of the feature; this way the cost is proportional to the number of locations where we measure the feature.[5]

We used 2000 images as a training set, and the number of steps, J, is 50. We chose specific features, given a value of meta-features, by re-drawing features randomly from a uniform distribution over the features that satisfied the given value of the meta-features until the full allowed budget was used up. We used 2-fold cross validation of the linear multi-class SVM (Shalev-Shwartz and Singer, 2006; Crammer, 2003) to check the quality of the set of selected features in each step. Finally, for each value of allowed budget we checked the results obtained by the linear SVM on the MNIST standard test set using the selected features.

We compared the results with those obtained using the features selected by Infogain as follows. We first drew features randomly using a budget which was 50 times larger, then we sorted them by Infogain (Quinlan, 1990) normalized by the cost[6] (that is, the value of Infogain divided by

5. The number of inputs does not affect the cost in our implementation since the feature value is calculated by 64-bit logic operations.
6. Infogain without normalization produces worse results.

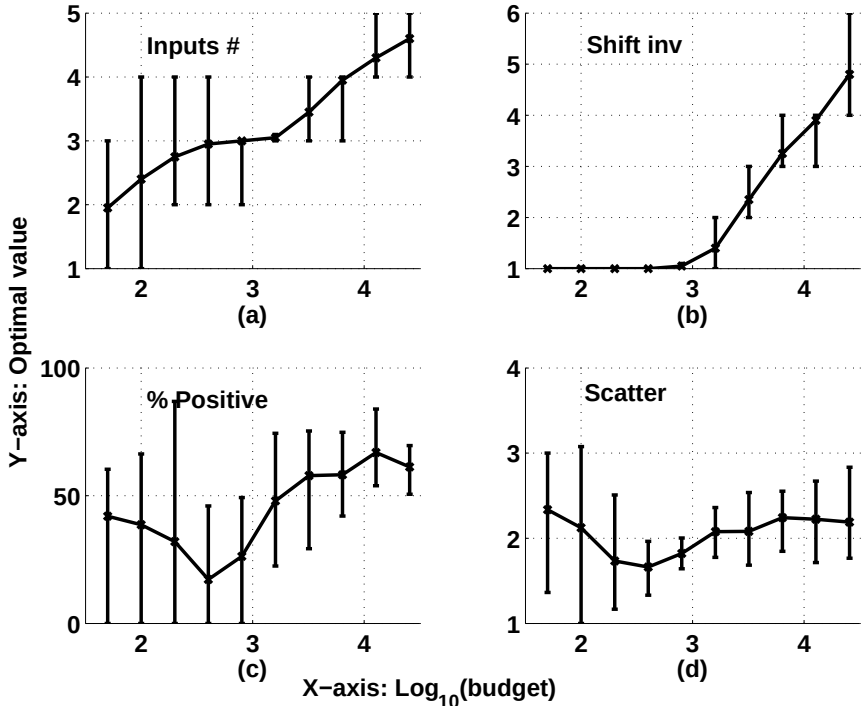

Figure 7: Optimal value of the different meta-features as a function of the budget. The results are averaged over 20 runs, and the error bars indicate the range where values fall in 80% of the runs. The size of the optimal shift invariance and the optimal number inputs increases with the budget.

computational cost of calculating the feature as defined above). We then selected the prefix that used the allowed budget. This method is referred to as *Norm Infogain*. As a sanity check, we also compared the results to those obtained by doing 50 steps of choosing features of the allowed budget randomly; that is, over all possible values of the meta-features. Then we used the set with the lowest 2-fold cross-validation error (referred to as *Rand Search*). We also compared our results to SVM with a polynomial kernel of degree 1-8, that uses the original pixels as input features. This comparison is relevant since SVM with a polynomial kernel of degree k implicitly uses ALL the products of up to k pixels, and the product is equal to AND for binary pixels. To evaluate the statistical significance, we repeated each experiment 20 times, with a different random selection of training sets out of the standard MNIST training set. For the test set, we use the entire $10,000$ test instances of the MNIST data set. The results are presented in Figure 6. It is clear that *Mufasa* outperforms the budget-dependent alternatives, and outperforms SVM for budgets larger than 3000 (about 600 features). It is worth mentioning that our goal here is not to compete with the state-of-art results on MNIST, but to illustrate our concept and to compare the results for the same kind of classifier with and without using our meta-features guided search. Note that our concept can be combined with most kinds of classification, feature selection, and feature extraction algorithms to improve them, as discussed in Section 9.

Another benefit of the meta-features guided search is that it helps understand the problem. To see this we need to take a closer look at the chosen values of the meta-features $(\mathbf{u}_{best})$ as a function of

the available budget. Figure 7 presents the average chosen value of each meta-feature as a function of the budget. As shown in Figure 7b, when the budget is very limited, it is better to take more cheap features rather than fewer more expensive shift invariant features. On the other hand, when we increase the budget, adding these expensive complex features is worth it. We can also see that when the budget grows, the optimal number of inputs increases. This occurs because for a small budget, we prefer features that are less specific, and have relatively high entropy, at the expense of "in class variance". For a large budget, we can permit ourselves to use sparse features (low probability of being 1), but with a gain in specificity. For the scatter meta-features, there is apparently no correlation between the budget and the optimal value. The vertical lines (error bars) represent the range of selected values in the different runs. It gives us a sense of the importance of each meta-feature. A smaller error bar indicates higher sensitivity of the classifier performance to the value of the meta-feature. For example, we can see that performance is sensitive to *shiftInvLen* and relatively indifferent to *percentPos*.

7. Theoretical Analysis

In this section we derive generalization bounds for the combined process of selection and classification when the selection process is based on meta-features. We show that in some cases, these bounds are far better than the bounds that assume each feature can be selected directly. This is because we can significantly narrow the number of possible selections, and still find a good set of features. In Section 7.1 we analyzed the case where the selection is made using *Mufasa* (Algorithm 3). In Section 7.2 we present a more general analysis, which is independent of the selection algorithm, and instead assumes that we have a given class of mappings from meta-features to a selection decision.

7.1 Generalization Bounds for *Mufasa* Algorithm

The bounds presented in this section assume that the selection is made using *Mufasa* (Algorithm 3), but they could be adapted to other meta-feature based selection algorithms. Before presenting the bounds, we need some additional notations. We assume that the classifier that is going to use the selected features is chosen from a hypothesis class $\mathcal{H}_c$ of real valued functions and the classification is made by taking the sign.

We also assume that we have a hypothesis class $\mathcal{H}_{fs}$, where each hypothesis is one possible way to select the n out of N features. Using the training set, our feature selection is limited to selecting one of the hypotheses that is included in $\mathcal{H}_{fs}$. As we show later, if $\mathcal{H}_{fs}$ contains all the possible ways of choosing n out of N features, then we get an unattractive generalization bound for large values of n and N. Thus we use meta-features to further restrict the cardinality (or complexity) of $\mathcal{H}_{fs}$. We have a combined learning scheme of choosing both $h_c \in \mathcal{H}_c$ and $h_{fs} \in \mathcal{H}_{fs}$. We can view this as choosing a single classifier from $\mathcal{H}_{fs} \times \mathcal{H}_c$. In the following paragraphs we analyze the equivalent size of hypothesis space $\mathcal{H}_{fs}$ of *Mufasa* as a function of the number of steps in the algorithm.

For the theoretical analysis, we need to bound the number of feature selection hypotheses *Mufasa* considers. For this purpose, we reformulate *Mufasa* as follows. First, we replace step 2(a) with an equivalent deterministic step. To do so, we add a "pre-processing" stage that generates (randomly) J different sets of features of size n according to $p(v|\mathbf{u})$ for any possible value of the point $\mathbf{u}$ in the meta-feature space.[7] Now, in step 2(a) we simply use the relevant set, according to

7. Later on we generalize to the case of infinite meta-feature space.

the current $\mathbf{u}$ and current j. Namely, in step j we use the jth set of features that was created in the pre-processing stage according to $p(v|\mathbf{u}_j)$, where $\mathbf{u}_j$ is the value of $\mathbf{u}$ in this step. Note that the resulting algorithm is identical to the original *Mufasa*, but this new formulation simplifies the theoretical analysis. The key point here is that the pre-processing is done before we see the training set, and that now *Mufasa* can only select one of the feature sets created in the pre-processing. Therefore, the size of $\mathcal{H}_{fs}$, denoted by $|\mathcal{H}_{fs}|$, is the number of hypotheses created in pre-processing.

The following two lemmas upper bound $|\mathcal{H}_{fs}|$, which is a dominant quantity in the generalization bound. The first one handles the case where the meta-features have discrete values, and there are a relatively small number of possible values for the meta-features. This number is denoted by $|MF|$.

Lemma 1 *Any run of* Mufasa *can be duplicated by first generating $J|MF|$ hypotheses and then running* Mufasa *using these hypotheses alone; that is, using $|\mathcal{H}_{fs}| \leq J|MF|$, where J is the number of iterations made by* Mufasa *and $|MF|$ is the number of different values the meta-features can be assigned.*

Proof

We first generate J random feature sets for each of the $|MF|$ possible values of meta-features. The total number of sets we get is $J|MF|$. We have only J iterations in the algorithm, and we generated J feature sets for each possible value of the meta-features. This guarantees that all the hypotheses required by *Mufasa* are available. ■

Note that in order to use the generalization bound of the algorithm, we cannot only consider the subset of J hypotheses that was tested by the algorithm. This is because this subset of hypotheses is affected by the training set (just as one cannot choose a single hypothesis using the training set, and then claim that the hypothesis space of the classifier includes only one hypothesis). However, from Lemma 1, the algorithm search is within no more than $J|MF|$ feature selection hypotheses that were determined *without* using the training set.

The next lemma handles the case where the cardinality of all possible values of meta-features is large relative to 2^J, or even infinite. In this case we can get a tighter bound that depends on J but not on $|MF|$.

Lemma 2 *Any run of* Mufasa *can be duplicated by first generating 2^{J-1} hypotheses and then running* Mufasa *using only these hypotheses; that is, using $|\mathcal{H}_{fs}| \leq 2^{J-1}$, where J is the number of iterations* Mufasa *performs.*

The proof of this lemma is based on PAC-MDL bounds (Blum and Langford, 2003). Briefly, a codebook that maps between binary messages and hypotheses is built without using the training set. Thus, the generalization bound then depends on the length of the message needed to describe the selected hypothesis. For a fixed message length, the upper bound on the number of hypotheses is 2^l where l is the length of the message in bits.

Proof

Mufasa needs to access a random number generator in steps 2(a) and 2(d). To simplify the proof, we move the random number generation used within *Mufasa* to a pre-processing stage that stores a long vector of random numbers. Thus, every time *Mufasa* needs to access a random number, it will

simply get the next stored random number. After this pre-processing, the feature set, which is the output of *Mufasa*, can be one of 2^{J-1} previously determined sets, since it only depends on the $J-1$ binary decisions in step 2(c) of the algorithm (in the first iteration the decision of step 2(c) is fixed, hence we only have $J-1$ decisions that depend on the training set). Thus, we can generate these 2^{J-1} hypotheses before we see the training set. ■

Using the above PAC-MDL technique, we can also reformulate the last part of the proof by showing that each of the feature-set hypotheses can be uniquely described by $J-1$ binary bits, which describes the decisions in step 2(c). A better generalization bound can be obtained if we assume that in the last steps a new hypothesis will rarely be better than the stored one, and hence the probability of replacing the hypothesis in step 2(c) is small. In this case, we can get a data-dependent bound that usually increases more slowly with the number of iterations (J), since the entropy of the message describing the hypothesis is likely to increase slowly for large J.

To state our theorem we also need the following standard definitions:

Definition 3 *Let $\mathcal{D}$ be a distribution over $\mathcal{S} \times \{\pm 1\}$ and $h : \mathcal{S} \to \{\pm 1\}$ a classification function. We denote by $er_{\mathcal{D}}(h)$ the generalization error of h w.r.t $\mathcal{D}$:*

$$er_{\mathcal{D}}(h) = Pr_{s,y\sim\mathcal{D}}[h(s) \neq y].$$

For a sample $S^m = \{(s_k, y_k)\}_{k=1}^m \in (\mathcal{S} \times \{\pm 1\})^m$ and a constant $\gamma > 0$, the γ-sensitive training error is:

$$\hat{er}_S^{\gamma}(h) = \frac{1}{m} |\{i : h(s_i) \neq y_i\} \quad or \quad (s_i \ \ has \ \ sample\text{-}margin < \gamma), |$$

where the sample-margin measures the distance between the instance and the decision boundary induced by the classifier.

Now we are ready to present the main result of this section:

Theorem 4 *Let $\mathcal{H}_c$ be a class of real valued functions. Let S be a sample of size m generated i.i.d from a distribution $\mathcal{D}$ over $\mathcal{S} \times \{\pm 1\}$. If we choose a set of features using* Mufasa*, with a probability of $1-\delta$ over the choices of S, for every $h_c \in \mathcal{H}_c$ and every $\gamma \in (0,1]$:*

$$er_{\mathcal{D}}(h_c) \leq \hat{er}_S^{\gamma}(h_c) +$$

$$\sqrt{\frac{2}{m}\left(d \ln\left(\frac{34em}{d}\right)\log(578m) + \ln\left(\frac{8}{\gamma\delta}\right) + g(J)\right)},$$

where

- *$d = fat_{\mathcal{H}_c}(\gamma/32)$ and $fat_{\mathcal{H}}(\cdot)$ denotes the fat-shattering dimension of class $\mathcal{H}$ (Bartlett, 1998).*

- $g(J) = \min(J\ln 2, \ln(J|MF|))$ *(where J is the number of steps* Mufasa *makes and $|MF|$ is the number of different values the meta-features can be assigned, if this value is finite, and ∞ otherwise).*

Our main tool in proving the above theorem is the following theorem:

Theorem 5 *(Bartlett, 1998)*

Let $\mathcal{H}$ be a class of real valued functions. Let S be a sample of size m generated i.i.d from a distribution $\mathcal{D}$ over $\mathcal{S} \times \{\pm 1\}$; then with a probability of $1-\delta$ over the choices of S, every $h \in \mathcal{H}$ and every $\gamma \in (0,1]$:

$$er_{\mathcal{D}}(h) \leq \hat{er}_S^{\gamma}(h) + \sqrt{\frac{2}{m}\left(d\ln\left(\frac{34em}{d}\right)\log(578m) + \ln\left(\frac{8}{\gamma\delta}\right)\right)},$$

where $d = fat_{\mathcal{H}}(\gamma/32)$

Proof (of theorem 4)

Let $\left\{F_1, ..., F_{|\mathcal{H}_{fs}|}\right\}$ be all possible subsets of the selected features. From Theorem 5 we know that

$$er_{\mathcal{D}}(h_c, F_i) \leq \hat{er}_S^{\gamma}(h_c, F_i) + \sqrt{\frac{2}{m}\left(d\ln\left(\frac{34em}{d}\right)\log(578m) + \ln\left(\frac{8}{\gamma\delta_{F_i}}\right)\right)},$$

where $er_{\mathcal{D}}(h_c, F_i)$ denotes the generalization error of the selected hypothesis for the fixed set of features F_i.

By choosing $\delta_F = \delta/|\mathcal{H}_{fs}|$ and using the union bound, we get that the probability that there exist F_i ($1 \leq i \leq |\mathcal{H}_{fs}|$) such that the equation below does not hold is less than δ

$$er_{\mathcal{D}}(h_c) \leq \hat{er}_S^{\gamma}(h_c) + \sqrt{\frac{2}{m}\left(d\ln\left(\frac{34em}{d}\right)\log(578m) + \ln\left(\frac{8}{\gamma\delta}\right) + \ln|\mathcal{H}_{fs}|\right)}.$$

Therefore, with a probability of $1-\delta$ the above equation holds for *any* algorithm that selects one of the feature sets out of $\left\{F_1, ..., F_{|H_{fs}|}\right\}$. Substituting the bounds for $|\mathcal{H}_{fs}|$ from Lemma 1 and Lemma 2 completes the proof. ■

An interesting point in this bound is that it is independent of the total number of possible features, N (which may be infinite in the case of feature generation). Nevertheless, it can select a good set of features out of $O\left(2^J\right)$ candidate sets. These sets may be non-overlapping, so the potential number of features that are candidates is $O\left(n2^J\right)$. For comparison, Gilad-Bachrach et al. (2004) gives the same kind of bound but for direct feature selection. Their bound has the same form as our bound, but $g(J)$ is replaced by a term of $O(\ln N)$, which is typically much larger than $J\ln 2$. If we substitute $N = n2^J$, then for the experiment described in Section 6.2 $n\ln N = Jn(\ln 2n) \cong 375000$ while $\ln(J|MF|) \cong 11$.

7.2 VC-dimension of Joint Feature Selection and Classification

In the previous section we presented an analysis which assumes that the selection of features is made using *Mufasa*. In this section we turn to a more general analysis, which is independent of the specific selection algorithm, and rather assumes that we have a given class $\mathcal{H}_s$ of mappings from meta-features to a selection decision. Formally, $\mathcal{H}_s$ is a class of mappings from meta-feature value to $\{0,1\}$; that is, for each $h_s \in \mathcal{H}_s$, $h_s : \mathbb{R}^k \to \{0,1\}$. h_s defines which features are selected as follows:

$$f \text{ is selected} \iff h_s(\mathbf{u}(f)) = 1,$$

where, as usual, $\mathbf{u}(f)$ is the value of the meta-features for feature f. Given the values of the meta-features of all the features together with h_s we get a single feature selection hypothesis. Therefore, $\mathcal{H}_s$ and the set of possible values of meta-features indirectly defines our feature selection hypothesis class, $\mathcal{H}_{fs}$. Since we are interested in selecting exactly n features (n is predefined), we use only a subset of $\mathcal{H}_s$ where we only include functions that imply the selection of n features.[8] For simplicity, in the analysis we use the VC-dim of $\mathcal{H}_s$ without this restriction, which is an upper bound of the VC-dim of the restricted class.

Our goal is to calculate an upper bound on the VC-dimension (Vapnik, 1998) of the joint problem of feature-selection and classification. To achieve this, we first derive an upper bound on $|\mathcal{H}_{fs}|$ as a function of VC-dim$(\mathcal{H}_s)$ and the number of features N.

Lemma 6 *Let $\mathcal{H}_s$ be a class of mappings from the meta-feature space ($\mathbb{R}^k$) to $\{0,1\}$, and let $\mathcal{H}_{fs}$ be the induced class of feature selection schemes; the following inequality holds:*

$$|\mathcal{H}_{fs}| \leq \left(\frac{eN}{\text{VC-dim}(\mathcal{H}_s)}\right)^{\text{VC-dim}(\mathcal{H}_s)}.$$

Proof

The above inequality follows directly from the well known fact that a class with VC-dim d cannot produce more than $\left(\frac{em}{d}\right)^d$ different partitions of a sample of size m (see, for example, Kearns and Vazirani 1994 pp. 57).

■

The next lemma relates the VC dimension of the classification concept class (d_c), the cardinality of the selection class ($|\mathcal{H}_{fs}|$) and the VC-dim of the joint learning problem.

Lemma 7 *Let $\mathcal{H}_{fs}$ be a class of the possible selection schemes for selecting n features out of N and let $\mathcal{H}_c$ be a class of classifiers over $\mathbb{R}^n$. Let $d_c = d_c(n)$ be the VC-dim of $\mathcal{H}_c$. If $d_c \geq 11$ then the VC-dim of the combined problem (that is, choosing $(h_{fs}, h_c) \in \mathcal{H}_{fs} \times \mathcal{H}_c$) is bounded by $(d_c + \log|\mathcal{H}_{fs}| + 1)\log d_c$.*

The proof of this lemma is given in Appendix A.

Now we are ready to state the main theorem of this section.

8. Note that one valid way to define $\mathcal{H}_s$ is by applying a threshold on a class of mappings from meta-feature values to feature quality, $\hat{Q} : \mathbb{R}^k \to \mathbb{R}$. See Example 2 at the end of this section.

Theorem 8 *Let $\mathcal{H}_s$ be a class of mappings from the meta-feature space ($\mathbb{R}^k$) to $\{0,1\}$, let $\mathcal{H}_{fs}$ be the induced class of feature selection schemes for selecting n out of N features and let $\mathcal{H}_c$ be a class of classifiers over $\mathbb{R}^n$. Let $d_c = d_c(n)$ be the VC-dim of the $\mathcal{H}_c$. If $d_c \geq 11$, then the VC-dim of the joint class $\mathcal{H}_{fs} \times \mathcal{H}_c$ is upper bounded as follows*

$$VC\text{-}dim(\mathcal{H}_{fs} \times \mathcal{H}_c) \leq \left(d_c + d_s \log \frac{eN}{d_s} + 1 \right) \log d_c,$$

where d_s is the VC-dim of $\mathcal{H}_s$.

The above theorem follows directly by substituting Lemma 6 in Lemma 7.

To illustrate the gain of the above theorem we calculate the bound for a few specific choices of $\mathcal{H}_s$ and $\mathcal{H}_c$:

1. First, note that if we do not use meta-features, but consider all the possible ways to select n out of N features the above bound is replaced by

$$\left(d_c + \log \binom{N}{n} + 1 \right) \log d_c, \tag{1}$$

   which is very large for reasonable values of N and n.

2. Assuming that both $\mathcal{H}_s$ and $\mathcal{H}_c$ are classes of linear classifiers on $\mathbb{R}^k$ and $\mathbb{R}^n$ respectively, then $d_s = k+1$ and $d_c = n+1$ and we get that the VC of the combined problem of selection and classification is upper bounded by

$$O\left((n + k \log N) \log n \right).$$

   If $\mathcal{H}_c$ is a class of linear classifiers, but we allow any selection of n features the bound is (by substituting in 1):

$$O\left((n + n \log N) \log n \right),$$

   which is much larger if $k \ll n$. Thus in the typical case where the number of meta-features is much smaller than the number of selected features (for example in Section 6.2) the bound for meta-feature based selection is much smaller.

3. Assuming that the meta-features are binary and $\mathcal{H}_s$ is the class of all possible functions from meta-feature to $\{0,1\}$, then $d_s = 2^k$ and the bound is

$$O\left(\left(d_c + 2^k \log N \right) \log d_c \right),$$

   which is still much better than the bound in equation 1 if $k \ll \log n$.

8. Choosing Good Meta-features

At first glance, it might seem that our new setting only complicates the learning problem. One might claim that in addition to the standard hard task of finding a good representation of the instances, now we also have to find a good representation of the features by meta-features. However, our point is that while our setting might be more complicated to understand, in many cases it facilitates

the difficult and crucial problem of finding a good representation. It gives us a systematic way to incorporate prior knowledge about the features in the feature selection and extraction process. It also enables us to use the acquired experience in order to guide the search for good features. The fact that the number of meta-features is typically significantly smaller than the number of features makes it easy to understand the results of the feature selection process. It is easier to guess which properties might be indicative of feature quality than to guess which exact features are good. Nevertheless, the whole concept can work only if we use "good" meta-features, and this requires design. In Sections 5 and 6.2 we demonstrated how to choose meta features for specific problems. In this section we give general guidelines on good choices of meta-features and mappings from meta-feature values to selection of features.

First, note that if there is no correlation between meta-features and quality, the meta-features are useless. In addition, if any two features with the same value of meta-features are redundant (highly correlated), we gain almost nothing from using a large set of them. In general, there is a trade-off between two desired properties:

1. Features with the same value of meta-features have similar quality.

2. There is low redundancy between features with the same value of meta-features.

When the number of features we select is small, we should not be overly concerned about redundancy and rather focus on choosing meta-features that are informative on quality. On the other hand, if we want to select many features, redundancy may be dominant, and this requires our attention. Redundancy can also be tackled by using a distribution over meta-features instead of a single point.

In order to demonstrate the above trade-off we carried out one more experiment using the MNIST data set. We used the same kind of features as in Section 6.2, but this time without shift-invariance and with fixed scatter. The task was to discriminate between 9 and 4 and we used 200 images as the training set and another 200 as the test set. Then we used *Mufasa* to select features, where the meta-features were either the (x,y)-location or the number of inputs. When the meta-feature was the (x,y)-location, the distribution of selecting the features, $p(v|\mathbf{u})$, was uniform in a 4×4 window around the chosen location (step 2a in *Mufasa*). Then we checked the classification error on the test set of a linear SVM (which uses the selected features). We repeated this experiment for different numbers of features.[9] The results are presented in Figure 8. When we use a small number of features, it is better to use the (x,y)-location as a meta-feature whereas when using many features it is better to use the number of inputs as a meta-feature. This supports our contention about the redundancy-homogeneity trade-off. The (x,y)-locations of features are good indicators of their quality, but features from similar positions tend to be redundant. On the other hand, constraints on the number of inputs are less predictive of feature quality but do not cause redundancy.

9. Summary and Discussion

In this paper we presented a novel approach to feature selection. Instead of merely selecting a set of better features out of a given set, we suggest learning the properties of good features. This approach can be used for predicting the quality of features without measuring them even on a single instance.

9. We do not use shift invariance here; thus all the features have the same cost.

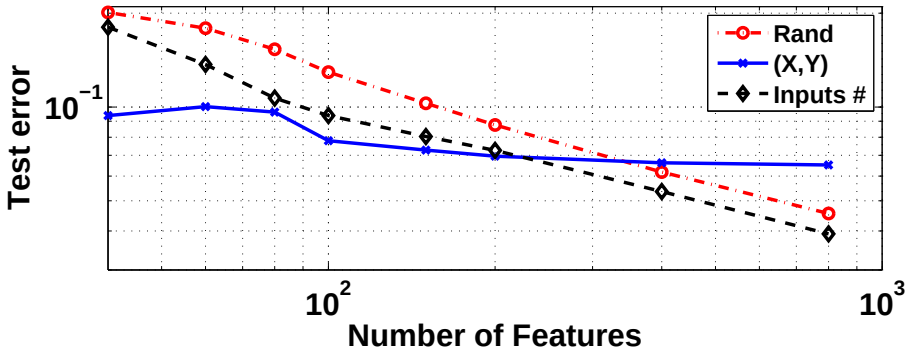

Figure 8: Different choices of meta-features. The generalization error as a function of the number of selected features. The two lines correspond to using different meta-features: (x,y)-location or number of inputs. The results of random selection of features are also presented.

We suggest exploring for new good features by assessing features with meta-feature values similar to those of known good features. Based on this idea, we presented two new algorithms that use feature prediction. The first algorithm is MF-PFS, which estimates the quality of individual features and obviates the need to calculate them on the instances. This is useful when the computational cost of measuring each feature is very high. The second algorithm is *Mufasa*, which efficiently searches for a good feature set without evaluating individual features. *Mufasa* is very helpful in feature extraction, where the number of potential features is huge. Further, it can also help avoiding overfitting in the feature selection task.

In the context of object recognition we showed that the feature (patch) quality can be predicted by its general statistical properties which are not dependent on the objects we are trying to recognize. This result supports the existence of a universal set of features (*universal-dictionary*) that can be used for recognition of most objects. The existence of such a dictionary is a key issue in computer vision and brain research. We also showed that when the selection of features is based on meta-features it is possible to derive better generalization bounds on the combined problem of selection and classification.

In Section 6 we used meta-features to guide feature selection. Our search for good features is computationally efficient and has good generalization properties because we do not examine each individual feature. However, avoiding examination of individual features may also be considered as a disadvantage since we may include some useless individual features. This can be solved by using a meta-features guided search as a fast but rough filter for good features, and then applying more computationally demanding selection methods that examine each feature individually.

In Krupka and Tishby (2007) meta-features were used to build a prior on the weight assigned to each feature by a linear classifier. In that study, the assumption was that meta-features are informative about the feature *weights* (including sign). In this work, however, meta-features should be informative about feature *relevance*, and the exact weight (and sign) is not important. An interesting future research direction would be to combine these concepts of using meta-features into a single framework.

We applied our approach to object recognition and a handwritten digit recognition problem, but we expect our method to be very useful in many other domains. For example, in the problem of

tissue classification according to a gene expression array where each gene is one feature, ontology-based properties may serve as meta-features. In most cases in this domain there are many genes and very few training instances; therefore standard feature selection methods tend to over-fit and thus yield meaningless results (Ein-Dor et al., 2006). A meta-feature based selection can help as it may reduce the complexity of the class of possible selections.

In addition to the applications presented here which involve predicting the quality of unseen features, the meta-features framework can also be used to improve estimation of the quality of features that we do see in the training set. We suggest that instead of using direct quality estimation, we use some regression function on the meta-feature space (as in Algorithm 1). When we have only a few training instances, direct approximation of the feature quality is noisy; thus we expect that smoothing the direct measure by using a regression function of the meta-features may improve the approximation.

Appendix A. A Proof for Lemma 7

Lemma 7 *Let $\mathcal{H}_{fs}$ be a class of the possible selection schemes for selecting n features out of N and let $\mathcal{H}_c$ be a class of classifiers over $\mathbb{R}^n$. Let $d_c = d_c(n)$ be the VC-dim of $\mathcal{H}_c$. If $d_c \geq 11$ then the VC-dim of the combined problem (that is, choosing $(h_{fs}, h_c) \in \mathcal{H}_{fs} \times \mathcal{H}_c$) is bounded by $(d_c + \log|\mathcal{H}_{fs}| + 1)\log d_c$.*

Proof

For a given set of selected features, the possible number of classifications of m instances is upper bounded $\left(\frac{em}{d_c}\right)^{d_c}$ (see Kearns and Vazirani 1994 pp. 57). Thus, for the combined learning problem, the total number of possible classifications of m instances is upper bounded by $|\mathcal{H}_{fs}|\left(\frac{em}{d_c}\right)^{d_c}$. The following chain of inequalities shows that if $m = \left(d_c + \log\left|\mathcal{H}_{fs}\right| + 1\right)\log d_c$ then $\left|\mathcal{H}_{fs}\right|\left(\frac{em}{d_c}\right)^{d_c} < 2^m$:

$$
\begin{aligned}
|\mathcal{H}_{fs}|\left(\frac{e\,(d_c+\log|\mathcal{H}_{fs}|+1)\log d_c}{d_c}\right)^{d_c} &= |\mathcal{H}_{fs}|\,(e\log d_c)^{d_c}\left(1+\frac{\log|\mathcal{H}_{fs}|+1}{d_c}\right)^{d_c} \\
&\leq e\,(|\mathcal{H}_{fs}|)^{1+\log e}\,(e\log d_c)^{d_c} && (2)\\
&\leq (|\mathcal{H}_{fs}|)^{2+\log e}\,(e\log d_c)^{d_c} && (3)\\
&\leq (|\mathcal{H}_{fs}|)^{2+\log e}\,d_c^{d_c+1} && (4)\\
&\leq d_c^{d_c+1}\,(|\mathcal{H}_{fs}|)^{\log d_c} && (5)\\
&= d_c^{d_c+1} d_c^{\left(\log|\mathcal{H}_{fs}|\right)} && (6)\\
&= 2^{\left(d_c+1+\log|\mathcal{H}_{fs}|\right)\log d_c},
\end{aligned}
$$

where we used the following equations / inequalities:

(2) $(1+a/d)^d \leq e^a \qquad \forall a,d>0$

(3) here we assume $|\mathcal{H}_{fs}| > e$, otherwise the lemma is trivial

(4) $(e\log d)^d \leq d^{d+1} \qquad \forall d \geq 1$

(5) $\log d_c > 2$ (since $d_c \geq 11$)

(6) $a^{\log b} = b^{\log a} \qquad \forall a,b > 1$

Therefore, $\left(d_c + \log\left|\mathcal{H}_{fs}\right| + 1\right)\log d_c$ is an upper bound on VC-dim of the combined learning problem.

■

Appendix B. Notation Table

The following table summaries the notation and definitions introduced in the paper for quick reference.

Notation	Short description	Sections
meta-feature	a property that describes a feature	
N	total number of candidate features	
n	number of selected features	
k	number of meta-features	
m	number of training instances	
$\mathcal{S}$	(abstract) instance space	2, 7.1
f	a feature: formally, $f : \mathcal{S} \to \mathbb{R}$	
c	a classification rule	
S^m	S^m is a labeled set of instances (a training set)	2, 3, 7.1
$u_i(f)$	the the value of the$i$'s meta-feature on feature f	2, 6
$\mathbf{u}(f)$	$\mathbf{u}(f) = (u_1(f), \ldots, u_k(f))$, a vector that describes the feature f	2, 6, 7.1
$\mathbf{u}$	a point (vector) in the meta-feature space	2, 6
$\hat{Q}$	a mapping from meta-features value to feature quality	3, 7.2
Y_{MF}	measured quality of the features (for instance Infogain)	3
X_{MF}	$X_{MF}(i,j) =$ the value of the j's meta-feature on the i's feature	3
F, F_j	a set of features	6
V	a random variable indicating which features are selected	6
$p(v\|\mathbf{u})$	the conditional distribution of V given meta-features values ($\mathbf{u}$)	6, 8
h_c	a classification hypothesis	7.1
$\mathcal{H}_c$	the classification hypothesis class	7.1
d_c	the VC-dimension of $\mathcal{H}_c$	7.2
h_{fs}	a feature selection hypothesis - says which n features are selected	7.1
$\mathcal{H}_{fs}$	The feature selection hypothesis class	7.1
h_s	A mapping form meta-feature space to $\{0,1\}$	7.2
$\mathcal{H}_s$	Class of mappings from meta-feature space to $\{0,1\}$	7.2
d_s	The VC-dimension of $\mathcal{H}_s$	
J	number of iteration *Mufasa* (Algorithm 3) does	6, 7.1
$\|MF\|$	Number of possible different values of meta-features	7.1
$er_{\mathcal{D}}(h)$	generalization error of h	7.1
$\hat{er}_S^{\gamma}(h)$	γ-sensitive training error (instance with margin $< \gamma$ count as error)	7.1

Abstract

Recent results about the robustness of kernel methods involve the analysis of influence functions. By definition the influence function is closely related to leave-one-out criteria. In statistical learning, the latter is often used to assess the generalization of a method. In statistics, the influence function is used in a similar way to analyze the statistical efficiency of a method. Links between both worlds are explored. The influence function is related to the first term of a Taylor expansion. Higher order influence functions are calculated. A recursive relation between these terms is found characterizing the full Taylor expansion. It is shown how to evaluate influence functions at a specific sample distribution to obtain an approximation of the leave-one-out error. A specific implementation is proposed using a L_1 loss in the selection of the hyperparameters and a Huber loss in the estimation procedure. The parameter in the Huber loss controlling the degree of robustness is optimized as well. The resulting procedure gives good results, even when outliers are present in the data.

Keywords: kernel based regression, robustness, stability, influence function, model selection

1. Introduction

Quantifying the effect of small distributional changes on the resulting estimator is a crucial analysis on many levels. A simple example is leave-one-out which changes the sample distribution slightly by deleting one observation. This leave-one-out error plays a vital role for example in model selection (Wahba, 1990) and in assessing the generalization ability (Poggio et al. 2004 through the concept of stability). Most of these analyses however are restricted to the sample distribution and the addition/deletion of some data points from this sample.

In the field of robust statistics the influence function was introduced in order to analyze the effects of outliers on an estimator. This influence function is defined for continuous distributions that are slightly perturbed by adding a small amount of probability mass at a certain place. In Section 2 some general aspects about the influence function are gathered. Recent results about influence functions in kernel methods include those of Christmann and Steinwart (2004, 2007) for classifica-

tion and regression. In Section 3 these results are stated and their importance is summarized. A new theoretical result concerning higher order influence functions is presented. In Section 4 we show how to evaluate the resulting expressions at sample distributions. Moreover we apply these influence functions in a Taylor expansion approximating the leave-one-out error. In Section 5 we use the approximation with influence functions to select the hyperparameters. A specific implementation is proposed to obtain robustness with a Huber loss function in the estimation step and a L_1 loss in the model selection step. The degree of robustness is controlled by a parameter that can be chosen in a data driven way as well. Everything is illustrated on a toy example and some experiments in Section 6.

2. The Influence Function

In statistics it is often assumed that a sample of data points is observed, all generated independently from the same distribution and some underlying process, but sometimes this is not sufficient. In many applications gathering the observations is quite complex, and many errors or subtle changes can occur when obtaining data. Robust statistics is a branch of statistics that deals with the detection and neutralization of such outlying observations. Roughly speaking a method is called robust if it produces similar results as the majority of observations indicates, no matter how a minority of other observations is placed. A crucial analysis in robust statistics is the behavior of a functional T, not only at the distribution of interest P, but in an entire neighborhood of distributions around P. The influence function measures this behavior. In this section we recall its definition and discuss some links with other concepts.

2.1 Definition

The pioneering work of Hampel et al. (1986) and Huber (1981) considers distributions $P_{\varepsilon,z} = (1-\varepsilon)P + \varepsilon\Delta_z$ where Δ_z denotes the Dirac distribution in the point $z \in \mathcal{X} \times \mathcal{Y}$, representing the contaminated part of the data. For having a robust T, $T(P_{\varepsilon,z})$ should not be too far away from $T(P)$ for any possible z and any small ε. The limiting case of $\varepsilon \downarrow 0$ is comprised in the concept of the influence function.

Definition 1 *Let P be a distribution. Let T be a functional $T : P \to T(P)$. Then the influence function of T at P in the point z is defined as*

$$IF(z;T,P) = \lim_{\varepsilon \to 0} \frac{T(P_{\varepsilon,z}) - T(P)}{\varepsilon}.$$

The influence function measures the effect on the estimator T when adding an infinitesimally small amount of contamination at the point z. Therefore it is a measure of the robustness of T. Of particular importance is the supremum over z. If this is unbounded, then an infinitesimally small amount of contamination can cause arbitrary large changes. For robust estimators, the supremum of its influence function should be bounded. Then small amounts of contamination cannot completely change the estimate and a certain degree of robustness is indeed present. The simplest example is the estimation of the location of a univariate distribution with density f symmetric around 0. The influence function of the mean at $z \in \mathbb{R}$ then equals the function z and is clearly unbounded. If the median of the underlying distribution is uniquely defined, that is if $f(0) > 0$, then the influence function of the median equals $\text{sign}(z)/(2f(0))$ which is bounded. The median is thus more robust than the mean.

2.2 Asymptotic Variance and Stability

From Definition 1 one can see that the influence function is a first order derivative of $T(P_{\varepsilon,z})$ at $\varepsilon = 0$. Higher order influence functions can be defined too:

Definition 2 *Let P be a distribution. Let T be a functional $T : P \to T(P)$. Then the k-th order influence function of T at P in the point z is defined as*

$$IF_k(z;T,P) = \frac{\partial}{\partial^k \varepsilon} T(P_{\varepsilon,z})|_{\varepsilon=0}.$$

If all influence functions exist then the following Taylor expansion holds:

$$T(P_{\varepsilon,z}) = T(P) + \varepsilon IF(z;T,P) + \frac{\varepsilon^2}{2!} IF_2(z;T,P) + \ldots \tag{1}$$

characterizing the estimate at a contaminated distribution in terms of the estimate at the original distribution and the influence functions.

Actually this is a special case of a more general Von Mises expansion (take $Q = P_{\varepsilon,z}$):

$$T(Q) = T(P) + \int IF(x;T,P)d(Q-P)(x) + \ldots$$

Now take Q equal to a sample distribution P_n of a sample $\{z_i\}$ of size n generated i.i.d. from P. Then

$$\begin{aligned} T(P_n) - T(P) &= \int IF(z;T,P)dP_n(z) + \ldots \\ &= \frac{1}{n}\sum_{i=1}^{n} IF(z_i;T,P) + \ldots. \end{aligned}$$

The first term on the right hand side is now a sum of n i.i.d. random variables. If the remaining terms are asymptotically negligible, the central limit theorem thus immediately shows that $\sqrt{n}(T(P_n) - T(P))$ is asymptotically normal with mean 0 and variance

$$ASV(T,P) = \int IF^2(z;T,P)dP(z).$$

Since the asymptotic efficiency of an estimator is proportional to the reciprocal of the asymptotic variance, the integrated squared influence function should be as small as possible to achieve high efficiency. Consider again the estimation of the center of a univariate distribution with density f. At a standard normal distribution the asymptotic variance of the mean equals $\int z^2 dP(z) = 1$, and that of the median equals $\int (\text{sign}(z)/(2f(0)))^2 dP(z) = 1.571$. Thus the mean is more efficient than the median at a normal distribution. However, at a Cauchy distribution for instance, this is completely different: the ASV of the median equals 2.47, but for the mean it is infinite since the second moment of a Cauchy distribution does not exist. Thus to estimate the center of a Cauchy, the median is a much better choice than the mean.

An interesting parallel can be drawn towards the concept of stability in learning theory. Several measures of stability were recently proposed in the literature. The leave-one-out error often plays a vital role, for example in hypothesis stability (Bousquet and Elisseeff, 2001), partial stability (Kutin

and Niyogi, 2002) and CV_{loo}-stability (Poggio et al., 2004). The basic idea is that the result of a learning map T on a full sample should not be very different from the result obtained when removing only one observation. More precisely, let P be a distribution on a set $\mathcal{X} \times \mathcal{Y}$ and $T : P \to T(P)$ with $T(P) : \mathcal{X} \to \mathcal{Y} : x \to T(P)(x)$. Let P_n^{-i} denote the empirical distribution of a sample without the ith observation $z_i = (x_i, y_i) \in \mathcal{X} \times \mathcal{Y}$. Poggio et al. (2004) call the map T CV_{loo}-stable for a loss function $L : \mathcal{Y} \to \mathbb{R}^+$ if

$$\lim_{n\to\infty} \sup_{i\in\{1,\ldots,n\}} |L(y_i - T(P_n)(x_i)) - L(y_i - T(P_n^{-i})(x_i))| \to 0 \tag{2}$$

for $n \to \infty$. This means intuitively that the prediction at a point x_i should not be too different whether or not this point is actually used constructing the predictor. If the difference is too large there is no stability, since in that case adding only one point can yield a large change in the result. Under mild conditions it is shown that CV_{loo}-stability is required to achieve good predictions. Let L be the absolute value loss and consider once again the simple case of estimating the location of a univariate distribution. Thus P_n is just a univariate sample of n real numbers $\{y_1, \ldots, y_n\}$. Then the left hand side of (2) equals

$$\lim_{n\to\infty} \sup_{i\in\{1,\ldots,n\}} |T(P_n) - T(P_n^{-i})|.$$

Let $y_{(i)}$ denote the ith order statistic. Consider T the median. Assuming that n is odd and $y_i < y_{(\frac{n+1}{2})}$ (the cases $y_i > y_{(\frac{n+1}{2})}$ and equality can easily be checked as well), we have that

$$|\mathrm{Med}(P_n) - \mathrm{Med}(P_n^{-i})| = \left| y_{(\frac{n+1}{2})} - \frac{1}{2}\left(y_{(\frac{n+1}{2})} + y_{(\frac{n+3}{2})} \right) \right| = \frac{1}{2} |y_{(\frac{n+1}{2})} - y_{(\frac{n+3}{2})}|.$$

If the median of the underlying distribution P is unique, then both $y_{(\frac{n+1}{2})}$ and $y_{(\frac{n+3}{2})}$ converge to this number and CV_{loo} stability is obtained. However, when taking the mean for T, we have that

$$|\mathbb{E}(P_n) - \mathbb{E}(P_n^{-i})| = \left| \frac{1}{n}\sum_{j=1}^{n} y_j - \frac{1}{n-1}\sum_{\substack{j=1 \\ j\neq i}}^{n} y_j \right| = \left| -\frac{1}{n(n-1)}\sum_{\substack{j=1 \\ j\neq i}}^{n} y_j + \frac{y_i}{n} \right|.$$

The first term in this sum equals the sample mean of P_n^{-i} divided by n and thus converges to 0 if the mean of the underlying distribution exists. The second term converges to 0 if

$$\lim_{n\to\infty} \sup_{i\in\{1,\ldots,n\}} \frac{|y_i|}{n} = 0.$$

This means that the largest absolute value of n points sampled from the underlying distribution should not grow too large. For a normal distribution for instance this is satisfied since the largest observation only grows logarithmically: for example the largest of 1000 points generated from a normal distribution only has a very small probability to exceed 5. This is due to the exponentially decreasing density function. For heavy tailed distribution it can be different. A Cauchy density for instance only decreases at the rate of the reciprocal function and $\sup_{i\in\{1,\ldots,n\}} |y_i|$ is of the order $O(n)$. Thus for a normal distribution the mean is CV_{loo} stable, but for a Cauchy distribution it is not.

In summary note that both the concepts of influence function and asymptotic variance on one hand and CV_{loo} stability on the other hand yield the same conclusions: using the sample median as

an estimator is ok as long as the median of the underlying distribution is unique. Then one has CV_{loo} stability and a finite asymptotic variance. Using the sample mean is ok for a normal distribution, but not for a Cauchy distribution (no CV_{loo} stability and an infinite asymptotic variance).

A rigorous treatment of asymptotic variances and regularity conditions can be found in Boos and Serfling (1980) and Fernholz (1983). In any event, it is an interesting link between perturbation analysis through the influence function and variance/efficiency in statistics on one hand, and between leave-one-out and stability/generalization in learning theory on the other hand.

2.3 A Strategy for Fast Approximation of the Leave-one-out Error

In leave-one-out crossvalidation $T(P_n^{-i})$ is computed for every i. This means that the algorithm under consideration has to be executed n times, which can be computationally intensive. If the influence functions of T can be calculated, the following strategy might provide a fast alternative. First note that

$$P_n^{-i} = (1-(\frac{-1}{n-1}))P_n + \frac{-1}{n-1}\Delta_{z_i}.$$

Thus, taking $P_{\varepsilon,z} = P_n^{-i}$, $\varepsilon = -1/(n-1)$ and $P = P_n$, Equation (1) gives

$$T(P_n^{-i}) = T(P_n) + \sum_{j=1}^{\infty}(\frac{-1}{n-1})^j \frac{IF_j(z_i;T,P_n)}{j!}. \tag{3}$$

The right hand side now only depends on the full sample P_n. In practice one can cut off the series after a number of steps ignoring the remainder term, or if possible one can try to estimate the remainder term.

The first goal of this paper is to apply this idea in the context of kernel based regression. Christmann and Steinwart (2007) computed the first order influence function. We will compute higher order terms in (1) and use these results to approximate the leave-one-out estimator applying (3).

3. Kernel Based Regression

In this section we recall some definitions on kernel based regression. We discuss the influence function and provide a theorem on higher order terms.

3.1 Definition

Let $\mathcal{X}, \mathcal{Y}$ be non-empty sets. Denote P a distribution on $\mathcal{X}\times\mathcal{Y} \subseteq \mathbb{R}^d \times \mathbb{R}$. Suppose we have a sample of n observations $(x_i, y_i) \in \mathcal{X}\times\mathcal{Y}$ generated i.i.d. from P. Then P_n denotes the corresponding finite sample distribution. A functional T is a map that maps any distribution P onto $T(P)$. A finite sample approximation is given by $T_n := T(P_n)$.

Definition 3 *A function $K : \mathcal{X}\times\mathcal{X} \to \mathbb{R}$ is called a kernel on $\mathcal{X}$ if there exists a $\mathbb{R}$-Hilbert space $\mathcal{H}$ and a map $\Phi : \mathcal{X} \to \mathcal{H}$ such that for all $x, x' \in \mathcal{X}$ we have*

$$K(x,x') \;=\; \langle \Phi(x), \Phi(x') \rangle .$$

We call Φ a feature map *and $\mathcal{H}$ a* feature space *of K.*

Frequently used kernels include the linear kernel $K(x_i,x_j) = x_i^t x_j$, polynomial kernel of degree p for which $K(x_i,x_j) = (\tau + x_i^t x_j)^p$ with $\tau > 0$ and RBF kernel $K(x_i,x_j) = \exp(-\|x_i - x_j\|_2^2/\sigma^2)$ with bandwidth $\sigma > 0$. By the reproducing property of $\mathcal{H}$ we can evaluate any $f \in \mathcal{H}$ at the point $x \in \mathcal{X}$ as the inner product of f with the feature map: $f(x) = \langle f, \Phi(x) \rangle$.

Definition 4 *Let K be a kernel function with corresponding feature space $\mathcal{H}$ and let $L : \mathbb{R} \to \mathbb{R}^+$ be a twice differentiable convex loss function. Then the functional $f_{\lambda,K} : P \to f_{\lambda,K}(P) = f_{\lambda,K,P} \in \mathcal{H}$ is defined by*

$$f_{\lambda,K,P} := \underset{f \in \mathcal{H}}{argmin} \mathbb{E}_P L(Y - f(X)) + \lambda \| f \|_{\mathcal{H}}^2$$

where $\lambda > 0$ is a regularization parameter.

The functional $f_{\lambda,K}$ maps a distribution P onto the function $f_{\lambda,K,P}$ that minimizes the regularized risk. When the sample distribution P_n is used, one has that

$$f_{\lambda,K,P_n} := \underset{f \in \mathcal{H}}{\operatorname{argmin}} \frac{1}{n} \sum_{i=1}^{n} L(y_i - f(x_i)) + \lambda \| f \|_{\mathcal{H}}^2. \tag{4}$$

Such estimators have been studied in detail, see for example Wahba (1990), Tikhonov and Arsenin (1977) or Evgeniou et al. (2000). In a broader framework (including for example classification, PCA, CCA etc.) primal-dual optimization methodology involving least squares kernel estimators were studied by Suykens et al. (2002b). Possible loss functions include

- the least squares loss: $L(r) = r^2$.
- Vapnik's ε-insensitive loss: $L(r) = \max\{|r| - \varepsilon, 0\}$, with special case the L_1 loss if $\varepsilon = 0$.
- the logistic loss: $L(r) = -\log(4\Lambda(r)[1 - \Lambda(r)])$ with $\Lambda(r) = 1/(1 + e^{-r})$. Note that this is not the same loss function as used in logistic regression.
- Huber loss with parameter $b > 0$: $L(r) = r^2$ if $|r| \leq b$ and $L(r) = 2b|r| - b^2$ if $|r| > b$. Note that the least squares loss corresponds to the limit case $b \to \infty$.

3.2 Influence Function

The following proposition was proven in Christmann and Steinwart (2007).

Proposition 5 *Let $\mathcal{H}$ be a RKHS of a bounded continuous kernel K on $\mathcal{X}$ with feature map $\Phi : \mathcal{X} \to \mathcal{H}$. Furthermore, let P be a distribution on $\mathcal{X} \times \mathcal{Y}$ with finite second moment. Then the influence function of $f_{\lambda,K}$ exists for all $z := (z_x, z_y) \in \mathcal{X} \times \mathcal{Y}$ and we have*

$$IF(z; f_{\lambda,K}, P) = -S^{-1}\left(2\lambda f_{\lambda,K,P}\right) + L'(z_y - f_{\lambda,K,P}(z_x)) S^{-1} \Phi(z_x)$$

where $S : \mathcal{H} \to \mathcal{H}$ is defined by $S(f) = 2\lambda f + \mathbb{E}_P\left[L''(Y - f_{\lambda,K,P}(X)) \langle \Phi(X), f \rangle \Phi(X)\right]$.

Thus if the kernel is bounded and the first derivative of the loss function is bounded, then the influence function is bounded as well. Thus L_1 type loss functions for instance lead to robust estimators. The logistic loss as well since the derivative of this loss function equals $L'(r) = 2 -$

$1/(1+e^{-r})$ which is bounded by 2. For the Huber loss $L'(r)$ is bounded by $2b$. This shows that the parameter b controls the amount of robustness: if b is very large than the influence function can become very large too. For a small b the influence function remains small. For a least squares loss function on the other hand, the influence function is unbounded ($L'(r) = 2r$): the effect of the smallest amount of contamination can be arbitrary large. Therefore it is said that the least squares estimator is not robust.

3.3 Higher Order Influence Functions

For the second order influence function as in Definition 2 the following theorem is proven in the Appendix.

Theorem 6 *Let P be a distribution on $\mathcal{X} \times \mathcal{Y}$ with finite second moment. Let L be a convex loss function that is three times differentiable. Then the second order influence function of $f_{\lambda,K}$ exists for all $z := (z_x, z_y) \in \mathcal{X} \times \mathcal{Y}$ and we have*

$$\begin{aligned} IF_2(z; f_{\lambda,K}, P) = & S^{-1}\Big(2\mathbb{E}_P[IF(z; f_{\lambda,K}, P)(X) L''(Y - f_{\lambda,K}(X))\Phi(X)] \\ & + \mathbb{E}_P[(IF(z; f_{\lambda,K}, P)(X))^2 L'''(Y - f_{\lambda,K,P}(X))] \\ & - 2[IF(z; f_{\lambda,K}, P)(z_x) L''(z_y - f_{\lambda,K}(z_x))\Phi(z_x)] \Big) \end{aligned}$$

where $S : \mathcal{H} \to \mathcal{H}$ is defined by $S(f) = 2\lambda f + \mathbb{E}_P\left[L''(Y - f_{\lambda,K,P}(X))\langle \Phi(X), f \rangle \Phi(X)\right]$.

When the loss function is infinitely differentiable, all higher order terms can in theory be calculated, but the number of terms grows rapidly since all derivatives of L come into play. However, in the special case that all derivatives higher than three are 0, a relatively simple recursive relation exists.

Theorem 7 *Let P be a distribution on $\mathcal{X} \times \mathcal{Y}$ with finite second moment. Let L be a convex loss function such that the third derivative is 0. Then the $(k+1)$th order influence function of $f_{\lambda,K}$ exists for all $z := (z_x, z_y) \in \mathcal{X} \times \mathcal{Y}$ and we have*

$$\begin{aligned} IF_{k+1}(z; f_{\lambda,K}, P) = (k+1) S^{-1}\Big(& \mathbb{E}_P[IF_k(z; f_{\lambda,K}, P)(X) L''(Y - f_{\lambda,K}(X))\Phi(X)] \\ & - [IF_k(z; f_{\lambda,K}, P)(z_x) L''(Z_y - f_{\lambda,K}(z_x))\Phi(z_x)] \Big) \end{aligned}$$

where $S : \mathcal{H} \to \mathcal{H}$ is defined by $S(f) = 2\lambda f + \mathbb{E}_P\left[L''(Y - f_{\lambda,K,P}(X))\langle \Phi(X), f \rangle \Phi(X)\right]$.

4. Finite Sample Expressions

Since the Taylor expansion in (1) is now fully characterized for any distribution P and any z, we can use this to assess the influence of individual points in a sample with sample distribution P_n. Applying Equation (3) with the KBR estimator f_{λ,K,P_n} from (4) we have that

$$f_{\lambda,K,P_n^{-i}}(x_i) = f_{\lambda,K,P_n}(x_i) + \sum_{j=1}^{\infty} \left(\frac{-1}{n-1}\right)^j \frac{IF_j(z_i; f_{\lambda,K}, P_n)(x_i)}{j!}. \tag{5}$$

Let us see how the right hand side can be evaluated in practice.

4.1 Least Squares Loss

First consider taking the least squares loss in (4). Denote Ω the $n \times n$ kernel matrix with i,j-th entry equal to $K(x_i,x_j)$. Let I_n be the $n \times n$ identity matrix and denote $S_n = \Omega/n + \lambda I_n$. The value of f_{λ,K,P_n} at a point $x \in \mathcal{X}$ is given by

$$f_{\lambda,K,P_n}(x) = \frac{1}{n}\sum_{i=1}^{n} \alpha_i K(x_i,x) \quad \text{with} \quad \begin{pmatrix} \alpha_1 \\ \vdots \\ \alpha_n \end{pmatrix} = S_n^{-1} \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix} \tag{6}$$

which is a classical result going back to Tikhonov and Arsenin (1977). This also means that the vector of predictions in the n sample points simply equals

$$\begin{pmatrix} f_{\lambda,K,P_n}(x_1) \\ \vdots \\ f_{\lambda,K,P_n}(x_n) \end{pmatrix} = H \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix} \tag{7}$$

with the matrix $H = \frac{1}{n} S_n^{-1}\Omega$, sometimes referred to as the smoother matrix.

To compute the first order influence function at the sample the expression in Proposition 5 should be evaluated at P_n. The operator S at P_n maps by definition any $f \in \mathcal{H}$ onto

$$S_{P_n}(f) = 2\lambda f + \mathbb{E}_{P_n} 2 f(X)\Phi(X) = 2\lambda f + \frac{2}{n}\sum_{j=1}^{n} f(x_j)\Phi(x_j)$$

and thus

$$\begin{aligned} \begin{pmatrix} S_{P_n}(f)(x_1) \\ \vdots \\ S_{P_n}(f)(x_n) \end{pmatrix} &= 2\lambda \begin{pmatrix} f(x_1) \\ \vdots \\ f(x_n) \end{pmatrix} + \frac{2}{n} \begin{pmatrix} K(x_1,x_1) & \dots & K(x_1,x_n) \\ \vdots & & \\ K(x_n,x_1) & & K(x_n,x_n) \end{pmatrix} \begin{pmatrix} f(x_1) \\ \vdots \\ f(x_n) \end{pmatrix} \\ &= 2S_n \begin{pmatrix} f(x_1) \\ \vdots \\ f(x_n) \end{pmatrix} \end{aligned}$$

which means that the matrix $2S_n$ is the finite sample version of the operator S at the sample P_n. From Proposition 5 it is now clear that

$$\begin{pmatrix} IF(z_i; f_{\lambda,K}, P_n)(x_1) \\ \vdots \\ IF(z_i; f_{\lambda,K}, P_n)(x_n) \end{pmatrix} = S_n^{-1} \left((y_i - f_{\lambda,K,P_n}(x_i)) \begin{pmatrix} K(x_i,x_1) \\ \vdots \\ K(x_i,x_n) \end{pmatrix} - \lambda \begin{pmatrix} f_{\lambda,K,P_n}(x_1) \\ \vdots \\ f_{\lambda,K,P_n}(x_n) \end{pmatrix} \right). \tag{8}$$

In order to evaluate the influence function at sample point z_i at a sample distribution P_n, we only need the full sample fit f_{λ,K,P_n} and the matrix S_n^{-1}, which is already obtained when computing f_{λ,K,P_n} (cf. Equation 6). From Theorem 7 one sees similarly that the higher order terms can be computed

recursively as

$$\begin{pmatrix} IF_{k+1}(z_i; f_{\lambda,K}, P_n)(x_1) \\ \vdots \\ IF_{k+1}(z_i; f_{\lambda,K}, P_n)(x_n) \end{pmatrix} = (k+1) S_n^{-1} \frac{\Omega}{n} \begin{pmatrix} IF(z_i; f_{\lambda,K}, P_n)(x_1) \\ \vdots \\ IF_k(z_i; f_{\lambda,K}, P_n)(x_n) \end{pmatrix} - (k+1) IF_k(z_i; f_{\lambda,K}, P_n)(x_i) S_n^{-1} \begin{pmatrix} K(x_i, x_1) \\ \vdots \\ K(x_i, x_n) \end{pmatrix}. \tag{9}$$

Define $[IFM_k]$ the matrix containing $IF_k(z_j; f_{\lambda,K}, P_n)(x_i)$ at entry i, j. Then (9) is equivalent to

$$[IFM_{k+1}] = (k+1)\left(H\,[IFM_k] - nH \bullet [IFM_k]\right)$$

with $\bullet$ denoting the entrywise matrix product (also known as the Hadamard product). Or equivalently

$$[IFM_{k+1}] = (k+1)\left(H([IFM_k] \bullet M(1-n))\right) \tag{10}$$

with M the matrix containing $1/(1-n)$ at the off-diagonal and 1 at the diagonal. A first idea is now to approximate the series in (5) by cutting it off at some step k:

$$f_{\lambda,K,P_n^{-i}}(x_i) \approx f_{\lambda,K,P_n}(x_i) + \sum_{j=1}^{k} \frac{1}{(1-n)^j j!} [IFM_j]_{i,i}. \tag{11}$$

However using (10) we can do a bit better. Expression (5) becomes

$$\begin{aligned} f_{\lambda,K,P_n^{-i}}(x_i) = f_{\lambda,K,P_n}(x_i) &+ \frac{1}{1-n}[IFM_1]_{i,i} + \frac{1}{1-n}[H(IFM_1 \bullet M)]_{i,i} \\ &+ \frac{1}{1-n}[H(H(IFM_1 \bullet M) \bullet M)]_{i,i} + \ldots \end{aligned}$$

In every term there is a multiplication with H and an entrywise multiplication with M. The latter means that all diagonal elements remain unchanged but the non-diagonal elements are divided by $1-n$. So after a few steps the non-diagonal elements will converge to 0 quite fast. It makes sense to set the non-diagonal elements 0 retaining only the diagonal elements:

$$\begin{aligned} f_{\lambda,K,P_n^{-i}}(x_i) &\approx f_{\lambda,K,P_n}(x_i) + \sum_{j=1}^{k-1} \frac{1}{(1-n)^j j!} [IFM_j]_{i,i} + \frac{1}{(1-n)^k k!} \sum_{j=0}^{\infty} H_{i,i}^j [IFM_k]_{i,i} \\ &= f_{\lambda,K,P_n}(x_i) + \sum_{j=1}^{k-1} \frac{1}{(1-n)^j j!} [IFM_j]_{i,i} + \frac{1}{(1-n)^k k!} \frac{[IFM_k]_{i,i}}{1-H_{i,i}} \end{aligned} \tag{12}$$

since $H_{i,i}$ is always smaller than 1.

4.2 Huber Loss

For the Huber loss function with parameter $b > 0$ we have that

$$L(r) = \begin{cases} r^2 & \text{if } |r| < b. \\ 2b|r| - b^2 & \text{if } |r| > b. \end{cases}$$

and thus

$$L'(r) = \begin{cases} 2r & \text{if } |r| < b \\ 2b \text{ sign}(r) & \text{if } |r| > b \end{cases}, \qquad L''(r) = \begin{cases} 2 & \text{if } |r| < b \\ 0 & \text{if } |r| > b \end{cases}.$$

Note that the derivatives in $|r| = b$ do not exist, but in practice the probability that a residual exactly equals b is 0, so we further ignore this possibility. The following equation holds:

$$f_{\lambda,K,P_n}(x) = \frac{1}{n}\sum_{i=1}^{n} \alpha_i K(x_i, x) \quad \text{with} \quad 2\lambda\alpha_j = L'(y_j - \frac{1}{n}\sum_{i=1}^{n} \alpha_i K(x_i, x_j)). \tag{13}$$

Thus a set of possibly non-linear equations has to be solved in α. Once the solution for the full sample is found, an approximation of the leave-one-out error is obtained in a similar way as for least squares. Proposition 5 for P_n gives the first order influence function.

$$\begin{pmatrix} IF(z_i; f_{\lambda,K}, P_n)(x_1) \\ \vdots \\ IF(z_i; f_{\lambda,K}, P_n)(x_n) \end{pmatrix} = S_b^{-1}\left(L'(y_i - f_{\lambda,K,P_n}(x_i)) \begin{pmatrix} K(x_i, x_1) \\ \vdots \\ K(x_i, x_n) \end{pmatrix} - \lambda \begin{pmatrix} f_{\lambda,K,P_n}(x_1) \\ \vdots \\ f_{\lambda,K,P_n}(x_n) \end{pmatrix} \right)$$

with $S_b = 2\lambda I_n + \Omega \bullet B/n$ and B the matrix containing $L''(y_i - f_{\lambda,K,P_n}(x_i)$ at every entry in the ith column. Let $H_b = S_b^{-1}\Omega/n \bullet B$. Starting from Theorem 7 one finds analogously as (10) the following recursion to compute higher order terms.

$$[IFM_{k+1}] = (k+1)\left(H_b([IFM_k] \bullet M(1-n))\right).$$

Finally one can use these matrices to approximate the leave-one-out estimator as

$$f_{\lambda,K,P_n^{-i}}(x_i) \approx f_{\lambda,K,P_n}(x_i) + \sum_{j=1}^{k-1} \frac{1}{(1-n)^j j!}[IFM_j]_{i,i} + \frac{1}{(1-n)^k k!}\frac{[IFM_k]_{i,i}}{1-[H_b]_{i,i}} \tag{14}$$

in the same way as in (12)

4.3 Reweighted KBR

In Equation (14) the full sample estimator f_{λ,K,P_n} is of course needed. For a general loss function L one has to solve Equation (13) to find f_{λ,K,P_n}. A fast way to do so is to use reweighted KBR with a least squares loss. Let

$$W(r) = \frac{L'(r)}{2r}. \tag{15}$$

Then we can rewrite (13) as

$$2\lambda f_{\lambda,K,P_n}(x_k) = \frac{1}{n}\sum_{i=1}^{n} L'(y_i - f_{\lambda,K,P_n}(x_i))K(x_i,x_k) \quad \forall 1 \le k \le n.$$
$$= \frac{1}{n}\sum_{i=1}^{n} 2W(y_i - f_{\lambda,K,P_n}(x_i))(y_i - f_{\lambda,K,P_n}(x_i))K(x_i,x_k).$$

Denoting $w_i = W(y_i - f_{\lambda,K,P_n}(x_i))$ this means that

$$\lambda f_{\lambda,K,P_n}(x_k) = \frac{1}{n}\sum_{i=1}^{n} w_i y_i K(x_i,x_k) - \frac{1}{n}\sum_{i=1}^{n} w_i f_{\lambda,K,P_n}(x_i)K(x_i,x_k) \quad \forall 1 \le k \le n.$$

Let I_w denote the $n \times n$ diagonal matrix with w_i at entry i,i. Then

$$\begin{pmatrix} f_{\lambda,K,P_n}(x_1) \\ \vdots \\ f_{\lambda,K,P_n}(x_n) \end{pmatrix} = \left(\frac{\Omega}{n} + \lambda I_w\right)^{-1} \frac{\Omega}{n} \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix} \tag{16}$$

and thus f_{λ,K,P_n} can be written as a reweighted least squares estimator with additional weights w_i compared to Equations (6) and (7). Of course these weights still depend on the unknown f_{λ,K,P_n}, so (16) only implicitly defines f_{λ,K,P_n}. It does suggest the following iterative reweighting algorithm.

1. Start with simple least squares computing (7). Denote the solution f^0_{λ,K,P_n}.
2. At step $k+1$ compute weights $w_{i,k} = W(y_i - f^k_{\lambda,K,P_n}(x_i))$.
3. Solve (16) using the weights $w_{i,k}$. Let the solution be f^{k+1}_{λ,K,P_n}.

In Suykens et al. (2002a) it is shown that this algorithm usually converges in very few steps. In Debruyne et al. (2006) the robustness of such stepwise reweighting algorithm is analyzed by calculating stepwise influence functions. It is shown that the influence function is stepwise reduced under certain conditions on the weight function.

For the Huber loss with parameter b Equation (15) means that the corresponding weight function equals $W(r) = 1$ if $|r| \le b$ and $W(r) = b/|r|$ if $|r| > b$. This gives a clear interpretation of this loss function: all observations with error smaller than b remain unchanged, but the ones with error larger than b are downweighted compared to the least squares loss. This also explains the gain in robustness. One can expect better robustness as b decreases.

It would be possible to compute higher order terms of such $k-$step estimators as well. Then one could explicitly use these terms to approximate the leave-one-out error of the $k-$step reweighted estimator. In this paper however we use the reweighting only to compute the full sample estimator f_{λ,K,P_n} and we assume that it is fully converged to the solution of (13). For the model selection (14) is then used.

5. Model Selection

Once the approximation of $f_{\lambda,K,P_n^{-i}}$ is obtained, one can proceed with model selection using the leave-one-out principle. In the next paragraphs we propose a specific implementation taking into account performance as well as robustness.

5.1 Definition

The traditional leave-one-out criterion is given by

$$\mathrm{LOO}(\lambda, K) = \frac{1}{n}\sum_{i=1}^{n} V(y_i - f_{\lambda,K,P_n^{-i}}(x_i)) \tag{17}$$

with V an appropriate loss function. The values of λ and of possible kernel parameters for which this criterion is minimal, are then selected to train the model. The idea we investigate is to replace the explicit leave-one-out by the approximation in (12) for least squares and (14) for the Huber loss.

Definition 8 *The k-th order influence function criterion at a regularization parameter $\lambda > 0$ and kernel K for Huber loss KBR with parameter b is defined as*

$$C_{IF}^k(\lambda, K, b) = \frac{1}{n}\sum_{i=1}^{n} V\left(y_i - f_{\lambda,K,P_n}(x_i) - \sum_{j=1}^{k-1}\frac{1}{(1-n)^j j!}[IFM_j]_{i,i} - \frac{1}{(1-n)^k k!}\frac{[IFM_k]_{i,i}}{1-[H_b]_{i,i}}\right).$$

For KBR with a least squares loss we write

$$C_{IF}^k(\lambda, K, \infty) = \frac{1}{n}\sum_{i=1}^{n} V\left(y_i - f_{\lambda,K,P_n}(x_i) - \sum_{j=1}^{k-1}\frac{1}{(1-n)^j j!}[IFM_j]_{i,i} - \frac{1}{(1-n)^k k!}\frac{[IFM_k]_{i,i}}{1-[H]_{i,i}}\right).$$

since a least squares loss is a limit case of the Huber loss as $b \to \infty$.

Several choices need to be made in practice. For k taking five steps seems to work very well in the experiments. If we refer to the criterion with this specific choice $k = 5$ we write C_{IF}^5. For V one typically chooses the squared loss or the absolute value corresponding to the mean squared error and the mean absolute error. Note that V does not need to be the same as the loss function used to compute f_{λ,K,P_n} (the latter is always denoted by L). Recall that a loss function L with bounded first derivative L' is needed to perform robust fitting. It is important to note that this result following from Proposition 5 holds for a fixed choice of λ and the kernel K. However, if these parameters are selected in a data driven way, outliers in the data might have a large effect on the selection of the parameters. Even if a robust estimator is used, the result could be quite bad if wrong choices are made for the parameters due to the outliers. It is thus important to use a robust loss function V as well. Therefore we set V equal to the absolute value loss function unless we explicitly state differently. In Section 6.1 an illustration is given on what can go wrong if a least squares loss is chosen for V instead of the absolute value.

5.2 Optimizing b

With k and V now specified, the criterion C_{IF}^5 can be used to select optimal hyperparameters for a KBR estimator with L the Huber loss with parameter b. Now the final question remains how to choose b. In Section 4.3 it was argued that b controls the robustness of the estimator since all observations with error smaller than b are downweighted compared to the least squares estimator. Thus we want to choose b small enough such that outlying observations receive sufficiently small weight, but also large enough such that the good non outlying observations are not downweighted too much. A priori it is quite difficult to find such a good choice for b, since this will depend on the scale of the errors.

However, one can also treat b as an extra parameter that is part of the optimization, consequently minimizing C^5_{IF} for λ, K and b simultaneously. The practical implementation we propose is as follows:

1. Let Λ be a set of reasonable values for the regularization parameter λ and let $\mathcal{K}$ be a set of possible choices for the kernel K (for instance a grid of reasonable bandwidths if one considers the RBF kernel).

2. Start with L the least squares loss. Find good choices for λ and K by minimizing $C^5_{IF}(\lambda, K, \infty)$ for all $\lambda \in \Lambda$ and $K \in \mathcal{K}$. Compute the residuals r_i with respect to the least squares fit with these optimal λ and K.

3. Compute a robust estimate of the scale of these residuals. We take the Median Absolute Deviation (MAD):

$$\hat{\sigma}_{err} = \text{MAD}(r_1, \ldots, r_n) = \frac{1}{\Phi^{-1}(0.75)} \text{median}(|r_i - \text{median}(r_i)|) \tag{18}$$

   with $\Phi^{-1}(0.75)$ the 0.75 quantile of a standard normal distribution.

4. Once the scale of the errors is estimated in the previous way, reasonable choices of b can be constructed, for example $\{1,2,3\} \times \hat{\sigma}_{err}$. This means that we compare downweighting observations further away than 1, 2, 3 standard deviations. We also want to compare to the least squares fit and thus set

$$\mathcal{B} = \{\hat{\sigma}_{err}, 2\hat{\sigma}_{err}, 3\hat{\sigma}_{err}, \infty\}.$$

5. Minimize $C^5_{IF}(\lambda, K, b)$ over all $\lambda \in \Lambda$, $K \in \mathcal{K}$ and $b \in \mathcal{B}$. The optimal values of b, λ and K can then be used to construct the final fit.

5.3 Generalized Cross Validation

The criterion C^5_{IF} uses influence functions to approximate the leave-one-out error. Other approximations have been proposed in the literature. In this section we very briefly mention some results that are described for example by Wahba (1990) in the context of spline regression. The following result can be proven.

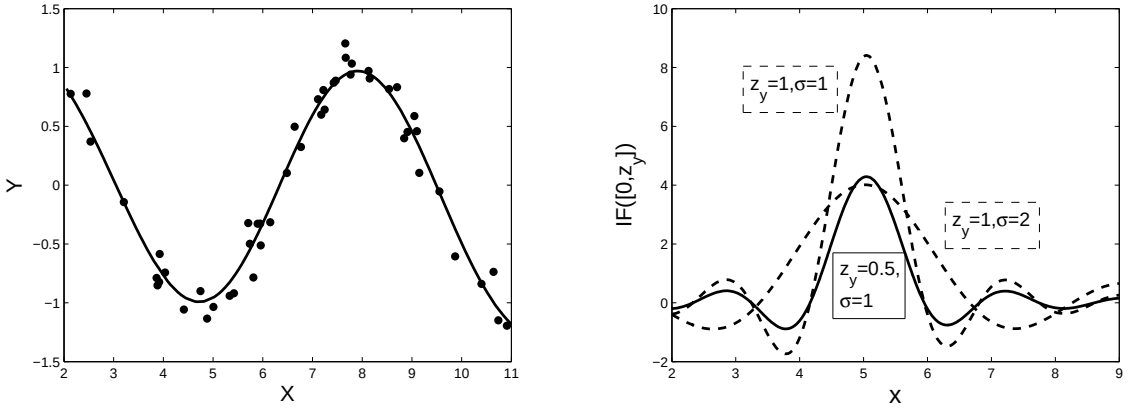
Let $\tilde{P}_n^{-i}$ be the sample P_n with observation (x_i, y_i) replaced by $(x_i, f_{\lambda,K,P_n^{-i}}(x_i))$. Suppose the following conditions are satisfied for any sample P_n:

$$(i) \quad f_{\lambda,K,\tilde{P}_n^{-i}}(x_i) = f_{\lambda,K,P_n^{-i}}(x_i). \tag{19}$$

$$(ii) \quad \text{There exists a matrix } H \text{ such that } \begin{pmatrix} f_{\lambda,K,P_n}(x_1). \\ \vdots \\ f_{\lambda,K,P_n}(x_n) \end{pmatrix} = H \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix}. \tag{20}$$

Then

$$f_{\lambda,K,P_n^{-i}}(x_i) = \frac{f_{\lambda,K,P_n}(x_i) - H_{i,i} y_i}{1 - H_{i,i}}. \tag{21}$$



(a) (b)

Figure 1: (a) Data and least squares fit. (b) Influence functions at $[5,0.5]$ with $\sigma = 1$, at $[5,1]$ with $\sigma = 1$ and $\sigma = 2$.

For KBR with the least squares loss condition (22) is indeed satisfied (cf. Equation 7), but condition (19) is not, although it holds approximately. Then (21) can still be used as an approximation of the leave-one-out estimator. The corresponding model selection criterion is given by

$$CV(\lambda,K) = \frac{1}{n}\sum_{i=1}^{n} V\left(\frac{y_i - f_{\lambda,K,P_n}(x_i)}{1-H_{i,i}}\right). \tag{22}$$

We call this approximation CV. Sometimes a further approximation is made replacing every $H_{i,i}$ by $\text{trace}(H)/n$. This is called Generalized Cross Validation (GCV, Wahba, 1990). Note that the diagonal elements of the hatmatrix H play an important role in the approximation with the influence function too (12). Both penalize small values on the diagonal of H.

For KBR with a general loss function one does not have a linear equation of the form of (22), and thus it is more difficult to apply this approximation. We shall thus use CV for comparison in the experiments only in the case of least squares.

6. Empirical Results

We illustrate the results on a toy example and a small simulation study.

6.1 Toy Example

As a toy example 50 data points were generated with x_i uniformly distributed on the interval $[2,11]$ and $y_i = \sin(x_i) + e_i$ with e_i Gaussian distributed noise with standard deviation 0.2. We start with kernel based regression with a least squares loss and a Gaussian kernel. The data are shown in Figure $1(a)$ as well as the resulting fit with $\lambda = 0.001$ and $\sigma = 2$. The first order influence function at $[5,0.5]$ is depicted in Figure $1(b)$ as the solid line. This reflects the asymptotic change in the fit when a point would be added to the data in Figure $1(a)$ at the position $(5,0.5)$. Obviously this influence is the largest at the x-position where we put the outlier, that is, $x = 5$. Furthermore we see that the influence is local, since it decreases as we look further away from $x = 5$. At $x = 8$ for

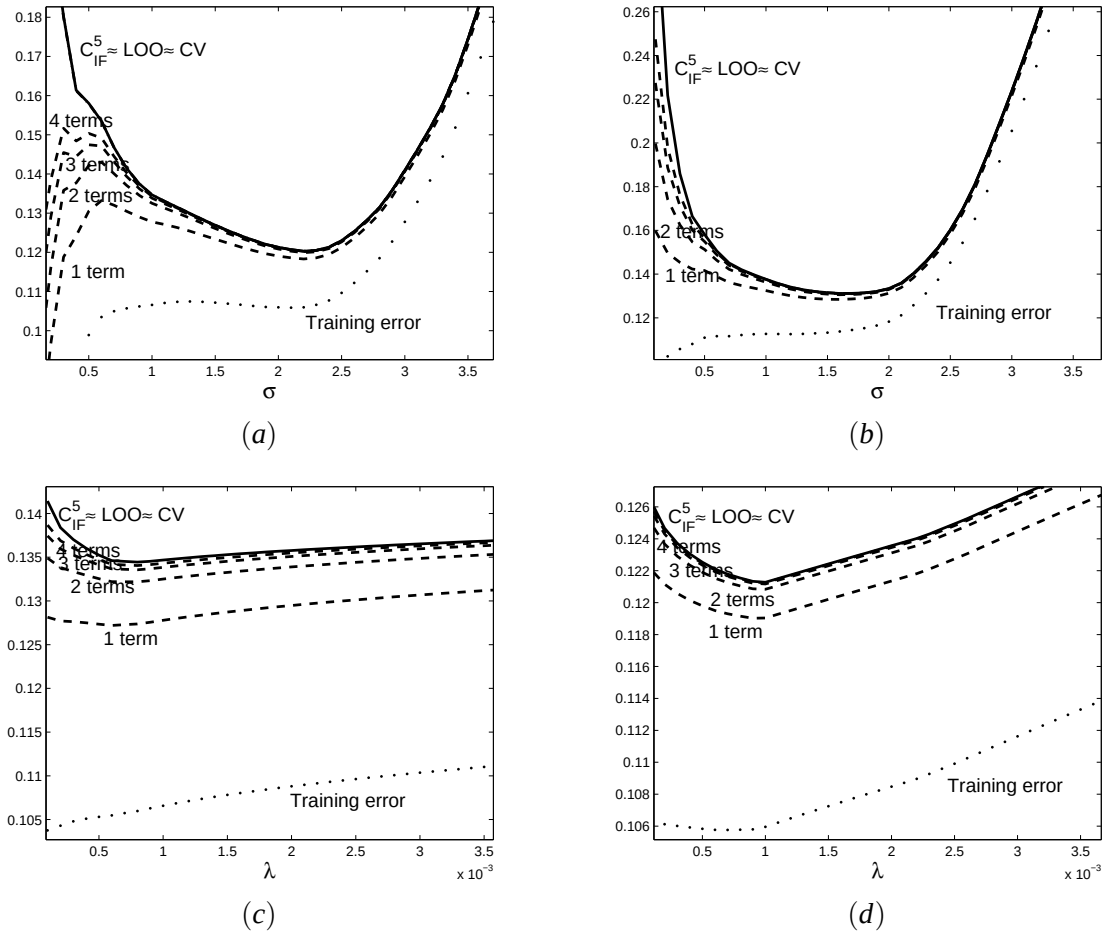


Figure 2: Comparison of training error (dotted line), approximations using (11) (dashed lines), the proposed criterion C_{IF}^k with $k = 5$ (solid line), the exact leave-one-out error and the CV approximation (both collapsing with C_{IF}^k on these plots). Situation (a): as a function of σ at $\lambda = 0.001$, (b) as a function of σ at $\lambda = 0.005$, (c) as a function of λ at $\sigma = 1$, (d) as a function of λ at $\sigma = 2$.

instance the influence function is almost 0. When we change z from $[5, 0.5]$ to $[5, 1]$, the influence function changes too. It still has the same oscillating behavior, but the peaks are now higher. This reflects the non-robustness of the least squares estimator: if we would continue raising the point z, then $IF(z; f_{\lambda,K})$ would become larger and larger, since it is an unbounded function of z. When it comes down to model selection, it is interesting to check the effect of the hyperparameters in play. When we change the bandwidth σ from 1 to 2, the peaks in the resulting influence function in Figure 1 are less sharp and less high. This reflects the loss in stability when small bandwidths are chosen: then the fit is more sensitive to small changes in the data and thus less stable.

Consider now the approximation of the leave-one-out error using the influence functions. We still use the same data as in the previous paragraph. The dashed lines in Figure $2(a)$ show the approximations using (11), that is simply cutting off the expansion after a number of steps, at fixed

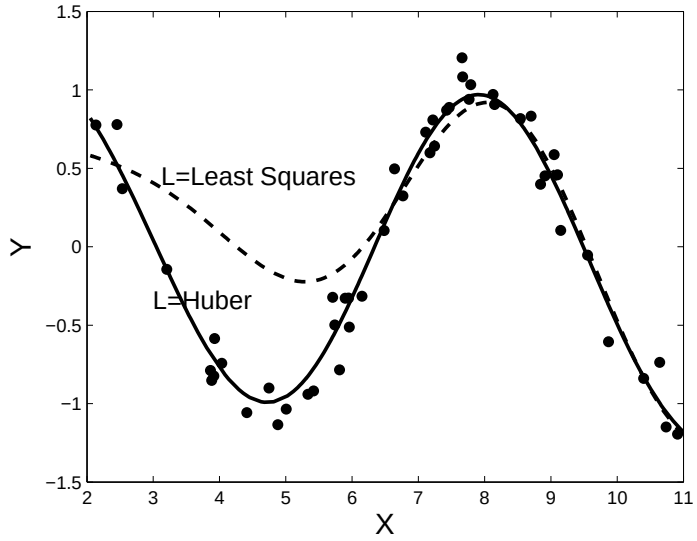

Figure 3: Data with outlier at $(4,5)$. The parameters $\lambda = 0.001$ and $\sigma = 2$ are fixed. Dashed: KBR with least squares loss function. Solid: KBR with Huber loss function ($b = 0.2$).

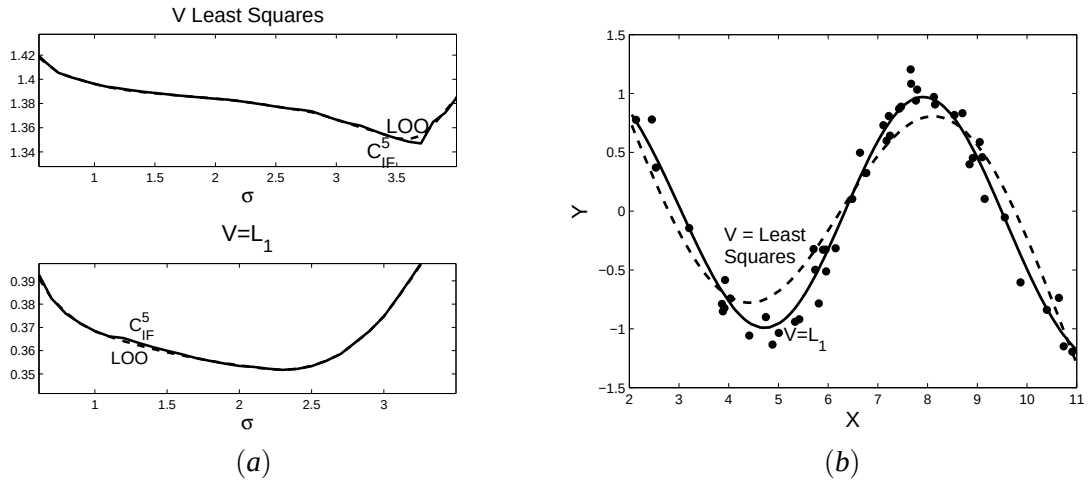
$\lambda = 0.001$ as a function of the bandwidth σ. We observe convergence from the training error towards the leave-one-out error as the number of terms included is increased. Unfortunately the convergence rate depends on the value of σ: convergence is quite slow at small values of σ. This is no surprise looking at (12). There we approximated the remainder term by a quantity depending on $(1-H_{i,i})^{-1}$. When σ is small, the diagonal elements of H become close to 1. In that case the deleted remainder term can indeed be quite large. Nevertheless, this approach can still be useful if some care is taken not to consider values of λ and σ that are too small. However, the criterion C_{IF}^5 from Definition 8 using the approximation in (12) is clearly superior. We see that the remainder term is now adequately estimated and a good approximation is obtained at any σ. The resulting curve is undistinguishable from the exact leave-one-out error. The mean absolute difference is $3.2\ 10^{-5}$, the maximal difference is $1.8\ 10^{-4}$. The CV approximation also yields a good result being indistinguishable from the exact leave-one-out error on the plot as well. The mean absolute difference is $4.1\ 10^{-4}$ and the maximal difference equals $1.8\ 10^{-3}$. Thus C_{IF}^5 is closer to the true leave-one-out error than CV, although the difference is irrelevant when it comes down to selecting a good σ.

Figure 2 also shows plots for the leave-one-out error and its various approximations at (b) $\lambda = 0.005$ as a function of σ, (c) $\sigma = 1$ as a function of λ, (d) $\sigma = 2$ as a function of λ. In these cases as well it is observed that the cutoff strategy yields decent results if a sufficient number of terms is taken into account and if one does not look at values of λ and σ that are extremely small. The best strategy is to take the remainder term into account using the criterion C_{IF}^k from Definition 8.

In Figure 3 we illustrate robustness. An (extreme) outlier was added at position $(4,5)$ (not visible on the plot). This outlier leads to a bad fit when LS-KBR is used with $\lambda = 0.001$ and $\sigma = 2$ (dashed line). When a Huber loss function is used with $b = 0.2$ a better fit is obtained that still nicely predicts the majority of observations. This behavior can be explained by Proposition 5. The least squares loss has an unbounded first derivative and thus the influence of outliers can be arbitrary large. The Huber loss has a bounded first derivative and thus the influence of outliers is bounded as



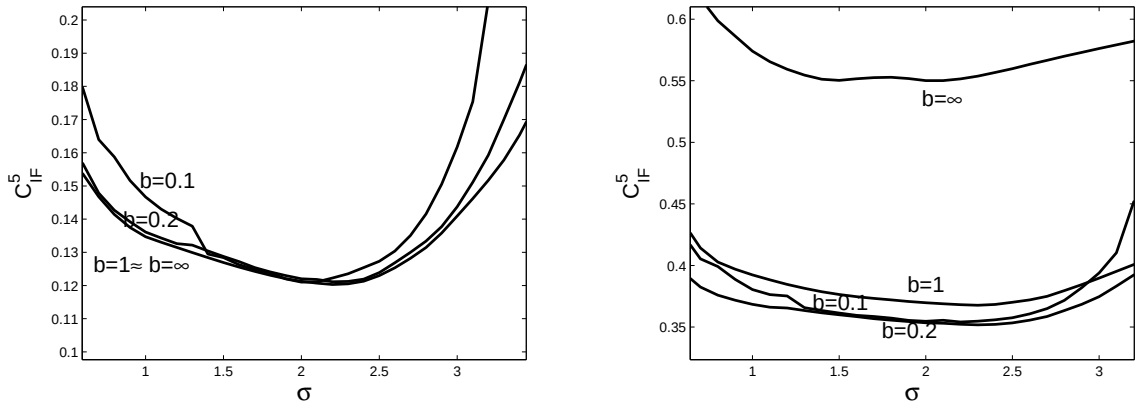
(a) (b)

Figure 4: (a) Optimization of σ at $\lambda = 0.001$. Upper: using least squares loss V in the model selection. Lower: using L_1 loss V in the model selection. For the estimation the loss function L is always the Huber loss with $b = 0.2$. (b) Resulting fits. Dashed line: $\sigma = 3.6$ (optimal choice using V least squares). Solid line: $\sigma = 2.3$ (optimal choice using L_1 loss for V.

well. However, note that in this example as well as in Proposition 5 the hyperparameters λ and σ are assumed to have fixed values. In practice one wants to choose these parameters in a data driven way. Figure $4(a)$ shows the optimization of σ at $\lambda = 0.001$ for KBR with L the Huber loss with $b = 0.2$. In the upper panel the least squares loss is used for V in the model selection criteria. Both exact leave-one-out and C^5_{IF} indicate that a value of $\sigma \approx 3.6$ should be optimal. This results in the dashed fit in Figure $4(b)$. In the lower panel of Figure 4 the L_1 loss is used for V in the model selection criteria. Both exact leave-one-out and C^5_{IF} indicate that a value of $\sigma \approx 2.3$ should be optimal. This results in the solid fit in Figure $4(b)$. We clearly see that, although in both cases a robust estimation procedure is used (Huber loss for L), the outlier can still be quite influential through the model selection. To obtain full protection against outliers, both the estimation and the model selection step require robustness, for example by selecting both L and V in a robust way.

Finally let us investigate the role of the parameter b used in the Huber loss function. We now use C^5_{IF} with V the L_1 loss. When we apply C^5_{IF} to the clean data without the outlier, we observe in Figure $5(a)$ that the choice of b does not play an important role. This is quite expected: since there are no outliers, there is no reason why least squares ($b = \infty$) would not perform well. On the contrary, if we use a small b such as $b = 0.1$ we get a slightly worse result. Again this is not a surprise, since with small b we will downweight a lot of points that are actually perfectly ok.

The same plot for the data containing the outlier yields a different view in Figure $5(b)$. The values of C^5_{IF} are much higher for least squares than for the Huber loss with smaller b. Thus it is automatically detected that a least squares loss is not the appropriate choice, which is a correct assessment since the outlier will have a large effect (cf. the dashed line in Figure 3). The criterion C^5_{IF} indicates a choice $b = 0.2$, which leads to a better result indeed (cf. the solid line in Figure 3)



(a) (b)

Figure 5: C^5_{IF} at $\lambda = 0.001$ as a function of σ for several values of b for (a) the clean data without the outlier, (b) the data with the outlier.

6.2 Other Examples

This part presents the results of a small simulation study. We consider some well known settings.

- Friedman 1 ($d = 10$): $y(x) = 10\sin(\pi x_1 x_2) + 20(x_3 - 1/2)^2 + 10x_4 + 5x_5 + \sum_{i=6}^{10} 0.x_i$. The covariates are generated uniformly in the hypercube in $\mathbb{R}^{10}$.

- Friedman 2 ($d = 4$): $y(x) = \frac{1}{3000}(x_1^2 + (x_2x_3 - (x_2x_4)^{-2}))^{1/2}$, with $0 < x_1 < 100$, $20 < x_2/(2\pi) < 280$, $0 < x_3 < 1$, $1 < x_4 < 11$.

- Friedman 3 ($d = 4$): $y(x) = \tan^{-1}(\frac{x_2x_3 - (x_2x_4)^{-2}}{x_1})$, with the same range for the covariates as in Friedman 2. For each of the Friedman data sets 100 observations were generated with Gaussian noise and 200 noise free test data were generated.

- Boston Housing Data from the UCI machine learning depository with 506 instances and 13 covariates. Each split 450 observations were used for training and the remaining 56 for testing.

- Ozone data from ftp://ftp.stat.berkeley.edu/pub/users/breiman/ with 202 instances and 12 covariates. Each split 150 observations were used for training and the remaining 52 for testing.

- Servo data from the UCI machine learning depository with 167 instances and 4 covariates. Each split 140 observations were used for training and the remaining 27 for testing.

For the real data sets (Boston, Ozone and Servo), new contaminated data set were constructed as well by adding large noise to 10 training points, making these 10 points outliers.

The hyperparameters λ and σ are optimized over the following grid of hyperparametervalues:

- $\lambda \in \{50, 10, 5, 3, 1, 0.8, 0.5, 0.3, 0.1, 0.08, 0.05, 0.01, 0.005\} \times 10^{-3}$.

- For each data set 500 distances were calculated between two randomly chosen observations. Let $d_{(i)}$ be the ith largest distance. Then the following grid of values for σ is considered: $\sigma \in \{\frac{1}{2}d_{(1)}, d_{(1)}, d_{(50)}, d_{(100)}, d_{(150)}, d_{(200)}, d_{(250)}, d_{(300)}, d_{(350)}, d_{(400)}, d_{(450)}, d_{(500)}, 2d_{(500)}\}$.

In each replicate the Mean Squared Error of the test data is computed. For every data set the average MSE over 20 replicates is shown in Table 1 (upper table). A two-sided paired Wilcoxon rank test is used to check statistical significance: values in italic are significantly different from the smallest value at significance level 0.05. If underlined significance holds even at significance level 10^{-4}. Standard errors are shown as well (lower table). First we consider the least squares loss for L with the criterion $C^5_{IF}(\lambda, \sigma, \infty)$ (Definition 8), with exact leave-one-out (17) and with CV (22). These are the first 3 columns in Table 1. We see that the difference between these 3 criteria is very small. This means that both CV and C^5_{IF} provide good approximations of the leave-one-out error.

Secondly, we considered each time the residuals of the least squares fit with optimal λ and σ according to $C^5_{IF}(\lambda, K, \infty)$. An estimate $\hat{\sigma}_{err}$ of the scale of the residuals is computed as the MAD of these residuals (18). Then we applied KBR with a Huber loss and parameter $b = 3\hat{\sigma}_{err}$. The resulting MSE with this loss and λ and σ minimizing $C^5_{IF}(\lambda, \sigma, 3\hat{\sigma}_{err})$ is given in column 4 in Table 1. Similar results are obtained for $b = 2\hat{\sigma}_{err}$ in column 5 and with $b = \hat{\sigma}_{err}$ in column 6. For the data sets without contamination we see that using a Huber loss instead of least squares gives similar results except for the Boston housing data, Friedman 1 and especially Friedman 2. For those data sets a small value of b is inappropriate. This might be explained by the relationship between the loss function and the error distribution. For a Gaussian error distribution least squares is often an optimal choice (cf. maximum likelihood theory). Since the errors in the Friedman data are explicitly generated as Gaussian, this might explain why least squares outperforms the Huber loss. For real data sets, the errors might not be exactly Gaussian, and thus other loss function can perform at least equally well as least squares. For the data sets containing the outliers the situation changes of course. Now least squares is not a good option because of its lack of robustness. Clearly the outliers have a large and bad effect on the quality of the predictions. This is not the case when the Huber loss function is chosen. Then the effect of the outliers is reduced. Choosing $b = 3\hat{\sigma}_{err}$ already leads to a large improvement. Decreasing b leads to even better results (note that the p-values are smaller than 10^{-4} for any significant pairwise comparison).

Finally we also consider optimizing b. We apply the algorithm outlined in Section 5.2. Corresponding MSE's are given in the last column of Table 1. For the Friedman 1 and Friedman 2 data sets for instance this procedure indeed detects that least squares is an appropriate loss function and automatically avoids choosing b too small. For the contaminated data sets the procedure detects that least squares is not appropriate and that changing to a Huber loss with a small b is beneficial, which is indeed a correct choice yielding smaller MSE's. In fact, only for the Friedman 2 data, the automatic choice of b is significantly worse than the optimal choice (p-value=0.03), whereas the benefits at the contaminated data are large (all p-values $< 10^{-4}$).

7. Conclusion

Heuristic links between the concept of the influence function and concepts as leave-one-out cross validation and stability were considered in Section 2, indicating some interesting applications of the influence function and the leave-one-out error in previous literature. New results include the calculation of higher order influence functions and a recursive relation between subsequent terms. It is shown that these theoretical results can be applied in practice to approximate the leave-one-out esti-

mator. Experiments indicate that the quality of this approximation is quite good. The approximation is used in a model selection criterion to select the regularization and kernel parameters.

We discussed the importance of robustness in the model selection step. A specific procedure is suggested using an L_1 loss in the model selection criterion and a Huber loss in the estimation. Due to an iterative reweighting algorithm to compute such a Huber loss estimator and due to the fast approximation of the leave-one-out error, everything can be computed fast starting from the least squares framework. With an a priori choice of the parameter b in the Huber loss this leads to better robustness if b is chosen small enough. If b is chosen too small on the other hand this might result in worse predictions. However, this parameter can be selected in a data driven way as well. Experiments suggest that this often yields a good trade-off between the robustness of choosing a small b and the sometimes better predictive capacity of least squares.

Proof of Theorem 6

Let P be a distribution, $z \in \mathcal{X} \times \mathcal{Y}$ and $P_{\varepsilon,z} = (1-\varepsilon)P + \varepsilon\Delta_z$ with Δ_z the Dirac distribution in z. We start from the representer theorem of DeVito et al. (2004) (a generalization of (13)):

$$2\lambda f_{\lambda,K,P_{\varepsilon,z}} = \mathbb{E}_{P_{\varepsilon,z}}[L'(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)].$$

By definition of $P_{\varepsilon,z}$ and since $\mathbb{E}_{\Delta_z} g(X) = g(z)$ for any function g:

$$2\lambda f_{\lambda,K,P_{\varepsilon,z}} = (1-\varepsilon)\mathbb{E}_P[L'(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] + \varepsilon L'(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x).$$

Taking the first derivative on both sides with respect to ε yields

$$\begin{aligned}
2\lambda\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}} =& (1-\varepsilon)\mathbb{E}_P[-\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\
&- \mathbb{E}_P[L'(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] + L'(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x) \\
&- \varepsilon\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(z_x))L''(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x).
\end{aligned}$$

The second derivative equals

$$\begin{aligned}
2\lambda\frac{\partial}{\partial^2\varepsilon} f_{\lambda,K,P_{\varepsilon,z}} =& -\mathbb{E}_P[-\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\
&+ (1-\varepsilon)\mathbb{E}_P[-\frac{\partial}{\partial^2\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\
&+ (1-\varepsilon)\mathbb{E}_P[-\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(X)L'''(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))(-\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\
&- \mathbb{E}_P[L''(Y - f_{\lambda,K,P_{\varepsilon,z}}(X))(-\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\
&- \frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x) \\
&- \varepsilon\frac{\partial}{\partial^2\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x) \\
&- \varepsilon\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(z_x)L'''(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))(-\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x) \\
&- L''(z_y - f_{\lambda,K,P_{\varepsilon,z}}(z_x))\frac{\partial}{\partial\varepsilon} f_{\lambda,K,P_{\varepsilon,z}}(z_x)\Phi(z_x).
\end{aligned}$$

Simplifying yields

$$\begin{aligned}2\lambda\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}} =& 2\mathbb{E}_P[\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\ &-(1-\varepsilon)\mathbb{E}_P[\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\ &+(1-\varepsilon)\mathbb{E}_P[\left(\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)\right)^2 L'''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\ &-2\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x) \\ &-\varepsilon\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x) \\ &+\varepsilon\left(\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)\right)^2 L'''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x).\end{aligned} \tag{23}$$

Evaluating at $\varepsilon=0$ and bringing all terms containing $\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}$ to the left hand side of the equation yields

$$\begin{aligned}2\lambda\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}|_{\varepsilon=0}+\mathbb{E}_P[\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)|_{\varepsilon=0}L''(Y-f_{\lambda,K,P}(X))\Phi(X)] \\ =2\mathbb{E}_P[\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)|_{\varepsilon=0}L''(Y-f_{\lambda,K,P}(X))\Phi(X)] \\ +\mathbb{E}_P[\left(\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}|_{\varepsilon=0}(X)\right)^2 L'''(Y-f_{\lambda,K,P}(X)) \\ -2\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P}(z_x)|_{\varepsilon=0}L''(z_y-f_{\lambda,K,P}(z_x))\Phi(z_x).\end{aligned}$$

Since by definition $\frac{\partial}{\partial\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}|_{\varepsilon=0}$ is $IF(z;f_{\lambda,K},P)$ and $\frac{\partial}{\partial^2\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}|_{\varepsilon=0}$ is $IF_2(z;f_{\lambda,K},P)$ we have that

$$\begin{aligned}S(IF_2(z;f_{\lambda,K},P)) = 2\mathbb{E}_P[&IF(z;f_{\lambda,K},P)(X)L''(Y-f_{\lambda,K,P}(X))\Phi(X)] \\ &+\mathbb{E}_P[\big(IF(z;f_{\lambda,K},P)(X)\big)^2 L'''(Y-f_{\lambda,K,P}(X)) \\ &-2IF(z;f_{\lambda,K},P)(z_x)L''(z_y-f_{\lambda,K,P}(z_x))\Phi(z_x)\end{aligned}$$

with the operator S defined by $S: f\rightarrow\lambda f+\mathbb{E}_P L''(Y-f_{\lambda,K,P}(X))f(X)\Phi(X)$. Christmann and Steinwart (2007) prove that S is an invertible operator and thus Theorem 6 follows.

Proof of Theorem 7

First we proof the following for all $2\leq k\in\mathbb{N}$:

$$\begin{aligned}2\lambda\frac{\partial}{\partial^k\varepsilon}f_{\lambda,K}(P_{\varepsilon,z}) =& (1-\varepsilon)\mathbb{E}_P[-\frac{\partial}{\partial^k\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\ &+k\mathbb{E}_P[\frac{\partial}{\partial^{k-1}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)] \\ &-kL''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\frac{\partial}{\partial^{k-1}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)\Phi(z_x) \\ &-\varepsilon L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\frac{\partial}{\partial^k\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)\Phi(z_x).\end{aligned} \tag{24}$$

Note that for $k=2$ this immediately follows from (23). For general k we give a proof by induction. We assume that (24) holds for k and we then prove that it automatically holds for $k+1$ as well. Taking the derivatives of both sides in (24) we find

$$\begin{aligned}
\lambda\frac{\partial}{\partial^{k+1}\varepsilon}f_{\lambda,K}(P_{\varepsilon,z}) =&(1-\varepsilon)\mathbb{E}_P[-\frac{\partial}{\partial^{k+1}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)]\\
&-\mathbb{E}_P[-\frac{\partial}{\partial^{k}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)]\\
&+k\mathbb{E}_P[\frac{\partial}{\partial^{k}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)]\\
&-k\frac{\partial}{\partial^{k}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x)\\
&-\varepsilon\frac{\partial}{\partial^{k+1}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x)\\
&-\frac{\partial}{\partial^{k}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(z_x)L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x)
\end{aligned}$$

from which it follows that (24) holds for $k+1$ indeed. Evaluating this expression in $\varepsilon=0$ yields:

$$\begin{aligned}
&\lambda\frac{\partial}{\partial^{k+1}\varepsilon}f_{\lambda,K}(P_{\varepsilon,z})|_{\varepsilon=0}+\mathbb{E}_P[\frac{\partial}{\partial^{k+1}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)|_{\varepsilon=0}L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)]\\
&=(k+1)\mathbb{E}_P[\frac{\partial}{\partial^{k}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}(X)|_{\varepsilon=0}L''(Y-f_{\lambda,K,P_{\varepsilon,z}}(X))\Phi(X)]\\
&-(k+1)\frac{\partial}{\partial^{k}\varepsilon}f_{\lambda,K,P_{\varepsilon,z}}|_{\varepsilon=0}(z_x)L''(z_y-f_{\lambda,K,P_{\varepsilon,z}}(z_x))\Phi(z_x).
\end{aligned}$$

Thus

$$\begin{aligned}
S(IF_{k+1}(z;f_{\lambda,K},P)) = (k+1)\Big(&\mathbb{E}_P[IF_k(z;f_{\lambda,K},P)(X)L''(Y-f_{\lambda,K}(X))\Phi(X)]\\
&-[IF_k(z;f_{\lambda,K},P)(z_x)L''(z_y-f_{\lambda,K}(z_x))\Phi(z_x)]\Big).
\end{aligned}$$

Since S is an invertible operator the result in Theorem 7 follows.

Abstract

Statistical models on full and partial rankings of n items are often of limited practical use for large n due to computational consideration. We explore the use of non-parametric models for partially ranked data and derive computationally efficient procedures for their use for large n. The derivations are largely possible through combinatorial and algebraic manipulations based on the lattice of partial rankings. A bias-variance analysis and an experimental study demonstrate the applicability of the proposed method.

Keywords: ranked data, partially ordered sets, kernel smoothing

1. Introduction

Rankers such as people, search engines, and classifiers, output full or partial rankings representing preference relations over n items or alternatives. For example in the case of $m = 6$ rankers issuing full or partial preferences over $n = 3$ items a possible data set is

$$3 \prec 1 \prec 2, \quad 3 \prec 2 \prec 1, \quad 1 \prec 3 \prec 2, \quad 1 \prec \{2,3\}, \quad 3 \prec \{1,2\}, \quad \{2,3\} \prec 1. \tag{1}$$

The first three expressions in (1) correspond to full rankings while the last three expressions correspond to partial rankings (the numbers correspond to items and the $\prec$ symbol corresponds to a preference relation). While it is likely that some rankings will contradict others, it is natural to assume that the data in (1) was sampled iid from some distribution p over rankings. The goal of this paper is to study non-parametric methods for the estimation of p based on data sets such as (1) in the case of large n.

Often, ranked data is not inherently associated with numeric score information. In other cases, numeric scores are available but are un-calibrated and cannot be compared to each other. For example, the assignment of numeric scores by people to items or alternatives is un-calibrated as each person has his or her own notion of what constitutes a certain numeric score. On the other hand, a preference of one item or alternative over another reflects a binary choice that is directly comparable across rankers. Thus, even in cases where numeric scores exist, modeling the scoreless preferences may achieve higher modeling accuracy.

Despite this motivating observation, modeling ranked data is less popular than modeling the existing numeric scores, or even made-up numeric scores in case the true scores are unavailable (such is the case with the frequently used Borda count). The main reason for this is that rankings over a large number of items n reside in an extremely large discrete space whose modeling often requires intractable computation.

Previous attempts at modeling ranked data have been mostly parametric and often designed to work with fully ranked data (Marden, 1996). Non-parametric modeling of fully ranked data has been recently addressed in the context of multi-object tracking (Kondor et al., 2007; Huang et al., 2008). They focus on maintaining and updating a distribution over permutations by a low frequency approximation of the distribution. Such an approximation results from a spectral decomposition of functions on the symmetric group on n items (Diaconis, 1988) and is essential for efficient probabilistic inference.

Most of aforementioned approaches are unsuitable for modeling partial rankings for medium and large n due to the computational difficulties of handling a probability space of size $n!$. The few possible exceptions (Critchlow, 1985; Marden, 1996) are usually more ad-hoc and do not correspond to an underlying permutation model making them ill suited to handle partial rankings of different types. In fact, most of the ranked data analyzed in the literature are limited to $n \leq 15$ and usually even $n \leq 5$ such as the popular APA election data set.

On the other hand, there has been a recent increase in data sets containing partial or full rankings for large n. Examples include (i) web-search data such as TREC[1] where n may be thought of as corresponding to the number of web-pages or approaching $+\infty$, (ii) movie review data sets such as the Netflix data set[2] where $n \approx 18000$ and MovieLens[3] where $n = 1682$, and (iii) multi-label text document data sets such as OHSUMED[4] where $n = 4904$ and Reuters RCV1[5] where $n = 103$. More details on how these data sets correspond to partial rankings may be found in Section 2.

These data sets and others lead to a growing number of somewhat ad-hoc but computationally efficient rank aggregation techniques. The techniques, developed primarily within the computer science community, are often non-probabilistic and output a single ranking summarizing the data. Unfortunately, such a summary ranking, while being useful, does not provide the data analysis capabilities offered by a full probabilistic model.

The main contribution of this paper is in proposing and studying a non-parametric estimator based on kernel smoothing for the estimation of the population distribution p. Some properties of the estimator are listed below. We are not aware of any other non-trivial estimator of p that satisfies these requirements, in particular for the case of large n.

(1) Estimate p based on full as well as partial rankings.

(2) The resulting estimate $\hat{p}$ should assign probabilities to full and partial rankings in a coherent and contradiction-free manner (described in Section 4).

(3) Estimate p based on partial rankings of different types (defined in Section 2).

(4) Statistical consistency $\hat{p} \xrightarrow{p} p$ as both the number of samples m and the number of items n grow to infinity.

(5) Statistical accuracy of $\hat{p}$ can be slow for fully ranked data but should be accelerated when restricted to simpler partial rankings.

(6) Obtaining the estimate $\hat{p}$ and using it to compute probabilities $\hat{p}(A)$ of partial rankings should be computationally feasible, even for large n.

All 6 properties above are crucial in the large n scenario: it is often impossible for rankers to specify full rankings over a very large number of items making the use of partial rankings a necessity. Different rankers may choose to output partial rankings of different types, for example, one ranker can output $3 \prec \{1,2\}$ (3 is preferred to both 1 and 2) and another ranker can output $\{1,3\} \prec 2$ (both 1 and 3 are preferred to 2). By considering the asymptotics $n \to \infty$ in addition to $m \to \infty$ (m being the number of samples) we provide a more realistic analysis for a large (and potentially growing) number of items. Computational feasibility is a major concern since most ranking models are incapable of modeling the data sets mentioned above due to their large n.

We continue next by reviewing basic concepts concerning partially ranked data and the Mallows model, and then proceed to define our non-parametric estimator. We conclude by demonstrating computational efficiency, statistical properties, and some experiments.

2. Permutations and Cosets

We begin by reviewing some basic concepts concerning permutations, with some of the notations and definitions borrowed from Critchlow (1985).

A permutation π is a bijective function $\pi : \{1,\ldots,n\} \to \{1,\ldots,n\}$ associating with each item $i \in \{1,\ldots,n\}$ a rank $\pi(i) \in \{1,\ldots,n\}$. In other words, $\pi(i)$ denotes the rank given to item i and $\pi^{-1}(i)$ denotes the item assigned to rank i. We denote a permutation π using the following vertical bar notation $\pi^{-1}(1)|\pi^{-1}(2)|\cdots|\pi^{-1}(n)$. For example, the permutation $\pi(1) = 2, \pi(2) = 3, \pi(3) = 1$ would be denoted as $3|1|2$. In this notation the numbers correspond to items and the locations of the items in their corresponding compartments correspond to their ranks. The collection of all permutations of n items forms the non-Abelian symmetric group of order n, denoted by $\mathfrak{S}_n$, using function composition as the group operation $\pi\sigma = \pi \circ \sigma$. We denote the identity permutation by e.

The concept of inversions and the result below will be of great use later on.

Definition 1 *The inversion set of a permutation π is the set of pairs*

$$U(\pi) \stackrel{\text{def}}{=} \{(i,j) : i < j,\ \pi(i) > \pi(j)\} \subset \{1,\ldots,n\} \times \{1,\ldots,n\}$$

whose cardinality is denoted by $i(\pi) \stackrel{\text{def}}{=} |U(\pi)|$.

For example, $i(e) = |\emptyset| = 0$, and $i(3|2|1|4) = |\{(1,2),(1,3),(2,3)\}| = 3$.

Proposition 1 (for example, Stanley, 2000) *The map $\pi \mapsto U(\pi)$ is a bijection.*

When n is large, the enormous number of permutations raises difficulties in using the symmetric group for modeling rankings. A reasonable solution is achieved by considering partial rankings which correspond to cosets of the symmetric group. For example, the subgroup of $\mathfrak{S}_n$ consisting of

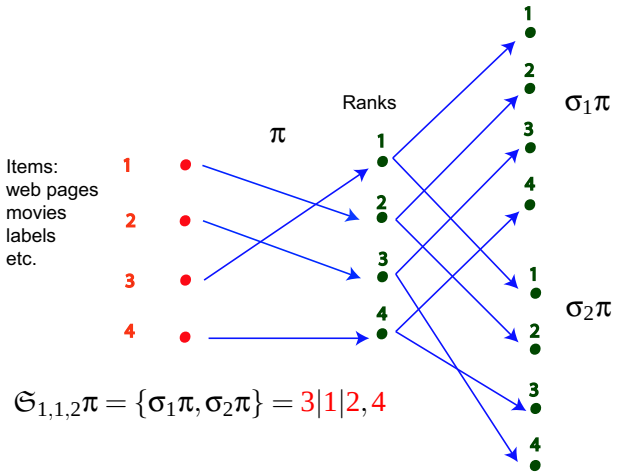

Figure 1: A partial ranking corresponds to a coset or a set or permutations

all permutations that fix the top k positions is denoted $\mathfrak{S}_{1,\ldots,1,n-k} = \{\pi \in \mathfrak{S}_n : \pi(i) = i,\ i = 1,\ldots,k\}$. The right coset $\mathfrak{S}_{1,\ldots,1,n-k}\pi = \{\sigma\pi : \sigma \in \mathfrak{S}_{1,\ldots,1,n-k}\}$ is the set of permutations consistent with the ordering of π on the k top-ranked items. It may thus be interpreted as a partial ranking of the top k items, that does not contain any information concerning the relative ranking of the bottom $n-k$ items. The set of all such partial rankings forms the quotient space $\mathfrak{S}_n/\mathfrak{S}_{1,\ldots,1,n-k}$. Figure 1 illustrates the identification of a coset as a partial ranking of the top 2 out of 4 items.

We generalize the above relationship between partial rankings and cosets through the following definition of a composition.

Definition 2 *A composition of n is a sequence $\gamma = (\gamma_1,\ldots,\gamma_r)$ of positive integers whose sum is n.*

Note that in contrast to a partition, in a composition the order of the integers matters. A composition $\gamma = (\gamma_1,\ldots,\gamma_r)$ corresponds to a partial ranking with γ_1 items in the first position, γ_2 items in the second position and so on. For such a partial ranking it is known that the first set of γ_1 items are to be ranked before the second set of γ_2 items etc., but no further information is conveyed about the orderings within each set. The partial ranking introduced earlier $\mathfrak{S}_{1,\ldots,1,n-k}\pi$ of the top k items is a special case corresponding to $\gamma = (1,\ldots,1,n-k)$.

More formally, let $N_1 = \{1,\ldots,\gamma_1\}, N_2 = \{\gamma_1+1,\ldots,\gamma_1+\gamma_2\},\cdots,N_r = \{\gamma_1+\cdots+\gamma_{r-1}+1,\ldots,n\}$. The subgroup $\mathfrak{S}_\gamma$ is defined as the set of all permutations $\pi \in \mathfrak{S}_n$ for which the following set equalities hold (the two sets on the left hand side and right hand side of the equality contain the same elements)

$$\pi(N_i) = N_i \qquad i = 1,\ldots,r.$$

In other words, the subgroup $\mathfrak{S}_\gamma$ contains permutations that only permute within each set N_i. It can be shown that the subgroup $\mathfrak{S}_\gamma$ is isomorphic to the product of subgroups $\mathfrak{S}_{\gamma_1} \times \cdots \times \mathfrak{S}_{\gamma_r}$ and is sometimes described by that product for notational purposes. A partial ranking of type γ is equivalent to a coset $\mathfrak{S}_\gamma\pi = \{\sigma\pi : \sigma \in \mathfrak{S}_\gamma\}$ and the set of such partial rankings forms the quotient space $\mathfrak{S}_n/\mathfrak{S}_\gamma$.

The vertical bar notation described above for permutations is particularly convenient for denoting partial rankings. We list items $1,\ldots,n$ separated by vertical bars, indicating that items on the left side of each vertical bar are preferred to (ranked higher than) items on the right side of the bar. On the other hand, there is no knowledge concerning the preference of items that are not separated by one or more vertical bars. For example, the partial ranking displayed in Figure 1 is denoted by $3|1|2,4$. The ordering of items not separated by a vertical line is meaningless, and for consistency we use the conventional ordering, for example, $1|2,3|4$ rather than the equivalent $1|3,2|4$.

The set of all partial rankings

$$\mathfrak{W}_n \stackrel{\text{def}}{=} \{\mathfrak{S}_\gamma \pi : \pi \in \mathfrak{S}_n, \forall \gamma\} \tag{2}$$

which includes the set of full rankings $\mathfrak{S}_n$, is a subset of all possible partial orders on $\{1,\ldots,n\}$. While the formalism of partial rankings in $\mathfrak{W}_n$ cannot realize all partial orderings, it is sufficiently powerful to include many useful and naturally occurring orderings as special cases. Furthermore, as demonstrated in later sections, it enables simplification of the otherwise overwhelming computational difficulty. Special cases of particular interest are the following partial rankings

- $\pi \in \mathfrak{S}_n$ corresponds to a permutation or a full ordering, for example, $3|2|4|1$.
- $\mathfrak{S}_{1,n-1}\pi$, for example, $3|1,2,4$, corresponds to selection of the top alternative. An example for such a ranking is a classification of x by a response variable $y \in \mathcal{Y} = \{1,\ldots,n\}$.
- $\mathfrak{S}_{1,\ldots,1,n-k}\pi$, for example, $1|3|2,4$, corresponds to full ordering of the top k items. An example for such a ranking is a ranked list of the top k webpages output by search engines in response to a query.
- $\mathfrak{S}_{k,n-k}\pi$, for example, $1,2,4|3,5$, corresponds to a more preferred and a less preferred dichotomy. Alternatively the dichotomy can be interpreted as right and wrong or relevant and irrelevant. An example for such a ranking is classification of alternatives into desirable and undesirable.
- $\mathfrak{S}_{1,\ldots,1,n-k-t,1,\ldots,1}\pi$, for example, $5|1|2,4,7|6|3|8$, corresponds to full ordering of the top k and the bottom t items. An example for such a ranking is a list of the safest and the most dangerous U.S. cities.[6]
- $\mathfrak{S}_{k,n-k-t,t}\pi$, for example, $1,5|2,4,7|3,6,8$, corresponds to a trichotomy of items. An example for such a ranking is selection of preferred and non-preferred items from a list.

Traditionally, data from each one of the special cases above was modeled using different tools and was considered fundamentally different. That problem was aggravated as different special cases were usually handled by different communities (statistics, computer science, information retrieval). As a first step towards presenting a unified framework for modeling partially ranked data, Lebanon and Lafferty (2003) demonstrated equivalence between several popular conditional models. We continue along this line and present in this paper a non-parametric framework capable of efficiently modeling a large variety of partially ranked data.

In constructing a statistical model on permutations or cosets, it is essential to relate one permutation to another. We do this using a distance function on permutations $d : \mathfrak{S}_n \times \mathfrak{S}_n \to \mathbb{R}$ that

6. List can be found at `http://www.infoplease.com/ipa/A0921299.html`.

satisfies the usual metric function properties, and in addition is invariant under right action of the symmetric group (Critchlow, 1985)

$$d(\pi,\sigma) = d(\pi\tau,\sigma\tau) \quad \forall\, \pi,\sigma,\tau \in \mathfrak{S}_n. \tag{3}$$

The invariance requirement (3) ensures that the distance does not change if the labeling of the items $\{1,\ldots,n\}$ (which is assumed to be arbitrary) is permuted.

There have been many propositions for such right-invariant distance functions, the most popular of them being Kendall's tau (Kendall, 1938)

$$d(\pi,\sigma) = \sum_{i=1}^{n-1}\sum_{l>i} I(\pi\sigma^{-1}(i) - \pi\sigma^{-1}(l)) \tag{4}$$

where $I(x) = 1$ for $x > 0$ and $I(x) = 0$ otherwise. Kendall's tau $d(\pi,\sigma)$ (4) measures the number of pairs of items for which π and σ have opposing orderings (also called disconcordant pairs). An equivalent definition for Kendall's tau is the minimum number of adjacent transpositions needed to bring π^{-1} to σ^{-1} (adjacent transposition flips a pair of items having adjacent ranks). By right invariance, $d(\pi,\sigma) = d(\pi\sigma^{-1}, e)$ which, for Kendall's tau equals the number of inversions $i(\pi\sigma^{-1})$. This is an important observation that will allow us to simplify many expressions concerning Kendall's tau using the combinatorial properties of inversions.

Kendall's tau $d(\pi,\sigma), \pi,\sigma \in \mathfrak{S}_n$ takes values between 0 for $\pi = \sigma$ and $n(n-1)/2$. It is sometimes desirable to consider the normalized Kendall's tau

$$d_n(\pi,\sigma) = \frac{2}{n(n-1)} \sum_{i=1}^{n-1}\sum_{l>i} I(\pi\sigma^{-1}(i) - \pi\sigma^{-1}(l)) \tag{5}$$

whose range is $[0,1]$ and consequentially may be compared across different values of n.

3. The Mallows Model and its Extension to Partial Rankings

The Mallows model (Mallows, 1957) is a location-scale model on permutations based on Kendall's tau distance

$$p_\kappa(\pi) = \exp\left(-c\, d(\pi,\kappa) - \log\psi(c)\right) \qquad \pi,\kappa \in \mathfrak{S}_n \quad c \in \mathbb{R}_+.$$

The normalization term $\psi(c) = \sum_{\pi\in\mathfrak{S}_n} \exp(-c\, d(\pi,\kappa))$ does not depend on the location parameter κ and has the closed form

$$\begin{aligned}\psi(c) &= \sum_{\pi\in\mathfrak{S}_n} e^{-c\, d(\pi,\kappa)} \\ &= (1+e^{-c})(1+e^{-c}+e^{-2c})\cdots(1+e^{-c}+\cdots+e^{-(n-1)c}) \\ &= \prod_{j=1}^{n} \frac{1-e^{-jc}}{1-e^{-c}}\end{aligned} \tag{6}$$

as shown by the fact that $d(\pi,\kappa) = i(\pi\kappa^{-1})$ and the following proposition.

Proposition 2 (for example, Stanley, 2000) *For $q > 0$, $\sum_{\pi\in\mathfrak{S}_n} q^{i(\pi)} = \prod_{j=1}^{n-1}\sum_{k=0}^{j} q^k$.*

Proof Due to the bijection between permutations and sets of inversions expressed in Proposition 1

$$\sum_{\pi\in\mathfrak{S}_n} q^{i(\pi)} = \sum_{a_1=0}^{n-1}\sum_{a_2=0}^{n-2}\cdots\sum_{a_n=0}^{0} q^{a_1+\ldots+a_n} = \left(\sum_{a_1=0}^{n-1} q^{a_1}\right)\left(\sum_{a_2=0}^{n-2} q^{a_2}\right)\cdots\left(\sum_{a_n=0}^{0} q^{a_n}\right)$$
$$= (1+q+\cdots+q^{n-1})\cdots(1+q+q^2)(1+q)1.$$

■

The Mallows model has been motivated on axiomatic grounds by Mallows and has been a major focus of statistical modeling on permutations. Various extensions of the Mallows model may be found in Fligner and Verducci (1986, 1988, 1993). One particular extension to partial rankings is to consider a partial ranking as censored data equivalent to the set of permutations in its related coset. In other words, we define the probability the model assigns to the partial ranking $\mathfrak{S}_\gamma\pi$ by

$$\sum_{\tau\in\mathfrak{S}_\gamma\pi} p_\kappa(\tau) = \psi^{-1}(c)\sum_{\tau\in\mathfrak{S}_\gamma\pi}\exp\left(-c\,d(\tau,\kappa)\right). \tag{7}$$

Fligner and Verducci (1986) showed that in the case of $\gamma = (1,\ldots,1,n-k)$ the summation in (7) has a simple closed form. However, the apparent absence of a closed form formula for more general partial rankings prevented the widespread use of Equation 7 for large n and encouraged more ad-hoc and heuristic models (Critchlow, 1985; Marden, 1996). Section 7 describes an efficient computational procedure for computing (7) for more general partial ranking types γ.

4. The Ranking Lattice

Partial rankings $\mathfrak{S}_\gamma\pi$ relate to each other in a natural way by expressing more general, more specific or inconsistent ordering. We define below the concepts of partially ordered sets and lattices and then relate them to partial rankings by considering the set of partial rankings $\mathfrak{W}_n$ as a lattice. Some of the definitions below are taken from Stanley (2000), where a thorough introduction to posets can be found.

Definition 3 *A partially ordered set or poset $(Q,\preceq)$, is a set Q endowed with a binary relation $\preceq$ satisfying $\forall x,y,z\in Q$ (i) reflexibility: $x\preceq x$, (ii) anti-symmetry: $x\preceq y$ and $y\preceq x\Rightarrow x=y$, and (iii) transitivity: $x\preceq y$ and $y\preceq z\Rightarrow x\preceq z$.*

We write $x\prec y$ when $x\preceq y$ and $x\neq y$. We say that y covers x when $x\prec y$ and there is no $z\in Q$ such that $x\prec z\prec y$. A finite poset is completely described by its covering relation. The planar Hasse diagram of $(Q,\preceq)$ is the graph connecting the elements of Q as nodes using edges that correspond to the covering relation. An additional requirement is that if y covers x then y is drawn higher than x. Two elements x,y are comparable if $x\preceq y$ or $y\preceq x$ and otherwise are incomparable. The set of partial rankings $\mathfrak{W}_n$ defined in (2) is naturally endowed with the partial order of ranking refinement, that is, $\pi\prec\sigma$ if π refines σ or alternatively if we can get from π to σ by dropping vertical lines (Lebanon and Lafferty, 2003). Figure 2 shows the Hasse diagram of $\mathfrak{W}_3$ and a partial Hasse diagram of $\mathfrak{W}_4$.

An interesting visualization of Kendall's tau distance $d(\pi,\sigma),\pi,\sigma\in\mathfrak{S}_n$ in terms of the Hasse diagram is that it is the minimum number of up and down moves needed to get from π to σ on the

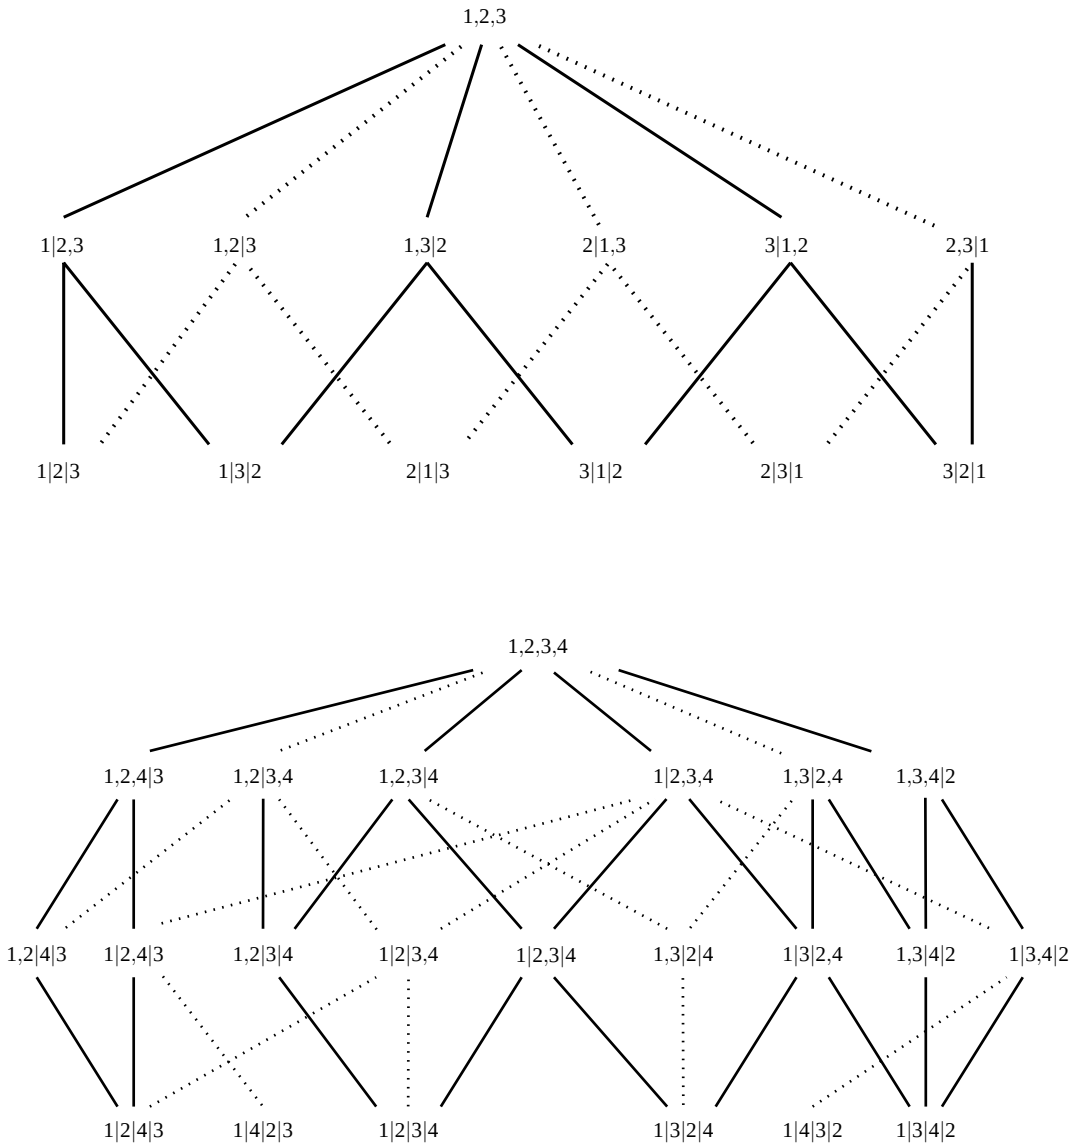

Figure 2: The Hasse diagram of $\mathfrak{W}_3$ (top) and a partial Hasse diagram of $\mathfrak{W}_4$ (bottom). Some of the lines are dotted for 3D visualization purposes (think 3D).

Hasse diagram. For example, in Figure 2 (top) we have $d(1|2|3,3|2|1) = 3$ realized by the three up-down moves along the shortest path

$$1|2|3\ (\nearrow 1,2|3 \searrow 2|1|3)\ (\nearrow 2|1,3 \searrow 2|3|1)\ (\nearrow 2,3|1 \searrow 3|2|1).$$

A lower bound z of two elements in a poset x,y satisfies $z \preceq x$ and $z \preceq y$. The greatest lower bound of x,y or infimum is a lower bound of x,y that is greater than or equal to any other lower bound of x,y. Infimum, and the analogous concept of supremum are denoted by $x \wedge y$ and $x \vee y$ or

$\bigwedge\{x_1,\ldots,x_k\}$ and $\bigvee\{x_1,\ldots,x_k\}$ respectively. Two elements $x,y \in \mathfrak{W}_n$ are said to be consistent if there exists a lower bound in $\mathfrak{W}_n$. Note that consistency is a weaker relation than comparability. For example, $1|2,3|4$ and $1,2|3,4$ are consistent but incomparable while $1|2,3|4$ and $2|1,3|4$ are both inconsistent and incomparable. Using the vertical bar notation, two elements are inconsistent iff there exist two items i,j that appear on opposing sides of a vertical bar in x and y, that is, $x = \cdots i|j \cdots$ while $y = \cdots j|i \cdots$. A poset for which $\wedge$ and $\vee$ always exist is called a lattice. Lattices satisfy many useful combinatorial properties - one of which is that they are completely described by the $\wedge$ and $\vee$ operations. In fact lattices are often defined by the supremum and infimum relation, rather than by the partial order. While the ranking poset is not a lattice, it may be turned into one by augmenting it with a minimum element $\hat{0}$.

Proposition 3 *The union $\tilde{\mathfrak{W}}_n \stackrel{\text{def}}{=} \mathfrak{W}_n \cup \{\hat{0}\}$ of the ranking poset and a minimum element is a lattice.*

Proof Since $\tilde{\mathfrak{W}}_n$ is finite, it is enough to show existence of $\wedge,\vee$ for pairs of elements (Stanley, 2000). We begin by showing existence of $x \wedge y$. If x,y are inconsistent, there is no lower bound in $\mathfrak{W}_n$ and therefore the unique lower bound $\hat{0}$ is also the infimum $x \wedge y$. If x,y are consistent, their infimum may be obtained as follows. Since x and y are consistent, we do not have a pair of items i,j appearing as $i|j$ in x and $j|i$ in y. As a result we can form a lower bound z to x,y by starting with a list of numbers and adding the vertical bars that are in either x or y, for example for $x = 3|1,2,5|4$ and $y = 3|2|1,4,5$ we have $z = 3|2|1,5|4$. The resulting $z \in \mathfrak{W}_n$, is smaller than x and y since by construction it contains all preferences (encoded by vertical bars) in x and y. It remains to show that for every other lower bound z' of x and y we have $z' \preceq z$. If z' is comparable to z, $z' \preceq z$ since removing any vertical bar from z results in an element that is not a lower bound. If z' is not comparable to z, then both z,z' contain the vertical bars in x and vertical bars in y possibly with some additional ones. By construction z contains only the essential vertical bars to make it a lower bound and hence $z' \prec z$, contradicting the assumption that z,z' are non-comparable.

By Proposition 3.3.1 of Stanley (2000) a poset for which an infimum is always defined and that has a supremum element is necessarily a lattice. Since we just proved that $\wedge$ always exists for $\tilde{\mathfrak{W}}_n$ and $1,\ldots,n = \bigvee \tilde{\mathfrak{W}}_n$, the proof is complete. ■

5. Probabilistic Models on the Ranking Lattice

The ranking lattice is a convenient framework to define and study probabilistic models on partial rankings. Given a probability model p on $\mathfrak{S}_n$, we define the functions $h,g : \tilde{\mathfrak{W}}_n \to [0,1]$

$$h(\alpha) = \begin{cases} p(\alpha) & \alpha \in \mathfrak{S}_n \\ 0 & \alpha \in \tilde{\mathfrak{W}}_n \setminus \mathfrak{S}_n \end{cases}$$
$$g(\alpha) = \sum_{\beta \in \tilde{\mathfrak{W}}_n : \beta \preceq \alpha} h(\beta). \tag{8}$$

Interpreting partial rankings $\mathfrak{S}_\gamma\pi \in \tilde{\mathfrak{W}}_n$ as the disjoint union of the events defined by the coset $\mathfrak{S}_\gamma\pi$ we have that

$$g(\mathfrak{S}_\gamma\pi) = \sum_{\tau \in \mathfrak{S}_\gamma\pi} p(\tau) \tag{9}$$

may be interpreted as the probability under p of the disjoint union $\mathfrak{S}_\gamma\pi$ of permutations. We refer to the function g as the partial ranking or lattice version of p. The motivation for defining g through h and not directly through p is that Equation (8) may be described and computed by the mechanism of Möbius inversion on lattices. More specifically, the Möbius inversion on lattices states that for two arbitrary real-valued functions on a lattice $h, g : \tilde{\mathfrak{W}}_n \to [0,1]$ we have

$$g(\tau) = \sum_{\tau' \preceq \tau} h(\tau') \quad \text{iff} \quad h(\tau) = \sum_{\tau' \preceq \tau} g(\tau')\mu(\tau', \tau) \qquad \tau, \tau \in \tilde{\mathfrak{W}}_n$$

where $\mu : \tilde{\mathfrak{W}}_n \times \tilde{\mathfrak{W}}_n \to \mathbb{R}$ is the Möbius function of the lattice $\tilde{\mathfrak{W}}_n$. In a certain sense this relationship between p and g generalizes the relationship between a probability mass function and the corresponding cdf. More details on Möbius functions and Möbius inversion on lattices and their computation may be found in Stanley (2000).

The function g is defined on the entire lattice, but when restricted to partial rankings of the same type $G = \{\mathfrak{S}_\gamma\pi : \pi \in \mathfrak{S}_n\} \subset \tilde{\mathfrak{W}}_n$, constitutes a normalized probability distribution on G. Estimating and examining a restriction of g to a subset $H \subset \tilde{\mathfrak{W}}_n$ (note that in general H may include more than one coset space G) rather than the function p is particularly convenient in cases of large n since H is often much smaller than the unwieldy $\mathfrak{S}_n$. In such cases it is tempting to specify the function g directly on H without referring to an underlying permutation model. However, doing so may lead to probabilistic contradictions such as $g(\mathfrak{S}_\gamma\pi) < g(\mathfrak{S}_\lambda\sigma)$ for $\mathfrak{S}_\lambda\sigma \subset \mathfrak{S}_\gamma\pi$. To avoid these and other probabilistic contradictions, g needs to satisfy a set of linear constraints equivalent to the existence of an underlying permutation model. Figure 3 illustrates this problem for partial rankings with the same (left) and different (right) number of vertical bars. A simple way to avoid such contradictions and satisfy the constraints is to define g indirectly in terms of a permutation model p as in (9). Applied to the context of statistical estimation, we define the estimator $\hat{g}$ in terms of an estimator $\hat{p}$ of the underlying permutation model p.

In addition to this construction which logically occurs after obtaining the estimator $\hat{p}$, we also need to consider how to use partially ranked data in the process of obtaining the estimator $\hat{p}$. Fully ranked data is often not available for large n since it is difficult for rankers (both human and others) to express with confidence full orderings over many items. Instead, the inference needs to be conducted based on a set of partial rankings

$$D = \{\mathfrak{S}_{\gamma_i}\pi_i : i = 1, \ldots, m\}. \tag{10}$$

A general way of using D in (10) to estimate $\hat{p}$ both parametrically and non-parametrically is to consider partially ranked data as censored or missing data. In other words, in the process of estimating $\hat{p}$, the data $\mathfrak{S}_\gamma\pi$ is considered as a single unknown permutation $\sigma \in \mathfrak{S}_\gamma\pi$ that is lost through a censoring process. Assuming uniformly random censoring in a parametric setting, we obtain the following observed likelihood with respect to the partially ranked data set D

$$\ell(\theta|D) = \sum_{i=1}^{m} \log \frac{1}{|\mathfrak{S}_{\gamma_i\pi_i}|} \sum_{\sigma \in \mathfrak{S}_{\gamma_i}\pi_i} p_\theta(\sigma) = \sum_{i=1}^{m} \log \sum_{\sigma \in \mathfrak{S}_{\gamma_i}\pi_i} p_\theta(\sigma) + \text{const.}$$

While the above likelihood function can be efficiently computed using tools developed in Section 7, its maximization is extremely difficult due to the discrete nature of the parametric space. In the next section we explore in detail a non-parametric kernel smoothing alternative to estimating p and g based on partially ranked data.

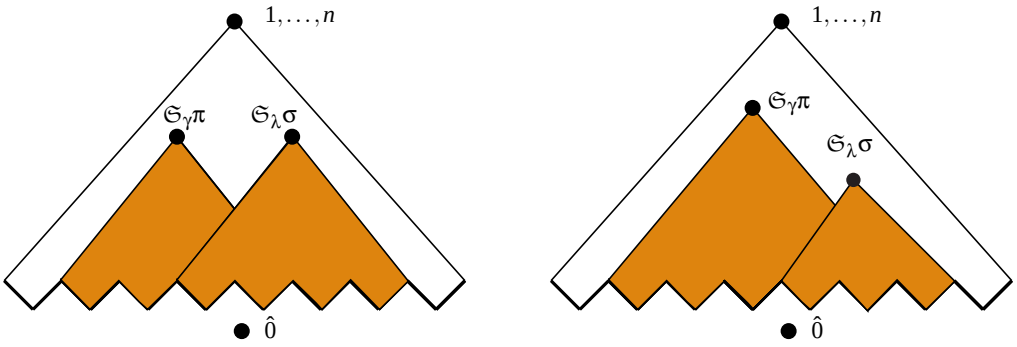

Figure 3: Two partial rankings with the same (left) and different (right) number of vertical bars in the Hasse diagram of $\tilde{\mathfrak{W}}_n$. The big triangles are schematic illustration of the Hasse diagram of $\mathfrak{W}_n$ as displayed in Figure 2 (top) with permutations occupying the bottom level illustrated by the jagged line. The shaded regions correspond to order-intervals, that is, all elements smaller or equal to the top vertices which correspond to partial rankings. To avoid probabilistic contradictions, the values of g at two non-disjoint partial rankings $\mathfrak{S}_\gamma\pi, \mathfrak{S}_\lambda\sigma$ cannot be specified in an independent manner.

6. Non-Parametric Kernel Smoothing on Partial Rankings

The Mallows model, which at first glance appears as a simple and effective analogue of the Gaussian distribution, suffers from several drawbacks. Its unimodal assumption is often too restrictive for high n as well as for low n (see experiments in Section 9). Another major drawback is that the location parameter space $\mathfrak{S}_n$ is discrete, making the maximum likelihood procedure an impossibly large discrete search problem.

The unimodality and symmetry of the Mallows model make it a good choice for use as a kernel in non-parametric smoothing. Since the normalization term ψ does not depend on the location parameter (6), the kernel smoothing estimator for p is

$$\hat{p}(\pi) = \frac{1}{m\,\psi(c)} \sum_{i=1}^{m} \exp(-c\,d(\pi,\pi_i)) \quad \pi,\pi_i \in \mathfrak{S}_n \tag{11}$$

assuming the data consists of complete rankings $\pi_1,\ldots,\pi_m \sim p$. Note that the kernel parameter c acts as an inverse scale parameter whose role is similar but inversely related to the traditional bandwidth parameter h in kernel smoothing (Wand and Jones, 1995).

In case the available data is partially ranked $D = \{\mathfrak{S}_{\gamma_i}\pi_i : i = 1,\ldots,m\}$ and obtained by uniform censoring as described in the previous section the kernel smoothing estimator becomes

$$\hat{p}(\pi) = \frac{1}{m\,\psi(c)} \sum_{i=1}^{m} \frac{1}{|\mathfrak{S}_{\gamma_i}|} \sum_{\tau\in\mathfrak{S}_{\gamma_i}\pi_i} \exp(-c\,d(\pi,\tau)) \qquad \pi \in \mathfrak{S}_n \tag{12}$$

where we used the fact that $|\mathfrak{S}_{\gamma_i}\pi_i| = |\mathfrak{S}_{\gamma_i}e| = |\mathfrak{S}_{\gamma_i}|$. The lattice or partial ranking version $\hat{g}$ corresponding to $\hat{p}$ in (12) is

$$\hat{g}(\mathfrak{S}_\lambda \pi) = \frac{1}{m\,\psi(c)} \sum_{i=1}^{m} \frac{1}{|\mathfrak{S}_{\gamma_i}|} \sum_{\kappa \in \mathfrak{S}_\lambda \pi} \sum_{\tau \in \mathfrak{S}_{\gamma_i}\pi_i} \exp(-c\,d(\kappa,\tau)) \qquad \mathfrak{S}_\gamma \pi \in \tilde{\mathfrak{W}}_n. \tag{13}$$

In the next section we derive efficient calculations and in some cases closed forms for expressions (12)-(13). These calculations are efficient even for large n as their complexities depend on the complexity of the compositions λ and $\gamma_1,\ldots,\gamma_m$ rather than on $n!$ or even n. We then move on to explore the bias and variance of $\hat{p}$ in Section 8 and describe practical applications of $\hat{p},\hat{g}$ and some experiments.

7. Efficient Computation and Inversion Combinatorics

In order to apply the estimators $\hat{p},\hat{g}$ in practice, it is crucial that the inner summations in Equations (12)-(13) be computed efficiently. We can achieve efficient computation of these summations by considering how the pairs constituting inversions $i(\tau)$ decompose with respect to certain cosets.

Proposition 4 *The following decomposition of $i(\tau)$ with respect to a composition $\gamma = (\gamma_1,\ldots,\gamma_r)$ holds*

$$i(\tau) = \sum_{k=1}^{r} a_k^\gamma(\tau) + \sum_{k=1}^{r}\sum_{l=k+1}^{r} b_{kl}^\gamma(\tau) \qquad \forall \tau \in \mathfrak{S}_n \tag{14}$$

where

$$a_k^\gamma(\tau) \stackrel{\text{def}}{=} \left| \left\{ (s,t) : s<t\,, \sum_{j=1}^{k-1}\gamma_j < \tau(t) < \tau(s) \le \sum_{j=1}^{k}\gamma_j \right\} \right|$$

$$b_{kl}^\gamma(\tau) \stackrel{\text{def}}{=} \left| \left\{ (s,t) : s<t\,, \sum_{j=1}^{k-1}\gamma_j < \tau(t) \le \sum_{j=1}^{k}\gamma_j \le \sum_{j=1}^{l-1}\gamma_j < \tau(s) \le \sum_{j=1}^{l}\gamma_j \right\} \right|.$$

Proof The set appearing in the definition of $a_k^\gamma(\tau)$ contains all pairs (s,t) that are inversions of τ and whose ranks appear in the k-compartment of the composition γ. The set appearing in the definition of $b_{kl}^\gamma(\tau)$ contains pairs (s,t) that are inversions of τ and for which s and t appear in the l and k compartments of γ respectively. Since any inversion pair appears in either one or two compartments, the above forms a partition of the inversion set. The decomposition holds since $i(\tau)$, the cardinality of the inversion set of the permutation τ, equals the summation of the cardinality of each subset in the partition. ■

Equation (14) actually represents a family of decompositions as it holds for all possible compositions γ. For example, $i(\tau) = 4$ for $\tau = 4|1|3|2$, with inversions $(1,4),(2,4),(3,4),(2,3)$ for τ. For the composition $\gamma = (2,2)$, the first compartment contains the inversion $(1,4)$ and so $a_1^\gamma(\tau) = 1$. The second compartment contains the inversion $(2,3)$ and so $a_2^\gamma(\tau) = 1$. The cross compartment inversions are $(2,4),(3,4)$ making $b_{12}^\gamma(\tau) = 2$.

The significance of (14) is that as we sum over all representatives of the coset $\tau \in \mathfrak{S}_\gamma\pi$ the cross compartmental inversions $b_{kl}^\gamma(\tau)$ remain constant while the within-compartmental inversions

$a_k^\gamma(\tau)$ vary over all possible combinations. As a result we obtain the following generalization of Proposition 2.

Proposition 5 *For $\pi \in \mathfrak{S}_n$, $q > 0$, and a composition $\gamma = (\gamma_1, \ldots, \gamma_r)$ we have*

$$\sum_{\tau \in \mathfrak{S}_\gamma \pi} q^{i(\tau)} = q^{\sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi)} \prod_{s=1}^r \prod_{j=1}^{\gamma_s - 1} \sum_{k=0}^j q^k. \tag{15}$$

Proof

$$\begin{aligned}
\sum_{\tau \in \mathfrak{S}_\gamma \pi} q^{i(\tau)} &= \sum_{\tau \in \mathfrak{S}_\gamma \pi} q^{\sum_{k=1}^r a_k^\gamma(\tau) + \sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\tau)} \\
&= q^{\sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi)} \sum_{\tau \in \mathfrak{S}_\gamma \pi} q^{\sum_{k=1}^r a_k^\gamma(\tau)} \\
&= q^{\sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi)} \prod_{s=1}^r \sum_{\tau \in \mathfrak{S}_{\gamma_s}} q^{i(\tau)} \\
&= q^{\sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi)} \prod_{s=1}^r \prod_{j=1}^{\gamma_s - 1} \sum_{k=0}^j q^k.
\end{aligned}$$

Above, we used two ideas: (i) disconcordant pairs between two different compartments of the coset $\mathfrak{S}_\gamma \pi$ are invariant under change of the coset representative, and (ii) the number of disconcordant pairs within a compartment varies over all possible choices enabling the replacement of the summation by a sum over a lower order symmetric group. ■

An important feature of (15) is that only the first and relatively simple term $q^{\sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi)}$ depends on π. The remaining terms depend only on the partial ranking type γ and thus may be pre-computed and tabulated for efficient computation.

Corollary 1

$$\sum_{\tau \in \mathfrak{S}_\gamma \pi} q^{i(\tau\kappa)} = q^{\sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi\kappa)} \prod_{s=1}^r \prod_{j=1}^{\gamma_s - 1} \sum_{k=0}^j q^k \qquad \kappa \in \mathfrak{S}_n.$$

Proof Using group theory, it can be shown that the set equality $(\mathfrak{S}_\gamma \pi)\kappa = \mathfrak{S}_\gamma(\pi\kappa)$ holds. As a result, $\sum_{\tau \in \mathfrak{S}_\gamma \pi} q^{i(\tau\kappa)} = \sum_{\tau' \in \mathfrak{S}_\gamma(\pi\kappa)} q^{i(\tau')}$. Proposition 5 completes the proof. ■

Corollary 2 *The partial ranking version g corresponding to the Mallows kernel p_κ is*

$$\begin{aligned}
p_\kappa(\mathfrak{S}_\gamma \pi) &= \frac{\prod_{s=1}^r \prod_{j=1}^{\gamma_s - 1} \sum_{k=0}^j e^{-kc}}{\prod_{j=1}^{n-1} \sum_{k=0}^j e^{-kc}} \, e^{-c \sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi\kappa^{-1})} \\
&\propto e^{-c \sum_{k=1}^r \sum_{l=k+1}^r b_{kl}^\gamma(\pi\kappa^{-1})}.
\end{aligned}$$

Proof Using Corollary 1 we have

$$\begin{aligned} g(\mathfrak{S}_\gamma\pi) &= \sum_{\tau\in\mathfrak{S}_\gamma\pi} p_\kappa(\tau) = \frac{\sum_{\tau\in\mathfrak{S}_\gamma\pi}\exp(-c\,d(\tau,\kappa))}{\sum_{\tau\in\mathfrak{S}_n}\exp(-c\,d(\tau,\kappa))} \\ &= \frac{\sum_{\tau\in\mathfrak{S}_\gamma\pi}\exp(-c\,i(\tau\kappa^{-1}))}{\prod_{j=1}^{n-1}\sum_{k=0}^{j}e^{-kc}} = \frac{\sum_{\tau\in\mathfrak{S}_\gamma\pi}(\exp(-c))^{i(\tau\kappa^{-1})}}{\prod_{j=1}^{n-1}\sum_{k=0}^{j}e^{-kc}} \\ &= e^{-c\sum_{k=1}^{r}\sum_{l=k+1}^{r}b_{kl}^{\gamma}(\pi\kappa^{-1})}\frac{\prod_{s=1}^{r}\prod_{j=1}^{\gamma_s-1}\sum_{k=0}^{j}e^{-kc}}{\prod_{j=1}^{n-1}\sum_{k=0}^{j}e^{-kc}}. \end{aligned}$$

■

Despite its daunting appearance, the expression in Corollary 2 can be computed relatively easily. The fraction does not depend on π or κ and in fact may be considered as a normalization constant that may be easily pre-computed and tabulated. The remaining term is relatively simple and depends on the location parameter κ and the coset representative π. Corollary 2 and Proposition 6 below, provide efficient computation for the estimators (12), (13).

Proposition 6

$$\sum_{\sigma\in\mathfrak{S}_\lambda\pi_1}\sum_{\tau\in\mathfrak{S}_\gamma\pi_2}e^{-c\,d(\sigma,\tau)} = \left(\sum_{\tau\in\pi_1\pi_2^{-1}\mathfrak{S}_\gamma}\prod_{k=1}^{r}\prod_{l=k+1}^{r}e^{-c\,b_{kl}^{\lambda}(\tau)}\right)\left(\prod_{s=1}^{r}\prod_{j=1}^{\lambda_s-1}\sum_{k=0}^{j}e^{-kc}\right). \tag{16}$$

Proof Using $(\mathfrak{S}_\gamma\pi)\tau = \mathfrak{S}_\gamma(\pi\tau)$, Corollary 1, and the fact that $\tau\in\mathfrak{S}_\gamma$ iff $\tau^{-1}\in\mathfrak{S}_\gamma$, we have

$$\begin{aligned} \sum_{\sigma\in\mathfrak{S}_\lambda\pi_1}\sum_{\tau\in\mathfrak{S}_\gamma\pi_2}e^{-cd(\sigma,\tau)} &= \sum_{\sigma\in\mathfrak{S}_\lambda}\sum_{\tau\in\mathfrak{S}_\gamma}e^{-cd(\sigma\pi_1,\tau\pi_2)} = \sum_{\sigma\in\mathfrak{S}_\lambda}\sum_{\tau\in\mathfrak{S}_\gamma}e^{-cd(\sigma\pi_1\pi_2^{-1}\tau^{-1},e)} \\ &= \sum_{\tau\in\mathfrak{S}_\gamma}\sum_{\sigma\in\mathfrak{S}_\lambda}e^{-c\,i(\sigma\pi_1\pi_2^{-1}\tau^{-1})} = \sum_{\tau\in\mathfrak{S}_\gamma}\sum_{\sigma\in\mathfrak{S}_\lambda}e^{-c\,i(\sigma(\pi_1\pi_2^{-1})\tau)} \\ &= \sum_{\tau\in\mathfrak{S}_\gamma}e^{-c\sum_{k=1}^{r}\sum_{l=k+1}^{r}b_{kl}^{\lambda}(\pi_1\pi_2^{-1}\tau)}\prod_{s=1}^{r}\prod_{j=1}^{\lambda_s-1}\sum_{k=0}^{j}e^{-kc}. \end{aligned}$$

■

The complexity of computing (16), (12), (13) for some popular partial ranking types appears in Table 1. The independence of these complexity terms from n enables the practical use of estimators (12), (13) in large n situations. Some of the details concerning this complexity analysis and algorithmic implementation may be found in Appendix A.

8. Statistical Properties of the Estimator

After studying the computational feasibility of the non-parametric estimator $\hat{p}$ in the previous section, we now turn to examine its statistical properties. In particular we examine its bias and variance,

$\lambda \diagdown \gamma$	$(1,n-1)$	$(1,\cdots,1,n-t)$	$(t,n-t)$
$(1,n-1)$	$O(1)$	$O(1)$	$O(1)$
$(1,\cdots,1,n-k)$	$O(k)$	$O(k+t)$	$O(k+t)$
$(k,n-k)$	$O(k)$	$O(k+t)$	$O(k+t)$

Table 1: Computational complexity for computing Equation (13) for each training example. The independence of the complexity terms from n enables the practical use of the estimators (12),(13) in $k \ll n$ situations.

show consistency for large n, and examine the statistical effect of using partially ranked or censored data in the estimation process. Due to the discreteness of the probability space we replace traditional Taylor series expansion with a bound based on the Lipschitz continuity of p. The Lipschitz continuity assumption is crucial since without such an assumption on the regularity of p, kernel based smoothing or other neighborhood operations make little sense.

Proposition 7 *Let $\pi_1,\ldots,\pi_m \in \mathfrak{S}_n$ be sampled iid from a Lipschitz continuous p, that is, $|p(\pi)-p(\tau)| \leq M\,d(\pi,\tau)$, $\forall \pi,\tau$. The following bounds with respect to $\hat{p}$ in* (11) *hold.*

$$|\mathit{bias}\,(\hat{p}(\pi))| \leq -M\frac{\psi'(c)}{\psi(c)},$$
$$\mathit{Var}\,(\hat{p}(\pi)) \leq \frac{p(\pi)}{m}\frac{\psi(2c)}{\psi^2(c)} - \frac{M}{m}\frac{\psi'(2c)}{\psi^2(c)}.$$

Proof Key properties in the following manipulations are the closed form expression of $\psi(c)$ in (6) and its independence from the location parameter of the Mallows kernel.

$$\begin{aligned}
|\mathsf{bias}\,(\hat{p}(\pi))| &= \left|\mathsf{E}_{p(\pi_1)}\left(\psi^{-1}(c)e^{-cd(\pi,\pi_1)}\right) - p(\pi)\right| \\
&\leq \psi^{-1}(c)\sum_{\pi_1\in\mathfrak{S}_n}|p(\pi_1)-p(\pi)|e^{-cd(\pi,\pi_1)} \\
&\leq \psi^{-1}(c)\sum_{\pi_1\in\mathfrak{S}_n}Md(\pi,\pi_1)e^{-cd(\pi,\pi_1)} = -M\frac{\psi'(c)}{\psi(c)}.
\end{aligned}$$

$$\begin{aligned}
\psi^2(c)\,m\,\mathsf{Var}\,(\hat{p}(\pi)) &= \mathsf{Var}_{\,p(\pi_1)}e^{-c\,d(\pi,\pi_1)} \leq \mathsf{E}_{\,p(\pi_1)}e^{-2cd(\pi,\pi_1)} \\
&= \sum_{\pi_1\in\mathfrak{S}_n}p(\pi_1)e^{-2c\,d(\pi,\pi_1)} \\
&\leq \sum_{\pi_1\in\mathfrak{S}_n}(p(\pi)+M\,d(\pi,\pi_1))e^{-2cd(\pi,\pi_1)} \\
&= p(\pi)\psi(2c) - M\psi'(2c).
\end{aligned}$$

■

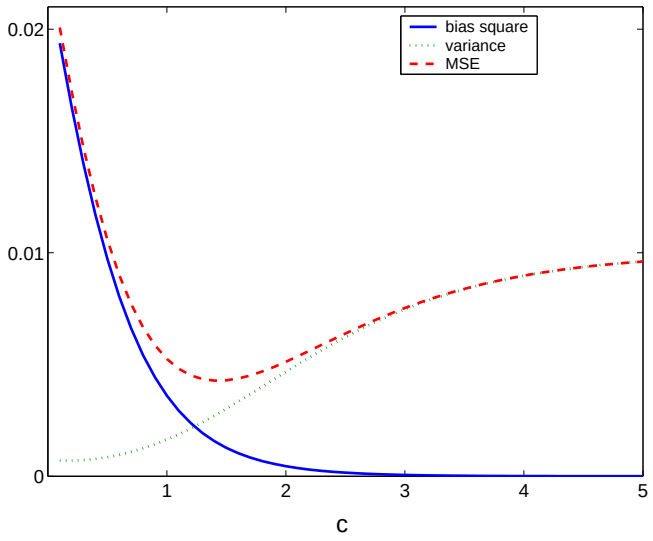

Figure 4: Upper bounds on squared bias, variance and MSE as functions of c: $M = 0.05$, $p(\pi) = 0.2$, $n = 4$, $m = 20$.

The upper bounds in Proposition 7 are illustrated as functions of c in Figure 4. These expressions may be written in a closed form using the formulas for $\psi(2c)/\psi^2(c)$ and $\psi'(c)/\psi(c)$ derived in the proof of Proposition 8 below.

Proposition 8 *Under the same conditions as Proposition 7 and assuming the asymptotics*

$$c, m, n \to \infty, \quad n = o(\exp(c)), \quad n = o(\sqrt{m})$$

the estimator $\hat{p}$ in (11) *is pointwise consistent.*

Proof We first derive closed form expressions for $\psi'(c)/\psi(c)$ and $\psi(2c)/\psi^2(c)$ and then proceed to demonstrate the convergence to 0 of the bias and variance bounds obtained in Proposition 7.

Using the result $\psi(c) = \prod_{j=1}^{n} \frac{1-e^{-jc}}{1-e^{-c}}$ shown in (6), we have

$$\frac{\psi'(c)}{\psi(c)} = (\log \psi(c))' = \sum_{j=1}^{n} \frac{j e^{-jc}}{1-e^{-jc}} - \frac{n e^{-c}}{1-e^{-c}}, \tag{17}$$

$$\begin{aligned} \frac{\psi(2c)}{\psi^2(c)} &= \prod_{j=1}^{n} \frac{1-e^{-2jc}}{1-e^{-2c}} \frac{(1-e^{-c})^2}{(1-e^{-jc})^2} = \prod_{j=1}^{n} \frac{1+e^{-jc}}{1+e^{-c}} \frac{1-e^{-jc}}{1-e^{-c}} \frac{(1-e^{-c})^2}{(1-e^{-jc})^2} \\ &= \prod_{j=1}^{n} \frac{1+e^{-jc}}{1-e^{-jc}} \frac{1-e^{-c}}{1+e^{-c}}. \end{aligned} \tag{18}$$

The term $-\psi'(c)/\psi(c)$ is the expected distance under the Mallows model

$$-\psi'(c)/\psi(c) = \sum_{\sigma \in \mathfrak{S}_n} d(\pi, \sigma) \psi^{-1}(c) \exp(-c\, d(\pi, \sigma))$$

and therefore is bounded by $\max_{\pi,\sigma} d(\pi,\sigma) \leq n^2$. The term $\psi(2c)/\psi^2(c)$ is bounded since it may be written as a product $\prod_{j=1}^{n} R_j(c)$, with $R_j(c) = \frac{1+e^{-jc}}{1-e^{-jc}} / \frac{1+e^{-c}}{1-e^{-c}} \leq 1$ for all $c \in \mathbb{R}_+$ and $j \geq 1$ since the function $\frac{1+\varepsilon}{1-\varepsilon}$ increases with $\varepsilon > 0$.

Based on Proposition 7 and Equations (17)-(18)

$$|\mathrm{bias}\,(\hat{p}(\pi))| \leq M\frac{ne^{-c}}{1-e^{-c}} - M\sum_{j=1}^{n}\frac{je^{-jc}}{1-e^{-jc}} \leq M\frac{ne^{-c}}{1-e^{-c}}$$

$$\mathrm{Var}\,(\hat{p}(\pi)) \leq \frac{p(\pi)}{m}\frac{\psi(2c)}{\psi^2(c)} - \frac{M}{m}\frac{\psi'(2c)}{\psi(2c)}\frac{\psi(2c)}{\psi^2(c)}.$$

The bias converges to 0 as $n\exp(-c) \to 0$ or alternatively, $c \to \infty, n = o(\exp(c))$. Since $\psi(2c)/\psi^2(c)$ is bounded and $-\psi'(2c)/\psi(2c) \leq n^2$ the variance converges to 0 as well if $m \to \infty$ and $n^2/m \to 0$. ■

Intuitively, the inverse scale parameter c has to go to ∞ in order for the bias to converge to 0 (similar to the requirement $h \to 0$ for the bandwidth parameter h in kernel smoothing). The number of samples m has to go to ∞ in order for the variance to go to 0. Allowing $n \to \infty$ enables us to study the behavior of $\hat{p}$ in situations containing a large number of items. The proposition above (with a slightly modified proof) also holds for fixed n.

The assumption above of Lipschitz continuity with respect to d is a very weak assumption since the distance d tends to grow as $n \to \infty$. In particular d takes values in $[0, n(n-1)/2]$ making the Lipschitz continuity assumption weaker and weaker as $n \to \infty$. A stronger assumption of Lipschitz continuity with respect to the normalized d_n (5)

$$|p(\pi) - p(\tau)| \leq M\, d_n(\pi,\tau), \quad \forall \pi,\tau$$

results in a similar conclusion to Proposition 8 asserting pointwise consistency of $\hat{p}$ under weaker asymptotic requirements.

For large n, it is often the case that partial, rather than full, rankings are available for estimating $\hat{p}$. Partially ranked data is easier for rankers to express than a lengthy list corresponding to a precise permutation. Furthermore, in many cases, rankers can make some partial ranking assertions with certainty but do not have a clear opinion on other preferences. Using the censored data interpretation of partially ranked data enables efficient use of partially ranked data of multiple types in the estimation process (12).

Statistically, expressing partially ranked data as censored data has the effect of increased smoothing and therefore it reduces the variance while increasing the bias. The following proposition quantifies this effect in terms of the bias and variance of $\hat{p}$. A consequence of this proposition which is also illustrated in Section 9 experimentally is that even if the fully ranked data is somehow available, estimating $\hat{p}$ based on the partial rankings obtained by censoring it tends to increase the estimation accuracy.

Proposition 9 *Assuming the same conditions as in Proposition 7, the bias and variance of the censored data or partial ranking estimator* (12) *for* $\gamma_1 = \ldots = \gamma_m = \gamma$ *satisfy*

$$|bias\,(\hat{p}(\pi))| \leq -M\frac{\psi'(c)}{\psi(c)} + M\frac{sp(\mathfrak{S}_\gamma)}{|\mathfrak{S}_\gamma|},$$
$$Var\,(\hat{p}(\pi)) \leq \frac{p(\pi)}{m}\frac{1}{|\mathfrak{S}_\gamma|} + \frac{M}{m}\frac{sp(\mathfrak{S}_n)}{|\mathfrak{S}_\gamma|^2} \tag{19}$$

where $sp(U) \stackrel{\text{def}}{=} \max_{x\in U}\sum_{y\in U} d(x,y)$.

The choice of using $\gamma_1 = \ldots = \gamma_m = \gamma$ above was made for simplicity. Similar results apply for more heterogenous partially ranked data.

Proof

$$\begin{aligned}
|\mathrm{bias}\,(\hat{p}(\pi))| &= \left|\psi^{-1}(c)|\mathfrak{S}_\gamma|^{-1}\mathsf{E}_{p(\pi_1)}\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} e^{-cd(\pi,\tau)} - p(\pi)\right| \\
&\stackrel{a}{\leq} \psi^{-1}(c)|\mathfrak{S}_\gamma|^{-1}\sum_{\pi_1\in\mathfrak{S}_n}\sum_{\tau\in\mathfrak{S}_\gamma\pi_1}|p(\pi_1)-p(\pi)|e^{-cd(\pi,\tau)} \\
&\leq M\psi^{-1}(c)|\mathfrak{S}_\gamma|^{-1}\sum_{\pi_1\in\mathfrak{S}_n}\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} d(\pi,\pi_1)e^{-cd(\pi,\tau)} \\
&\leq M\psi^{-1}(c)|\mathfrak{S}_\gamma|^{-1}\sum_{\pi_1\in\mathfrak{S}_n}\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} (d(\pi,\tau)+d(\tau,\pi_1))e^{-cd(\pi,\tau)} \\
&\stackrel{b}{=} -M\frac{\psi'(c)}{\psi(c)} + \frac{M}{\psi(c)|\mathfrak{S}_\gamma|}\sum_{\pi_1\in\mathfrak{S}_n}\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} d(\tau,\pi_1)e^{-cd(\pi,\tau)}
\end{aligned}$$

where *a* and *b* follow from the fact that

$$\sum_{\pi_1\in\mathfrak{S}_n}\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} e^{-cd(\pi,\tau)} = |\mathfrak{S}_\gamma|\sum_{\tau\in\mathfrak{S}_n} e^{-cd(\pi,\tau)} = |\mathfrak{S}_\gamma|\psi(c).$$

The inner summation depends on π_1 only through the coset $\mathfrak{S}_\gamma\pi_1$ it resides in. To simplify the expression, we separate the single outer summation to summations of π_1 over the distinct cosets C_j. Since the number of distinct $\mathfrak{S}_\gamma$ cosets in $\mathfrak{S}_n$ is the index $[\mathfrak{S}_n : \mathfrak{S}_\gamma] = |\mathfrak{S}_n|/|\mathfrak{S}_\gamma|$, we have

$$\begin{aligned}
|\mathrm{bias}\,(\hat{p}(\pi))| &\leq -M\frac{\psi'(c)}{\psi(c)} + \frac{M}{\psi(c)|\mathfrak{S}_\gamma|}\sum_{j=1}^{[\mathfrak{S}_n:\mathfrak{S}_\gamma]}\sum_{\tau\in C_j}\left(\sum_{\pi_1\in C_j} d(\tau,\pi_1)\right)e^{-cd(\pi,\tau)} \\
&\leq -M\frac{\psi'(c)}{\psi(c)} + \frac{M\,\mathrm{sp}(\mathfrak{S}_\gamma)}{\psi(c)|\mathfrak{S}_\gamma|}\sum_{j=1}^{[\mathfrak{S}_n:\mathfrak{S}_\gamma]}\sum_{\tau\in C_j} e^{-cd(\pi,\tau)} \\
&= -M\frac{\psi'(c)}{\psi(c)} + M\frac{\mathrm{sp}(\mathfrak{S}_\gamma)}{|\mathfrak{S}_\gamma|}
\end{aligned}$$

using the fact that the spread is the same for all cosets of the same type $\mathrm{sp}(\mathfrak{S}_\gamma\pi) = \mathrm{sp}(\mathfrak{S}_\gamma)$.

$$
\begin{aligned}
m\psi^2(c)\,|\mathfrak{S}_\gamma|^2\,\mathsf{Var}\,(\hat{p}(\pi)) &= \mathsf{Var}_{\,p(\pi_1)} \sum_{\tau\in\mathfrak{S}_\gamma\pi_1} e^{-cd(\pi,\tau)} \le \mathsf{E}_{\,p(\pi_1)} \left(\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} e^{-cd(\pi,\tau)} \right)^2 \\
&\le \sum_{\pi_1\in\mathfrak{S}_n} (p(\pi) + Md(\pi,\pi_1)) \left(\sum_{\tau\in\mathfrak{S}_\gamma\pi_1} e^{-cd(\pi,\tau)} \right)^2 \\
&= \sum_{j=1}^{[\mathfrak{S}_n:\mathfrak{S}_\gamma]} \left(\sum_{\tau\in C_j} e^{-cd(\pi,\tau)} \right)^2 \left(p(\pi)|\mathfrak{S}_\gamma| + M \sum_{\sigma\in C_j} d(\pi,\sigma) \right) \\
&\le p(\pi)|\mathfrak{S}_\gamma|\psi^2(c) + M\mathrm{sp}(\mathfrak{S}_n)\psi^2(c).
\end{aligned}
$$

In the last inequality we used the Cauchy-Schwartz inequality $\langle u,v\rangle \le \|u\|_2\|v\|_2 \le \|u\|_1\|v\|_1$ to obtain

$$
\sum_{j=1}^{[\mathfrak{S}_n:\mathfrak{S}_\gamma]} \left(\sum_{\tau\in C_j} e^{-cd(\pi,\tau)} \right)^2 \le \left(\sum_{j=1}^{[\mathfrak{S}_n:\mathfrak{S}_\gamma]} \sum_{\tau\in C_j} e^{-cd(\pi,\tau)} \right)^2 = \psi^2(c).
$$

■

Contrasting the expressions in Proposition 9 with those in Proposition 7 indicates that reverting to partial rankings tends to increase the bias but reduce the variance. Intuitively, the bias increases since we no longer have enough data, in general, to precisely estimate the permutation model p. The variance (19), on the other hand, experiences a substantial reduction as compared to the fully ranked case. Figure 5 displays the behavior of the quantities $\frac{\mathrm{sp}(\mathfrak{S}_\gamma)}{|\mathfrak{S}_\gamma|}$ and $\frac{\mathrm{sp}(\mathfrak{S}_n)}{|\mathfrak{S}_\gamma|^2}$. The first quantity $\frac{\mathrm{sp}(\mathfrak{S}_\gamma)}{|\mathfrak{S}_\gamma|}$, which bounds the bias, increases as the composition γ represents a lower degree of specificity. On the other hand, the second quantity $\frac{\mathrm{sp}(\mathfrak{S}_n)}{|\mathfrak{S}_\gamma|^2}$ which bounds the variance decreases as the composition γ represents less specificity.

The precise changes in the bias and variance that occur due to using partial rankings depend on γ, n, m, c, M. However, generally speaking, the variance reduction becomes more pronounced as n and $|\mathfrak{S}_\gamma|$ grow. Indeed, in the common case described earlier where the number of items n is large, switching to partially ranked data can dramatically improve the estimation accuracy. This observation, which is illustrated in Section 9 using experiments on real world data, becomes increasingly important as n increases. It is remarkable that this statistical motivation to use partial rather than full rankings is aligned with the data availability and ease of use as well as with the computational efficiency demonstrated in the previous section.

9. Applications and Experiments

The estimator $\hat{p}$ defined in (11), (12) and its lattice version $\hat{g}$ defined in (13) can be used in a number of data analysis tasks. We briefly outline some of these tasks below and then proceed to describe some experimental results.

Visual or computational exploration of the model probabilities $\{\hat{p}(\pi) : \pi \in \mathfrak{S}_n\}$ can be a useful exploratory data analysis tool. Such exploration can be done by visualizing the values $\{\hat{p}(\pi) : \pi \in \mathfrak{S}_n\}$ for small n using the techniques developed in Thompson (1993). For medium and large n

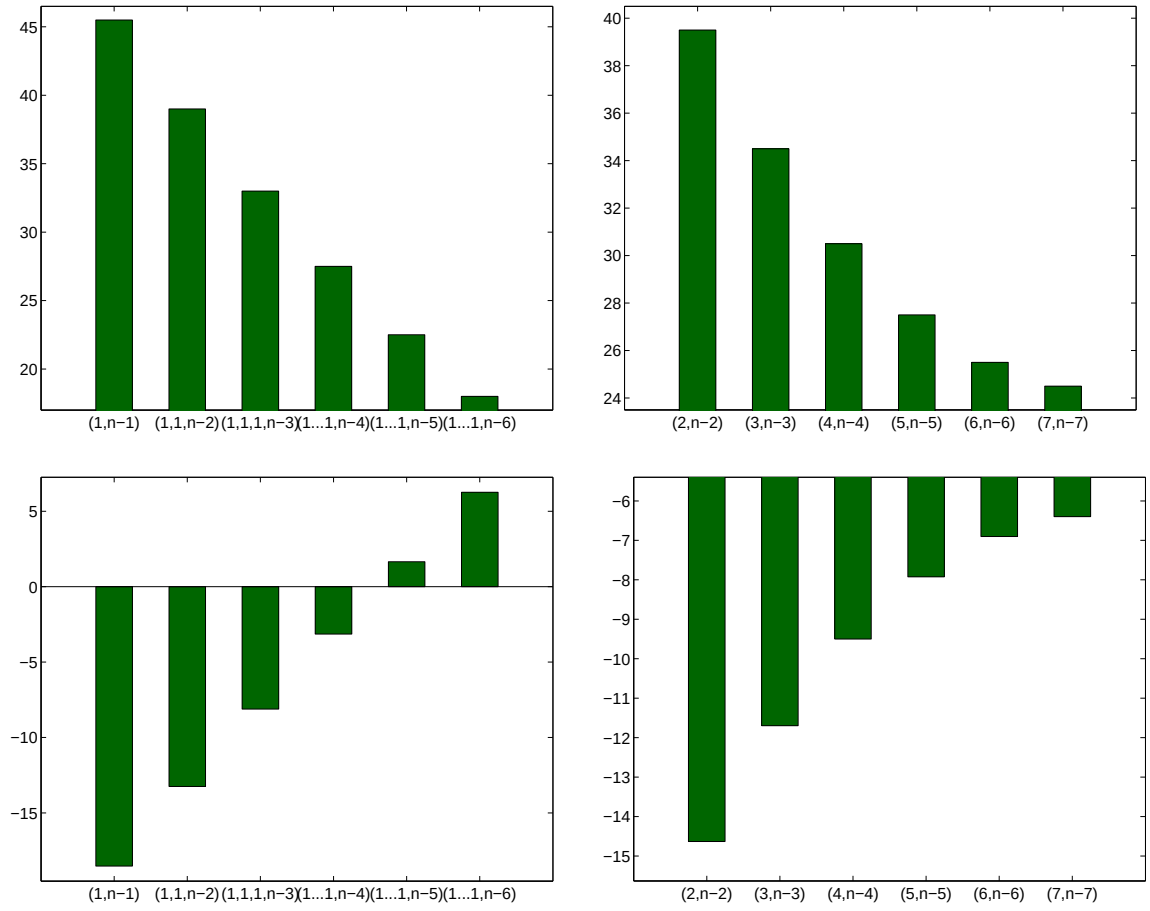

Figure 5: Values of $\frac{\mathrm{sp}(\mathfrak{S}_\gamma)}{|\mathfrak{S}_\gamma|}$(top row), and $\log \frac{\mathrm{sp}(\mathfrak{S}_n)}{|\mathfrak{S}_\gamma|^2}$ (bottom row) for $n = 15$ and various partial ranking types. Note that $\frac{\mathrm{sp}(\mathfrak{S}_\gamma)}{|\mathfrak{S}_\gamma|}$ (which serves as a bound for the bias) decreases and $\frac{\mathrm{sp}(\mathfrak{S}_n)}{|\mathfrak{S}_\gamma|^2}$ (which serves as a bound for the variance) increases for decreasing $|\mathfrak{S}_\gamma|$.

similar visualization techniques can be used to explore the values of the lattice version $\hat{g}$ restricted to certain subset $H \subset \tilde{\mathfrak{W}}_n$ of the ranking lattice. Since the number of distinct γ-cosets $|\mathfrak{S}_n|/|\mathfrak{S}_\gamma|$ may be much smaller than $|\mathfrak{S}_n|$, visualizing $\{\hat{g}(A) : A \in H\}$ can be more effective than visualizing $\{\hat{p}(\pi) : \pi \in \mathfrak{S}_n\}$. Other explorations such as identifying the local modes of $\hat{p}$ and $\hat{g}$ may be automated and computed without human intervention.

In some cases, the main objective of inference is a conditional version of $\hat{p}$ such as $\hat{p}(\pi \in A | \pi \in B)$, $A, B \subset \mathfrak{S}_n$. A popular example is collaborative filtering which is the task of recommending items to a user based on partial preference information that is output by that user (Resnick et al., 1994). In this case, $\hat{p}$ is estimated based on a large data set of partial preferences provided by many users. Given a particular partial ranking $\mathfrak{S}_\gamma\pi$ output by a certain user we can predict its most likely refinement $\arg\max_{\mathfrak{S}_\lambda\sigma} \hat{p}(\mathfrak{S}_\lambda\sigma | \mathfrak{S}_\gamma\pi)$. This task is central to many recommendation systems and

has recently gained popularity in the machine learning research community due to its commercial applications.

Statistics such as expectations and variances can be useful as summaries in situations where the entire distribution is not necessary. For example, summaries such as the expectation and variance of an item's rank $\mathsf{E}_{\hat{p}}(\pi(k))$, $\mathsf{Var}_{\hat{p}}(\pi(k))$ or probabilities such as $\hat{p}(\pi(i) > \pi(j))$ may be useful in some cases. On the other hand, in situations where $\hat{p}$ is a complex multimodal distribution, the summaries need to be complemented with a careful examination of $\hat{p}$.

We experimented with three different data sets. The first is the APA data set (Diaconis, 1989) which contains several thousand rankings of 5 APA presidential candidates. The second is the Jester data set containing rankings of 100 jokes by 73,496 users. The third data set is the EachMovie data set containing rankings of 1628 movies by 72,916 users. In our experiments, we trained models based on a randomly sampled training set and evaluated the log-likelihood on a separate held-out testing set. We repeated this procedure 10 times and report the average log-likelihood in order to reduce sampling noise.

Figure 6 displays the test set log-likelihood for the parametric Mallows model (fitted by maximum likelihood) and the non-parametric estimator. The log-likelihood, computed as a function of the train set size, is displayed for several values of c for the non-parametric estimator. In the case of the Mallows model we only display the optimal c. Due to the computational difficulty associated with maximum likelihood for the Mallows model for large n we experimented with rankings over a small number of items. The three panels of the figure display the log-likelihood with respect to the APA data with $n = 5$ (top), the Jester data restricted to the $n = 5$ most frequently rated jokes (middle), and the EachMovie data restricted to the $n = 4$ most frequently rated movies. In all three cases, the non-parametric estimator performed better than the parametric Mallows model given sufficient training examples. As c increases, the non-parametric model tends to perform better for large data sets and worse for small data sets, reflecting the non-parametric consistency as $m, c \to \infty$.

The increased flexibility of the non-parametric model illustrated in Figure 6 can be visualized further by comparing the probabilities assigned by the Mallows model and the non-parametric model. We display these probabilities in the case of $n = 4$ (movies no. 357, 1356, 440, 25 from the EachMovie data) by scaling appropriately the vertices of the permutation polytope. The vertices of the permutation polytope, displayed in Figure 7, correspond to $\mathfrak{S}_4$ and its edges correspond to pairs of permutations with Kendall's tau distance 1. In fact, Kendall's tau distance $d(\pi, \sigma)$ corresponds to the length of the shortest path connecting the two vertices representing π and σ. As a result, the 3D embedding of the permutation polytope effectively visualizes the discrete metric space $(\mathfrak{S}_4, d)$. In the figure, the radiuses of the vertices were scaled proportionally to $(\hat{p}(\pi))^{5/7}$ where $\hat{p}(\pi)$ are the probabilities estimated by maximum likelihood Mallows model (left) and the non-parametric model (right). The scaling exponent of $5/7$ was chosen in agreement with Steven's law (Cleveland, 1985) for effective visualization. Figure 7 shows that the probabilities assigned by the Mallows model form a diffuse unimodal function centered at $2|1|3|4$. The non-parametric estimator, on the other hand, discovers the true global mode $2|3|1|4$ and an additional local mode at $4|1|2|3$ both of which were undiscovered by the Mallows model due to its unimodality property.

Figure 8 demonstrates non-parametric modeling of partial rankings for $n = 100$ (the Mallows model maximum likelihood estimator cannot be computed for such n). We used 10043 rankings from the Jester data set which contain users ranking all $n = 100$ jokes. As before, the figures display the test-set log-likelihood as a function of the train set size. Due to the large n, we measured the test

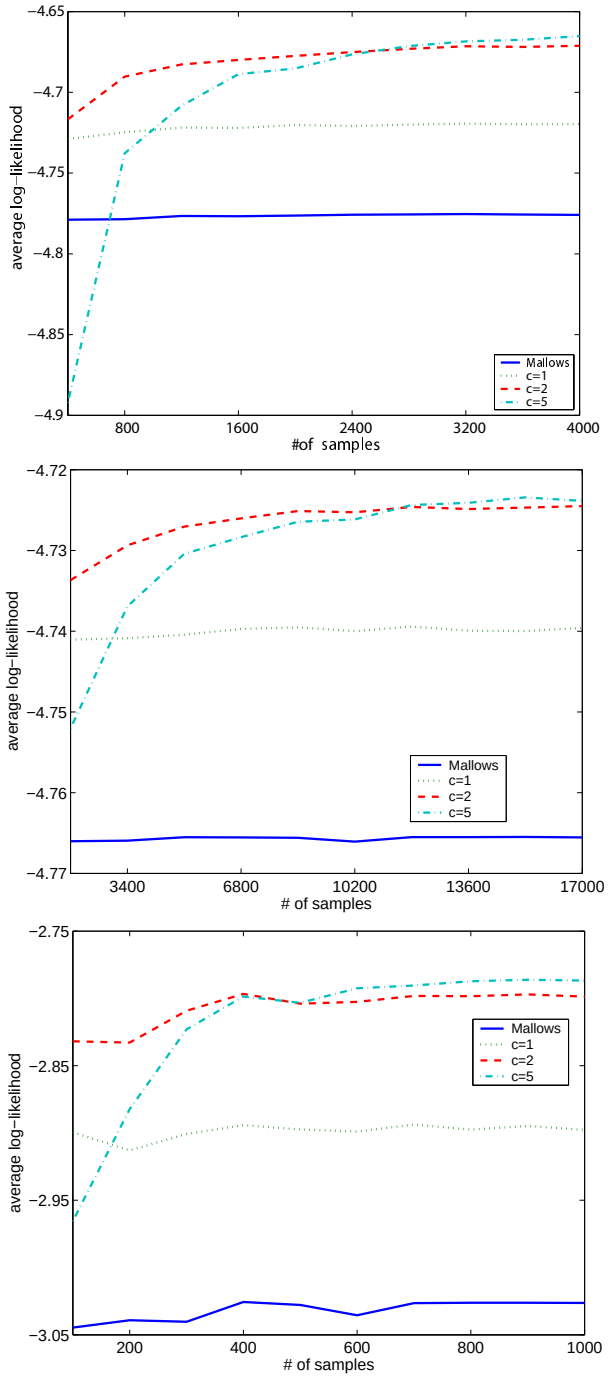

Figure 6: Average test log-likelihood as a function of the train set size: the maximum likelihood Mallows model vs. the non-parametric estimator for (a) APA data $n = 5$, (b) $n = 5$ most frequently rated Jester jokes, (c) $n = 4$ most frequently rated movies from EachMovie data. In general, the non-parametric model provides a better fit than the Mallows model. The non-parametric consistency is illustrated in the case of $c, m \to \infty$.

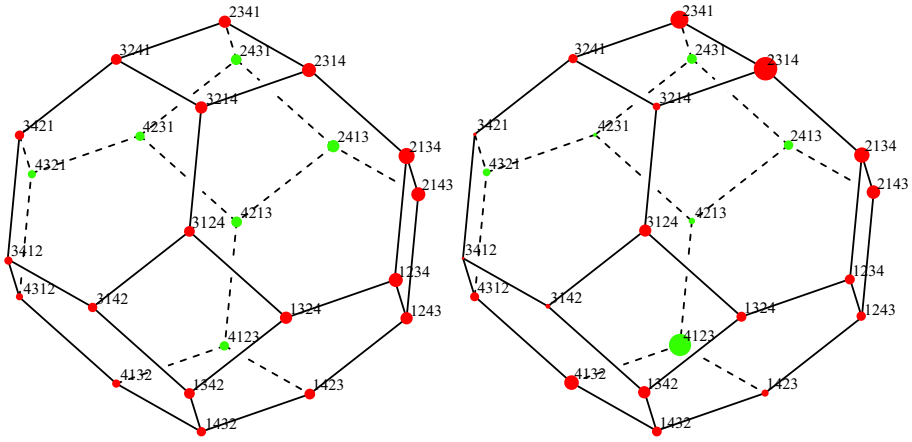

Figure 7: Visualizing estimated probabilities for EachMovie data by permutation polytopes: Mallows model (left) and non-parametric model for $c = 2$ (right). The Mallows model locates a single mode at $2|1|3|4$ while the non-parametric estimator locates the global mode at $2|3|1|4$ and a second local mode at $4|1|2|3$.

set log-likelihood with respect to the lattice version $\hat{g}(\mathfrak{S}_\gamma \pi)$ of the non-parametric estimator $\hat{p}$ for partial ranking $\gamma = (5, n-5)$ (top) and $\gamma = (1,1,1,n-3)$ (bottom).

The different lines in Figure 8 correspond to the performance of $\hat{p}$ obtained by censoring the training data in different ways. We compared $\hat{p}$ for the following censored data: full ranking (no censoring), $\gamma = (1,\ldots,1,n-k)$ for $k = 1,2,3,5$ and $\gamma = (k, n-k)$. The value of k in the censoring corresponding to $\gamma = (k, n-k)$ was chosen based on thresholding the scores output by the users. In particular, $(k(s), n-k(s))$ corresponds to k being the number of jokes receiving a score of s or higher (the users provided scores in the range $[-10, 10]$). The figure illustrates the statistical benefit of estimating $\hat{p}$ based on partial rather than full rankings. The variance reduction by $(k, n-k)$ partial rankings clearly outweighs the bias increase.

10. Discussion

As the number of items n increases, the space $\mathfrak{S}_n$ grows exponentially making discrete search methods such as maximum likelihood for the Mallows model difficult to compute. Similarly, it is typically the case for large n that both the data available for estimating $\hat{p}$ and the use of $\hat{p}$ will be restricted to partial rankings or cosets of the symmetric group.

Attempts to define a probabilistic model directly on multiple types of partial rankings $H \subset \tilde{\mathfrak{W}}_n$ face a challenging problem of preventing probabilistic contradictions. A simple solution is to define the partial ranking model $\hat{g}$ in terms of a permutation model $\hat{p}$ through the mechanism of Möbius inversion and censored data interpretation. However, doing so raises computational concerns that often severely limit the practical use of such models for large n.

In this paper, we present a non-parametric kernel smoothing technique that uses the Mallows model as a smoothing kernel on permutations. Using combinatorial properties of inversions and of the symmetric group we simplify the computational difficulties and exhibit its practical use inde-

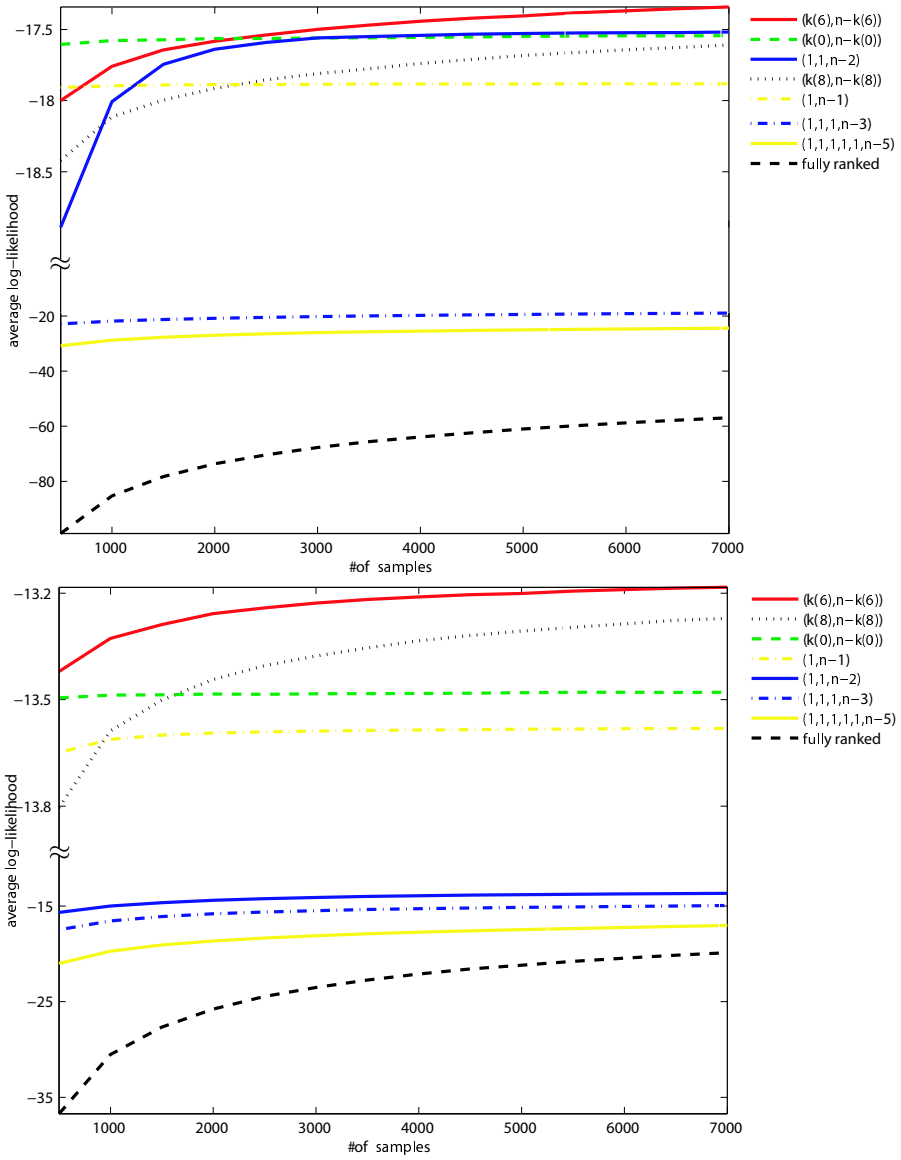

Figure 8: Test-set loglikelihood for $\hat{g}(\mathfrak{S}_\gamma\pi)$ with $\gamma=(5,n-5)$ (top) and $\gamma=(1,1,1,n-3)$ (bottom) as a function of train set size (Jester data set with $n=100$). The different lines correspond to obtaining $\hat{p}$ based on different censoring strategies of the fully ranked training data (see description in text). The legend entries are sorted in roughly the same order as the lines in the figures for increased visibility.

pendently of the number of items n. Theoretical and experimental examinations demonstrate the role of the inverse scale parameter c in the bias-variance tradeoff. We also examine the effect of using partial, rather than full, rankings on the bias and variance of the estimator. This effect plays a similar role to increased kernel smoothing and often leads to increased estimation accuracy.

Appendix A. Complexity Issues

Table 1 lists the computational complexity results for computing (13) for some popular partial ranking types γ and λ. The arguments or proofs for these expressions are rather involved and contain some details. We include in this appendix the details corresponding to the case of $\lambda = (k, n-k)$ and $\gamma = (t, n-t)$. The other cases in Table 1 follow similarly, but with some differences.

Proposition 10 *The complexity for computing*

$$\psi^{-1}(c)\,|\mathfrak{S}_\gamma|^{-1} \sum_{\sigma \in \mathfrak{S}_\lambda \pi_1} \sum_{\tau \in \mathfrak{S}_\gamma \pi_2} e^{-cd(\sigma,\tau)}$$

for $\lambda = (k, n-k)$ and $\gamma = (t, n-t)$ is $O(k+t)$.

Proof We first generalize the definition of cross compartment inversions $b^{\gamma}_{kl}(\tau)$ in Proposition 4 by defining

$$b_{XY}(\tau) = |\{(u,v) : u < v, \tau(v) \in X, \tau(u) \in Y\}|$$

where X and Y are arbitrary disjoint sets. If $X = \left\{ \sum_{j=1}^{k-1} \gamma_j + 1, \ldots, \sum_{j=1}^{k} \gamma_j \right\}$ and $Y = \left\{ \sum_{j=1}^{l-1} \gamma_j + 1, \ldots, \sum_{j=1}^{l} \gamma_j \right\}$, we have $b_{XY}(\tau) = b^{\gamma}_{kl}(\tau)$. If $x < y, \forall x \in X$ and $y \in Y$, $b_{XY}(\tau)$ counts a subset of inversion pairs of τ. However, in its most general form, $b_{XY}(\tau)$ may include non-inversion pairs if some numbers in X are greater than some numbers in Y.

We use the following definitions in our proof

$$\begin{aligned}
A &= \{1, \cdots, k\} \cap \{\pi_1 \pi_2^{-1}(1), \cdots, \pi_1 \pi_2^{-1}(t)\}, \\
\bar{A} &= \{1, \cdots, k\} \setminus A, \\
B &= \{k+1, \cdots, n\} \cap \{\pi_1 \pi_2^{-1}(1), \cdots, \pi_1 \pi_2^{-1}(t)\}, \\
\bar{B} &= \{k+1, \cdots, n\} \setminus B.
\end{aligned}$$

Note $A, \bar{A}, B, \bar{B}$ constitute a partition of $\{1, \ldots, n\}$ and satisfy

$$\begin{aligned}
A \cup \bar{A} &= \{1, \ldots, k\}, \\
B \cup \bar{B} &= \{k+1, \ldots, n\}, \\
A \cup B &= \{\pi_1 \pi_2^{-1}(1), \cdots, \pi_1 \pi_2^{-1}(t)\}, \\
\bar{A} \cup \bar{B} &= \{1, \cdots, n\} \setminus \{\pi_1 \pi_2^{-1}(1), \cdots, \pi_1 \pi_2^{-1}(t)\}.
\end{aligned}$$

Since $\lambda = (k, n-k)$, we have $b^{\lambda}_{12}(\tau) = b_{AB}(\tau) + b_{A\bar{B}}(\tau) + b_{\bar{A}B}(\tau) + b_{\bar{A}\bar{B}}(\tau)$, and the expression in the first parenthesis of Equation 16 is simplified to be

$$\begin{aligned}
\sum_{\tau\in\pi_1\pi_2^{-1}\mathfrak{S}_\gamma}\prod_{k=1}^{r}\prod_{l=k+1}^{r} e^{-cb^{\lambda}_{kl}(\tau)} &= \sum_{\tau\in\pi_1\pi_2^{-1}\mathfrak{S}_\gamma} e^{-cb^{\lambda}_{12}(\tau)} \\
&= \sum_{\tau\in\pi_1\pi_2^{-1}\mathfrak{S}_\gamma} e^{-c(b_{AB}(\tau)+b_{A\bar{B}}(\tau)+b_{\bar{A}B}(\tau)+b_{\bar{A}\bar{B}}(\tau))} \\
&= \sum_{\tau\in\pi_1\pi_2^{-1}\mathfrak{S}_\gamma} e^{-c(b_{AB}(\tau)+0+|\bar{A}||B|+b_{\bar{A}\bar{B}}(\tau))} \\
&= e^{-c|\bar{A}||B|}\sum_{\tau\in\pi_1\pi_2^{-1}\mathfrak{S}_\gamma} e^{-c(b_{AB}(\tau)+b_{\bar{A}\bar{B}}(\tau))} \\
&= e^{-c|\bar{A}||B|}\sum_{\tau\in\mathfrak{S}_t} e^{-cb^{\gamma_1}_{12}(\tau)}\sum_{\tau\in\mathfrak{S}_{n-t}} e^{-cb^{\gamma_2}_{12}(\tau)}
\end{aligned}$$

where $\gamma_1 = (|A|, t-|A|)$ and $\gamma_2 = (|\bar{A}|, n-t-|\bar{A}|)$. The last equality comes from the fact that $\forall\tau \in \pi_1\pi_2^{-1}\mathfrak{S}_\gamma$

$$\begin{aligned}
&\tau^{-1}(i) \in \{1,\ldots,t\} && \text{if} \quad i \in A\cup B, \\
&\tau^{-1}(i) \in \{t+1,\ldots,n\} && \text{if} \quad i \in \bar{A}\cup\bar{B}
\end{aligned}$$

and the choice of representatives π_1, π_2 of the cosets $\mathfrak{S}_\lambda\pi_1, \mathfrak{S}_\gamma\pi_2$ does not change $|A|, |\bar{A}|, |B|$ or $|\bar{B}|$.

By Proposition 11, we have

$$\begin{aligned}
\sum_{\tau\in\mathfrak{S}_t} e^{-cb^{\gamma_1}_{12}(\tau)} &= \frac{|A|!(t-|A|)!\prod_{j=t-|A|+1}^{t}(1-e^{-jc})}{\prod_{j=1}^{|A|}(1-e^{-jc})} \\
\sum_{\tau\in\mathfrak{S}_{n-t}} e^{-cb^{\gamma_2}_{12}(\tau)} &= \frac{|\bar{A}|!(n-t-|\bar{A}|)!\prod_{j=n-t-|\bar{A}|+1}^{n-t}(1-e^{-jc})}{\prod_{j=1}^{|\bar{A}|}(1-e^{-jc})}.
\end{aligned}$$

Substituting the above results into Equation 16, we get

$$\begin{aligned}
&\psi^{-1}(c)|\mathfrak{S}_\gamma|^{-1}\sum_{\sigma\in\mathfrak{S}_\lambda\pi_1}\sum_{\tau\in\mathfrak{S}_\gamma\pi_2} e^{-cd(\sigma,\tau)} \\
&= \frac{\left(e^{-c|\bar{A}||B|}\sum_{\tau\in\mathfrak{S}_t} e^{-cb^{\gamma_1}_{12}(\tau)}\sum_{\tau\in\mathfrak{S}_{n-t}} e^{-cb^{\gamma_2}_{12}(\tau)}\right)\left(\prod_{j=1}^{k}\frac{1-e^{-jc}}{1-e^{-c}}\prod_{j=1}^{n-k}\frac{1-e^{-jc}}{1-e^{-c}}\right)}{\left(\prod_{j=1}^{n}\frac{1-e^{-jc}}{1-e^{-c}}\right)t!(n-t)!} \\
&= \frac{\left(\frac{|A|!(t-|A|)!\prod_{j=t-|A|+1}^{t}(1-e^{-jc})}{\prod_{j=1}^{|A|}(1-e^{-jc})}\right)\left(\frac{|\bar{A}|!(n-t-|\bar{A}|)!\prod_{j=n-t-|\bar{A}|+1}^{n-t}(1-e^{-jc})}{\prod_{j=1}^{|\bar{A}|}(1-e^{-jc})}\right)e^{-c|\bar{A}||B|}\prod_{j=1}^{k}\left(1-e^{-jc}\right)}{t!(n-t)!\prod_{j=n-k+1}^{n}(1-e^{-jc})} \\
&= \frac{|A|!|\bar{A}|!(t-|A|)!e^{-c|\bar{A}||B|}}{t!\prod_{j=n-t-|\bar{A}|+1}^{n-t} j}\left(\frac{\prod_{j=t-|A|+1}^{t}(1-e^{-jc})\prod_{j=n-t-|\bar{A}|+1}^{n-t}(1-e^{-jc})\prod_{j=1}^{k}\left(1-e^{-jc}\right)}{\prod_{j=1}^{|A|}(1-e^{-jc})\prod_{j=1}^{|\bar{A}|}(1-e^{-jc})\prod_{j=n-k+1}^{n}(1-e^{-jc})}\right).
\end{aligned}$$

Note $|A| \le \min(k,t)$, $|\bar{A}| \le k$ and $|B| \le t$, therefore the above expression takes $O(k+t)$ to evaluate. Assuming π_1^{-1} and π_2^{-1} are given, it takes $O(k)$ to get a representative π_1 for the coset $\mathfrak{S}_\lambda\pi_1$, and

$O(t)$ to get the set $\{\pi_1\pi_2^{-1}(1),\cdots,\pi_1\pi_2^{-1}(t)\}$, which completes the proof. ■

Proposition 11 *For $\gamma=(k,n-k)$, let*

$$\mathbf{Q}(k,n) \stackrel{\text{def}}{=} \sum_{\pi\in\mathfrak{S}_n} q^{b_{12}^{\gamma}(\pi)} \tag{20}$$

where $b_{12}^{\gamma}(\pi)$ is defined in Proposition 4, we have

$$\mathbf{Q}(k,n) = k!(n-k)!\frac{\prod_{i=n-k+1}^{n}(1-q^i)}{\prod_{i=1}^{k}(1-q^i)} \quad \forall n\geq k. \tag{21}$$

Proof We first derive an equivalent expression for (20). For fixed π, we sort $\{\pi^{-1}(1),\pi^{-1}(2),\cdots,\pi^{-1}(k)\}$ in ascending order and denote them by $a_1<a_2<\cdots<a_k$. Note that

$$b_{12}^{\gamma}(\pi) = (a_1-1)+(a_2-2)+\cdots+(a_k-k) = \sum_{i=1}^{k}(a_i-i).$$

Due to this observation and since there are $k!(n-k)!$ different permutations for each sequence $(a_1,a_2,\cdots,a_k)$, we have

$$\begin{aligned}\mathbf{Q}(k,n) &= \sum_{\pi\in\mathfrak{S}_n} q^{b_{12}^{\gamma}(\pi)} = k!(n-k)!\sum_{a_k=k}^{n}\sum_{a_{k-1}=k-1}^{a_k-1}\cdots\sum_{a_1=1}^{a_2-1} q^{(a_1+\cdots+a_k-1-\cdots-k)}\\ &= \frac{k!(n-k)!}{q^{\frac{(1+k)k}{2}}}\sum_{a_k=k}^{n} q^{a_k}\sum_{a_{k-1}=k-1}^{a_k-1} q^{a_{k-1}}\cdots\sum_{a_1=1}^{a_2-1} q^{a_1}.\end{aligned} \tag{22}$$

We then prove (21) by mathematical induction on k using the result from (22).

(a) *Base case*: Considering (20) for the case $k=0$ we see that $b_{12}^{(0,n)}(\pi)\equiv 0$ and therefore $\mathbf{Q}(k,n)=n!$ for $n\geq k$. A similar result follows from substituting $k=0$ in the right hand side of (21).

(b) *Inductive step*: Assuming (21) holds $\forall n\geq k$ for some k, we have for $k+1$

$$\begin{aligned}\frac{\mathbf{Q}(k+1,n)}{(k+1)!(n-k-1)!} &\stackrel{a}{=} \frac{1}{q^{\frac{(2+k)(1+k)}{2}}}\sum_{a_{k+1}=k+1}^{n} q^{a_{k+1}}\sum_{a_k=k}^{a_{k+1}-1} q^{a_k}\cdots\sum_{a_1=1}^{a_2-1} q^{a_1}\\ &= \frac{1}{q^{1+k}}\sum_{a_{k+1}=k+1}^{n} q^{a_{k+1}}\left(\frac{1}{q^{\frac{(1+k)k}{2}}}\sum_{a_k=k}^{a_{k+1}-1} q^{a_k}\cdots\sum_{a_1=1}^{a_2-1} q^{a_1}\right)\\ &\stackrel{b}{=} \frac{1}{q^{1+k}}\sum_{a_{k+1}=k+1}^{n} q^{a_{k+1}}\frac{\prod_{i=a_{k+1}-k}^{a_{k+1}-1}(1-q^i)}{\prod_{i=1}^{k}(1-q^i)}\\ &\stackrel{c}{=} \frac{\prod_{i=n-k}^{n}(1-q^i)}{\prod_{i=1}^{k+1}(1-q^i)}\end{aligned}$$

where equality *a* follows from (22), equality *b* follows from the induction hypothesis, and equality *c* follows from Proposition 12.

■

Proposition 12

$$\frac{1}{q^{k+1}} \sum_{j=k+1}^{n} q^j \prod_{i=1}^{k} (1-q^{j-i}) = \frac{1}{1-q^{k+1}} \prod_{i=n-k}^{n} (1-q^i) \qquad \forall n > k.$$

Proof We prove by mathematical induction on n.

(a) *Base Case*: Carefully substituting $n = k+1$ in both the left hand side and the right hand side yields equality.

(b) *Inductive step*:

$$\begin{aligned}
\frac{1}{q^{k+1}} \sum_{j=k+1}^{n+1} q^j \prod_{i=1}^{k} (1-q^{j-i}) &= \frac{1}{q^{k+1}} \left(\sum_{j=k+1}^{n} q^j \prod_{i=1}^{k} (1-q^{j-i}) + q^{n+1} \prod_{i=n-k+1}^{n} (1-q^i) \right) \\
&= \frac{1}{1-q^{k+1}} \prod_{i=n-k}^{n} (1-q^i) + q^{n-k} \prod_{i=n-k+1}^{n} (1-q^i) \\
&= \left(\frac{1-q^{n-k}}{1-q^{k+1}} + q^{n-k} \right) \prod_{i=n-k+1}^{n} (1-q^i) \\
&= \frac{\prod_{i=n-k+1}^{n+1} (1-q^i)}{1-q^{k+1}}
\end{aligned}$$

where in the second equality we used the induction hypothesis.

Abstract

Binary matrices, and their associated submatrices of 1s, play a central role in the study of random bipartite graphs and in core data mining problems such as frequent itemset mining (FIM). Motivated by these connections, this paper addresses several statistical questions regarding submatrices of 1s in a random binary matrix with independent Bernoulli entries. We establish a three-point concentration result, and a related probability bound, for the size of the largest square submatrix of 1s in a square Bernoulli matrix, and extend these results to non-square matrices and submatrices with fixed aspect ratios. We then consider the noise sensitivity of frequent itemset mining under a simple binary additive noise model, and show that, even at small noise levels, large blocks of 1s leave behind fragments of only logarithmic size. As a result, standard FIM algorithms, which search only for submatrices of 1s, cannot directly recover such blocks when noise is present. On the positive side, we show that an error-tolerant frequent itemset criterion can recover a submatrix of 1s against a background of 0s plus noise, even when the size of the submatrix of 1s is very small.[1]

Keywords: frequent itemset mining, bipartite graph, biclique, submatrix of 1s, statistical significance

1. Introduction

In many situations, the data obtained from a standard numerical experiment can be represented by a rectangular matrix, whose columns correspond to subjects or samples, and whose rows correspond to variables or features measured for each subject. In a number of important cases, the measured features can take one of two values, and the resulting data can be represented as a binary matrix. Prominent examples include data mining tasks such as frequent pattern mining, single nucleotide polymorphism (SNP) data obtained from inbred strains having two allelic variants, and quantized versions of continuous measurements.

1. A preliminary version of some of the results described here appeared in the work "Significance and Recovery of Block Structures in Binary Matrices with Noise", X. Sun and A.B. Nobel, Proceedings of the 19th Annual Conference on Learning Theory (COLT), H.U. Simon and G. Lugosi eds., Springer, 2006.

The initial analysis of large data sets (typically involving many features and small to moderate numbers of samples) is often exploratory, reflecting the increasing use of such data for hypothesis generation, as well as more traditional hypothesis testing. In unsupervised settings, exploratory analysis seeks to identify patterns or other regularities in the observed data that may point to useful (and potentially unknown) associations between variables, samples or both.

The most common form of exploratory analysis is clustering. Clustering algorithms divide the available samples or variables into disjoint groups so that objects in the same group are, in a suitable sense, close together, while objects in different groups are far apart. A natural extension of standard clustering, usually called biclustering or subspace clustering, looks directly for associations between sets of samples and sets of variables. These associations are represented by submatrices of the data matrix.

In the case of binary matrices, the simplest submatrices of interest are constant, with all entries equal to 1. Submatrices of this sort play a key role in data mining applications, and arise naturally in the study of bipartite graphs (see the discussion below). Motivated in part by these connections, this paper considers the extremal properties of submatrices of 1s in a random binary matrix, and considers the recovery of such submatrices in the presence of noise. More specifically, our analyses are based on a model in which the entries of the principal matrix, and the noise, respectively, are independent Bernoulli(p) random variables. We provide significance bounds for the size of submatrices of 1s under the Bernoulli null hypothesis, and use these to establish limits on the performance of standard data mining methods in the presence of Bernoulli noise. In the same context, we establish several results on the precise asymptotic size of maximal submatrices of 1s, extending to the setting of bipartite graphs earlier work of Bollobás and Erdős (1976) and Matula (1976) on the size of maximal cliques in random graphs. Lastly, we establish finite sample and asymptotic results concerning the recovery of all-1s submatrices in the presence of noise.

1.1 Overview

Connections between binary matrices, frequent itemset mining, and bipartite graphs are discussed in the next section. Section 3 is devoted to the size of the largest square submatrix of 1s in a random binary matrix. Extensions to non-square matrices are described in Section 4. Section 5 contains a short simulation study that supports our theoretical bounds in a non-asymptotic setting. Section 6 is devoted to the noise sensitivity of frequent itemset mining and the recoverability of block structures in the presence of noise.

2. Motivation and Background

An $m \times n$ binary matrix is an indexed family $X = \{x_{i,j} : i \in [m], j \in [n]\}$ where $x_{i,j} \in \{0,1\}$ and $[k]$ denotes the set $\{1,\ldots,k\}$. A submatrix of X is a sub-family $U = \{x_{i,j} : i \in A, j \in B\}$ where $A \subseteq [m]$ and $B \subseteq [n]$; the Cartesian product $C = A \times B$ will be called the index set of U, and we will write $U = X[C]$. When no ambiguity will arise, the index set C itself will be referred to as a submatrix of X.

2.1 Frequent Itemset Mining

Frequent itemset mining (FIM) (Agrawal et al., 1993, 1996), also known as market basket analysis, is a central problem in the field of Data Mining. Generalizations such as bi-clustering and

subspace clustering (Agrawal et al., 1998; Cheng and Church, 2000; Tanay et al., 2002) remain active areas of research. A discussion of FIM and related methods can be found in Hand et al. (2001), Goethals (2003), Madeira and Oliveira (2004) and Tanay et al. (2005).

In the frequent itemset problem, the available data is described by a list $S = \{s_1, \ldots, s_n\}$ of items and a set $T = \{t_1, \ldots, t_m\}$ of transactions. Each transaction t_i consists of a subset of the items in S. If S contains the items available for purchase at a store, then t_i represents a record of the items purchased during the ith transaction, without multiplicity. The goal of FIM is to identify every (maximal) set of items that appear together in more than k transactions, where $k \geq 1$ is a threshold that quantifies "frequent". The data for the FIM problem can readily be represented by an $m \times n$ binary matrix X, with entry $x_{i,j} = 1$ if transaction t_i contains item s_j, and $x_{i,j} = 0$ otherwise. In this form the FIM problem can be stated as follows: given X and $k \geq 1$, find every submatrix of 1s in X having at least k rows, and report the associated set of columns. If the threshold k is allowed to vary, then FIM algorithms essentially seek to find every maximal submatrix of 1s in the data matrix X.

The ongoing application of FIM to large data sets for the purposes of exploratory and related analyses raises a number of natural statistical questions, which we address below in the general setting of random binary matrices. One natural question is how to assign a nominal significance value to the discovery of a moderately sized submatrix of 1s in a large data matrix, accounting for the obvious issue of multiple comparisons arising in this case. Another question is how standard FIM methods perform in the presence of noise, a common feature of many high-throughput measurement technologies. The third question is how one can recover a submatrix of 1s embedded in a larger matrix of 0s when noise is present.

2.2 Bipartite Graphs

Binary matrices are in one to one correspondence with bipartite graphs. An $m \times n$ binary matrix X can be viewed as the adjacency matrix of a graph $G = (V, E)$, where the vertex set V of G is the disjoint union of two sets V_1 and V_2, with $|V_1| = m$ and $|V_2| = n$, corresponding to the rows and columns of X, respectively. There is an edge $(i, j) \in E$ between vertices $i \in V_1$ and $j \in V_2$ if and only if $x_{i,j} = 1$; there are no edges between vertices in V_1 or vertices in V_2. A submatrix U of X with index set $C = A \times B$ corresponds to the subgraph G' of G induced by the vertex set $A \cup B$. If every entry of U is equal to one, then there is an edge (i, j) between every pair of vertices $i \in A$ and $j \in B$, and G' is then a complete bipartite subgraph of G. Thus maximal submatrices of 1s in X correspond to bicliques in G. This connection is the basis for the biclustering algorithm of Tanay et al. (2002).

It is known (cf., Garey and Johnson, 1979; Hochbaum, 1998; Peeters, 2003) that the problem of finding a biclique with the largest number of edges in a given bipartite graph G is NP-complete, and thus the same is true of the general frequent itemset problem with no restriction on the threshold k. Several approximate methods (Hochbaum, 1998; Dawande et al., 2001; Mishra et al., 2004) have been proposed for finding large bicliques in bipartite graphs in polynomial time. Mishra et al. (2004) show that the results provided by their randomized algorithm overlap a large fraction of the largest bicliques with high probability.

Our interest here is in assessing the significance and extremal size of maximal bicliques in random bipartite graphs. We do not address the question of how to search for such bicliques, and refer the interested reader to the papers above and the references therein for more details.

3. Largest Submatrices of 1s: Square Case

In this section we study the size of the largest square submatrix of 1s in a square binary matrix whose entries are independent Bernoulli(p) random variables. Non-square matrices and submatrices are considered in Section 4.

Definition: Let $Z = \{z_{i,j} : i, j \geq 1\}$ be an infinite array of independent binary random variables with $P(z_{i,j} = 1) = p = 1 - P(z_{i,j} = 0)$, where the probability $p \in (0,1)$ is fixed. For $n \geq 1$, let $Z_n = \{z_{i,j} : 1 \leq i, j \leq n\}$.

Thus Z_n is an $n \times n$ binary random matrix comprising the "upper left corner" of the collection $\{z_{i,j}\}$. This definition allows us to make almost-sure type statements concerning the asymptotic behavior of functions of Z_n.

Definition: Given a binary matrix X, let $M(X)$ be the largest k such that there exists a $k \times k$ submatrix of 1s in X. Note that $M(X)$ is invariant under row and column permutations of X.

From a statistical point of view, the random matrix Z_n follows a simple null model under which the observed binary data matrix has no special structure, and $M(\cdot)$ acts as a natural test statistic with which to detect departures from the null. Our analysis begins with a bound on the probability that $M(Z_n)$ exceeds a fixed integer $k \geq 1$. We follow a standard first moment argument (cf., Alon and Spencer, 1991).

Fix n for the moment, and for each $1 \leq k \leq n$ let U_k be the number of $k \times k$ submatrices of ones in Z_n. Then, letting $S = \{C = A \times B : A, B \subseteq [n], |A| = |B| = k\}$, we may write

$$U_k \;=\; \sum_{C \in S} I\{\text{all entries of } Z_n[C] \text{ are } 1\}$$

from which it follows that

$$EU_k \;=\; |S| \cdot P(\text{all entries of } Z_n[C] \text{ are } 1) \;=\; \binom{n}{k}^2 p^{k^2}.$$

By Markov's inequality and the previous display,

$$P\,(M(Z_n) \geq k) \;=\; P(U_k \geq 1) \;\leq\; EU_k \;=\; \binom{n}{k}^2 p^{k^2}. \tag{1}$$

We wish to identify an integer k_n for which EU_{k_n} is approximately equal to one. For values $k > k_n$ the rightmost expression in (1) provides an effective means for bounding the probability on the left. Note that $EU_n = p^{n^2} < 1$, and $EU_1 = n^2 p > 1$ when n is sufficiently large. Moreover, it is clear from the definition that $U_{k+1} \leq U_k$, so that EU_k is non-increasing in k. Using the Stirling approximation of the rightmost expression in (1), define

$$\phi_n(s) \;=\; (2\pi)^{-\frac{1}{2}}\, n^{n+\frac{1}{2}}\, s^{-s-\frac{1}{2}}\, (n-s)^{-(n-s)-\frac{1}{2}}\, p^{\frac{s^2}{2}}, \qquad s \in (0,n).$$

The quantity $\phi_n(k)$ is an approximation of $(EU_k)^{1/2}$: the ratio $\phi_n(k)/(EU_k)^{1/2}$ is bounded away from zero and infinity, independent of n, k, and tends to one if k and $n-k$ tend to infinity with n. Let $s(n)$ be any positive real root of the equation

$$1 = \phi_n(s). \tag{2}$$

The next lemma shows that $s(n)$ is unique and grows as logarithmically with n.

Lemma 1. *When n is sufficiently large, the Equation (2) has a unique root $s(n)$ satisfying $\log_b n < s(n) < 2\log_b n$, where $b = p^{-1}$.*

Using the bounds of Lemma 1 and some technical but straightforward calculations, one may obtain a simple asymptotic expression for $s(n)$.

Lemma 2. *The root $s(n)$ defined by (2) has the form*

$$s(n) \;=\; 2\log_b n - 2\log_b \log_b n + C + o(1)$$

where $b = p^{-1}$ and $C = 2\log_b e - 2\log_b 2$.

The proofs of Lemmas 1 and 2 can be found in Section 7.1. Let $k(n) = \lceil s(n) \rceil$ be the least integer greater than or equal to $s(n)$. The next proposition provides an upper bound on $P(M(Z_n) \geq k)$ for $k > k(n)$. Its proof appears in Section 7.2.

Proposition 1. *For each $\varepsilon > 0$, when n is sufficiently large, $P\left(M(Z_n) \geq k(n) + r\right) \leq n^{-2r} \left(\log_b n\right)^{2r+\varepsilon}$.*

One may obtain a cruder bound, on the probability that $M(Z_n)$ is at least $2\log_b n + r$, in a simpler fashion by noting that

$$EU_k = \binom{n}{k}^2 p^{k^2} \leq \frac{n^{2k}}{k!^2} e^{-k^2 \log b} \leq \frac{e^{2k\ln n - k^2 \ln b}}{k^2} \leq n^{-2r}$$

when $k \geq 2\log_b n + r$. Both the upper bound of Proposition 1 and the definition of $s(n)$ are based on the inequality (1), which follows from a simple union bound on the probability that $M(Z_n)$ is at least k. The union bound is typically quite loose, but it is sufficiently strong in this context to ensure that, for large n, the random variable $M(Z_n)$ is close to the threshold $s(n)$. Indeed, it follows from Proposition 1 and the first Borel Cantelli Lemma that, with probability one, $M(Z_n)$ is eventually less than $s(n) + 1$. Using a more involved second moment argument, one can establish a corresponding lower bound on $M(Z_n)$. Together these bounds yield the following result.

Theorem 1. *Given any $\varepsilon > 0$, with probability one, $s(n) - 1 - \varepsilon < M(Z_n) < s(n) + \varepsilon$ when n is sufficiently large.*

It follows from Theorem 1 that for large n the size of the largest square submatrix of 1s in Z_n can take one of at most two integer values in an interval of width $1 + 2\varepsilon$ containing the number $s(n)$. Indeed, it is shown in the proof of Theorem 1 that there is a sequence of integers $\{r(n)\}$ close to $\{s(n)\}$ such that, with probability one, when n is sufficiently large $M(Z_n) \in \{r_n - 1, r(n)\}$. Thus $M(Z_n)$ exhibits two-point concentration and does not possess a limiting continuous distribution.

The proof of Theorem 1 is given in Section 8. The outline of the proof follows arguments of Bollobás and Erdős (1976), who studied the size of the largest clique $cl(G_n)$ in a random graph G_n with n vertices, where each edge is included independently with probability p. They showed that for a deterministic function $c(n)$, equal to $s(n)$ up to the constant and lower order terms, eventually almost surely $|cl(G_n) - c(n)| < 3/2$. Matula (1976) independently established a similar result. See these references or Bollobás (2001) for more details. Theorem 1 extends these results to balanced

bicliques in balanced bipartite random graphs. (Unbalanced bipartite graphs are considered in the next section.)

Dawande et al. (2001) used first and second moment arguments to show (in our terminology) that $P(\log_b n \leq M(Z_n) \leq 2\log_b n) \to 1$ as n tends to infinity. Improving these results, Park and Szpankowski (2005) showed that $P((1+\varepsilon)\log_b n \leq M(Z_n) \leq (2-\varepsilon)\log_b n)$ tends to 1 as n tends to infinity for any fixed $0 < \varepsilon < 1$. Koyutürk et al. (2004) studied the problem of finding dense patterns in binary data matrices. They used a Chernoff type bound for the binomial distribution to assess whether an individual submatrix has an enriched fraction of ones, and employed the resulting test as the basis for a heuristic search for significant bi-clusters. However, the effects of multiple testing are not considered in their assessments of significance. Tanay et al. (2002) assessed the significance of bi-clusters in a real-valued matrix using likelihood-based weights, a normal approximation and a standard Bonferroni correction to account for the multiplicity of submatrices. Use of the normal approximation for individual submatrices leads to subtoptimal bounds in non-Gaussian settings.

3.1 Smallest Maximal Submatrix of 1s

Square submatrices of 1s will occur by chance in a random binary matrix. The largest such submatrix has approximately $2\log_b n - 2\log_b \log_b n$ rows. Conversely, one may ask about the size of the *smallest* maximal square submatrix of 1s. (A square submatrix of 1s is maximal if there is no larger square submatrix of 1s that properly contains it.)

Definition: Let $L(Z_n)$ be the smallest k such that there exists at least one $k \times k$ maximal submatrix of 1's in Z_n.

Theorem 1 implies that $L(Z_n) \leq 2\log_b n$. An analysis based on second moment arguments similar to those used in the proof of Theorem 1 yields the following, tighter bound. The proof can be found in Sun (2007).

Theorem 2. *With probability one,*

$$\lim_{n\to\infty} \frac{L(Z_n)}{\log_b n} = 1.$$

Bollobás and Erdős (1976) establish a related result on the size of the smallest clique in a random graph. However their proof can not be directly extended to obtain the theorem above. Indeed, an extension of their argument provides a lower bound on the size of the smallest square submatrix of 1s that is not properly contained within a rectangular submatrix of 1s, and the resulting bound is necessarily larger than the one in Theorem 2.

4. Non-Square Matrices

In this section we consider the case where the primary matrix and the target submatrices of 1s may be rectangular, but maintain fixed row/column aspect ratios as the size of the primary matrix grows. Natural analogs of Proposition 1 and Theorem 1 are obtained in this setting. For $m, n \geq 1$ define the random matrix $Z(m,n) = \{z_{i,j} : i \in [m], j \in [n]\}$.

Definition: Let $\alpha > 0$ and $\beta > 0$ be aspect ratios for the primary matrix and target submatrices, respectively. Define $M_n(Z : \alpha, \beta)$ to be the largest k such that $Z(\lceil \alpha n \rceil, n)$ contains a $\lceil \beta k \rceil \times k$ submatrix of 1s.

The asymptotic behavior of $M_n(Z:\alpha,\beta)$ is the same as that of $M_n(Z:\alpha^{-1},\beta^{-1})$, so we assume in what follows that $\beta \geq 1$. The analysis of $M_n(Z:\alpha,\beta)$ proceeds along the same lines as that of $M(Z_n)$. Investigating the value of k for which the expected number of $\lceil \beta k \rceil \times k$ submatrices of 1s in $Z(\lceil \alpha n \rceil, n)$ is equal to 1, we arrive at the function

$$s(n,\alpha,\beta) \;=\; \frac{1+\beta}{\beta}\log_b n - \frac{1+\beta}{\beta}\log_b\left(\frac{1+\beta}{\beta}\log_b n\right) + \log_b \alpha + C(\beta) + o(1),$$

where $b = p^{-1}$ and $C(\beta) = \beta^{-1}((1+\beta)\log_b e - \beta \log_b \beta)$ depends only on β.

Note that the aspect ratio α of the primary matrix appears only in the constant term of $s(n,\alpha,\beta)$, and therefore plays only a minor role in what follows. The proofs of Proposition 2 and Theorem 3 below are similar to their analogs in the square case, with additional notation and work required to handle the two aspect ratios, and are omitted. Detailed arguments can be found in Sun (2007).

Proposition 2. *Fix aspect ratios $\alpha > 0$, $\beta \geq 1$. For every $\varepsilon > 0$, when n is sufficiently large* $P(M_n(Z:\alpha,\beta) \geq \lceil s(n,\alpha,\beta) \rceil + r) \;\leq\; n^{-(\beta+1)r}(\log_b n)^{(\beta+1+\varepsilon)r}$.

Remark: When the aspect ratio α of the primary matrix is fixed, it does not play an essential role in the asymptotic behavior of $M_n(Z:\alpha,\beta)$, which is dominated by higher order factors involving only the aspect ratio β of the target submatrices. It is natural then to consider a situation in which the aspect ratio α of the primary matrix can increase with n. This might model, for example, the scaling and cost structure of a given high-throughput technology over time. In the case where $\alpha(n) = n^{\gamma}$ for some $\gamma > 0$, the proof of Proposition 2 can be modified to show that

$$P\left(M_n(Z:n^{\gamma},\beta) \geq \left(\gamma + \frac{\beta+1}{\beta}\right)\log_b n\right) \leq n^{-(\beta+1)r}(\log_b n)^{(\beta+1+\varepsilon)r}.$$

On the other hand, one can readily show that if $\beta \geq 1$ is fixed and m grows exponentially with n, then $Z(m,n)$ will contain a $\lceil \beta n \rceil \times n$ submatrix of 1's with probability bounded away from zero. For fixed aspect ratios α and β one may obtain an asymptotic concentration result for $M_n(Z:\alpha,\beta)$ analogous to Theorem 1.

Theorem 3. *For fixed $\alpha > 0$ and $\beta \geq 1$, with probability one $|M_n(Z:\alpha,\beta) - s(n,\alpha,\beta)| \leq \frac{5}{2}$ when n is sufficiently large.*

Theorem 3 implies that $Z(\alpha n, n)$ contains a submatrix of 1s having aspect ratio β and area $(\beta+1)\log_b^2 n$, the latter increasing with β. Park and Szpankowski (2005) establish a related result, showing that if we do not restrict β, the aspect ratio of the submatrices, then with high probability the submatrix of 1s in $Z(m,n)$ with the largest area is of size $O(n) \times \ln b$ or $\ln b \times O(n)$.

5. Simulation Study

The results of the previous sections hold when n is sufficiently large. In order to assess their validity for moderate values of n, we carried out a simple simulation study. For $n = 40$ and $n = 80$ we generated 400 $n \times n$ random binary matrices with $p = .2$, $p = .3$ and $p = .35$ respectively. Then we applied the FP-growth algorithm (Han et al., 2000) to identify all maximal submatrices of ones. For each maximal submatrix of ones we recorded the length of its shorter side, and let $\hat{M}$ be the maximum among these lengths. Thus $\hat{M}$ is the side length of the largest square submatrix of 1's in

p	n	$s(n)$	k	Proportion of $\hat{M}=k$
0.2	40	3.55	3	85.75%
			4	14.25%
	80	4.58	4	97%
			5	3%
0.3	40	4.78	4	50.5%
			5	49.5%
	80	5.64	5	85%
			6	15%
0.35	40	5.22	4	63.75%
			5	36%
			6	0.25%
	80	6.21	5	7.75%
			6	90.75%
			7	1.50%

Table 1: Distribution of observed $\hat{M}(Z_n)$ based on simulation

the generated random matrix. We recorded the values of $\hat{M}$ over all simulations and compared these values to the corresponding bounds. Table 1 summarizes the results. Note that in each simulation $-1.5 < \hat{M} - s(n) < 1$.

In order to check the theoretical bounds on $M_n(Z:1,\beta)$ with $\beta \geq 1$, we considered the 400 random 80×80 matrices with p=0.3 used to evaluate the result for square submatrices above. For each such matrix, we identified all maximal rectangular submatrices of 1s, and recorded the length of both their longer and shorter sides. For each $\beta \geq 1$ we defined $\hat{M}(\beta)$ to be the largest k such that at least one $\lceil \beta k \rceil \times k$ or $k \times \lceil \beta k \rceil$ submatrix of 1's was observed. The difference between $\hat{M}(\beta)$ and $s(80,1,\beta)$ was calculated and is displayed in Figure 1. The x-axes in both panels are equal to $1/\beta$. The y-axis in the left panel is the difference between $\hat{M}(\beta)$ and $s(80,1,\beta)$, and the y-axis in the right panel is the proportion of simulations which are inconsistent with the theoretical predictions of Theorem 3. Note that even for the moderate matrix size $n = 80$, the theoretical predictions are very accurate when the aspect ratio β is less than 2.5. In these cases, all the observed size lengths are within the range of predicted values.

6. Fragmentation and Recovery in the Presence of Noise

In this section we shift our attention from submatrices of 1s in Z_n to a setting in which Z_n plays the role of binary noise. Formally, we study the additive model

$$Y_n \;=\; X_n \oplus Z_n, \tag{3}$$

where each matrix is of dimension $n \times n$. The operation $\oplus$ is the standard exclusive-or: $0 \oplus 0 = 1 \oplus 1 = 0$ and $0 \oplus 1 = 1 \oplus 0 = 1$. The matrix $X_n = \{x_{i,j}\}$ is a non-random binary matrix that contains the "true" values of interest, in the absence of noise, and Z_n is a random binary matrix that acts as noise, with intensity $p \in (0,1)$. The matrix $Y_n = \{y_{i,j} = x_{i,j} \oplus z_{i,j}\}$ represents the observed binary

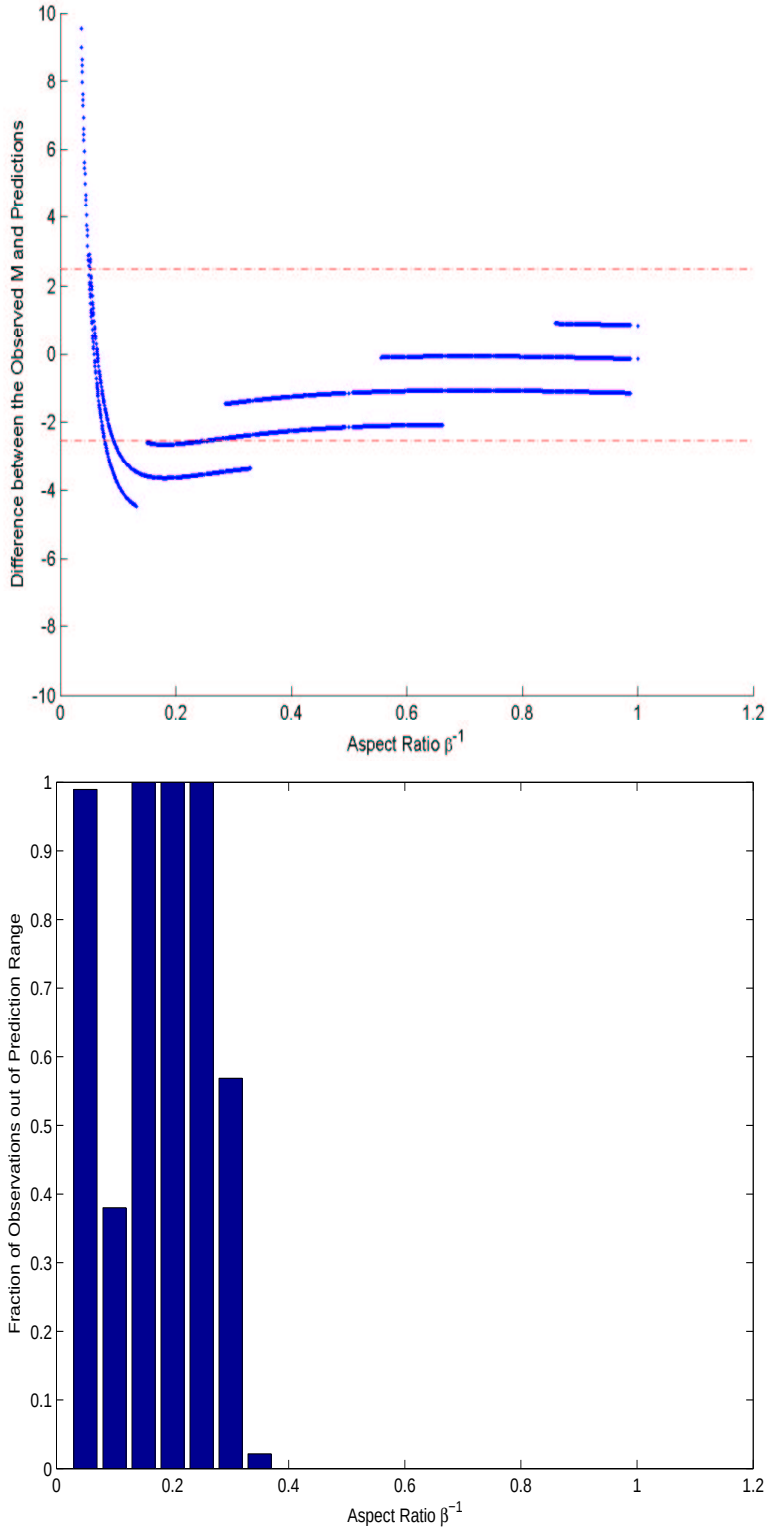

Figure 1: Difference between observed $\hat{M}(\beta)$ and its predicted value from theory.

data. Thus the effect of the noise is to randomly flip some of the values of X in Y. The model (3) is the binary version of the standard additive noise model common in statistical inference.

6.1 Noise Sensitivity

Much of the data to which data mining methods are applied is obtained by high-throughput technologies or the automated collection of information from diverse sources with varying levels of reliability. The resulting data sets are often subject to moderate levels of error and noise. Noise can also arise when binary data are obtained by thresholding continuous data, as is sometimes done in microarray analyses. Whatever its source, noise can potentially have serious consequences for frequent itemset methods if they are applied in a direct way to identify submatrices of 1s.

Indeed, this conclusion is already apparent from Theorem 1. If each entry of the target matrix X_n is zero, then $Y_n = Z_n$ and the largest $k \times k$ submatrix of ones in Y_n has $k \approx 2\log_b n$ with $b = p^{-1}$. At the other extreme, if every entry of X_n is equal to one, then the entries of Y_n are independent Bernoulli$(1-p)$ random variables, and in this case the largest square submatrix of ones in Y has side-length $k \approx 2\log_{b'} n$ with $b' = (1-p)^{-1}$. The next result extends this reasoning to any underlying target matrix X_n.

Proposition 3. *Fix $0 < p < 1/2$. Let $\{X_n\}$ be any sequence of $n \times n$ square binary matrices, and let $Y_n = X_n \oplus Z_n$. For each $\varepsilon > 0$, eventually almost surely $(2-\varepsilon)\log_b n < M(Y_n) \leq 2\log_{b'} n$, where $b = p^{-1}$ and $b' = (1-p)^{-1}$.*

Proof of Proposition 3: Fix n and let $\tilde{W}_n = \{\tilde{w}_{i,j}\}$ be an $n \times n$ binary matrix with independent entries, defined on the same probability space as $\{z_{i,j}\}$, such that

$$\tilde{w}_{i,j} = \begin{cases} \text{Bern}\left(\frac{1-2p}{1-p}\right) & \text{if } x_{ij} = y_{ij} = 0 \\ 1 & \text{if } x_{ij} = 0, y_{ij} = 1 \\ y_{i,j} & \text{if } x_{ij} = 1 \end{cases}$$

where the Bernoulli variable in the first condition is independent of $\{z_{i,j}\}$. Define $\tilde{Y}_n = Y_n \vee \tilde{W}_n$ to be the entry-wise maximum of Y_n and $\tilde{W}_n$. Then clearly $M(Y_n) \leq M(\tilde{Y}_n)$, as any submatrix of ones in Y_n must also be present in $\tilde{Y}_n$. Moreover, the variables $\tilde{y}_{i,j}$ are i.i.d. with $P(\tilde{y}_{i,j} = 1) = 1-p$, so that we may regard $\tilde{Y}_n$ as a Bern$(1-p)$ noise matrix. It then follows from Theorem 1 that $M(Y_n) \leq 2\log_{b'} n$ eventually almost surely. To obtain the other inequality, define

$$\hat{w}_{i,j} = \begin{cases} \text{Bern}\left(\frac{p}{1-p}\right) & \text{if } x_{ij} = y_{ij} = 1 \\ 0 & \text{if } x_{ij} = 1, y_{ij} = 0 \\ y_{i,j} & \text{if } x_{ij} = 0 \end{cases}$$

and let $\hat{Y}_n = Y_n \wedge \hat{W}_n$ be the entry-wise maximum of Y_n and $\hat{W}_n$. It is easy to verify that $M(Y_n) \geq M(\hat{Y}_n)$, and that the entries in $\hat{Y}_n$ are i.i.d. Bern(p). Theorem 1 then implies that $M(Y_n) \geq (2-\varepsilon)\log_b n$ eventually almost surely.

Proposition 3 can be interpreted as follows. No matter what type of block structures might exist in X, in the presence of random noise these structures leave behind only logarithmic fragments in the observed data. Under the additive noise model (3), block structures in X cannot be recovered directly by methods such as frequent itemset mining that look for maximal submatrices of ones without errors.

6.2 Recovery

In light of Proposition 3, it is natural to consider methods for identifying submatrices of 1s that may be contaminated with a certain fraction of 0s. These submatrices correspond, in the data mining and bipartite graph settings, to approximate frequent itemsets and approximate bicliques, respectively. A number of different error-tolerant frequent itemset mining algorithms have been proposed in the literature (Pei et al., 2001, 2002; Yang et al., 2001; Seppänen and Mannila, 2004; Liu et al., 2005, 2006). Most are based on criteria that require the average of the identified submatrices to be greater than a user specified threshold τ. One can readily adapt the first moment argument to obtain significance bounds for submatrices with a large fraction of 1s; details can be found in Sun (2007).

Here we consider the simple problem of recovering a (potentially small) submatrix C of 1s embedded in a matrix of 0s from a single noisy observation. Proposition 3 shows that one cannot recover C directly using standard frequent itemset mining; instead we consider the Approximate Frequent Itemset (AFI) algorithm developed in Liu et al. (2005).

Definition: Given a binary matrix U with index set C, let $F(U) = |C|^{-1} \sum_{(i,j)\in C} u_{i,j}$ be the fraction of ones in U, or equivalently, the average of the entries of U.

Let u_{i*} and u_{*j} denote the rows and columns, respectively, of a given submatrix U.

Definition: Let $\tau \in [0,1]$ be fixed. A submatrix U of a binary matrix Y is a τ-*approximate frequent itemset* (τ-AFI) if each of its rows satisfies $F(u_{i*}) \geq \tau$ and each of its columns satisfies $F(u_{*j}) \geq \tau$. Define $\mathrm{AFI}_\tau(Y)$ to be the collection of all τ-AFIs in Y.

The definition above comes from Liu et al. (2005), who presented an algorithm for identifying AFIs in binary matrices.

Let X_n be an $n \times n$ binary matrix that consists of an $l \times l$ submatrix of ones having index set C^*, with all other entries equal to 0. (The rows and columns of C^* need not be contiguous.) Suppose that $Y_n = X_n \oplus Z_n$, where Z_n has noise level $p \in (0, 1/2)$. We wish to recover the index set C^* of the target submatrix from Y_n.

To this end, assume that the noise level p is unknown, but that there is a known upper bound p_0 such that $p < p_0 < 1/2$, and let $\tau = 1 - p_0$ be an associated error threshold. We estimate C^* by the index set of the largest square τ-AFI in the observed matrix Y_n. More precisely, let $\hat{\mathscr{C}}$ be the family of index sets of square submatrices $U \in \mathrm{AFI}_\tau(Y_n)$, and let

$$\hat{C} = \operatorname*{argmax}_{C \in \hat{\mathscr{C}}} |C|$$

be the index set of any maximal sized submatrix in $\hat{\mathscr{C}}$. (The set $\hat{\mathscr{C}}$ contains 1×1 submatrices with entry 1, so it is non-empty whenever Y_n is not identically 0.) Note that $\hat{\mathscr{C}}$ and $\hat{C}$ depend only on the observed matrix Y_n. Let the ratio

$$\Lambda = |\hat{C} \cap C^*| / |\hat{C} \cup C^*|$$

measure the overlap between the estimated index set $\hat{C}$ and the true index set C^*. Clearly $0 \leq \Lambda \leq 1$, and values of Λ close to one indicate better overlap. The proof of the next theorem is given in Section 9.

Theorem 4. *When n is sufficiently large, for any* $0 < \alpha < 1$ *such that* $8\alpha^{-1}(\log_b n + 2) \le l$ *we have*

$$P\left(\Lambda \le \frac{1-\alpha}{1+\alpha}\right) \le \Delta_1(l) + \Delta_2(\alpha, l).$$

Here $\Delta_1(l) = 2le^{-\frac{3l(p-p_0)^2}{8p}}$ *and* $\Delta_2(\alpha, l) = 2n^{-\frac{1}{4}\alpha l + 2\log_b n}$, *with* $b = \exp\{3(1-2p_0)^2/8p\}$.

Remarks: The second term $\Delta_2(\alpha, l)$ is less than $2n^{-4/\alpha}$ and is the dominant term in the probability upper bound if $l/\ln(n)$ is large. The logarithmic base b is derived from an upper bound on the tails of the binomial distribution, and is always larger than $\tilde{b} = \exp\{3(1-2p_0)^2/8p_0\}$. By a crude bound, $\Delta_1(l) \le \tilde{\Delta}_1(l) := e^{-\sqrt{l}}$ when l is sufficiently large. Thus, by replacing b with $\tilde{b}$ and $\Delta_1(l)$ with $\tilde{\Delta}_1(l)$, one obtains a probability bound that does not depend on the unknown parameter p.

As a corollary of Theorem 4, we can also get results in an asymptotic setting. Suppose that $\{X_n : n \ge 1\}$ is a sequence of square binary matrices, and that X_n contains an $l_n \times l_n$ submatrix C_n^* of 1s with all other entries equal to 0. Let $Y_n = X_n \oplus Z_n$, and let Λ_n measure the overlap between C_n^* and the estimate $\hat{C}_n$ produced by the AFI-based recovery method above. The following result follows from Theorem 4 and the Borel Cantelli lemma.

Corollary 1. *If* $l_n \ge 8\psi(n)(\log_b n + 2)$ *where* $\psi(n) \to \infty$ *as* $n \to \infty$, *then eventually almost surely*

$$\Lambda_n \ge \frac{1-\psi(n)^{-1}}{1+\psi(n)^{-1}} \to 1.$$

Reuning-Scherer studied several recovery problems in his thesis (Reuning-Scherer, 1997). In the case considered here, he calculated the fraction of 1s in every row and every column of Y, and then selected those rows and columns for which these fractions exceeded an appropriate threshold. His algorithm is easily seen to be consistent when $l \ge n^\alpha$ for $\alpha > 1/2$. However, it is easy to show using the central limit theorem that individual row and column sums alone are not sufficient to recover C^* when $l \le n^\alpha$ for $\alpha < 1/2$. In the latter case, one gains considerable power by directly considering submatrices, and as the result above demonstrates, one can consistently recover C_n^* if $l_n/\ln(n) \to \infty$.

7. Proofs of Preliminary Results

In this section, we will begin with the proofs of Lemma 1 and Lemma 2 then follow with the proof of Proposition 1.

7.1 Proofs of Lemmas 1 and 2

Proof of Lemma 1: Differentiating $\log_b(\phi_n(s))$ yields

$$\frac{\partial \log_b(\phi_n(s))}{\partial s} = \frac{1}{2(n-s)\ln b} + \log_b(n-s) - s - \log_b s - \frac{1}{2s\ln b},$$

which is negative when $\log_b n < s < 2\log_b n$. A routine calculation shows that for $0 < s \le \log_b n$,

$$\begin{aligned}\log_b \phi_n(s) &= (n+\frac{1}{2})\log_b n - (s+\frac{1}{2})\log_b s - (n-s+\frac{1}{2})\log_b(n-s) - \frac{s^2}{2} - \frac{1}{2}\log_b 2\pi \\ &\ge s\left(\log_b(n-\log_b n) - \frac{s}{2} - \log_b \log_b n\right) - \frac{1}{2}\log_b s - \frac{1}{2}\log_b 2\pi \ > 0\end{aligned}$$

when n is sufficiently large. Similarly, for $2\log_b n \le s < n$,

$$\begin{aligned}\log_b \phi_n(s) &\le s\left(\log_b(n-s) - \frac{s}{2} - \log_b s\right) - \frac{1}{2}\log_b s - \frac{1}{2}\log_b 2\pi + 2s + \frac{s\log_b s}{2} \\ &\le s\left(2 - \frac{\log_b s}{2}\right) - \frac{1}{2}\log_b s - \frac{1}{2}\log_b 2\pi \;<\; 0\end{aligned}$$

when n is sufficiently large. Thus for sufficiently large n, there exists a unique solution $s(n)$ of the equation $\phi_n(s) = 1$ with $s(n) \in (\log_b n, 2\log_b n)$. ■

Proof of Lemma 2: Taking logarithms of both sides of the equation $\phi_n(s) = 1$ and rearranging terms yields

$$\frac{1}{2}\log_b \frac{n}{n-s} + n\log_b \frac{n}{n-s} - (s+\frac{1}{2})\log_b s + s\log_b(n-s) - \frac{s^2}{2} = \frac{\log_b 2\pi}{2}.$$

Lemma 1 implies that $s(n)$ belongs to the interval $(\log_b n, 2\log_b n)$, so we consider the above equation in the case that $n >> s$. Dividing both sides of the equation by s yields

$$\log_b(n-s) - \frac{s}{2} - \log_b s = -\log_b e + O(\frac{\log_b s}{s}),$$

which can be rewritten as

$$\log_b n - \frac{s}{2} - \log_b \log_b n = \log_b \frac{s}{\log_b n} - \log_b \frac{n-s}{n} - \log_b e + O(\frac{\log_b s}{s}). \tag{4}$$

For each n, define $R(n)$ via the equation

$$s(n) \;=\; 2\log_b n - 2\log_b \log_b n + R(n).$$

Plugging this expression into (4), it follows that $R(n) = 2\log_b e - 2\log_b 2 + o(1)$, and the result follows from the uniqueness of $s(n)$. ■

7.2 Proof of Proposition 1

To establish the bound with r independent of n, it suffices to consider a sequence r_n that changes with n in such a way that $1 \le r_n \le n$. Fix n for the moment, let $l = k(n) + r_n$, and let U_l be the number of $l \times l$ submatrices of 1s in Z_n. Then by Markov's inequality and Stirling's approximation,

$$P(M(Z_n) \ge l) \;=\; P(U_l \ge 1) \;\le\; E(U_l) \;=\; \binom{n}{l}^2 p^{l^2} \;\le\; 2\phi_n^2(l).$$

A straightforward calculation using the definition of $\phi_n(\cdot)$ shows that one can decompose the rightmost term above as follows:

$$2\phi_n^2(l) \;=\; 2\,\phi_n^2(k(n))\, p^{r\cdot k(n)}\, [A_n(r)\, B_n(r)\, C_n(r)\, D_n(r)\,]^2,$$

where

$$A_n(r) = \left(\frac{n-r-k(n)}{n-k(n)}\right)^{-n+r+k(n)+\frac{1}{2}}, \quad B_n(r) = \left(\frac{r+k(n)}{k(n)}\right)^{-k(n)-\frac{1}{2}},$$

$$C_n(r) = \left(\frac{n-k(n)}{r+k(n)}\, p^{\frac{k(n)}{2}}\right)^{r}, \quad D_n(r) = p^{\frac{r^2}{2}}.$$

Note that $p^{r\cdot k(n)} = o(n^{-2r}(\log_b n)^{2r+\varepsilon})$ for any fixed $\varepsilon > 0$, and that $\phi_n^2(k(n)) \le 1$ by the monotonicity of $\phi_n(\cdot)$ and the definition of $k(n)$. Thus it suffices to show that $A_n(r)\cdot B_n(r)\cdot C_n(r)\cdot D_n(r) = O(1)$ when n is sufficiently large. To begin, note that for any fixed $\delta \in (0,1/2)$, when n is sufficiently large,

$$C_n(r)^{\frac{1}{r}} = \frac{n-k(n)}{r+k(n)}\, p^{\frac{k(n)}{2}} \le \frac{n}{k(n)}\, p^{\frac{k(n)}{2}} \le \frac{n}{(2-\delta)\log_b n}\frac{\frac{2+\delta}{2}\log_b n}{n},$$

which is less than one. Note that $B_n(r) \le 1$. It only remains to show $A_n(r)\cdot D_n(r) = O(1)$. Simple calculations yield that $\ln A_n(r) \le r$. Consequently, $\ln(A_n(r)\cdot D_n(r)) \le r - \frac{r^2 \ln b}{2}$, which is bounded from above. ■

8. Proof of Theorem 1

The proof of Theorem 1 is established via a sequence of technical lemmas. Modifying our earlier notation slightly, let $U_k(n)$ denote the number of $k\times k$ submatrices of 1s in Z_n. In what follows ε is a fixed positive number less than $\frac{1}{2}$. Our argument parallels that outlined in Bollobás (2001). We begin with the following definition.

Definition: For each $k \ge 1$, let n_k' be the least integer n such that

$$EU_k(n) \ge k^{3+\varepsilon},$$

and let n_k be the largest integer n such that

$$EU_k(n) \le k^{-3-\varepsilon}.$$

Note that n_k and n_k' exist for sufficiently large $k \ge 1$, as $EU_k(k) = p^{k^2} \le k^{-3-\varepsilon}$, $EU_k(n)$ is monotone increasing in n, and $EU_k(n) \to \infty$ as $n \to \infty$.

Lemma 3. *Let n_k and n_k' be defined as above.*

a. When k is sufficiently large, $n_k' < n_{k+1}$.

b. When k is sufficiently large, $n_k' - n_k < C_1 \frac{n_k \ln k}{k}$ for some constant $C_1 > 2$.

c. $\lim_{k\to\infty} \frac{n_{k+2}-n_{k+1}}{n_{k+1}-n_k} = b^{\frac{1}{2}}$.

Proof of (a): It follows from the definition of n_k that

$$\binom{n_k}{k} p^{\frac{k^2}{2}} \le k^{-\frac{(3+\varepsilon)}{2}} \quad \text{and} \quad \binom{n_k+1}{k} p^{\frac{k^2}{2}} \ge k^{-\frac{(3+\varepsilon)}{2}}. \tag{5}$$

Rearranging terms in the first inequality, and noting that $(n_k-k)!/n_k! \leq (n_k-k)^{-k}$ we obtain, in turn, the inequalities

$$\frac{k^{\frac{(3+\varepsilon)}{2}}}{k!\, b^{\frac{k^2}{2}}} \leq \frac{1}{(n_k-k)^k} \quad \text{and} \quad n_k \leq b^{\frac{k}{2}} \left[\frac{k!}{k^{\frac{(3+\varepsilon)}{2}}}\right]^{\frac{1}{k}} + k.$$

Rearranging the terms in the second inequality of (5), one may establish by a similar argument the inequalities

$$k^{\frac{(3+\varepsilon)}{2}} \geq b^{\frac{k^2}{2}} \frac{k!}{(n+1)^k} \quad \text{and} \quad n_k \geq b^{\frac{k}{2}} \left(\frac{k!}{k^{\frac{3+\varepsilon}{2}}}\right)^{\frac{1}{k}} - 1.$$

Combining the two bounds on n_k above, yields

$$b^{\frac{k}{2}} \left(k!\, k^{-\frac{3+\varepsilon}{2}}\right)^{\frac{1}{k}} - 1 \leq n_k \leq b^{\frac{k}{2}} \left(k!\, k^{-\frac{(3+\varepsilon)}{2}}\right)^{\frac{1}{k}} + k \tag{6}$$

and the asymptotic relation

$$n_k = b^{\frac{k}{2}} (k!)^{\frac{1}{k}} + o(k b^{\frac{k}{2}}). \tag{7}$$

From the definition of n'_k, one can establish in a similar fashion the inequalities

$$b^{\frac{k}{2}} \left(k!\, k^{\frac{3+\varepsilon}{2}}\right)^{\frac{1}{k}} \leq n'_k \leq b^{\frac{k}{2}} \left(k!\, k^{\frac{(3+\varepsilon)}{2}}\right)^{\frac{1}{k}} + k + 1. \tag{8}$$

and the asymptotic relation

$$n'_k = b^{\frac{k}{2}} (k!)^{\frac{1}{k}} + o(k b^{\frac{k}{2}}). \tag{9}$$

The asymptotic expressions for n_k and n'_k ensure that $n'_k < n_{k+1}$ when k is sufficiently large.

Proof of (b): It follows from inequalities (6) and (8) that, when k is sufficiently large,

$$\begin{aligned} n'_k - n_k &\leq b^{\frac{k}{2}} \left(k!\, k^{\frac{(3+\varepsilon)}{2}}\right)^{\frac{1}{k}} + k + 1 - \left[b^{\frac{k}{2}} \left(k!\, k^{-\frac{3+\varepsilon}{2}}\right)^{\frac{1}{k}} - 1\right] \\ &\leq b^{\frac{k}{2}} \left(k!\, k^{-\frac{3+\varepsilon}{2}}\right)^{\frac{1}{k}} (k^{\frac{3+\varepsilon}{k}} - 1) + k + 2 \\ &\leq (n_k+1)(k^{\frac{3+\varepsilon}{k}} - 1) + k + 2 \\ &< n_k C_1 \frac{\log k}{k}. \end{aligned}$$

for some constant $C_1 > 2$. The third inequality above is a consequence of (6), while the last inequality follows from the fact that $x - 1 < 2\ln x$ for x close to 1.

Proof of (c): It follows from Equations (7) and (9) that

$$\frac{n_{k+1}}{n_k} = b^{\frac{1}{2}} + o(1) \quad \text{and} \quad \frac{n_{k+2}}{n_{k+1}} = b^{\frac{1}{2}} + o(1).$$

Therefore, as k tends to infinity,

$$\frac{n_{k+2} - n_{k+1}}{n_{k+1} - n_k} = \frac{\frac{n_{k+2}}{n_{k+1}} - 1}{1 - \frac{n_k}{n_{k+1}}} \to b^{\frac{1}{2}}.$$

This completes the proof of Lemma 3. ■

We now continue the analysis of $U_k(n)$. The second moment argument used below requires bounds on the ratio

$$g(U_k(n)) := \mathrm{Var}(U_k(n))/(EU_k(n))^2$$

which arises in a standard Chebyshev bound on the tails of $U_k(n)$. Letting

$$S = \{C = A \times B : A, B \subseteq [n], |A| = |B| = k\}$$

be the family of index sets of $k \times k$ submatrices, we see that

$$U_k(n)^2 \;=\; \sum_{C,C' \in S} I\{\text{each entry of } Z_n[C] \text{ and } Z_n[C'] \text{ is } 1\}.$$

From the last display one may readily derive that

$$EU_k(n)^2 \;=\; \sum_{l=1}^{k} \binom{n}{k}\binom{k}{l}\binom{n-k}{k-l} \sum_{r=1}^{k} \binom{n}{k}\binom{k}{r}\binom{n-k}{k-r} \cdot p^{2k^2-lr},$$

where the indices k and l indicate the number of rows and columns, respectively, that the submatrices C and C' have in common. As $EU_k(n) = \binom{n}{k}^2 p^{k^2}$, we find that

$$g(U_k) \;=\; \sum_{l=0}^{k}\sum_{r=0}^{k} \frac{\binom{k}{l}\binom{n-k}{k-l}}{\binom{n}{k}} \frac{\binom{k}{r}\binom{n-k}{k-r}}{\binom{n}{k}} b^{lr} - 1,$$

where $b = p^{-1}$. Recall that $0 < \varepsilon < \frac{1}{2}$ is fixed.

Lemma 4. *There exists a constant $C_0 > 0$ such that $g(U_k(n)) \le C_0 k^{-1-\varepsilon}$ for every sufficiently large k and every $n_k' \le n \le n_{k+1}$.*

Proof of Lemma 4: To begin, note that

$$\begin{aligned}
g(U_k(n)) &= \sum_{l=0}^{k}\sum_{r=0}^{k} \frac{\binom{k}{l}\binom{n-k}{k-l}}{\binom{n}{k}} \frac{\binom{k}{r}\binom{n-k}{k-r}}{\binom{n}{k}} (b^{lr} - 1) \\
&= \sum_{l=1}^{k}\sum_{r=1}^{k} \frac{\binom{k}{l}\binom{n-k}{k-l}}{\binom{n}{k}} \frac{\binom{k}{r}\binom{n-k}{k-r}}{\binom{n}{k}} (b^{lr} - 1) \\
&< \sum_{l=1}^{k}\sum_{r=1}^{k} \frac{\binom{k}{l}\binom{n-k}{k-l}}{\binom{n}{k}} \frac{\binom{k}{r}\binom{n-k}{k-r}}{\binom{n}{k}} b^{lr} \le \left(\sum_{r=1}^{k} \frac{\binom{k}{r}\binom{n-k}{k-r}}{\binom{n}{k}} (b^{r^2/2}) \right)^2,
\end{aligned}$$

where the last inequality follows from the fact that $b^{lr} \le b^{\frac{l^2+r^2}{2}}$. Thus it suffices to show that

$$\sum_{r=1}^{k} h(r) = O(k^{-1/2-\varepsilon/2}) \;\text{ where }\; h(r) := \frac{\binom{k}{r}\binom{n-k}{k-r}}{\binom{n}{k}} b^{r^2/2}. \tag{10}$$

If $n \ge n_k'$, then by inequality (8), $n \ge b^{\frac{k}{2}} \left(k!\, k^{\frac{3+\varepsilon}{2}} \right)^{\frac{1}{k}}$, which implies that $k \le 2\log_b n$. Similarly, inequality (6) implies that if $n \le n_{k+1}$ then $k \ge (2-\eta)\log_b n$ for some fixed $0 < \eta < 1/2$. Finally,

it follows from the assumption that $n \geq n'_k$ and the definition of n'_k that $\binom{n}{k} p^{\frac{k^2}{2}} = \sqrt{EU_k(n)} \geq \sqrt{EU_k(n'_k)} \geq k^{3/2+\varepsilon/2}$. Using these inequalities, one can upper bound $h(1)$, $h(k-1)$ and $h(k)$ as follows:

$$h(1) \;=\; \frac{\binom{k}{1}\binom{n-k}{k-1}}{\binom{n}{k}} b^{1/2} \;=\; \frac{b^{1/2}k^2(n-k)!(n-k)!}{(n-2k+1)!n!} \;<\; \frac{b^{1/2}k^2}{n-k} = O(k^2 b^{-k/2}),$$

$$h(k-1) \;=\; \frac{k(n-k)}{\binom{n}{k}} b^{\frac{k^2}{2}-k+\frac{1}{2}} \;\leq\; \frac{knb^{\frac{1}{2}-k}}{\sqrt{EU_k(n)}} \;=\; O\left(k^{-1/2-\varepsilon/2} b^{-k(1-\eta)/(2-\eta)}\right),$$

$$h(k) \;=\; \frac{b^{\frac{k^2}{2}}}{\binom{n}{k}} \;=\; \frac{1}{\sqrt{EU_k(n)}} \;\leq\; k^{-3/2-\varepsilon/2},$$

In order to establish inequality (10), it therefore suffices to verify that when k is sufficiently large,

$$h(r) \leq h(1) + h(k-1) \tag{11}$$

for any $1 < r < k-1$. To this end, note that

$$\frac{h(r+1)}{h(r)} = \frac{(k-r)^2 b^{r+\frac{1}{2}}}{(r+1)(n-2k+r+1)}.$$

When $r \leq \frac{1}{3}k$, the inequality $k \leq 2\log_b n$ implies that

$$\frac{h(r+1)}{h(r)} \leq \frac{bk^2 b^{\frac{k}{3}}}{n-2k+r+1} \leq \frac{bk^2 n^{\frac{2}{3}}}{n-2k+r+1} < 1.$$

When $\frac{2}{3}k \leq r < k-1$ the inequality $k \geq (2-\eta)\log_b n$ with $0 < \eta < 1/2$ implies that

$$\frac{h(r+1)}{h(r)} \geq \frac{b^{\frac{2k}{3}}}{k(n+r+1)} \geq \frac{n^{\frac{2(2-\eta)}{3}}}{k(n+r+1)} > 1.$$

In order to show inequality (11), it now suffices to show that $h(r)$ is log-convex for all integer $r \in [\lceil \frac{k}{3} \rceil - 1, \lceil \frac{2k}{3} \rceil]$. Since for $r \in [\lceil \frac{k}{3} \rceil - 1, \lceil \frac{2k}{3} \rceil]$,

$$\ln h(r) = \ln h(\lceil \frac{k}{3} \rceil - 1) + \sum_{i=0}^{r-\lceil \frac{k}{3} \rceil} \ln \frac{h(\lceil \frac{k}{3} \rceil + i)}{h(\lceil \frac{k}{3} \rceil + i - 1)},$$

it is equivalent to show that $\frac{h(r+1)}{h(r)}$ is monotone increasing. To verify this, note that the derivative $\partial[h(r+1)/h(r)]/\partial r$ is equal to

$$\frac{b^{\frac{2r+1}{2}}(k-r)}{(r+1)(n-2k+r+1)} \left[\frac{-2(r+1)(n-2k+r+1) - (k-r)(2r+n-2k+2)}{(r+1)(n-2k+1)} + (k-r)\ln b \right].$$

When k is sufficiently large and $n \gg k > r$, the sum of the leading terms on the last expression above is

$$-2n(r+1) - (k-r)n + (k-r)(r+1)n\ln b \;=\; n(-r^2\ln b + kr\ln b - k - r + (k-r)\ln b - 2).$$

By plugging in $r = \frac{k}{3}$ and $r = \frac{2k}{3}$, it is not hard to check that this quadratic form in r is positive for any $r \in [\lceil \frac{k}{3} \rceil - 1, \lceil \frac{2k}{3} \rceil]$ when k is sufficiently large, and the desired monotonicity follows. ■

Lemma 5. *With probability one, when k is sufficiently large, $M(Z_n) = k$ whenever $n'_k \le n \le n_{k+1}$.*

Proof of Lemma 5: By the definition of n_{k+1} and Markov's inequality, when $n \le n_{k+1}$,

$$P(M(Z_n) > k) \le E(U_{k+1}(n)) \le E(U_{k+1}(n_{k+1})) \le (k+1)^{-3-\varepsilon}.$$

Moreover, Chebyshev's inequality and Lemma 4 together imply that for $n'_k \le n \le n_{k+1}$,

$$P(M(Z_n) < k) = P(U_k(n) = 0) \le \frac{Var(U_k(n))}{(EU_k(n))^2} \le C_0 \cdot k^{-1-\varepsilon}.$$

As $M(Z_n)$ is monotone increasing with n, the previous bounds yield

$$\begin{aligned}\sum_{k\ge 1} P\left(\bigcup_{n=n'_k}^{n_{k+1}} \{M(Z_n) \ne k\}\right) &\le \sum_{k\ge 1} P\left(M(Z_{n'_k}) < k\right) + \sum_{k\ge 1} P\left(M(Z_{n_{k+1}}) \ge k\right) \\ &\le \sum_{k\ge 1}\left(C_0 \cdot k^{-1-\varepsilon} + \frac{1}{k^{3+\varepsilon}}\right) < \infty.\end{aligned}$$

and the result follows from the Borel-Cantelli lemma. ■

Proof of Theorem 1: From Lemma 5 we may deduce that with probability one $M(Z_n)$ is eventually equal to one of two possible consecutive integers, whose values depend only on n. It follows from their definition that $n_k < n'_k$, and by Lemma 3 both integers tend to infinity as k tends to infinity. Therefore for every k greater than or equal to some k_0 we have

$$\ldots < n_k < n'_k < n_{k+1} < n'_{k+1} < \ldots.$$

Thus for all $n \ge n_{k_0}$ there exists a unique integer k (depending on n) such that $n'_k \le n \le n_{k+1}$ or $n_k < n < n'_k$. In the former case, Lemma 5 implies that $M(Z_n) = k$ when n is sufficiently large. In the latter case, Lemma 5 and the monotonicity of $M(Z_n)$ in n imply that

$$k-1 = M(Z_{n_k}) \le M(Z_n) \le M(Z_{n'_k}) = k,$$

when n is sufficiently large, so that $M(Z_n)$ can take one of at most two possible values, $k-1$ and k.

It remains to connect $M(Z_n)$ and $s(n)$. To begin, let n be such that $n'_k \le n \le n_{k+1}$ for some $k \ge k_0$. Then by definition of n_{k+1} and $s(n)$,

$$(1+o(1))\,\phi_n(k+1) = (EU_{k+1}(n))^{1/2} \le (EU_{k+1}(n_{k+1}))^{1/2} \le k^{-3/2-\varepsilon/2} < 1 = \phi_n(s(n)).$$

As $\phi_n(k)$ is monotone decreasing in k, we conclude that $s(n) < k+1$ when n is sufficiently large. Similarly,

$$(1+o(1))\,\phi_n(k) = (E\,U_k(n))^{1/2} \ge (E\,U_k(n'_k))^{1/2} \ge k^{3/2+\varepsilon/2} > 1 = \phi_n(s(n)),$$

which implies $s(n) > k$. Thus, with probability one, when n is sufficiently large

$$n'_k \le n \le n_{k+1} \text{ implies } k < s(n) < k+1 \text{ and } M(Z_n) = k. \tag{12}$$

Suppose now that $n_k \le n \le n'_k$. Then $s(n_k) \le s(n) \le s(n'_k)$ and the arguments above show that $s(n_k) < k$ and $s(n'_k) > k$. We establish that $s(n'_k) - s(n_k) = o(1)$. To this end, note that

$$0 < s(n'_k) - s(n_k) = 2\log_b \frac{n'_k}{n_k} - 2\log_b \frac{\log_b n'_k}{\log_b n_k} + o(1) \le 2\log_b \frac{n'_k}{n_k} + o(1)$$

as $\frac{\log_b n'_k}{\log_b n_k} > 1$. It therefore suffices to show that $\log_b \frac{n'_k}{n_k} = o(1)$, but this follows from part (b) of Lemma 3. Putting the bounds above together with Lemma 5, we find that with probability one, when n is sufficiently large

$$n_k \le n \le n'_k \text{ implies } k - \varepsilon < s(n) < k + \varepsilon \text{ and } M(Z_n) \in \{k-1, k\}. \tag{13}$$

Combining relations (12) and (13) yields the desired bound on $M(Z_n)$. ■

9. Proof of Theorem 4

The following lemmas are used in the proof of Theorem 4. Lemma 6 shows that $|\hat{C}|$ is greater than or equal to $|C^*|$ with high probability, and Lemma 9 shows that $\hat{C}$ can only contain a small proportion of entries outside C^*. Lemma 7 and Lemma 8 are used in the proof of Lemma 9.

Lemma 6. *Under the conditions of Theorem 4,* $P\left(|\hat{C}| < l^2\right) \le \Delta_1(l)$.

Proof of Lemma 6: Let $u_{1*}, \ldots, u_{l*}$ be the rows of C^* in Y, and let V be the number of rows satisfying $F(u_{i*}) < \tau = 1 - p_0$. By the union bound and a standard bound (Devroye et al., 1996) on the tail of the binomial distribution, $P(V \ge 1) \le l \cdot e^{-\frac{3l(p-p_0)^2}{8p}}$. The same inequality holds for the number V' of columns u_{*j} of C^* such that $F(u_{*i}) < 1 - p_0$. Since $\{|\hat{C}| < l^2 = |C^*|\} \subset \{C^* \notin AFI_\tau(Y)\} \subset \{V \ge 1\} \cup \{V' \ge 1\}$, we have

$$\begin{aligned} P\{|\hat{C}| < l^2\} &\le P(V \ge 1) + P(V' \ge 1) \\ &\le 2le^{-\frac{3}{8p}l(p-p_0)^2} = \Delta_1(l). \quad ■ \end{aligned}$$

Lemma 7. *Given* $0 < \tau_0 < 1$, *if there exists a* $k \times r$ *binary matrix* V *such that* $F(V) \ge \tau_0$, *then there exists a* $v \times v$ *submatrix* U *of* V *such that* $F(U) \ge \tau_0$, *where* $v = \min\{k, r\}$.

Proof of Lemma 7: Without loss of generality, assume $v = k \le r$. Order the columns of V in descending order of the number of 1s they contain. If U contains the first v columns in this order, then $F(U) \ge \tau_0$. ■

Lemma 8. *Let* $1 < \gamma < 2$. *Let* W *be a binary matrix, and let* R_1 *and* R_2 *be two square submatrices of* W *such that (i)* $|R_2| = k^2$, *(ii)* $|R_1 \backslash R_2| > k^\gamma$ *and (iii)* $R_1 \in AFI_\tau(W)$. *Then when* k *is sufficiently large there exists a square submatrix* $D \subset R_1 \backslash R_2$ *such that* $|D| \ge k^{2\gamma-2}/16$ *and* $F(D) \ge \tau$.

Proof of Lemma 8: The result is clearly true if $R_1 \cap R_2 = \emptyset$, so we assume that R_1 and R_2 overlap after suitable row and column permutations, $R_1 \backslash R_2$ can be expressed either as a single maximal rectangular submatrix W_1, or as the union of two overlapping maximal rectangular $W_1 \cup W_2$. (A submatrix W of $R_1 \backslash R_2$ is maximal if there is no other submatrix of $R_1 \backslash R_2$ that contains it.)

Case 1: R_1 and R_2 overlap on an edge. Suppose that the difference $R_1 \backslash R_2$ can be expressed as a single rectangular submatrix W_1. Let l_1 and l_2 be the side lengths of W_1. In this case, the side length of the square submatrix R_1 must be less than k, and consequently $\max(l_1, l_2) \leq k$. Since $|R_1 \backslash R_2| \geq k^\gamma$, it follows that $\min(l_1, l_2) \geq k^{\gamma-1}$. As $R_1 \in AFI_\tau(W)$ we have $F(W_1) \geq \tau$. By Lemma 7, there exists a $v \times v$ submatrix D of W_1 such that $F(D) \geq \tau$ and $v \geq \min(l_1, l_2) \geq k^{\gamma-1}$.

Case 2: R_1 and R_2 overlap on a corner. Suppose $R_1 \backslash R_2$ is the union $W_1 \cup W_2$ of two maximal rectangular submatrices. Then clearly $\max(|W_1|, |W_2|) \geq \frac{|R_1 \backslash R_2|}{2}$. Without loss of generality, we assume that $|W_1| \geq |W_2|$. As $R_1 \in AFI_\tau(W)$, $F(W_1) \geq \tau$, and it suffices by Lemma 7 to show that the length of the shorter side of W_1 is greater than $k^{\gamma-1}/4$.

Let $l_1 \leq l_2$ be the side lengths of W_1 and suppose for the moment that $l_1 < k^{\gamma-1}/4$. Then $l_2 > \frac{|R_1 \backslash R_2|}{2k^{\gamma-1}/4}$ and $|R_1| = l_2^2 \geq \frac{|R_1 \backslash R_2|^2}{k^{2\gamma-2}/4}$, and it follows that

$$|R_1 \backslash R_2| \ \geq \ |R_1| - |R_2| \ > \ \frac{|R_1 \backslash R_2|^2}{k^{2\gamma-2}/4} - k^2.$$

Dividing both sides of the previous inequality by $|R_1 \backslash R_2|$ and using the assumption $|R_1 \backslash R_2| \geq k^\gamma$ yields

$$1 \ > \ \frac{|R_1 \backslash R_2|}{k^{2\gamma-2}/4} - \frac{k^2}{|R_1 \backslash R_2|} \ \geq \ 4k^{(2-\gamma)} - k^{(2-\gamma)} \ = \ 3k^{(2-\gamma)}.$$

When k is sufficiently large, this yields a contradiction and completes the proof. ■

Lemma 9. *Let $\mathscr{A}$ be the collection of $C \in \hat{\mathscr{C}}$ such that $|C| \geq l^2$ and $\frac{|C \cap C^{*c}|}{|C|} \geq \alpha$, where $\alpha \in (0,1)$ satisfies $l \geq 8\alpha^{-1}(\log_b n + 2)$. Let A be the event that $\mathscr{A} \neq \emptyset$. If n is sufficiently large,*

$$P(A) \ \leq \ \Delta_2(\alpha, l).$$

Proof of Lemma 9: Recall that $|C^*| = l^2$. If $C \in \mathscr{A}$ then $C \in \mathrm{AFI}_{1-p_0}(Y)$ and

$$|C \backslash C^*| \ = \ |C| \cdot \frac{|C \cap C^{*c}|}{|C|} \ \geq \ l^2 \cdot \alpha \ = \ l^\gamma$$

where $\gamma \ = \ 2 + \log_l \alpha$. Thus, by Lemma 8 there exists a $v \times v$ submatrix D of $C \backslash C^*$ such that $F(D) \ \geq \ 1 - p_0$ and $v \ \geq \ \frac{\alpha l}{4}$. It follows that

$$\max_{c \in \hat{\mathscr{C}}} M^\tau(C \cap C^{*c}) \ \geq \ v \ \geq \ \frac{\alpha l}{4},$$

where $\tau = 1 - p_0$ and $M^\tau(X)$ is size of the largest square submatrix with average greater than τ in a given matrix X.

Let $W = W(Y, C^*)$ be an $n \times n$ binary random matrix, with $w_{ij} = y_{ij}$ if $(i,j) \notin C^*$, and $w_{ij} \sim \mathrm{Bern}(p)$ otherwise. Then it is clear that

$$M^\tau(W) \ \geq \ \max_{c \in \hat{\mathscr{C}}} M^\tau(C \cap C^{*c}) \ \geq \ \frac{\alpha l}{4}.$$

When n is sufficiently large and $l \geq 8\alpha^{-1}(\log_b n + 2)$, we can bound $P(A)$ as follows

$$\begin{aligned} P(A) &\leq P(\max_{c \in \hat{\mathscr{C}}} M^{\tau}(C \cap C^{*c}) \geq \frac{\alpha l}{4}) \\ &\leq P(M^{\tau}(W) \geq \frac{\alpha l}{4}) \leq 2n^{-(\alpha l/4 - 2\log_{b'} n)}, \end{aligned} \tag{14}$$

where $b' = e^{\frac{3(1-p_0-p)^2}{8p}}$. Note that the last inequality follows from a first moment argument similar to that in the proof of Proposition 1 and a standard inequality for the tails of the binomial distribution(cf., Problem 8.3 of Devroye et al. 1996). As $p_0 > p$, $b < b'$, and consequently one can bound the right hand side of inequality (14) by $\Delta_2(\alpha, l)$. For detailed proof of inequality (14), please refer to Proposition 3.3.1 in Sun (2007). ■

Proof of Theorem 4: Let E be the event that $\{\Lambda \leq \frac{1-\alpha}{1+\alpha}\}$. It is clear that E can be expressed as the union of two disjoint events E_1 and E_2, where

$$E_1 = \{|\hat{C}| < |C^*|\} \cap E \text{ and } E_2 = \{|\hat{C}| \geq |C^*|\} \cap E.$$

One can bound $P(E_1)$ by $\Delta_1(l)$ via Lemma 6.

It remains to bound $P(E_2)$. By the definition of Λ, the inequality $\Lambda \leq \frac{1-\alpha}{1+\alpha}$ can be rewritten equivalently as

$$1 + \frac{|\hat{C} \cap C^{*c}|}{|\hat{C} \cap C^*|} + \frac{|\hat{C}^c \cap C^*|}{|\hat{C} \cap C^*|} \geq \frac{1+\alpha}{1-\alpha}.$$

When $|\hat{C}| \geq |C^*|$, one can verify that $|\hat{C} \cap C^{*c}| \geq |\hat{C}^c \cap C^*|$, which implies that

$$1 + \frac{|\hat{C} \cap C^{*c}|}{|\hat{C} \cap C^*|} + \frac{|\hat{C}^c \cap C^*|}{|\hat{C} \cap C^*|} \leq 1 + 2\frac{|\hat{C} \cap C^{*c}|}{|\hat{C} \cap C^*|}.$$

Therefore, $E_2 \subset E_2^*$, where

$$\begin{aligned} E_2^* &= \{|\hat{C}| \geq |C^*|\} \cap \left\{1 + 2\frac{|\hat{C} \cap C^{*c}|}{|\hat{C} \cap C^*|} \geq \frac{1+\alpha}{1-\alpha}\right\} \\ &\subset \{|\hat{C}| \geq l^2\} \cap \left\{1 + 2\frac{|\hat{C} \cap C^{*c}|}{|\hat{C} \cap C^*|} \geq \frac{1+\alpha}{1-\alpha}\right\}. \end{aligned}$$

Notice that $1 + 2\frac{|\hat{C} \cap C^{*c}|}{|\hat{C} \cap C^*|} \geq \frac{1+\alpha}{1-\alpha}$ implies $\frac{|\hat{C} \cap C^{*c}|}{|\hat{C}|} \geq \alpha$. Therefore, by Lemma 9, $P(E_2^*) \leq \Delta_2(\alpha, l)$. ■

Acknowledgments

The authors would like to thank Professors Gábor Lugosi and Robin Pemantle for helpful discussions regarding early versions of this work, and two referees and the editor for helpful comments and suggestions. Comments from one anonymous referee led to a simpler proof, and improved statement, of Theorem 1. The work presented in this paper was supported in part by NSF grant DMS 0406361.

Abstract

It is well known that solutions to the nonlinear independent component analysis (ICA) problem are highly non-unique. In this paper we propose the "minimal nonlinear distortion" (MND) principle for tackling the ill-posedness of nonlinear ICA problems. MND prefers the nonlinear ICA solution with the estimated mixing procedure as close as possible to linear, among all possible solutions. It also helps to avoid local optima in the solutions. To achieve MND, we exploit a regularization term to minimize the mean square error between the nonlinear mixing mapping and the best-fitting linear one. The effect of MND on the inherent trivial and non-trivial indeterminacies in nonlinear ICA solutions is investigated. Moreover, we show that local MND is closely related to the smoothness regularizer penalizing large curvature, which provides another useful regularization condition for nonlinear ICA. Experiments on synthetic data show the usefulness of the MND principle for separating various nonlinear mixtures. Finally, as an application, we use nonlinear ICA with MND to separate daily returns of a set of stocks in Hong Kong, and the linear causal relations among them are successfully discovered. The resulting causal relations give some interesting insights into the stock market. Such a result can not be achieved by linear ICA. Simulation studies also verify that when doing causality discovery, sometimes one should not ignore the nonlinear distortion in the data generation procedure, even if it is weak.

Keywords: nonlinear ICA, regularization, minimal nonlinear distortion, mean square error, best linear reconstruction

1. Introduction

Independent component analysis (ICA) is a popular statistical technique aiming to recover independent sources from their observed mixtures, without knowing the mixing procedure or any specific knowledge of the sources (Hyvärinen et al., 2001; Cardoso, 1998; Cichocki and Amari, 2003). In the case that the observed mixtures are a linear transformation of the sources, under weak assumptions, ICA can recover the original sources with the trivial permutation and scaling indeterminacies. Linear ICA is currently a popular method for blind source separation (BSS) of linear mixtures.

However, nonlinear ICA does not necessarily lead to nonlinear BSS. In Hyvärinen and Pajunen (1999), it was shown that solutions to nonlinear ICA always exist and that they are highly non-unique. Actually, one can easily construct a nonlinear transformation of some non-Gaussian independent variables to produce independent outputs. Below are a few examples. Let $y_1, ..., y_n$ be some independent variables. Their component-wise nonlinear functions are still mutually indepen-

dent. If we use Gaussianization (Chen and Gopinath, 2001) to transform y_i into Gaussian variables u_i, any component-wise nonlinear function of $\mathbf{U} \cdot \mathbf{u}$, where $\mathbf{u} = (u_1, ..., u_n)^T$ and $\mathbf{U}$ is an orthogonal matrix, still has mutually independent components. Taleb and Jutten (1999) also gave an example in which nonlinear mixtures of independent variables are still independent. One can see that nonlinear BSS is impossible without additional prior knowledge on the mixing model, since the independence assumption is not strong enough in the general nonlinear mixing case (Jutten and Taleb, 2000; Taleb, 2002).

If we constrain the nonlinear mixing mapping to have some specific forms, the indeterminacies in the results of nonlinear ICA can be reduced dramatically, and as a consequence, nonlinear ICA may lead to nonlinear BSS. For example, in Burel (1992), a parametric form of the mixing transformation is assumed known and one just needs to adjust the unknown parameters. The learning algorithms were improved in Yang et al. (1998). By exploiting the extensions of the Darmois-Skitovich theorem (Kagan et al., 1973) to nonlinear functions, a particular class of nonlinear mixing mappings, which satisfy an addition theorem in the sense of the theory of functional equations, were considered in Eriksson and Koivunen (2002). In particular, the post-nonlinear (PNL) mixing model (Taleb and Jutten, 1999), which assumes that the mixing mapping is a linear transformation followed by a component-wise nonlinear one, has drawn much attention.

In practice, the exact form of the nonlinear mixing procedure is probably unknown. Consequently, in order to model arbitrary nonlinear mappings, one may need to resort to a flexible nonlinear function approximator, such as the multi-layer perceptron (MLP) or the radial basis function (RBF) network, to represent the nonlinear separation system. Almeida (2003) uses the MLP to model the separation system and trains the MLP by information-maximization (Infomax). Moreover, the smoothness constraint,[1] which is implicitly provided by MLP's with small initial weights and with a relatively small number of hidden units, was believed to be a suitable regularization condition to achieve nonlinear BSS. In Tan et al. (2001), a RBF network is adopted to represent the separation system, and partial moments of the outputs of the separation system are used for regularization. The matching between the relevant moments of the outputs and those of the original sources was expected to guarantee a unique solution. But the moments of the original sources may be unknown. In addition, if the transformation from the original sources to the recovered sources is non-trivial,[2] this regularization could not help to recover the original sources. Variational Bayesian nonlinear ICA (Lappalainen and Honkela, 2000; Valpola, 2000) uses the MLP to model the nonlinear mixing transformation. By resorting to the variational Bayesian inference technique, this method can do model selection and avoid overfitting. If we can have some additional knowledge about the nonlinear mixing transformation and incorporate it efficiently, the results of nonlinear ICA will be much more meaningful and reliable.

Although we may not know the form of the nonlinearity in the data generation procedure, fortunately, in many cases the nonlinearity for generating natural signals we deal with is not strong. Hence, provided that the nonlinear ICA outputs are mutually independent, we would prefer the solution with the estimated data generation procedure of minimal nonlinear distortion (MND). This

1. Following Tikhonov and Arsenin (1977), here we use the term "smoothness" in a very general sense. Often it means that that the function does not change abruptly and/or that it does not oscillate too much.
2. For the definition of a trivial transformation, one may see Jutten and Taleb (2000). A one-to-one mapping $\mathcal{H}$ is trivial if and only if it satisfies $\mathcal{H}_i(y_1, y_2, ..., y_n) = h_i(y_{\sigma(i)})$, $i = 1, 2, ..., n$, where h_i are arbitrary functions and σ is any permutation over $\{1, .2, ..., n\}$. That is, a trivial mapping of $\mathbf{y}$ is a permutation of y_i followed by a component-wise transformation.

information can help to reduce the indeterminacies in nonlinear ICA greatly, and moreover, to avoid local optima in the solutions to nonlinear ICA. The minimal nonlinear distortion of the mixing system is achieved by the technique of regularization. The objective function of nonlinear ICA with MND is the mutual information between outputs penalized by some terms measuring the level of "closeness to linear" of the mixing system. The mean square error (MSE) between the nonlinear mixing system and its best-fitting linear one provides such a regularization term. To ensure that nonlinear ICA results in nonlinear BSS, one may also need to enforce the local MND of the nonlinear mapping averaged at every point, which turns out to be the smoothness regularizer exploiting second-order partial derivatives.

MND, as well as the smoothness regularizer, can be incorporated in various nonlinear ICA methods to improve the results. Here we consider two nonlinear ICA methods. The first one is the MISEP method (Almeida, 2003), where the MLP is used to represent the separation system. As regularization is powerful for complexity control in neural networks (Bishop, 1995), the structure of the MLP is not optimized during the learning process, that is, it is fixed. The second one is nonlinear ICA based on kernels (Zhang and Chan, 2007a), in which the nonlinear separation system is modeled using some kernel methods. We then explain why MND helps to alleviate the ill-posedness in nonlinear ICA solutions, by investigating the effect of MND on trivial and non-trivial indeterminacies in nonlinear ICA solutions systematically. Next, we conduct experiments using synthetic data to compare the performance of several nonlinear ICA methods. The results confirm the effectiveness of the proposed MND principle to avoid unwanted solutions and to improve the separation performance. Finally, nonlinear ICA with MND is used to discover linear causal relations in the Hong Kong stock market and give encouraging results. We also give experimental results on synthetic data, which illustrate that when performing ICA-based causality discovery on the data whose generation procedure involves nonlinear distortion, one should take into account the nonlinear effect in the ICA separation system, even if it is mild.[3]

2. Nonlinear ICA with Minimal Nonlinear Distortion

In this section we first briefly review the general nonlinear ICA problem, and then propose the minimal nonlinear distortion (MND) principle for regularization of nonlinear ICA.

2.1 Nonlinear ICA

In the nonlinear ICA model, the observed data $\mathbf{x} = (x_1, ..., x_n)^T$ are assumed to be generated from a vector of independent variables $\mathbf{s} = (s_1, ..., s_n)^T$ by a nonlinear transformation:

$$\mathbf{x} = \mathcal{F}(\mathbf{s}), \tag{1}$$

where $\mathcal{F}$ is an unknown real-valued n-component mixing function. Here for simplicity, we have assumed that the number of observed variables equals that of the original independent variables. The general nonlinear ICA problem is to find a mapping $\mathcal{G} : \mathbb{R}^n \to \mathbb{R}^n$ such that

$$\mathbf{y} = \mathcal{G}(\mathbf{x})$$

has statistically independent components. As mentioned in Section 1, the results of nonlinear ICA are highly non-unique. In order to achieve nonlinear BSS, which aims at recovering the original sources s_i, we should resort to additional prior information or suitable regularization constraints.

3. Some preliminary results of this paper were presented at ICML2007 (Zhang and Chan, 2007b).

2.2 With Minimum Nonlinear Distortion

We now propose the MND principle to restrict the space of nonlinear ICA solutions. As a consequence, the ill-posedness of the nonlinear ICA problem is alleviated. Under the condition that the separation outputs y_i are mutually independent, this principle prefers the solution with the estimated mixing transformation $\hat{\mathcal{F}}$ as close as possible to linear.

Now we need a measure of "closeness to linear" of a mapping. Given a nonlinear mapping $\hat{\mathcal{F}}$, its deviation from the affine mapping $\mathbf{A}^*$, which fits $\hat{\mathcal{F}}$ best among all affine mappings $\mathbf{A}$, is an indicator of its "closeness to linear", or the level of its nonlinear distortion. The deviation can be measured in various ways. The MSE is adopted here, as it greatly facilitates subsequent analysis. Consequently, the "closeness to linear" of $\hat{\mathcal{F}} = \mathcal{G}^{-1}$ can be measured by the MSE between $\mathcal{G}^{-1}$ and $\mathbf{A}^*$. We denote this measure by $R_{MSE}(\theta)$, where θ denotes the set of unknown parameters in the nonlinear ICA system. Let $\mathbf{x}^* = (x_1^*, \cdots, x_n^*)^T$ be the output of the affine transformation from $\mathbf{y}$ by $\mathbf{A}^*$. Let $\tilde{\mathbf{y}} = [\mathbf{y}; 1]$. $R_{MSE}(\theta)$ can then be written as the MSE between x_i and x_i^*:

$$\begin{aligned} R_{MSE}(\theta) &= E\{(\mathbf{x}-\mathbf{x}^*)^T(\mathbf{x}-\mathbf{x}^*)\}\text{, where} \\ \mathbf{x}^* &= \mathbf{A}^*\tilde{\mathbf{y}}, \text{ and } \mathbf{A}^* = \arg_{\mathbf{A}} \min E\{(\mathbf{x}-\mathbf{A}\mathbf{y})^T(\mathbf{x}-\mathbf{A}\mathbf{y})\}. \end{aligned} \tag{2}$$

Here $\mathbf{A}^*$ is a $n \times (n+1)$ matrix.[4] Figure 1 shows the separation system $\mathcal{G}$ together with the generation process of R_{MSE}.

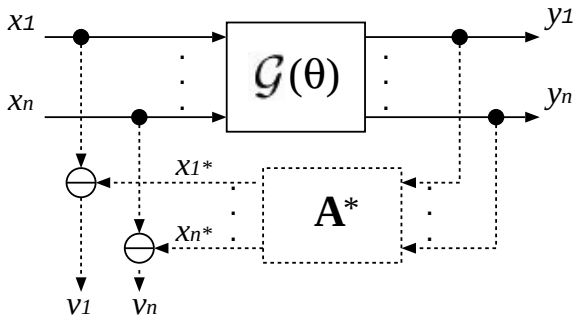

Figure 1: The separation system $\mathcal{G}$ (solid line) and the generation of the regularization term R_{MSE} (dashed line). $R_{MSE} = \sum_{i=1}^{n} v_i^2$, where $v_i = x_i - x_i^*$.

With R_{MSE} measuring the level of nonlinear distortion, nonlinear ICA with MND can be formulated as the following constrained optimization problem. It aims to minimize the mutual information between outputs, that is, $I(\mathbf{y})$, subject to $R_{MSE}(\theta) \le t$, where t is a pre-assigned parameter. The Lagrangian for this optimization problem is $L(\theta, \lambda) = I(\mathbf{y}) + \lambda[R_{MSE}(\theta) - t]$ with $\lambda \ge 0$. To find θ, we need to minimize

$$J = I(\mathbf{y}) + \lambda R_{MSE}(\theta). \tag{3}$$

The non-negative constant λ depends on the pre-assigned parameter t.

Another advantage of the MND principle is that it tends to make the mapping $\mathcal{G}$ invertible. In the general nonlinear ICA problem, it is assumed that both $\mathcal{F}$ and $\mathcal{G}$ are invertible. But in practice

4. If $E(\mathbf{y}) = E(\mathbf{x}) = \mathbf{0}$, $\mathbf{x}^*$ can be obtained as $\mathbf{x}^* = \mathbf{A}^*\mathbf{y}$ instead, and here $\mathbf{A}^*$ is a $n \times n$ matrix.

it is not easy to guarantee the invertibility of the mapping provided by a flexible nonlinear function approximator, like the MLP. MND pushes $\mathcal{G}$ to be close to a linear invertible transformation. Hence when nonlinearity in $\mathcal{F}$ is not too strong, MND helps to guarantee the invertibility of the nonlinear ICA separation system $\mathcal{G}$.

2.2.1 SIMPLIFICATION OF R_{MSE}

R_{MSE}, given in Eq. 2, can be further simplified. According to Eq. 2, the derivative of R_{MSE} w.r.t. $\mathbf{A}^*$ is $\frac{\partial R_{MSE}}{\partial \mathbf{A}^*} = -2E\{(\mathbf{x}-\mathbf{A}^*\tilde{\mathbf{y}})\tilde{\mathbf{y}}^T\}$. Setting the derivative to $\mathbf{0}$ gives $E\{(\mathbf{x}-\mathbf{A}^*\tilde{\mathbf{y}})\tilde{\mathbf{y}}^T\} = \mathbf{0}$, which implies

$$\mathbf{A}^* = E\{\mathbf{x}\tilde{\mathbf{y}}^T\}[E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\}]^{-1}. \tag{4}$$

We can see that due to the adoption of the MSE, $\mathbf{A}^*$ can be obtained in closed form. This greatly simplifies the derivation of learning rules.

Due to Eq. 4, we have $E\{\mathbf{A}^*\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\mathbf{A}^{*T}\} = E\{\mathbf{x}\tilde{\mathbf{y}}^T\}\mathbf{A}^{*T}$,and R_{MSE} then becomes

$$\begin{aligned} R_{MSE} &= \mathrm{Tr}\big(E\{(\mathbf{x}-\mathbf{A}^*\tilde{\mathbf{y}})(\mathbf{x}-\mathbf{A}^*\tilde{\mathbf{y}})^T\}\big) \\ &= \mathrm{Tr}\big(E\{\mathbf{x}\mathbf{x}^T - \mathbf{A}^*\tilde{\mathbf{y}}\mathbf{x}^T - \mathbf{x}\tilde{\mathbf{y}}^T\mathbf{A}^{*T} + \mathbf{A}^*\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\mathbf{A}^{*T}\}\big) \\ &= \mathrm{Tr}\big(E\{\mathbf{x}\mathbf{x}^T - \mathbf{A}^*\tilde{\mathbf{y}}\mathbf{x}^T - \mathbf{x}\tilde{\mathbf{y}}^T\mathbf{A}^{*T} + \mathbf{x}\tilde{\mathbf{y}}^T\mathbf{A}^{*T}\}\big) \\ &= -\mathrm{Tr}\big(E\{\mathbf{A}^*\tilde{\mathbf{y}}\mathbf{x}^T\}\big) + \mathrm{Tr}\big(E\{\mathbf{x}\mathbf{x}^T\}\big) \\ &= -\mathrm{Tr}\big(E\{\mathbf{x}\tilde{\mathbf{y}}^T\}[E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\}]^{-1}E\{\tilde{\mathbf{y}}\mathbf{x}^T\}\big) + \text{const.} \end{aligned} \tag{5}$$

Since y_i are independent from each other, they are uncorrelated. We can also easily make y_i zero-mean. Consequently, $E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\} = \mathrm{diag}\{E(y_1^2), E(y_2^2), ..., E(y_n^2), 1\}$, and R_{MSE} becomes

$$\begin{aligned} R_{MSE} &= -\mathrm{Tr}\big(E\{\mathbf{x}\tilde{\mathbf{y}}^T\} \cdot [\mathrm{diag}\{E(y_1^2), ..., E(y_n^2), 1\}]^{-1} \cdot E\{\tilde{\mathbf{y}}\mathbf{x}^T\}\big) + \text{const} \\ &= -\sum_{j=1}^{n}\sum_{i=1}^{n} \frac{E^2(x_j y_i)}{E(y_i^2)} + \text{const.} \end{aligned} \tag{6}$$

R_{MSE} depends only on the inputs and the outputs of the nonlinear ICA system $\mathcal{G}(\theta)$. Given a form for $\mathcal{G}$, the learning rule for nonlinear ICA with MND is derived by minimizing Eq. 3. Note that R_{MSE}, given in Eq. 2, is inconsistent with certain scaling properties of the observations $\mathbf{x}$. To avoid this, one needs to normalize the variance of the observations x_i through preprocessing, if necessary.

2.2.2 DETERMINATION OF THE REGULARIZATION PARAMETER λ

We suggest initializing λ with a large value λ_0 at the beginning of training and decreasing it to a small constant λ_c during the learning process. A large value for λ at the beginning reduces the possibility of getting into unwanted solutions, which may be non-trivial transformations of the original sources s_i or local optima. As training goes on, the influence of the regularization term is relaxed, and $\mathcal{G}$ gains more freedom. Hopefully, nonlinearity will be introduced, if necessary. The choice of λ_c depends on the level of nonlinear distortion in the mixing procedure. If the nonlinear distortion is considerable, we should use a very small value for λ_c to give the $\mathcal{G}$ network enough flexibility. In our experiments, we found that the separation performance of nonlinear ICA with MND is robust to the value of λ_c in a certain range. If the variance of the observations x_i is normalized, typical values used in our experiments are $\lambda_0 = 5$ and $\lambda_c = 0.01$.

2.3 Relation to Previous Works

The MISEP method has been reported to solve some nonlinear BSS problems successfully, including separating a real-life nonlinear image mixture (Almeida, 2005, 2003). Almeida (2003) claimed that the MLP itself may provide suitable regularization for nonlinear ICA. Some means were also used for regularization in the experiments there. For example, first, direct connections between inputs and output units were incorporated in the $\mathcal{G}$ network. Direct connections can quickly adapt the linear part of the mapping $\mathcal{G}$. Second, in Almeida (2005), the $\mathcal{G}$ network was initialized with an identity mapping, and during the first 100 epochs, it was constrained to be linear (by keeping the output weights of the hidden layer equal to zero). After that, the $\mathcal{G}$ network began learning the nonlinear distortion. $\mathcal{G}$ is therefore expected to be not far from linear, and MND is achieved to some extent. Accordingly, nice experimental results reported there could support the usefulness of the MND principle. We should mention that the MND principle formulated here, as well as the corresponding regularizer, provides a way to control the nonlinearity of the mixing mapping. It can be incorporated by any nonlinear ICA method, including MISEP. Later, we will investigate the effect of MND on nonlinear ICA solutions theoretically, and compare various related nonlinear ICA methods empirically.

In the kernel-based nonlinear BSS method (Harmeling et al., 2003), the data are first mapped to a high-dimensional kernel feature space. Next, a BSS method based on second order temporal decorrelation is performed. In this way a large number of components are extracted. When the nonlinearity in data generation is not too strong, the MND principle provides a way to select a subset of output components corresponding to the original sources. Assume that the outputs y_i are made zero-mean and of unit variance. From Eq. 6 we can see that one can select y_i with large $\sum_{j=1}^{n} \frac{E^2(x_j y_i)}{E(y_i^2)} = \sum_{j=1}^{n} E^2(x_j y_i) = \sum_{j=1}^{n} \mathrm{var}(x_j) \cdot \mathrm{corr}^2(x_j, y_i)$.

It is worth mention that the principle of least mean square error reconstruction has been used for training a class of neural networks and gives some interesting results (Xu, 1993). For one-layer networks with linear/nonlinear units, this principle leads to principal component analysis (PCA)/ICA. We should address that the reconstruction in their work is quite different from that discussed in Section 2.2 in this paper. In their work, the forward process and the reconstruction process share the same weights; in this paper, reconstructed signals are an affine mapping of the outputs, and parameters in the affine mapping are determined by minimizing the reconstruction error.

Smoothness provides a constraint to prevent a neural network from overfitting noisy data. It is also useful to ensure nonlinear ICA to result in nonlinear BSS (Almeida, 2003). In fact, the smoothness regularizer exploiting second-order derivatives (Tikhonov and Arsenin, 1977; Poggio et al., 1985) is also related to the MND principle, as shown below.

2.4 Local Minimal Nonlinear Distortion: Smoothness

R_{MSE}, given in Eq. 2, indicates the deviation of the mapping $\hat{\mathcal{F}}$ from the affine mapping which fits $\hat{\mathcal{F}}$ *globally* best. In contrast, one may enforce the *local* MND of the nonlinear mapping averaged at every point. We will show that this regularization actually leads to the smoothness regularizer exploiting second-order partial derivatives (Tikhonov and Arsenin, 1977; Poggio et al., 1985; Bishop, 1993).

For a one-dimensional sufficiently smooth function $g(\mathbf{x})$, we can use the second-order Taylor expansion to approximate its function value in the vicinity of $\mathbf{x}$ in terms of $g(\mathbf{x})$:

$$g(\mathbf{x}+\varepsilon) \approx g(\mathbf{x}) + \Big(\frac{\partial g}{\partial \mathbf{x}}\Big)^T \cdot \varepsilon + \frac{1}{2}\varepsilon^T \mathbf{H}_{\mathbf{x}} \varepsilon,$$

where ε is a small variation of $\mathbf{x}$ and $\mathbf{H}_{\mathbf{x}}$ denotes the Hessian matrix of g. Let $\bigtriangledown_{ij} = \frac{\partial^2 g}{\partial x_i \partial x_j}$. If we use the first-order Taylor expansion of g, which is a linear function, to approximate $g(\mathbf{x}+\varepsilon)$, the square error is

$$\begin{aligned} & \Big|\Big| g(\mathbf{x}+\varepsilon) - g(\mathbf{x}) - \Big(\frac{\partial g}{\partial \mathbf{x}}\Big)^T \cdot \varepsilon \Big|\Big|^2 \approx \frac{1}{4}\big|\big|\varepsilon^T \mathbf{H}_{\mathbf{x}} \varepsilon\big|\big|^2 = \frac{1}{4}\Big(\sum_{i,j=1}^{n} \bigtriangledown_{ij} \varepsilon_i \varepsilon_j\Big)^2 \\ \leq \; & \frac{1}{4}\Big(\sum_{i,j=1}^{n} \bigtriangledown_{ij}^2\Big)\Big(\sum_{i,j=1}^{n} \varepsilon_i^2 \varepsilon_j^2\Big) = \frac{1}{4}\Big(\sum_{i,j=1}^{n} \bigtriangledown_{ij}^2\Big)\Big(\sum_{i=1}^{n} \varepsilon_i^2\Big)^2 = \frac{1}{4}||\varepsilon||^4 \cdot \sum_{i,j=1}^{n} \bigtriangledown_{ij}^2. \end{aligned}$$

The above inequality holds due to the Cauchy's inequality. Now we can see that in order to achieve the local MND of g averaged in the domain of $\mathbf{x}$, we just need to minimize the following

$$\int_{\mathbb{D}_{\mathbf{x}}} \sum_{i,j=1}^{n} \bigtriangledown_{ij}^2 d\mathbf{x} = \int_{\mathbb{D}_{\mathbf{x}}} \Big(\sum_{i=1}^{n} \bigtriangledown_{ii}^2 + 2 \sum_{\substack{i,j=1,\\ i<j}}^{n} \bigtriangledown_{ij}^2\Big) d\mathbf{x}. \tag{7}$$

This regularizer has been used for achieving the smoothness constraint (see, e.g., Grimson 1982 for its application in computer vision). When the mapping is vector-valued, we need to apply the above regularizer to each component of the mapping.

Originally we intended to do regularization on the mixing mapping $\hat{\mathcal{F}}$, but it is difficult to do since it is hard to evaluate $\frac{\partial^2 x_l}{\partial y_i \partial y_j}$. Instead, we do regularization on $\mathcal{G}$, the inverse of $\hat{\mathcal{F}}$. The regularization term in Eq. 3 then becomes

$$R_{local}(\theta) = \int_{\mathbb{D}_{\mathbf{x}}} \sum_{l=1}^{n} \sum_{i=1}^{n} \sum_{j=1}^{n} \Big(\frac{\partial^2 y_l}{\partial x_i \partial x_j}\Big)^2 d\mathbf{x} = \int_{\mathbb{D}_{\mathbf{x}}} \sum_{i=1}^{n} \sum_{j=1}^{n} P_{ij} d\mathbf{x}, \tag{8}$$

where $P_{ij} \triangleq \sum_{l=1}^{n} \Big(\frac{\partial^2 y_l}{\partial x_i \partial x_j}\Big)^2$. Nonlinear ICA with a smooth de-mixing mapping can be achieved by minimizing the mutual information between y_i, with R_{local}, given by Eq. 8, as the regularization term. There are totally $\frac{n^2(n+1)}{2}$ different terms $\Big(\frac{\partial^2 y_l}{\partial x_i \partial x_j}\Big)^2$ in the integrand of R_{local}. For simplicity and computational reasons, sometimes one may drop the cross derivatives in Eq. 8, that is, $\Big(\frac{\partial^2 y_l}{\partial x_i \partial x_j}\Big)^2$ with $i \neq j$, and consequently obtain the curvature-driven smoothing regularizer proposed in Bishop (1993), with the number of different terms in the integrand being n^2.

3. Incorporation of MND in Different Nonlinear ICA Methods

Now we should choose a model for the nonlinear ICA separation system $\mathcal{G}(\theta)$ and give the learning rule for nonlinear ICA with MND as well as nonlinear ICA with the smoothness constraint for $\mathcal{G}$. Two nonlinear ICA methods are considered here. They are MISEP (Almeida, 2003) and nonlinear ICA based on kernels (Zhang and Chan, 2007a).

3.1 MISEP with MND

Before incorporating MND into the MISEP method (Almeida, 2003) for nonlinear ICA, we give an overview of this method.

3.1.1 MISEP FOR NONLINEAR ICA

MISEP adopts the MLP to model the separation function $\mathcal{G}$ in the nonlinear ICA problem. Figure 2 shows the structure used in this method. This method extends the original Infomax method for linear ICA (Bell and Sejnowski, 1995) in two aspects. First, the separation system is a nonlinear transformation, which is modeled by the MLP. Second, the nonlinearities ψ_i are not fixed in advance, but tuned by the Infomax principle, together with $\mathcal{G}$.

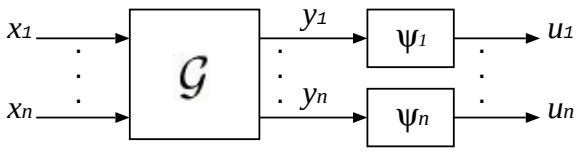

Figure 2: The network structure used in Infomax and MISEP. $\mathcal{G}$ is the separation system, and ψ_i are the nonlinearities applied to the separated signals. In MISEP, $\mathcal{G}$ is a nonlinear transformation, and both $\mathcal{G}$ and ψ_i are learned by the Infomax principle.

With the Infomax principle, parameters in $\mathcal{G}$ and ψ_i are learned by maximizing the joint entropy of the outputs of the structure in Figure 2, which can be written as $H(\mathbf{u}) = H(\mathbf{x}) + E\{\log|\det \mathbf{J}|\}$, where $\mathbf{J} = \frac{\partial \mathbf{u}}{\partial \mathbf{x}}$ is the Jacobian of the nonlinear transformation from $\mathbf{x}$ to $\mathbf{u}$. As $H(\mathbf{x})$ does not depend on the parameters in $\mathcal{G}$ and ψ_i, it can be considered as a constant. Maximizing $H(\mathbf{u})$ is thus equivalent to minimizing

$$J_1(\theta) = -E\{\log|\det \mathbf{J}|\}, \tag{9}$$

where θ denotes the set of unknown parameters. The learning rules for θ were derived by Almeida (2003), in a manner similar to the back-propagation algorithm.

The MLP adopted in this paper has linear output units and a single hidden layer. For the hidden units, the activation function $l(\cdot)$ may be the logistic sigmoid function, the arctan function, etc. Direct connections between the inputs and output units are also allowed. Let $\mathbf{a} = [a_1, ..., a_M]^T$ be the inputs to the hidden units, $\mathbf{z} = [z_1, ..., z_M]^T$ be the output of the hidden units, and $\mathbf{W}$ and $\mathbf{b}$ denote the weights and biases, respectively. We use superscripts to distinguish the locations of these parameters: $\mathbf{W}^{(d)}$ denotes the weights from the inputs to output units, $\mathbf{W}^{(1)}$ those from the inputs to the hidden layer, and $\mathbf{W}^{(2)}$ those from the hidden layer to the output units. $\mathbf{b}^{(1)}$ and $\mathbf{b}^{(2)}$ are the bias vectors in the hidden layer and in the output units, respectively. The output of the $\mathcal{G}$ network represented by this MLP takes the form:

$$\begin{aligned} \mathbf{y} &= \mathbf{W}^{(2)} \cdot \mathbf{z} + \mathbf{W}^{(d)}\mathbf{x} + \mathbf{b}^{(2)}, \text{ where} \\ z_i &= l(a_i), \text{ and } \mathbf{a} = \mathbf{W}^{(1)}\mathbf{x} + \mathbf{b}^{(1)}. \end{aligned} \tag{10}$$

3.1.2 MISEP WITH MND

For MISEP with MND, the objective function to be minimized is Eq. 9 regularized by R_{MSE} given in Eq. 6. The learning rule for θ to minimize Eq. 9 has been considered in Almeida (2003). Hence here we only give the gradient of R_{MSE} w.r.t. θ.

Using the chain rule, also noting Eq. 10, the gradient of $R_{MSE}(\theta)$ w.r.t. $\mathbf{W}^{(2)}$ can be obtained:

$$\frac{\partial R_{MSE}}{\partial \mathbf{W}^{(2)}} = E\Big\{\sum_{i=1}^{n} 2\Big[\frac{E^2(x_j y_i)}{E^2(y_i^2)} y_i - \frac{E(x_j y_i)}{E(y_i^2)} x_i\Big] \cdot \frac{\partial y_i}{\partial \mathbf{W}^{(2)}}\Big\} = E\{\mathbf{K} \cdot \mathbf{z}^T\}, \tag{11}$$

where $\mathbf{K} \triangleq [K_1, ..., K_n]^T$ with its i-th element being $K_i = 2\sum_j \left[\frac{E^2(x_j y_i)}{E^2(y_i^2)} y_i - \frac{E(x_j y_i)}{E(y_i^2)} x_j\right]$, and $\mathbf{z} = [z_1, z_2, ..., z_M]^T$ is the output of the hidden layer of the MLP. For the gradient of R_{MSE} w.r.t. $\mathbf{W}^{(1)}$, $\mathbf{W}^{(d)}$, $\mathbf{b}^{(2)}$, and $\mathbf{b}^{(1)}$, see Appendix A.

3.1.3 MISEP WITH SMOOTHNESS CONSTRAINT ON $\mathcal{G}$

The mapping provided by a MLP may not be smooth enough to make nonlinear ICA result in nonlinear BSS. So here we also implement MISEP with the smoothness constraint on $\mathcal{G}$. The objective function to be minimized becomes Eq. 9 regularized by R_{local} given in Eq. 8. P_{ij} appears in the expression of R_{local}. We first derive its gradient w.r.t. θ in a way analogous to that in Bishop (1993); see Appendix B.

In calculation of $\frac{\partial R_{local}}{\partial \theta}$, the integral in Eq. 8 is difficult to evaluate. Below are two ways to tackle this problem. A very simple way to approximate Eq. 7 is to use the average of the integrand over all observations instead of the integral (ignoring a constant scaling factor), just as Bishop (1993) does:

$$R_{local}^{(1)}(\theta) = E\Big\{\sum_{i=1}^{n}\sum_{j=1}^{n} P_{ij}\Big\}. \tag{12}$$

This approximation actually assumes that the distribution of $\mathbf{x}$ is close to uniform, as seen from below. Eq. 8 can be rewritten as

$$R_{local}(\theta) = \int_{\mathbb{D}_\mathbf{x}} p(\mathbf{x}) \cdot \frac{1}{p(\mathbf{x})} \sum_{i=1}^{n}\sum_{j=1}^{n} P_{ij} d\mathbf{x} = E\Big\{\frac{1}{p(\mathbf{x})}\sum_{i=1}^{n}\sum_{j=1}^{n} P_{ij}\Big\}. \tag{13}$$

If $p(\mathbf{x})$ is a constant in the domain $\mathbb{D}_\mathbf{x}$, Eq. 12 is equivalent to Eq. 13; otherwise, the approximation using Eq. 12 may result in large error, and we may need another way to approximate the integral in Eq. 8.

When the nonlinear ICA algorithm has run for a certain number of epochs, $\mathbf{u}$, the output of the system in Figure 2, has approximately independent components and is approximately uniformly distributed in $[0,1]^n$. This means that $p(\mathbf{u})$ is approximately 1. As $p(\mathbf{x}) = p(\mathbf{u}) \cdot |\det \mathbf{J}|$, one can see that $p(\mathbf{x})$ is approximately equal to $|\det \mathbf{J}|$. Consequently Eq. 13 becomes $R_{local}(\theta) \approx E\Big\{\frac{1}{|\det \mathbf{J}|}\sum_{i=1}^{n}\sum_{j=1}^{n} P_{ij}\Big\}$. The gradient of $R_{local}(\theta)$ is

$$\frac{\partial R_{local}(\theta)}{\partial \theta} \approx E\Big\{\frac{1}{|\det \mathbf{J}|}\sum_{i=1}^{n}\sum_{j=1}^{n} \frac{\partial P_{ij}}{\partial \theta}\Big\}. \tag{14}$$

As $\mathbf{J} = \frac{\partial \mathbf{u}}{\partial \mathbf{x}}$ can be easily calculated according to the network structure in Figure 2, Eq. 14 is also easy to evaluate, using Eq. 20 of Appendix B.

3.2 MND for Nonlinear ICA Based on Kernels

Nonlinear ICA based on kernels (Zhang and Chan, 2007a) exploits kernel methods to construct the separation system $\mathcal{G}$, and unknown parameters are adjusted by minimizing the mutual information between outputs y_i.[5] We have applied the MND principle and the smoothness regularizer to nonlinear ICA based on kernels; for details, see Zhang and Chan (2007a). Note that unlike the mapping provided by a MLP, which is comparatively smooth, the mapping constructed by kernel methods may not be smooth. So it is quite necessary to explicitly enforce the smoothness constraint for nonlinear ICA based on kernels.

4. Investigation of the Effect of MND

In this section we intend to explain why the MND principle, including the smoothness regularization, helps to alleviate the ill-posedness of nonlinear ICA from a mathematical viewpoint. There are two types of indeterminacies in solutions to nonlinear ICA, namely trivial indeterminacies and non-trivial indeterminacies. Trivial indeterminacies mean that the estimate of s_j produced by nonlinear ICA may be any nonlinear function of s_j; non-trivial indeterminacies mean that the outputs of nonlinear ICA, although mutually independent, are still a mixing of the original sources. Let us begin with the effect of MND on trivial indeterminacies.

4.1 For Trivial Indeterminacies

Let us assume in this section that, in the solutions of nonlinear ICA, each component depends only on one of the sources. Before presenting the main result, let us first give the following lemma.

Lemma 1 *Suppose that we are given the random vector* $\mathbf{d} = (d_1, d_2, \cdots, d_n)^T$. *Let* R_y *be the mean square error of reconstructing* $\mathbf{d}$ *from the variable* y *with the best-fitting linear transformation, that is,* $R_y = \min_{\mathbf{a}} E\{||\mathbf{d} - \mathbf{a} \cdot y||^2\}$, *where* $\mathbf{a} = (a_1, a_2, \cdots, a_n)^T$. *The variable* y *which gives the minimum* R_y *is the first non-centered principal component of* $\mathbf{d}$ *multiplied by a constant, and if* y *is constrained to be zero-mean, it is the first principal component of* $\mathbf{d}$ *multiplied by a constant.*

See Appendix C for a proof. Now let us consider a particular kind of nonlinear mixtures, in which each observed nonlinear mixture x_i is assumed to be generated by

$$x_i = f_{i1}(s_1) + f_{i2}(s_2) + \cdots + f_{in}(s_n), \tag{15}$$

where f_{ij} are invertible functions. We call such nonlinear mixtures distorted source (DS) mixtures, since each observation is a linear mixture of nonlinearly distorted sources. For this nonlinear mixing model, we have the following theorem on the effect of MND on trivial indeterminacies in its nonlinear ICA solutions. Here the following assumptions are made:

A1: In the output of nonlinear ICA, each component depends only on one of the sources and is zero-mean.

A2: The nonlinear ICA system has enough flexibility to reach the minimum of the MND regularization term R_{MSE} defined by Eq. 2.

5. The difference between nonlinear ICA based on kernels discussed here and the kernel-based nonlinear BSS method by Harmeling et al. (2003) should be made clear. Both of them use kernels. However, the former produces statistically independent outputs, while the latter exploits the temporal structure of the sources for separation.

Theorem 1 *Suppose that each observed nonlinear mixture x_i is generated according to Eq. 15. Under assumptions A1 & A2, the estimate of s_j produced by nonlinear ICA with MND is the first principal component of $\mathbf{f}_{*j}(s_j) = [f_{1j}(s_j), \cdots, f_{nj}(s_j)]^T$, multiplied by a constant.*

See Appendix D for a proof. The DS mixing model Eq. 15 may be restrictive. Now let us consider the case where nonlinearity in $\mathcal{F}$ is mild such that $\mathcal{F}$ can be well approximated by its Maclaurin expansion of degree 3. Let

$$\nabla_{i,j} = \frac{\partial x_i}{\partial s_j}\Big|_{s_j=0}, \nabla_{i,jk} = \frac{\partial^2 x_i}{\partial s_j \partial s_k}\Big|_{s_j,s_k=0}, \text{ and } \nabla_{i,jkl} = \frac{\partial^3 x_i}{\partial s_j \partial s_k \partial s_l}\Big|_{s_j,s_k,s_l=0}.$$

The following theorem discusses the effect of MND on trivial indeterminacies of nonlinear ICA solutions in this case. In particular, it states that by incorporating MND into the nonlinear ICA system, trivial indeterminacies in nonlinear ICA solutions are overcome; it shows how the outputs of the nonlinear ICA system, as the estimate of the sources, are related to the original sources s_i and the mixing system $\mathcal{F}$.

Theorem 2 *Suppose that each component of the mixing mapping $\mathcal{F} = (f_1, \cdots, f_n)^T$ in Eq. 1 is generated by the following Maclaurin series of degree 3:*

$$x_i = f_i(\mathbf{s}) = f_i(\mathbf{0}) + \sum_j \nabla_{i,j} s_j + \frac{1}{2}\sum_{j,k} \nabla_{i,jk} \cdot s_j s_k + \frac{1}{6}\sum_{j,k,l} \nabla_{i,jkl} \cdot s_j s_k s_l,$$

where $E\{s_j\} = 0$ and $E\{s_j^2\} = 1$, for $j = 1, \cdots, n$. Let

$$D_{ij}(s_j) \triangleq \left(\nabla_{i,j} + \frac{1}{2}\sum_{k\neq j} \nabla_{i,jkk}\right) \cdot s_j + \frac{1}{2}\nabla_{i,jj} \cdot s_j^2 + \frac{1}{6}\nabla_{i,jjj} \cdot s_j^3.$$

And let $\tilde{D}_{ij}(s_j)$ be the centered version of $D_i(s_j)$, that is, $\tilde{D}_{ij}(s_j) = D_{ij}(s_j) - E_i\{D_{ij}(s_j)\}$. Under assumptions A1 & A2, the estimate of s_j produced by nonlinear ICA with MND is the first principal component of $\tilde{\mathbf{D}}_{*j}(s_j) = [\tilde{D}_{1j}(s_j), \cdots, \tilde{D}_{nj}(s_j),]^T$, multiplied by a constant.

See Appendix E for a proof. Under the condition that nonlinear distortion in the mixing mapping $\mathcal{F}$ is not strong, $\tilde{D}_{ij}(s_j)$ would not be far from linear. Moreover, if the nonlinear part of $\tilde{D}_{ij}(s_j)$ varies for different i, the estimate of s_j is expected to be closer to linear than $\tilde{D}_{ij}(s_j)$, because it is the first principal component (PC) of $\tilde{\mathbf{D}}_{*j}(s_j)$. To summarize, Theorems 1 and 2 show that trivial indeterminacies in nonlinear ICA solutions can be overcome by the MND principle; and when the mixing mapping is not strong, the nonlinear distortion in the nonlinear ICA outputs w.r.t. the original sources is weak.

4.1.1 REMARK

In the proof of Theorems 1 and 2, we have made use of the fact that mutual information is invariant to any component-wise strictly monotonic nonlinear transformation of the variables. Consequently, trivial transformations do not affect the first term in Eq. 3, and they can be determined by minimizing R_{MSE} only, as claimed in the theorems. However, in practical implementations of nonlinear ICA algorithms, one needs to estimate the densities of y_i or their variations. Due to estimation error, the

gradient of the mutual information $I(y_1,\cdots,y_n)$ may be sensitive to the distribution of y_i, or it may be slightly affected by trivial transformations. This may cause the results of Theorems 1 and 2 to be violated slightly.

Fortunately, this phenomenon can be avoided easily. To model the trivial transformations, we apply a separate nonlinear function approximator (such as a MLP) to each output of nonlinear ICA to generate the final nonlinear ICA result. These nonlinear function approximators are then learned by minimizing R_{MSE} (Eq. 6). This provides a way to tackle the trivial indeterminacies; after performing nonlinear ICA with any nonlinear ICA method, if we know that there only exist trivial indeterminacies, we can adopt the above technique to determine the trivial transformations.

4.2 For Non-Trivial Indeterminacies

Now let us investigate the effect of MND on non-trivial indeterminacies in nonlinear ICA solutions. Generally speaking, there exist an infinite number of ways in which non-trivial indeterminacies occur, and it is impossible to formulate all of them. Hyvärinen and Pajunen (1999) gave some families of non-trivial transformations preserving mutual independence.

4.2.1 A PARTICULAR CLASS OF NON-TRIVIAL INDETERMINACIES

For the convenience of analysis, here we consider the following manner to construct non-trivial transformations preserving mutual independence. First, using the Gaussianization technique (Chen and Gopinath, 2001), we transform each of the independent variables s_i to a standard Gaussian variable u_i with an strictly increasing function q_i, that is, $u_i = q_i(s_i)$. Clearly u_i are mutually independent. Second, we can apply an orthogonal transformation $\mathbf{U}$ to $\mathbf{u} = (u_1,\cdots,u_n)^T$. The components of $\mathbf{e} = \mathbf{U}\mathbf{u}$ are still jointly Gaussian and mutually independent.[6] Finally, let $\mathbf{y} = \mathbf{r}(\mathbf{e})$, where $\mathbf{r} = (r_1,\cdots,r_n)^T$ is a component-wise function with each r_i strictly increasing. Components of $\mathbf{y}$ are still mutually independent. That is, $\mathbf{y}$ *is always a solution to nonlinear ICA of the nonlinear mixture* $\mathbf{x} = \mathcal{F}(s)$. The procedure transforming $\mathbf{s}$ to $\mathbf{y}$ can be described as $\mathbf{r}\circ\mathbf{U}\circ\mathbf{q}$, as shown in Figure 3. When $\mathbf{U}$ is a permutation matrix, this transformation is trivial; otherwise it is not.

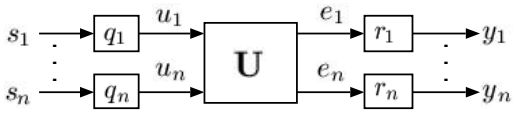

Figure 3: A non-trivial transformation from $\mathbf{s}$ to $\mathbf{y}$ preserving independence, that is, $\mathbf{r}\circ\mathbf{U}\circ\mathbf{q}$.

4.2.2 EFFECT OF MND

To see the effect of MND on $\mathbf{y}$ in Figure 3 (recall that $\mathbf{y}$ is a solution to nonlinear ICA of $\mathbf{x} = \mathcal{F}(\mathbf{s})$), we need to find how MND affects $\mathbf{U}$, as well as r_i. First, let us consider the case where the outputs y_i are Gaussian, meaning that each component of $\tilde{\mathbf{r}}$ is a linear mapping. Without loss of generality, we further assume that y_i are zero-mean and of unit variance, that is, $E\{\mathbf{y}\mathbf{y}^T\} = \mathbf{I}$. Consequently, r_i are identity mappings and $\mathbf{y} = \mathbf{e} = \mathbf{U}\mathbf{u}$. Assuming x_i are zero-mean, according to Eq. 5, We have $R_{MSE} = -\mathrm{Tr}\big(E\{\mathbf{x}\mathbf{y}^T\}E\{\mathbf{y}\mathbf{x}^T\}\big) + \mathrm{const} = -\mathrm{Tr}\big(E\{\mathbf{x}\mathbf{u}^T\}\mathbf{U}^T\mathbf{U}E\{\mathbf{u}\mathbf{x}^T\}\big) + \mathrm{const} = -\mathrm{Tr}\big(E\{\mathbf{x}\mathbf{u}^T\}E\{\mathbf{u}\mathbf{x}^T\}\big) + \mathrm{const}$. In this case R_{MSE} is not affected by $\mathbf{U}$, and the MND principle

6. $\mathbf{U}$ may depend on $||\mathbf{u}||$. In other words, $\mathbf{U}$ may be different for $\mathbf{u}$ of different norms.

could not help to avoid such non-trivial indeterminacies. We have empirically found that in general, when y_i are close to Gaussian, the separation performance tends to be bad. To make sure that the separation result is reliable, one should check the non-Gaussianity of y_i after the algorithm converges.

Next, suppose that that both s_l and y_j are non-Gaussian. r_i are then nonlinear. Consider the extreme case that the mixing mapping $\mathcal{F}$ is linear; in order to minimize R_{MSE} (Eq. 2), $\mathbf{U}$ in Figure 3 must be a permutation matrix. One can then image that if nonlinearity in $\mathcal{F}$ is weak enough, $\mathbf{U}$ in Figure 3 should be approximately a permutation matrix, meaning that the original sources $\mathbf{s}$ could be recovered.

However, if nonlinearity in $\mathcal{F}$ is strong, $\mathbf{U}$ may not be a permutation matrix, and non-trivial transformations from $\mathbf{s}$ to $\mathbf{y}$ may occur. This is actually quite natural. Consider the mixing mapping $\mathbf{x} = \mathcal{F}(\mathbf{s})$ which can be decomposed as a non-trivial transformation of $\mathbf{s}$ shown in Figure 3 (denote by $\mathbf{z}$ its output), followed by a nonlinear transformation $\mathbf{x} = \mathcal{F}_L(\mathbf{z})$ which is close enough to linear. In this situation, the output of nonlinear ICA with MND would be an estimate of $\mathbf{z}$, and if no additional knowledge of the mixing mapping is given, it is impossible to recover the original sources s_i.

Below we give an two-channel example to illustrate the relationship between R_{MSE} and the orthogonal matrix $\mathbf{U}$ when nonlinearity in $\mathbf{F}$ is strong. The two independent sources are a uniformly distributed signal and a super-Gaussian signal, and their scatter plot is given in Figure 9(a). The observations x_i, whose scatter plot is shown in Figure 4(a), are generated by applying a 2-3-2 MLP to the source signals. From this figure we can see that nonlinearity in the mixing procedure is comparatively strong. The orthogonal matrix $\mathbf{U}$ in Figure 3 is parameterized as $\mathbf{U} = [\cos(\alpha), -\sin(\alpha); \sin(\alpha), \cos(\alpha)]$. From Eq. 6 and Figure 3, one can see that R_{MSE} depends on α and r_i. For each value of α, r_i ($i = 1, 2$) are modelled by a 1-6-1 MLP and they are learned by minimizing R_{MSE}. Finally, $\min_{r_i} R_{MSE}$ is a function of α, with a period of 90 degrees, as plotted in Figure 4(b). In this example, α determined by the MND principle is about 11 degrees. It is not that close to zero, but it is still comparatively small and consequently the sources s_i are recovered approximately.

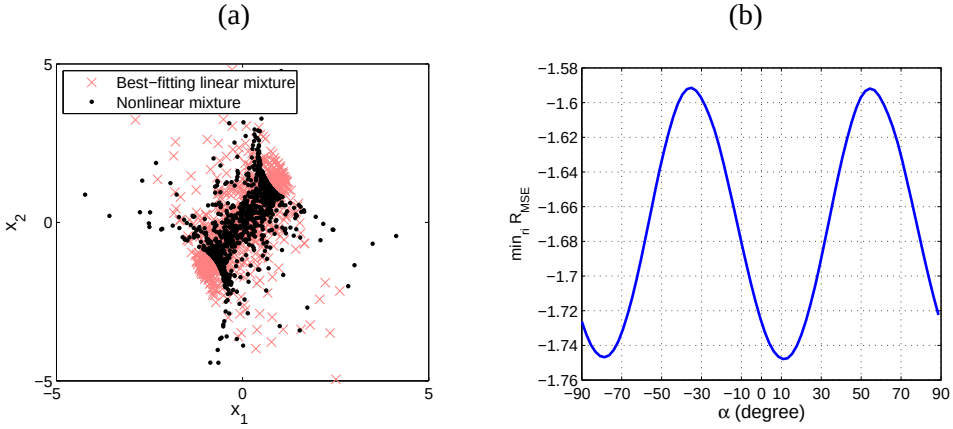

Figure 4: (a) Nonlinear mixtures of a sinusoid source signal and a super-Gaussian source signal (whose scatter plot is given in Figure 9.a) generated by a 2-3-2 MLP. x-mark points show linear mixtures of the sources which fit the nonlinear mixtures best. (b) $\min_{r_i} R_{MSE}$ as a function of α, whose minimum is achieved at $\alpha \approx 11$ degrees.

5. Simulations

In this section we investigate the performance of the proposed principle for solving nonlinear ICA using synthetic data. The experiments in Zhang and Chan (2007a) have empirically shown that both MND and the smoothness constraint are useful to ensure nonlinear ICA based on kernels to result in nonlinear BSS, when nonlinear distortion in the mixing procedure is not very strong. As its performance depends somewhat crucially on the choice of the kernel function, nonlinear ICA based on kernels is not used for comparison here. The following six methods (schemes) were used to separate various nonlinear mixtures:

1. MISEP: The MISEP method (Almeida, 2003) with parameters θ randomly initialized.[7] Note that in this method, the smoothness constraint has been implicitly incorporated to some extent, due to the property of the adopted MLP.

2. Linear init.: The MISEP method with $\mathcal{G}$ initialized as a linear mapping. This was achieved by adopting the regularization term Eq. 2 with $\lambda = 5$ (which is very large) in the first 50 epochs.

3. MND: The MISEP method incorporating MND, with R_{MSE}, the mean square error of the best linear reconstruction, as the regularization term (Section 2.2). The regularization parameter λ decayed from $\lambda_0 = 5$ to $\lambda_c = 0.01$ in the first 350 epochs. After that λ was fixed as λ_c.

4. Smooth (I): The MISEP method with the smoothness regularizer (Section 2.4) explicitly incorporated. λ decayed from 1 to 0.004 in the first 350 epochs.

5. Smooth (II): Same as Smooth (I), but λ was fixed to 0.007.

6. VB-NICA: Bayesian variational nonlinear ICA (Lappalainen and Honkela, 2000; Valpola, 2000).[8] PCA was used for initialization. After obtaining nonlinear factor analysis solutions using the package, we applied linear ICA (FastICA by Hyvärinen 1999 was used) to achieve nonlinear BSS.

In addition, in order to show the necessity of nonlinear ICA methods for separating nonlinear mixtures, linear ICA (FastICA was adopted) was also used to separate the nonlinear mixtures.

It was addressed in Section 2.3 that the incorporation of direct connections between inputs and output units in the MLP representing $\mathcal{G}$ implicitly and roughly implements the MND principle. To check that, in our experiments, the MLP without direct connections and that with direct connections were both adopted to represent $\mathcal{G}$, for comparison reasons. Like in Almeida (2003), the MLP has 20 arctan hidden units, 10 of which are connected to each of the output units of $\mathcal{G}$.

We use the signal to noise ratio (SNR) of y_i relative to s_i, denoted by $\mathrm{SNR}(y_i)$, to assess the separation performance of s_i. Besides, we apply a flexible nonlinear transformation h to y_i to minimize the MSE between $h(y_i)$ and s_i, and use the SNR of $h(y_i)$ relative to s_i as another performance measure. In this way possible trivial transformations between s_i and y_i are eliminated. In our experiments h was implemented by a two-layer MLP with eight hidden units with the hyperbolic tangent activation function and a linear output unit. This MLP was trained using the MATLAB neural network toolbox.

7. Source code is available at http : //www.lx.it.pt/ $\sim$ lbalmeida/ica/mitoolbox.html.
8. Source code is available at http : //www.cis.hut.fi/projects/bayes/. The following MATLAT commands were used to produce the ouput **y**: [nlfa_sources, net, params, status, fs] = nlfa(x, 'searchsources', 2, 'hidneurons', 15, 'iters', 2000); y = fastica(nlfa_sources.e, 'approach', 'symm', 'g', 'tanh');

Three kinds of nonlinear mixtures were investigated. They are distorted source (DS) mixtures, post-nonlinear (PNL) mixtures, and generic nonlinear (GN) mixtures which are generated by a MLP. Both super-Gaussian and sub-Gaussian sources were used.

5.1 For Distorted Source Mixtures

We first considered the DS mixtures defined in Eq. 15. Specifically, in the experiments the two-channel mixtures x_i were generated according to $x_1 = a_{11}s_1 + f_{12}(s_2)$, $x_2 = f_{21}(s_1) + a_{22}s_2$, where $a_{11} = a_{22} = 1$, and $f_{12}(s_i) = f_{21}(s_i) = 3\tanh(s_i/4) + 0.1s_i$. We used two super-Gaussian source signals, which are generated by $s_i = \frac{3}{5}n_i + \frac{2}{5}n_i^3$, where n_i are independent Gaussian signals. Each signal has 1000 samples. Figure 5 shows the scatter plot of the sources s_i and that of the observations x_i. To see the level of nonlinear distortion in the mixing transformation, we also give the scatter plot of the affine transformation of s_i which fits x_i the best.

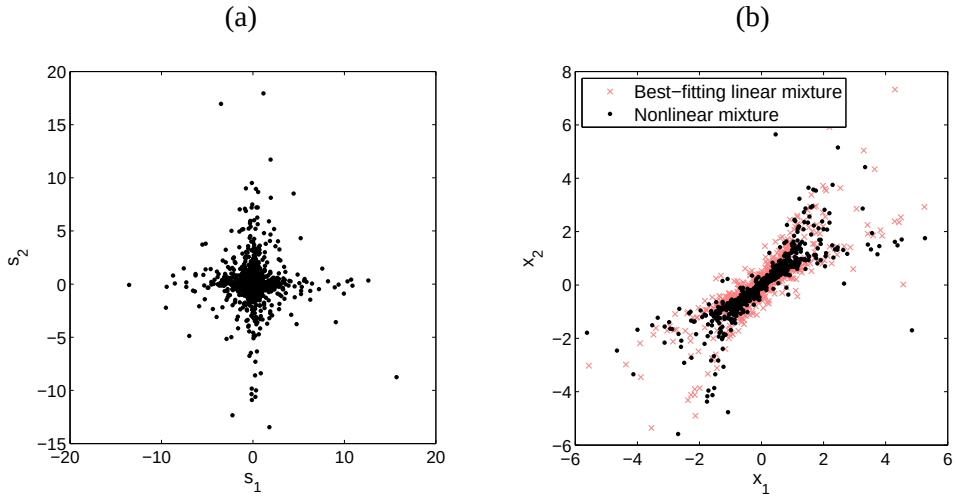

Figure 5: (a) Scatter plot of the sources s_i generating the DS mixtures. (b) Scatter plot of the DS mixtures x_i. x-mark points are linear mixtures of s_i which fit x_i best.

To reduce the random effect, all methods were repeated for 40 runs, and in each run the MLP was randomly initialized. We found that the separated results in the two channels have a similar SNR, so for saving space, here we just give the SNR in the first channel. Figure 6 compares the boxplot of SNR(y_1) and SNR$(h(y_1))$ for different methods. In Figure 6 (a, b), the MLP has no direct connections between inputs and output units, while in (c, d) the MLP has direct connections. We can see that in this case the methods MND, Smooth(I), and Smooth(II) give very high SNR, and at the same time, produce fewest unwanted results. Moreover, the MLP with direct connections behaves better than that without direct connections. The performance of VB-NICA is not very good. The reason may be that this method does not take into account the very useful information that nonlinearity in the mixing mapping is not very strong. It should be noted that VB-NICA may not exhibit its potential powerfulness in the experiments, since the source number is given and no noise is considered.

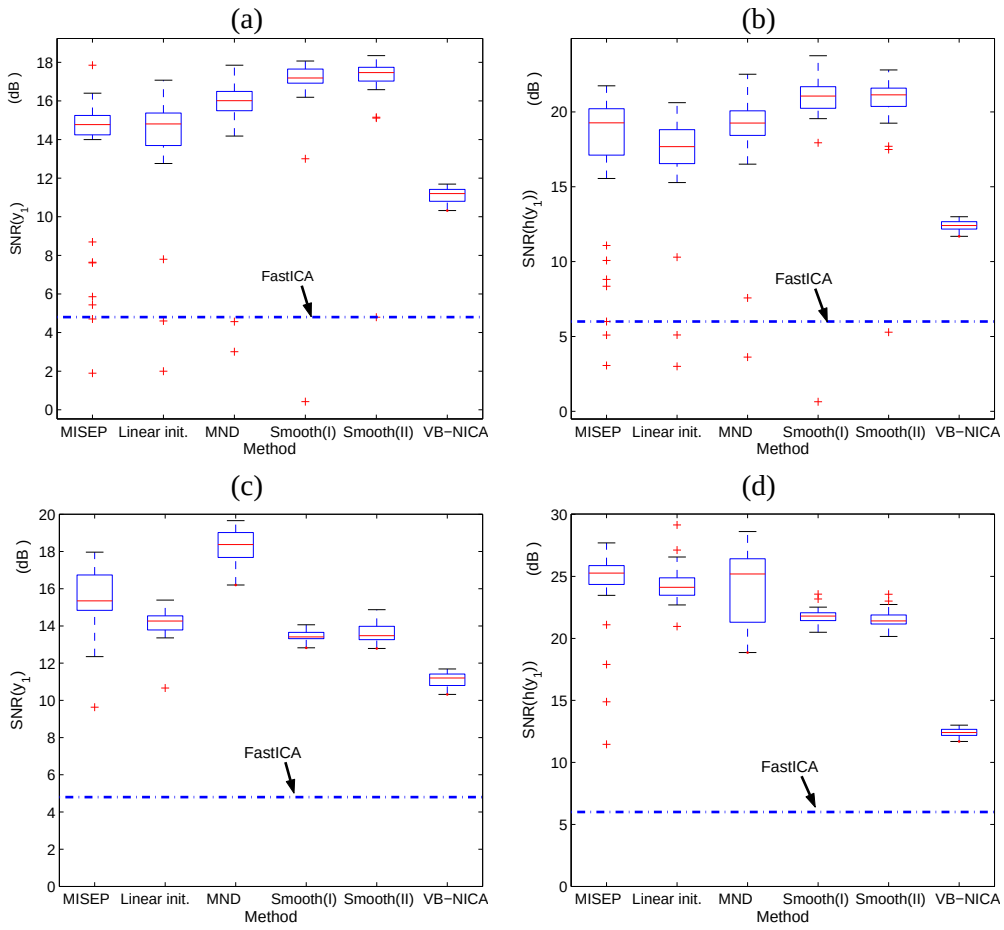

Figure 6: Boxplot of the SNR of separating the DS mixtures by the MLP without or with direct connections between inputs and output units. Top: Without direct connections. Bottom: With direct connections. (a, c) SNR(y_1). (b, d) SNR$(h(y_1))$.

5.2 For Post-Nonlinear Mixtures

The second experiment is to separate PNL mixtures. We used two sub-Gaussian source signals, which are a uniformly distributed white signal and a sinusoid waveform. The sources were first mixed with the mixing matrix $\mathbf{A} =$ [-0.2261, -0.1189; -0.1706, -0.2836], producing linear mixtures $\mathbf{z}$. The observations were then generated as $x_1 = z_1/2.5 + \tanh(3z_1)$ and $x_2 = z_2 + z_2^3/1.5$. Figure 7 shows the scatter plot of the sources and that of the PNL mixtures (after standardization). Figure 8 gives the separation performance of s_1 by various methods.[9] In this case, the proposed nonlinear ICA with MND (labelled by MND) also gives almost the best results; especially for the MLP without direct connections, the result of nonlinear ICA with MND is clearly the best. Again, the MLP with direct connections produces better results. Moreover, one can see that compared to the DS

9. If we use the PNL mixing model (Taleb and Jutten, 1999) to separate such mixtures, theoretically the sources could be well recovered. But in this paper we assume that the form of the mixing procedure is unknown, and treat it as a general nonlinear ICA problem.

mixtures in Section 5.1, the PNL mixtures considered here are comparatively hard to be separated by the MLP structure.

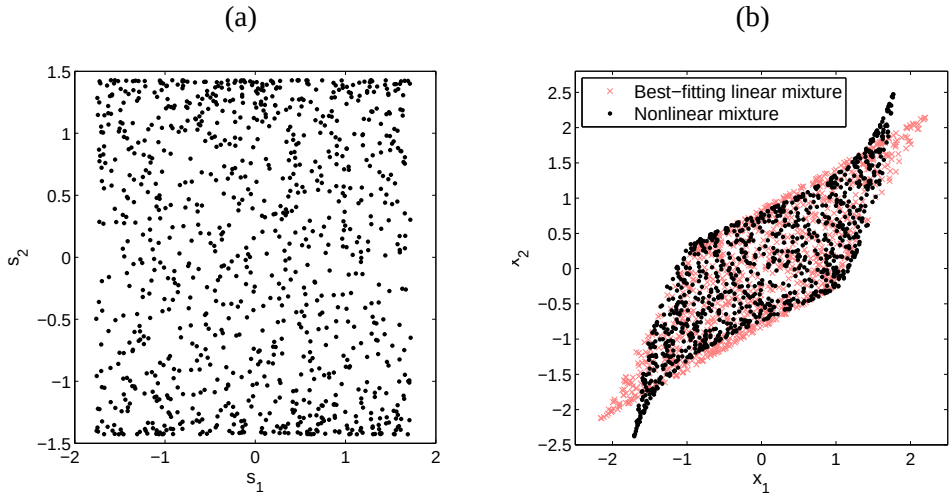

Figure 7: (a) Scatter plot of the sources s_i generating PNL mixtures. (b) Scatter plot of the PNL mixtures x_i.

5.3 For Generic Nonlinear Mixtures

We used a 2-2-2 MLP to generate nonlinear mixtures from sources. Hidden units have the arctan activation function. The weights between the input layer and the hidden layer are random numbers between -1 and 1. They are not large such that the mixing mapping is invertible and the nonlinear distortion produced by the MLP would not be very strong. The sources used here were the first source in Experiment 1 (super-Gaussian) and the second one in Experiment 2 (sub-Gaussian). Figure 9 shows the scatter plot of the sources and that of the GN mixtures. The performance of various methods for separating such mixtures is given in Figures 10. Apparently nonlinear ICA with MND gives the best separation results in this case.

Summed over all the three cases discussed above, we can see that MISEP with MND produces promising results for the general nonlinear ICA problem, provided that nonlinearity in the mixing mapping is not very strong. Specifically, it gives the fewest unwanted solutions, and its separation performance is very good. Moreover, the MLP with direct connections usually performs better than that without direct connections, but we also found that in some cases it got stuck into unwanted solutions more easily.

5.4 On Trivial Indeterminacies

In Section 4.1 we have discussed the effect of the MND principle on trivial indeterminacies of nonlinear ICA solutions. In particular, Theorem 1 states that for DS mixtures, if there are only trivial indeterminacies, each output of nonlinear ICA with MND is the PC of the contributions of the corresponding source to all mixtures. Now let us illustrate this with the help of the DS mixtures used in Section 5.1.

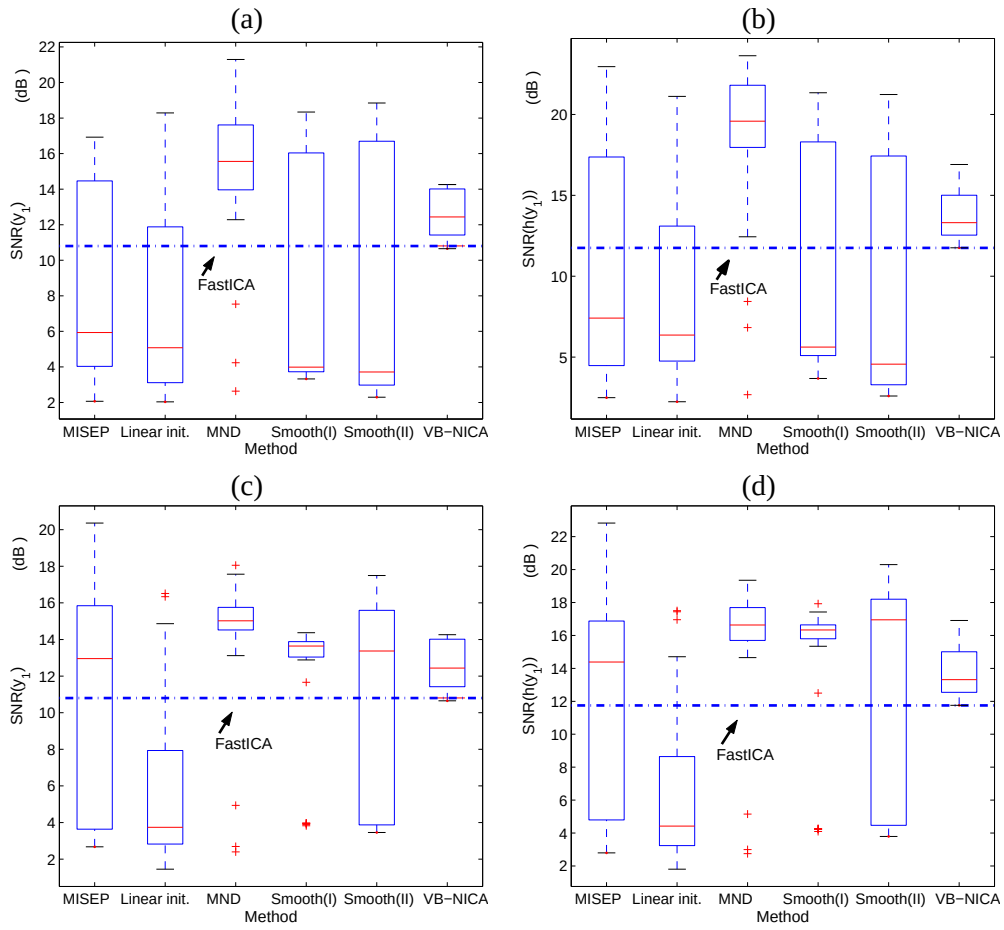

Figure 8: Boxplot of the SNR of separating the PNL mixtures by the MLP without or with direct connections between inputs and output units. Top: Without direct connections. Bottom: With direct connections. (a, c) SNR(y_1). (b, d) SNR$(h(y_1))$.

Figure 11 shows the relationship between y_i obtained by MISEP with MND in one run and the PC of $\mathbf{f}_{*i}(s_i) = [f_{1i}(s_i), f_{2i}(s_i)]^T$. We can see that each y_i is actually not very close to the corresponding PC, which may be caused by two reasons. First, there may exist some weak non-trivial transformation in the solution, as seen from the points close to the origin in Figure 11(b); y_2 is not solely dependent on s_2, but also slightly affected by s_1. The other reason is the error in estimating the density of y_i or its variation involved in the MISEP method, as explained in Section 4.1.1. We use the method proposed there to avoid the effect of the estimation error: a 1-8-1 MLP, denoted by τ_i, is applied to each y_i, and $\tau_i(y_i)$ is taken as the final nonlinear ICA output. Each τ_i is learned by minimizing R_{MSE} (Eq. 6). The resulting $\tau_i(y_i)$ is almost identical to the corresponding PC of $\mathbf{f}_{*i}(s_i)$, as seen from Figure 12. This has confirmed Theorem 1 and the validity of the method for tackling trivial indeterminacies proposed in Section 4.1.1.

6. Application to Causality Discovery in the Hong Kong Stock Market

In this section we give a real-life application of nonlinear ICA with MND. Specifically, we use this method to discover linear causal relations among the daily returns of a set of stocks. The empirical results were ever reported in Zhang and Chan (2006), without much detail of the method.

6.1 Introduction

It is well known that financial assets are not independent of each other, and that there may be some relations among them. Such relations can be described in different ways. In risk management, correlations are used to describe them and help to construct portfolios. The business group, which is a collection of firms bound together in some formal and/or informal ways, focuses on ties between financial assets and has attracted a lot of interest (Khanna and Rivkin, 2006). But these descriptions cannot tell us the causal relations among the financial assets.

The return of a particular stock may be influenced by those of other stocks, for many reasons, such as the ownership relations and financial interlinkages (Khanna and Rivkin, 2006). According to the efficient market hypothesis, such influence should be reflected in the stock returns immediately. In this part we aim to discover the causal relations among selected stocks by analyzing their daily returns.[10]

Traditionally, causality discovery algorithms for continuous variables usually assume that the dependencies are of a linear form and that the variables are Gaussian distributed (Pearl, 2000). Under the Gaussianity assumption, only the correlation structure of variables is considered and all higher-order information is neglected. As a consequence, one obtains some possible causal dia-

10. In other words, here we aim to find the "instantaneous" causality in the stock market. In contrast, Granger causality (Granger, 1980) analysis has become an important tool to find the "lagged" causality between time series. A time series x_1 "Granger causes" another series x_2 if by incorporating the past history of x_1 can improve a prediction of x_2 over a prediction based only on the history of x_2 alone. The efficient market hypothesis implies no significant Granger causality between stock returns. In fact, we have applied the approach by Reale and Tunnicliffe Wilson (2001) and partial directed coherence (Baccala and Sameshima, 2001) to find the Granger causality among the selected stocks, and very few Granger causal relations were found.

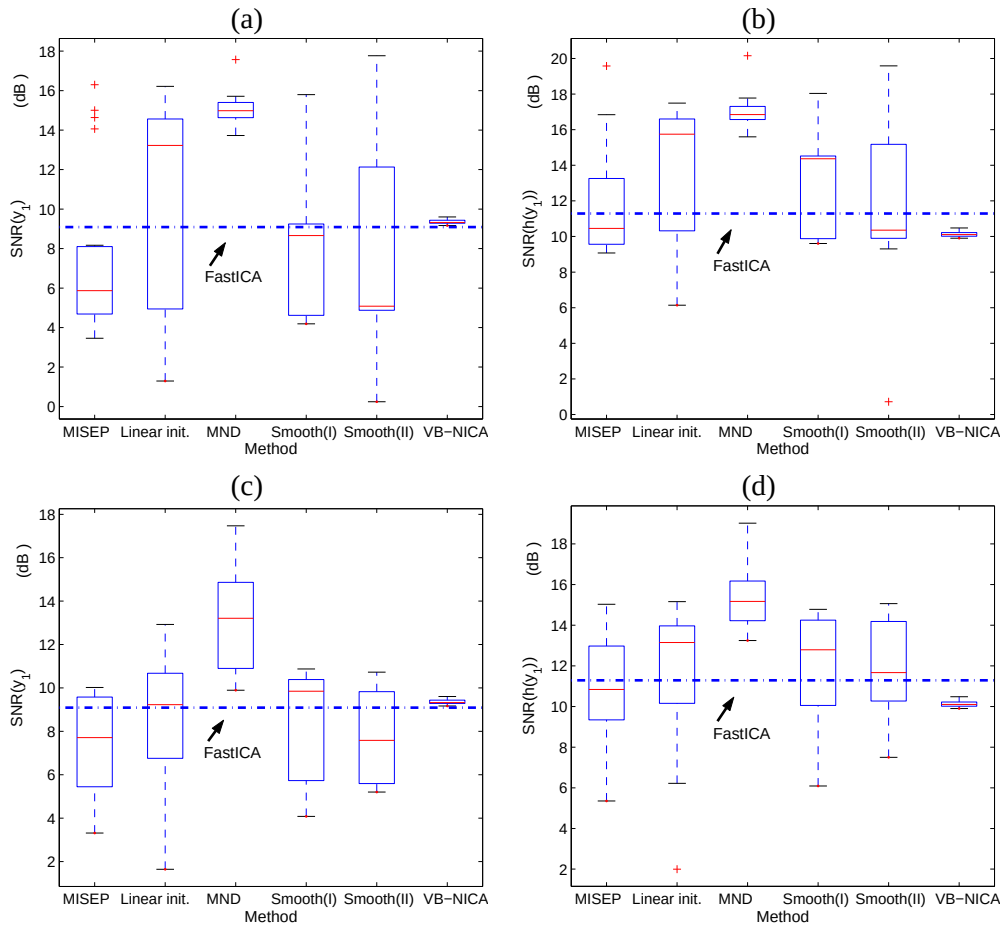

Figure 10: Boxplot of the SNR of separating the GN mixtures by the MLP without or with direct connections between inputs and output units. Top: Without direct connections. Bottom: With direct connections. (a, c) SNR(y_1). (b, d) SNR$(h(y_1))$.

grams which are equivalent in their correlation structure, and cannot find the true causal directions. Recently, it has been shown that the non-Gaussianity distribution of the variables allows us to distinguish the explanatory variable from the response variable, and consequently, to identify the full causal model (Dodge and Rousson, 2001; Shimizu et al., 2006).

In particular, in Shimizu et al. (2006) an elegant and efficient method was proposed for identifying the *linear, non-Gaussian, acyclic causal model* (abbreviated LiNGAM) by exploiting ICA. If the data are generated according to the LiNGAM model, theoretically, the ICA de-mixing matrix $\mathbf{W}$ can be permuted to lower triangularity. However, in practice, this may not hold, due to the finite sample effect, the existence of unobserved confounder variables (Pearl, 2000), or mild nonlinearity and noise that are often encountered in the data generation procedure. To tackle possible mild nonlinearity in the data generation procedure, we use nonlinear ICA with MND, instead of linear ICA, to separate the observed data. As the nonlinear distortion is mild, it can be neglected and consequently, linear causal relations among the observed data can be discovered.

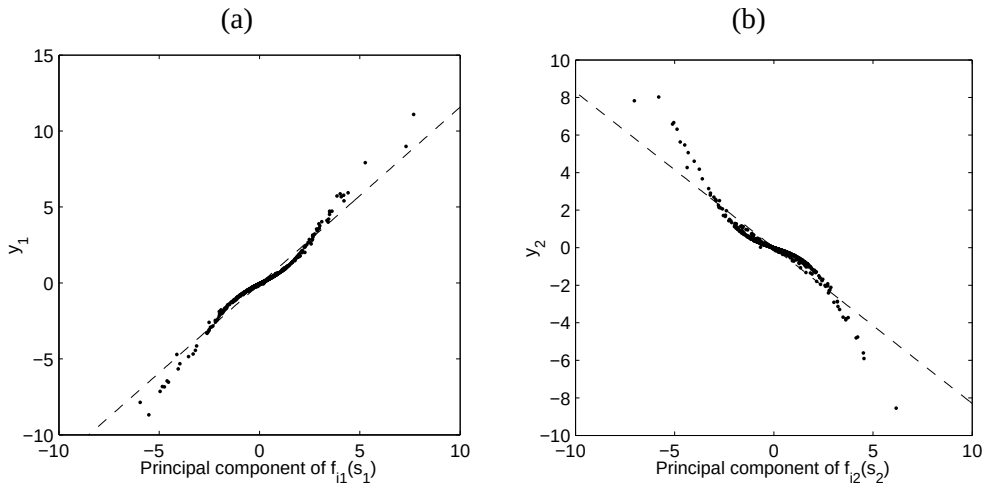

Figure 11: (a) y_1 recovered by MISEP with MND versus the PC of the contributions of s_1 to the DS mixtures used in Section 5.1. The SNR of y_1 w.r.t. the PC of the contributions of s_1 is 13.48dB. The dashed line is the linear function fitting the points best. (b) y_2 versus the PC of the contributions of s_2 to the DS mixtures. The SNR is 9.12dB.

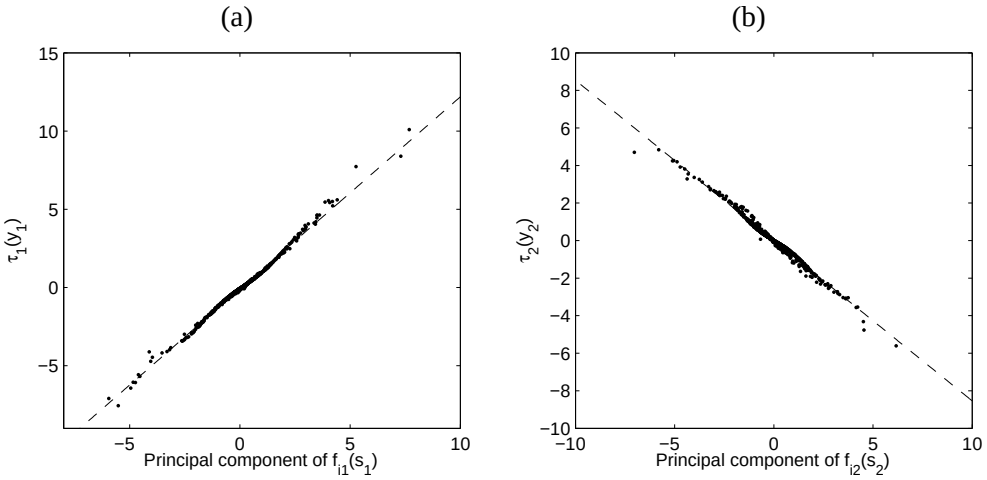

Figure 12: (a) $\tau_1(y_1)$ versus the PC of the contributions of s_1 to x_i. τ_1 is modelled by a 1-8-1 MLP and is learned by minimizing R_{MSE} (Eq. 6). The SNR is 20.99dB. (b) $\tau_2(y_2)$ versus the PC of the contributions of s_2 to x_i. The SNR is 18.64dB.

6.2 Causality Discovery by ICA: Basic Idea

The LiNGAM model assumes that the generation procedure of the observed data follows the following properties (Shimizu et al., 2006). *1.* It is recursive. This is, the observed variables x_i, $i = 1,...,n$, can be arranged in a causal order, such that no later variable causes any earlier variable. This causal order is denoted by $k(i)$. *2.* The value of x_i is a linear function of the values assigned to the earlier variables, plus a disturbance term e_i and an optional constant c_i: $x_i = \sum_{k(j)<k(i)} b_{ij} x_j + e_i + c_i$. *3.*

e_i are independent continuous-valued variables with non-Gaussian distributions (or at most one is Gaussian).

After centering of the variables, the causal relations among x_i can be written in the matrix form: $\mathbf{x} = \mathbf{B}\mathbf{x} + \mathbf{e}$, where $\mathbf{x} = (x_1, ..., x_n)^T$, $\mathbf{e} = (e_1, ..., e_n)^T$, and the matrix $\mathbf{B}$ can be permuted (by simultaneous equal row and column permutations) to strict lower triangularity if one knows the causal order $k(i)$ of x_i. We then have $\mathbf{e} = \mathbf{W}\mathbf{x}$, where $\mathbf{W} = \mathbf{I} - \mathbf{B}$. This is exactly the ICA separation procedure (Hyvärinen et al., 2001). Therefore, the LiNGAM model can be estimated by ICA. We can permute the rows of the ICA de-mixing matrix $\mathbf{W}$ such that it produces a matrix $\widetilde{\mathbf{W}}$ without any zero on its diagonal (or in practice, $\sum_i |\widetilde{\mathbf{W}}_{ii}|$ is maximized). Dividing each row of $\widetilde{\mathbf{W}}$ by the corresponding diagonal entry gives a new matrix $\widetilde{\mathbf{W}}'$ with all entries on its diagonal equal to 1. Finally, by applying equal row and column permutations on $\mathbf{B} = \mathbf{I} - \widetilde{\mathbf{W}}'$, we can find the matrix $\widetilde{\mathbf{B}}$ which is as close as possible to strictly lower triangularity. $\widetilde{\mathbf{B}}$ contains the causal relations of x_i. For details, see Shimizu et al. (2006).

6.3 With Nonlinear ICA with Minimal Nonlinear Distortion

We now consider a general case of the nonlinear distortion often encountered in the data generation procedure, provided that the nonlinear distortion is smooth and mild. We use the MLP structure described in Section 3.1.1, which is a linear transformation coupled with an ordinary MLP, as shown in Figure 13, to model the nonlinear transformation from the the observed variables x_i to the disturbance variables e_i.

According to Figure 13, we have $\mathbf{e} = \mathbf{W}\mathbf{x} + \mathbf{h}(\mathbf{x})$, and consequently $\mathbf{x} = (\mathbf{I} - \mathbf{W})\mathbf{x} - \mathbf{h}(\mathbf{x}) + \mathbf{e}$, where $\mathbf{h}(\mathbf{x})$ denotes the output of the MLP. As it is difficult to analyze the relations among x_i implied by the nonlinear transformation $\mathbf{h}(\mathbf{x})$, we expect that $\mathbf{h}(\mathbf{x})$ is weak such that its effect can be neglected. The *linear* causal relations among x_i can then be discovered by analyzing $\mathbf{W}$.

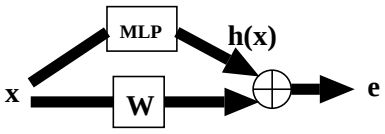

Figure 13: Structure used to model the transformation from the observed data x_i to independent disturbances e_i. $\mathbf{h}(\mathbf{x})$ accounts for nonlinear distortion if necessary.

In order to do causality discovery, the separation system in Figure 13 is expected to exhibit the following properties. *1*. The outputs e_i are mutually independent, since independence of e_i is a crucial assumption in LiNGAM. This can be achieved since nonlinear ICA always has solutions. *2*. The matrix $\mathbf{W}$ is sparse enough such that it can be permuted to lower triangularity. This can be enforced by incorporating the L_1 (Hyvärinen and Karthikesh, 2000) or smoothly clipped absolute deviation (SCAD) penalty (Fan and Li, 2001) on the entries of $\mathbf{W}$. *3*. The nonlinear mapping modeled by the MLP is weak enough such that we just care about the linear causal relations indicated by $\mathbf{W}$. To achieve that, we use MISEP with MND given in Section 3.1. In addition, we initialize the system with linear ICA results. That is, $\mathbf{W}$ is initialized by the linear ICA de-mixing matrix, and the initial values for weights in the MLP $\mathbf{h}(\mathbf{x})$ are very close to 0. The training process is terminated once the LiNGAM property holds for $\mathbf{W}$. After the algorithm terminates, $\frac{\text{var}(h_i(\mathbf{x}))}{\text{var}(e_i)}$ can be used to measure the level of nonlinear distortion in each channel, if needed.

6.4 Simulation Study

We examined the performance of the scheme discussed in Section 6.3 for identifying linear causal relations using simulated data. To make the nonlinear distortion in the data generation procedure weak, we used the structure in Figure 13 to generate the 8-dimensional observed data x_i from some independent and non-Gaussian variables e_i, that is, x_i are generated by a linear transformation coupled with a MLP.

The linear transformation in the data generation procedure was generated by $\mathbf{A} = (\mathbf{I} - \mathbf{B})^{-1}$. It satisfies the LiNGAM property since $\mathbf{B}$ was made strict lower triangular. The magnitude of non-zero entries of $\mathbf{B}$ is uniformly distributed between 0.05 and 0.5, and the sign is random. To examine if spurious causal relations would be caused, we also randomly selected 9 entries in the strict lower triangular part of $\mathbf{B}$ and set them to zero. The disturbance variables were obtained by passing independent Gaussian variables through power non-linearities with the exponent between 1.5 and 2. The variances of e_i were randomly chosen between 0.2 and 1. These settings are similar to those in the simulation studies by Shimizu et al. (2006). The sample size is 1000. The nonlinear part is a 8-10-8 MLP with the arctan activation function in the hidden layer. The weights from the inputs to the hidden layer are between -3 and 3, that is, they are comparatively large, while those from the hidden layer to the outputs are small, such that the nonlinear distortion is weak. The nonlinear distortion level in the generation procedure is measured by the ratio of the variance of the MLP output to that of the linear output. We considered two cases where the nonlinear distortion level is 0.01 and 0.03, respectively.

We used the scheme detailed in Section 6.3 to identify the linear causal relations among x_i. The SCAD penalty was used, and there are 10 arctan hidden units connected to each output of the MLP. We repeated the simulation for 100 trials. In each trial the maximum iteration number was set to 800. The results are given in Table 1 (numbers in parentheses are corresponding standard errors). The failure rate (the chance that LiNGAM does not hold for $\mathbf{W}$ within 800 iterations), the percentages of correctly identified non-zero edges, correctly identified large edges (with the magnitude larger than 0.2), and spurious edges in the successful cases, and the resulting nonlinear distortion level $\frac{\mathrm{var}(h_i(\mathbf{x}))}{\mathrm{var}(e_i)}$ in the separation system are reported. We can see that $\mathbf{W}$ almost always satisfies the LiNGAM property, and that most causal relations (especially large ones) are successfully identified. The setting $\lambda = 0.12$, meaning that MND is explicitly incorporated, gives better results than $\lambda = 0$ does, although the difference is not large. This is not surprising because even with $\lambda = 0$, nonlinear ICA with the separation structure of Figure 13 and with $\mathbf{W}$ initialized by linear ICA could achieve MND to some extent. However, when $\lambda = 0.12$, the nonlinear distortion in the separation system is much weaker, and we found that estimated values of the entries of $\mathbf{B}$ are closer to the true ones. The penalization parameter for SCAD, λ_{SCAD}, plays an important role. A larger λ_{SCAD} would make $\mathbf{W}$ satisfy the LiNGAM property more easily, but as a price, in the result more causal relations tend to disappear or be weaker.

For comparison, we also used linear ICA with the de-mixing matrix penalized by SCAD[11] for causality discovery. The result is reported in Table 2. Even when λ_{SCAD} is very large, which causes many causal relations to disappear, as seen from the table, there is still a high probability that the resulting de-mixing matrix fails to satisfy the LiNGAM property. These results show that for

11. The algorithm can be derived by maximizing the ICA likelihood penalized by the SCAD penalty on each entry of the de-mixing matrix. We used the natural gradient learning rule, with the score function adaptively estimated from the data.

Nonl. level in $\mathcal{F}$	Settings $(\lambda, \lambda_{SCAD})$	Fail. in 800 iter.	Edges identified	Large edges identified	Spurious edges	Nonl. level $\frac{\text{var}(h_i(\mathbf{x}))}{\text{var}(e_i)}$

the data whose generation procedure has weak nonlinear distortion and approximately satisfies the LiNGAM property, nonlinear ICA with MND, together with the SCAD penalty, is useful to identify their linear causal relations.

6.5 Empirical Results

The Hong Kong stock market has some structural features different from the US and UK markets (Ho et al., 2004). One typical feature is the concentration of market activities and equity ownership in relatively small group of stocks, which probably makes causal relations in the Hong Kong stock market more obvious.

6.5.1 DATA

Here we aim at discovering the causality network among 14 stocks selected from the Hong Kong stock market.[12] The selected 14 stocks are constituents of Hang Seng Index (HSI).[13] They are almost the largest companies of the Hong Kong stock market. We used the daily dividend/split adjusted closing prices from Jan. 4, 2000 to Jun. 17, 2005, obtained from the Yahoo finance database. For the few days when the stock price is not available, we used simple linear interpolation to estimate the price. Denoting the closing price of the ith stock on day t by P_{it}, the corresponding return is calculated by $x_{it} = \frac{P_{it} - P_{i,t-1}}{P_{i,t-1}}$. The observed data are $\mathbf{x}_t = (x_{1t}, ..., x_{14,t})^T$. Each return series contains 1331 samples.

Recently ICA has been exploited as a possible way to explain the driving forces for financial returns (Back, 1997; Kiviluoto and Oja, 1998; Chan and Cha, 2001). We conjecture that nonlinear ICA would be more suitable than linear ICA to serve this task, since it seems reasonable that the

12. For saving space, they are not listed here; see the legend in Figure 15.

13. The only exception is Hang Lung Development Co. Ltd (0010.hk), which was removed from HSI on Dec. 2, 2002.

ICA mixing model varies slightly for returns at different levels. So we use nonlinear ICA with MND to analyze the stock returns and to do causality discovery. However, we should be aware that it is probably very hard to discover causal relations among the selected stocks, since the financial data are somewhat non-stationary, the data generation mechanism is not clear, and there may be many confounder variables.

6.5.2 RESULTS

We first applied a standard ICA algorithm to perform ICA on the data $\mathbf{x}_t$. The natural gradient algorithm (Amari et al., 1996) with the score function adaptively estimated from data was adopted. We used the LiNGAM software[14] to permute $\mathbf{W}$ and obtain the matrix $\mathbf{B} = \mathbf{I} - \widetilde{\mathbf{W}}'$. $\mathbf{B}$ seems unlikely to be lower-triangular; in fact, the ratio of the sum of squares of its upper-triangular entries to that of all entries is 0.24, which is very large. We also exploited linear ICA with the de-mixing matrix penalized by SCAD to do causality discovery. It was found that the learned de-mixing matrix $\mathbf{W}$ does not follow LiNGAM for $\lambda_{SCAD} \leq 0.25$. The value 0.25 for λ_{SCAD} is so large that statistical independence between outputs is affected. (In fact, most correlations between outputs have a magnitude larger than 0.1 when $\lambda_{SCAD} = 0.25$.) We may conclude that the data do not satisfy the LiNGAM model.

We then adopted the method proposed in Section 6.3. The SCAD penalty was applied to entries of $\mathbf{W}$ with $\lambda_{SCAD} = 0.04$. The regularization parameter for nonlinear ICA with MND (Eqs. 11 and 16–19) was $\lambda = 0.14$. After 195 epochs, $\mathbf{W}$ satisfies the LiNGAM assumption and the training process is terminated. Figure 14 shows the scatter plot of each output e_i and its linear part, from which we can see that the nonlinear distortion is weak. Based on the learned $\mathbf{W}$, we found the linear causal relations among these stocks, as shown in Figure 15. This figure was plotted using the LiNGAM software.

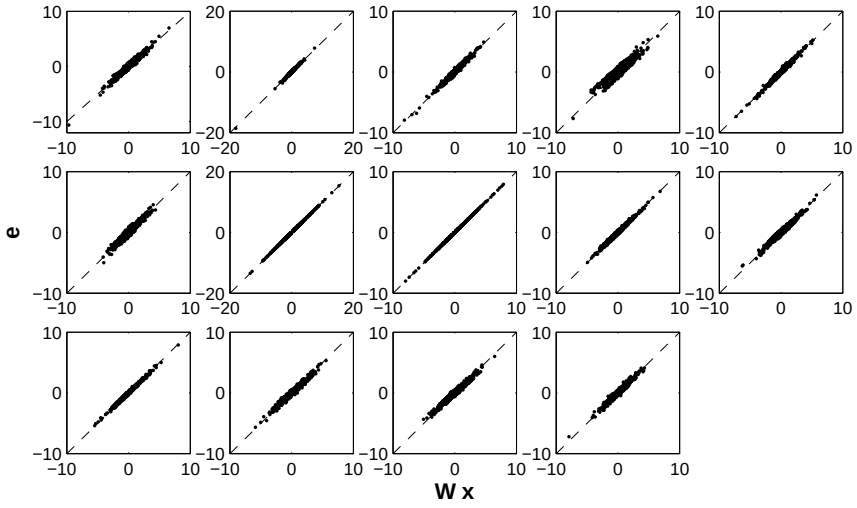

Figure 14: Scatter plot of each output of the system in Figure 13 and its linear part. The nonlinear distortion level $\frac{\mathrm{var}(h_i(\mathbf{x}))}{\mathrm{var}(e_i)}$ is 0.0485, 0.0145, 0.0287, 0.2075, 0.0180, 0.0753, 0, 0.0001, 0.0193, 0.0652, 0.0146, 0.0419, 0.0544, and 0.0492, respectively, for the 14 outputs e_i.

14. It is available at http : //www.cs.helsinki.fi/group/neuroinf/lingam/.

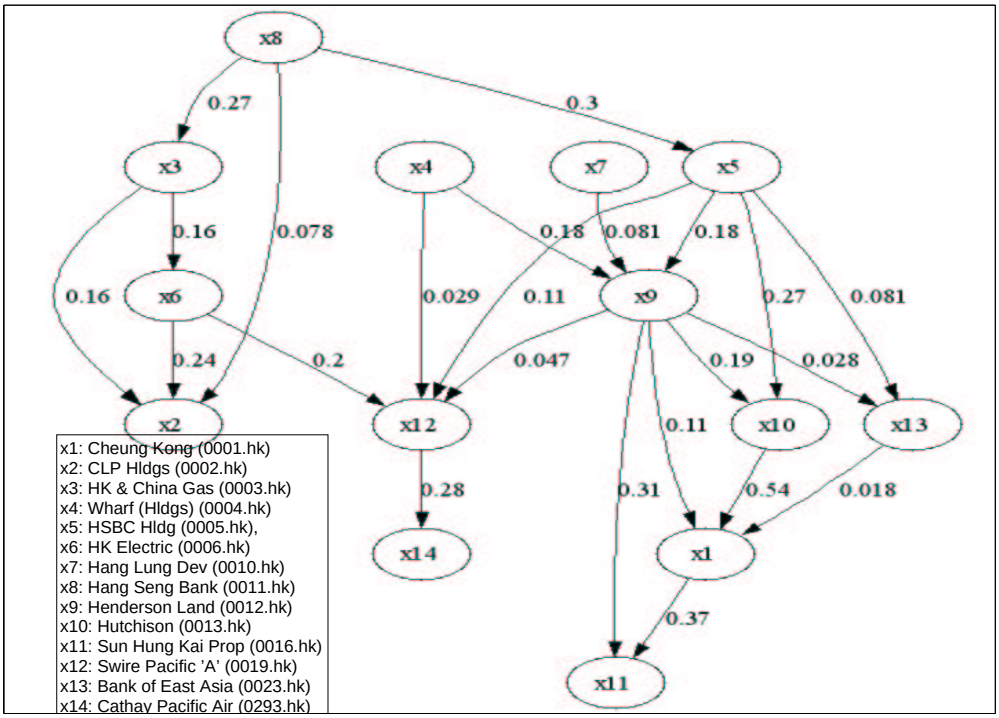

Figure 15: Causal diagram of the 14 stocks.

Figure 15 gives some interesting findings. *1*. Ownership relations tend to cause causal relations. If A is a holding company of B, there tends to be a causal relation from B to A. There are two significant relations $x_8 \to x_5$ and $x_{10} \to x_1$. In fact, x_5 owns some 60% of x_8, and x_1 holds about 50% of x_{10}. *2*. Stocks belonging to the same subindex tend to be connected together. For example, x_2, x_3, and x_6, which are linked together, are the only three constituents of Hang Seng Utilities Index. x_1, x_9, and x_{11} are constituents of Hang Seng Property Index. *3*. Large bank companies are the cause of many stocks. Here x_5 and x_8 are the two largest banks in Hong Kong. 4. Returns of stocks in Hang Seng Property Index tend to depend on many other stocks, while they hardly influence other stocks. Note that Here x_1, x_9, and x_{11} are in Hang Seng Property Index.

7. Conclusion

We have proposed the "minimal nonlinear distortion" principle to overcome the ill-posedness of the nonlinear ICA problem. With this principle, the nonlinear ICA solution whose estimated mixing system is close to linear would be preferred. This principle was implemented by a regularization technique that minimizes the mean square error of the best linear reconstruction of the observed mixtures. We explained how the proposed principle overcomes trivial and non-trivial indeterminacies in nonlinear ICA solutions. Experimental results on synthetic data in various situations showed that nonlinear ICA with minimal nonlinear distortion behaves very well and confirmed our theoretical claims. Since nonlinearity is usually encountered in practice and is not very strong in many cases, nonlinear ICA with minimal nonlinear distortion is expected to be capable of solving some real-life problems. Its successful application to causality discovery in the Hong Kong stock market illustrated the applicability of the method and the validity of the "minimal nonlinear distortion"

principle for some real problems. The result also supports the independent factor model in finance to some extent. Finally, it should be noted that solutions to nonlinear ICA or nonlinear BSS rely heavily on the prior information on the sources or the mixing mappings. "Minimal nonlinear distortion" is one type of such information for some problems. If more precise prior information, such as the form of the mixing mapping, the temporal structure of the sources, etc., is available, the separation result may be more meaningful.

Acknowledgments

Appendix A. Gradient of R_{MSE}

Let $\mathbf{H} = diag\{h'(a_1), h'(a_2), ..., h'(a_M)\}$, and $\mathbf{W}_j^{(2)}$ denote the j-th column of $\mathbf{W}^{(2)}$. We have

$$\begin{aligned}
\frac{\partial R_{MSE}(\theta)}{\partial \mathbf{W}^{(1)}} &= E\Big\{\sum_{i=1}^{n} K_i \cdot \frac{\partial y_i}{\partial \mathbf{W}^{(1)}}\Big\} = E\Big\{\sum_{i=1}^{n} K_i \cdot \Big[\sum_{j=1}^{M} \frac{\partial y_i}{\partial a_j} \cdot \frac{\partial a_j}{\partial \mathbf{W}^{(1)}}\Big]\Big\} \\
&= E\Big\{\sum_{j=1}^{M} \Big[\Big(\frac{\partial \mathbf{y}}{\partial a_j}\Big)^T \mathbf{K}\Big] \cdot \frac{\partial a_j}{\partial \mathbf{W}^{(1)}}\Big\} = E\Big\{\sum_{j=1}^{M} \big[h'(a_j) \cdot \mathbf{W}_j^{(2)T} \cdot \mathbf{K}\big] \cdot \frac{\partial a_j}{\partial \mathbf{W}^{(1)}}\Big\} \\
&= E\{\mathbf{H} \cdot \mathbf{W}^{(2)T} \cdot \mathbf{K} \cdot \mathbf{x}^T\}, \qquad (16) \\
\frac{\partial R_{MSE}(\theta)}{\partial \mathbf{W}^{(d)}} &= E\Big\{\sum_{i=1}^{n} K_i \cdot \frac{\partial y_i}{\partial \mathbf{W}^{(d)}}\Big\} \\
&= E\{\mathbf{K}\mathbf{x}^T\}, \qquad (17) \\
\frac{\partial R_{MSE}(\theta)}{\partial \mathbf{b}^{(2)}} &= E\{\mathbf{K}\}, \qquad (18) \\
\frac{\partial R_{MSE}(\theta)}{\partial \mathbf{b}^{(1)}} &= E\{\mathbf{H} \cdot \mathbf{W}^{(2)T} \cdot \mathbf{K}\}. \qquad (19)
\end{aligned}$$

Appendix B. Gradient of P_{ij} in Eq. 8

Noting that $\frac{\partial}{\partial\theta}\left(\frac{\partial^2 y_l}{\partial x_i \partial x_j}\right) = \frac{\partial^2}{\partial x_i \partial x_j}\left(\frac{\partial y_l}{\partial \theta}\right)$ since θ is independent from x_i, we can obtain the following rule after tedious derivation:

$$\begin{aligned}
\frac{P_{ij}}{\partial w_{lm}^{(2)}} &= \frac{\partial^2 y_l}{\partial x_i \partial x_j} \cdot \frac{\partial^2 z_m}{\partial x_i \partial x_j}, \\
\frac{\partial P_{ij}}{\partial w_{mk}^{(1)}} &= \Delta_{ijm} \cdot \left\{ h''(a_m)[w_{mi}^{(1)} \cdot \delta_{kj} + w_{mj}^{(1)} \cdot \delta_{ik}] + h'''(a_m) \cdot w_{mj}^{(1)} \cdot w_{mi}^{(1)} \cdot x_k \right\}, \\
\frac{\partial P_{ij}}{\partial b_m^{(1)}} &= \Delta_{ijm} \cdot h'''(a_m) \cdot w_{mj}^{(1)} \cdot w_{mi}^{(1)}, \\
\frac{\partial P_{ij}}{\partial \mathbf{W}^{(d)}} &= \mathbf{0}, \\
\frac{\partial P_{ij}}{\mathbf{b}^{(2)}} &= \mathbf{0},
\end{aligned} \tag{20}$$

where $\Delta_{ijm} = \sum_{l=1}^{n} w_{lm}^{(2)} \cdot \frac{\partial^2 y_l}{\partial x_i \partial x_j}$, $\frac{\partial^2 y_l}{\partial x_i \partial x_j} = \sum_{m=1}^{M} w_{lm}^{(2)} \cdot \frac{\partial^2 z_m}{\partial x_i \partial x_j}$, $\frac{\partial^2 z_m}{\partial x_i \partial x_j} = h''(a_m) \cdot w_{mi}^{(1)} \cdot w_{mj}^{(1)}$, and δ_{ik} is the Kronecker delta function.

Appendix C. Proof of Lemma 1

Proof. The mean square error of reconstructing $\mathbf{d}$ from y with the linear transformation $\mathbf{a}$ is

$$\begin{aligned}
& E\{||\mathbf{d} - \mathbf{a} \cdot y||^2\} = E\{(\mathbf{d} - \mathbf{a} \cdot y)^T (\mathbf{d} - \mathbf{a} \cdot y)\} \\
= \; & E\{\mathbf{d}^T \cdot \mathbf{d} - 2\mathbf{a}^T \mathbf{d} \cdot y + \mathbf{a}^T \mathbf{a} \cdot y^2\} \\
= \; & E\left\{ \mathbf{a}^T \mathbf{a} \cdot \left(y - \frac{\mathbf{a}^T \mathbf{d}}{\mathbf{a}^T \mathbf{a}} \right)^2 - \frac{(\mathbf{a}^T \mathbf{d})^2}{\mathbf{a}^T \mathbf{a}} + \mathbf{d}^T \mathbf{d} \right\} \\
= \; & \mathbf{a}^T \mathbf{a} \cdot E\left\{ \left(y - \frac{\mathbf{a}^T \mathbf{d}}{\mathbf{a}^T \mathbf{a}} \right)^2 \right\} - E\left\{ \frac{(\mathbf{a}^T \mathbf{d})^2}{\mathbf{a}^T \mathbf{a}} \right\} + E\{\mathbf{d}^T \mathbf{d}\}.
\end{aligned} \tag{21}$$

The first term of Eq. 21 is always non-negative. No matter what value $\mathbf{a}$ takes, in order to minimize Eq. 21, we should choose

$$y = \mathbf{a}^T \mathbf{d} \cdot (\mathbf{a}^T \mathbf{a})^{-1} \tag{22}$$

to make this term vanish, meaning that y is the linear combination of d_i with the coefficients $\mathbf{a} \cdot (\mathbf{a}^T \mathbf{a})^{-1}$.

Next, when the first term of Eq. 21 vanishes, minimizing this function w.r.t. $\mathbf{a}$ is reduced to maximizing $E\{(\mathbf{a}^T \mathbf{d})^2 \cdot (\mathbf{a}^T \mathbf{a})^{-1}\} = E\{\mathbf{a}^T \mathbf{d}\mathbf{d}^T \mathbf{a} \cdot (\mathbf{a}^T \mathbf{a})^{-1}\}$. Letting $\mathbf{a}' = \mathbf{a}/\sqrt{\mathbf{a}^T \mathbf{a}}$, this is equivalent to the constrained optimization problem: $\max \mathbf{a}'^T \cdot E\{\mathbf{d}\mathbf{d}^T\} \cdot \mathbf{a}'$, s.t. $\mathbf{a}'^T \mathbf{a}' = 1$. Clearly this is the PCA problem. So $\mathbf{a}'$ is the eigenvector of $E\{\mathbf{d}\mathbf{d}^T\}$ associated with the largest eigenvalue, and according to Eq. 22, y is the principal component of $\mathbf{d}$ multiplied by a constant.

Now let us consider the case where y is constrained to be zero-mean. Let $\overline{\mathbf{d}} = E\{\mathbf{d}\}$, and $\tilde{\mathbf{d}} = \mathbf{d} - \overline{\mathbf{d}}$. We have $E\{||\mathbf{d} - \mathbf{a} \cdot y||^2\} = E\{(\tilde{\mathbf{d}} - \mathbf{a} \cdot y + \overline{\mathbf{d}})^T (\tilde{\mathbf{d}} - \mathbf{a} \cdot y + \overline{\mathbf{d}})\} = E\{(\tilde{\mathbf{d}} - \mathbf{a} \cdot y)^T (\tilde{\mathbf{d}} - \mathbf{a} \cdot y)\} + \overline{\mathbf{d}}^T \overline{\mathbf{d}}$. $\overline{\mathbf{d}}^T \overline{\mathbf{d}}$ can be considered as a constant. Using the result above, we can see that when R_y is minimized, y is the principal component of $\tilde{\mathbf{d}}$ multiplied by a constant. (Q.E.D)

Appendix D. Proof of Theorem 1

Proof: As it has been assumed here that each output of nonlinear ICA depends only on one of the sources, we can denote by $h_j(s_j)$ the estimate of s_j produced by nonlinear ICA. For the sake of simplicity, we make both x_i and $h_j(s_j)$ zero-mean, that is, $E\{x_i\} = E\{h_j(s_j)\} = 0$. So the matrix $\mathbf{A}^*$ in Eq. 2 is $n \times n$. Denote by a^*_{ij} the (i,j)th entry of $\mathbf{A}^*$. R_{MSE} defined by Eq. 2 is

$$\begin{aligned} R_{MSE} &= \sum_i E\Big\{x_i - \sum_j a^*_{ij} h_j(s_j)\Big\}^2 = \sum_i E\Big\{\sum_j \Big[f_{ij}(s_j) - a^*_{ij} h_j(s_j)\Big]\Big\}^2 \\ &= \sum_i \Big\{\sum_j E\big(f_{ij}(s_j) - a^*_{ij} h_j(s_j)\big)^2 \\ &\qquad + \sum_{k\neq l} E\big[\big(f_{ik}(s_k) - a^*_{ik} h_k(s_k)\big)\cdot\big(f_{il}(s_l) - a^*_{il} h_l(s_l)\big)\big]\Big\}. \end{aligned}$$

As $E\{h_k(s_k)h_l(s_l)\} = E\{h_k(s_k) f_{il}(s_l)\} = 0$ for $k \neq l$, the above equation becomes

$$\begin{aligned} R_{MSE} &= \sum_i \Big\{\sum_j E\big(f_{ij}(s_j) - a^*_{ij} h_j(s_j)\big)^2 + \sum_{k\neq l} E\big(f_{ik}(s_k) f_{il}(s_l)\big)\Big\} \\ &= \sum_j \Big\{\sum_i E\big(f_{ij}(s_j) - a^*_{ij} h_j(s_j)\big)^2\Big\} + \text{const.} \end{aligned}$$

One can see that minimization of the above function can be achieved by minimizing $\sum_i E\big(f_{ij}(s_j) - a^*_{ij} h_j(s_j)\big)^2$ independently for each j. That is, $h_j(s_j)$ and a^*_{ij} are adjusted to minimize $\sum_i E\big(f_{ij}(s_j) - a^*_{ij} h_j(s_j)\big)^2$. According to Lemma 1, $h_j(s_j)$ produced by nonlinear ICA with MND is the first principal component of $\mathbf{f}_{*j}(s_j) = [f_{1j}(s_j), \cdots, f_{nj}(s_j)]^T$, multiplied by a constant. (Q.E.D)

Appendix E. Proof of Theorem 2

Proof. Denote by $h_j(s_j)$ the estimate of s_j produced by nonlinear ICA, and assume that both x_i and $h_j(s_j)$ zero-mean. Denote by a^*_{ij} the (i,j)th entry of $\mathbf{A}^*$. Note that $\sum_{j,k,l} \nabla_{i,jkl} \cdot s_j s_k s_l = \sum_j \nabla_{i,jjj} \cdot s_j s_j s_j + 3 \cdot \sum_j \sum_{k\neq j} \nabla_{i,jkk} \cdot s_j s_k^2 + \sum_j \sum_{k\neq j} \sum_{\substack{l\neq j \\ l\neq k}} \nabla_{i,jkl} \cdot s_j s_k s_l$, and that $E\{s_j\} = 0$ and $E\{s_j^2\} = 1$. R_{MSE} defined by Eq. 2 becomes

$$\begin{aligned} & R_{MSE} = \sum_i E\Big\{x_i - \sum_j a^*_{ij} h_j(s_j)\Big\}^2 \\ = \; & \sum_i E\Big\{f_i(\mathbf{0}) + \sum_j \nabla_{i,j}\cdot s_j + \frac{1}{2}\sum_{j,k} \nabla_{i,jk}\cdot s_j s_k + \frac{1}{6}\sum_{j,k,l} \nabla_{i,jkl}\cdot s_j s_k s_l - \sum_j a^*_{ij} h_j(s_j)\Big\}^2 \\ = \; & \sum_{i=1}^n E\Big\{f_i(\mathbf{0}) + \sum_j \Big[\nabla_{i,j}\cdot s_j + \frac{1}{2}\nabla_{i,jj}\cdot s_j^2 + \frac{1}{6}\nabla_{i,jjj}\cdot s_j^3 + \frac{3}{6}\sum_{k\neq j} \nabla_{i,jkk}\cdot s_j s_k^2 \\ & - a^*_{ij} h_j(s_j)\Big] + \frac{1}{2}\sum_j \sum_{k\neq j} \nabla_{i,jk}\cdot s_j s_k + \frac{1}{6}\sum_j \sum_{k\neq j} \sum_{\substack{l\neq j \\ l\neq k}} \nabla_{i,jkl}\cdot s_j s_k s_l\Big\}^2. \end{aligned} \tag{23}$$

Bearing in mind that s_j are mutually independent, and also taking all the terms independent of $h_j(s_j)$ and a_{ij}^* as constants, we can re-write Eq. 23 as

$$\begin{aligned}
& R_{MSE} \\
= & \sum_i E\Big\{ \sum_j \Big[\nabla_{i,j} \cdot s_j + \frac{1}{2} \nabla_{i,jj} \cdot s_j^2 + \frac{1}{6} \nabla_{i,jjj} \cdot s_j^3 + \frac{3}{6} \sum_{k \neq j} \nabla_{i,jkk} \cdot s_j s_k^2 - a_{ij}^* h_j(s_j) \Big] \Big\}^2 + \text{const} \\
= & \sum_i E\Big\{ \sum_j \Big[\nabla_{i,j} \cdot s_j + \frac{1}{2} \nabla_{i,jj} \cdot s_j^2 + \frac{1}{6} \nabla_{i,jjj} \cdot s_j^3 - a_{ij}^* h_j(s_j) \Big] + \frac{1}{2} \sum_j \sum_{k \neq j} \nabla_{i,jkk} \cdot s_j s_k^2 \Big\}^2 + \text{const} \\
= & \sum_i E\Big\{ \Big[\sum_j \Big(\nabla_{i,j} \cdot s_j + \frac{1}{2} \nabla_{i,jj} \cdot s_j^2 + \frac{1}{6} \nabla_{i,jjj} \cdot s_j^3 - a_{ij}^* h_j(s_j) \Big) \Big]^2 \\
& - \sum_j \Big(a_{ij}^* h_j(s_j) \cdot \sum_{k \neq j} \nabla_{i,jkk} \cdot s_j s_k^2 \Big) \Big\} + \text{const} \\
= & \sum_i E\Big\{ \sum_j \Big(\nabla_{i,j} \cdot s_j + \frac{1}{2} \nabla_{i,jj} \cdot s_j^2 + \frac{1}{6} \nabla_{i,jjj} \cdot s_j^3 - a_{ij}^* h_j(s_j) \Big)^2 \\
& - \sum_j \Big(a_{ij}^* h_j(s_j) \cdot \sum_{k \neq j} \nabla_{i,jkk} \cdot s_j \Big\} + \text{const} \\
= & \sum_i \sum_j E\Big\{ \Big(\nabla_{i,j} + \frac{1}{2} \sum_{k \neq j} \nabla_{i,jkk} \Big) \cdot s_j + \frac{1}{2} \nabla_{i,jj} \cdot s_j^2 + \frac{1}{6} \nabla_{i,jjj} \cdot s_j^3 - a_{ij}^* h_j(s_j) \Big\}^2 + \text{const} \\
= & \sum_j \Big[\sum_i E\big(D_{ij}(s_j) - a_{ij}^* h_j(s_j) \big)^2 \Big] + \text{const.}
\end{aligned}$$

Note that there is no dependence relationship between $h_j(\cdot)$, as well as a_{ij}^*, with different j. To minimize the above function, we just need to adjust $h_j(s_j)$ and a_{ij}^* to minimize $\sum_i E\big(D_i(s_j) - a_{ij}^* h_j(s_j)\big)^2$, independently for each j. According to Lemma 1, $h_j(s_j)$ is the first principal component of $\tilde{\mathbf{D}}_{*j}(s_j) = [\tilde{D}_{1j}(s_j), \cdots, \tilde{D}_{nj}(s_j),]^T$, multiplied by a constant. (Q.E.D)

On the Equivalence of Linear Dimensionality-Reducing Transformations

Abstract

In this JMLR volume, Ye (2008) demonstrates the essential equivalence of two sets of solutions to a generalized Fisher criterion used for linear dimensionality reduction (see Ye, 2005; Loog, 2007). Here, I point out the basic flaw in this new contribution.

Keywords: linear discriminant analysis, equivalence relation, linear subspaces, Bayes error

1. Introduction

Some time ago, Ye (2005) studied an optimization criterion for linear dimensionality reduction and tried to characterize the family of solutions to this objective function. The description, however, merely covers a part of the full solution set and is therefore, in fact, not at all a characterization. Loog (2007) has corrected this mistake, giving the proper, larger set of solutions. In this volume, Ye (2008) now demonstrates that the two solution sets are essentially equivalent.

In principle, Ye (2008) is correct and the two sets of dimension reducing transforms can indeed be considered equivalent. At the base of this fact is that mathematically speaking anything can be equivalent to anything else. The point I would like to convey, however, is that the equivalence considered is not essential and, as a result, the two sets are in fact essentially different. The main question in this is what is 'essential' in the context of supervised linear dimensionality reduction?

2. Essential Equivalence

Concerned with classification tasks, the performance of every dimensionality reduction criterion should primarily be discussed in relation to the Bayes error (see Fukunaga, 1990, Chapter 10). As such, transformations might be considered essentially equivalent if their Bayes errors in the reduces spaces are equal. A closely related definition is to consider transformations A and B equivalent if there is a nonsingular transformation T such that $A = T \circ B$ (see Fukunaga, 1990). The latter is more restrictive than the former as the existence of T implies an equal Bayes error for A and B, but the implication in the other direction does not necessarily hold. When A and B are linear and there is such a transform T, both of them span the same subspace of the original feature space, obviously

∗. Also in the Image Group, University of Copenhagen, Universitetsparken 1, 2100 Copenhagen Ø, Denmark.

resulting in the equality of the Bayes errors. Based on the foregoing, two linear transformations are also considered essentially equivalent if they span the same subspace.

Now, without providing any rationale, Ye (2008) declares two linear transformations A and B to be equivalent if there is a vector v such that $A(x_i - v) = B(x_i - v)$ for all feature vectors x_i in the training set. The following very simple examples demonstrate, however, why the latter definition of equivalence is flawed.

Let $x_1 = (0,0)^t$ and $x_2 = (1,0)^t$ be two training samples, $A = (1,0)$, $B = (-1,0)$, $C = (1,1)$, $D = (0,0)$, and $E = (0,1)$ be linear transformations, and let v equal to $(v_1, v_2)^t$. Now, firstly, one cannot have both $-v_1 = A(x_1 - v) = B(x_1 - v) = v_1$ and $1 - v_1 = A(x_2 - v) = B(x_2 - v) = -1 + v_1$, and therefore A is not equivalent to B even thought $A = -B$. That is, two transforms that trivially define the same subspace are apparently not equivalent. Secondly, $D(x_i - v) = 0 = E(x_i - v)$ shows that transforms spanning subspaces of different dimensions can be equivalent. Finally, a straightforward calculation shows that A and C are equivalent, that is, two transforms that obviously span different subspaces, and therefore most probably result in different Bayes errors, are considered equivalent.

3. In Conclusion

Maintaining that the equivalence relation in Ye (2008) is flawed, it directly follows that it cannot be concluded that the different sets of solutions as given by Loog (2007) and Ye (2005) are essentially equivalent. In fact, as should be obvious from Loog (2007), they are essentially different. Given that x_1 and x_2 (as defined above) come from two different classes, one can easily check that the solution set by Ye (2005) is given by $\{(a,0)|a \in \mathbb{R}\backslash 0\}$, that is, nondegenerate multiples of $A = (1,0)$, while the true set also contains transformations like $C = (1,1)$. Both define different subspaces and, generically, lead to different Bayes errors.

Abstract

Multiple kernel learning (MKL) aims at simultaneously learning a kernel and the associated predictor in supervised learning settings. For the support vector machine, an efficient and general multiple kernel learning algorithm, based on semi-infinite linear programming, has been recently proposed. This approach has opened new perspectives since it makes MKL tractable for large-scale problems, by iteratively using existing support vector machine code. However, it turns out that this iterative algorithm needs numerous iterations for converging towards a reasonable solution. In this paper, we address the MKL problem through a weighted 2-norm regularization formulation with an additional constraint on the weights that encourages sparse kernel combinations. Apart from learning the combination, we solve a standard SVM optimization problem, where the kernel is defined as a linear combination of multiple kernels. We propose an algorithm, named SimpleMKL, for solving this MKL problem and provide a new insight on MKL algorithms based on mixed-norm regularization by showing that the two approaches are equivalent. We show how SimpleMKL can be applied beyond binary classification, for problems like regression, clustering (one-class classification) or multiclass classification. Experimental results show that the proposed algorithm converges rapidly and that its efficiency compares favorably to other MKL algorithms. Finally, we illustrate the usefulness of MKL for some regressors based on wavelet kernels and on some model selection problems related to multiclass classification problems.

1. Introduction

During the last few years, kernel methods, such as support vector machines (SVM) have proved to be efficient tools for solving learning problems like classification or regression (Schölkopf and Smola, 2001). For such tasks, the performance of the learning algorithm strongly depends on the data representation. In kernel methods, the data representation is implicitly chosen through the so-called kernel $K(x,x')$. This kernel actually plays two roles: it defines the similarity between two examples x and x', while defining an appropriate regularization term for the learning problem.

Let $\{x_i,y_i\}_{i=1}^{\ell}$ be the learning set, where x_i belongs to some input space $\mathcal{X}$ and y_i is the target value for pattern x_i. For kernel algorithms, the solution of the learning problem is of the form

$$f(x) = \sum_{i=1}^{\ell} \alpha_i^\star K(x,x_i) + b^\star, \tag{1}$$

where $\alpha_i^\star$ and $b^\star$ are some coefficients to be learned from examples, while $K(\cdot,\cdot)$ is a given positive definite kernel associated with a reproducing kernel Hilbert space (RKHS) $\mathcal{H}$.

In some situations, a machine learning practitioner may be interested in more flexible models. Recent applications have shown that using multiple kernels instead of a single one can enhance the interpretability of the decision function and improve performances (Lanckriet et al., 2004a). In such cases, a convenient approach is to consider that the kernel $K(x,x')$ is actually a convex combination of *basis* kernels:

$$K(x,x') = \sum_{m=1}^{M} d_m K_m(x,x') \ , \quad \text{with } d_m \geq 0 \ , \ \sum_{m=1}^{M} d_m = 1 \ ,$$

where M is the total number of kernels. Each basis kernel K_m may either use the full set of variables describing x or subsets of variables stemming from different data sources (Lanckriet et al., 2004a). Alternatively, the kernels K_m can simply be classical kernels (such as Gaussian kernels) with different parameters. Within this framework, the problem of data representation through the kernel is then transferred to the choice of weights d_m.

Learning both the coefficients α_i and the weights d_m in a single optimization problem is known as the multiple kernel learning (MKL) problem. For binary classification, the MKL problem has been introduced by Lanckriet et al. (2004b), resulting in a quadratically constrained quadratic programming problem that becomes rapidly intractable as the number of learning examples or kernels become large.

What makes this problem difficult is that it is actually a convex but non-smooth minimization problem. Indeed, Bach et al. (2004a) have shown that the MKL formulation of Lanckriet et al. (2004b) is actually the dual of a SVM problem in which the weight vector has been regularized according to a mixed (ℓ_2,ℓ_1)-norm instead of the classical squared ℓ_2-norm. Bach et al. (2004a) have considered a smoothed version of the problem for which they proposed a SMO-like algorithm that enables to tackle medium-scale problems.

Sonnenburg et al. (2006) reformulate the MKL problem of Lanckriet et al. (2004b) as a semi-infinite linear program (SILP). The advantage of the latter formulation is that the algorithm addresses the problem by iteratively solving a classical SVM problem with a single kernel, for which many efficient toolboxes exist (Vishwanathan et al., 2003; Loosli et al., 2005; Chang and Lin, 2001), and a linear program whose number of constraints increases along with iterations. A very nice feature of this algorithm is that is can be extended to a large class of convex loss functions. For instance, Zien and Ong (2007) have proposed a multiclass MKL algorithm based on similar ideas.

In this paper, we present another formulation of the multiple learning problem. We first depart from the primal formulation proposed by Bach et al. (2004a) and further used by Bach et al. (2004b) and Sonnenburg et al. (2006). Indeed, we replace the mixed-norm regularization by a weighted ℓ_2-norm regularization, where the sparsity of the linear combination of kernels is controlled by a ℓ_1-norm constraint on the kernel weights. This new formulation of MKL leads to a smooth and convex optimization problem. By using a variational formulation of the mixed-norm regularization, we show that our formulation is equivalent to the ones of Lanckriet et al. (2004b), Bach et al. (2004a) and Sonnenburg et al. (2006).

The main contribution of this paper is to propose an efficient algorithm, named SimpleMKL, for solving the MKL problem, through a primal formulation involving a weighted ℓ_2-norm regularization. Indeed, our algorithm is simple, essentially based on a gradient descent on the SVM objective value. We iteratively determine the combination of kernels by a gradient descent wrapping a standard SVM solver, which is SimpleSVM in our case. Our scheme is similar to the one of Sonnenburg et al. (2006), and both algorithms minimize the same objective function. However, they differ in that we use reduced gradient descent in the primal, whereas Sonnenburg et al.'s SILP relies on cutting planes. We will empirically show that our optimization strategy is more efficient, with new evidences confirming the preliminary results reported in Rakotomamonjy et al. (2007).

Then, extensions of SimpleMKL to other supervised learning problems such as regression SVM, one-class SVM or multiclass SVM problems based on pairwise coupling are proposed. Although it is not the main purpose of the paper, we will also discuss the applicability of our approach to general convex loss functions.

This paper also presents several illustrations of the usefulness of our algorithm. For instance, in addition to the empirical efficiency comparison, we also show, in a SVM regression problem involving wavelet kernels, that automatic learning of the kernels leads to far better performances. Then we depict how our MKL algorithm behaves on some multiclass problems.

The paper is organized as follows. Section 2 presents the functional settings of our MKL problem and its formulation. Details on the algorithm and discussion of convergence and computational complexity are given in Section 3. Extensions of our algorithm to other SVM problems are discussed in Section 4 while experimental results dealing with computational complexity or with comparison with other model selection methods are presented in Section 5.

A SimpleMKL toolbox based on Matlab code is available at `http://www.mloss.org`. This toolbox is an extension of our SVM-KM toolbox (Canu et al., 2003).

2. Multiple Kernel Learning Framework

In this section, we present our MKL formulation and derive its dual. In the sequel, i and j are indices on examples, whereas m is the kernel index. In order to lighten notations, we omit to specify that summations on i and j go from 1 to ℓ, and that summations on m go from 1 to M.

2.1 Functional Framework

Before entering into the details of the MKL optimization problem, we first present the functional framework adopted for multiple kernel learning. Assume $K_m, m = 1,...,M$ are M positive definite kernels on the same input space $\mathcal{X}$, each of them being associated with an RKHS $\mathcal{H}_m$ endowed with an inner product $\langle \cdot, \cdot \rangle_m$. For any m, let d_m be a non-negative coefficient and $\mathcal{H}'_m$ be the Hilbert space

derived from $\mathcal{H}_m$ as follows:

$$\mathcal{H}'_m = \{ f \mid f \in \mathcal{H}_m : \frac{\|f\|_{\mathcal{H}_m}}{d_m} < \infty \} \ ,$$

endowed with the inner product

$$\langle f, g \rangle_{\mathcal{H}'_m} = \frac{1}{d_m} \langle f, g \rangle_m \ .$$

In this paper, we use the convention that $\frac{x}{0} = 0$ if $x = 0$ and ∞ otherwise. This means that, if $d_m = 0$ then a function f belongs to the Hilbert space $\mathcal{H}'_m$ only if $f = 0 \in \mathcal{H}_m$. In such a case, $\mathcal{H}'_m$ is restricted to the null element of $\mathcal{H}_m$.

Within this framework, $\mathcal{H}'_m$ is a RKHS with kernel $K(x,x') = d_m \, K_m(x,x')$ since

$$\begin{aligned} \forall f \in \mathcal{H}'_m \subseteq \mathcal{H}_m \ , \quad f(x) &= \langle f(\cdot), K_m(x,\cdot) \rangle_m \\ &= \frac{1}{d_m} \langle f(\cdot), d_m K_m(x,\cdot) \rangle_m \\ &= \langle f(\cdot), d_m K_m(x,\cdot) \rangle_{\mathcal{H}'_m} \ . \end{aligned}$$

Now, if we define $\mathcal{H}$ as the direct sum of the spaces $\mathcal{H}'_m$, that is,

$$\mathcal{H} = \bigoplus_{m=1}^{M} \mathcal{H}'_m \ ,$$

then, a classical result on RKHS (Aronszajn, 1950) says that $\mathcal{H}$ is a RKHS of kernel

$$K(x,x') = \sum_{m=1}^{M} d_m K_m(x,x') \ .$$

Owing to this simple construction, we have built a RKHS $\mathcal{H}$ for which any function is a sum of functions belonging to $\mathcal{H}_m$. In our framework, MKL aims at determining the set of coefficients $\{d_m\}$ within the learning process of the decision function. The multiple kernel learning problem can thus be envisioned as learning a predictor belonging to an adaptive hypothesis space endowed with an adaptive inner product. The forthcoming sections explain how we solve this problem.

2.2 Multiple Kernel Learning Primal Problem

In the SVM methodology, the decision function is of the form given in Equation (1), where the optimal parameters $\alpha_i^\star$ and $b^\star$ are obtained by solving the dual of the following optimization problem:

$$\begin{array}{ll} \min\limits_{f,b,\xi} & \frac{1}{2}\|f\|^2_{\mathcal{H}} + C \sum\limits_i \xi_i \\ \text{s.t.} & y_i(f(x_i)+b) \geq 1 - \xi_i \quad \forall i \\ & \xi_i \geq 0 \quad \forall i \ . \end{array}$$

In the MKL framework, one looks for a decision function of the form $f(x) + b = \sum_m f_m(x) + b$, where each function f_m belongs to a different RKHS $\mathcal{H}_m$ associated with a kernel K_m. According to the above functional framework and inspired by the multiple smoothing splines framework of

Wahba (1990, chap. 10), we propose to address the MKL SVM problem by solving the following convex problem (see proof in appendix), which we will be referred to as the primal MKL problem:

$$\begin{array}{ll} \min\limits_{\{f_m\},b,\xi,d} & \frac{1}{2}\sum\limits_m \frac{1}{d_m}\|f_m\|^2_{\mathcal{H}_m} + C\sum\limits_i \xi_i \\ \text{s.t.} & y_i\sum\limits_m f_m(x_i) + y_i b \geq 1-\xi_i \quad \forall i \\ & \xi_i \geq 0 \quad \forall i \\ & \sum\limits_m d_m = 1\ , \quad d_m \geq 0 \quad \forall m\ , \end{array} \tag{2}$$

where each d_m controls the squared norm of f_m in the objective function.

The smaller d_m is, the smoother f_m (as measured by $\|f_m\|_{\mathcal{H}_m}$) should be. When $d_m = 0$, $\|f_m\|_{\mathcal{H}_m}$ has also to be equal to zero to yield a finite objective value. The ℓ_1-norm constraint on the vector d is a sparsity constraint that will force some d_m to be zero, thus encouraging sparse basis kernel expansions.

2.3 Connections With mixed-norm Regularization Formulation of MKL

The MKL formulation introduced by Bach et al. (2004a) and further developed by Sonnenburg et al. (2006) consists in solving an optimization problem expressed in a functional form as

$$\begin{array}{ll} \min\limits_{\{f\},b,\xi} & \frac{1}{2}\left(\sum\limits_m \|f_m\|_{\mathcal{H}_m}\right)^2 + C\sum\limits_i \xi_i \\ \text{s.t.} & y_i\sum\limits_m f_m(x_i) + y_i b \geq 1-\xi_i \ \ \forall i \\ & \xi_i \geq 0 \ \ \forall i. \end{array} \tag{3}$$

Note that the objective function of this problem is not smooth since $\|f_m\|_{\mathcal{H}_m}$ is not differentiable at $f_m = 0$. However, what makes this formulation interesting is that the mixed-norm penalization of $f = \sum_m f_m$ is a soft-thresholding penalizer that leads to a sparse solution, for which the algorithm performs kernel selection (Bach, 2008). We have stated in the previous section that our problem should also lead to sparse solutions. In the following, we show that the formulations (2) and (3) are equivalent.

For this purpose, we simply show that the variational formulation of the mixed-norm regularization is equal to the weighted 2-norm regularization, (which is a particular case of a more general equivalence proposed by Micchelli and Pontil 2005), that is, by Cauchy-Schwartz inequality, for any vector d on the simplex:

$$\begin{aligned} \left(\sum_m \|f_m\|_{\mathcal{H}_m}\right)^2 &= \left(\sum_m \frac{\|f_m\|_{\mathcal{H}_m}}{d_m^{1/2}} d_m^{1/2}\right)^2 \\ &\leqslant \left(\sum_m \frac{\|f_m\|^2_{\mathcal{H}_m}}{d_m}\right)\left(\sum_m d_m\right) \\ &\leqslant \sum_m \frac{\|f_m\|^2_{\mathcal{H}_m}}{d_m}\ , \end{aligned}$$

where equality is met when $d_m^{1/2}$ is proportional to $\|f_m\|_{\mathcal{H}_m}/d_m^{1/2}$, that is:

$$d_m = \frac{\|f_m\|_{\mathcal{H}_m}}{\sum_q \|f_q\|_{\mathcal{H}_q}} \ ,$$

which leads to

$$\min_{d_m \geq 0, \sum_m d_m = 1} \sum_m \frac{\|f_m\|^2_{\mathcal{H}_m}}{d_m} = \left(\sum_m \|f_m\|_{\mathcal{H}_m} \right)^2 \ .$$

Hence, owing to this variational formulation, the non-smooth mixed-norm objective function of problem (3) has been turned into a smooth objective function in problem (2). Although the number of variables has increased, we will see that this problem can be solved more efficiently.

2.4 The MKL Dual Problem

The dual problem is a key point for deriving MKL algorithms and for studying their convergence properties. Since our primal problem (2) is equivalent to the one of Bach et al. (2004a), they lead to the same dual. However, our primal formulation being convex and differentiable, it provides a simple derivation of the dual, that does not use conic duality.

The Lagrangian of problem (2) is

$$\begin{aligned} \mathcal{L} \ = \ & \frac{1}{2}\sum_m \frac{1}{d_m}\|f_m\|^2_{\mathcal{H}_m} + C\sum_i \xi_i + \sum_i \alpha_i \left(1 - \xi_i - y_i \sum_m f_m(x_i) - y_i b\right) - \sum_i \nu_i \xi_i \\ & + \lambda\left(\sum_m d_m - 1\right) - \sum_m \eta_m d_m \ , \end{aligned} \tag{4}$$

where α_i and ν_i are the Lagrange multipliers of the constraints related to the usual SVM problem, whereas λ and η_m are associated to the constraints on d_m. When setting to zero the gradient of the Lagrangian with respect to the primal variables, we get the following

$$\begin{aligned} &\text{(a)} \quad \frac{1}{d_m} f_m(\cdot) = \sum_i \alpha_i y_i K_m(\cdot, x_i) \ , \quad \forall m, \\ &\text{(b)} \quad \sum_i \alpha_i y_i = 0, \\ &\text{(c)} \quad C - \alpha_i - \nu_i = 0 \ , \quad \forall i, \\ &\text{(d)} \quad -\frac{1}{2}\frac{\|f_m\|^2_{\mathcal{H}_m}}{d_m^2} + \lambda - \eta_m = 0 \ , \quad \forall m \ . \end{aligned} \tag{5}$$

We note again here that $f_m(\cdot)$ has to go to 0 if the coefficient d_m vanishes. Plugging these optimality conditions in the Lagrangian gives the dual problem

$$\begin{aligned} \max_{\alpha_i, \lambda} \quad & \sum_i \alpha_i - \lambda \\ \text{s.t.} \quad & \sum_i \alpha_i y_i = 0 \\ & 0 \leq \alpha_i \leq C \quad \forall i \\ & \frac{1}{2}\sum_{i,j} \alpha_i \alpha_j y_i y_j K_m(x_i, x_j) \leq \lambda \ , \quad \forall m \ . \end{aligned} \tag{6}$$

This dual problem[1] is difficult to optimize due to the last constraint. This constraint may be moved to the objective function, but then, the latter becomes non-differentiable causing new difficulties (Bach et al., 2004a). Hence, in the forthcoming section, we propose an approach based on the minimization of the primal. In this framework, we benefit from differentiability which allows for an efficient derivation of an approximate primal solution, whose accuracy will be monitored by the duality gap.

3. Algorithm for Solving the MKL Primal Problem

One possible approach for solving problem (2) is to use the alternate optimization algorithm applied by Grandvalet and Canu (1999, 2003) in another context. In the first step, problem (2) is optimized with respect to f_m, b and ξ, with d fixed. Then, in the second step, the weight vector d is updated to decrease the objective function of problem (2), with f_m, b and ξ being fixed. In Section 2.3, we showed that the second step can be carried out in closed form. However, this approach lacks convergence guarantees and may lead to numerical problems, in particular when some elements of d approach zero (Grandvalet, 1998). Note that these numerical problems can be handled by introducing a perturbed version of the alternate algorithm as shown by Argyriou et al. (2008).

Instead of using an alternate optimization algorithm, we prefer to consider here the following constrained optimization problem:

$$\min_d J(d) \quad \text{such that} \quad \sum_{m=1}^{M} d_m = 1,\ d_m \geq 0 \ , \tag{7}$$

where

$$J(d) = \left\{ \begin{array}{ll} \min\limits_{\{f\},b,\xi} & \frac{1}{2}\sum\limits_m \frac{1}{d_m}\|f_m\|^2_{\mathcal{H}_m} + C\sum\limits_i \xi_i \quad \forall i \\ \text{s.t.} & y_i \sum\limits_m f_m(x_i) + y_i b \geq 1 - \xi_i \\ & \xi_i \geq 0 \quad \forall i \ . \end{array} \right. \tag{8}$$

We show below how to solve problem (7) on the simplex by a simple gradient method. We will first note that the objective function $J(d)$ is actually an optimal SVM objective value. We will then discuss the existence and computation of the gradient of $J(\cdot)$, which is at the core of the proposed approach.

3.1 Computing the Optimal SVM Value and its Derivatives

The Lagrangian of problem (8) is identical to the first line of Equation (4). By setting to zero the derivatives of this Lagrangian according to the primal variables, we get conditions (5) (a) to (c), from which we derive the associated dual problem

$$\begin{array}{ll} \max\limits_{\alpha} & -\frac{1}{2}\sum\limits_{i,j}\alpha_i\alpha_j y_i y_j \sum\limits_m d_m K_m(x_i,x_j) + \sum\limits_i \alpha_i \\ \text{with} & \sum\limits_i \alpha_i y_i = 0 \\ & C \geq \alpha_i \geq 0 \quad \forall i \ , \end{array} \tag{9}$$

1. Note that Bach et al. (2004a) formulation differs slightly, in that the kernels are weighted by some pre-defined coefficients that were not considered here.

which is identified as the standard SVM dual formulation using the combined kernel $K(x_i,x_j) = \sum_m d_m K_m(x_i,x_j)$. Function $J(d)$ is defined as the optimal objective value of problem (8). Because of strong duality, $J(d)$ is also the objective value of the dual problem:

$$J(d) = -\frac{1}{2}\sum_{i,j}\alpha_i^\star\alpha_j^\star y_i y_j \sum_m d_m K_m(x_i,x_j) + \sum_i \alpha_i^\star \quad , \tag{10}$$

where $\alpha^\star$ maximizes (9). Note that the objective value $J(d)$ can be obtained by any SVM algorithm. Our method can thus take advantage of any progress in single kernel algorithms. In particular, if the SVM algorithm we use is able to handle large-scale problems, so will our MKL algorithm. Thus, the overall complexity of SimpleMKL is tied to the one of the single kernel SVM algorithm.

From now on, we assume that each Gram matrix $(K_m(x_i,x_j))_{i,j}$ is positive definite, with all eigenvalues greater than some $\eta > 0$ (to enforce this property, a small ridge may be added to the diagonal of the Gram matrices). This implies that, for any admissible value of d, the dual problem is strictly concave with convexity parameter η (Lemaréchal and Sagastizabal, 1997). In turn, this strict concavity property ensures that $\alpha^\star$ is unique, a characteristic that eases the analysis of the differentiability of $J(\cdot)$.

Existence and computation of derivatives of optimal value functions such as $J(\cdot)$ have been largely discussed in the literature. For our purpose, the appropriate reference is Theorem 4.1 in Bonnans and Shapiro (1998), which has already been applied by Chapelle et al. (2002) for tuning squared-hinge loss SVM. This theorem is reproduced in the appendix for self-containedness. In a nutshell, it says that differentiability of $J(d)$ is ensured by the uniqueness of $\alpha^\star$, and by the differentiability of the objective function that gives $J(d)$. Furthermore, the derivatives of $J(d)$ can be computed as if $\alpha^\star$ were not to depend on d. Thus, by simple differentiation of the dual function (9) with respect to d_m, we have:

$$\frac{\partial J}{\partial d_m} = -\frac{1}{2}\sum_{i,j}\alpha_i^\star\alpha_j^\star y_i y_j K_m(x_i,x_j) \qquad \forall m \ . \tag{11}$$

We will see in the sequel that the applicability of this theorem can be extended to other SVM problems. Note that complexity of the gradient computation is of the order of $m \cdot n_{SV}^2$, with n_{SV} being the number of support vectors for the current d.

3.2 Reduced Gradient Algorithm

The optimization problem we have to deal with in (7) is a non-linear objective function with constraints over the simplex. With our positivity assumption on the kernel matrices, $J(\cdot)$ is convex and differentiable with Lipschitz gradient (Lemaréchal and Sagastizabal, 1997). The approach we use for solving this problem is a reduced gradient method, which converges for such functions (Luenberger, 1984).

Once the gradient of $J(d)$ is computed, d is updated by using a descent direction ensuring that the equality constraint and the non-negativity constraints on d are satisfied. We handle the equality constraint by computing the reduced gradient (Luenberger, 1984, Chap. 11). Let d_μ be a non-zero entry of d, the reduced gradient of $J(d)$, denoted $\nabla_{red}J$, has components:

$$[\nabla_{red}J]_m = \frac{\partial J}{\partial d_m} - \frac{\partial J}{\partial d_\mu} \ \ \forall m \neq \mu \ , \text{ and } [\nabla_{red}J]_\mu = \sum_{m\neq\mu}\left(\frac{\partial J}{\partial d_\mu} - \frac{\partial J}{\partial d_m}\right) \ .$$

We chose μ to be the index of the largest component of vector d, for better numerical stability (Bonnans, 2006).

The positivity constraints have also to be taken into account in the descent direction. Since we want to minimize $J(\cdot)$, $-\nabla_{red}J$ is a descent direction. However, if there is an index m such that $d_m = 0$ and $[\nabla_{red}J]_m > 0$, using this direction would violate the positivity constraint for d_m. Hence, the descent direction for that component is set to 0. This gives the descent direction for updating d as

$$D_m = \begin{cases} 0 & \text{if } d_m = 0 \text{ and } \frac{\partial J}{\partial d_m} - \frac{\partial J}{\partial d_\mu} > 0 \\ -\frac{\partial J}{\partial d_m} + \frac{\partial J}{\partial d_\mu} & \text{if } d_m > 0 \text{ and } m \neq \mu \\ \sum_{g \neq \mu, d_\nu > 0} \left(\frac{\partial J}{\partial d_\nu} - \frac{\partial J}{\partial d_\mu} \right) & \text{for } m = \mu \ . \end{cases} \tag{12}$$

The usual updating scheme is $d \leftarrow d + \gamma D$, where γ is the step size. Here, as detailed in Algorithm 1, we go one step beyond: once a descent direction D has been computed, we first look for the maximal admissible step size in that direction and check whether the objective value decreases or not. The maximal admissible step size corresponds to a component, say d_ν, set to zero. If the objective value decreases, d is updated, we set $D_\nu = 0$ and normalize D to comply with the equality constraint. This procedure is repeated until the objective value stops decreasing. At this point, we look for the optimal step size γ, which is determined by using a one-dimensional line search, with proper stopping criterion, such as Armijo's rule, to ensure global convergence.

In this algorithm, computing the descent direction and the line search are based on the evaluation of the objective function $J(\cdot)$, which requires solving an SVM problem. This may seem very costly but, for small variations of d, learning is very fast when the SVM solver is initialized with the previous values of $\alpha^\star$ (DeCoste and Wagstaff., 2000). Note that the gradient of the cost function is not computed after each update of the weight vector d. Instead, we take advantage of an easily updated descent direction as long as the objective value decreases. We will see in the numerical experiments that this approach saves a substantial amount of computation time compared to the usual update scheme where the descent direction is recomputed after each update of d. Note that we have also investigated gradient projection algorithms (Bertsekas, 1999, Chap 2.3), but this turned out to be slightly less efficient than the proposed approach, and we will not report these results.

The algorithm is terminated when a stopping criterion is met. This stopping criterion can be either based on the duality gap, the KKT conditions, the variation of d between two consecutive steps or, even more simply, on a maximal number of iterations. Our implementation, based on the duality gap, is detailed in the forthcoming section.

3.3 Optimality Conditions

In a convex constrained optimization algorithm such as the one we are considering, we have the opportunity to check for proper optimality conditions such as the KKT conditions or the duality gap (the difference between primal and dual objective values), which should be zero at the optimum. From the primal and dual objectives provided respectively in (2) and (6), the MKL duality gap is

$$\text{DualGap} = J(d^\star) - \sum_i \alpha_i^\star + \frac{1}{2} \max_m \sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j K_m(x_i, x_j) \ ,$$

Algorithm 1 SimpleMKL algorithm

set $d_m = \frac{1}{M}$ for $m = 1, \ldots, M$
while stopping criterion not met **do**
  compute $J(d)$ by using an SVM solver with $K = \sum_m d_m K_m$
  compute $\frac{\partial J}{\partial d_m}$ for $m = 1, \ldots, M$ and descent direction D (12).
  set $\mu = \underset{m}{\operatorname{argmax}}\, d_m$, $J^\dagger = 0$, $d^\dagger = d$, $D^\dagger = D$
  while $J^\dagger < J(d)$ **do** {descent direction update}
    $d = d^\dagger$, $D = D^\dagger$
    $\nu = \underset{\{m|D_m<0\}}{\operatorname{argmin}} -d_m/D_m$, $\gamma_{\max} = -d_\nu/D_\nu$
    $d^\dagger = d + \gamma_{\max} D$, $D^\dagger_\mu = D_\mu - D_\nu$, $D^\dagger_\nu = 0$
    compute $J^\dagger$ by using an SVM solver with $K = \sum_m d^\dagger_m K_m$
  end while
  line search along D for $\gamma \in [0, \gamma_{\max}]$ {calls an SVM solver for each γ trial value}
  $d \leftarrow d + \gamma D$
end while

where $d^\star$ and $\{\alpha_i^\star\}$ are optimal primal and dual variables, and $J(d^\star)$ depends implicitly on optimal primal variables $\{f_m^\star\}$, $b^\star$ and $\{\xi_i^\star\}$. If $J(d^\star)$ has been obtained through the dual problem (9), then this MKL duality gap can also be computed from the single kernel SVM algorithm duality gap DG_{SVM}. Indeed, Equation (10) holds only when the single kernel SVM algorithm returns an exact solution with $DG_{\text{SVM}} = 0$. Otherwise, we have

$$DG_{\text{SVM}} = J(d^\star) + \frac{1}{2}\sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j \sum_m d_m^\star K_m(x_i, x_j) - \sum_i \alpha_i^\star$$

then the MKL duality gap becomes

$$\text{DualGap} = DG_{\text{SVM}} - \frac{1}{2}\sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j \sum_m d_m^\star K_m(x_i, x_j) + \frac{1}{2}\max_m \sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j K_m(x_i, x_j) \quad .$$

Hence, it can be obtained with a small additional computational cost compared to the SVM duality gap.

In iterative procedures, it is common to stop the algorithm when the optimality conditions are respected up to a tolerance threshold ε. Obviously, SimpleMKL has no impact on DG_{SVM}, hence, one may assume, as we did here, that DG_{SVM} needs not to be monitored. Consequently, we terminate the algorithm when

$$\max_m \sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j K_m(x_i, x_j) - \sum_{i,j} \alpha_i^\star \alpha_j^\star y_i y_j \sum_m d_m^\star K_m(x_i, x_j) \leq \varepsilon \quad . \tag{13}$$

For some of the other MKL algorithms that will be presented in Section 4, the dual function may be more difficult to derive. Hence, it may be easier to rely on approximate KKT conditions as a stopping criterion. For the general MKL problem (7), the first order optimality conditions are

obtained through the KKT conditions:

$$\begin{aligned} \frac{\partial J}{\partial d_m} + \lambda - \eta_m &= 0 \quad \forall m \ , \\ \eta_m \cdot d_m &= 0 \quad \forall m \ , \end{aligned}$$

where λ and $\{\eta_m\}$ are respectively the Lagrange multipliers for the equality and inequality constraints of (7). These KKT conditions imply

$$\begin{aligned} \frac{\partial J}{\partial d_m} &= -\lambda \quad \text{if } d_m > 0 \ , \\ \frac{\partial J}{\partial d_m} &\geq -\lambda \quad \text{if } d_m = 0 \ . \end{aligned}$$

However, as Algorithm 1 is not based on the Lagrangian formulation of problem (7), λ is not computed. Hence, we derive approximate necessary optimality conditions to be used for termination criterion. Let's define $dJ_{\min}$ and $dJ_{\max}$ as

$$dJ_{\min} = \min_{\{d_m | d_m > 0\}} \frac{\partial J}{\partial d_m} \quad \text{and} \quad dJ_{\max} = \max_{\{d_m | d_m > 0\}} \frac{\partial J}{\partial d_m} \ ,$$

then, the necessary optimality conditions are approximated by the following termination conditions:

$$|dJ_{\min} - dJ_{\max}| \leq \varepsilon \quad \text{and} \quad \frac{\partial J}{\partial d_m} \geq dJ_{\max} \quad \text{if } d_m = 0 \ .$$

In other words, we are considered at the optimum when the gradient components for all positive d_m lie in a ε-tube and when all gradient components for vanishing d_m are outside this tube. Note that these approximate necessary optimality conditions are available right away for any differentiable objective function $J(d)$.

3.4 Cutting Planes, Steepest Descent and Computational Complexity

As we stated in the introduction, several algorithms have been proposed for solving the original MKL problem defined by Lanckriet et al. (2004b). All these algorithms are based on equivalent formulations of the same dual problem; they all aim at providing a pair of optimal vectors (d, α).

In this subsection, we contrast SimpleMKL with its closest relative, the SILP algorithm of Sonnenburg et al. (2005, 2006). Indeed, from an implementation point of view, the two algorithms are alike, since they are wrapping a standard single kernel SVM algorithm. This feature makes both algorithms very easy to implement. They, however, differ in computational efficiency, because the kernel weights d_m are optimized in quite different ways, as detailed below.

Let us first recall that our differentiable function $J(d)$ is defined as:

$$J(d) = \left\{ \begin{array}{ll} \max\limits_{\alpha} & -\frac{1}{2} \sum\limits_{i,j} \alpha_i \alpha_j y_i y_j \sum\limits_m d_m K_m(x_i, x_j) + \sum\limits_i \alpha_i \\ \text{with} & \sum\limits_i \alpha_i y_i = 0, \qquad C \geq \alpha_i \geq 0 \quad \forall i \ , \end{array} \right.$$

and both algorithms aim at minimizing this differentiable function. However, using a SILP approach in this case, does not take advantage of the smoothness of the objective function.

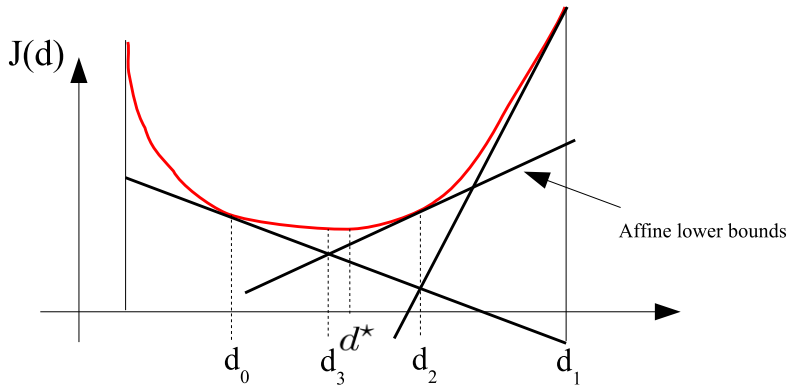

Figure 1: Illustrating three iterations of the SILP algorithm and a gradient descent algorithm for a one-dimensional problem. This dimensionality is not representative of the MKL framework, but our aim is to illustrate the typical oscillations of cutting planes around the optimal solution (with iterates d_0 to d_3). Note that computing an affine lower bound at a given d requires a gradient computation. Provided the step size is chosen correctly, gradient descent converges directly towards the optimal solution without overshooting (from d_0 to $d^\star$).

The SILP algorithm of Sonnenburg et al. (2006) is a *cutting plane* method to minimize J with respect to d. For each value of d, the best α is found and leads to an affine lower bound on $J(d)$. The number of lower bounding affine functions increases as more (d,α) pairs are computed, and the next candidate vector d is the minimizer of the current lower bound on $J(d)$, that is, the maximum over all the affine functions. Cutting planes method do converge but they are known for their instability, notably when the number of lower-bounding affine functions is small: the approximation of the objective function is then loose and the iterates may oscillate (Bonnans et al., 2003). Our steepest descent approach, with the proposed line search, does not suffer from instability since we have a differentiable function to minimize. Figure 1 illustrates the behaviour of both algorithms in a simple case, with oscillations for cutting planes and direct convergence for gradient descent.

Section 5 evaluates how these oscillations impact on the computational time of the SILP algorithm on several examples. These experiments show that our algorithm needs less costly gradient computations. Conversely, the line search in the gradient base approach requires more SVM retrainings in the process of querying the objective function. However, the computation time per SVM training is considerably reduced, since the gradient based approach produces estimates of d on a smooth trajectory, so that the previous SVM solution provides a good guess for the current SVM training. In SILP, with the oscillatory subsequent approximations of $d^\star$, the benefit of warm-start training severely decreases.

3.5 Convergence Analysis

In this paragraph, we briefly discuss the convergence of the algorithm we propose. We first suppose that problem (8) is always exactly solved, which means that the duality gap of such problem is 0. With such conditions, the gradient computation in (11) is exact and thus our algorithm performs reduced gradient descent on a continuously differentiable function $J(\cdot)$ (remember that we have

assumed that the kernel matrices are positive definite) defined on the simplex $\{d | \sum_m d_m = 1, d_m \geq 0\}$, which does converge to the global minimum of J (Luenberger, 1984).

However, in practice, problem (8) is not solved exactly since most SVM algorithms will stop when the duality gap is smaller than a given ε. In this case, the convergence of our reduced gradient method is no more guaranteed by standard arguments. Indeed, the output of the approximately solved SVM leads only to an ε-subgradient (Bonnans et al., 2003; Bach et al., 2004a). This situation is more difficult to analyze and we plan to address it thoroughly in future work (see for instance D'Aspremont 2008 for an example of such analysis in a similar context).

4. Extensions

In this section, we discuss how the proposed algorithm can be simply extended to other SVM algorithms such as SVM regression, one-class SVM or pairwise multiclass SVM algorithms. More generally, we will discuss other loss functions that can be used within our MKL algorithms.

4.1 Extensions to Other SVM Algorithms

The algorithm we described in the previous section focuses on binary classification SVMs, but it is worth noting that our MKL algorithm can be extended to other SVM algorithms with only little changes. For SVM regression with the ε-insensitive loss, or clustering with the one-class soft margin loss, the problem only changes in the definition of the objective function $J(d)$ in (8).

For SVM regression (Vapnik et al., 1997; Schölkopf and Smola, 2001), we have

$$J(d) = \left\{ \begin{array}{ll} \min\limits_{f_m, b, \xi_i} & \frac{1}{2} \sum\limits_m \frac{1}{d_m} \| f_m \|^2_{\mathcal{H}_m} + C \sum\limits_i (\xi_i + \xi_i^*) \\ \text{s.t.} & y_i - \sum\limits_m f_m(x_i) - b \leq \varepsilon + \xi_i \quad \forall i \\ & \sum\limits_m f_m(x_i) + b - y_i \leq \varepsilon + \xi_i^* \quad \forall i \\ & \xi_i \geq 0, \xi_i^* \leq 0 \quad \forall i \quad , \end{array} \right. \tag{14}$$

and for one-class SVMs (Schölkopf and Smola, 2001), we have:

$$J(d) = \left\{ \begin{array}{ll} \min\limits_{f_m, b, \xi_i} & \frac{1}{2} \sum\limits_m \frac{1}{d_m} \| f_m \|^2_{\mathcal{H}_m} + \frac{1}{\nu \ell} \sum\limits_i \xi_i - b \\ \text{s.t.} & \sum\limits_m f_m(x_i) \geq b - \xi_i \\ & \xi_i \geq 0 \quad . \end{array} \right.$$

Again, $J(d)$ can be defined according to the dual functions of these two optimization problems, which are respectively

$$J(d) = \left\{ \begin{array}{ll} \max\limits_{\alpha, \beta} & \sum\limits_i (\beta_i - \alpha_i) y_i - \varepsilon \sum\limits_i (\beta_i + \alpha_i) - \frac{1}{2} \sum\limits_{i,j} (\beta_i - \alpha_i)(\beta_j - \alpha_j) \sum\limits_m d_m K_m(x_i, x_j) \\ \text{with} & \sum\limits_i (\beta_i - \alpha_i) = 0 \\ & 0 \leq \alpha_i \ , \ \beta_i \leq C, \quad \forall i \ , \end{array} \right.$$

and

$$J(d) = \left\{ \begin{array}{ll} \max\limits_{\alpha} & -\frac{1}{2}\sum\limits_{i,j}\alpha_i\alpha_j\sum\limits_m d_m K_m(x_i,x_j) \\ \text{with} & 0 \le \alpha_i \le \frac{1}{\nu\ell} \quad \forall i \\ & \sum\limits_i \alpha_i = 1 \ , \end{array} \right.$$

where $\{\alpha_i\}$ and $\{\beta_i\}$ are Lagrange multipliers.

Then, as long as $J(d)$ is differentiable, a property strictly related to the strict concavity of its dual function, our descent algorithm can still be applied. The main effort for the extension of our algorithm is the evaluation of $J(d)$ and the computation of its derivatives. Like for binary classification SVM, $J(d)$ can be computed by means of efficient off-the-shelf SVM solvers and the gradient of $J(d)$ is easily obtained through the dual problems. For SVM regression, we have:

$$\frac{\partial J}{\partial d_m} = -\frac{1}{2}\sum_{i,j}(\beta_i^\star - \alpha_i^\star)(\beta_j^\star - \alpha_j^\star)K_m(x_i,x_j) \qquad \forall m \ ,$$

and for one-class SVM, we have:

$$\frac{\partial J}{\partial d_m} = -\frac{1}{2}\sum_{i,j}\alpha_i^\star\alpha_j^\star K_m(x_i,x_j) \qquad \forall m \ ,$$

where $\alpha_i^\star$ and $\beta_i^\star$ are the optimal values of the Lagrange multipliers. These examples illustrate that extending SimpleMKL to other SVM problems is rather straightforward. This observation is valid for other SVM algorithms (based for instance on the ν parameter, a squared hinge loss or squared-ε tube) that we do not detail here. Again, our algorithm can be used provided $J(d)$ is differentiable, by plugging in the algorithm the function that evaluates the objective value $J(d)$ and its gradient. Of course, the duality gap may be considered as a stopping criterion if it can be computed.

4.2 Multiclass Multiple Kernel Learning

With SVMs, multiclass problems are customarily solved by combining several binary classifiers. The well-known *one-against-all* and *one-against-one* approaches are the two most common ways for building a multiclass decision function based on pairwise decision functions. Multiclass SVM may also be defined right away as the solution of a global optimization problem (Weston and Watkins, 1999; Crammer and Singer, 2001), that may also be addressed with structured-output SVM (Tsochantaridis et al., 2005). Very recently, an MKL algorithm based on structured-output SVM has been proposed by Zien and Ong (2007). This work extends the work of Sonnenburg et al. (2006) to multiclass problems, with an MKL implementation still based on a QCQP or SILP approach.

Several works have compared the performance of multiclass SVM algorithms (Duan and Keerthi, 2005; Hsu and Lin, 2002; Rifkin and Klautau, 2004). In this subsection, we do not deal with this aspect; we explain how SimpleMKL can be extended to pairwise SVM multiclass implementations. The problem of applying our algorithm to structured-output SVM will be briefly discussed later.

Suppose we have a multiclass problem with P classes. For a *one-against-all* multiclass SVM, we need to train P binary SVM classifiers, where the p-th classifier is trained by considering all examples of class p as positive examples while all other examples are considered negative. For a *one-against-one* multiclass problem, $P(P-1)/2$ binary SVM classifiers are built from all pairs

of distinct classes. Our multiclass MKL extension of SimpleMKL differs from the binary version only in the definition of a new cost function $J(d)$. As we now look for the combination of kernels that *jointly* optimizes all the pairwise decision functions, the objective function we want to optimize according to the kernel weights $\{d_m\}$ is:

$$J(d) = \sum_{p \in \mathcal{P}} J_p(d) \ ,$$

where $\mathcal{P}$ is the set of all pairs to be considered, and $J_p(d)$ is the binary SVM objective value for the classification problem pertaining to pair p.

Once the new objective function is defined, the lines of Algorithm 1 still apply. The gradient of $J(d)$ is still very simple to obtain, since owing to linearity, we have:

$$\frac{\partial J}{\partial d_m} = -\frac{1}{2} \sum_{p \in \mathcal{P}} \sum_{i,j} \alpha^\star_{i,p} \alpha^\star_{j,p} y_i y_j K_m(x_i, x_j) \qquad \forall m \ ,$$

where $\alpha_{j,p}$ is the Lagrange multiplier of the j-th example involved in the p-th decision function. Note that those Lagrange multipliers can be obtained *independently* for each pair.

The approach described above aims at finding the combination of kernels that *jointly* optimizes all binary classification problems: this one set of features should maximize the sum of margins. Another possible and straightforward approach consists in running independently SimpleMKL for each classification task. However, this choice is likely to result in as many combinations of kernels as there are binary classifiers.

4.3 Other Loss Functions

Multiple kernel learning has been of great interest and since the seminal work of Lanckriet et al. (2004b), several works on this topic have flourished. For instance, multiple kernel learning has been transposed to least-square fitting and logistic regression (Bach et al., 2004b). Independently, several authors have applied mixed-norm regularization, such as the additive spline regression model of Grandvalet and Canu (1999). This type of regularization, which is now known as the *group lasso*, may be seen as a linear version of multiple kernel learning (Bach, 2008). Several algorithms have been proposed for solving the group lasso problem. Some of them are based on projected gradient or on coordinate descent algorithm. However, they all consider the non-smooth version of the problem.

We previously mentioned that Zien and Ong (2007) have proposed an MKL algorithm based on structured-output SVMs. For such problem, the loss function, which differs from the usual SVM hinge loss, leads to an algorithm based on cutting planes instead of the usual QP approach.

Provided the gradient of the objective value can be obtained, our algorithm can be applied to group lasso and structured-output SVMs. The key point is whether the theorem of Bonnans et al. (2003) can be applied or not. Although we have not deeply investigated this point, we think that many problems comply with this requirement, but we leave these developments for future work.

4.4 Approximate Regularization Path

SimpleMKL requires the setting of the usual SVM hyperparameter C, which usually needs to be tuned for the problem at hand. For doing so, a practical and useful technique is to compute the so-called regularization path, which describes the set of solutions as C varies from 0 to ∞.

Exact path following techniques have been derived for some specific problems like SVMs or the lasso (Hastie et al., 2004; Efron et al., 2004). Besides, regularization paths can be sampled by predictor-corrector methods (Rosset, 2004; Bach et al., 2004b).

For model selection purposes, an approximation of the regularization path may be sufficient. This approach has been applied for instance by Koh et al. (2007) in regularized logistic regression.

Here, we compute an approximate regularization path based on a warm-start technique. Suppose, that for a given value of C, we have computed the optimal $(d^\star, \alpha^\star)$ pair; the idea of a warm-start is to use this solution for initializing another MKL problem with a different value of C. In our case, we iteratively compute the solutions for decreasing values of C (note that $\alpha^\star$ has to be modified to be a feasible initialization of the more constrained SVM problem).

5. Numerical Experiments

In this experimental section, we essentially aim at illustrating three points. The first point is to show that our gradient descent algorithm is efficient. This is achieved by binary classification experiments, where SimpleMKL is compared to the SILP approach of Sonnenburg et al. (2006). Then, we illustrate the usefulness of a multiple kernel learning approach in the context of regression. The examples we use are based on wavelet-based regression in which the multiple kernel learning framework naturally fits. The final experiment aims at evaluating the multiple kernel approach in a model selection problem for some multiclass problems.

5.1 Computation Time

The aim of this first set of experiments is to assess the running times of SimpleMKL.[2] First, we compare with SILP regarding the time required for computing a single solution of MKL with a given C hyperparameter. Then, we compute an approximate regularization path by varying C values. We finally provide hints on the expected complexity of SimpleMKL, by measuring the growth of running time as the number of examples or kernels increases.

5.1.1 TIME NEEDED FOR REACHING A SINGLE SOLUTION

In this first benchmark, we put SimpleMKL and SILP side by side, for a fixed value of the hyperparameter C ($C = 100$). This procedure, which does not take into account a proper model selection procedure, is not representative of the typical use of SVMs. It is however relevant for the purpose of comparing algorithmic issues.

The evaluation is made on five data sets from the UCI repository: *Liver*, *Wpbc*, *Ionosphere*, *Pima*, *Sonar* (Blake and Merz, 1998). The candidate kernels are:

- Gaussian kernels with 10 different bandwidths σ, on all variables and on each single variable;
- polynomial kernels of degree 1 to 3, again on all and each single variable.

All kernel matrices have been normalized to unit trace, and are precomputed prior to running the algorithms.

Both SimpleMKL and SILP wrap an SVM dual solver based on SimpleSVM, an active constraints method written in Matlab (Canu et al., 2003). The descent procedure of SimpleMKL is

2. All the experiments have been run on a Pentium D-3 GHz with 3 GB of RAM.

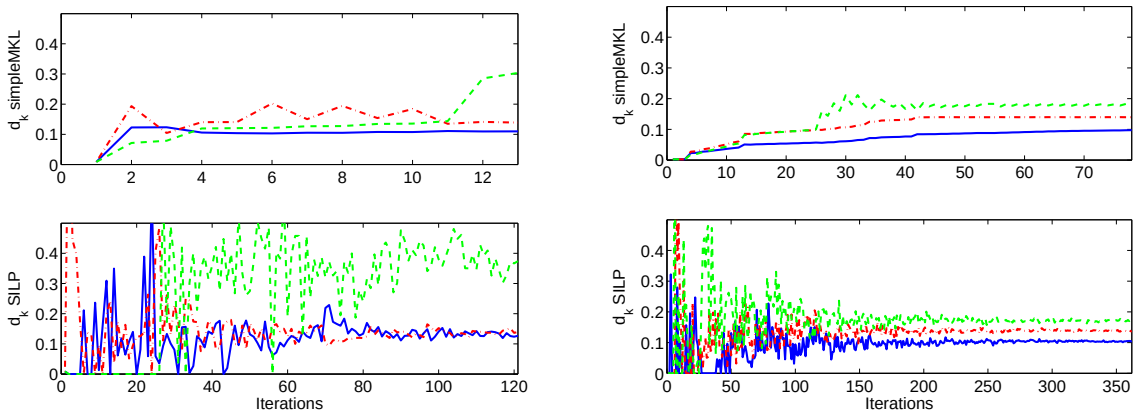

Figure 2: Evolution of the three largest weights d_m for SimpleMKL and SILP; left row: *Pima*; right row: *Ionosphere*.

also implemented in Matlab, whereas the linear programming involved in SILP is implemented by means of the publicly available toolbox LPSOLVE (Berkelaar et al., 2004).

For a fair comparison, we use the same stopping criterion for both algorithms. They halt when, either the duality gap is lower than 0.01, or the number of iterations exceeds 2000. Quantitatively, the displayed results differ from the preliminary version of this work, where the stopping criterion was based on the stabilization of the weights, but they are qualitatively similar (Rakotomamonjy et al., 2007).

For each data set, the algorithms were run 20 times with different train and test sets (70% of the examples for training and 30% for testing). Training examples were normalized to zero mean and unit variance.

In Table 1, we report different performance measures: accuracy, number of selected kernels and running time. As the latter is mainly spent in querying the SVM solver and in computing the gradient of J with respect to d, the number of calls to these two routines is also reported.

Both algorithms are nearly identical in performance accuracy. Their number of selected kernels are of same magnitude, although SimpleMKL tends to select 10 to 20% more kernels. As both algorithms address the same convex optimization problem, with convergent methods starting from the same initialization, the observed differences are only due to the inaccuracy of the solution when the stopping criterion is met. Hence, the trajectories chosen by each algorithm for reaching the solution, detailed in Section 3.4, explain the differences in the number of selected kernels. The updates of d_m based on the descent algorithm of SimpleMKL are rather conservative (small steps departing from $1/M$ for all d_m), whereas the oscillations of cutting planes are likely to favor extreme solutions, hitting the edges of the simplex.

This explanation is corroborated by Figure 2, which compares the behavior of the d_m coefficients through time. The instability of SILP is clearly visible, with very high oscillations in the first iterations and a noticeable residual noise in the long run. In comparison, the trajectories for SimpleMKL are much smoother.

If we now look at the overall difference in computation time reported in Table 1, clearly, on all data sets, SimpleMKL is faster than SILP, with an average gain factor of about 5. Furthermore, the

Liver $\ell = 241$ $M = 91$

Algorithm	# Kernel	Accuracy	Time (s)	# SVM eval	# Gradient eval

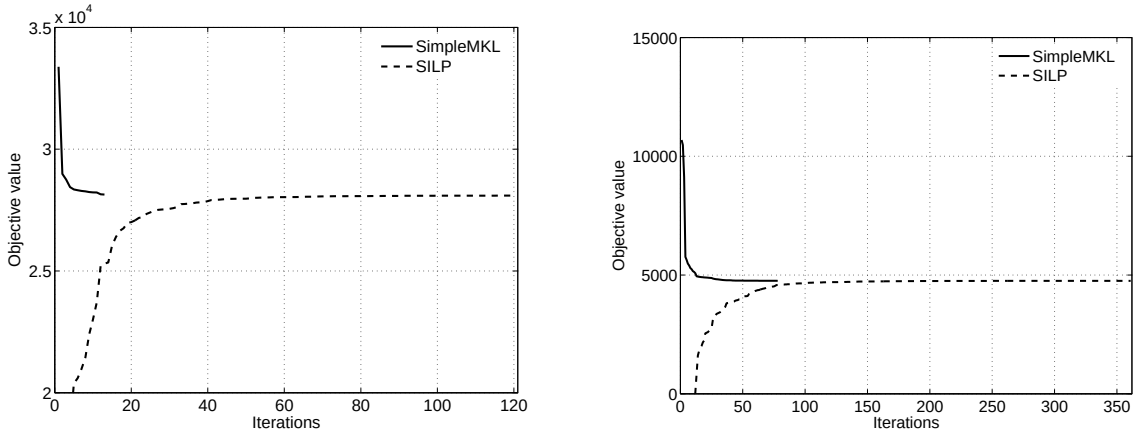
larger the number of kernels is, the larger the speed gain we achieve. Looking at the last column of Table 1, we see that the main reason for improvement is that SimpleMKL converges in fewer iterations (that is, gradient computations). It may seem surprising that this gain is not counterbalanced by the fact that SimpleMKL requires many more calls to the SVM solver (on average, about 4 times). As we stated in Section 3.4, when the number of kernels is large, computing the gradient may be expensive compared to SVM retraining with warm-start techniques.

To understand why, with this large number of calls to the SVM solver, SimpleMKL is still much faster than SILP, we have to look back at Figure 2. On the one hand, the large variations in subsequents d_m values for SILP, entail that subsequent SVM problems are not likely to have similar solutions: a warm-start call to the SVM solver does not help much. On the other hand, with the smooth trajectories of d_m in SimpleMKL, the previous SVM solution is often a good guess for the



Pima *Ionosphere*

Figure 3: Evolution of the objective values for SimpleMKL and SILP; left row: *Pima*; right row: *Ionosphere*.

current problem: a warm-start call to the SVM solver results in much less computation than a call from scratch.

Table 1 also shows the results obtained when replacing the update scheme described in Algorithm 1 by a usual reduced gradient update, which, at each iteration, modifies d by computing the optimal step size on the descent direction D (12). The training of this variant is considerably slower than SimpleMKL and is only slightly better than SILP. We see that the gradient descent updates require many more calls to the SVM solver and a number of gradient computations comparable with SILP. Note that, compared to SILP, the numerous additional calls to the SVM solver have not a drastic effect on running time. The gradient updates are stable, so that they can benefit from warm-start contrary to SILP.

To end this first series of experiments, Figure 3 depicts the evolution of the objective function for the data sets that were used in Figure 2. Besides the fact that SILP needs more iterations for achieving a good approximation of the final solution, it is worth noting that the objective values rapidly reach their steady state while still being far from convergence, when d_m values are far from being settled. Thus, monitoring objective values is not suitable to assess convergence.

5.1.2 TIME NEEDED FOR GETTING AN APPROXIMATE REGULARIZATION PATH

In practice, the optimal value of C is unknown, and one has to solve several SVM problems, spanning a wide range of C values, before choosing a solution according to some model selection criterion like the cross-validation error. Here, we further pursue the comparison of the running times of SimpleMKL and SILP, in a series of experiments that include the search for a sensible value of C.

In this new benchmark, we use the same data sets as in the previous experiments, with the same kernel settings. The task is only changed in the respect that we now evaluate the running times needed by both algorithms to compute an approximate regularization path.

For both algorithms, we use a simple warm-start technique, which consists in using the optimal solutions $\{d_m^\star\}$ and $\{\alpha_i^\star\}$ obtained for a given C to initialize a new MKL problem with $C + \Delta C$

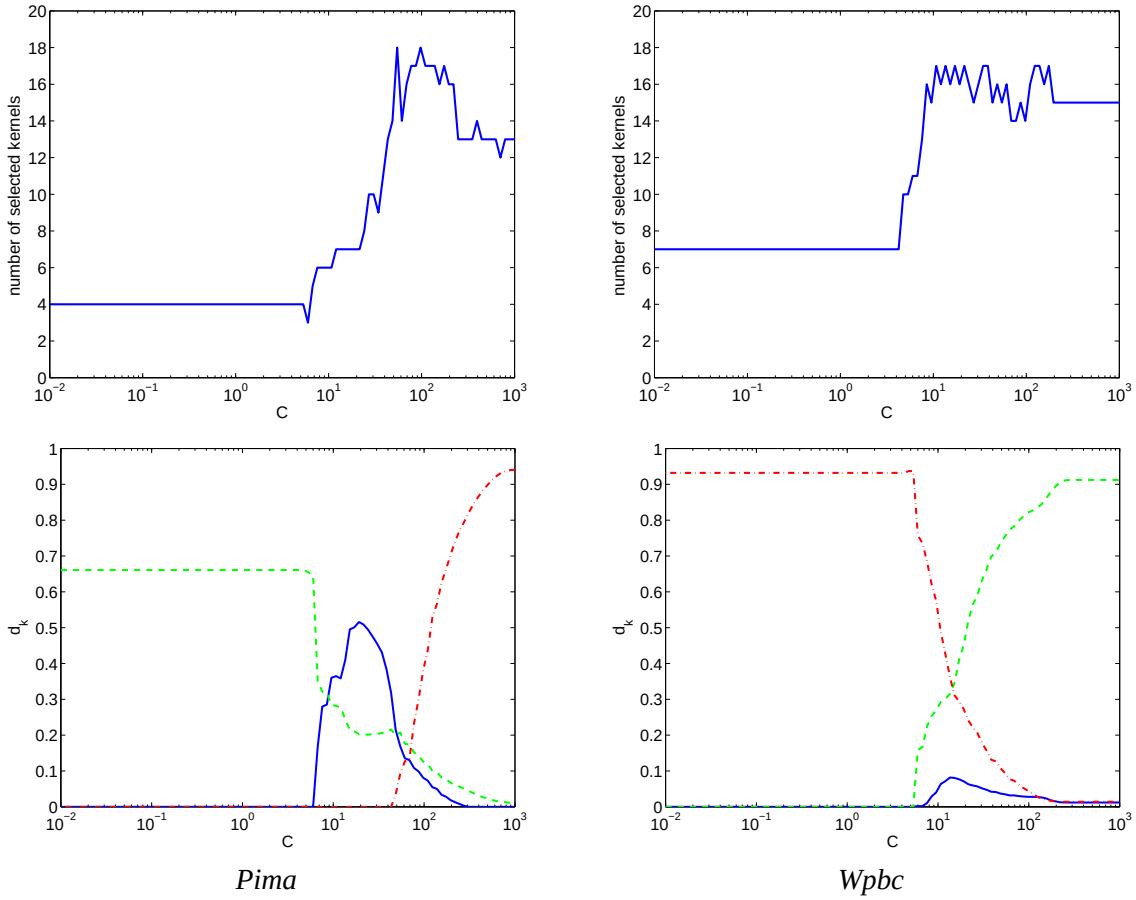


Figure 4: Regularization paths of some d_m and the number of selected kernels versus C; left row: *Pima*; right row: *Wpbc*.

(DeCoste and Wagstaff., 2000). As described in Section 4.4, we start from the largest C and then approximate the regularization path by decreasing its value. The set of C values is obtained by evenly sampling the interval $[0.01, 1000]$ on a logarithmic scale.

Figure 4 shows the variations of the number of selected kernels and the values of d along the regularization path for the *Pima* and *Wpbc* data sets. The number of kernels is not a monotone function of C: for small values of C, the number of kernels is somewhat constant, then, it rises rapidly. There is a small overshoot before reaching a plateau corresponding to very high values of C. This trend is similar for the number of leading terms in the kernel weight vector d. Both phenomenon were observed consistently over the data sets we used.

Table 2 displays the average computation time (over 10 runs) required for building the approximate regularization path. As previously, SimpleMKL is more efficient than SILP, with a gain factor increasing with the number of kernels in the combination. The range of gain factors, from 5.9 to 23, is even more impressive than in the previous benchmark. SimpleMKL benefits from the continuity of solutions along the regularization path, whereas SILP does not take advantage of warm starts. Even provided with a good initialization, it needs many cutting planes to stabilize.

Data Set	SimpleMKL	SILP	Ratio
Liver	148 ± 37	875 ± 125	5.9
Pima	1030 ± 195	6070 ± 1430	5.9
Ionosphere	1290 ± 927	8840 ± 1850	6.8

Sonar	625 ± 174	$1.52 \cdot 10^5$ (*)	243

Table 2: Average computation time (in seconds) for getting an approximate regularization path. For the *Sonar* data set, SILP was extremely slow, so that regularization path was computed only once.

5.1.3 MORE ON SIMPLEMKL RUNNING TIMES

Here, we provide an empirical assessment of the expected complexity of SimpleMKL on different data sets from the UCI repository. We first look at the situation where kernel matrices can be pre-computed and stored in memory, before reporting experiments where the memory are too high, leading to repeated kernel evaluations.

In a first set of experiments, we use Gaussian kernels, computed on random subsets of variables and with random width. These kernels are precomputed and stored in memory, and we report the average CPU running times obtained from 20 runs differing in the random draw of training examples. The stopping criterion is the same as in the previous section: a relative duality gap less than $\varepsilon = 0.01$.

The first two rows of Figure 5 depicts the growth of computation time as the number of kernel increases. We observe a nearly linear trend for the four learning problems. This growth rate could be expected considering the linear convergence property of gradient techniques, but the absence of overhead is valuable.

The last row of Figure 5 depicts the growth of computation time as the number of examples increases. Here, the number of kernels is set to 10. In these plots, the observed trend is clearly superlinear. Again, this trend could be expected, considering that SVM expected training times are superlinear in the number of training examples. As we already mentioned, the complexity of SimpleMKL is tightly linked to the one of SVM training (for some examples of single kernel SVM running time, one can refer to the work of Loosli and Canu 2007).

When all the kernels used for MKL cannot be stored in memory, one can resort to a decomposition method. Table 3 reports the average computation times, over 10 runs, in this more difficult situation. The large-scale SVM scheme of Joachims (1999) has been implemented, with basis kernels recomputed whenever needed. This approach is computationally expensive but goes with no memory limit. For these experiments, the stopping criterion is based on the variation of the weights d_m. As shown in Figure 2, the kernel weights rapidly reach a steady state and many iterations are spent for fine tuning the weight and reach the duality gap tolerance. Here, we trade the optimality guarantees provided by the duality gap for substantial computational time savings. The algorithm terminates when the kernel weights variation is lower than 0.001.

Results reported in Table 3 just aim at showing that medium and large-scale situations can be handled by SimpleMKL. Note that Sonnenburg et al. (2006) have run a modified version of their SILP algorithm on a larger scale data sets. However, for such experiments, they have taken advantage of some specific feature map properties. And, as they stated, for general cases where

kernel matrices are dense, they have to rely on the SILP algorithm we used in this section for efficiency comparison .

5.2 Multiple Kernel Regression Examples

Several research papers have already claimed that using multiple kernel learning can lead to better generalization performances in some classification problems (Lanckriet et al., 2004a; Zien

Data Set	Nb Examples	# Kernel	Accuracy (%)	Time (s)
Yeast	1335	22	77.25	1130
Spamdata	4140	71	93.49	34200

Table 3: Average computation time needed by SimpleSVM using decomposition methods.

and Ong, 2007; Harchaoui and Bach, 2007). This next experiment aims at illustrating this point but in the context of regression. The problem we deal with is a classical univariate regression problem where the design points are irregular (D'Amato et al., 2006). Furthermore, according to Equation (14), we look for the regression function $f(x)$ as a linear combination of functions each belonging to a wavelet based reproducing kernel Hilbert space.

The algorithm we use is a classical SVM regression algorithm with multiple kernels where each kernel is built from a set of wavelets. These kernels have been obtained according to the expression:

$$K(x,x') = \sum_j \sum_s \frac{1}{2^j} \psi_{j,s}(x) \psi_{j,s}(x')$$

where $\psi(\cdot)$ is a mother wavelet and j,s are respectively the dilation and translation parameters of the wavelet $\psi_{j,s}(\cdot)$. The theoretical details on how such kernels can been built are available in D'Amato et al. (2006); Rakotomamonjy and Canu (2005); Rakotomamonjy et al. (2005).

Our hope when using multiple kernel learning in this context is to capture the multiscale structure of the target function. Hence, each kernel involved in the combination should be weighted accordingly to its correlation to the target function. Furthermore, such a kernel has to be built according to the multiscale structure we wish to capture. In this experiment, we have used three different choices of multiple kernels setting. Suppose we have a set of wavelets with $j \in [j_{min}, j_{max}]$ and $s \in\in [s_{min}, s_{max}]$.

First of all, we have build a single kernel from all the wavelets according to the above equation. Then we have created kernels from all wavelets of a given scale (dilation)

$$K_{Dil,J}(x,x') = \sum_{s=s_{min}}^{s_{max}} \frac{1}{2^j} \psi_{J,s}(x) \psi_{J,s}(x') \qquad \forall J \in [j_{min}, j_{max}]$$

and lastly, we have a set of kernels, where each kernel is built from wavelets located at a given scale and given time-location:

$$K_{Dil-Trans,J,\mathcal{S}}(x,x') = \sum_{s=\mathcal{S}} \frac{1}{2^j} \psi_{J,s}(x) \psi_{J,s}(x') \qquad \forall J \in [j_{min}, j_{max}]$$

where $\mathcal{S}$ is a given set of translation parameter. These sets are built by splitting the full translation parameters index in contiguous and non-overlapping index. The mother wavelet we used is a *Symmlet* Daubechies wavelet with 6 vanishing moments. The resolution levels of the wavelet goes from $j_{min} = -3$ to $j_{min} = 6$. According to these settings, we have 10 dilation kernels and 48 dilation-translation kernels.

We applied this MKL SVM regression algorithm to simulated data sets which are well-known functions in the wavelet literature (Antoniadis and Fan, 2001). Each signal length is 512 and a Gaussian independent random has been added to each signal so that the signal to noise ratio is equal to 5. Examples of the true signals and their noisy versions are displayed in Figure 6. Note that

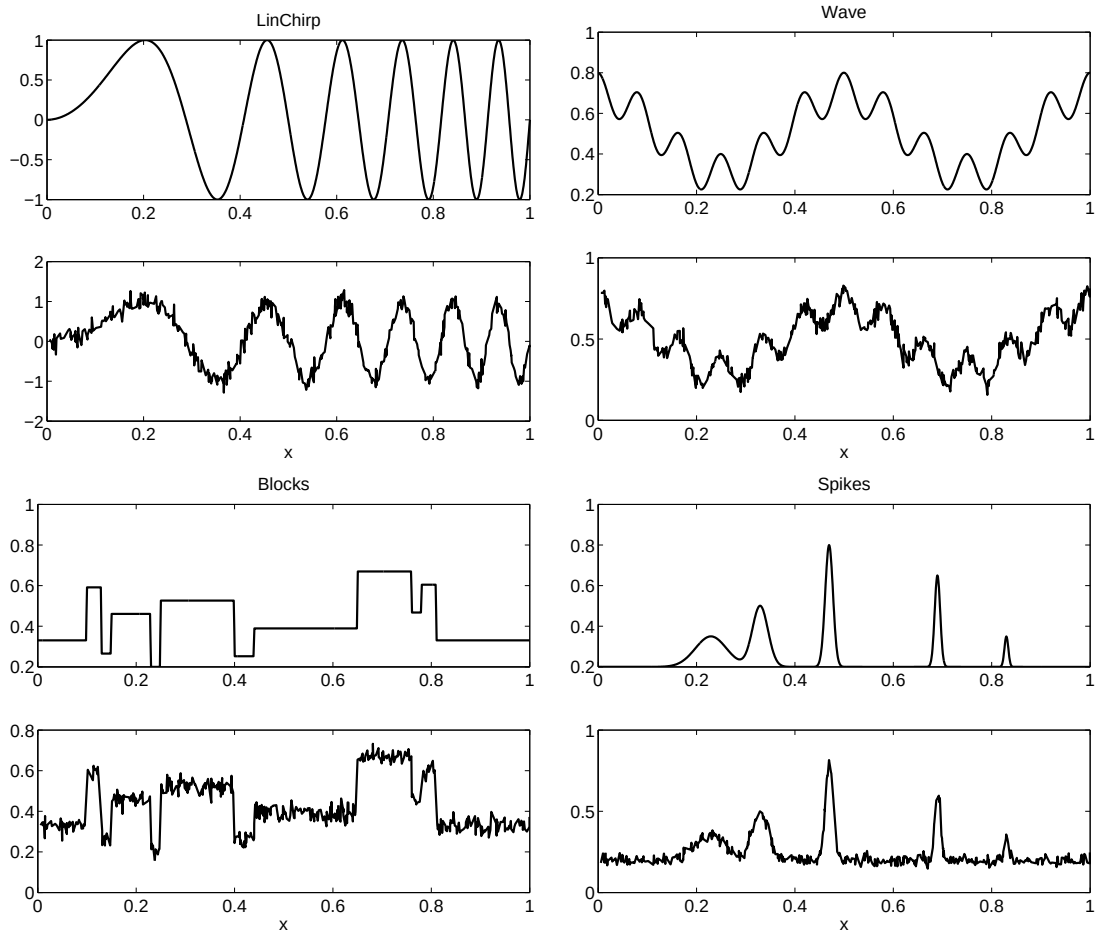

Figure 6: Examples of signals to approximate in the regression problem. (top-left) LinChirp. (top-right) Wave. (bottom-left) Blocks. (bottom-right) Spikes. For each figure, the top plot depicts the true signal while the bottom one presents an example of their randomly sampled noisy versions.

the *LinChirp* and *Wave* signals present some multiscale features that should suit well to an MKL approach.

Performance of the different multiple kernel settings have been compared according to the following experimental setting. For each training signal, we have estimated the regularization parameter C of the MKL SVM regression by means of a validation procedure. The 512 samples have been randomly separated in a learning and a validation sets. Then, by means of an approximate regularization path as described in Section 4.4, we learn different regression functions for 20 samples of C logarithmically sampled on the interval $[0.01, 1000]$. This is performed for 5 random draws of the learning and validation sets. The C value that gives the lowest average normalized mean-square error is considered as the optimal one. Finally, we use all the samples of the training signal and the optimal C value to train an MKL SVM regression. The quality of the resulting regression function is then evaluated with respect to 1000 samples of the true signal. For all the simulations the ε has been fixed to 0.1.

	Single Kernel	Kernel *Dil*		Kernel *Dil-Trans*	
Data Set	Norm. MSE (%)	#Kernel	Norm. MSE	#Kernel	Norm. MSE
LinChirp	1.46 ± 0.28	7.0	1.00 ± 0.15	21.5	0.92 ± 0.20
Wave	0.98 ± 0.06	5.5	0.73 ± 0.10	20.6	0.79 ± 0.07
Blocks	1.96 ± 0.14	6.0	2.11 ± 0.12	19.4	1.94 ± 0.13
Spike	6.85 ± 0.68	6.1	6.97 ± 0.84	12.8	5.58 ± 0.84

Table 4: Normalized Mean Square error for the data described in Figure 6. The results are averaged over 20 runs. The first column give the performance of a SVM regression using a single kernel which is the average sum of all the kernels used for the two other results. Results corresponding to the columns *Kernel Dil* and *Kernel Dil-Trans* are related to MKL SVM regression with multiple kernels. # Kernel denotes the number of kernels selected by SimpleMKL.

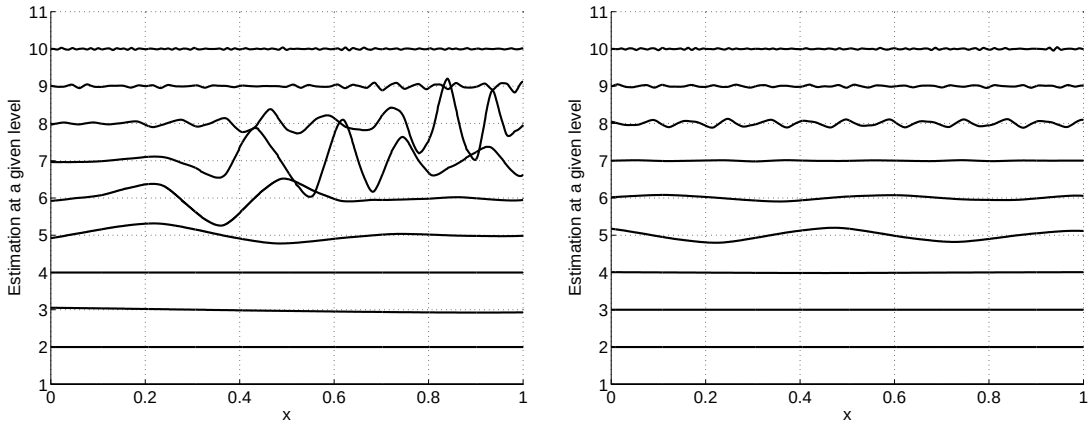

Figure 7: Examples of multiscale analysis of the *LinChirp* signal (left) and the *Wave* signal (right) when using Dilation based multiple kernels. The plots show how each function $f_m(\cdot)$ of the estimation focuses on a particular scale of the target function. The y-axis denotes the scale j of the wavelet used for building the kernel. We can see that some low resolution space are not useful for the target estimation.

Table 4 summarizes the generalization performances achieved by the three different kernel settings. As expected, using a multiple kernel learning setting outperforms the single kernel setting especially when the target function presents multiscale structure. This is noticeable for the *LinChirp* and *Wave* data set. Interestingly, for these two signals, performances of the multiple kernel settings also depend on the signal structure. Indeed, *Wave* presents a frequency located structure while *LinChirp* has a time and frequency located structure. Therefore, it is natural that the Dilation set of kernels performs better than the Dilation-Translation ones for *Wave*. Figure 7 depicts an example of multiscale regression function obtained when using the Dilation set of kernels. These plots show how the kernel weights adapt themselves to the function to estimate. For the same reason of adaptivity to the signal, the Dilation-Translation set of kernels achieves better performances for *Wave* and *Spikes*. We also notice that for the *Blocks* signal using multiple kernels only slightly improves performance compared to a single kernel.

			Training Set Size

WAV	15.18 ± 0.90 (15)	15.43 ± 0.97	14.26 ± 0.68 (8)	14.09 ± 0.55

Table 6: Comparison of the generalization performances of an MKL approach and a cross-validation approach for selecting models in some multiclass problems. We have reported the average (over 20 runs) the test set errors of our algorithm while the errors obtained for the SV approach have been extracted from Duan and Keerthi (2005). Results also depend on the training set sizes.

5.3 Multiclass Problem

For selecting the kernel and regularization parameter of a SVM, one usually tries all pairs of parameters and picks the couple that achieves the best cross-validation performance. Using an MKL approach, one can instead let the algorithm combine all available kernels (obtained by sampling the parameter) and just selects the regularization parameter by cross-validation. This last experiment aims at comparing on several multi-class data sets problem, these two model selection approaches (using MKL and CV) for choosing the kernel. Thus, we evaluate the two methods on some multi-class data sets taken from the UCI collection: *dna*, *waveform*, *image segmentation* and *abe* a subset problem of the Letter data set corresponding to the classes A, B and E. Some information about the data set are given in Table 5. For each data set, we divide the whole data into a training set and a test set. This random splitting has been performed 20 times. For ease of comparison with previous works, we have used the splitting proposed by Duan and Keerthi (2005) and available at `http://www.keerthis.com/multiclass.html`. Then we have just computed the performance of SimpleMKL and report their results for the CV approach.

In our MKL *one-against-all* approach, we have used a polynomial kernel of degree 1 to 3 and Gaussian kernel for which σ belongs to $[0.5, 1, 2, 5, 7, 10, 12, 15, 17, 20]$. For the regularization parameter C, we have 10 samples over the interval $[0.01, 10000]$. Note that Duan and Keerthi (2005) have used a more sophisticated sampling strategy based on a coarse sampling of σ and C and followed by fine-tuned sampling procedure. They also select the same couple of C and σ over all pairwise decision functions. Similarly to Duan and Keerthi (2005), the best hyperparameter C has been tuned according to a five-fold cross-validation. According to this best C, we have learned an MKL all the full training set and evaluated the resulting decision function on the test set.

The comparison results are summarized on Table 6. We can see that the generalization performances of an MKL approach is either similar or better than the performance obtained when selecting the kernel through cross-validation, even though we have roughly searched the kernel and regularization parameter space. Hence, we can deduce that MKL can favorably replace cross-validation on kernel parameters. This result based on empirical observations is in accordance with some other works (Lanckriet et al., 2004b; Fung et al., 2004; Kim et al., 2006). However, we think that MKL and thus SimpleMKL in particular, can be better exploited and thus performs better than cross-validation when the kernels have been obtained from heterogeneous source as described for instance in Lanckriet et al. (2004a); Zien and Ong (2007); Harchaoui and Bach (2007).

6. Conclusion

In this paper, we introduced SimpleMKL, a novel algorithm for solving the Multiple Kernel Learning problem. Our formalization of the MKL problem results in a smooth and convex optimization problem, which is actually equivalent to other MKL formulations available in the literature. The main added value of the smoothness of our new objective function is that descent methods become practical and efficient means to solve the optimization problem that wraps a single kernel SVM solver. We provide optimality conditions, analyze convergence and computational complexity issues for binary classification. The SimpleMKL algorithm and the resulting analyses can be easily be transposed to SVM regression, one-class SVM and multiclass SVM to name a few.

We provide experimental evidence that SimpleMKL is significantly more efficient than the state-of-the art SILP approach (Sonnenburg et al., 2006). This efficiency permits to demonstrate the usefulness of our algorithm on wavelet kernel based regression. We also illustrate in multiclass problems that MKL is a viable alternative to cross-validation for selecting a model.

Possible extensions of this work include other learning problems, such as semi-supervised learning or kernel eigenvalue problem like kernel Fisher discriminant analysis. We also plan to explore two different ways to speed up the algorithm. As a first direction, we will investigate ways to obtain a better the descent direction, for example with second-order methods. Note however that computing the Hessian needs the derivative of the dual variable with respects to the weights d. This operation requires solving a linear system (Chapelle et al., 2002) and thus may produce some computational overhead. The second direction is motivated by the observation that most of the computational load is to the computation of the kernel combination. Hence, coordinate-wise optimizers may provide promising routes for improvements.

Appendix A.

This appendix addresses the convexity and differentiability issue of our MKL formulation.

A.1 Proof of Convexity of the Weighted Squared Norm MKL Formulation

The convexity of the MKL problem (2) introduced in Section 2.2 will be established if we prove the convexity of

$$J(f,t) = \frac{1}{t}\langle f, f\rangle_{\mathcal{H}} \quad \text{where } f \in \mathcal{H} \text{ and } t \in \mathbb{R}^{*+}.$$

Since $J(f,t)$ is differentiable with respects to its arguments, we only have to make sure that the first order conditions for convexity are verified. As the convexity of the domain of J is trivial, we verify that, for any (f,t) and $(g,s) \in \mathcal{H} \times \mathbb{R}^{*+}$, the following holds:

$$J(g,s) \geq J(f,t) + \langle \nabla_f J, g-f\rangle_{\mathcal{H}} + (s-t)\nabla_t J \ .$$

As $\nabla_f J = \frac{2}{t} f$ and $\nabla_t J = -\frac{1}{t^2}\langle f, f\rangle_{\mathcal{H}}$, this inequality can be written as

$$\begin{aligned} & \frac{1}{s}\langle g,g\rangle_{\mathcal{H}} \geq \frac{2}{t}\langle f,g\rangle_{\mathcal{H}} - \frac{s}{t^2}\langle f,f\rangle_{\mathcal{H}} \ , \\ \Leftrightarrow \quad & \langle t\,g - s\,f, t\,g - s\,f\rangle_{\mathcal{H}} \geq 0 \ , \end{aligned}$$

where we used that s and t are positive. The above inequality holds since the scalar product on the left-hand-side is a norm. Hence problem (2) minimizes the sum of convex functions on a convex set; it is thus convex. Note that when $\mathcal{H}$ is a finite dimension space, the function $J(f,t)$ is known as the perspective of f, whose convexity is proven in textbooks (Boyd and Vandenberghe, 2004).

A.2 Differentiability of Optimal Value Function

The algorithm we propose for solving the MKL problem heavily relies on the differentiability of the optimal value of the primal SVM objective function. For the sake of self-containedness, we reproduce here a theorem due to Bonnans and Shapiro (1998) that allows us to compute the derivatives of $J(d)$ defined in (8).

Theorem 1 *(Bonnans and Shapiro, 1998) Let X be a metric space and U be a normed space. Suppose that for all $x \in X$ the function $f(x,\cdot)$ is differentiable, that $f(x,u)$ and $D_u f(x,u)$ the derivative of $f(x,\cdot)$ are continuous on $X \times U$ and let Φ be a compact subset of X. Let define the optimal value function as $v(u) = \inf_{x\in\Phi} f(x,u)$. The optimal value function is directionally differentiable. Furthermore, if for $u^0 \in U$, $f(\cdot,u^0)$ has a unique minimizer x^0 over Φ then $v(u)$ is differentiable at u^0 and $Dv(u^0) = D_u f(x^0,u^0)$.*

Abstract

The causal discovery from data is important for various scientific investigations. Because we cannot distinguish the different directed acyclic graphs (DAGs) in a Markov equivalence class learned from observational data, we have to collect further information on causal structures from experiments with external interventions. In this paper, we propose an active learning approach for discovering causal structures in which we first find a Markov equivalence class from observational data, and then we orient undirected edges in every chain component via intervention experiments separately. In the experiments, some variables are manipulated through external interventions. We discuss two kinds of intervention experiments, randomized experiment and quasi-experiment. Furthermore, we give two optimal designs of experiments, a batch-intervention design and a sequential-intervention design, to minimize the number of manipulated variables and the set of candidate structures based on the minimax and the maximum entropy criteria. We show theoretically that structural learning can be done locally in subgraphs of chain components without need of checking illegal v-structures and cycles in the whole network and that a Markov equivalence subclass obtained after each intervention can still be depicted as a chain graph.

Keywords: active learning, causal networks, directed acyclic graphs, intervention, Markov equivalence class, optimal design, structural learning

1. Introduction

A directed acyclic graph (DAG) (also called a Bayesian network) is a powerful tool to describe a large complex system in various scientific investigations, such as bioinformatics, epidemiology, sociology and business (Pearl, 1988; Lauritzen, 1996; Whittaker, 1990; Aliferis et al., 2003; Jansen et al., 2003; Friedman, 2004). A DAG is also used to describe causal relationships among variables. It is crucial to discover the structure of a DAG for understanding a large complex system or for doing uncertainty inference on it (Cooper and Yoo, 1999; Pearl, 2000). There are many methods of structural learning, and the main methods are Bayesian methods (Cooper and Yoo, 1999; Heckerman, 1997) and constraint-based methods (Spirtes et al., 2000). From data obtained in observational studies, we may not have enough information to discover causal structures completely, but we can obtain only a Markov equivalence class. Thus we have to collect further information of causal structures via experiments with external interventions. Heckerman et al. (1995) discussed structural learning of Bayesian networks from a combination of prior knowledge and statistical data. Cooper and Yoo (1999) presented a method of causal discovery from a mixture of experimental and obser-

vational data. Tian and Pearl (2001a,b) proposed a method of discovering causal structures based on dynamic environment. Tong and Koller (2001) and Murphy (2001) discussed active learning of Bayesian network structures with posterior distributions of structures based on decision theory. In these methods, causal structures are discovered by using additional information from domain experts or experimental data.

Chain graphs were introduced as a natural generalization of DAGs to admit more flexible causal interpretation (Lauritzen and Richardson, 2002). A chain graph contains both directed and undirected edges. A chain component of a chain graph is a connected undirected graph obtained by removing all directed edges from the chain graph. Andersson et al. (1997) showed that DAGs in a Markov equivalence class can be represented by a chain graph. He et al. (2005) presented an approach of structural learning in which a Markov equivalence class of DAGs is sequentially refined into some smaller subclasses via domain knowledge and randomized experiments.

In this paper, we discuss randomized experiments and quasi-experiments of external interventions. We propose a method of local orientations in every chain component, and we show theoretically that the method of local orientations does not create any new v-structure or cycle in the whole DAG provided that neither v-structure nor cycle is created in any chain component. Thus structural learning can be done locally in every chain component without need of checking illegal v-structures and cycles in the whole network. Then we propose the optimal designs of interventional experiments based on the minimax and maximum entropy criteria. These results greatly extend the approach proposed by He et al. (2005). In active learning, we first find a Markov equivalence class from observational data, which can be represented by a chain graph, and then we orient undirected edges via intervention experiments. Two kinds of intervention experiments can be used for orientations. One is randomized experiment, in which an individual is randomly assigned to some level combination of the manipulated variables at a given probability. Randomization can disconnect the manipulated variables from their parent variables in the DAG. Although randomized experiments are most powerful for learning causality, they may be inhibitive in practice. The other is quasi-experiment, in which the pre-intervention distributions of some variables are changed via external interventions, but we cannot ensure that the manipulated variables can be disconnected from their parent variables in the DAG, and thus the post-intervention distributions of manipulated variables may still depend on their parent variables. For example, the pre-intervention distribution of whether patients take a vaccine or not may depend on some variables, and the distribution may be changed by encouraging patients with some benefit in the quasi-experiment, but it may still depend on these variables. Furthermore, we discuss the optimal designs by which the number of manipulated variables is minimized or the uncertainty of candidate structures is minimized at each experiment step based on the minimax and the maximum entropy criteria. We propose two kinds of optimal designs: a batch-intervention experiment and a sequential intervention experiment. For the former, we try to find the minimum set of variables to be manipulated in a batch such that undirected edges are all oriented after the interventions. For the latter, we first choose a variable to be manipulated such that the Markov equivalence class can be reduced by manipulating the variable into a subclass as small as possible, and then according to the current subclass, we repeatedly choose a next variable to be manipulated until all undirected edges are oriented.

In Section 2, we introduce notation and definitions and then show some theoretical results on Markov equivalence classes. In Section 3, we present active learning of causal structures via external interventions and discuss randomized experiments and quasi-experiments. In Section 4, we propose two optimal designs of intervention experiments, a batch-intervention design and a sequen-

tial intervention design. In Section 5, we show simulation results to evaluate the performances of intervention designs proposed in this paper. Conclusions are given in Section 6. Proofs of theorems are given in Appendix.

2. Causal DAGs and Markov Equivalence Class

A graph G can be defined to be a pair $G = (\mathbb{V}, \mathbb{E})$, where $\mathbb{V} = \{V_1, \cdots, V_n\}$ denotes the node set and $\mathbb{E}$ denotes the edge set which is a subset of the set $\mathbb{V} \times \mathbb{V}$ of ordered pairs of nodes. If both ordered pairs (V_i, V_j) and (V_j, V_i) are in $\mathbb{E}$, we say that there is an undirected edge between V_i and V_j, denoted as $V_i - V_j$. If $(V_i, V_j) \in \mathbb{E}$ and $(V_j, V_i) \notin \mathbb{E}$, we call it a directed edge, denoted as $V_i \to V_j$. We say that V_i is a neighbor of V_j if there is an undirected or directed edge between V_i and V_j. A graph is directed if all edges of the graph are directed. A graph is undirected if all edges of the graph are undirected.

A sequence $(V_1, V_2, \cdots, V_k)$ is called a *partially directed path* from V_1 to V_k if either $V_i \to V_{i+1}$ or $V_i - V_{i+1}$ is in G for all $i = 1, \ldots, k-1$. A partially directed path is a directed path if there is not any undirected edge in the path. A node V_i is an *ancestor* of V_j and V_j is a *descendant* of V_i if there is a directed path from V_i to V_j. A *directed cycle* is a directed path from a node to itself, and a *partially directed cycle* is a partially directed path from a node to itself.

A graph with both directed and undirected edges is a chain graph if there is not any partially directed cycle. Figure 1 shows a chain graph with five nodes. A chain component is a node set whose nodes are connected in an undirected graph obtained by removing all directed edges from the chain graph. An undirected graph is chordal if every cycle of length larger than or equal to 4 possesses a chord.

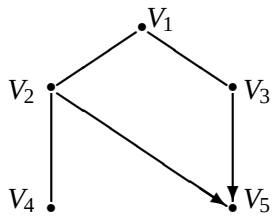

Figure 1: A chain graph G^* depicts the essential graph of G, G_1, G_2 and G_3.

A directed acyclic graph (DAG) is a directed graph which does not contain any directed cycle. A causal DAG is a DAG which is used to describe the causal relationships among variables $V_1, \cdots, V_n$. In the causal DAG, a directed edge $V_i \to V_j$ is interpreted as that the *parent* node V_i is a cause of the *child* node V_j, and that V_j is an effect of V_i. Let $pa(V_i)$ denote the set of all parents of V_i and $ch(V_i)$ denote the set of all *children* of V_i. Let τ be a node subset of $\mathbb{V}$. The *subgraph* $G_\tau = (\tau, \mathbb{E}_\tau)$ induced by the subset τ has the node set τ and the edge set $\mathbb{E}_\tau = \mathbb{E} \cap (\tau \times \tau)$ which contains all edges falling into τ. Two graphs have *the same skeleton* if they have the same set of nodes and the same set of edges regardless of their directions. A head-to-head structure is called a *v-structure* if the parents are not adjacent, such as $V_1 \to V_2 \leftarrow V_3$.

Figure 2 shows four different causal structures of five nodes. The causal graph G in Figure 2 depicts that V_1 is a cause of V_3, which in turn is a cause of V_5.

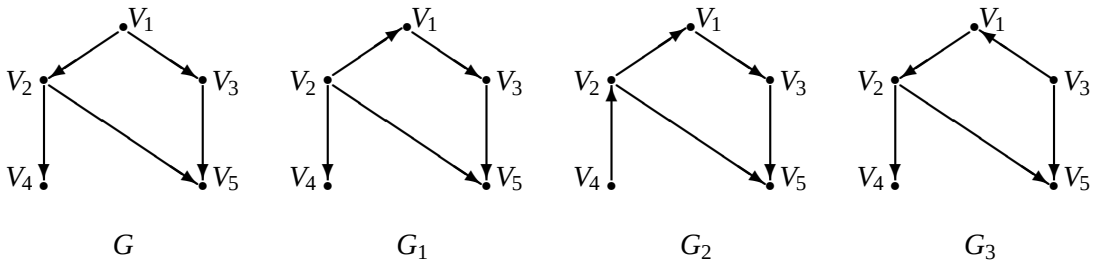

Figure 2: The equivalence class $[G]$.

A joint distribution P satisfies Markov property with respect to a graph G if any variable of G is independent of all its non-descendants in G given its parents with respect to the joint distribution P. Furthermore, the distribution P can be factored as follows

$$P(v_1, v_2, \cdots, v_n) = \prod_{i=1}^{n} P(v_i | pa(v_i)),$$

where v_i denotes a value of variable V_i, and $pa(v_i)$ denotes a value of the parent set $pa(V_i)$ (Pearl, 1988; Lauritzen, 1996; Spirtes et al., 2000). In this paper, we assume that any conditional independence relations in P are entailed by the Markov property, which is called the faithfulness assumption (Spirtes et al., 2000). We also assume that there are no latent variables (that is, no unmeasured variables) in causal DAGs. Different DAGs may encode the same Markov properties. A Markov equivalence class is a set of DAGs that have the same Markov properties. Let $G_1 \sim G_2$ denote that two DAGs G_1 and G_2 are Markov equivalent, and let $[G]$ denote the equivalence class of a DAG G, that is, $[G] = \{G' : G' \sim G\}$. The four DAGs G, G_1, G_2 and G_3 in Figure 2 form a Markov equivalence class $[G]$. Below we review two results about Markov equivalence of DAGs given by Verma and Pearl (1990) and Andersson et al. (1997).

Lemma 1 *(Verma and Pearl, 1990) Two DAGs are Markov equivalent if and only if they have the same skeleton and the same v-structures.*

Andersson et al. (1997) used an essential graph G^* to represent the equivalence class $[G]$.

Definition 2 *The essential graph $G^* = (\mathbb{V}, \mathbb{E}^*)$ of G has the same node set and the same skeleton as G, whose one edge is directed if and only if it has the same orientation in every DAG in $[G]$ and whose other edges are undirected.*

For example, G^* in Figure 1 is the essential graph of G in Figure 2. The edges $V_2 \rightarrow V_5$ and $V_3 \rightarrow V_5$ in G^* are directed since they have the same orientation for all DAGs of $[G]$ in Figure 2, and other edges are undirected.

Lemma 3 *(Andersson et al., 1997) Let G^* be the essential graph of $G = (\mathbb{V}, \mathbb{E})$. Then G^* has the following properties:*

(i) *G^* is a chain graph,*

(ii) *G^*_τ is chordal for every chain component τ, and*

(iii) *$V_i \to V_j - V_k$ does not occur as an induced subgraph of G^*.*

Suppose that G is an unknown underlying causal graph and that its essential graph $G^* = (\mathbb{V}, \mathbb{E})$ has been obtained from observational data, and has k chain components $\{\tau_1, \cdots, \tau_k\}$. Its edge set $\mathbb{E}$ can be partitioned into the set $\mathbb{E}_1$ of directed edges and the set $\mathbb{E}_2$ of undirected edges. Let G^*_τ denote a subgraph of the essential G^* induced by a chain component τ of G^*. Any subgraph of the essential graph induced by a chain component is undirected. Since all v-structures can be discovered from observational data, any subgraph G'_τ of G' should not have any v-structure for $G' \in [G]$. For example, the essential graph G^* in Figure 1 has one chain component $\tau = \{V_1, V_2, V_3, V_4\}$. It can been seen that G'_τ has no v-structure for $G' \in \{G, G_1, G_2, G_3\}$.

Given an essential graph G^*, we need to orient all undirected edges in each chain component to discover the whole causal graph G. Below we show that the orientation can be done separately in every chain component. We also show that there are neither new v-structures nor cycles in the whole graph as long as there are neither v-structures nor cycles in any chain component. Thus in the orientation process, we only need to ensure neither v-structures nor cycles in any component, and we need not check new v-structures and cycles for the whole graph.

Theorem 4 *Let τ be a chain component of an essential graph G^*. For each undirected edge $V - U$ in G^*_τ, neither orientation $V \to U$ nor $V \leftarrow U$ can create a v-structure with any node W outside τ, that is, neither $V \to U \leftarrow W$ nor $W \to V \leftarrow U$ can occur for any $W \notin \tau$.*

Theorem 4 means that there is not any node W outside the component τ which can build a v-structure with two nodes in τ.

Theorem 5 *Let τ be a chain component of G^*. If orientation of undirected edges in the subgraph G^*_τ does not create any directed cycle in the subgraph, then the orientation does not create any directed cycle in the whole DAG.*

According to Theorems 4 and 5, we find that the undirected edges can be oriented separately in each chain component regardless of directed and undirected edges in other part of the essential graph as long as neither cycles nor v-structures are constructed in any chain component. Thus the orientation for one chain component does not affect the orientations for other components. The orientation approach and its correctness will be discussed in Section 3.

3. Active Learning of Causal Structures via External Interventions

To discover causal structures further from a Markov equivalence class obtained from observational data, we have to perform external interventions on some variables. In this section, we consider two kinds of external interventions. One is the randomized experiment, in which the post-intervention distribution of the manipulated variable V_i is independent of its parent variables. The other is the quasi-experiment, in which the distribution of the manipulated variable V_i conditional on its parents $pa(V_i)$ is changed by manipulating V_i. For example, the distribution of whether patients take a vaccine or not is changed by randomly encouraging patients at a discount.

3.1 Interventions by Randomized Experiments

In this subsection, we conduct interventions as randomized experiments, in which some variables are manipulated from external interventions by assigning individuals to some levels of these variables in a probabilistic way. For example, in a clinical trial, every patient is randomly assigned to a treatment group of $V_i = v_i$ at a probability $P'(v_i)$. The randomized manipulation disconnects the node V_i from its parents $pa(V_i)$ in the DAG. Thus the pre-intervention conditional probability $P(v_i|pa(v_i))$ of $V_i = v_i$ given $pa(V_i) = pa(v_i)$ is replaced by the post-intervention probability $P'(v_i)$ while all other conditional probabilities $P(v_j|pa(v_j))$ for $j \neq i$ are kept unchanged in the randomized experiment. Then the post-intervention joint distribution is

$$P_{V_i}(v_1, v_2, \cdots, v_n) = P'(v_i) \prod_{j \neq i} P(v_j|pa(v_j)),$$

(Pearl, 1993). From this post-intervention distribution, we have $P_{V_i}(v_i|pa(v_i)) = P_{V_i}(v_i)$, that is, the manipulated variable V_i is independent of its parents $pa(V_i)$ in the post-intervention distribution. Under the faithfulness assumption, it is obvious that an undirected edge between V_i and its neighbor V_j can be oriented as $V_i \leftarrow V_j$ if the post-intervention distribution has $V_i \perp\!\!\!\perp V_j$, otherwise it is oriented as $V_i \rightarrow V_j$, where $V_i \perp\!\!\!\perp V_j$ denotes that V_i is independent of V_j. The orientation only needs an independence test for the marginal distribution of variables V_i and V_j. Notice that the independence is tested by using only the experimental data without use of the previous observational data.

Let $e(V_i)$ denote the orientation of edges which is determined by manipulating node V_i. If V_i belongs to a chain component τ (that is, it connects at least one undirected edge), then the Markov equivalence class $[G]$ can be reduced by manipulating V_i to the post-intervention Markov equivalence class $[G]_{e(V_i)}$

$$[G]_{e(V_i)} = \{G' \in [G] | G' \text{ has the same orientation as } e(V_i)\}.$$

A Markov equivalence class is split into several subclasses by manipulating V_i, each of which has different orientations $e(V_i)$. Let $G^*_{e(V_i)}$ denote the post-intervention essential graph which depicts the post-intervention Markov equivalence class $[G]_{e(V_i)}$. We show below that $G^*_{e(V_i)}$ also has the properties of essential graphs.

Theorem 6 *Let τ be a chain component of the pre-intervention essential graph G^* and V_i be a node in the component τ. The post-intervention graph $G^*_{e(V_i)}$ is also a chain graph, that is, $G^*_{e(V_i)}$ has the following properties:*

(i) *$G^*_{e(V_i)}$ is a chain graph,*

(ii) *$G^*_{e(V_i)}$ is chordal, and*

(iii) *$V_j \rightarrow V_k - V_l$ does not occur as an induced subgraph of $G^*_{e(V_i)}$.*

By Theorem 6, the pre-intervention chain graph is changed by manipulating a variable to another chain graph which has less undirected edges. Thus variables in chain components can be manipulated repeatedly until the Markov equivalence subclass is reduced to a subclass with a single DAG, and properties of chain graphs are not lost in this intervention process.

According to the above results, we first learn an essential graph from observational data, which is a chain graph (Andersson et al., 1997) and depicts a Markov equivalence class (Heckerman et

al., 1995; Verma and Pearl, 1990; Castelo and Perlman, 2002). Next we choose a variable V_i to be manipulated from a chain component, and we can orient the undirected edges connecting V_i and some other undirected edges whose reverse orientations create v-structures or cycles. Repeating this process, we choose a next variable to be manipulated until all undirected edges are oriented. Below we give an example to illustrate the intervention process.

Example 1. Consider an essential graph in Figure 3, which depicts a Markov equivalence class with 12 DAGs in Figure 4. After obtaining the essential graph from observational data, we manipulate some variables in randomized experiments to identify a causal structure in the 12 DAGs. For example, Table 1 gives four possible orientations and Markov equivalence subclasses obtained by manipulating V_1. A class with 12 DAGs is split into four subclasses by manipulating V_1. The post-intervention subclasses (ii) and (iv) have only a single DAG separately. Notice that undirected edges not connecting V_1 can also be oriented by manipulating V_1. The subclasses (i) and (iii) are depicted by post-intervention essential graphs (a) and (b) in Table 1 respectively, both of which are chain graphs. In Table 2, the first column gives four possible independence sets obtained by manipulating V_1. For the set with $V_1 \perp\!\!\!\perp V_2$ and $V_1 \not\perp\!\!\!\perp V_3$, the causal structure is the DAG (3) in Figure 4, and thus we need not further manipulate other variables. For the third set with $V_1 \not\perp\!\!\!\perp V_2$ and $V_1 \not\perp\!\!\!\perp V_3$, we manipulate the next variable V_2. If $V_2 \perp\!\!\!\perp V_3$, then the causal structure is the DAG (1), otherwise it is the DAG (2). For the fourth set with $V_1 \perp\!\!\!\perp V_2$ and $V_1 \perp\!\!\!\perp V_3$, we may need further to manipulate variables V_2, V_3 and V_4 to identify a causal DAG.

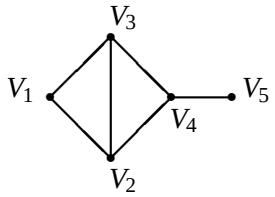

Figure 3: An essential graph of DAGs

3.2 Interventions by Quasi-experiments

In the previous subsection we discussed interventions by randomized experiments. Although randomized experiments are powerful tools to discover causal structures, it may be inhibitive or impractical. In this subsection we consider quasi-experiments. In a quasi-experiment, individuals may choose treatments non-randomly, but their behaviors of treatment choices are influenced by experimenters. For example, some patients may not comply with the treatment assignment from a doctor, but some of them may comply, which is also called an indirect experiment in Pearl (1995).

If we perform an external intervention on V_i such that V_i has a conditional distribution $P'(v_i|pa(v_i))$ different from the pre-intervention distribution $P(v_i|pa(v_i))$ in (1) and other distributions are kept unchanged, then we have the post-intervention joint distribution

$$P_{V_i}(v_1, v_2, \cdots, v_n) = P'(v_i|pa(v_i)) \prod_{j \neq i} P(v_j|pa(v_j)).$$

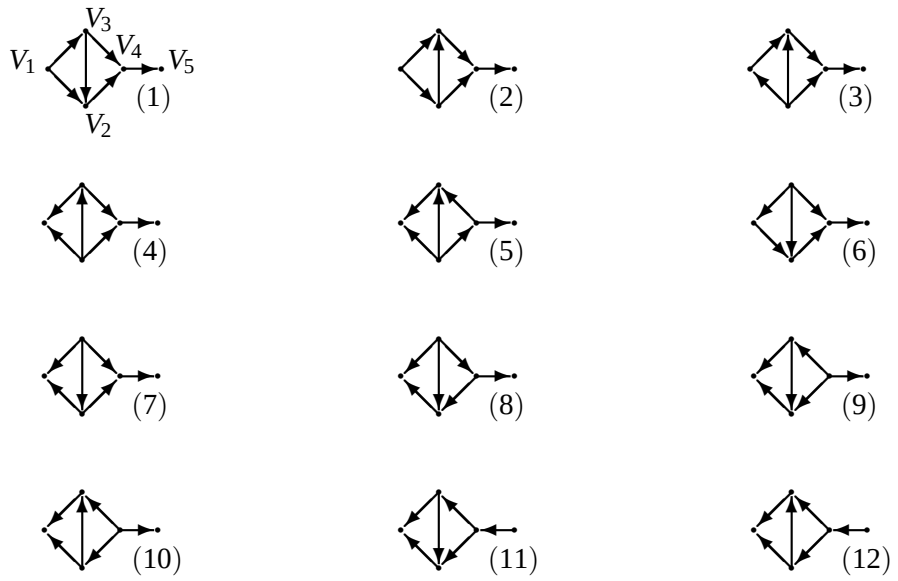

Figure 4: All DAGs in the equivalence class given in Figure 3.

No of subclass	$e(V_1)$	DAGs in a subclass	post-intervention essential graphs
(i)	$V_2 \leftarrow V_1 \rightarrow V_3$	$(1,2)$	V_1 (a)
(ii)	$V_2 \rightarrow V_1 \rightarrow V_3$	(3)	
(iii)	$V_2 \rightarrow V_1 \leftarrow V_3$	$(4,5,$ $7-12)$	V_1 (b)
(iv)	$V_2 \leftarrow V_1 \leftarrow V_3$	(6)	

Table 1: The post-intervention subclasses and essential graphs obtained by manipulating V_1.

In the external intervention, we may not be able to manipulate V_i, but we only need to change its conditional distribution, which may still depend on its parent variables. We call such an experiment a quasi-experiment. Below we discuss how to orient undirected edges via such quasi-experiments. Let τ be a chain component of the essential graph G^*, $ne(V_k)$ be the neighbor set of V_k, C be the children of V_k outside τ (that is, $C = ch(V_k) \setminus \tau$), and B be the set of all potential parents of V_k, that is, $B = ne(V_k) \setminus C$ is the neighbor set of V_k minus the children of V_k which have been identified in the chain graph. Let $V_i - V_k$ be an undirected edge in a chain component τ, and we want to orient the undirected edge by manipulating V_i. Since B is the neighbor set of V_k, we have $V_i \in B$ and thus

Table 2: The intervention process to identify a causal structure from the essential graph in Figure 3, where $*$ means that the intervention is unnecessary.

$B \neq \emptyset$. Below we show a result which can be used to identify the direction of the undirected edge $V_i - V_k$ via a quasi-experiment of intervention on V_i.

Theorem 7 *For a quasi-experiment of intervention on V_i, we have the following properties*

1. $P_{V_i}(v_k|B) = P(v_k|B)$ *for all v_k and B if V_i is a parent of V_k, and*
2. $P_{V_i}(v_k) = P(v_k)$ *for all v_k if V_i is a child of V_k.*

According to Theorem 7, we can orient the undirected edge $V_i - V_k$ as

1. $V_i \leftarrow V_k$ if $P_{V_i}(v_k|B) \neq P(v_k|B)$ for some v_k and B, or
2. $V_i \rightarrow V_k$ if $P_{V_i}(v_k) \neq P(v_k)$ for some v_k.

The nonequivalence of pre- and post-intervention distributions is tested by using both experimental data and observational data, which is different from that of randomized experiments.

Example 1 (continued). Consider again the essential graph in Figure 3. We use a quasi-experiment of manipulating V_1 in order to orient the undirected edges connecting V_1 ($V_3 - V_1 - V_2$). We may test separately four null hypotheses $P_{V_1}(v_2) = P(v_2)$, $P_{V_1}(v_3) = P(v_3)$, $P_{V_1}(v_2|v_1, v_3, v_4) = P(v_2|v_1, v_3, v_4)$ and $P_{V_1}(v_3|v_1, v_2, v_4) = P(v_3|v_1, v_2, v_4)$ with both observational and experimental data. We orient $V_1 - V_2$ as $V_1 \rightarrow V_2$ if $P_{V_1}(v_2) \neq P(v_2)$, otherwise as $V_1 \leftarrow V_2$ (or further check whether there is a stronger evidence of $P_{V_1}(v_2|v_1, v_3, v_4) \neq P(v_2|v_1, v_3, v_4)$). Similarly we can orient $V_1 - V_3$. Finally we obtain four possible orientations as shown in Table 1.

If both $P_{V_i}(v_k) = P(v_k)$ and $P_{V_i}(v_k|B) = P(v_k|B)$ for all v_k and B hold for a quasi-experiment, then we cannot identify the direction of edge $V_i - V_k$ from the intervention. For example, suppose that there are only two variables V_1 and V_2, V_1 has three levels and V_1 is the parent of V_2. If the true conditional distribution of V_2 given V_1 is: $p(v_2|V_1 = 1) = p(v_2|V_1 = 2) \neq p(v_2|V_1 = 3)$, then the

undirected edge $V_1 - V_2$ cannot be oriented with the intervention on V_1 with $p_{V_1}(V_1 = v) \neq p(V_1 = v)$ for $v = 1$ and 2 but $p_{V_1}(V_1 = 3) = p(V_1 = 3)$ because we have that $p_{V_1}(v_2) = p(v_2)$ for all v_2 and that $p_{V_1}(v_2|B) = p(v_2|B)$ where $B = \{V_1\}$. In a quasi-experiment, an experimenter may not be able to manipulate V_1, and thus this phenomenon can occur. If V_1 can be manipulated, then the experimenter can choose the distribution of V_2 to avoid this phenomenon.

4. Optimal Designs of Intervention Experiments

In this section, we discuss the optimal designs of intervention experiments which are used to minimize the number of manipulated variables or to minimize the uncertainty of candidate structures after an intervention experiment based on some criteria. Since the orientation for one chain component is unrelated to the orientations for other components, we can design an intervention experiment for each chain component separately. As shown in Section 2, given a chain component τ, we orient the subgraph over τ into a DAG G_τ without any v-structure or cycle via experiments of interventions in variables in τ. For simplicity, we omit the subscript τ in this section. In the following subsections, we discuss intervention designs for only one chain component. We first introduce the concept of sufficient interventions and discuss their properties of sufficient interventions, then we present the optimal design of batch interventions, and finally we give the optimal design of sequential interventions. For optimizing quasi-experiments of interventions, we assume that intervention on a variable V_i will change the marginal distribution of its child V_j, that is, there is a level v_j such that $P_{V_i}(v_j) \neq P(v_j)$ for $V_i \to V_j$. Under this assumption, all undirected edges connecting a node V_i can be oriented via a quasi-experiment of intervention on variable V_i. Without the assumption, there may be some undirected edge which cannot be oriented even if we perform interventions in both of its two nodes.

4.1 Sufficient Interventions

It is obvious that we can identify a DAG in a Markov equivalence class if we can manipulate all variables which connect undirected edges. However, it may be unnecessary to manipulate all of these variables. Let $\mathcal{S} = (V_1, V_2, \cdots, V_k)$ denote a sequence of manipulated variables. We say that a sequence of manipulated variables is sufficient for a Markov equivalence class $[G]$ if we can identify one DAG from all possible DAGs in $[G]$ after these variables in the sequence are manipulated. That is, we can orient all undirected edges of the essential graph G^* no matter which G in $[G]$ is the true DAG. There may be several sufficient sequences for a Markov equivalence class $[G]$.

Let g denote the number of nodes in the chain component, and h the number of undirected edges within the component. Then there are at most 2^h possible orientation of these undirected edges, and thus there are at most 2^h DAGs over the component in the Markov equivalence class. Given a permutation of nodes in the component, a DAG can be obtained by orienting all undirected edges backwards in the direction of the permutation, and thus there are at most $\min\{2^h, g!\}$ DAGs in the class.

Theorem 8 *If a sequence $\mathcal{S} = (V_1, V_2, \cdots, V_k)$ of manipulated variables is sufficient, then any permutation of $\mathcal{S}$ is also sufficient.*

According to Theorem 8, we can ignore the order of variables in an intervention sequence and treat the sequence as a variable set. Thus, if $\mathcal{S}$ is a sufficient set, then $\mathcal{S}'$ which contains $\mathcal{S}$

is also sufficient. Manipulating V_i, we obtain a class $E(V_i) = \{e(V_i)\}$ of orientations (see Table 1 as an example). Given an orientation $e(V_i)$, we can obtain the class $[G]_{e(V_i)}$ by (3). We say that $e(V_1,\ldots,V_k) = \{e(V_1),\ldots,e(V_k)\}$ is a legal combination of orientations if there is not any v-structure or cycle formed and there is not any undirected edge oriented in two different directions by these orientations. For a set $\mathcal{S} = (V_1,\ldots,V_k)$ of manipulated variables, the Markov equivalence class is reduced into a class

$$[G]_{e(V_1,\ldots,V_k)} = [G]_{e(V_1)} \cap \ldots \cap [G]_{e(V_k)}$$

for a legal combination $e(V_1,\ldots,V_k)$ of orientations. If $[G]_{e(V_1,\ldots,V_k)}$ has only one DAG for all possible legal combinations $e(V_1,\ldots,V_k) \in E(V_1) \times \ldots \times E(V_k)$, then the set $\mathcal{S}$ is a sufficient set for identifying any DAG in $[G]$. Let $\mathbb{S}$ denote the class of all sufficient sets, that is, $\mathbb{S} = \{\mathcal{S} : \mathcal{S} \text{ is sufficient}\}$. We say that a sequence $\mathcal{S}$ is minimum if any subset of $\mathcal{S}$ is not sufficient.

Theorem 9 *The intersection of all sufficient sets is an empty set, that is, $\bigcap_{\mathcal{S}\in\mathbb{S}} \mathcal{S} = \varnothing$. In addition, the intersection of all minimum sufficient sets is also an empty set.*

From Theorem 9, we can see that there is not any variable that must be manipulated to identify a causal structure. Especially, any undirected edge can be oriented by manipulating either of its two nodes.

4.2 Optimization for Batch Interventions

We say that an intervention experiment is a batch-intervention experiment if all variables in a sufficient set $\mathcal{S}$ are manipulated in a batch to orient all undirected edges of an essential graph. Let $|\mathcal{S}|$ denote the number of variables in $\mathcal{S}$. We say that a batch intervention design is optimal if its sufficient set $\mathcal{S}_o$ has the smallest number of manipulated variables, that is, $|\mathcal{S}_o| = \min\{|\mathcal{S}| : \mathcal{S} \in \mathbb{S}\}$. Given a Markov equivalence class $[G]$, we try to find a sufficient set S which has the smallest number of manipulated variables for identifying all possible DAGs in the class $[G]$. Below we give an algorithm to find the optimal design for batch interventions, in which we first try all sets with a single manipulated variable, then try all sets with two variables, and so on, until each post-intervention Markov equivalence class has a single DAG.

Given a Markov equivalence class $[G]$, we manipulate a node V and obtain an orientation of some edges, denoted by $e(V)$. The class $[G]$ is split into several subclasses, denoted by $[G]_{e(V)}$ for all possible orientations $e(V)$. Let $[G]_{e(V_1,V_2)}$ denote a subclass with an orientation obtained by manipulating V_1 and V_2. The following algorithm 1 performs exhaustive search for the optimal design of batch interventions. Before calling Algorithm 1, we need to enumerate all DAGs in the class $[G]$, and then we can easily find $[G]_{e(V_i)}$ according to (3). There are at most $\min\{g!, 2^h\}$ DAGs in the class $[G]$, and thus the upper bound of the complexity for enumerating all $\{[G]_{e(V_i)}\}$ is $\min\{g!, 2^h\}$. We may be able to have an efficient method to find all $\{[G]_{e(V_i)}\}$ using the structure of the chain component.

Algorithm 1 Algorithm for finding the optimal designs of batch interventions

Input: A chain graph G induced by a chain component $\tau = \{V_1, \ldots, V_g\}$, and $[G]_{e(V_i)}$ for all $e(V_i)$ and i.

Output: All optimal designs of batch interventions.

```
Initialize the size k of the minimum intervention set as k = 0.
repeat
  Set k = k + 1.
  for all possible variable subsets S = {V_{i_1}, ..., V_{i_k}} do
    if |[G]_{e(S)}| = 1 for all possible legal combination e(S) of orientations then
      return the minimum sufficient set S
    end if
  end for
until find some sufficient sets
```

Algorithm 1 exhaustively searches all combinations of manipulated variables to find the minimum sufficient sets, and its complexity is $O(g!)$, although Algorithm 1 may stop whenever it finds some minimum sets. The calculations in Algorithm 1 are only simple set operations

$$[G]_{e(\mathcal{S})} = [G]_{e(V_{i_1})} \cap \ldots \cap [G]_{e(V_{i_k})},$$

where all $[G]_{e(V_i)}$ have been found before calling Algorithm 1. Notice that a single chain component usually has a size g much less than the total number n of variables. Algorithm 1 is feasible for a mild size g. A more efficient algorithm or a greedy method is needed for a large g and h. In this case, there are too many DAGs to enumerate. We can first take a random sample of DAGs from the class $[G]$ with the simulation method proposed in the next subsection, and then we use the sample approximately to find an optimal design.

A possible greedy approach is to select a node to be first manipulated from the chain component which has the largest number of neighbors such that the largest number of undirected edges are oriented by manipulating it, and then delete these oriented edges. Repeat this process until there is not any undirected edge left. But there are cases where the sufficient set obtained from the greedy method is not minimum.

Example 1 (continued). Consider the essential graph in Figure 3, which depicts a Markov equivalence class with 12 DAGs in Figure 4. From Algorithm 1, we can find that $\{1,2,4\}$, $\{1,3,4\}$, $\{2,3,4\}$ and $\{2,3,5\}$ are all the minimum sufficient sets. The greedy method can obtain the same minimum sufficient sets for this example.

4.3 Optimization for Sequential Interventions

The optimal design of batch interventions presented in the previous subsection tries to find a minimum sufficient set $\mathcal{S}$ before any variable is manipulated, and thus it cannot use orientation results obtained by manipulating the previous variables during the intervention process. In this subsection, we propose an experiment of sequential interventions, in which variables are manipulated sequentially. Let $\mathcal{S}^{(t)}$ denote the set of variables that have been manipulated before step t and $\mathcal{S}^{(0)} = \emptyset$. At step t of the sequential experiment, according to the current Markov equivalence class $[G]_{e(\mathcal{S}^{(t-1)})}$ obtained by manipulating the previous variables in $\mathcal{S}^{(t-1)}$, we choose a variable V to be manipulated

based on some criterion. We consider two criteria for choosing a variable. One is the minimax criterion based on which we choose a variable V such that the maximum size of subclasses $[G]_{e(\mathcal{S}^{(t)})}$ for all possible orientations $e(\mathcal{S}^{(t)})$ is minimized. The other is the maximum entropy criterion based on which we choose a variable V such that the following entropy is maximized for any V in the chain component τ

$$H_V = -\sum_{i=1}^{M} \frac{l_i}{L} \log \frac{l_i}{L},$$

where l_i denotes the number of possible DAGs of the chain component with the ith orientation $e(V)_i$ obtained by manipulating V, $L = \sum_i l_i$ and M is the number of all possible orientations $e(V)_1, \ldots, e(V)_M$ obtained by manipulating V. Based on the maximum entropy criterion, the post-intervention subclasses have sizes as small as possible and they have sizes as equal as possible, which means uncertainty for identifying a causal DAG from the Markov equivalence class is minimized by manipulating V. Below we give two examples to illustrate how to choose variables to be manipulated in the optimal design of sequential interventions based on the two criteria.

Example 1 (continued). Consider again the essential graph in Figure 3, which depicts a Markov equivalence class with 12 DAGs in Figure 4. Tables 3 to 6 show the results for manipulating one of variables V_1, V_2 (symmetry to V_3), V_4 and V_5 respectively in order to distinguish the possible DAGs in Figure 4. The first row in these tables gives possible orientations obtained by manipulating the corresponding variable. The second row gives DAGs obtained by the orientation, where numbers are used to index DAGs in Figure 4. The third row gives the number l_i of DAGs of this chain component for the ith orientation. The entropies for manipulating $V_1, \ldots, V_5$ are 0.9831, 1.7046, 1.7046, 1.3480, 0.4506, respectively. Based on the maximum entropy criterion, we choose variable V_2 or V_3 to be manipulated first. The maximum numbers l_i of DAGs for manipulating one of $V_1, \ldots, V_5$ are 8, 3, 3, 6, 10, respectively. Based on the minimax criterion, we also choose variable V_2 or V_3 to be manipulated first.

Although the same variable V_2 or V_3 is chosen to be manipulated first in the above example, in general, the choice may be different based on the two criteria. The minimax criterion tends to be more conservative, and the entropy criterion tends to be more uniform. For example, consider two interventions for an equivalence class with 10 DAGs: one splits the class into 8 subclasses with the numbers $(l_1, \ldots, l_8) = (1,1,1,1,1,1,1,3)$ of DAGs, the other splits it into 5 subclasses with the numbers of DAGs equal to (2,2,2,2,2). Then the minimax criterion chooses the second intervention, while the maximum entropy criterion chooses the first intervention.

To find the number (l_i for $i = 1, \cdots, M$), we need to enumerate all DAGs in the class $[G]$ and then count the number l_i of DAGs with the same orientations as $e(V)_i$. As discussed in Section 4.2, the upper bound of the complexity for calculating all l_i is $O(\min\{g!, 2^h\})$. Generally the size g of a chain component is much less than the number n of the full variable set and the number h of undirected edges in a chain component is not very large. In the following example, we show a special case with a tree structure, where the calculation is easy.

Example 2. In this example, we consider a special case that a chain component has a tree structure. It does not mean that a DAG is a tree, and it is not uncommon in a chain component (see Figure 1). Since there are no v-structures in any chain component, all undirected edges in a subtree can be oriented as long as we find its root. Manipulating a node V in a tree, we can

Orientation	$V_2 \leftarrow V_1 \rightarrow V_3$	$V_2 \rightarrow V_1 \rightarrow V_3$	$V_2 \rightarrow V_1 \leftarrow V_3$	$V_2 \leftarrow V_1 \leftarrow V_3$
DAGs	$\{1,2\}$	$\{3\}$	$\{4,5,7,8,9,10,11,12\}$	$\{6\}$
l_i	2	1	8	1
Entropy is 0.9831 and maximum l_i is 8				

Table 3: Manipulating V_1

Orientation						
DAGs	$\{8,9,11\}$	$\{10,12\}$	$\{3,4,5\}$	$\{2\}$	$\{1,6\}$	$\{7\}$
l_i	3	2	3	1	2	1
Entropy is 1.7046 and maximum l_i is 3						

Table 4: Manipulating V_2

Orientation					
DAGs	$\{1,2,3,4,6,7\}$	$\{5\}$	$\{8\}$	$\{9,10\}$	$\{11,12\}$
l_i	6	1	1	2	2
Entropy is 1.3480 and maximum l_i is 6					

Table 5: Manipulating V_4

Orientation	$V_4 \rightarrow V_5$	$V_4 \leftarrow V_5$
DAGs	$\{1,2,3,4,5,6,7,8,9,10\}$	$\{11,12\}$
l_i	10	2
Entropy is 0.4506 and maximum l_i is 10		

Table 6: Manipulating V_5

determinate all orientations of edges connecting V, and thus all subtrees that are emitted from V can be oriented, but only one subtree with V as a terminal cannot be oriented. Suppose that node V connects M undirected edges, and let l_i denote the number of nodes in the ith subtree connecting V for $i = 1,\ldots,M$. Since each node in the ith subtree may be the root of this subtree, there are l_i possible orientations for the ith subtree. Thus we have the entropy for manipulating V

$$H_V = -\sum_{i=1}^{M} \frac{l_i}{L} log \frac{l_i}{L}.$$

Consider the chain component $\tau = \{V_1,\ldots,V_4\}$ of the chain graph G^* in Figure 1, which has a tree structure. In Table 7, the first column gives variables to be manipulated, the second column gives possible orientations via the intervention, the third column gives the equivalence subclasses (see Figure 2) for each orientation, the fourth column gives the number l_i of possible DAGs for the ith

orientation and the last column gives the entropy for each intervention. From Table 7, we can see that manipulating V_1 or V_2 has the maximum entropy and the minimax size.

Intervention	Orientation	Subclass of DAGs	l_i	H_V
V_1	$V_2 \leftarrow V_1 \rightarrow V_3$	G	1	1.0397
	$V_2 \rightarrow V_1 \rightarrow V_3$	G_1, G_2	2	
	$V_2 \leftarrow V_1 \leftarrow V_3$	G_3	1	
V_2	$V_4 \leftarrow V_2 \leftarrow V_1$	G, G_3	2	1.0397
	$V_4 \leftarrow V_2 \rightarrow V_1$	G_1	1	
	$V_4 \rightarrow V_2 \rightarrow V_1$	G_2	1	
V_3	$V_1 \rightarrow V_3$	G, G_1, G_2	3	0.5623
	$V_1 \leftarrow V_3$	G_3	1	
V_4	$V_4 \leftarrow V_2$	G, G_1, G_3	3	0.5623
	$V_4 \rightarrow V_2$	G_2	1	

Table 7: Manipulating variables in a chain component with a tree structure.

An efficient algorithm or an approximate algorithm is necessary when both g and h are very large. A simulation algorithm can be used to estimate l_i/L. In this simulation method, we randomly take a sample of DAGs without any v-structure from the class $[G]$. To draw such a DAG, we randomly generate a permutation of all nodes in the class, orient all edges backwards in the direction of the permutation, and keep only the DAG without any v-structure. There may be some DAGs in the sample which are the same, and we keep only one of them. Then we count the number l_i' of DAGs in the sample which have the same orientation as $e(V)_i$. We can use l_i'/L' to estimate l_i/L, where $L' = \sum_i l_i'$. When the sample size tends to infinite, all DAGs in the class can be drawn, and then the estimate l_i'/L' tends to l_i/L. Another way to draw a DAG is that we randomly orient each undirected edge of the essential graph, but we need to check whether there is any cycle besides v-structure.

5. Simulation

In this section, we use two experiments to evaluate the active learning approach and the optimal designs via simulations. In the first experiment, we evaluate a whole process of structural learning and orientation in which we first find an essential graph using the PC algorithm and then orient the undirected edges using the approaches proposed in this paper. In the second experiment, we compare various designs for orientations starting with the same underlying essential graph. For both experiments, the DAG (1) in Figure 4 is used as the underlying DAG and all variables are binary. Its essential graph is given in Figure 3 and there are other 11 DAGs which are Markov equivalent to the underlying DAG (1), as shown in Figure 4. This essential graph can also be seen as a chain component of a large essential graph. All conditional probabilities $P(v_j|pa(v_j))$ are generated from the uniform distribution $U(0,1)$. We repeat 1000 simulations with the sample size $n = 1000$.

In each simulation of the first experiment, we first use the PC algorithm to find an essential graph with the significance level $\alpha = 0.15$ with which the most number of true essential graphs were obtained among various significance levels in our simulations. Then we use the intervention approach proposed in Section 3 to orient undirected edges of the essential graph. To compare the performances of orientations for different significance levels and sample sizes used in

intervention experiments, we run simulations for various combinations of significance levels $\alpha_I = 0.01, 0.05, 0.10, 0.15, 0.20, 0.30$ and sample sizes $n_I = 50, 100, 200, 500$ in intervention experiments. To compare the performance of the experiment designs, we further give the numbers of manipulated variables that are necessary to orient all undirected edges of the same essential graphs in various intervention designs. We run the simulations using R 2.6.0 on an Intel(R) Pentium(R) M Processor with 2.0 GHz and 512MB RAM and MS XP. It takes averagely 0.4 second of the processor time for a simulation, and each simulation needs to finish the following works: (1) generate a joint distribution and then generate a random sample of size $n = 1000$, (2) find an essential graph using the PC algorithm, (3) find an optimal design, and (4) repeatedly generate experimental data of size n_I until identifying a DAG.

To make the post-intervention distribution $P'(v_i|pa(v_i))$ different from the pre-intervention $P(v_i|pa(v_i))$, we use the post-intervention distribution of the manipulated variable V_i as follows

$$P'(v_i|pa(v_i)) = P'(v_i) = \begin{cases} 1, & P(v_i) \leq 0.5; \\ 0, & \text{otherwise.} \end{cases}$$

To orient an undirected edge $V_i - V_j$, we implemented both the independence test of the manipulated V_i and its each neighbor variable V_j for randomized experiments and the equivalence test of pre- and post-intervention distributions (i.e., $P_{V_i}(v_j) = P(v_j)$ for all v_j) in our simulations. Both tests have the similar results and the independence test is little more efficient than the equivalence test. To save space, we only show the simulation results of orientations obtained by the equivalence test and the optimal design based on the maximum entropy criterion in Table 8, and other designs have the similar results of orientations.

To evaluate the performance of orientation, we define the percentage of correct orientations as the ratio of the number of correctly oriented edges to the number of edges that are obtained from the PC algorithm and belong to the DAG (1) in Figure 4. The third column λ in Table 8 shows the average percentages of correctly oriented edges of the DAG (1) in 1000 simulations. To separate the false orientations due to the PC algorithm from those due to intervention experiments, we further check the cases that the essential graph in Figure 3 is correctly obtained from the PC algorithm. The fourth column *m* shows the number of correct essential graphs obtained from the PC algorithm in 1000 simulations. In the fifth column, we show the percentage λ' of correct orientations for the correct essential graph. Both λ and λ' increase as n_I increases. Comparing λ and λ', it can be seen that there are more edges oriented correctly when the essential graph is correctly obtained from the PC algorithm. From the sixth to eleven columns, we give the cumulative distributions of the number of edges oriented correctly when the essential graph is correctly obtained. The column labeled '$\geq i$' means that we correctly oriented more than or equal to *i* of 6 edges of the essential graph in Figure 3, and the values in this column denote the percents of DAGs with more than or equal to *i* edges correctly oriented in those simulations. For example, the column '≥ 5' means that more than or equal to 5 edges are oriented correctly (i.e., the DAGs (1), (2) and (6) in Figure 4), and 0.511 in the first line means that 51.1% of $m = 409$ correct essential graphs were oriented with '≥ 5' correct edges. The column '6' means that the underlying DAG (1) is obtained correctly. From this column, it can be seen that more and more DAGs are identified correctly as the size n_I increases. The cumulative distribution for ≥ 0 is equal to one and is omitted. From these columns, it can be seen that more and more edges are correctly oriented as the size n_I increases. From λ and λ', we can see that a larger α_I is preferable for a smaller size n_I, and a smaller α_I is preferable for a larger

n_I. For example, $\alpha_I = 0.20$ is the best for $n_I = 50$, $\alpha_I = 0.10$ for $n_I = 100$, $\alpha_I = 0.05$ for $n_I = 200$, $\alpha_I = 0.01$ for $n_I = 500$.

					The number of edges oriented correctly					
n_I	α_I	λ	m	λ'	6	≥ 5	≥ 4	≥ 3	≥ 2	≥ 1

Table 8: The simulation results

In the second experiment, we compare the numbers of manipulated variables to orient the same underlying essential graph for different experimental designs. In the following simulations, we set $n_I = 100$ and $\alpha_I = 0.1$, and all orientations start with the true essential graph in Figure 3. As shown in Section 4.2, the optimal batch design and the design by the greedy method always need three variables to be manipulated for orientation of the essential graph. For the optimal sequential designs, the frequencies of the numbers of manipulated variables in 1000 simulations are given in Table 9. In the random design labeled 'Random', we randomly select a variable to be manipulated at each sequential step, only one variable is manipulated for orientations in 268 of 1000 simulations, and four variables are manipulated in 55 of 1000 simulations. In the middle of Table 9, we show the simulation results of the optimal sequential designs based on the minimax criterion and its approximate designs obtained by drawing a sample of DAGs. The minimax design needs only one or two variables to be manipulated in all 1000 simulations. We show three approximate designs which draw h, $h \times 5$ and $h \times 10$ DAGs from a chain component with h undirected edges respectively. For

example, the sample sizes of DAGs from the initial essential graph $[G]$ with $h = 6$ undirected edges are 6, 30 and 60, respectively. As the sample size increases, the distribution of the manipulated variable numbers tends to the distribution for the exact minimax design. The optimal sequential design based on the maximum entropy criterion has a very similar performance as that based on the minimax criterion, as shown in the bottom of Table 9. According to Table 9, all of the sequential intervention designs (Random, Minimax, Entropy and their approximations) are more efficient than the batch design, and the optimal designs based on the minimax and the maximum entropy criteria are more efficient than the random design.

6. Conclusions

In this paper, we proposed a framework for active learning of causal structures via intervention experiments, and further we proposed optimal designs of batch and sequential interventions based on the minimax and the maximum entropy criteria. A Markov equivalence class can be split into subclasses by manipulating a variable, and a causal structure can be identified by manipulating variables repeatedly. We discussed two kinds of external intervention experiments, the randomized experiment and the quasi-experiment. In a randomized experiment, the distribution of a manipulated variable does not depend on its parent variables, while in a quasi-experiment, it may depend on its parents. For a randomized experiment, the orientations of an undirected edge can be determined by testing the independence of the manipulated variable and its neighbor variable only with experimental data. For a quasi-experiment, the orientations can be determined by testing the equivalence of pre- and post-intervention distributions with both experimental and observational data. We discussed two optimal designs of batch and sequential interventions. For the optimal batch design, a smallest set of variables to be manipulated is found before interventions, which is sufficient to orient all undirected edges of an essential graph. But the optimal batch design does not use orientation results obtained by manipulating the previous variables during the intervention process, and thus it may be less efficient than the optimal sequential designs. For the optimal sequential design, we choose a variable to be manipulated sequentially such that the current Markov equivalence class can be reduced to a subclass with potential causal DAGs as little as possible. We discussed two

criteria for optimal sequential designs, the minimax and the maximum entropy criteria. The exact, approximate and greedy methods are presented for finding the optimal designs.

The scalability of the optimal designs proposed in this paper depends only on the sizes of chain components but does not depend on the size of a DAG since the optimal designs are performed separately within every chain component. As discussed in Section 4, the optimal designs need to find the number of possible DAGs in a chain component, which has a upper bound $\min\{2^h, g!\}$. When both the number h of undirected edges and the number g of nodes in a chain component are very large, instead of using the optimal designs, we may use the approximate designs via sampling DAGs. We checked several standard graphs found at the Bayesian Network Repository (http://compbio.cs.huji.ac.il/Repository/). We extracted their chain components and found that most of their chain components have tree structures and their sizes are not large. For example, ALARM with 37 nodes has 4 chain components with only two nodes in each component, HailFinder with 56 nodes has only one component with 18 nodes, Carpo with 60 nodes has 9 components with at most 7 nodes in each component, Diabets with 413 nodes has 25 components with at most 3 nodes, and Mumin 2 to Mumin 4 with over 1000 nodes have at most 21 components with at most 35 nodes. Moreover, all of those largest chain components have tree structures, and thus we can easily carry out optimal designs as discussed in Example 2.

In this paper, we assume that there are no latent variables. Though the algorithm can orient the edges of an essential graph and output a DAG based on a set of either batch or sequential interventions, the application of the method for learning causality in the real word is pretty limited because latent or hidden variables are typically present in real-world data sets.

Appendix A. Proofs of Theorems

Before proving Theorems 4 and 5, we first give a lemma which will be used in their proofs.

Lemma 10 *If a node $V \in \mathbb{V}$ is a parent of a node U in a chain component τ of G^* (i.e., $(V \to U) \in G^*$, $U \in \tau$, $V \in \mathbb{V}$ and $V \notin \tau$), then V is a parent of all nodes in τ (i.e., $(V \to W) \in G$ for any $W \in \tau$).*

Proof By (iii) of Lemma 3, $V \to U - W$ does not occur in any induced subgraph of G^*. Thus for any neighbor of U in the chain component τ, W and V must be adjacent in G^*. Because $V \notin \tau$, the edge between V and W is directed. There are two alternatives as shown in Figures 5 and 6 for the subgraph induced by $\{V, U, W\}$.

If it is the subgraph in Figure 6 (i.e., the $V \to W \in G'$ for any $G' \in [G]$), then $W \to U$ must be in G' for any $G' \in [G]$ in order to avoid a directed cycle, as shown in Figure 7. So $W \to U$ must be in G^*. It is contrary to the fact that $\{U, W\} \in \tau$ is in a chain component of G^*. So V must also be a parent of W. Because all variables in τ are connected by undirected edges in G^*_τ, V must be a parent

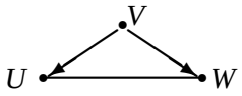

Figure 5: SG_1

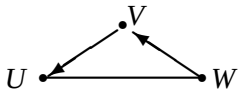

Figure 6: SG_2

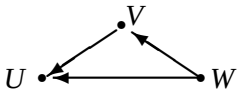

Figure 7: SG_3

of all other variables in τ. ■

Proof of Theorem 4. According to Lemma 10, if a node W outside a component τ points at a node V in τ, then W must point at each node U in τ. Thus W, V and U cannot form a v-structure. ■

Proof of Theorem 5. Suppose that Theorem 5 does not hold, that is, there is a directed path $V_1 \to \cdots \to V_k$ in G_τ which is not a directed cycle, but $W_1 \to \cdots \to W_i \to V_1 \to \cdots \to V_k \to W_{i+1} \to \cdots \to W_1$ is a directed cycle, where $W_i \notin \tau$. We denote this cycle as DC. From Lemma 10, W_i must also be a parent of V_k, and thus $W_1 \to \cdots \to W_i \to V_k \to W_{i+1} \to \cdots \to W_1$ is also a directed cycle, denoted as DC'. Now, every edge of DC' is out of G_τ. Similarly, we can remove all edges in other chain components from DC' and keep the path being a directed cycle. Finally, we can get a directed cycle in the directed subgraph of G^*. It contradicts the fact that G^* is an essential graph of a DAG. So we proved Theorem 5. ■

To prove Theorem 6, we first present an algorithm for finding the post-intervention essential graph $G^*_{e(V)}$ via the orientation $e(V)$, then we show the correctness of the algorithm using several lemmas, and finally we give the proof of Theorem 6 with $G^*_{e(V)}$ obtained by the algorithm. In order to prove that $G^*_{e(V)}$ is also a chain graph, we introduce an algorithm (similar to Step D of SGS and the PC algorithm in Spirtes et al., 2000) for constructing a graph, in which some undirected edges of the initial essential graph are oriented with the information of $e(V)$. Let τ be a chain graph of G^*, $V \in \tau$ and $e(V)$ be an orientation of undirected edges connecting V.

Algorithm 2 Find the post-intervention essential graph via orientation $e(V)$

Input: The essential graph G^* and $e(V)$

Output: The graph H

Orient the undirected edges connecting V in the essential graph G^* according to $e(V)$ and denote the graph as H.

Repeat the following two rules to orient some other undirected edges until no rules can be applied:

(i) if $V_1 \to V_2 - V_3 \in H$ and V_1 and V_3 are not adjacent in H, then orient $V_2 - V_3$ as $V_2 \to V_3$ and update H;

(ii) if $V_1 \to V_2 \to V_3 \in H$ and $V_1 - V_3 \in H$, then orient $V_1 - V_3$ as $V_1 \to V_3$ and update H.

return the graph H

It can be shown that H constructed by Algorithm 2 is a chain graph and H is equal to the post-intervention essential graph $G^*_{e(V)}$. We show those results with the following three Lemmas.

Lemma 11 *Let G^* be the essential graph of DAG G, τ be a chain component of G^* and I be a DAG over τ. Then there is a DAG $G' \in [G]$ such that $I = G'_\tau$ if and only if I is a DAG with the same skeleton as G^*_τ and without v-structures.*

Proof If there is a DAG $G' \in [G]$ such that $I = G'_\tau$, we have from Lemma 1 that I is a DAG with the same skeleton as G^*_τ and without v-structures.

Let I be a DAG with the same skeleton as G^*_τ and without v-structures, and G' be any DAG in the equivalence class $[G]$. We construct a new DAG I' from G' by substituting the subgraph G'_τ of G' with I. I' has the same skeleton as G'. From Theorems 4 and 5, I' has the same v-structures as G'. Thus I' is equivalent to G' and $I' \in [G]$. ■

Lemma 12 *Let H be a graph constructed by Algorithm 2. Then H is a chain graph.*

Proof If H is not a chain graph, there must be a directed cycle in subgraph H_τ for some chain component of G^*. Moreover, G^*_τ is chordal and $H \subset G^*$, and thus H_τ is chordal too. So we can get a three-edge directed cycle in H_τ as given in Figure 8 or 9.

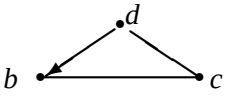

Figure 8: SG_6

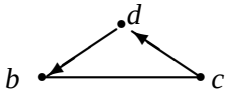

Figure 9: SG_{6_1}

If Figure 9 is a subgraph of H obtained at some step of Algorithm 2, then the undirected edge b—c is oriented as $b \leftarrow c$ according to Algorithm 2. Thus only Figure 8 can be a subgraph of H.

According to Lemma 10, we have that the directed edge $d \rightarrow b$ is not in G^*. Since all edges connecting a have been oriented in Step 1 of Algorithm 2, $d \rightarrow b$ is not an edge connecting a. So $d \rightarrow b$ must be identified at step 2 of Algorithm 2. There are two situations, one is to avoid a v-structure as shown in Figure 10, the other is to avoid a directed cycle as Figure 13.

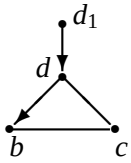

Figure 10: SG_7

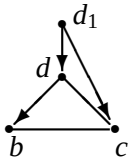

Figure 11: SG_8

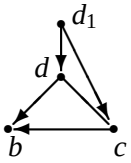

Figure 12: SG_9

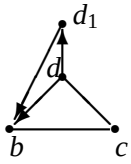

Figure 13: SG_{10}

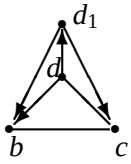

Figure 14: SG_{11}

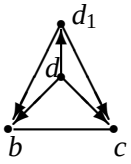

Figure 15: SG_{12}

We can arrange all directed edges in H_τ in order of orientations performed at Step 2 of Algorithm 2. First, we prove that the directed edge $d \rightarrow b$ in Figure 8 is not the first edge oriented at Step 2 of Algorithm 2.

In the first case as Figure 10, if $d \to b$ is the first edge oriented at Step 2 of Algorithm 2, we have $d_1 = a$. Because b and a are not adjacent, and $d—c$ is an undirected edge in H, we have that $d_1 \to c$ must be in H as Figure 11, where $d_1 = a$. Now we consider the subgraph $b—c \leftarrow d_1$. According to the rules (i) and (ii) in Algorithm 2, we have that $b \leftarrow c$ is in $G^*_{e(a)}$ as Figure 12, which contradicts the assumption that $b—c \in H$.

In the second case as Figure 13, if $d \to b$ is the first edge oriented at Step 2 of Algorithm 2, we have $d_1 = a$.

Considering the structure $d_1 \to b—c$ and that $d—c$ is an undirected edge in H, we have that $d_1 \to c$ must be in H as Figure 14. Now we consider the subgraph of $\{d, d_1, c\}$. By Algorithm 2, $d \to c$ is in H as Figure 15, which contradicts the assumption that $d—c \in H$. Thus we have that the first edge oriented at Step 2 of Algorithm 2 is not in any directed cycle. Suppose that the first k oriented edges at Step 2 of Algorithm 2 are not in any directed cycle. Then we want to prove that the $(k+1)th$ oriented edge is also not in a directed cycle.

Let $d \to b$ be the $(k+1)th$ oriented edge at Step 2 of Algorithm 2, and Figure 8 be a subgraph of H. There are also two cases as Figures 10 and 13 for orienting $d \to b$.

In the case of Figure 10, since $d_1 \to d$ is in the first k oriented edges and $d—c \in H$, we have that $d_1 \to c$ must be in H. We also get that $b \leftarrow c$ must be in H as Figure 12, which contradicts the assumption that $b—c \in H$.

In the case of Figure 10, since $d_1 \to b$ and $d \to d_1$ are in the first k oriented edges and $b—c \in H$, we have that $d_1 \to c$ must be in H. We also get that $d \leftarrow c$ must be in H as Figure 15, which contradicts the assumption that $d—c \in H$. So the $(k+1)$th oriented edge is also not in any directed cycle. Now we can get that every directed edge in H_τ is not in any directed cycle. It implies that there are no directed cycles in H_τ, and thus H is a chain graph. ■

Lemma 13 *Let $G^*_{e(V)}$ be the post intervention essential graph with the orientation $e(V)$ and H be the graph constructed by Algorithm 2. We have $G^*_{e(V)} = H$.*

Proof We first prove $G^*_{e(a)} \subseteq H$. We just need to prove that all directed edges in H must be in $G^*_{e(a)}$. We use induction to finish the proof.

After Step 1 of Algorithm 2, all directed edges in H are in $G^*_{e(a)}$. We now prove that the first directed edge oriented at Step 2 of Algorithm 2, such as $b \leftarrow c$, is in $G^*_{e(a)}$. Because $b \leftarrow c$ must be oriented by the rule (i) of Algorithm 2, there must be a node $d \notin \tau$ such that $b—c \leftarrow d$ is the subgraph of H. So $b \leftarrow c \leftarrow d$ must be a subgraph in each $G' \in G^*_{e(a)}$. Otherwise, $b \to c \leftarrow d$ forms a v-structure such that $G' \notin [G]$. Thus we have $b \leftarrow c \in G^*_{e(a)}$.

Suppose that the first k oriented edges at Step 2 of Algorithm 2 are in $G^*_{e(a)}$. We now prove that the $(k+1)$th oriented edge at Step 2 of Algorithm 2 is also in $G^*_{e(a)}$. Denoting the $(k+1)$th oriented edge as $l \leftarrow h$, according to the rules in Algorithm 2, there are two cases to orient $l \leftarrow h$ as shown in Figures 16 and 17.

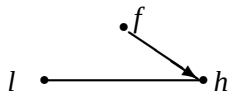

Figure 16: SG_4

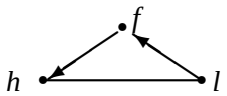

Figure 17: SG_5

In Figure 16, because $f \to h$ is in every DAG $G' \in G^*_{e(a)}$, in order to avoid a new v-structure, we have that $l \leftarrow h$ must be in every DAG $G' \in G^*_{e(a)}$. Thus we have $l \leftarrow h \in G^*_{e(a)}$. In Figure 17, because $l \to f$ and $f \to h$ are in every DAG $G' \in G^*_{e(a)}$, in order to avoid a directed cycle, we have that $h \leftarrow l$ must be in every DAG $G' \in G^*_{e(a)}$. Thus we have $h \leftarrow l \in G^*_{e(a)}$. Now we get that the $(k+1)$th oriented edge at Step 2 of Algorithm 2 is also in $G^*_{e(a)}$. Thus all directed edges in H are also in $G^*_{e(a)}$ and then we have $G^*_{e(a)} \subseteq H$.

Because H is a chain graph by Lemma 12, we also have $H \subseteq G^*$. By Lemma 11, for any undirect edge a—b of H_τ where τ is a chain component of H, there exist G_1 and $G_2 \in G^*_{e(a)}$ such that $a \to b$ occurs in G_1 and $a \leftarrow b$ occurs in G_2. It means that a—b also occurs in $G^*_{e(a)}$. So we have $H \subseteq G^*_{e(a)}$, and then $G^*_{e(a)} = H$. ■

Proof of Theorem 6. By definition of $G^*_{e(V)}$, we have that $G^*_{e(V)}$ has the same skeleton as the essential graph G^* and contains all directed edges of G^*. That is, all directed edges in G^* are also directed in $G^*_{e(V)}$. So property 2 of Theorem 6 holds. Property 3 of Theorem 6 also holds because all DAGs represented by $G^*_{e(V)}$ are Markov equivalent. From Lemmas 12 and 13, we can get that $G^*_{e(V)}$ is a chain graph. ■

Proof of Theorem 7. We first prove property 1. Let $C = ch(V_k) \setminus \tau$. Then $B = ne(V_k) \setminus C$ contains all parents of V_k and the children of V_k in τ. Let $A = An(\{B, V_k\})$ be the ancestor set of all nodes in $\{B, V_k\}$. Since V_i is a parent of V_k for property 1, we have $V_i \in A$. The post-intervention joint distribution of A is

$$P_{V_i}(A) = P'(v_i|pa(v_i)) \prod_{v_j \in A \setminus V_i} P(v_j|pa(v_j)). \tag{1}$$

Let $U = A \setminus \{B, V_k\}$. Then we have from the post-intervention joint distribution (1)

$$\begin{aligned} P_{V_i}(v_k|B) &= \frac{\sum_U P'(v_i|pa(v_i)) \prod_{v_j \in A \setminus V_i} P(v_j|pa(v_j)))}{\sum_{U,V_k} P'(v_i|pa(v_i)) \prod_{V_j \in A \setminus V_i} P(v_j|pa(v_j))} \\ &= \frac{\sum_U P'(v_i|pa(v_i)) \prod_{v_j \in A \setminus \{ch(V_k) \cap \tau, V_k\}} P(v_j|pa(v_j)) \prod_{v_j \in \{ch(V_k) \cap \tau, V_k\}} P(v_j|pa(v_j))}{\sum_{U,V_k} P'(v_i|pa(v_i)) \prod_{v_j \in A \setminus \{ch(V_k) \cap \tau, V_k\}} P(v_j|pa(v_j)) \prod_{v_j \in \{ch(V_k) \cap \tau, V_k\}} P(v_j|pa(v_j))}, \end{aligned}$$

where $\sum_U$ denotes a summation over all variables in the set U.

Below we want to factorize the denominator into a production of summation over U and summation over V_k. First we show that the factor $P'(v_i|pa(v_i)) \prod_{v_j \in A \setminus \{ch(V_k) \cap \tau, V_k\}} P(v_j|pa(v_j))$ does not contain V_k because V_k appears only in the conditional probabilities of $ch(V_k)$ and the conditional probability of V_k. Next we show that $\prod_{v_j \in \{ch(V_k) \cap \tau, V_k\}} P(v_j|pa(v_j))$ does not contain any variable in U. From definition of B, we have $B \supseteq (ch(V_k) \cap \tau)$. Then from definition of U, we have that V_j in $\{ch(V_k) \cap \tau, V_k\}$ is not in U. Now we just need to show that any parent of any node V_j in $\{ch(V_k) \cap \tau, V_k\}$ is also not in U:

1. By definitions of B and U, the parents of V_k is not in U.

2. Consider parents of nodes in $\{ch(V_k) \cap \tau\}$. Let W is such a parent, that is, $W \to V_j$ for $V_j \in \{ch(V_k) \cap \tau\}$. There is a head to head path ($W \to V_j \leftarrow V_k$). We show that W is not in U separately for two cases: $W \in \tau$ and $W \notin \tau$. For the first case of $W \in \tau$, there is an undirected

edge between W and V_k in G^*_τ since there is no v-structure in the subgraph G'_τ for any $G' \in [G]$. Then from definition of B, we have $W \in B$. For the second case of $W \notin \tau$, W must be a parent of V_k by Lemma 10, and then W is in B. Thus we obtain $W \notin U$.

We showed that the factor $\prod_{V_j \in \{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j))$ does not contain any variable in U. Thus the numerator and the summations over U and V_k in the denominator can be factorized as follows

$$\begin{aligned}
&P_{V_i}(v_k|B) \\
&= \frac{\prod_{v_j \in \{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j)) \sum_U P'(v_i|pa(v_i)) \prod_{v_j \in A\setminus\{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j))}{\sum_{V_k} \prod_{v_j \in \{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j)) \sum_U P'(v_i|pa(v_i)) \prod_{v_j \in A\setminus\{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j))} \\
&= \frac{\prod_{v_j \in \{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j))}{\sum_{V_k} \prod_{v_j \in \{ch(V_k)\cap\tau, V_k\}} P(v_j|pa(v_j))} = P(v_k|B).
\end{aligned}$$

Thus we proved property 1.

Property 2 is obvious since manipulating V_i does not change the distribution of its parent V_k. Formally, let $an(V_k)$ be the ancestor set of V_k. If $V_k \in pa(V_i)$, then we have $P_{V_i}(an(v_k), v_k) = P(an(v_k), v_k)$ and thus $P_{V_i}(V_k) = P(V_k)$. ■

Proof of Theorem 8. Manipulating a node V_i will orient all of undirected edges connecting V_i. Thus the orientations of undirected edges do not depend on the order in which the variables are manipulated. If a sequence $\mathcal{S}$ is sufficient, then its permutation is also sufficient. ■

Proof of Theorem 9. Suppose that $\mathcal{S} = (V_1, \ldots, V_K)$ is a sufficient set. We delete a node, say V_i, from $\mathcal{S}$, and define $\mathcal{S}'_{[i]} = \mathcal{S} \setminus \{V_i\}$. If the set $\mathcal{S}'_{[i]}$ is no longer sufficient, then we can add other variables to $\mathcal{S}'_{[i]}$ without adding V_i such that $\mathcal{S}'_{[i]}$ becomes to be sufficient. This is feasible since any undirected edge can be oriented by manipulating either of its two nodes. Thus we have $\bigcap_{i=1}^{K} \mathcal{S}'_{[i]} = \varnothing$. Since all $\mathcal{S}'_{[i]}$ belong to $\mathbb{S}$, we proved $\bigcap_{\mathcal{S}\in\mathbb{S}} \mathcal{S} = \varnothing$.

Similarly, for each minimum sequence $\mathcal{S}$, we can define $\mathcal{S}'_{[i]}$ such that it does not contain V_i and it is a minimum sufficient set. Thus the intersection of all minimum sufficient sets is empty. ■

Abstract

Most discriminative techniques for detecting instances from object categories in still images consist of looping over a partition of a pose space with dedicated binary classifiers. The efficiency of this strategy for a complex pose, that is, for fine-grained descriptions, can be assessed by measuring the effect of sample size and pose resolution on accuracy and computation. Two conclusions emerge: (1) fragmenting the training data, which is inevitable in dealing with high in-class variation, severely reduces accuracy; (2) the computational cost at high resolution is prohibitive due to visiting a massive pose partition.

To overcome data-fragmentation we propose a novel framework centered on pose-indexed features which assign a response to a pair consisting of an image and a pose, and are designed to be stationary: the probability distribution of the response is always the same if an object is actually present. Such features allow for efficient, one-shot learning of pose-specific classifiers. To avoid expensive scene processing, we arrange these classifiers in a hierarchy based on nested partitions of the pose; as in previous work on coarse-to-fine search, this allows for efficient processing.

The hierarchy is then ”folded” for training: all the classifiers at each level are derived from one base predictor learned from all the data. The hierarchy is ”unfolded” for testing: parsing a scene amounts to examining increasingly finer object descriptions only when there is sufficient evidence for coarser ones. In this way, the detection results are equivalent to an exhaustive search at high resolution. We illustrate these ideas by detecting and localizing cats in highly cluttered greyscale scenes.

Keywords: supervised learning, computer vision, image interpretation, cats, stationary features, hierarchical search

1. Introduction

This work is about a new strategy for supervised learning designed for detecting and describing instances from semantic object classes in still images. Conventional examples include faces, cars and pedestrians. We want to do more than say whether or not there are objects in the scene; we want to provide a description of the pose of each detected instance, for example the locations of certain landmarks. More generally, pose could refer to any properties of object instantiations which

are not directly observed; however, we shall concentrate on geometric descriptors such as scales, orientations and locations.

The discriminative approach to object detection is to induce classifiers directly from training data without a data model. Generally, one learns a pose-specific binary classifier and applies it many times (Rowley et al., 1998; Papageorgiou and Poggio, 2000; Viola and Jones, 2004; LeCun et al., 2004). Usually, there is an outer loop which visits certain locations and scales with a sliding window, and a purely learning-based module which accommodates all other sources of variation and predicts whether or not a sub-window corresponds to a target. Parsing the scene in this manner already exploits knowledge about transformations which preserve object identities. In particular, translating and scaling the training images to a reference pose allows for learning a base classifier with all the training examples. We refer to such learning methods, which use whole image transforms in order to normalize the pose, as "data-aggregation" strategies.

However such transforms, which must be applied online during scene parsing as well as offline during training, may be costly, or even ill-defined, for complex poses. How does one "normalize" the pose of a cat? In such cases, an alternative strategy, which we call "data-fragmentation," is to reduce variation by learning many separate classifiers, each dedicated to a sub-population of objects with highly constrained poses and each trained with only those samples satisfying the constraints. Unfortunately, this approach to invariance might require a massive amount of training data due to partitioning the data. As a result, the discriminative approach has been applied almost exclusively to learning rather coarse geometric descriptions, such as a facial landmark and in-plane orientation, by some form of data-aggregation. Summarizing: aggregating the data avoids sparse training but at the expense of costly image transforms and restrictions on the pose; fragmenting the data can, in principle, accommodate a complex pose but at the expense of crippling performance due to impoverished training.

A related trade-off is the one between computation and pose resolution. Sample size permitting, a finer subpopulation (i.e., higher pose resolution) allows for training a more discriminating classifier. However, the more refined the pose partitioning, the more online computation because regardless of how the classifiers are trained, having more of them means more costly scene parsing. This trade-off is clearly seen for cascades (Viola and Jones, 2004; Wu et al., 2008): at a high true positive rate, reducing false positives could only come at the expense of considerable computation due to dedicating the cascade to a highly constrained pose, hence increasing dramatically the number of classifiers to train and evaluate in order to parse the scene.

To set the stage for our main contribution, a multi-resolution framework, we attempted to quantify these trade-offs with a single-resolution experiment on cat detection. We considered multiple partitions of the space of poses at different resolutions or granularities. For each partition, we built a binary classifier for each cell. There are two experimental variables besides the resolution of the partition: the data may be either fragmented or aggregated during training and the overall cost of executing all the classifiers may or may not be equalized. Not surprisingly, the best performance occurs with aggregated training at high resolution, but the on-line computational cost is formidable. The experiment is summarized in an Appendix A and described in detail in Fleuret and Geman (2007).

Our framework is designed to avoid these trade-offs. It rests on two core ideas. One, which is not new, is to control online computation by using a hierarchy of classifiers corresponding to a recursive partitioning of the pose space, that is, parameterizations of increasing complexity. A richer parametrization is considered only when "necessary", meaning the object hypothesis cannot

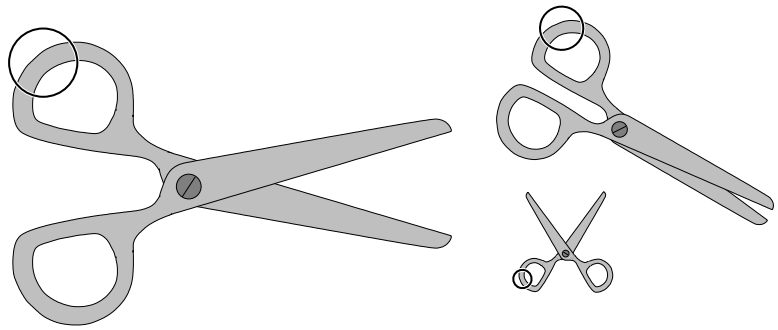

Figure 1: An idealized example of stationary features. The pose of the scissors could be the locations of the screw and the two tips, in which case one might measure the relative frequency a particular edge orientation inside in a disc whose radius and location, as well as the chosen orientation, depends on the pose. If properly designed, the response statistics have a distribution which is invariant to the pose when in fact a pair of scissors is present (see § 3.3).

be ruled out with a simpler one (see, e.g., Fleuret and Geman, 2001; Stenger et al., 2006). (Note that cascades are efficient for a similar reason - they are coarse-to-fine in terms of background rejection.) However, hierarchical organization alone is unsatisfactory because it does not solve the data-fragmentation problem. Unless data can be synthesized to generate many dedicated sets of positive samples, one set per node in the hierarchy, the necessity of training a classifier for every node leads to massive data fragmentation, hence small node-specific training sets, which degrades performance.

The second idea, the new one, is to avoid data-fragmentation by using pose-specific classifiers trained with "stationary features", a generalization of the underlying implicit parametrization of the features by a scale and a location in all the discriminative learning techniques mentioned earlier. Each stationary feature is "pose-indexed" in the sense of assigning a numerical value to each combination of an image and a pose (or subset of poses). The desired form of stationarity is that, for any given pose, the *distribution* of the responses of the features over images containing an object at that pose does not depend on the pose. Said another way, if an image and an object instance at a given pose are selected, and only the responses of the stationary features are provided, one cannot guess the pose. This is illustrated in Figure 1: knowing only the proportion of edges at a pose-dependent orientation in the indicated disk provides no information about the pose of the scissors.

Given that objects are present, a stationary feature evaluated at one pose is then the "same" as at any other, but not in a literal, point-wise sense as functions, but rather in the statistical, population sense described above. In particular, stationary features are not "object invariants" in the deterministic sense of earlier work (Mundy and Zisserman, 1992) aimed at discovering algebraic and geometric image functionals whose actual values were invariant with respect to the object pose. Our aim is less ambitious: our features are only "invariant" in a statistical sense. But this is enough to use all the data to train each classifier.

Of course the general idea of connecting features with object poses is relatively common in object recognition. As we have said, pose-indexing is done implicitly when transforming images to a

reference location or scale, and explicitly when translating and scaling Haar wavelets or edge detectors to compute the response of a classifier for a given location and scale. Surprisingly, however, this has not been formulated and analyzed in general terms, even though stationarity is all that is needed to aggregate data while maintaining the standard properties of a training set. Stationarity makes it possible, and effective, to analytically construct an entire family of pose-specific classifiers—all those at a given level of the hierarchy—using one base classifier induced from the entire training set. In effect, each pose-specific classifier is a "deformation" of the base classifier. Hence the number of classifiers to train grows linearly, not exponentially, with the depth of the pose hierarchy. This is what we call a folded hierarchy of classifiers: a tree-structured hierarchy is collapsed, like a fan, into a single chain for training and then expanded for coarse-to-fine search.

The general formulation opens the way for going beyond translation and scale, for example for training classifiers based on checking consistency among parts or deformations of parts instead of relying exclusively on their marginal appearance. Such a capability is indeed exploited by the detector we designed for finding cats and greatly improves the performance compared to individual part detection. This gain is shown in Figure 2, the main result of the paper, which compares ROC curves for two detectors, referred to as "H+B" and "HB" in the figure. In the "H+B" case, two separate detectors are trained by data aggregation, one dedicated to heads and the other to bodies; the ROC curve is the best we could do in combining the results. The "HB" detector is a coordinated search based on stationary features and a two-level hierarchy; the search for the belly location in the second-level is conditional on a pending head location and data fragmentation is avoided with pose-indexed features in a head-belly frame. A complete explanation appears in § 6.

In §2, we summarize previous, related work on object detection in still images. Our notation and basic ideas are formally introduced in §3, highlighting the difference between transforming the signal and the features. The motivational experiment, in which we substantiate our claims about the forced trade-offs when conventional approaches are applied to estimating a complex pose, could be read at this point; see Appendix A. Embedding pose-indexed classifiers in a hierarchy is described in §4 and the base classifier, a variation on boosting, is described in §5. In §6 we present our main experiment - an application of the entire framework, including the specific base features, pose hierarchy and pose-indexed features, to detecting cats in still images. Finally, some concluding remarks appear in §7.

2. Related Work

We characterize other work in relation to the two basic components of our detection strategy: explicit modeling of a hidden pose parameter, as in many generative and discriminative methods, and formulating detection as a controlled "process of discovery" during which computation is invested in a highly adaptive and unbalanced way depending on the ambiguities in the data.

2.1 Hidden Variables

A principal source of the enormous variation in high-dimensional signals (e.g., natural images) is the existence of a hidden state which influences many components (e.g., pixel intensities) simultaneously, creating complex statistical dependencies among them. Still, even if this hidden state is of high dimension, it far simpler than the observable signal itself. Moreover, since our objective is to interpret the signal at a semantic level, much of the variation in the signal is irrelevant.

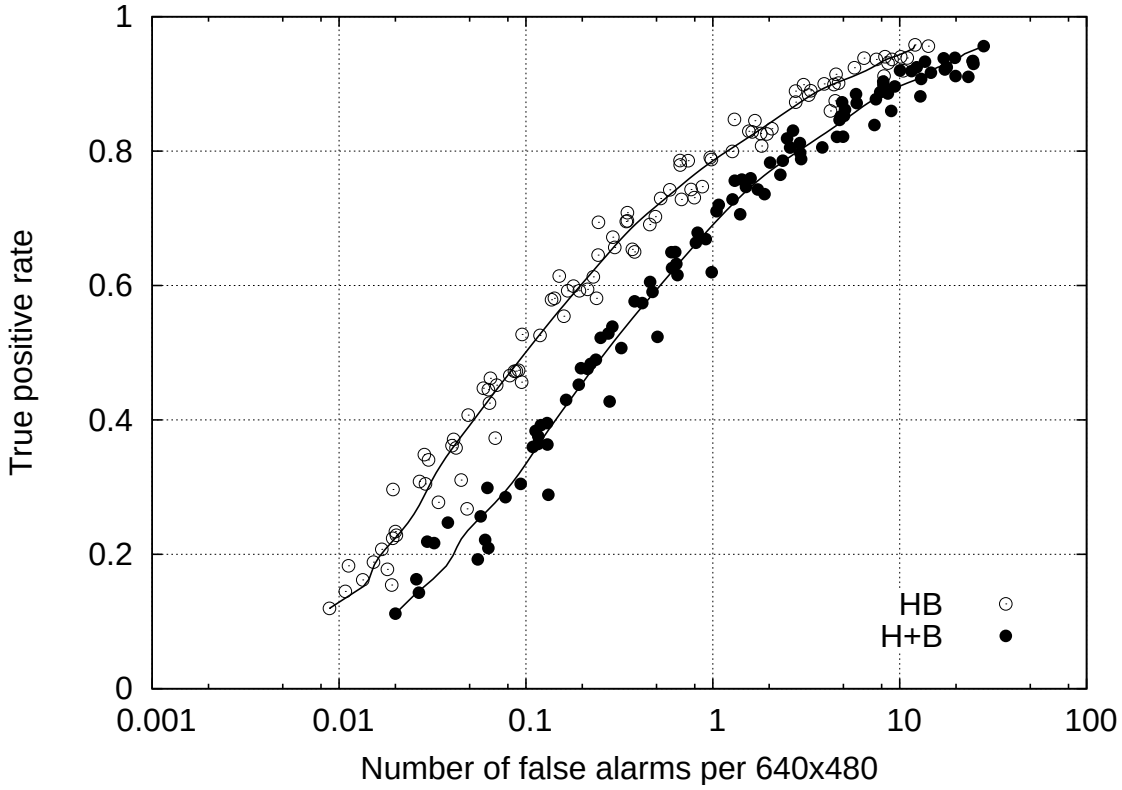

Figure 2: ROC curves for head-belly detection. The criterion for a true detection is that the estimates of the head location, head size and belly location all be close to the true pose (see § 6.6). The H+B detector is built from separate head and body detectors while the HB detector is built upon pose indexed features (see § 6.5).

In fact, conditioning on the value of the hidden state, which means, in practice, testing for the presence of a target with a given pose, often leads to very simple, yet powerful, statistical models by exploiting the increased degree of independence among the components of the signal. This means decisions about semantic content can be based on directly aggregating evidence (naive Bayes). The problem is computational: there are many possible hidden states.

The extreme application of this conditioning paradigm is classical template matching (Grenander, 1993): if the pose is rich enough to account for all non-trivial statistical variation, then even a relatively simple metric can capture the remaining uncertainty, which is basically noise. But this requires intense online computation to deform images or templates many times. One motivation of our approach is to avoid such online, global image transformations.

Similarly, the purest learning techniques, such as boosting (Viola and Jones, 2004) and convolution neural networks (LeCun et al., 2004), rely on explicitly searching through a subset of possible scales and locations in the image plane; that is, coarse scale and coarse location are not learned. Nor is invariance to illumination, usually handled at the feature level. However, invariance to other

geometric aspects of the pose, such as rotation, and to fine changes in scale and translation, are accommodated implicitly, that is, during classifier training.

On the contrary, "Part and Structure" models and other generative (model-based) approaches aim at more complex representations in terms of properties of "parts" (Li et al., 2003; Schneiderman and Kanade, 2004; Crandall and Huttenlocher, 2006). However, tractable learning and computation often require strong assumptions, such as conditional independence in appearance and location. In some cases, each part is characterized by the response of a feature detector, and the structure itself—the arrangement of parts—can either be captured by a complex statistical model, incurring severe computation in both training and testing, or by a simple model by assuming conditional independence among part locations given several landmarks, which can lead to very efficient scene parsing with the use of distance transforms. Some of these techniques do extend to highly articulated and deformable objects; see, for example, Huttenlocher and Felzenszwalb (2005). Still, modeling parts of cats (heads, ears, paws, tails, etc.) in this framework may be difficult due to the low resolution and high variation in their appearance, and in the spatial arrangements among them. Compositional models (Geman et al., 2002; Zhu and Mumford, 2006; Ommer et al., 2006) appear promising. Among these, in the "patchwork of parts" model (citepamit-trouve2007, the feature extractors are, like here, defined with respect to the pose of the object to detect, in that case a series of control points. This strategy allows for aggregating training samples with various poses through the estimation of common distributions of feature responses.

2.2 A Process of Discovery

We do not regard the hidden pose as a "nuisance" parameter, secondary to detection itself, but rather as part of what it means to "recognize" an object. In this regard, we share the view expressed in Geman et al. (2002), Crandall and Huttenlocher (2006) and elsewhere that scene interpretation should go well beyond pure classification towards rich annotations of the instantiations of the individual objects detected.

In particular, we envision detection as an organized process of discovery, as in Amit et al. (1998), and we believe that computation is a crucial issue and should be highly concentrated. Hierarchical techniques, which can accomplish focusing, are based on a recursive partitioning of the pose space (or object/pose space), which can be either ad-hoc (Geman et al., 1995; Fleuret and Geman, 2001) or learned (Stenger et al., 2006; Gangaputra and Geman, 2006). There is usually a hierarchy of classifiers, each one trained on a dedicated set of examples—those carrying a pose in the corresponding cell of the hierarchy. Often, in order to have enough data to train the classifiers, samples must be generated synthetically, which requires a sophisticated generative model.

Our work is also related to early work on hierarchical template-matching (Gavrila, 1998) and hierarchical search of pose space using branch and bound algorithms (Huttenlocher and Rucklidge, 1993), and to the cascade of classifiers in Viola and Jones (2004) and Wu et al. (2008).

Relative to the tree-based methods, we use the stationary features to aggregate data and build only one base classifier per level in the hierarchy, from which all other classifiers are defined analytically. Finally, the fully hierarchical approach avoids the dilemma of cascades, namely the sacrifice of selectivity if the pose space is coarsely explored and the sacrifice of computation if it is finely explored, that is, the cascades are dedicated to a very fine subset of poses.

3. Stationary Features

We regard the image as a random variable I assuming values in $\mathcal{I}$. The set of possible poses for an object appearing in I is $\mathcal{Y}$. We only consider geometric aspects of pose, such as the sizes of well-defined parts and the locations of distinguished points.

Let $\mathcal{Y}_1,\ldots,\mathcal{Y}_K$ be a partition of $\mathcal{Y}$. As we will see in § 4, we are interested in partitions of varying granularities for the global process of detection, ranging from rather coarse resolution (small K) to rather fine resolution (larger K), but in this section we consider one fixed partition.

For every $k = 1\ldots K$, let Y_k be a Boolean random variable indicating whether or not there is a target in I with pose in $\mathcal{Y}_k$. The binary vector $(Y_1,\ldots,Y_K)$ is denoted $\mathbf{Y}$.

In the case of merely detecting and localizing an object of fixed size in a gray-scale image of size $W \times H$, natural choices would be $\mathcal{I} = [0,1]^{WH}$ and $\mathcal{Y} = [0,W] \times [0,H]$, the image plane itself; that is, the pose reduces to one location. If the desired detection accuracy were 5 pixels, then the pose cells might be disjoint 5×5 blocks and K would be approximately $\frac{WH}{25}$. On the other hand, if the pose accommodated scale and multiple points of interest, then obviously the same accuracy in the prediction would lead to a far larger K, and any detection algorithm based on looping over pose cells would be highly costly.

We denote by $\mathcal{T}$ a training set of images labeled with the presences of targets

$$\mathcal{T} = \left\{ \left(I^{(t)}, \mathbf{Y}^{(t)} \right) \right\}_{1 \le t \le T},$$

where each $I^{(t)}$ is a full image, and $\mathbf{Y}^{(t)}$ is the Boolean vector indicating the pose cells occupied by targets in $I^{(t)}$. We write

$$\xi : \mathcal{I} \to \mathbb{R}^N,$$

for a family of N image features such as edge detectors, color histograms, Haar wavelets, etc. These are the "base features" $(\xi_1,\ldots,\xi_N)$ which will be used to generate our stationary feature vector. We will write $\xi(I)$ when we wish to emphasize the mapping and just ξ for the associated random variable. The dimension N is sufficiently large to account for all the variations of the feature parameters, such as locations of the receptive fields, orientations and scales of edges, etc.

In the next section, § 3.1, we consider the problem of "data-fragmentation", meaning that specialized predictors are trained with subsets of the positive samples. Then, in § 3.2, we formalize how fragmentation has been conventionally avoided in simple cases by normalizing the signal itself; we then propose in § 3.3 the idea of pose-indexed, stationary features, which avoids global signal normalization both offline and online and opens the way for dealing with complex pose spaces.

3.1 Data Fragmentation

Without additional knowledge about the relation between $\mathbf{Y}$ and I, the natural way to predict Y_k for each $k = 1\ldots K$ is to train a dedicated classifier

$$f_k : \mathcal{I} \to \{0,1\}$$

with the training set

$$\left\{ \left(I^{(t)}, Y_k^{(t)} \right) \right\}_{1 \le t \le T}$$

derived from $\mathcal{T}$. This corresponds to generating a single sample from each training scene, labeled according to whether or not there is a target with pose in $\mathcal{Y}_k$. This is *data-fragmentation*: training

$\mathcal{Y}$, the pose space
$\mathcal{Y}_1,\ldots,\mathcal{Y}_K$, a partition of the pose space $\mathcal{Y}$
$\mathcal{Z}$, a $W \times H$ pixel lattice
$I = \{0,\ldots,255\}^{\mathcal{Z}}$, a set of gray-scale images of size $W \times H$
I, a random variable taking values in I
Y_k, a Boolean random variable indicating if there is a target in I with pose in $\mathcal{Y}_k$
$\mathbf{Y} = (Y_1,\ldots,Y_K)$
T, the number of training images, each with or without targets
$\mathcal{T} = \left\{\left(I^{(t)},\mathbf{Y}^{(t)}\right)\right\}_{1\leq t\leq T}$, the training set
$f_k : I \to \{0,1\}$, a predictor of Y_k based on the image
Q, number of image features
$\xi : I \to \mathbb{R}^N$, a family of base image features
$\psi : \{1,\ldots,K\} \times I \to I$, an image transformation intended to normalize a given pose
$\mathbf{X} : \{1,\ldots,K\} \times I \to \mathbb{R}^Q$, a family of pose-indexed features
$\mathbf{X}(k)$, the r.v. corresponding to $\mathbf{X}(k,I)$
$g : \mathbb{R}^Q \to \{0,1\}$, a predictor trained from all the data

Table 1: Notation

f_k involves only those data which exactly satisfy the pose constraint; no synthesis or transformations are exploited to augment the number of samples available for training. Clearly, the finer the partitioning of the pose space $\mathcal{Y}$, the fewer positive data points are available for training each f_k.

Such a strategy is evidently foolhardy in the standard detection problems where the pose to be estimated is the location and scale of the target since it would mean separately training a predictor for every location and every scale, using as positive samples only full scenes showing an object at that location and scale. The relation between the signal and the pose is obvious and normalizing the positive samples to a common reference pose by translating and scaling them is the natural procedure; only one classifier is trained with all the data. However, consider a face detection task for which the faces to detect are known to be centered and of fixed scale, but are of unknown out-of-plane orientation. Unless 3D models are available, from which various views can be synthesized, the only course of action is data-fragmentation: partition the pose space into several cells corresponding to different orientation ranges and train a dedicated, range-specific classifier with the corresponding positive samples.

3.2 Transforming the Signal to Normalize the Pose

As noted above, in simple cases the image samples can be normalized in pose. More precisely, both training and scene processing involve normalizing the image through a pose-indexed transformation

$$\psi : \{1,\ldots,K\} \times I \to I.$$

The "normalization property" we desire with respect to ξ is that the conditional probability distribution of $\xi(\psi(k,I))$ given $Y_k = 1$ be the same for every $1 \leq k \leq K$.

The intuition behind this property is straightforward. Consider for instance a family of edge detectors and consider again a pose consisting of a single location z. In such a case, the transformation ψ applies a translation to the image to move the center of pose cell $\mathcal{Y}_k$ to a reference location. If

a target was present with a pose in $\mathcal{Y}_k$ in the original image, it is now at a reference location in the transformed image, and the distribution of the response of the edge detectors in that transformed image does not depend on the initial pose cell $\mathcal{Y}_k$.

We can then define a new training set

$$\left\{\left(\xi\left(\psi(k,I^{(t)})\right),Y_k^{(t)}\right)\right\}_{1\le k\le K,1\le t\le T}$$

with elements residing in $\mathbb{R}^N\times\{0,1\}$. Due to the normalization property, and under mild conditions, the new training set indeed consists of independent and identically distributed components (see the discussion in the following section). Consequently, this set allows for training a classifier

$$g:\mathbb{R}^N\to\{0,1\}$$

from which we can analytically define a predictor of Y_k for any k by

$$f_k(I)=g\left(\xi(\psi(k,I))\right).$$

This can be summarized algorithmically as follows: In order to predict if there is a target in image I with pose in $\mathcal{Y}_k$, first normalize the image with ψ so that a target with pose in $\mathcal{Y}_k$ would be moved to a reference pose cell, then extract features in that transformed image using ξ, and finally evaluate the response of the predictor g from the computed features.

3.3 Stationary Features

The pose-indexed, image-to-image mapping ψ is computationally intensive for any non-trivial transformation. Even rotation or scaling induces a computational cost of $O(WH)$ for every angle or scale to test during scene processing, although effective shortcuts are often employed. Moreover, this transformation does not exist in the general case. Consider the two instances of cats shown in Figure 3. Rotating the image does not allow for normalizing the body orientation without changing the head orientation, and designing a non-affine transformation to do so would be unlikely to produce a realistic cat image as well as be computationally intractable when done many times. Finally, due to occlusion and other factors, there is no general reason *a priori* for ψ to even exist.

Instead, we propose a different mechanism for data-aggregation based on pose-indexed features which directly assign a response to a pair consisting of an image and a pose cell and which satisfy a stationarity requirement. This avoids assuming the existence of a normalizing mapping in the image space, not to mention executing such a mapping many times online.

A **stationary feature vector** *is a pose-indexed mapping*

$$\mathbf{X}:\{1,\ldots,K\}\times I\to\mathbb{R}^Q,$$

with the property that the probability distribution

$$P(\mathbf{X}(k)=\mathbf{x}\,|\,Y_k=1),\ \mathbf{x}\in\mathbb{R}^Q \tag{1}$$

is the same for every $k=1,\ldots,K$, where $\mathbf{X}(k)$ denotes the random variable $\mathbf{X}(k,I)$.

The idea can be illustrated with two simple examples, a pictorial one in Figure 1 and a numerical one in § 3.4.

Figure 3: Aggregating data for efficient training by normalizing the pose at the image level is difficult for complex poses. For example, linear transformations cannot normalize the orientation of the body without changing that of the head.

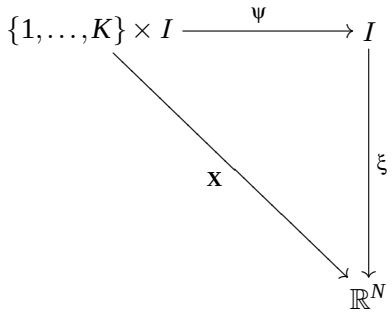
In practice, the relationship with ξ, the base feature vector, is simply that the components of the feature vector $\mathbf{X}(k)$ are chosen from among the components of ξ; the choice depends on k. In this case, we can write

$$\mathbf{X}(k) = (\xi_{\pi_1(k)}, \xi_{\pi_2(k)}, \ldots, \xi_{\pi_Q(k)}),$$

where $\{\pi_1(k), \ldots, \pi_Q(k)\} \subset \{1, \ldots, N\}$ is the ordered selection for index k. The ordering matters because we want (1) to hold and hence there is a correspondence among individual components of $\mathbf{X}(k)$ from one pose cell to another.

Note: We shall refer to (1) as the "stationarity" or "weak invariance" assumption. As seen below, this property justifies data-aggregation in the sense of yielding an aggregated training set satisfying the usual conditions. Needless to say, however, demanding that this property be satisfied exactly is not practical, even arguably impossible. In particular, with our base features, various discretizing effects come into play, including using quantized edge orientations and indexing base features with rectangular windows. Even designing the pose-indexed features to approximate stationarity by appropriately selecting and ordering the base features is non-trivial; indeed, it is the main challenge in our framework. Still, using pose-indexed features which are even approximately stationary will turn out to be very effective in our experiments with cat detection.

The contrast between signal and feature transformations can be illustrated with the following commutative diagram: Instead of first applying a normalizing mapping ψ to transform I in accordance with a pose cell k, and then evaluating the base features, we directly compute the feature responses as functions of both the image and the pose cell.



Once provided with $\mathbf{X}$, a natural training set consisting of TK samples is provided by

$$\mathcal{T}_{agg} = \left\{ \left(\mathbf{X}^{(t)}(k), Y_k^{(t)} \right) \right\}_{1 \le t \le T, 1 \le k \le K}. \tag{2}$$

Under certain conditions, the elements of this training set will satisfy the standard assumption of being independent and identically distributed. One condition, the key one, is stationarity, but technically three additional conditions would be required: 1) property (1) extend to conditioning on $Y_k = 0$; 2) the "prior" distribution $P(Y_k = 1)$ be the same for every $k = 1,\ldots,K$; 3) for each t, the samples $\mathbf{X}^{(t)}(k), k = 1,\ldots,K$, be independent. The first condition says that the background distribution of the pose-indexed features is spatially homogeneous, the second that all pose cells are *a priori* equally likely and the third, dubious but standard, says that the image data associated with different pose cells are independent despite some overlap. In practice, we view these as rough guidelines; in particular, we make no attempt to formally verify any of them.

It therefore makes sense to train a predictor $g : \mathbb{R}^Q \to \{0,1\}$ using the training set (2). We can then *define*

$$f_k(I) = g(\mathbf{X}(k,I)),\ k = 1,\ldots,K.$$

Notice that the family of classifiers $\{f_k\}$ is also "stationary" in the sense that conditional distribution of f_k given $Y_k = 1$ does not depend on k.

3.4 Toy Example

We can illustrate the idea of stationary features with a very simple roughly piecewise constant, one-dimensional signal $I(n), n = 1,...,N$. The base features are just the components of the signal itself: $\xi(I) = I$. The pose space is

$$\mathcal{Y} = \left\{ (\theta_1, \theta_2) \in \{1,\ldots,N\}^2, 1 < \theta_1 < \theta_2 < N \right\}$$

and the partition is the finest one whose cells are individual poses $\{(\theta_1,\theta_2)\}$; hence $K = |\mathcal{Y}|$. For simplicity, assume there is at most one object instance, so we can just write $Y = (\theta_1,\theta_2) \in \mathcal{Y}$ to denote an instance with pose (θ_1,θ_2). For $\mathbf{u} = (u_1,...,u_N) \in \mathbb{R}^N$, the conditional distribution of I given Y is

$$\begin{aligned} P(I = \mathbf{u} \,|\, Y = (\theta_1,\theta_2)) &= \prod_n P(I(n) = u_n \,|\, Y = (\theta_1,\theta_2)) \\ &= \prod_{n<\theta_1} \phi_0(u_n) \prod_{\theta_1 \le n \le \theta_2} \phi_1(u_n) \prod_{\theta_2 < n} \phi_0(u_n) \end{aligned}$$

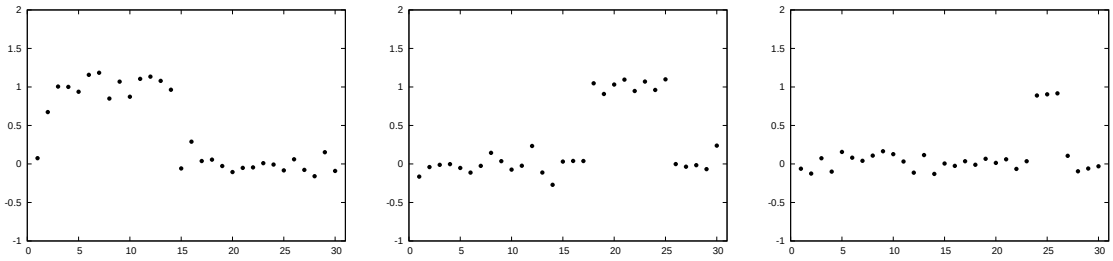


Figure 4: Examples of toy scenes

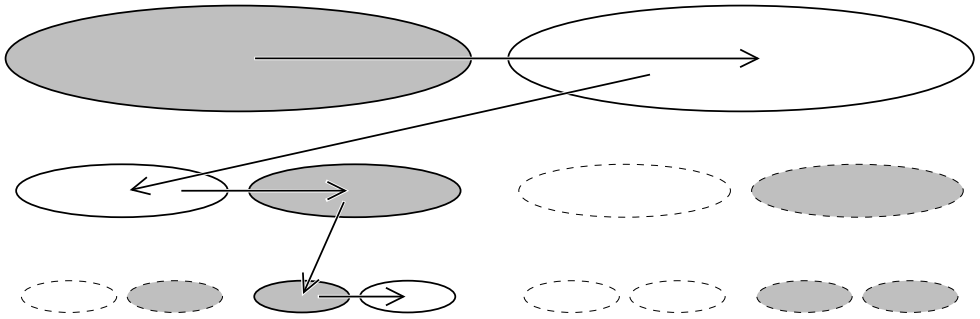

Figure 5: Hierarchical detection. Each ellipse on stands for a pose cell $\mathcal{Y}_k^{(d)}, k = 1,\ldots,K_d, d = 1,\ldots,D$. Here, $D = 3$ and $K_1 = 2$, $K_2 = 4$, $K_3 = 8$. Gray ellipses correspond to pose cells whose $f_k^{(d)}$ respond positively, and dashed ellipses correspond to pose cells whose classifiers are not evaluated during detection. As shown by the arrows, the algorithm ignores all sub-cells of a cell whose classifier responds negatively.

where ϕ_μ is a normal law with mean μ and standard deviation 0.1. Hence the signal fluctuates around 0 on the "background" and around 1 on the target, see Figure 4.

We define a four-dimensional pose-indexed feature vector taking the values of the signal at the extremities of the target, that is

$$\mathbf{X}((\theta_1,\theta_2),I) = (I(\theta_1-1),I(\theta_1),I(\theta_2),I(\theta_2+1)).$$

Clearly,

$$P(\mathbf{X}(\theta_1,\theta_2) = (x_1,x_2,x_3,x_4)\,|\,Y_{\theta_1,\theta_2} = 1) = \phi_0(x_1)\phi_1(x_2)\phi_1(x_3)\phi_0(x_4)$$

which is not a function of θ_1,θ_2. Consequently, $\mathbf{X}$ is stationary and the common law in (1) is $\phi_0 \times \phi_1 \times \phi_1 \times \phi_0$.

4. Folded Hierarchies

We have proposed normalizing the samples through a family of pose-indexed features instead of whole image transforms in order to avoid fragmentation of the data. Since only one classifier must be built for any partition of the pose space, and no longer for every cell of such a partition, neither

the cost of learning nor the required size of the training set grows linearly with the number K of pose cells in the partition. However, one main drawback remains: We must still visit all the pose cells online, which makes the cost of scene processing itself linear in K.

A natural strategy to address computational cost is an hierarchical search strategy based upon a recursive partitioning of $\mathcal{Y}$. As in previous work (Fleuret and Geman, 2001; Gangaputra and Geman, 2006), there is a succession of nested partitions of increasing resolution and a binary classifier assigned to each cell. Given such a hierarchy, the detection process is adaptive: a classifier is evaluated for a certain pose cell only if all the classifiers for its ancestor cells have been evaluated and responded positively.

Note: This is *not* a decision tree, both in terms of representation and processing. The hierarchy recursively partitions the space of hidden variables not the feature space, and the edges from a node to its children do not represent the possible values of a node classifier. Moreover, during processing, a data point may traverse many branches at once and may reach no leaves or reach many leaves.

The crucial difference with previous work is that, using stationary features, only one classifier must be trained for each level, not one classifier for each cell. In essence, the hierarchy is "folded" (like a fan) for training: The entire learning strategy described in §3 is repeated for each level in the hierarchy. This is quite straightforward and only summarized below.

Consider a sequence of partitions of $\mathcal{Y}$

$$\left\{\mathcal{Y}_1^{(d)},\ldots,\mathcal{Y}_{K_d}^{(d)}\right\},\quad 1\leq d\leq D,$$

for which any cell $\mathcal{Y}_k^d$ for $k=1,\ldots,K_{d+1}$, is a (disjoint) union of cells at the next level $d+1$. Consequently, we can identify every $\mathcal{Y}_k^{(d)}$ with the node of a multi-rooted tree: A leaf node for $d=D$ and an internal node otherwise. A three-level hierarchy is shown in Figure 5.

Given such a pose hierarchy, we can construct a scene parsing algorithm aimed at detecting all instances of objects at a pose resolution corresponding to the finest partition. Again, the processing strategy is now well-known. This algorithm has the desirable property of concentrating computation on the ambiguous pose-image pairs.

Let $Y_k^{(d)}$ denote a Boolean random variable indicating whether or not there is a target in I with pose in $\mathcal{Y}_k^{(d)}$ and let $\mathbf{X}^{(d)}$ denote a pose-indexed feature vector adapted to the partition $\{\mathcal{Y}_1^{(d)},\ldots,\mathcal{Y}_{K_d}^{(d)}\}$. For each level d, we train a classifier $g^{(d)}$ exactly as described in §3.3, and define a predictor of $Y_k^{(d)}$ by

$$f_k^{(d)}(I)=g^{(d)}\left(\mathbf{X}^{(d)}(k,I)\right).$$

The hierarchy is "unfolded" for testing and the predictors are evaluated in an adaptive way by visiting the nodes (cells) according to breadth-first "coarse-to-fine" search. A classifier is evaluated if and only if all its ancestors along the branch up to its root have been evaluated and returned a positive response. In particular, once a classifier at a node responds negatively, none of the descendant classifiers are ever evaluated. The result of the detection process is the list of leaves which are reached and respond positively. In this way, pose cells corresponding to obvious non-target regions such as flat areas are discarded early in the search and the computation is invested the ambiguous areas, for example, parts of images with "cat-like" shape or texture.

5. Base Classifier

As described in §4, given a family of pose-indexed features and a hierarchical partitioning of the pose space, we build a binary classifier $g^{(d)}$ for each level d in the hierarchy, trained from a set of examples of the type described in §3.3. In this section we describe that classifier, dropping the superscript d for clarity. The actual parameter values we used for the experiments on cat detection are given in §6.5.

Evidently, inducing such a mapping g is a standard machine learning problem. A simple candidate is a thresholded linear combination of V stumps trained with Adaboost (Freund and Schapire, 1999):

$$g(x) = \begin{cases} 1 & \text{if } \sum_{i=1}^{V} \alpha_i 1_{\{x^{\delta_i} \geq \tau_i\}} \geq \rho \\ 0 & \text{otherwise.} \end{cases}$$

Here, x^j is the j'th coordinate of the feature vector.

For any given true positive rate η, the threshold ρ in g, and more generally the thresholds $\rho^{(d)}$ in $g^{(d)}, 1 \leq d \leq D$, are chosen to achieve on a validation set a targeted decreasing sequence of true positive rates yielding η.

To select the stumps, that is the α_i, δ_i and τ_i, special attention must be given to the highly unbalanced populations we are dealing with. Of course in our detection problem, the prior distribution is very skewed, with an extremely low probability of the presence of a target at a pose picked at random. Correspondingly, the number of samples we have from the positive population (cats in our case) is orders of magnitude smaller than the number of samples we can easily assemble from the negative population. Still, any tractable sampling of the negative population is still too sparse to account for the negative sub-population which lives close to positive examples. To address these issues, we propose a variation the standard weighting-by-sampling in order to approximate standard Adaboost using a training set containing one million negative examples.

The popular cascade approach handles that dilemma with bootstrapping: training each level with a sample of negative examples which survive the filtering of the previous classifiers in the cascade. In this way the sampling is eventually concentrated on the "difficult" negative samples. This is similar in practice to what boosting itself is intended to do, namely ignore easily classified samples and concentrate on the difficult ones. We avoid the complexity of tuning such a cascade by using all the negative examples through an asymmetric, sampling-based version of standard boosting. This provides an excellent approximation to the exact weighting for a fraction of the computational cost.

When picking a stump we approximate the weighted error with an error computed over all positive samples and a *random subset of negative samples* drawn according to the current boosting weights. Hence, we keep the response of the strong classifier up-to-date on $S \simeq 10^6$ samples, but we pick the optimal weak learners at every step based on $M \simeq 10^4$ samples.

More precisely, at a certain iteration of the boosting procedure, let ω_s denote the weight of sample $s = 1, \ldots, S$, let $Y_s \in \{0,1\}$ be its true class, and let

$$\omega_{neg} = \sum_s \omega_s \mathbf{1}_{\{Y_s = 0\}}$$

be the total weight of the negative samples. We sample independently M indices $S_1,\ldots,S_M$ in $\{1,\ldots,S\}$ according to the negative sample density

$$P(S_m = s) = \frac{\omega_s \mathbf{1}_{\{Y_s=0\}}}{\omega_{neg}},\ m = 1,\ldots,M.$$

Then we re-weight the training samples as follows:

$$\omega'_s = \begin{cases} \omega_s & \text{if } Y_s = 1 \\ \omega_{neg}\dfrac{\|\{m : S_m = s\}\|}{M} & \text{otherwise.} \end{cases}$$

This can be seen as an approximation to the distribution on the full training set obtained by (1) keeping all positive samples with their original weights, and (2) selecting a random subset of negative samples according to their original weights, and giving them a uniform weight.

However, sampling the negative examples at every boosting step is computationally very expensive, mainly because it requires loading into memory all the training images, and extracting the edge features at multiple scales. Consequently, we decompose the total number of stumps V into B blocks of U stumps, and run this sampling strategy at the beginning of every block. We also sample a subset of R features among the millions of features available at the beginning of every block. Hence, our overall learning process can be seen as a standard boosting procedure decomposed into B blocks of U steps. At the beginning of every block, we sample M negative samples among S according to their current boosting weight and we sample R features uniformly among the Q to consider. We then run U boosting steps based on these features and these training samples.

This process ensures that any sample for which the classifier response is strongly incorrect will eventually be picked. In our experiments we sample ten negative examples for every positive example. From a computational perspective this sampling is negligible as it only accounts for about 1% of the total training time.

6. Cat Detection

We now specialize everything above to cat detection. The original training images and available ground truth are described in §6.1. Then, in §6.2, we define a family of highly robust, base image features based on counting edge frequencies over rectangular areas, and in §6.3 we propose a way to index such features with the pose of a cat defined by its head location and scale and belly location. The specific pose cell hierarchy is described in §6.4 and choice of parameters for the classifiers in §6.5. Finally, the results of our experiments are presented in §6.6, including the similarity criteria used for performance evaluation, the post-processing applied to the raw detections in order to reduce "duplicate" detections and the manner of computing ROC curves.

6.1 Cat Images and Poses

The cat images were randomly sampled from the web site RateMyKitten[1] and can be downloaded from `http://www.idiap.ch/folded-ctf`. Images of cluttered scenes without cats, mostly home interiors, were sampled from various web sites. The complete database we are using has 2,330 images containing a total of 1,988 cats.

1. Web site can be found at `http://www.ratemykitten.com`.

Figure 6: Each target is labeled by hand with a pose $(h,r,b) \in \mathcal{Z} \times \mathbb{R}^+ \times \mathcal{Z}$ specifying the head location, the head radius and the belly location.

Each cat was manually annotated with one circle roughly outlining the head, from which the head size (diameter) and head location (center) are derived, and one point placed more or less, quite subjectively, at the center of mass, which we have referred to as the "belly" location (see Figure 6). Hence, the pose of a cat is (h,r,b) where h is the location in the image plane $\mathcal{Z}$ of the center of the head, r its radius, and b is the belly location.

For each experiment, we split this database at random into a training set containing 75% of the images and a test set containing the other 25%. Two-thirds of the training set are used for choosing the weak learners and one-third for the thresholds.

6.2 Base Image Features

As described in §3, the pose-indexed features are defined in terms of base image features. First, an image is processed by computing, at every location $z \in \mathcal{Z}$, the responses of eight edge-detectors similar to those proposed in Amit et al. (1998) (see Figures 7 and 8), but at three different scales, ending up with 24 Boolean features $e_1(z), \ldots, e_{24}(z)$ corresponding to four orientations and two polarities. In addition, we add a variance-based binary test $e_0(z)$ which responds positively if the variance of the gray levels in a 16×16 neighborhood of z exceeds a fixed threshold. Our features are based on counting the number of responses of these 25 detectors over a rectangular areas (Fan, 2006), which can be done in constant time by using 25 integral images (Simard et al., 1999).

From these edge maps and the raw gray levels we define the following three types of base image features:

1. **Edge proportion:** The proportion of an edge type in a rectangular window. Given a rectangular window W and an edge type $\lambda \in \{0,1,\ldots,24\}$, the response is the number of pixels z in W for which $e_\lambda(z) = 1$, divided by the total number of pixels in W if $\lambda = 0$ or by the number of pixels in W for which $e_0(z) = 1$ if $\lambda > 0$.

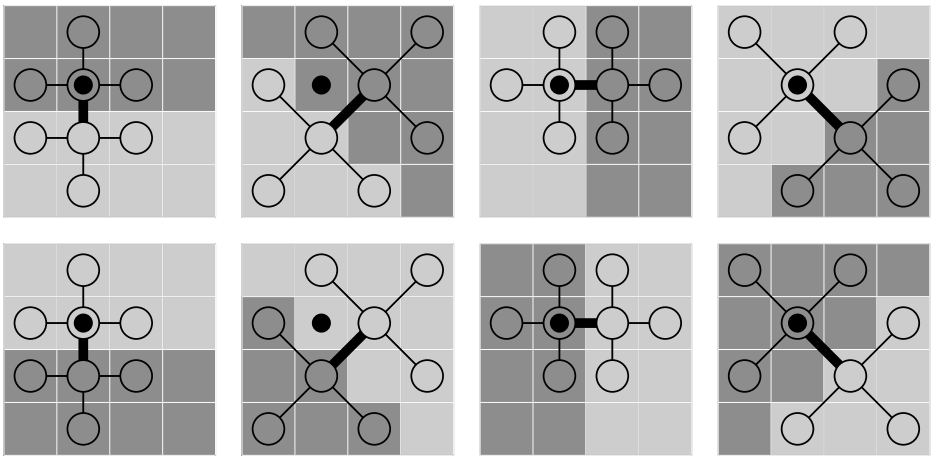

Figure 7: Our edge-detectors: For each of four orientations and two polarities, an edge is detected at a certain location (the dark circle) if the absolute difference between the intensities of the two pixels linked by the thick segment is greater than each of the six intensity differences for pixels connected by a thin segment.

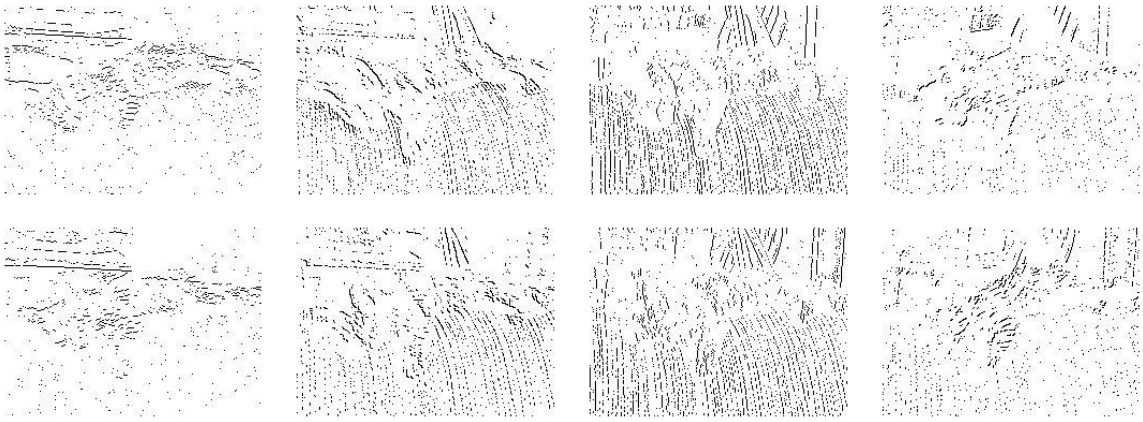

Figure 8: Result of the edge detector. Each one of the eight binary images in the two bottom rows corresponds to one orientation of the edge detectors of Figure 7.

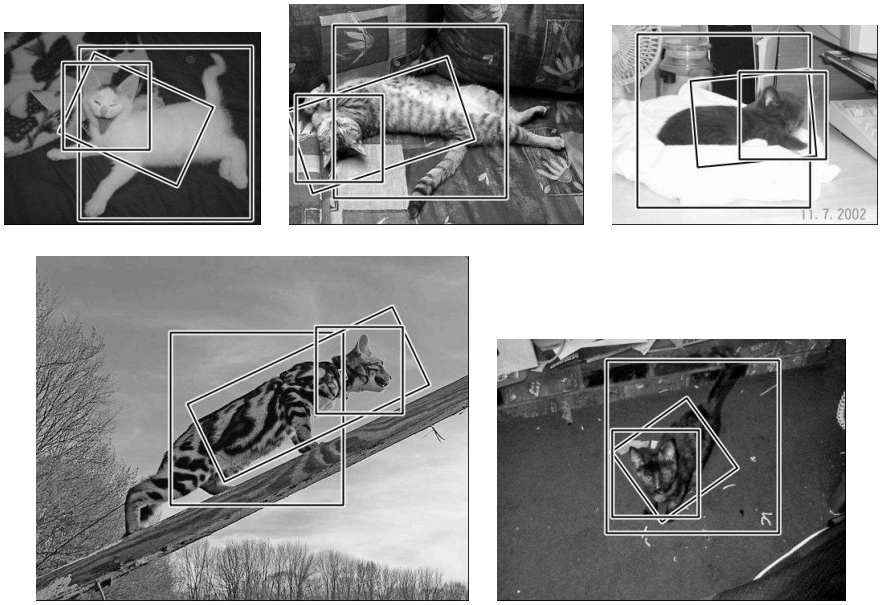

Figure 9: From the centroid of any pose cell, we define three reference frames: The *head frame* is centered on the head center, of size twice the head size; the *belly frame* is centered on the belly and of size four times the head size; the *head-belly frame* is centered on the middle point between the head and the belly, of height twice the head size, of width twice the distance between the head and the belly, and is tilted accordingly.

2. **Edge orientation histogram distance:** Given again two rectangular windows W_1 and W_2, and a scale s, the response is the L^1 norm between the empirical eight-bin histograms of orientations corresponding to the eight edge detectors at scale s.

3. **Gray-scale histogram distance:** Given two rectangular windows W_1 and W_2, the response is the L^1 norm between the sixteen-bin empirical histograms of gray-scales for the two windows.

The rational behind the features of type 1 is to endow the classifiers with the ability to check for the presence of certain pieces of outlines or textures. The motivation for types 2 and 3 is to offer the capability of checking for similarity in either edge or gray-scale statistics between different parts of the image, typically to check for a silhouette in the case of very blurry contours. Some examples of features actually picked during the training are shown in Figures 10 and 11.

6.3 Indexing Features by Pose

As formalized in §3.3, a pose-indexed feature is a real-valued function of both a pose cell and an image. The features described in the previous section are standard functionals of the image alone. Since the response of any of them depends on counting certain edge types over rectangular windows in the image, we construct our family of pose-indexed features indirectly by indexing both the edge types and the window locations with the pose cell.

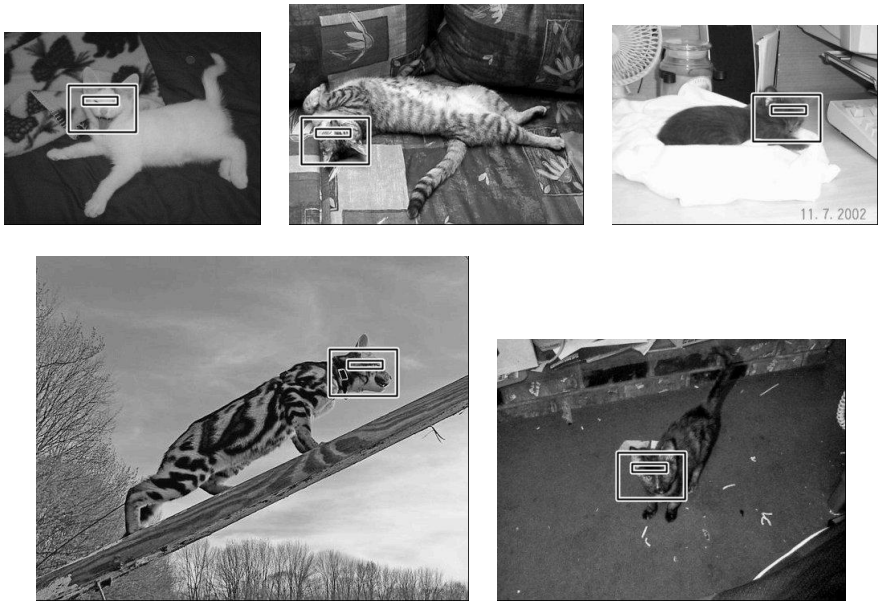

Figure 10: Registration on the true poses of the first feature selected in the HB detector (see §6.5), which compares edge orientation histograms. Both windows are defined relative to the head frame.

For any pose cell index k, we compute the average head location $h = h_k$, the average belly location $b = b_k$, and the average head radius $r = r_k$ of the pose cell $\mathcal{Y}_k$. From these parameters we compute three reference frames, as shown on Figure 9:

1. The **head frame** is a square centered on h and of size $4r$.
2. The **belly frame** is a square centered on b and of size $8r$.
3. The **head-belly frame** is a rectangle centered on the midpoint of h and b, tilted accordingly, and of height $4r$ and width twice $\|h-b\|$.

Note that the definition of such a frame actually involves the definition of a vector basis, hence an orientation. The three types of frames are oriented according to the relative horizontal locations of the head and belly of the cat, so a reflection around a horizontal axis of the image, hence of the cat pose, would move the points defined in these frames consistently.

We add to the parameterization of each feature window a discrete parameter specifying in which of these three reference frames the window is defined. Windows relative to the head or the belly frame are simply translated and scaled accordingly. Windows relative to the head-belly frame are translated so that their centers remain fixed in the frame, and are scaled according to the average of the height and width of the frame. See Figures 10 and 11.

Finally, we add another binary flag to windows defined in the head-belly frame to specify if the edge detectors are also registered. In that case, the orientation of the edges is rotated according to the tilt of the head-belly frame.

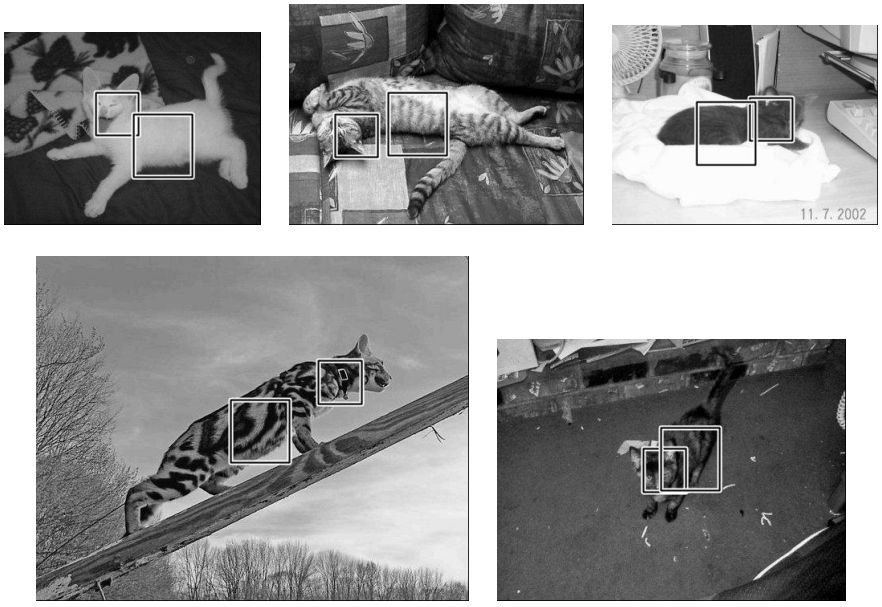

Figure 11: Registration on the true poses of the third feature selected in the second level of the HB detector (see §6.5), which compares grayscale histograms. One window is relative to the head-belly frame, and the second one to the belly frame.

6.4 Hierarchy of Poses

We only consider triples (h,r,b) which are consistent with the relative locations seen on the training set. For instance, this discards poses with very large ratios $\|h-b\|/r$. However, h and b may be very close together, for example when the belly is behind the head, or very far apart, for example when the cat is stretched out. Hence the full pose space is $\mathcal{Y} \subset \mathcal{Z} \times \mathbb{R}^+ \times \mathcal{Z}$.

We use a hierarchy with only $D = 2$ levels in order to concentrate on folded learning with stationary features. The first level $\{\mathcal{Y}_1^{(1)}, \ldots, \mathcal{Y}_{K_1}^{(1)}\}$ is based on first restricting the head radius to $[25, 200]$, and on splitting that domain into 15 sub-intervals of the form $[r, 2^{1/5} r]$. For each such scale interval, we divide the full lattice $\mathcal{Z}$ into non-overlapping regular squares of the form $[x_h, x_h + r/5] \times [y_h, y_h + r/5]$. This procedure creates $K_1 \simeq 50,000$ head parameter cells $[x_h, x_h + r/5] \times [y_h, y_h + r/5] \times [r, 2^{1/5} r]$ for a 640×480 image. For any such cell, the admissible domain for the belly locations is the convex envelope of the belly locations seen in the training examples, normalized in location and scale with respect to the head location and radius.

The second level $\{\mathcal{Y}_1^{(2)}, \ldots, \mathcal{Y}_{K_2}^{(2)}\}$ is obtained by splitting the belly location domain into regular squares $[x_b, x_b + r/2] \times [y_b, y_b + r/2]$. There are $\simeq 500$ such belly squares, hence the total number of pose cells in the second level is $K_2 \simeq 2.5 \times 10^7$.

The top-left illustration in Figure 12 depicts the cells in the first level of the hierarchy as open circles and cells in the second level as black dot connected to an open circle "kept alive" during processing the first level. More specifically, as shown in Figure 12, the algorithmic process corresponding to this two-level hierarchy is as follows:

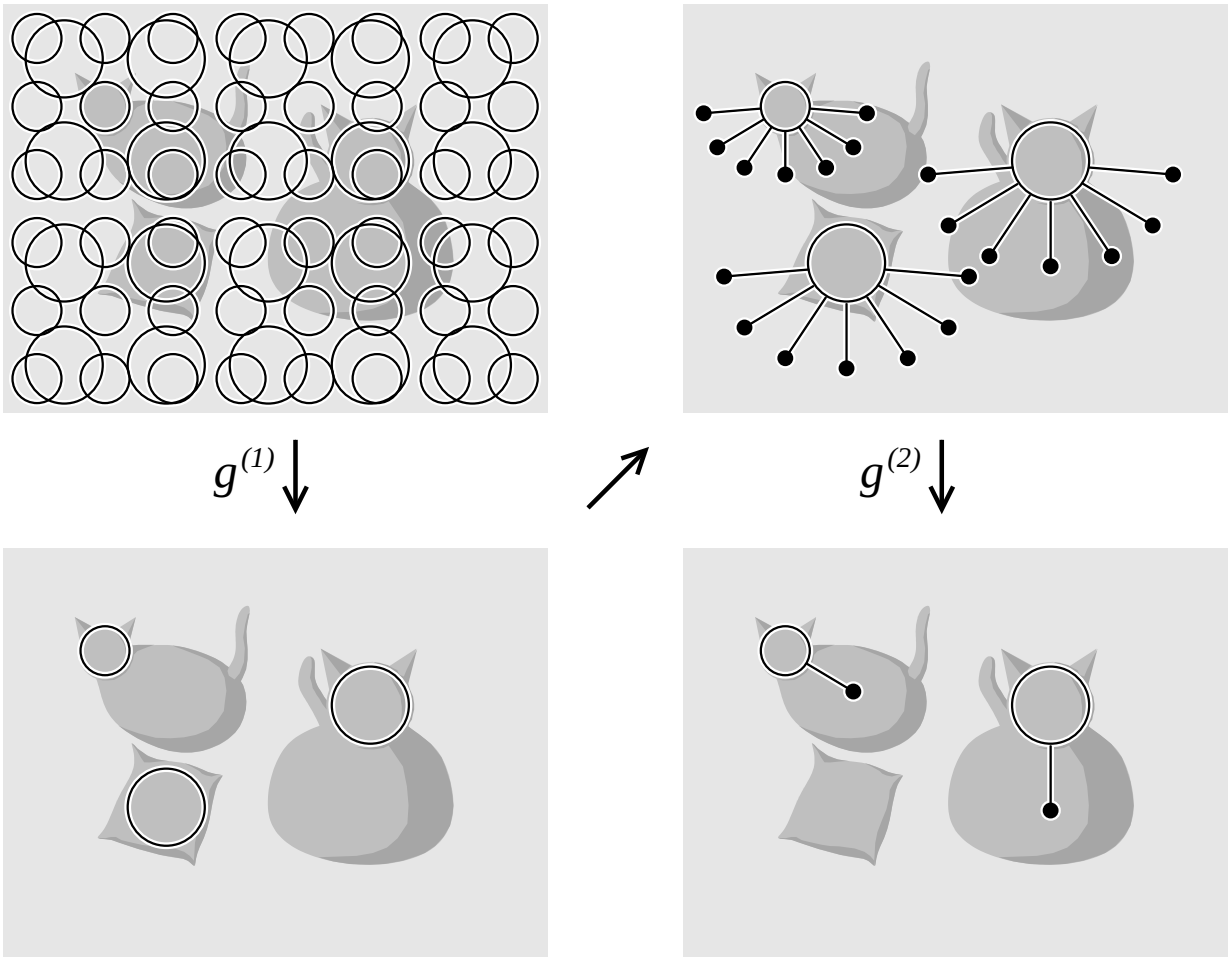

Figure 12: Parsing a scene with a two-level hierarchy to find cats: First, a classifier $g^{(1)}$ is evaluated over a sublattice of possible head locations and all alarms above a very low threshold are retained. Then a classifier $g^{(2)}$ is evaluated for each pair of head-belly locations on a sublattice consistent with the retained head alarms and with observed statistics about joint head-belly locations. For clarity, the depicted discretization of the pose space is idealized, and far coarser than in the actual experiments; for an image of size 640×480 pixels, we consider $\simeq 50,000$ head pose cells and $\simeq 2.5 \times 10^7$ head-belly pose cells.

1. The first stage loops over a sublattice of possible head locations and scales in the scene, evaluates the response of the appropriate first-level classifier and retains all alarms using a very low (i.e., conservative) threshold.

2. The second stage visits each location and scale tagged by the first stage, scans a sublattice of all "consistent" belly locations (all those actually observed on training images) and evaluates an appropriate second-level classifier for every such candidate pair of locations.

6.5 Detectors

Whereas our aim is to detect both the head and the body, detecting the head alone is similar to the well-studied problem of detecting frontal views of human faces. As stated earlier, if the pose reduces to a single position, data-aggregation is straightforward by translating either whole images or features. Still, detecting cat heads is a logical first step in trying to find cats since the head is clearly the most stable landmark and the part of the cat with the least variation, assuming of course that the head is visible, which is the case with our data (for the same reason that family photographs display the faces of people). Moreover, comparing the performance of varying strategies (field of view, "checking" for the belly separately, demanding "consistency", etc.) provides some insight on the nature of the problem and serves as a simple way of demonstrating the power of the base feature set and the asymmetrical weighting by sampling. Detecting heads alone does not, however, expose the full strength of the folded hierarchy; for that we need to address the harder task of accurately estimating (h,r,b) for the visible cats, our core objective, and for which we will compare our pose-indexed method with a more standard parts-based detector.

In all the experiments we present, the classifiers are trained as described in §5, with $B = 25$ blocks of $U = 100$ stumps (thresholded features), and we optimize over a sample of $R = 10,000$ pose-indexed features in every such block. The total number of negative samples we consider is $S \simeq 10^6$, and we sample $M \simeq 10^4$ of these per block.

In measuring performance, we consider the two following detections strategies:

- **H+B** is a standard parts detector, implemented adaptively. The "+" between H and B indicates that the two part detectors are trained separately.

  The first level classifier $g^{(1)}$ can only use pose-indexed feature defined relatively to the head frame and the second level classifier $g^{(2)}$ can only use pose-indexed features defined relatively to the belly frame. Since that second-level detector is designed not to exploit the information in the joint locations of the head and belly, the frames here have fixed orientation, and reflecting the cat pose horizontally would move but not invert the frames. See §6.3 for details about the orientations of the frames.

- **HB** is the hierarchical detector based on the two-level hierarchy and folded learning.

  The difference with H+B is that HB uses stationary features in the second level which can be defined relatively to any of the three reference frames (head, belly or head-belly) in order to take into account the position of the head in searching for the belly. For instance, a pose-indexed features in this detector could compare the texture between a patch located on the head and a patch located on the belly.

6.6 Results

In order to be precise about what a constitutes a true detection, we define two criteria of similarity. We say that two poses (h,r,b) and (h',r',b') **collide** if (1) The head radii are very similar: $1/1.25 \leq r/r' \leq 1.25$; and (2) Either the head or belly locations are close: $\min(\|h-h'\|, \|b-b'\|) \leq 0.25\sqrt{rr'}$. And we will say that two poses are **similar** if (1) The head radii are similar: $1/1.5 \leq r/r' \leq 1.5$; (2) the head locations are nearby each other: $\|h-h'\| \leq 2\sqrt{rr'}$; and (3) the belly locations are nearby each other: $\|b-b'\| \leq 4\sqrt{rr'}$. See Figure 13.

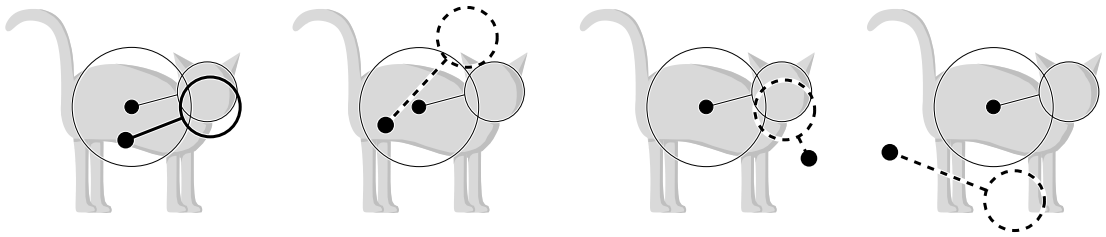

Figure 13: Two alarms are considered as similar if the head radii are similar and if, as shown on this figure, the distance between the two head locations is less than the average head radius, and if the distance between the belly locations is less than twice the average head radius. See §6.6. Based on that criterion, if the true pose is the one shown in thin lines and the thick poses are detections, only the leftmost one would be counted as a true hit. The three others, shown in dashed lines, would be counted as false alarms.

Given these two criteria, the alarms kept after thresholding the classifier responses are post-processed with a crude clustering. We visit the alarms in the order of the response of the detector, and for each alarm we remove all others that collide with it. Then we visit these surviving alarms again in the order of the response and for each alarm we remove all the other alarms which are similar.

The procedure we use to produce ROC curves is the following. We run ten rounds in which the training and test images are selected at random, and in each round we estimate the classifier thresholds for achieving ten different true-positive rates η (see § 5). Hence, we generate 100 pairs of rates, each consisting of a true-positive rate and an average number of false alarms per image. An alarm is counted as true positive if there exists a cat in the image with a similar pose according to the criterion described above.

The error rates in Figure 2 and Table 2 demonstrate the power of conditioning on the full pose. Using stationary features to build classifiers dedicated to fine cells allows the search for one part to be informed by the location of the other, and allows for consistency checks. This is more discriminating than checking for individual parts separately. Indeed, the error rates are cut be a factor of roughly two at very high true-positive rates and a factor of three at lower true-positive rates. It should be emphasized as well that even the weaker ROC curve is impressive in absolute terms, which affirms the efficacy of even the naive stationary features used by the H+B detector and the modified boosting strategy for learning.

An example of how features selected in the second-level of the HB classifier exploit the full pose can be seen in Figure 11. Such a feature allows the HB detector to check for highly discriminating properties of the data, such as the continuity of appearance between the head and the belly, or discontinuities in the direction orthogonal to the head-belly axis.

More then two-thirds of the false positives are located on or very near cats; see Figure 14. Such false positives are exceedingly difficult to filter out. For instance, a false head detection lying around or on the belly will be supported by the second-level classifier because the location of the true belly will usually be visited.

TP	H+B	HB
90%	12.84	5.85
80%	3.53	1.63
70%	1.35	0.50
60%	0.61	0.23
50%	0.33	0.12
40%	0.18	0.06
30%	0.10	0.03

Table 2: Average number of false alarms per images of size 640×480 vs. the true positive rate for the head-belly detection, as defined by the similarity criterion of §6.6 and Figure 13.

Finally, we performed a similar experiment by testing the classifiers trained on the Ratemykitten data set on a sample of cat images chosen from the PASCAL VOC2007 challenge set images.[2] The PASCAL data set was assembled for evaluating methods for *classification*, that is, labeling an entire image according to one of the object categories, rather than methods for object detection and localization. There are 332 cat images in the PASCAL set; our test set consists of those 201 images for which the body is at least partially visible. This provides an even more challenging test set than the images from Ratemykitten and the performance of our classifier is somewhat reduced. For instance, at a true positive rate of 51%, the average number of false alarms per image of size 640×480 is 0.9. The results on a random sample of twenty of the 201 test images is shown in Figure 15.

7. Conclusion

We have presented a novel detection algorithm for objects with a complex pose. Our main contribution is the idea of stationary, pose-indexed features, a variation on deformable templates without whole image transforms. This makes it possible to train pose-specific classifiers without clustering the data, and hence without reducing the number of training examples. Moreover, combining simultaneous training with a sequential exploration of the pose space overcomes the main drawback of previous coarse-to-fine strategies, especially for going beyond scale and translation. Unlike in earlier variations, graded, tree-structured representations can now be learned efficiently because there is only one classifier to train per level of the hierarchy rather than one per node.

We have illustrated these stationary features by detecting cats in cluttered still images. As indicated earlier, the data are available at `http://www.idiap.ch/folded-ctf`. We chose boosting with edge and intensity counts, but any base learning algorithm and any flexible base feature set could be used. Indeed, the framework can accommodate very general features, for instance the average color or average response of any local feature in an area defined by the pose. The resulting algorithm is a two-stage process, first visiting potential head locations alone and then examining additional aspects of the pose consistent with and informed by candidate head locations.

In principle, our approach can deal with very complex detection problems in which multiple objects of interest are parametrized by a rich hidden pose. However, two basic limitations must

Figure 14: Detection results with stationary features and a folded two-level hierarchy on scenes picked uniformly at random in the RateMykitten test set, with a true-positive rate of 71%. The circle shows the estimated head size and location, and the dot the estimated belly location.

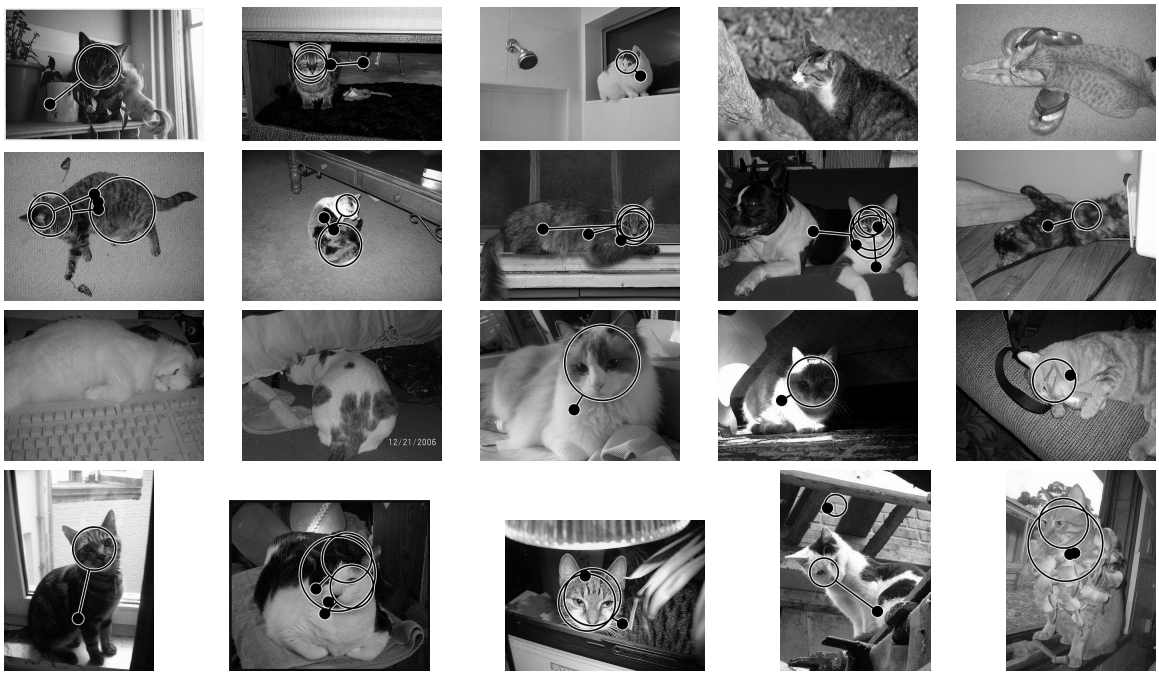

Figure 15: Detection results with stationary features and a folded two-level hierarchy on scenes picked uniformly at random in the PASCAL VOC2007 challenge test set, with a true-positive rate of 50%. The circle shows the estimated head size and location, and the dot the estimated belly location.

first be addressed. The first is the design of adequate stationary features. Whereas difficult, this is far simpler than the search for full geometric invariants. Since the hidden state is explicitly examined in traversing the hierarchy, there is no need to integrate over all possible values of the hidden quantities. The second difficulty is labeling a training set with rich ground truth. One way to tackle this problem is by exploiting other information available during training, for instance temporal consistency if there are motion data. Our viewpoint is that small, richly annotated, training sets are at least as appealing for general learning as large ones with minimal annotation.

Bottom two rows: samples from the head-belly experiments. The crosses depict the head and belly centers provided on the training data. The boxes show the admissible pose domain $\mathcal{Y}$.

Appendix A. Quantifying Trade-offs

We summarize two series of experiments designed to study the impact on accuracy of data-fragmentation, with and without controlling for total online computation. In both series the goal is to predict the presence of a target with high accuracy in pose. A more detailed account of these experiments can be found in Fleuret and Geman (2007).

A.1 Settings

Since training with fragmentation is not feasible for any complete partition of a complex pose space at a realistic resolution, the images we consider in these experiments have been cropped from the original data set so that the pose space $\mathcal{Y}$ is already strongly constrained.

In the first series of experiments the target pose is the center of the cat head, constrained to $\mathcal{Y} = [-20,20] \times [-20,20]$ in a 100×100 image. It is this pose space that will be investigated at different resolutions. The top row of Figure 16 shows a few of these scenes with a target. In the second series of experiments the pose is the *pair of locations* (h,b) for the head and belly, constrained to $\mathcal{Y} = ([0,5] \times [0,5]) \times ([-80,80] \times [-20,80])$ in a 200×140 image centered at the square. The two bottom rows of Figure 16 show a few of these scenes with a target.

In both series, our objective is to compare the performance of classifiers when the training data are either fragmented or aggregated and when the computational cost is either equalized or not. More precisely, we consider three partitions of $\mathcal{Y}$ into $K = 1$, 4 and 16 pose cells. In each series, we build four detection systems. Three of them are trained under data-fragmentation at the three considered resolutions, namely $K = 1$, $K = 4$ or $K = 16$ pose cells. The fourth classifier is trained with the pose-indexed, stationary features at the finest resolution $K = 16$. The stationary features are based on the head frame alone for the head experiments, and on both the head frame and the head-belly frame for the head-belly experiments.

The computational cost for evaluating one such classifier is proportional to the number of stumps it combines. In the particular case of boosting, a classifier combining only a fixed number of weak learners is still effective, and hence, unlike many discriminative methods, computation is easy to control. This motivates a very simple strategy to equalize the cost among experiments: We simply control the total number of feature evaluations.

As a measure of performance, we estimate the number of false alarms for any given true positive rate. In order to compare results across resolutions, the labeling of detections as true or false positives occurs at the coarsest resolution. For simplicity, for the head-belly case, we only score the estimated head location.

A.2 Results

The results demonstrate the gain in performance in constraining the population provided there is no fragmentation of the data. In the head experiments, even with fragmentation, higher resolution results in fewer false alarms. The improvement is marginal at high true positive rates, but increases to two-fold for a true positive rate of 70%. This is not true for the head-belly experiments, where sixteen pose cells do worse than four, with or without cost equalization, which can be explained to some extent by the lower variation in the appearance of cat heads than full cat bodies, and hence fewer samples may be sufficient for accurate head detection.

As expected, without controlling the on-line computational cost, aggregation with stationary features is more discriminating than the fragmented classifiers in both experiments and at any true positive rate, reducing the false positive rate by a factor of three to five. Still, the performance of the classifiers when cost is equalized shows the influence of computation in this framework: at the finest resolution, the number of false alarms in the head experiments increases by a factor greater than four at any true-positive rate, and by two orders of magnitude in the head-belly experiments.

These results also demonstrate the pivotal role of computation if we are to extend this approach to a realistically fine partition of a complex pose space. Consider an image of resolution 640×480 and a single scale range for the head. Obtaining an accuracy in the locations of the head and the belly of five pixels requires more than 7×10^6 pose cells. Investing computation *uniformly* among cells is therefore hopeless, and argues for an adaptive strategy able to distribute computation in a highly special and uneven manner.

The conclusions drawn can be summarized in two key points:

1. **The need for data-aggregation**: *Dealing with a rich pose by training specialized predictors from constrained sub-populations is not feasible, both in terms of offline computation and sample size requirements. Aggregation of data using stationary features appears to be a sound strategy to overcome the sample size dilemma as it transfers the burden of learning to the design of the features.*

2. **The need for adaptive search**: *If fragmentation can be avoided and a single classifier built from all the data and analytically transformed into dedicated classifiers, the computation necessary to cover a partition of a pose space of reasonable accuracy is not realistic if the effort is uniformly distributed over cells.*

As indicated, stationary features provide a coherent strategy for dealing with data-aggregation but do not resolve the computational dilemma resulting from investigating many possible poses during scene processing. Hierarchical representations largely do.

Abstract

We present a new technique called "t-SNE" that visualizes high-dimensional data by giving each datapoint a location in a two or three-dimensional map. The technique is a variation of Stochastic Neighbor Embedding (Hinton and Roweis, 2002) that is much easier to optimize, and produces significantly better visualizations by reducing the tendency to crowd points together in the center of the map. t-SNE is better than existing techniques at creating a single map that reveals structure at many different scales. This is particularly important for high-dimensional data that lie on several different, but related, low-dimensional manifolds, such as images of objects from multiple classes seen from multiple viewpoints. For visualizing the structure of very large data sets, we show how t-SNE can use random walks on neighborhood graphs to allow the implicit structure of all of the data to influence the way in which a subset of the data is displayed. We illustrate the performance of t-SNE on a wide variety of data sets and compare it with many other non-parametric visualization techniques, including Sammon mapping, Isomap, and Locally Linear Embedding. The visualizations produced by t-SNE are significantly better than those produced by the other techniques on almost all of the data sets.

Keywords: visualization, dimensionality reduction, manifold learning, embedding algorithms, multidimensional scaling

1. Introduction

Visualization of high-dimensional data is an important problem in many different domains, and deals with data of widely varying dimensionality. Cell nuclei that are relevant to breast cancer, for example, are described by approximately 30 variables (Street et al., 1993), whereas the pixel intensity vectors used to represent images or the word-count vectors used to represent documents typically have thousands of dimensions. Over the last few decades, a variety of techniques for the visualization of such high-dimensional data have been proposed, many of which are reviewed by de Oliveira and Levkowitz (2003). Important techniques include iconographic displays such as Chernoff faces (Chernoff, 1973), pixel-based techniques (Keim, 2000), and techniques that represent the dimensions in the data as vertices in a graph (Battista et al., 1994). Most of these techniques simply provide tools to display more than two data dimensions, and leave the interpretation of the

data to the human observer. This severely limits the applicability of these techniques to real-world data sets that contain thousands of high-dimensional datapoints.

In contrast to the visualization techniques discussed above, dimensionality reduction methods convert the high-dimensional data set $\mathcal{X} = \{x_1, x_2, ..., x_n\}$ into two or three-dimensional data $\mathcal{Y} = \{y_1, y_2, ..., y_n\}$ that can be displayed in a scatterplot. In the paper, we refer to the low-dimensional data representation $\mathcal{Y}$ as a map, and to the low-dimensional representations y_i of individual datapoints as map points. The aim of dimensionality reduction is to preserve as much of the significant structure of the high-dimensional data as possible in the low-dimensional map. Various techniques for this problem have been proposed that differ in the type of structure they preserve. Traditional dimensionality reduction techniques such as Principal Components Analysis (PCA; Hotelling, 1933) and classical multidimensional scaling (MDS; Torgerson, 1952) are linear techniques that focus on keeping the low-dimensional representations of dissimilar datapoints far apart. For high-dimensional data that lies on or near a low-dimensional, non-linear manifold it is usually more important to keep the low-dimensional representations of very similar datapoints close together, which is typically not possible with a linear mapping.

A large number of nonlinear dimensionality reduction techniques that aim to preserve the local structure of data have been proposed, many of which are reviewed by Lee and Verleysen (2007). In particular, we mention the following seven techniques: (1) Sammon mapping (Sammon, 1969), (2) curvilinear components analysis (CCA; Demartines and Hérault, 1997), (3) Stochastic Neighbor Embedding (SNE; Hinton and Roweis, 2002), (4) Isomap (Tenenbaum et al., 2000), (5) Maximum Variance Unfolding (MVU; Weinberger et al., 2004), (6) Locally Linear Embedding (LLE; Roweis and Saul, 2000), and (7) Laplacian Eigenmaps (Belkin and Niyogi, 2002). Despite the strong performance of these techniques on artificial data sets, they are often not very successful at visualizing real, high-dimensional data. In particular, most of the techniques are not capable of retaining both the local and the global structure of the data in a single map. For instance, a recent study reveals that even a semi-supervised variant of MVU is not capable of separating handwritten digits into their natural clusters (Song et al., 2007).

In this paper, we describe a way of converting a high-dimensional data set into a matrix of pairwise similarities and we introduce a new technique, called "t-SNE", for visualizing the resulting similarity data. t-SNE is capable of capturing much of the local structure of the high-dimensional data very well, while also revealing global structure such as the presence of clusters at several scales. We illustrate the performance of t-SNE by comparing it to the seven dimensionality reduction techniques mentioned above on five data sets from a variety of domains. Because of space limitations, most of the $(7+1) \times 5 = 40$ maps are presented in the supplemental material, but the maps that we present in the paper are sufficient to demonstrate the superiority of t-SNE.

The outline of the paper is as follows. In Section 2, we outline SNE as presented by Hinton and Roweis (2002), which forms the basis for t-SNE. In Section 3, we present t-SNE, which has two important differences from SNE. In Section 4, we describe the experimental setup and the results of our experiments. Subsequently, Section 5 shows how t-SNE can be modified to visualize real-world data sets that contain many more than $10,000$ datapoints. The results of our experiments are discussed in more detail in Section 6. Our conclusions and suggestions for future work are presented in Section 7.

2. Stochastic Neighbor Embedding

Stochastic Neighbor Embedding (SNE) starts by converting the high-dimensional Euclidean distances between datapoints into conditional probabilities that represent similarities.[1] The similarity of datapoint x_j to datapoint x_i is the conditional probability, $p_{j|i}$, that x_i would pick x_j as its neighbor if neighbors were picked in proportion to their probability density under a Gaussian centered at x_i. For nearby datapoints, $p_{j|i}$ is relatively high, whereas for widely separated datapoints, $p_{j|i}$ will be almost infinitesimal (for reasonable values of the variance of the Gaussian, σ_i). Mathematically, the conditional probability $p_{j|i}$ is given by

$$p_{j|i} = \frac{\exp\left(-\|x_i - x_j\|^2/2\sigma_i^2\right)}{\sum_{k\neq i}\exp\left(-\|x_i - x_k\|^2/2\sigma_i^2\right)}, \tag{1}$$

where σ_i is the variance of the Gaussian that is centered on datapoint x_i. The method for determining the value of σ_i is presented later in this section. Because we are only interested in modeling pairwise similarities, we set the value of $p_{i|i}$ to zero. For the low-dimensional counterparts y_i and y_j of the high-dimensional datapoints x_i and x_j, it is possible to compute a similar conditional probability, which we denote by $q_{j|i}$. We set[2] the variance of the Gaussian that is employed in the computation of the conditional probabilities $q_{j|i}$ to $\frac{1}{\sqrt{2}}$. Hence, we model the similarity of map point y_j to map point y_i by

$$q_{j|i} = \frac{\exp\left(-\|y_i - y_j\|^2\right)}{\sum_{k\neq i}\exp\left(-\|y_i - y_k\|^2\right)}.$$

Again, since we are only interested in modeling pairwise similarities, we set $q_{i|i} = 0$.

If the map points y_i and y_j correctly model the similarity between the high-dimensional datapoints x_i and x_j, the conditional probabilities $p_{j|i}$ and $q_{j|i}$ will be equal. Motivated by this observation, SNE aims to find a low-dimensional data representation that minimizes the mismatch between $p_{j|i}$ and $q_{j|i}$. A natural measure of the faithfulness with which $q_{j|i}$ models $p_{j|i}$ is the Kullback-Leibler divergence (which is in this case equal to the cross-entropy up to an additive constant). SNE minimizes the sum of Kullback-Leibler divergences over all datapoints using a gradient descent method. The cost function C is given by

$$C = \sum_i KL(P_i||Q_i) = \sum_i \sum_j p_{j|i} \log \frac{p_{j|i}}{q_{j|i}}, \tag{2}$$

in which P_i represents the conditional probability distribution over all other datapoints given datapoint x_i, and Q_i represents the conditional probability distribution over all other map points given map point y_i. Because the Kullback-Leibler divergence is not symmetric, different types of error in the pairwise distances in the low-dimensional map are not weighted equally. In particular, there is a large cost for using widely separated map points to represent nearby datapoints (i.e., for using

1. SNE can also be applied to data sets that consist of pairwise similarities between objects rather than high-dimensional vector representations of each object, provided these simiarities can be interpreted as conditional probabilities. For example, human word association data consists of the probability of producing each possible word in response to a given word, as a result of which it is already in the form required by SNE.
2. Setting the variance in the low-dimensional Gaussians to another value only results in a rescaled version of the final map. Note that by using the same variance for every datapoint in the low-dimensional map, we lose the property that the data is a perfect model of itself if we embed it in a space of the same dimensionality, because in the high-dimensional space, we used a different variance σ_i in each Gaussian.

a small $q_{j|i}$ to model a large $p_{j|i}$), but there is only a small cost for using nearby map points to represent widely separated datapoints. This small cost comes from wasting some of the probability mass in the relevant Q distributions. In other words, the SNE cost function focuses on retaining the local structure of the data in the map (for reasonable values of the variance of the Gaussian in the high-dimensional space, σ_i).

The remaining parameter to be selected is the variance σ_i of the Gaussian that is centered over each high-dimensional datapoint, x_i. It is not likely that there is a single value of σ_i that is optimal for all datapoints in the data set because the density of the data is likely to vary. In dense regions, a smaller value of σ_i is usually more appropriate than in sparser regions. Any particular value of σ_i induces a probability distribution, P_i, over all of the other datapoints. This distribution has an entropy which increases as σ_i increases. SNE performs a binary search for the value of σ_i that produces a P_i with a fixed perplexity that is specified by the user.[3] The perplexity is defined as

$$Perp(P_i) = 2^{H(P_i)},$$

where $H(P_i)$ is the Shannon entropy of P_i measured in bits

$$H(P_i) = -\sum_j p_{j|i} \log_2 p_{j|i}.$$

The perplexity can be interpreted as a smooth measure of the effective number of neighbors. The performance of SNE is fairly robust to changes in the perplexity, and typical values are between 5 and 50.

The minimization of the cost function in Equation 2 is performed using a gradient descent method. The gradient has a surprisingly simple form

$$\frac{\delta C}{\delta y_i} = 2\sum_j (p_{j|i} - q_{j|i} + p_{i|j} - q_{i|j})(y_i - y_j).$$

Physically, the gradient may be interpreted as the resultant force created by a set of springs between the map point y_i and all other map points y_j. All springs exert a force along the direction $(y_i - y_j)$. The spring between y_i and y_j repels or attracts the map points depending on whether the distance between the two in the map is too small or too large to represent the similarities between the two high-dimensional datapoints. The force exerted by the spring between y_i and y_j is proportional to its length, and also proportional to its stiffness, which is the mismatch $(p_{j|i} - q_{j|i} + p_{i|j} - q_{i|j})$ between the pairwise similarities of the data points and the map points.

The gradient descent is initialized by sampling map points randomly from an isotropic Gaussian with small variance that is centered around the origin. In order to speed up the optimization and to avoid poor local minima, a relatively large momentum term is added to the gradient. In other words, the current gradient is added to an exponentially decaying sum of previous gradients in order to determine the changes in the coordinates of the map points at each iteration of the gradient search. Mathematically, the gradient update with a momentum term is given by

$$\mathcal{Y}^{(t)} = \mathcal{Y}^{(t-1)} + \eta \frac{\delta C}{\delta \mathcal{Y}} + \alpha(t)\left(\mathcal{Y}^{(t-1)} - \mathcal{Y}^{(t-2)}\right),$$

3. Note that the perplexity increases monotonically with the variance σ_i.

where $\mathcal{Y}^{(t)}$ indicates the solution at iteration t, η indicates the learning rate, and $\alpha(t)$ represents the momentum at iteration t.

In addition, in the early stages of the optimization, Gaussian noise is added to the map points after each iteration. Gradually reducing the variance of this noise performs a type of simulated annealing that helps the optimization to escape from poor local minima in the cost function. If the variance of the noise changes very slowly at the critical point at which the global structure of the map starts to form, SNE tends to find maps with a better global organization. Unfortunately, this requires sensible choices of the initial amount of Gaussian noise and the rate at which it decays. Moreover, these choices interact with the amount of momentum and the step size that are employed in the gradient descent. It is therefore common to run the optimization several times on a data set to find appropriate values for the parameters.[4] In this respect, SNE is inferior to methods that allow convex optimization and it would be useful to find an optimization method that gives good results without requiring the extra computation time and parameter choices introduced by the simulated annealing.

3. t-Distributed Stochastic Neighbor Embedding

Section 2 discussed SNE as it was presented by Hinton and Roweis (2002). Although SNE constructs reasonably good visualizations, it is hampered by a cost function that is difficult to optimize and by a problem we refer to as the "crowding problem". In this section, we present a new technique called "t-Distributed Stochastic Neighbor Embedding" or "t-SNE" that aims to alleviate these problems. The cost function used by t-SNE differs from the one used by SNE in two ways: (1) it uses a symmetrized version of the SNE cost function with simpler gradients that was briefly introduced by Cook et al. (2007) and (2) it uses a Student-t distribution rather than a Gaussian to compute the similarity between two points *in the low-dimensional space*. t-SNE employs a heavy-tailed distribution in the low-dimensional space to alleviate both the crowding problem and the optimization problems of SNE.

In this section, we first discuss the symmetric version of SNE (Section 3.1). Subsequently, we discuss the crowding problem (Section 3.2), and the use of heavy-tailed distributions to address this problem (Section 3.3). We conclude the section by describing our approach to the optimization of the t-SNE cost function (Section 3.4).

3.1 Symmetric SNE

As an alternative to minimizing the sum of the Kullback-Leibler divergences between the conditional probabilities $p_{j|i}$ and $q_{j|i}$, it is also possible to minimize a single Kullback-Leibler divergence between a joint probability distribution, P, in the high-dimensional space and a joint probability distribution, Q, in the low-dimensional space:

$$C = KL(P||Q) = \sum_i \sum_j p_{ij} \log \frac{p_{ij}}{q_{ij}}.$$

where again, we set p_{ii} and q_{ii} to zero. We refer to this type of SNE as symmetric SNE, because it has the property that $p_{ij} = p_{ji}$ and $q_{ij} = q_{ji}$ for $\forall i, j$. In symmetric SNE, the pairwise similarities in

4. Picking the best map after several runs as a visualization of the data is not nearly as problematic as picking the model that does best on a test set during supervised learning. In visualization, the aim is to see the structure in the training data, not to generalize to held out test data.

the low-dimensional map q_{ij} are given by

$$q_{ij} = \frac{\exp\left(-\|y_i - y_j\|^2\right)}{\sum_{k \neq l} \exp\left(-\|y_k - y_l\|^2\right)}, \tag{3}$$

The obvious way to define the pairwise similarities in the high-dimensional space p_{ij} is

$$p_{ij} = \frac{\exp\left(-\|x_i - x_j\|^2/2\sigma^2\right)}{\sum_{k \neq l} \exp\left(-\|x_k - x_l\|^2/2\sigma^2\right)},$$

but this causes problems when a high-dimensional datapoint x_i is an outlier (i.e., all pairwise distances $\|x_i - x_j\|^2$ are large for x_i). For such an outlier, the values of p_{ij} are extremely small for all j, so the location of its low-dimensional map point y_i has very little effect on the cost function. As a result, the position of the map point is not well determined by the positions of the other map points. We circumvent this problem by defining the joint probabilities p_{ij} in the high-dimensional space to be the symmetrized conditional probabilities, that is, we set $p_{ij} = \frac{p_{j|i} + p_{i|j}}{2n}$. This ensures that $\sum_j p_{ij} > \frac{1}{2n}$ for all datapoints x_i, as a result of which each datapoint x_i makes a significant contribution to the cost function. In the low-dimensional space, symmetric SNE simply uses Equation 3. The main advantage of the symmetric version of SNE is the simpler form of its gradient, which is faster to compute. The gradient of symmetric SNE is fairly similar to that of asymmetric SNE, and is given by

$$\frac{\delta C}{\delta y_i} = 4 \sum_j (p_{ij} - q_{ij})(y_i - y_j).$$

In preliminary experiments, we observed that symmetric SNE seems to produce maps that are just as good as asymmetric SNE, and sometimes even a little better.

3.2 The Crowding Problem

Consider a set of datapoints that lie on a two-dimensional curved manifold which is approximately linear on a small scale, and which is embedded within a higher-dimensional space. It is possible to model the small pairwise distances between datapoints fairly well in a two-dimensional map, which is often illustrated on toy examples such as the "Swiss roll" data set. Now suppose that the manifold has ten intrinsic dimensions[5] and is embedded within a space of much higher dimensionality. There are several reasons why the pairwise distances in a two-dimensional map cannot faithfully model distances between points on the ten-dimensional manifold. For instance, in ten dimensions, it is possible to have 11 datapoints that are mutually equidistant and there is no way to model this faithfully in a two-dimensional map. A related problem is the very different distribution of pairwise distances in the two spaces. The volume of a sphere centered on datapoint i scales as r^m, where r is the radius and m the dimensionality of the sphere. So if the datapoints are approximately uniformly distributed in the region around i on the ten-dimensional manifold, and we try to model the distances from i to the other datapoints in the two-dimensional map, we get the following "crowding problem": the area of the two-dimensional map that is available to accommodate moderately distant datapoints will not be nearly large enough compared with the area available to accommodate nearby datapoints. Hence, if we want to model the small distances accurately in the map, most of the points

5. This is approximately correct for the images of handwritten digits we use in our experiments in Section 4.

that are at a moderate distance from datapoint i will have to be placed much too far away in the two-dimensional map. In SNE, the spring connecting datapoint i to each of these too-distant map points will thus exert a very small attractive force. Although these attractive forces are very small, the very large number of such forces crushes together the points in the center of the map, which prevents gaps from forming between the natural clusters. Note that the crowding problem is not specific to SNE, but that it also occurs in other local techniques for multidimensional scaling such as Sammon mapping.

An attempt to address the crowding problem by adding a slight repulsion to all springs was presented by Cook et al. (2007). The slight repulsion is created by introducing a uniform background model with a small mixing proportion, ρ. So however far apart two map points are, q_{ij} can never fall below $\frac{2\rho}{n(n-1)}$ (because the uniform background distribution is over $n(n-1)/2$ pairs). As a result, for datapoints that are far apart in the high-dimensional space, q_{ij} will always be larger than p_{ij}, leading to a slight repulsion. This technique is called UNI-SNE and although it usually outperforms standard SNE, the optimization of the UNI-SNE cost function is tedious. The best optimization method known is to start by setting the background mixing proportion to zero (i.e., by performing standard SNE). Once the SNE cost function has been optimized using simulated annealing, the background mixing proportion can be increased to allow some gaps to form between natural clusters as shown by Cook et al. (2007). Optimizing the UNI-SNE cost function directly does not work because two map points that are far apart will get almost all of their q_{ij} from the uniform background. So even if their p_{ij} is large, there will be no attractive force between them, because a small change in their separation will have a vanishingly small *proportional* effect on q_{ij}. This means that if two parts of a cluster get separated early on in the optimization, there is no force to pull them back together.

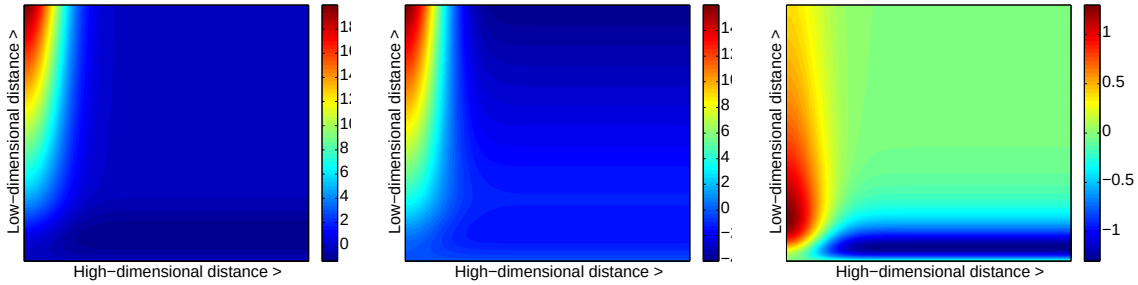
3.3 Mismatched Tails can Compensate for Mismatched Dimensionalities

Since symmetric SNE is actually matching the joint probabilities of pairs of datapoints in the high-dimensional and the low-dimensional spaces rather than their distances, we have a natural way of alleviating the crowding problem that works as follows. In the high-dimensional space, we convert distances into probabilities using a Gaussian distribution. In the low-dimensional map, we can use a probability distribution that has much heavier tails than a Gaussian to convert distances into probabilities. This allows a moderate distance in the high-dimensional space to be faithfully modeled by a much larger distance in the map and, as a result, it eliminates the unwanted attractive forces between map points that represent moderately dissimilar datapoints.

In t-SNE, we employ a Student t-distribution with one degree of freedom (which is the same as a Cauchy distribution) as the heavy-tailed distribution in the low-dimensional map. Using this distribution, the joint probabilities q_{ij} are defined as

$$q_{ij} = \frac{\left(1+\|y_i - y_j\|^2\right)^{-1}}{\sum_{k \neq l} \left(1+\|y_k - y_l\|^2\right)^{-1}}. \tag{4}$$

We use a Student t-distribution with a single degree of freedom, because it has the particularly nice property that $\left(1+\|y_i - y_j\|^2\right)^{-1}$ approaches an inverse square law for large pairwise distances $\|y_i - y_j\|$ in the low-dimensional map. This makes the map's representation of joint probabilities (almost) invariant to changes in the scale of the map for map points that are far apart. It also means that large clusters of points that are far apart interact in just the same way as individual points, so the optimization operates in the same way at all but the finest scales. A theoretical justification for our



(a) Gradient of SNE. (b) Gradient of UNI-SNE. (c) Gradient of t-SNE.

Figure 1: Gradients of three types of SNE as a function of the pairwise Euclidean distance between two points in the high-dimensional and the pairwise distance between the points in the low-dimensional data representation.

selection of the Student t-distribution is that it is closely related to the Gaussian distribution, as the Student t-distribution is an infinite mixture of Gaussians. A computationally convenient property is that it is much faster to evaluate the density of a point under a Student t-distribution than under a Gaussian because it does not involve an exponential, even though the Student t-distribution is equivalent to an infinite mixture of Gaussians with different variances.

The gradient of the Kullback-Leibler divergence between P and the Student-t based joint probability distribution Q (computed using Equation 4) is derived in Appendix A, and is given by

$$\frac{\delta C}{\delta y_i} = 4 \sum_j (p_{ij} - q_{ij})(y_i - y_j) \left(1 + \|y_i - y_j\|^2\right)^{-1}. \tag{5}$$

In Figure 1(a) to 1(c), we show the gradients between two low-dimensional datapoints y_i and y_j as a function of their pairwise Euclidean distances in the high-dimensional and the low-dimensional space (i.e., as a function of $\|x_i - x_j\|$ and $\|y_i - y_j\|$) for the symmetric versions of SNE, UNI-SNE, and t-SNE. In the figures, positive values of the gradient represent an attraction between the low-dimensional datapoints y_i and y_j, whereas negative values represent a repulsion between the two datapoints. From the figures, we observe two main advantages of the t-SNE gradient over the gradients of SNE and UNI-SNE.

First, the t-SNE gradient strongly repels dissimilar datapoints that are modeled by a small pairwise distance in the low-dimensional representation. SNE has such a repulsion as well, but its effect is minimal compared to the strong attractions elsewhere in the gradient (the largest attraction in our graphical representation of the gradient is approximately 19, whereas the largest repulsion is approximately 1). In UNI-SNE, the amount of repulsion between dissimilar datapoints is slightly larger, however, this repulsion is only strong when the pairwise distance between the points in the low-dimensional representation is already large (which is often not the case, since the low-dimensional representation is initialized by sampling from a Gaussian with a very small variance that is centered around the origin).

Second, although t-SNE introduces strong repulsions between dissimilar datapoints that are modeled by small pairwise distances, these repulsions do not go to infinity. In this respect, t-SNE differs from UNI-SNE, in which the strength of the repulsion between very dissimilar datapoints

    set $\mathcal{Y}^{(t)} = \mathcal{Y}^{(t-1)} + \eta \frac{\delta C}{\delta \mathcal{Y}} + \alpha(t)\left(\mathcal{Y}^{(t-1)} - \mathcal{Y}^{(t-2)}\right)$
  end
end

is proportional to their pairwise distance in the low-dimensional map, which may cause dissimilar datapoints to move much too far away from each other.

Taken together, t-SNE puts emphasis on (1) modeling dissimilar datapoints by means of large pairwise distances, and (2) modeling similar datapoints by means of small pairwise distances. Moreover, as a result of these characteristics of the t-SNE cost function (and as a result of the approximate scale invariance of the Student t-distribution), the optimization of the t-SNE cost function is much easier than the optimization of the cost functions of SNE and UNI-SNE. Specifically, t-SNE introduces long-range forces in the low-dimensional map that can pull back together two (clusters of) similar points that get separated early on in the optimization. SNE and UNI-SNE do not have such long-range forces, as a result of which SNE and UNI-SNE need to use simulated annealing to obtain reasonable solutions. Instead, the long-range forces in t-SNE facilitate the identification of good local optima without resorting to simulated annealing.

3.4 Optimization Methods for t-SNE

We start by presenting a relatively simple, gradient descent procedure for optimizing the t-SNE cost function. This simple procedure uses a momentum term to reduce the number of iterations required and it works best if the momentum term is small until the map points have become moderately well organized. Pseudocode for this simple algorithm is presented in Algorithm 1. The simple algorithm can be sped up using the adaptive learning rate scheme that is described by Jacobs (1988), which gradually increases the learning rate in directions in which the gradient is stable.

Although the simple algorithm produces visualizations that are often much better than those produced by other non-parametric dimensionality reduction techniques, the results can be improved further by using either of two tricks. The first trick, which we call "early compression", is to force the map points to stay close together at the start of the optimization. When the distances between map points are small, it is easy for clusters to move through one another so it is much easier to explore the space of possible global organizations of the data. Early compression is implemented by adding an additional L2-penalty to the cost function that is proportional to the sum of squared

distances of the map points from the origin. The magnitude of this penalty term and the iteration at which it is removed are set by hand, but the behavior is fairly robust across variations in these two additional optimization parameters.

A less obvious way to improve the optimization, which we call "early exaggeration", is to multiply all of the p_{ij}'s by, for example, 4, in the initial stages of the optimization. This means that almost all of the q_{ij}'s, which still add up to 1, are much too small to model their corresponding p_{ij}'s. As a result, the optimization is encouraged to focus on modeling the large p_{ij}'s by fairly large q_{ij}'s. The effect is that the natural clusters in the data tend to form tight widely separated clusters in the map. This creates a lot of relatively empty space in the map, which makes it much easier for the clusters to move around relative to one another in order to find a good global organization.

In all the visualizations presented in this paper and in the supporting material, we used exactly the same optimization procedure. We used the early exaggeration method with an exaggeration of 4 for the first 50 iterations (note that early exaggeration is not included in the pseudocode in Algorithm 1). The number of gradient descent iterations T was set 1000, and the momentum term was set to $\alpha^{(t)} = 0.5$ for $t < 250$ and $\alpha^{(t)} = 0.8$ for $t \geq 250$. The learning rate η is initially set to 100 and it is updated after every iteration by means of the adaptive learning rate scheme described by Jacobs (1988). A Matlab implementation of the resulting algorithm is available at `http://ticc.uvt.nl/~lvdrmaaten/tsne`.

4. Experiments

To evaluate t-SNE, we present experiments in which t-SNE is compared to seven other non-parametric techniques for dimensionality reduction. Because of space limitations, in the paper, we only compare t-SNE with: (1) Sammon mapping, (2) Isomap, and (3) LLE. In the supporting material, we also compare t-SNE with: (4) CCA, (5) SNE, (6) MVU, and (7) Laplacian Eigenmaps. We performed experiments on five data sets that represent a variety of application domains. Again because of space limitations, we restrict ourselves to three data sets in the paper. The results of our experiments on the remaining two data sets are presented in the supplemental material.

In Section 4.1, the data sets that we employed in our experiments are introduced. The setup of the experiments is presented in Section 4.2. In Section 4.3, we present the results of our experiments.

4.1 Data Sets

The five data sets we employed in our experiments are: (1) the MNIST data set, (2) the Olivetti faces data set, (3) the COIL-20 data set, (4) the word-features data set, and (5) the Netflix data set. We only present results on the first three data sets in this section. The results on the remaining two data sets are presented in the supporting material. The first three data sets are introduced below.

The MNIST data set[6] contains 60,000 grayscale images of handwritten digits. For our experiments, we randomly selected 6,000 of the images for computational reasons. The digit images have $28 \times 28 = 784$ pixels (i.e., dimensions). The Olivetti faces data set[7] consists of images of 40 individuals with small variations in viewpoint, large variations in expression, and occasional addition of glasses. The data set consists of 400 images (10 per individual) of size $92 \times 112 = 10,304$ pixels, and is labeled according to identity. The COIL-20 data set (Nene et al., 1996) contains images of 20

6. The MNIST data set is publicly available from `http://yann.lecun.com/exdb/mnist/index.html`.
7. The Olivetti faces data set is publicly available from `http://mambo.ucsc.edu/psl/olivetti.html`.

different objects viewed from 72 equally spaced orientations, yielding a total of 1,440 images. The images contain $32 \times 32 = 1,024$ pixels.

4.2 Experimental Setup

In all of our experiments, we start by using PCA to reduce the dimensionality of the data to 30. This speeds up the computation of pairwise distances between the datapoints and suppresses some noise without severely distorting the interpoint distances. We then use each of the dimensionality reduction techniques to convert the 30-dimensional representation to a two-dimensional map and we show the resulting map as a scatterplot. For all of the data sets, there is information about the class of each datapoint, but the class information is only used to select a color and/or symbol for the map points. The class information is not used to determine the spatial coordinates of the map points. The coloring thus provides a way of evaluating how well the map preserves the similarities within each class.

The cost function parameter settings we employed in our experiments are listed in Table 1. In the table, $Perp$ represents the perplexity of the conditional probability distribution induced by a Gaussian kernel and k represents the number of nearest neighbors employed in a neighborhood graph. In the experiments with Isomap and LLE, we only visualize datapoints that correspond to vertices in the largest connected component of the neighborhood graph.[8] For the Sammon mapping optimization, we performed Newton's method for 500 iterations.

Technique	*Cost function parameters*
t-SNE	$Perp = 40$
Sammon mapping	none
Isomap	$k = 12$
LLE	$k = 12$

Table 1: Cost function parameter settings for the experiments.

4.3 Results

In Figures 2 and 3, we show the results of our experiments with t-SNE, Sammon mapping, Isomap, and LLE on the MNIST data set. The results reveal the strong performance of t-SNE compared to the other techniques. In particular, Sammon mapping constructs a "ball" in which only three classes (representing the digits 0, 1, and 7) are somewhat separated from the other classes. Isomap and LLE produce solutions in which there are large overlaps between the digit classes. In contrast, t-SNE constructs a map in which the separation between the digit classes is almost perfect. Moreover, detailed inspection of the t-SNE map reveals that much of the local structure of the data (such as the orientation of the ones) is captured as well. This is illustrated in more detail in Section 5 (see Figure 7). The map produced by t-SNE contains some points that are clustered with the wrong class, but most of these points correspond to distorted digits many of which are difficult to identify.
Figure 4 shows the results of applying t-SNE, Sammon mapping, Isomap, and LLE to the Olivetti faces data set. Again, Isomap and LLE produce solutions that provide little insight into the class

8. Isomap and LLE require data that gives rise to a neighborhood graph that is connected.

structure of the data. The map constructed by Sammon mapping is significantly better, since it models many of the members of each class fairly close together, but none of the classes are clearly separated in the Sammon map. In contrast, t-SNE does a much better job of revealing the natural classes in the data. Some individuals have their ten images split into two clusters, usually because a subset of the images have the head facing in a significantly different direction, or because they have a very different expression or glasses. For these individuals, it is not clear that their ten images form a natural class when using Euclidean distance in pixel space.

Figure 5 shows the results of applying t-SNE, Sammon mapping, Isomap, and LLE to the COIL-20 data set. For many of the 20 objects, t-SNE accurately represents the one-dimensional manifold of viewpoints as a closed loop. For objects which look similar from the front and the back, t-SNE distorts the loop so that the images of front and back are mapped to nearby points. For the four types of toy car in the COIL-20 data set (the four aligned "sausages" in the bottom-left of the t-SNE map), the four rotation manifolds are aligned by the orientation of the cars to capture the high

(d) Visualization by LLE.

Figure 5: Visualizations of the COIL-20 data set.

similarity between different cars at the same orientation. This prevents t-SNE from keeping the four manifolds clearly separate. Figure 5 also reveals that the other three techniques are not nearly as good at cleanly separating the manifolds that correspond to very different objects. In addition, Isomap and LLE only visualize a small number of classes from the COIL-20 data set, because the data set comprises a large number of widely separated submanifolds that give rise to small connected components in the neighborhood graph.

5. Applying t-SNE to Large Data Sets

Like many other visualization techniques, t-SNE has a computational and memory complexity that is quadratic in the number of datapoints. This makes it infeasible to apply the standard version of t-SNE to data sets that contain many more than, say, 10,000 points. Obviously, it is possible to pick a random subset of the datapoints and display them using t-SNE, but such an approach fails to

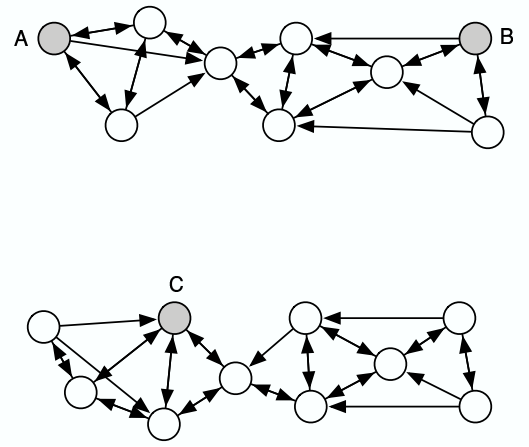

Figure 6: An illustration of the advantage of the random walk version of t-SNE over a standard landmark approach. The shaded points A, B, and C are three (almost) equidistant landmark points, whereas the non-shaded datapoints are non-landmark points. The arrows represent a directed neighborhood graph where $k = 3$. In a standard landmark approach, the pairwise affinity between A and B is approximately equal to the pairwise affinity between A and C. In the random walk version of t-SNE, the pairwise affinity between A and B is much larger than the pairwise affinity between A and C, and therefore, it reflects the structure of the data much better.

make use of the information that the undisplayed datapoints provide about the underlying manifolds. Suppose, for example, that A, B, and C are all equidistant in the high-dimensional space. If there are many undisplayed datapoints between A and B and none between A and C, it is much more likely that A and B are part of the same cluster than A and C. This is illustrated in Figure 6. In this section, we show how t-SNE can be modified to display a random subset of the datapoints (so-called landmark points) in a way that uses information from the entire (possibly very large) data set.

We start by choosing a desired number of neighbors and creating a neighborhood graph for all of the datapoints. Although this is computationally intensive, it is only done once. Then, for each of the landmark points, we define a random walk starting at that landmark point and terminating as soon as it lands on another landmark point. During a random walk, the probability of choosing an edge emanating from node x_i to node x_j is proportional to $e^{-\|x_i - x_j\|^2}$. We define $p_{j|i}$ to be the fraction of random walks starting at landmark point x_i that terminate at landmark point x_j. This has some resemblance to the way Isomap measures pairwise distances between points. However, as in diffusion maps (Lafon and Lee, 2006; Nadler et al., 2006), rather than looking for the shortest path through the neighborhood graph, the random walk-based affinity measure integrates over all paths through the neighborhood graph. As a result, the random walk-based affinity measure is much less sensitive to "short-circuits" (Lee and Verleysen, 2005), in which a single noisy datapoint provides a bridge between two regions of dataspace that should be far apart in the map. Similar approaches using random walks have also been successfully applied to, for example, semi-supervised learning (Szummer and Jaakkola, 2001; Zhu et al., 2003) and image segmentation (Grady, 2006).

The most obvious way to compute the random walk-based similarities $p_{j|i}$ is to explicitly perform the random walks on the neighborhood graph, which works very well in practice, given that one can easily perform one million random walks per second. Alternatively, Grady (2006) presents an analytical solution to compute the pairwise similarities $p_{j|i}$ that involves solving a sparse linear system. The analytical solution to compute the similarities $p_{j|i}$ is sketched in Appendix B. In preliminary experiments, we did not find significant differences between performing the random walks explicitly and the analytical solution. In the experiment we present below, we explicitly performed the random walks because this is computationally less expensive. However, for very large data sets in which the landmark points are very sparse, the analytical solution may be more appropriate.

Figure 7 shows the results of an experiment, in which we applied the random walk version of t-SNE to 6,000 randomly selected digits from the MNIST data set, using all 60,000 digits to compute the pairwise affinities $p_{j|i}$. In the experiment, we used a neighborhood graph that was constructed using a value of $k = 20$ nearest neighbors.[9] The inset of the figure shows the same visualization as a scatterplot in which the colors represent the labels of the digits. In the t-SNE map, all classes are clearly separated and the "continental" sevens form a small separate cluster. Moreover, t-SNE reveals the main dimensions of variation within each class, such as the orientation of the ones, fours, sevens, and nines, or the "loopiness" of the twos. The strong performance of t-SNE is also reflected in the generalization error of nearest neighbor classifiers that are trained on the low-dimensional representation. Whereas the generalization error (measured using 10-fold cross validation) of a 1-nearest neighbor classifier trained on the original 784-dimensional datapoints is 5.75%, the generalization error of a 1-nearest neighbor classifier trained on the two-dimensional data representation produced by t-SNE is only 5.13%. The computational requirements of random walk t-SNE are reasonable: it took only one hour of CPU time to construct the map in Figure 7.

6. Discussion

The results in the previous two sections (and those in the supplemental material) demonstrate the performance of t-SNE on a wide variety of data sets. In this section, we discuss the differences between t-SNE and other non-parametric techniques (Section 6.1), and we also discuss a number of weaknesses and possible improvements of t-SNE (Section 6.2).

6.1 Comparison with Related Techniques

Classical scaling (Torgerson, 1952), which is closely related to PCA (Mardia et al., 1979; Williams, 2002), finds a linear transformation of the data that minimizes the sum of the squared errors between high-dimensional pairwise distances and their low-dimensional representatives. A linear method such as classical scaling is not good at modeling curved manifolds and it focuses on preserving the distances between widely separated datapoints rather than on preserving the distances between nearby datapoints. An important approach that attempts to address the problems of classical scaling is the Sammon mapping (Sammon, 1969) which alters the cost function of classical scaling by dividing the squared error in the representation of each pairwise Euclidean distance by the original Euclidean distance in the high-dimensional space. The resulting cost function is given by

$$C = \frac{1}{\sum_{ij} \|x_i - x_j\|} \sum_{i \neq j} \frac{(\|x_i - x_j\| - \|y_i - y_j\|)^2}{\|x_i - x_j\|},$$

9. In preliminary experiments, we found the performance of random walk t-SNE to be very robust under changes of k.

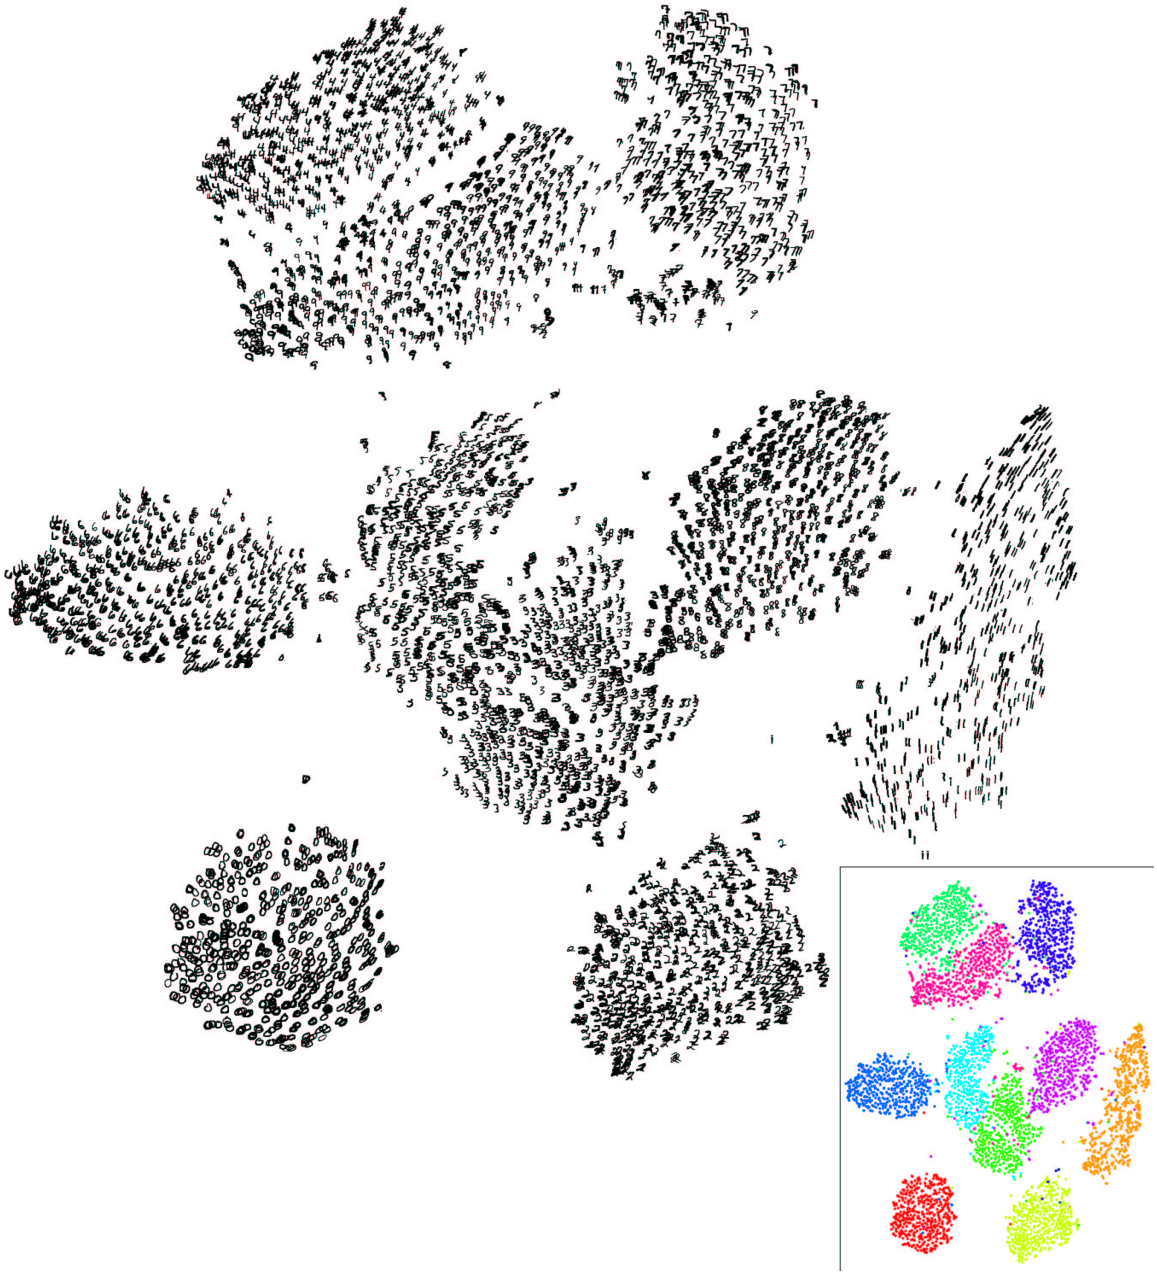

Figure 7: Visualization of 6,000 digits from the MNIST data set produced by the random walk version of t-SNE (employing all 60,000 digit images).

where the constant outside of the sum is added in order to simplify the derivation of the gradient. The main weakness of the Sammon cost function is that the importance of retaining small pairwise distances in the map is largely dependent on small differences in these pairwise distances. In particular, a small error in the model of two high-dimensional points that are extremely close together results in a large contribution to the cost function. Since all small pairwise distances constitute the local structure of the data, it seems more appropriate to aim to assign approximately equal importance to all small pairwise distances.

In contrast to Sammon mapping, the Gaussian kernel employed in the high-dimensional space by t-SNE defines a soft border between the local and global structure of the data and for pairs of datapoints that are close together relative to the standard deviation of the Gaussian, the importance of modeling their separations is almost independent of the magnitudes of those separations. Moreover, t-SNE determines the local neighborhood size for each datapoint separately based on the local density of the data (by forcing each conditional probability distribution P_i to have the same perplexity).

The strong performance of t-SNE compared to Isomap is partly explained by Isomap's susceptibility to "short-circuiting". Also, Isomap mainly focuses on modeling large geodesic distances rather than small ones.

The strong performance of t-SNE compared to LLE is mainly due to a basic weakness of LLE: the only thing that prevents all datapoints from collapsing onto a single point is a constraint on the covariance of the low-dimensional representation. In practice, this constraint is often satisfied by placing most of the map points near the center of the map and using a few widely scattered points to create large covariance (see Figure 3(b) and 4(d)). For neighborhood graphs that are almost disconnected, the covariance constraint can also be satisfied by a "curdled" map in which there are a few widely separated, collapsed subsets corresponding to the almost disconnected components. Furthermore, neighborhood-graph based techniques (such as Isomap and LLE) are not capable of visualizing data that consists of two or more widely separated submanifolds, because such data does not give rise to a connected neighborhood graph. It is possible to produce a separate map for each connected component, but this loses information about the relative similarities of the separate components.

Like Isomap and LLE, the random walk version of t-SNE employs neighborhood graphs, but it does not suffer from short-circuiting problems because the pairwise similarities between the high-dimensional datapoints are computed by integrating over all paths through the neighborhood graph. Because of the diffusion-based interpretation of the conditional probabilities underlying the random walk version of t-SNE, it is useful to compare t-SNE to diffusion maps. Diffusion maps define a "diffusion distance" on the high-dimensional datapoints that is given by

$$D^{(t)}(x_i, x_j) = \sqrt{\sum_k \frac{\left(p_{ik}^{(t)} - p_{jk}^{(t)}\right)^2}{\psi(x_k)^{(0)}}},$$

where $p_{ij}^{(t)}$ represents the probability of a particle traveling from x_i to x_j in t timesteps through a graph on the data with Gaussian emission probabilities. The term $\psi(x_k)^{(0)}$ is a measure for the local density of the points, and serves a similar purpose to the fixed perplexity Gaussian kernel that is employed in SNE. The diffusion map is formed by the principal non-trivial eigenvectors of the Markov matrix of the random walks of length t. It can be shown that when all $(n-1)$ non-trivial eigenvec-

tors are employed, the Euclidean distances in the diffusion map are equal to the diffusion distances in the high-dimensional data representation (Lafon and Lee, 2006). Mathematically, diffusion maps minimize

$$C = \sum_i \sum_j \left(D^{(t)}(x_i, x_j) - \|y_i - y_j\| \right)^2.$$

As a result, diffusion maps are susceptible to the same problems as classical scaling: they assign much higher importance to modeling the large pairwise diffusion distances than the small ones and as a result, they are not good at retaining the local structure of the data. Moreover, in contrast to the random walk version of t-SNE, diffusion maps do not have a natural way of selecting the length, t, of the random walks.

In the supplemental material, we present results that reveal that t-SNE outperforms CCA (Demartines and Hérault, 1997), MVU (Weinberger et al., 2004), and Laplacian Eigenmaps (Belkin and Niyogi, 2002) as well. For CCA and the closely related CDA (Lee et al., 2000), these results can be partially explained by the hard border λ that these techniques define between local and global structure, as opposed to the soft border of t-SNE. Moreover, within the range λ, CCA suffers from the same weakness as Sammon mapping: it assigns extremely high importance to modeling the distance between two datapoints that are extremely close.

Like t-SNE, MVU (Weinberger et al., 2004) tries to model all of the small separations well but MVU insists on modeling them perfectly (i.e., it treats them as constraints) and a single erroneous constraint may severely affect the performance of MVU. This can occur when there is a short-circuit between two parts of a curved manifold that are far apart in the intrinsic manifold coordinates. Also, MVU makes no attempt to model longer range structure: It simply pulls the map points as far apart as possible subject to the hard constraints so, unlike t-SNE, it cannot be expected to produce sensible large-scale structure in the map.

For Laplacian Eigenmaps, the poor results relative to t-SNE may be explained by the fact that Laplacian Eigenmaps have the same covariance constraint as LLE, and it is easy to cheat on this constraint.

6.2 Weaknesses

Although we have shown that t-SNE compares favorably to other techniques for data visualization, t-SNE has three potential weaknesses: (1) it is unclear how t-SNE performs on general dimensionality reduction tasks, (2) the relatively local nature of t-SNE makes it sensitive to the curse of the intrinsic dimensionality of the data, and (3) t-SNE is not guaranteed to converge to a global optimum of its cost function. Below, we discuss the three weaknesses in more detail.

1) Dimensionality reduction for other purposes. It is not obvious how t-SNE will perform on the more general task of dimensionality reduction (i.e., when the dimensionality of the data is not reduced to two or three, but to $d > 3$ dimensions). To simplify evaluation issues, this paper only considers the use of t-SNE for data visualization. The behavior of t-SNE when reducing data to two or three dimensions cannot readily be extrapolated to $d > 3$ dimensions because of the heavy tails of the Student-t distribution. In high-dimensional spaces, the heavy tails comprise a relatively large portion of the probability mass under the Student-t distribution, which might lead to d-dimensional data representations that do not preserve the local structure of the data as well. Hence, for tasks

in which the dimensionality of the data needs to be reduced to a dimensionality higher than three, Student t-distributions with more than one degree of freedom[10] are likely to be more appropriate.

2) Curse of intrinsic dimensionality. t-SNE reduces the dimensionality of data mainly based on local properties of the data, which makes t-SNE sensitive to the curse of the intrinsic dimensionality of the data (Bengio, 2007). In data sets with a high intrinsic dimensionality and an underlying manifold that is highly varying, the local linearity assumption on the manifold that t-SNE implicitly makes (by employing Euclidean distances between near neighbors) may be violated. As a result, t-SNE might be less successful if it is applied on data sets with a very high intrinsic dimensionality (for instance, a recent study by Meytlis and Sirovich (2007) estimates the space of images of faces to be constituted of approximately 100 dimensions). Manifold learners such as Isomap and LLE suffer from exactly the same problems (see, e.g., Bengio, 2007; van der Maaten et al., 2008). A possible way to (partially) address this issue is by performing t-SNE on a data representation obtained from a model that represents the highly varying data manifold efficiently in a number of nonlinear layers such as an autoencoder (Hinton and Salakhutdinov, 2006). Such deep-layer architectures can represent complex nonlinear functions in a much simpler way, and as a result, require fewer datapoints to learn an appropriate solution (as is illustrated for a d-bits parity task by Bengio 2007). Performing t-SNE on a data representation produced by, for example, an autoencoder is likely to improve the quality of the constructed visualizations, because autoencoders can identify highly-varying manifolds better than a local method such as t-SNE. However, the reader should note that it is by definition impossible to fully represent the structure of intrinsically high-dimensional data in two or three dimensions.

3) Non-convexity of the t-SNE cost function. A nice property of most state-of-the-art dimensionality reduction techniques (such as classical scaling, Isomap, LLE, and diffusion maps) is the convexity of their cost functions. A major weakness of t-SNE is that the cost function is not convex, as a result of which several optimization parameters need to be chosen. The constructed solutions depend on these choices of optimization parameters and may be different each time t-SNE is run from an initial random configuration of map points. We have demonstrated that the same choice of optimization parameters can be used for a variety of different visualization tasks, and we found that the quality of the optima does not vary much from run to run. Therefore, we think that the weakness of the optimization method is insufficient reason to reject t-SNE in favor of methods that lead to convex optimization problems but produce noticeably worse visualizations. A local optimum of a cost function that accurately captures what we want in a visualization is often preferable to the global optimum of a cost function that fails to capture important aspects of what we want. Moreover, the convexity of cost functions can be misleading, because their optimization is often computationally infeasible for large real-world data sets, prompting the use of approximation techniques (de Silva and Tenenbaum, 2003; Weinberger et al., 2007). Even for LLE and Laplacian Eigenmaps, the optimization is performed using iterative Arnoldi (Arnoldi, 1951) or Jacobi-Davidson (Fokkema et al., 1999) methods, which may fail to find the global optimum due to convergence problems.

7. Conclusions

The paper presents a new technique for the visualization of similarity data that is capable of retaining the local structure of the data while also revealing some important global structure (such as clusters

10. Increasing the degrees of freedom of a Student-t distribution makes the tails of the distribution lighter. With infinite degrees of freedom, the Student-t distribution is equal to the Gaussian distribution.

at multiple scales). Both the computational and the memory complexity of t-SNE are $O(n^2)$, but we present a landmark approach that makes it possible to successfully visualize large real-world data sets with limited computational demands. Our experiments on a variety of data sets show that t-SNE outperforms existing state-of-the-art techniques for visualizing a variety of real-world data sets. Matlab implementations of both the normal and the random walk version of t-SNE are available for download at `http://ticc.uvt.nl/~lvdrmaaten/tsne`.

In future work we plan to investigate the optimization of the number of degrees of freedom of the Student-t distribution used in t-SNE. This may be helpful for dimensionality reduction when the low-dimensional representation has many dimensions. We will also investigate the extension of t-SNE to models in which each high-dimensional datapoint is modeled by several low-dimensional map points as in Cook et al. (2007). Also, we aim to develop a parametric version of t-SNE that allows for generalization to held-out test data by using the t-SNE objective function to train a multilayer neural network that provides an explicit mapping to the low-dimensional space.

Appendix A. Derivation of the t-SNE gradient

t-SNE minimizes the Kullback-Leibler divergence between the joint probabilities p_{ij} in the high-dimensional space and the joint probabilities q_{ij} in the low-dimensional space. The values of p_{ij} are defined to be the symmetrized conditional probabilities, whereas the values of q_{ij} are obtained by means of a Student-t distribution with one degree of freedom

$$p_{ij} = \frac{p_{j|i} + p_{i|j}}{2n},$$

$$q_{ij} = \frac{\left(1 + \|y_i - y_j\|^2\right)^{-1}}{\sum_{k \neq l} \left(1 + \|y_k - y_l\|^2\right)^{-1}},$$

where $p_{j|i}$ and $p_{i|j}$ are either obtained from Equation 1 or from the random walk procedure described in Section 5. The values of p_{ii} and q_{ii} are set to zero. The Kullback-Leibler divergence between the two joint probability distributions P and Q is given by

$$\begin{aligned} C = KL(P||Q) &= \sum_i \sum_j p_{ij} \log \frac{p_{ij}}{q_{ij}} \\ &= \sum_i \sum_j p_{ij} \log p_{ij} - p_{ij} \log q_{ij}. \end{aligned} \tag{6}$$

In order to make the derivation less cluttered, we define two auxiliary variables d_{ij} and Z as follows

$$d_{ij} = \|y_i - y_j\|,$$
$$Z = \sum_{k \neq l} (1 + d_{kl}^2)^{-1}.$$

Note that if y_i changes, the only pairwise distances that change are d_{ij} and d_{ji} for $\forall j$. Hence, the gradient of the cost function C with respect to y_i is given by

$$\begin{aligned} \frac{\delta C}{\delta y_i} &= \sum_j \left(\frac{\delta C}{\delta d_{ij}} + \frac{\delta C}{\delta d_{ji}} \right) (y_i - y_j) \\ &= 2 \sum_j \frac{\delta C}{\delta d_{ij}} (y_i - y_j). \end{aligned} \tag{7}$$

The gradient $\frac{\delta C}{\delta d_{ij}}$ is computed from the definition of the Kullback-Leibler divergence in Equation 6 (note that the first part of this equation is a constant).

$$\begin{aligned} \frac{\delta C}{\delta d_{ij}} &= -\sum_{k \neq l} p_{kl} \frac{\delta (\log q_{kl})}{\delta d_{ij}} \\ &= -\sum_{k \neq l} p_{kl} \frac{\delta (\log q_{kl} Z - \log Z)}{\delta d_{ij}} \\ &= -\sum_{k \neq l} p_{kl} \left(\frac{1}{q_{kl} Z} \frac{\delta ((1 + d_{kl}^2)^{-1})}{\delta d_{ij}} - \frac{1}{Z} \frac{\delta Z}{\delta d_{ij}} \right) \end{aligned}$$

The gradient $\frac{\delta ((1+d_{kl}^2)^{-1})}{\delta d_{ij}}$ is only nonzero when $k = i$ and $l = j$. Hence, the gradient $\frac{\delta C}{\delta d_{ij}}$ is given by

$$\frac{\delta C}{\delta d_{ij}} = 2 \frac{p_{ij}}{q_{ij} Z} (1 + d_{ij}^2)^{-2} - 2 \sum_{k \neq l} p_{kl} \frac{(1 + d_{ij}^2)^{-2}}{Z}.$$

Noting that $\sum_{k \neq l} p_{kl} = 1$, we see that the gradient simplifies to

$$\begin{aligned} \frac{\delta C}{\delta d_{ij}} &= 2 p_{ij} (1 + d_{ij}^2)^{-1} - 2 q_{ij} (1 + d_{ij}^2)^{-1} \\ &= 2 (p_{ij} - q_{ij}) (1 + d_{ij}^2)^{-1}. \end{aligned}$$

Substituting this term into Equation 7, we obtain the gradient

$$\frac{\delta C}{\delta y_i} = 4 \sum_j (p_{ij} - q_{ij}) (1 + \|y_i - y_j\|^2)^{-1} (y_i - y_j).$$

Appendix B. Analytical Solution to Random Walk Probabilities

Below, we describe the analytical solution to the random walk probabilities that are employed in the random walk version of t-SNE (see Section 5). The solution is described in more detail by Grady (2006).

It can be shown that computing the probability that a random walk initiated from a non-landmark point (on a graph that is specified by adjacency matrix W) first reaches a specific landmark point is equal to computing the solution to the combinatorial Dirichlet problem in which the boundary conditions are at the locations of the landmark points, the considered landmark point is fixed to unity, and the other landmarks points are set to zero (Kakutani, 1945; Doyle and Snell, 1984). In practice, the solution can thus be obtained by minimizing the combinatorial formulation of the Dirichlet integral

$$D[x] = \frac{1}{2} x^T L x,$$

where L represents the graph Laplacian. Mathematically, the graph Laplacian is given by $L = D - W$, where $D = \text{diag}\left(\sum_j w_{1j}, \sum_j w_{2j}, ..., \sum_j w_{nj}\right)$. Without loss of generality, we may reorder the landmark points such that the landmark points come first. As a result, the combinatorial Dirichlet integral decomposes into

$$\begin{aligned} D[x_N] &= \frac{1}{2} \begin{bmatrix} x_L^T & x_N^T \end{bmatrix} \begin{bmatrix} L_L & B \\ B^T & L_N \end{bmatrix} \begin{bmatrix} x_L \\ x_N \end{bmatrix} \\ &= \frac{1}{2} \left(x_L^T L_L x_L + 2 x_N^T B^T x_M + x_N^T L_N x_N \right), \end{aligned}$$

where we use the subscript $\cdot_L$ to indicate the landmark points, and the subscript $\cdot_N$ to indicate the non-landmark points. Differentiating $D[x_N]$ with respect to x_N and finding its critical points amounts to solving the linear systems

$$L_N x_N = -B^T. \tag{8}$$

Please note that in this linear system, B^T is a matrix containing the columns from the graph Laplacian L that correspond to the landmark points (excluding the rows that correspond to landmark points). After normalization of the solutions to the systems X_N, the column vectors of X_N contain the probability that a random walk initiated from a non-landmark point terminates in a landmark point. One should note that the linear system in Equation 8 is only nonsingular if the graph is completely connected, or if each connected component in the graph contains at least one landmark point (Biggs, 1974).

Because we are interested in the probability of a random walk initiated from a *landmark point* terminating at another landmark point, we duplicate all landmark points in the neighborhood graph, and initiate the random walks from the duplicate landmarks. Because of memory constraints, it is not possible to store the entire matrix X_N into memory (note that we are only interested in a small number of rows from this matrix, viz., in the rows corresponding to the duplicate landmark points). Hence, we solve the linear systems defined by the columns of $-B^T$ one-by-one, and store only the parts of the solutions that correspond to the duplicate landmark points. For computational reasons, we first perform a Cholesky factorization of L_N, such that $L_N = CC^T$, where C is an upper-triangular matrix. Subsequently, the solution to the linear system in Equation 8 is obtained by solving the linear systems $Cy = -B^T$ and $Cx_N = y$ using a fast backsubstitution method.

Abstract

This paper presents a new method of model selection for regression problems using the modulus of continuity. For this purpose, we suggest the prediction risk bounds of regression models using the modulus of continuity which can be interpreted as the complexity of functions. We also present the model selection criterion referred to as the modulus of continuity information criterion (MCIC) which is derived from the suggested prediction risk bounds. The suggested MCIC provides a risk estimate using the modulus of continuity for a trained regression model (or an estimation function) while other model selection criteria such as the AIC and BIC use structural information such as the number of training parameters. As a result, the suggested MCIC is able to discriminate the performances of trained regression models, even with the same structure of training models. To show the effectiveness of the proposed method, the simulation for function approximation using the multilayer perceptrons (MLPs) was conducted. Through the simulation for function approximation, it was demonstrated that the suggested MCIC provides a good selection tool for nonlinear regression models, even with the limited size of data.

Keywords: regression models, multilayer perceptrons, model selection, information criteria, modulus of continuity

1. Introduction

The task of learning from data is to minimize the expected risk (or generalization error) of a regression model (or an estimation function) under the constraint of the absence of *a priori* model of data generation and with the limited size of data. For this learning task, it is necessary to consider nonparametric regression models such as artificial neural networks, as the functional form of the target function is usually unknown. Furthermore, a mechanism to minimize the expected risk from the limited size of data is required. In this context, the model selection is an important issue in the selection of a reasonable network size in order to minimize the expected risk. However, the proper network size (or number of parameters) of a regression model is difficult to choose, as it is possible to obtain the empirical risk only in the case of the limited size of data while the expected risk of a regression model should be measured for the entire data distribution. For the expected risk of a regression model, the loss function of the error square is usually measured, and the expecta-

tion of the loss function for the entire data distribution is considered. This expected risk can be decomposed by the bias and variance terms of the regression models. If the number of parameters is increased, the bias term is decreased while the variance term is increased, and the opposite also applies. If the number of parameters is exceedingly small and the performance is thus not optimal due to a large bias term, a situation known as under-fitting of the regression models arises. If the number of parameters is especially large and the performance is thus not optimal due to a large variance term, over-fitting of the regression models arises. Hence, a trade-off exists between the under-fitting and over-fitting of regression models. Here, an important issue is measuring the model complexity associated with the variance term. Related to this issue, the statistical methods of model selection use a penalty term for the measurement of model complexity. Well known criteria using this penalty term are the Akaike information criterion (AIC) (Akaike, 1973), the Bayesian information criterion (BIC) (Schwartz, 1978), the generalized cross-validation (GCV) (Wahba et al., 1979), the minimum description length (MDL) (Rissanen, 1986; Barron et al., 1998), and the risk inflation criterion (RIC) (Foster and George, 1994). These methods can be well fitted with linear regression models when enough samples are available. However, they suffer the difficulty of selecting the optimal structure of the estimation networks in the case of nonlinear regression models and/or a small number of samples. For more general forms of regression models, Vapnik (1998) proposed a model selection method based on the structural risk minimization (SRM) principle. One of the characteristics of this method is that the model complexity is described by structural information such as the VC dimension of the hypothesis space associated with estimation networks, which indicates the number of samples that can be shattered, in other words, which can be completely classified by the given structure of estimation networks. This method can be applied to nonlinear models and also regression models trained for a small number of samples. For this problem, Chapelle et al. (2002), Cherkassky (1999), and Cherkassky and Ma (2003) showed that the SRM-based model selection is able to outperform other statistical methods such as AIC or BIC in regression problems with the limited size of data. On the other hand, these methods require the actual VC dimension of the hypothesis space associated with the estimation functions, which is usually not easy to determine in the case of nonlinear regression models. In this context, we consider the bounds on the expected risks using the modulus of continuity representing a measure of the continuity for the given function. Lorentz (1986) applied the modulus of continuity to function approximation theories. In the proposed method, this measure is applied to determine the bounds on the prediction risk. To be exact, it seeks the expected risk of an estimation function when predicting new observations. To describe these bounds, the modulus of continuity is analyzed for both the target and estimation functions, and the model selection criterion referred to as the modulus of continuity information criterion (MCIC) is derived from the prediction risk bounds in order to select the optimal structure of regression models. One of the characteristics in the suggested MCIC is that it can be estimated directly from the given samples and a trained estimation function. Through the simulation for function approximation using multi-layer perceptrons (MLPs), it is demonstrated that the suggested MCIC is effective for nonlinear model selection problems, even with the limited size of data.

This paper is organized as follows: in Section 2, we introduce the model selection criteria based on statistics such as the AIC and BIC, the model selection criteria based on Shannon's information theory such as the MDL, and the VC dimension based criteria. Section 3 describes the suggested model selection method referred to as the MCIC method starting from the definition of the modulus of continuity for continuous functions. We also describe how we can estimate the modulus of continuity for the regression models with different type of kernel functions. Section 4 describes

the simulation results for regression problems for various benchmark data using model selection methods including the suggested MCIC method. Finally, Section 5 presents the conclusion.

2. Model Selection Criteria for Regression Models

For the selection of regression models, the proper criteria for the decision methods are required. Here, various criteria used for the selection of regression models are described. First, let us consider a regression problem of estimating a continuous function f in $C(X,\mathbb{R})$ where $X \subset \mathbb{R}^m$ ($m \geqslant 1$) and $C(X,\mathbb{R})$ is a class of continuous functions. The observed output y for $\mathbf{x} \in X$ can be represented by

$$y(\mathbf{x}) = f(\mathbf{x}) + \varepsilon, \tag{1}$$

where $f(\mathbf{x})$ represents the target function and ε represents random noise with a mean of zero and a variance of σ_ε^2. Here, for regression problems, a data set $D = \{(\mathbf{x}_i, y_i) | \ i = 1, \cdots, N\}$, where $(\mathbf{x}_i, y_i)$ represents the ith pair of input and output samples, is considered. It is assumed that these pairs of input and output samples are randomly generated according to the distribution $P(\mathbf{x}),\ \mathbf{x} \in X$; that is,

$$y_i = f(\mathbf{x}_i) + \varepsilon_i, \ \ \mathbf{x}_i \in X, \tag{2}$$

where $\varepsilon_i,\ i = 1, \cdots, N$ represent independent and identically distributed (*i.i.d.*) random variables having the same distribution with ε. For these samples, our goal of learning is to construct an estimation function $f_n(\mathbf{x}) \in F_n$ (the function space with n parameters) that minimizes the expected risk

$$R(f_n) = \int_{X \times \mathbb{R}} L(y, f_n(\mathbf{x})) dP(\mathbf{x}, y) \tag{3}$$

with respect to the number of parameters n, where $L(y, f_n(\mathbf{x}))$ is a given loss functional, usually the square loss function $L(y, f_n(\mathbf{x})) = (y - f_n(\mathbf{x}))^2$ for regression problems. In general, an estimation function f_n can be constructed as a linear combination of kernel functions; that is,

$$f_n(\mathbf{x}) = \sum_{k=1}^{n} w_k \phi_k(\mathbf{x}), \tag{4}$$

where w_k and ϕ_k represent the kth weight value and kernel function, respectively.

To minimize the expected risk (3), it is necessary to identify the distribution $P(\mathbf{x}, y)$; however, this is usually unknown. Rather, we usually find f_n by minimizing the empirical risk $R_{emp}(f_n)$ evaluated by the mean of loss function values for the given samples; that is,

$$R_{emp}(f_n) = \frac{1}{N} \sum_{i=1}^{N} L(y_i, f_n(\mathbf{x}_i)). \tag{5}$$

Here, if the number of parameters n is increased, the empirical risk of (5) is decreased so that the bias of the estimation function is decreased while the variance of the estimation function is increased, or vice versa. Therefore, a reasonable trade-off must be made between the bias and variance in order to minimize the expected risk. One way of solving this problem is to estimate the expected risks for the given parameters of regression models. In statistical regression models, a popular criterion is the Akaike information criterion (AIC), in which an estimate of the expected risk is given by

$$\mathrm{AIC}(f_n) = R_{emp}(f_n) + 2 \cdot \frac{n}{N} \sigma_\varepsilon^2 \tag{6}$$

under the assumption that the noise term ε has a normal distribution. Here, the noise term $\hat{\sigma}_\varepsilon^2$ can be estimated by

$$\hat{\sigma}_\varepsilon^2 = \frac{RSS}{N - DoF(f_n)}, \tag{7}$$

where RSS represents the sum of the square error over the training samples; that is, $RSS = NR_{emp}(f_n)$, and $DoF(f_n)$ represents the degree of freedom of an estimation function f_n. This criterion is derived in the sense of the maximum-likelihood estimate of the regression parameters. As an alternative to this criterion, the Bayesian approach to model selection referred to as the Bayesian information criterion (BIC) can be considered:

$$\mathrm{BIC}(f_n) = R_{emp}(f_n) + \log N \cdot \frac{n}{N}\sigma_\varepsilon^2. \tag{8}$$

Compared to the AIC, the BIC treats complex models more heavily, giving preference to simpler models, when $N > e^2$, in which e represents the base of natural logarithms. Here, it is important to note that in both criteria, prior knowledge of the variance of noise term σ_ε^2 is needed or estimation of this term using (7) is required. These criteria are good for linear regression models with a large number of samples, as the AIC and BIC formulas hold asymptotically as the number of samples N goes to infinity.

As an alternative to the AIC or BIC, a frequently used model selection criterion is the minimum description length (MDL) criterion. In this method, for the regression model f_n and the data D, the description length $l(f_n, D)$ is described by

$$l(f_n, D) = l(D|f_n) + l(f_n),$$

where $l(f_n)$ represents the length of the regression model and $l(D|f_n)$ represents the length of the data given the regression model. According to Shannon's information theory, the description length in number of bits is then described by

$$l(f_n, D) = -\log_2 p(D|f_n) - \log_2 p(f_n),$$

where $p(f_n|D)$ represents the probability of the output data given the regression model and $p(f_n)$ represents a priori model probability. For a priori model probability, Hinton and Camp (1993) used a zero-mean Gaussian distribution for the neural network parameters. With the additional assumption that the errors of the regression model are $i.i.d.$ with a normal distribution, the description length of the regression model (Cohen and Intrator, 2004) can be described by

$$\mathrm{MDL}(f_n) = \log R_{emp}(f_n) + \frac{n}{N}\left(\log(2\pi) + \log(\frac{1}{n}\sum_{k=1}^{n} w_k^2) + 1\right). \tag{9}$$

This formula for the MDL shows that the description length of the regression model is composed of the empirical risk and the complexity term, which is mainly dependent upon the ratio of the number of parameters to the number of samples and the mean square of weight values. Here, minimizing the description length is equivalent to maximizing the posterior probability of the regression model. Hence the MDL method can be considered as another interpretation of the BIC method. In this context, a regression model that minimizes the description length should be chosen.

A good measure of model complexity in nonlinear models is the VC dimension (Vapnik, 1998) of the hypothesis space associated with estimation networks. The VC dimension can represent the

capacity (or complexity) of the estimation network in terms of the number of samples; that is, the maximum number of samples which can be shattered (classified in every possible way) by the estimation network. As the hypothesis space increases, the empirical risk can be decreased but the confidence interval associated with the complexity of the estimation network then increases. From this point of view, it is necessary to make a proper trade-off between the empirical risk and the confidence interval. The structural risk minimization (SRM) principle considers both the empirical risk and the complexity of the regression model to decide the optimal structure of the regression model. In this approach, for the VC dimension h_n measured for the hypothesis space F_n of regression models and the confidence parameter δ (a constant between 0 and 1), the expected risk satisfies the following inequality with a probability of at least $1-\delta$ (Vapnik, 1998; Cherkassky, 1999; Cherkassky and Ma, 2003):

$$R(f_n) \leqslant R_{emp}(f_n) \left(1 - c\sqrt{\frac{h_n(1+\ln(N/h_n)) - \ln\delta}{N}}\right)_+^{-1}, \tag{10}$$

where c represents a constant dependent on the norm and tails of the loss function distribution and $u_+ = \max\{u, 0\}$.

If the basis functions $\{\phi_1(\mathbf{x}), \cdots, \phi_n(\mathbf{x})\}$ are orthogonal with respect to the probability measure $P(\mathbf{x})$, the form of (10) can be described in a way that is easier to calculate. For the experimental set up, Chapelle et al. (2002) suggested the following bound with the confidence parameter $\delta = 0.1$:

$$R(f_n) \leqslant R_{emp}(f_n) T_{SEB}(n, N), \tag{11}$$

where

$$T_{SEB}(n,l) = \frac{1 + n/(NK)}{1 - (n/N)} \quad \text{and}$$

$$K = \left(1 - \sqrt{\frac{n(1+\ln(2N/n)) + 4}{N}}\right)_+.$$

These risk estimates of (10) and (11) were successfully applied to the model selection of regression problems with the limited size of data. In these risk estimates, the VC dimension of regression models should be estimated. For the case of nonlinear regression models such as artificial neural networks, the bounds on VC dimensions (Karpinski and Macintyre, 1995; Sakurai, 1995) can be determined. However, in general, it is difficult to estimate the VC dimension of nonlinear regression models accurately.

In this work, we consider a useful method for the selection of nonlinear regression models with the limited size of data. For this problem, the AIC or BIC method may not be effective in view of the fact that the number of samples may not be large enough to apply the AIC or BIC method. Moreover, an estimation of the VC dimension of nonlinear regression models is generally not straightforward. In this context, we consider to use the modulus of continuity representing a measure of continuity for the given function. In the proposed method, this measure is applied to determine the bounds on the prediction risk; that is, the expected risk of the estimation function when predicting new observations. From this result, a model selection criterion referred to as the modulus of continuity information criterion (MCIC) is suggested and it is applied to the selection of nonlinear regression models. The backgrounds and theories related to the suggested method are described in the next section.

3. Model Selection Criteria Based on the Modulus of Continuity

For the description of the bounds on expected risks, the modulus of continuity defined for continuous functions is used. In this section, starting from the definition of the modulus of continuity, the bounds on expected risks are described and the model selection criterion referred to as the MCIC using the described bounds is suggested.

3.1 The Modulus of Continuity for Continuous Functions

The modulus of continuity is a measure of continuity for continuous functions. First, it is assumed that X is a compact subset of Euclidean space $\mathbb{R}^m$; that is, the set X is bounded and closed in Euclidean space $\mathbb{R}^m$. Here, let us consider the case of univariate functions; that is, $m = 1$. Then, the measure of continuity $w(f,h)$ of a function $f \in C(X)$ can be described by the following form (Lorentz, 1986):

$$\omega(f,h) = \max_{x,x+t\in X,|t|\leqslant h} |f(x+t) - f(x)|, \tag{12}$$

where h is a positive constant. This modulus of continuity of f has the following properties:

- $\omega(f,h)$ is continuous at h for each f,
- $\omega(f,h)$ is positive and increases as h increases, and
- $\omega(f,h)$ is sub-additive; that is, $\omega(f,h_1+h_2) \leqslant \omega(f,h_1) + \omega(f,h_2)$ for positive constants h_1 and h_2.

As a function of f, the modulus of continuity has the following properties of a semi-norm:

$$\omega(af,h) \leqslant |a|\omega(f,h) \quad \text{for a constant } a \text{ and}$$

$$\omega(f_1+f_2,h) \leqslant \omega(f_1,h) + \omega(f_2,h) \quad \text{for } f_1 \text{ and } f_2 \in C(X).$$

One famous example of the modulus of continuity of a function f is that f is defined on $A = [a,b]$ ($b > a$) and satisfies a Lipschitz condition with the constant $M \geqslant 0$ and the exponent α ($0 < \alpha \leqslant 1$), denoted by $\mathrm{Lip}_M\alpha$; that is,

$$|f(a_1) - f(a_2)| \leqslant M|a_1 - a_2|^\alpha, \;\; a_1, a_2 \in A.$$

In this case, the modulus of continuity is given by

$$\omega(f,h) \leqslant Mh^\alpha.$$

In the multi-dimensional input spaces; that is, $X \subset \mathbb{R}^m$ ($m > 1$), there are different definitions of the modulus of continuity for a continuous function f. The following two definitions of the modulus of continuity are considered (Lorentz, 1986; Anastassiou and Gal, 2000):

Definition 1 *Let $m = 2$ and $X \subset \mathbb{R}^m$.*

- *Then, the modulus of continuity for $f \in C(X)$ is defined by*

$$\omega^A(f,h) = \sup\{|f(x_1,y_1) - f(x_2,y_2)|\}$$
$$\text{subject to } \begin{cases} (x_1,y_1),(x_2,y_2) \in X \text{ and} \\ \|(x_1,y_1) - (x_2,y_2)\|_2 \leqslant h, \;\; \text{for } h > 0. \end{cases}$$

- *Another definition of the modulus of continuity is*

$$\omega^B(f,\alpha,\beta) = \sup\left\{ \begin{array}{l} |f(x_1,y) - f(x_2,y)|, \\ |f(x,y_1) - f(x,y_2)| \end{array} \right\} \tag{13}$$
$$\text{subject to } \left\{ \begin{array}{l} (x_1,y),(x_2,y),(x,y_1),(x,y_2) \in X \text{ and} \\ |x_1 - x_2| \leqslant \alpha, |y_1 - y_2| \leqslant \beta, \text{for } \alpha,\beta > 0. \end{array} \right.$$

For $f \in C(X)$ on a compact subset $X \subset \mathbb{R}^m$, where $m > 2$, it is possible to define the modulus of continuity by induction.

The main difference in these two definitions of the modulus of continuity is the direction. The first definition measures the variation of all directions at some point $\mathbf{x} \in X$ while the second is dependent upon axis directions only at some point $\mathbf{x} \in X$. The relationship between the two definitions of the modulus of continuity can be described by the following lemma:

Lemma 1 *For $f \in C(X)$, two definitions of the modulus of continuity, $\omega^A(f,h)$ and $\omega^B(f,h,h)$ have the following relationship:*

$$\omega^B(f,h,h) \leqslant \omega^A(f,h) \leqslant 2\omega^B(f,h,h),$$

where h represents a positive constant.

For the proof of this lemma, refer to the Appendix A.1. Furthermore, each definition of the modulus of continuity has the following upper bound:

Lemma 2 *Let $f \in C^1(X)$, the class of continuous functions having continuous 1st derivative on X, a compact subset of $\mathbb{R}^m, m > 1$. Then, for $h > 0$, the modulus of continuity w^A and w^B have the following upper bounds:*

$$\omega^A(f,h) \leqslant h\sqrt{\sum_{i=1}^{m} \left\| \frac{\partial f}{\partial x_i} \right\|_\infty^2} \quad \textit{and}$$

$$\omega^B(f,h,\cdots,h) \leqslant h \max_{1 \leqslant i \leqslant m} \left\{ \left\| \frac{\partial f}{\partial x_i} \right\|_\infty \right\},$$

where x_i represents the ith coordinate in the point $\mathbf{x} = (x_1, x_2, \cdots, x_m) \in X$ and $\|\cdot\|_\infty$ represents the supremum norm (or L_∞ norm); that is, for a real- or complex-valued bounded function $g(\mathbf{x})$,

$$\|g\|_\infty = \sup\{|g(\mathbf{x})| \mid \mathbf{x} \in X_g\},$$

where X_g represents the domain of g.

For the proof of this lemma, refer to the Appendix A.2. From this lemma, the second definition of the modulus of continuity $w^B(f,h,h)$ was chosen because it has a smaller upper bound compared to the first modulus of continuity. For our convenience, the notation $w(f,h)$ is used to represent $w^B(f,h,\cdots,h)$ in the remaining sections of this paper.

The computation of the modulus of continuity requires the value of h. First, let us consider the following definition of a density of input samples (Tinman, 1963):

Definition 2 *The density D of an input sample set $\{\mathbf{x}_1, \cdots, \mathbf{x}_N\} \subset X$, a compact subset of $\mathbb{R}^m, m > 1$, is defined by*

$$D(\mathbf{x}_1, \cdots, \mathbf{x}_N) = \sup_{\mathbf{x} \in X} \inf_{1 \leqslant i \leqslant N} d(\mathbf{x}_i, \mathbf{x}),$$

where $d(\mathbf{x}_i, \mathbf{x})$ represents the distance between $\mathbf{x}_i$ and $\mathbf{x} \in X$, which is explicitly any metric function such that, for every $\mathbf{x}, \mathbf{y}, \mathbf{z} \in X$, the following properties are satisfied: $d(\mathbf{x}, \mathbf{y}) \geqslant 0$ with the equality if and only if $\mathbf{x} = \mathbf{y}$, $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{y}, \mathbf{x})$, and $d(\mathbf{x}, \mathbf{z}) \leqslant d(\mathbf{x}, \mathbf{y}) + d(\mathbf{y}, \mathbf{z})$.

Let us also consider a point $\mathbf{x}_0 \in X$ such that

$$\mathbf{x}_0 = \arg\max_{\mathbf{x} \in X} |f(\mathbf{x}) - f_n(\mathbf{x})|.$$

Then, the value of h can be bounded by

$$\min_{1 \leqslant i \leqslant N} d(\mathbf{x}_i, \mathbf{x}_0) \leqslant h \leqslant D(\mathbf{x}_1, \cdots, \mathbf{x}_N) \tag{14}$$

to cover the input space X using balls $B(\mathbf{x}_i, h)$ with centers as input samples $\mathbf{x}_i$ and a radius of h: $B(\mathbf{x}_i, h) = \{\mathbf{x} \,|\, \|\mathbf{x}_i - \mathbf{x}\| < h\}$. This range of h is considered to describe the modulus of continuity for the target and estimation functions.

3.2 Risk Bounds Based on the Modulus of Continuity

In this subsection, the modulus of continuity for the target and estimation functions are investigated, and the manner in which they are related to the expected risks is considered. First, let us consider the loss function for the observed model y and the estimation function $f_n(\mathbf{x})$ with n parameters as $L(y, f_n) = |y - f_n(\mathbf{x})|$. Then, the expected and the empirical risks are defined by the following L_1 measure:

$$R(f_n)_{L_1} = \int_{X \times \mathbb{R}} |y - f_n(\mathbf{x})| dP(\mathbf{x}, y) \quad \text{and}$$

$$R_{emp}(f_n)_{L_1} = \frac{1}{N} \sum_{i=1}^{N} |y_i - f_n(\mathbf{x}_i)|.$$

In the first step, let us consider the case of a univariate target function; that is, $f \in C(X)$ with $X \subset \mathbb{R}$. Then, with the definition of the modulus of continuity of (12) and the bound of h as described by (14), the relationship between the expected and empirical risks is described using the modulus of continuity as follows:

Theorem 1 *Let the target function $f \in C^1(X)$ of (1) with X, a compact subset of $\mathbb{R}$, be approximated by the estimation function f_n of (4), that is, a linear combination of weight parameters w_k and basis functions ϕ_k, $k = 1, \cdots, n$ for the given samples (x_i, y_i), $i = 1, \cdots, N$ generated by (2). Then, for the confidence parameters δ (a constant between 0 and 1), the expected risk in the L_1 sense is bounded by the following inequality with a probability of at least $1 - 2\delta$:*

$$R(f_n)_{L_1} \leqslant R_{emp}(f_n)_{L_1} + \frac{1}{N^2} \sum_{i,j=1}^{N} (|y_i - y_j| + |f_n(x_i) - f_n(x_j)|)$$

$$+ (\omega(f_n, h_0) + C) \sqrt{\frac{1}{2N} \ln \frac{2}{\delta}} \quad \textit{and} \tag{15}$$

$$C = |f_n(x_0) - f_n(x_0')| + 2\|f\|_\infty + 2\sigma_\varepsilon \sqrt{\frac{1}{\delta}} \quad \textit{for } x_0, x_0' \in \{x_1, \cdots, x_N\},$$

where $w(f_n, h_0)$ represents the modulus of continuity of the estimation function f_n and h_0 represents a constant satisfying (14).

For the proof of this theorem, refer to the Appendix A.3. This theorem states that the expected risk $R(f_n)_{L_1}$ is bounded by the empirical risk $R_{emp}(f_n)_{L_1}$, the second term of (15) representing the variations of output samples and also the variations of estimation function values for the given input samples, and the third term representing the modulus of continuity for the estimation function $w(f_n, h_0)$ and a constant C associated with target function. Here, let us consider the second term. By investigating this term further, it can be decomposed it into the empirical risk and the term depending on the target function. The next corollary shows the bounds on the expected risks with this decomposition:

Corollary 1 *Let H_y be the $N \times N$ matrix in which the ij-th entry is given by $|y_i - y_j|$. Then, the following inequality holds with a probability of at least $1-2\delta$:*

$$R(f_n)_{L_1} \leqslant 3R_{emp}(f_n)_{L_1} + \frac{2}{N}\max\{\lambda_i\} + (\omega(f_n, h_0) + C)\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}}, \tag{16}$$

where λ_i represents the ith eigenvalue of the matrix H_y.

For the proof of this lemma, refer to the Appendix A.4. This corollary states that the dominant terms related to the estimation function f_n in the expected risk are the empirical risk $R_{emp}(f_n)$ and the modulus of continuity $w(f_n, h_0)$, as the eigenvalue λ_i of H_f is not dependent upon f_n and a constant C has little influence on the shape of expected risks as the number of parameters n increases. The bounds on the expected risks of (16) appear to be overestimated, as the empirical risk is multiplied by 3. However, for the purpose of determining the model selection criteria, an estimation of the tight bound on the expected risk is not essential. Rather, the coefficient ratio between the empirical risk and modulus of continuity terms plays an important role for model selection problems because only these two terms are mainly dependent upon the estimation function f_n. From this point of view, the following model selection criterion referred to as the modulus of continuity information criterion (MCIC) is suggested:

$$\mathrm{MCIC}(f_n) = R_{emp}(f_n)_{L_1} + \frac{\omega(f_n, h_0)}{3}\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}}. \tag{17}$$

Suppose we have fixed number of samples N. Then, as the number of parameters n increases, the empirical risk $R_{emp}(f_n)$ decreases while the modulus of continuity $\omega(f_n, h_0)$ increases, as the estimation function f_n becomes a more complex function. Accordingly, it is necessary to make a trade-off between the over-fitting and under-fitting of regression models using the MCIC for the optimization of the regression models.

This far, univariate continuous functions are addressed. At this point, let us consider the case of $X \subset \mathbb{R}^m$ with $m > 1$; that is, the case of multivariate continuous functions. Here, it is possible to show that the prediction risk bounds take a similar form to those of univariate continuous functions. The following theorem of the prediction risk bounds for multivariate continuous functions is suggested using the definition of the modulus of continuity (13):

Theorem 2 *Let $f \in C^1(X)$ with X, a compact subset of $\mathbb{R}^m$ ($m > 1$), and h_0 be a constant satisfying (14). Then, for the confidence parameter δ (a constant between 0 and 1), the expected risk in L_1 sense is bounded by the following inequality with a probability of at least $1-\delta$:*

$$R(f_n)_{L_1} \leqslant R_{emp}(f_n)_{L_1} + \left\{\omega(f - f_n, h_0) + |f(\mathbf{x}_{i_0}) - f_n(\mathbf{x}_{i_0})| + \sigma_\varepsilon\sqrt{\frac{2}{\delta}}\right\}\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}},$$

where $w(f-f_n,h_0)$ represents the modulus of continuity of the function $f-f_n$, h_0 represents a constant satisfying (14), and $\mathbf{x}_{i_0}$ represents an element of an input sample set $\{\mathbf{x}_1,\cdots,\mathbf{x}_N\}$.

For the proof of this theorem, refer to the Appendix B.1. In this theorem, $w(f-f_n,h_0)$ can be replaced with $w(f,h_0)+w(f_n,h_0)$; that is, the sum of the modulus of continuity for the target and estimation functions because the following inequalities always hold:

$$\omega(f_n,h_0)-\omega(f,h_0)\leqslant\omega(f-f_n,h_0)\leqslant\omega(f_n,h_0)+\omega(f,h_0).$$

The suggested theorem states that the expected risk is mainly bounded by the empirical risk $R_{emp}(f_n)$, the modulus of continuity for the target function $w(f,h_0)$, and also the modulus of continuity for the estimation function $w(f_n,h_0)$. As the number of parameters n varies, the empirical risk, the modulus of continuity for the estimation function, and the term $|f(\mathbf{x}_{i_0})-f_n(\mathbf{x}_{i_0})|$ are changed while other terms remain constant. Here, in order to find the optimal model complexity $n=n^*$ that minimizes expected risk $R(f_n)$, these varying terms should be considered. In this case, the effect of the term $|f(\mathbf{x}_{i_0})-f_n(\mathbf{x}_{i_0})|$ is small compared with the other two terms, as the regression model becomes well fitted to the samples as the number of parameters n increases. This implies that the model selection criteria for multivariate estimation functions have the same form as (17) except with a coefficient $1/3$ of $\omega(f_n,h_0)$. In practice, the performance of MCIC for model selection problems is not so sensitive to this coefficient. Summarizing the properties of the suggested MCIC, the distinct characteristics are described as follows:

- The suggested MCIC is dependent upon the modulus of continuity for the trained estimation function.
- The suggested MCIC is also dependent upon the value of h_0 which varies according to the sample distribution.

Considering these characteristics, for model selection problems, the MCIC is a measure sensitive to the trained estimation function using a certain learning algorithm and also sensitive to the distribution of samples while other model selection criteria such as the AIC and BIC depend on structural information such as the number of parameters. For the computation of the suggested MCIC, the modulus of continuity of the trained estimation function should be evaluated, as explained in the next subsection.

3.3 The Modulus of Continuity for Estimation Functions

The modulus of continuity for the estimation function $w(f_n,h)$ is dependent upon the basis function ϕ_k in (4). Here, examples of computing $w(f_n,h)$ according to the type of basis functions are presented:

- A case of the estimation function f_n with algebraic polynomials on $X=[a,b]\subset\mathbb{R}$:

$$\phi_k(x)=x^k \quad \text{for } k=0,1,\cdots,n.$$

  Applying the mean value theorem to ϕ_k, we get

$$\begin{aligned}\omega(\phi_k,h)&\leqslant\left\|\phi_k'\right\|_\infty\cdot h\\&\leqslant kh\cdot\max\left\{|a|^{k-1},|b|^{k-1}\right\},\ k=1,\cdots,n.\end{aligned}$$

Therefore, the modulus of continuity for f_n has the following upper bound:

$$\omega(f_n,h) \leqslant \sum_{k=1}^{n} kh|w_k| \cdot \max\left\{|a|^{k-1},|b|^{k-1}\right\}.$$

- A case of the estimation function f_n with trigonometric polynomials $\phi_k(x)$ on $X \subset \mathbb{R}$:

$$\phi_k(x) = \begin{cases} 1/2 & \text{if } k=0 \\ \sin\left((k+1)x/2\right) & \text{if } k = \text{odd number} \\ \cos\left(kx/2\right) & \text{if } k = \text{even number} \end{cases}$$

for $k = 1,\cdots,n$. Applying the mean value theorem to ϕ_k, we get

$$\begin{aligned} \omega(\phi_k,h) &\leqslant \|\phi_k'\|_\infty h \\ &\leqslant \left\lfloor \frac{k}{2} \right\rfloor h, \text{ for } k=1,\cdots,n. \end{aligned}$$

Therefore, the modulus of continuity for f_n has the following upper bound:

$$\omega(f_n,h) \leqslant \sum_{k=0}^{n} h|w_k| \cdot \left\lfloor \frac{k}{2} \right\rfloor.$$

- A case of the estimation function f_n with sigmoid function $\phi_k(\mathbf{x}) = \phi_k(x_1,\cdots,x_m)$ on $X \subset \mathbb{R}^m$:

$$f_n(\mathbf{x}) = \sum_{k=1}^{n} w_k \phi_k(x_1,\cdots,x_m) + w_0,$$

where

$$\phi_k(x_1,\cdots,x_m) = \tanh\left(\sum_{j=1}^{m} v_{kj}x_j + v_{k0}\right).$$

Applying the mean value theorem to ϕ_k with respect to each coordinate $x_1,\cdots,x_m$, we get

$$|f_n(\cdots,x_j,\cdots) - f_n(\cdots,x_j-h,\cdots)| \leqslant h \cdot \left\| \frac{\partial f_n}{\partial x_j} \right\|_\infty \text{ for } j=1,\cdots,m.$$

Therefore, the modulus of continuity for f_n has the following upper bound:

$$\begin{aligned} \omega(f_n,h) &\leqslant h \cdot \max_{1\leqslant j\leqslant m} \left\| \frac{\partial f_n}{\partial x_j} \right\|_\infty \\ &\leqslant h \cdot \max_{1\leqslant j\leqslant m} \left\| \sum_{k=1}^{n} w_k v_{kj} \cdot \left(1 - \tanh^2\left(\sum_{i=1}^{m} v_{ki}x_i + v_{k0}\right)\right) \right\|_\infty \\ &\leqslant h \cdot \max_{1\leqslant j\leqslant m} \sum_{k=1}^{n} \left|w_k v_{kj}\right|. \end{aligned} \tag{18}$$

As shown in these examples, the modulus of continuity for the estimation function f_n is dependent upon the trained parameter values associated with f_n and h_0 whose range is given by (14). However, the proper value of h_0 satisfying (14) requires the intensive search of the input space. From this point of view, in practice, the value of h_0 is considered as the half of the average distance between two adjacent samples. Assuming a uniform distribution of input samples, the value of h_0 can be determined from the range of data values in each coordinate. For example, for m dimensional input patterns, h_0 can be determined by

$$h_0 = \frac{1}{2}\left(\frac{1}{m}\sum_{i=1}^{m}\frac{\max_i - \min_i}{N-1}\right)^{1/m}, \tag{19}$$

where $\max_i$ and $\min_i$ represent the maximum and minimum values of the samples in the ith coordinate.

After the value of h_0 is determined, the computation of the modulus of continuity requires access to all the parameter values of f_n which are obtained after the learning of training samples. In this context, the computational complexity of the modulus of continuity is proportional to the number of parameters n in the estimation function, that is, in big-O notation, $O(n)$. This computational complexity is not so heavy compared to the calculation of the empirical risk term, as it requires the computational complexity of $O(N)$ and in general, $N \gg n$. Hence, in total, the computational complexity of MCIC is described by $O(N)$ which is equivalent to the computational complexity of the AIC or BIC.

Once the modulus of continuity is determined, the MCIC can be determined by (17). Then, the model with the smallest value of MCIC will then be selected. Here, $\widehat{n}$ is selected such that

$$\widehat{n} = \arg\min_n \mathrm{MCIC}(f_n).$$

The validity of the suggested MCIC is shown in the next section through the simulation for nonlinear model selection problems.

4. Simulation

The simulation for function approximation was performed using the multilayer perceptrons (MLPs) composed of the input, hidden, and output layers. For this simulation, the number of sigmoid units n in the hidden layer was increased from 1 to 50. Here, f_n was denoted as the MLP with a hidden layer including n sigmoid units with the m dimensional input. The functional form of the estimation function is given by

$$f_n(x) = \sum_{k=1}^{n} w_k \tanh\left(\sum_{j=1}^{m} v_{kj}x_j + v_{k0}\right) + w_0,$$

where v_{kj} and w_k represent the input and output weights, respectively, that are associated with the kth sigmoid unit, and v_{k0} and w_0 represent the bias terms of the kth sigmoid unit and of the estimation function, respectively. In this regression model, the conjugate gradient method was used for the training of the input and output weights of the MLPs. As for the different type of kernel functions, we presented the model selection method using the suggested MCIC for the regression model with trigonometric polynomials (Koo and Kil, 2006) and showed the effectiveness of the MCIC compared to other model selection criteria.

As the benchmark data for this simulation of function approximation, the target functions given by Donoho and Johnstone (1995) were used: they are Blocks, Bumps, Heavysine, and Doppler functions, as illustrated in Figure 1. To generate the data for each target function from D-J (Donoho and Johnstone), the input values x_i, $i = 1, \cdots, N$ were generated from a uniform distribution within the interval of $[0, 2\pi]$. Here, for the normalization of D-J data, the outputs were adjusted to have the mean square value of 1 within the interval of $[0, 2\pi]$. The noise terms were also generated from a normal distribution with a mean of zero and a standard deviation of $\sigma_\varepsilon = 0.2$ or 0.4. They were then added to the target values computed from the randomly generated input values. For these target functions, 100 sets of N (= 200) training samples were generated randomly to train the MLP. In addition to the training samples, 1000 test samples were also generated separately according to identical input and noise distributions.

As for another application of the MCIC, simulations for the target functions with binary output values were considered using the benchmark data suggested by Hastie et al. (2003): the target value is defined by

$$y(\mathbf{x}) = \begin{cases} 1 & \text{if} \sum_{j=1}^{10} x_j > 5 \\ 0 & \text{otherwise,} \end{cases}$$

where $\mathbf{x}$ is uniformly generated in $[0,1]^{20}$. For the training of this target function, 100 sets of 50 samples were generated. In addition to the training samples, 500 test samples were also generated separately. The noise terms were also generated from a normal distribution with a mean of 0 and a standard deviation of $\sigma_\varepsilon = 0.0$ or 0.2. They were then added to the target values computed from the randomly generated input values.

For the simulation of selecting regression models with multi-dimensional input data, the benchmark data suggested by Chang and Lin (2001) were also used: they are Abalone, CPU_Small, MG, and Space_GA data sets as described in Table 1. For each data set, 30 sets of 500 samples were randomly generated as the training samples and the remaining samples in each set were used as the test samples; that is, 30 sets of test samples were also generated. For these data sets, the range of input and output was normalized between -1 and 1.

Data Set	Description	No. of Features	No. of Data
Abalone	predicting the age of abalone	8	4177
CPU_Small	predicting a computer system activity	12	8192
MG	predicting the Mackey-Glass time series	6	1385
Space_GA	election data on 3107 US counties	6	3107

Table 1: The benchmark data sets for regression problems

For our experiments, various model selection methods such as the AIC, BIC, MDL, and the suggested MCIC-based methods were tested. Once the MLP was trained, the empirical risk $R_{emp}(f_n)$ evaluated by the training samples was obtained, and the estimated risk $\widehat{R}(f_n)$ value could then be determined by the AIC, BIC, MDL, and MCIC-based methods. In the cases of the AIC and BIC methods, we selected the estimation function $f_{\hat{n}}$ which gives the smallest value of information criterion described as (6) and (8), respectively. In these criteria, we assume that the noise variance σ_ε^2 value was known. In the case of MDL, we selected the estimation function $f_{\hat{n}}$ which gives the smallest value of the description length of (9). In the suggested method, we used the following form

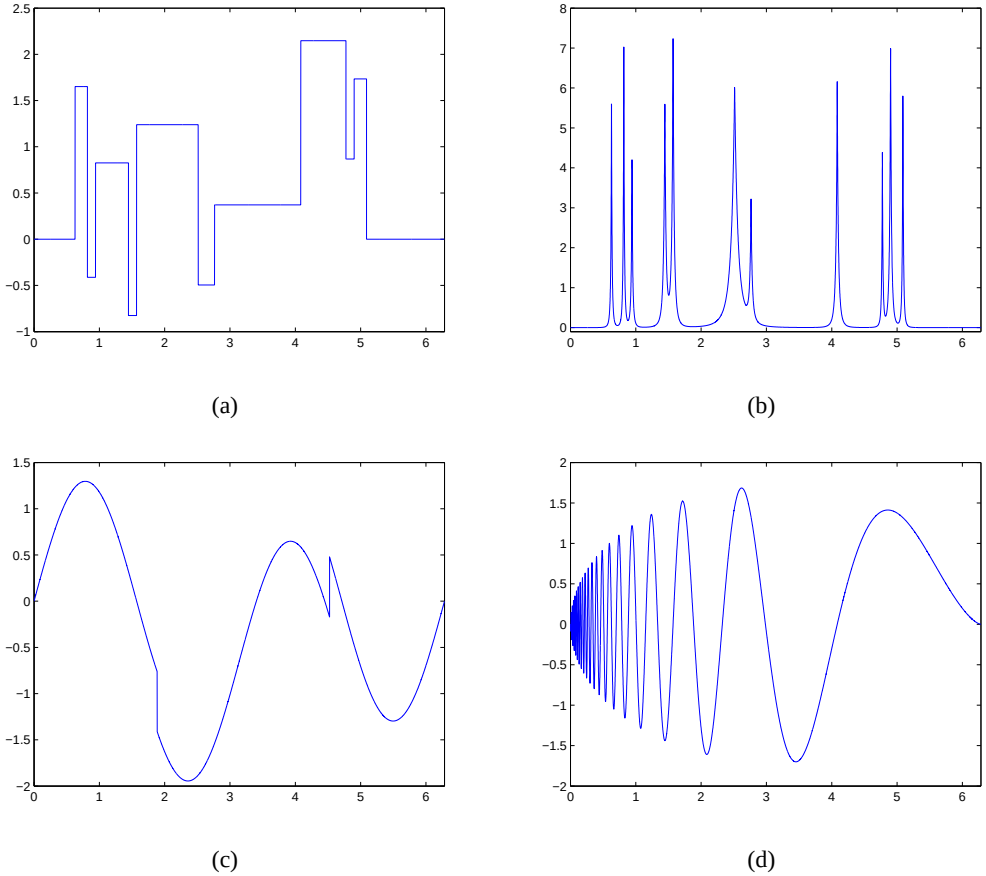

Figure 1: Target functions from Donoho and Johnstone (1995): (a), (b), (c), and (d) represent the Blocks, Bumps, Heavysine, and Doppler functions respectively.

of MCIC for MLPs using the modulus of continuity described as (18):

$$\mathrm{MCIC}(f_n) = R_{emp}(f_n)_{L_1} + \frac{h_0}{3} \max_{1 \leqslant j \leqslant m} \sum_{k=1}^{n} \left| w_k v_{kj} \right| \sqrt{\frac{1}{2N} \ln \frac{2}{\delta}}, \tag{20}$$

where h_0 was set to the half of the average distance between two adjacent samples using (19) and δ was set to 0.05. In our case, we selected $f_{\hat{n}}$ which gave the smallest value of (20).

To compare the performance of the model selection methods, the risks for the selected $f_{\hat{n}}$ were evaluated by the test samples and the results were compared with the minimum risk among all risks for f_n, $n = 1, \cdots, 50$. Quantitatively, the log ratio r_R of two risks $R_{test}(f_n)$ and $\min_n R(f_n)$ were computed:

$$r_R = \log \frac{R_{test}(f_{\hat{n}})}{\min_n R_{test}(f_n)}, \tag{21}$$

where R_{test} represents the empirical risk for the squared error loss function evaluated by the test samples. This risk ratio represents the quality of the estimated distance between the optimal and the estimated optimal risks.

Table 3: Risk ratios for the regression of the four D-J target functions with $\sigma_\varepsilon = 0.4$.

After all experiments had been repeated for the given number of training sample sets, the means and standard deviations of the risk ratios of (21) for each target function were presented. First, in the case of D-J data sets, the simulation results of the model selection using the AIC, BIC, MDL, and MCIC based methods are presented in Tables 2 and 3. These simulation results showed that the suggested MCIC method provided the top level performances in all cases except the blocks and bumps target functions when $\sigma_\varepsilon = 0.2$ in which the AIC method showed the best performances. This was mainly due to the fact that the known noise standard deviation of σ_ε was used in the AIC method. To clarify this fact, another simulation for these target functions in which the AIC and BIC methods with the estimation of noise variances using (7) were used. These simulation results are presented in Table 4. In this simulation, as we expected, the suggested MCIC method showed the best performance.

We also observed the dependency of the number of samples during the selection of regression models. For this simulation, the numbers of samples were set to $N = 100$, 200, 400, and 800 for the regression of the Doppler target function with a noise standard deviation of $\sigma_\varepsilon = 0.4$. The simulation results are presented in Table 5. Here, note that the complexity of the doppler target function increases as the input value decreases. These results showed that the performances of the AIC, BIC, MDL, and MCIC methods were improved as the number of samples becomes larger as shown in Table 5. Among these model selection methods, the MCIC method always showed the better performances compared to other model selection methods, even in the smaller numbers of samples. This is mainly due to the fact that in the MCIC method, the modulus of continuity, which can be interpreted as the complexity of the estimation function was computed for each trained estimation function directly.

In the case of Hastie et al.'s benchmark data, the MDL model selection methods showed some merits in performances compared to other model selection methods as shown in Table 6. One of the reasons why the MCIC method does not show the better performances in this target function compared to other model selection methods is that this target function can be properly solved by the classification problem (not regression problem) in which the discriminant function is linear.

800	0.0174	0.0275	0.0610	0.0565	0.0860	0.0774	**0.0035**	0.0107

Table 5: The variation of risk ratios for the regression of Doppler function with $\sigma_\varepsilon = 0.4$ using the AIC, BIC, MDL, and MCIC methods according to the number of samples $N = 100$, 200, 400, and 800.

However, even in this case, if the sample size is reduced, the proposed method can have the merits in performances since the MCIC includes the complexity term of the estimation function using the modulus of continuity and for smaller number of samples, this complexity term has the high influence on the bounds on the expected risk. To clarify this fact, we made another simulation results for the number of samples reduced by half; that is, $N = 25$ and compared with the previous simulation results as shown in Table 7. These simulation results showed that the MCIC method demonstrated the better performances compared to other model selection methods by reducing the sample size.

Table 6: Risk ratios for the regression of the binary target function using the AIC, BIC, MDL, and MCIC methods when the number of samples N is 50.

The simulation results for the selection of regression models with multi-dimensional input data are summarized in Table 8. These simulation results showed that the suggested MCIC method achieved top or second level performances compared to other model selection methods. As shown in the previous case; that is, the regression problem of Hastie et al.'s benchmark data, the MCIC method is more effective when the sample size is small. To see the effect on smaller number of samples, we also made another simulation results for the number of samples reduced by half; that is,

	AIC		BIC		MDL		MCIC	
σ_ε	mean	s. dev.	mean	s. dev.	mean	s. dev.	mean	s. dev.
0.0	0.3620	0.1977	0.3620	0.1977	0.3430	0.1855	**0.2652**	0.1589
0.2	1.7428	0.9582	1.7428	0.9582	0.3169	0.1816	**0.2716**	0.1743

Table 7: The variation of risk ratios for the regression of the binary target function when the number of samples is reduced by half; that is, $N = 25$.

$N = 250$ and compared with the previous simulation results as shown in Table 9. These simulation results showed that the MCIC method demonstrated the top level performances compared to other model selection methods. All of these observations support that the suggested MCIC method is quite effective for nonlinear regression models especially for smaller number of samples. This is mainly due to the fact that the complexity term as a form of the modulus of continuity of the trained regression model provides high influence on selecting the regression model especially for smaller number of samples. This can be explained by the following observations:

- Once the estimation function is trained, the estimation function provides accurate values for the training samples. In this estimation function, the variation of the predicted values for the unobserved data with respect to the function values for the known data (or training samples) can be described by the modulus of continuity, as presented in the definition of the modulus of continuity.
- If the number of samples decreases, the density of input space becomes low and it makes a big value of h. Then, in the suggested MCIC, this makes high influence of the modulus of continuity compared to the empirical risk which usually has a small value.
- If there are enough number of samples for the target function, the opposite phenomenon of the above case happens.

In summary, through the simulation for function approximation using the MLPs, we have shown that the suggested MCIC provides performance advantages for the selection of regression models compared to other model selection methods in various situations of benchmark data. Compared to other model selection methods, the MCIC methods provides the considerable merits in performances especially when no knowledge of noise variances for the given samples is available and also when not enough number of samples considering the complexity of target function is available.

5. Conclusion

We have suggested a new method of model selection in regression problems based on the modulus of continuity. The prediction risk bounds are investigated from a view point of the modulus of continuity for the target and estimation functions. We also present the model selection criterion referred to as the MCIC which is derived from the suggested prediction risk bounds. The suggested MCIC is sensitive to the trained regression model (or estimation function) obtained from a specific learning algorithm and is also sensitive to the distribution of samples. As a result, the suggested MCIC is able to discriminate the performances of the trained regression models, even with the same structure of regression models. To verify the validity of the suggested criterion, the selection

of regression models using the MLPs that were applied to function approximation problems was performed. Through the simulation for function approximation using the MLPs, it was shown that the model selection method using the suggested MCIC has the advantages of risk ratio performances over other model selection methods such as the AIC, BIC, and MDL methods in various situations of benchmark data. Compared to other model selection methods, this merit of regression performances is significant especially when not enough number of samples considering the complexity of target function is available. Furthermore, the suggested MCIC method does not require any knowledge of a noise variance of samples which is usually given or estimated in other model selection methods. For regression models with other types of estimation functions that have some smoothness constraints, the suggested MCIC method can be easily extended to the given regression models by evaluating the modulus of continuity for the corresponding estimation functions.

Appendix A.

In this appendix, we prove the lemmas 1 and 2 in Section 3.1. We also prove the theorem 1 and corollary 1 in Section 3.2; that is, the case of univariate target functions.

A.1 Proof of Lemma 1

Since $\omega^A(f,h)$ are considered all directions on h-ball on X, the following inequality always holds:

$$\omega^B(f,h,h) \leqslant \omega^A(f,h).$$

From the triangular inequality, the following inequality holds:

$$|f(x_1,y_1) - f(x_2,y_2)| \leqslant |f(x_1,y_1) - f(x_1,y_2)| + |f(x_1,y_2) - f(x_2,y_2)|.$$

Let $\|(x_1,y_1) - (x_2,y_2)\| \leqslant h$. Then, $|x_1 - x_2| \leqslant h$ and $|y_1 - y_2| \leqslant h$. Therefore, from the definition of the modulus of continuity, we obtain

$$\omega^A(f,h) \leqslant 2\omega^B(f,h,h).$$

□

A.2 Proof of Lemma 2

- Upper bound of $w^A(f,h)$: Let $\mathbf{x} \in X$ and $\mathbf{x} - \mathbf{h} \in X$ satisfying $\|\mathbf{h}\| \leqslant h$. Then,

$$\begin{aligned}
|f(\mathbf{x}) - f(\mathbf{x}-\mathbf{h})| &\leqslant |\nabla f(\mathbf{x} - \xi\mathbf{h}) \cdot \mathbf{h}| \quad \text{for some } \xi \in (0,1) \\
&\leqslant \|\mathbf{h}\| \, \|\nabla f(\mathbf{x} - \xi\mathbf{h})\| \\
&\qquad \text{(because of Cauchy-Schwartz inequality)} \\
&= \|\mathbf{h}\| \sqrt{\sum_{i=1}^{m} \left| \frac{\partial f}{\partial x_i}(\mathbf{x} - \xi\mathbf{h}) \right|^2} \\
&\leqslant \|\mathbf{h}\| \sqrt{\sum_{i=1}^{m} \left\| \frac{\partial f}{\partial x_i} \right\|_\infty^2}.
\end{aligned}$$

  Since the last term of the above equation is independent of $\mathbf{x} \in X$, we can conclude that

$$\omega^A(f,h) \leqslant h \sqrt{\sum_{i=1}^{m} \left\| \frac{\partial f}{\partial x_i} \right\|_\infty^2}.$$

- Upper bound of $w^B(f,h,h)$: Let $\alpha \in \mathbb{R}$ and $|\alpha| \leqslant h$. Here, let us define $\mathbf{e}_i$ as a vector on $\mathbb{R}^m$ whose i-th coordinate is 1 and the others are 0. Then, there exists $\xi \in (0,1)$ such that

$$|f(\mathbf{x}) - f(\mathbf{x} - h\mathbf{e}_i)| \leqslant \left| \frac{\partial f}{\partial x_i}(\mathbf{x} - \xi\alpha\mathbf{e}_i) \right| |h| \quad \text{for } i = 1, \cdots, m.$$

  This implies that

$$\max_i \{|f(\mathbf{x}) - f(\mathbf{x} - \alpha\mathbf{e}_i)|\} \leqslant |\alpha| \max_{1 \leqslant i \leqslant m} \left\{ \left| \frac{\partial f}{\partial x_i}(\mathbf{x} - \xi\alpha\mathbf{e}_i) \right| \right\}.$$

  Therefore, we can conclude that

$$\omega^B(f,h,\cdots,h) \leqslant h \max_{1 \leqslant i \leqslant m} \left\{ \left\| \frac{\partial f}{\partial x_i} \right\|_\infty \right\}.$$

□

A.3 Proof of Theorem 1

Before the description of main proof, let us introduce the Hoeffding inequality (Hoeffding, 1963): Given *i.i.d.* random variables $Y_1, \ldots, Y_N$, let us define a new random variable

$$S_N = \frac{1}{N}\sum_{i=1}^{N} Y_i$$

and we assume that there exist real numbers a_i and b_i for $i = 1, \ldots, N$ such that $\Pr\{Y_i \in [a_i, b_i]\} = 1$. Then, for any $\varepsilon > 0$, we have

$$\Pr\{E[S_N] - S_N \geqslant \varepsilon\} \leqslant \exp\left(-\frac{2\varepsilon^2 N^2}{\sum_{i=1}^{N}(b_i - a_i)^2}\right).$$

First, let us consider the noiseless case; that is, $y = f(x)$ in (1). For the input samples $x_1, \cdots, x_N$, an event A is defined by

$$\frac{1}{N}\sum_{i=1}^{N}\int_X |f_n(x) - f_n(x_i)| dP(x) - \frac{1}{N}\sum_{j=1}^{N}\frac{1}{N}\sum_{i=1}^{N}|f_n(x_j) - f_n(x_i)| \geqslant \varepsilon,$$

where the first and second terms represent the average over the expectation of $|f_n(x) - f_n(x_i)|$ and the unbiased estimator of the first term respectively.

Then, from the Hoeffding inequality, the probability of an event A is bounded by

$$\Pr\{A\} \leqslant \exp\left(\frac{-2\varepsilon^2 N}{\left(\max_{x\in X}\frac{1}{N}\sum_{i=1}^{N}|f_n(x) - f_n(x_i)|\right)^2}\right).$$

For the denominator in the argument of the exponent, we can consider the following inequality:

$$\begin{aligned}\max_{x\in X}\frac{1}{N}\sum_{i=1}^{N}|f_n(x) - f_n(x_i)| &\leqslant \frac{1}{N}\sum_{i=1}^{N}\max_{x\in X}|f_n(x) - f_n(x_i)| \\ &\leqslant \max_i \max_{x\in X}|f_n(x) - f_n(x_i)|.\end{aligned}$$

Let $x_i' = \arg\max_{x\in X}|f_n(x) - f_n(x_i)|$, $x_{i'} = \arg\min_j d(x_j, x_i')$, and $h_i = d(x_i', x_{i'})$ where $d(x,y)$ represents the distance measure defined by $d(x,y) = |x-y|$. Then,

$$\begin{aligned}\max_{x\in X}\frac{1}{N}\sum_{i=1}^{N}|f_n(x) - f_n(x_i)| &\leqslant \max_i\left(|f_n(x_i') - f_n(x_{i'})| + |f_n(x_{i'}) - f_n(x_i)|\right) \\ &\leqslant \max_i\left(\omega(f_n, h_i) + |f_n(x_{i'}) - f_n(x_i)|\right) \\ &\leqslant \omega(f_n, h_0) + |f_n(x_0') - f_n(x_0)|,\end{aligned}$$

where $h_0 \in \{h_1, \ldots, h_N\}$ and $x_0, x_0' \in \{x_1, \ldots, x_N\}$ satisfy

$$\omega(f_n, h_i) + |f_n(x_i) - f_n(x_j)| \leqslant \omega(f_n, h_0) + |f_n(x_0) - f_n(x_0')| \quad \text{for } i, j = 1, \cdots, N.$$

For the illustration of this concept, refer to Figure 2.

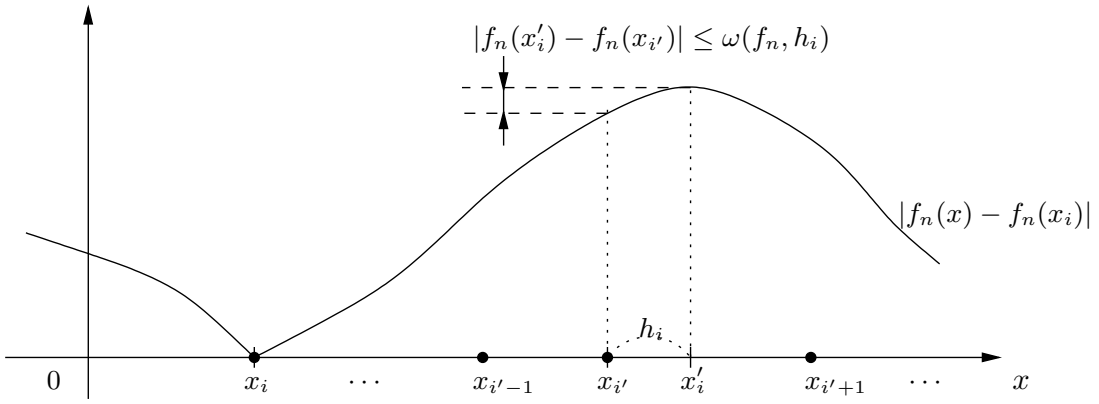

Figure 2: The plot of $|f_n(x) - f_n(x_i)|$ versus x: the value of $|f_n(x) - f_n(x_i)|$ is maximum at x_i' and this maximum value is decomposed by two factors: one is the value of $|f_n(x) - f_n(x_i)|$ at a sample point $x_{i'}$ and another is the modulus of continuity $\omega(f_n, h_i)$ with respect to h_i. The value h_i is chosen by the distance $d(x_i', x_{i'})$.

Thus, the probability of an event A is bounded by

$$\Pr\{A\} \leqslant \exp\left(\frac{-2\varepsilon^2 N}{(\omega(f_n, h_0) + |f_n(x_0) - f_n(x_0')|)^2}\right).$$

Here, let us set

$$\frac{\delta_1}{2} = \exp\left(\frac{-2\varepsilon^2 N}{(\omega(f_n, h_0) + |f_n(x_0) - f_n(x_0')|)^2}\right).$$

Then, with a probability of at least $1 - \delta_1/2$, we have

$$\frac{1}{N}\sum_{i=1}^{N}\int_X |f_n(x) - f_n(x_i)| dP(x) \leqslant \frac{1}{N^2}\sum_{i,j=1}^{N} |f_n(x_i) - f_n(x_j)| + \sqrt{\frac{1}{2N}\ln\frac{2}{\delta_1}}\left(\omega(f_n, h_0) + |f_n(x_0) - f_n(x_0')|\right). \quad (22)$$

On the other hand, for the target function f, we can apply a similar method. As a result, with a probability of at least $1 - \delta_1/2$, the following inequality holds:

$$\frac{1}{N}\sum_{i=1}^{N}\int_X |f(x) - f(x_i)| dP(x) \leqslant \frac{1}{N^2}\sum_{i,j=1}^{N} |f(x_i) - f(x_j)| + 2\|f\|_\infty \sqrt{\frac{1}{2N}\ln\frac{2}{\delta_1}}. \quad (23)$$

Let us consider the difference between the expected and empirical errors of $|f(x)-f_n(x)|$:

$$\begin{aligned}\int_X |f(x)-f_n(x)|dP(x) &- \frac{1}{N}\sum_{i=1}^{N}|f(x_i)-f_n(x_i)| \\ &= \frac{1}{N}\sum_{i=1}^{N}\int_X (|f(x)-f_n(x)-f(x_i)+f_n(x_i)+f(x_i)-f_n(x_i)| \\ &\quad -|f(x_i)-f_n(x_i)|)dP(x) \\ &\leqslant \frac{1}{N}\sum_{i=1}^{N}\int_X |f(x)-f_n(x)-f(x_i)-f_n(x_i)|dP(x) \\ &\leqslant \frac{1}{N}\sum_{i=1}^{N}\int_X (|f(x)-f(x_i)|+|f_n(x)-f_n(x_i)|)dP(x).\end{aligned}$$

Then, from (22) and (23), the difference between the true and empirical risks is bounded by the following inequality with a probability of at least $1-\delta_1$:

$$\begin{aligned}\int_X |f(x)-f_n(x)|dP(x) - \frac{1}{N}\sum_{i=1}^{N}|f(x_i)-f_n(x_i)| & \\ \leqslant \frac{1}{N^2}\sum_{i,j=1}^{N}(|f(x_i)-f(x_j)|+|f_n(x_i)-f_n(x_j)|) & \\ + \sqrt{\frac{1}{2N}\ln\frac{2}{\delta_1}}\,(\omega(f_n,h_0)+|f_n(x_0)-f_n(y_0)|+2\|f\|_\infty). & \quad (24)\end{aligned}$$

Second, let us consider the noisy condition; that is, $y=f(x)+\varepsilon$. Here, we assume that for the output samples $y_1,\cdots,y_N$, the noise terms $\varepsilon_1,\ldots,\varepsilon_N$ are *i.i.d.* random variables with a mean of 0 and a variance of σ_ε^2. We will define the event B as

$$|\varepsilon| \geqslant a, \quad (25)$$

where a is a positive constant. Then, from the Chebyshev inequality,

$$\Pr\{B\} \leqslant \frac{\sigma_\varepsilon^2}{a^2}.$$

Let us set

$$\delta_2 = \frac{\sigma_\varepsilon^2}{a^2}.$$

Then, with a probability of at least $1-\delta_2$,

$$|\varepsilon| \leqslant \sigma_\varepsilon\sqrt{\frac{1}{\delta_2}}.$$

This implies that with a probability of at least $1-\delta_2$,

$$|y| \leqslant |f(x)|+|\varepsilon| \leqslant \|f\|_\infty + \sigma_\varepsilon\sqrt{\frac{1}{\delta_2}}.$$

Here, let us define the event E as

$$\frac{1}{N}\sum_{i=1}^{N}\int_{\mathbb{R}}|y-y_i|dP(y)-\frac{1}{N}\sum_{i=1}^{N}\frac{1}{N}\sum_{j=1}^{N}|y_j-y_i|>\varepsilon.$$

Then, from the Hoeffding inequality, we obtain

$$\begin{aligned}\Pr\{E|B^c\} &\leqslant \exp\left\{\frac{-2\varepsilon^2 N}{\left(\max_{y\in\mathbb{R}}\frac{1}{N}\sum_{i=1}^{N}|y-y_i|\right)^2}\right\}\\ &\leqslant \exp\left\{\frac{-\varepsilon^2 N}{2(\|f\|_\infty+\sigma_\varepsilon\sqrt{1/\delta_2})^2}\right\}.\end{aligned}$$

Let us set

$$\frac{\delta_1}{2}=\exp\left\{\frac{-\varepsilon^2 N}{2(\|f\|_\infty+\sigma_\varepsilon\sqrt{1/\delta_2})^2}\right\}.$$

Then, with a probability of at least $1-\delta_1/2-\delta_2$,

$$\frac{1}{N}\sum_{i=1}^{N}\int|y-y_i|dP(y)-\frac{1}{N^2}\sum_{i,j=1}^{N}|y_i-y_j|\leqslant\sqrt{\frac{2}{N}\ln\frac{2}{\delta_1}}\left(\|f\|_\infty+\sigma_\varepsilon\sqrt{\frac{1}{\delta_2}}\right)\tag{26}$$

since

$$\begin{aligned}\Pr\{E^c\} &\geqslant Pr\{E^c,B^c\}\\ &\geqslant Pr\{E^c|B^c\}Pr\{B^c\}\\ &\geqslant\left(1-\frac{\delta_1}{2}\right)(1-\delta_2)\\ &>1-\frac{\delta_1}{2}-\delta_2.\end{aligned}$$

Similar to (24), the difference between the expected and empirical risks of $|y-f_n(x)|$ is bounded by

$$\begin{aligned}\int_{X\times\mathbb{R}}|y-f_n(x)|dP(x,y) &- \frac{1}{N}\sum_{i=1}^{N}|y_i-f_n(x_i)|\\ &\leqslant \frac{1}{N}\sum_{i=1}^{N}\int_{X\times\mathbb{R}}|y-y_i|+|f_n(x)-f_n(x_i)|dP(x,y).\end{aligned}$$

Here, let us set $\delta_1=\delta_2=\delta$. This is possible by controlling the value of a in (25). Then, finally, from (22) and (26), with a probability of at least $1-2\delta$

$$\begin{aligned}\int_{X\times\mathbb{R}}|y-f_n(x)|dP(x,y) &- \frac{1}{N}\sum_{i=1}^{N}|y_i-f_n(x_i)|\\ &\leqslant \frac{1}{N^2}\sum_{i,j=1}^{N}(|y_j-y_i|+|f_n(x_j)-f_n(x_i)|)\\ &\quad+(\omega(f_n,h_0)+C)\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}},\end{aligned}\tag{27}$$

where $C=|f_n(x_0)-f_n(y_0)|+2\|f\|_\infty+2\sigma_\varepsilon\sqrt{1/\delta}$. □

A.4 Proof of Corollary 1

Let H_y be a matrix in which the ijth element is given by $|y_i - y_j|$ and an N dimensional vector $\mathbf{a}$ be given by

$$\mathbf{a} = \frac{1}{\sqrt{N}}(1, \cdots, 1)^T.$$

Then,

$$\frac{1}{N}\sum_{i,j=1}^{N} |y_i - y_j| = \mathbf{a}^T H_y \mathbf{a}. \tag{28}$$

Here, the matrix H_y can be decomposed by

$$H_y = E\Lambda E^T = \sum_{i=1}^{N} \lambda_i \mathbf{e}_i \mathbf{e}_i^T, \tag{29}$$

where E represents a matrix in which the ith column vector is the ith eigenvector $\mathbf{e}_i$ and Λ represents the diagonal matrix in which the ith diagonal element is the ith eigenvalue λ_i. Then, from (28) and (29),

$$\frac{1}{N}\sum_{i,j=1}^{N} |y_i - y_j| = \sum_{i=1}^{N} \lambda_i (\mathbf{a}^T \mathbf{e}_i)^2 \leqslant \max_i \{\lambda_i\}.$$

Now, let us consider the following inequality:

$$\begin{aligned}
\frac{1}{N^2}\sum_{i,j=1}^{N} |f_n(x_i) - f_n(x_j)| &\leqslant \frac{1}{N^2}\sum_{i,j=1}^{N} |f_n(x_i) - y_i| \\
&\quad + \frac{1}{N^2}\sum_{i,j=1}^{N} |y_i - y_j| + \frac{1}{N^2}\sum_{i,j=1}^{N} |y_j - f_n(x_j)| \\
&= 2R_{emp}(f_n)_{L_1} + \frac{1}{N^2}\sum_{i,j=1}^{N} |y_i - y_j| \\
&\leqslant 2R_{emp}(f_n)_{L_1} + \frac{1}{N}\max_i \{\lambda_i\}.
\end{aligned}$$

Therefore, from the above inequality and (27), the following inequality holds with a probability of at least $1 - 2\delta$:

$$R(f_n) \leqslant 3R_{emp}(f_n) + \frac{2}{N}\max_i \{\lambda_i\} + (\omega(f_n, h_0) + C)\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}}.$$

□

Appendix B.

In this appendix, we prove the theorem 2 in Section 3.2; that is, the case of multivariate target functions.

B.1 Proof of Theorem 2

First, let us consider noise free target function; that is,

$$y = f(\mathbf{x}).$$

The probability that the difference between the expected and empirical risks is larger than a positive constant ε can be described by

$$\Pr\{R(f_n)_{L_1} - R_{emp}(f_n)_{L_1} > \varepsilon\} \leqslant \exp\left\{\frac{-2\varepsilon^2 N}{(\max_{\mathbf{x}\in X}|y - f_n(\mathbf{x})|)^2}\right\} \tag{30}$$

from the Hoeffding inequality (Hoeffding, 1963). Here, there exist $\mathbf{x}_0 \in X$ and $\mathbf{x}_{i_0} \in \{\mathbf{x}_0, \cdots, \mathbf{x}_N\}$ such that

$$\mathbf{x}_0 = \arg\max_{\mathbf{x}\in X} |f(\mathbf{x}) - f_n(\mathbf{x})| \text{ and } d(\mathbf{x}_{i_0}, \mathbf{x}_0) \leqslant h_0$$

because $f - f_n \in C(X)$ and X is a compact subset of $\mathbb{R}^m$. Thus, from the dominator term of the righthand side of (30), we have

$$\begin{aligned}\max_{\mathbf{x}\in X} |f(\mathbf{x}) - f_n(\mathbf{x})| &\leqslant |f(\mathbf{x}_0) - f_n(\mathbf{x}_0) - f(\mathbf{x}_{i_0}) + f_n(\mathbf{x}_{i_0})| + |f(\mathbf{x}_{i_0}) - f_n(\mathbf{x}_{i_0})| \\ &\leqslant \omega(f - f_n, h_0) + |f(\mathbf{x}_{i_0}) - f_n(\mathbf{x}_{i_0})|. \end{aligned} \tag{31}$$

Here, we set the bound on the probability of (30) as

$$\begin{aligned}\exp\left\{\frac{-2\varepsilon^2 N}{(\max_{\mathbf{x}\in X}|f(\mathbf{x}) - f_n(\mathbf{x})|)^2}\right\} &\leqslant \exp\left\{\frac{-2\varepsilon^2 N}{(\omega(f - f_n, h_0) + |f(\mathbf{x}_{i_0}) - f_n(\mathbf{x}_{i_0})|)^2}\right\} \\ &\leqslant \frac{\delta}{2}. \end{aligned} \tag{32}$$

Therefore, from (30), (31), and (32), the following inequality holds with a probability of at least $1 - \delta/2$:

$$R(f_n)_{L_1} \leqslant R_{emp}(f_n)_{L_1} + \{\omega(f - f_n, h_0) + |f(\mathbf{x}_{i_0}) - f_n(\mathbf{x}_{i_0})|\}\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}}. \tag{33}$$

Second, let us consider the noisy target function; that is,

$$y = f(\mathbf{x}) + \varepsilon.$$

From Chebyshev inequality, the following inequality always holds:

$$\Pr\{|\varepsilon| > a\} \leqslant \frac{\sigma_\varepsilon^2}{a^2}, \tag{34}$$

where a represents a positive constant. In this case, from the triangular inequality, $|y - f_n(\mathbf{x})|$ has the following upper bound:

$$\max_{\mathbf{x}\in X} |y - f_n(\mathbf{x})| \leqslant \max_{\mathbf{x}\in X} |f(\mathbf{x}) - f_n(\mathbf{x})| + |\varepsilon|. \tag{35}$$

Let us set the bound on the probability of (34) as

$$\frac{\sigma_\varepsilon^2}{a^2} = \frac{\delta}{2}. \tag{36}$$

Then, from (31), (35), and (36), the following inequality holds with a probability of at least $1-\delta/2$:

$$\begin{aligned}\max_{\mathbf{x}\in X}|y-f_n(\mathbf{x})| &\leqslant \max_{\mathbf{x}\in X}|f(\mathbf{x})-f_n(\mathbf{x})|+\sigma_\varepsilon\sqrt{\frac{2}{\delta}} \\ &\leqslant \omega(f-f_n,h_0)+|f(\mathbf{x}_{i_0})-f_n(\mathbf{x}_{i_0})|+\sigma_\varepsilon\sqrt{\frac{2}{\delta}}. \end{aligned} \tag{37}$$

Therefore, from (33) and (37), the following inequality holds with a probability of at least $1-\delta$:

$$R(f_n)_{L_1} \leqslant R_{emp}(f_n)_{L_1}+\left\{\omega(f-f_n,h_0)+|f(\mathbf{x}_{i_0})-f_n(\mathbf{x}_{i_0})|+\sigma_\varepsilon\sqrt{\frac{2}{\delta}}\right\}\sqrt{\frac{1}{2N}\ln\frac{2}{\delta}}.$$

Abstract

Multi Agent Reinforcement Learning (MARL) has received continually growing attention in the past decade. Many algorithms that vary in their approaches to the different subtasks of MARL have been developed. However, the theoretical convergence results for these algorithms do not give a clue as to their practical performance nor supply insights to the dynamics of the learning process itself. This work is a comprehensive empirical study conducted on *MGS*, a simulation system developed for this purpose. It surveys the important algorithms in the field, demonstrates the strengths and weaknesses of the different approaches to MARL through application of FriendQ, OAL, WoLF, FoeQ, Rmax, and other algorithms to a variety of fully cooperative and fully competitive domains in self and heterogeneous play, and supplies an informal analysis of the resulting learning processes. The results can aid in the design of new learning algorithms, in matching existing algorithms to specific tasks, and may guide further research and formal analysis of the learning processes.

Keywords: reinforcement learning, multi-agent reinforcement learning, stochastic games

1. Introduction

Multi-Agent Reinforcement Learning (MARL) deals with the problem of learning to behave well through trial and error interaction within a multi-agent dynamics environment when the environmental dynamic and the algorithms employed by the other agents are initially unknown. Potential applications of MARL range from load balancing in networks (Schaerf et al., 1995) and e-commerce (Sridharan and Tesauro, 2000) to planetary exploration by mobile robot teams (Zheng et al., 2006).

MARL adopts the game theory model of a Stochastic (a.k.a. Markov) Game (SG) to model the multi-agent-environment interaction. The non-cooperative[1] game theoretic solution concept for SGs is the Nash Equilibrium (NE). A NE is a behavioral profile, namely a set of decision rules, or policies, for all agents, such that no agent can benefit from unilaterally changing its behavior. However, SGs may have multiple NEs with different values, none of which is necessarily strictly optimal (i.e., preferable by all agents to all other NEs). Thus, in the general case, it is not clear which behavior should be considered "optimal," even when the environmental dynamics and the other players' set of possible strategies are known. For this reason, development of MARL algorithms

*. A preliminary version of this paper that covered some of the results on common-interest games appeared in Bab and Brafman (2004).

1. In this context, the meaning of 'non-cooperative' is that agents are selfish and do not collaborate or communicate with other agents, except through the game.

has concentrated on algorithms for classes of SGs in which there is a unique NE, or in which all NEs have the same value. In such cases, it is possible to measure the performance of learning algorithms against a well defined target.[2] In particular, most MARL algorithms are shown to converge to such NEs in self play in either Common Interest SGs (CISGs) or Fixed Sum SGs (FSSGs), which we describe next.

CISGs model environments in which the agents share common interests and have no conflicting interests. In such environments, defining an optimal joint behavior for all agents is straightforward—it is the joint behavior that maximizes the common interests. However, since the agents are independent, they face the task of coordinating such joint behavior in the case in which there are several optimal options. FSSGs, on the other hand, model environments in which two agents have fully conflicting interests. In FSSGs, there is a well defined *minimax* solution (Filar and Vrieze, 1997).

Several different MARL algorithms have been proved to converge in the limit to optimal behavior in CISGs (Littman, 2001; Wang and Sandholm, 2002) and in FSSGs (Littman, 1994). One has been shown to converge to ε-optimal behavior in polynomial time in both CISGs and FSSGs (Brafman and Tennenholtz, 2002, 2003). Since MARL is, by its nature, an online task, determining the abilities of the algorithms in practical domains is important. However, existing theoretical results tell us very little about the practical efficacy of the algorithms;[3] to this end a comprehensive empirical comparison is necessary. Experimental results that have been published in the literature on CISGs (Claus and Boutilier, 1997; Wang and Sandholm, 2002; Chalkiadakis and Boutilier, 2003) and on FSSGs (Littman, 1994; Uther and Veloso, 2003; Bowling and Veloso, 2002), do not meet this demand. They do not examine representative samples of algorithms and/or use small and simple test models and/or do not examine online learning. Furthermore, the different experimental setups used in different publications do not enable cross comparisons of the algorithms they examine.

This work provides a comprehensive empirical study of MARL algorithms in CISGs and FSSGs. It offers a decomposition of the MARL task into subtasks. It then compares three algorithms for learning in CISGs: FriendQ (Littman, 2001), OAL (Wang and Sandholm, 2002), and Rmax (Brafman and Tennenholtz, 2002); and three algorithms for learning in FSSGs: FoeQ (Littman, 1994, 2001), WoLF (Bowling and Veloso, 2002) and Rmax (Brafman and Tennenholtz, 2002). These algorithms were selected because they represent a variety of approaches to the offered subtasks, while providing certain convergence guarantees. We experimented with diverse variants of these algorithms on several non-trivial test environments which we designed to demonstrate the efficacy of the different approaches in each of the subtasks. To concentrate attention on the basic learning task, full state observability and perfect monitoring (that is, the ability to observe the actions of other agents) are assumed. The results allow us to rank the performance of the algorithms according to properties of the environment and possible performance measures.

The experiments for this work have been conducted using MGS, a Markov Game Simulation system developed for this purpose. MGS is implemented in the Java programming language and supplies interfaces and abstract classes for the simple creation of players and grid worlds and convenient logging. We believe that MGS can be of good service to both MARL algorithm designers and users. MGS is free, open source software available at `http://www.cs.bgu.ac.il/~mal`.

2. Much recent work is concerned with the question of how to define and evaluate the performance of learning algorithms in more general games. See, for example, Vohraa and Wellman (2007) which is devoted to this issue.
3. Vidal and Durfee (2003) take a step towards theoretical analysis of the learning dynamics. They offer theoretical tools to analyzing and predicting behavior of multi-agent systems that are represented by simpler models than SGs. Powers and Shoham (2005) offer experimental results on iterative games, which are a much simpler model than SGs.

The paper is organized as follows. Necessary background is given in Section 2. Sections 3 and 4 describe the particular problems and algorithms for CISGs and FSSGs, respectively, and present experimental results and analysis. Section 5 describes MGS and Section 6 concludes the paper.

2. Multi-Agent Reinforcement Learning and Stochastic Games

Multi-Agent Reinforcement Learning (MARL) is an extension of RL (Sutton and Barto, 1998; Kaelbling et al., 1996) to multi-agent environments. It deals with the problems associated with the learning of optimal behavior from the point of view of an agent acting in a multi-agent environment. At the outset, the environmental dynamics and the algorithms employed by the other players are unknown to the given agent. The environment is modeled by a finite set of states and the agents-environment interaction is discretized into time steps. At each time step, the players simultaneously choose actions, available from individual sets of actions. Depending stochastically on the joint action, the environment transitions into its next state and each player is rewarded. The present work assumes full state observability and perfect monitoring, namely, the agent observes the actions taken and rewards received by the other players. It also assumes that the agents have no additional means of communication. The multi-agent-environment interaction is modeled by a Stochastic (a.k.a Markov) Game (SG).

Definition 2.1 (Stochastic Game) *An SG* $G := \{\alpha, A, S, T, R\}$ *consists of:*

- $\alpha = \{1, ..., n\}$ *- a set of players. We will typically use n to denote the number of players.*
- $A = A_1 \times A_2 \times ... \times A_n$ *– a set of joint actions.* A_i *is a set of private actions available to player i.*
- S *- a set of states.*
- $T : S \times A \times S \to [0,1]$ *- a transition function.* $T(s,a,s') = Pr(s' \mid s,a)$ *is the probability that the system transitions to state* s' *when joint action a is taken at state s (*$\sum_{s'} T(s,a,s') = 1$*).*
- $R : S \times A \times S \to \mathbb{R}^n$ *- a payoff function.* $[R(s,a,s')]_i$ *is i's reward upon transition from state s to state* s' *under joint action a.*

The behavior of player i in an SG is described by a *policy*. A policy is a mapping $\pi_i : \mathscr{H} \to \mathscr{PD}(A_i)$ where $\mathscr{H} := \{(s_0, a_1, s_1, a_2, ..., s_j) \mid j \geq 0\}$ is the set of possible histories of the process and $\mathscr{PD}(A_i)$ is a probability distribution over A_i. A policy that depends only on the current state of the process, that is, $\pi_i : S \to \mathscr{PD}(A_i)$ is called *stationary*. A deterministic policy, that is a mapping, $\pi_i : \mathscr{H} \to A_i$ is called *pure*, whereas a stochastic policy is called *mixed*. A tuple of policies $\pi = (\pi_1, \ldots, \pi_n)$ for n players of a SG is called a *policy profile*. The objective of an agent in a SG is to maximize some function of its accumulated payoffs, referred to as the agent's return. In this study, the infinite horizon discounted return (IHDR) is considered. The expected IHDR for player i, resulting from policy profile π, is defined by the sum $\sum_{t=0}^{\infty} \gamma^t E^{\pi}(r_t^i)$ where r_t^i is player i's payoff at time t and $\gamma \in [0,1)$ is a discount factor. Consequently, a state-policy value function, V is defined by $V_i(s,\pi) = \sum_{t=0}^{\infty} \gamma^t E^{\pi}(r_t^i \mid s_0 = s)$.

We note that different algorithms optimize different objectives. Yet, typically, the same underlying ideas can be used to formulate different variants of the same basic algorithm that aim to

maximize different natural objectives. While we use formulations that aim to maximize IHDR, the games we experiment on are such that any good policy will reach an absorbing state (following which the agents are placed in their initial states) quickly. In this setting, given a reasonably high discount factor, γ, IHDR maximizing behavior will be identical to behavior maximizing average reward. Consequently, we will sometimes find it more natural to report performance measures such as average reward per step.

For single agent domains, where $n = 1$, there is always an optimal pure stationary policy that maximizes $V(s,\pi)$ for all $s \in S$ (Filar and Vrieze, 1997). The single-agent state-policy value function for the optimal policy, referred to as the state-value function, is the unique fixed point of the Bellman optimality equations

$$V^*(s) = \max_{a \in A} \left(R(s,a) + \gamma \sum_{s' \in S} T(s,a,s') V^*(s') \right), \forall s \in S \, .$$

An optimal policy may be specified by $\pi^*(s) = arg\max_{a \in A}(R(s,a) + \gamma \sum_{s' \in S} T(s,a,s') V^*(s'))$ (Puterman, 1994). Many single agent Reinforcement Learning (RL) methods interleave approximation of the value function with derivation of a learning policy from the current approximation.

In MARL, maximizing the IHDR cannot be done by simply maximizing over (private) policies since the return depends also on the other players' policies which, in turn, may depend on the agent's actions. Hence, to maximize the IHDR, the agent must adopt a policy that is a *best response* to the other players' policies. Formally, π_i is a best response to $\pi^{-i} = (\pi_1, ..., \pi_{i-1}, \pi_{i+1}, ..., \pi_n)$ if $V_i(s, \pi_1, ..., \pi_i, ..., \pi_n) \geq V_i(s, \pi_1, ..., \pi_i', ..., \pi_n)$ for all π_i' and $s \in S$. A best response function is defined by $BR(\pi^{-i}) = \left\{ \pi_i \mid \pi_i \textit{ is a best response to } \pi^{-i} \right\}$. In general, $\bigcap_{\pi^{-i}} BR(\pi^{-i}) = \emptyset$, namely, there is no policy that is a best response to all of the possible behaviors of the other players.

Whereas the goal of single-agent reinforcement learning is clear—maximizes some aggregate of your reward stream, the picture is more complex in multi-agent settings. Here, one's performance depends on what the other agents do, and strategic considerations come to the fore. For instance, the well-known notion of Nash Equilibria does not, in general, provide a clear target for learning algorithms, as many such equilibria may exist in a game, none of which dominates the others. Although some recent work has attempted to clarify this issue (Brafman and Tennenholtz, 2004; Shoham et al., 2007), there is still no clear agreement on the goal of MARL. However, there are two special classes of SGs in which there is a clear target for learning: Common-interest SGs, and Fixed-sum SGs. These are two extreme cases of SGs where players are either fully cooperative or fully opposed. Much work in the area of MARL has concentrated on these classes of SGs, and algorithms with good theoretical guarantees exist for each of them. In this paper, we analyze a number of algorithms for such games.

3. Learning in CISGs

In CISGs, the payoffs are identical for all agents. That is, for any given choice of s, a and s' and any pair i, j of agents, we have that $[R(s,a,s')]_i = [R(s,a,s')]_j$. Therefore, all agents have identical interests and we may speak of optimal joint policies, namely, policy profiles that maximize the common IHDR for the team of agents. Such profiles are also NEs because no agent can gain by deviating from them. CISGs pose all the standard challenges of single-agent RL, in particular the need to balance exploration and exploitation and to propagate new experience. In addition, they challenge the agents to coordinate behavior since to obtain maximum value may require that agents

select a particular joint action. On the other hand, CISGs do not require that agents confront the more difficult task of optimizing behavior against an adversary.

For efficient learning in CISGs, agents are required to coordinate on two levels: (i) select whether to explore or exploit in unison; and (ii) coordinate the exploration and exploitation moves. This requirement stems from the dependence of the team's next state on the actions of *all* its members. Hence, it is impossible for the team to exploit unless all agents exploit together, and using the same choice of exploitation strategy. Exploration, too, can be less effective when only some agents explore.

Furthermore, even when the model is known, multiple NEs yielding maximal payoffs to the agents are likely to exist, and the agents still face the task of reaching consensus on which specific NE to play.

This section describes and compares three algorithms for learning in CISGs: OAL (Wang and Sandholm, 2002), FriendQ (Littman, 2001), and Rmax (Brafman and Tennenholtz, 2002). They were selected because each embodies a different approach to learning, while guaranteeing convergence to optimal behavior in CISGs. Diverse variants of these algorithms are examined with the aim of gaining better understanding of their performance with respect to their approach to exploration-exploitation, information propagation, and coordination tasks.[4] These variants and the tasks on which they were tested are described in the following subsections.

3.1 FriendQ

FriendQ (Littman, 2001) extends single agent Q-learning into CISGs. After taking a joint action $a = (a_1, ..., a_n)$ in state s at time t and reaching state s' with reward r_{cur}, each agent updates its Q-value estimates for $\langle s, a \rangle$ as follows:

$$Q_t(s,a) \leftarrow (1-\alpha_t)Q_{t-1}(s,a) + \alpha_t \left(r_{cur} + \gamma \max_{a' \in A} Q(s', a') \right).$$

As in single agent Q-learning, given that $\sum_{t=0}^{\infty} \alpha_t = \infty$, $\sum_{t=0}^{\infty} \alpha_t^2 < \infty$ and that every joint action is performed infinitely often in every state, the Q-values are guaranteed to converge asymptotically to Q^* (Littman, 2001). Convergence to optimal behavior is achieved using *Greedy in the Limit with Infinite Exploration Learning Policies* (GLIELP) (Sutton and Barto, 1998).

There are two types of GLIELPs, *directed* and *undirected*. Directed GLIELPs reason about the uncertainty of the current belief about action values (Kaelbling, 1993; Dearden et al., 1998, 1999; Chalkiadakis and Boutilier, 2003). However, the computational complexity of the underlying statistical methods makes directed exploration impractical for simulations of the size conducted in this study.[5] Two popular undirected exploration methods are ε-greedy action selection and Boltzman distributed action selection. There is no established technique for applying Boltzman exploration to FriendQ, so in our experiments it is executed with ε-greedy exploration only. ε-greedy exploration is applied to SGs in the following way: each agent randomly picks an exploratory private action with probability ε, and with probability $1-\varepsilon$ takes its part of an optimal (greedy) joint action with

4. By this we mean the ability of the algorithm to propagate information observed in one state to other states. For example, Q-learning does not propagate information beyond the current state, unless techniques such as eligibility traces are used.

5. It can be argued that many realistic applications impose severe constraints on the length of trajectories. In this case, directed exploration techniques and techniques such as transfer learning appear to be essential for success. Conducting a study of algorithms for such contexts would seem to be of great interest.

respect to the current Q-value (Claus and Boutilier, 1997). ε is asymptotically decreased to zero over time.

Since full state observability, perfect monitoring, and identical initial Q-values to all agents are assumed, all agents maintain identical Q-values throughout the process, and consequently the same classification of greedy actions. But, two problems arise: (i) Because randomization is used to select exploration *or* exploitation, the agents cannot coordinate their choice of when and what to explore. (ii) In the case of multiple optimal policies, that is, several joint actions with maximal Q-values in a certain state, the agents must agree on one such action. The original FriendQ algorithm has no explicit mechanism for handling these issues.

This work compares some enhanced versions of FriendQ: First, Uncoordinated FriendQ (UFQ), the simple version described above, is tested. Next, the effect of adding coordination of greedy joint actions by using techniques introduced by Brafman and Tennenholtz (2003) is examined. Basically, a shared order over joint actions is used for selecting among equivalent NEs. If such an order is not built into the agents, it is established during a preliminary phase using an existing technique (Brafman and Tennenholtz, 2003). This version is referred to as Coordinated FriendQ (CFQ). Then, coordination of exploration and exploratory actions is added in Deterministic FriendQ (DFQ). In DFQ, the agents explore and exploit in unison, always exploring the least tried joint action. An exploratory action is taken each $\lfloor 1/\varepsilon \rfloor' th$ move. Finally, we add Eligibility Traces (Sutton and Barto, 1998) to DFQ (ETDFQ).[6] Eligibility Traces propagate new experience to update Q-values of previously visited states and not only the most recently visited state.

3.2 OAL

OAL combines classic *model-based* reinforcement learning with a new *fictitious play* algorithm for action and equilibrium selection named BAP (Biased Adaptive Play) (Wang and Sandholm, 2002). BAP is an action-selection method for a class of repeated games that contains common interest games. Here, BAP is described in the context of common interest repeated games. Let m and k be integers such that $1 \leq k \leq m$. Each agent maintains a memory of the past m joint actions. At the first m steps of the repeated game, each player randomly chooses its actions. Starting from step $m+1$, each agent randomly samples k out of the m most recent joint actions. Let SP_i be the set of k joint actions drawn by agent i at some time step. If (i) there is a joint action a' that is estimated to be ε-optimal, such that for all $a \in SP_i$, $a^{-i} \subset a'$ (where $a^{-i} \subset a'$ denotes the fact that the individual actions of all agents other than agent i are identical in a and a'), and (ii) there is at least one optimal joint action $a \in SP_i$, then agent i chooses its part of the most recent optimal joint action in SP_i. If the above two conditions are not met, then agent i chooses an action a_i that maximizes its expected payoff under the assumption that the other players' sampled history reflects their future behavior. This type of action selection is known as *fictitious play* (Brown, 1951).

$$EP(a_i) = \sum_{a^{-i} \in SP_i} R(a_i \cup a^{-i}) \frac{N(a^{-i}, SP_i)}{k}$$

where $N(a^{-i}, SP_i)$ is the number of occurrences of a^{-i} in SP_i. Given that there is no sub-optimal NE and $m \geq k(n+2)$, BAP is guaranteed to converge to a NE. It was shown that, for every game that satisfies these conditions, there is some positive probability p and some positive integer T such that

6. A variant of Eligibility Traces called Replacing Traces was used (Singh and Sutton, 1996). In Replacing Traces, the eligibility traces are bounded by 1.

for any history of plays, with probability at least p, BAP converges to a consensus in T steps. That is, all players agree in the same joint-action which is a NE.

After observing a transition from state s on action a, OAL updates Q-values according to the learning rule

$$Q_{t+1}(s,a) = R_t(s,a) + \gamma \sum_{s'} T_t(s,a,s') \max_{a'} Q_t(s',a')$$

where R_t, the approximated mean reward, and T_t, the approximated transition probability are estimated using the statistics gathered up to time t. At each step, OAL constructs a Virtual Game (VG) for the current state-game (the matrix game defined by the current state's Q-values) and plays according to it. The VG has common payoff 1 for any optimal joint action and payoff 0 for any other action. In our implementation we use the VG in conjunction with ε-greedy as well as Boltzman action selection. Boltzman action selection is implemented as follows: At each step, an action is sampled according to the Boltzman distribution induced by the Expected Payoffs in the current VG

$$\frac{e^{EP(s,a)/\tau}}{\sum_b e^{EP(s,b)/\tau}} .$$

If a sub-optimal action is sampled, it is explored by the agent, otherwise BAP is executed on the VG to select an exploitation action.

We examine OAL also with an addition of Prioritized Sweeping (PS) (Moore and Atkeson, 1993) to the underlying Q-learning algorithm (PSOAL). PS is a heuristic method for optimizing finite propagation of TD-errors in the model. PS attempts to order propagation according to the size of the change to the Q-values, for example, states that are liable to have a greater update should be updated first. For comparison, a combination of the model-based Q-learning algorithm used by OAL with the action and equilibrium-selection technique used by CFQ is also examined. This combination is referred to as ModelQ (MQ).

3.3 Rmax

Rmax (Brafman and Tennenholtz, 2002) is a model-based algorithm designed to handle learning in MDPs and in fixed-sum stochastic games. However, because Rmax does not make random decisions (e.g., random exploration), its MDP version can also be used to tackle MARL in CISGs. Brafman and Tennenholtz (2003) view a CISG as an MDP controlled by a distributed team of agents and show how such a team can coordinate its behavior given a deterministic algorithm such as Rmax. In a preliminary phase of the game, a protocol is used to establish common knowledge of the individual action sets, of orders over these sets, and of an order over the agents. At each point in time, all agents have an identical model of the environment and know what joint action needs to be executed next (when a number of actions are optimal with respect to the current state, the agents use the shared order over joint actions to select among these actions). Thus, each agent plays its part of this action. It is shown that even weaker coordination devices can be used, and that these ideas can be employed even under imperfect monitoring.

Rmax maintains a model of the environment, initialized in a particular optimistic manner. It always behaves optimally with respect to its current model, while updating this model (and hence its behavior) when new observations are made. The model M' used by Rmax consists of $n+1$ states $S' = \{s_0, ..., s_n\}$ where $s_1, ..., s_n$ correspond to the states of the real model M, and s_0 is a fictitious state.[7] The transition probabilities in M' are initialized to $T_{M'}(s,a,s_0) = 1 \ \forall \langle s,a \rangle \in S' \times A$. The

7. The model may be constructed online as states are discovered.

reward function is initialized to $R_{M'}(s,a) = R_{max}\ \forall \langle s,a\rangle \in S' \times A$, where R_{max} is an upper bound on $\max_{s\in S, a\in A} R(s,a)$. Each state/joint-action pair in M' is classified either as *known* or as *unknown*. Initially, all entries are unknown.

Rmax computes an optimal policy with respect to M' and follows this policy until some entry becomes known. It keeps the following records: (i) number of times each action was taken at each state and the resulting state; (ii) the actual rewards, $r_{ac}(s,a)$, received at each entry. An entry (s,a) becomes known after it has been sampled $K1$ times, such that with high probability $T_M(s,a,s') - \rho \leq PE(s,a,s'|K1) \leq T_M(s,a,s') + \rho$ where T_M is the transition function in M, $PE(s,a,\cdot\ |K1)$ is the empirical transition probability according to the $K1$ samples, and ρ is the accuracy required from M'. When an entry (s,a) becomes known, the following updates are made: $T_{M'}(s,a,\cdot) \leftarrow PE(s,a,\cdot\ |K1)$ and $R_{M'}(s,a) \leftarrow r_{ac}(s,a)$. Then, a new deterministic optimal policy with respect to the updated model is computed and followed. Rmax converges to an ε-optimal policy in polynomial number of steps.

The worst-case bounds on $K1$ (Brafman and Tennenholtz, 2002) assume maximal entropy on the transition probabilities, that is, $T_M(s,a,s') = 1/|S|$ for all s,a,s'. These bounds, although polynomial, are impractical. In the experiments, these bounds are violated, which enables us to eliminate knowledge of the state space size. Furthermore, R_{max} is not assumed to be known. Instead, it is initialized to some positive value and updated online to be twice the highest reward encountered so far.

3.4 Discussion of Algorithms

Returning to the FriendQ algorithm, the efficiency of GLIELPs depends on the topology and dynamic of the environment. If the probability to explore falls low before "profitable" parts of the environment are sufficiently sampled, the increasing bias to exploit may keep the agents in suboptimal states. As a result, GLIELPs can exhibit significant differences depending on the particular schedule of exploration. In model free algorithms, and FriendQ, in particular, this phenomenon is intensified by the decreasing learning rate that makes learning from the same experience slower over time. GLIELPs also suffer from their inability to completely stop exploration at some point. Thus, even when greedy behavior is optimal, the agent is unable to attain optimal return.

The exploration method of Rmax is less susceptible to the structure of the environment. As long as Rmax cannot achieve actual return ε-close to optimal, it will have a strong bias for exploration since unknown entries seem very attractive. This strategy is profitable when the model can be learned in a short time. However, the theoretical worst-case bounds for convergence in Rmax are impractical. In practice, much lower values of $K1$ suffice. Bayesian exploration (Dearden et al., 1999; Chalkiadakis and Boutilier, 2003) and locality considerations might help to obtain better adaptive bounds, but these approaches are not pursued here.

GLIELPs make learning "slower" as the agents get "older". To accelerate learning, an algorithm can try to use new experience in a more exhaustive manner, using it to improve behavior in previously visited states. Eligibility traces are used to propagate information in FriendQ. In model-based algorithms, an exhaustive computation per new experience is too expensive (in CPU time). Thus, OAL is tested with Prioritized Sweeping and Rmax makes one exhaustive computation each time a new entry becomes known (and does no further computation).

Exploration in FriendQ and OAL algorithms is not coordinated. Each of the agents independently chooses an exploratory action with some diminishing probability. Thus, joint actions that

have no element (private action) of some optimal joint action have a lower chance of being explored. Hence, some popular techniques for decreasing exploration in the single agent case lead to finite exploration in the multi agent case. For example, taking $\varepsilon = 1/time$ for ε-greedy policies will make the chance of exploring such joint actions $1/time^n$, where *n* is the number of agents.

Equilibrium selection in Rmax and CFQ comes with no cost. In OAL, it is essentially a random protocol for achieving consensus. This protocol may take long to reach consensus with respect to the current Q-values, but provides for another exploration mechanism at early stages, when Q-values are frequently updated.

All three algorithms have parameters that need to be preset. Parameter tuning is task specific and based more on intuition and trial and error than on theoretical results. FriendQ has a range of parameters for decaying the learning rate, the exploration probability and the eligibility traces, which also pose inter-parameter dependencies. For decreasing the learning rate parameter, we used the results presented in Even-Dar and Mansour (2003). OAL takes parameters for history sample size and for exploration. In this respect, Rmax is friendlier. It has a single and very intuitive parameter—number of visits to declare an entry *known*. When the value of this parameter is high, a very accurate model is learned and behavior will be, eventually, very close to optimal. But this comes at the cost of possibly unnecessary exploration and delayed exploitation.

Table 1 summarizes the differences between the three algorithms according to the features mentioned above.

property	**UFQ**	**CFQ**	**DFQ**	**OAL**	**Rmax**
Exploration	ε-greedy with exponential and polynomial decay of ε			Boltzman & ε-greedy (polynomial decay)	Greedy w.r.t optimistic model
Coordination	None	Common order; non-deterministic	Common order; deterministic	Random protocol; non-deterministic	Common order; deterministic
Greedy Action Selection	Maximize common return			Fictitious play/consensus	Maximize common return
Information Propagation	Single sweep per step & ET			Single sweep per step & PS	Limited exhaustive computations
Parameter Tuning	Many parameters, task sensitive, not intuitive				One parameter, not sensitive, intuitive

Table 1: Major differences between the experimented algorithms.

3.5 Experimental Results & Analysis

This section describes experiments with the FriendQ, OAL, and Rmax algorithms on three CISGs. The games were designed to evaluate the effects of exploration, coordination, and information-propagation methods on performance in different environments. All games are grid-based. The grid cells are referred to by *(row, column)* coordinates indexed from $(0,0)$ at the top left corner of the grid. In all games, the available actions for each agent are *up*, *down*, *left*, *right*, and *stand*. The games were played in both deterministic and stochastic modes. In deterministic mode, the action always succeeds. In stochastic mode, each action, excluding *stand*, succeeds with probability 0.6. With probability 0.4, uniformly at random, the agent is moved to the each of the other adjacent cells or left in place. Action *stand* succeeds with probability 1. If the direction of motion is towards a wall, the player remains in place. Similarly, two players cannot occupy the same position. Therefore, if

two agents attempt to move into the same cell, they both fail and remain in their current place. Note that in stochastic mode, these rules apply to the actual (stochastic) outcome of the action.

Additionally, for each game, we examined the results of learning by heterogeneous agents, that is, agents using different learning algorithms. Finally, to test how well each algorithm scales up with the number of players, we introduced a fourth game in which the state and action spaces do not grow too fast with the number of players. With this game, we were able to play games with up to 5 players.

Adjusting the parameters of the different algorithms was done by a process of trial and error. The algorithms were repeatedly executed in an experimental setup, varying their parameters between executions until some optimum was reached. The parameters that achieved the best performance were then used throughout. Each set of experimental conditions, other than those related to Rmax, was subjected to 100 repeated trials. For Rmax, 20 trials were carried out using $K1 = 50$, 40 with $K1 = 100$ and 40 with $K1 = 200$.[8] The discount factor was 0.98 in all trials. Unless mentioned otherwise, the presented results are averages over all trials.

The following parameter settings were tested:

FriendQ

Exploration: ε-greedy with (i) $\varepsilon_t \leftarrow 1/count_t^{0.5000001}$ where $count_t$ is the number of exploratory steps taken by time t. (ii)$\varepsilon_t \leftarrow 0.99998^{count_t}$. (Unless specified otherwise, (i) is used.)[9]

Learning rate: $\alpha_{s,a} \leftarrow 1/n(s,a)^{0.5000001}$ where $n(s,a)$ is the number of times action a was taken in state s.

Q-value were initialized to 0.

OAL

Exploration: For ε-greedy, $\varepsilon_t \leftarrow 1/count_t^{0.5000001}$, as in FriendQ. For Boltzman exploration, the temperature parameter was decreased by $\tau \leftarrow 100/count^{0.7}$.

History: Random history sample size $k = 5$. History memory size $m = 20$ (m must satisfy $m \geq k \times (n+2)$. OAL with ε-greedy exploration is referred to as ε-OAL, and OAL with Boltzman exploration is referred to as B-OAL.

Q-value were initialized to 0.

Rmax

Sampling: values of 50, 100, 200 and 300 for K1 (visits to mark an entry known) were tested.

Accuracy of Policy Iteration: Offline policy iteration was halted when the difference between two successive approximations was less than 0.001.

8. Because Rmax is a deterministic algorithm, fewer samples were required.
9. Exponential decay of ε violates the infinite exploration condition for convergence.

3.5.1 GAME 1

This game, introduced in Hu and Wellman (1998), was devised to emphasize the effects of equilibrium-selection methods. It has a single goal state (the only reward-yielding state) and several optimal ways of reaching it. The game is depicted in Figure 1. $S(X)$ and $G(X)$ are the respective initial and goal positions of agent X. In the goal state G, both agents are in their goal positions and their reward is 48. Upon reaching the goal, the agents are reset to their initial position. The underlying SG has 71 states. The optimal behavior in deterministic mode reaches G in four steps and yields an average reward per step (a.r.p.s.) of 12.[10] There are 11 different optimal equilibria. In stochastic mode, the optimal policies yield an a.r.p.s. of $\sim$5.285. Algorithms were executed for 10^7 rounds on both settings.

S(B)		G(A)

Figure 1: Game 1 - initial and goal states.

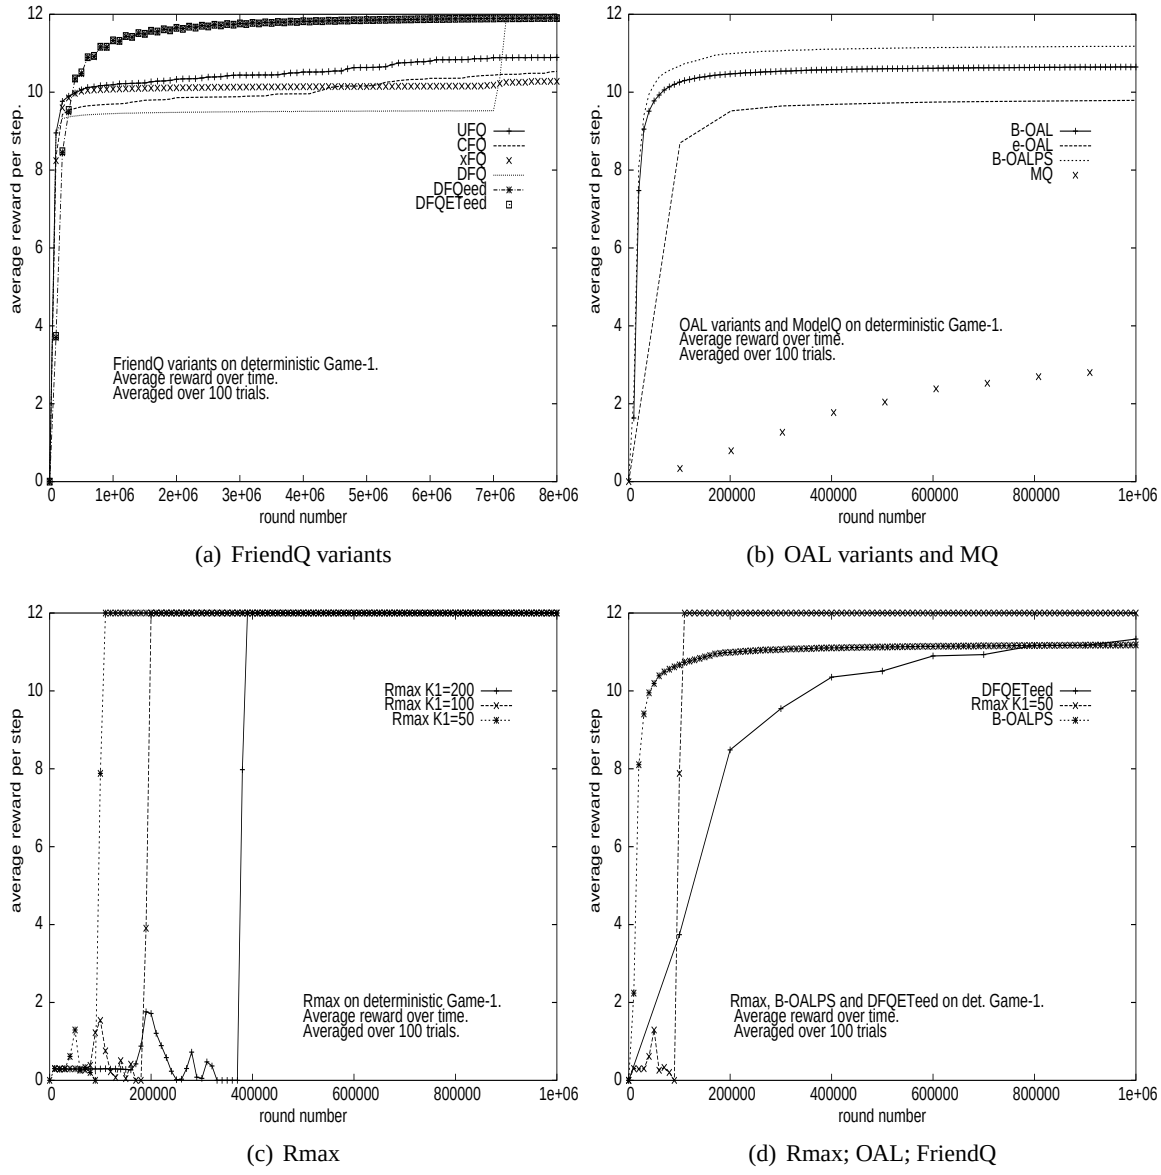
Deterministic Mode

Table 2 reports the number of trials (of 100 in total) in which each algorithm learned a policy, with four levels of final performance based on the number of steps required to reach the goal. For this deterministic domain, we find this measure, which is directly correlated with the more standard a.r.p.s. measure, to be more informative. Here xFQ is a variant of FriendQ in which the agents explore in unison but do not coordinate exploratory actions. The suffix "εed" denotes exponential decay of ε. In the present context, the agents' learning of an optimal policy means that their greedy choice of actions is optimal. That is, with any residual exploration deactivated. Figure 2 presents the a.r.p.s. obtained by the agents over time.

steps to goal	UFQ	CFQ	xFQ	DFQ	DFQεed	ε-OAL	B-OAL	B-OALPS	MQ	Rmax
4	62	49	47	100	100	26	49	41/60	1	100
5	38	49	46			62	51	19/60	49	
6+		2	7			12			29	
∞									21	

Table 2: Game 1 – classification of final performance of learned policies for 100 trials of each algorithm

10. As we noted earlier, our implementation is based on the widely used discounted reward model. But in our goal oriented domains, optimal and near-optimal strategies require a relatively small number of steps to reach the goal. Thus, we chose to report the performance of the learned policies using more intuitive measures such as average reward per step and average steps to reach the goal.



(a) FriendQ variants

(b) OAL variants and MQ

(c) Rmax

(d) Rmax; OAL; FriendQ

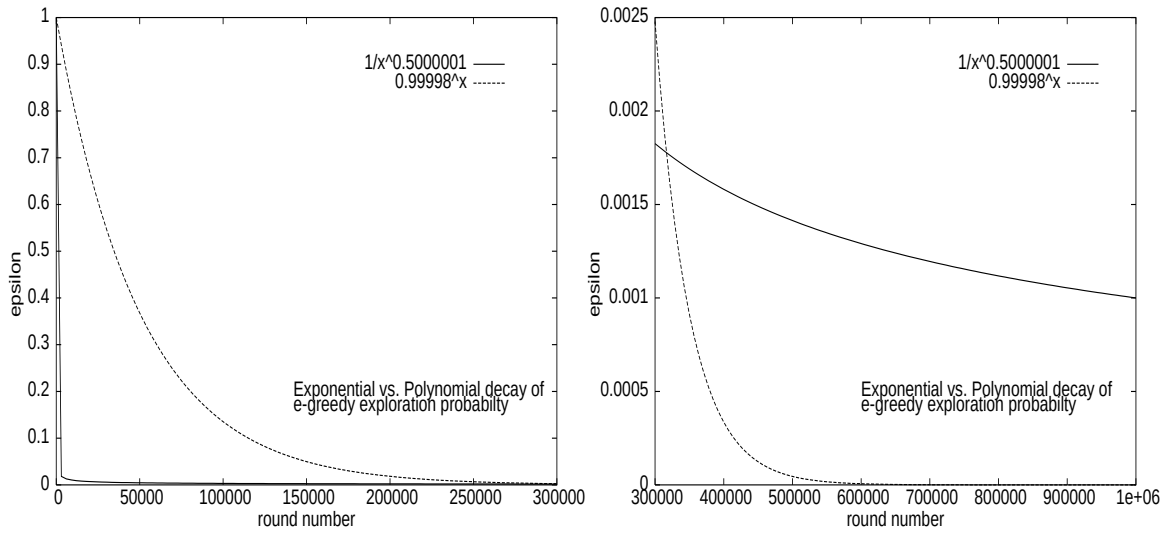
Figure 2: Game 1 – average reward per step under deterministic mode. (a) presents first 8×10^6 rounds. (b), (c) and (d) present first 10^6 rounds.

As can be inferred from the table, in this problem optimal behavior is such that the agents reach the goal in four steps. FriendQ converges quickly to second-best behavior (Figure 2a). From that point on, the average learning curves of UFQ, CFQ and xFQ increase stepwise rather than continuously (although this is a bit difficult to see in the figure). This behavior results from a sudden switch of the FriendQ agents from sub-optimal to optimal behavior once the relative order of the Q-values of different agents changes.

ε-OAL does not present a similar trend. In the trials in which OAL converged to second-best behavior in the first 2.5×10^5 rounds, it failed to find an optimal policy even after 10^7 rounds (Figure 2b). In DFQ, since exploration is deterministic, this switch is always at the same time, specifically after 7×10^6 rounds(Fig. 2a).

Surprisingly, UFQ fares better than CFQ (Table 2, Fig. 2a), in spite of its less sophisticated coordination strategy. At an early learning stage, dis-coordination leads to exploration. Later on, the estimated Q-values of optimal actions are rarely equal, and thus, coordinating exploitation does not pose a problem (at the examined time interval). Exponential decay of ε supplies more exploration at an early period than polynomial decay (Fig. 3) leading to faster convergence of DFQεed (Fig. 2a).

Eligibility traces did not contribute much in this example. The parameters of eligibility traces were hard to tune and very sensitive to change in other parameters or environment dynamics.



(a) Rounds 1 to 300,000

(b) Rounds 300,000 to 1,000,000

Figure 3: Exponential vs. polynomial decay of ε-greedy exploration probability

OAL agents converge relatively quickly to optimal or second-best behavior, and from that time onwards stick to their behavior (Fig. 2b). Whether, in the latter case, they fail to structure the Q-values properly, or the fictitious play prevents the agents from changing their behavior after the Q-values are ordered properly, is not clear from the data. B-OAL converges faster and more often to optimal than ε-OAL (Fig. 2b, Table 2). This behavior seems to stem from the effect of the decay methods we used. The Boltzman method yields more exploration than the ε-greedy method in the early period of learning. Later on, ε-greedy maintains a low exploration probability that decays very slowly while Boltzman exploration drops faster to zero. Thus, even when ε-OAL learns optimal behavior, it keeps achieving only near-optimal average-reward.

As expected B-OALPS improves on the performance of B-OAL (Fig. 2b, Table 2) because of its more rapid propagation of learned information.

The performance of ModelQ is inferior to that of OAL (Fig. 2b, Table 2), presumably because ModelQ does not explore as much as OAL: At early stages of learning, fictitious play provides OAL with other means of exploration. When the agents make many stochastic action choices in

early stages of learning, fictitious play amplifies the random behavior. However, at later stages of learning, deviation from constant action choice is rare and will probably not affect fictitious play. In this setting, ModelQ shows slower convergence than the model-free FriendQ.

The learning graph of Rmax can be precisely divided into two periods, an initial learning period in which Rmax attains very low return due to exploration, followed by a period of exploitation in which Rmax attains optimal return (Fig. 2c). The length of the initial period depends linearly on $K1$.[11] Figure 2d compares the best performing variant of each algorithm.

Stochastic Mode

Figure 4 presents the results for the stochastic mode. As expected, due to the stochastic effects of actions, the value of the optimal policy decreases, and more importantly, the learning algorithms require more trials to converge. By contrast to the deterministic case, MQ performs as well as ε-OAL (Fig. 4a). This improvement is attributable to additional exploration stemming from the stochastic nature of the environment. For the same reason, CFQ performs almost the same as UFQ (Fig. 4a). When we compare the gap between the DFQεed to U/CFQ at the first 10^6 rounds in stochastic mode vs. the deterministic mode we find that the gap is smaller. This difference is due to the fact that the additional early exploration supplied by the exponential decay of ε is redundant in the stochastic case. The slightly higher return gained by DFQεed later on is due to the faster decay of ε. Another interesting difference from the deterministic setting is that initially ε-OAL gains lower return than B-OAL but while B-OAL keeps attaining the same average reward, ε-OAL improves slowly over time and eventually gains a higher average reward than B-OAL. In this case, the slower convergence of the exploration probability to zero enables ε-OAL to "overcome" randomly "bad" exploration in initial learning phases.

Rmax behaves similarly in stochastic and deterministic modes. While the other algorithms achieve only near-optimal return, Rmax attains optimal return (Fig. 4b,c). Rmax's strong exploration bias results in low return until model entries are known. From that point on, Rmax attains an optimal return. The histogram (Fig. 4d) shows that Rmax converges to higher return than the other algorithms not only in the average case but also in the worst case (i.e., almost all runs of Rmax were better than the best runs for the other algorithms). Very low values for $K1$, which mean rough transition probability estimates, are enough for computing near-optimal behavior. Indeed, the exploration vs. exploitation tradeoff is evident even in this simple example. We see how a smaller value of $K1$ leads to faster convergence, but at the cost of slightly smaller average reward.

Overall, it appears that the major issue for the FQ and OAL class of algorithms is exploration. As the space of joint-actions is quite large, there are many relevant options to try. Especially in the deterministic case, the rather standard exploration techniques we used appear to be insufficient. Although stochastic domains naturally lead to more exploration, we can see that the model-free algorithms are sub-optimal. It appears that model-free algorithms—at least in their standard form—have difficulty determining whether certain states were explored sufficiently, and that standard exploration schemes are too crude. Overall, many of the phenomena observed in Game 1 were present in Games 2 and 3. Therefore, in the following experiments, only phenomena not observed in Game 1 will be emphasized.

11. If it is known ahead of time that the environment is deterministic, then $K1$ can be set to 1. Similar locality considerations on stochastic environments can help determine tight bounds on $K1$.

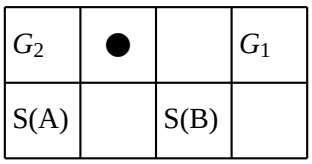
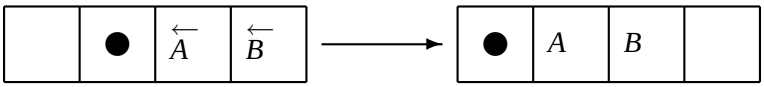
3.5.2 GAME 2

This game was designed to minimize the effects of equilibrium selection, to show how GLIELPs may keep agents exploiting suboptimal possibilities, and to emphasize the importance of coordinated exploration. The game has four goal states and one optimal equilibrium. The game is depicted in Figure 5(a). It consists of an additional element, an object that can be moved by the agents. The agents can move in four directions or stay in place. They can push the object by standing to its right(left) and moving left(right) and pull the object by standing to its right(left) and

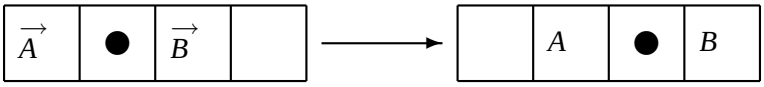
moving right(left). However, the object is too heavy for one agent and requires cooperation of the two agents to be moved. The manner by which the object is moved is depicted in Figure 5(b). Note that the push/pull effect is a by-product of the agents' moves. Thus, in stochastic mode, what determines if the action is push or pull is not the chosen action but its actual effect.



(a) Initial state and Goal states.



(b1) Moving the object by pushing simultaneously.
(Agents' order does not matter).



(b2) Moving the object by pushing and pulling simultaneously.
(Agents' order does not matter).

Figure 5: Game 2

The agents' goal is to move the object into one of the upper corners of the grid, at which point the game is reset to its initial state. Moving the object to the upper right (G_1) or left (G_2) corner yields a reward of 80 and 27, respectively. The optimal behavior under deterministic mode is to move the object to G_1 in 8 steps. The average reward per step of an optimal strategy under deterministic mode is 10, and the discounted return is ~ 465. The second-best strategy is moving the object to G_2 in 4 steps, with an a.r.p.s. of 9 and discounted return of ~ 440. In stochastic mode, the optimal policy may stochastically lead to one of the goal positions. The a.r.p.s. of the optimal policy in stochastic mode is ~ 3.8. The underlying CISG contains 164 states. Algorithms were executed for 3×10^7 rounds.

Deterministic Mode

Table 3 classifies the number of trials (of 100 per algorithm) according to the algorithms and learned policies. Figure 6 shows the a.r.p.s. over time obtained by the different algorithms.

The main reasons for the sub-optimal performance of OAL and CFQ in this game are: (i) Random exploration has a greater chance of reaching G_2 than G_1. Discovering G_2 before G_1 further reduces the chance of visiting G_1 because of the increasing bias toward exploitation. (ii) Exploration of the CFQ and OAL agents is not coordinated. If reaching G_2 is the current greedy policy, then G_1 will not be visited unless both agents explore simultaneously. Game 1 demonstrated an advantage of exponential decay of the ε-greedy exploration probability over polynomial decay of this probability. Game 2 demonstrates an opposite phenomenon, Fig. 6a and Table 3 show that CFQ does better with polynomial decay of ε than with exponential decay. This result stems from finite exploration supplied by exponential decay. However, this finite amount of exploration is sufficient

Goal	steps to goal	CFQ	CFQεed	DFQεed	ε-OAL	B-OAL	Rmax
G_1	8			100		1	100
G_2	3	99	65		54	91	
G_2	4	1	35		46	8

when exploration is coordinated as shown by the learning curve of DFQεed (Fig. 6b) and by Table 3. Furthermore, DFQεed converges to optimal greedy behavior while both CFQ variants do not.

Stochastic Mode

Figure 7 presents statistics for the stochastic mode. It exhibits two interesting phenomena that have not been observed in the previous experiments. One is that, in contrast to previous results, ModelQ outperforms ε-OAL (Fig. 7a,c). Since the only difference between ε-OAL and ModelQ is the greedy action selection method, a reasonable explanation is that BAP (OAL's action selection mechanism) delays behavioral change that should follow Q-value updates (which in turn may delay learning of Q-values). This outcome is because BAP plays a best response to the strategy implied by the other agent's past plays. Since both agents react to each other's past plays using BAP, it may take long to converge to a new NE when the optimal joint actions are changed. The second phenomenon is that Rmax requires larger values of $K1$ to converge to optimal behavior (Fig. 7b). This finding can be explained by the fact that the optimal behavior involves longer cycles of state transitions and hence the model has to be more accurate.

As in Game 1, we see that exploration strategies have a great impact on the ability of different algorithms to converge. In this respect, Game 2 highlights the need for coordinated exploration.

Thus, in cooperative multi-agent systems, we face the standard problem, clearly visible in Game 1, of ensuring sufficient exploration, but we need to ensure that this exploration is effective by coordinating exploratory moves of different agents.

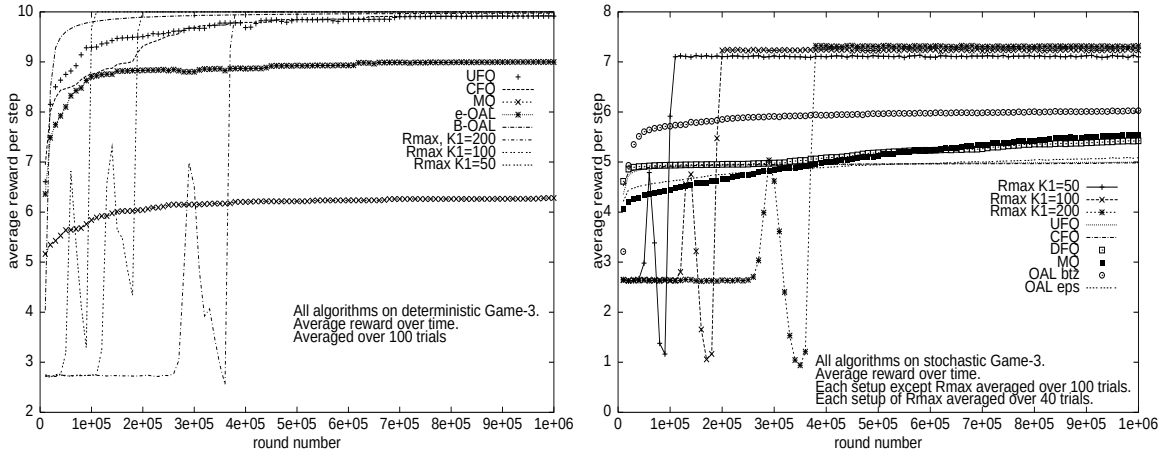
(c) Average Reward of Learned Policies per Number of Trials

Figure 7: Game 2 – Average reward per step and learned policies per number of trials under stochastic mode. (a) presents all 3×10^7 rounds; (b) presents first 3×10^6 rounds.

3.5.3 GAME 3

In the previous games, one had to explore considerable parts of the state space in order to construct good policies. This game is characterized by a maximum return attainable by staying in a small local set of states anywhere on the state graph. The initial position of the agents within a 3×3 grid is random. They are rewarded for reaching a position in which their locations are adjacent. If this position is attained by unaltered positions of both agents, the reward is 5. If movement is involved, the reward is 10. Algorithms were executed for 10^6 rounds.

As opposed to previous experiments, in deterministic mode, B-OAL and the FriendQ variants converged faster to optimal (greedy) behavior than Rmax (Fig. 8a). Rmax explores the whole model before it starts exploiting while FriendQ's and OAL's choice of greedy actions is optimal long before good estimates of all Q-values are attained. However, in stochastic mode the GLIELPs no longer have this advantage since stochastic transitions do not enable the agents to concentrate on exploiting a local set of states (Fig. 8b).



(a) deterministic mode (b) stochastic mode

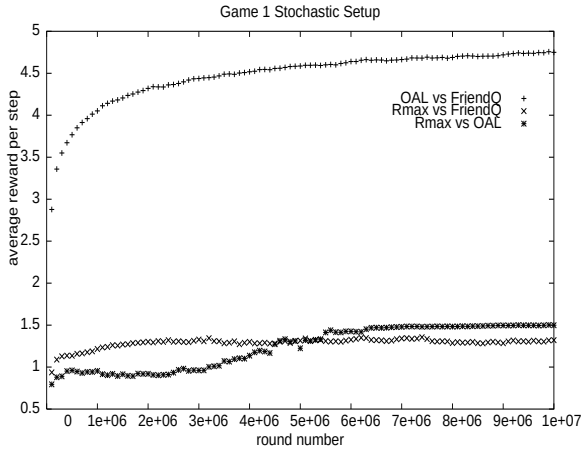
Figure 8: Game 3 – average reward per step under deterministic and stochastic modes.

3.5.4 HETEROGENEOUS PLAYERS

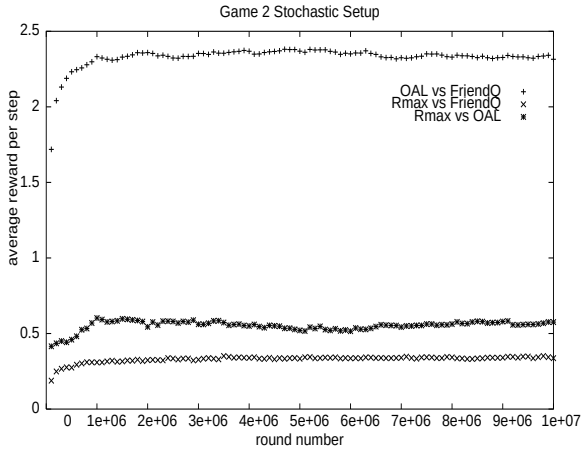
A CISG is most naturally viewed as a model of a distributed stochastic system. As such, it is natural to have in mind a view of a system's designer, and one would expect such a designer to equip the players with identical algorithms. However, CISGs arise also when self-interested agents need to coordinate, typically on the use of some resource, where coordination is beneficial to all parties involved. Examples include which side of the road to travel on, the meaning attached to a symbol, etc. Thus, it is natural to ask how the algorithms tested fare in the context of other algorithms. We reran the above experiments with pairs of different algorithms. The results, presented in Figure 9 are, quite uniform (similar performance is observed in the deterministic games). The top performance, and as is clearly visible, by a wide margin, was obtained by OAL+FriendQ. Pairs containing Rmax performed much worse, with Rmax+OAL typically fairing slightly better than Rmax+FriendQ. In fact, comparing the results to the homogeneous case, the OAL+FriendQ combination performed almost optimally in Game 1: 4.7 vs. 5. In Game 2 it obtained 2.3 vs. 3.8, and in Game 3 it achieved 5.85 vs. 7.2.[12] And while Rmax and, to a lesser extent, FriendQ do better against their own kind, OAL does better against FriendQ. It may be the case that for equilibrium selection, OAL's mechanism works best when one agent "insists" more on a particular equilibrium, thus more quickly breaking up symmetries.

These results might be interpreted as an indication of the "rigidity" of each of the algorithms. FriendQ is the simplest of the three algorithms, it makes no internal assumptions about its partners

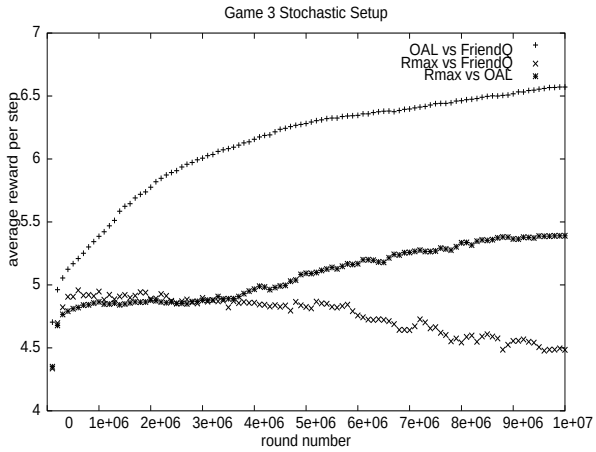
12. The version of FriendQ used was CFQ with replacing traces. The OAL version used ε-greedy exploration.



(a) Game 1 stochastic mode



(b) Game 2 stochastic mode



(c) Game 3 stochastic mode

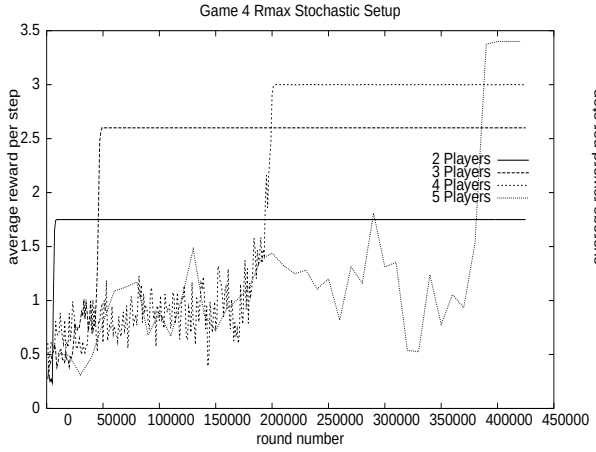
Figure 9: Heterogeneous play games 1-3.

and simply adapts. Rmax is at the other extreme, it strongly relies on the behavior of its partners in order to systematically explore and then exploit. OAL is somewhere in between. It does have a sophisticated mechanism for selecting among different equilibria, but this mechanism is stochastic and can handle noise, and is based on fictitious play, which is a mechanism that adapts to the empirical behavior of the other agents. Thus, one would expect Rmax to fail when its assumptions are not met, as its implicit coordination mechanism is based upon them. In contrast, FriendQ and OAL, which make weak internal assumptions about their peers, should work well, especially when their opponent shows some flexibility and adaptivity.

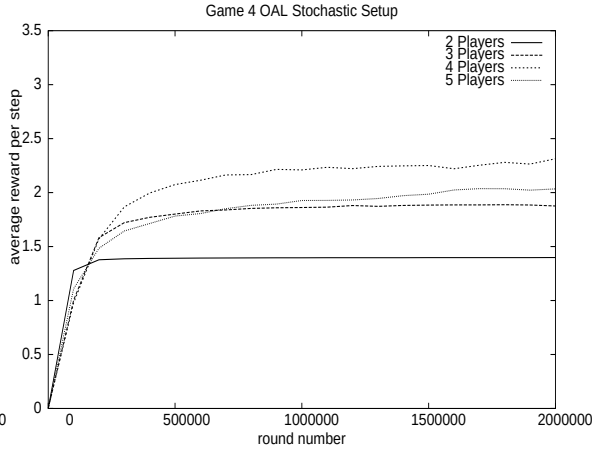
3.5.5 $n > 2$ PLAYERS

So far, we considered only two-player games. The reason is practical: Experiments conducted on large state spaces take long to execute. It is especially true for Rmax which must solve the MDP each time the model changes. This effort grows with the state-space, and the state-space grows

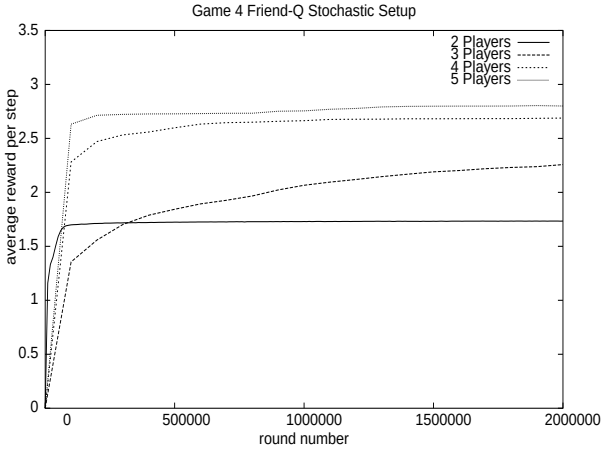
exponentially with the number of players. Thus, to get an idea of how these algorithms fare with a large number of players, we devised a simpler, fourth game in which we could run experiment with up to 5 players. This is a simple linear grid with 5 positions. Players can move to the left and the right. When two players attempt to move to the same position, the result is with probability 1/3 none move, and with probability 1/3 each one of the players makes the move and the other stays in place. In the initial state, player i is in position $5-i$. The goal position of each player is i. Generally, the reward at each state is the number of players located at their goal positions. However, when all players are in their goal position, they receive a reward of 3 *times* the number of players, at which point all players transition automatically to the initial position.



(a) Game 4 R-max



(b) Game 4 OAL



(c) Game 4 Friend-Q

Figure 10: Results for 2-5 players on game 4.

The results are presented in Figure 10. Note the difference in scale for the X-axis for OAL and FriendQ, which is intended to show that the suboptimal a.r.p.s. to which they converge does not increase even when we look at millions of steps. As in the previous section, we used the CFQ version of FriendQ with replacing traces, ε-greedy exploration for OAL, and $K_1 = 100$ for Rmax.

For all algorithms, the value is greater as the number of players increases due to the game's reward definition, which is sensitive to the number of players. All algorithms converge quickly on this game for all number of players. However, the values they converge to differ. Among the three algorithms, Rmax converges to the highest average per step reward, FriendQ is next, and OAL is last. The relative performance is consistent with the performance displayed in the three earlier two-player games. This finding is a reasonable indication that the relative performance of these algorithms is qualitatively similar regardless of the number of players, at least for small player sets.

3.5.6 SUMMARY

Section 3.5 presents an experimental study of three fundamentally different algorithm families for learning in CISGs. The results illustrate the strengths and weaknesses of different aspects of these algorithms in different settings, highlighting the accentuated importance of effective exploration, which is enabled in this class of games only by coordinated behavior, the advantage of deterministic behavior for attaining such coordinated behavior, and the benefits of propagation of information.

Each of the experimental domains emphasizes different aspects of the learning task in CISGs. The results show that the parameters of OAL and FriendQ are very sensitive to environmental topology and dynamic. Exploration and coordination strategies suitable for one environment may be very inefficient in other environments. Rmax, on the other hand, is stable in this respect. It has a single parameter, $K1$, that has to be preset. Its convergence time depends linearly on $K1$ (and the size of the state-action space) and it turns out that Rmax converges to near optimal behavior using values of $K1$ that achieve faster convergence than that of OAL and FriendQ. However, the convergence dynamics of Rmax does not suit tasks in which the agents must attain some value during the learning period, because during its exploration phase, Rmax is indifferent to rewards lower than R_{max}. However, Rmax is also the simplest algorithm, and thus it is easy to alter it, for instance, to obtain satisficing behavior, for example, by lowering the value of R_{max} in the model, or by starting with a moderate value and then increasing it as better values are observed. Overall, when we control the algorithm of all agents in the system, Rmax seems to be the best alternative—it converges quickly to values higher than those of OAL and FriendQ, it does not seem to be sensitive to an increase in the number of players, except through its effect on the state space, and most importantly, it has very simple exploration strategy. As we saw in games 1 and 2, the choice of exploration strategy has much influence on the results of FriendQ and OAL, and the precise choice is sensitive to the nature of the game, number of equilibria and their nature. Thus, the simple exploration behavior of Rmax and the potential to alter it in various transparent ways is a clear benefit. Yet, when we may need to coordinate with other players with unknown coordination mechanisms, or if our underlying state space is too big for repeated value computations, FriendQ seems to offer the best choice.

4. Learning in FSSGs

In two-player *Zero Sum* SGs (ZSSGs), the players' payoffs sum up to zero at every entry. That is, $[R(s,a^1,a^2)]_1 = -[R(s,a^1,a^2)]_2$ for every $s \in S$, $a^1 \in A_1$ and $a^2 \in A_2$. Such payoffs indicate that the agents' interests completely conflict. A ZSSG can be modeled with a single payoff function $R'(s,a^1,a^2) = [R(s,a^1,a^2)]_1$ by redefining Player's 2 objective as to minimize the IHDR (infinite horizon discounted reward). For the rest of this section, it is assumed that Player 1 is the maximizer and Player 2 is the minimizer the payoff function R. Let $V(s,\pi_1,\pi_2)$ denote the expected IHDR for starting at state s and playing the profile (π_1,π_2) of stationary mixed policies there-

after, and $V(\pi_1,\pi_2) = (V(1,\pi_1,\pi_2),...,V(|S|,\pi_1,\pi_2))$. Since the best response in a ZSSG is also the worst for the opponent, ZSSGs have a unique NE value. To see this, assume by negation that $V(s,\pi_1,\pi_2) > V(s,\mu_1,\mu_2)$ and that both (π_1,π_2) and (μ_1,μ_2) are NE. Since $\pi_2 \in BR(\pi_1)$, it follows that $V(s,\pi_1,\mu_2) \geq V(s,\pi_1,\pi_2) > V(s,\mu_1,\mu_2)$, which contradicts $\mu_1 \in BR(\mu_2)$. The value of a policy π may be defined as $V(\pi,BR(\pi))$. In ZSSGs, this definition coincides with that of a NE (any pair of optimal policies is a NE and vice versa).

Consequently, the state-value function $V(s)$ is redefined to be the expected IHDR under a profile of optimal policies and $Q(s,a_1,a_2)$ the expected IHDR for taking joint action (a_1,a_2) in state s and continuing according to a NE thereafter. For any stationary strategy profile (π_1,π_2) in a ZSSG G, $(\pi_1(s),\pi_2(s))$ is a NE for the matrix games defined by $[Q(s,a^1,a^2)]_{a^1\in A_1,a^2\in A_2}$ for all $s \in S$ if and only if (π_1,π_2) is a NE for G and the NE values for the matrix games correspond to the state values $V(s,\pi_1,\pi_2)$ (Filar and Vrieze, 1997). Thus, the Bellman optimality equations can be rewritten for ZSSGs as

$$\begin{aligned} Q^*(s,a^1,a^2) &= R(s,a^1,a^2) + \gamma \sum_{s'} T(s,a^1,a^2,s')V^*(s') \\ V^*(s) &= \sum_{a^1\in A_1,a^2\in A_2} \pi_1(a^1)\pi_2(a^2)Q(s,a^1,a^2) \end{aligned} \quad (1)$$

where (π_1,π_2) is a NE for the matrix game defined by the Q-values in state s. Given a method that computes NE for zero sum matrix games, Equation (1) can be used as an iterative approximation rule to compute the Q-values (Littman, 1994) and given the Q-values an optimal policy can be derived. The NE policies for a zero sum matrix game $M = [r(a_i,b_j)]_{i=1,j=1}^{k,l}$ are the solutions to the linear program that maximizes v under the constraints (Filar and Vrieze, 1997)

$$\left\{ \sum_{i=1}^{k} \pi(a_i) r(a_i,b_j) \geq v \mid j \in \{1,...,l\} \right\}.$$

In the following sections, this linear program is abbreviated as:

$$v = \max_{\pi\in PD(A)} \min_{b\in B} \sum_{a\in A} \pi(a) r(a,b).$$

If SG G is obtained from ZSSG G' by adding a constant c to all payoffs of **both** players, then $V_i^G(\pi_1,\pi_2) = V_i^{G'}(\pi_1,\pi_2) + c/(1-\gamma)$ for any policy profile (π_1,π_2) and the strategic properties of the game are unchanged. G is referred to as a Fixed Sum Stochastic Game (FSSG). The adversarial nature of FSSGs calls for agents that perform well not only in self play but also in *heterogeneous play*, namely when engaged by agents that employ different learning algorithms. Under this setting, the exploration/exploitation tradeoff wears a new guise as attempted exploration and exploitation may be interfered by the opponent.

This section compares three algorithms for learning in FSSGs: FoeQ (Littman, 1994, 2001), WoLF (Bowling and Veloso, 2002) and Rmax (Brafman and Tennenholtz, 2002). They were selected because they represent different approaches to the exploration/exploitation tradeoff and to information propagation while providing some theoretical guarantees. Specifically, Rmax and FoeQ converge to a NE in FSSGs in self-play, while WoLF is known to converge in 2 player, 2 action, repeated games.

4.1 FoeQ

FoeQ (a.k.a MinimaxQ) (Littman, 1994, 2001) extends Q-learning into FSSGs by using a sample backup learning rule based on Equation 1 (Littman, 1994). After taking a joint action (a,b) in state s at time t and reaching state s' with reward r_{cur}, the agent updates the Q-value of $\langle s,(a,b)\rangle$ by

$$Q_t(s,a,b) \leftarrow (1-\alpha_t)Q_{t-1}(s,a,b) + \alpha_t \left(r_{cur} + \gamma \max_{\pi \in PD(A)} \min_{b' \in B} \sum_{a' \in A} \pi(a') Q(s',a',b') \right).$$

Q_t converges in the limit to Q^* under the standard Q-learning conditions stated in Section 3.1. Also, for similar reasons to those stated in Section 3.1, FoeQ is executed with an ε-greedy learning policy.

4.2 WoLF

WoLF (Bowling and Veloso, 2002) is designed to converge to a best response rather than a NE. WoLF does not explicitly consider an adversary. It applies the standard single-agent Q-learning rule to approximate Q-values of private actions and uses hill climbing to update its mixed policy. That is, the policy is improved by increasing the probability of selecting a greedy action according to a policy learning rate δ (which is distinct from the Q-value learning rate α), enabling mixed policies. The uniqueness of WoLF is in using a *variable* policy learning rate according to the "Win or Learn Fast" (hence WoLF) principle: if the expected return of the current policy given the current Q-values is below (above) a certain threshold then a high, δ_l (low, δ_w), learning rate is set. A good threshold would be the NE value of the game because if the player is receiving less than its value, its likely playing a sub-optimal strategy, whereas if it receives more than the NE value, the other players must be playing sub-optimally. Since the NE value is unknown, it is approximated by the expected return of the average policy (averaged over the history of the game) given the current Q-values. The motivation for the WoLF variable policy learning rate is to enable convergence to a NE. Indeed, Bowling and Veloso (2002) show that gradient ascent with WoLF is guaranteed to converge to a NE in self play on two-player, two-action, repeated matrix-games, while gradient ascent without a variable learning rate is shown not to. Furthermore, they provide empirical results on FSSGs in which WoLF converges to NE in self play. WoLF, as single agent Q-learning, is guaranteed to converge in the limit to a best response under the standard conditions and given that the opponent(s) converge to stationary policies.

4.3 Rmax

Section 3.3 describes the Rmax algorithm in the context of MDPs. The same algorithm is applicable to FSSGs with the only difference that joint actions are considered and optimal policies with respect to the fictitious model are computed according to (1). As mentioned in Section 3.3, Rmax always behaves optimally with respect to an approximated, initially optimistic, model M' of the real model M. Since unknown entries are modeled in an attractive manner in M', Rmax has a strong bias to explore. Seeing that the optimal policy maximizes return against the worst opponent, if the opponent prevents Rmax from visiting unknown entries then Rmax attains near-optimal return because the known entries are accurately modeled. Thus, Rmax is guaranteed to either attain near optimal return in the real model M or, with sufficiently high probability, visit unknown entries (Brafman and Tennenholtz, 2002). This property assures that Rmax will attain near-optimal average reward after a polynomial number of steps in FSSGs as well as in MDPs.

As in the CISGs experiments, $K1$, the number of visits required to declare an entry known, is treated as a parameter that has to be preset and R_{max} is not assumed to be known. Instead, R_{max} is initialized to some positive value and updated online to be twice the highest reward encountered so far.

4.4 Discussion of Algorithms

The shortcoming of GLIELPs discussed in Section 3.4, namely the possibility of untimely greediness, applies also to FoeQ and WoLF in fixed sum environments and may be further exploited by an informed adversary. Furthermore, FoeQ and WoLF do not reason about how the opponent affects exploration. Thus, attempted exploration may result, depending on the opponent's action choice, in joint actions that are of low informative and materialistic value. FoeQ's and WoLF's single step backups and possible premature decrease of the Q-learning rates may cause poor use of new experience.

WoLF compensates for the above limitations by the following properties: (i) Hill climbing adjustment of the policy for enhanced exploration. Specifically, this exploration is regulated by the variable policy learning rate to explore more while "winning". The gradual policy update also prevents formation of big gaps between Q-values of different entries and thus contributes to both fast adjustment to changes in the adversary's behavior and reduction of the effect of untimely greediness. (ii) WoLF's greedy policy is a best response rather than a NE. This fact results in high payoffs during learning, fast growth of Q-values and hence fast convergence. (iii) WoLF does not explicitly model the opponent. It maintains Q-values for the small action space of private actions resulting in faster propagation of state-action values.

A major conceptual difference between WoLF and both Rmax and FoeQ is the target of learning, which also implies the definition of greediness during learning. Rmax's and FoeQ's greedy policies are NE policies. Playing a NE policy is the best strategy against a rational opponent. It also makes sense even if the adversary does not play a BR since it ensures at least the value of the game. However, playing a NE policy w.r.t. a non-accurate model/Q-values during learning makes the hidden assumption that the opponent is not only rational but also acts according to the same model/Q-values. Under heterogeneous play, this assumption is not valid and may result in low payoffs during learning. FoeQ typically maintains pessimistic Q-values during learning. The resulting (greedy) NE learning policy will attempt to avoid entries that are not well known since they seem unprofitable. Thus, FoeQ's greedy action choice may have low informative and materialistic value when engaged in heterogeneous play. For model free algorithms, fast convergence depends on high payoffs during learning. Rmax does not distinguish exploration from exploitation and guarantees to either exploit or explore independent of the adversary's actions. Thus, low payoffs during learning are traded for faster convergence to a NE policy. However, Rmax is biased to explore and may play exploratory actions even when it "knows" a submodel in which the value is attainable. WoLF pursues the best response policy during learning. This strategy is efficient against adversaries that converge to stationary policies. However, an adversary that knows WoLF's strategy may play a "decoy" policy until WoLF's learning is slow and then switch to a best response.

Notwithstanding formal results (Even-Dar and Mansour, 2003), parameter tuning is still a task that requires expert experience and intuition. In this respect, WoLF is the most complicated among the three algorithms. On top of the parameters for decaying exploration and Q learning rates, which also appear in FoeQ, it involves presetting the decay rate of the policy-learning rates and the relation

between the two policy-learning rates δ_w and δ_l. Rmax is the simplest to tune among the three with a single parameter, $K1$, the number of visits to declare an entry "known".

Finally, We note that our discussion of convergence rates and the especially our experimental evaluation focuses on the number of time steps,or multi-agent encounters rather than CPU-time. Although the algorithms we evaluated are all considered practical for online reinforcement learning, it should be noted that WoLF requires considerably less computation than FoeQ or Rmax since it does not involve linear programming computations of equilibria.

4.5 Experimental Results & Analysis

This section describes experimental results on three 2-agent fixed-sum grid games. The games were designed to evaluate the effects of exploration, information propagation, action selection and other methods, on the performance of FoeQ, WoLF and Rmax in different environments. The algorithms were tested in both self play and heterogeneous play. The available actions, indexing of the grid, transition probabilities for the deterministic and stochastic modes, discount factor etcȧre the same as in the CISG experiments. The process of adjusting the parameters was also similar to the CISG experiments and was conducted on the "deterministic 3×3 Wall game" (see below).

The following parameter settings were used for testing:

FoeQ

Exploration: ε-greedy, $\varepsilon_t \leftarrow \max\left\{0.99999^{count_t}, 1/count_t^{0.5000001}\right\}$ where $count_t$ is the number of exploratory steps taken by time t.

Learning rate: $\alpha_{s,a} \leftarrow \max\left\{0.99908^{n(s,a)}, 1/n(s,a)^{0.75}\right\}$ where $n(s,a)$ is the number of times action a was taken in state s.

Q-values were initialized to 0.

WoLF

Exploration: ε-greedy, $\varepsilon_t \leftarrow \max\left\{0.5000001^{count_t}, 1/count_t^{0.5000001}\right\}$.

Q Learning rate: $\alpha_{s,a} \leftarrow \max\left\{0.95^{n(s,a)}, 1/n(s,a)^{0.0.5000001}\right\}$.

Policy Learning rate: $\delta_l = 0.7 \times \alpha_{s,a_g}, \quad \delta_w = 0.175 \times \alpha_{s,a_g}$ where a_g is a greedy action in the current state s.

Rmax

Sampling: values of 50, 100 and 200 for $K1$ (visits to mark an entry known) were tested.

Accuracy of Policy Iteration: Offline Policy Iteration was halted when the difference between two successive approximations was less than 0.001

4.5.1 3×3 WALL GAME

In this 3×3 grid game, one player, A, is an Attacker and the other, D, is a Defender. Figure 11a depicts the initial position of the game. A's goal is to reach the rightmost column of the grid. If both players try to enter the same square or to enter each other's current positions (that is, switch places) then their locations are unchanged. The only exception to this rule is when the players are in diagonally adjacent squares—in this case A moves and D's position is unchanged (Fig. 11b), so that

the attacker has a slight advantage. The fixed sum of the game is 40. When A reaches the rightmost column of the grid, it receives a reward of 40, D receives a reward of 0 and the players are reset in their initial positions. For any other move, A is rewarded by 15 and D is rewarded by 25. The game was played under deterministic transition probabilities. Every experimental trial was over 4×10^6 rounds. The minimax a.r.p.s. for the Attacker is ~ 21.36.

Table 4: 3×3 wall game – The first row reports the action probabilities of a NE policy profile in the initial state, the Q-values for action $\langle stand, stand \rangle$ in the initial state and the number of entries in the game. The next rows classify the average learned policies in the initial state, the average learned Q-values for actions $\langle stand, stand \rangle / \langle stand \rangle$ by the FoeQ/WoLF players, respectively, in the initial state and the average number of known entries by Rmax, after 4×10^6 rounds, according to the players' types. RX, FQ and WF are abbreviations for Rmax, FoeQ and WoLF respectively. The first column, titled *A*, provides the Attacker's type. The second column, titled *D*, provides the Defender's type. The third column, titled $K1$, states the value of Rmax's $K1$ parameter. The columns titled *u*, *l*, *d*, *r*, *s* specify the probabilities for actions *up, left, down, right,* and *stand*, respectively, according to the learned policies. The columns titled *Q-val* and *KE* specify the learned Q values by FoeQ or WoLF and the number of known entries by Rmax.

Figure 12 presents the a.r.p.s. obtained by the different agents playing the Attacker's role in self and heterogeneous play.[13] Table 4 classifies some significant variables of the average state of the learning algorithms after 4×10^6 rounds according to the players' types.

Self Play

In self play, all algorithms converge to minimax or almost minimax values (Fig. 12a,b). FoeQ converges to within 0.5 of the minimax value within the first 10^6 rounds and from then on improves very slowly because of its increasing bias to exploit combined with its decreasing learning rates. The FoeQ Defender learns correct Q-values and an optimal policy while the Attacker learns a rough estimation of the Q-values and a suboptimal policy (Table 4).[14] WoLF converges to the minimax value within 1.5×10^6 rounds and then oscillates around this value while the players keep updating

13. In figures where the behavior does not change after a certain point, we show only the initial phases. For example, in Figure 12c).

14. The first row of Table 4 presents the policies as outputted by a value-iteration solver. It should be noted that there are equivalent optimal policies in the initial state: i. For the Attacker, a probability mass of .514 may be divided in any way between the actions *up* and *down*; ii. For the Defender, the actions *right* and *stand* are equivalent since it is next to the right border of the grid, and for the Attacker, *left* and *stand* are equivalent.

their best responses to each other (Fig. 12b). WoLF learns almost optimal policies and Q-values (Table 4). Three main differences make WoLF more robust than FoeQ: first, it maintains a considerably smaller state-action space since it considers only private actions. This difference results in more efficient back propagation of the Q-values. Second, its learning policy is a best response policy rather than an equilibrium policy. For this reason, it collects higher rewards during early phases of learning and in turn the Q-values converge faster. And third, the hill climbing policy updates combined with the variable learning rate serve as an additional exploration mechanism. As long as the WoLF players have not converged to equilibrium, an increased policy learning rate will always be used by one of the players. As in the CISG case, Rmax's learning period depends almost linearly on $K1$. With $K1 = 50$, Rmax converges to the minimax value within 10^6 rounds (Fig. 12a). Unlike the CISG case, Rmax converges to optimal policies before all entries become *known* (Table 4), thus the unknown entries will not be (unnecessarily) further explored.

In self play, the identical exploration and exploitation techniques of both players gives rise to efficient *joint* exploration and hence to fast convergence to policies that are close or equal to the minimax policies. In contrast, when the opponents employ different learning algorithms, joint exploration is impeded.

Heterogeneous Players

Figure 12c depicts the average learning curves for plays of FoeQ against Rmax. The curves start at ~ 16.25, which is the a.r.p.s. for the Attacker when random policies are played. The learning curve for the FoeQ Attacker may be divided into three phases: in the first 50,000 to 100,000 rounds (depending on $K1$), FoeQ's a.r.p.s. increases rapidly, then drops back down to ~ 17 and changes very slowly thereafter. During the first phase, Rmax plays exploratory policies that enable FoeQ to reach its goal states by playing suboptimal policies. As a result, FoeQ propagates Q-values of entries that are not frequently visited by the NE strategies of the game and constructs a wrong estimate of the strategic structure of the game. During the next phase, Rmax learns improved strategies. At this stage, FoeQ is too biased to exploitation and the learning rates for some entries are too small to overcome the distorted estimation in the first phase. In the third phase, new entries rarely become known because of FoeQ's bias to exploit and its slow learning. For lower values of the $K1$ parameter in Rmax, FoeQ yields lower return in the first phase but recovers faster in the third phase because the first phase is shorter for lower values of $K1$. This property in turn results in lower estimation of the Q-values (Table 4) and hence smaller gaps between the true strategic structure of the game and the strategic structure estimated by FoeQ after the first phase. The smaller gaps are easier to overcome in the third phase. The learning curves and learned values and policies for the opposite mode, Rmax Attacks FoeQ, are a bit less distinct but express similar dynamics. The main advantages of Rmax over FoeQ, expressed in the results, are: An exploration technique that is not time dependent instead of increasing greediness, exhaustive computations instead of single backup per step, and the Rmax learning technique that is guaranteed to either explore or attain return that is at least near the minimax, instead of heuristic exploration. Since, from some early stage, FoeQ mainly attempts to exploit w.r.t. its inaccurate estimation of Q-values and strategic structure and since unknown entries are estimated by FoeQ as having low Q-values, the joint policy does not frequently reach unknown entries but rather yields high rewards for Rmax.[15] Figure 12c also shows the learning curves for

15. It is known that Q-learning with low initial values can behave sub-optimally. Thus, the observed behavior of FoeQ may be a consequence of the fact that Q-values are initialized to 0. However, unless prior information about the possible rewards or their magnitude is available, this appears to be the most unbiased choice.

plays of FoeQ against WoLF. The combination of FoeQ's slow learning, fast "aging" and playing an equilibrium policy w.r.t. its pessimistic estimated Q-values with WoLF's fast learning of a good response produces very poor performance for FoeQ in our particular set of experiments.

The average learning curves for plays of WoLF against Rmax, presented in Figure 12d, converge to the minimax value within the examined time interval under the following settings: Rmax Attacks and $K1 = 50$, Rmax Defends and $K1 = 50$ or $K1 = 100$. Prior to convergence, WoLF gains return higher than the minimax. In the cases of convergence to minimax value, Rmax also converges to, at least almost, a NE policy. WoLF in these cases does not converge to NE but rather to some other best response (Table 4). The dynamic of the learning process can roughly be divided into stages, defined by the discovery of new entries by Rmax and the following policy updates. Rmax starts off with a uniformly mixed policy. Before new entries become known to Rmax, WoLF learns a deterministic response policy with a higher return to WoLF than the minimax value. In turn, entries associated with WoLF's deterministic policy are the first to become known to Rmax. Each joint policy that results from Rmax's policy updates has one of the following properties: (i) The new joint policy seldom visits unknown entries. This policy provides Rmax with return close to or greater than the minimax. (ii) The new joint policy frequently visits unknown entries and provides Rmax with higher return than its average so far. (iii) The new joint policy frequently visits unknown entries and provides Rmax with return equal or lower than its average return so far. In cases (i) and (ii), WoLF will switch to "learn fast" mode and, unless Rmax is already playing the minimax policy, will manage to learn a new response policy with return higher than the minimax before the next stage. This joint policy is guaranteed to visit unknown entries but directs exploration to entries more profitable to WoLF. WoLF's hill climbing method, variable learning rate and small action space enable it to adjust fast to Rmax's new policies and maintain an average return higher than the minimax until Rmax converges to the NE policy. Since Rmax starts off with highly exploratory policies, WoLF is able to attain high payoffs at an early learning phase and thus maintain a high threshold for determining switching of learning rates. By playing a best response, WoLF directs joint exploration as to delay convergence of Rmax on one hand and encourage fast growth of its estimated Q-values on the other.

The relation between the value of $K1$ in Rmax to the convergence time is not as clear as in self play because higher values for $K1$ give WoLF more time to adapt and exploit each new policy of Rmax. It should be noted that for deterministic models, $K1$ can be set to 1, leading to very rapid convergence of Rmax. However, our parameter selection attempts to optimize for a wide range of environmental dynamics and assumes this dynamic is not known ahead of time.

The phenomena observed in this game were repeated in the games described in the following sections. Therefore, in the following, only phenomena not observed in the 3×3 Wall game are discussed.

4.5.2 5×2 WALL GAME

The transition rules of this game are identical to the 3×3 Wall game. It is played on a 5×2 grid under deterministic transition probabilities. Figure 13 depicts the initial position of the game and A's reward structure. When A reaches the right column of the grid in row i, it is rewarded by r_i, where $r_0 = 100$ and $r_i = r_{i-1} + 10i$ for $i \in \{1,2,3,4\}$, and the agents are reset in their initial positions. Otherwise A is rewarded by 90. The fixed sum of the game is 200. The minimax a.r.p.s. for the Attacker is ~ 105.18. The game is designed to fool GLIELPs with random exploration played by

A. If *A* explores randomly, it will probably discover the high rewards in the top rows before it will discover the higher rewards in the lower rows. Later, its growing bias to exploit will prevent it from sufficiently exploring the lower rows.

Table 5: 5×2 wall game – NE policies and Average learned policies for state $\langle (2,0),(2,1) \rangle$, average learned Q-values for action $\langle stand, stand \rangle / \langle stand \rangle$ in the initial state by FoeQ/WoLF, respectively, and average number of known entries by Rmax, after 4×10^6 rounds, classified by players' types. See format explanation in Table 4.

Figure 14 presents the a.r.p.s. obtained by the different agents playing the Attacker's role. Table 5 classifies the average learned policies in state $\langle (2,0),(2,1) \rangle$ (both players on middle row), the average learned values for action $\langle stand, stand \rangle / \langle stand \rangle$ in the initial state by the FoeQ/WoLF players and the average number of known entries by the Rmax players, according to the agents playing *A* and *D*. The minimax policy for *A* and *D* when they are both in rows 0, 1 or 2 is to move *down*. When *A* and *D* are both in rows 3 or 4 their minimax policy is mixed.

Self Play

Rmax with $K1 = 50$ converges to the minimax values (Fig. 14a) and policies (Table 5). With values of 100 and 200 of $K1$, Rmax still has a small exploration bias after 4×10^6 rounds (Table 5) and attains almost the minimax value (Fig. 14a). WoLF's convergence to near the minimax value is exceptionally fast in this domain, despite its GLIELP (Fig. 14b). The gradual increase in payoffs for attacking in lower rows both guides exploration and speeds up learning by causing many switches in the learning rate. By employing a high policy learning rate to find a best response, the WoLF Attacker very quickly discovers the high return in the bottom rows and the WoLF Defender follows by defending them. FoeQ on the other hand falls in the designed trap and converges to a suboptimal policy (Fig. 14b). The FoeQ Attacker believes that it can gain higher rewards in the top rows and assigns a high probability to action *up* in state $\langle (2,0),(2,1) \rangle$ instead of *down*. The FoeQ defender, as well, believes that the upper rows are more worth defending and also assigns a high probability to action *up* in this state (Fig. 14b, Table 5).[16]

Heterogeneous Players

Figure 14c shows *A*'s a.r.p.s. over time for plays of FoeQ against Rmax. FoeQ's behavior is

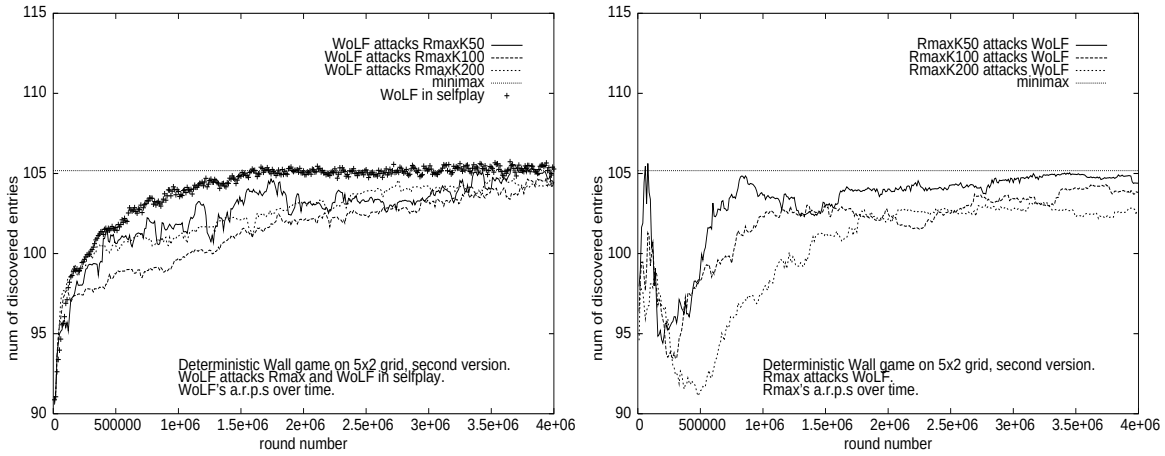
16. Again, this behavior, too, could be attributed to low initial Q-values.

similar to its behavior in self play. When D is played by FoeQ, it attempts to defend the top rows while Rmax attacks in the bottom ones. When A is played by FoeQ, it attempts to Attack only in the top rows (Table 5). Since the entries associated with states of both players being in the bottom rows are unknown to the Rmax Defender, they are modeled as unrewarding by FoeQ, and hence, its policy defends only in the top rows. The low numbers of known entries to Rmax (Table 5) is evidence of FoeQ's inability to sufficiently explore.

In plays of Rmax against WoLF, the players converge to minimax in the examined time interval only for Rmax with $K1 = 50$ and WoLF gains a.r.p.s. higher than the minimax all the way to convergence (Fig. 14d). During the learning period, WoLF's policy is "one step ahead" of Rmax's. In particular, it assigns a greater probability to action *down* in the middle row. This advantage is also expressed by the differences in the probability assigned to action *down* between the learned policies for the different values of $K1$ (Table 5). When WoLF plays the Defender, it adjusts quickly to the behavioral changes of Rmax. When WoLF plays the Attacker, the gradual increase of rewards for attacking in lower rows directs WoLF's exploration while maintaining a high a.r.p.s.

Removing the Intermediate Rewards

To eliminate the incentive to explore and learn quickly given to WoLF by the intermediate rewards, we studied a variant of the 5×2 Wall game: the Attacker's payoffs for attacking in the second and third rows are modified to 100. All the other payoffs and transitions are unchanged. The minimax policies and values are also unchanged since the attacker's optimal policy in both settings attacks only in the two bottom rows.



(a) WoLF attacks Rmax and WoLF in self-play

(b) Rmax attacks WoLF

Figure 15: Modified 5×2 wall game – a.r.p.s. over time

The convergence of WoLF in self play (Fig. 15a) is slower than its convergence on the first reward structure, yet still faster than the other algorithms in self play. In plays of WoLF against Rmax, WoLF has a disadvantage when it plays as the Attacker: The threshold for switching learning rates does not grow in early learning and hence a low learning rate is more frequent while more exploration is required to discover the benefits of attacking in the bottom rows. As an Attacker, WoLF gains a lower return than the minimax value all the way to convergence (Fig. 15a). In the

Defender's role, WoLF's variable learning rate responds to the Rmax Attacker's "initiatives," and WoLF gains higher return than the minimax value all the way to convergence (Fig. 15b).

4.5.3 2×4 TAG GAME

This section describes the results of executing the algorithms on a *stochastic* Tag game. The game is played on a 2×4 grid with a missing corner. One of the players, C, is the tagger and the other, E, is the Escaper. Fig. 16 depicts the initial configuration of the game. A tagging event (tag) occurs when both players have the same positions. In the case of a tag, C receives a reward of 40, E receives a reward of 0 and the players' positions are unchanged. Otherwise C's reward is 15 and E's reward is 25. C's a.r.p.s. under the minimax policy is ~ 18.22. C's optimal strategy is to attempt to trap E in the rightmost cell of the grid while E's optimal strategy is to avoid this situation. To this end, the minimax strategy is deterministic at all states except $\langle (0,2),(0,3) \rangle$.[17] For example, in state $\langle (0,1),(1,1) \rangle$ the Escaper should move *left* and not *right* to avoid the danger of being forced to the corner.

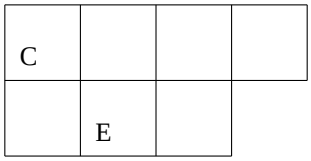


Figure 16: 2x4 tag game – initial position

Figure 17 presents the a.r.p.s. obtained by the different agents playing the tagger's role. Table 6 classifies the average learned policies in state $\langle (0,1),(1,1) \rangle$, the average learned values for action $\langle stand, stand \rangle$ / $\langle stand \rangle$ in state $\langle (0,2),(0,3) \rangle$ by the FoeQ/WoLF players, and the average number of known entries by the Rmax players, after 4×10^6 rounds, according to the agents playing C and E.

Self Play

In self play, the Rmax Escaper does not learn an optimal policy. Furthermore, in contrast to the deterministic games, E's policy improves with greater values of $K1$, although fewer entries become known (Table 6).[18] This is because more sampling is required to approximate the transition probabilities. However, the learned policies yield an 0.2-optimal return (Fig. 17a), closer to the optimal value than the other algorithms. FoeQ and WoLF converge to near the minimax value within the first 6×10^5 rounds and both learn almost optimal/minimax policies. FoeQ performs much better in this domain than in the previous deterministic domains because the stochastic transitions amplify exploration.

Heterogeneous Players

When Rmax plays against FoeQ, more entries become known and FoeQ's value estimates are better compared to the deterministic games, again due to the amplification of exploration by the

17. Positions are denoted *(row,column)*, with (0,0) being the upper left position. From state $\langle (0,2),(0,3) \rangle$ the players can transit to state $\langle (0,3),(0,2) \rangle$ by the joint action $\langle$*right,left*$\rangle$ without the occurrence of a tag.
18. Recall that as $K1$ increases, more visits are required to mark an entry known. Therefore, fewer entries will be marked within a given time frame.

Figure 17: 2×4 tag game – average reward per step

stochastic environmental dynamic. When FoeQ plays Escaper against Rmax, FoeQ learns better policies when Rmax uses larger values of $K1$ (Table 6) and receives a greater average reward (Fig. 17b)—opposite to what was observed in the 3×3 Wall Game. It seems that the longer periods of Rmax playing fixed policies enable FoeQ to better approximate the different Q-values associated with that policy. Despite the stochastic nature of the environment playing "in favor" of FoeQ, Rmax is still superior in heterogeneous play. In plays of Rmax against WoLF, the algorithms converge to the minimax value in five out of the six different configurations, whereas in the deterministic games they converged in two or three out of the six. The convergence dynamic is similar to that observed in the first two games, and WoLF receives an a.r.p.s. greater than the minimax value all the way to convergence.

Table 6: 2×4 tag game – NE policies and average learned policies for state $\langle (0,1),(1,1) \rangle$, average Q-values for action $\langle stand, stand \rangle$ / $\langle stand \rangle$ in state $\langle (0,2),(0,3) \rangle$ by FoeQ/WoLF and average number of known entries by Rmax, after 4×10^6 rounds, classified by players' types. See format explanation in Table 4.

4.5.4 SUMMARY

The adversarial exploration/exploitation tradeoff in FSSGs is more complicated than that observed in the common interest CISG case. Optimizing behavior during learning introduces a tradeoff between exercising opponents' exploration in order to gain higher return (may-be at the expense of fast convergence to some fixed learning target), to exercising opponents' exploration for joint exploration. When one algorithm takes the time to explore, the other algorithm can exploit and obtain payoff higher than the NE. To this end, learning a best response proves better than learning a NE, when combined in the WoLF algorithm with other properties that ensure fast adaptation to a changing adversary.

Indeed, WoLF appears to be the preferred algorithm in heterogeneous play, with good performance in self-play as well. Nevertheless, WoLF fails to converge to NE in heterogeneous play against an adversary that does converge to a NE, which may be its Achilles heel. WoLF's robustness makes up for the classic weakness of GLIELPs discussed in Section 3.4 (that is, the great sensitivity to the exploration schedule in some domains), but not completely. Thus, while in most cases WoLF is preferable over the other presented algorithms, in some situations this anomaly manifests itself and Rmax outperforms WoLF.

Additional practical issues may affect the choice of algorithm for a specific task. WoLF is computationally more efficient, mainly because it does not involve equilibrium computations. Rmax is much simpler for pre-tuning, with a single intuitive parameter, but requires solving the underlying stochastic game.

5. MGS

MGS is a Markov Game Simulation system designed to evaluate online performance of MARL algorithms. Three main software components take part in a simulation:

Players – user-defined implementations of MARL algorithms.

Referee – a user-defined program that represents a multi-agent environment.

Simulator – mediates between the Players and Referee.

MGS provides Java interfaces and an abstract Referee class that implements the backbone of typical grid-world environments and makes the programming of grid worlds simple and easy. It should be noted that the description of software components and methods in the rest of this section is for illustrative purposes and is partial and incomplete.

Modeling real world environments (or simplifications of such environments) as Stochastic Games is a tedious task for humans. To simplify the modeling task, MGS supports simple creation of grid-world environments referred to as Grid Games (GG). In a GG, agents can move about between squares of a grid, move/carry objects etc. GGs induce MGs in which the set of states S are the possible assignments to the state variables, which are typically the position of the agents and various objects. Actions change the positions of the agents and the state of the objects.

5.1 The Referee

This program represents a GG. The state variables of the GG are memory variables of the Referee program and reachable internal states of the Referee correspond to possible assignments to the state variables. The Referee may manage additional memory variables, that is, variables that capture the previous assignment to the state variables in order to implement the payoff function. The Referee implements methods that simulate the environment such as:

- `getStateIndex()` - enumerates the state space. Returns a unique integer that corresponds to the current state of the Referee.
- `giveActions(int[] actions)` - receives the action choices of the players and updates the state variables to characterize the new state of the environment.
- `getPlayerReward(int p)` - returns the payoff for player `p`.

5.2 The Players

They implement the methods:

- `play(int s)` - returns the action choice in state `s`.
- `update(int s, int[] acts, double r)` - updates the algorithm's model / values according to the new state `s`, other Players' actions `acts` and payoff `r`.

5.3 The Simulator

This module is the active process during simulation. Schematically, the Simulator loops over the following steps:

1. get the Players' actions in the current state.
2. pass the joint action to the Referee.
3. compute the index of the new state of the environment.
4. pass the new state index and payoffs to the players.

Typically, GGs involve actions that move the agents up, down, left and right on a two-dimensional grid. To unburden the user from modeling these aspects of the environment, they are already built into the system. The abstract Referee class implements various methods for manipulating the positions of the agents on a grid represented by a two dimensional integer array. The Simulator also computes the new positions of the agents according to the five default actions `up`, `left`, `down`, `right` and `stand`, and according to user input transition probabilities. In Step 2 above, the Simulator also passes to the Referee the results of this computation in the form of suggested new positions for the players.

MGS is a very flexible tool. Despite the implemented GG features, it can in fact be used to model *any* discrete state-action space MG (although doing so may require more complicated programming than the simple implementation of GGs). MGS offers various features that make it a convenient experimental tool. Input can be specified either by a GUI or by a script. Scripts may specify multiple independent simulations and may also include parameters for the Players' algorithms. MGS logs statistics of payoffs and selected actions and also supports logging by the Players. For further information on MGS, see `http://www.cs.bgu.ac.il/~mal`.

6. Conclusions

This paper presents a large empirical study of representative MARL algorithms conducted using the MGS tool. Such comprehensive studies in this area are rare. The only other related study we are aware of appeared in Powers and Shoham (2005) and involved the much simpler class of repeated games with known game matrices. While most authors run some empirical studies, these often focus on their algorithms and do provide a comprehensive comparison of strengths and weaknesses.

We believe that our results and analysis can serve to guide researchers in developing more powerful algorithms and formal analytic tools, and practitioners in selecting and tuning algorithms for specific tasks. Some of our results are closely related to phenomena observed in single-agent reinforcement-learning algorithms, especially in common-interest environments, which can be viewed as describing a distributed version of single-agent RL. In this domain, the issue of exploration vs. exploitation appears to play a major role in the success of different algorithms. Here, we found Rmax's exhaustive approach to be very useful, being much less susceptible to being stuck in local minima compared to GLIELP exploration. Of course, one does expect this almost-exhaustive exploration approach to be costly in large domains. However, in our examples, Rmax was able to perform well with small sample sizes, partly due to the locality of actions—that is, the fact that most actions have a small number of possible outcomes and these effects do not change the agent's state drastically. In general, many real-world domains tend to have this property. We believe that

online identification of locality properties may be used to construct more practical variants of Rmax as well as other methods. Rmax also provides another capability we found important in common interest games: coordinated exploration. It also seems to scale well with the number of agents. Perhaps most important is the fact that it is very simple to understand its behavior, and consequently, we believe, to modify it given background knowledge. However, Rmax is completely inadequate if cooperation is to be obtained given a system with heterogeneous agents.

Fixed sum games provided an interesting setting, where we could test algorithms against each other. We found that learning is more efficient when the greedy component of the learning policy is a best response rather than a minimax strategy. The WoLF algorithm achieves fast adaptation to a changing opponent by maintaining values for only the private action space and by regulating behavior according to the dynamics of the learning process, and it seems to be the best choice in such competitive environments.

Overall, it seems that there is much potential for improved performance by multi-agent learning algorithms. We hope this study will motivate the design of algorithms that improve upon the current state of the art, and we believe that the MGS test bed can be a useful tool for testing such new techniques.

Acknowledgments

We are grateful to the reviewers for their useful suggestions and comments, and to the associate editor, Michael Littman, for his many useful and detailed comments. Abstract

In a recently published paper in JMLR, Demšar (2006) recommends a set of non-parametric statistical tests and procedures which can be safely used for comparing the performance of classifiers over multiple data sets. After studying the paper, we realize that the paper correctly introduces the basic procedures and some of the most advanced ones when comparing a control method. However, it does not deal with some advanced topics in depth. Regarding these topics, we focus on more powerful proposals of statistical procedures for comparing $n \times n$ classifiers. Moreover, we illustrate an easy way of obtaining adjusted and comparable p-values in multiple comparison procedures.

Keywords: statistical methods, non-parametric test, multiple comparisons tests, adjusted p-values, logically related hypotheses

1. Introduction

In the Machine Learning (ML) scientific community there is a need for rigorous and correct statistical analysis of published results, due to the fact that the development or modifications of algorithms is a relatively easy task. The main inconvenient related to this necessity is to understand and study the statistics and to know the exact techniques which can or cannot be applied depending on the situation, that is, type of results obtained. In a recently published paper in JMLR by Demšar (2006), a group of useful guidelines are given in order to perform a correct analysis when we compare a set of classifiers over multiple data sets. Demšar recommends a set of non-parametric statistical techniques (Zar, 1999; Sheskin, 2003) for comparing classifiers under these circumstances, given that the sample of results obtained by them does not fulfill the required conditions and it is not large enough for making a parametric statistical analysis. He analyzed the behavior of the proposed statistics on classification tasks and he checked that they are more convenient than parametric techniques.

Recent studies apply the guidelines given by Demšar in the analysis of performance of classifiers (Esmeir and Markovitch, 2007; Marrocco et al., 2008). In them, a new proposal or methodology is offered and it is compared with other methods by means of pairwise comparisons. Another type of studies assume an empirical comparison or review of already proposed methods. In these cases, no proposal is offered and a statistical comparison could be very useful in determining the differences among the methods. In the specialized literature, many papers provide reviews on a specific topic and they also use statistical methodology to perform comparisons. For example, in a review of

ensembles of decision trees, non-parametric tests are also applied in the analysis of performance (Banfield et al., 2007). However, only the rankings computed by Friedman's method (Friedman, 1937) are stipulated and authors establish comparisons based on them, without taking into account significance levels. Demšar focused his work in the analysis of new proposals, and he introduced the Nemenyi test for making all pairwise comparisons (Nemenyi, 1963). Nevertheless, the Nemenyi test is very conservative and it may not find any difference in most of the experimentations. In recent papers, the authors have used the Nemenyi test in multiple comparisons. Due to the fact that this test posses low power, authors have to employ many data sets (Yang et al., 2007b) or most of the differences found are not significant (Yang et al., 2007a; Núñez et al., 2007). Although the employment of many data sets could seem beneficial in order to improve the generalization of results, in some specific domains, that is, imbalanced classification (Owen, 2007) or multi-instance classification (Murray et al., 2005), data sets are difficult to find.

Procedures with more power than Nemenyi's one can be found in specialized literature. We have based on the necessity to apply more powerful procedures in empirical studies in which no new method is proposed and the benefit consists of obtaining more statistical differences among the classifiers compared. Thus, in this paper we describe these procedures and we analyze their behavior by means of the analysis of multiple repetitions of experiments with randomly selected data sets.

On the other hand, we can see other works in which the *p*-value associated to a comparison between two classifiers is reported (García-Pedrajas and Fyfe, 2007). Classical non-parametric tests, such as Wilcoxon and Friedman (Sheskin, 2003), may be incorporated in most of the statistical packages (SPSS, SAS, R, etc.) and the computation of the final *p*-value is usually implemented. However, advanced procedures such as Holm (1979), Hochberg (1988), Hommel (1988) and the ones described in this paper are usually not incorporated in statistical packages. The computation of the correct *p*-value, or Adjusted *P*-Value (APV) (Westfall and Young, 2004), in a comparison using any of these procedures is not very difficult and, in this paper, we show how to include it with an illustrative example.

The paper is set up as follows. Section 2 presents more powerful procedures for comparing all the classifiers among them in a $n \times n$ comparison of multiple classifiers and a case study. In Section 3 we describe the procedures for obtaining the APV by considering the post-hoc procedures explained by Demšar and the ones explained in this paper. In Section 4, we perform an experimental study of the behavior of the statistical procedures and we discuss the results obtained. Finally, Section 5 concludes the paper.

2. Comparison of Multiple Classifiers: Performing All Pairwise Comparisons

In the paper Demšar (2006), referring to carrying out comparisons of more than two classifiers, a set of useful guidelines were given for detecting significant differences among the results obtained and post-hoc procedures for identifying these differences. Friedman's test is an omnibus test which can be used to carry out these types of comparison. It allows to detect differences considering the global set of classifiers. Once Friedman's test rejects the null hypothesis, we can proceed with a post-hoc test in order to find the concrete pairwise comparisons which produce differences. Demšar described the use of the Nemenyi test used when all classifiers are compared with each other. Then, he focused on procedures that control the family-wise error when comparing with a control classifier, arguing that the objective of a study is to test whether a newly proposed method is better than the existing

ones. For this reason, he described and studied in depth more powerful and sophisticated procedures derived from Bonferroni-Dunn such as Holm's, Hochberg's and Hommel's methods.

Nevertheless, we think that performing all pairwise comparisons in an experimental analysis may be useful and interesting in different cases when proposing a new method. For example, it would be interesting to conduct a statistical analysis over multiple classifiers in review works in which no method is proposed. In this case, the repetition of comparisons choosing different control classifiers may lose the control of the family-wise error.

Our intention in this section is to give a detailed description of more powerful and advanced procedures derived from the Nemenyi test and to show a case study that uses these procedures.

2.1 Advanced Procedures for Performing All Pairwise Comparisons

A set of pairwise comparisons can be associated with a set or family of hypotheses. Any of the post-hoc tests which can be applied to non-parametric tests (that is, those derived from the Bonferroni correction or similar procedures) work over a family of hypotheses. As Demšar explained, the test statistics for comparing the i-th and j-th classifier is

$$z = \frac{(R_i - R_j)}{\sqrt{\frac{k(k+1)}{6N}}},$$

where R_i is the average rank computed through the Friedman test for the i-th classifier, k is the number of classifiers to be compared and N is the number of data sets used in the comparison.

The z value is used to find the corresponding probability (p-value) from the table of normal distribution, which is then compared with an appropriate level of significance α (Table A1 in Sheskin, 2003). Two basic procedures are:

- Nemenyi (1963) procedure: it adjusts the value of α in a single step by dividing the value of α by the number of comparisons performed, $m = k(k-1)/2$. This procedure is the simplest but it also has little power.

- Holm (1979) procedure: it was also described in Demšar (2006) but it was used for comparisons of multiple classifiers involving a control method. It adjusts the value of α in a step down method. Let $p_1, ..., p_m$ be the ordered p-values (smallest to largest) and $H_1, ..., H_m$ be the corresponding hypotheses. Holm's procedure rejects H_1 to $H_{(i-1)}$ if i is the smallest integer such that $p_i > \alpha/(m-i+1)$. Other alternatives were developed by Hochberg (1988), Hommel (1988) and Rom (1990). They are easy to perform, but they often have a similar power to Holm's procedure (they have more power than Holm's procedure, but the difference between them is not very notable) when considering all pairwise comparisons.

The hypotheses being tested belonging to a family of all pairwise comparisons are logically interrelated so that not all combinations of true and false hypotheses are possible. As a simple example of such a situation suppose that we want to test the three hypotheses of pairwise equality associated with the pairwise comparisons of three classifiers $C_i, i = 1, 2, 3$. It is easily seen from the relations among the hypotheses that if any one of them is false, at least one other must be false. For example, if C_1 is better/worse than C_2, then it is not possible that C_1 has the same performance as C_3 and C_2 has the same performance as C_3. C_3 must be better/worse than C_1 or C_2 or the two classifiers at the same time. Thus, there cannot be one false and two true hypotheses among these three.

Based on this argument, Shaffer proposed two procedures which make use of the logical relation among the family of hypotheses for adjusting the value of α (Shaffer, 1986).

- Shaffer's static procedure: following Holm's step down method, at stage j, instead of rejecting H_i if $p_i \leq \alpha/(m-i+1)$, reject H_i if $p_i \leq \alpha/t_i$, where t_i is the maximum number of hypotheses which can be true given that any $(i-1)$ hypotheses are false. It is a static procedure, that is, $t_1, ..., t_m$ are fully determined for the given hypotheses $H_1, ..., H_m$, independent of the observed p-values. The possible numbers of true hypotheses, and thus the values of t_i can be obtained from the recursive formula

$$S(k) = \bigcup_{j=1}^{k} \{ \binom{j}{2} + x : x \in S(k-j) \},$$

  where $S(k)$ is the set of possible numbers of true hypotheses with k classifiers being compared, $k \geq 2$, and $S(0) = S(1) = \{0\}$.

- Shaffer's dynamic procedure: it increases the power of the first by substituting α/t_i at stage i by the value α/t_i^*, where t_i^* is the maximum number of hypotheses that could be true, given that the previous hypotheses are false. It is a dynamic procedure since t_i^* depends not only on the logical structure of the hypotheses, but also on the hypotheses already rejected at step i. Obviously, this procedure has more power than the first one. In this paper, we have not used this second procedure, given that it is included in an advanced procedure which we will describe in the following.

In Bergmann and Hommel (1988) was proposed a procedure based on the idea of finding all elementary hypotheses which cannot be rejected. In order to formulate Bergmann-Hommel's procedure, we need the following definition.

Definition 1 *An index set of hypotheses $I \subseteq \{1, ..., m\}$ is called* exhaustive *if exactly all H_j, $j \in I$, could be true.*

In order to exemplify the previous definition, we will consider the following case: We have three classifiers, and we will compare them in a $n \times n$ comparison. We will obtain three hypotheses:

- H_1 = C_1 es equal in behavior than C_2.
- H_2 = C_1 es equal in behavior than C_3.
- H_3 = C_2 es equal in behavior than C_3.

and eight possible sets S_i:

- S_1: All H_j are true.
- S_2: H_1 and H_2 are true and H_3 is false.
- S_3: H_1 and H_3 are true and H_2 is false.

- S_4: H_2 and H_3 are true and H_1 is false.
- S_5: H_1 is true and H_2 and H_3 are false.
- S_6: H_2 is true and H_1 and H_3 are false.
- S_7: H_3 is true and H_1 and H_2 are false.
- S_8: All H_j are false.

Sets S_1, S_5, S_6, S_7 and S_8 can be possible, because their hypotheses can be true at the same time, so they are exhaustive sets. Set S_2, basing on logically related hypotheses principles, is not possible because the performance of C_1 cannot be equal to C_2 and C_3, whereas C_2 has different performance than C_3. The same consideration can be done to S_3 and S_4, which are not exhaustive sets.

Under this definition, it works as follows.

- Bergmann and Hommel (1988) procedure: Reject all H_j with $j \notin A$, where the *acceptance set*

$$A = \bigcup \{I : I \textit{ exhaustive}, \ min\{P_i : i \in I\} > \alpha/|I|\}$$

  is the index set of null hypotheses which are retained.

  For this procedure, one has to check for each subset I of $\{1,...,m\}$ if I is exhaustive, which leads to intensive computation. Due to this fact, we will obtain a set, named E, which will contain all the possible exhaustive sets of hypotheses for a certain comparison. A rapid algorithm which was described in Hommel and Bernhard (1994) allows a substantial reduction in computing time. Once the E set is obtained, the hypotheses that do not belong to the A set are rejected.

  Figure 1 shows a valid algorithm for obtaining all the exhaustive sets of hypotheses, using as input a list of classifiers C. E is a set of families of hypotheses; likewise, a family of hypotheses is a set of hypotheses. The most important step in the algorithm is the number 6. It performs a division of the classifiers into two subsets, in which the last classifier k always is inserted in the second subset and the first subset cannot be empty. In this way, we ensure that a subset yielded in a division is never empty and no repetitions are produced. For example, suppose a set C with three classifiers $C = \{1,2,3\}$. All possible divisions without taking into account the previous assumptions are: $D_1 = \{C_1 = \{\}, C_2 = \{1,2,3\}\}, D_2 = \{C_1 = \{1\}, C_2 = \{2,3\}\}, D_3 = \{C_1 = \{2\}, C_2 = \{1,3\}\}, D_4 = \{C_1 = \{1,2\}, C_2 = \{3\}\}, D_5 = \{C_1 = \{3\}, C_2 = \{1,2\}\}, D_6 = \{C_1 = \{1,3\}, C_2 = \{2\}\}, D_7 = \{C_1 = \{2,3\}, C_2 = \{1\}\}, D_8 = \{C_1 = \{1,2,3\}, C_2 = \{\}\}$. Divisions D_1 and D_8, D_2 and D_7, D_3 and D_6, D_4 and D_5 are equivalent, respectively. Furthermore, divisions D_1 and D_8 are not interesting. Using the assumptions in step 6 of the algorithm, the possible divisions are: $D_1 = \{C_1 = \{1\}, C_2 = \{2,3\}\}, D_2 = \{C_1 = \{2\}, C_2 = \{1,3\}\}, D_3 = \{C_1 = \{1,2\}, C_2 = \{3\}\}$. In this case, all the divisions are interesting and no repetitions are yielded. The computational complexity of the algorithm for obtaining exhaustive sets is $O(2^{n^2})$. However, the computation requirements may be reduced by means of using storage capabilities. Relative exhaustive sets for $k-i$, $1 \leq i \leq (k-2)$ classifiers can be stored in memory and there is no necessity of invoking the *obtainingExhaustive* function recursively. The computational complexity using storage capabilities is $O(2^n)$, so the algorithm still requires intensive computation.

An example illustrating the algorithm for obtaining all exhaustive sets is drawn in Figure 2. In it, four classifiers, enumerated from 1 to 4 in the C set, are used. The comparisons or hypotheses are denoted by pairs of numbers without a separation character between them. This illustration does not show the case in which the set $|C_i| < 2$, for simplifying the representation. When $|C_i| < 2$, no comparisons can be performed, so the *obtainExhaustive* function returns an empty set E.

An edge connecting two boxes represents an invocation of this function. In each box, the list of classifiers given as input and the first initialization of the E set are displayed. The main edges, whose starting point is the initial box, are labeled by the order of invocation. Below the graph, the resulting E subset in each main edge is denoted. The final E will be composed by the union of these E subsets. At the end of the process, 14 distinct exhaustive sets are found: $E = \{(12,13,14,23,24,34),(23,24,34),(13,14,34),(12,14,24),(12,13,23),$ $(12),(13),(14),(23),(24),(34),(12,34),(13,24),(23,14)\}$.

Table 1 gives the number of hypotheses (m), the number (2^n) of index sets I and the number of exhaustive index sets (n_e) for k classifiers being compared.

Function obtainExhaustive($C = \{c_1, c_2, ..., c_k\}$: list of classifiers)

1. Let $E = \emptyset$
2. $E = E \cup \{$set of all possible and distinct pairwise comparisons using $C\}$
3. If $E == \emptyset$
   4. Return E
5. End if
6. For all possible divisions of C into two subsets C_1 and C_2, $c_k \in C_2$ and $C_1 \neq \emptyset$
   7. $E_1 = obtainExhaustive(C_1)$
   8. $E_2 = obtainExhaustive(C_2)$
   9. $E = E \cup E_1$
   10. $E = E \cup E_2$
   11. For each family of hypotheses e_1 of E_1
      12. For each family of hypotheses e_2 of E_2
         13. $E = E \cup (e_1 \cup e_2)$
      14. End for
   15. End for
16. End for
17. Return E

Figure 1: Algorithm for obtaining all exhaustive sets

The following subsections present a case study of a $n \times n$ comparison of some well-known classifiers over thirty data sets. In it, the four procedures explained above are employed.

2.2 Performing All Pairwise Comparisons: A Case Study

In the following, we show an example involving the four procedures described with a comparison of five classifiers: C4.5 (Quinlan, 1993); One Nearest Neighbor (1-NN) with Euclidean distance,

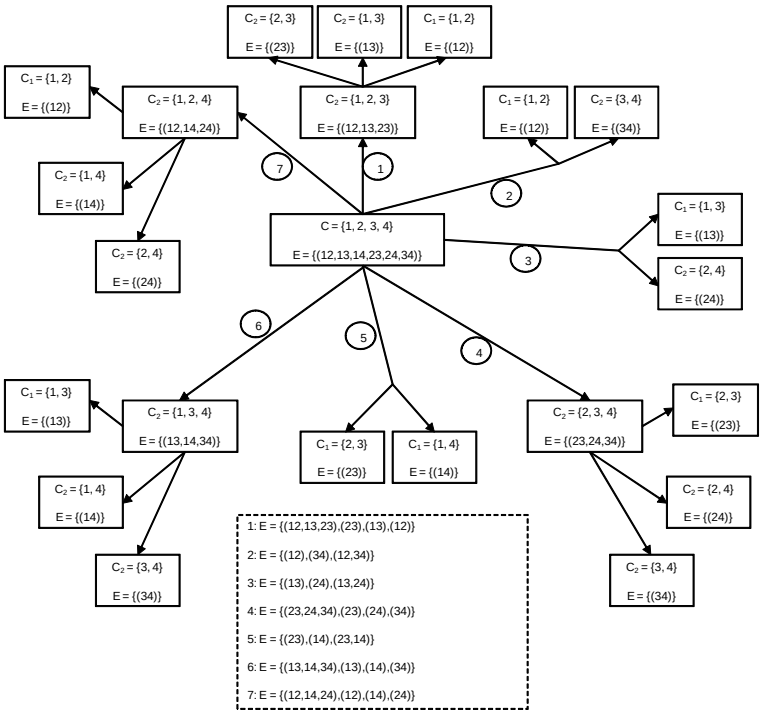

Figure 2: Example of the obtaining of exhaustive sets of hypotheses considering 4 classifiers

k	$m = \binom{k}{2}$	2^m	n_e
4	6	64	14
5	10	1024	51
6	15	32768	202
7	21	2097152	876
8	28	$2.7 \cdot 10^8$	4139
9	36	$6.7 \cdot 10^{10}$	21146

Table 1: All pairwise comparisons of k classifiers

NaiveBayes, Kernel (McLachlan, 2004)[1] and, finally, CN2 (Clark and Niblett, 1989).[2] The parameters used are specified in Section 4. We have used 10-fold cross validation and standard parameters for each algorithm. The results correspond to average accuracy or $1 - class\_error$ in test data. We have used 30 data sets.[3] Table 2 shows the overall process of computation of average rankings.

Friedman (1937) and Iman and Davenport (1980) tests check whether the measured average ranks are significantly different from the mean rank $R_j = 3$. They respectively use the χ^2 and the F statistical distributions to determine if a distribution of observed frequencies differs from the theoretical expected frequencies. Their statistics use nominal (categorical) or ordinal level data, instead of using means and variances. Demšar (2006) detailed the computation of the critical values in each distribution. In this case, the critical values are 9.488 and 2.45, respectively at $\alpha = 0.05$, and the Friedman's and Iman-Davenport's statistics are:

$$\chi^2_F = 39.647, F_F = 14.309.$$

Due to the fact that the critical values are lower than the respective statistics, we can proceed with the post-hoc tests in order to detect significant pairwise differences among all the classifiers. For this, we have to compute and order the corresponding statistics and p-values. The standard error in the pairwise comparison between two classifiers is $SE = \sqrt{\frac{k(k+1)}{6N}} = \sqrt{\frac{5 \cdot 6}{6 \cdot 30}} = 0.408$. Table 3 presents the family of hypotheses ordered by their p-value and the adjustment of α by Nemenyi's, Holm's and Shaffer's static procedures.

- Nemenyi's test rejects the hypotheses [1–4] since the corresponding p-values are smaller than the adjusted α's.
- Holm's procedure rejects the hypotheses [1–5].
- Shaffer's static procedure rejects the hypotheses [1–6].
- Bergmann-Hommel's dynamic procedure first obtains the exhaustive index set of hypotheses. It obtains 51 index sets. We can see them in Table 4. From the index sets, it computes the A set.[4] It rejects all hypotheses H_j with $j \notin A$, so it rejects the hypotheses [1–8].

  Bergmann-Hommel's dynamic procedure allows to clearly distinguishing among three groups of classifiers, attending to their performance:

- Best classifiers: C4.5 and NaiveBayes.
- Middle classifiers: 1-NN and CN2.
- Worst classifier: Kernel.

1. Kernel method is a bayesian classifier which employs a non-parametric estimation of density functions through a gaussian kernel function. The adjustment of the covariance matrix is performed by the ad-hoc method.
2. NaiveBayes and CN2 are classifiers for discrete domains, so we have discretized the data prior to learning with them. The discretizer algorithm is Fayyad and Irani (1993).
3. Data sets marked with '*' have been subsampled being adapted to slow algorithms, such as CN2.
4. We have considered that each classifier follows the order: 1 - C4.5, 2 - 1-NN, 3 - NaiveBayes, 4 - Kernel, 5 - CN2. For example, the hypothesis 13 represents the comparison between C4.5 and NaiveBayes.

In Demšar (2006), we can find a discussion about the power of Hochberg's and Hommel's procedures with respect to Holm's one. They reject more hypothesis than Holm's, but the differences are in practice rather small (Shaffer, 1995). The most powerful procedures detailed in this paper, Shaffer's and Bergmann-Hommel's, work following the same method of Holm's procedure, so it is possible to hybridize them with other types of step up procedures, such as Hochberg's, Hommel's and Rom's methods. When we apply these methods by using the logical relationships among hypothesis in a static way, they do not control the family-wise error (Hochberg and Rom, 1995). In opposite, when applying these methods by detecting dynamical relationships, they control the family-wise error. In Hochberg and Rom (1995), several extensions were given in this way. Furthermore, a small improvement of power in the Bergmann-Hommel procedure described here can be achieved when using Simes conjecture (Simes, 1986) in the obtaining of A set (see Hommel and Bernhard, 1999, for more details).

3. Adjusted P-Values

The smallest level of significance that results in the rejection of the null hypothesis, the p-value, is a useful and interesting datum for many consumers of statistical analysis. A p-value provides information about whether a statistical hypothesis test is significant or not, and it also indicates something about "how significant" the result is: The smaller the p-value, the stronger the evidence against the null hypothesis. Most important, it does this without committing to a particular level of significance.

When a p-value is within a multiple comparison, as in the example in Table 3, it reflects the probability error of a certain comparison, but it does not take into account the remaining comparisons belonging to the family. One way to solve this problem is to report APVs which take into account that multiple tests are conducted. An APV can be compared directly with any chosen significance level α. In this paper, we encourage the use of APVs due to the fact that they provide more information in a statistical analysis.

In the following, we will explain how to compute the APVs depending on the post-hoc procedure used in the analysis, following the indications given in Wright (1992) and Hommel and Bernhard (1999). We also include the post-hoc tests explained in Demšar (2006) and other for comparisons with a control classifier. The notation used in the computation of the APVs is the following:

- Indexes i and j correspond each one to a concrete comparison or hypothesis in the family of hypotheses, according to an incremental order by their p-values. Index i always refers to the hypothesis in question whose APV is being computed and index j refers to another hypothesis in the family.
- p_j is the p-value obtained for the j-th hypothesis.
- k is the number of classifiers being compared.
- m is the number of possible comparisons in an all pairwise comparisons design; that is, $m = \frac{k \cdot (k-1)}{2}$.
- t_j is the maximum number of hypotheses which can be true given that any $(j-1)$ hypotheses are false (see the description of Shaffer's static procedure in Section 2.1).

The procedures of p-value adjustment can be classified into:

- one-step.
  - Bonferroni APV_i: $min\{v;1\}$, where $v=(k-1)p_i$.
  - Nemenyi APV_i: $min\{v;1\}$, where $v=m\cdot p_i$.
- step-up.
  - Hochberg APV_i: $max\{(k-j)p_j : (k-1)\geq j\geq i\}$.
  - Hommel APV_i: see algorithm at Figure 3.
- step-down.
  - Holm APV_i (using a control classifier): $min\{v;1\}$, where $v=max\{(k-j)p_j : 1\leq j\leq i\}$.
  - Nemenyi APV_i: $min\{v;1\}$, where $v=m\cdot p_i$.
  - Holm APV_i (using it in all pairwise comparisons): $min\{v;1\}$, where $v=max\{(m-j+1)p_j : 1\leq j\leq i\}$.
  - Shaffer static APV_i: $min\{v;1\}$, where $v=max\{t_j p_j : 1\leq j\leq i\}$.
  - Bergmann-Hommel APV_i: $min\{v;1\}$, where $v=max\{|I|\cdot min\{p_j, j\in I\} : I\ exhaustive, i\in I\}$.

1. Set $APV_i=p_i$ for all i.
2. For each $j=k-1,k-2,...,2$ (in that order)
   3. Let $B=\emptyset$.
   4. For each i, $i>(k-1-j)$
      5. Compute value $c_i=(j\cdot p_i)/(j+i-k+1)$.
      6. $B=B\cup c_i$.
   7. End for
   8. Find the smallest c_i value in B; call it c_{min}.
   9. If $APV_i<c_{min}$, then $APV_i=c_{min}$.
   10. For each i, $i\leq(k-1-j)$
      11. Let $c_i=min(c_{min},j\cdot p_i)$.
      12. If $APV_i<c_i$, then $APV_i=c_i$.
   13. End for

Figure 3: Algorithm for calculating APVs based on Hommel's procedure

Table 5 shows the results in the final form of APVs for the example considered in this section. As we can see, this example is suitable for observing the difference of power among the test procedures. Also, this table can provide information about the state of retainment or rejection of any hypothesis, comparing its associated APV with the level of significance previously fixed.

i	hypothesis	p_i	APV_{NM}	APV_{HM}	APV_{SH}	APV_{BH}
1	C4.5 vs .Kernel	$4.487 \cdot 10^{-8}$	$4.487 \cdot 10^{-7}$	$4.487 \cdot 10^{-7}$	$4.487 \cdot 10^{-7}$	$4.487 \cdot 10^{-7}$
2	NaiveBayes vs .Kernel	$1.736 \cdot 10^{-7}$	$1.736 \cdot 10^{-6}$	$1.563 \cdot 10^{-6}$	$1.042 \cdot 10^{-6}$	$1.042 \cdot 10^{-6}$

4. Experimental Framework

In this section, we want to determine the power and behavior of the studied procedures through the experiments in which we repeatedly compared the classifiers on sets of ten randomly chosen data sets, recording the number of equivalence hypothesis rejected and APVs. We follow a similar method used in Demšar (2006).

The classifiers used are the same as in the case study of the previous subsection: C4.5 with minimum number of item-sets per leaf equal to 2 and confidence level fitted for optimal accuracy and pruning strategy, naive Bayesian learner with continuous attributes discretized using Fayyad and Irani (1993) discretization, classic 1-Nearest-Neighbor classifier with Euclidean distance, CN2 with Fayyad-Irani's discretizer, star size = 5 and 95% of examples to cover and Kernel classifier with $sigmaKernel = 0.01$, which is the inverse value of the variance that represents the radius of neighborhood. All classifiers are available in KEEL software (Alcalá-Fdez et al., 2008).[5]

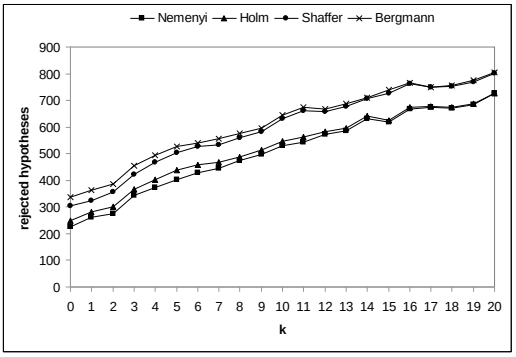
For performing this study, we have compiled a sample of fifty data sets from the UCI machine learning repository (Asuncion and Newman, 2007), all of them valid for a classification task.[6] We measured the performance of each classifier by means of accuracy in test by using ten-fold cross validation. As Demšar did, when comparing two classifiers, samples of ten data sets were randomly selected so that the probability for the data set i being chosen was proportional to $1/(1+e^{-kd_i})$, where d_i is the (positive or negative) difference in the classification accuracies on that data set and k is the bias through which we can regulate the differences between the classifiers. With $k = 0$, the selection is purely random and as k is being higher, the selected data sets are favorable to a particular classifier.

In comparisons of multiple classifiers, samples of data sets have to be selected with the probabilities computed from the differences in accuracy of two classifiers. We have chosen C4.5 and 1-NN, due to the fact that we have found significant differences between them in the study conducted before (Section 2.2) which involved thirty data sets. Note that the repeated comparisons done here only involve ten data sets each time, so the rejection of equivalence of two classifiers is more difficult at the beginning of the process.

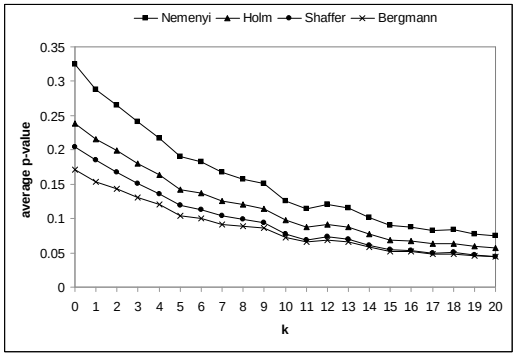
5. It is also available at `http://www.keel.es`.

6. The data sets used are: abalone, adult, australian, autos, balance, bands, breast, bupa, car, cleveland, dermatology, ecoli, flare, german, glass, haberman, hayes-roth, heart, iris, led7digit, letter, lymphography, magic, monks, mushrooms, newthyroid, nursery, optdigits, pageblocks, penbased, pima, ring, satimage, segment, shuttle, spambase, splice, tae, thyroid, tic-tac-toe, twonorm, vehicle, vowel, wine, wisconsin, yeast, zoo.

Figure 4 shows the results of this study considering the pairwise comparison between C4.5 and 1-NN. It gives an approximation of the power of the statistical procedures considered in this paper. Figure 4(a) reflects the number of times they rejected the equivalence of C4.5 and 1-NN. Obviously, the Bergmann-Hommel procedure is the most powerful, followed by Shaffer's static procedure. The graphic also informs us about the use of logically related hypothesis, given that the procedures that use this information have a bias towards the same point and those which do not use this information, tend to a lower point than the first. When the selection of data sets is purely random ($k = 0$), the benefit of using the Bergmann-Hommel procedure is appreciable. Figure 4(b) shows the average APV of the same comparison of classifiers. As we can see, the Nemenyi procedure is too conservative in comparison with the remaining procedures. Again, the benefit of using more sophisticated testing procedures is easily noticeable.



(a) Number of hypotheses rejected in pairwise comparisons



(b) Average APV in pairwise comparisons

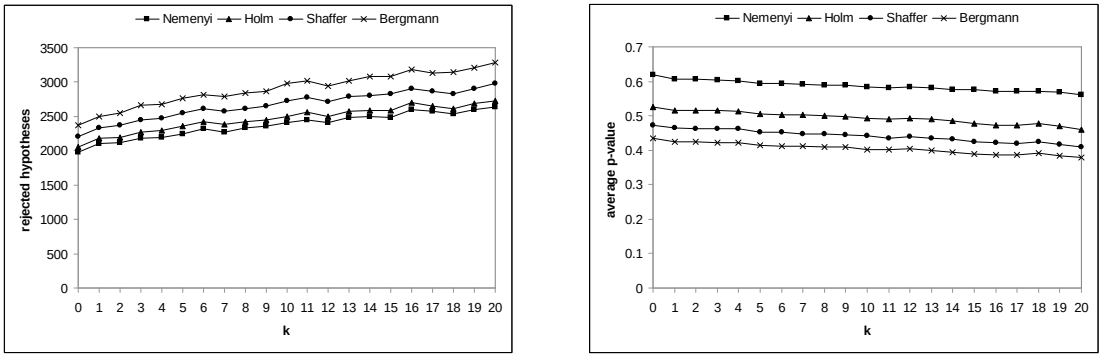
Figure 4: C4.5 vs. 1-NN

Figure 5 shows the results of this study considering all possible pairwise comparisons in the set of classifiers. It helps us to compare the overall behavior of the four testing procedures. Figure 5(a) presents the number of times they rejected any comparison belonging to the family. Although it could seem that the selection of data sets determined by the difference of accuracy between two classifiers may not influence on the overall comparison, the graphic shows us that it occurs. Furthermore, the lines drawn follow a parallel behavior, indicating us the relation and magnitude of power among the four procedures. In Figure 5(b) we illustrate the average APV for all the comparisons of classifiers. We can notice that the conservatism of the Nemenyi test is obvious with respect to the rest of procedures. The benefit of using a more advanced testing procedure is similar with respect to the following less-powerful procedure, except for Holm's procedure.

Finally, our recommendation on the usage of a certain procedure depends on the results obtained in this paper and in our experience in understanding and implementing them:

- We do not recommend the use of Nemenyi's test, because it is a very conservative procedure and many of the obvious differences may not be detected.

- When we use a considerable number of data sets with regards to number of classifiers, we could proceed with the Holm procedure.



(a) Total number of hypotheses rejected

(b) Average APV in all comparisons

Figure 5: All comparisons

- However, conducting the Shaffer static procedure means a not very significant increase of the difficulty with respect to the Holm procedure. Moreover, the benefit of using information about logically related hypothesis is noticeable, thus we strongly encourage the use of this procedure.

- Bergmann-Hommel's procedure is the best performing one, but it is also the most difficult to understand and computationally expensive. We recommend its usage when the situation requires so (i.e., the differences among the classifiers compared are not very significant), given that the results it obtains are as valid as using other testing procedure.

5. Conclusions

The present paper is an extension of Demšar (2006). Demšar does not deal in depth with some topics related to multiple comparisons involving all the algorithms and computations of adjusted p-values.

In this paper, we describe other advanced testing procedures for conducting all pairwise comparisons in a multiple comparisons analysis: Shaffer's static and Bergmann-Hommel's procedures. The advantage that they obtain is produced due to the incorporation of more information about the hypotheses to be tested: in $n \times n$ comparisons, a logical relationship among them exists. As a general rule, the Bergmann-Hommel procedure is the most powerful one but it requires intensive computation in comparisons involving numerous classifiers. The second one, Shaffer's procedure, can be used instead of Bergmann-Hommel's in these cases. Moreover, we present the methods for obtaining the adjusted p-values, which are valid p-values associated to each comparison useful to be compared with any level of significance without restrictions and they also provide more information. We have illustrated them with a case study and we have checked that the new described methods are more powerful than the classical ones, Nemenyi's and Holm's procedures.

Acknowledgments

Abstract

JNCC2 implements the *naive credal classifier 2* (NCC2). This is an extension of naive Bayes to imprecise probabilities that aims at delivering robust classifications also when dealing with small or incomplete data sets. Robustness is achieved by delivering set-valued classifications (that is, returning multiple classes) on the instances for which (i) the learning set is not informative enough to smooth the effect of choice of the prior density or (ii) the uncertainty arising from missing data prevents the reliable indication of a single class. JNCC2 is released under the GNU GPL license.

Keywords: imprecise probabilities, missing data, naive Bayes, naive credal classifier 2, Java

1. Introduction

JNCC2 is the Java implementation of *naive credal classifier 2* (NCC2) (Corani and Zaffalon, 2008). NCC2 extends naive Bayes (NBC) to *imprecise probabilities* (Walley, 1991) in order to deliver reliable classifications even on small or incomplete data sets.

A problem of NBC is that, on small data sets, it may return *prior-dependent* classifications, that is, it might identify a different class as the most probable one, depending on the prior density adopted to infer the classifier. In some cases this can lead NBC to issue fragile predictions. To deal with this problem, NCC2 specifies a set of prior densities, referred to as *prior credal set*; the credal set is then turned into a set of posteriors via element-wise application of Bayes' rule. Eventually, NCC2 returns the classes that are *non-dominated* with respect to the set of posterior densities (class c_1 dominates class c_2 if the probability of c_1 is larger than the probability of c_2 for *all* the posteriors). When faced with an instance that would be classified in a prior-dependent way by naive Bayes, NCC2 will detect multiple non-dominated classes and will then return multiple classes; this is an *indeterminate classification*.

As for missing data, NCC2 assumes that the missingness process (MP) which generates missing data can be either *MAR* (that is, missing at random), or unknown; in the latter case, it is referred to as non-MAR. As MAR missing data can be safely ignored (Little and Rubin, 1987), NCC2 ignores them. On the other hand, NCC2 deals *conservatively* with non-MAR missing data, that is, it considers all the possible replacements for non-MAR missing data. NCC2 can handle mixed situations where some features are subject to a MAR MP and some others to a non-MAR MP; moreover, the list of features subject to the MAR and to the unknown MP can be different between training and test set. The conservative treatment of non-MAR missing data generates additional

indeterminacy of NCC2, as a way to preserve reliability despite the information hidden by missing values and by the fact that the MP is unknown.

NCC2 can hence be seen as separating "easy" instances, over which it returns a single class, from "hard" instances, over which it returns an indeterminate classification. Experimental evaluations have shown that the accuracy of naive Bayes sharply drops on the hard instances, while on the same instances NCC2 remains reliable thanks to the indeterminate classifications.

Programming language: Java. *Developer*: Giorgio Corani (IDSIA, Switzerland). *Open source license*: GNU GPL. *Website*: `www.idsia.ch/~giorgio/jncc2.html`. *Software required*: Java Runtime Environment 5.0 or higher. *Operating system*: OS independent. *User interface*: command-line.

Figure 1: Essential information about JNCC2.

The zip file downloadable from the JNCC2 website contains executables, sources, examples, user manual and tutorial. A GUI version of the software will be released in the near future and will be published on the same website.

2. Indicators of Performance

The performance of NBC is measured by the *accuracy*, that is, the percentage of correct classifications.

The performance of NCC2 is measured by several indicators: *determinacy*: the percentage of classifications having as output a unique class; *single accuracy*: the accuracy of NCC2 when it is determinate; *indeterminate output size*: the average number of classes returned when NCC2 is indeterminate; *set-accuracy*: the percentage of indeterminate classifications that contain the actual class.

To assess the effectiveness of the approach based on imprecise probabilities, the accuracy of naive Bayes is moreover measured separately on the instances recognized as hard and easy by NCC2. If NCC2 is effective at separating easy from hard instances, a significant difference will be found between the two measures.

Moreover, JNCC2 computes the confusion matrices of NBC and NCC2; in case of NCC2 the confusion matrix refers to the determinate classifications only.

3. Some Implementation Details

JNCC2 loads data from ARFF files; this is a plain text format, originally developed for WEKA (Witten and Frank, 2005). A large number of ARFF data sets, including the data sets from the UCI repository, is available from the address `http://www.cs.waikato.ac.nz/ml/weka/index_datasets.html`.

As a pre-processing step, JNCC2 discretizes all the numerical features, using the supervised discretization algorithm of Fayyad and Irani (1993). The discretization intervals are computed on the training set, and then applied unchanged on the test set.

NCC2 is implemented exploiting the computationally efficient procedure described in (Corani and Zaffalon, 2008, Appendix A).

Algorithm 1 Pseudocode for validation via testing file.

```
validateTestFile()

  /*loads training and test file; reads list of non-Mar features; discretizes features*/
  parseArffFile();
  parseArffTestingFile();
  parseNonMar();
  discretizeNumFeatures();

  /*learns and validates NBC*/
  nbc = new NaiveBayes(trainingSet);
  nbc.classifyInstances(testSet);

  /*learns and validates NCC2; the list of non-Mar features in training and testing is required*/
  ncc2 = new NaiveCredalClassifier2(trainingSet, nonMarTraining, nonMarTesting);
  ncc2.classifyInstances(testingSet);

  /*writes output files*/
  writePerfIndicators();
  writePredictions();
```

JNCC2 can perform three kinds of experiments: training and testing, cross-validation, and classification of instances of the test set whose class is unknown. The pseudo code of the experiment with training and testing is described by Algorithm 1.

4. Examples

To run the following examples, move to the directory `examples/completeData`, generated under the JNCC2 directory after unzipping the package. To perform a training and testing experiment, type for instance:

"`java jncc20.Jncc . iris.training.arff iris.testing.arff`".

As a consequence, JNCC2 will load the training and test set, discretize the numerical features, learn both NBC and NCC2, and use them to predict the instances of the test set. Then it will write the performance measures and the predictions to file. Similar experiments can be performed also with the glass and contact-lenses data sets, provided in the same directory.

To run a cross-validation experiment, type for instance:

"`java jncc20.Jncc . iris.training.arff cv`".

JNCC2 will perform 10 runs of 10-folds stratified cross-validation, that is, 100 training/test experiments. JNCC2 will report the performance indicators to file, together with their observed standard deviations, but it will not write the predictions. (As a side remark, if one wants to run cross-validation, there is no need of splitting the original data set into a training and a testing file, as it is has been done in this directory.)

The directory `examples/missingData` contains two examples of data sets containing missing data; a look at the provided files `NonMar.txt` should make it clear how to declare the non-MAR features.

The directory `examples/unkClasses` contains two examples in which the class of the instances of the testing set is not available. For the iris data set, the experiment is for instance started as follows:

```
"java jncc20.Jncc .  iris.training.arff iris.testingUnkClasses.arff
                                unknownclasses".
```

Abstract

With the increased availability of data for complex domains, it is desirable to learn Bayesian network structures that are sufficiently expressive for generalization while at the same time allow for tractable inference. While the method of thin junction trees can, in principle, be used for this purpose, its fully greedy nature makes it prone to overfitting, particularly when data is scarce. In this work we present a novel method for learning Bayesian networks of bounded treewidth that employs global structure modifications and that is polynomial both in the size of the graph and the treewidth bound. At the heart of our method is a dynamic triangulation that we update in a way that facilitates the addition of chain structures that increase the bound on the model's treewidth by at most one. We demonstrate the effectiveness of our "treewidth-friendly" method on several real-life data sets and show that it is superior to the greedy approach as soon as the bound on the treewidth is nontrivial. Importantly, we also show that by making use of global operators, we are able to achieve better generalization even when learning Bayesian networks of unbounded treewidth.

Keywords: Bayesian networks, structure learning, model selection, bounded treewidth

1. Introduction

Recent years have seen a surge of readily available data for complex and varied domains. Accordingly, increased attention has been directed towards the automatic learning of large scale probabilistic graphical models (Pearl, 1988), and in particular to the learning of the graph structure of a Bayesian network. With the goal of making predictions or providing probabilistic explanations, it is desirable to learn models that generalize well and at the same time have low inference complexity or a small treewidth (Robertson and Seymour, 1987).

Chow and Liu (1968) showed that the optimal Markov or Bayesian network can be learned efficiently when the underlying structure of the network is constrained to be a tree. Learning the structure of general Bayesian networks, however, is computationally difficult (Dagum and Luby, 1993), as is the learning of simpler structures such as poly-trees (Dasgupta, 1999) or even unconstrained chains (Meek, 2001). Several works try to generalize the work of Chow and Liu (1968) either by making assumptions about the generating distribution (e.g., Narasimhan and Bilmes, 2003; Abbeel et al., 2006), by searching for a local maxima of a mixture of trees model (Meila and Jordan, 2000), or by providing an approximate method that is polynomial in the size of the graph but

exponential in the treewidth bound (e.g., Karger and Srebro, 2001; Chechetka and Guestrin, 2008). In the context of general Bayesian networks, Bach and Jordan (2002) propose a local greedy approach that upper bounds the treewidth of the model at each step. Because evaluating the bound on the treewidth of a graph is super-exponential in the treewidth (Bodlaender, 1996), their approach relies on heuristic techniques for producing tree-decompositions (clique trees) of the model at hand, and uses that decomposition as an upper bound on the true treewidth of the model. This approach, like standard structure search, does not provide guarantees on the performance of the model, but is appealing in its ability to efficiently learn Bayesian networks with an arbitrary treewidth bound.

While tree-decomposition heuristics such as the one employed by Bach and Jordan (2002) are efficient and useful on average, there are two concerns when using such a heuristic in a fully greedy manner. First, even the best of heuristics exhibits some variance in the treewidth estimate (see, for example, Koster et al., 2001) and thus a single edge modification can result in a jump in the treewidth estimate despite the fact that adding a single edge to the network can increase the true treewidth by at most one. More importantly, most structure learning scores (e.g., BIC, MDL, BDe, BGe) tend to learn spurious edges that result in overfitting when the number of samples is relatively small, a phenomenon that is made worse by a fully greedy approach. Intuitively, to generalize well, we want to learn bounded treewidth Bayesian networks where structure modifications are globally beneficial (contribute to the score in many regions of the network).

In this work we propose a novel approach for efficiently learning Bayesian networks of bounded treewidth that addresses these concerns. At the heart of our method is the idea of dynamically updating a valid moralized triangulation of our model in a particular way, and using that triangulation to upper bound the model's treewidth. Briefly, we use a novel triangulation procedure that is treewidth-friendly: the treewidth of the triangulated graph is guaranteed to increase by at most one when an edge is added to the Bayesian network. Building on the single edge triangulation, we are also able to characterize sets of edges that *jointly* increase the treewidth of the triangulation by at most one. We make use of this characterization of treewidth-friendly edge sets in a dynamic programming approach that learns the optimal treewidth-friendly chain with respect to a node ordering. Finally, we learn a bounded treewidth Bayesian network by iteratively augmenting the model with such chains.

Importantly, instead of local edge modifications, our method progresses by making use of chain structure operators that are more globally beneficial, leading to greater robustness and improving our ability to generalize. At the same time, we are able to *guarantee* that the bound on the model's treewidth grows by at most one at each iteration. Thus, our method resembles the global nature of the method of Chow and Liu (1968) more closely than the thin junction tree approach of Bach and Jordan (2002), while being applicable in practice to any desired treewidth.

We evaluate our method on several challenging real-life data sets and show that our method is able to learn richer models that generalize better on test data than a greedy variant for a range of treewidth bounds. Importantly, we show that even when models with unbounded treewidth are learned, by employing global structure modification operators, we are better able to cope with the problem of local maxima in the search and learn models that generalize better.

The rest of the paper is organized as follows. After briefly discussing background material in Section 2, we provide a high-level overview of our approach in Section 3. In Section 4 we present our treewidth-friendly triangulation procedure in detail, followed by a multiple edge update discussion in Section 5. In Section 6 we show how to learn a treewidth-friendly chain given a node ordering and in Section 7 we propose a practical node ordering that is motivated by the properties of

our triangulation procedure. We evaluate the merits of our method in Section 8 and conclude with a discussion in Section 9.

2. Background

In this section we provide a basic review of Bayesian Networks as well as introduce the graph theoretic concepts of treewidth-decompositions and treewidth.

2.1 Bayesian Networks

Consider a finite set $\mathcal{X} = \{X_1, \ldots, X_n\}$ of random variables. A *Bayesian network* (Pearl, 1988) is an annotated directed acyclic graph that encodes a joint probability distribution over $\mathcal{X}$. Formally, a Bayesian network over $\mathcal{X}$ is a pair $B = \langle \mathcal{G}, \Theta \rangle$. The first component, $\mathcal{G} = (V, E)$, is a directed acyclic graph whose vertices V correspond to the random variables in $\mathcal{X}$. The edges E in the graph represent direct dependencies between the variables. The graph $\mathcal{G}$ represents independence properties that are assumed to hold in the underlying distribution: each X_i is independent of its non-descendants given its parents $\mathbf{Pa}_i \subset \mathcal{X}$ denoted by $(X_i \perp \mathit{NonDescendants}_i \mid \mathbf{Pa}_i)$. The second component, Θ, represents the set of parameters that quantify the network. Each node is annotated with a *conditional probability distribution* $P(X_i \mid \mathbf{Pa}_i)$, representing the conditional probability of the node X_i given its parents in $\mathcal{G}$, defined by the parameters $\Theta_{X_i|\mathbf{Pa}_i}$. A Bayesian network defines a unique joint probability distribution over $\mathcal{X}$ given by

$$P(X_1, \ldots, X_n) = \prod_{i=1}^{n} P(X_i \mid \mathbf{Pa}_i).$$

A *topological ordering* O_T of variables with respect to a Bayesian network structure is an ordering where each variable appears before all of its descendants in the network.

Given a Bayesian network model, we are interested in the task of probabilistic inference, or evaluating queries of the form $P_B(Y \mid Z)$ where Y and Z are arbitrary subsets of $\mathcal{X}$. This task is, in general, NP-hard (Cooper, 1990), except when $\mathcal{G}$ is tree structured. The actual complexity of inference in a Bayesian network (whether by variable elimination, by belief propagation in a clique tree, or by cut-set conditioning on the graph) is proportional to its *treewidth* (Robertson and Seymour, 1987) which, roughly speaking, measures how closely the network resembles a tree (see Section 2.2 for more details).

Given a network structure $\mathcal{G}$, the problem of learning a Bayesian network can be stated as follows: given a training set $\mathcal{D} = \{x[1], \ldots, x[M]\}$ of instances of $X \subseteq \mathcal{X}$, we want to learn parameters for the network. In the *Maximum Likelihood* setting we want to find the parameter values θ that maximize the log-likelihood function

$$\log P(\mathcal{D} \mid \mathcal{G}, \theta) = \sum_{m} \log P(x[m] \mid \mathcal{G}, \theta).$$

This function can be equivalently (up to a multiplicative constant) written as $\boldsymbol{E}_{\hat{P}}[\log P(X \mid \mathcal{G}, \theta)]$ where $\hat{P}$ is the empirical distribution in $\mathcal{D}$. When all instances in $\mathcal{D}$ are complete (that is, each training instance assigns values to all of the variables), estimating the *maximum likelihood* parameters can be done efficiently using a closed form solution for many choices of conditional probability distributions (for more details see Heckerman, 1998).

Learning the structure of a network poses additional challenges as the number of possible structures is super-exponential in the number of variables and the task is, in general, NP-hard (Chickering, 1996; Dasgupta, 1999; Meek, 2001). In practice, structure learning is typically done using a local search procedure, which examines local structure changes that are easily evaluated (add, delete or reverse an edge). This search is usually guided by a scoring function such as the MDL principle based score (Lam and Bacchus, 1994) or the *Bayesian score* (BDe) (Heckerman et al., 1995). Both scores penalize the likelihood of the data to limit the model complexity. An important characteristic of these scoring functions is that when the data instances are complete the score is *decomposable*. More precisely, a decomposable score can be rewritten as the sum

$$Score(\mathcal{G}:\mathcal{D}) = \sum_i \text{FamScore}_{X_i}(\mathbf{Pa}_i \ : \ \mathcal{D}).$$

where $\text{FamScore}_{X_i}(\mathbf{Pa}_i \ : \ \mathcal{D})$ is the *local* contribution of X_i to the total network score. This term depends only on values of X_i and $\mathbf{Pa}_{X_i}$ in the training instances.

Chow and Liu (1968) showed that maximum likelihood trees can be learned efficiently via a maximum spanning tree whose edge weights correspond to the empirical information between the two variables corresponding to the edge's endpoints. Their result can be easily generalized for any decomposable score.

2.2 Tree-Decompositions and Treewidth

The notions of tree-decompositions (or clique trees) and treewidth were introduced by Robertson and Seymour (1987).[1]

Definition 2.1: A tree-decomposition of an undirected graph $\mathcal{H} = (V,E)$ is a pair $(\{C_i\}_{i\in\mathcal{T}}, \mathcal{T})$ with $\{C_i\}_{i\in\mathcal{T}}$ a family of subsets of V, one for each node of $\mathcal{T}$, and $\mathcal{T}$ a tree such that

- $\bigcup_{i\in\mathcal{T}} C_i = V$.
- for all edges $(v,w) \in E$ there exists an $i \in \mathcal{T}$ with $v \in C_i$ and $w \in C_i$.
- for all $i,j,k \in \mathcal{T}$: if j is on the (unique) path from i to k in $\mathcal{T}$, then $C_i \cap C_k \subseteq C_j$.

∎

The treewidth of a tree-decomposition $(\{C_i\}_{i\in\mathcal{T}}, \mathcal{T})$ is defined to be $\max_{i\in\mathcal{T}} |C_i| - 1$. The treewidth $TW(\mathcal{H})$ of an undirected graph $\mathcal{H}$ is the minimum treewidth over all possible tree-decompositions of $\mathcal{H}$. An equivalent notion of treewidth can be phrased in terms of a graph that is a triangulation of $\mathcal{H}$.

Definition 2.2: An induced path $\mathcal{P} = p_1 — p_2 \ldots p_L$ in an undirected graph $\mathcal{H}$ is a path such that for every non-adjacent $p_i, p_j \in \mathcal{P}$ there is no edge $(p_i — p_j)$ in $\mathcal{H}$. An induced (non-chordal) cycle is an induced path whose endpoints are the same vertex. ∎

Definition 2.3: A triangulated or chordal graph is an undirected graph that has no induced cycles. Equivalently, it is an undirected graph in which every cycle of length greater than three contains a chord. ∎

1. The properties defining a tree-decomposition are equivalent to the corresponding *family preserving* and *running intersection* properties of clique trees introduced by Lauritzen and Spiegelhalter (1988) at around the same time.

It can be easily shown (Robertson and Seymour, 1987) that the treewidth of a given triangulated graph is the size of the maximal clique of the graph minus one. The treewidth of an undirected graph $\mathcal{H}$ is then equivalently the minimum treewidth over all possible triangulations of $\mathcal{H}$.

For the underlying directed acyclic graph of a Bayesian network, the treewidth can be characterized via a triangulation of the moralized graph.

Definition 2.4: A moralized graph $\mathcal{M}$ of a directed acyclic graph $\mathcal{G}$ is an undirected graph that includes an edge $(i—j)$ for every edge $(i \rightarrow j)$ in $\mathcal{G}$ and an edge $(p—q)$ for every pair of edges $(p \rightarrow i), (q \rightarrow i)$ in $\mathcal{G}$. ∎

The treewidth of a Bayesian network graph $\mathcal{G}$ is defined as the treewidth of its moralized graph $\mathcal{M}$, and corresponds to the complexity of inference in the model. It follows that the maximal clique of *any* moralized triangulation of $\mathcal{G}$ is an upper bound on the treewidth of the model, and thus its inference complexity.[2]

3. Learning Bounded Treewidth Bayesian Networks: Overview

Our goal is to develop an efficient algorithm for learning Bayesian networks with an arbitrary treewidth bound. As learning the optimal such network is NP-hard (Dagum and Luby, 1993), it is important to note the properties that we would like our algorithm to have. First, we would like our algorithm to be *provably* polynomial in the number of variables *and* in the desired treewidth. Thus, we cannot rely on methods such as that of Bodlaender (1996) to verify the boundedness of our network as they are super-exponential in the treewidth and are practical only for small treewidths. Second, we want to learn networks that are non-trivial. That is, we want to ensure that we do not quickly get stuck in local maxima due to the heuristic employed for bounding the treewidth of our model. Third, similar to the method of Chow and Liu (1968), we want to employ global structure operators that are optimal in some sense. In this section we present a brief high-level overview of our algorithm. In the next sections we provide detailed description of the different components along with proof of correctness and running time guarantees.

At the heart of our method is the idea of using a dynamically maintained moralized triangulated graph to upper bound the treewidth of the current Bayesian network. When an edge is added to the Bayesian network we update this (moralized) triangulated graph in a particular manner that is not only guaranteed to produce a valid triangulation, but that is also treewidth-friendly. That is, our update is guaranteed to increase the size of the maximal clique of the triangulated graph, and hence the treewidth bound, by at most one. As we will see, the correctness of our treewidth-friendly edge update as well as the fact that we can carry it out efficiently will both directly rely on the dynamic nature of our method. We discuss our edge update procedure in detail in Section 4.

An important property of our edge update is that we can characterize the parts of the network that are "contaminated" by the update by using the notion of blocks (bi-connected components) in the triangulated graph. This allows us to define sets of edges that are *jointly* treewidth-friendly. That is, these edge sets are guaranteed to increase the treewidth of the triangulated graph by at most one when all edges in the set are added to the Bayesian network structure. We discuss multiple edge updates in Section 5.

2. It also follows that the size of a family (a node and its parents) provides a lower bound on the treewidth, although we will not make use of this property in our work.

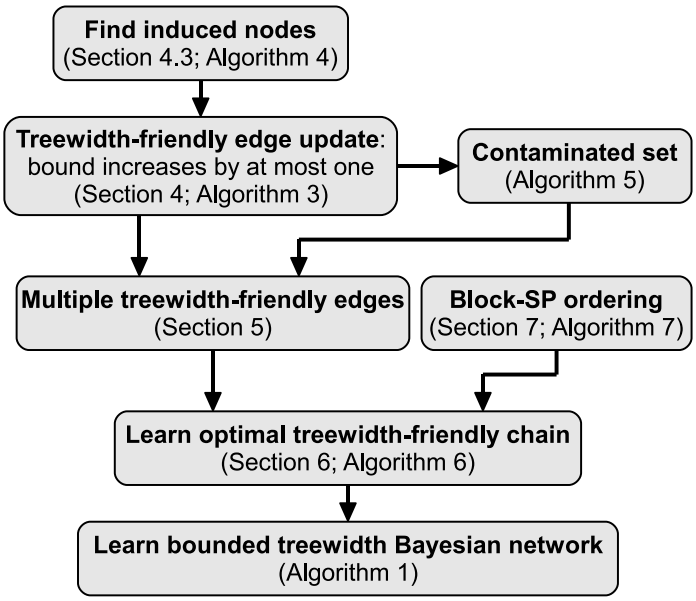

Figure 1: The building blocks of our method for learning Bayesian networks of bounded treewidth and how they depend on each other.

Building on the characterization of treewidth-friendly sets, we propose a dynamic programming approach for efficiently learning the optimal treewidth-friendly chain with respect to a node ordering. We present this procedure in Section 6. To encourage chains that are rich in structure (have many edges), in Section 7 we propose a block shortest-path node ordering that is motivated by the properties of our triangulation procedure.

Finally, we learn Bayesian networks with bounded treewidth by starting with a Chow-Liu tree (Chow and Liu, 1968) and iteratively applying a global structure modification operator where the current structure is augmented with a treewidth-friendly chain that is optimal with respect to the ordering chosen. Appealingly, as each global modification can increase our estimate of the treewidth by at most one, if our bound on the treewidth is K, at least K such chains will be added before we even face the problem of local maxima. In practice, as some chains do not increase the treewidth, many more such chains are added for a given maximum treewidth bound. Figure 1 illustrates the relationship between the different components of our approach.

Algorithm (1) shows pseudo-code of our method. Briefly, Line 4 initializes our model with a Chow and Liu (1968) tree; Line 8 produces a node ordering given the model at hand; Line 9 finds the optimal chain with respect to that ordering; and Line 10 augments the current model with the new edges. We then use our treewidth-friendly edge update procedure to perform the moralization and triangulation on $\mathcal{M}^+$ for each edge added to the Bayesian network $\mathcal{G}$ (Line 12). Once the maximal clique size reaches the treewidth bound K, we continue to add edges greedily until no more edges can be added without increasing the treewidth (Line 16).

Theorem 3.1: Given a treewidth bound K, Algorithm (1) runs in time polynomial in the number of variables and K.

Algorithm 1: Learning A Bayesian Network with Bounded Treewidth

Input : $\mathcal{D}$ // training set
K // maximum treewidth
Output: $\mathcal{G}$ // a graph structure with treewidth at most K

$\mathcal{G} \leftarrow$ maximum scoring spanning tree
$\mathcal{M}^+ \leftarrow$ undirected skeleton of $\mathcal{G}$
$k \leftarrow 1$
while $k < K$ *and positive scoring edges exist* **do**
  $O \leftarrow$ node ordering given $\mathcal{G}$ and $\mathcal{M}^+$ // Algorithm (7)
  $\mathcal{C} \leftarrow$ maximum scoring chain with respect to O // Algorithm (6)
  $\mathcal{G} \leftarrow \mathcal{G} \cup \mathcal{C}$
  foreach $(i \rightarrow j) \in \mathcal{C}$ **do**
    $\mathcal{M}^+ \leftarrow$ EdgeUpdate$(\mathcal{M}^+, (i \rightarrow j))$ // Algorithm (3)
  end foreach
  $k \leftarrow$ maximal clique size of $\mathcal{M}^+$
end
Greedily add edges to $\mathcal{G}$ that do not increase treewidth beyond K
return $\mathcal{G}$

We will prove this result gradually using the developments of the next sections. Note that we will show that our method is guaranteed to be polynomial both in the size of the graph *and* the treewidth bound. Thus, like the greedy thin junction tree approach of Bach and Jordan (2002), it can be used to learn a Bayesian networks given an arbitrary treewidth bound. It is also important to note that, as in the case of the thin junction tree method, the above result is only useful if the actual Bayesian network learned is expressive enough to be useful for generalization. As we will demonstrate in Section 8, by making use of global treewidth-friendly updates, our method indeed improves on the greedy approach and learns models that are rich and useful in practice.

4. Treewidth-Friendly Edge Update

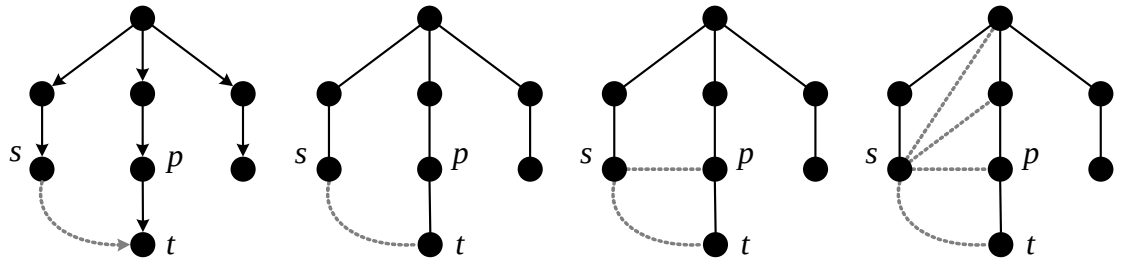
In this section we consider the basic building block of our method: the manner in which we update the triangulated graph when a single edge is added to the Bayesian network structure. Throughout this section we will build on the dynamic nature of our method and make use of the valid moralized triangulation graph that was constructed before adding an edge $(s \rightarrow t)$ to the Bayesian network structure. We will start by augmenting it with $(s$—$t)$ and any edges required for moralization. We will then triangulate the graph in a treewidth-friendly way, increasing the size of the maximal clique in the triangulated graph by at most one. For clarity of exposition, we start with a simple variant of our triangulation procedure in Section 4.1 and refine it in Section 4.2.

4.1 Single-source Triangulation

To gain intuition into how the dynamic nature of our update is useful, we use the notion of induced paths or paths with no shortcuts (see Section 2), and make explicit the following obvious fact.

Algorithm 2: SingleSourceEdgeUpdate: Update of $\mathcal{M}^+$ when adding $(s \rightarrow t)$ to $\mathcal{G}$

1 **Input** : $\mathcal{M}^+$ // triangulated moralized graph of $\mathcal{G}$
2 $(s \rightarrow t)$ // edge to be added to $\mathcal{G}$
3 **Output**: ${\mathcal{M}^+}_{(s \rightarrow t)}$ // a triangulated moralized graph of $\mathcal{G} \cup (s \rightarrow t)$
4 ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow \mathcal{M}^+ \cup (s—t)$
5 **foreach** $p \in \mathbf{Pa}_t$ **do**
6 ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow {\mathcal{M}^+}_{(s \rightarrow t)} \cup (s—p)$ // moralization
7 **end foreach**
8 **foreach** *node v on an induced path between s and* $t \cup \mathbf{Pa}_t$ *in* $\mathcal{M}^+$ **do**
9 ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow {\mathcal{M}^+}_{(s \rightarrow t)} \cup (s—v)$
10 **end foreach**
11 **return** ${\mathcal{M}^+}_{(s \rightarrow t)}$



(a) Bayesian network $\mathcal{G} \cup (s \rightarrow t)$

(b) Addition of $(s—t)$ to $\mathcal{M}^+$ (line 4)

(c) Addition of moralizing edges (lines 5-7)

(d) Addition of the triangulating edges (lines 8-10)

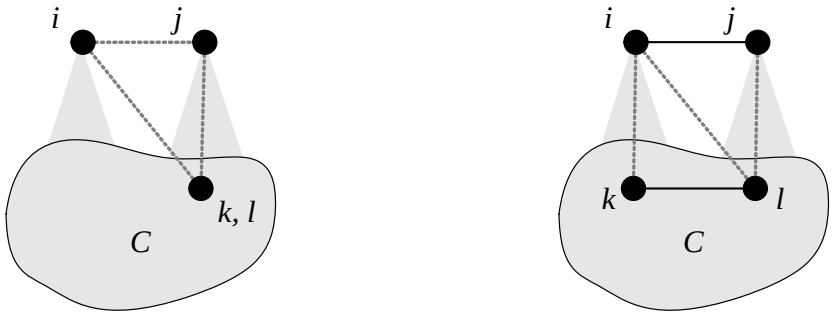
Figure 2: Example showing the application of the single-source triangulation procedure of Algorithm (2) to a simple graph. The treewidth of the original graph is one, while the graph augmented with $(s \rightarrow t)$ has a treewidth of two (maximal clique of size three).

Observation 4.1: Let $\mathcal{G}$ be a Bayesian network structure and let $\mathcal{M}^+$ be a moralized triangulation of $\mathcal{G}$. Let $\mathcal{M}_{(s \rightarrow t)}$ be $\mathcal{M}^+$ augmented with the edge $(s—t)$ and with the edges $(s—p)$ for every parent p of t in $\mathcal{G}$. Then, every non-chordal cycle in $\mathcal{M}_{(s \rightarrow t)}$ involves s and either t or a parent of t and an induced path between the two vertices.

Stated simply, if the graph was triangulated before the addition of $(s \rightarrow t)$ to the Bayesian network, then we only need to triangulate cycles created by the addition of the new edge or those forced by moralization. This observation immediately suggests the straight-forward *single-source triangulation* outlined in Algorithm (2): add an edge $(s—v)$ for every node v on an induced path between s and t or s and a parent p of t before the edge update. Figure 2 shows an application of the procedure to a simple graph. Clearly, this naive method results in a valid moralized triangulation of $\mathcal{G} \cup (s \rightarrow t)$. Surprisingly, we can also show that it is treewidth-friendly.

Theorem 4.2: The treewidth of the output graph ${\mathcal{M}^+}_{(s \rightarrow t)}$ of Algorithm (2) is greater than the treewidth of the input graph $\mathcal{M}^+$ by at most one.

Proof: Let C be the nodes in any maximal clique $\mathcal{M}^+$. We consider the minimal set of edges required to increase the size of C by more than one and show that this set cannot be a subset of the edges added by our single-source triangulation. In order for the clique to grow by more than one node, at least two nodes i and j not originally in C must become connected to all nodes in C. Since there exists at least one node $k \in C$ that is not adjacent to i and similarly there exists at least one node $l \in C$ not adjacent to j, both edges $(i—k)$ and $(j—l)$ are needed to form the larger clique. There are two possibilities illustrated below (the dotted edges are needed to increase the treewidth by two and all other edges between i, j and the current maximal clique are assumed to exist):

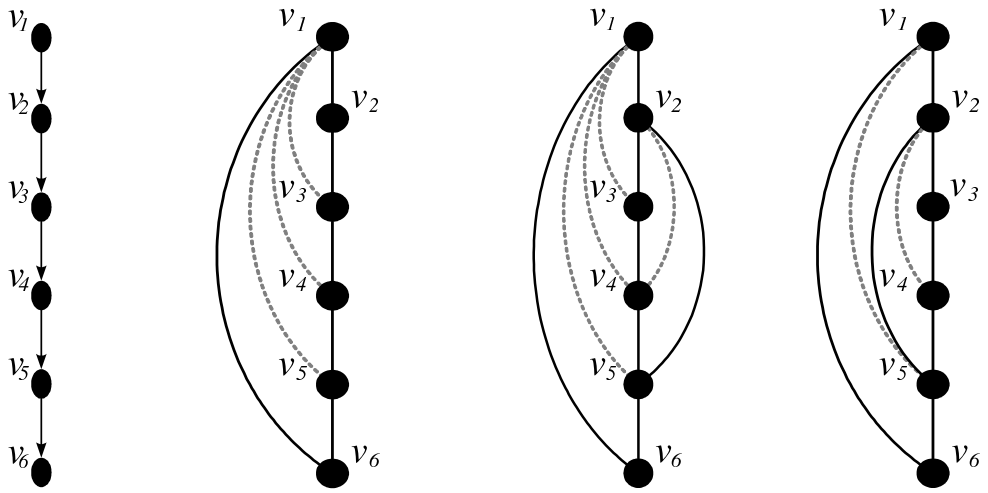


(a) $(i—j)$ does not exist (b) $(i—j)$ exists

- $(i—j)$ **does not exist (a)**. In this case k and l can be the same node but the missing edge $(i—j)$ is also required to form the larger clique.
- $(i—j)$ **exists (b)**. In this case k and l cannot be the same node or the original clique was not maximal since $C \cup i \cup j \setminus k$ would have formed a larger clique. Furthermore one of k or l must not be connected to both i and j otherwise $i—j—k—l—i$ forms a non-chordal cycle of length four contradicting our assumption that the original graph was triangulated. Thus, in this case either $(i—l)$ or $(j—k)$ are also required to form the larger clique.

In both scenarios, at least two nodes have two incident edges and the three edges needed cannot all be incident to a single vertex. Now consider the triangulation procedure. Since, by construction, all edges added in Algorithm (2) emanate from s, the above condition (requiring two nodes to have two incident edges and the three edges not all incident to a single vertex) is not met and the size of the maximal clique in the new graph cannot be larger than the size of the maximal clique in $\mathcal{M}^+$ by more than one. It follows that the treewidth of the moralized triangulated graph cannot increase by more than one. ∎

One problem with the proposed single-source triangulation, despite it being treewidth-friendly, is the fact that so many vertices are connected to the source node making the triangulations shallow (the length of the shortest path between any two nodes is small). While this is not a problem when considering a single edge update, it can have an undesirable effect on future edges and increases the chances of the formation of large cliques. As an example, Figure 3 shows a simple case where two successive single-source edge updates increase the treewidth by two while an alternative approach increases the treewidth by only one. In the next section, we present a refinement of the single-source triangulation that is motivated by this example.



(a) Chain network (b) Triangulation after $(v_1 \rightarrow v_6)$ is added (c) Triangulation after $(v_2 \rightarrow v_5)$ is added (d) Alternative triangulation

Figure 3: Example demonstrating that the single-source edge update of Algorithm (2) can be problematic for later edge additions. (a) shows a simple six nodes chain Bayesian network; (b) a single-source triangulation when $(v_1 \rightarrow v_6)$ is added to the network with a treewidth of two; (c) a single-source triangulation when in addition $(v_2 \rightarrow v_5)$ is added to the model with a treewidth of three; (d) an alternative triangulation to (b). This triangulation already includes the edge $(v_2$—$v_5)$ and the moralizing edge $(v_2$—$v_4)$ and thus is also a valid moralized triangulation after $(v_2 \rightarrow v_5)$ has been added, but has a treewidth of only two.

4.2 Alternating Cut-vertex Triangulation

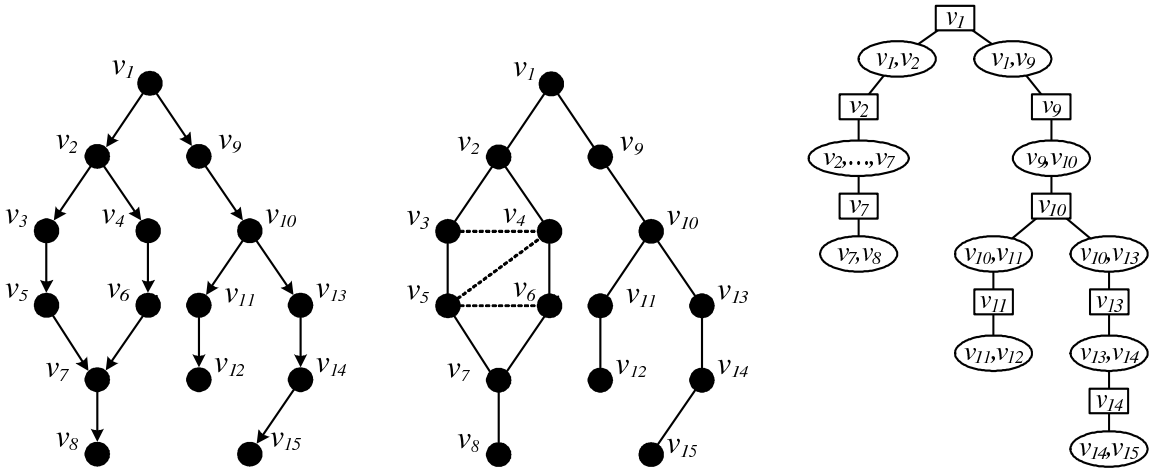
To refine the single-source triangulation discussed above with the goal of addressing the problem exemplified in Figure 3 we make use of the concepts of cut-vertices, blocks, and block trees (see, for example, Diestel, 2005).

Definition 4.3: A block, or biconnected component, of an undirected graph is a set of connected nodes that cannot be disconnected by the removal of a single vertex. By convention, if the edge $(u$—$v)$ is in the graph then u and v are in the same block. Vertices that separate (are in the intersection of) blocks are called cut-vertices. ∎

It follows directly from the definition that between every two nodes in a block (of size greater than two), there are at least two distinct paths, that is, a cycle. There are also no simple cycles involving nodes in different blocks.

Definition 4.4: A block tree $\mathcal{B}$ of an undirected graph $\mathcal{H}$ is a graph with nodes that correspond both to cut-vertices and to blocks of $\mathcal{H}$. The edges in the block tree connect any block node B_i with a cut-vertex node v_j if and only if $v_j \in B_i$ in $\mathcal{H}$. ∎

It can be easily shown that the above connectivity condition indeed forces a tree structure and that this tree is unique (see Figure 4 for an example). In addition, any path in $\mathcal{H}$ between two nodes



(a) Bayesian network, $\mathcal{G}$ (b) A possible triangulated graph, $\mathcal{M}^+$ (c) Unique block tree, $\mathcal{B}$

Figure 4: Example of a Bayesian network with a corresponding moralized triangulated graph and the unique block tree. Boxes in the block tree denote cut-vertices, ellipses denote blocks.

in different blocks passes through all the cut-vertices along the path between the blocks in $\mathcal{B}$. An important consequence that directly follows from the result of Dirac (1961) is that an undirected graph whose blocks are triangulated is overall triangulated.

We can now describe our improved treewidth-friendly triangulation outlined in Algorithm (3) and illustrated via an example in Figure 5. First, the triangulated graph is augmented by the edge $(s—t)$ and any edges needed for moralization (Figure 5(b) and (c)). Second, if s and t are not in the same block, a block level triangulation is carried out by starting from s and zig-zagging across the cut-vertices along the unique path between the blocks containing s and t and its parents in the block tree (Figure 5(d)). Next, within each block along the path (not containing s or t), a chord is added between the "entry" and "exit" cut-vertices along the *block path*, thereby short-circuiting any other *node path* through the block. In addition, within each such block we perform a single-source triangulation with respect to s' by adding an edge $(s'—v)$ between the first cut-vertex s' and any node v on an induced path between s' and the second cut-vertex t'. The block containing s is treated the same as other blocks on the path with the exception that the short-circuiting edge is added between s and the first cut-vertex along the path from s to t. For the block containing t and its parents, instead of adding a chord between the entry cut-vertex and t, we add chords directly from s to any node v (within the block) that is on an *induced path* between s and t (or parents of t) (Figure 5(e)). This is required to prevent moralization and triangulation edges from interacting in a way that will increase the treewidth by more than one (see Figure 5(f) for an example). If s and t happen to be in the same block, then we only triangulate the induced paths between s and t, that is, the last step outlined above. Finally, in the special case that s and t are in *disconnected* components of $\mathcal{G}$, the only edges added are those required for moralization.

We now show that this revised edge update is a valid triangulation procedure and that it is also treewidth-friendly. To do so we start with the following observations that are a direct consequence of the definition of a block and block tree.

Algorithm 3: EdgeUpdate: Update of $\mathcal{M}^+$ when adding $(s \rightarrow t)$ to $\mathcal{G}$

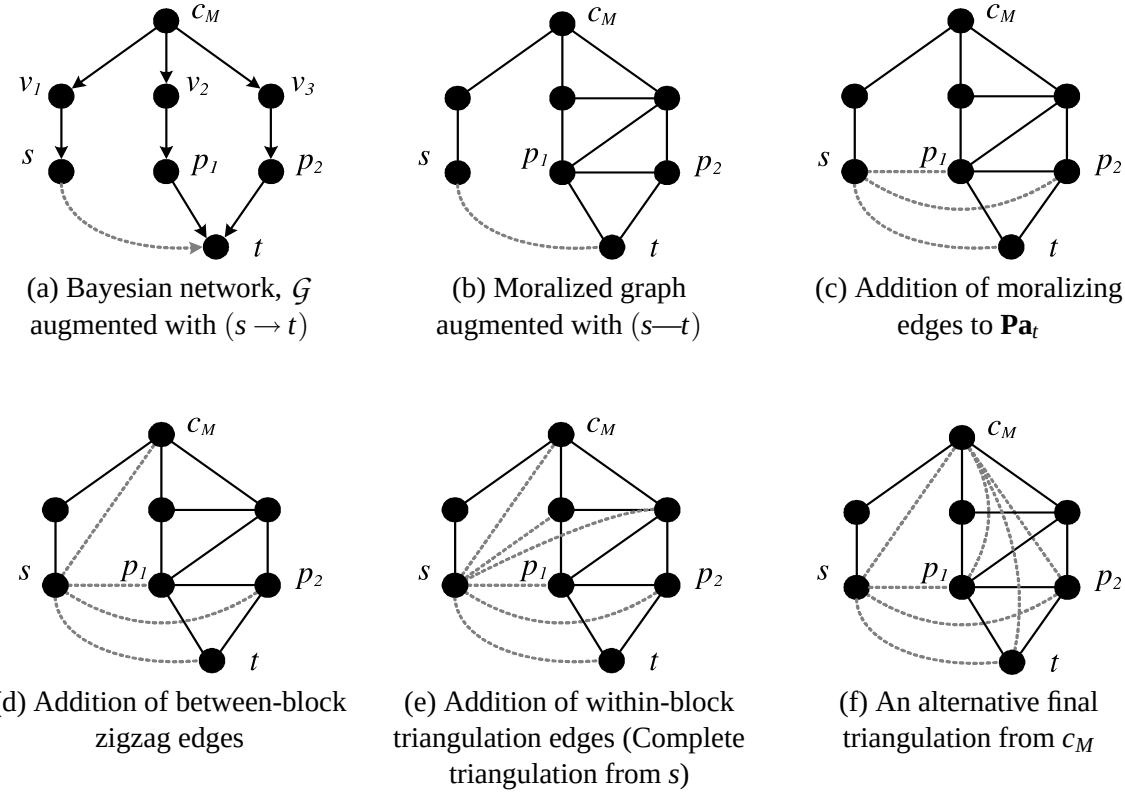
Input : $\mathcal{M}^+$ // triangulated moralized graph of $\mathcal{G}$
O // node ordering
$(s \rightarrow t)$ // edge to be added to $\mathcal{G}$
Output: ${\mathcal{M}^+}_{(s \rightarrow t)}$ // a triangulated moralized graph of $\mathcal{G} \cup (s \rightarrow t)$

$\mathcal{B} \leftarrow$ block tree of $\mathcal{M}^+$
${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow \mathcal{M}^+ \cup (s — t)$
foreach $p \in \mathbf{Pa}_t$ **do**
  ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow {\mathcal{M}^+}_{(s \rightarrow t)} \cup (s — p)$ // moralization
end foreach
// triangulate (cut-vertices) between blocks
$\mathcal{C} = \{c_1, \ldots, c_M\} \leftarrow$ sequence of cut-vertices on the path from s to $t \cup \mathbf{Pa}_t$ in block tree $\mathcal{B}$
Add $(s — c_M), (c_M — c_1), (c_1 — c_{M-1}), (c_{M-1} — c_2), \ldots$ to ${\mathcal{M}^+}_{(s \rightarrow t)}$
// triangulate nodes within blocks on path from s to $t \cup \mathbf{Pa}_t$
$\mathcal{E} \leftarrow \{(s — c_1), (c_1 — c_2), \ldots, (c_{M-1} — c_M)\}$
foreach *edge* $(s' — t') \in \mathcal{E}$ **do**
  ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow {\mathcal{M}^+}_{(s \rightarrow t)} \cup (s' — t')$
  foreach *node v on an induced path between s' and t' in the* **original** *block containing both* **do**
    ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow {\mathcal{M}^+}_{(s \rightarrow t)} \cup (s' — v)$
  end foreach
end foreach
// triangulate s with nodes in block containing $t \cup \mathbf{Pa}_t$
foreach *node v on an induced path between s and $t \cup \mathbf{Pa}_t$ in the* **new** *block containing them* **do**
  ${\mathcal{M}^+}_{(s \rightarrow t)} \leftarrow {\mathcal{M}^+}_{(s \rightarrow t)} \cup (s — v)$
end foreach
return ${\mathcal{M}^+}_{(s \rightarrow t)}$

Observation 4.5: (Family Block). Let u be a node in a Bayesian network $\mathcal{G}$ and let $\mathbf{Pa}_u$ be the set of parents of u. Then the block tree for any moralized triangulated graph $\mathcal{M}^+$ of $\mathcal{G}$ has a unique block containing $\{u, \mathbf{Pa}_u\}$.

Observation 4.6: (Path Nodes). Let $\mathcal{B} = (\{B_i\} \cup \{c_j\}, \mathcal{T})$ be the block tree of $\mathcal{M}^+$ with blocks $\{B_i\}$ and cut-vertices $\{c_j\}$. Let s and t be nodes in blocks B_s and B_t, respectively. If t is a cut-vertex then let B_t be the (unique) block that also contains $\mathbf{Pa}_t$. If s is a cut-vertex, then choose B_s to be the block containing s closest to B_t in $\mathcal{T}$. Then a node v is on a path from s to t or from s to a parent of t if and only if it is in a block that is on the unique path from B_s to B_t.

Figure 4(c) shows an example of a block tree for a small Bayesian network. Here, for example, selecting s to be the node v_6 and t to be the node v_{10} in $\mathcal{G}$, it is clear that all paths between s and t include only the vertices that are in blocks along the unique block path between B_s and B_t. Furthermore, every path between s and t passes through all the cut-vertices on this block path, that



(a) Bayesian network, $\mathcal{G}$ augmented with $(s \to t)$

(b) Moralized graph augmented with $(s—t)$

(c) Addition of moralizing edges to $\mathbf{Pa}_t$

(d) Addition of between-block zigzag edges

(e) Addition of within-block triangulation edges (Complete triangulation from s)

(f) An alternative final triangulation from c_M

Figure 5: Example showing our triangulation procedure (b)-(e) for s and t in different blocks. (The blocks are $\{s, v_1\}$, $\{v_1, c_M\}$, and $\{c_M, v_2, v_3, p_1, p_2, t\}$ with corresponding cut-vertices v_1 and c_M). The original graph has a treewidth of two, while the graph augmented with $(s \to t)$ has treewidth three (maximal clique of size four). An alternative triangulation (f), connecting c_M to t, however, would result in a clique of size five $\{s, c_M, p_1, p_2, t\}$.

is, $\{v_2, v_1, v_9\}$. We can now use these properties to show that our edge update procedure produces a valid triangulation.

Lemma 4.7: *If $\mathcal{M}^+$ is a valid moralized triangulation of the graph $\mathcal{G}$ then Algorithm (3) produces a moralized triangulation $\mathcal{M}^+{}_{(s \to t)}$ of the graph $\mathcal{G}_{(s \to t)} \equiv \mathcal{G} \cup (s \to t)$.*

Proof: Since $\mathcal{M}^+$ was triangulated, every cycle of length greater than or equal to four in $\mathcal{G}_{(s \to t)}$ is the result of the edge $(s—t)$ or one of the moralizing edges, together with an induced path (path with no shortcuts) between the endpoints of the edge. We consider three cases:

- s **and** t **are disconnected in** $\mathcal{M}^+$**:** There are no induced paths between s and t so the only edges required are those for moralization. These edges do not produce any induced cycles.

- s **and** t **are in the same block:** The edge $(s—t)$ does not create a new block and all simple cycles that involve both s and t must be within the block. Thus, by construction, the edges added in Line 16 triangulate all newly introduced induced cycles. If the parents of t are in the same block as s and t, the same reasoning holds for all induced paths between a parent p of

t and s. Otherwise, t is a cut-vertex between the block that contains its parents and the block that contains s. It follows that all paths (including induced ones) from a parent of t to s pass through t and the edges added for the s,t-block triangulate all newly created induced cycles that result from the moralizing edges.

- **s and t are not in the same block:** As noted in Observation 4.6, all paths in $\mathcal{M}^+$ from s to t or a parent of t pass through the unique cut-vertex path from the block containing s to the block containing t and its parents. The edges added in Line 14 short-circuit the in-going s' and out-going t' of each block creating a path containing only cut-vertices between s and t. Line 11 triangulates this path by forming cycles of length three containing s', t' and some other cut-vertex. The only induced cycles remaining are contained within blocks and contain the newly added edge $(s'—t')$ or involve the edge between s and the last cut-vertex $(s—c_M)$ and one of the edges between s and t or a parent of t. It follows that within-block triangulation with respect to s' and t' will shortcut the former induced cycles, and the edges added from s in Line 20 will shortcut the later induced cycles.

To complete the proof, we need to show that any edge added from s (or s') to an induced node v does not create new induced cycles. Any such induced cycle would have to include an induced path from the endpoints of the edge added and thus would have been a sub-path of some induced cycle that includes both s and v. This cycle would have already been triangulated by our procedure. ∎

Having shown that our update produces a valid triangulation, we now prove that our edge update is indeed treewidth-friendly and that it can increase the treewidth of the moralized triangulated graph by at most one.

Theorem 4.8: The treewidth of the output graph $\mathcal{M}^+{}_{(s\rightarrow t)}$ of Algorithm (3) is greater than the treewidth of the input graph $\mathcal{M}^+$ by at most one.

Proof: As shown in the proof of Theorem 4.2, the single-source triangulation within a block is guaranteed not to increase the maximal clique size by more than one. In addition, from the properties of blocks it follows directly that the inner block triangulation does not add edges that are incident to nodes outside of the block. It follows that all the inner block single-source triangulations independently effect disjoint cliques. Thus, the only way that the treewidth of the graph can further increase is via the zig-zag edges. Now consider two cliques in different blocks. Since our block level zig-zag triangulation only touches two cut-vertices in each block, it cannot join two cliques of size greater than two into a single larger one. In the simple case of two blocks with two nodes (a single edge) and that intersect at a single cut-vertex, a zig-zag edge can indeed increase the treewidth by one. In this case, however, there is no within-block triangulation and so the overall treewidth cannot increase by more than one. ∎

4.3 Finding Induced Nodes

We finish the description of our edge update (Algorithm (3)) by showing that it can be carried out efficiently. That is, we have to be able to efficiently find the vertices on *all* induced paths between two nodes in a graph. In general, this task is computationally difficult as there are potentially exponentially many such paths between any two nodes. To cope with this problem, we again make use of the dynamic nature of our method.

The idea is simple. As implied by Observation 4.1, any induced path between s' and t' in a triangulated graph will be part of an induced cycle if $(s'—t')$ is added to the graph. Furthermore,

Algorithm 4: InducedNodes: compute set of nodes on induced path between s' and t' in $\mathcal{M}^+$

```
1  Input  : M+    // moralized triangulated graph
2           s',t' // two nodes in M+
3  Output: I      // set of nodes on induced paths between s' and t'
4  H ← block (subgraph) of M+ ∪ (s'—t') containing s' and t'
5  I ← ∅
6  while edges being added do
       // maximum cardinality search
7      X ← all nodes in H except s'
8      Y ← {s'}
9      while X ≠ ∅ do
10         Find v ∈ X with maximum number of neighbors in Y
11         X ← X \ {v} and Y ← Y ∪ {v}   // remove from X, add to Y
12         if there exists u,w ∈ Y such that (u—w) ∉ H then
13             I ← I ∪ {u,v,w}
14             Add edges (s'—u), (s'—v) and (s'—w) to H
15             Restart maximum cardinality search
16         end
17     end
18 end
19 return I
```

after adding $(s'—t')$ to the graph, *every* cycle detected will involve an induced path between the two nodes. Using this observation, we can make use of the ability of the maximum cardinality search algorithm (Tarjan and Yannakakis, 1984) to iteratively detect non-chordal cycles.

The method is outlined in Algorithm (4). At each iteration we attempt to complete a maximum cardinality search starting from s' (Line 7 to Line 17). If the search fails, we add the node at which it failed, v, together with its non-adjacent neighboring nodes $\{u,w\}$ to the set of induced nodes and augment the graph with triangulating edges from s' to each of $\{u,v,w\}$. If the search completes then we have successfully triangulated the graph and hence found all induced nodes. Note that using the properties of blocks and cut-vertices, we only need to consider the subgraph that is the block created after the addition of $(s'—t')$ to the graph.

Lemma 4.9: (Induced Nodes). *Let $\mathcal{M}^+$ be a triangulated graph and let s' and t' be any two nodes in $\mathcal{M}^+$. Then Algorithm (4) efficiently returns all nodes on any induced path between s' and t' in $\mathcal{M}^+$, unless those nodes are connected directly to s'.*

Proof: During a maximum cardinality search, if the next node chosen v has two neighbors u and w that are not connected then the triplet $u—v—w$ is part of an induced cycle. As the graph was triangulated before adding the edge $(s'—t')$, all such cycles must contain s' and adding $(s'—v)$ obviously shortcuts such a cycle. This is also true for v and v' that are on the same induced cycle. It remains to show that the edges added do not create new induced cycle. Such an induced cycle would have to include the edge $(s'—v)$ as well as an induced path between s' and v. However, such

a path must have been part of another cycle where v was an induced node and hence would have been triangulated. ∎

Thus Algorithm (4) returns exactly the set of nodes on induced paths from s' to t' that s' needs to connect to in order to triangulate the graph $\mathcal{M}^+ \cup (s—t)$. The efficiency of our edge update procedure of Algorithm (3) follows immediately as all other operations are simple.

5. Multiple Edge Updates

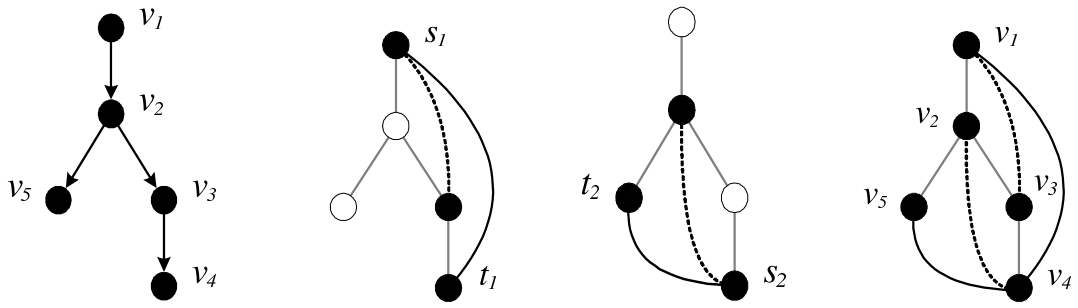
In this section we define the notion of a *contaminated set*, or the subset of nodes that are incident to edges added to $\mathcal{M}^+$ in Algorithm (3), and characterize sets of edges that are jointly guaranteed not to increase the treewidth of the triangulated graph by more than one. We begin by formally defining the terms *contaminate* and *contaminated set*.

Definition 5.1: We say that a node v is contaminated by the addition of the edge $(s \rightarrow t)$ to $\mathcal{G}$ if it is incident to an edge added to the moralized triangulated graph $\mathcal{M}^+$ by a call to Algorithm (3). The contaminated set for an edge $(s \rightarrow t)$ is the set of all nodes v that would be contaminated (with respect to $\mathcal{M}^+$) by adding $(s \rightarrow t)$ to $\mathcal{G}$, including s, t, and the parents of t. ∎

Figure 6 shows some examples of contaminated sets for different edge updates. Note that our definition of contaminated set only includes nodes that are incident to *new* edges added to $\mathcal{M}^+$ and, for example, excludes nodes that were already connected to s before $(s \rightarrow t)$ is added, such as the two nodes adjacent to s in Figure 6(b).

Using the separation properties of cut-vertices, one might be tempted to claim that if the contaminated sets of two edges overlap at most by a single cut-vertex then the two edges jointly increase the treewidth by at most one. This however, is not true in general as the following example shows.

Example 5.2: Consider the Bayesian network shown below in (a) and its triangulation (b) after $(v_1 \rightarrow v_4)$ is added, increasing the treewidth from one to two. (c) is the same for the case when $(v_4 \rightarrow v_5)$ is added to the network. Despite the fact that the contaminated sets (solid nodes) of two edge additions overlap only by the cut-vertex v_4, (d) shows that jointly adding the two edges to the graph results in a triangulated graph with a treewidth of three. ∎



(a) (b) (c) (d)

The problem in the above example lies in the overlap of *block paths* between the endpoints of the two edges, a property that we have to take into account while characterizing sets of treewidth-friendly edges.

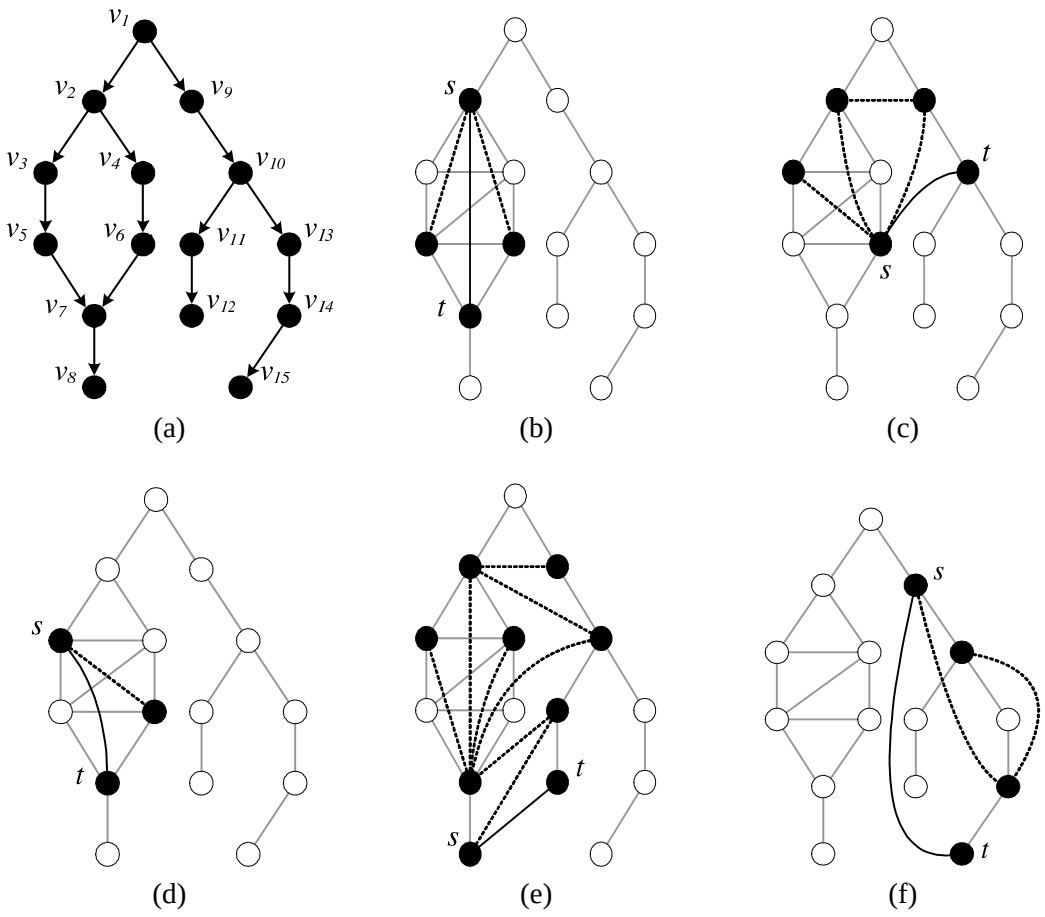


Figure 6: Some examples of contaminated sets (solid nodes) that are incident to edges added (dashed) by Algorithm (3) for different candidate edge additions $(s \rightarrow t)$ to the Bayesian network shown in (a). In (b), (c), (d), and (e) the treewidth is increased by one; In (f) the treewidth does not change.

Theorem 5.3: (Treewidth-friendly pair). Let $\mathcal{G}$ be a Bayesian network graph structure and $\mathcal{M}^+$ be its corresponding moralized triangulation. Let $(s \rightarrow t)$ and $(u \rightarrow v)$ be two distinct edges that are topologically consistent with $\mathcal{G}$. Then the addition of the edges to $\mathcal{G}$ does not increase the treewidth of $\mathcal{M}^+$ by more than one if *one* of the following conditions holds:

- the contaminated sets of $(s \rightarrow t)$ and $(u \rightarrow v)$ are disjoint.
- the endpoints of each of the two edges are not in the same block *and* the block paths between the endpoints of the two edges do not overlap *and* the contaminated sets of the two edge overlap at a single cut-vertex.

Proof: As in the proof of Algorithm (3) a maximal clique can grow by two nodes only if three undirected edges are added so that at least two nodes are incident to two of them. Obviously, this

Algorithm 5: ContaminatedSet: compute contaminated set for $(s \rightarrow t)$

Input : $\mathcal{G}$ // Bayesian network
$\mathcal{M}^+$ // moralized triangulated graph
$(s \rightarrow t)$ // candidate edge
Output: $\mathcal{C}_{s,t}$ // contaminated set for $(s \rightarrow t)$

$\mathcal{C}_{s,t} \leftarrow \{s,t\} \cup \{p \in \mathbf{Pa}_t \mid (s\text{—}p) \notin \mathcal{M}^+\}$
foreach *edge* $(s'\text{—}t') \in \mathcal{E}$ *in procedure Algorithm (3) with* $(s'\text{—}t') \notin \mathcal{M}^+$ **do**
  $I = \text{InducedNodes}(\mathcal{M}^+, \{s',t'\})$
  $\mathcal{C}_{s,t} \leftarrow \mathcal{C}_{s,t} \cup \{v \in I \mid (s'\text{—}v) \notin \mathcal{M}^+\}$
end foreach
$\mathcal{H} \leftarrow \{s\}$ and block containing $t \cup \mathbf{Pa}_t$
$\mathcal{H} \leftarrow \mathcal{H} \cup \{(s\text{—}p) \mid p \in \mathbf{Pa}_t\} \cup (s\text{—}c)$ where c is the cut-vertex closest to s in the block containing t
$I = \text{InducedNodes}(\mathcal{H}, \{s,t\})$
$\mathcal{C}_{s,t} \leftarrow \mathcal{C}_{s,t} \cup \{v \in I \mid (s'\text{—}v) \notin \mathcal{M}^+\}$
return $\mathcal{C}_{s,t}$

can only happen if the contamination sets of the two edge updates are not completely disjoint. Now, consider the case when the two sets overlap by a single cut-vertex. By construction all triangulating edges added are along the block path between the endpoints of each edge. Since the block paths of the two edge updates do not overlap there can not be an edge between a node in the contaminated set of $(s \rightarrow t)$ and the contaminated set of $(u \rightarrow v)$ (except for the single cut-vertex). But then no node from either contaminated set can become part of a clique involving nodes from the other contaminated set. Thus there are no two nodes that can be added to the same clique. It follows that the maximal clique size of $\mathcal{M}^+$, and hence the treewidth bound, cannot grow by more than one. ∎

The following result is an immediate consequence.

Corollary 5.4: (Treewidth-friendly set). *Let $\mathcal{G}$ be a Bayesian network graph structure and $\mathcal{M}^+$ be its corresponding moralized triangulation. If $\{(s_i \rightarrow t_i)\}$ is a set of edges so that every pair of edges satisfies the condition of Theorem 5.3 then adding all edges to $\mathcal{G}$ can increase the treewidth bound by at most one.*

The above result characterizes treewidth-friendly sets. In the search for such sets that are useful for generalization (see Section 6), we will need be able to efficiently compute the contaminated set of candidate edges. At the block level, adding an edge between s and t in $\mathcal{G}$ can only contaminate blocks between the block containing s and that containing t and its parents in the block tree for $\mathcal{M}^+$ (Observation 4.6). Furthermore, identifying the nodes that are incident to moralizing edges and edges that are part of the zigzag block level triangulation is easy. Finally, within a block, the contaminated set is easily computed using Algorithm (4) for finding the induced nodes between two vertices. Algorithm (5) outlines this procedure. Its correctness follows directly from the correctness of Algorithm (4) and the fact that it mirrors the edge update procedure of Algorithm (3).

6. Learning Optimal Treewidth-Friendly Chains

We now want to build on the results of the previous sections to facilitate the addition of global moves that are both optimal in some sense and are guaranteed to increase the treewidth by at most one. Specifically, we consider adding optimal chains that are consistent with some topological node ordering. On the surface, one might question the need for a specific node ordering altogether if chain global operators are to be used—given the result of Chow and Liu (1968), one might expect that learning the optimal chain with respect to *any* ordering can be carried out efficiently. However, Meek (2001) showed that learning such an optimal chain over a set of random variables is computationally difficult. Furthermore, conditioning on the current model, the problem of identifying the optimal chain is equivalent to learning the (unconditioned) optimal chain.[3] Thus, during any iteration of our algorithm, we cannot expect to find the overall optimal chain.

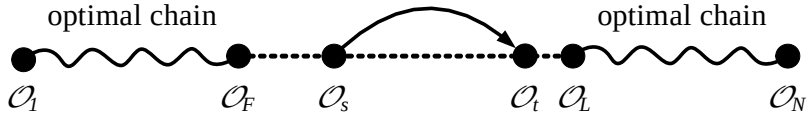
Instead, we commit to a single node ordering that is topologically consistent and learn the optimal chain *with respect to that order*. In this section we will complete the development of our algorithm and show how we can efficiently learn chains that are optimal with respect to any such ordering. In Section 7 we will also suggest a useful node ordering motivated by the characteristics of contaminated sets. We start by formally defining the chains that we will learn.

Definition 6.1: A treewidth-friendly chain $\mathcal{C}$ with respect to a node ordering O is a chain with respect to O such that the contamination conditions of Theorem 5.3 hold for the set of edges in $\mathcal{C}$. ∎

Given a treewidth-friendly chain $\mathcal{C}$ to be added for Bayesian network $\mathcal{G}$, we can apply the edge update of Algorithm (3) successively to every edge in $\mathcal{C}$ to produce a valid moralized triangulation of $\mathcal{G} \cup \mathcal{C}$. The result of Theorem 5.4 ensures that the resulting moralized triangulation will have treewidth at most one greater than the original moralized triangulation $\mathcal{M}^+$.

To find the optimal treewidth-friendly chain in polynomial time, we use a straightforward dynamic programming approach: the best treewidth-friendly chain that contains $(O_s \rightarrow O_t)$ is the concatenation of

- the best treewidth-friendly chain from the first node in the order O_1 to O_F, the first ordered node contaminated by the edge $(O_s \rightarrow O_t)$
- the edge $(O_s \rightarrow O_t)$
- the best treewidth-friendly chain starting from O_L, the last node contaminated by the edge $(O_s \rightarrow O_t)$, to the last node in the order, O_N.



We note that when the end nodes are not separating cut-vertices, we maintain a gap so that the contamination sets are disjoint and the conditions of Theorem 5.3 are met.

3. Consider, for example, the star-network where a single node acts as parent to all other nodes (with no other edges), then learning the optimal chain amounts to learning a chain over the $n-1$ children.

Formally, we define $C[i,j]$ as the optimal chain whose contamination starts at or after O_i and ends at or before O_j. To find the optimal treewidth-friendly chain with respect to a node ordering O for a Bayesian network with N variables, our goal is then to compute $C[1,N]$. Using the shorthand notation F to denote the first node ordered in the contamination set of $(s \rightarrow t)$ and L to denote the last ordered node in the contamination set, we can readily compute $C[1,N]$ via the following recursive update principle

$$C[i,j] = \max \begin{cases} \max_{s,t:F=i,L=j}(s \rightarrow t) & \text{no split} \\ \max_{k=i+1:j-1} C[i,k] \cup C[k,j] & \text{split} \\ \emptyset & \text{leave a gap} \end{cases}$$

where the maximization is with respect to the score (e.g., BIC) of the structures considered. In simple words, the maximum chain in any sub-sequence $[i,j]$ in the node ordering is the maximum of three alternatives: all edges whose contamination boundaries are exactly i and j (no split); all two chain combinations that are in the sub-sequence $[i,j]$ and are joined at some node $i < k < j$ (split); a gap between i and j in the case that there is no edge whose contamination is contained in this range and that increases the score.

Algorithm (6) outlines a simple backward recursion that computes $C[1,N]$. At each node, the algorithm maintains a list of the best partial chains evaluated so far that contaminates nodes up to, but not preceding, that node in the ordering. That is, the list of best partial chains is indexed by where the contamination boundary of each chain starts in the ordering. By recursing backwards from the last node, the algorithm is able to update this list by evaluating all candidate edges *terminating* at the current node. It follows that, once the algorithm iterates past a node t we have the optimal chain *starting* from that node. Thus, at the end of the recursion we are left with the optimal non-contaminating chain starting from the first node in the ordering.

The recursion starts at Line 7. If for node O_t the best chain starting from the succeeding node O_{t+1} is better than the best chain starting from O_t, we replace the best chain from O_t with the one from O_{t+1} simply leaving a gap in the chain (Line 8). Then, for every edge terminating at O_t, we find the first ordered node O_F and the last ordered node O_L that would be contaminated by adding that edge. If the score for the edge plus the score for the best partial non-contaminating chain from O_F is better than the current best partial chain from O_L then we replace the best chain from O_L with the one just found (Line 19).

With the ability to learn optimal chains with respect to a node ordering, we have completed the description of all the components of our algorithm for learning bounded treewidth Bayesian network outlined in Algorithm (1). Its efficiency is a direct consequence of our ability to learn treewidth-friendly chains in time that is polynomial both in the number of variables and in the treewidth at each iteration. For completeness we now restate and prove Theorem 3.1.

Theorem 3.1: Given a treewidth bound K, Algorithm (1) runs in time polynomial in the number of variables and K.

Proof: The initial Chow-Liu tree and its corresponding undirected skeleton can be obtained in polynomial time using a standard max-spanning-tree algorithm. The maximum scoring chain can be computed in polynomial time (using Algorithm (6)) at each iteration. As we proved, the same is true of the triangulation procedure of Algorithm (3). All other steps are trivial. Since the algorithm adds at least one edge per iteration it cannot loop for more than $K \cdot N$ iterations before exceeding a treewidth of K (where N is the number of variables). ∎

Algorithm 6: LearnChain: learn optimal non-contaminating chain with respect to topological node ordering

Input : $\mathcal{O}$ // topological node ordering
Output: $\mathcal{C}$ // non-contaminating chain

// initialize dynamic programming data
for $i = 1$ **to** $|\mathcal{O}| + 1$ **do**
  bestChain$[i] \leftarrow \emptyset$ // best chain from i-th node
  bestScore$[i] \leftarrow 0$ // best score from i-th node
end

// backward recursion
for $t = |\mathcal{O}|$ **down to** 1 **do**
  if (bestScore$[t+1] >$ bestScore$[t]$) **then**
    bestChain$[t] \leftarrow$ bestChain$[t+1]$
    bestScore$[t] \leftarrow$ bestScore$[t+1]$
  end
  for $s = 1$ **to** $t-1$ **do** // evaluate edges
    $\mathcal{V} \leftarrow$ contaminated set for candidate edge $(O_s \rightarrow O_t)$
    $f \leftarrow$ first ordered node in $\mathcal{V}$ // must be $\leq s$
    $l \leftarrow$ last ordered node in $\mathcal{V}$ // must be $\geq t$
    if bestChain$[l]$.last *and* $(O_s \rightarrow O_t)$ *do not satisfy the conditions of Theorem 5.3* **then**
      $l \leftarrow l+1$ // leave a gap
    end
    if ($\Delta Score(O_s \rightarrow O_t) +$ bestScore$[l] >$ bestScore$[f]$) **then**
      bestChain$[f] \leftarrow \{(O_s \rightarrow O_t)\} \cup$ bestChain$[l]$
      bestScore$[f] \leftarrow \Delta Score(O_s \rightarrow O_t) +$ bestScore$[l]$
    end
  end
end

// return optimal non-contaminating chain
return bestChain$[1]$

7. Block-Shortest-Path Ordering

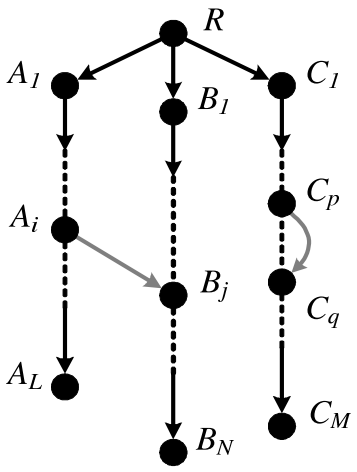
In the previous sections we presented an algorithm for learning bounded treewidth Bayesian networks given any topological ordering of the variables. In order to make the most of our method, we would like our ordering to facilitate rich structures that will have beneficial generalization properties. Toward that end, in this section we consider the practical matter of a concrete node ordering. We will present a block shortest-path (BSP) node ordering that is motivated by the specific properties of our triangulation method.[4]

4. We also considered several other strategies for ordering the variables. As none was better than the intuitive ordering described here, we only present results for our block-shortest-path ordering.

To make our node ordering concrete, since the contamination resulting from edges added within an existing block is limited to the block, we start by grouping together all nodes that are within a block (cut-vertices that appear in multiple blocks are included in the first block chosen). Our node ordering is then a topologically consistent ordering over the blocks combined with a topologically consistent ordering over the nodes within each block. We use topological consistency to facilitate as many edges as possible though this is not required by the theory (and, in particular, Theorem 5.3).

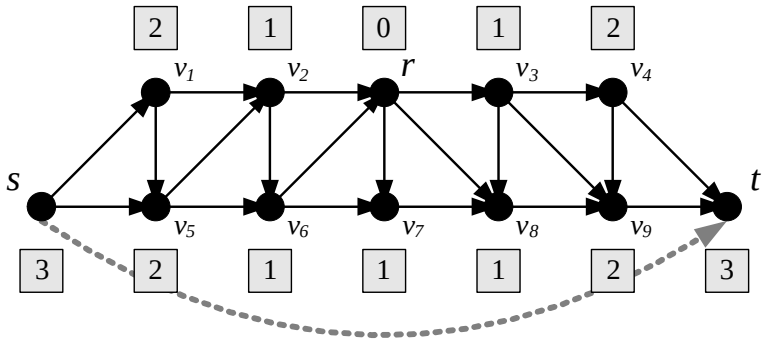
We now consider how to order interchangeable blocks by taking into account that our triangulation following an edge addition $(s \to t)$ only involves variables that are in blocks along the unique path between the block containing s and the block containing t and its parents. The following example motivates a natural choice for this ordering.

Example 7.1: Consider a Bayesian network with root node R and three branches: $R \to A_1 \to \ldots \to A_L$, $R \to B_1 \to \ldots \to B_N$, and $R \to C_1 \to \ldots \to C_M$. If we add an edge $A_i \to B_j$ to the network, then by the block contamination results, our triangulation procedure will touch (almost) every node on the path between A_i and B_j. This implies that we can not include additional edges of the type $B_k \to C_l$ in our chain since the block path from B_k to R overlaps with the block path from B_j to R. Note, however, that any edge $C_p \to C_{q>p}$ is still allowed to be added since its contaminated set does not overlap with that of $A_i \to B_j$. Now, consider the two obvious topological node orderings: $O^{\text{BFS}} = (R, A_1, B_1, C_1, A_2, \ldots)$ and $O^{\text{DFS}} = (R, A_1, \ldots, A_L, B_1, \ldots, B_N, C_1, \ldots)$. Only the DFS ordering, obtained by grouping the B_i's together, allows us to consider such edge combinations. ∎



Motivated by the above example to order interchangeable blocks, we use a block level depth-first ordering. The question now is whether a further characterization of the contaminated set can be provided in order to better order topologically interchangeable nodes within a block. To answer this question we consider the following example.

Example 7.2: Consider the Bayesian network shown below whose underlying undirected structure is a valid moralized triangulation and forms a single block. Numbers in the boxes indicate the (undirected) distance of each node from r, a property that we make use of below.



The single edge addition $(s \rightarrow t)$ will contaminate every node in the block (other than those already adjacent to it) since all nodes lie on induced paths between s and t. However other edge additions, such as $(v_3 \rightarrow t)$ have a much smaller contamination set: $\{v_3, t\}$. ∎

Based on the above example, one may think that no within-block ordering can improve the expected contamination of edges added, and that we may be forced to only add a single edge per block, making our method greedier than we would like. Fortunately, there is a straightforward way to characterize the within-block contamination set using the notion of shortest path length. Let $\mathcal{G}$ be a Bayesian network over variables $\mathcal{X}$. We denote by $d^M_{\min}(u,v)$ the minimum distance (shortest path) between nodes $u, v \in \mathcal{X}$ in $\mathcal{M}^+$. We note the following useful properties of $d^M_{\min}(\cdot,\cdot)$:

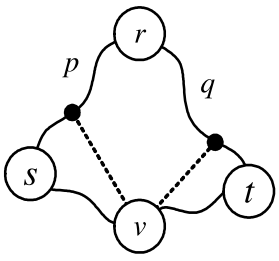
- $d^M_{\min}(u,v) \geq 0$ with equality if and only if $u = v$
- $d^M_{\min}(u,w) + d^M_{\min}(v,w) \geq d^M_{\min}(u,v)$ with equality if and only if w is on the (possibly non-unique) shortest path between u and v
- if u and v are disconnected in $\mathcal{M}^+$ then, by convention, $d^M_{\min}(u,v) = \infty$

Theorem 7.3: Let r, s and t be nodes in some block B (of size ≥ 3) in the triangulated graph $\mathcal{M}^+$ with $d^M_{\min}(r,s) \leq d^M_{\min}(r,t)$. Then for any v on an induced path between s and t we have

$$d^M_{\min}(r,v) \leq d^M_{\min}(r,t)$$

Proof: Since the nodes are all in the same block we know that there must be at least two paths between any two nodes. Let p and q be the shortest paths from nodes r to s and r to t, respectively (denoted $r \xrightarrow{p} s$ and $r \xrightarrow{q} t$). If p and q meet at some node other than r then they will share the path from that node to r (otherwise they cannot be shortest paths). Let such a shared node furthest from r be r'. Then $d^M_{\min}(r,t) = d^M_{\min}(r,r') + d^M_{\min}(r',t)$ and $d^M_{\min}(r,v) \leq d^M_{\min}(r,r') + d^M_{\min}(r',v)$ so if the result holds for r' it holds for r. Without loss of generality assume that there is no such r'. Now consider the following cases:

- If q contains v then $d^M_{\min}(r,v) = d^M_{\min}(r,t) - d^M_{\min}(v,t) < d^M_{\min}(r,t)$.
- If p contains v then $d^M_{\min}(r,v) = d^M_{\min}(r,s) - d^M_{\min}(v,s) < d^M_{\min}(r,s) \leq d^M_{\min}(r,t)$.
- Otherwise v is on some other (induced) path between s and t. But now $r \xrightarrow{p} s \xrightarrow{} v \xrightarrow{} t \xrightarrow{q} r$ forms a cycle of length ≥ 4. Since $\mathcal{M}^+$ is triangulated there must be an edge from v to some node on p or q. There cannot be an edge between s and t or else there would not be any induced paths between s and t. But then $d^M_{\min}(r,v) \leq d^M_{\min}(r,t)$.

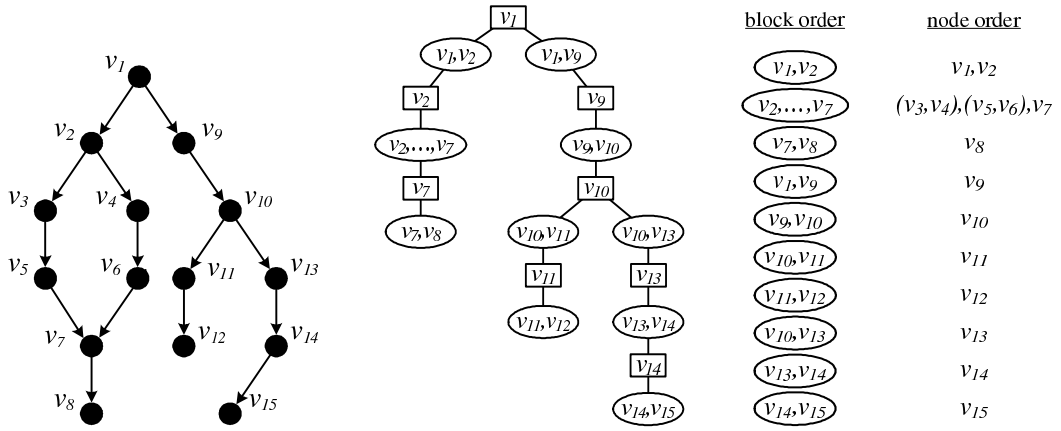


∎

Algorithm 7: Block-Shortest-Path Ordering

Input : $\mathcal{G}$ // input Bayesian network
$\mathcal{M}^+$ // corresponding moralized triangulation
Output: O // an ordering $X_1,\ldots,X_N$

$O \leftarrow \emptyset$
$O_T \leftarrow$ topological ordering of the nodes in $\mathcal{G}$
$O_B \leftarrow$ depth-first search ordering of blocks in $\mathcal{M}^+$
while $O_B \neq \emptyset$ **do**
  $B \leftarrow$ pop O_B
  $R \leftarrow$ cut-vertex of B with lowest O_T
  Push nodes in B to O in order of $(O_T, d^M_{\min}(R,\cdot))$
end
return O



(a) Bayesian Network, $\mathcal{G}$ (b) Block Tree, $\mathcal{B}$ (c) BSP Ordering

Figure 7: Concrete example of BSP ordering using the Bayesian network from Figure 4. Nodes in parentheses are the same distance from the root cut-vertex and can be ordered arbitrarily.

We now use this result to order nodes according to their distance from the cut-vertex in the block that connects it to the blocks already ordered (which we call the root cut-vertex). Algorithm (7) shows how our Block-Shortest-Path (BSP) ordering is constructed and Figure 7 demonstrates the application of that ordering to a concrete example.

Finally, we note that the above ordering, while almost strict, still allows for variables that are the same distance from the root cut-vertex of the block to be ordered arbitrarily. Indeed, as the following example shows two nodes that are the same distance from the block cut-vertex can be symmetrically contaminating. We break such ties arbitrarily.

Example 7.4: Consider, again, the example network shown in Example 7.2. The set of nodes $\{v_2, v_3, v_6, v_7, v_8\}$ are all the adjacent to r and so can be ordered arbitrarily. An edge from v_2 to v_8 (or vice versa) will contaminate v_7. Likewise an edge from v_3 to v_6 (or vice versa) will also contaminate v_7. It turns out that for any ordering of these nodes, it is always possible to add an edge that will contaminate other nodes in the set. This is consistent with the contamination result of Theorem 7.3 since these nodes are all equi-distant from r. ∎

8. Experimental Evaluation

In this section we perform experimental validation of our approach and show that it is beneficial for learning Bayesian networks of bounded treewidth. Specifically, we demonstrate that by making use of global structure modification steps, our approach leads to superior generalization. In order to evaluate our method we compare against two strong baseline approaches.

The first baseline is an improved variant of the thin junction tree approach of Bach and Jordan (2002). We start, as in our method, with a Chow-Liu forest and iteratively add the single best scoring edge. To make the approach as comparable to ours as possible, at each iteration, we triangulate the model using either the maximum cardinality search or minimum fill-in heuristics (see, for example, Koster et al., 2001), as well as using our treewidth friendly triangulation, and take the triangulation that results in a lower treewidth.[5] As in our method, when the treewidth bound is reached, we continue to add edges that improve the model selection score until no such edges can be found that do not also increase the treewidth bound.

The second baseline is an aggressive structure learning approach that combines greedy edge modifications with a TABU list (e.g., Glover and Laguna, 1993) and random moves. This approach is not constrained by a treewidth bound. Comparison to this baseline allows us to evaluate the merit of our method with respect to an unconstrained state-of-the-art search procedure.

We evaluate our method on four real-world data sets that are described below. Where relevant we also compare our results to the results of Chechetka and Guestrin (2008).

8.1 Gene Expression

In our first experiment, we consider a continuous data set based on a study that measures the expression of the baker's yeast genes in 173 experiments (Gasch et al., 2000). In this study, researchers measured the expression of 6152 yeast genes in response to changes in the environmental conditions, resulting in a matrix of 173×6152 measurements. The measurements are real-valued and, in our experiments, we learn sigmoid Bayesian networks using the Bayesian Information Criterion (BIC) (Schwarz, 1978) for model selection. For practical reasons, we consider the fully observed set of 89 genes that participate in general metabolic processes (Met). This is the larger of the two sets used by Elidan et al. (2007), and was chosen since part of the response of the yeast to changes in its environment is in altering the activity levels of different parts of its metabolism. We treat the genes as variables and the experiments as instances so that the learned networks indicate possible regulatory or functional connections between genes (Friedman et al., 2000).

Figure 8 shows test log-loss results for the 89 variable gene expression data set as a function of the treewidth bound. The first obvious phenomenon is that both our method (solid blue squares) and

5. We note that in all of our experiments there was only a small difference between the minimum fill-in and maximum cardinality search heuristics for upper bounding the treewidth of the model at hand.

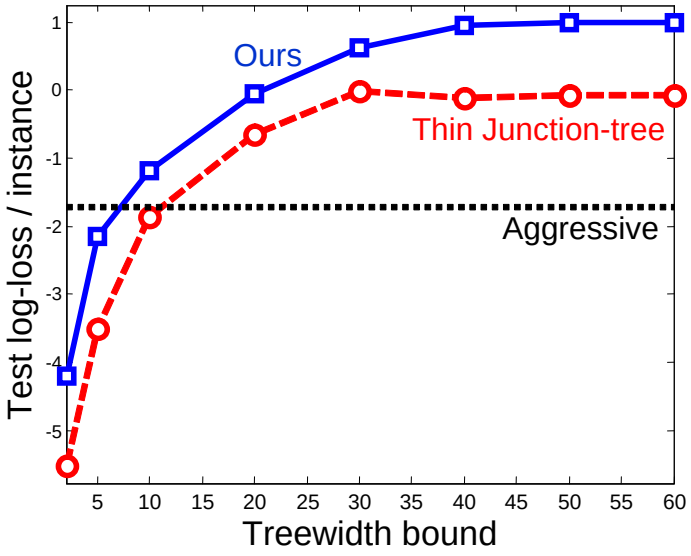


Figure 8: Average test set log-loss per instance over five folds (y-axis) versus the treewidth bound (x-axis) for the 89 variable gene expression data set. Compared are our method (solid blue squares) with the **Thin junction tree** approach (dashed red circles), and an **Aggressive** greedy approach of unbounded treewidth that also uses a TABU list and random moves (dotted black).

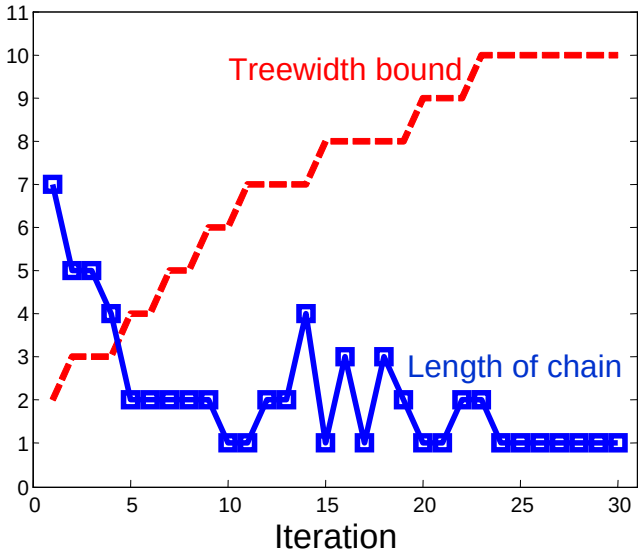

Figure 9: Plot showing the number of edges (in the learned chain) added during each iteration for a typical run with treewidth bound of 10 for the 89 variables gene expression data set. The graph also shows our treewidth estimate at the end of each iteration.

the greedy junction tree approach (dashed red circles) are superior to the aggressive baseline (dotted black). As one might expect, the aggressive baseline achieves a higher BIC score on training data (not shown), but overfits due to the scarcity of the data. By greedy edge addition (the junction tree approach) or global chain addition (our approach), this overfitting is avoided. Indeed, a better choice of edges, that is, ones chosen using a global operator, can lead to increased robustness and better generalization. This is evident by the consistent superiority of our method (solid blue squares) over the greedy variant (dashed red circles). Importantly, even when the treewidth bound is increased passed the saturation point our method surpasses both the thin junction tree approach of Bach and Jordan (2002) and the aggressive search strategy. In this case, we are learning unbounded Bayesian networks and all of the benefit comes from the global nature of our structure modifications.

To qualitatively illustrate the progression of our algorithm from iteration to iteration, we plot the number of edges in the chain (solid blue squares) and treewidth estimate (dashed red) at the end of each iteration. Figure 9 shows a typical run for the 89 variable gene expression data set with treewidth bound set to 10. Our algorithm aggressively adds many edges (making up an optimal chain) per iteration until parts of the network reach the treewidth bound. At that point (iteration 24) the algorithm resorts to adding the single best edge per iteration until no more edges can be added without increasing the treewidth (or that have an adverse effect on the score). To appreciate the non-triviality of some of the chains learned with 4, 5 or 7 edges, we recall that the example shows edges added *after* a Chow-Liu model was initially learned. It is also worth noting that despite their complexity, some chains do not increase the treewidth estimate and for a given treewidth bound K, we typically have more than K iterations (in this example 24 chains are added before reaching the treewidth bound). The number of such iterations is still polynomially bounded as for a Bayesian network with N variables adding more than $K \cdot N$ edges will necessarily result in a treewidth that is greater than K.

In order to verify the efficiency of our method we measured the running time of our algorithm as a function of treewidth bound. Figure 10 shows results for the 89 variable gene expression data set. Observe that our method (solid blue squares) and the greedy thin junction tree approach (dashed red circles) are both approximately linear in the treewidth bound. Appealingly, the additional computation required by our method is not significant and the differences between the two approaches are at most 25%. This should not come as a surprise since the bulk of the time is spent on the collection of sufficient statistics from the data.

It is also worthwhile to discuss the range of treewidths considered in the above experiment as well as the Haplotype sequence experiment considered below. While treewidths of 30 and beyond may seem excessive for exact inference, state-of-the-art exact inference techniques (e.g., Darwiche, 2001; Marinescu and Dechter, 2005) can often handle inference in such networks (for some examples see Bilmes and Dechter, 2006). Since, as shown in Figure 8, it is beneficial to learn models with large treewidth, methods such as ours for learning and the state-of-the-art techniques for inference allow practitioners to push the envelope of the complexity of models learned for real applications.

8.2 The Traffic and Temperature Data Sets

We now compare our method to the mutual-information based LPACJT method for learning bounded treewidth model of Chechetka and Guestrin (2008) (we compare to better of the variants presented in that work). While providing theoretical guarantees (under some assumptions), their method is exponential in the treewidth and cannot be used in a setting similar to the gene expression experi-

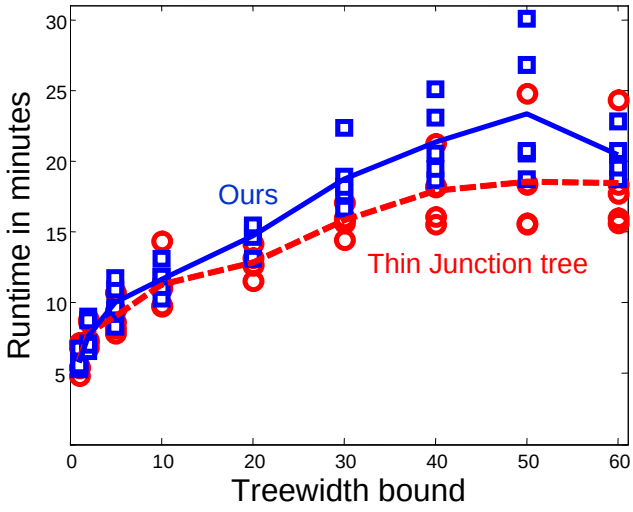

Figure 10: Running time in minutes on the 89 variable gene expression data set (y-axis) as a function of treewidth bound (x-axis). The graph compares our method (solid blue squares) with the thin junction tree approach (dashed red circles). The markers show times for the 5 different fold runs for each treewidth while the line shows the average running time.

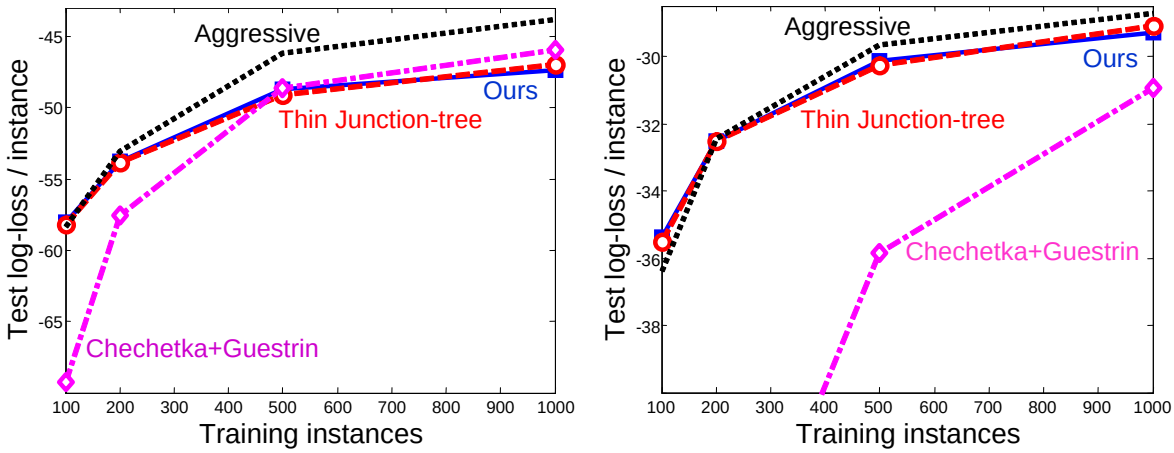
ment above. Instead, we compare on the two discrete real-life data set considered in Chechetka and Guestrin (2008). The temperature data is from a two-month deployment of 54 sensor nodes (15K data points) (Deshpande et al., 2004) where each variable was discretized into 4 bins. The traffic data set contains traffic flow information measured every five minutes in 32 locations in California for one month (Krause and Guestrin, 2005). Values were discretized into 4 bins. For both data sets, to make the comparison fair, we used the same discretization and train/test splits as in Chechetka and Guestrin (2008). Furthermore, as their method can only be applied to a small treewidth bound, we also limited our model to a treewidth of two. Figure 11 compares the different methods. Both our method and the thin junction tree approach significantly outperform the LPACJT on small sample size. This result is consistent with that reported in Chechetka and Guestrin (2008) and is due to the fact that the LPACJT method does not naturally use regularization which is crucial in the sparse-data regime. The performance of our method is comparable to the greedy thin junction tree approach with no obvious superiority to either method. This should not come as a surprise since the fact that the unbounded aggressive approach is not significantly better suggests that the strong signal in the data can be captured rather easily. In fact, Chechetka and Guestrin (2008) show that even a Chow-Liu tree does rather well on these data sets (compare this to the gene expression data set where the aggressive variant was superior even at a treewidth of four).

8.3 Haplotype Sequences

Finally we consider a more difficult discrete data set consisting of a sequence of binary single nucleotide polymorphism (SNP) alleles from the Human HapMap project (Consortium, 2003). Our



(a) Temperature (54 variables)

(b) Traffic (32 variables)

Figure 11: Average test set log-loss per instance over five folds (y-axis) versus the number of training instances (x-axis) for the temperature and traffic data sets. Compared are our method (solid blue squares), the **Thin junction tree** approach (dashed red circles), an **Aggressive** greedy approach of unbounded treewidth that also uses a TABU list and random moves (dotted black), and the mutual-information based method of Chechetka and Guestrin (2008) (dash-dot magenta diamonds). For all of our methods except the unbounded **Aggressive**, the treewidth bound was set to two.

model is defined over 200 SNPs (variables) from chromosome 22 of a European population consisting of 60 individuals.[6] In this case, there is a natural ordering of variables that corresponds to the position of the SNPs in the DNA sequence. Figure 12 shows test log-loss results when this ordering is enforced (thicker lines) and when it is not (thinner) lines. Our small benefit over the greedy thin junction tree approach of Bach and Jordan (2002) when the treewidth bound is non-trivial (>2) grows significantly when we take advantage of the natural variable order. Interestingly, this same order decreases the performance of the thin junction tree method. This should not come as a surprise as the greedy method does not make use of a node ordering, while our method provides optimality guarantees with respect to a variable ordering at each iteration. Whether constrained to the natural variable ordering or not, our method ultimately also surpasses the performance of the aggressive unbounded search approach.

9. Discussion and Future Work

In this work we presented a novel method for learning Bayesian networks of bounded treewidth in time that is polynomial in *both* the number of variables and the treewidth bound. Our method builds on an edge update algorithm that dynamically maintains a valid moralized triangulation in a way that facilitates the addition of chains that are guaranteed to increase the treewidth by at most one. We demonstrated the effectiveness of our treewidth-friendly method on real-life data sets, and

6. We considered several different sequences along the chromosome with similar results.

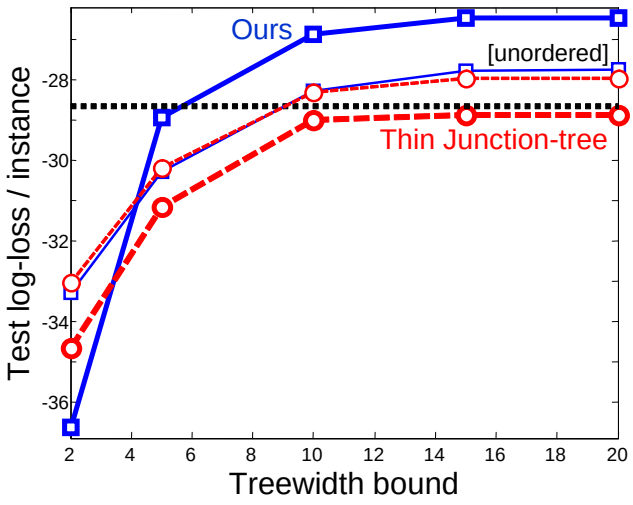


Figure 12: Average test set log-loss per data instance over five folds (y-axis) versus the treewidth bound (x-axis) for the 200 variable Hapmap data set. The graph compares our method (solid blue squares) with the greedy approach (dashed red circles), and an aggressive greedy approach of unbounded treewidth that also uses a TABU list and random moves (dotted black). The thicker lines show the results for a fixed ordering of the variables according to the location along the DNA sequence. The thinner lines show the results without any constraint on the node ordering.

showed that by using global structure modification operators, we are able to learn better models than competing methods even when the treewidth of the models learned is not constrained.

Our method can be viewed as a generalization of the work of Chow and Liu (1968) that is constrained to a chain structure but that provides an optimality guarantee (with respect to a node ordering) at every treewidth. In addition, unlike the thin junction trees approach of Bach and Jordan (2002), we also provide a guarantee that our estimate of the treewidth bound will not increase by more than one at each iteration. Furthermore, we add multiple edges at each iteration, which in turn allows us to better cope with the problem of local maxima in the search. To our knowledge, ours is the first method for efficiently learning bounded treewidth Bayesian networks with structure modifications that are not fully greedy.

Several other methods aim to generalize the work of Chow and Liu (1968). Karger and Srebro (2001) propose a method that is guaranteed to learn a good approximation of the optimal Markov network given a treewidth bound. Their method builds on a hyper-graph that is exponential in the treewidth bound. Chechetka and Guestrin (2008) also propose an innovative method with theoretical guarantees on the quality of the learned model (given some mild assumptions on the generating distribution), but in the context of Bayesian networks. However, like the approach of Karger and Srebro (2001), the method is exponential in the treewidth bound. Thus, both approaches are only practical for treewidths that are much smaller than the ones we consider in this work. In addition, the work of Chechetka and Guestrin (2008) does not naturally allow for the use of regularization.

This has significant impact on performance when the number of training samples is limited, as demonstrated in Section 8.

Meila and Jordan (2000) suggested the use of a mixture of trees, generalizing the Chow-Liu tree on an axis that is orthogonal to a more complex Bayesian network. They provide an efficient method for obtaining a (penalized) likelihood local maxima but their work is limited to a particular and relatively simple structure. Dasgupta (1999) suggested the use of poly-trees but proved that learning the optimal poly-tree is computationally difficult. Other works study this question but in the context where the *true distribution* is assumed to have bounded treewidth (e.g., Beygelzimer and Rish, 2004; Abbeel et al., 2006, and references within).

Our method motivates several exciting future directions. It would be interesting to see to what extent we could overcome the limitation of having to commit to a specific node ordering at each iteration. While we provably cannot consider any node ordering, it may be possible to polynomially provide a reasonable approximation. Second, it may be possible to refine our characterization of the contamination that results from an edge update, which in turn may facilitate the addition of more complex treewidth-friendly structures at each iteration. Finally, we are most interested in exploring whether tools similar to the ones employed in this work could be used to dynamically update the bounded treewidth structure that is the approximating distribution in a variational approximate inference setting.

Abstract

Bayesian inference from high-dimensional data involves the integration over a large number of model parameters. Accurate evaluation of such high-dimensional integrals raises a unique set of issues. These issues are illustrated using the exemplar of model selection for principal component analysis (PCA). A Bayesian model selection criterion, based on a Laplace approximation to the model evidence for determining the number of signal principal components present in a data set, has previously been show to perform well on various test data sets. Using simulated data we show that for d-dimensional data and small sample sizes, N, the accuracy of this model selection method is strongly affected by increasing values of d. By taking proper account of the contribution to the evidence from the large number of model parameters we show that model selection accuracy is substantially improved. The accuracy of the improved model evidence is studied in the asymptotic limit $d \to \infty$ at fixed ratio $\alpha = N/d$, with $\alpha < 1$. In this limit, model selection based upon the improved model evidence agrees with a frequentist hypothesis testing approach.

Keywords: PCA, Bayesian model selection, random matrix theory, high dimensional inference

1. Introduction

The generation of high dimensional data is fast becoming a common place occurrence. Examples range from genomics and molecular biology, for example high-throughput single nucleotide polymorphism (SNP) genotyping scans (Price et al., 2006) and microarray gene expression studies (Golub et al., 1999), to geophysical imaging, for example hyperspectral image data (Landgrebe, 2002). Intuitive visualization of the data and construction of novel features from the data are key tasks in processing such high-dimensional data. This often involves dimensionality reduction, for which a number of algorithms exist. Principal component analysis (PCA) is a ubiquitous method of data analysis and dimensionality reduction (Joliffe, 1986). Its utility and success stems from the simplicity of the method - one simply calculates the eigenvectors and eigenvalues of the sample covariance matrix $\hat{C}$ of the data set. A subset of the eigenvectors of $\hat{C}$, the principal components, are then selected to represent the data. A 'kernelized' version has been formulated - kernel PCA (Scholköpf, Smola, and Müller, 1998), and building on probabilistic formulations (Roweis, 1998; Tipping and Bishop, 1999a) it has also been extended to a mixture of principal component analysers (Tipping and Bishop, 1999b). In the latter case a number of local linear models are embedded in the high dimensional data space, with the properties of each local model being determined from the local responsibility-weighted covariance matrix.

Clearly selection of the correct number of principal components is crucial to the success of PCA in representing a data set. Identification of the appropriate signal dimensionality is just a model selection process to which the techniques of Bayesian model selection can be applied via a suitable approximation of the Bayesian evidence (MacKay, 1992). What is the most suitable method of approximating the evidence for high-dimensional data and what are the inherent problems? These are the research questions we address and a roadmap for the paper is given below,

• In Section 2 we motivate why high-dimensional small sample size data sets present a challenge for Bayesian model selection.

• In Section 3 we summarize the behaviour of the eigenvectors and eigenvalues of sample covariance matrices formed from high-dimensional small sample size data sets.

• In Section 4.1 we review the formalism of Bayesian model selection for PCA, and evaluate through simulation the model selection accuracy of an existing approximation to the Bayesian evidence.

• In Section 4.2 we develop an improved approximation to the Bayesian evidence specifically for high dimensional data.

• In Section 5 we evaluate the asymptotic properties of the improved approximation to the model evidence.

• In Section 6 the model selection performance of the improved approximation to the model evidence is compared with a frequentist hypothesis testing approach to model selection.

2. The Challenge of High-Dimensional Data for Bayesian Model Selection

A number of Bayesian formulations of PCA have followed from the probabilistic formulation of Tipping and Bishop (1999a), with the necessary marginalization being approximated through both Laplace approximations (Bishop, 1999a; Minka, 2000, 2001a) and variational bounds (Bishop, 1999b). More recently, work within the statistics research community has used a Bayesian variational approach to derive an explicit conditional probability distribution for the signal dimension given the data (Šmídl and Quinn, 2007). However, these results have only been tested on low dimensional data with relatively large sample sizes. A somewhat more tractable expression for the signal dimension posterior was also obtained by Minka (2000, 2001a) and it is that Bayesian formulation of PCA that we draw upon. By performing a Laplace approximation (Wong, 1989), that is, expanding about the maximum posterior solution, Minka derived an elegant approximation to the probability, the model evidence $p(D|k)$, of observing a data set D given the number of principal components k (Minka, 2000, 2001a). The signal dimensionality of the given data set is then estimated by the value of k that maximizes $p(D|k)$. As with any Bayesian model selection procedure, if the data has truly been generated by a model of the form proposed, then one is guaranteed to select the correct model dimensionality as the sample increases to an infinite size. Minka's dimensionality selection method performs well when tested on data sets of moderate size and dimensionality. Indeed, the Laplace approximation incorporates the leading order term in an asymptotic expansion of the Bayesian evidence, with the sample size N playing the role of the 'large' parameter, and so we would expect the Laplace approximation to be increasingly accurate as $N \to \infty$. In real-world data sets, such as those emanating from molecular biology experiments, the number of variables d is often very much greater than the sample size N, with $d \sim 10^4$ yet $N \sim 10$ or $N \sim 10^2$ not uncommon (Hoyle and Rattray, 2003). Typically, data sets with a sample size of $N = 100$ might be considered as large enough to be well approximated by the asymptotic limit $N \to \infty$, and therefore the Laplace

approximation to be appropriate. However, though retaining only a small number of terms from the asymptotic expansion of the evidence would be increasingly accurate as $N \to \infty$, individual expansion coefficients may be significant due to the large data dimensionality d. This suggests that for real finite sample size data sets, higher order terms in the asymptotic expansion not encapsulated within the Laplace approximation will make significant contributions to the evidence, and model selection based upon a simplistic application of the Laplace approximation will perform poorly. What then defines a 'large' sample size N is clearly dependent on the data dimensionality d. We would expect the conjectures about the previously derived Laplace approximation to the evidence to be increasingly true when the data dimensionality is very much larger than the sample size, that is, $N \ll d$, the situation encountered for many modern data sets. For high dimensional data, rather than considering the evidence to be close to its value obtained in the asymptotic limit $N \to \infty$ at fixed d, it may be more appropriate to consider the evidence as being close to its value in the distinguished limit $d, N \to \infty$ at fixed $\alpha = N/d$. Within this paradigm, developing a suitable Gaussian approximation requires us to identify all contributions to the evidence that would scale extensively, that is increase linearly with N, as $N, d \to \infty$ at fixed α. This would be increasingly important for $\alpha < 1$, where the contribution to the evidence resulting from many features can be significant. Ideally we should re-formulate the evidence as an integration over a set of variables which remains finite in number in the distinguished limit.

To be more explicit, consider that the Bayesian approach to model selection in PCA starts from the probability $p(D|k,\boldsymbol{\theta})p(\boldsymbol{\theta}|k)$ and integrates over the model parameters $\boldsymbol{\theta}$ to obtain the evidence $p(D|k)$. This integration is often evaluated by the aforementioned Laplace approximation - expansion about the maximum of $p(D|k,\boldsymbol{\theta})p(\boldsymbol{\theta}|k)$ and evaluation of the consequent tractable Gaussian integrals. For high-dimensional data the model parameters may consist of a small set of parameters, $\boldsymbol{\theta}_k$, of order of the signal dimensionality k, and a much larger set of parameters, $\boldsymbol{\theta}_d$, of order of the data dimensionality. For example, the latter may be the principal vectors, in the d-dimensional space, that form part of the model. Overall we can write $\boldsymbol{\theta} = (\boldsymbol{\theta}_d, \boldsymbol{\theta}_k)$. Integration over $\boldsymbol{\theta}_d$ provides a significant contribution to $p(D|k)$ due simply to the large number of individual model parameters that we are integrating over. In this scenario, the values of $\boldsymbol{\theta}_k$ obtained from maximizing $\int p(D|k,\boldsymbol{\theta}_d,\boldsymbol{\theta}_k)p(\boldsymbol{\theta}_d,\boldsymbol{\theta}_k|k)d\boldsymbol{\theta}_d$ and $p(D|k,\boldsymbol{\theta}_d,\boldsymbol{\theta}_k)p(\boldsymbol{\theta}_d,\boldsymbol{\theta}_k|k)$ do not coincide. In fact for large values of d they may be significantly different. The more accurate estimates of $\boldsymbol{\theta}_k$ are naturally obtained from the maximum of $\int p(D|k,\boldsymbol{\theta}_d,\boldsymbol{\theta}_k)p(\boldsymbol{\theta}_d,\boldsymbol{\theta}_k|k)d\boldsymbol{\theta}_d$, and consequently the more accurate estimates of the evidence $p(D|k)$ are obtained by expanding about this maximum.

The distorting effects of high dimensionality upon covariance matrix eigenvalue spectra and eigenvectors are well known from random matrix theory (RMT) studies (Johnstone, 2006). The RMT studies inform us about the expected sample covariance eigenvalue spectrum in the limit $d \to \infty$ (at fixed α), and consequently the limits of any model selection procedure based upon the observed eigenvalue spectra. As PCA is based upon the eigenvalues and eigenvectors of $\hat{\boldsymbol{C}}$, understanding their behaviour for small sample sizes and high data dimensions is key to understanding the behaviour of the existing model selection criterion, including the Bayesian model selection approach of Minka. Results from RMT studies are summarized in Section 3.

3. High-Dimensional Sample Covariance Matrices

We envisage a scenario where one has N, d-dimensional data vectors $\boldsymbol{\xi}_\mu, \mu = 1, \ldots, N$, with sample mean $\bar{\boldsymbol{\xi}}$, which are drawn from a multi-variate Gaussian distribution with covariance $\boldsymbol{C}$. The eigen-

values of $\boldsymbol{C}$ we denote by Λ_i, $i = 1,\ldots,d$. The sample data vectors $\boldsymbol{\xi}_\mu$ contain both signal and noise components so we represent,

$$\boldsymbol{C} = \sigma^2 \boldsymbol{I} + \sum_{m=1}^{S} \sigma^2 A_m \boldsymbol{B}_m \boldsymbol{B}_m^T \quad , \quad \boldsymbol{B}_m^T \boldsymbol{B}_{m'} = \delta_{mm'} \quad , \quad A_m \geq 0 \; \forall m \; , \tag{1}$$

corresponding to a population covariance $\boldsymbol{C}$ that contains a small number, S, of orthogonal signal components, $\{\boldsymbol{B}_m\}_{m=1}^S$, but that is otherwise isotropic. Here, σ^2 represents the variance of the additive noise component of the sample data vectors. Such models have been termed "spiked" covariance models within the statistics research literature (Johnstone, 2001), due to the small number of δ-function spikes in the population covariance eigenspectrum. In this case the population eigenvalues are $\Lambda_i = \sigma^2(1+A_i)$, $i \leq S$ and $\Lambda_i = \sigma^2$, $i > S$. The signal strengths $\sigma^2 A_m$ merely determine the population covariance eigenvalues corresponding to signal directions, and so the number of signal components S is commonly estimated by some process of inspection of the ordered eigenvalues $\lambda_i, i = 1,\ldots,d$, of the sample covariance matrix $\hat{\boldsymbol{C}} = N^{-1}\sum_\mu (\boldsymbol{\xi}_\mu - \bar{\boldsymbol{\xi}})(\boldsymbol{\xi}_\mu - \bar{\boldsymbol{\xi}})^T$.

When the sample size is greater than the dimensionality, that is, $N > d$, the sample covariance eigenvalues λ_i may be reasonable estimators of the population covariance eigenvalues Λ_i, and indeed are asymptotically unbiased estimators, that is, $\lambda_i \to \Lambda_i$ as $N \to \infty$ for fixed dimensionality d (Anderson, 1963). However, for small sample sizes $N \leq d$ the sample covariance $\hat{\boldsymbol{C}}$ is singular with a $d - N + 1$ degenerate zero eigenvalue. Similarly, the non-zero sample covariance eigenvalues, λ_i, $i = 1,\ldots,N-1$, can display considerable bias. This is reflected in the expected eigenspectrum, $\rho(\lambda)$, which is simply defined as the expectation over data sets of the empirical eigenvalue density,

$$\rho(\lambda) \; = \; \mathrm{E}_{\boldsymbol{\xi}} \left(\frac{1}{d} \sum_{i=1}^{d} \delta(\lambda - \lambda_i) \right) \; .$$

Here $\delta(x)$ is the Dirac δ-function, and we have used $\mathrm{E}_{\boldsymbol{\xi}}(\cdot)$ to denote expectation over the ensemble of sample data sets. The empirical eigenvalue density is considered to be a self-averaging quantity, such that as $N \to \infty$ the eigenvalue density from any individual sample covariance matrix is well represented by the ensemble average. Therefore, for large sample covariance matrices studying the behaviour of the expected sample covariance eigenvalue distribution provides us with insight into the behaviour of individual sample covariance matrices and consequently the behaviour of any model selection algorithms based upon the sample covariance eigenvalues.

When no signal components are present, that is, $\boldsymbol{C} = \sigma^2 \boldsymbol{I}$, and in the limit $d \to \infty$ with $\alpha = N/d$ fixed, the expected distribution of sample eigenvalues tends to the Marčenko-Pastur distribution (Marčenko and Pastur, 1967),

$$\begin{aligned} \rho(\lambda) \; = \; \rho_{bulk}(\lambda) \quad &= \quad (1-\alpha)\Theta(1-\alpha)\delta(\lambda) \\ &+ \quad \frac{\alpha}{2\pi\lambda\sigma^2} \sqrt{\max[0, (\lambda - \lambda_{min})(\lambda_{max} - \lambda)]} \; , \end{aligned} \tag{2}$$

where $\lambda_{max} = \sigma^2(1+\alpha^{-\frac{1}{2}})^2$, $\lambda_{min} = \sigma^2(1-\alpha^{-\frac{1}{2}})^2$, and $\Theta(x)$ is the Heaviside step function. Figure 1 shows examples of the Marčenko-Pastur distribution for different values of α. It should be noted that although the mean sample eigenvalue is an unbiased estimator of σ^2, that is, $\int_{0^-}^{\infty} d\lambda \, \lambda \rho_{bulk}(\lambda) = \sigma^2$, the individual non-zero sample covariance eigenvalues lie in the interval $[\lambda_{min}, \lambda_{max}]$ and so for $\alpha < 1$ are highly biased estimators of the corresponding population eigenvalues.

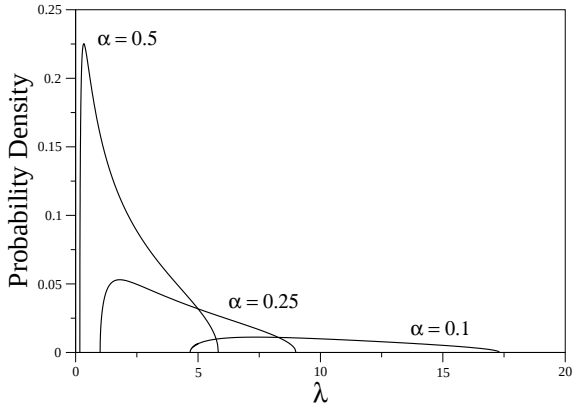

Figure 1: The Marčenko-Pastur limiting distribution for sample covariance eigenvalues, at $\alpha = 0.1, 0.25, 0.5$. In all cases $\sigma^2 = 1$. We have shown only the part of the distribution pertaining to non-zero eigenvalues. For $\alpha < 1$ there is also a δ-function peak at $\lambda = 0$ due to the singular nature of the sample covariance matrix - see main text.

Hoyle and Rattray (2004a) studied the expected behaviour of the sample covariance eigenvalue spectrum for "spiked" covariance models in the asymptotic limit $d \to \infty$ at fixed α, by using techniques from statistical physics. Similar results have been obtained within the statistics research community (Baik and Silverstein, 2006). As the addition of a small number, S, of signal directions provides a relatively small perturbation to an isotropic population covariance, the majority, or bulk of eigenvalues are still distributed according to the Marčenko-Pastur law. For this reason we have used $\rho_{bulk}(\lambda)$ to denote the Marčenko-Pastur distribution. For the "spiked" covariance models of Equation (1) the expected eigenvalue distribution $\rho(\lambda)$ is modified from $\rho_{bulk}(\lambda)$. At finite but large values of d and N the expected sample covariance eigenvalue density can be approximated by,

$$\begin{aligned}\rho(\lambda) &= (1-\alpha)\Theta(1-\alpha)\delta(\lambda) + \frac{1}{d}\sum_{m=1}^{S}\delta(\lambda-\lambda_u(A_m))\Theta(\alpha-A_m^{-2}) \\ &+ \left(1-d^{-1}\sum_{m=1}^{S}\Theta(\alpha-A_m^{-2})\right)\frac{\alpha}{2\pi\lambda\sigma^2}\sqrt{\max[0,(\lambda-\lambda_{min})(\lambda_{max}-\lambda)]}\ , \qquad (3)\end{aligned}$$

where $\lambda_u(A) = \sigma^2(1+A)(1+(\alpha A)^{-1})$. A number of interesting features are present in this spectrum. A transition occurs at $\alpha = A_m^{-2}$, such that for $\alpha > A_m^{-2}$ a sample eigenvalue located at $\lambda = \lambda_u(A_m)$ can be resolved separately from the remaining Marčenko-Pastur bulk of eigenvalues. Thus for S signal components within the "spiked" covariance model we can observe up to S transitions in the sample covariance eigenspectrum, on increasing α. The first transition point $\alpha = A_1^{-2}$ corresponds to the transition point in learning the leading signal direction $\boldsymbol{B}_1$. The scenario of learning a single signal component $\boldsymbol{B}_1$ of strength A_1 has been studied by Reimann et al. (1996), who

considered the behaviour (as $d \to \infty$ at fixed α) of the expectation value of R_1^2, where $R_1 = \boldsymbol{B}_1 \cdot \boldsymbol{J}_1$ is the overlap between the first principal component $\boldsymbol{J}_1$ of the sample covariance and $\boldsymbol{B}_1$. One observes the phenomenon of retarded learning whereby $R_1^2 = 0$ for $\alpha < A_1^{-2}$ and $R_1^2 > 0$ for $\alpha > A_1^{-2}$. This has been generalized to learning multiple orthogonal signals and one observes a separate retarded learning transition at $\alpha = A_m^{-2}$ for each of the overlaps $R_m^2 = (\boldsymbol{B}_m \cdot \boldsymbol{J}_m)^2$, where $\boldsymbol{J}_m$ is the m^{th} principal component (Hoyle and Rattray, 2007). That the ability to detect the signal components is reflected in the sample covariance eigenvalue structure (with retarded learning transitions coinciding with transitions in the eigenspectrum) demonstrates the utility of the sample covariance eigenspectrum for model selection. It also highlights that if the true signal dimensionality is S then asymptotically we have at most only S sample covariance eigenvalues separated from the Marčenko-Pastur bulk distribution, dependent on the value of α. If, for the given value of α, we have $\hat{S}$ eigenvalues separated from the Marčenko-Pastur bulk distribution, then the asymptotic equivalence of the observed sample covariance eigenspectra when $\boldsymbol{C}$ contains S signals or $\hat{S} \leq S$ signals means that no correct Bayesian model selection procedure can, asymptotically, select greater than $\hat{S}$ principal components (applying an Occam's Razor like argument), since both models are equally capable of explaining the observed eigenspectra. Equally, for sufficiently small α it is impossible, asymptotically, to distinguish the sample spectrum from one which has been generated from a model containing no signal structure, that is, from a population covariance $\boldsymbol{C} = \sigma^2 \boldsymbol{I}$. Within these constraints placed by the expected behaviour of the observed eigenspectra we now attempt to derive a suitable Bayesian model selection procedure that performs well in the distinguished asymptotic limit $N, d \to \infty$ at fixed α.

4. Bayesian Model Selection

In this section we summarize the Bayesian model selection procedure for PCA. We start in Section 4.1 by reproducing the formulation of the Bayesian model evidence as outlined by Minka (2000, 2001a) and the subsequent Laplace approximation. In Section 4.2 we re-express the evidence in a form that is more suitable for application of a Gaussian approximation when $d, N \to \infty$ at fixed $\alpha < 1$.

4.1 Laplace Approximation of Minka

The data vectors $\boldsymbol{\xi}_\mu$ are modelled as being drawn from a multi-variate Gaussian distribution with mean $\boldsymbol{m}$ and covariance $\boldsymbol{\Sigma} = v\boldsymbol{I} + \boldsymbol{H}\boldsymbol{H}^T$. Thus $\boldsymbol{\Sigma}$ acts as a model of the true population covariance $\boldsymbol{C}$. The matrix $\boldsymbol{H}$ represents the signal considered present in the data and so is modelled as being due to a small number, k, of orthogonal signal components $\boldsymbol{u}_i$, $i = 1, \ldots, k$. Consequently we set,

$$\boldsymbol{H} = \boldsymbol{U}(\boldsymbol{L} - v\boldsymbol{I}_k)^{1/2}\boldsymbol{W} \ , \ \boldsymbol{U}^T\boldsymbol{U} = \boldsymbol{I}_k \ , \ \boldsymbol{W}^T\boldsymbol{W} = \boldsymbol{I}_k \ ,$$

where the columns of the orthonormal matrix $\boldsymbol{U}$ are formed from the vectors $\boldsymbol{u}_i$. The parameter v provides an estimator of the true population noise level σ^2. The diagonal matrix $\boldsymbol{L}$ has elements l_i, $i = 1, \ldots, k$, which represent estimators of the population covariance eigenvalues Λ_i. The orthonormal matrix $\boldsymbol{W}$ represents an irrelevant rotation within the subspace and is subsequently eliminated from the calculation. Model selection proceeds via the standard use of Bayes' theorem,

$$p(\boldsymbol{H}, \boldsymbol{m}, v|D) \ = \ \frac{p(D|\boldsymbol{H}, \boldsymbol{m}, v)p(\boldsymbol{H}, \boldsymbol{m}, v)}{p(D)} \ .$$

The signal dimensionality, k, is implicit in the matrix $\boldsymbol{H}$. With a non-informative prior, the mean $\boldsymbol{m}$ can be integrated out to yield the probability of observing the data set D given $\boldsymbol{H}$ and v (Minka, 2001a),

$$p(D|\boldsymbol{H},v) \;=\; N^{-d/2}(2\pi)^{-(N-1)d/2}|\boldsymbol{H}\boldsymbol{H}^T+v\boldsymbol{I}|^{-(N-1)/2}\exp\left(-\frac{N}{2}\mathrm{tr}((\boldsymbol{H}\boldsymbol{H}^T+v\boldsymbol{I})^{-1}\hat{\boldsymbol{C}})\right)\,.$$

Given a prior $p(\boldsymbol{U},\boldsymbol{W},\boldsymbol{L},v)$ the evidence for a signal dimensionality k is then,

$$p(D|k) \;=\; \int d\boldsymbol{U}d\boldsymbol{W}d\boldsymbol{L}dv\,p(D|\boldsymbol{U},\boldsymbol{W},\boldsymbol{L},v)p(\boldsymbol{U},\boldsymbol{W},\boldsymbol{L},v)\,.$$

The integration over the elements $l_i,\ i=1,\ldots,k$ is restricted to the region $l_i \geq 0 \forall i$. Similarly, the integration over $\boldsymbol{U}$ and $\boldsymbol{W}$ is over the entire space of $d\times k$ and $k\times k$ orthonormal matrices respectively. For the relevant integration over $\boldsymbol{U}$ this is equivalent to integration over the Stiefel manifold $V_k(\mathbb{R}^d)$ defined by the set of all orthonormal k-frames in $\mathbb{R}^d$ (James, 1954) .

Minka chooses a conjugate prior,

$$p(\boldsymbol{U},\boldsymbol{W},\boldsymbol{L},v) \;\propto\; |\boldsymbol{H}\boldsymbol{H}^T+v\boldsymbol{I}|^{-(\eta+2)/2}\exp(-\frac{\eta}{2}\mathrm{tr}((\boldsymbol{H}\boldsymbol{H}^T+v\boldsymbol{I})^{-1}))\,, \tag{4}$$

where the hyper-parameter η controls the sharpness of the prior. For a non-informative prior η should be small and ultimately we shall take $\eta\to 0^+$ in our resulting approximation to the evidence $p(D|k)$. With the prior given in Equation (4) the evidence is Minka (2000, 2001a),

$$\begin{aligned} p(D|k) \;&=\; \frac{\mathcal{N}_k(d)}{\mathrm{Area}(V_k(\mathbb{R}^d))}\int d\boldsymbol{U}d\boldsymbol{L}dv\,|\boldsymbol{H}\boldsymbol{H}^T+v\boldsymbol{I}|^{-(N+1+\eta)/2} \\ &\times\; \exp(-\frac{N}{2}\mathrm{tr}((\boldsymbol{H}\boldsymbol{H}^T+v\boldsymbol{I})^{-1}(\hat{\boldsymbol{C}}+N^{-1}\eta\boldsymbol{I})))\,, \end{aligned} \tag{5}$$

with,

$$\mathcal{N}_k(d) \;=\; \frac{N^{-d/2}(2\pi)^{-(N-1)d/2}}{\Gamma\left((\frac{1}{2}\eta+1)(d-k)-1\right)}\,(\eta(d-k)/2)^{(\frac{1}{2}\eta+1)(d-k)-1}\,\frac{1}{\Gamma(\eta/2)^k}\,(\eta/2)^{\eta k/2}\,,$$

and here $1/\mathrm{Area}(V_k(\mathbb{R}^d))$ is the reciprocal of the area of the Stiefel manifold $V_k(\mathbb{R}^d)$ (James, 1954),

$$\frac{1}{\mathrm{Area}(V_k(\mathbb{R}^d))} \;=\; 2^{-k}\prod_{i=1}^{k}\Gamma((d-i+1)/2)\pi^{-(d-i+1)/2}\,.$$

The dependence of $\mathcal{N}_k(d)$ upon k is relatively weak compared to other factors contributing to $\ln p(D|k)$, and so Minka drops $\mathcal{N}_k(d)$ from further consideration in approximating $p(D|k)$. As with the maximum likelihood case (Tipping and Bishop, 1999a), for a fixed choice, k, of the number of principal components, the maximum posterior estimators for $\{\boldsymbol{u}_i\}_{i=1}^k$ are known to be the eigenvectors of $\hat{\boldsymbol{C}}$ corresponding to the k largest eigenvalues of $\hat{\boldsymbol{C}}$. Minka approximates the evidence $p(D|k)$ in Equation (5) using a Laplace approximation, expanding about the maximum posterior solution. The stationary point values of v and $\{l_i\}_{i=1}^k$ are denoted by $\hat{v}$ and $\{\hat{l}_i\}_{i=1}^k$ respectively, and are given by (on taking $\eta\to 0$),

$$\hat{l}_i \;=\; \frac{N\lambda_i}{N-1} \;\simeq\; \lambda_i \quad,\quad \hat{v} \;=\; \frac{N\sum_{j=k+1}^{d}\lambda_j}{(N+1)(d-k)-2}\,. \tag{6}$$

Within this approximation $\hat{l}_i$ provides a point estimate of the i^{th} population covariance eigenvalue Λ_i. For $\alpha < 1$, as we have already commented in the previous section, λ_i can be highly biased and consequently a poor point estimate of Λ_i. Continuing with the Laplace approximation and setting $m = dk - k(k+1)/2$, Minka finds (again after taking $\eta \to 0$),

$$p(D|k) \simeq \frac{1}{\text{Area}(V_k(\mathbb{R}^d))} \left(\prod_{j=1}^{k} \lambda_j \right)^{-N/2} \hat{v}^{-N(d-k)/2} (2\pi)^{(m+k)/2} |\boldsymbol{A}_Z|^{-1/2} N^{-k/2} , \tag{7}$$

where,

$$|\boldsymbol{A}_Z| = \prod_{i=1}^{k} \prod_{j=i+1}^{d} (\hat{\Lambda}_j^{-1} - \hat{\Lambda}_i^{-1})(\lambda_i - \lambda_j) N .$$

The estimator $\hat{\Lambda}_i$ is given by $\hat{\Lambda}_i = \hat{l}_i \simeq \lambda_i$ for $i \leq k$ and $\hat{\Lambda}_i = \hat{v}$ for $i > k$.

Figure 2 shows simulation estimates of the performance of a model selection criterion based upon the evidence given by Equation (7). We have sampled data vectors $\boldsymbol{\xi}_\mu$ from a population covariance $\boldsymbol{C}$ containing three signal components. The noise level has been set to $\sigma^2 = 1$ and the signal strengths are $A_1^2 = 30, A_2^2 = 20, A_3^2 = 10$. The simulation results are averages evaluated over 1000 simulated data sets. Plotted in Fig.2(a) is the probability of selecting the correct model dimension against d, for different fixed values of N. As expected the accuracy of the model selection decreases with increasing d, with greater accuracy for larger sample sizes N at a given value of d. Plotted in Fig.2(b) is the probability of selecting the correct model dimension against d, for different fixed values of α. Note that the smallest value studied, $\alpha = 0.2$, is still greater than the retarded learning transition point of the weakest signal component, which occurs at $\alpha = A_3^{-2} = 0.1$.

The accuracy of the model selection procedure can potentially be improved by noting that PCA can simply be considered as constructing a representation of a matrix, in this case the mean centred sample data matrix. As such the transpose of the representation of the mean centred data matrix is equally as valid, which can be evaluated as the eigen-decomposition of the transpose of the mean centred data matrix. Given that we then model the transposed data matrix using k, N-dimensional vectors rather than k, d-dimensional vectors, then with $N < d$ and thus effectively lower model complexity, we would expect model selection based upon using the transposed mean centred data matrix to display superior accuracy. This is borne out by simulation results for model selection accuracy when applied to the transposed centred data matrix that are also shown in Fig.2. In all cases shown in Fig.2 the accuracy of the model selection is greater when using the transpose of the mean centred data matrix. One should note from Fig.2a, that even with transposing the centred data matrix, the model selection accuracy decreases with increasing data dimensionality d, at fixed sample size N. Taking a data set with $\alpha < 1$ and transposing does not produce an effective value of α that is larger than one - if true this would suggest one could have arbitrarily large effective values of α (by taking $d \to \infty$ at fixed N) and consequently asymptotically perfect model selection even though, as has already been highlighted, the expected spectrum in this limit is indistinguishable from that obtained by sampling from a distribution with an isotropic population covariance matrix. Consequently the accuracy of model selection based upon the sample covariance eigenspectrum will always decrease with increasing d, at fixed N, due to the distorting effects of high data dimensionality. We can attempt to mitigate these effects by taking proper account of the high dimensional contributions to the model evidence. This we do in the next section.

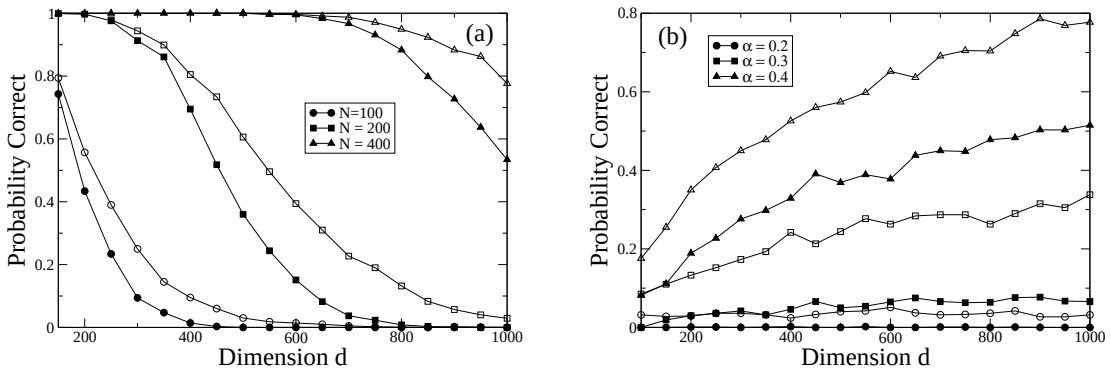

Figure 2: Probability of correct model selection using the method of Minka. The solid lines provide a guide to the eye. (a) & (b) Plots of model selection accuracy against data dimension d - (a) Fixed values of N, (b) Fixed values of α. The data is generated with a population covariance $\boldsymbol{C}$ containing three signal components -see main text for details. Solid symbols represent simulation results from the model selection procedure applied to the mean centred data matrix, whilst open symbols represent simulation results from the model selection procedure applied to the transpose of the mean centred data matrix.

4.2 Overlap Method

Although for $\alpha < 1$ the top k eigenvectors of $\hat{\boldsymbol{C}}$ are the maximum posterior choice of model principal components $\{\boldsymbol{u}_i\}_{i=1}^k$, for non-maximum posterior choices of $\boldsymbol{U}$ one still has a large rotational degeneracy of the k-frame within the d-dimensional space, which will make a large contribution to the integral in Equation (5). The integrand in Equation (5) can be written in terms of the overlaps $R_{ij} = \boldsymbol{u}_i \cdot \boldsymbol{v}_j$ between the model principal components $\boldsymbol{u}_i, i = 1,\ldots,k$, and the eigenvectors $\boldsymbol{v}_j$, $j = 1,\ldots,N-1$, of $\hat{\boldsymbol{C}}$ that correspond to the non-zero eigenvalues of $\hat{\boldsymbol{C}}$. One finds,

$$
\begin{aligned}
& |\boldsymbol{H}\boldsymbol{H}^T + \nu\boldsymbol{I}|^{-(N+1+\eta)/2} \exp(-\frac{N}{2}\mathrm{tr}((\boldsymbol{H}\boldsymbol{H}^T + \nu\boldsymbol{I})^{-1}(\hat{\boldsymbol{C}} + N^{-1}\eta\boldsymbol{I}))) \\
= \;& \exp\left[-\frac{N+1+\eta}{2}\left(\sum_{i=1}^{k} \ln l_i + (d-k)\ln\nu \right) - \frac{N}{2\nu}\sum_{j=1}^{N-1}\lambda_j \right. \\
+ \;& \left. \frac{N}{2}\sum_{i=1}^{k}(\nu^{-1} - l_i^{-1})\sum_{j=1}^{N-1}\lambda_j R_{ij}^2 \; - \; \frac{\eta d}{2\nu} \; + \; \frac{\eta}{2}\sum_{i=1}^{k}(\nu^{-1} - l_i^{-1}) \right] .
\end{aligned}
$$

This suggests performing the integration over $\{\boldsymbol{u}_i\}_{i=1}^k$ in terms of $\{R_{ij}\}$. The volume element that results from integrating over $\{\boldsymbol{u}_i\}_{i=1}^k$ at fixed $\{R_{ij}\}$ is $\det \boldsymbol{M}^{(d-N-1)/2} \times \mathrm{Area}(V_k(\mathbb{R}^{d-N+1}))$, where the matrix elements $M_{ii'} = \delta_{ii'} - \sum_j R_{ij}R_{i'j}$. For high dimensional spaces we might expect the vectors $\boldsymbol{u}_i, \boldsymbol{u}_{i'}$ to be orthogonal over any high-dimensional subspace, not just the entire d-dimensional space. Therefore we can approximate the matrix elements by $M_{ii'} = \delta_{ii'}(1 - \sum_j R_{ij}^2)$, and $\det \boldsymbol{M}$ is easily evaluated. With this approximation the evidence is,

$$p(D|k) \simeq \mathcal{N}_k(d)\frac{\text{Area}(V_k(\mathbb{R}^{d-N+1}))}{\text{Area}(V_k(\mathbb{R}^d))}\int\prod_{ij}dR_{ij}\int\prod_i dl_i\int dv$$
$$\times \quad \exp\left[\frac{d-N-1}{2}\sum_{i=1}^{k}\ln\left(1-\sum_{j=1}^{N-1}R_{ij}^2\right) - \frac{N+1+\eta}{2}\left(\sum_{i=1}^{k}\ln l_i + (d-k)\ln v\right)\right.$$
$$\left. - \frac{N}{2v}\sum_{j=1}^{N-1}\lambda_j + \frac{N}{2}\sum_{i=1}^{k}(v^{-1}-l_i^{-1})\sum_{j=1}^{N-1}\lambda_j R_{ij}^2 - \frac{\eta d}{2v} + \frac{\eta}{2}\sum_{i=1}^{k}(v^{-1}-l_i^{-1})\right] . \qquad (8)$$

Approximations to the model evidence can now be made by approximating this integration over the overlap variables $\{R_{ij}\}$, and consequently this approach is termed the "overlap" method. For large values of d and N we would expect the integral in Equation (8) to be dominated by the stationary points of the exponent and a Laplace approximation to the integral can be constructed. Denoting stationary point values by $\hat{v}, \hat{l}_i, \hat{R}_{ij}$, it is an easy matter to find that, on taking $\eta \to 0$, stationary points of Equation (8) satisfy for some j,

$$1-\hat{R}_{ij}^2 = \frac{(\hat{v}^{-1}-\hat{l}_i^{-1})N\lambda_j}{d-N-1} \quad , \quad \hat{R}_{ij'} = 0 \ , \ j' \neq j \, .$$

The dominant stationary point solution has the overlap between the i^{th} signal direction estimate, $\boldsymbol{u}_i$ and the i^{th} sample covariance eigenvector, $\boldsymbol{v}_i$, being non-zero, that is, $\hat{R}_{ii}^2 > 0$, $\hat{R}_{ii'}^2 = 0, \forall i \neq i'$,

For $j > k$ the dominant stationary point has $\hat{R}_{ij}^2 = 0$. Within this approximation the expectation value of R_{ij}^2 will be $O(N^{-1})$ due to small fluctuations about this stationary point. However, we have an extensive number, that is, proportional to N, of such overlap variables. Thus we expect $\sum_{j>k}R_{ij}^2 \sim 1$, and consequently the contribution from these small fluctuations cannot be ignored. The fluctuations in R_{ij}, for $j > k$, collectively affect the stationary point behaviour of the overlaps R_{ij} for $j \leq k$. To progress we integrate out the fluctuations by setting,

$$b_i = \sum_{j>k} R_{ij}^2 \, ,$$

and perform the integration over $\{R_{ij}\}_{j>k}$ by writing,

$$\int\prod_i\prod_{j>k}dR_{ij} = \int\prod_i\prod_{j>k}dR_{ij}\prod_i db_i\,\delta\left(b_i - \sum_{j>k}R_{ij}^2\right) .$$

Using the standard Fourier representation of a Dirac δ-function,

$$\delta(x) = \frac{1}{2\pi}\int_{-i\infty}^{i\infty}dp\,e^{px} \, ,$$

we obtain,

$$\int\prod_i\prod_{j>k}dR_{ij} = \frac{1}{(2\pi)^k}\int\prod_i db_i\,dp_i\prod_i\prod_{j>k}dR_{ij}\exp\left[\sum_i p_i\left(b_i - \sum_{j>k}R_{ij}^2\right)\right] , \qquad (9)$$

where the path of integration for p_i is between $-i\infty$ and $+i\infty$. Combining the integrand in Equation (9) with the integrand in Equation (8), the integration over $\{R_{ij}\}_{j>k}$ is Gaussian and so easily performed. We obtain,

$$\int dv \int \prod_{i=1}^{k} dl_i db_i dp_i \prod_i \prod_{j\leq k} dR_{ij} \exp\left(\sum_{i=1}^{k} p_i b_i \; + \; \frac{1}{2}(d-N-1)\sum_{i=1}^{k} \ln[1-\sum_{j=1}^{k} R_{ij}^2 - b_i] \right.$$
$$-\frac{1}{2}\sum_{i=1}^{k}\sum_{j>k} \ln[2p_i - N(v^{-1}-l_i^{-1})\lambda_j] \; - \; \frac{N+1}{2}\left[\sum_{i=1}^{k} \ln l_i \; + \; (d-k)\ln v\right]$$
$$\left. -\frac{N}{2}v^{-1}\sum_{j=1}^{N-1}\lambda_j \; + \; \frac{N}{2}\sum_{i=1}^{k}(v^{-1}-l_i^{-1})\sum_{j=1}^{k}\lambda_j R_{ij}^2 \right) . \tag{10}$$

With the path of integration for p_i being along the imaginary axis the remaining integrals in Equation (10) are approximated via steepest descent (Wong, 1989). For brevity we give only the solutions to the saddle point equations, with the caret again denoting saddle-point values of the corresponding integration variables,

$$\hat{v} \;=\; \frac{N}{(N+1)(d-k)}\left[\sum_{j=1}^{N-1}\lambda_j \; - \; \sum_{i=1}^{k}(1+N^{-1})\hat{l}_i\right] , \tag{11}$$

$$0 \;=\; \hat{l}_i^2\hat{v}^{-1}(1+N^{-1}) \; - \; \hat{l}_i(\lambda_i\hat{v}^{-1} - \alpha^{-1} + 1 + N^{-1}(k+3)) \; + \; \lambda_i \, , \tag{12}$$

$$\hat{R}_{ii}^2 \;=\; 1 \; - \; \frac{(d-N-1)}{N(\hat{v}^{-1}-\hat{l}_i^{-1})\lambda_i} \; - \; \frac{1}{N}\sum_{j>k}\frac{1}{(\hat{v}^{-1}-\hat{l}_i^{-1})(\lambda_i-\lambda_j)} \, , \tag{13}$$

$$\hat{R}_{ij}^2 \;=\; 0 \quad , j\neq i \, , \; j\leq k \, ,$$

$$\hat{p}_i \;=\; \frac{N}{2}(\hat{v}^{-1}-\hat{l}_i^{-1})\lambda_i \, , \tag{14}$$

$$\hat{b}_i \;=\; 1 \; - \; \hat{R}_{ii}^2 \; - \; \frac{(d-N-1)}{N(\hat{v}^{-1}-\hat{l}_i^{-1})\lambda_i} \, . \tag{15}$$

Again the saddle-point solution values $\hat{v}$ and $\hat{l}_i$ provide us with point estimates for the population noise level σ^2 and population signal eigenvalue Λ_i respectively. Equations (11) and (12) can be solved efficiently via an iterative process starting from an initial estimate of $\hat{v} = d^{-1}\sum_j \lambda_j$. Obtaining real-valued estimates, $\hat{l}_i$, for the population covariance eigenvalues is clearly dependent upon the quadratic equation in (12) having a non-negative discriminant. In practice, we have interpreted complex-valued estimates $\hat{l}_i$ for a particular choice of signal dimensionality k as meaning that the particular choice for k is not appropriate and should not be considered. From analysis of the asymptotic behaviour of the "overlap" approximation (see next section) we find that the discriminant of Equation (12) becomes negative for sample covariance eigenvalues λ_i which are below the edge of the Marčenko-Pastur bulk distribution given in Equation (2), that is, $\lambda_i < \lambda_{max} = \sigma^2(1+\alpha^{-\frac{1}{2}})^2$, so that indeed a negative discriminant is consistent with attempting to extract more signal components than can be genuinely distinguished from an isotropic population covariance. In other words complex solutions to Equation (12) suggest that the data do not support a model with that number, k, of signal components.

Once solutions for $\hat{v}$ and $\{\hat{l}_i\}_{i=1}^k$ have been obtained, values for $\hat{R}_{ii}^2, \hat{p}_i, \hat{b}_i$ follow from Equations (13), (14) and (15) respectively. Following Minka (2001a) and dropping the relatively weak k-dependence in $\mathcal{N}_k(d)$ we derive an approximation for the log-evidence as,

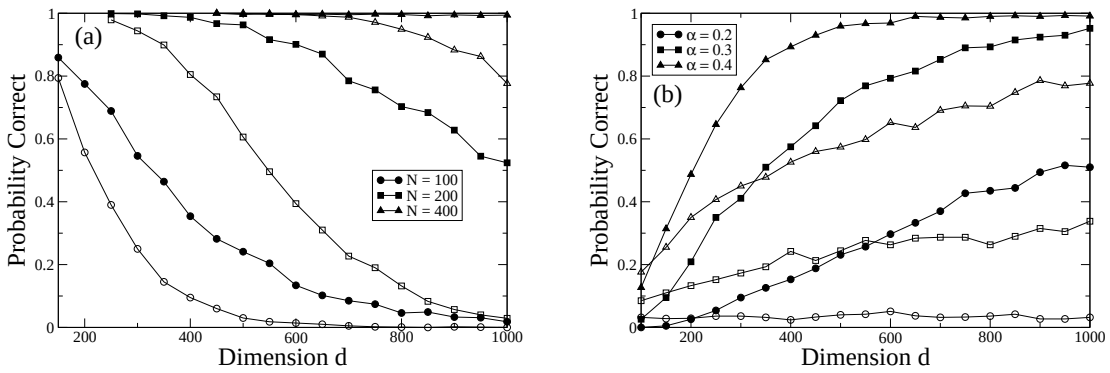

Figure 3: Plot of model selection accuracy for the "overlap" method. (a)Plot of model selection accuracy against data dimension d at fixed values of N. (b)Plot of model selection accuracy against data dimension for fixed values of α. For comparison open symbols represent simulation results from the model selection procedure of Minka applied to the transpose of the mean centred data matrix.

$$\begin{aligned}
\ln p(D|k) \;\simeq\; & \frac{N}{2}\sum_{i=1}^{k}(\hat{v}^{-1}-\hat{l}_i^{-1})\lambda_i \;-\; \frac{k}{2}(d-N-1) \;+\; k\frac{d-N-1}{2}\ln\left(\frac{d-N-1}{N}\right) \\
- \;& \frac{d-N-1}{2}\sum_{i=1}^{k}\ln((\hat{v}^{-1}-\hat{l}_i^{-1})\lambda_i) \;-\; \frac{k}{2}(N-k)\ln N \;-\; \frac{N-k}{2}\sum_{i=1}^{k}\ln(\hat{v}^{-1}-\hat{l}_i^{-1}) \\
- \;& \frac{1}{2}\sum_{i=1}^{k}\sum_{j>k}\ln(\lambda_i-\lambda_j) \;-\; \frac{N+1}{2}\sum_{i=1}^{k}\ln\hat{l}_i \;-\; \frac{N+1}{2}(d-k)\ln\hat{v} \;-\; \frac{N}{2}\hat{v}^{-1}\sum_{j=1}^{N-1}\lambda_j \\
+ \;& \frac{k}{2}(N-k-1)\ln 2\pi \;+\; \ln\left(\frac{\mathrm{Area}(V_k(\mathbb{R}^{d-N+1}))}{\mathrm{Area}(V_k(\mathbb{R}^{d}))}\right) \;-\; \frac{1}{2}\ln\det \boldsymbol{H}_s \\
+ \;& \frac{3k+k^2+1}{2}\ln 2\pi\,, \qquad (16)
\end{aligned}$$

where $\boldsymbol{H}_s$ is the Hessian of the exponent in the integrand evaluated at the saddle point. The last two terms in (16) come from integrating over the small fluctuations about the saddle point. Since the Hessian is of small dimension, and so not strongly dependent on N and d, we subsequently drop the last two terms from our approximation of the log-evidence. The "overlap" approximation to the log-evidence, given in Equation (16), can be used for model selection by selecting the value of k that has the highest value of $\ln p(D|k)$.

Figure 3 shows simulation estimates of the accuracy of the "overlap" model selection criterion given in Equation (16). Fig.3(a) shows the probability of selecting the correct model dimension against d, for different fixed values of N. Plotted in Fig.3(b) is the probability of selecting the correct model dimension against d, for different fixed values of α. Sample sizes and model pa-

rameter values are identical to those in Figure 2. Also reproduced (open symbols) in Fig.3(a) and Fig.3(b) are the simulation estimates of model selection accuracy for Minka's approximation to the model evidence applied to the transposed mean centred data. From Fig.3(a) it is clear that the "overlap" model selection criterion only suffers from degradation in performance at significantly higher values of dimension d compared to the approximation to the evidence in Equation (7). Similarly, Fig.3(b) demonstrates the superior model selection accuracy of the "overlap" method for increasing dimensionality d, at fixed values of α.

5. Asymptotic Analysis

The "overlap" approximation to the model evidence has been developed by applying a steepest descent approximation to the Bayesian evidence that has been re-formulated in terms of integration over variables that remain finite in number in the distinguished asymptotic limit $d, N \to \infty$, at fixed α. The "overlap" approximation essentially contains the leading order term of an asymptotic expansion of the evidence in that distinguished limit. It would be expected that the approximation to the model evidence would therefore become increasingly accurate in this limit. Note that this is very different from the traditional large sample limit $N \to \infty$ at fixed d, for which Minka's approximation to the Bayesian evidence will become increasingly accurate. It has been argued that since for many real high-dimensional data sets $\alpha \ll 1$, one would expect that approximations to the model evidence that are accurate in the distinguished limit will have superior model selection accuracy at finite values of d, N. The simulation results presented in Fig.3 would appear to confirm this. However, more concrete understanding of the accuracy of the "overlap" method in the distinguished asymptotic limit is required. A theoretical analysis of model selection accuracy in this limit would provide us with a firmer comparison of Minka's original Laplace approximation and the "overlap" method, in addition to the comparison provided by simulation study in Section 4.2. A number of quantities such as the eigenvalue spectrum are self-averaging in the asymptotic limit, that is, have vanishing sampling variation, so that for large data dimensions, d, the value for a single data set, $\{\boldsymbol{\xi}_\mu\}$, is well approximated by the ensemble average over data sets. Studying the ensemble expectation, in the asymptotic limit of $d \to \infty$ at fixed α, of the "overlap" approximation to the model evidence provides us with insight into its accuracy as a model selection procedure for high dimensional data.

From Equation (11) it is evident that $\hat{v} = d^{-1} \sum_{j=1}^{N-1} \lambda_j + O(N^{-1})$ as $N \to \infty$. Consequently, due to the self-averaging nature of the sample covariance eigenvalue spectrum, we have that $\hat{v} \to \mathrm{E}_{\boldsymbol{\xi}}(\lambda)$ as $N \to \infty$, where we have used $\mathrm{E}_{\boldsymbol{\xi}}(\cdot)$ to denote expectation over the ensemble of sample data sets. We already commented in Section 3 that $\mathrm{E}_{\boldsymbol{\xi}}(\lambda) = \sigma^2$ in the asymptotic limit $N \to \infty$ at fixed α, and so $\hat{v}$ provides an asymptotically unbiased estimate of the population noise level. Estimates of the population signal eigenvalues are given by $\{\hat{l}_i\}_{i=1}^k$, and in the distinguished asymptotic limit solutions to Equation (12) for $\hat{l}_i$ are given by,

$$\hat{l}_i = \frac{\hat{v}}{2}\left[(1+\lambda_i\hat{v}^{-1}-\alpha^{-1}) \pm \sqrt{(1+\lambda_i\hat{v}^{-1}-\alpha^{-1})^2 - 4\lambda_i\hat{v}^{-1}}\right] . \tag{17}$$

If we consider a "spiked" population covariance model of the form in Equation (1) the population covariance eigenvalues correspond to signal eigenvalues $\Lambda_i = \sigma^2(1+A_i)$, $i \leq S$ and noise eigenvalues $\Lambda_i = \sigma^2$, $i > S$. The resulting expected sample covariance eigenspectrum is given in Equation (3). Taking those sample eigenvalues which are separated from the bulk and also those at the upper bulk edge and substituting into Equation (17) we obtain on setting $\hat{v} = \sigma^2$ (on taking the positive

solution branch),

$$\begin{aligned}\hat{l}_i &= \sigma^2(1+A_i) \quad ,\text{for } \lambda_i = \sigma^2(1+A_i)(1+(1/\alpha A_i))\,,\\ \hat{l}_i &= \sigma^2(1+\alpha^{-\frac{1}{2}}) \quad ,\text{for } \lambda_i = \sigma^2(1+\alpha^{-\frac{1}{2}})^2\,.\end{aligned}$$

For sample covariance eigenvalues that are below the edge of the Marčenko-Pastur bulk distribution, that is, $\lambda_i < \sigma^2(1+\alpha^{-\frac{1}{2}})^2$, we obtain only complex solutions from Equation (17). Conversely, when $\lambda_i = \sigma^2(1+A_i)(1+(1/\alpha A_i))$, that is, when the sample covariance spectrum displays eigenvalues which are distinct from the bulk of the distribution, the estimator $\hat{l}_i = \sigma^2(1+A_i) = \Lambda_i$ and so gives an asymptotically unbiased estimate of the population signal eigenvalue Λ_i.

What is the asymptotic behaviour of the log-evidence? Inspecting Equation (16) we can see that, potentially, we need to evaluate $O(N^{-1})$ contributions to $\mathrm{E}_{\boldsymbol{\xi}}(\hat{\nu})$. However, it is easily shown that $O(N^{-1})$ contributions to $\mathrm{E}_{\boldsymbol{\xi}}(\hat{\nu})$ cancel out when evaluating $\mathrm{E}_{\boldsymbol{\xi}}(\ln p(D|k))$, and so we do not pursue them further here. We can evaluate the ensemble average $\mathrm{E}_{\boldsymbol{\xi}}(\sum_{j>k}\ln(\lambda_i-\lambda_j))$ through use of the replica trick (see Appendix A). Specifically we have for $\alpha > A_i^{-2}$,

$$\lim_{N,d\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right) \;=\; \ln\sigma^2 \;-\; (\alpha^{-1}-1)\ln(1+A_i) \;+\; \alpha^{-1}\ln A_i \;+\; \frac{1}{\alpha A_i}\,, \qquad (18)$$

whilst for $\alpha < A_i^{-2}$ we have,

$$\lim_{N,d\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right) \;=\; \ln\sigma^2 \;-\; (\alpha^{-1}-1)\ln(1+\alpha^{-\frac{1}{2}}) \;+\; \alpha^{-1}\ln\alpha^{-\frac{1}{2}} \;+\; \alpha^{-\frac{1}{2}}\,. \quad (19)$$

The asymptotic behaviour of the ratio $\mathrm{Area}(V_k(\mathbb{R}^{d-N+1}))/\mathrm{Area}(V_k(\mathbb{R}^d))$ is easily evaluated to give,

$$\ln\left(\frac{\mathrm{Area}(V_k(\mathbb{R}^{d-N+1}))}{\mathrm{Area}(V_k(\mathbb{R}^d))}\right) \;=\; \frac{Nk}{2}\left[-\ln\pi \;+\; \ln\frac{d}{2} \;-\; (\alpha^{-1}-1)\ln(1-\alpha) \;-1\right] \;+\; O(\ln N)\,. \quad (20)$$

Substituting Equations (18),(19),(20) and the asymptotic values for $\hat{\nu}$ and $\hat{l}_i$ into Equation (16), we obtain after some straight-forward algebra,

$$\begin{aligned}\mathrm{E}_{\boldsymbol{\xi}}(\ln p(D|k)) &= \frac{N}{2}\sum_{i=1}^{k}\Theta(\alpha-A_i^{-2})\left[A_i-\frac{1}{\alpha A_i} \;+\; (\alpha^{-1}-1)\ln\left(\frac{1+A_i}{1+(1/\alpha A_i)}\right) \;+\; \alpha^{-1}\ln\left(\frac{1}{\alpha A_i^2}\right)\right]\\ &- \frac{Nd}{2}\ln\sigma^2 \;-\; \frac{Nd}{2} \;+\; O(\ln N)\,. \qquad (21)\end{aligned}$$

If we set $x = \alpha^{-1}$ we can write the summand in Equation (21) as $\Theta(\alpha - A_i^{-2})\,f(x,A_i)$ where,

$$f(x,A) = A \;+\; x\ln x \;+\; (x-1)\ln(1+A) \;-\; 2x\ln A \;-\; (x-1)\ln(1+xA^{-1}) \;-\; xA^{-1}\,.$$

We find that,

$$f(A^2,A) \;=\; 0 \quad , \quad \left.\frac{\partial f}{\partial x}\right|_{x=A^2} \;=\; 0 \quad , \quad \frac{\partial^2 f}{\partial x^2} \;>\; 0 \;\text{ for } x \;<\; A^2\,,$$

and so for $\alpha > A_i^{-2}$ the summand in Equation (21) is positive. Consequently if $\alpha > A_i^{-2}$, so that the sample covariance eigenvalue spectrum reflects the presence of the signal $\boldsymbol{B}_i$, then the addition of

i^{th} principal component results in an increase in the asymptotic approximation to the log-evidence. Conversely if $\alpha < A_i^{-2}$ there is no change in the asymptotic approximation to the log-evidence on including the i^{th} principal component. This is a satisfying result since we have already commented in Section 3 that for $\alpha < A_i^{-2}$ the sample covariance eigenspectrum is asymptotically indistinguishable from that produced from a population model with $A_i \equiv 0$, and so therefore from a Bayesian model selection perspective all population models with $A_i < \alpha^{-\frac{1}{2}}$ are equally likely (provide an equally accurate description of the observed data). Ultimately this is due to the fact that we are considering models with a finite number, k, of signal components, and so in the asymptotic limit we are considering a vanishingly small proportion of sample covariance eigenvalues as representing signal components. With the non-zero sample covariance eigenvalues giving a dense covering of the range $[\lambda_{min}, \lambda_{max}]$ in the asymptotic limit, the largest few sample covariance eigenvalues, which are not distinct from the Marčenko-Pastur bulk distribution given in Equation (2) will be aggregated at the upper edge of the bulk, where they do not lead to any change in the log-evidence. For finite sample sizes we would expect the higher order terms in the expansion of the log-evidence to lead to a decrease in the log-evidence on inclusion of principal components that correspond to sample covariance eigenvalues that are below the bulk edge. However, in the asymptotic limit we can apply an Occam's Razor like argument and only select those principal components that increase the log-evidence. The limiting model selection estimate, $\hat{S}$, for the true signal dimensionality, S, then simply corresponds to counting the number of sample covariance eigenvalues that are beyond the upper edge of the Marčenko-Pastur bulk distribution. That is,

$$\hat{S} \;=\; \sum_{j=1}^{d} \Theta(\lambda_j \;-\; \lambda_{max}) \,.$$

The asymptotic analysis of the "overlap" method reveals that unbiased estimates of the population signal eigenvalues can be recovered and that, asymptotically, model selection based upon the "overlap" approximation to the log-evidence performs optimally. From Fig.2b it would appear that, at least for larger values of α, model selection based upon Minka's approximation to the log-evidence also approaches 100% accuracy as $d \to \infty$. Is it possible that the two different approximations to the log-evidence asymptotically have the same model selection performance? Starting from Minka's approximation to the Bayesian evidence $p(D|k)$ given in Equation (7) we have,

$$\begin{aligned} \ln p(D|k) \;\;\simeq\;\; & -\ln \text{Area}(V_k(\mathbb{R}^d)) \;-\; \frac{N}{2}\sum_{i=1}^{k} \ln \lambda_i \;-\; \frac{N}{2}(d-k)\ln \hat{\nu} \;+\; \frac{m+k}{2}\ln 2\pi \\ & -\frac{1}{2}\sum_{i=1}^{k}\sum_{j=i+1}^{d}\Big[\ln(\hat{\Lambda}_j^{-1} - \hat{\Lambda}_i^{-1}) \;+\; \ln(\lambda_i - \lambda_j) \;+\; \ln N\Big] \;-\; \frac{k}{2}\ln N \,, \end{aligned} \tag{22}$$

where $\hat{\Lambda}_i = N\lambda_i/(N-1)$ for $i \leq k$ and $\hat{\Lambda}_i = \hat{\nu}$ for $i > k$, with $\hat{\nu}$ defined in Equation (6). In this instance $O(N^{-1})$ contributions to $\text{E}_{\boldsymbol{\xi}}(\hat{\nu})$ do make a contribution to the leading order asymptotic term in $\text{E}_{\boldsymbol{\xi}}(\ln p(D|k))$. From the definition of the point estimate $\hat{\nu}$ in (6) we find,

$$\text{E}_{\boldsymbol{\xi}}(\hat{\nu}) \;=\; (1 + N^{-1}(k\alpha - 1))\text{E}_{\boldsymbol{\xi}}(d^{-1}\text{tr}\hat{\boldsymbol{C}}) \;-\; \frac{\alpha}{N}\sum_{j=1}^{k}\text{E}_{\boldsymbol{\xi}}(\lambda_j) \;+\; O(N^{-2}) \,.$$

For the "spiked" covariance model of Equation (1) this can then be refined to,

$$\begin{aligned}\mathrm{E}_{\boldsymbol{\xi}}(\hat{v}) &= \sigma^2 + \frac{\alpha\sigma^2}{N}\sum_{j=1}^{S} A_j + \frac{\sigma^2}{N}(k\alpha - 1) \\ &\quad - \frac{\alpha\sigma^2}{N}\sum_{i=1}^{k}\left[\Theta(\alpha - A_i^{-2})(1+A_i)(1+(1/\alpha A_i)) + \Theta(A_i^{-2}-\alpha)(1+\alpha^{-\frac{1}{2}})^2\right] \\ &\quad + O(N^{-2})\,.\end{aligned}$$

Retaining only k-dependent terms, the leading order asymptotic contribution to $\mathrm{E}_{\boldsymbol{\xi}}(\ln p(D|k))$ can be obtained within this approximation as,

$$\mathrm{E}_{\boldsymbol{\xi}}(\ln p(D|k)) = \frac{N}{2}\sum_{i=1}^{k}\left[\Theta(\alpha - A_i^{-2})\, f_M(x,A_i) + \Theta(A_i^{-2}-\alpha)\, f_M(x,\alpha^{-\frac{1}{2}})\right] + O(\ln N)\,,$$

where the subscript M on the function $f_M(x,A)$ is used to denote the asymptotic incremental change to the log-evidence obtained from Minka's approximation given in Equation (22), and again $x = \alpha^{-1}$. Specifically $f_M(x,A)$ is given as,

$$f_M(x,A) = A + x\ln x + (x-1)\ln(1+A) - 2x\ln A - x\ln\left[1 + xA^{-1} + xA^{-2}\right]\,. \qquad (23)$$

The transition point at which a signal component is strong enough to be distinguishable from the Marčenko-Pastur bulk distribution in Equation (2) is given by a signal strength $A = \alpha^{-\frac{1}{2}}$. If we put $A = y\alpha^{-\frac{1}{2}} = y\sqrt{x}$, then y directly measures the signal strength relative to that at which it is first detectable. We can then write Equation (23) as,

$$f_M(x, A = y\sqrt{x}) = (x-1)\ln(1+y\sqrt{x}) - x\ln\left(1 + y\sqrt{x} + y^2\right) + y\sqrt{x}\,.$$

A plot of $f_M(x = \alpha^{-1}, A = y\alpha^{-\frac{1}{2}})$ against y for different fixed values of α is shown in Figure 4. From Fig.4 we can see that at the transition point, $y = 1$, f_M is negative, and so selection of the i^{th} principal component will result in a reduction of the log-evidence, even if the signal strength A_i is sufficiently strong enough for the i^{th} sample covariance eigenvalue to be distinct from the Marčenko-Pastur bulk distribution. Thus, even though a detectable signal is present model selection based upon Equation (22) would not include that signal component. For the largest value of α shown f_M does not become positive until approximately $y > 1.8$. Therefore, even for $\alpha = 0.9$, not until the signal strength A_i is 1.8 times stronger than it need be for detection will the i^{th} signal component be correctly selected whilst using Minka's approximation to the log-evidence in Equation (22). For smaller values of α even stronger signal strengths are required, for example, $y > 2.0$ at $\alpha = 0.1$. For the simulations results shown in Fig.2b it is only at the largest value of α shown that we have $f_M > 0$ for all three signal components, and thus that all three signal components are guaranteed to be detectable in the asymptotic limit.

6. Comparison with Frequentist Approaches

In the distinguished asymptotic limit $N, d \to \infty$ the model selection process based upon the "overlap-method"approximation to the log-evidence simplifies (after applying a Occam's Razor like argument) to retaining those principal components whose corresponding eigenvalues are greater than

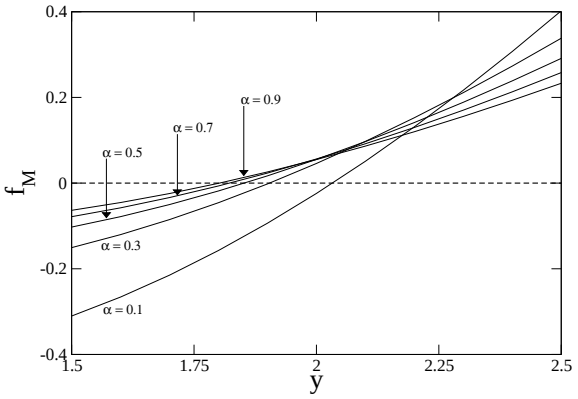

Figure 4: Plot of the function $f_M(x=\alpha^{-1}, A=y\alpha^{-\frac{1}{2}})$ against y for different values of α. $N f_M/2$ represents the incremental change (to leading order) in the log-evidence on retaining a principal component corresponding to a signal component of strength $A=y\alpha^{-\frac{1}{2}}$. The horizontal dashed line denotes the zero level for f_M.

the upper spectral edge, $\lambda_{max}=\sigma^2(1+\alpha^{-\frac{1}{2}})^2$, of the bulk eigenvalue distribution. Whilst this result appears intuitive from the viewpoint of the behaviour of eigenspectra of large sample covariance matrices presented in Section 3, we have also shown that not all approximations to the Bayesian evidence reduce in the asymptotic limit to this optimal choice for model selection. How then does the "overlap" method for model selection compare to other approaches, for example more traditional non-Bayesian approaches for dimensionality selection in PCA? In the asymptotic limit $N\rightarrow\infty$, where we have an infinite amount of data, we would naively expect frequentist and correctly formulated Bayesian approaches to model selection to give similar answers.

One of the most commonly applied techniques for dimensionality selection for PCA is to select sample covariance eigenvalues (and corresponding eigenvectors) that account for a fixed percentage of the total variance, for example, 90%. Typically this may only be the top two or three eigenvalues. Alternative methods consist of producing a 'scree plot', that is, plot of eigenvalue against rank, and attempting to detect by eye an 'elbow' in the plot where there is a significant change in scale of the sample covariance eigenvalues, supposedly reflecting the change from signal dominated eigenvalues to noise dominated eigenvalues. However, with sample covariance eigenvalues potentially being highly biased even when the population covariance is isotropic this is not always a reliable or easily implemented technique.

Hypothesis tests have been developed to detect departure from sphericity of the population covariance, based upon using $\mathrm{tr}\hat{\boldsymbol{C}}$ as the test statistic (John, 1971; Nagao, 1973). This approach has been modified by Ledoit and Wolf (2002) to account for smaller sample sizes but is still essentially only appropriate for $\alpha>1$. The effect of smaller values of α can be accounted for since the asymptotic form of the expected spectrum is given by the Marčenko-Pastur distribution (2) when $\boldsymbol{C}=\sigma^2\boldsymbol{I}$. Wachter has used this by producing Q-Q plots of the sample covariance eigenvalue quantiles against the Marčenko-Pastur distribution quantiles (Wachter, 1976). Sample covariance eigenvalues above

the 45 degree line in these Wachter plots indicate potentially signal containing principal components. At finite values of d a more principled, but non-Bayesian, approach would be to perform a series of iterative hypothesis tests whereby the null-hypothesis H_0 is that of a model containing k signal components. Comparison of the $(k+1)^{\text{th}}$ sample covariance eigenvalue, λ_{k+1}, against the sampling distribution of λ_{k+1} under H_0 would allow for potential rejection of the null-hypothesis and inclusion of the $(k+1)^{\text{th}}$ principal component as representing genuine signal in the data. After setting a rate at which one wishes to control the Type-I error, for example, $\gamma = 0.05$, testing of the $(k+1)^{\text{th}}, (k+2)^{\text{th}}, \ldots$ principal components proceed via,

$H_0 \; : \; \boldsymbol{C} \equiv \hat{\sigma}^2 \boldsymbol{I} \;\; , \;\; \hat{\sigma}^2 \; = \; d^{-1} \sum_{j=1}^{d} \lambda_j \;\; , \;\; k = 0$
while $p(\lambda > \lambda_{k+1} | k, d, N) < \gamma$
$k \rightarrow k+1$
$\hat{\Lambda}_k \; = \; \lambda_k$
$\hat{\sigma}^2 \; = \; (d-k)^{-1} \sum_{j=k+1}^{d} \lambda_j$
$H_0 \; : \; \boldsymbol{C} \equiv \text{diag}(\hat{\Lambda}_1, \ldots, \hat{\Lambda}_k, \hat{\sigma}^2, \ldots, \hat{\sigma}^2)$
end while

To implement this testing procedure we need the cumulative sampling distribution $p(\lambda > \lambda_{k+1} | k, d, N)$ of the $(k+1)^{\text{th}}$ sample covariance eigenvalue under the null hypothesis of $\boldsymbol{C}$ containing k signal components - that is the probability, when the population covariance contains only k signal components, of the $(k+1)^{\text{th}}$ sample covariance eigenvalue being larger than the eigenvalue λ_{k+1} observed in the real sample data. Johnstone (2001) has derived the sampling distribution for $k = 0$ by extending the analysis of Tracy and Widom (1996) on the Gaussian Orthogonal Ensemble (GOE) of random matrices. We can define location and scale constants,

$$\mu_{Nd} \; = \; N^{-1} \left(\sqrt{N-1} \, + \, \sqrt{d} \right)^2 \, ,$$

and

$$\sigma_{Nd} \; = \; N^{-1} \left(\sqrt{N-1} \, + \, \sqrt{d} \right) \left(\frac{1}{\sqrt{N-1}} \, + \, \frac{1}{\sqrt{d}} \right)^{\frac{1}{3}} \, .$$

Then for data drawn from an isotropic population covariance, $\boldsymbol{C} \; = \; \sigma^2 \boldsymbol{I}$, the largest sample covariance eigenvalue λ_1 (suitably centred and scaled) converges in distribution to the Tracy-Widom distribution W_1. Specifically one has,

$$\frac{(\lambda_1 / \sigma^2) - \mu_{Nd}}{\sigma_{Nd}} \xrightarrow{\mathcal{D}} W_1 \sim F_1 \, ,$$

where,

$$F_1(s) \; = \; \exp \left\{ -\frac{1}{2} \int_s^{\infty} q(x) + (x-s) q^2(x) dx \right\} \, ,$$

with $q(x)$ being the solution to the Painlevé II differential equation that is asymptotically equivalent to the Airy function $\text{Ai}(x)$,

$$\begin{aligned} \frac{d^2 q(x)}{dx^2} \; &= \; x q(x) \, + \, 2 q^3(x) \, , \\ q(x) \; &\sim \; \text{Ai}(x) \;\; , x \rightarrow \infty \, . \end{aligned}$$

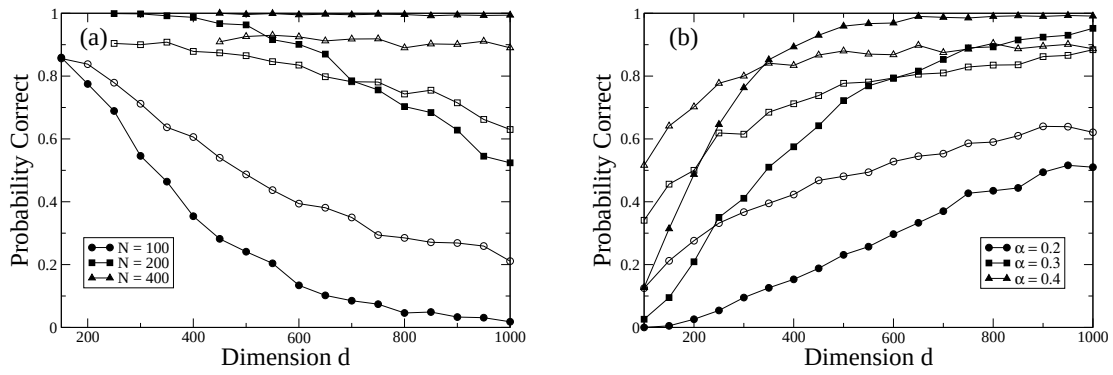

Figure 5: Comparison of the model selection accuracy for the "overlap" method (solid black symbols) with a null hypothesis test based upon the Tracy-Widom distribution for the largest eigenvalue of a sample covariance matrix (open symbols). a)Plot of model selection accuracy against data dimension d at fixed values of N. (b)Plot of model selection accuracy against data dimension for fixed values of α.

Note that the centering constant $\mu_{Nd} \to \lambda_{max}$, up to an irrelevant factor of σ^2. That is, the edge of the Marčenko-Pastur distribution, as $N, d \to \infty$ at fixed α. More recent analysis of the distribution of λ_1 when the data is complex and contains signal has been performed by Baik et al. (2005). The authors provide conjectures for the behaviour of the sampling distribution of λ_1 when the data is real, based upon their analysis of the complex case, but this still does not provide a means of calculating the sampling distribution $p(\lambda_{k+1}|k,d,N)$ for $k > 0$. Instead Johnstone (2001) derives the inequality $p(\lambda > \lambda_{k+1}|k,d,N) < p(\lambda > \lambda_1|0,d-k,N)$, with the latter distribution being given in terms of the Tracy-Widom distribution. Consequently, at finite N this provides a conservative hypothesis test since use of $p(\lambda_1|0,d-k,N)$ yields an over-estimate of the tail area of the sampling distribution $p(\lambda_{k+1}|k,d,N)$, and therefore an over-estimate of the Type-I error rate. With the variance σ^2_{Nd} tending to zero as $N \to \infty$, then in the asymptotic limit $N \to \infty$ the series of hypothesis tests given above corresponds simply to determining how many sample covariance eigenvalues λ_i are above λ_{max} - the edge of the Marčenko-Pastur bulk distribution - and so, as naively expected, is in agreement with the behaviour of the "overlap" method in the distinguished asymptotic limit.

Although in the distinguished asymptotic limit the Bayesian and frequentist approaches to model selection agree, it is interesting to compare model selection accuracies for finite values of N and d. For real data sets the sampling distribution of the individually ranked eigenvalues will have an effect upon the performance of the hypothesis test approach and likewise accuracy of point estimates for model parameters will impact upon the performance of the Bayesian methods. Figure 5 shows the model selection accuracy for the "overlap" method compared to that for the null hypothesis test outlined above that is based upon the Tracy-Widom distribution. Fig.5(a) shows the probability of selecting the correct model dimension against d, for different fixed values of N. Plotted in Fig.5(b) is the probability of selecting the correct model dimension against d, for different fixed values of α. Sample sizes and model parameter values are identical to those in Figure 2

and Figure 3. We have controlled the Type-I error at the 5% level ($\gamma = 0.05$) with the value of the abscissa for the 95^{th} centile of the Tracy-Widom distribution taken from Johnstone (2001). Within Fig.5(b) we would expect all model selection accuracies to converge to 1 as $d, N \to \infty$ since all the signal strengths have been chosen to be above their respective retarded learning transition points and therefore the sample eigenvalues corresponding to signal directions are all distinguishable from the Marčenko-Pastur bulk in this limit. However, for finite d and N Fig.5(a) and (b) reveal that overall the hypothesis testing approach has a superior model selection accuracy when both N and α are relatively small. By definition, the hypothesis test only considers a sample covariance eigenvalue to represent a signal if it exceeds that expected from the null model by more than reasonable sampling variation. As sampling variation will be greater at smaller values of N we might expect the hypothesis testing approach to be more sensitive for model selection than the "overlap" approach within this regime, particularly since higher order terms in the asymptotic expansion of the Bayesian evidence, that have not been incorporated into the "overlap" evidence approximation, will be more significant for smaller values of d and N. For larger values of d and N, the conservative nature of any hypothesis testing approach may adversely affect its model selection accuracy in comparison to a Bayesian evidence based approach.

7. Discussion & Conclusions

For calculations within high-dimensional inference problems we have argued that, rather than using results obtained by considering the traditional large sample limit $N \to \infty$, better approximations may be obtained by considering them to be close to the asymptotic value obtained in some distinguished limit, even though the sample size N may naively be considered large enough for routine application of the Laplace approximation to be accurate. What constitutes a large sample size, N, should clearly be defined with respect to the data dimensionality d. For PCA the appropriate distinguished asymptotic limit is $d, N \to \infty$, with $\alpha = N/d$ fixed, though for other models different distinguished limits may need to be considered in order to observe meaningful non-trivial behaviour that is distinct from the large sample limit, $N \to \infty$. For example, statistical physics studies of independent component analysis (ICA) suggests that $d \to \infty$ with $N = \alpha d^{\frac{3}{2}}$ at fixed α would be the appropriate distinguished limit to consider (Urbanczik, 2003). However, irrespective of the particular distinguished limit considered when developing an asymptotic approximation, one needs to be careful to keep track of the increasing number of contributions as $d \to \infty$, and potentially large contributions resulting from the rotational degeneracy of the integrand in the formulation of the Bayesian evidence.

The effect of high data dimensionality on model selection accuracy when $\alpha < 1$ is apparent from the simulation results shown in Fig.2a and Fig.3a. Ultimately this is due to the biased sample covariance eigenvalues and the poor accuracy of the sample covariance eigenvectors in representing the signal directions when $\alpha < 1$. The high-dimensional nature of the data leads to high-dimensional integral formulations of the Bayesian evidence. Approximation of the evidence has to be done carefully. Within the "overlap" method, inclusion of large contributions to the evidence from rotational degeneracy of the model $k-$frame and extensive Gaussian fluctuations leads to improved model selection accuracy. The observation that reformulating the integrand can lead to improved Laplace estimates of marginal distributions is not necessarily a new one (MacKay, 1998). For high-dimensional data the reformulation is essential, and for the "overlap" method reformulation of the evidence calculation in terms of a finite number of variables has ultimately led to an integrand that is better approximated by a single Gaussian, via a steepest descent calculation. There may exist

potentially superior estimation schemes, based upon a Gaussian parametrization of the integrand, that perform well when the integrand is essentially unimodal, for example expectation propagation based schemes (Minka, 2001b) or variational approximation similar to that employed by Bishop (1999b) for model selection within Bayesian PCA, although it should be noted that Bishop (1999b) does not impose an orthogonal constraint upon the low dimensional decomposition of the population covariance. However, it is the fact that one has to reformulate the evidence calculation for a Gaussian approximation to be accurate that is our main finding here, not the particular choice of approximation scheme that one employs once the reformulation has been made. Of greater interest perhaps is the fact that we have been able to demonstrate the asymptotic equivalence of the Bayesian evidence based model selection criterion and the frequentist hypothesis testing approach to model selection. Furthermore, analysis of the asymptotic behaviour of the "overlap" approximation to the log-evidence reveals that the estimators of the population signal eigenvalues are unbiased, at least for the "spiked" covariance models considered here.

The influence of high data dimensionality on estimates of model parameters can be explicitly demonstrated by re-visiting Minka's original Laplace approximation to the evidence. Although Minka's derivation provides a poorer approximation to the model evidence, in the distinguished limit $N, d \to \infty$ at fixed α, in comparison to the "overlap" approximation, it is still the correct leading order approximation in the asymptotic limit $N \to \infty$ at arbitrary fixed values of d. Therefore it contains information about how the model evidence behaves for large values of N and d. This suggests that Minka's Laplace approximation to the model evidence could be re-used to develop improved point estimates of population covariance eigenvalues $\{\Lambda_i\}$. One proceeds by noting that the eigenvectors of $\hat{\boldsymbol{C}}$ are the maximum posterior estimates of $\boldsymbol{U}$ for arbitrary choices of $\{l_i\}$ and v, since projection of the sample data onto the sample covariance eigenvectors retains the greatest variance. We can simply re-use Minka's approach to perform the Gaussian integration over $\boldsymbol{U}$ about this maximum posterior point, yielding $p(D|\{l_i\}, v)$ which can then be optimized with respect to $\{l_i\}$ and v. Specifically we have the following approximation to the log-evidence (taking $\eta \to 0$),

$$\begin{aligned} & -\frac{N+1}{2}\left(\sum_{i=1}^{k}\ln l_i \,+\, (d-k)\ln v\right) \,-\, \frac{N}{2v}\sum_{j=1}^{N-1}\lambda_j \,+\, \frac{N}{2}\sum_{i=1}^{k}(v^{-1}-l_i^{-1})\lambda_i \\ - \quad & \frac{1}{2}\ln|\boldsymbol{A}_Z| \,+\, \ln \mathcal{N}_k(d) \,-\, \ln \mathrm{Area}(V_k(\mathbb{R}^d)) \,+\, \frac{m+k}{2}\ln 2\pi \,-\, \frac{k}{2}\ln N\,, \end{aligned} \tag{24}$$

$$\ln|\boldsymbol{A}_Z| \,=\, m\ln N \,+\, \sum_{i=1}^{k}\left((d-k)\ln(v^{-1}-l_i^{-1}) \,+\, \sum_{j=i+1}^{k}\ln(l_j^{-1}-l_i^{-1}) \,+\, \sum_{j=i+1}^{d}\ln(\lambda_i-\lambda_j)\right).$$

It should be noted that the contribution from $\ln|\mathbf{A}_Z|$ is extensive in d and therefore affects the construction of point estimates for $\{l_i\}$ and v. Retaining only extensive terms in Equation (24) and locating stationary points with respect to l_i and v yields estimators $\hat{l}_i, \hat{v}$. In the asymptotic limit $N \to \infty$ these estimators are given by,

$$\begin{aligned} 0 \;&=\; \hat{v}^{-1}\hat{l}_i^2 \,-\, \hat{l}_i(1+\hat{v}^{-1}\lambda_i-\alpha^{-1}) \,+\, \lambda_i\,, \\ \hat{v} \;&=\; d^{-1}\sum_{j=1}^{N-1}\lambda_j\,. \end{aligned}$$

The equation above, determining the asymptotic behaviour of the estimator $\hat{l}_i$ is asymptotically identical to that given in Equation (12) for the "overlap" method and so, as already noted, gives asymptotically unbiased estimates for the population signal eigenvalue. Although this leading order approximation to the log-evidence can yield asymptotically unbiased estimators of the population covariance eigenvalues, it is still not an accurate estimation of the log-evidence and will still give inferior model selection performance in comparison to the "overlap" method. This is because higher order terms in the asymptotic expansion of the integral in Equation (5) will also be extensive in N, on taking the asymptotic limit $N, d \to \infty$ at fixed α. Ultimately this can seen from the "overlap" reformulation of the integral defining the evidence, which introduces higher than quadratic order terms in the extensive integration variables R_{ij} in the exponent of the integrand in Equation (8). These higher than quadratic order terms only arise for $\alpha < 1$ due to the contribution of the determinant $\det \boldsymbol{M}^{(d-N-1)/2}$ that results on changing integration variables from orthonormal vectors $\{\boldsymbol{u}_i\}_{i=1}^k$ of the model k-frame to the overlap variables R_{ij}. However, as we have demonstrated with the increased model selection accuracy of the "overlap" method, it is important to explicitly reformulate the integration in terms of variables that are finite in number even in the asymptotic limit $N, d \to \infty$ at fixed α.

For the simulations presented within this paper we have taken the signal dimensionality k to be finite and relatively small, for example, $k = 1, 2, 3$, so that $k \ll N < d$. This choice reflects the current interest in "spiked" covariance models and the generic challenge of identifying a fixed low-dimensional subspace as more and more features are considered. However, it is entirely feasible to imagine scenarios where the signal dimensionality is much larger than $k = 3$, and potentially even comparable to the sample size N. The derivation of the approximation to the log-evidence given in Equation (16) is valid for any finite value of k and thus can be used for model selection even for data sets where larger values of k are appropriate. Studying the accuracy of model selection for such data sets would prove more problematic. What would be the appropriate asymptotic limit to consider? If we consider a distinguished limit characterised by $N/d \to \alpha < 1$ and $k/N \to \beta < 1$ as $N, d, k \to \infty$, then any asymptotic analysis will need to take account of the effect a non-vanishing proportion of signal population eigenvalues has upon the distribution of sample covariance eigenvalues. The signal directions would no longer represent a small number of rank one perturbations of the identity matrix, with the consequence that the limiting sample covariance eigenvalue distribution would no longer correspond to the Marčenko-Pastur distribution given in Equation (2). Whilst tools exist to characterise the expected sample covariance eigenspectrum for an arbitrary population covariance eigenspectrum (Marčenko and Pastur, 1967; Wachter, 1978; Hoyle and Rattray, 2004b), obtaining closed form analytical results and proving the asymptotic correctness of the model selection for an arbitrary expected sample eigenspectrum would be difficult.

Finally, we should comment that we have illustrated ideas and concepts using model selection for PCA, in particular for $\alpha < 1$. Even today, with readily available compute power and sophisticated statistical learning algorithms, PCA is still a popular tool for dimensionality reduction or exploratory analysis. The application of PCA to extremely high-dimensional small sample size data sets has only increased the need for accurate model selection procedures. We also chose PCA as our exemplar because there already exists an elegant formulation of the Bayesian model selection problem (Minka, 2000, 2001a), and an approximation to the model evidence obtained by routine application of the Laplace approximation had already been developed. However, we believe that many of the ideas presented here are valid more generally. A large contribution to the Bayesian evidence for PCA arises from the rotational degeneracy of the model likelihood, that is, that there are many

orientations of the k-frame formed by the model signal vectors, $\{\boldsymbol{u}_i\}_{i=1}^k$, that are equally capable of accounting for the observed data. This ultimately stems from the fact that we are attempting to make inferences about vectors in $\mathbb{R}^d$ whilst we only have N sample vectors from which to construct a basis for the space. Thus, the degeneracy of the model likelihood is due to a combination of small sample size, $N < d$, and that the likelihood is expressed in terms of projections of the sample data onto the model signal vectors. This is true irrespective of whether the signal vectors $\{\boldsymbol{u}_i\}_{i=1}^k$ are constrained to be orthogonal or not, and so we expect that the issues illustrated here with PCA will be equally applicable to a number of other dimensionality reduction algorithms.

The author would like to thank Dr. Magnus Rattray for beneficial discussions and comments on the manuscript.

Appendix A.

Evaluation over data sets of the expectation value, $\mathrm{E}_{\boldsymbol{\xi}}(\sum_{j>k}\ln(\lambda_i-\lambda_j))$ (for $i \leq k$), would appear to be problematic. Since we are interested in the leading order behaviour of this expectation value, that is, the scaling with N, we can change the summation over j to include only those eigenvalues in the bulk distribution given in Equation (2). Potentially the leading order term can then be evaluated via,

$$\lim_{N,d\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right) = \alpha^{-1}\int_{\lambda_{min}}^{\lambda_{max}} d\lambda \ln(\lambda_i-\lambda)\rho_{bulk}(\lambda)\,, \tag{25}$$

and where $\rho_{bulk}(\lambda)$ is the Marčenko-Pastur bulk distribution given in Equation (2). Even if some sample covariance eigenvalues λ_j lie outside the Marčenko-Pastur bulk for $j > k$ the asymptotic result given in (25) is still valid since $N^{-1}\ln(\lambda_i-\lambda) \sim O(N^{-1})$ for $\lambda_i > \lambda > \lambda_{max}$. Thus contributions to $N^{-1}\mathrm{E}_{\boldsymbol{\xi}}(\sum_{j>k}\ln(\lambda_i-\lambda_j))$ from a small number of sample eigenvalues outside of the bulk distribution are vanishingly small in the asymptotic limit. The direct evaluation of the integral in (25) is difficult, so we prefer to use an indirect method. Since we are restricting the summation over j to eigenvalues in the bulk then if we denote the interval $[\lambda_{min},\lambda_{max}] \equiv I_{bulk}$, we can write,

$$\lim_{N,d\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{\lambda_j\in I_{bulk}}\ln(\lambda_i-\lambda_j)\right) = \lim_{N,d\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\mathrm{tr}\ln(\lambda_i\boldsymbol{I} - N^{-1}\boldsymbol{G})\right)\,. \tag{26}$$

where $\boldsymbol{G}$ is the Gram matrix formed from N, d-dimensional samples drawn from a multi-variate zero-mean Gaussian distribution with population covariance $\boldsymbol{C} = \sigma^2\boldsymbol{I}$, that is, the matrix $\boldsymbol{G}$ has elements $G_{\mu\mu'} = \boldsymbol{\xi}_\mu^T\boldsymbol{\xi}_{\mu'}$. The expectation, over data sets $\{\boldsymbol{\xi}_\mu\}_{\mu=1}^N$, of $\mathrm{tr}\ln(\lambda_i\boldsymbol{I} - N^{-1}\boldsymbol{G})$ is performed with the aid of the replica trick, which uses the representation,

$$\ln y = \lim_{n\to 0}\frac{(y^n-1)}{n}\,.$$

The calculation proceeds in a straight-forward fashion. We only give brief details here and the reader is referred to more in-depth explanations, given elsewhere, of the use of the replica trick in statistical physics and machine learning (Mezard et al., 1987; Hertz et al., 1991; Engel and Van den

Broeck, 2001). We find that evaluation of Equation (26) is given by the extremal value (with respect to x and q_1) of,

$$-\left\{\ln x + \frac{q_1}{x} - \alpha^{-1}\ln(1-\sigma^2 x) - \frac{\alpha^{-1}\sigma^2 q_1}{1-\sigma^2 x} - \lambda_i(x+q_1) + 1\right\}. \tag{27}$$

Differentiating with respect to x and q_1 the expression in (27) is easily maximized to give (for $\lambda_i = \sigma^2(1+A_i)(1+\alpha^{-1}A_i^{-1})$),

$$\ln\sigma^2 - (\alpha^{-1}-1)\ln(1+A_i) + \alpha^{-1}\ln A_i + \frac{1}{\alpha A_i}. \tag{28}$$

Here we have assumed the sample covariance eigenvalue λ_i will correspond to that from a "spiked" population covariance and that we are above the retarded learning transition for the i^{th} signal component. For $\alpha < A_i^{-2}$ we are below the retarded learning transition for the i^{th} signal and we expect λ_i to be located approximately at the upper edge of the bulk distribution so that $\lambda_i \simeq \sigma^2(1+\alpha^{-\frac{1}{2}})^2$. We expect the summation in $N^{-1}\sum_{j>k}\ln(\lambda_i-\lambda_j)$ will still converge since it is restricted to $j > k \geq i$. Setting $\lambda_i = \lambda_{max}$ in the previous replica calculation still yields a well-behaved estimate for $\lim_{N\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right)$, namely,

$$\ln\sigma^2 - (\alpha^{-1}-1)\ln(1+\alpha^{-\frac{1}{2}}) + \alpha^{-1}\ln\alpha^{-\frac{1}{2}} + \alpha^{-\frac{1}{2}}. \tag{29}$$

Since $A_i = \alpha^{-\frac{1}{2}}$ is the limit at which λ_i is indistinguishable from the bulk distribution, that is, $\lambda_i \to \lambda_{max}$, it is unsurprising that Equation (29) is obtained as the limit of Equation (28) as $A_i \to \alpha^{-\frac{1}{2}}$.

Figure 6a compares the limiting theoretical estimates for $N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right)$, given in Equations (28) and (29) with simulation for different values of α. Different plotted symbols represent different values of i, with $i = 1,\ldots,5$ running from top to bottom respectively. For each series we have set $k = i$ in the evaluation of the simulation averages. This was considered to be better than artificially setting $k = 3$, the true signal dimensionality which in general would not be known. Although in some cases, for evaluation of the simulation averages, this will lead to summation over sample covariance eigenvalues that are outside of the Marčenko-Pastur bulk distribution these will make only $O(N^{-1})$ contributions to $N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right)$, and so the simulation averages still provide a relevant test of the theoretical estimate of the asymptotic limiting value $\lim_{N\to\infty} N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right)$. Asymptotically, in the limit $N\to\infty$ and for the population covariance signal strengths chosen, three sample covariance eigenvalues are expected to be separated from the bulk distribution over the entire range of α plotted. Consequently we expect simulation averages to have a distinctly different behaviour for $i \leq 3$ compared to $i > 3$. A common limiting value for $N^{-1}\mathrm{E}_{\boldsymbol{\xi}}\left(\sum_{j>k}\ln(\lambda_i-\lambda_j)\right)$ when $i > 3$ is apparent from Figure 6a. Figure 6b compares simulation averages with the theoretical estimates in Equations (28) and (29) for different signal strengths. In this case the population covariance contains a single signal component, of strength A, whilst we have fixed $\alpha = 0.1$. The sample covariance eigenspectrum is expected to display a transition at $A = 1.0/\sqrt{\alpha} \simeq 3.16$. This is clearly reflected in the behaviour of the simulation average. The convergence towards the limiting theoretical estimate is also apparent from the comparison of simulation averages for $d = 1000$ and $d = 2000$.

Abstract

In many applications, one has to actively select among a set of expensive observations before making an informed decision. For example, in environmental monitoring, we want to select locations to measure in order to most effectively predict spatial phenomena. Often, we want to select observations which are robust against a number of possible objective functions. Examples include minimizing the maximum posterior variance in Gaussian Process regression, robust experimental design, and sensor placement for outbreak detection. In this paper, we present the *Submodular Saturation* algorithm, a simple and efficient algorithm with strong theoretical approximation guarantees for cases where the possible objective functions exhibit *submodularity*, an intuitive diminishing returns property. Moreover, we prove that better approximation algorithms do not exist unless NP-complete problems admit efficient algorithms. We show how our algorithm can be extended to handle complex cost functions (incorporating non-unit observation cost or communication and path costs). We also show how the algorithm can be used to near-optimally trade off expected-case (e.g., the Mean Square Prediction Error in Gaussian Process regression) and worst-case (e.g., maximum predictive variance) performance. We show that many important machine learning problems fit our robust submodular observation selection formalism, and provide extensive empirical evaluation on several real-world problems. For Gaussian Process regression, our algorithm compares favorably with state-of-the-art heuristics described in the geostatistics literature, while being simpler, faster and providing theoretical guarantees. For robust experimental design, our algorithm performs favorably compared to SDP-based algorithms.

Keywords: observation selection, experimental design, active learning, submodular functions, Gaussian processes

1. Introduction

In tasks such as sensor placement for environmental monitoring or experimental design, one has to select among a large set of possible, but expensive, observations. In environmental monitoring, we can choose locations where measurements of a spatial phenomenon (such acidicity in rivers and lakes, cf., Figure 1(a)) should be obtained. In experimental design, we frequently have a menu of possible experiments which can be performed. Often, there are several different objective functions which we want to simultaneously optimize. For example, in the environmental monitoring problem, we want to minimize the marginal posterior variance of our acidicity estimate at all locations simultaneously. In experimental design, we often have uncertainty about the model parameters, and we want our experiments to be informative no matter what the true parameters of the model are. In sensor placement for contamination detection in water distribution networks (cf., Figure 1(b)), we want to place sensors in order to quickly detect any possible contamination event.

Our goal in all these problems is to select observations (sensor locations, experiments) which are *robust* against a worst-case objective function (location to evaluate predictive variance, model parameters, contamination event, etc.). Often, the individual objective functions, for example, the marginal variance at one location, or the information gain for a fixed set of parameters (Das and Kempe, 2008; Krause et al., 2007b; Krause and Guestrin, 2005; Guestrin et al., 2005), satisfy *submodularity*, an intuitive diminishing returns property: Adding a new observation helps less if we have already made many observations, and more if we have made few observation thus far. While NP-hard, the problem of selecting an optimal set of k observations maximizing a single submodular objective can be approximately solved using a simple greedy forward-selection algorithm, which is guaranteed to perform near-optimally (Nemhauser et al., 1978). However, as we show, this simple *myopic* algorithm performs arbitrarily badly in the case of a worst-case objective function. In this paper, we address the fundamental problem of nonmyopically selecting observations which are robust against such an adversarially chosen submodular objective function. In particular:

- We present SATURATE, an efficient algorithm for the robust submodular observation selection problem. Our algorithm guarantees solutions which are at least as informative as the optimal solution, at only a slightly higher cost.
- We prove that our approximation guarantee is the best possible, that is, the guarantee cannot be improved unless NP-complete problems admit efficient algorithms.
- We discuss several extensions of our approach, handling complex cost functions and trading off worst-case and average-case performance.
- We extensively evaluate our algorithm on several real-world tasks, including minimizing the maximum posterior variance in Gaussian Process regression, finding experiment designs which are robust with respect to parameter uncertainty, and sensor placement for outbreak detection.

This manuscript is organized as follows. In Section 2, we formulate the robust submodular observation selection problem, and in Section 3, we analyze its hardness. We subsequently present

SATURATE, an efficient approximation algorithm for this problem (Section 4), and show that our approximation guarantees are best possible, unless NP-complete problems admit efficient algorithms (Section 5). In Section 6, we discuss how many important machine learning problems are instances of our robust submodular observation selection formalism. We then discuss extensions (Section 7) and evaluate the performance of SATURATE on several real-world observation selection problems (Section 8). Section 9 presents heuristics to improve the computational performance of our algorithm, Section 10 reviews related work, and Section 11 presents our conclusions.

2. Robust Submodular Observation Selection

In this section, we first review the concept of submodularity (Section 2.1), and then introduce the *robust submodular observation selection (*RSOS*)* problem (Section 2.2).

2.1 Submodular Observation Selection

Let us consider a spatial prediction problem, where we want to estimate the pH values across a horizontal transect of a river, for example, using the NIMS robot shown in Figure 1(a). We can discretize the space into a finite number of locations V, where we can obtain measurements, and model a joint distribution $P(X_V)$ over variables X_V associated with these locations. One example of such models, which have found common use in geostatistics (cf., Cressie, 1991), are Gaussian Processes (cf., Rasmussen and Williams, 2006). Based on such a model, a typical goal in spatial monitoring is to select a subset of locations $A \subseteq V$ to observe, such that the average predictive variance,

$$V(A) = \frac{1}{n}\sum_i \sigma^2_{i|A},$$

is minimized (cf., Section 6.1 for more details). Hereby, $\sigma^2_{i|A}$ denotes the predictive variance at location i after observing locations A, that is,

$$\sigma^2_{i|A} = \int P(\mathbf{x}_A)\mathbb{E}\left[(X_i - \mathbb{E}[X_i \mid \mathbf{x}_A])^2 \mid \mathbf{x}_A\right] d\mathbf{x}_A.$$

Unfortunately, the problem

$$A^* = \operatorname*{argmin}_{|A|\leq k} V(A)$$

is NP-hard in general (Das and Kempe, 2008), and the number of candidate solutions is very large, so generally we cannot expect to efficiently find the optimal solution. Fortunately, as Das and Kempe (2008) show, in many cases, the *variance reduction*

$$F_s(A) = \sigma^2_s - \sigma^2_{s|A}$$

at any particular location s, satisfies the following diminishing returns behavior: Adding a new observation reduces the variance at s more, if we have made few observations so far, and less, if we have already made many observations. This formalism can be formalized using the combinatorial concept of *submodularity* (cf., Nemhauser et al., 1978):

Definition 1 *A set function $F : 2^V \to \mathbb{R}$ is called* submodular, *if for all subsets $A, B \subseteq V$ it holds that $F(A \cup B) + F(A \cap B) \leq F(A) + F(B)$.*

Nemhauser et al. (1978) prove a convenient characterization of submodular functions: F is submodular if and only if for all $A \subseteq B \subseteq V$ and $s \in V \setminus B$ it holds that $F(A \cup \{s\}) - F(A) \geq F(B \cup \{s\}) - F(B)$. This characterization exactly matches our diminishing returns intuition about the variance reduction F_s at location s. Since each of the variance reduction functions F_s is submodular, the *average variance reduction*

$$F(A) = V(\emptyset) - V(A) = \frac{1}{n}\sum_s F_s(A)$$

is also submodular. The average variance reduction is also *monotonic*, that is, for all $A \subseteq B \subseteq V$ it holds that $F(A) \leq F(B)$, and *normalized* ($F(\emptyset) = 0$).

Hence, the problem of minimizing the average variance is an instance of the problem

$$\max_{A\subseteq V} F(A), \quad \text{subject to} \quad |A| \leq k, \tag{1}$$

where F is normalized, monotonic and submodular, and k is a bound on the number of observations we can make. As Krause and Guestrin (2007a) show, many other observation selection problems are instances of Problem (1).

Since solving Problem (1) is NP-hard in most interesting instances (Feige, 1998; Krause et al., 2006, 2007b; Das and Kempe, 2008), in practice, heuristics are often used. One such heuristic is the *greedy algorithm*. This algorithm starts with the empty set, and iteratively adds the element $s^* = \operatorname{argmax}_{s\in V\setminus A} F(A \cup \{s\})$, until k elements have been selected. Perhaps surprisingly, a fundamental result by Nemhauser et al. (1978) states that for submodular functions, the greedy algorithm achieves a constant factor approximation:

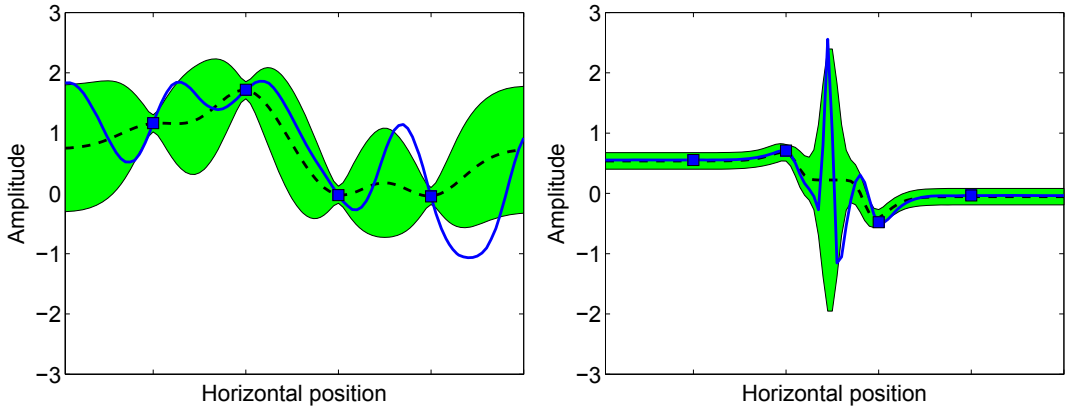
Theorem 2 (Nemhauser et al. 1978) *In the case of any normalized, monotonic submodular function F, the set A_G obtained by the greedy algorithm achieves at least a constant fraction $(1-1/e)$ of the objective value obtained by the optimal solution, that is,*

$$F(A_G) \geq (1-1/e) \max_{|A|\leq k} F(A).$$

Moreover, no polynomial time algorithm can provide a better approximation guarantee unless P = NP (Feige, 1998).

2.2 The Robust Submodular Observation Selection (RSOS) Problem

For phenomena, such as the one indicated in Figure 2(a), which are spatially homogeneous (isotropic), maximizing this average variance reduction leads to effective variance reduction everywhere in the space. However, many spatial phenomena are nonstationary, being smooth in certain areas and highly variable in others, such as the example indicated in Figure 2(b). In such a case, maximizing the average variance reduction will typically put only few examples in the areas highly variable areas. However, those regions are typically the most interesting, since they are most difficult to predict. In such cases, we might want to simultaneously minimize the variance everywhere in the space.



(a) *High average variance* (b) *High maximum variance*

Figure 2: Spatial predictions using Gaussian Processes with a small number of observations. The blue solid line indicates the unobserved latent function, and blue squares indicate observations. The plots also show confidence bands (green). Dashed line indicates the prediction. (b) shows an example with high maximum predictive variance, but low average variance, whereas (a) shows an example with high average variance, but lower maximum variance. Note, that in (b) we are most uncertain about the most variable (and interesting, since it is hard to predict) part of the curve, suggesting that the maximum variance should be optimized.

More generally, in many applications (such as the spatial monitoring problem discussed above, and several other examples which we present in Section 6), we want to perform equally well with respect to *multiple* objectives. We will hence consider settings where we are given a *collection* of

A	$F_1(A)$	$F_2(A)$	$\min_i F_i(A)$

Table 1: Functions F_1 and F_2 used in the counterexample.

normalized monotonic submodular functions $F_1,\ldots,F_m$, and we want to solve

$$\max_{A\subseteq V} \min_i F_i(A), \quad \text{subject to} \quad |A| \leq k. \tag{2}$$

The goal of Problem (2) is to find a set A of observations, which is robust against the worst possible objective, $\min_i F_i$, from our set of possible objectives. Consider the spatial monitoring setting for example, and assume that the prior variance σ_i^2 is constant (we will relax this assumption in Section 7.2) over all locations i. Then, the problem of minimizing the maximum variance, as motivated by the example in Figure 2, is equivalent to maximizing the minimum variance reduction, that is, solving Problem (2) where F_i is the variance reduction at location i.

We call Problem (2) the *Robust Submodular Observation Selection (*RSOS*)* problem. Note, that even if the F_i are all submodular, $F_{wc}(A) = \min_i F_i(A)$ is generally *not* submodular. In fact, we show below that, in this setting, the simple greedy algorithm (which performs near-optimally in the single-criterion setting) can perform arbitrarily badly. While the example in Table 1 might seem artificial, as we show in Section 8 (especially Section 8.3), the greedy algorithm exhibits very poor performance when applied to practical problems.

3. Hardness of the Robust Submodular Observation Selection Problem

Given the near-optimal performance of the greedy algorithm for the single-objective problem, a natural question is if the performance guarantee generalizes to the more complex robust optimization setting. Unfortunately, this hope is far from true, even in the simpler case of *modular* (additive) functions F_i. Consider a case with two submodular functions, F_1 and F_2, where the set of observations is $V = \{s_1,s_2,t_1,t_2\}$. The functions take values as indicated in Table 1. Optimizing for a set of 2 elements, the greedy algorithm maximizing $F_{wc}(A) = \min\{F_1(A),F_2(A)\}$ would first choose t_1 (or t_2), as this choice increases the objective $\min\{F_1,F_2\}$ by 1, as opposed to 0 for s_1 and s_2. The greedy solution for $k = 2$ would then be the set $\{t_1,t_2\}$, obtaining a score of 2. However, the optimal solution with $k = 2$ is $\{s_1,s_2\}$, with a score of n. Hence, as $n \to \infty$, the greedy algorithm performs arbitrarily worse than the optimal solution.

Given that the greedy algorithm performs arbitrarily badly, our next hope would be to obtain a different good approximation algorithm. However, we can show that most likely this is not possible:

Theorem 3 *Unless* P = NP, *there cannot exist* any *polynomial time approximation algorithm for Problem* (2). *More precisely: If there exists a positive function* $\gamma(\cdot) > 0$ *and an algorithm that, for all n and k, in time polynomial in the size of the problem instance n, is guaranteed to find a set* A' *of size k such that* $\min_i F_i(A') \geq \gamma(n) \max_{|A|\leq k} \min_i F_i(A)$, *then* P = NP.

Thus, unless P = NP, there cannot exist any algorithm which is guaranteed to provide, for example, even an exponentially small fraction ($\gamma(n) = 2^{-n}$) of the optimal solution. All proofs can be found in the Appendix.

4. The Submodular Saturation Algorithm

We now present an algorithm that finds a set of observations which perform at least as well as the optimal set, but at slightly increased cost; moreover, we show that no efficient algorithm can provide better guarantees (under reasonable complexity-theoretic assumptions).

4.1 Algorithm Overview

For now we assume that all F_i take only integral values; this assumption is relaxed in Section 7.1. The key idea is to consider the following alternative problem formulation:

$$\max_{c,A} c, \qquad \text{subject to} \qquad F_i(A) \geq c \text{ for } 1 \leq i \leq m \text{ and } |A| \leq k. \tag{3}$$

We want a set A of size at most k, such that $F_i(A) \geq c$ for all i, and c is as large as possible. Note that Problem (3) is equivalent to the original Problem (2): Maximizing c subject to the existence of a set A, $|A| \leq k$ such that $F_i(A) \geq c$ for all i is equivalent to maximizing $\min_i F_i(A)$.

Now suppose we had an algorithm that, for any given value c, solves the following optimization problem:

$$A_c = \operatorname*{argmin}_A |A| \qquad \text{subject to} \qquad F_i(A) \geq c \text{ for } 1 \leq i \leq m \tag{4}$$

that is, finds the smallest set A with $F_i(A) \geq c$ for all i. If this set has at most k elements, then c (and the set A) is feasible for the RSOS Problem (3). If we cannot find a set A satisfying $F_i(A) \geq c$ for all i and containing at most k elements, then c is infeasible. A binary search on c would then allow us to find the optimal solution with the maximum feasible c. We call Problem (4) the MINCOVER$_c$ problem, as it requires to find the smallest set guaranteeing an equal amount of coverage, c, for all objective functions F_i.

Since Theorem 3 rules out *any* approximation algorithm which respects the constraint k on the size of the set A, our only hope for non-trivial guarantees requires us to relax this constraint. Our algorithm is based on the following approach:

- We define a relaxed version of the RSOS problem with a superset of feasible solutions that we call RELRSOS.
- We will maintain a lower bound (a feasible solution) for RELRSOS, and an upper bound for RSOS.

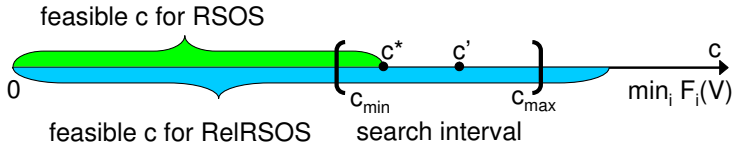

Figure 3: Illustration of feasible regions for the RSOS and RELRSOS problems. $[c_{\min}, c_{\max}]$ is the search interval during some iteration of SATURATE. c^* is the optimal solution to the RSOS problem, and c' is the solution that will eventually be returned by SATURATE.

- We will then successively improve the upper and lower bounds using a binary search procedure. Upon convergence, we are thus guaranteed a feasible solution to RELRSOS, that performs at least as well as the optimal solution to the RSOS problem.

We now define the RELRSOS problem, the relaxed version of the RSOS Problem (3).

$$\max_{c,A} c, \qquad \text{subject to} \quad F_i(A) \geq c \text{ for } 1 \leq i \leq m \text{ and } |A| \leq \alpha k. \tag{5}$$

Hereby, $\alpha \geq 1$ is a parameter relaxing the constraint on $|A|$. If $\alpha = 1$, we recover the RSOS Problem (3).

As described above, our goal will be to *approximately* solve the RELRSOS Problem (5) for a fixed constant α. More formally, we will develop an efficient algorithm, SATURATE, which returns a solution (c', A') that is feasible for the RELRSOS Problem (5), and achieves a score that is at least as good as an optimal solution (c^*, A^*) to the RSOS Problem (3), that is, $c' \geq c^*$ and $|A'| \leq \alpha |A^*| \leq \alpha k$.

The basic idea of SATURATE is to use the binary search procedure (maintaining a search interval $[c_{\min}, c_{\max}]$) as described above, but using an *approximate* algorithm, GPC (for *Greedy Partial Coverage*) that we will develop below, for the MINCOVER$_c$ Problem (4). When invoked with a fixed value c, the GPC algorithm will return a feasible solution $|A'_c|$ to the MINCOVER$_c$ Problem (4). We will furthermore guarantee that

- $|A'_c| > \alpha k$ implies that $c > c^*$, that is, c is an upper bound to the RSOS Problem (3), and hence it is safe to set $c_{\max} = c$, and
- $|A'_c| \leq \alpha k$ implies that A'_c is a feasible solution (lower bound) to the RELRSOS Problem (5). A'_c is then kept as best current solution and we can set $c_{\min} = c$.

The binary search procedure will hence always maintain an upper bound $c_{\max}$ to the RSOS Problem (3), and a lower bound $c_{\min}$ to the RELRSOS Problem (5). Upon termination, it is thus guaranteed to find a solution A_S for which it holds that $\min_i F_i(A_S) \geq c^*$ (since A_S is an upper bound to the RSOS Problem (3)) and $|A_S| \leq \alpha k$ (since A_S is feasible for the RELRSOS Problem (5)). Hence, the approximate solution A_S obtains minimum value at least as high as the best possible score obtainable using k elements, but using slightly more (at most αk) elements than k elements. Figure 3 illustrates the feasible regions of the RSOS and RELRSOS problems, as well as the binary search procedure.

4.2 Algorithm Details

We will now provide formal details for the algorithm sketched in Section 4.1. As trivial lower and upper bounds for the RSOS problem we can initially set $c_{\min} = 0 \leq \min_i F_i(\emptyset)$, and $c_{\max} = \min_i F_i(V)$, due to monotonicity of the F_i.

First, we will develop the efficient algorithm GPC which approximately solves the MINCOVER$_c$ Problem (4). For any value c that could possibly be feasible (i.e., $0 \leq c \leq \min_i F_i(V)$), define $\widehat{F}_{i,c}(A) = \min\{F_i(A), c\}$, the original function F_i truncated at score level c. The key insight is that these truncated functions $\widehat{F}_{i,c}$ remain monotonic and submodular (Fujito, 2000). Figure 4 illustrates this truncation concept. Let $\overline{F}_c(A) = \frac{1}{m}\sum_i \widehat{F}_{i,c}(A)$ be their average value. Since monotonic submodular functions are closed under convex combinations, $\overline{F}_c$ is also submodular and monotonic. Furthermore, $F_i(A) \geq c$ for all $1 \leq i \leq m$ if and only if $\overline{F}_c(A) = c$. Hence, in order to determine whether some c is feasible for Problem (5), we need to determine whether there exists a set of size at most αk such that $\overline{F}_c(A) = c$. Note, that due to monotonicity of $\overline{F}_c$ and the choice of c it holds that that $c = \overline{F}_c(V)$. We hence need to solve the following optimization problem:

$$A_c^* = \operatorname*{argmin}_{A \subseteq V} |A|, \quad \text{such that} \quad \overline{F}_c(A) = \overline{F}_c(V). \tag{6}$$

Problems of the form $\min_A |A|$ such that $F(A) = F(V)$, where F is a monotonic submodular function, are called *submodular covering problems*. Since $\overline{F}_c$ satisfies these requirements, the MINCOVER$_c$ Problem (6) is an instance of such a submodular covering problem. While such problems are NP-hard in general (Feige, 1998), Wolsey (1982) shows that the greedy algorithm, that starts with the empty set ($A = \emptyset$) and iteratively adds the element s increasing the score the most until $F(A) = F(V)$, achieves near-optimal performance on this problem. We can hence use the greedy algorithm applied to the truncated functions $\overline{F}_c$ as our approximate algorithm *GPC*, which is formalized in Algorithm 1. Using Wolsey's result and the observation that α can be chosen independently of the truncation threshold c, we find:

Lemma 4 *Given integral valued*[1] *monotonic submodular functions $F_1, \ldots, F_m$ and a (feasible) constant c, Algorithm 1 (with input $\overline{F}_c$) finds a set A_G such that $F_i(A_G) \geq c$ for all i, and $|A_G| \leq \alpha |A_c^*|$, where A_c^* is an optimal solution to Problem* (6)*, and*

$$\alpha = 1 + \log\left(\max_{s \in V} \sum_i F_i(\{s\})\right).$$

We can compute this approximation guarantee α for any given instance of the RSOS problem. Hence, if for a given value of c the greedy algorithm returns a set of size greater than αk, there cannot exist a solution A' with $|A'| \leq k$ with $F_i(A') \geq c$ for all i. Thus, c is an upper bound to the RSOS Problem (3). We can use this argument to conduct the binary search discussed in Section 4.1 to find the optimal value of c. The binary search procedure maintains an interval $[c_{\min}, c_{\max}]$, initialized $[0, \min_i F_i(V)]$. At every iteration, we test the current center of the interval, $c = (c_{\min} + c_{\max})/2$, and check feasibility of c using the greedy algorithm. If c is feasible, we retain the current best feasible solution and set $c_{\min} = c$. If c is infeasible (which we detect by comparing the number of elements picked by the greedy algorithm with αk), we set $c_{\max} = c$.

1. This bound is only meaningful for integral F_i, otherwise it could be arbitrarily improved by scaling the F_i. We relax the constraint on integrality of the F_i in Section 7.1.

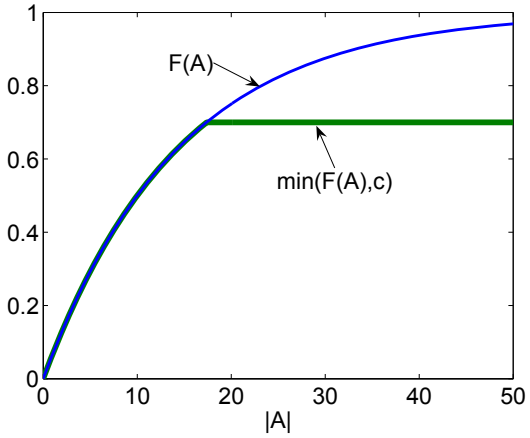

Figure 4: Truncating an objective function F preserves submodularity and monotonicity.

GPC ($\overline{F}_c$, c)
$A \leftarrow \emptyset$;
while $\overline{F}_c(A) < c$ **do**
  foreach $s \in V \setminus A$ **do** $\delta_s \leftarrow \overline{F}_c(A \cup \{s\}) - \overline{F}_c(A)$;
  $A \leftarrow A \cup \{\text{argmax}_s \, \delta_s\}$;
end

Algorithm 1: The greedy submodular partial cover (GPC) algorithm.

We call Algorithm 2, which formalizes this procedure, the *submodular saturation algorithm* (SATURATE), as the algorithm considers the truncated objectives $\widehat{F}_{i,c}$, and chooses sets which *saturate* all these objectives. In the pseudo-code of Algorithm 2 we pass α as a parameter. Theorem 5 (given below) states that SATURATE, when applied with α chosen as in Lemma 4, is guaranteed to find a set which achieves worst-case score $\min_i F_i$ at least as high as the optimal solution, if we allow the set to be logarithmically (a factor α) larger than the optimal solution.

Theorem 5 *For any integer k,* SATURATE *finds a solution A_S such that*

$$\min_i F_i(A_S) \geq \max_{|A| \leq k} \min_i F_i(A) \quad \text{and} \quad |A_S| \leq \alpha k,$$

for $\alpha = 1 + \log\left(\max_{s \in V} \sum_i F_i(\{s\})\right)$. The total number of submodular function evaluations is

$$O\left(|V|^2 m \log\left(m \min_i F_i(V)\right)\right).$$

Note, that the algorithm still makes sense for any value of α. However, if $\alpha < 1 + \log\left(\max_{s \in V} \sum_i F_i(\{s\})\right)$, the guarantee of Theorem 5 does not hold. As argued in Section 4.1, if we had an exact algorithm for submodular coverage, then we would set $\alpha = 1$, and SATURATE would return the optimal solution to the RSOS problem. Since, in our experience, the greedy algorithm for optimizing submodular functions works very effectively (cf., Krause et al. 2007b), in our experiments, we call SATURATE with $\alpha = 1$. This choice empirically performs very well, as demonstrated in Section 8.

SATURATE $(F_1,\ldots,F_m,k,\alpha)$
$c_{\min} \leftarrow 0$; $c_{\max} \leftarrow \min_i F_i(V)$; $A_{best} \leftarrow \emptyset$;
while $(c_{\max} - c_{\min}) \geq \frac{1}{m}$ **do**
  $c \leftarrow (c_{\min} + c_{\max})/2$;
  Define $\overline{F}_c(A) \leftarrow \frac{1}{m}\sum_i \min\{F_i(A), c\}$;
  $\widehat{A} \leftarrow GPC(\overline{F}_c, c)$;
  if $|\widehat{A}| > \alpha k$ **then**
    $c_{\max} \leftarrow c$;
  else
    $c_{\min} \leftarrow c$; $A_{best} = \widehat{A}$
  end
end

Algorithm 2: The Submodular Saturation algorithm.

If we apply SATURATE to the example problem described in Section 3, we would start with $c_{\max} = n$. Running the coverage algorithm (GPC) with $c = n/2$ would first pick element s_1 (or s_2), since $\overline{F}_c(\{s_1\}) = n/2$, and, next, pick s_2 (or s_1 resp.), hence finding the optimal solution.

The worst-case running time guarantee is quite pessimistic, and in practice the algorithm is much faster: Using a priority queue and lazy evaluations, Algorithm 1 can be sped up drastically. Lazy evaluations exploit the fact that, due to submodularity, the differences $\delta_s(A) = \overline{F}_c(X_{A\cup s}) - \overline{F}_c(X_A)$ that are computed by GPC are monotonically decreasing in A, which allows to avoid a large number of function evaluations (cf., Robertazzi and Schwartz 1989 for details). In addition, for many submodular functions F_i, such as the variance reduction, it is often cheaper to compute $\overline{F}_c(X_{A\cup s}) - \overline{F}_c(X_A)$ instead of $\overline{F}_c(X_{A\cup s})$. This observation can be exploited to drastically speed up GPC. Furthermore, in practical implementations, one would stop GPC once $\alpha k + 1$ elements have been selected, which already proves that the optimal solution with k elements cannot achieve score c. Also, Algorithm 2 can be terminated once $c_{\max} - c_{\min}$ is sufficiently small; in our experiments, 10-15 iterations usually sufficed.

5. Hardness of Bicriterion Approximation

Guarantees of the form presented in Theorem 5 are often called *bicriterion* guarantees. Instead of requiring that the obtained objective score is close to the optimal score *and all* constraints are exactly met, a bicriterion guarantee requires a bound on the suboptimality of the objective, as well as bounds on how much the constraints are violated. Theorem 3 showed that—unless P = NP—no approximation guarantees can be obtained which do not violate the constraint on the cost k, thereby necessitating the bricriterion analysis.

One might ask, whether the guarantee on the size of the set, α, can be improved. Unfortunately, this is not likely, as the following result shows:

Theorem 6 *If there were a polynomial time algorithm which, for any integer k, is guaranteed to find a solution A_S such that $\min_i F_i(A_S) \geq \max_{|A|\leq k} \min_i F_i(A)$ and $|A_S| \leq \beta k$, where $\beta \leq (1-\varepsilon)(1+\log\max_{s\in V}\sum_i F_i(\{s\}))$ for some fixed $\varepsilon > 0$, then* NP $\subseteq$ DTIME$(n^{\log\log n})$.

Hereby, DTIME($n^{\log\log n}$) is a class of deterministic, slightly superpolynomial (but sub-exponential) algorithms (Feige, 1998); the inclusion NP $\subseteq$ DTIME($n^{\log\log n}$) is considered unlikely (Feige, 1998). Taken together, Theorem 3 and Theorem 6, provide strong theoretical evidence that SATURATE achieves best possible theoretical guarantees for the problem of maximizing the minimum over a set of submodular functions.

6. Examples of Robust Submodular Observation Selection problems

We now demonstrate that many important machine learning problems can be phrased as RSOS problems. Section 8 provides more details and experimental results for these domains.

6.1 Minimizing the Maximum Kriging Variance

Consider a Gaussian Process (GP) (cf., Rasmussen and Williams, 2006) X_V defined over a finite set of locations (indices) V. Hereby, X_V is a set of random variables, one variable X_s for each location $s \in V$. Given a set of locations $A \subseteq V$ which we observe, we can compute the predictive distribution $P(X_{V\setminus A} \mid X_A = \mathbf{x}_A)$, that is, the distribution of the variables $X_{V\setminus A}$ at the unobserved locations $V \setminus A$, conditioned on the measurements at the selected locations, $X_A = \mathbf{x}_A$. Let $\sigma^2_{s|A}$ be the residual variance after making observations at A. Let Σ_{AA} be the covariance matrix of the measurements at the chosen locations A, and Σ_{sA} be the vector of cross-covariances between the measurements at s and A. Then, the predictive variance (often called Kriging variance in the geostatistics literature), given by

$$\sigma^2_{s|A} = \sigma^2_s - \Sigma_{sA}\Sigma^{-1}_{AA}\Sigma_{As},$$

depends only on the set A, and *not* on the observed values $\mathbf{x}_A$.[2] As argued in Section 2, an often (especially in the case of nonstationary phenomena) appropriate criterion is to select locations A such that the maximum marginal variance is as small as possible, that is, we want to select a subset $A^* \subseteq V$ of locations to observe such that

$$A^* = \operatorname*{argmin}_{|A|\leq k} \max_{s\in V} \sigma^2_{s|A}. \tag{7}$$

Let us assume for now that the a priori variance σ^2_s is constant for all locations s (in Section 7, we show how our approach generalizes to non-constant marginal variances). Furthermore, let us define the *variance reduction* $F_s(A) = \sigma^2_s - \sigma^2_{s|A}$. Solving Problem (7) is then equivalent to maximizing the minimum variance reduction over all locations s. For a particular location s, Das and Kempe (2008) show that the variance reduction F_s (often) is a monotonic submodular function. Hence the problem

$$A^* = \operatorname*{argmax}_{|A|\leq k} \min_{s\in V} F_s(A) = \operatorname*{argmax}_{|A|\leq k} \min_{s\in V} \sigma^2_s - \sigma^2_{s|A}$$

is an instance of the RSOS problem.

2. This independence is a particular property of the Gaussian distribution. When such independence is present, there is no benefit of sequentially selecting observations (cf., Krause and Guestrin, 2007b).

6.2 Variable Selection under Parameter Uncertainty

Consider an application, where we want to diagnose a failure of a complex system, by performing a number of tests. We can model this problem by using a set of discrete random variables $X_V = \{X_1, \ldots, X_n\}$ indexed by $V = \{1, \ldots, n\}$, which model both the hidden state of the system and the outcomes of the diagnostic tests. The interaction between these variables is modeled by a joint distribution $P(X_V \mid \theta)$ with parameters θ. Krause et al. (2007b) and Krause and Guestrin (2005) show that many variable selection problems can be formulated as the problem of optimizing a submodular utility function (measuring, for example, the information gain $I(X_U, X_A)$ with respect to some variables of interest U, or the mutual information $I(X_A; X_{V \setminus A})$ between the observed and unobserved variables, etc.). However, the informativeness of a chosen set A typically depends on the particular parameters θ, and these parameters might be uncertain. In some applications, it might not be reasonable to impose a prior distribution over θ, and we may want to perform well even under the worst-case parameters. In these cases, we can associate, with each parameter setting θ, a different submodular objective function F_θ, for example,

$$F_\theta(A) = I(X_A; X_U \mid \theta),$$

and we might want to select a set A which simultaneously performs well for all possible parameter values. In practice, we can discretize the set of possible parameter values θ (for example around a 95% confidence interval estimated from initial data) and optimize the worst case F_θ over the resulting discrete set of parameters.

6.3 Robust Experimental Designs

Another application is experimental design under nonlinear dynamics (Flaherty et al., 2006). The goal is to estimate a set of parameters θ of a nonlinear function $y = f(\mathbf{x}, \theta) + w$, by providing a set of experimental stimuli $\mathbf{x}$, and measuring the (noisy) response y. In many cases, experimental design for linear models (where $y = A(\mathbf{x})^T \theta + w$ with Gaussian noise w) can be efficiently solved by semidefinite programming (Boyd and Vandenberghe, 2004). In the nonlinear case, a common approach (cf., Chaloner and Verdinelli, 1995) is to *linearize* f around an initial parameter estimate θ_0, that is,

$$y = f(\mathbf{x}, \theta_0) + V(\mathbf{x})(\theta - \theta_0) + w, \tag{8}$$

where $V(\mathbf{x})$ is the Jacobian of f with respect to the parameters θ, evaluated at θ_0. Subsequently, a *locally-optimal* design is sought, which is optimal for the linear design Problem (8) for initial parameter estimates θ_0. Flaherty et al. (2006) show that the efficiency of such a locally optimal design can be very sensitive with respect to the initial parameter estimates θ_0. Consequently, they develop an efficient semi-definite program (SDP) for E-optimal design (i.e., the goal is to minimize the maximum eigenvalue of the error covariance) which is robust against perturbations of the Jacobian V. However, it might be more natural to directly consider robustness with respect to perturbation of the initial parameter estimates θ_0, around which the linearization is performed. We show how to find (Bayesian A-optimal) designs which are robust against uncertainty in these parameter estimates. In this setting, the objectives $F_{\theta_0}(A)$ are the reductions of the trace of the parameter covariance,

$$F_{\theta_0}(A) = \operatorname{tr}\left(\Sigma_\theta^{(\theta_0)}\right) - \operatorname{tr}\left(\Sigma_{\theta|A}^{(\theta_0)}\right),$$

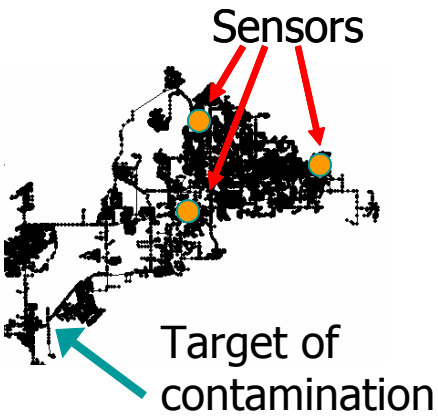

Figure 5: Securing a municipal water distribution network against contaminations performed under knowledge of the sensor placement is another instance of the RSOS problem.

where $\Sigma^{(\theta_0)}$ is the joint covariance of observations and parameters after linearization around θ_0; thus, F_{θ_0} is the sum of marginal parameter variance reductions, which are (often) individually monotonic and submodular (Das and Kempe, 2008), and so F_{θ_0} is monotonic and submodular as well. Hence, in order to find a robust design, we maximize the minimum variance reduction, where the minimum is taken over (a discretization into a finite subset of) all initial parameter values θ_0.

6.4 Sensor Placement for Outbreak Detection

Another class of examples are outbreak detection problems on graphs, such as contamination detection in water distribution networks (Leskovec et al., 2007). Here, we are given a graph $G = (V, E)$, and a phenomenon spreading dynamically over the graph. We define a set of *intrusion scenarios* I; each scenario $i \in I$ models an outbreak (e.g., spreading of contamination) starting from a given node $s \in V$ in the network. By placing sensors at a set of locations $A \subseteq V$, we can detect such an outbreak, and thereby minimize the adverse effects on the network.

More formally, for each possible outbreak scenario $i \in I$ and for each node $v \in V$ we define the detection time $T_i(v)$ as the time when the outbreak affects node v (and $T_i(v) = \infty$ if node v is never affected). We furthermore define a penalty function $\pi_i(t)$ which models the penalty incurred for detecting outbreak i at time t. We require $\pi_i(t)$ to be monotonically non-decreasing in t (i.e., we never prefer late over early detection), and bounded above by $\pi_i(\infty) \in \mathbb{R}$. Our goal is to minimize the worst-case penalty: We extend π_i to observation sets A as $\pi_i(A) = \pi_i(\min_{s \in A} T_i(s))$. Then, our goal is to solve

$$A^* = \operatorname*{argmin}_{|A| \leq k} \max_{i \in I} \pi_i(A).$$

Equivalently, we can define the *penalty reduction* $F_i(A) = \pi_i(\infty) - \pi_i(A)$. Clearly, $F_i(\emptyset) = 0$, F_i is monotonic. In Leskovec et al. (2007), it was shown that F_i is also guaranteed to be submodular. For now, let us assume that $\pi_i(\infty)$ is constant for all i (we will relax this assumption in Section 7.2). Our goal in sensor placement is then to select a set of sensors A such that the minimum penalty

reduction is as large as possible, that is, we want to select

$$A^* = \operatorname*{argmax}_{|A|\leq k} \min_{i\in I} F_i(A).$$

In other words, an adversary observes our sensor placement A, and then decides on an intrusion i for which our utility $F_i(A)$ is as small as possible. Hence, our goal is to find a placement A which performs well against such an adversarial opponent.

6.5 Robustness Against Sensor Failures and Feature Deletion

Another interesting instance of the RSOS problem arises in the context of robust sensor placements. For example, in the outbreak detection problem, sensors might *fail*, due to hardware problems or manipulation by an adversary. We can model this problem in the following way: Consider the case where all sensors at a subset $B \subseteq V$ of locations fail. Given a submodular function F (e.g., the utility for placing a set of sensors), and the set $B \subseteq V$ of failing sensors, we can define a new function $F_B(A) = F(A \setminus B)$, corresponding to the (reduced) utility of placement A after the sensor failures. It is easy to show that if F is nondecreasing and submodular, so is F_B. Hence, the problem of optimizing sensor placements which are robust to sensor failures results in a problem of simultaneously maximizing a collection of submodular functions, for example, for the worst-case failure of $k' < k$ sensors we solve

$$A^* = \operatorname*{argmax}_{|A|\leq k} \min_{|B|\leq k'} F_B(A).$$

We can also combine the optimization against adversarial contamination scenarios as discussed in Section 6.3 with adversarial sensor failures, and optimize[3]

$$A^* = \operatorname*{argmax}_{|A|\leq k} \min_{i\in I} \min_{|B|\leq k'} F_i(A \setminus B).$$

Another important problem in machine learning is feature selection. In feature selection, the goal is to select a subset of features which are informative with respect to, for example, a given classification task. One objective frequently considered is the problem of selecting a set of features which maximize the information gained about the class variable X_Y after observing the features X_A, $F(A) = H(X_Y) - H(X_Y \mid X_A)$, where H denotes the Shannon entropy. Krause and Guestrin (2005) show, that in a large class of graphical models, the information gain $F(A)$ is in fact a submodular function. Now we can consider a setting, where an adversary can delete features which we selected (as considered, for example, by Globerson and Roweis 2006). The problem of selecting features robustly against such arbitrary deletion of, for example, m features, is hence equivalent to the problem of maximizing $\min_{|B|\leq m} F_B(A)$, where B are the deleted features.

3. Note that for larger values of k', computing the average truncated utility can be computationally complex. See Section 9 for possible approaches to reduce this complexity. Also note that in practice, one can expect that sensor failures have structure (e.g., sensors that are spatially collocated, or share other common features, are more likely to simultaneously fail). Such structured failures can potentially be modeled by appropriately choosing the collection of sets B of failing nodes.

6.5.1 IMPROVED GUARANTEES FOR SENSOR FAILURES

As discussed above, in principle, we could find a placement robust to single sensor failures by using SATURATE to (approximately) solve

$$A^* = \operatorname*{argmax}_{|A|\leq k} \min_s F_s(A).$$

However, since $|V|$ can be very large, and the approximation guarantee α depends logarithmically on $|V|$, such a direct approach might not be desirable. We can improve the guarantee from $O(\log|V|)$ to $O(\log(k\log|V|))$, which typically is much tighter, if $k \ll |V|/\log|V|$ (i.e., we place far fewer sensors than we have possible sensor locations). We can improve the approximation guarantee drastically by noticing that $F_s(A) = F(A)$ if $s \notin A$. Hence,

$$\overline{F}_c(A) = \frac{|V|-|A|}{|V|}\min\{F(A),c\} + \frac{1}{|V|}\sum_{s\in A}\widehat{F}_{s,c}(A).$$

We can replace this objective by a new objective function,

$$\overline{F}'_c(A) = \frac{k'-|A|}{k'}\min\{F(A),c\} + \frac{1}{k'}\sum_{s\in A}\widehat{F}_{s,c}(A)$$

for some constant $\hat{k}$ to be specified below. This modified objective is still monotonic and submodular when restricted to sets of size at most $\hat{k}$. It still holds that, for all subsets $|A| \leq \hat{k}$, that

$$\overline{F}'_c(A) \geq c \Leftrightarrow F_s(A) \geq c \text{ for all } s \in V.$$

How large should we choose $\hat{k}$? We have to choose $\hat{k}$ large enough such that SATURATE will never choose sets larger than $\hat{k}$. A sufficient choice for $\hat{k}$ is hence $\lceil \alpha k \rceil$, where $\alpha = 1+\log(|V|\max_{s\in V} F(\{s\}))$. For this choice of $\hat{k}$, our new approximation guarantee will be

$$\begin{aligned}\alpha' &= 1+\log\left(\alpha k \max_{s\in V} F(\{s\})\right) = 1+\log\left(\left(1+\log\left(|V|\max_{s\in V}F(\{s\})\right)\right)k\max_{s\in V}F(\{s\})\right)\\ &\leq 1+2\log\left(k\log(|V|)\max_{s\in V}F(\{s\})\right)\end{aligned}$$

Hence, for the new objective $\overline{F}'_c$, we get a tighter approximation guarantee, $\alpha' = 1+2\log(k\log(|V|)\max_{s\in V}F(\{s\}))$, which now depends logarithmically on $k\log|V|$, instead of the number of available locations $|V|$. Note that this same approach can also provide tighter approximation guarantees in the case of multiple sensor failures.

7. Extensions

We now show how some of the assumptions made in our presentation above can be relaxed. We also discuss several extensions, allowing more complex cost functions, and the tradeoff between worst-case and average-case scores.

7.1 Non-integral Objectives

In our analysis of SATURATE (Section 4), we have assumed, that each of the objective functions F_i only take values in the positive integers. However, most objective functions of interest in observation selection (such as those discussed in Section 6) typically do not meet this assumption. If the F_i take on rational numbers, we can scale the objectives by multiplying by their common denominator.

If we allow small additive approximation error (i.e., are indifferent if the approximate solution differs from the optimal solution in low order bits), we can also approximate the values assumed by the functions F_i by their highest order bits. In this case, we replace the functions $F_i(A)$ by the approximations

$$F_i'(A) = \frac{\lceil 2^j F_i(A) \rceil}{2^j}.$$

By construction, $F_i'(A) \leq F_i(A) \leq F_i'(A)(1+2^{-j})$, that is, F_i' is within a factor of $(1+2^{-j})$ of F_i. Also, $2^j F_i'(A)$ is integral. However, $F_i'(A)$ is not guaranteed to be submodular. Nevertheless, an analysis similar to the one presented by Krause et al. (2007b) can be used to bound the effect of this approximation on the theoretical guarantees α obtained by the algorithm, which will now scale linearly with the number j of high order bits considered. In practice, as we show in Section 8, SATURATE provides state-of-the-art performance, even without rounding the objectives to the highest order bits.

7.2 Non-constant Thresholds

Consider the example of minimizing the maximum variance in Gaussian Process regression. Here, the $F_i(A) = \sigma_i^2 - \sigma_{i|A}^2$ denote the variance reductions at location i. However, rather than guaranteeing that $F_i(A) \geq c$ for all i (which, in this example, means that the *minimum variance reduction* is c), we want to guarantee that $\sigma_{i|A}^2 \leq c$ for all i, which requires a different amount of variance reduction for each location. We can easily adapt our approach to handle this case: Instead of defining $\widehat{F}_{i,c}(A) = \min\{F_i(A), c\}$, we define $\widehat{F}_{i,c}(A) = \min\{F_i(A), \sigma_i^2 - c\}$, and then again perform binary search over c, but searching for the smallest c instead. The algorithm, using objectives modified in this way, will bear the same approximation guarantees.

7.3 Non-uniform Observation Costs

We can extend SATURATE to the setting where different observations have different costs. In the spatial monitoring setting for example, certain locations might be more expensive to acquire a measurement from. Suppose a cost function $g : V \to \mathbb{R}^+$ assigns each element $s \in V$ a positive cost $g(s)$; the cost of a set of observations is then $g(A) = \sum_{s \in A} g(s)$. The problem is to find $A^* = \operatorname{argmax}_{A \subset V} \min_i F_i(A)$ subject to $g(A) \leq B$, where $B > 0$ is a *budget* we can spend on making observations. In this case, we use the rule

$$\delta_s \leftarrow \frac{\overline{F}_c(A \cup \{s\}) - \overline{F}_c(A)}{g(s)}$$

in Algorithm 1. For this modified algorithm, Theorem 5 still holds, with $|A|$ replaced by $g(A)$ and k replaced by B. This more general result holds, since the analysis of the greedy algorithm for submodular covering of Wolsey (1982), which we used to prove Lemma 4, applies to the more general setting of non-uniform cost functions.

7.4 Handling More Complex Cost Functions

So far, we considered problems where we are given an *additive* cost function $g(A)$ over the possible sets A of observations. In some applications, more complex cost functions arise. For example, when placing wireless sensor networks, the placements A should not only be informative (i.e., $F_i(A)$ should be high for all utility functions F_i), but the placement should also have *low communication cost*. Krause et al. (2006) describe such an approach, where the cost $g(A)$ measures the *expected number of retransmissions* required for sending messages across an optimal routing tree connecting the sensors A. Formally, the observations s are considered to be nodes in a graph $G = (V, E)$, with edge weights $w(e)$ for each edge $e \in E$. The cost $g(A)$ is the cost of a minimum Steiner Tree (cf., Vazirani 2003) connecting the observations A in the graph G.

More generally, we want to solve problems of the form

$$\operatorname*{argmax}_A \min_i F_i(A) \text{ subject to } g(A) \leq B,$$

where $g(A)$ is a complex cost function. The key insight of the SATURATE algorithm is that the non-submodular robust optimization problem can be approximately solved by solving a submodular covering problem. In the case where $g(A) = |A|$ this problem requires solving (6). More generally, we can apply SATURATE to any problem where we can (approximately) solve

$$A_c = \operatorname*{argmin}_{A \subseteq V} g(A), \quad \text{such that} \quad \overline{F}_c(A) = c. \tag{9}$$

Problem (9) can be (approximately) solved for a variety of cost functions, such as those arising from communication constraints (Krause et al., 2006) and path constraints (Singh et al., 2007; Meliou et al., 2007).

Let us summarize our analysis as follows:

Proposition 7 *Assume we have an algorithm which, given a monotonic submodular function F and a cost function g, returns a solution A' such that $F(A') = F(V)$ and*

$$g(A') \leq \alpha_F \min_{A: F(A) = F(V)} g(A),$$

where α_F depends on the function F. SATURATE*, using this covering algorithm, can obtain a solution A_S to the* RSOS *problem such that*

$$\min_i F_i(A_S) \geq \max_{g(A) \leq B} \min_i F_i(A),$$

and

$$g(A_S) \leq \alpha_{\overline{F}} B,$$

where $\alpha_{\overline{F}}$ is the approximation factor of the covering algorithm, when applied to $\overline{F} = \frac{1}{m}\sum_i F_i$.

Note that the formalism developed in this section also allows to handle robust versions of combinatorial optimization problems such as the *Knapsack* (cf., Martello and Toth, 1990), Orienteering (cf., Laporte and Martello, 1990; Blum et al., 2003) and *Budgeted Steiner Tree* (cf., Johnson et al., 2000) problems. In these problems, instead of a general *submodular* objective function, the special case of a *modular* (additive) function F is optimized:

$$A^* = \operatorname*{argmax}_{g(A) \leq B} F(A).$$

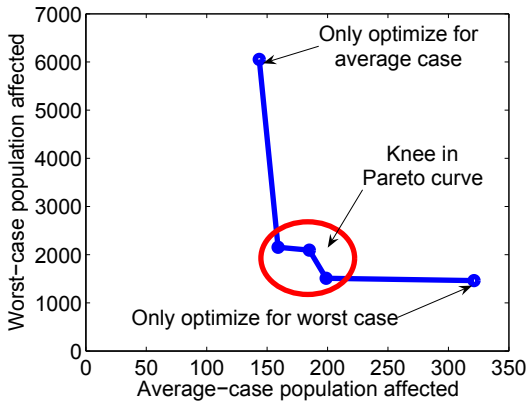

Figure 6: Tradeoff curve for simultaneously optimizing the average- and worst-case score in the water distribution network monitoring application. Notice the knee in the tradeoff curve, indicating that by performing multi-criterion optimization, solutions performing well for both average- and worst-case scores can be obtained.

The problems differ only in the choice of the complex cost function. In *Knapsack* for example, g is additive, in the *Budgeted Steiner Tree* problem, $g(A)$ is the cost of a minimum Steiner tree connecting the nodes A in a graph, and in *Orienteering*, $g(A)$ is the cost of a shortest path connecting the nodes A in a graph. In practice, often the utility function $F(A)$ is not exactly known, and a solution is desired which is robust against worst-case choice of the utility function. Since modular functions are a special case of submodular functions, such problems can be approximately solved using Proposition 7.

7.5 Trading Off Average-case and Worst-case Scores

In some applications, optimizing the worst-case score $F_{wc}(A) = \min_i F_i(A)$ might be a too pessimistic approach. On the other hand, ignoring the worst-case and only optimizing the average-case (the expected score under a distribution over the objectives) $F_{ac}(A) = \frac{1}{m}\sum_i F_i(A)$ might be too optimistic. In fact, in Section 8 we show that optimizing the average-case score F_{ac} can often lead to drastically poor worst-case scores. In general, we might be interested in solutions, which perform well both in the average- and worst-case scores.

Formally, we can define a multicriterion optimization problem, where we intend to optimize the *vector* $[F_{ac}(A), F_{wc}(A)]$. In this setting, we can only hope for *Pareto-optimal* solutions (cf., Boyd and Vandenberghe, 2004, in the context of convex functions). A set A^*, $|A^*| \leq k$ is called *Pareto-optimal*, if it is not *dominated*, that is, there does not exist another set B, $|B| \leq k$ with $F_{ac}(B) > F_{ac}(A^*)$ and $F_{wc}(B) \geq F_{wc}(A^*)$ (or $F_{ac}(B) \geq F_{ac}(A^*)$ and $F_{wc}(B) > F_{wc}(A^*)$).

One possible approach to find such Pareto-optimal solutions is constrained optimization:[4] for a specified value of c_{ac}, we desire a solution to

$$A^* = \operatorname*{argmax}_{|A|\leq k} F_{wc}(A) \text{ such that } F_{ac}(A) \geq c_{ac}. \tag{10}$$

4. Another approach is *scalarization*, where we optimize $F_\lambda(A) = \lambda F_{wc}(A) + (1-\lambda)F_{ac}(A)$ for some λ, $0 < \lambda < 1$. SATURATE can be modified to handle such scalarized objectives as well.

By specifying different values of c_{ac} in (10), we would obtain different Pareto-optimal solutions.[5] Figure 6 presents an example of several Pareto-optimal solutions, based on data from the outbreak detection problem (Details will be discussed in Section 8.3). This curve shows that, using the techniques described below, multicriterion solutions can be found which combine the advantages of worst-case and average-case solutions.

We can modify SATURATE to solve Problem (10) in the following way. Let us again assume we know the optimal value c_{wc} achievable for Problem (10). Then, Problem (10) is equivalent to solving

$$A^* = \operatorname*{argmin}_A |A| \text{ subject to } F_{wc}(A) \geq c_{wc} \text{ and } F_{ac}(A) \geq c_{ac}.$$

Now, using our notation from Section 4, this problem is again equivalent to

$$A^* = \operatorname*{argmin}_A |A| \text{ subject to } \overline{F}_{c_{wc},c_{ac}} = c_{wc} + c_{ac}, \tag{11}$$

where

$$\overline{F}_{c_{wc},c_{ac}}(A) = \overline{F}_{c_{wc}}(A) + \min\{F_{ac}(A), c_{ac}\}.$$

Note that $\overline{F}_{c_{wc},c_{ac}}$ is a submodular function, and hence (11) is a submodular covering problem, which can be approximately solved using the greedy algorithm.

For any choice of c_{ac}, we can find the optimal value of c_{wc} by performing binary search on c_{wc}. We summarize our analysis in the following Theorem:

Theorem 8 *For any integer k and constraint c_{ac},* SATURATE *finds a solution A_S (if it exists) such that*

$$F_{wc}(A_S) \geq \max_{|A| \leq k, F_{ac}(A) \geq c_{ac}} F_{wc}(A),$$

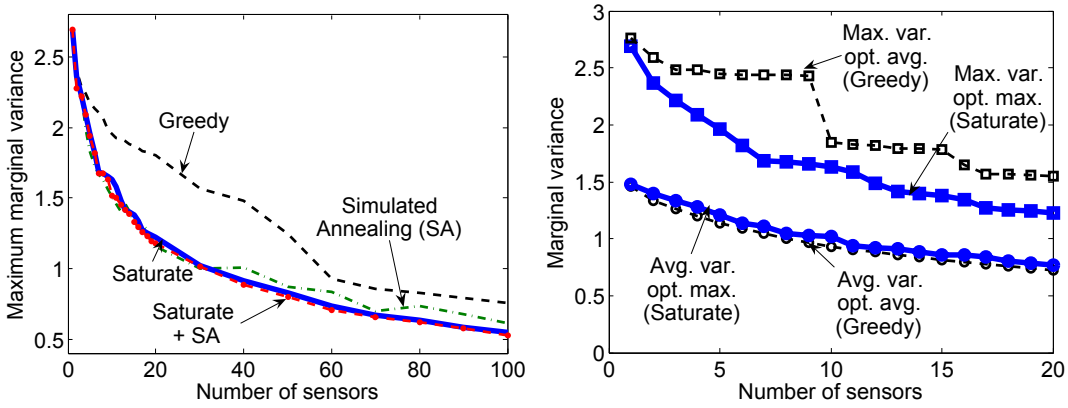
$F_{ac}(A_S) \geq c_{ac}$, and $|A_S| \leq \alpha k$, for $\alpha = 1 + \log(2 \max_{s \in V} \sum_i F_i(\{s\}))$. Each such solution A_S is approximately *Pareto-optimal, that is, there does not exist a set B, $|B| \leq k$ such that B dominates A_S. The total number of submodular function evaluations is $O\left(|V|^2 m \log(\sum_i F_i(V))\right)$.*

8. Experimental Results

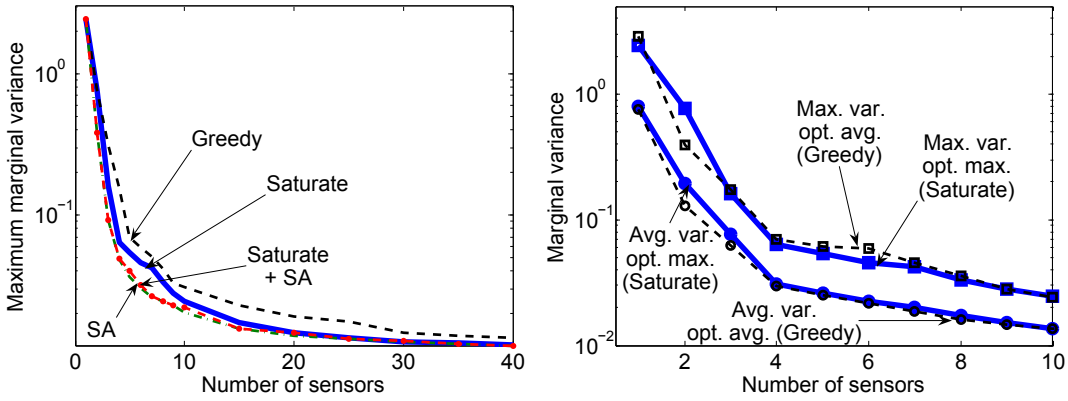
In this section, we present experimental results on several robust observation selection problems.

8.1 Minimizing the Maximum Kriging Variance

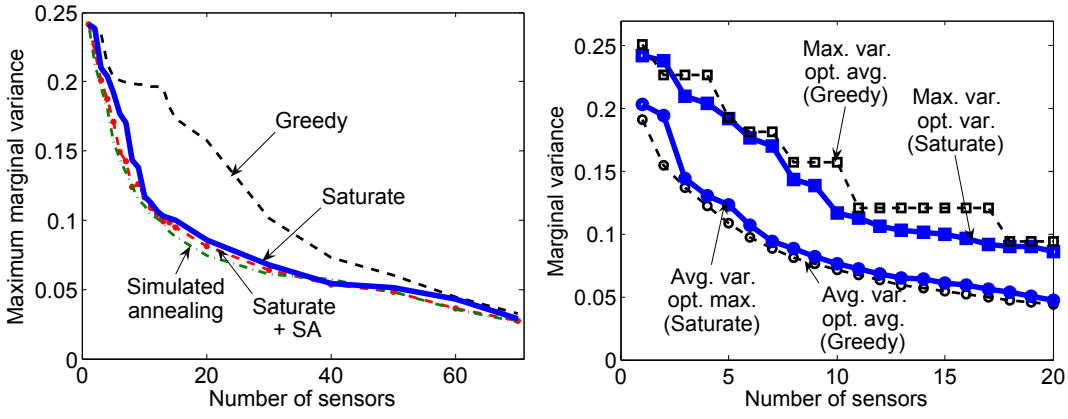
First, we use SATURATE to select observations in a GP to minimize the maximum posterior variance (cf., Section 6.1). We consider three data sets: [T] temperature data from a deployment of 52 sensors at Intel Research Berkeley, [P] Precipitation data from the Pacific Northwest of the United States (Widmann and Bretherton, 1999) and [L] temperature data from the NIMS sensor node (Harmon et al., 2006) deployed at a lake near the University of California, Merced. For the three monitoring problems, [T], [P], and [L], we discretize the space into 46, 167 and 86 locations each, respectively. For [T], we consider the empirical covariance matrix of temperature sensor measurements obtained over a period of 5 days. For [P], we consider the empirical covariance of 50 years of data, which we preprocessed as described by Krause et al. (2007b). For [L], we train a nonstationary Gaussian Process using data from a single scan of the lake by the NIMS sensor node, using a method described by Krause and Guestrin (2007b).



(a) *[P] Algorithm comparison* (b) *[P] Avg. vs max. variance*



(c) *[T] Algorithm comparison* (d) *[T] Avg. vs max. variance*



(e) *[L] Algorithm comparison* (f) *[L] Avg. vs max. variance*

Figure 7: (a,c,e) SATURATE, greedy and SA on the (a) precipitation, (b) building temperature and (c) lake temperature data. SATURATE performs comparably with the fine-tuned SA algorithm, and outperforms it for larger placements. (b,d,f) Optimizing for the maximum variance (using SATURATE) leads to low average variance, but optimizing for average variance (using greedy) does not lead to low maximum variance.

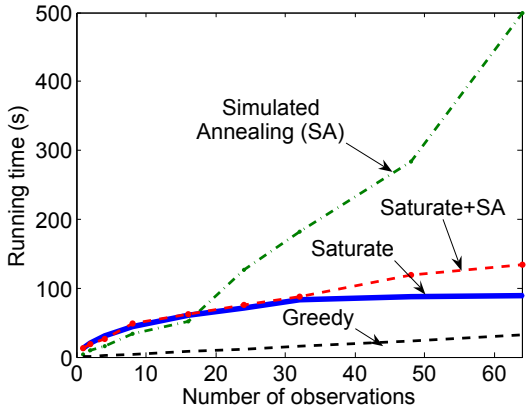


Figure 8: Running time for algorithms on the precipitation data set [P].

In the geostatistics literature, the predominant choice of optimization algorithms for selecting locations in a GP to minimize the (maximum and average) predictive variance are carefully tuned local search procedures, prominently simulated annealing (cf., Sacks and Schiller 1988; Wiens 2005; van Groenigen and Stein 1998). We compare our SATURATE algorithm against a state-of-the-art implementation of such a simulated annealing (SA) algorithm, first proposed by Sacks and Schiller (1988). We use an optimized implementation described recently by Wiens (2005). This algorithm has 7 parameters which need to be tuned, describing the annealing schedule, distribution of iterations among several inner loops, etc. We use the parameter settings as reported by Wiens (2005), and present the best result of the algorithm among 10 random trials. In order to compare observation sets of the same size, we called SATURATE with $\alpha = 1$.

Figures 7(a), 7(c) and 7(e) compare simulated annealing, SATURATE, and the greedy algorithm which greedily selects elements which decrease the maximum variance the most on the three data sets. We also used SATURATE to initialize the simulated annealing algorithm (using only a single run of simulated annealing, as opposed to 10 random trials). In all three data sets, SATURATE obtains placements which are drastically better than the placements obtained by the greedy algorithm. Furthermore, the performance is very close to the performance of the simulated annealing algorithm. In our largest monitoring data set [P], SATURATE even strictly outperforms the simulated annealing algorithm when selecting 30 and more sensors. Furthermore, as Figure 8 shows, SATURATE is significantly faster than simulated annealing, by factors of 5-10 for larger problems. When using SATURATE in order to initialize the simulated annealing algorithm, the resulting performance almost always resulted in the best solutions we were able to find with any method, while still executing faster than simulated annealing with 10 random restarts as proposed by Wiens (2005). These results indicate that SATURATE compares favorably to state-of-the-art local search heuristics, while being faster, requiring no parameters to tune, and providing theoretical approximation guarantees.

Optimizing for the maximum variance could potentially be considered too pessimistic. Hence we compared placements obtained by SATURATE, minimizing the maximum marginal posterior variance, with placements obtained by the greedy algorithm, where we minimize the *average* marginal variance. Note, that, whereas the maximum variance reduction is non-submodular, the *average* variance reduction is (often) submodular (Das and Kempe, 2008), and hence the greedy algorithm can

5. In fact, *all* Pareto-optimal solutions can be found in this way (Papadimitriou and Yannakakis, 2000).

be expected to provide near-optimal placements. Figures 7(b), 7(d) and 7(f) present the maximum and average marginal variances for both algorithms. On all three data sets, our results show that if we optimize for the maximum variance we still achieve comparable average variance. If we optimize for average variance however, the maximum posterior variance remains much higher.

8.2 Robust Experimental Design

We consider the robust design of experiments (cf., Section 6.3) for the Michaelis-Menten mass-action kinetics model, as discussed by Flaherty et al. (2006). The goal is least-square parameter estimation for a function $y = f(x,\theta)$, where x is the chosen experimental stimulus (the initial substrate concentration S_0), and $\theta = (\theta_1,\theta_2)$ are two parameters as described by Flaherty et al. (2006). The stimulus x is chosen from a menu of six options, $x \in \{1/8,1,2,4,8,16\}$, each of which can be repeatedly chosen. The goal is to produce a fractional design $\mathbf{w} = (w_1,\ldots,w_6)$, where each component w_i measures the relative frequency according to which the stimulus x_i is chosen. Since f is nonlinear, f is linearized around an initial parameter estimate $\theta_0 = (\theta_{01},\theta_{02})$, and approximated by its Jacobian V_{θ_0}. Classical experimental design considers the error covariance of the least squares estimate $\hat{\theta}$, $\mathrm{Cov}(\hat{\theta} \mid \theta_0,\mathbf{w}) = \sigma^2(V_{\theta_0}^T W V_{\theta_0})^{-1}$, where $W = \mathrm{diag}(\mathbf{w})$, and aims to find designs $\mathbf{w}$ which minimize this error covariance. E-optimality, the criterion adopted by Flaherty et al. (2006), measures smallness in terms of the maximum eigenvalue of the error covariance matrix. The optimal $\mathbf{w}$ can be found using Semidefinite Programming (SDP) (Boyd and Vandenberghe, 2004).

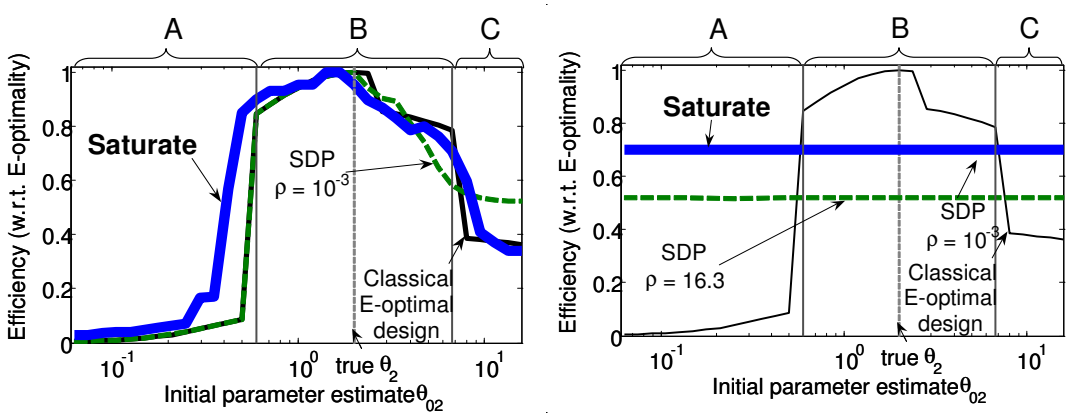
The estimate $\mathrm{Cov}(\hat{\theta} \mid \theta_0,\mathbf{w})$ depends on the initial parameter estimate θ_0, where linearization is performed. However, since the goal is parameter estimation, a "certain circularity is involved" (Flaherty et al., 2006). To avoid this problem, Flaherty et al. (2006) find a design $\mathbf{w}_\rho(\theta_0)$ by solving a robust SDP which minimizes the error size, subject to a worst-case perturbation Δ on the Jacobian V_{θ_0}; the robustness parameter ρ bounds the spectral norm of Δ. As evaluation criterion, Flaherty et al. (2006) define a notion of *efficiency*, which is the error size of the optimal design with correct initial parameter estimate, divided by the error when using a robust design obtained at the wrong initial parameter estimates, that is,

$$\text{efficiency} \equiv \frac{\lambda_{\max}[\mathrm{Cov}(\hat{\theta} \mid \theta_{true}, \mathbf{w}_{opt}(\theta_{true}))]}{\lambda_{\max}[\mathrm{Cov}(\hat{\theta} \mid \theta_{true}, \mathbf{w}_\rho(\theta_0))]},$$

where $\mathbf{w}_{opt}(\theta)$ is the E-optimal design for parameter θ. They show that for appropriately chosen values of ρ, the robust design is more *efficient* than the optimal design, if the initial parameter θ_0 does not equal the true parameter.

While their results are very promising, an arguably more natural approach than perturbing the Jacobian would be to perturb the initial parameter estimate, around which linearization is performed. For example, if the function f describes a process which behaves characteristically differently in different "phases", and the parameter θ controls which of the phases the process is in, then a robust design should intuitively "hedge" the design against the behavior in each possible phase. In such a case, the uniform distribution (which the robust SDP chooses for large ρ) would not be the most robust design.

If we discretize the space of possible parameter perturbations (within a reasonably chosen interval), we can use SATURATE to find robust experimental designs. While the classical E-optimality is not submodular (Krause et al., 2007b), Bayesian A-optimality is (usually) submodular (Das and Kempe, 2008; Krause et al., 2007b). Here, the goal is to minimize the *trace* instead of maximum



(a) *Low uncertainty in* θ_0 (b) *High uncertainty in* θ_0

Figure 9: Efficiency of robust SDP of Flaherty et al. (2006) and SATURATE on a biological experimental design problem. (a) Low assumed uncertainty in initial parameter estimates: SDP performs better in region C, SATURATE performs better in region A. (b) High assumed uncertainty in initial parameter estimates: SATURATE outperforms the SDP solutions.

eigenvalue size of the covariance matrix. Furthermore, we equip the parameters θ with an uninformative normal prior (which we chose as $\mathrm{diag}([20^2, 20^2])$) as typically done in Bayesian experimental design. We then minimize the expected trace of the posterior error covariance, $\mathrm{tr}(\Sigma_{\theta|A})$. Hereby, A is a discrete design of 20 experiments, where each option x_i can be chosen repeatedly. In order to apply SATURATE, for each θ_0, we define $F_{\theta_0}(A)$ as the normalized variance reduction

$$F_{\theta_0}(A) = \frac{1}{Z_{\theta_0}} \left(\mathrm{tr}\left(\Sigma_{\theta}^{(\theta_0)}\right) - \mathrm{tr}\left(\Sigma_{\theta|A}^{(\theta_0)}\right) \right).$$

The normalization Z_{θ_0} is chosen such that $F_{\theta_0}(A) = 1$ if

$$A = \operatorname*{argmax}_{|A'|=20} F_{\theta_0}(A'),$$

that is, if A is chosen to maximize only F_{θ_0}. SATURATE is then used to maximize the worst-case normalized variance reduction.

We reproduced the experiment of Flaherty et al. (2006), where the initial estimate of the second component θ_{02} of θ_0 was varied between 0 and 16, the "true" value being $\theta_2 = 2$. For each initial estimate of θ_{02}, we computed a robust design, using the SDP approach and using SATURATE, and compared them using the efficiency metric of Flaherty et al. (2006). Note that this efficiency metric is defined with respect to E-optimality, even though we optimize Bayesian A-optimality, hence potentially putting SATURATE at a disadvantage. We first optimized designs which are robust against a small perturbation of the initial parameter estimate. For the SDP, we chose a robustness parameter $\rho = 10^{-3}$, as reported in Flaherty et al. (2006). For SATURATE, we considered an interval around $[\theta\frac{1}{1+\varepsilon}, \theta(1+\varepsilon)]$, discretized in a 5×5 grid, with $\varepsilon = .1$.

Figure 9(a) shows three characteristically different regions, *A*, *B*, *C*, separated by vertical lines. In region *B* which contains the true parameter setting, the E-optimal design (which is optimal if

the true parameter is known, that is, $\theta_{02} = \theta_2$) performs similar to both robust methods. Hence, in region B (i.e., small deviation from the true parameter), robustness is not really necessary. Outside of region B however, where the standard E-optimal design performs badly, both robust designs do not perform well either. This is an intuitive result, as they were optimized to be robust only to small parameter perturbations.

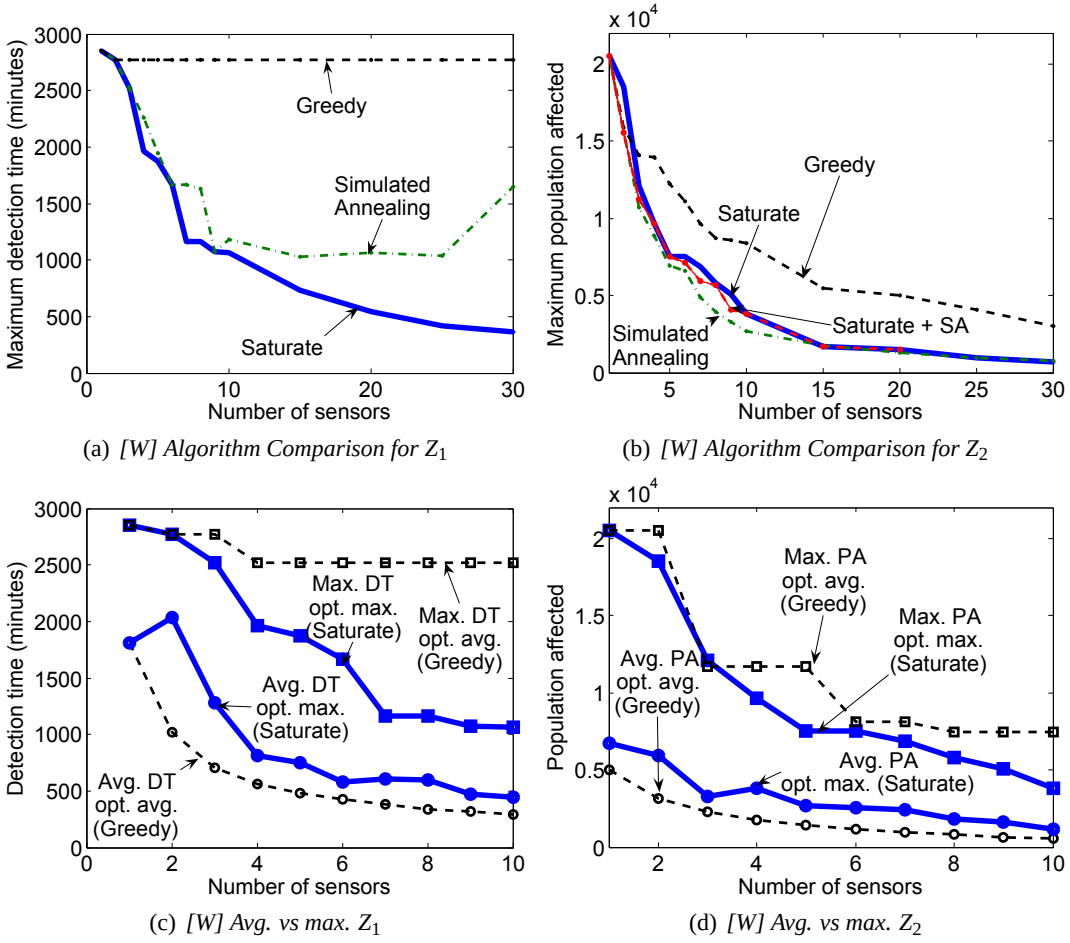
Consequently, we compared designs which are robust against a *large* parameter range. For SDP, we chose $\rho = 16.3$, which is the maximum spectral variation of the Jacobian when we consider all initial estimates from θ_{02} varying between 0 and 16. For SATURATE, we optimized a single design which achieves the maximum normalized variance reduction over all values of θ_{02} between 0 and 16. Figure 9(b) shows, that in this case, the design obtained by SATURATE achieves an efficiency of 69%, whereas the efficiency of the SDP design is only 52%. In the regions A and C, the SATURATE design strictly outperforms the other robust designs. This experiment indicates that designs which are robust against a large range of initial parameter estimates, as provided by SATURATE, can be more efficient than designs which are robust against perturbations of the Jacobian (the SDP approach).

8.3 Outbreak Detection

Consider a city water distribution network, delivering water to households via a system of pipes, pumps, and junctions. Accidental or malicious intrusions can cause contaminants to spread over the network, and we want to select a few locations (pipe junctions) to install sensors, in order to detect these contaminations as quickly as possible (cf., Section 6.3). In August 2006, the Battle of Water Sensor Networks (BWSN) (Ostfeld et al., 2006) was organized as an international challenge to find the best sensor placements for a real (but anonymized) metropolitan water distribution network, consisting of 12,527 nodes. In this challenge, a set of intrusion scenarios is specified, and for each scenario a realistic simulator provided by the EPA (Rossman, 1999) is used to simulate the spread of the contaminant for a 48 hour period. An intrusion is considered detected when one selected node shows positive contaminant concentration. BWSN considered a variety of impact measures, including the time to detection (called Z_1), and the size of the affected population calculated using a realistic disease model (Z_2). The goal of BWSN was to minimize the *expectation* of the impact measures Z_1 and Z_2 given a *uniform distribution* over intrusion scenarios.

In this paper, we consider the *adversarial* setting, where an opponent chooses the contamination scenario with knowledge of the sensor locations. The objective functions Z_1 and Z_2 are in fact submodular for a fixed intrusion scenario (Leskovec et al., 2007), and so the robust optimization problem of minimizing the impact of the worst possible intrusion fits into our formalism. For these experiments, we consider scenarios which affect at least 10% of the network, resulting in a total of 3424 scenarios. Figures 10(a) and 10(b) compare the greedy algorithm, SATURATE and the simulated annealing (SA) algorithm for the problem of maximizing the worst-case detection time (Z_1) and worst-case affected population (Z_2).

Interestingly, the behavior is very different for the two objectives. For the affected population (Z_2), greedy performs reasonably, and SA sometimes even outperforms SATURATE. For the detection time (Z_1), however, the greedy algorithm did not improve the objective at all, and SA performs poorly. The reason is that for Z_2, the maximum achievable scores, $F_i(V)$, vary drastically, since some scenarios have much higher impact than others. Hence, there is a strong "gradient", as the worst-case objective changes quickly when the high impact scenarios are covered. This gradient



(a) *[W] Algorithm Comparison for* Z_1

(b) *[W] Algorithm Comparison for* Z_2

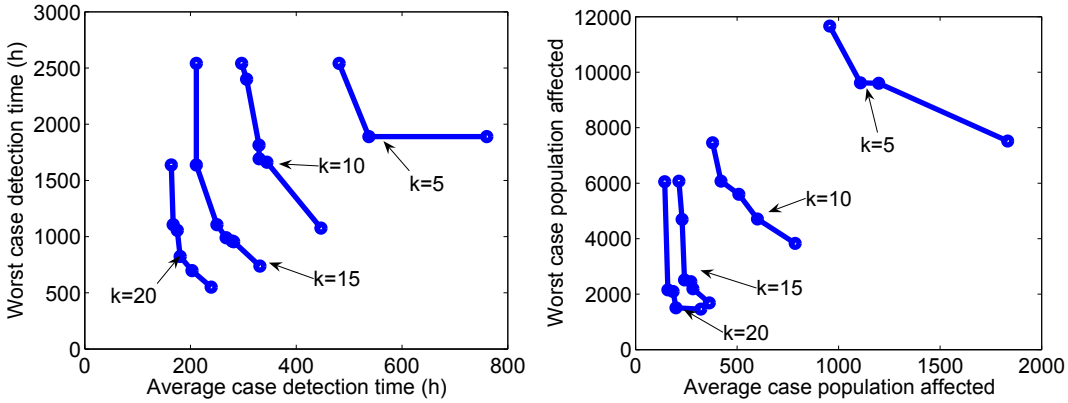
(c) *[W] Avg. vs max.* Z_1

(d) *[W] Avg. vs max.* Z_2

Figure 10: (a,b) compare SATURATE, greedy and SA in the water network setting, when optimizing worst-case detection time (Z_1, (a)) and affected population (Z_2, (b)). SATURATE performs comparably to SA for Z_2 and strictly outperforms SA for Z_1. (c,d) compare optimizing for the worst-case vs. average-case objectives. Optimizing for the worst-case leads to good average case performs, but not vice versa.

allows greedy and SA to work well. On other hand, for Z_1, the maximum achievable scores, $F_i(V)$, are constant, since all scenarios have the same simulation duration. Unless *all* scenarios are detected, the worst-case detection time stays constant at the simulation length. Hence, many node exchange proposals considered by SA, as well as the addition of a new sensor location by greedy, do not change the worst-case objective, and the algorithms have no useful performance metric.

Figures 10(c) and 10(d) compare the placements of SATURATE (when optimizing the worst-case penalty), and greedy (when optimizing the average-case penalty, which is submodular). Similarly to the results in the GP setting, optimizing the worst-case score leads to reasonable performance in the average case score, but not necessarily vice versa (especially when considering the detection time).



(a) *[W] Pareto curve for Z_1*

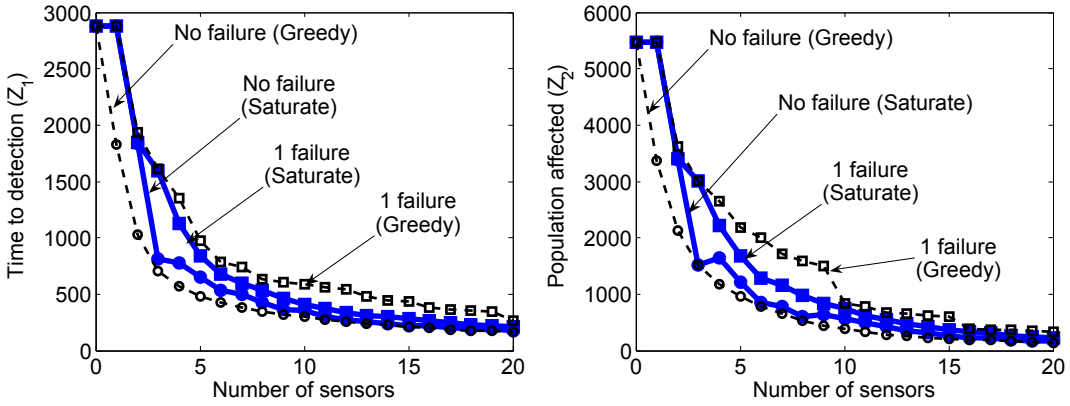
(b) *[W] Pareto curve for Z_2*

Figure 11: Experiments on trading off worst-case and average-case penalties on the water network [W] data, minimizing detection time (a) and affected population (b).

We also performed experiments trading off the worst-case and average-case penalty reductions, using the approach discussed in Section 7.5. We first ran the greedy algorithm to optimize the average-case score, and then ran SATURATE to optimize the worst-case score. We considered the average-case scores c_{ac}^{greedy} and $c_{ac}^{Saturate}$ obtained by both algorithms, and uniformly discretized the interval bounded by these average-case scores. For each score level c_{ac} in the discretization, we use the modified SATURATE algorithm as described in Section 7.5, maximizing the worst-case score, subject to a constraint on the average-case score. Each possible value of the constraint on c_{ac} can lead to a different solution, trading off average- and worst-case scores. Figure 11(a) presents the tradeoff curve obtained in this fashion for the detection time (Z_1) metric, for different numbers k of placed sensors. We generally observe that there is more variability in the worst-case score than in the average-case score. We can also see that when placing 5 sensors, there is a prominent knee in the tradeoff curve, effectively achieving the minimum worst-case penalty but drastically reducing the average-case penalty incurred when compared to only optimizing for the worst-case score. The other tradeoff curves do not exhibit quite such prominent knees, but nevertheless allow flexibility in trading off worst- and average-case scores. Figure 11(b) presents the same experiment for the population affected (Z_2) metric. Here, we notice prominent knees when placing $k = 15$ and 20 sensors. We can generally conclude that trading off average- and worst-case scores allows to effectively achieve a compromise between too pessimistic (only optimizing for the worst case) and optimistic (only optimizing for the average case) objectives.

8.4 Sensor Failures

We also performed experiments on analyzing worst-case sensor failures (cf., Section 6.5). We consider the outbreak detection application, and optimize the average score, that is, $F(A) = \frac{1}{m}\sum_i F_i(A)$ (modeling, for example, accidental contaminations). We use SATURATE in order to optimize the modified objective function $\overline{F}'_c$ described in Section 6.5.1, for increasing numbers of sensors k. We also use the greedy algorithm to optimize sensor placements, ignoring possible sensor failures. For both algorithms, we compute the expected scores (penalty reductions Z_1 and Z_2) in the case of no



(a) *[W] Sensor failures for Z_1*

(b) *[W] Sensor failures for Z_2*

Figure 12: (a,b) compare Greedy (ignoring sensor failures) and SATURATE (optimizing for the worst-case sensor failure) on water network data with detection time (a) and population affected (b) scores.

sensor failure, and in the case of a single, worst-case sensor failure. Figure 12(a) presents the results for the time to detection objective (Z_1). We can see, that initially, with small numbers of sensors, failures can strongly diminish the Z_1 score. However, as the number of sensors increases, the placement scores optimized using SATURATE for sensor failures quickly approach those of Greedy in the case of no sensor failures. Hence, even if only a small number of sensors are placed, SATURATE can quickly exploit redundancy and find sensor placements, which perform well both with and without sensor failures. On the other hand, when not taking sensor failures into account, such failures can drastically diminish the utility of a placed set of sensors. Figure 12(b) presents analogous results when minimizing the affected population (Z_2).

8.5 Parameter Uncertainty

We also conducted experiments on selecting variables under parameter uncertainty (cf., Section 6.2). More specifically, we consider a sensor placement problem for monitoring temperature in a building. In such a problem, we would like to place sensors in order to get accurate predictions at various times of the day. However, since phenomena such as temperature in buildings change over time, at different times of the day, different placements would be most informative.

In our experiment, we consider the temperature data set [T], and learn four models, described by parameters $\theta_1, \ldots, \theta_4$, during four six-hour time periods over the day: 12am-6am, 6am-12pm, 12pm-6pm and 6pm-12am. As models, we use the empirical covariances $\Sigma^{(\theta_i)}$ from the corresponding time periods of the 5 day historical training data. We also use the single model Σ for the entire day, as described in Section 8.1. We then use the greedy algorithm to optimize sensor placement of increasing sizes for the single model Σ, optimizing the average variance reduction objective function. Similarly, we use SATURATE to optimize the minimum variance reduction over the four models $\Sigma^{(i)}$, normalized by the average variance over the entire space.

Subsequently, we used both placements to compute the average Root Mean Squared (RMS) prediction error over the entire day on 2 days of held out test data. We also computed the maximum

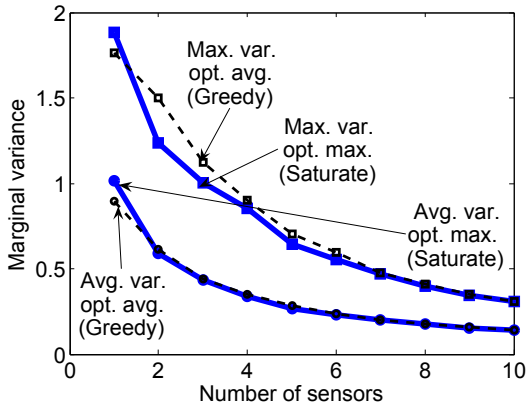


Figure 13: [T] Average and Maximum variance when optimizing for four different covariance models obtained during different parts of the day.

RMS error over the four six-hour time periods. Figure 13 presents the results of this experiment. While the average RMS error is roughly equal for both placements, the maximum RMS error is larger for the greedy sensor placement, as compared to the robust placement of SATURATE, especially for small numbers of sensors (six and less sensors).

9. Reducing the Number of Objective Functions

In many of the examples considered in Section 6, the number m of objective functions F_i can be quite large (e.g., one F_i per parameter setting, or outbreak scenario), which impacts both the running time (which depends linearly on m) and the approximation guarantees (which depend logarithmically on m) of SATURATE. Hence, showing that we can work with a smaller set of objectives has both computational and theoretical advantages.

9.1 Removal of Dominated Strategies

One direct approach to eliminate objective functions (and hence speed up computation and improve the approximation guarantee) is to remove dominated objectives. An objective function F_i is dominated by another objective F_j, if $F_i(A) \geq F_j(A)$ for all sets $A \subseteq V$. Hence, an F_i is dominated by F_j if an adversary can always reduce our score by choosing F_j instead of F_i. For example, when considering sensor failures or feature deletion (as discussed in Section 6.5), for two sets $B \subseteq B'$, the objective F_B is dominated by the objective $F_{B'}$, that is, the score decreases more if more sensors fail. Similarly, in the case of outbreak detection, some outbreak scenarios have much more impact on the network than others. Even though objective functions measuring the impact reductions F_i for scenarios $i \in I$ might not be *exactly* dominated, they might be ε-dominated, that is, $F_i(A) \geq F_j(A) - \varepsilon$ for some $\varepsilon > 0$ and all $A \subseteq V$. In such cases, these approximately dominated scenarios can be removed, incurring at most an error of ε in the quality of the approximate solution.

9.2 Constraint Generation

Another possible approach to reduce the number m of objective functions is constraint generation (cf., Benders 1962). In this approach, one starts with an arbitrary single objective function, F_1. In iteration $j+1$, ($j \geq 1$), after functions $F_1, \ldots, F_j$ have been considered, one searches for set A_j maximizing $\max_A \min_{1 \leq i \leq j} F_j(A)$. Subsequently, one selects F_{j+1} minimizing $\min_i F_i(A_j)$. The iteration terminates once F_{j+1} is contained in the already selected objectives $F_1, \ldots, F_j$. Another option is to terminate once the new objective F_{j+1} is ε-dominated by some objective F_i, $1 \leq i \leq j$. In this case, the approximate solution is guaranteed to incur at most an absolute error of ε as compared to the optimal solution.

In order to implement this constraint generation scheme, one must be able to efficiently solve problem $\min_i F_i(A_j)$. In some settings, this problem might admit an efficient (perhaps approximate) solution. In many problems, such as the experimental design setting, one actually wants to perform well against an (uncountably) infinite set of possible objective functions, corresponding to parameters $\theta \in D$ in some (typically compact and convex set D). In such a setting, $\min_\theta F_\theta(A_j)$ could potentially be (at least heuristically) solved using a numerical optimization approach such as a conjugate gradient method.

10. Related Work

In this section, we review related work in submodular function optimization, robust discrete optimization, robust methods in statistics, sensor placement, game theory and machine learning.

10.1 Submodular Function Optimization

In their seminal work, Nemhauser et al. (1978) and Wolsey (1982) analyze the greedy algorithm for optimizing monotonic submodular functions. Lovász (1983) discusses the relationship between submodular functions and convexity. He also shows that under certain conditions, the minimum of two submodular functions remains submodular (and hence can be efficiently optimized using the greedy algorithm). The objective functions resulting from observation selection problems typically do not satisfy these properties, and, as we have shown, the greedy algorithm can perform arbitrarily badly. Fujito (2000) uses submodularity of truncated functions to find sets with partial submodular coverage; however, they do not consider the case of multiple objectives, which we address in this paper. Bar-Ilan et al. (2001) consider covering problems for a generalization of submodular functions; they use a similar binary search technique combined with multiple applications of the greedy algorithm. Their approach does not apply to maximizing the minimum over a set of submodular functions. Golovin and Streeter (2008) present an algorithm for online maximization of a single submodular set function. An interesting question for future work would be to investigate whether our approach for maximizing the minimum over a collection of submodular functions can be generalized to an online setting as well.

A large part of the theory of optimizing submodular functions is concerned with *minimizing* instead of maximizing a single submodular function. Queyranne (1995) present the first algorithm for minimizing symmetric submodular functions; Iwata et al. (2001) and Schrijver (2000) present combinatorial algorithms for minimizing *arbitrary* (not necessarily symmetric) submodular functions.

10.2 Robust Discrete Optimization

Robust optimization of submodular functions is an instance of a robust discrete optimization problem. In such problems, the goal generally is to perform well with respect to a worst-case choice of evaluation scenario. Other instances of robust discrete problems have been studied by a number of authors. Kouvelis and Yu (1997) introduce several notions of robust discrete problems, presents hardness results and a class of robust problems that can be optimally solved. Averbakh (2001) shows that a class of robust optimization problems (selecting a k-element subset of elements of minimum cost) is solvable in polynomial time if the uncertain cost coefficients are contained in an interval, but NP-hard under an arbitrary (finite) set of adversarially chosen scenarios. Bertsimas and Sim (2003) proposes a class of robust mixed integer programs, accommodating uncertainty both in cost and data coefficients. They show that in certain cases (robust matching, spanning tree, etc.), the robust formulations are solvable in polynomial time if the non-robust problem instances are solvable in polynomial time. In the case of NP-hard but α-approximable non-robust problems, they show that the corresponding robust formulations also remain α-approximable. However, their results do not transfer to our setting of robust submodular optimization, since in this case, even though non-robust solutions are $(1-1/e)$ approximable, the non-robust formulation does not admit any approximation guarantees (cf., Section 3).

10.3 Robust Methods in Statistics

In this section, we review related work in robust experimental design and robust spatial prediction.

10.3.1 ROBUST EXPERIMENTAL DESIGN

Experimental design under parameter uncertainty has been studied in statistics; most of the earlier work is reviewed in the excellent survey of Chaloner and Verdinelli (1995). In the survey, the authors discuss Bayesian approaches to handling parameter uncertainty, as well as robust Bayesian (cf., Berger 1984) approaches, which perform worst-case analyses over prior and likelihood functions. In experimental design, most approaches have focused on *locally* optimal designs, that is, those selecting an optimal design based on a linearization around an initial parameter estimate, for reasons of computational tractability. In order to cope with uncertainty in the initial parameter estimates around which linearization is performed, heuristic techniques have been developed, such as the SDP based approach of Flaherty et al. (2006), or a clustering heuristic described by Dror and Steinberg (2006). We are not aware of approaches which allow to find designs in the context of such parameter uncertainty that bear theoretical guarantees similar to the approach described in this paper.

10.3.2 MINIMAX KRIGING

Minimizing the maximum predictive variance in Gaussian Process regression has been proposed as a design criterion by Burgess et al. (1981) and since then extensively used. (cf., Sacks and Schiller, 1988; van Groenigen and Stein, 1998). To our knowledge, prior to this work, no algorithms with approximation guarantees are known for this criterion.

Several authors consider the problem of spatial prediction under unknown covariance parameters. Pilz et al. (1996) describes an approach for selecting—for a fixed set of observed sites—the Kriging estimate minimizing the maximum prediction error, where the worst-case over a fixed class of covariance functions is assumed. Wiens (2005) consider a similar setting but also addresses

the design problem of choosing locations in order to minimize the mean squared prediction error against the worst-case covariance function. Algorithmically, Wiens (2005) use the simulated annealing algorithm described in Section 8.1 with 7 tuned parameter settings. Note that the SATURATE algorithm can be used in this context as well.

10.4 Sensor Placement and Facility Location

Carr et al. (2006) consider the problem of robust sensor placements in water distribution networks. They formulate Mixed Integer Programs for selecting sensor placements robust against uncertainty in adversarial strategies and in water demands. Due to computational complexity of Mixed Integer Programming, in their experiments, they used only small networks of at most 470 nodes. SATURATE can potentially be applied to handle uncertainty in demands as well, which is an interesting direction for future work. Watson et al. (2006) consider different notions of robustness in the context of water distribution networks, intended to remove some of the pessimistic assumptions of purely robust sensor placements. They develop integer programs, as well as heuristics, and apply them to networks of similar size as the one considered in this paper. Their local search heuristic performs a sequence of local moves similar to those performed by the simulated annealing algorithm considered in Section 8.3, and does not provide any theoretical guarantees.

Closely related to the adversarial outbreak detection problem is the *k-center* problem. In this problem, one is given a graph $G = (V, E)$ along with a distance function defined over pairs of nodes in V. The goal is to select a subset $A \subseteq V$ of size at most k, such that the maximum distance between any unselected node $s \in V \setminus A$ and its nearest center $s' \in A$ is minimized. For this problem, Minieka (1970) discuss a technique reducing the solution of this problem to a sequence of set cover problems combined in a binary search, similar in spirit to SATURATE. However, they do not discuss any implications regarding approximation guarantees, and do not consider the case of arbitrary submodular functions. Mladenovic et al. (2003) presents a Tabu search heuristic for k-center, also without theoretical guarantees. Gonzalez (1985) and Hochbaum and Shmoys (1985) present a 2 approximation for the k-center problem in the case of symmetric distance functions satisfying the triangle inequality. Panigrahy and Vishwanathan (1998) present a $\log^*(n)$ approximation in the case of distance functions satisfying the asymmetric triangle inequality, which is shown to be best possible by Chuzhoy et al. (2005). Chuzhoy et al. (2005) also show that even for bicriterion algorithms (such as SATURATE), k-center is $\log^*(n)$ hard to approximate, even if $O(k)$ additional centers can be selected. Note that SATURATE can be used to solve k-center problems (without any requirements on symmetry or on the triangle inequality), hence the bicriterion hardness result of Chuzhoy et al. (2005) gives further evidence on the tightness of the guarantees described in Section 5.

Anthony et al. (2008) consider robust and stochastic notions of facility location problems (such as k-center and k-median, where, instead of the maximum distance the average distance is optimized). In contrast to the robust problems in this paper which want to select k elements to *maximize* the minimum value achieved by these k elements over the m scenarios, the problems in Anthony et al. (2008) try to select k "centers" in a metric space to *minimize* the maximum cost incurred over the m scenarios—where the cost is some function of the distances between non-selected vertices to the selected centers. For several such robust cost-minimization problems in cases where distances satisfy the symmetric triangle inequality, they present an algorithm that opens k "centers" and achieves an approximation ratio of $O(\log n + \log m)$ (where n is the number of nodes in the

graph, and m is the number of scenarios): this should be compared to the impossibility results for approximating robust value-maximization problems presented in this paper.

10.5 Relationship to Game Theory and Allocation Problems

The RSOS problem can be viewed as the problem of finding an optimal pure strategy for a zero-sum matrix game with player ordering. In this matrix game, the rows would correspond to the possible sensor placements, and the columns would correspond to the objective functions F_i. The entry for cell (A, F_i) is our payoff $F_i(A)$. In the RSOS problem, we want to select a row of the matrix, our adversary selects a column F_i (knowing our choice A, hence the player ordering) minimizing our score $F_i(A)$. A very related class of game theoretic problems are *allocation problems*. In these problems, one is typically given a set V of objects, and the goal is to allocate the objects to m agents (bidders), each of whom has a (potentially different) valuation function $F_i(A_i)$ defined over subsets of received items A_i. The problem of finding the best such allocation (partition) is NP-hard, but recently, several approximation algorithms have been proposed. The allocation problem most similar to the RSOS problem is

$$\pi^* = \operatorname*{argmax}_{\text{partition } \pi=(A_1,\ldots,A_m)} \min_i F_i(A_i).$$

The main difference is that in the allocation problem, the full set V is partitioned into subsets $A_1,\ldots,A_m$, and the functions F_i are evaluated on the respective subset A_i each. In the case of *additive* objective functions F_i, Asadpour and Saberi (2007) provide an $O(\sqrt{k}\log^3 k)$ approximation algorithm. In the case of the function being *subadditive* (which is implied by, and is more general than, submodularity), Ponnuswami and Khot (2007) present an $O(2k-1)$ approximation algorithm. For settings where the *sum* of the valuations is optimized, that is,

$$\pi^* = \operatorname*{argmax}_{\text{partition } \pi=(A_1,\ldots,A_m)} \sum_i F_i(A_i),$$

Feige (2006) develop a randomized 2-approximation for subadditive and $1-1/e$ approximation for submodular valuation functions.

The problem of trading off safety (i.e., improvements in worst-case scores) and average case performance has been studied by several authors. Johanson et al. (2007) consider the problem of opponent modeling in games, and develop an algorithm which can exploit opponents which it can accurately model, and falls back to a safe (Nash) strategy in case the models do not capture the opponents behavior. Their algorithm has a tradeoff parameter which controls the eagerness of exploiting, and they present Pareto-curves similar to those presented in Section 7.5. However, their approach does not apply to our robust submodular observation selection setting. Watson et al. (2006) consider different optimization problem formulations allowing to control risk in the water distribution network monitoring application, but they only present heuristic algorithms without guarantees for coping with large networks.

10.6 Relationship to Machine Learning

Submodular function optimization has found increasing use in machine learning. The algorithm of Queyranne (1995) for minimizing symmetric submodular functions has been used for learning graphical models by Narasimhan and Bilmes (2004) and for clustering by Narasimhan et al. (2005).

We are not aware of any work on optimizing the minimum over a collection of submodular functions.

Observation selection approaches have been used in the context of active learning (cf., Sollich, 1996; Freund et al., 1997; Axelrod et al., 2001; MacKay, 1992; Cohn, 1994). Test point selection has been used to minimize average predictive variance in Gaussian Processes regression by Seo et al. (2000), and to speed up Gaussian Process inference in the Informative Vector Machine (IVM) by Seeger et al. (2003); Lawrence et al. (2003). In these approaches, the sequential setting is considered, where previous measurements are taken into account when deciding on the next observation to make. A note by Seeger (2004) proves that the greedy algorithm in the IVM optimizes a submodular function. The extension of the robust techniques discussed in this paper, which address the a priori selection problem (i.e., observations are selected before measurements are obtained), to the sequential setting is an important direction for future research.

Balcan et al. (2006) consider the problem of active learning in the presence of *adversarial* noise. While their method is very different, our results potentially generalize to active learning settings, since, as Hoi et al. (2006) show, certain active learning objectives are (approximately) submodular.

Price and Messinger (2005) consider the problem of constructing recommendation sets, and show that this problem is an instance of a k-median problem (cf., Section 10.4). The analogue of the k-center problem in the preference set construction would be to construct a preference set which maximizes the utility of displayed items under worst-case instantiation of the parameters. This analogue seems natural, and an interesting direction for future work would be to explore the use of SATURATE in the recommendation set context.

10.7 Relationship to Previous Work of the Authors

A previous version of this paper appeared in (Krause et al., 2007a). The present version is significantly extended, providing new theoretical analyses (described in Section 7, Section 9), new examples demonstrating the generality of the observation selection problem (Section 6) and additional empirical results (Section 8). In previous work, the authors demonstrated that several important observation selection objectives are submodular (Krause et al., 2007b; Leskovec et al., 2007; Krause and Guestrin, 2005, 2007a). Krause et al. (2006) consider the problem of optimizing the placement of a network of wireless sensors. In this context, the chosen locations must be both informative and communicate well, constraining the chosen locations not to be too far apart. Singh et al. (2007) and Meliou et al. (2007) consider the problem of planning informative paths for multiple robots, where the informativeness is modeled using a submodular objective function, and a constraint on path lengths connecting the locations is specified. In the context of such more complex (communication and path) constraints—similarly to the robust setting—the greedy algorithm can fail arbitrarily badly, and more complex algorithms have to be developed. Using the techniques described in Section 7.4, both approaches can be made robust with respect to a worst-case submodular function.

11. Conclusions

In this paper, we considered the RSOS problem of robustly selecting observations which are informative with respect to a worst-case submodular objective function. We demonstrated the generality of this problem, and showed how it encompasses the problem of sensor placements which minimize the maximum posterior variance in Gaussian Process regression, variable selection under parameter uncertainty, robust experimental design, and detecting events spreading over graphs, even in the

case of adversarial sensor failures. In each of these settings, the individual objectives are submodular and can be approximated well using, for example, the greedy algorithm; the robust objective, however, is not submodular.

We proved that there cannot exist any approximation algorithm for the robust optimization problem if the constraint on the observation set size must be exactly met, unless P = NP. Consequently, we presented an efficient approximation algorithm, SATURATE, which finds observation sets which are guaranteed to be least as informative as the optimal solution, and only logarithmically more expensive. In a strong sense, this guarantee is the best possible under reasonable complexity theoretic assumptions.

We provided several extensions to our methodology, accommodating more complex cost functions (non-uniform observation costs, communication and path costs). Additionally, we described how a compromise between worst-case and average-case performance can be achieved. We also discussed several approaches for reducing the number of objective functions, improving both running times and theoretical guarantees.

We extensively evaluated our algorithm on several real-world problems. For Gaussian Process regression, for example, we showed that SATURATE compares favorably to state-of-the-art heuristics, while being simpler, faster, and providing theoretical guarantees. For robust experimental design, SATURATE performs favorably compared to SDP based approaches. We believe that the ideas developed in this paper will help the development of robust monitoring systems and provide new insights for adapting machine learning algorithms to cope with adversarial environments.

Appendix A. Proofs

Proof [Theorem 3] Consider a hitting set instance with m subsets $S_i \subseteq V$ on a ground set V. Our task is to select a set $A \subseteq V$ with which intersects all sets S_i, and such that $|A| = k$ is as small as possible. For each set S_i, define a function F_i such that $F_i(A) = 1$ if A intersects S_i, and 0 otherwise. It can be seen that F_i is clearly monotonic. F_i is also submodular, since for $A \subseteq B \subseteq V$ and $x \in V \setminus B$, if $F_i(B) = 0$ and $F_i(B \cup \{x\}) = 1$, then it $x \in S_i$, hence $F_i(A \cup \{x\}) = 1$ and $F_i(A) = 0$. Now assume the optimal hitting set A^* is of size k. Hence $\min_i F_i(A^*) = 1$. If there were an algorithm for solving Problem (2) with approximation guarantee $\gamma(n)$ it would select a set A' of size $|A'| \leq k$ with $\min_i F_i(A') \geq \gamma(n) \min_i F_i(A^*) = \gamma(n) > 0$. But $\min_i F_i(A') > 0$ implies $\min_i F_i(A') = 1$, hence A' would be a hitting set. Hence, this approximation algorithm would be able to decide, whether there exists a hitting set of size k, contradicting the NP-hardness of the hitting set problem (Feige, 1998). ■

Proof [Lemma 4] Wolsey (1982) proves that, given a monotonic submodular function F on a ground set V, it holds that that greedy algorithm (GPC), applied to the optimization problem

$$\min_A |A| \text{ such that } F(A) = F(V)$$

returns a solution A' such that $|A'| \leq |A^*|(1+\log\max_{s\in V} F(\{s\}))$, where A^* is an optimal solution. We apply Wolsey's result to the monotonic submodular function $\overline{F}_c$. In order to use GPC in the inner loop of the binary search over c, we need to make sure that the approximation guarantee for the greedy algorithm is independent of c. This can be achieved by choosing

$$\alpha = 1 + \log\left(\max_{s\in V}\sum_i F_i(\{s\})\right) \geq 1 + \log\left(m\max_{s\in V}\overline{F}_c(\{s\})\right),$$

that is, the choice of α stated in Lemma 4 is independent of the truncation threshold c. ■

Proof [Theorem 5] Lemma 4 proves that during each of the iterations of the saturation algorithm it holds that $\min_i F_i(A^*) \leq c_{\max}$, where A^* is an optimal solution. Furthermore, it holds that $\min_i F_i(A_{best}) \geq c_{\min}$, and $|A_{best}| \leq \alpha k$. Since the F_i are integral, if $c_{\max} - c_{\min} < \frac{1}{m}$ then it must hold that $\min_i F_i(A_{best}) \geq \min_i F_i(A^*)$ as claimed by Theorem 5.

For the running time, since at the first iteration, $c_{\max} - c_{\min} \leq \min_i F_i(V)$, and $c_{\max} - c_{\min}$ is halved during each iteration, it follows that after $1 + \lceil \log_2 m \min_i F_i(V) \rceil$ iterations, $c_{\max} - c_{\min} < \frac{1}{m}$, at which point the algorithm terminates. During each iteration, Algorithm 1 is invoked once, which requires $O(|V|^2 m)$ function evaluations. ■

Proof [Theorem 6] We use the same hitting set construction as in Theorem 3. If there were an algorithm for selecting a set A' of size $|A'| \leq \beta k$ with $\min_i F_i(A') = 1$, and $\beta \leq (1-\varepsilon)\alpha$, for some fixed $\varepsilon > 0$, then we would have an approximation algorithm for hitting set with guarantee $(1-\varepsilon)\log m$ which would imply NP $\subseteq$ DTIME$(n^{\log\log n})$ (Feige, 1998). ■

Proof [Theorem 8] The proof is analogous to the proof of Theorem 5. The approximation guarantee α is established by noticing that the greedy algorithm is applied to the modified (integral) objective

$$\overline{F}_{c_{wc},c_{ac}}(A) = \sum_i \min\{F_i(A), c_{wc}\} + \min\left\{\sum_i F_i(A), mc_{ac}\right\}.$$

The guarantee α is obtained from the analysis of the greedy submodular coverage algorithm of Wolsey (1982), similar to Lemma 4. Approximate Pareto-optimality follows directly from Pareto-optimality of any solution to (10). ■

Abstract

Most approaches to structured output prediction rely on a hypothesis space of *prediction functions* that compute their output by maximizing a linear *scoring function*. In this paper we present two novel learning algorithms for this hypothesis class, and a statistical analysis of their performance. The methods rely on efficiently computing the first two moments of the scoring function over the output space, and using them to create convex objective functions for training. We report extensive experimental results for sequence alignment, named entity recognition, and RNA secondary structure prediction.

Keywords: structured output prediction, discriminative learning, Z-score, discriminant analysis, PAC bound

1. Introduction

The last few years have seen a growing interest in learning algorithms that operate over structured data: given a set of training input-output pairs, they learn to predict the output corresponding to a previously unseen input, where either the input or the output (or both) are more complex than traditional data types such as vectors.

Examples of such problems abound: learning to align biological sequences, learning to parse strings, learning to translate natural language, learning to find the optimal route in a graph, learning to understand speech, and much more. This problem setting subsumes as a special case the standard regression, binary classification, and multiclass classification problems. In fact in many cases the structured output prediction approach matches practice more closely. However, this broad generality and applicability comes with a number of significant theoretical and practical challenges.

In standard regression the output space is real-valued, and in classification the output space consists of a relatively small unstructured set of labels. In contrast, in structured output prediction the output space is typically massive, containing a rich structure relating the different output values

with each other. Because of this, even the prediction task itself requires a search (or optimization) over the complete output space, which in itself is often nontrivial. A fortiori, the task of learning to predict poses important new challenges in comparison with standard machine learning approaches such as regression and classification.

1.1 Graphical and Grammatical Models for Structured Data

An immediate approach for structured output prediction would be to use a probabilistic model jointly over the input and the output variables. Probabilistic graphical models (PGMs) or stochastic context free grammars (SCFGs) are two examples of techniques that allow one to specify probabilistic models for a variety of inputs and outputs, explicitly encoding the structure that is present. For a given input, the predicted output can then be found as the one that maximizes the a posteriori probability. This way of predicting structured outputs is referred to as maximum a posteriori (MAP) estimation. The learning phase then boils down to modeling the distribution of the joint of input and output data.

However, it is well known that this indirect approach of first modeling the distribution (disregarding the prediction task of interest) and subsequently using MAP estimation for prediction, risks to be suboptimal. Instead a direct discriminative approach is more appropriate, which directly focuses on the prediction task of interest. Such methods, known as discriminative learning algorithms (DLAs), make predictions by optimizing a scoring function over the output space, where this scoring function has not necessarily a probabilistic interpretation.

Recently studied DLAs include maximum entropy Markov models (McCallum et al., 2000), conditional random fields (CRFs) (Lafferty et al., 2001), re-ranking with perceptron (Collins, 2002b), hidden Markov perceptron (HMP) (Collins, 2002a), sequence labeling with boosting (Altun et al., 2003a), maximal margin (MM) algorithms (Altun et al., 2003b; Taskar et al., 2003; Tsochantaridis et al., 2005), Gaussian process models (Altun et al., 2004), and kernel conditional random fields (Lafferty et al., 2004).

Interestingly, both the generative modeling approach and the DLAs mentioned above make use of formally the same hypothesis class of prediction functions. In particular, they all make use of a scoring function that is linear in a set of parameters to score each element of the output space. In the generative approach, this linear function is the log-probability of the joint of the input and output data; in the discriminative approach this can be any linear function. The actual prediction function then selects the output that achieves the highest value of the scoring function (i.e., the highest score). In the generative approach this means that the a posteriori (log)-probability of the output is maximized, such that the MAP estimate is obtained as pointed out above.

1.2 The Contributions of this Paper

In this paper we will adopt the hypothesis space of prediction functions defined as above. The distribution of scores induced by any hypothesis over all possible outputs is a central concept in various approaches, and can be used to compare hypotheses, and hence to train. For example MM approaches (Altun et al., 2003b; Taskar et al., 2003; Tsochantaridis et al., 2005) prescribe to seek hypotheses that make the score of the correct outputs in the training set larger than all incorrect ones (by a certain margin).

We argue that the problem can be better approached by considering the entire distribution of the scores over the output space, and in particular by computing its first two moments. Different

choices of parameters can be assessed by comparing (a function of) those moments. Such an approach would account for all possible output values at once, rather than just the ones with a high score as in the maximum margin approaches. However these moments cannot be computed by brute force enumeration: in all practical cases the output space is far too large to exhaustively traverse it. Nevertheless in this paper we show how the first and second order moments can often be computed efficiently by means of dynamic programming (DP), without explicitly enumerating the output space. We provide specific examples of how these moments can be computed for three types of structured output prediction problems: the sequence alignment problem, sequence labeling, and learning to parse with a context free grammar for RNA secondary structure prediction.

We then present two ways in which these moments can be used to design a convex objective function for a learning algorithm. **The first approach** is the maximization of the Z-score, a common statistical measure of surprise, which is large if the scores of the correct outputs in the training set are significantly different from the scores of all incorrect outputs in the output space. We show that the Z-score is a convex cost function, such that it can be optimized efficiently. **A second approach**—also convex—is reminiscent of Fisher's discriminant analysis (FDA). We call this new algorithm SODA (structured output discriminant analysis) since the optimization criterion is a similar function of the first and second order statistics as in FDA.

We report extensive experimental results for the proposed algorithms applied to three different problem settings: learning to align, sequence labeling, and RNA folding.

Finally we derive learning-theoretic bounds on the performance of these algorithms, showing that the SODA cost function is related to the rank of the correct output among the other outputs and analyzing its statistical stability within the Rademacher framework; additionally, we present a general PAC bound that applies to any algorithm using this hypothesis class.

1.3 Outline of this Paper

The rest of the paper is structured as follows: Section 2 formally introduces the problem of structured output learning and the hypothesis space considered. Section 3 deals with the computation of the first and second order moments of the score distribution through DP. In Section 4 we introduce the two algorithms. In Section 5 we present our experimental results, and in Section 6 we outline learning-theoretical bounds, whose proof is however left for the appendix.

2. Learning to Predict Structured Outputs

We address the general problem of learning a *prediction function* $h : \mathcal{X} \to \mathcal{Y}$, with $\mathcal{Y}$ a potentially highly structured space containing a potentially large number N of elements. The learning is based on a training set of input-output pairs $\mathcal{T} = \{(\mathbf{x}^1, \overline{\mathbf{y}}^1), (\mathbf{x}^2, \overline{\mathbf{y}}^2), \ldots, (\mathbf{x}^\ell, \overline{\mathbf{y}}^\ell)\}$ drawn i.i.d. from some fixed but unknown distribution $P(\mathbf{x}, \mathbf{y})$ over $\mathcal{X} \times \mathcal{Y}$. The inputs and the outputs may be highly structured objects that parameterize sequences, trees or graphs. For example in sequence alignment learning the output variables parameterize the alignment between two sequences, in sequence labeling $\mathbf{y}$ is the label sequence associated to the observed sequence $\mathbf{x}$, and when learning to parse $\mathbf{y}$ represents a parse tree corresponding to a given sequence $\mathbf{x}$.

2.1 Scoring Functions, Prediction Functions, and the Hypothesis Space

As in standard machine learning approaches, we consider learning methods that choose the prediction function from a hypothesis space by minimizing a cost function evaluated on the training data. To establish the type of hypothesis space we will consider, we will rely on the notion *scoring function*, which is a function $s : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ that assigns a numerical score $s(\mathbf{x}, \mathbf{y})$ to a pair $(\mathbf{x}, \mathbf{y})$ of input-output variables. Furthermore, we will assume that s is linear in a parameter vector $\theta \in \mathbb{R}^d$:

Definition 1 (Linear scoring function) *A linear scoring function is a function $s_\theta : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ defined as:*

$$s_\theta(\boldsymbol{x}, \boldsymbol{y}) = \theta^T \phi(\boldsymbol{x}, \boldsymbol{y}), \tag{1}$$

where the vector $\phi(\boldsymbol{x}, \boldsymbol{y}) = (\phi_1(\boldsymbol{x}, \boldsymbol{y}),\ \phi_2(\boldsymbol{x}, \boldsymbol{y}),\ \ldots,\ \phi_d(\boldsymbol{x}, \boldsymbol{y}))^T$ is defined by a specified set of integer-valued feature functions $\phi_i : \mathcal{X} \times \mathcal{Y} \to [0, C]$ for a fixed upper bound C.

Based on this, we can define prediction functions as considered in this paper as follows:

Definition 2 (Prediction function) *Given a linear scoring function s_θ, we can define a prediction function $h_\theta : \mathcal{X} \to \mathcal{Y}$ as:*

$$h_\theta(\boldsymbol{x}) = \arg\max_{\boldsymbol{y} \in \mathcal{Y}} s_\theta(\boldsymbol{x}, \boldsymbol{y}). \tag{2}$$

This type of prediction function has been used in previous approaches for structured output prediction. For example, when using a discrete-valued PGM to model the joint distribution of the input and output data, the logarithm of the probability distribution is a linear scoring function as defined above. The vector $\phi(\mathbf{x}, \mathbf{y})$ is then the vector of sufficient statistics, and the parameter vector θ corresponds to the logarithms of the clique potentials or conditional probabilities. Then, a MAP estimator corresponds to a prediction function as defined above. Furthermore, note that each feature function ϕ_i that counts a sufficient statistic is either an indicator function, or the sum of an indicator function evaluated on a set of cliques over which the parameter θ_i is reused. Therefore, each of the features must be an integer between 0 and the number of cliques C, as required for linear scoring functions in Definition 1.

Typically, in PGMs the parameters θ would be inferred by Maximum Likelihood. On the contrary in DLAs θ is computed by minimizing criteria that are more directly linked to the prediction performance. Moreover with DLAs richer feature vectors (with features not necessarily associated to clique potentials or conditional probabilities) are allowed to describe more effectively the relation between input and output variables. This means that the score $s_\theta(\mathbf{x}, \mathbf{y})$ looses its interpretation as a log-likelihood function.

In summary, the hypothesis space we consider in this paper is defined as:

$$\mathcal{H} = \{h_\theta : \theta \in \mathbb{R}^d\}. \tag{3}$$

This is a slightly larger hypothesis space as compared to the one considered in PGMs, since the parameters θ are not restricted to represent log probabilities.

While we choose to abandon the probabilistic interpretations, it is often worthwhile to keep the analogy with PGMs in mind: they teach us when the evaluation of the prediction function (2) can be carried out efficiently by means of Viterbi-like algorithms, despite the huge size of the

output space $\mathcal{Y}$. In fact, it is often convenient to define or derive the scoring function starting from a PGM, to ensure that it is easily maximized by a dynamic programming procedure such as the Viterbi algorithm. Subsequently the constraints on the parameters that are meant to guarantee that the scoring function is a log-probability function can be removed, in order to arrive at a hypothesis space of the form (3).

2.2 Ideal Loss Functions

In order to select an appropriate prediction function from the hypothesis space, a cost function needs to be defined. Here we will provide an overview of a few conceptually interesting cost functions, but which are unfortunately hard to optimize. Nevertheless, they can often be approximated as seen from literature, and as we will demonstrate further on.

Consider a *loss function* $\mathcal{L}_\theta$ that maps the input $\mathbf{x}$ and the true training output $\bar{\mathbf{y}}$ to a positive real number $\mathcal{L}_\theta(\mathbf{x},\bar{\mathbf{y}})$, in some way measuring the discrepancy between the prediction $h_\theta(\mathbf{x})$ and $\bar{\mathbf{y}}$. Empirical risk minimization strategies attempt to find the vector $\theta \in \mathbb{R}^d$ such that the *empirical risk*, defined as:

$$\mathcal{R}_\theta(\mathcal{T}) = \frac{1}{\ell}\sum_{i=1}^{\ell} \mathcal{L}_\theta(\mathbf{x}^i,\bar{\mathbf{y}}^i)$$

is minimized, in hopes that this will guarantee that the expected loss $E\{\mathcal{L}_\theta(\mathbf{x},\bar{\mathbf{y}})\}$ is small as well. Often it is beneficial to introduce regularization in order to prevent overfitting to occur, but let us first consider on the empirical risk itself.

Clearly the choice of the loss function is critical, and different choices may be appropriate in different situations. The simplest one is a natural extension of the zero-one loss in binary classification task, defined as:

$$\mathcal{L}_\theta^{ZO}(\mathbf{x},\bar{\mathbf{y}}) \quad = \quad I(h_\theta(\mathbf{x}) \neq \bar{\mathbf{y}})$$

where $I(\cdot)$ is an indicator function. Unfortunately the zero-one loss function is discontinuous and NP-hard to optimize. Therefore algorithms such as CRFs (Lafferty et al., 2001) and MM methods (Altun et al., 2003b) minimize an upper bound on this loss rather than the loss itself, combined with an appropriate regularization term.

However, in structured output prediction, the zero-one loss is quite crude, in the sense that it makes no distinction in the type of mistake that has been made. For example, assume that the outputs $\mathbf{y}$ are sequences of length m, or vectors: $\mathbf{y} = (y_1, y_2, \ldots, y_m)$. In that case, a wrong prediction is likely to be less damaging if it is due to only one or a few incorrectly predicted symbols in the sequence. A better loss function that distinguishes incorrect predictions in this way is the Hamming loss, originally proposed in Taskar et al. (2003) for MM algorithms:

$$\mathcal{L}_\theta^{H}(\mathbf{x},\bar{\mathbf{y}}) \quad = \quad \sum_j I(h_{\theta,j}(\mathbf{x}) \neq \bar{y}_j),$$

counting the number of elements (i.e., the symbols in a sequence, or coordinates in a vector) of the output where a mistake has been made.

However, the Hamming loss is not necessarily a good measure for the severity of an incorrect prediction. For example, certain sentences can be parsed in totally different ways that can all be correct, with a large Hamming distance separating them. Similarly, RNA molecules can have two

totally different stable fold states, both with functional relevance. Therefore, where perfect prediction of the data cannot be achieved using the hypothesis space considered, it could be more useful to measure the fraction of outputs for which the score is ranked higher than for the correct output. This is the main motivation to use what we call the relative ranking (RR) loss:

$$\mathcal{L}_0^{RR}(\mathbf{x},\overline{\mathbf{y}}) = \frac{1}{N}\sum_{j=1}^{N} I(s(\mathbf{x},\overline{\mathbf{y}}) \leq s(\mathbf{x},\mathbf{y}_j)),$$

We refer to this loss as the relative ranking loss, since the rank divided by the total size of the output space N is computed. This loss and related loss functions have been proposed in Freund et al. (1998), Schapire and Singer (1999) and Altun et al. (2003a).

2.3 Playing with Sequences: Labeling, Aligning and Parsing

In order to further clarify the framework of structured output learning we present three typical problems which we will use in the rest of the paper as illustrative examples: sequence labeling learning, sequence alignment learning and parse learning.

2.3.1 SEQUENCE LABELING LEARNING

In sequence labeling tasks a sequence is taken as an input, and the output to be predicted is a sequence that annotates the input sequence, that is, with a symbol corresponding to each symbol in the input sequence. This problem arises in several application such as gene finding or protein structure prediction in computational biology or named entity recognition and part of speech tagging in the natural language processing field. Traditionally a special type of PGM, namely hidden Markov models (HMMs) (Rabiner, 1989), is used in sequence labeling, where the parameters can be learned by maximum likelihood, and subsequently predictions can be made by MAP estimation. In order to derive a DLA for this setting, we will first derive the prediction function corresponding to MAP estimation based on HMMs, and subsequently remove the constraints on the parameters that allow for the probabilistic interpretation of HMMs. Then an appropriate cost function for discrimination can be optimized to select a good parameter setting.

In an HMM (Fig. 1) there is a sequence of observed variables $\mathbf{x} = (x_1, x_2, ..., x_m) \in \mathcal{X}$ which will be the input in the terminology of the paper, along with a sequence of corresponding hidden variables $\mathbf{y} = (y_1, y_2, ..., y_m) \in \mathcal{Y}$, in the present terminology corresponding to the output sequence to be predicted. Each observed symbol x_i is an element of the observed symbol alphabet Σ_x, and the hidden symbols y_i are elements of Σ_y, with $n_o = |\Sigma_x|$ and $n_h = |\Sigma_y|$ the respective alphabet sizes. Therefore the output space is $\mathcal{Y} = {\Sigma_y}^m$, while $\mathcal{X} = {\Sigma_x}^m$. The number of cliques $C = 2m-1$ of the HMM graphical model is equal to the number of edges.

An HMM is defined as a probabilistic model for the joint distribution of the hidden and observed sequence, whereby it is assumed that the probability distribution of each hidden symbol y_k depends solely on the value of the previous symbol in the sequence y_{k-1} (this is the Markov assumption which is quantified by $P(y_k|y_{k-1})$). Furthermore, it is assumed that the probability distribution of the observed symbol x_k depends solely on the value of y_k (quantified by the emission probability distribution $P(x_k|y_k)$). For simplicity, we ignore the probability distribution of the first element of the hidden chain in this exposition. The MAP estimator predicts the hidden sequence $\mathbf{y}$ that is most

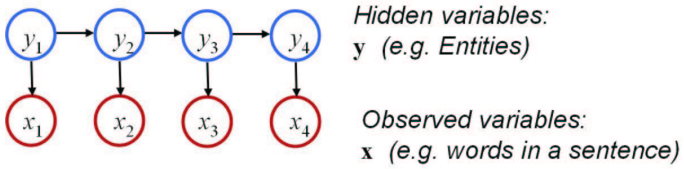

Figure 1: The graph of an HMM with $m = 4$.

likely given the observation sequence $\mathbf{x}$. In formulas:

$$\begin{aligned} h(\mathbf{x}) &= \arg\max_{\mathbf{y}\in\mathcal{Y}} P(\mathbf{y}|\mathbf{x}) = \arg\max_{\mathbf{y}\in\mathcal{Y}} \frac{P(\mathbf{y},\mathbf{x})}{P(\mathbf{x})} = \arg\max_{\mathbf{y}\in\mathcal{Y}} P(\mathbf{y})P(\mathbf{x}|\mathbf{y}), \\ &= \arg\max_{\mathbf{y}\in\mathcal{Y}} \prod_{k=2}^{m} P(y_k|y_{k-1}) \prod_{k=1}^{m} P(x_k|y_k), \\ &= \arg\max_{\mathbf{y}\in\mathcal{Y}} \left[\sum_{k=2}^{m} \log P(y_k|y_{k-1}) + \sum_{k=1}^{m} \log P(x_k|y_k) \right], \end{aligned}$$

where we made use of the fact that the argmax of a function is equal to the argmax of its logarithm.

Thus, to fully specify the HMM, one needs to consider all the transition probabilities (denoted t_{ij} for $i, j \in \Sigma_y$ for the transition from symbol i to j), and the emission probabilities (denoted e_{io} for the emission of symbol $o \in \Sigma_x$ by symbol $i \in \Sigma_y$). Using this notation, we can rewrite the prediction function as follows (with $I(\cdot)$ equal to one if the equalities between brackets hold):

$$\begin{aligned} h(\mathbf{x}) = \quad \arg\max_{\mathbf{y}\in\mathcal{Y}} \quad & \sum_{i,j\in\Sigma_y} \log(t_{ij}) \sum_{k=2}^{m} I(y_{k-1} = i, y_k = j) \\ & + \sum_{i\in\Sigma_y, o\in\Sigma_x} \log(e_{io}) \sum_{k=1}^{m} I(y_k = i, x_k = o). \end{aligned}$$

For simplicity of notation let us replace all logarithms of parameters t_{ij} and e_{io} by parameters θ_i summarized in a $d = n_h n_o + n_h^2$ dimensional parameter vector θ. Additionally, let us summarize the corresponding sufficient statistics $\sum_{k=2}^{m} I(y_{k-1} = i, y_k = j)$ and $\sum_{k=1}^{m} I(y_k = i, x_k = o)$ in a corresponding feature vector $\phi(\mathbf{x},\mathbf{y}) = [\phi_1(\mathbf{x},\mathbf{y})\ \phi_2(\mathbf{x},\mathbf{y})\ \ldots\ \phi_d(\mathbf{x},\mathbf{y})]^T$. (Note that these sufficient statistics count the number of occurrences of each specific transition and emission.) Then we can rewrite the prediction function in a linear form as required:

$$h_\theta(\mathbf{x}) = \arg\max_{\mathbf{y}\in\mathcal{Y}} \theta^T \phi(\mathbf{x},\mathbf{y}).$$

This prediction can be evaluated efficiently by means of the Viterbi algorithm. Note that in order to learn the parameters by means of maximum likelihood estimation, constraints are imposed to ensure that they represent log-probabilities. In order to arrive at a DLA that operates in the same setting, it suffices to ignore these constraints, and to minimize an appropriate empirical risk subject to some regularization, as outlined in Section 2.2. Moreover relaxing also the Markov assumption the proposed formulation can be extended to the case of arbitrary features. In general in fact the

vector $\phi(\mathbf{x},\mathbf{y})$ contains not only statistics associated to transition and emission probabilities but also any feature that reflects the properties of the objects represented by the nodes of the HMM. For example in most of the natural language processing tasks, feature vectors also contain information about spelling properties of words. Sometimes also the so-called 'overlapping features' (Lafferty et al., 2001) are employed, which indicate relations between observations and some previous and future labels. Most of DLAs dealing with this task have proceeded in this way (McCallum et al., 2000; Lafferty et al., 2001; Collins, 2002a; Altun et al., 2003a,b; Taskar et al., 2003).

2.3.2 SEQUENCE ALIGNMENT LEARNING

As second case studied, we consider the problem of learning how to align sequences: given as training examples a set of correct pairwise global alignments, find the parameter values that ensure sequences are optimally aligned. This task is also known as inverse parametric sequence alignment problem (IPSAP) and since its introduction in Gusfield et al. (1994), it has been widely studied (Gusfield and Stelling, 1996; Kececioglu and Kim, 2006; Joachims et al., 2005; Pachter and Sturmfels, 2004; Sun et al., 2004).

Consider two strings S_1 and S_2 of lengths n_1 and n_2 respectively. The strings are ordered sequences of symbols $s_i \in \mathcal{S}$, with $\mathcal{S}$ a finite alphabet of size $n_{\mathcal{S}}$. In case of biological applications, for DNA sequences the alphabet contains the symbols associated with nucleotides ($\mathcal{S} = \{\mathtt{A},\mathtt{C},\mathtt{G},\mathtt{T}\}$), while for amino acids sequences the alphabet is $\mathcal{S} = \{\mathtt{A},\mathtt{R},\mathtt{N},\mathtt{D},\mathtt{C},\mathtt{Q},\mathtt{E},\mathtt{G},\mathtt{H},\mathtt{I},\mathtt{L},\mathtt{K},\mathtt{M},\mathtt{F},\mathtt{P},\mathtt{S},\mathtt{T},\mathtt{W},\mathtt{Y},\mathtt{V}\}$.

An alignment of two strings S_1 and S_2 of lengths n_1 and n_2 is defined as a pair of sequences T_1 and T_2 of equal length $n \geq n_1, n_2$ that are obtained by taking S_1 and S_2 respectively and inserting symbols $-$ at various locations in order to arrive at strings of length n. Two symbols in T_1 and T_2 are said to correspond if they occur at the same location in the respective string. If corresponding symbols are equal, this is called a *match*. If they are not equal, this is a *mismatch*. If one of the symbols is a $-$, this is called a *gap*.

With each possible match, mismatch or gap a score is attached. To quantify these scores, three score parameters can be used: one for matches (θ_m), one for mismatches (θ_s), and one for gaps (θ_g). In analogy with the notation in this paper, the pair of given sequences S_1 and S_2 represent the input variable $\mathbf{x}$ while their alignment is the output $\mathbf{y}$. The score of the global alignment is defined as the sum of this score over the length of T_1 and T_2, that is, as a linear function of the alignment parameters:

$$s_\theta(\mathbf{x},\mathbf{y}) = \theta^T \phi(\mathbf{x},\mathbf{y}) = \theta_m m + \theta_s s + \theta_g g$$

where $\phi(\mathbf{x},\mathbf{y}) = [m\, s\, g]^T$ and m, s and g represent the number of matches, mismatches and gaps in the alignment. Fig. 2 depicts a pairwise alignment between two sequences and the associated path in the alignment graph. The number N of all possible alignments between S_1 and S_2 is clearly exponential in the size of the two strings. However, an efficient DP algorithm for computing the alignment with maximal score $\bar{\mathbf{y}}$ is known in literature: the Needleman-Wunsch algorithm (Needleman, 1970).

The scoring models presented above consider a local form of gap penalty: the gap penalty is fixed independently of the other gaps in the alignment. However for biological reasons it is often preferable to consider an affine function for gap penalties, that is to assign different costs if the gap starts (gap opening penalty θ_o) in a given position or if it continues (gap extension penalty θ_e). Then the score of an alignment is:

$$s_\theta(\mathbf{x},\mathbf{y}) = \theta_m m + \theta_s s + \theta_o o + \theta_e e$$

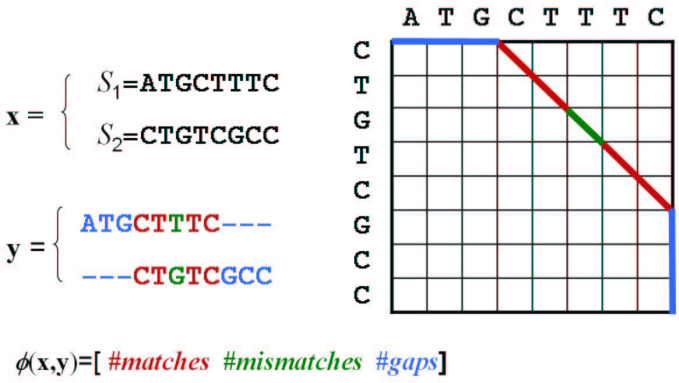

Figure 2: An alignment $\mathbf{y}$ between two sequences S_1 and S_2 can be represented by a path in the alignment graph.

where m, s, o and e represent the number of match, mismatch, gap openings and gap extensions respectively and θ_m, θ_s, θ_o, θ_e are the associated costs. As before we can define the vectors $\theta = [\theta_m\ \theta_s\ \theta_o\ \theta_e]^T$ and $\phi(\mathbf{x},\mathbf{y}) = [m\ s\ o\ e]^T$. Therefore the score is still a linear function of the parameters and the prediction can be computed by a DP algorithm.

More often a different model is considered where a (symmetric) scoring matrix specifies different score values for each possible pair of symbols. In general there are $d = \frac{n_S(n_S+1)}{2}$ different parameters in θ associated with the symbols of the alphabet plus two additional ones corresponding to the gap penalties. This means that to align sequences of amino acids we have 210 parameters to determine plus other 2 parameters for gap opening and gap extension. We denote with z_{jk} the number of pairs where a symbol of T_1 is j and it corresponds to a symbol k in T_2. Again the score is a linear function of the parameters:

$$s_\theta(\mathbf{x},\mathbf{y}) = \sum_{j \geq k} \theta_{jk} z_{jk} + \theta_o o + \theta_e e$$

and the optimal alignment is computed by the Needleman-Wunsch algorithm.

2.3.3 LEARNING TO PARSE

In learning to parse the input $\mathbf{x}$ is given by a sequence, and the output is given by its associated parse tree according to a context free grammar. Usually weighted context-free grammars (WCFGs) (Manning and Schetze, 1999) are used to approach this problem. Learning to parse has been already studied as a particular instantiation of structured output learning, both in natural language processing applications (Tsochantaridis et al., 2005; Taskar et al., 2004) and in computational biology for RNA secondary structure alignment (Sato and Sakakibara, 2005) and prediction (Do et al., 2006). In this paper we consider the latter and we use WCFGs to model the structure of RNA sequences. Two examples of RNA secondary structure for two sequences are shown in Fig. 3.

A WCFG is defined as five tuples $(\Upsilon, \Sigma_x, R, S, \theta)$, where $\Upsilon = \{\Upsilon_1, \ldots, \Upsilon_{|\Upsilon|}\}$ is a set of nonterminals, $\Sigma_x = \{X_1, \ldots, X_{|\Sigma_x|}\}$ is a set of terminals, $R = \{\Upsilon_i \rightarrow \alpha | \Upsilon_i \in \Upsilon, \alpha \in (\Upsilon \cup \Sigma_x)^*\}$ is a set of rules,

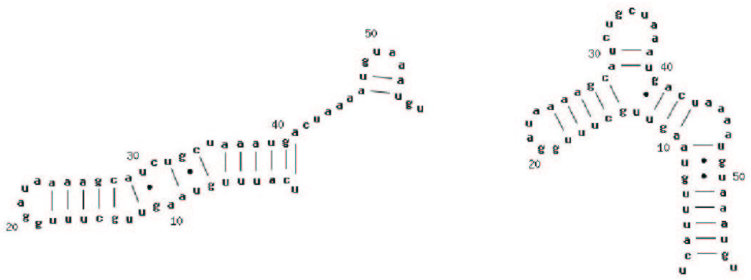

Figure 3: Two examples of RNA secondary structures for two sequences of the Rfam database (Griffiths-Jones et al., 2003).

$S \in \Upsilon$ is the starting symbol, and θ is a set of weights. We use rules of the forms $\Upsilon_i \to X$, $\Upsilon_i \to \Upsilon_j \Upsilon_k$, $\Upsilon_i \to X \Upsilon_j X'$, and $\Upsilon_i \to \Upsilon_{j'}$ ($j' > i$). R is also indexed by an ordering $\{r_1, \ldots, r_{|R|}\}$ and $d = |R|$. Each node in the parse tree $\mathbf{y}$ corresponds to a grammar rule and each weight $\theta_i \in \theta$ is associated with a rule $r_i \in R$. Given a sequence $\mathbf{x}$ and an associated parse tree $\mathbf{y}$ we can define a feature vector $\phi(\mathbf{x}, \mathbf{y})$ which contains a count of the number of occurrences of each of the rules in the parse tree $\mathbf{y}$. Given a parameter vector θ, the prediction function $h_\theta(\mathbf{x})$ is computed by finding the best parse tree. For SCFGs, this can be done efficiently with the Cocke-Younger-Kasami (CYK) algorithm (Younger, 1967).

3. Computing the Moments of the Scoring Function

An interesting corollary of the proposed structured output approach based on linear scoring functions is that certain statistics of the score $s(\mathbf{x}, \mathbf{y})$ can be expressed as function of the parameter vector θ. More specifically given an observed vector $\mathbf{x}$, we can consider the first order moment or mean $M_{1,\theta}(\mathbf{x})$ and the centered second order moment or covariance $M_{2,\theta}(\mathbf{x})$ of the scores along all possible N output variables $\mathbf{y}_j$. It is straightforward to see that $M_{1,\theta}(\mathbf{x})$ is a linear function of θ, that is,

$$\begin{aligned} M_{1,\theta}(\mathbf{x}) &\triangleq \frac{1}{N}\sum_{j=1}^{N} s_\theta(\mathbf{x}, \mathbf{y}_j) \\ &= \theta^T \frac{1}{N}\sum_{j=1}^{N} \phi(\mathbf{x}, \mathbf{y}_j) \\ &= \theta^T \mu \end{aligned}$$

with $\mu = [\mu_1 \ldots \mu_d]^T = \frac{1}{N}\sum_{j=1}^{N} \phi(\mathbf{x}, \mathbf{y}_j)$. Similarly, for the covariance:

$$\begin{aligned} M_{2,\theta}(\mathbf{x}) &\triangleq \frac{1}{N}\sum_{j=1}^{N} (s_\theta(\mathbf{x}, \mathbf{y}_j) - M_{1,\theta}(\mathbf{x}))^2 \\ &= \theta^T \left(\frac{1}{N}\sum_{j=1}^{N} (\phi(\mathbf{x}, \mathbf{y}_j) - \mu)(\phi(\mathbf{x}, \mathbf{y}_j) - \mu)^T \right) \theta \end{aligned}$$

$$= \quad \theta^T C \theta.$$

The matrix C is a matrix with elements:

$$\begin{aligned} c_{pq} &= \frac{1}{N}\sum_{j=1}^{N}(\phi_p(\mathbf{x},\mathbf{y}_j)-\mu_p)(\phi_q(\mathbf{x},\mathbf{y}_j)-\mu_q) \\ &= \frac{1}{N}\sum_{j=1}^{N}\left(\phi_p(\mathbf{x},\mathbf{y}_j)\phi_q(\mathbf{x},\mathbf{y}_j)\right)-\mu_p\mu_q = \nu_{pq}-\mu_p\mu_q \end{aligned} \tag{4}$$

where $1 \leq p,q \leq d$.

3.1 Magic Moments

It should be clear that in practical structured output learning problems the number N of possible output vectors associated to a given input $\mathbf{x}$ can be massive. At first sight, this leaves little hope that the above sums can ever be computed for realistic problems. However, it turns out that the same ideas that allow one to perform inference in PGMs allow one to compute these sums efficiently using DP, be it with somewhat more complicated recursions.

The underlying ideas to derive the recursions for μ are based on the commutativity of the semiring that is used in the Viterbi (or more generally the max-product and related algorithms) in PGMs. In particular, this recursion is used in various forms:

$$E\left\{\sum_{i=1}^{k} a_i\right\} \quad = \quad E\left\{\sum_{i=1}^{k-1} a_i\right\} + E\left\{a_k\right\},$$

where the expectations are jointly over independent random variables a_i. For the recursions for the second order moment (which can be used to compute the centered second order moment as shown in (4)), the following recursive expression is applied in different variations:

$$E\left\{\left(\sum_{i=1}^{k} a_i\right)^2\right\} \quad = \quad E\left\{\left(\sum_{i=1}^{k-1} a_i\right)^2\right\} + 2E\left\{a_k \sum_{i=1}^{k-1} a_i\right\} + E\left\{a_k^2\right\},$$

where again the expectations are jointly over independent random variables a_i. Note that the middle term on the right hand side is computed by previous iterations for the first order moment. For concreteness, we will now consider separately the three illustrative scenarios introduced above.

3.2 Sequence Labeling Learning

Given a fixed input sequence $\mathbf{x}$, we show here for the sequence labeling example that the elements of μ and C can be computed exactly and efficiently by dynamic programming routines.

We first consider the vector μ and construct it in a way that the first $n_h n_o$ elements contain the mean values associated with the emission probabilities and the remaining n_h^2 elements correspond to transition probabilities. Each value of μ can be determined by Algorithm 1.

In the emission part for each element a $n_h \times m$ dynamic programming table μ^e_{pq} is considered. The index p denotes the hidden state ($1 \leq p \leq n_h$) and q refers to the observation ($1 \leq q \leq n_o$). For example the first component of μ corresponds to the DP table μ^e_{11}. In practice each cell of the DP

table correspond to a node of the HMM trellis. At the same time another $n_h \times m$ DP table, denoted by π, is considered and filled in a way that each element $\pi(i,j)$ contains the number of all possible paths in the HMM trellis terminating at position (i,j). Then a recursive relation is considered to compute each element $\mu^e_{pq}(i,j)$, $\forall 1 \leq j \leq m$, $\forall 1 \leq i \leq n_h$. Basically at step (i,j) the mean value $\mu^e_{pq}(i,j)$ is given summing the occurrences of emission probabilities e_{pq} at the previous steps (e.g., $\sum_i \mu^e_{pq}(i,j-1)\pi(i,j-1)$) with the number of paths in the previous steps (if the current observation x_j is q and the current state y_j is p) and dividing this quantity by $\pi(i,j)$.

In a similar way the mean values associated to the transition probabilities are computed. Dynamic programming tables μ^t_{pz}, $1 \leq p,z \leq n_h$ are filled with recursive formulas in Algorithm 4 in appendix E.

Analogously the elements of the covariance matrix C can be obtained. We have five sets of values: variances of emission probabilities (c^e_{pq}, $1 \leq p \leq n_h, 1 \leq q \leq n_o$), variances of transition probabilities (c^t_{pz}, $1 \leq p,z \leq n_h$), covariances of emission probabilities ($c^e_{pqp'q'}$, $1 \leq p,p' \leq n_h, 1 \leq q,q' \leq n_o$), covariances of transition probabilities ($c^t_{pzp'z'}$, $1 \leq p,p',z,z' \leq n_h$) and mixed covariances ($c^{et}_{pqp'z}$, $1 \leq p,p',z \leq n_h, 1 \leq q \leq n_o$). To determine each of them we consider (4) and we compute the values v^e_{pq}, v^t_{pz}, $v^e_{pqp'q'}$, $v^t_{pzp'z'}$ and $v^{et}_{pqp'z}$ since the mean values are already known. This computation is again performed following Algorithm 1 but with recursive relations given in Algorithm 4, in appendix E (the number 5, 11, 12 in Algorithm 4 are meant to indicate the lines of Algorithm 1 where the formulas must be inserted).

Algorithm 1 Computation of μ^e_{pq} for sequence labeling learning

Input: $\mathbf{x} = (x_1, x_2, ..., x_m)$, p, q.

for $i = 1$ **to** n_h
    $\pi(i,1) := 1$
    if $q = x_1 \wedge p = i$, **then** $\mu^e_{pq}(i,1) := 1$
end
for $j = 2$ **to** m
    for $i = 1$ **to** n_h
        $M := 0$
        $\pi(i,j) := \sum_i \pi(i,j-1)$
        if $q = x_j \wedge p = i$, **then** $M := 1$
        $\mu^e_{pq}(i,j) := \frac{\sum_i (\mu^e_{pq}(i,j-1)+M)\pi(i,j-1)}{\pi(i,j)}$
    end
end

Output: $\frac{\sum_i \mu^e_{pq}(i,m)\pi(i,m)}{\sum_i \pi(i,m)}$

3.2.1 COMPUTATIONAL COST ANALYSIS

At first sight the calculation of μ and C requires running a DP algorithm like Algorithm 1 d times for μ and d^2 times for C. Hence the overall computational cost seems to depend strongly on d. However, most of the DP routines are redundant since many cells of μ and C have the same values. In fact, the following can be shown:

Proposition 3 *The number of dynamic programming routines required to calculate* μ and C *increases linearly with the size of the observation alphabet.*

An outline of proof can be found in appendix A.

Algorithms 1 and 4 assume that the HMM is 'fully connected', that is, transitions are allowed from and to any possible hidden states and every symbol can be emitted in every state. However, this condition is often not satisfied in practical applications. We should point out that their adaptation for such situations is straightforward and involves computing only sums that correspond to allowed paths in the DP table. In this case the number of distinct parameters as well as the computational cost increases with respect to complete models. However this effect may be offset by the fact that each DP becomes less time consuming. Furthermore the mean and the covariance values associated to transition probabilities are independent from observations. To calculate them a closed form expression can be used without the need of running any DP routine.

Moreover usually in most applications the size of the observation alphabet (for example the size of the dictionary in a natural language processing system) is very large while the sequences to be labeled are short. This means that the number of distinct observations in each sequence $\mathbf{x}$ is much lower than n_o. In such cases the number of different values in μ and C scales linearly with it.

We point out that the proposed algorithm can be easily extended to the case of arbitrary features in the vector $\phi(\mathbf{x},\mathbf{y})$ (not only those associated with transition and emission probabilities). To compute μ and C in these situations the derivation of appropriate formulas similar to those of μ^e_{pq}, c^e_{pq} and $c^{et}_{pqp'z}$ is straightforward.

3.2.2 ESTIMATING μ AND C BY RANDOM SAMPLING

Still, the computational cost increases with the number of features since for HMMs that are not 'fully connected', it may occur that the number of different values in the matrix C scales quadratically with the observations alphabet size n_o. However we show that in this case accurate and efficient approximation algorithms can be used to obtain close estimates of the mean and the variance values with a significantly reduced computational cost. This can be achieved by considering a finite subsample of all possible values for the output $\mathbf{y}$, rather than using the DP approaches. This comment holds generally for all learning problems considered in this paper, and we come back to this in the theoretical discussion in 6.1 as well as in the experimental results in 5 to support this claim empirically.

3.3 Sequence Alignment Learning

For the sequence alignment learning task we consider separately the three parameter model, the model with affine gap penalties and the model with substitution matrices.

3.3.1 THE SIMPLEST SCORING SCHEME: MATCH, MISMATCH, GAP

In this model the vector $\mu = [\mu_m\ \mu_s\ \mu_g]^T$ contains the average number of matches, mismatches and gaps computed considering all possible alignments. Its elements can be obtained using Algorithm 2. In a nutshell, the algorithm works as follows. First, a matrix π is filled. Every cell $\pi(i,j)$ contains the number of all possible alignments between two prefixes of the strings S_1 and S_2. In fact each alignment corresponds to a path in the alignment graph associated with the DP matrix. At the same time the DP tables for μ_m, μ_s and μ_g are gradually filled according to appropriate recursive relations.

For example each element $\mu_m(i,j)$ is computed dividing the total number of matches by the number of alignments $\pi(i,j)$. If a match occur in position (i,j) ($M=1$) the total number of matches at step (i,j) is obtained adding to the number of matches in the previous steps ($\mu_m(i,j-1)\pi(i,j-1)$, $\mu_m(i-1,j-1)\pi(i-1,j-1)$ and $\mu_m(i-1,j)\pi(i-1,j)$) $\pi(i-1,j-1)$ times a match. Once the algorithm is terminated, the mean values can be read in the cells $\mu_m(n_1,n_2)$, $\mu_s(n_1,n_2)$ and $\mu_g(n_1,n_2)$.

The covariance matrix C is the 3×3 matrix with elements c_{pq}, $p,q\in\{m,s,g\}$ and it is symmetric ($c_{sg}=c_{gs}$, $c_{mg}=c_{gm}$, $c_{sm}=c_{ms}$). Each value c_{pq} can be obtained considering (4) and computing the associated values v_{pq} with appropriate recursive relations (see Algorithm 2).

3.3.2 AFFINE GAP PENALTIES

As before we can define the vector $\mu=[\mu_m\ \mu_s\ \mu_o\ \mu_e]^T$ and the covariance matrix C as the 4×4 symmetric matrix with elements c_{pq} with $p,q\in\{m,s,o,e\}$. The values of μ and C are computed with DP. In particular μ_m, μ_s, v_{mm}, v_{ms} and v_{ss} are calculated as above, while the other values are obtained with the formulas in Algorithm 5 in appendix E. The terms v_{se} and v_{so} are missing since they can be calculated with the same formulas of v_{me} and v_{mo} simply changing M with $1-M$ and μ_m with μ_s. Note that in some situations for low values of (i,j) some terms are not defined (i.e., $\pi(i,j-3)$ when $j=2$). In such situations they must be ignored in the computation.

3.3.3 EXTENSION TO A GENERAL SCORING MATRIX

The formulas illustrated in the previous paragraphs can be extended to the case of a general substitution matrix with minor modifications. Concerning the mean values, μ_o and μ_e are calculated as before. For the others it is:

$$\mu_{z_{pq}}(i,j):=\frac{\mu_{z_{pq}}(i-1,j)\pi(i-1,j)+\mu_{z_{pq}}(i,j-1)\pi(i,j-1)+(\mu_{z_{pq}}(i-1,j-1)+M)\pi(i-1,j-1)}{\pi(i,j)}$$

where $M=1$ when two corresponding symbols in the alignment are equal to p and q or vice versa with $p,q\in\mathcal{S}$. The matrix C is a symmetric matrix 212×212. The values v_{eo}, v_{ee} and v_{oo} are calculated as above. The derivation of formulas for $v_{z_{pq}z_{p'q'}}$ is straightforward from v_{ms} considering the appropriate values for M and the mean values. The formulas for v_{zo} and v_{ze} follow with minor modification from v_{mo} and v_{me}.

3.4 Learning to Parse

For a given input string $\mathbf{x}$, let μ_p and c_{pq} be the mean of occurrences of rule p and the covariance between the numbers of occurrences of rules p and q, respectively, that is, the elements of μ and C. The following relations hold:

$$\begin{aligned}\mu_p &= \frac{1}{N}\sum_{j=1}^{N}\phi_p(\mathbf{x},\mathbf{y}_j)=\frac{1}{N}\psi_p,\\ nc_{pq} &= \frac{1}{N}\sum_{j=1}^{N}\left(\phi_p(\mathbf{x},\mathbf{y}_j)\phi_q(\mathbf{x},\mathbf{y}_j)\right)-\mu_p\mu_q=\frac{1}{N}\gamma_{pq}-\mu_p\mu_q,\end{aligned}$$

where N is the number of all possible parse trees associated to $\mathbf{x}$, ψ_p is the number of occurrences of the rule p in all the parse tree $\mathbf{y}_j$ given $\mathbf{x}$, and γ_{pq} denotes the cooccurrences of p and q.

To compute C and μ an algorithm based on a bottom-up dynamic programming can be developed. Similarly to sequence labeling three types of recurrence equations must be defined: one to

Algorithm 2 Computation of μ and C with matches, mismatches and gaps.

Input: a pair of sequences S_1 and S_2.

$\pi(0,0) := 1$
$\mu_m(0,0) = \mu_s(0,0) = \mu_g(0,0) := 0$
$v_{mm}(0,0) = v_{ms}(0,0) = v_{ss}(0,0) = v_{sg}(0,0) = v_{mg}(0,0) = v_{gg}(0,0) := 0$
for $i = 1 : n_1$
    $\pi(i,0) := 1$
    $\mu_g(i,0) := \mu_g(i-1,0) + 1$
    $v_{gg}(i,0) := v_{gg}(i-1,0) + 2\mu_g(i-1,0) + 1$
end
for $j = 1 : n_2$
    $\pi(0,j) := 1$
    $\mu_g(0,j) := \mu_g(0,j-1) + 1$
    $v_{gg}(0,j) := v_{gg}(0,j-1) + 2\mu_g(0,j-1) + 1$
end
for $i = 1 : n_1$
    for $j = 1 : n_2$
        $\pi(i,j) := \pi(i-1,j-1) + \pi(i,j-1) + \pi(i-1,j)$
        if $s_1(i) = s_2(j)$ **then** $M := 1$ **else** $M := 0$
        $\mu_m(i,j) := \frac{\mu_m(i-1,j)\pi(i-1,j) + \mu_m(i,j-1)\pi(i,j-1) + (\mu_m(i-1,j-1)+M)\pi(i-1,j-1)}{\pi(i,j)}$
        $\mu_s(i,j) := \frac{\mu_s(i-1,j)\pi(i-1,j) + \mu_s(i,j-1)\pi(i,j-1) + (\mu_s(i-1,j-1)+(1-M))\pi(i-1,j-1)}{\pi(i,j)}$
        $\mu_g(i,j) := \frac{\mu_g(i-1,j)+1)\pi(i-1,j) + (\mu_g(i,j-1)+1)\pi(i,j-1) + \mu_g(i-1,j-1)\pi(i-1,j-1)}{\pi(i,j)}$
        $v_{mm}(i,j) := \frac{1}{\pi(i,j)}(v_{mm}(i-1,j)\pi(i-1,j) + v_{mm}(i,j-1)\pi(i,j-1)$
            $+(v_{mm}(i-1,j-1) + 2M\mu_m(i-1,j-1) + M)\pi(i-1,j-1))$
        $v_{ss}(i,j) := \frac{1}{\pi(i,j)}(v_{ss}(i-1,j)\pi(i-1,j) + v_{ss}(i,j-1)\pi(i,j-1)$
            $+(v_{ss}(i-1,j-1) + 2(1-M)\mu_s(i-1,j-1) + (1-M))\pi(i-1,j-1))$
        $v_{gg}(i,j) := \frac{1}{\pi(i,j)}(v_{gg}(i-1,j) + 2\mu_g(i-1,j) + 1)\pi(i-1,j)$
            $+(v_{gg}(i,j-1) + 2\mu_g(i,j-1) + 1)\pi(i,j-1) + v_{gg}(i-1,j-1)\pi(i-1,j-1))$
        $v_{mg}(i,j) := \frac{1}{\pi(i,j)}(v_{mg}(i-1,j) + \mu_m(i-1,j))\pi(i-1,j) + (v_{mg}(i,j-1)$
            $+\mu_m(i,j-1))\pi(i,j-1) + (v_{mg}(i-1,j-1) + M\mu_g(i-1,j-1))\pi(i-1,j-1))$
        $v_{sg}(i,j) := \frac{1}{\pi(i,j)}(v_{sg}(i-1,j) + \mu_s(i-1,j))\pi(i-1,j) + (v_{sg}(i-1,j-1)$
            $+(1-M)\mu_g(i-1,j-1) + (v_{sg}(i,j-1) + \mu_s(i,j-1))\pi(i,j-1))\pi(i-1,j-1))$
        $v_{ms}(i,j) := \frac{1}{\pi(i,j)}(v_{ms}(i-1,j)\pi(i-1,j) + v_{ms}(i,j-1)\pi(i,j-1)$
            $+(v_{ms}(i-1,j-1) + M\mu_s(i-1,j-1) + (1-M)\mu_m(i-1,j-1))\pi(i-1,j-1))$
    end
end

Output: $\mu_m(n_1,n_2)$, $\mu_s(n_1,n_2)$, $\mu_g(n_1,n_2)$,
    $c_{mm}(n_1,n_2) := v_{mm}(n_1,n_2) - \mu_m(n_1,n_2)^2$,
    $c_{ss}(n_1,n_2) := v_{ss}(n_1,n_2) - \mu_m(n_1,n_2)^2$,
    $c_{gg}(n_1,n_2) := v_{gg}(n_1,n_2) - \mu_m(n_1,n_2)^2$,
    $c_{ms}(n_1,n_2) := v_{ms}(n_1,n_2) - \mu_m(n_1,n_2)\mu_s(n_1,n_2)$,
    $c_{mg}(n_1,n_2) := v_{mg}(n_1,n_2) - \mu_m(n_1,n_2)\mu_g(n_1,n_2)$,
    $c_{sg}(n_1,n_2) := v_{sg}(n_1,n_2) - \mu_s(n_1,n_2)\mu_g(n_1,n_2)$

compute the number of parse trees N, another the number of occurrences ψ of each parameter, and the latter the number of cooccurrences γ of each pair of parameters.

For a given input string $\mathbf{x} = (x_1\ x_2 \ldots\ x_m)$, x_s denotes the s-th symbol of $\mathbf{x}$, and $x_{s|t}$ the substring from the s-th symbol to the t-th symbol. We count the number of possible trees N given $\mathbf{x}$ with a DP algorithm such as the CYK algorithm. We use two types of auxiliary variables, $\pi(s,t,\Upsilon_i)$ and $\pi(s,t,\Upsilon_i,\alpha)$ which are the number of possible parse trees whose root is Υ_i for substring $x_{s|t}$, and the number of possible parse trees whose root is applied to rule $\Upsilon_i \to \alpha$ for substring $x_{s|t}$, where $(\Upsilon_i \to \alpha) \in R$.

Then $\pi(s,t,\Upsilon_i)$ is calculated as follows:

$$\pi(s,t,\Upsilon_i) = \sum_{\alpha:(\Upsilon_i\to\alpha)\in\Upsilon} \pi(s,t,\Upsilon_i,\alpha),$$

where:

$$\pi(s,t,\Upsilon_i,\alpha) \quad = \quad \begin{cases} 1 & \alpha = X \in \Sigma_x,\ s=t, \text{ and } X = x_s, \\ \sum_{r=s}^{t-1} \pi(s,r,\Upsilon_{k_1})\pi(r+1,t,\Upsilon_{k_2}) & \alpha = \Upsilon_{k_1}\Upsilon_{k_2} \text{ and } s<t, \\ \pi(s,t,\Upsilon_k) & \alpha = \Upsilon_k, \\ \pi(s+1,t-1,\Upsilon_k) & \alpha = X\Upsilon_k X',\ X = x_s, \text{ and } X' = x_t, \\ 0 & \text{otherwise.} \end{cases}$$

Upon completion of the recursion, $N = \pi(1,m,S)$ is the number of all possible parse trees given $\mathbf{x}$.

We then count the number of occurrences of each rule in all possible parse trees. $\psi_p(s,t,\Upsilon_i)$ denotes the number of occurrences of rule p in all possible parse trees whose root is Υ_i for $x_{s|t}$. We compute $\psi_p(s,t,\Upsilon_i)$ as follows:

$$\psi_p(s,t,\Upsilon_i) = \sum_{\alpha:(\Upsilon_i\to\alpha)\in\Upsilon} \psi_p(s,t,\Upsilon_i,\alpha),$$

where:

$$\begin{aligned} &\psi_p(s,t,\Upsilon_i,\alpha) \\ &= \begin{cases} 1 & \alpha = X = x_s,\ s=t, \\ & \text{and } p = \Upsilon_i \to X, \\ \sum_{r=s}^{t-1} (\psi_p(s,r,\Upsilon_{k_1})\pi(r+1,t,\Upsilon_{k_2}) & \\ \quad +\pi(s,r,\Upsilon_{k_1})\psi_p(r+1,t,\Upsilon_{k_1})) & \\ \quad +I(p,\Upsilon_i\to\alpha)\pi(s,r,\Upsilon_{k_1})\pi(r+1,t,\Upsilon_{k_2}) & \alpha = \Upsilon_{k_1}\Upsilon_{k_2}, \text{ and } s<t, \\ \psi_p(s,t,\Upsilon_k) + I(p,\Upsilon_i\to\alpha)\pi(s,t,\Upsilon_k) & \alpha = \Upsilon_k, \\ \psi_p(s+1,t-1,\Upsilon_k) + I(p,\Upsilon_i\to\alpha)\pi(s+1,t-1,\Upsilon_k) & \alpha = X\Upsilon_k X' \text{ and } s+1<t, \\ 0 & \text{otherwise.} \end{cases} \end{aligned}$$

with $I(p,\Upsilon_i\to\alpha) = 1$ if $p = (\Upsilon_i \to \alpha)$, otherwise it is $I(p,\Upsilon_i\to\alpha) = 0$. Then, $\psi_p(1,m,S)$ is the number of occurrences of p in all parse trees given $\mathbf{x}$.

We count the number of cooccurrences $\gamma_{pq}(s,t,\Upsilon_i)$ in each pair p and q of rules. $\gamma_{pq}(s,t,\Upsilon_i,\alpha)$ denotes the number of cooccurrences in all possible parse trees whose root is Υ_i for $x_{s|t}$. We calculate $\gamma_{pq}(s,t,\Upsilon_i)$ as follows:

$$\gamma_{pq}(s,t,\Upsilon_i) = \sum_{\alpha:(\Upsilon_i\to\alpha)\in\Upsilon} \gamma_{pq}(s,t,\Upsilon_i,\alpha),$$

where:

$$
\gamma_{pq}(s,t,\Upsilon_i,\alpha)
$$

$$
= \begin{cases}
0 & \alpha = X \text{ and } p \neq q, \\
1 & \alpha = X \text{ and } p = q = (\Upsilon_i \rightarrow \alpha), \\
\sum_{r=s}^{t-1} \Big(\gamma_{pq}(s,r,\Upsilon_{k_1})\pi(r+1,t,\Upsilon_{k_2}) & \\
+\pi(s,r,\Upsilon_{k_1})\gamma_{pq}(r+1,t,\Upsilon_{k_2}) & \\
+\psi_p(s,r,\Upsilon_{k_1})\psi_q(r+1,t,\Upsilon_{k_2}) & \\
+\psi_q(s,r,\Upsilon_{k_1})\psi_p(r+1,t,\Upsilon_{k_2}) & \\
+I(p,\Upsilon_i \rightarrow \alpha) f(p,s,r,t,\Upsilon_{k_1},\Upsilon_{k_2}) & \\
+I(q,\Upsilon_i \rightarrow \alpha) f(q,s,r,t,\Upsilon_{k_1},\Upsilon_{k_2}) & \\
+I(p,\Upsilon_i \rightarrow \alpha) I(q,\Upsilon_i \rightarrow \alpha)\pi(s,r,\Upsilon_{k_1})\pi(r+1,t,\Upsilon_{k_2}) \Big) & \alpha = \Upsilon_{k_1}\Upsilon_{k_2} \text{ and } s < t, \\
\gamma_{pq}(s,t,\Upsilon_k) & \\
+I(p,\Upsilon_i \rightarrow \alpha)\psi_q(s,t,\Upsilon_i) + I(q,\Upsilon_i \rightarrow \alpha)\psi_p(s,t,\Upsilon_i) & \\
+I(p,\Upsilon_i \rightarrow \alpha) I(q,\Upsilon_i \rightarrow \alpha)\pi(s,t,\Upsilon_i) & \alpha = \Upsilon_k, \\
\gamma_{pq}(s+1,t-1,\Upsilon_k) & \\
+I(p,\Upsilon_i \rightarrow \alpha)\psi_q(s+1,t-1,\Upsilon_k) & \\
+I(q,\Upsilon_i \rightarrow \alpha)\psi_p(s+1,t-1,\Upsilon_k) & \\
+I(p,\Upsilon_i \rightarrow \alpha) I(q,\Upsilon_i \rightarrow \alpha)\pi(s+1,t-1,\Upsilon_k) & \alpha = X\Upsilon_k X',\ s+1 < t, \\
 & x_s = X, \text{ and } x_t = X', \\
0 & \text{otherwise}
\end{cases}
$$

with $f(p,s,r,t,\Upsilon_{k_1},\Upsilon_{k_2}) = \psi_p(s,r,\Upsilon_{k_1})\pi(r+1,t,\Upsilon_{k_2}) + \pi(s,r,\Upsilon_{k_1})\psi_p(r+1,t,\Upsilon_{k_2})$. Finally, $\gamma_{pq}(1,m,S)$ is the number of cooccurrences of rules p and q in all parse trees given $\mathbf{x}$.

In the following section we discuss how we can use the computed first and second order statistics to define a suitable objective function which can be optimized for structured output learning tasks.

4. Moment-based Approaches to Structured Output Prediction

Suppose we have a training set of input-output pairs $\mathcal{T} = \{(\mathbf{x}^1,\overline{\mathbf{y}}^1),(\mathbf{x}^2,\overline{\mathbf{y}}^2),\ldots,(\mathbf{x}^\ell,\overline{\mathbf{y}}^\ell)\}$. The task we consider is to find the parameter values θ such that the optimal given output variables $\overline{\mathbf{y}}^i$ can be reconstructed from $\mathbf{x}^i$, $\forall\ 1 \leq i \leq \ell$. We want to fulfill this task by defining a suitable objective function which is a convex function of the first and second order statistics we presented before. Based on this idea we introduce two possible approaches.

4.1 Training Sets of Size One

To give an intuition of the main idea behind both methods, we first analyze the situation where the training set in made of only one pair $(\mathbf{x},\overline{\mathbf{y}})$. In this situation, both methods are identical to each other.

The idea is to consider the distribution of the scores for all possible $\mathbf{y}$. We then define a measure of separation between the score of the correct training output, and the entire distribution of all scores for all possible outputs. More specifically, the objective function we propose is the difference between the score of the true output and the mean score of the distribution, divided by the square root of the variance as a normalization. Mathematically:

$$
\max_{\theta} \frac{s_\theta(\mathbf{x},\overline{\mathbf{y}}) - M_{1,\theta}(\mathbf{x})}{\sqrt{M_{2,\theta}(\mathbf{x})}} \quad = \quad \max_{\theta} \frac{\theta^T b}{\sqrt{\theta^T C \theta}} \tag{5}
$$

where $b = \phi(\mathbf{x}, \overline{\mathbf{y}}) - \mu$ is the difference between the feature vector associated to the optimal output and the average feature vector μ. Maximizing this objective over θ means that we search for a parameter vector θ that makes the score of the correct output $\overline{\mathbf{y}}$ as different as possible from the mean score, measured in number of standard deviations. This corresponds to a well known quantity in statistics: the Z-score. Given the distribution of all possible scores (i.e., given its mean and its variance), the Z-score of the correct pair $(\mathbf{x}, \overline{\mathbf{y}})$ is defined as the number of standard deviations its score $s(\mathbf{x}, \overline{\mathbf{y}})$ is away from the mean of the distribution.

The Z-score is an interesting measure of separation between the correct output and the bulk of all possible outputs corresponding to a given input. Under normality assumptions, it is directly equivalent to a *p*-value. Hence, maximizing the Z-score can be interpreted as maximizing the significance of the score of the correct pair: the larger the Z-score, the more significant it is, and the fewer other outputs would achieve a larger score. If the normality assumption is too unrealistic, one could still apply a (looser) Chebyshev tail bound to show that the number of scores that exceed the score of a large training output score $s_\theta(\mathbf{x}, \overline{\mathbf{y}})$ is small.

To quantify this connection between the Z-score of a training pair and the rank of its score among all other scores, we would like to introduce an alternative formulation for optimization problem (5).

Proposition 4 *Optimization problem (5) is equivalent to:*

$$\begin{array}{rl} \min_\theta & \frac{1}{N}\sum_{j=1}^N \xi_j^2 \\ s.t. & \theta^T\left(\phi(\boldsymbol{x},\overline{\boldsymbol{y}}) - \phi(\boldsymbol{x},\boldsymbol{y}_j)\right) = 1 + \xi_j \quad \forall j \end{array} \tag{6}$$

in the sense that it is optimized by the same value of θ *or a scalar multiple of it.*

Proof Substituting ξ_j from the constraint in the objective, the objective of optimization problem (6) is equivalent to:

$$\begin{aligned} & \frac{1}{N}\theta^T \sum_{j=1}^N (\phi(\mathbf{x},\overline{\mathbf{y}}) - \phi(\mathbf{x},\mathbf{y}_j))(\phi(\mathbf{x},\overline{\mathbf{y}}) - \phi(\mathbf{x},\mathbf{y}_j))^T\theta - \frac{2}{N}\theta^T \sum_{j=1}^N (\phi(\mathbf{x},\overline{\mathbf{y}}) - \phi(\mathbf{x},\mathbf{y}_j)) + 1 \\ = \;& \frac{1}{N}\theta^T \sum_{j=1}^N (\mu - \phi(\mathbf{x},\mathbf{y}_j))(\mu - \phi(\mathbf{x},\mathbf{y}_j))^T\theta + \theta^T(\phi(\mathbf{x},\overline{\mathbf{y}}) - \mu)(\phi(\mathbf{x},\overline{\mathbf{y}}) - \mu)^T\theta \\ & -2(\phi(\mathbf{x},\overline{\mathbf{y}}) - \mu) + 1 \\ = \;& \theta^T C\theta + (\theta^T b - 1)^2. \end{aligned}$$

Hence, the optimization problem (6) is equivalent to:

$$\min_\theta \quad \theta^T C\theta + (\theta^T b - 1)^2.$$

Now, note that the objective in optimization problem (5) is invariant with respect to scaling of θ. Hence, we can fix the scale arbitrarily, and require $\theta^T b = 1$. The optimization problem then reduces to (using the monotonicity of the square root):

$$\begin{array}{rl} \min_\theta & \theta^T C\theta \\ \text{s.t.} & \theta^T b = 1. \end{array}$$

The optimality conditions of the former are $C\theta + bb^T\theta = b \Leftrightarrow C\theta = (1 - b^T\theta)b$, and the Lagrange optimality conditions of the latter are $C\theta = \lambda b$ with λ a Lagrange multiplier. Hence, both optimality conditions and optimization problems are equivalent in the sense that they are optimized by the

same θ up to a scaling factor. ■

The following interesting theorem now establishes the link between the relative ranking loss $\mathcal{L}_\theta^{RR}$ as defined in Section 2.2 and the above optimization problem.

Theorem 5 (Relative ranking loss upper bound) *Let us denote by $\mathcal{L}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}})$ the value of the objective of optimization problem (6) evaluated on training pair $(\boldsymbol{x},\bar{\boldsymbol{y}})$:*

$$\mathcal{L}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}}) \quad = \quad \frac{1}{N}\sum_{j=1}^{N}\xi_i^2 = \frac{1}{N}\sum_{j=1}^{N}\left(\theta^T\left(\phi(\boldsymbol{x},\bar{\boldsymbol{y}})-\phi(\boldsymbol{x},\boldsymbol{y}_j)\right)-1\right)^2.$$

Then,

$$\mathcal{L}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}}) \geq \mathcal{L}_\theta^{RR}(\boldsymbol{x},\bar{\boldsymbol{y}}).$$

(The RRU in the superscript stands for Relative Ranking Upper bound.)

Proof The rank of $s_\theta(\mathbf{x},\bar{\mathbf{y}})$ among all $s_\theta(\mathbf{x},\mathbf{y}_j)$ for all possible $\mathbf{y}_j$ is given by the number of $\mathbf{y}_j$ for which $\theta^T\left(\phi(\mathbf{x},\bar{\mathbf{y}})-\phi(\mathbf{x},\mathbf{y}_j)\right)\leq 0$. Hence, this is the number of times that $\xi_i \leq -1$ in optimization problem (6), such that the objective is at least as large as the rank divided by N, that is, the relative rank. ■

Additionally, we would like to point out that optimization problem (5) and equivalently (6) is also strongly connected to Fisher's discriminant analysis (FDA). Intuitively, maximizing our objective function corresponds to maximizing the distance between the mean of the distribution of the scores for all possible incorrect pairs and the 'mean' of the 'distribution' of the score for the single correct output, normalized by the sum of the standard deviations (note that one class reduces to one data point so the associated standard deviation is zero). Then (5) is equivalent to performing FDA when one class reduces to a single data point as defined by the correct training label.

4.2 Training Sets of General Sizes

Having introduced the main idea on the special case of a training set of size 1, we now turn back to the general situation where we are interested in computing the optimal parameter vector given a training set $\mathcal{T}$ of ℓ pairs of sequences. We will consider two different generalizations to which we refer as the Z-score based approach, and as structured output discriminant analysis (SODA).

4.3 Z-score Based Algorithm

In the first generalization, we will emphasize the Z-score interpretation. For training sets containing more than one input-output pair, we need to redefine the Z-score for a set of ℓ pairs of sequences $\mathcal{T}=\{(\mathbf{x}^1,\bar{\mathbf{y}}^1),(\mathbf{x}^2,\bar{\mathbf{y}}^2),\ldots,(\mathbf{x}^\ell,\bar{\mathbf{y}}^\ell)\}$. A natural way is to do this based on the global score: the sum of the scores for all sequence pairs in the set. Its mean is the sum of the means for all sequence pairs $(\mathbf{x}^i,\bar{\mathbf{y}}^i)$ separately, and can be summarized by $\bar{b}=\sum_i b_i$. Similarly, for the covariance matrix: $\bar{C}=\sum_i C_i$. Hence, the Z-score definition can naturally be extended to more than one input-output pair by using $\bar{b}$ and $\bar{C}$ instead of b and C in (5). In summary, extending the optimization problem (5) to the general situation of a given training set $\mathcal{T}$, the optimization problem we are interested in is:

$$\max_\theta \quad \frac{\theta^T\bar{b}}{\sqrt{\theta^T\bar{C}\theta}}. \tag{7}$$

The solution of (7) can be computed by simply solving the linear system $\bar{C}\theta = \bar{b}$, where $\bar{C}$ is a symmetric positive definite matrix. If $\bar{C}$ is not symmetric positive definite, regularization can be introduced in a straightforward way (similar as in FDA) by solving $(\bar{C} + \lambda I)\theta = \bar{b}$ instead. This effectively amounts to restricting the norm of θ to small values. Then the optimal parameter vector can be obtained extremely efficiently by using iterative methods such as the conjugate gradient method.

4.3.1 INCORPORATING THE HAMMING DISTANCE

A nice property of this approach is that it can be extended to take into account the Hamming distance between the output vectors. For each pair $(\mathbf{x}, \mathbf{y})$ we consider the score:

$$s(\mathbf{x}, \mathbf{y}) = \theta^T \phi(\mathbf{x}, \mathbf{y}) + \delta_H(\mathbf{y}, \bar{\mathbf{y}}) = \theta'^T \phi'(\mathbf{x}, \mathbf{y})$$

where we have defined the vectors $\theta'^T = \begin{bmatrix} \theta^T & 1 \end{bmatrix}$ and $\phi'(\mathbf{x}, \mathbf{y})^T = \begin{bmatrix} \phi(\mathbf{x}, \mathbf{y})^T & \delta_H(\mathbf{y}, \bar{\mathbf{y}}) \end{bmatrix}$. It is easy to verify that the associated optimization problem has the same form of (7) when the vectors θ' and ϕ' are considered. In practice the covariance matrix C is augmented with one column (and one row, since it is symmetric) containing the covariance values between the loss term and all the other parameters. We refer to this column as c_δ. Analogously the mean vector is augmented by one value (μ_δ) that represents the mean value of the terms $\delta_H(\mathbf{y}, \bar{\mathbf{y}})$ computed along all negative pseudoexamples. When the Hamming distance is adopted the computation of μ_δ and c_δ can be realized with DP algorithms. For example for sequence labeling learning Algorithm 1 is used with recursive relations similar to those in Algorithm 4.

4.3.2 Z-SCORE APPROACH WITH CONSTRAINTS

As a side remark, let us draw a connection with existing MM approaches such as described in Taskar et al. (2003) and in Tsochantaridis et al. (2005).

Their approach to structured output learning is to explicitly search for the parameter values θ such that the optimal hidden variables $\bar{\mathbf{y}}^i$ can be reconstructed from $\mathbf{x}^i$, $\forall 1 \leq i \leq \ell$. In formulas these conditions can be expressed as:

$$\theta^T \phi(\mathbf{x}^i, \bar{\mathbf{y}}^i) \geq \theta^T \phi(\mathbf{x}^i, \mathbf{y}^i_j) \quad \forall 1 \leq i \leq \ell \quad \forall 1 \leq j \leq N_i. \tag{8}$$

This set of constraints defines a convex set in the parameter space and its number is massive, due to the huge size of the output space. To obtain an optimal set of parameters θ that successfully fulfill (8) usually an optimization problem is formulated with these constraints, together with a suitable objective function. In MM approaches for example this objective function is typically chosen to be the squared norm of the parameter vector.

Interestingly, using the Z-score as objective function, we observe that most (and often all) of the constraints (8) are satisfied automatically, which often leads to a satisfactory result with a good generalization performance without considering the constraints explicitly.

However, in the cases where the result of (7) still violates some of the constraints and one wishes to avoid this, one can choose to impose these explicitly. The resulting optimization problem is still convex and it reduces to:

$$\begin{aligned} \min_\theta \quad & \theta^T \bar{C} \theta \\ \text{s.t.,} \quad & \theta^T \bar{b} \geq 1 \\ & \theta^T \phi(\mathbf{x}^i, \bar{\mathbf{y}}^i) \geq \theta^T \phi(\mathbf{x}^i, \mathbf{y}^i_j) \quad \forall 1 \leq i \leq \ell \quad \forall 1 \leq j \leq N_i. \end{aligned} \tag{9}$$

We have developed an incremental algorithm that implements problem (9), shown in Algorithm 3 (see Tsochantaridis et al., 2005, for a similar approach and a more detailed study). First a feasible solution is determined without adding any constraints. Then the following steps are repeated until convergence. For each training example, the most likely hidden variables are determined by a Viterbi-like algorithm. If its score is higher than the given one, the associated constraint is added to the set of constraints of the problem (9) and (9) is solved. The convergence is guaranteed from the convexity of the problem. Each added constraint provides the effect of restricting the feasible region.

Algorithm 3 Iterative algorithm to incorporate the active constraints.

Input: The training set $\mathcal{T} = \{(\mathbf{x}^1, \overline{\mathbf{y}}^1)(\mathbf{x}^2, \overline{\mathbf{y}}^2) \dots (\mathbf{x}^\ell, \overline{\mathbf{y}}^\ell)\}$

$\mathcal{C} := \oslash$
for $i = 1, \dots, \ell$ compute $\underline{b}_i$ and C_i
Compute $\underline{b} := \sum_i b_i$ and $\overline{C} := \sum_i C_i$
Find θ_{opt} solving (7)
Repeat
  $exit := 0$
  for $i = 1, \dots, \ell$
    Compute $\tilde{\mathbf{y}}^i := \arg\max_{\mathbf{y}} \ \theta_{opt}^T \phi(\mathbf{x}^i, \mathbf{y})$
    If $\theta_{opt}^T(\phi(\mathbf{x}^i, \overline{\mathbf{y}}^i) - \phi(\mathbf{x}^i, \tilde{\mathbf{y}}^i)) \leq 0$
      $exit := 1$
      $\mathcal{C} := \mathcal{C} \cup \{\theta^T(\phi(\mathbf{x}^i, \overline{\mathbf{y}}^i) - \phi(\mathbf{x}^i, \tilde{\mathbf{y}}^i)) \geq 0\}$
      Find θ_{opt} solving (7) s.t. $\mathcal{C}$
    end
  end
until $exit = 1$

Output: θ_{opt}

Often, real data sets do not allow a feasible solution θ. A possible way to deal with this problem is by the introduction of slack variables or relaxing the constraints by requiring the inequalities to hold subject to the small possible used-defined tolerance ε (Ricci et al., 2007). However, we argue that in such cases simply optimizing the Z-score as described earlier without adding any constraints may offer a natural and computationally attractive alternative to using soft-margin constraints.

4.3.3 RELATED WORK

It is worth noting that the Z-score has previously been used in the context of sequence alignment, although in previous work it was computed with respect to different distributions. In Doolittle (1981) Z-scores are used to assess the significance of a pairwise alignment between two aminoacid sequences and are computed calculating the mean and the standard deviation values over a random sample taken from a standard database or obtained permuting the given sequence. A high Z-score corresponds to an alignment that is less likely to occur by chance and therefore biologically significant.

To our knowledge, there are no methods to calculate the Z-scores on a set of random sequences in exact way. The only attempt to this aim is due to Booth et al. (2004). They proposed an efficient algorithm that finds the standardized score in the case of permutations of the original sequences but this approach is limited to the ungapped sequences. We have to stress that we consider a much wider range of applications (not only sequence alignment) and a slightly different definition of the Z-score: for example, for sequence alignment for each pair of given sequences the mean and standard deviation are computed over the set of all possible alignments (also with gaps and not only the optimal ones) without any permutations.

4.4 SODA: Structured Output Discriminant Analysis

Another way to extend problem (5) to the general situation of a training set $\mathcal{T}$ is to minimize the empirical risk associated to the upper bound on the relative ranking loss $\mathcal{R}^{RRU}$, defined in the usual way as:

$$\mathcal{R}_\theta^{RRU}(\mathcal{T}) \quad = \quad \sum_{i=1}^{\ell} \mathcal{L}_\theta^{RRU}(\mathbf{x}^i, \overline{\mathbf{y}}^i).$$

This simple summing of the loss for individual data points leaves the connection with FDA more intact, hence the name SODA for structured output discriminant analysis. As usual in empirical risk minimization, the hope is that minimizing the empirical risk will ensure that the expected loss $E_{(\mathbf{x},\bar{\mathbf{y}})}\left\{\mathcal{L}_\theta^{RRU}(\mathbf{x},\overline{\mathbf{y}})\right\}$ (here the relative ranking loss) is small as well, and we will shortly prove that this is the case in 6.1. Filling everything in, the resulting empirical risk minimization problem becomes:

$$\begin{aligned} \min_\theta \quad & \sum_{i=1}^{\ell} \frac{1}{N_i} \sum_{j=1}^{N_i} \xi_{ij}^2 \\ \text{s.t.} \quad & \theta^T(\phi(\mathbf{x}^i, \overline{\mathbf{y}}^i) - \phi(\mathbf{x}^i, \mathbf{y}_j^i)) = 1 + \xi_{ij} \quad \forall i. \end{aligned} \tag{10}$$

This is the optimization problem we solve in SODA. To solve it easily, and to elucidate more clearly the analogy with the Z-score approach, we rewrite it one more time as follows.

Proposition 6 *Optimization problem (10) is equivalent to:*

$$\max_\theta \frac{\theta^T b^*}{\sqrt{\theta^T C^* \theta}} \tag{11}$$

where we have defined $b^* = \sum_i b_i$ and $C^* = \sum_i (C_i + b_i {b_i}^T)$. Here, by equivalent we mean that the optimal values for θ differ by a constant scaling factor only. It can be solved efficiently by solving the linear system of equations $C^*\theta = b^*$.

Note that this optimization problem has the same shape as (7) and can be solved again with conjugate gradient algorithms.

Proof We can follow exactly the same procedure as in the proof of Theorem 5 to show that optimization problem (11) is equivalent with:

$$\begin{aligned} \min_\theta \sum_{i=1}^{\ell} \theta^T C_i \theta + (\theta^T b_i - 1)^2 \quad & \Leftrightarrow \quad \min_\theta \theta^T \sum_{i=1}^{\ell} (C_i + b_i b_i^T)\theta - 2\theta^T \sum_{i=1}^{\ell} b_i + 1 \\ & \Leftrightarrow \quad \min_\theta \theta^T C^* \theta - 2\theta b^* + 1. \end{aligned}$$

	MM	HMP	CRFs
Z-score	$5.67e^{-11}$	$1.97e^{-7}$	0.016
SODA	$5.12e^{-10}$	$3.13e^{-6}$	0.04

Table 1: p-values for level of noise $p = 0.4$ and for an HMM with $n_h = 2$ and $n_o = 4$.

The optimality conditions is $C^*\theta = b^*$. In a similar way as in the proof of Theorem 5, we can show that the optimality conditions of optimization problem (10) are given by $C^*\theta = \lambda b^*$, leading to the same value for θ after appropriate scaling. ■

5. Experimental Results

In this subsection we provide some experimental results for the three illustrative examples proposed: sequence labeling, sequence alignment and sequence parse learning.

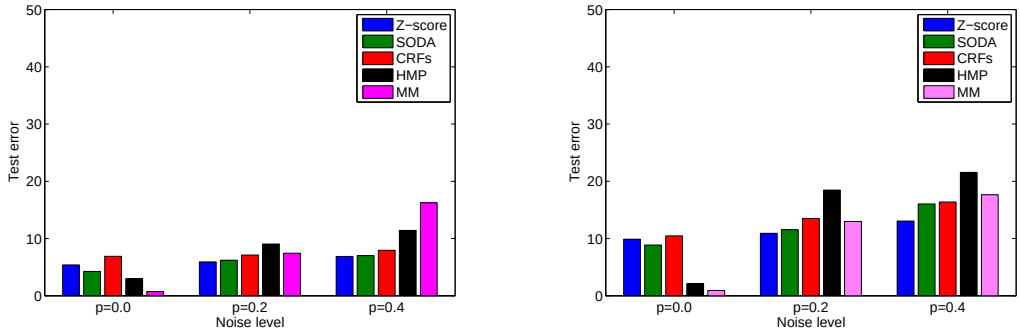
5.1 Sequence Labeling Learning

The first series of experiments, developed in the context of sequence labeling learning, analyzes the behavior of the Z-score based algorithm and of the SODA using both artificial data and sequences of text for named entity recognition. The main aim of this section is to compare our approaches with other existing DLAs on small and medium size data sets.

5.2 Simulation Results

We first present experiments that demonstrate the robustness of our approaches in problems with an increasing degree of noise. We consider two different HMMs, one with $n_h = 2$, $n_o = 4$ and one with $n_h = 3$, $n_o = 5$, with assigned transition and emission probabilities. For these models, we generate hidden and observed sequences of length 100. The training set size is fixed to 20 pairs, while the test set is made up of 100 pairs. Then we add some noise with probabilities $p \in [0,1]$ flipping labels in hidden sequences. More specifically we consider three different scenarios: absence of noise ($p = 0$), moderate level of noise ($p = 0.2$) and noisy data ($p = 0.4$). After learning the parameter, the labeling error (average number of incorrect labels) is measured. We observe the performance of the proposed approaches in comparison with other DLAs such as CRFs, hidden Markov perceptron (HMP) and a MM method with Hamming loss (SVM-struct implementation Tsochantaridis et al., 2005) and linear kernel. The regularization parameters associated to each method are determined based on the performance on a separate validation set of 100 sequences generated together with the training and the test sets. Results are averaged over 1000 training/test samples. In both cases our algorithms outperform other methods for high level of noise, as can be expected (Fig. 4). We also observe slightly better performance of the SODA with respect to the Z-score based algorithm for low p values while with the Z-score a smaller test error is achieved with very noisy data.

To assess the significance of the results obtained comparing our methods with the other DLAs we also run some paired t-tests and compute the associated p-values for both the HMM models and all the levels of noise. Here we only show the p-values obtained by the experiments with high level



(a) (b)

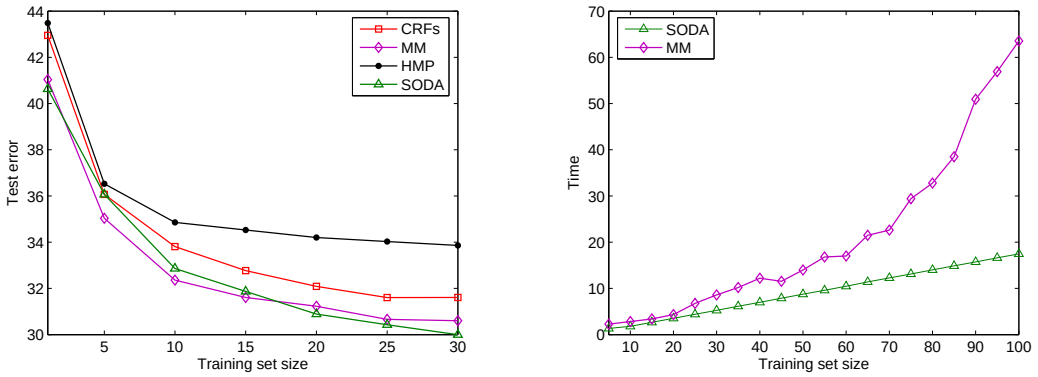
Figure 4: Average number of incorrect labels at varying level of noise for an HMM with (a) $n_h = 2$ and $n_o = 4$ and (b) $n_h = 3$ and $n_o = 5$.

	MM	**HMP**	**CRFs**
Z-score	$11.11e^{-6}$	$3.01e^{-12}$	0.0076
SODA	$8.8e^{-4}$	$5.45e^{-10}$	0.16

Table 2: p-values for level of noise $p = 0.4$ and for an HMM with $n_h = 3$ and $n_o = 5$.

of noise (Tab. 1 and Tab. 2) in order to demonstrate that our approaches significantly outperforms HMP and the MM algorithm in situations where data are noisy. In this scenario SODA and Z-score achieve better performance than CRFs even if in this case the difference of the test error is less evident. On the other hand we also observe that for separable data (absence of noise) the MM algorithm does significantly better than our algorithms (e.g., for the HMM model with $n_h = 2$ and $n_o = 4$ the p-value is $5.04e^{-9}$ for SODA and $1.06e^{-11}$ for the Z-score algorithm). A similar situation occurs also for the HMP (e.g., for the HMM model with $n_h = 2$ and $n_o = 4$ the p-value is $8.65e^{-5}$ for SODA and $4.86e^{-6}$ for the Z-score algorithm). However SODA and Z-score approach still outperform CRFs (e.g., for the HMM model with $n_h = 2$ and $n_o = 4$ the p-value is $3.51e^{-4}$ for SODA and $2.53e^{-3}$ for the Z-score algorithm).

For this series of experiments we also depict some typical learning curves computed for all DLAs considered. We show the curves associated to a HMM model with $n_h = 3$, $n_o = 5$, sequences of length equal to 50 and noise level $p = 0.2$. In this case for the MM algorithm the soft margin parameter C is set equal to 1 and a constant $\varepsilon = 10^{-12}$ specifies the accuracy for constraints to be satisfied. The maximum number of iterations of the averaged perceptron is $T = 100$. CRFs are optimized using a conjugate gradient method. Concerning our approaches we plot results just for the SODA since in this situation (moderate quantity of noise) the learning curves for the Z-score algorithm is almost superimposed to the SODA's one. For the SODA the regularization parameter is $\lambda = 10^{-8}$. The SODA performs better than other methods and among the competing DLAs, the MM approach provides the best performance (Fig. 5.a). Moreover if for the same experiment we also examine the training time we observe (Fig. 5.b) that SODA is definitely faster than the MM algorithm especially for larger data sets.



(a) (b)

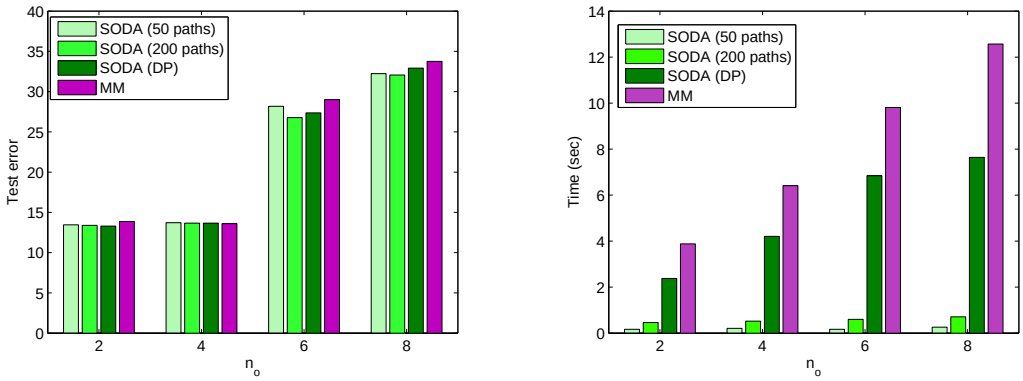
Figure 5: (a) Average number of incorrect labels and (b) computational time as function of the training set size for an HMM with $n_h = 3$ and $n_o = 5$.

A further series of experiments have been conducted to confirm the theoretical results presented in the previous subsection, that is, we want to show that learning with SODA is effectively achieved when mean and covariance matrices are estimated considering just a small subset of incorrect outputs (i.e., incorrect hidden label sequences), taken by random sampling. In fact in the situations where the size of the hidden and the observed space is large and long sequences must be considered, the computation of b^* and C^* with DP can be quite time consuming. Then using random sampling, the computational burden of DP is avoided and the labeling accuracy is still reasonably high, if a sufficient number of possible outputs is sampled. To support this claim we conduct the following experiment. Sequences of length 10 are considered. The training set is fixed to 50 pairs, the test set contains 100 pairs. Sequence pairs are generated with a level of noise $p = 0.2$ obtained by flipping labels. We pick various HMMs: the hidden alphabet size is fixed, $n_h = 3$, while n_o varies. The average labeling error on test set and the time required for computation are reported for SODA with exact matrices, when matrices are computed on a set of 50 and 200 random paths and for the MM method. Results are shown in Fig. 6. While the performance in terms of labeling error are essentially the same for all the algorithms (Fig. 6.a), the computational advantage considering the training time for the sampling approaches is considerable (Fig. 6.b).

5.3 Named Entity Recognition

The second series of experiments have been performed in the context of named entity recognition (NER). In NER phrases in text must be classified as belonging to predefined categories such as persons, organizations, locations, temporal and numerical expressions.

We consider 300 sentences extracted from the Spanish news wire article corpus used for the Special Session of CoNLL2002 on NER. Our subset contains more than 7000 tokens (about 2000 unique) and each sentence has an average length of 30 words. The hidden alphabet is limited to $n_h = 9$ different labels, since the expression types are only persons, organizations, locations and miscellaneous names. Our aim here is not to compete with large scale NER systems but to perform comparison with previous methods so we deliberately choose a small subset and an experimental



(a) (b)

Figure 6: (a) Labeling error on test set and (b) average training time as function of the observation alphabet size n_o.

setup similar to that in Altun et al. (2003b). We perform experiments into different settings: HMM features (the parameters to be determined are the transition and emission probabilities) ($\mathcal{S}_1$) and HMM features of the previous and the next words ($\mathcal{S}_2$). Experiments have been made with a 5-fold cross validation. We compare the performances of our approaches with CRFs, HMP and the MM algorithm with Hamming loss in (Altun et al., 2003b). For the SODA and the Z-score algorithm the regularization parameter is $\lambda = 10^{-8}$. For CRFs we used a public available software (Kudo, 2005) where a quasi-newton optimization technique method is used for optimization. For the MM algorithm a linear kernel is considered, $C = 1$ and $\varepsilon = 0.01$. The number of iterations of the HMP is $T = 200$.

The test errors, reported in Tab. 3, demonstrate the competitiveness of the proposed methods. SODA outperforms all the other approaches for $\mathcal{S}_1$, while it performs slightly worse than the MM algorithm for features $\mathcal{S}_2$. On the other hand for $\mathcal{S}_2$ the best performance is obtained by the Z-score algorithm.

Since the length of feature vectors is large, our approaches are generally slower than MM methods. For very large numbers of parameters, in fact, the time required to compute b^* and C^* may exceed the computation time of competing MM approaches. However, in this case, the sampling strategy can be used to approximate the matrices C^* and b^*. For example in the $\mathcal{S}_1$ setting, the average running time for the SODA is about 9967.47 sec while with SVM-struct the same task is performed in 1043.16 sec. However with the use of approximate matrices computed sampling on 150 random paths and solving the linear system by a conjugate gradient method the computational time is only 656.46 sec.

	Z-score	**SODA**	**MM**	**HMP**	**CRFs**
$\mathcal{S}_1$	11.07	*10.13*	10.97	20.99	11.96
$\mathcal{S}_2$	*7.89*	8.27	8.11	13.78	8.25

Table 3: Classification error on test set on NER (300 sentences).

	Z-score	**SODA**	**MM**	**HMP**	**CRFs**
$\mathcal{S}_1$	9.43	*8.80*	9.35	11.01	9.07
$\mathcal{S}_2$	8.57	8.01	*7.33*	7.83	8.40

Table 4: Classification error on test set on NER (1500 sentences).

To address this problem of scalability of our approach when the number of features is large we also developed a method for solving the linear systems of SODA and of the Z-score approach which is *ad hoc* for problems such as NER where the size of the observation alphabet n_o (i.e., the size of dictionary) tends to be huge while the size of the hidden alphabet n_h (i.e., the number of different labels) is moderate.

The main problem of using our algorithms for tasks with a large number of features is represented by the fact that the matrices C^* and $\bar{C}$ needs to be stored into memory. Moreover solving the corresponding linear systems with conjugate gradient techniques has computational cost $O(d^2)$ which is problematic when d is large. To overcome these difficulties we propose an approach which exploits the sparsity and the redundancy of the covariance matrices to limit the storage requirements and to solve the corresponding linear system with reduced computational cost. This approach is briefly presented in appendix B in the case of sequence labeling and HMM features but an extension of it for other possible configurations of features is possible and quite easy to derive.

Using this method we are able to perform experiments for the NER task on a large subset of the Spanish news wire article corpus of CoNLL2002. We used 1500 sentences which correspond to a dictionary of about 10000 different words. The hidden alphabet is again represented by $n_h = 9$ different labels. The experimental setting is the same of the small data set: we consider the same configuration for features ($\mathcal{S}_1$ and $\mathcal{S}_2$) and we compare the performances of our approaches with CRFs (using CRFs toolkit Kudo, 2005), HMP and the MM algorithm with Hamming loss (SVM-struct implementation Tsochantaridis et al., 2005). Experiments have been made with a 5-fold cross validation procedure and the regularization parameters which provide better performances have been set for all the methods.

From the results, shown in Tab. 4, we can draw similar conclusions that for the small data set: SODA outperforms all the other approaches for $\mathcal{S}_1$, while the MM algorithm provides the smallest test error for $\mathcal{S}_2$. It is somehow surprising that the HMP provides the second best performance for $\mathcal{S}_2$ despite its simplicity. We explain this result considering that with an increased set of features the data tend to be more separable and the HMP tend to outperform our approaches and CRFs.

Note that without having developed an *ad hoc* method such as that described in appendix B we would not have been able to run this second series of experiments on a normal machine since our $d \times d$ covariance matrices are too large to fit into memory (d is about 90000 only for set of features $\mathcal{S}_1$!). For sake of clarity we should also say that sometimes using this method we experienced numerical problems (especially for small regularization parameters) that are probably due to the fact that the approach is based on formulas for matrix inversions. Therefore in the future we plan to develop a better method (e.g., based on updating matrices decompositions such as Cholesky) in order to overcome numerical difficulties.

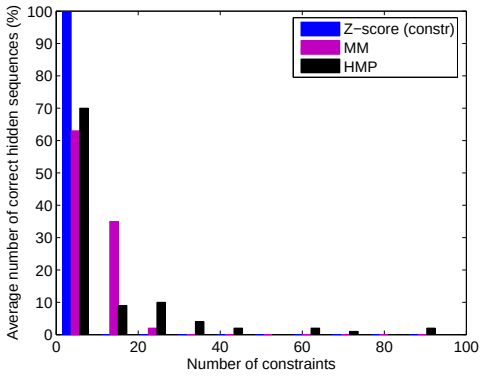


Figure 7: Average number of correctly reconstructed hidden sequences for an HMM with $n_h = 2$ and $n_o = 4$.

5.4 Z-score with Constraints

The last series of experiments shows some results associated with the Z-score approach with constraints (9). We observe experimentally that this approach improves the performance of the unconstrained problem (7) if the noise in the data is limited (i.e., in the feasible or nearly feasible case). For example for the experiments in Fig. 4 when the noise level is $p = 0$ with the constrained Z-score the labeling error is 3.96 and 5.76 respectively for the HMM with $n_h = 2$, $n_o = 4$ and for the HMM with $n_h = 3$, $n_o = 5$ while for the unconstrained problem the error is 5.39 and 9.87 respectively.

Moreover, comparing Algorithm 3 with other iterative approaches (HMP Collins 2002b and MM algorithm Tsochantaridis et al. 2005), the use of the Z-score as objective function ensures that the number of iterations is generally much smaller. Then the computational cost is greatly reduced since adding one inequality means running the Viterbi algorithm. To demonstrate this, we perform the following experiment. A pair of observed and hidden sequences of length $m = 100$ is considered. The task is to estimate the values of transition and emission probabilities such that the observed sequences are generated by the hidden one. The number of constraints needed in the training phase to reconstruct the matrices is averaged on 100 experiments. In Fig. 7 the histograms obtained binning the number of constraints needed to reconstruct the original transition and emission probabilities is shown for an HMM with $n_h = 2$ and $n_o = 4$. For sake of comparison the number of constraints needed when learning is performed with the perceptron (Collins, 2002b) and a MM approach (Tsochantaridis et al., 2005) is also provided. As expected, optimizing the Z-score, much less constraints are needed.

5.5 Sequence Alignment Learning

The second series of experiments has been performed in the context of sequence alignment learning. The aim of this section is to compare the performance of our algorithms with a traditional generative approach. Among the proposed methods we present the results associated to SODA since the performance obtained with the Z-score algorithm are nearly identical.

We construct substitution matrices with elements generated randomly but such that the values on the main diagonal are larger than the other. In particular we consider two types of matrices associated respectively with a 3 parameter model (i.e., matches, mismatches and gaps) and a 211

n	**SODA (3)**	**SODA (211)**	**Generative**	**HMP**
1	5.1 ± 1.2	96.12 ± 13.3	98.14 ± 14.5	93.8 ± 12.1
2	2.9 ± 0.8	84.7 ± 7.5	98.01 ± 12.2	83.98 ± 8.6
5	2.32 ± 1.0	74.81 ± 6.2	97.4 ± 7.4	76.13 ± 5.2
10	2.11 ± 0.7	60.08 ± 3.2	92.93 ± 5.2	57.93 ± 2.9
20	2.1 ± 0.5	43.18 ± 2.2	79.13 ± 4.2	42.68 ± 2.1
50	1.87 ± 0.3	35.56 ± 1.4	48.31 ± 2.9	31.92 ± 1.2
100	1.53 ± 0.4	30.84 ± 1.0	32.05 ± 1.5	28.4 ± 0.9
500	0.98 ± 0.3	23.47 ± 0.2	26.11 ± 0.6	21.7 ± 0.4

Table 5: Classification error (mean and standard deviation) on test set as function of the training set size n.

parameter models (substitution matrix plus gap penalty). Starting from these matrices we then generate random pairs of sequences of length 10 from a 20 letter alphabet. Pairs are constructed in a way that 50% of symbols between the two sequences are equal. The task we consider is to reconstruct the given matrices starting from training sets of varying size n.

Table 5 shows the results in terms of the test error (number of incorrectly aligned sequences), averaged on 100 runs. A small regularization value $\lambda = 10^{-12}$ is used for SODA. The first two columns of Tab. 5 present the test error for SODA respectively for the 3 and the 211 parameter model. As expected from theory, the convergence to zero error is faster for the 3 parameter model. For the 211 parameter model we also compare SODA with a generative sequence alignment model, where substitution rates between amino acids are computed using Laplace estimates. The gap penalty must be set manually and we choose the value $\theta_g = -0.1$ which guarantees the best performance on the test set. The third column of Tab. 5 shows the associated results: SODA performs better than the generative approach, especially for training set of small size. We also compare the performance of our method with another discriminative approach: the hidden Markov perceptron. In this situation the test error of SODA is slightly larger than that of the HMP. This is in accordance to what we observe in the sequence labeling learning task: when data are linearly separable other discriminative approaches appear more suitable than SODA.

For the SODA algorithm with the 211 parameter model and for a training set with $n = 100$ aligned pairs we also depict the substitution matrix computed by SODA and we compare it with the given one. As one can easily observe, the computed matrix has a similar structure of the correct matrix, having the elements with higher values on the diagonal (Fig. 8).

Note that, in the context of sequence alignment, being the number of parameters limited at most to 211 the training phase is not time consuming even for large training set. In fact the computational cost is dominated by the calculation of mean and covariance matrices which can be greatly sped up by sampling while solving the linear system $C^*\theta = b^*$ is indeed very fast. Here we only consider training sets of size up to 500 pairs of sequences since the advantage in terms of test error for SODA (and in general for all discriminative approaches) with respect to generative approaches is more evident for training sets of small sizes.

Table 6: Summary of the data set of RNA sequences

5.6 Learning to Parse

Lastly, we analyze the RNA secondary structure prediction problem: given an RNA sequence, the task is to predict the basepairs in the sequence. With weighted context-free grammars, this prediction can be accomplished by parsing the RNA sequence. To describe basepairs in RNA sequences, we used the G6 grammar in Dowell and Eddy (2004), which we call $G = \{\Upsilon, \Sigma_x, R, S, \theta\}$, where $\Upsilon = \{S, L, F\}$, $\Sigma_x = \{\mathtt{a}, \mathtt{u}, \mathtt{g}, \mathtt{c}\}$, and $R = \{S \to LS|L, L \to \mathtt{a}F\mathtt{u}|\mathtt{u}F\mathtt{a}|\mathtt{g}F\mathtt{c}|\mathtt{c}F\mathtt{g}|\mathtt{g}F\mathtt{u}|\mathtt{u}F\mathtt{g}|\mathtt{a}|\mathtt{u}|\mathtt{c}|\mathtt{g}, F \to \mathtt{a}F\mathtt{u}|\mathtt{u}F\mathtt{a}|\mathtt{g}F\mathtt{c}|\mathtt{c}F\mathtt{g}|\mathtt{g}F\mathtt{u}|\mathtt{u}F\mathtt{g}|LS\}$. We consider RNA sequences of five families (see Tab. 6) extracted from the Rfam database (Griffiths-Jones et al., 2003). We use sequences including only standard basepairs, that is, a–u, c–g, and g–u.

Results for the experiments conducted with Z-score with constraints, with a generative model, and with the hidden Markov perceptron in a 5-fold cross validation setting are shown. Weights of the grammar are optimized with a training set, and structures associated to sequences in the test set are predicted by the Viterbi algorithm. For the Z-score with constraints, the best results obtained varying the regularization parameter are reported. For the HMP, values ranging from T=100 to T=1000 are used as the number of iterations, and the best result is shown. For the generative model, parameters are estimated with Laplace smoothing.

We measure the performance of the methods in terms of sensitivity and specificity of predicted basepairs. The sensitivity is defined as the number of correctly predicted basepairs over the number

of true basepairs, and the specificity is the number of correctly predicted basepairs over the number of predicted basepairs. In Tab. 7, the values of sensitivity and specificity corresponding to the maximum product, are shown for each algorithm. The Z-score and the HMP have comparable performances and generally outperform the generative approach. For the Z-score approach also the average number of constraints is shown: it is worth noting that only very few constraints are needed for each family, often less than the number of iterations in the HMP by an order of magnitude or more.

6. Statistical Learning Analysis

We present here two learning theory results. The first one is specific for the ranking loss in any algorithm using this hypothesis space, and hence covers the SODA algorithm. The second one applies to any algorithm using the zero-one loss with this hypothesis class, and hence covers most previous approaches.

6.1 Rademacher Theory for SODA

Here we present a Rademacher bound for the SODA showing that learning based on this upper bound on the relative rank is effectively achieved. For full generality, we want our bound to hold also in the case where the matrices μ and C are estimated by sampling, as we suggested in subsection 3.2.2. We also provide some experimental results for this in the following subsection. Hence, our bound needs to account for finiteness in two ways. First of all for each input-output pair only a limited number n of incorrect outputs may be considered to estimate μ and C; secondly only a finite number ℓ of input-output pairs is given in the training set.

In appendix C, we prove the following theorem. It shows that the empirical expectation of the estimated loss (estimated by computing C and b by random sampling) is a good approximate upper bound for the expected loss. Hereby it is good to keep in mind that this loss itself is an upper bound for the relative ranking loss, such that the Rademacher bound is also a bound on the expectation of the relative ranking loss.

Theorem 7 (Rademacher bound for SODA) *With probability at least* $1-\delta$ *over the joint of the random sample* $\mathcal{T}$ *and the random samples from the output space for each* $(\boldsymbol{x},\bar{\boldsymbol{y}}) \in \mathcal{T}$ *that are taken to approximate the matrices* C^* *and* b^**, the following bound holds for any* θ *with squared norm smaller than* c*:*

$$E_{(\boldsymbol{x},\bar{\boldsymbol{y}})}\left\{\mathcal{L}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}})\right\} \quad \leq \quad \widehat{E}_{(\boldsymbol{x},\bar{\boldsymbol{y}})}\left\{\widehat{\mathcal{L}}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}})\right\}$$

$$+ \quad \widehat{E}_{(\boldsymbol{x},\bar{\boldsymbol{y}})}\left\{\hat{\mathfrak{R}}_{1,(\boldsymbol{x},\bar{\boldsymbol{y}})}\right\} + \hat{\mathfrak{R}}_2$$
$$+ \quad 3M\sqrt{\frac{\log(2\ell/\delta)}{2n}} + 3M\sqrt{\frac{\log(2/\delta)}{2\ell}}.$$

whereby we assume that the number of random samples for each training pair is equal to n.

The Rademacher complexity terms $\hat{\mathfrak{R}}_{1,(\boldsymbol{x},\bar{\boldsymbol{y}})}$ and $\hat{\mathfrak{R}}_2$ decrease with $\frac{1}{\sqrt{n}}$ and $\frac{1}{\sqrt{\ell}}$ respectively, such that the bound becomes tight for increasing n and ℓ, as long as n grows faster than $\log(\ell)$.

For details relating to the exact value of the Rademacher complexity terms, the value of the constant M, and the proofs, we refer to the appendix C.

6.2 PAC Bound

In appendix D, we prove the following theorem that applies to a generic DLA: given a training set of sample pairs $(\mathbf{x}^i, \overline{\mathbf{y}}^i)$, can we learn to predict the output for a previously unseen observation? For example, given a training set of aligned protein sequences, can we learn how to align a previously unseen pair? Or, given a training set of correctly parsed sentences, can we learn how to parse a previously unseen sentence? To be clear, in this section we consider the zero-one loss only, which has been considered most often in previous work on structured output learning.

DLAs directly learn the model parameters such that the accuracy of the prediction is somehow optimized. All these algorithms are in some sense empirical risk minimizers, in that they optimize the prediction performance on a training set. However till now there have been few works trying to address the question whether a small empirical risk guarantees a small expected risk. A first generalization bound has been developed by Collins for the case of the perceptron algorithm (Collins, 2002a) and a capacity bound in terms of covering numbers for the maximum margin approach has been proposed by Taskar et al. (2003). These bounds have subsequently been reconsidered in McAllester (2007) and have been improved in order to achieve consistency for any arbitrary loss. In this paper we answer the learnability question affirmatively from another point of view, independent of the learning approach taken, and we propose a new PAC bound which makes use of a result which bounds the cardinality of the hypothesis space of prediction functions derived from DLAs.

We go back to the original problem of structured output learning. Given is a training set $\mathcal{T} = \{(\mathbf{x}^1, \overline{\mathbf{y}}^1), (\mathbf{x}^2, \overline{\mathbf{y}}^2), \ldots, (\mathbf{x}^\ell, \overline{\mathbf{y}}^\ell)\}$ of observation-output pairs, with observations $\mathbf{x}^i \in \mathcal{X}$ and outputs $\overline{\mathbf{y}}^i \in \mathcal{Y}$ jointly drawn i.i.d. from an unspecified probability distribution $P(\mathbf{x}, \mathbf{y})$. Based on $\mathcal{T}$ we want to infer a prediction function $h_\theta : \mathcal{X} \to \mathcal{Y}$ such that the probability $P(h_\theta(\mathbf{x}) = \overline{\mathbf{y}})$ of an observation-output pair $(\mathbf{x}, \overline{\mathbf{y}})$ with $h_\theta(\mathbf{x}) = \overline{\mathbf{y}}$ is as large as possible. For learnability, the choice of h_θ should be restricted to a limited hypothesis space, and DLAs provide one way to achieve this.

Our hypothesis space $\mathcal{H}$ is the space containing all prediction functions h_θ with $\theta \in \mathbb{R}^d$, defined as:

$$h_\theta(\mathbf{x}) \quad = \quad \arg\max_{\mathbf{y}\in\mathcal{Y}} \; s_\theta(\mathbf{x}, \mathbf{y}) = \arg\max_{\mathbf{y}\in\mathcal{Y}} \; \theta^T \phi(\mathbf{x}, \mathbf{y}),$$

and this for a fixed feature map ϕ with integer features between 0 and C.

For this hypothesis space we can prove (in appendix D) the following theorem.

Theorem 8 (On the PAC-learnability of structured output prediction) *Given a hypothesis space $\mathcal{H}$ of prediction functions h_θ as defined above. Furthermore, consider a training set $\mathcal{T} =$*

$\{(\boldsymbol{x}^1,\bar{\boldsymbol{y}}^1),(\boldsymbol{x}^2,\bar{\boldsymbol{y}}^2),\ldots,(\boldsymbol{x}^\ell,\bar{\boldsymbol{y}}^\ell)\}$ of observation-output pairs, sampled i.i.d. from a fixed but unknown distribution. Then, with probability at least $1-\delta$ over the random sample $\mathcal{T}$, for any $h_\theta \in \mathcal{H}$ for which $h_\theta(\boldsymbol{x}^i)=\bar{\boldsymbol{y}}^i$ for all $(\boldsymbol{x}^i,\bar{\boldsymbol{y}}^i)\in\mathcal{T}$ the expected risk can be bounded as:

$$E_{(\boldsymbol{x},\bar{\boldsymbol{y}})\sim\mathcal{D}}\{h_\theta(\boldsymbol{x})\neq\bar{\boldsymbol{y}}\}\leq\frac{d^2\log(2C)-(d-2)\log(d-2)+d-\log(\delta)}{\ell}.$$

We can thus conclude that learning is guaranteed as soon as $\ell >> d^2\log(2C)$.

This result proves that learning based on DLAs can be achieved effectively, and d and C are the factors that are relevant in determining the learning rate. Importantly this bound holds regardless of the method used to estimate the parameter vector θ. Interestingly, it suggests that the number C (bounded by to the number of cliques for DLAs derived from PGMs) is less important than the number of parameters d.

Note that this bound only holds for the realizable case, such that its practical relevance is limited. Furthermore, unlike the results from McAllester (2007), the bound does not depend on the norm of the weight vector θ, making it loose for small values of $\|\theta\|$. Nevertheless, we believe it is of interest due to the simplicity of its derivation based on results from combinatorics and basic PAC theory.

7. Conclusions

We have presented a formal framework for learning to predict over structured output spaces. The hypothesis space we consider is based on linear scoring functions, much like most previous approaches to this problem.

The distribution of this linear scoring function over all possible outputs contains information that we can use to train the parameters of the learning algorithm. We can compute efficiently the first two moments of this distribution, and we use them to derive convex objective functions for parameter optimization.

In this way, we have derived two new efficient algorithms for structured output prediction that rely on these statistics, both of which can be solved by solving one linear system of equations.

Interestingly, and thanks to the use of the moments, one of the proposed objective functions (SODA) represents a convex upper bound on the relative ranking loss: the fraction of outputs from the output space that rank better than the correct output. Thanks to this property, SODA naturally and adequately deals with the infeasible case where there exists no parameter setting for which the correct given pairs are optimal. We justify this fact theoretically, providing a Rademacher bound, and experimentally, reporting results that are competitive with existing methods, and better than other methods in the infeasible case.

Appendix A. Proof of Proposition 3

The number of DP routines needed to compute μ and C are $7n_o+6$.

In fact in general in the mean vector μ there are n_o+1 different values. All the elements associated to transition probabilities assume the same values while for emission probability $\mu^e_{pq}=\mu^e_{ef}$, $\forall\, q=f$.

We analyze the structure of the matrix C. It is a symmetric block matrix made basically by three components: the block associated to emission probabilities, that of transition probabilities and that relative to mixed terms. To compute it $6n_o+5$ DP routines are required. In the emission part there are $2n_o$ possible different values since $c^e_{pq}=c^e_{ef}$, $\forall q=f$, $c^e_{pqp'q'}=0$, $\forall q\neq q'$ and $c^e_{pqp'q'}=c^e_{efe'f'}$ $\forall q=q'=f=f'$. In the transition block there are only 5 possible different values. In particular for the second order moments, it holds that $c^t_{pz}=c^t_{eg}$, $\forall p=z=e=g$ and $c^t_{pz}=c^t_{eg}$, $\forall p=e$, $z=g$ and $p\neq z$. For the remaining three values there holds that $c^t_{pzp'z'}=0$, $\forall p\neq p'$, $z\neq z'$, $c^t_{pzp'z'}=c^t_{ege'g'}$, $\forall p=p'$, $z\neq z'$, $e=e'$, $g\neq g'$ and $c^t_{pzp'z'}=c^t_{ege'g'}$, $\forall p\neq p'$, $z=z'$, $e\neq e'$, $g=g'$. The block relative to mixed terms is made of $4n_o$ possible different value. In fact there are n_o values $c^{et}_{pqp'z}$ with $p=p'=z'$, n_o values $c^{et}_{pqp'z}$, with $p=p'$, $p'\neq z'$, n_o values $c^{et}_{pqp'z}$, with $p=z'$, $p'\neq z'$ and n_o values $c^{et}_{pqp'z}$, with $p\neq p'$, $z\neq z'$.

The redundancy in the structure of matrix C and of the vector μ can be observed in Fig. 9 for an HMM with $n_s=3$ and $n_o=4$.

Appendix B. Solving Linear Systems for Large Feature Spaces

This paragraph provides a brief description of an approach for solving the linear systems $C^*\theta=b^*$ and $\bar{C}\theta=\bar{b}$ avoiding to store the entire matrices C^* and $\bar{C}$. This approach is suited to sequence labeling problems and HMM features and it is particularly effective for problems when n_h, the size of the hidden state alphabet, is small and n_o, the size of the observation alphabet, is large.

We describe the procedure to solve $C^*\theta=b^*$. In fact it subsumes the method for solving $\bar{C}\theta=\bar{b}$. The main idea behind this procedure is that exploiting the structure of C^* we can store just a part of it and compute the optimal parameter vector θ effectively.

The matrix C^* in case of sequence labeling and HMMs features is sparse and redundant. In fact this matrix is given by the sum of two parts: $\bar{C}=\sum_i C_i$ and $BB^T=\sum_i b_i b_i^T$. We first consider the

first part $\bar{C} = \sum_i C_i$. Each C_i is very sparse and has a regular structure as discussed in appendix A. Then also the matrix $\bar{C}$ has the same structure, that is, is a matrix made by four block:

$$\bar{C} = \begin{pmatrix} E & M \\ M^T & T \end{pmatrix}.$$

Here E denotes the block associated to emission probabilities, T that corresponding to transition probabilities and M that relative to mixed terms. We are interested in finding the inverse of the matrix $\bar{C}$ without storing it entirely. Note that in many situations (e.g., sequence labeling problems for text analysis such as NER or POS) the emission part represents the main bottleneck in the computation of the inverse since its size is dependent on n_o (e.g., the size of the dictionary). The size of the transition part instead is usually moderate since it is given by n_h^2 (e.g., the number of different tags). The inverse of $\bar{C}$ can be computed by:

$$\bar{C}^{-1} = \begin{pmatrix} E^{-1} + E^{-1}MP^{-1}M^TE^{-1} & -E^{-1}MP^{-1} \\ -P^{-1}M^TE^{-1} & P^{-1} \end{pmatrix}$$

where $P = T - M^TE^{-1}M$ represent the Schur complement of E. The inverse of the matrix E can be computed easily due to the structure of the matrix E. In fact E is a block matrix:

$$E = \begin{pmatrix} E_d & E_o & E_o & \cdots & E_o \\ E_o & E_d & E_o & \cdots & E_o \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ E_o & \cdots & E_o & E_o & E_d \end{pmatrix}$$

where E_d and E_o are both diagonal matrices. Therefore we can rewrite the matrix E as:

$$\begin{aligned} E = & \begin{pmatrix} E_d - E_o & 0 & 0 & \cdots & 0 \\ 0 & E_d - E_o & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & 0 & E_d - E_o \end{pmatrix} + \begin{pmatrix} I \\ I \\ \vdots \\ I \end{pmatrix} E_o \begin{pmatrix} I & I & \cdots & I \end{pmatrix} \\ = & \quad D + H^T E_o H. \end{aligned}$$

Then the inverse can be computed easily considering the formula for the inverse of a sum of matrices:

$$E^{-1} = D^{-1} - D^{-1}H^T(I + E_oHD^{-1}H^T)^{-1}E_oHD^{-1}$$

where D is a diagonal matrix. Due to the special structure of D, H and E, it turns out that the inverse of E is also a block matrix with similar structure of E, that is,

$$E^{-1} = \begin{pmatrix} \bar{E}_d & \bar{E}_o & \bar{E}_o & \cdots & \bar{E}_o \\ \bar{E}_o & \bar{E}_d & \bar{E}_o & \cdots & \bar{E}_o \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \bar{E}_o & \cdots & \bar{E}_o & \bar{E}_o & \bar{E}_d \end{pmatrix}$$

where $\bar{E}_d = (E_d - E_o)^{-1}$ and $\bar{E}_o = \bar{E}_d(I + E_oN_H\bar{E}_d)^{-1}\bar{E}_d$ (N_H is a diagonal matrix with elements on the main diagonal equal to n_h). Then it is not necessary to compute and store the entire matrix E^{-1} but only the small blocks $\bar{E}_d$ and $\bar{E}_o$.

Once the matrix E^{-1} has been obtained then the computation of the Schur complement P and its inverse it is straightforward. This is not a time consuming procedure since its size n_h^2 is typically small and E^{-1} is very sparse. Due to the redundancy and the particular structure of the matrix M we can also compute quite easily all the other terms. In particular the matrix obtained by $E^{-1}MP^{-1}M^TE^{-1}$ is a block matrix made by $n_h \times n_h$ equal blocks. Then it suffices to compute and to store just one of each block.

The inverse of the matrix $\bar{C}$ has then been obtained and we can use it directly to compute the solution of the linear system for the Z-score approach $\theta = \bar{C}^{-1}\bar{b}$. Instead if we want to obtain the optimal parameter vector associated to SODA we must compute the solution of the linear system $(\bar{C}+BB^T)\theta = b^*$. In practice what we need is a method to perform n rank one updates (one for each sample in the training set) of the inverse of the matrix $\bar{C}$ without storing the matrices $\bar{C}^{-1}$ and BB^T entirely. We can use the Sherman-Morrison-Woodbury formula:

$$\bar{C}+BB^T = \bar{C}^{-1} - \bar{C}^{-1}B(I+B^T\bar{C}^{-1}B)B^T\bar{C}^{-1}$$

to calculate the solution of our linear system:

$$\theta = (\bar{C}+BB^T)^{-1}b^* = \bar{C}^{-1}b^* - \bar{C}^{-1}B(I+B^T\bar{C}^{-1}B)B^T\bar{C}^{-1}b^*.$$

In practice we first compute $z = \bar{C}^{-1}b^*$ and use this value to solve the linear system by Cholesky decomposition:

$$(I+B^T\bar{C}^{-1}B)t = B^Tz.$$

Note that the cost of this operation is $O(n^3)$ but it is usually moderate since $n << d$. The computational cost here is dominated by the calculation of z since in theory it requires d^3 multiplications. However in practice this cost is still reasonable since $\bar{C}^{-1}$ tend to be sparse. Once we have computed t we can obtain our solution for SODA simply by $\theta = z - \bar{C}^{-1}Bt$.

Appendix C. Proof of the Rademacher Bound

We consider two types of randomness in our bound: the randomness in choosing the finite sample of training input-output pairs, and the randomness in sampling from the output space for each of the training inputs. Our aim is to provide a learning theory bound for the expected relative rank of the score $s_\theta(\mathbf{x},\bar{\mathbf{y}})$ among all scores $s_\theta(\mathbf{x},\mathbf{y})$ for all $\mathbf{y} \in \mathcal{Y}$.

More exactly, we are interested in bounding $E_{(\mathbf{x},\bar{\mathbf{y}})}\left\{\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})\right\}$ where the value of the loss $\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}}) = E_{\mathbf{y}}\left\{\left[\theta^T\left(\phi(\mathbf{x},\bar{\mathbf{y}})-\phi(\mathbf{x},\mathbf{y})\right)-1\right]^2\right\}$ is known to be an upper bound on the relative rank of the score of $(\mathbf{x},\bar{\mathbf{y}})$ among all scores of $(\mathbf{x},\mathbf{y})$ for all possible $\mathbf{y}$ (see Theorem 5).

For clarity, let us first consider a fixed training pair $(\mathbf{x},\bar{\mathbf{y}})$. We will derive a Rademacher bound that shows that the loss function $\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})$ is approximately upper bounded by its empirical estimate $\widehat{\mathcal{L}}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}}) = \widehat{E}_{\mathbf{y}}\left\{\left[\theta^T\left(\phi(\mathbf{x},\bar{\mathbf{y}})-\phi(\mathbf{x},\mathbf{y})\right)-1\right]^2\right\}$, obtained by averaging over a random sample of n values of $\mathbf{y}$. In particular we will show that with a probability of at least $1-\delta_1$ over the random sample of size n:

$$\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}}) \leq \widehat{\mathcal{L}}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}}) + \hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})} + 3M\sqrt{\frac{\log(1/\delta_1)}{2n}},$$

with $\hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})}$ an empirical Rademacher complexity term. The constant M is an upper bound on the value of $\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})$ valid for all allowable θ, and is a finite number. Such an upper bound can be computed as $M = (C\sqrt{dc}+1)^2$, by considering the constraint $\|\theta\|^2 \leq c$ and the fact that for all d features $0 \leq \phi_i(\mathbf{x},\mathbf{y}) \leq C$.

Second, we will show that the expectation of $\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})$ over $(\mathbf{x},\bar{\mathbf{y}})$ is approximately upper bounded by its empirical expectation over the training set of size l. We will show that with probability at least $1-\delta_2$ over the training set $\mathcal{T}$ of size ℓ,

$$E_{(\mathbf{x},\bar{\mathbf{y}})}\left\{\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})\right\} \leq \widehat{E}_{(\mathbf{x},\bar{\mathbf{y}})}\left\{\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})\right\} + \hat{\mathfrak{R}}_2 + 3M\sqrt{\frac{\log(1/\delta_2)}{2\ell}},$$

with $\hat{\mathfrak{R}}_2(\mathcal{T})$ an empirical Rademacher complexity term, and with the same constant M.

Putting these two partial results together with $\delta_1 = \frac{\delta}{2\ell}$ and $\delta_2 = \frac{\delta}{2}$, we have shown the following theorem:

Theorem 9 (Rademacher bound for SODA) *With probability at least $1-\delta_2-\ell\delta_1 = 1-\delta$ over the joint of the random sample $\mathcal{T}$ and the random samples from the output space for each $(\boldsymbol{x},\bar{\boldsymbol{y}}) \in \mathcal{T}$, the following bound holds for any θ with squared norm smaller than c:*

$$\begin{aligned} E_{(\boldsymbol{x},\bar{\boldsymbol{y}})}\left\{\mathcal{L}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}})\right\} &\leq \widehat{E}_{(\boldsymbol{x},\bar{\boldsymbol{y}})}\left\{\widehat{\mathcal{L}}_\theta^{RRU}(\boldsymbol{x},\bar{\boldsymbol{y}})\right\} \\ &+ \widehat{E}_{(\boldsymbol{x},\bar{\boldsymbol{y}})}\left\{\hat{\mathfrak{R}}_{1,(\boldsymbol{x},\bar{\boldsymbol{y}})}\right\} + \hat{\mathfrak{R}}_2 \\ &+ 3M\sqrt{\frac{\log(2\ell/\delta)}{2n}} + 3M\sqrt{\frac{\log(2/\delta)}{2\ell}}. \end{aligned}$$

The first term on the right hand side of the inequality is the empirical risk, which is minimized on the training set. The next two terms are Rademacher complexity terms, and we will see below that these decrease to zero with increasing ℓ and n. Also the last two terms decrease to zero with increasing ℓ and n, as long as n is chosen to increase faster than $\log(\ell)$.

Both these partial results can be derived by using the generalization error bound in Bartlett and Mendelson (2002, Theorem 2) and applying the McDiarmid's concentration inequality (McDiarmid, 1989). In the following we show how to compute upper bounds on the empirical Rademacher complexities $\hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})}$ and $\hat{\mathfrak{R}}_2$.

C.1 Rademacher Bound for the Relative Rank of a Single Pair

Given a training pair $(\mathbf{x},\bar{\mathbf{y}})$ and a set $\{\mathbf{y}_1,\mathbf{y}_2,\ldots,\mathbf{y}_n\}$ of n randomly sampled values for $\mathbf{y}$ corresponding to $\mathbf{x}$. For notational convenience, let us denote $\varphi_j = \phi(\mathbf{x},\bar{\mathbf{y}}) - \phi(\mathbf{x},\mathbf{y}_j)$. Then we can write the empirical estimate of the loss as

$$\widehat{\mathcal{L}}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}}) = \frac{1}{n}\sum_{j=1}^{n}\left(\theta^T\varphi_j - 1\right)^2.$$

Using this notation, and with σ a vector of length n containing the independently distributed Rademacher variables σ_j being uniformly distributed over 1 and -1, the Rademacher complexity term $\hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})}$ can be written and bounded as:

$$\hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})} = E_\sigma\left\{\max_\theta\left|\frac{2}{n}\sum_{j=1}^{n}\sigma_j\left(\theta^T\varphi_j - 1\right)^2\right|\right\}$$

$$
\begin{aligned}
&= E_\sigma\left\{\max_\theta\left|\frac{2}{n}\sum_{j=1}^{n}\sigma_j\left((\theta^T\varphi_j)^2-2(\theta^T\varphi_j)+1\right)\right|\right\}\\
&\leq E_\sigma\left\{\max_\theta\frac{2}{n}\left(\left|\sum_{j=1}^{n}\sigma_j(\theta^T\varphi_j)^2\right|+\left|\sum_{j=1}^{n}2\sigma_j(\theta^T\varphi_j)\right|+\left|\sum_{j=1}^{n}\sigma_j\right|\right)\right\}. \qquad (12)
\end{aligned}
$$

The first equality is the definition of the empirical Rademacher complexity, and the second equality is a trivial rewriting. The first inequality holds since the absolute value of the sum is smaller than or equal to the sum of absolute values. We now first use the fact that the maximum of a sum of functions is smaller than or equal to the sum of their maxima to show that:

$$
\begin{aligned}
(12) \quad &\leq \frac{2}{n}E_\sigma\left\{\max_\theta\left|\sum_{j=1}^{n}\sigma_j(\theta^T\varphi_j)^2\right|+\max_\theta\left|\sum_{j=1}^{n}2\sigma_j(\theta^T\varphi_j)\right|+\max_\theta\left|\sum_{j=1}^{n}\sigma_j\right|\right\}\\
&= \frac{2}{n}E_\sigma\left\{\sqrt{\max_\theta\left(\sum_{j=1}^{n}\sigma_j(\theta^T\varphi_j)^2\right)^2}\right\}\\
&\quad +\frac{2}{n}E_\sigma\left\{\sqrt{\max_\theta\left(\sum_{j=1}^{n}2\sigma_j(\theta^T\varphi_j)\right)^2}\right\}+\frac{2}{n}E_\sigma\left\{\sqrt{\max_\theta\left(\sum_{j=1}^{n}\sigma_j\right)^2}\right\}. \qquad (13)
\end{aligned}
$$

Here we used the fact that the absolute value is the square root of the square, and that the square root of a positive function is maximized when that function itself is maximized. We proceed by rewriting this expression using bracket notation, $\langle \mathbf{a}, \mathbf{b}\rangle$ denoting the inner product between vectors (or matrices) **a** and **b**. Furthermore, we use the fact that the maximum of a sum (or expectation) is smaller than or equal to the sum (or expectation) of the maxima of the individual sums, to show that:

$$
\begin{aligned}
(13) \quad &\leq \frac{2}{n}\sqrt{E_\sigma\left\{\max_\theta\sum_{j,k=1}^{n}\sigma_j\sigma_k\langle\theta\theta^T,\varphi_j\varphi_j^T\rangle\langle\theta\theta^T,\varphi_k\varphi_k^T\rangle\right\}}\\
&\quad +\frac{2}{n}\sqrt{E_\sigma\left\{\max_\theta\sum_{j,k=1}^{n}4\sigma_j\sigma_k\langle\theta,\varphi_j\rangle\langle\theta,\varphi_k\rangle\right\}}+\frac{2}{n}\sqrt{E_\sigma\left\{\sum_{j,k=1}^{n}\sigma_j\sigma_k\right\}}. \qquad (14)
\end{aligned}
$$

We now invoke the Cauchy-Schwartz inequality, and use the fact that $\|\theta\|^2 \leq c$ and hence $\|\theta\theta^T\|^2 \leq c^2$, to show that:

$$
\begin{aligned}
(14) \quad &\leq \frac{2}{n}\sqrt{E_\sigma\left\{\sum_{j,k=1}^{n}\sigma_j\sigma_k c^2\|\varphi_j\|^2\|\varphi_k\|^2\right\}}\\
&\quad +\frac{2}{n}\sqrt{E_\sigma\left\{\sum_{j,k=1}^{n}4c\sigma_j\sigma_k\|\varphi_j\|\|\varphi_k\|\right\}}+\frac{2}{n}\sqrt{E_\sigma\left\{\sum_{j,k=1}^{n}\sigma_j\sigma_k\right\}}. \qquad (15)
\end{aligned}
$$

Since for $i \neq k$, there holds that $E_\sigma\left\{\sigma_j\sigma_k\right\} = 0$ and $E_\sigma\left\{\sigma_j^2\right\} = 1$, we can finally write that:

$$(15) \quad = \quad \frac{2}{\sqrt{n}}\left(c\sqrt{\frac{1}{n}\sum_{j=1}^{n}\|\varphi_j\|^4} + 2\sqrt{c}\sqrt{\frac{1}{n}\sum_{j=1}^{n}\|\varphi_j\|^2} + 1\right).$$

In summary, we have found the following upper bound on the first empirical Rademacher complexity:

Proposition 10 (Rademacher complexity $\hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})}$) *The Rademacher complexity term $\hat{\mathfrak{R}}_{1,(\boldsymbol{x},\bar{\boldsymbol{y}})}$ can be bounded as:*

$$\hat{\mathfrak{R}}_{1,(\boldsymbol{x},\bar{\boldsymbol{y}})} \leq \frac{2}{\sqrt{n}}\left(c\sqrt{\frac{1}{n}\sum_{j=1}^{n}\|\varphi_j\|^4} + 2\sqrt{c}\sqrt{\frac{1}{n}\sum_{j=1}^{n}\|\varphi_j\|^2} + 1\right),$$

which, given the boundedness of $\|\varphi_j\|$, decreases to zero as n increases to infinity, as required.

C.2 Rademacher Complexity for the Empirical Expectation of the Loss

Given a randomly sampled training set $\mathcal{T} = \{(\mathbf{x}^1,\bar{\mathbf{y}}^1),(\mathbf{x}^2,\bar{\mathbf{y}}^2),\ldots,(\mathbf{x}^\ell,\bar{\mathbf{y}}^\ell)\}$. The empirical expectation of the loss can be written as:

$$\begin{aligned}\widehat{E}_{(\mathbf{x},\bar{\mathbf{y}})}\left\{\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})\right\} &= \frac{1}{\ell}\sum_{i=1}^{\ell}\mathcal{L}_\theta^{RRU}(\mathbf{x}^i,\bar{\mathbf{y}}^i)\\ &= \frac{1}{\ell}\sum_{i=1}^{\ell}\left(\frac{1}{N_i}\sum_{j=1}^{N_i}(\theta^T\varphi_j^i - 1)^2\right),\end{aligned}$$

where $\varphi_j^i = \phi(\mathbf{x}^i,\mathbf{y}_j^i) - \phi(\mathbf{x}^i,\bar{\mathbf{y}}^i)$ and N_i is the cardinality of the output space corresponding to $\mathbf{x}^i$.

For notational convenience, let us introduce the matrix Φ^i containing all vectors ${\varphi_j^i}^T$ as its rows. Then we can rewrite the expected loss function in a more compact form as:

$$\begin{aligned}\widehat{E}_{(\mathbf{x},\bar{\mathbf{y}})}\left\{\mathcal{L}_\theta^{RRU}(\mathbf{x},\bar{\mathbf{y}})\right\} &= \frac{1}{\ell}\sum_{i=1}^{\ell}\frac{\|\Phi^i\theta - \mathbf{1}\|^2}{N_i}\\ &= \frac{1}{\ell}\sum_{i=1}^{\ell}\frac{\langle\theta\theta^T,{\Phi^i}^T\Phi^i\rangle - 2\langle\theta,{\Phi^i}^T\mathbf{1}\rangle + \langle\mathbf{1},\mathbf{1}\rangle}{N_i}.\end{aligned}$$

We have rewritten this in a form that contains a term linear in $\theta\theta^T$, a term linear in θ, and a constant term. It is exactly this decomposition of the empirical expectation of the loss that has allowed us to derive a bound on the Rademacher term $\hat{\mathfrak{R}}_{1,(\mathbf{x},\bar{\mathbf{y}})}$, so we can follow the same principles here. We omit the details here, and just state the result:

Proposition 11 (Rademacher complexity $\hat{\mathfrak{R}}_2$) *The Rademacher complexity term $\hat{\mathfrak{R}}_2$ can be bounded as:*

$$\hat{\mathfrak{R}}_2 \leq \frac{2}{\sqrt{\ell}}\left(c\sqrt{\frac{1}{\ell}\sum_{i=1}^{\ell}\left(\frac{\sum_{j,k=1}^{N_i}({\varphi_j^i}^T\varphi_k^i)^2}{N_i^2}\right)} + 2\sqrt{c}\sqrt{\frac{1}{\ell}\sum_{i=1}^{\ell}\left\|\frac{\sum_{j=1}^{N_i}\varphi_j^i}{N_i}\right\|^2} + 1\right),$$

which again decreases to zero as ℓ increases to infinity.

Appendix D. Proof of the PAC Bound

This section contains the proof of the PAC bound stated in subsection 6.2.

D.1 Bounding the Effective Cardinality of the Hypothesis Space

The number of possible functions mapping the input space on the output space is potentially huge: $|\mathcal{Y}|^{|\mathcal{X}|}$ for an observation space of size $|\mathcal{X}|$ and an output space of size $|\mathcal{Y}|$. To make this more concrete, for the HMM prediction problem discussed earlier, this is equal to $\left(n_h^m\right)^{n_o^m} = n_h^{mn_o^m}$, which is doubly exponential in the length of the sequences m.

It would clearly be impossible to achieve learning if we had to consider all of these possible functions mapping observations onto outputs. However, we will show that the hypothesis class of prediction functions defined above contains only a very small subset of these functions. This means that, while the cardinality of functions h_θ is infinite (one such function for each $\theta \in \mathbb{R}^d$), the effective cardinality is low, since many of these functions are equivalent. We will subsequently use this upper bound on the effective cardinality to obtain a PAC bound on the generalization.

To upper bound the effective cardinality of the hypothesis space $\mathcal{H}$, we borrow and reformulate the so-called *few inference functions theorem* by Elizalde (to appear) in the terminology of the present paper:

Theorem 12 (Elizalde) *Let d and C be fixed positive integers. Let $\phi : \mathcal{X} \times \mathcal{Y} \to \{0,1,\ldots,C\}^d$ be a fixed function (called the feature map). Then the hypothesis space $\mathcal{H}$ defined as $\mathcal{H} = \left\{h_\theta | h_\theta(\boldsymbol{x},\boldsymbol{y}) = \arg\max_{\boldsymbol{y}} \theta^T \phi(\boldsymbol{x},\boldsymbol{y}) | \theta \in \mathbb{R}^d\right\}$ has an effective cardinality of at most*

$$K = \frac{2^{d^2-d+1}}{(d-2)!} C^{d(d-1)}.$$

that is, the number of different *prediction functions in $\mathcal{H}$ is at most K.*

D.2 A PAC Bound for Learning Prediction Functions

Based on the effective cardinality of the hypothesis space we can now derive a PAC bound on the expected risk. Let us derive the bound for the case where the empirical risk is equal to zero. Deriving a PAC bound in the case of nonzero empirical risk is a well-known variation (Vapnik, 1998), and we will not discuss it in the current paper.

The probability of classifying all the ℓ training examples correctly with any fixed prediction function is:

$$P(\text{all } \ell \text{ correct } | p) \leq (1-p)^\ell \leq \exp(-\ell p)$$

where p is the expected risk for this prediction function. However in general, the prediction function is chosen from the hypothesis space $\mathcal{H}$. The probability over the sample that *any of K prediction functions* with an expected error rate of at least p faultlessly performs on all training examples is bounded by

$$P(\text{all } \ell \text{ correct, for any prediction function } \in \mathcal{H} | p) \quad \leq \quad K \exp(-\ell p),$$

where K is the effective cardinality of $\mathcal{H}$. Hence, the probability to get a zero training set error, for any of the prediction functions and thus for any of the parameter values, is at most $K \exp(-\ell p)$,

where p is the minimal error probability. Thus, we found an upper bound which holds with confidence at least δ for the expected error rate p as:

$$p \leq \frac{\log(K) - \log(\delta)}{\ell}$$

As we have seen in Theorem 12, the effective cardinality of $\mathcal{H}$ is upper bounded by $K = \frac{2^{d^2-d+1}}{(d-2)!} C^{d(d-1)}$, and thus (using $\log(n!) \leq n\log(n) - n$), we have proven the Theorem 8.

Appendix E. Algorithms

This section contains additional formulas that can be used for moments computation respectively in case of sequence labeling (Algorithm 4) and of sequence alignment (Algorithm 5).

Abstract

Chain graphs present a broad class of graphical models for description of conditional independence structures, including both Markov networks and Bayesian networks as special cases. In this paper, we propose a computationally feasible method for the structural learning of chain graphs based on the idea of decomposing the learning problem into a set of smaller scale problems on its decomposed subgraphs. The decomposition requires conditional independencies but does not require the separators to be complete subgraphs. Algorithms for both skeleton recovery and complex arrow orientation are presented. Simulations under a variety of settings demonstrate the competitive performance of our method, especially when the underlying graph is sparse.

Keywords: chain graph, conditional independence, decomposition, graphical model, structural learning

1. Introduction

Graphical models are widely used to represent and analyze conditional independencies and causal relationships among random variables. Monographs on this topic include Cowell et al. (1999), Cox and Wermuth (1996), Edwards (2000), Lauritzen (1996), Pearl (1988) and Spirtes et al. (2000). Two most well-known classes of graphical models are *Markov networks* (undirected graph) and *Bayesian networks* (directed acyclic graph). Wermuth and Lauritzen (1990) introduced the broader class of *block-recursive graphical models* (chain graph models), which includes, but is not limited to, the above two classes.

Among a multitude of research problems about graphical models, structural learning (also called model selection in statistics community) has been extensively discussed and continues to be a field of great interest. There are primarily two categories of methods: score-based methods (using AIC, BIC, posterior score, etc.) and constraint-based methods (using significance testing). Lauritzen (1996, Section 7.2) provides a good summary of the most important works done in the last century. Recent works in this area include Ravikumar et al. (2008), Friedman et al. (2007), Kalisch and Bühlmann (2007), Meinshausen and Bühlmann (2006), Tsamardinos et al. (2006), Ellis and Wong (2006), Friedman and Koller (2003), Chickering (2002), Friedman et al. (1999), etc. However, most of these studies are exclusively concerned with either Markov networks or Bayesian

†. Also in the Department of Statistics, Harvard University, Cambridge, MA 02138.

networks. To our limited knowledge, Studený (1997) is the only work that addresses the issue of learning chain graph structures in the literature. Recently, Drton and Perlman (2008) studied the special case of Gaussian chain graph models using a multiple testing procedure, which requires prior knowledge of the dependence chain structure.

Chain graph models are most appropriate when there are both response-explanatory and symmetric association relations among variables, while Bayesian networks specifically deal with the former and Markov networks focus on the later. Given the complexity of many modern systems of interest, it is usually desirable to include both types of relations in a single model. See also Lauritzen and Richardson (2002).

As a consequence of the versatility, chain graph models have received a growing attention as a modeling tool in statistical applications recently. For instance, Stanghellini et al. (1999) constructed a chain graph model for credit scoring in a case study in finance. Carroll and Pavlovic (2006) employed chain graphs to classify proteins in bioinformatics, and Liu et al. (2005) used them to predict protein structures. However, in most applications, chain graphs are by far not as popular as Markov networks and Bayesian networks. One important reason, we believe, is the lack of readily available algorithms for chain graph structure recovery.

To learn the structure of Bayesian networks, Xie et al. (2006) proposed a 'divide-and-conquer' approach. They showed that the structural learning of the whole DAG can be decomposed into smaller scale problems on (overlapping) subgraphs. By localizing the search of d-separators, their algorithm can reduce the computational complexity greatly.

In this paper, we focus on developing a computationally feasible method for structural learning of chain graphs along with this decomposition approach. As in structural learning of a Bayesian network, our method starts with finding a decomposition of the entire variable set into subsets, on each of which the local skeleton is then recovered. However, unlike the case of Bayesian networks, the structural learning of chain graph models is more complicated due to the extended Markov property of chain graphs and the presence of both directed and undirected edges. In particular, the rule in Xie et al. (2006) for combining local structures into a global skeleton is no longer applicable and a more careful work must be done to ensure a valid combination. Moreover, the method for extending a global skeleton to a Markov equivalence class is significantly different from that for Bayesian networks.

In particular, the major contribution of the paper is twofold: (a) for learning chain graph skeletons, an algorithm is proposed which localizes the search for c-separators and has a much reduced runtime compared with the algorithm proposed in Studený (1997); (b) a polynomial runtime algorithm is given for extending the chain graph skeletons to the Markov equivalence classes. We also demonstrate the efficiency of our methods through extensive simulation studies.

The rest of the paper is organized as follows. In Section 2, we introduce necessary background for chain graph models and the concept of decomposition via separation trees. In Section 3, we present the theoretical results, followed by a detailed description of our learning algorithms. Moreover, we discuss the issue of how to construct a separation tree to represent the decomposition. The computational analysis of the algorithms are presented in Section 4. Numerical experiments are reported in Section 5 to demonstrate the performance of our method. Finally, we conclude with some discussion in Section 6. Proofs of theoretical results and correctness of algorithms are shown in Appendices.

2. Definitions and Preliminaries

In this section, we first introduce the necessary graphical model terminology in Section 2.1 and then give the formal definition of separation trees in Section 2.2.

2.1 Graphical Model Terminology

For self-containedness, we briefly introduce necessary definitions and notations in graph theory here, most of which follow those in Studený (1997) and Studený and Bouckaert (2001). For a general account, we refer the readers to Cowell et al. (1999) and Lauritzen (1996).

A graph $\mathcal{G} = (V, E)$ consists of a vertex set V and an edge set E. For vertices $u, v \in V$, we say that there is an undirected edge $u - v$ if $(u, v) \in E$ and $(v, u) \in E$. If $(u, v) \in E$ and $(v, u) \notin E$, we say that there is a directed edge from u to v and write $u \to v$. We call undirected edges *lines* and directed edges *arrows*. The *skeleton* $\mathcal{G}'$ of a graph $\mathcal{G}$ is the undirected graph obtained by replacing the arrows of $\mathcal{G}$ by lines. If every edge in graph $\mathcal{G}$ is undirected, then for any vertex u, we define the *neighborhood* $\mathrm{ne}_{\mathcal{G}}(u)$ of u to be the set of vertices v such that $u - v$ in $\mathcal{G}$.

A *route* in $\mathcal{G}$ is a sequence of vertices $(v_0, \cdots, v_k), k \geq 0$, such that $(v_{i-1}, v_i) \in E$ or $(v_i, v_{i-1}) \in E$ for $i = 1, \cdots, k$, and the vertices v_0 and v_k are called *terminals* of the route. It is called *descending* if $(v_{i-1}, v_i) \in E$ for $i = 1, \cdots, k$. We write $u \mapsto v$ if there exists a descending route from u to v. If $v_0, \cdots, v_k$ are distinct vertices, the route is called a *path*. A route is called a *pseudocycle* if $v_0 = v_k$, and a *cycle* if further $k \geq 3$ and $v_0, \cdots, v_{k-1}$ are distinct. A (pseudo) cycle is *directed* if it is descending and there exists at least one $i \in \{1, \cdots, k\}$, such that $(v_i, v_{i-1}) \notin E$.

A graph with only undirected edges is called an *undirected graph* (UG). A graph with only directed edges and without directed cycles is called a *directed acyclic graph* (DAG). A graph that has no directed (pseudo) cycles is called a *chain graph*.

By a *section* of a route $\rho = (v_0, \cdots, v_k)$ in $\mathcal{G}$, we mean a maximal undirected subroute $\sigma : v_i - \cdots - v_j,\ 0 \leq i \leq j \leq k$ of ρ. The vertices v_i and v_j are called the *terminals* of the section σ. Further the vertex v_i (or v_j) is called a *head-terminal* if $i > 0$ and $v_{i-1} \to v_i$ in $\mathcal{G}$ (or $j < k$ and $v_j \leftarrow v_{j+1}$ in $\mathcal{G}$), otherwise it is called a *tail-terminal*. A section σ of a route ρ is called a *head-to-head* section with respect to ρ if it has two head-terminals, otherwise it is called *non head-to-head*. For a set of vertices $S \subset V$, we say that a section $\sigma : v_i - \cdots - v_j$ is *outside* S if $\{v_i, \cdots, v_j\} \cap S = \emptyset$. Otherwise we say that σ is *hit* by S.

A *complex* in $\mathcal{G}$ is a path $(v_0, \cdots, v_k),\ k \geq 2$, such that $v_0 \to v_1$, $v_i - v_{i+1}$ (for $i = 1, \cdots, k-2$) and $v_{k-1} \leftarrow v_k$ in $\mathcal{G}$, and no additional edge exists among vertices $\{v_0, \cdots, v_k\}$ in $\mathcal{G}$. We call the vertices v_0 and v_k the *parents* of the complex and the set $\{v_1, \cdots, v_{k-1}\}$ the *region* of the complex. The set of parents of a complex κ is denoted by $\mathrm{par}(\kappa)$. Note that the concept of complex was proposed in Studený (1997) and is equivalent to the notion of 'minimal complex' in Frydenberg (1990).

An arrow in a graph $\mathcal{G}$ is called a *complex arrow* if it belongs to a complex in $\mathcal{G}$. The *pattern* of $\mathcal{G}$, denoted by $\mathcal{G}^*$, is the graph obtained by turning the arrows that are not in any complex of $\mathcal{G}$ into lines. The *moral graph* $\mathcal{G}^m$ of $\mathcal{G}$ is the graph obtained by first joining the parents of each complex by a line and then turning arrows of the obtained graph into lines.

Studený and Bouckaert (2001) introduced the notion of *c-separation* for chain graph models. Hereunder we introduce the concept in the form that facilitates the proofs of our results. We say that a route ρ on $\mathcal{G}$ is *intervented* by a subset S of V if and only if there exists a section σ of ρ such that:

1. either σ is a head-to-head section with respect to ρ, and σ is outside S; or

2. σ is a non head-to-head section with respect to ρ, and σ is hit by S.

Definition 1 *Let A, B, S be three disjoint subsets of the vertex set V of a chain graph $\mathcal{G}$, such that A, B are nonempty. We say that A and B are* c-separated by S on $\mathcal{G}$, *written as $\langle A, B \,|\, S \rangle_{\mathcal{G}}^{sep}$, if every route with one of its terminals in A and the other in B is intervented by S. We also call S a* c-separator *for A and B.*

For a chain graph $\mathcal{G} = (V, E)$, let each $v \in V$ be associated with a random variable X_v with domain $\mathcal{X}_v$ and μ the underlying probability measure on $\prod_{v \in V} \mathcal{X}_v$. A probability distribution P on $\prod_{v \in V} \mathcal{X}_v$ is *strictly positive* if $\mathrm{d}P(x)/\mathrm{d}\mu > 0$ for any $x \in \prod_{v \in V} \mathcal{X}_v$. From now on, all probability distributions considered are assumed to be strictly positive. A probability distribution P on $\prod_{v \in V} \mathcal{X}_v$ is *faithful* with respect to $\mathcal{G}$ if for any triple (A, B, S) of disjoint subsets of V such that A and B are non-empty, we have

$$\langle A, B \,|\, S \rangle_{\mathcal{G}}^{sep} \;\Leftrightarrow\; X_A \perp\!\!\!\perp X_B \,|\, X_S \,, \tag{1}$$

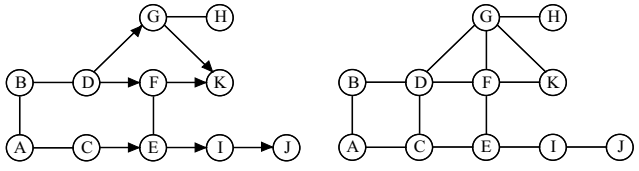
where $X_A = \{X_v : v \in A\}$ and $X_A \perp\!\!\!\perp X_B | X_S$ means the conditional independency of X_A and X_B given X_S; P is *Markovian* with respect to $\mathcal{G}$ if (1) is weakened to

$$\langle A, B \,|\, S \rangle_{\mathcal{G}}^{sep} \;\Rightarrow\; X_A \perp\!\!\!\perp X_B \,|\, X_S \,.$$

In the rest of the paper, $A \perp\!\!\!\perp B | S$ is used as short notation for $X_A \perp\!\!\!\perp X_B | X_S$ when confusion is unlikely.

It is known that chain graphs can be classified into *Markov equivalence classes*, and those in the same equivalence class share the same set of Markovian distributions. The following result from Frydenberg (1990) characterizes equivalence classes graphically: Two chain graphs are Markov equivalent if and only if they have the same skeleton and complexes, that is, they have the same pattern. The following example illustrates some of the concepts that are introduced above.

Example 1. Consider the chain graph $\mathcal{G}$ in Fig. 1(a). $D \to F - E \leftarrow C$ and $F \to K \leftarrow G$ are the two complexes. The route $\rho = (D, F, E, I, E, C)$ is intervented by an empty set since the head-to-head section $(E \to) I (\leftarrow E)$ is outside the empty set. It is also intervented by E since the non head-to-head section $(D \to) F - E (\to I)$ is hit by E. However, D and C are not c-separated by E since the route (D, F, E, C) is not intervented by E. The moral graph $\mathcal{G}^m$ of $\mathcal{G}$ is shown in Fig. 1(b), where edges $C - D$ and $F - G$ are added due to moralization. ■



(a) (b)

Figure 1: (a) a chain graph $\mathcal{G}$; (b) its moral graph $\mathcal{G}^m$.

2.2 Separation Trees

In this subsection, we introduce the notion of *separation trees* which is used to facilitate the representation of the decomposition. The concept is similar to the junction tree of cliques and the independence tree introduced for DAG as 'd-separation trees'(Xie et al., 2006).

Let $\mathcal{C} = \{C_1, \cdots, C_H\}$ be a collection of distinct variable sets such that for $h = 1, \cdots, H$, $C_h \subseteq V$. Let $\mathcal{T}$ be a tree where each node corresponds to a distinct variable set in $\mathcal{C}$, to be displayed as a triangle (see, for example, Fig. 2). The term 'node' is used for a separation tree to distinguish from the term 'vertex' for a graph in general. An undirected edge $e = (C_i, C_j)$ connecting nodes C_i and C_j in $\mathcal{T}$ is attached with a *separator* $S = C_i \cap C_j$, which is displayed as a rectangle. A separator S is *connected to a node* C if there is some other node C', such that S attaches to the edge (C, C'). Removing an edge e or equivalently, removing a separator S from $\mathcal{T}$ splits $\mathcal{T}$ into two subtrees $\mathcal{T}_1$ and $\mathcal{T}_2$ with node sets $\mathcal{C}_1$ and $\mathcal{C}_2$ respectively. We use $V_i = \cup_{C \in \mathcal{C}_i} C$ to denote the unions of the vertices contained in the nodes of the subtree $\mathcal{T}_i$ for $i = 1, 2$.

Definition 2 *A tree $\mathcal{T}$ with node set $\mathcal{C}$ is said to be a* separation tree *for a chain graph $\mathcal{G} = (V, E)$ if*

1. $\cup_{C \in \mathcal{C}} C = V$, *and*
2. *for any separator S in $\mathcal{T}$ with V_1 and V_2 defined as above by removing S, we have $\langle V_1 \backslash S, V_2 \backslash S \,|\, S \rangle_{\mathcal{G}}^{sep}$.*

Notice that a separator is defined in terms of a tree whose nodes consist of variable sets, while the c-separator is defined based on a chain graph. In general, these two concepts are not related, though for a separation tree its separator must be some corresponding c-separator in the underlying chain graph.

Example 1. (Continued). Suppose that

$$\mathcal{C} = \{\{A,B,C\}, \{B,C,D\}, \{C,D,E\}, \{D,E,F\}, \{E,I,J\}, \{D,F,G,H,K\}\}$$

is a collection of vertex sets. A separation tree $\mathcal{T}$ of $\mathcal{G}$ in Fig. 1(a) with node set $\mathcal{C}$ is shown in Fig. 2. If we delete the separator $\{D,E\}$, we obtain two subtrees $\mathcal{T}_1$ and $\mathcal{T}_2$ with node sets $\mathcal{C}_1 = \{\{A,B,C\}, \{B,C,D\}, \{C,D,E\}\}$ and $\mathcal{C}_2 = \{\{D,E,F\}, \{E,I,J\}, \{D,F,G,H,K\}\}$. In $\mathcal{G}$, the separator $S = \{D,E\}$ c-separates $V_1 \backslash S = \{A,B,C\}$ and $V_2 \backslash S = \{F,G,H,I,J,K\}$. ■

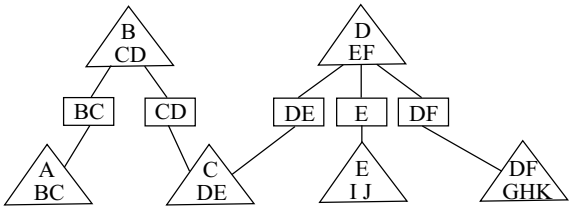


Figure 2: A separation $\mathcal{T}$ of the graph $\mathcal{G}$ in Fig. 1(a).

Not surprisingly, the separation tree could be regarded as a scheme for decomposing the knowledge represented by the chain graph into local subsets. Reciprocally, given a separation tree, we

can combine the information obtained locally to recover the global information, an idea that will be formalized and discussed in subsequent sections.

The definition of separation trees for chain graphs is similar to that of junction trees of cliques, see Cowell et al. (1999) and Lauritzen (1996). Actually, it is not difficult to see that a junction tree of a chain graph $\mathcal{G}$ is also its separation tree. However, we point out two differences here: (a) a separation tree is defined with *c*-separation and it does not require that every node is a clique or that every separator is complete on the moral graph; (b) junction trees are mostly used as inference engines, while our interest in separation trees is mainly derived from its power in facilitating the decomposition of structural learning.

3. Structural Learning of Chain Graphs

In this section, we discuss how separation trees can be used to facilitate the decomposition of the structural learning of chain graphs. Theoretical results are presented first, followed by descriptions of several algorithms that are the summary of the key results in our paper. It should be emphasized that even with perfect knowledge on the underlying distribution, any two chain graph structures in the same equivalence class are indistinguishable. Thus, we can only expect to recover a pattern from the observed data, that is, an equivalence class to which the underlying chain graph belongs. To this end, we provide two algorithms: one addresses the issue of learning the skeleton and the other focuses on extending the learned skeleton to an equivalence class. We also discuss at the end of the section the problem of constructing separation trees. Throughout the rest of the paper, we assume that any distribution under consideration is faithful with respect to some underlying chain graph.

3.1 Theoretical Results

It is known that for P faithful to a chain graph $\mathcal{G} = (V,E)$, an edge (u,v) is in the skeleton $\mathcal{G}'$ if and only if $X_u \not\perp\!\!\!\perp X_v \,|\, X_S$ for any $S \subseteq V \setminus \{u,v\}$ (see Studený 1997, Lemma 3.2 for a proof). Therefore, learning the skeleton of $\mathcal{G}$ reduces to searching for *c*-separators for all vertex pairs. The following theorem shows that with a separation tree, one can localize the search into one node or a small number of tree nodes.

Theorem 3 *Let $\mathcal{T}$ be a separation tree for a chain graph $\mathcal{G}$. Then vertices u and v are c-separated by some set $S_{uv} \subset V$ in $\mathcal{G}$ if and only if one of the following conditions hold:*

1. *u and v are not contained together in any node C of $\mathcal{T}$,*
2. *u and v are contained together in some node C, but for any separator S connected to C, $\{u,v\} \nsubseteq S$, and there exists $S'_{uv} \subseteq C$ such that $\langle u, v \,|\, S'_{uv} \rangle^{sep}_{\mathcal{G}}$,*
3. *u and v are contained together in a node C and both of them belong to some separator connected to C, but there is a subset S'_{uv} of either $\bigcup_{u \in C'} C'$ or $\bigcup_{v \in C'} C'$ such that $\langle u, v \,|\, S'_{uv} \rangle^{sep}_{\mathcal{G}}$.*

For DAGs, condition 3 in Theorem 3 is unnecessary, see Xie et al. (2006, Theorem 1). However, the example below indicates that this is no longer the case for chain graphs.

Example 1. (Continued). Consider the chain graph in Fig. 1(a) and its separation tree in Fig. 2. Let $u = D$ and $v = E$. The tree nodes containing u and v together are $\{C,D,E\}$ and $\{D,E,F\}$. Since the

separator $\{D,E\}$ is connected to both of them, neither condition 1 nor 2 in Theorem 3 is satisfied. Moreover, $u \not\perp\!\!\!\perp v|S$ for $S = \emptyset, \{C\}$ or $\{F\}$. However, we have $u \perp\!\!\!\perp v|\{C,F\}$. Since $\{C,F\} = S'$ is a subset of both $\bigcup_{u\in C'} C' = \{B,C,D\} \cup \{C,D,E\} \cup \{D,E,F\} \cup \{D,F,G,H,K\} = \{B,C,D,E,F,G,H,K\}$ and $\bigcup_{v\in C'} C' = \{C,D,E\} \cup \{D,E,F\} \cup \{E,I,J\} = \{C,D,E,F,I,J\}$, condition 3 of Theorem 3 applies. ■

Given the skeleton of a chain graph, we extend it into the equivalence class by identifying and directing all the complex arrows, to which the following result is helpful.

Proposition 4 *Let $\mathcal{G}$ be a chain graph and $\mathcal{T}$ a separation tree of $\mathcal{G}$. For any complex κ in $\mathcal{G}$, there exists some tree node C of $\mathcal{T}$ such that* $\mathrm{par}(\kappa) \subseteq C$.

By Proposition 4, to identify the parents for each complex, we need only pay attention to those vertex pairs contained in each tree node.

3.2 Skeleton Recovery with Separation Tree

In this subsection, we propose an algorithm based on Theorem 3 for the identification of chain graph skeleton with separation tree information.

Let $\mathcal{G}$ be an unknown chain graph of interest and P be a probability distribution that is faithful to it. The algorithm, summarized as Algorithm 1, is written in its population version, where we assume perfect knowledge of all the conditional independencies induced by P.

Algorithm 1 consists of three main parts. In part 1 (lines 2-10), local skeletons are recovered in each individual node of the input separation tree. By condition 1 of Theorem 3, edges deleted in any local skeleton are also absent in the global skeleton. In part 2 (lines 11-16), we combine all the information obtained locally into a partially recovered global skeleton which may have extra edges not belonging to the true skeleton. Finally, we eliminate such extra edges in part 3 (lines 17-22).

The correctness of Algorithm 1 is proved in Appendix B. We conclude this subsection with some remarks on the algorithm.

Remarks on Algorithm 1:

1. Although we assume perfect conditional independence knowledge in Algorithm 1, it remains valid when these conditional independence relations are obtained via performing hypotheses tests on data generated over P as in most real-world problems. When this is the case, we encounter the problem of multiple testing. See Sections 3.4 and 5 for more details.

2. The c-separator set $\mathcal{S}$ is not necessary for skeleton recovery. However, it will be useful later in Section 3.3 when we try to recover the pattern based on the learned skeleton.

3. Part 3 of Algorithm 1 is indispensable as is illustrated by the following example.

Example 1. (Continued) We apply Algorithm 1 to the chain graph $\mathcal{G}$ in Fig. 1(a) and the corresponding separation tree given in Fig. 2. The local skeletons recovered in part 1 of the algorithm are shown in Fig. 3(a). The c-separators found in this part are $S_{BC} = \{A\}$, $S_{CD} = \{B\}$, $S_{EJ} = \{I\}$, $S_{DK} = \{F,G\}$, $S_{DH} = \{F,G\}$, $S_{FG} = \{D\}$, $S_{FH} = \{G\}$ and $S_{HK} = \{G\}$. In part 2, the local skeletons are combined by deleting the edges that are absent in at least one of the local skeletons, leading to the result in Fig. 3(b). The edge $B - C$ is deleted since it is absent in the local skeleton for the tree

Algorithm 1: Skeleton Recovery with a Separation Tree.

Input: A separation tree $\mathcal{T}$ of $\mathcal{G}$; perfect conditional independence knowledge about P.
Output: The skeleton $\mathcal{G}'$ of $\mathcal{G}$; a set $\mathcal{S}$ of c-separators.

1 Set $\mathcal{S} = \emptyset$;
2 **foreach** *Tree node* C_h **do**
3 Start from a complete undirected graph $\mathcal{G}_h$ with vertex set C_h;
4 **foreach** *Vertex pair* $\{u,v\} \subset C_h$ **do**
5 **if** $\exists S_{uv} \subset C_h$ *s.t.* $u \perp\!\!\!\perp v | S_{uv}$ **then**
6 Delete the edge (u,v) in $\mathcal{G}_h$;
7 Add S_{uv} to $\mathcal{S}$;
8 **end**
9 **end**
10 **end**
11 Combine the graphs $\mathcal{G}_h = (C_h, E_h), h = 1, \cdots, H$ into an undirected graph $\mathcal{G}' = (V, \cup_{h=1}^{H} E_h)$;
12 **foreach** *Vertex pair* $\{u,v\}$ *contained in more than one tree node and* $(u,v) \in \mathcal{G}'$ **do**
13 **if** $\exists C_h$ *s.t.* $\{u,v\} \subset C_h$ *and* $(u,v) \notin E_h$ **then**
14 Delete the edge (u,v) in $\mathcal{G}'$;
15 **end**
16 **end**
17 **foreach** *Vertex pair* $\{u,v\}$ *contained in more than one tree node and* $(u,v) \in \mathcal{G}'$ **do**
18 **if** $u \perp\!\!\!\perp v | S_{uv}$ *for some* $S_{uv} \subset \mathrm{ne}_{\mathcal{G}'}(u)$ *or* $\mathrm{ne}_{\mathcal{G}'}(v)$ *such that it is not a subset of any* C_h *with* $\{u,v\} \subset C_h$ **then**
19 Delete the edge (u,v) in $\mathcal{G}'$;
20 Add S_{uv} to $\mathcal{S}$;
21 **end**
22 **end**

node $\{A,B,C\}$. In part 3, we need to check $D-E$ and $D-F$. $D-E$ is deleted since $D \perp\!\!\!\perp E | \{C,F\}$, and we record $S_{DE} = \{C,F\}$. The recovered skeleton is finally shown in Fig. 3(c). ■

3.3 Complex Recovery

In this subsection, we propose Algorithm 2 for finding and orienting the complex arrows of $\mathcal{G}$ after obtaining the skeleton $\mathcal{G}'$ in Algorithm 1. We call this stage of structural learning *complex recovery*. As in the previous subsection, we assume separation tree information and perfect conditional independence knowledge. For simplicity, let S^c denote $V \backslash S$ for any vertex set $S \subseteq V$.

Example 1. (Continued) After performing Algorithm 1 to recover the skeleton of $\mathcal{G}$, we apply Algorithm 2 to find and orient all the complex arrows. For example, when we pick $[C,D]$ in line 2 of Algorithm 2 and consider $C-E$ in line 3 for the inner loop, we find $S_{CD} = \{B\}$ and $C \not\perp\!\!\!\perp D | S_{CD} \cup \{E\}$. Therefore, we orient $C \to E$ in line 5. Similarly, we orient $D \to F, F \to K$ and $G \to K$ when considering $[D,C]$ with $D-F$ (in the inner loop), $[F,G]$ with $F-K$ and $[G,F]$ with $G-K$ and observing that $C \not\perp\!\!\!\perp D | S_{CD} \cup \{F\}$ and $F \not\perp\!\!\!\perp G | S_{FG} \cup \{K\}$, where the c-separators $S_{CD} = \{B\}$ and

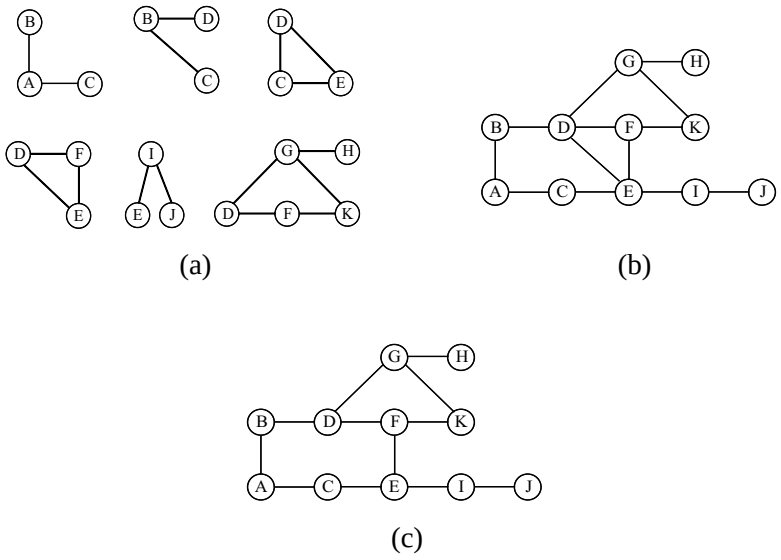

Figure 3: (a) local skeletons recovered in part 1 of Algorithm 1 for all nodes of $\mathcal{T}$ in Fig. 2; (b) partially recovered global skeleton of $\mathcal{G}$ in part 2 of Algorithm 1; (c) completely recovered global skeleton of $\mathcal{G}$ in part 3 of Algorithm 1.

Algorithm 2: Complex Recovery.

Input: Perfect conditional independence knowledge; the skeleton $\mathcal{G}'$ and the set $\mathcal{S}$ of c-separators obtained in Algorithm 1.

Output: The pattern $\mathcal{G}^*$ of $\mathcal{G}$.

```
Initialize G* = G';
foreach Ordered pair [u, v] such that S_uv ∈ S do
    foreach u − w in G* do
        if u ⊥̸ v | S_uv ∪ {w} then
            Orient u − w as u → w in G*;
        end
    end
end
Take the pattern of G*.
```

$S_{FG} = \{K\}$ were obtained during the execution of Algorithm 1. We do not orient any other edge in Algorithm 2. The resulting graph is shown in Fig. 4, which is exactly the pattern for our original chain graph $\mathcal{G}$ in Fig. 1(a). ■

The correctness of Algorithm 2 is guaranteed by Proposition 4. For the proof, see Appendix B.

Remarks on Algorithm 2:

1. As Algorithm 1, Algorithm 2 is valid when independence test is correctly performed using data and again, multiple testing becomes an important issue here.

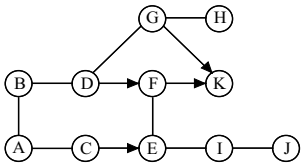

Figure 4: The pattern of $\mathcal{G}$ recovered by applying Algorithm 2.

2. In Algorithm 2, the set $\mathcal{S}$ obtained in Algorithm 1 helps avoid the computationally expensive looping procedure taken in the pattern recovery algorithm in Studený (1997) for complex arrow orientation.

3. Line 9 of Algorithm 2 is necessary for chain graphs in general, see Example 2 below.

4. To get the pattern of $\mathcal{G}^*$ in line 9, at each step, we consider a pair of candidate complex arrows $u_1 \to w_1$ and $u_2 \to w_2$ with $u_1 \neq u_2$, then we check whether there is an undirected path from w_1 to w_2 such that none of its intermediate vertices is adjacent to either u_1 or u_2. If there exists such a path, then $u_1 \to w_1$ and $u_2 \to w_2$ are labeled (as complex arrows). We repeat this procedure until all possible candidate pairs are examined. The pattern is then obtained by removing directions of all unlabeled arrows in $\mathcal{G}^*$.

Example 2. Consider the chain graph $\tilde{\mathcal{G}}$ in Fig. 5(a) and the corresponding separation tree $\tilde{\mathcal{T}}$ in Fig. 5(e). After applying Algorithm 1, we obtain the skeleton $\tilde{\mathcal{G}}'$ of $\tilde{\mathcal{G}}$. In the execution of Algorithm 2, when we pick $[B,F]$ in line 2 and A in line 3, we have $B \perp\!\!\!\perp F | \emptyset$, that is, $S_{BF} = \emptyset$, and find that $B \not\perp\!\!\!\perp F | A$. Hence we orient $B - A$ as $B \to A$ in line 5, which is not a complex arrow in $\tilde{\mathcal{G}}$. Note that we do not orient $A - B$ as $A \to B$: the only chance we might do so is when $u = A$, $v = F$ and $w = B$ in the inner loop of Algorithm 2, but we have $B \in S_{AF}$ and the condition in line 4 is not satisfied. Hence, the graph we obtain before the last step in Algorithm 2 must be the one given in Fig. 5(c), which differs from the recovered pattern in Fig. 5(d). This illustrates the necessity of the last step in Algorithm 2. To see how the edge $B \to A$ is removed in the last step of Algorithm 2, we observe that, if we follow the procedure described in Remark 4 on Algorithm 2, the only chance that $B \to A$ becomes one of the candidate complex arrow pair is when it is considered together with $F \to D$. However, the only undirected path between A and D is simply $A - D$ with D adjacent to B. Hence $B \to A$ stays unlabeled and will finally get removed in the last step of Algorithm 2. ■

3.4 Sample Versions of Algorithms 1 and 2

In this section, we present a brief description on how to obtain a sample version of the previous algorithms and the related issues.

To apply the previous methods to a data set, we proceed in the exactly same way as before. The only difference in the sample version of the algorithms lies in that statistical hypothesis tests are needed to evaluate the predicate on line 5, 13 and 19 in Algorithm 1 and on line 4 in Algorithm 2. Specifically, conditional independence test of two variables u and v given a set C of variables is required. Let the null hypothesis H_0 be $u \perp\!\!\!\perp v | C$ and alternative H_1 be that H_0 may not hold. Generally

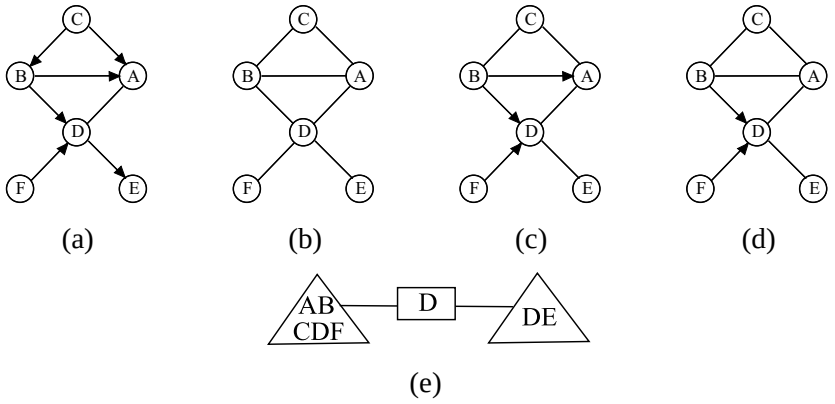

Figure 5: (a) the chain graph $\tilde{\mathcal{G}}$ in Example 2; (b) the skeleton $\tilde{\mathcal{G}}'$ of $\tilde{\mathcal{G}}$; (c) the graphical structure $\tilde{\mathcal{G}}^*$ before executing the last line in Algorithm 2; (d) the graphical structure $\tilde{\mathcal{G}}^*$ obtained after executing Algorithm 2; (e) a separation tree $\tilde{\mathcal{T}}$ for $\tilde{\mathcal{G}}$ in (a).

we can use the likelihood ratio test statistic

$$G^2 = -2\log\frac{\sup\{L(\theta|D) \text{ under } H_0\}}{\sup\{L(\theta|D) \text{ under } H_1\}},$$

where $L(\theta|D)$ is the likelihood function of parameter θ with observed data D. Under H_0, the statistic G^2 asymptotically follows the χ^2 distribution with df degrees of freedom being equal to the difference of the dimensions of parameters for the alternative and null hypothesis (Wilks, 1938).

Let $\mathbf{X}_k$ be a vector of variables and N be the sample size. For the case of a Gaussian distribution, the test statistic for testing $X_i \perp\!\!\!\perp X_j|\mathbf{X}_k$ can be simplified to

$$\begin{aligned} G^2 &= -N \times \log(1-\text{corr}^2(X_i, X_j|\mathbf{X}_k)) \\ &= N \times \log\frac{\det(\hat{\Sigma}_{\{i,k\}\{i,k\}})\det(\hat{\Sigma}_{\{j,k\}\{j,k\}})}{\det(\hat{\Sigma}_{\{i,j,k\}\{i,j,k\}})\det(\hat{\Sigma}_{k,k})}, \end{aligned}$$

which has an asymptotic χ^2 distribution with $df = 1$. Actually, the exact null distribution or a better approximate distribution of G^2 can be obtained based on Bartlett decomposition, see Whittaker (1990) for details.

For the discrete case, let N_s^m be the observed frequency in a cell of $X_s = m$ where s is an index set of variables and m is category of variables X_s. For example, N_{ijk}^{abc} denotes the frequency of $X_i = a$, $X_j = b$ and $\mathbf{X}_k = c$. The G^2 statistic for testing $X_i \perp\!\!\!\perp X_j|\mathbf{X}_k$ is then given by

$$G^2 = 2\sum_{a,b,c} N_{ijk}^{abc} \log\frac{N_{ijk}^{abc} N_k^c}{N_{ik}^{ac} N_{jk}^{bc}},$$

which is asymptotically distributed as a χ^2 distribution under H_0 with degree of freedom

$$\text{df} = (\#(X_i)-1)(\#(X_j)-1)\prod_{X_l \in \mathbf{X}_k} \#(X_l),$$

where $\#(X)$ is the number of categories of variable X.

3.4.1 THE MULTIPLE TESTING PROBLEM

As mentioned in the remarks of Algorithms 1 and 2, when perfect knowledge of the population conditional independence structure is not available, we turn to hypotheses testing for obtaining these conditional independence relations from data and run into the problem of multiple testing. This is because we need to test the existence of separators for multiple edges, and we typically consider more than one candidate separators for each edge.

Although a theoretical analysis of the impact of the multiple testing problem on the overall error rate (see, for example, Drton and Perlman 2008) for the proposed method is beyond the scope of this paper, simulation studies are conducted on randomly generated chain graphs to show the impact of choices of different significance levels on our method in Section 5.1. Based on our empirical study there, we feel that choosing a small significance level (e.g., $\alpha = 0.005$ or 0.01) for the individual tests usually yields good and stable results when the sample size is reasonably large and the underlying graph is sparse.

3.5 Construction of Separation Trees

Algorithms 1 and 2 depend on the information encoded in the separation tree. In the subsection, we address the issue of how to construct a separation tree.

As proposed by Xie et al. (2006), one can construct a d-separation tree from observed data, from domain or prior knowledge of conditional independence relations or from a collection of databases. Their arguments are also valid in the current setting. In the rest of this subsection, we first extend Theorem 2 of Xie et al. (2006), which guarantees that their method for constructing a separation tree from data is valid for chain graph models. Then we propose an algorithm for constructing a separation tree from background knowledge encoded in a labeled block ordering (Roverato and La Rocca, 2006) of the underlying chain graph. We remark that Algorithm 2 of Xie et al. (2006), which constructs d-separation trees from hyper-graphs, also works in the current context.

3.5.1 FROM UNDIRECTED INDEPENDENCE GRAPH TO SEPARATION TREE

For a chain graph $\mathcal{G} = (V,E)$ and a faithful distribution P, an undirected graph $\mathcal{U}$ with a vertex set V is an *undirected independence graph* (UIG) of $\mathcal{G}$ if for any $u,v \in V$,

$$(u,v) \text{ is not an edge of } \mathcal{U} \;\Rightarrow\; u \perp\!\!\!\perp v \mid V \setminus \{u,v\} \text{ in } P. \tag{2}$$

We generalize Theorem 2 of Xie et al. (2006) as follows.

Theorem 5 *Let $\mathcal{G}$ be a chain graph. Then a junction tree constructed from any undirected independence graph of $\mathcal{G}$ is a separation tree for $\mathcal{G}$.*

Since there are standard algorithms for constructing junction trees from UIGs (see Cowell et al. 1999, Chapter 4, Section 4), the construction of separation trees reduces to the construction of UIGs. In this sense, Theorem 5 enables us to exploit various techniques for learning UIGs to serve our purpose.

As suggested by relation (2), one way of learning UIGs from data is testing the required conditional independencies. Agresti (2002) and Anderson (2003) provides general techniques for discrete and Gaussian data respectively. Recently, there are also works on estimating UIGs via ℓ_1-regularization, see, for instance, Friedman et al. (2007) for Gaussian data and Ravikumar et al.

(2008) for the discrete case. Edwards (2000, Chapter 6) presents some other established methods for UIG learning, including those that are valid when X_V includes both continuous and discrete variables. All these methods can be used to construct separation trees from data.

3.5.2 FROM LABELED BLOCK ORDERING TO SEPARATION TREE

When learning graphical models, it is a common practice to incorporate substantive background knowledge in structural learning, mostly to reduce the dimensionality of the search spaces for both computational and subject matter reasons.

Recently, Roverato and La Rocca (2006) studied in detail a general type of background knowledge for chain graphs, which they called *labeled block ordering*. We introduce this concept here and investigate how it is related to the construction of separation trees.

By summarizing Definitions 5 and 6 in Roverato and La Rocca (2006), we define the labeled block ordering as the following.

Definition 6 *Let $V_1, \cdots, V_k$ be a partition of a set of vertices V. A* labeled block ordering $\mathcal{B}$ *of V is a sequence $(V_i^{l_i}, i = 1, \cdots, k)$ where $l_i \in \{u, d, g\}$ and with the convention that $V_i = V_i^g$. We say a chain graph $\mathcal{G} = (V, E)$ is* $\mathcal{B}$-consistent *if*

1. *every edge connecting vertices $A \in V_i$ and $B \in V_j$ for $i \neq j$ is oriented from $A \to B$ if $i < j$;*
2. *for every $l_i = u$, the subgraph $\mathcal{G}_{V_i}$ is a UG;*
3. *for every $l_i = d$, the subgraph $\mathcal{G}_{V_i}$ is a DAG;*
4. *for every $l_i = g$, the subgraph $\mathcal{G}_{V_i}$ may have both directed and undirected edges.*

Example 1. (Continued) Let $V_1 = \{A, B, C, D, E, F\}$, $V_2 = \{G, H, K\}$ and $V_3 = \{I, J\}$. Then Fig. 6 shows that for a labeled block ordering $\mathcal{B} = (V_1^g, V_2^g, V_3^d)$, $\mathcal{G}$ in Fig. 1(a) is $\mathcal{B}$-consistent. ■

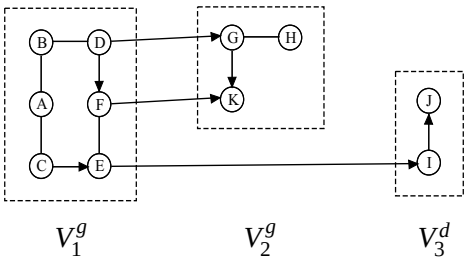

Figure 6: A labeled block ordering $\mathcal{B} = (V_1^g, V_2^g, V_3^d)$ for which $\mathcal{G}$ in Fig. 1(a) is $\mathcal{B}$-consistent.

To show how labeled block ordering helps learning separation trees, we start with the following simple example.

Example 3. Suppose that the underlying chain graph is the one in Fig. 7(a) which is $\mathcal{B}$-consistent with $\mathcal{B} = \{V_1^g, V_2^g, V_3^g\}$. Then for $V_1 = \{A, B\}, V_2 = \{C, D\}$ and $V_3 = \{E, F\}$, we have $V_1 \perp\!\!\!\perp V_3 | V_2$. Together with the total ordering on them, we can construct the DAG in Fig. 7(b) with vertices as

blocks $V_i,\ i = 1,2,3$, which depicts the conditional independence structures on the three blocks. By taking the junction tree of this DAG and replacing the blocks by the vertices they contain, we obtain the tree structure in Fig. 7(c). This is a separation tree of the chain graph in Fig. 7(a). ■

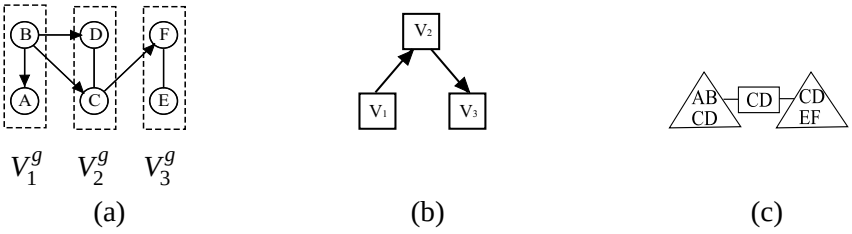

Figure 7: (a) a chain graph with a labeled block ordering; (b) the DAG constructed for the blocks; (c) the tree structure obtained from the junction tree of the DAG in (b).

Below we propose Algorithm 3 for constructing a separation tree from labeled block ordering knowledge. The idea is motivated by the preceding toy example. By omitting independence structures within each block, we can treat each block as a vertex in a DAG. The total ordering on the blocks and the conditional independence structures among them enable us to build a DAG on these blocks. By taking the junction tree of this particular DAG, we obtain a separation tree of the underlying chain graph model.

Algorithm 3: Separation Tree Construction with Labeled Block Ordering.

Input: A labeled block ordering $\mathcal{B} = (V_i^{l_i}, i = 1, \cdots, k)$ of V; perfect conditional independence knowledge.

Output: A separation tree $\mathcal{T}$ of $\mathcal{G}$.

1 Construct a DAG $\mathcal{D}$ with blocks $V_i, i = 1, \cdots, k$;
2 Construct a junction tree $\mathcal{T}$ by triangulating $\mathcal{D}$;
3 In $\mathcal{T}$, replace each block V_i by the original vertices it contains.

We note that a labeled block ordering gives a total ordering of the blocks $V_i, i = 1, \cdots, k$. Given a total ordering of the vertices of a DAG, one can use the Wermuth-Lauritzen algorithm (Spirtes et al., 2000; Wermuth and Lauritzen, 1983) for constructing (the equivalence class of) the DAG from conditional independence relations. Spirtes et al. (2000) also discussed how to incorporate the total ordering information in the PC algorithm for constructing DAGs from conditional independence relations. Since these approaches rely only on conditional independence relations, they can be used in Algorithm 3 for constructing the DAG $\mathcal{D}$. The only difference is that each vertex represents a random vector rather than a random variable now. The correctness of Algorithm 3 is proved in Appendix B.

3.5.3 SEPARATION TREE REFINEMENT

In practice, the nodes of a separation tree constructed from a labeled block ordering or other methods may still be large. Since the complexities of our skeleton and complex recovery algorithms are largely dominated by the cardinality of the largest node on the separation tree, it is desirable to further refine our separation tree by reducing the sizes of the nodes. To this end, we propose the following algorithm.

Algorithm 4: Separation Tree Refinement.

Input: A crude separation tree $\mathcal{T}_c$ for $\mathcal{G}$; perfect conditional independence knowledge.
Output: A refined separation tree $\mathcal{T}$ for $\mathcal{G}$.

1 Construct an undirected independence subgraph over each node of $\mathcal{T}_c$;
2 Combine the subgraphs into a global undirected independence graph $\bar{\mathcal{G}}$ whose edge set is the union of all edge sets of subgraphs;
3 Construct a junction tree $\mathcal{T}$ of $\bar{\mathcal{G}}$.

If the current separation tree contains a node whose cardinality is still relatively large, the above algorithm can be repeatedly used until no further refinement is available. However, we remark that the cardinality of the largest node on the separation tree is eventually determined by the sparseness of the underlying chain graph together with other factors including the specific algorithms for constructing undirected independence subgraphs and junction tree. The correctness of the algorithm is proved in Appendix B.

4. Computational Complexity Analysis

In this section, we investigate the computational complexities of Algorithms 1 and 2 and compare them with the pattern recovery algorithm proposed by Studený (1997). We divide our analysis into two stages: (a) skeleton recovery stage (Algorithm 1); (b) complex recovery stage (Algorithm 2). In each stage, we start with a discussion on Studený's algorithm and then give a comprehensive analysis of ours.

4.1 Skeleton Recovery Stage

Let $\mathcal{G} = (V,E)$ be the unknown chain graph, p the number of vertices and e the number of edges, including both lines and arrows. In Studený's algorithm, to delete an edge between a vertex pair u and v, we need to check the independence of u and v conditional on all possible subsets S of $V\backslash\{u,v\}$. Therefore, the complexity for investigating each possible edge in the skeleton is $O(2^p)$ and hence the complexity for constructing the global skeleton is $O(p^2 2^p)$.

For Algorithm 1, suppose that the input separation tree has H nodes $\{C_1,\cdots,C_H\}$ where $H \leq p$ and $m = \max\{\text{card}(C_h), 1 \leq h \leq H\}$. The complexity for investigating all edges within each tree node is thus $O(m^2 2^m)$. Thus, the complexity for the first two parts of Algorithm 1 is $O(Hm^2 2^m)$. For the analysis of the third step, suppose that $k = \max\{\text{card}(S), S \in \mathcal{T}\}$ is the cardinality of the largest separator on the separation tree. Since the tree with H nodes has $H-1$ edges, we also have $H-1$ separators. Thus, the edge to be investigated in step 3 is $O(Hk^2)$. Then, let d be the maximum of the degrees of vertices in the partially recovered skeleton obtained after step 2. By our algorithm,

the complexity for checking each edge is $O(2^d)$. Hence, the total complexity for step 3 is $O(Hk^2 2^d)$. Combining all the three parts, the total complexity for our Algorithm 1 is $O(H(m^2 2^m + k^2 2^d))$. It is usually the case that m, k and d are much smaller than p, and therefore, our Algorithm 1 is computationally less expensive than Studený's algorithm, especially when $\mathcal{G}$ is sparse.

4.2 Complex Recovery Stage

For complex arrow orientation, Studený's algorithm needs to first find a candidate complex structure of some pre-specified length l and then check a collection of conditional independence relations. Finding a candidate structure can be accomplished in a polynomial (of p) time. The complexity of the algorithm is determined by the subsequent investigation on conditional independence relations. Actually, the number of conditional independence relations to be checked for each candidate structure is $2^{p-2} - 1$. Hence, the complexity of Studený's algorithm is exponential in p.

In Algorithm 2, the computational complexity of the large double loop (lines 2-8) is determined by the number of conditional independence relations we check in line 4. After identifying u, w and v, we need only to check one single conditional independence with the conditioning set $S_{uv} \cup \{w\}$, which can be done in $O(1)$ time. The pair $\{u, w\}$ must be connected on $\mathcal{G}'$, thus the number of such pairs is $O(e)$. Since the number of v for each $\{u, w\}$ pair is at most p, we execute line 4 at most $O(pe)$ times. The complexity for the double loop part is thus controlled by $O(pe)$. Next we show that the complexity for taking the pattern of the graph is $O(e^2(p+e))$. As in the remarks on Algorithm 2, in each step, we propose a pair of candidate complex arrows $u_1 \to w_1$ and $u_2 \to w_2$ and then check whether there is an undirected path from w_1 to w_2 whose intermediate vertices are adjacent to neither u_1 nor u_2. This can be done by performing a graph traversal algorithm on an undirected graph which is obtained by deleting all existing arrows on the current graph with the adjacency relations checked on the original graph. By a breadth-first search algorithm, the complexity is $O(p+e)$ (Cormen et al., 2001). Since the number of candidate complex arrow pairs is controlled by $O(e^2)$, the total complexity for finding the pattern is $O(e^2(p+e))$. Since $pe = O(e^2(p+e))$, the total complexity for Algorithm 2 is $O(e^2(p+e))$.

By incorporating the information obtained in the skeleton recovery stage, we greatly reduce the number of conditional independence tests to be checked and hence obtain an algorithm of only polynomial time complexity for the complex recovery stage. The improvement is achieved with additional cost: we need to store the c-separator information S_{uv}'s obtained from Algorithm 1 in the set $\mathcal{S}$. The possible number of $\{u, v\}$ combinations is $O(p^2)$, while the length of S_{uv} is $O(p)$. Hence, the total space we need to store $\mathcal{S}$ is $O(p^3)$, which is still polynomially complex.

4.3 Comparison with a DAG Specific Algorithm When the Underlying Graph is a DAG

In this subsection, we compare our algorithm with Algorithm 1 in Xie et al. (2006) that is designed specifically for DAG structural learning when the underlying graph structure is a DAG. We make this choice of the DAG specific algorithm so that both algorithms can have the same separation tree as input and hence are directly comparable.

Combining the analyses in the above two subsections, we know that the total complexity of our general algorithm is $O(H(m^2 2^m + k^2 2^d) + e^2(p+e))$, while the complexity of the DAG specific algorithm is $O(Hm^2 2^m)$ as claimed in Xie et al. (2006, Section 6). So the extra complexity in the worst case is $O(Hk^2 2^d + e^2(p+e))$. The term that might make a difference is $O(Hk^2 2^d)$, which occurs as the complexity of step 3 in our Algorithm 1 and involves an exponential term in

d. Note that d is defined as the maximum degree of the vertices in the partially recovered skeleton $\mathcal{G}'$ obtained after step 2 of Algorithm 1, where $\mathcal{G}'$ is exactly the skeleton for the underlying DAG in the current situation (i.e., step 3 of Algorithm 1 does not make any further modification to $\mathcal{G}'$ when $\mathcal{G}$ is a DAG). Hence, if the underlying graph is sparse, d is small and the extra complexity $O(Hk^2 2^d + e^2(p+e))$ is well under control.

Therefore, if we believe that the true graph is sparse, the case where our decomposition approach is most applicable, we can apply our general chain graph structural learning algorithm without worrying much about significant extra cost even when the underlying graph is indeed a DAG.

5. Simulation

In this section, we investigate the performance of our algorithms under a variety of circumstances using simulated data sets. We first demonstrate various aspects of our algorithms by running them on randomly generated chain graph models. We then compare our methods with DAG-specific learning algorithms on data generated from the ALARM network, a Bayesian network that has been widely used in evaluating the performance of structural learning algorithms. The simulation results show the competitiveness of our algorithms, especially when the underlying graph is sparse. From now on, we refer to our method as the LCD (Learn Chain graph via Decomposition) method. Algorithms 1 and 2 have been implemented in the R language. All the results reported here are based on the R implementation.

5.1 Performance on Random Chain Graphs

To assess the quality of a learning method, we adopt the way Kalisch and Bühlmann (2007) used in investigating the performance of PC algorithm on Bayesian networks. We perform our algorithms on randomly generated chain graphs and report summary error measures.

5.1.1 DATA GENERATION PROCEDURE

First we discuss the way in which the random chain graphs and random samples are generated. Given a vertex set V, let $p = |V|$ and N denote the average degree of edges (including undirected and pointing out and pointing in) for each vertex. We generate a random chain graph on V as follows:

1. Order the p vertices and initialize a $p \times p$ adjacency matrix A with zeros;

2. For each element in the lower triangle part of A, set it to be a random number generated from a Bernoulli distribution with probability of occurrence $s = N/(p-1)$;

3. Symmetrize A according to its lower triangle;

4. Select an integer k randomly from $\{1, \cdots, p\}$ as the number of chain components;

5. Split the interval $[1, p]$ into k equal-length subintervals $I_1, \cdots, I_k$ so that the set of variables falling into each subinterval I_m forms a chain component C_m;

6. Set $A_{ij} = 0$ for any (i, j) pair such that $i \in I_l, j \in I_m$ with $l > m$.

This procedure then yields an adjacency matrix A for a chain graph with ($A_{ij} = A_{ji} = 1$) representing an undirected edge between V_i and V_j and ($A_{ij} = 1, A_{ji} = 0$) representing a directed edge from V_i to V_j. Moreover, it is not hard to see that $\mathbb{E}[\text{vertex degree}] = N$ where an adjacent vertex can be linked by either an undirected or a directed edge.

Given a randomly generated chain graph $\mathcal{G}$ with ordered chain components $C_1, \cdots, C_k$, we generate a Gaussian distribution on it via the incomplete block-recursive regression as described in Wermuth (1992). Let X_m be the $|C_m| \times 1$ random vector, and $X = (X_k^T, \cdots, X_1^T)^T$. Then we have the block-recursive regression system as

$$B^* X = W^*,$$

where

$$B^* = \begin{pmatrix} \Sigma^{k,k} & \Sigma^{k,k-1} & \cdots & \Sigma^{k,1} \\ 0 & \Sigma^{k-1,k-1.k} & \cdots & \Sigma^{k-1,1.k} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & \Sigma^{1,1.23\cdots k} \end{pmatrix}.$$

Let

$$T = \begin{pmatrix} \Sigma^{k,k} & & 0 \\ & \ddots & \\ 0 & & \Sigma^{1,1.23\cdots k} \end{pmatrix}$$

be the block-diagonal part of B^*. Each block diagonal element $\Sigma^{i,i.i+1\cdots k}$ of B^* is the inverse covariance matrix of X_i conditioning on $(X_{i+1}, \cdots, X_k)$, an element of which is set to be zero if the corresponding edge within the chain component is missing. The upper triangular part of B^* has all the conditional covariances between X_i and $(X_1, \cdots, X_{i-1})$. The zero constraints on the elements correspond to missing directed edges among different components. Finally, $W^* \sim N(0, T)$.

For the chain component C_i, suppose the corresponding vertices are $V_{i_1}, \cdots, V_{i_r}$, and in general, let $B^*[V_l, V_m]$ be the element of B^* that corresponds to the vertex pair (V_l, V_m). In our simulation, we generate the B^* matrix in the following way:

1. For the diagonal block $\Sigma^{i,i.i+1\cdots k}$ of B^*, for $1 \le j < j' \le r$, we fix $B^*[V_{i_j}, V_{i_j}] = 1$ and set $B^*[V_{i_j}, V_{i_{j'}}] = 0$ if the vertices V_{i_j} and $V_{i_{j'}}$ are non-adjacent in C_i and otherwise sampled randomly from $(-1.5/r, -0.5/r) \cup (0.5/r, 1.5/r)$, and finally we symmetrize the matrix according to its upper triangular part.

2. For $\Sigma^{i,j.i+1\cdots k}, 1 \le j \le i-1$, an element $B^*[V_l, V_m]$ is set to be zero if $V_l \in C_i$ is not pointed to by an arrow starting from $V_m \in C_1 \cup \cdots \cup C_{i-1}$, and sampled randomly from $(-1.5/r, -0.5/r) \cup (0.5/r, 1.5/r)$ otherwise.

3. If any of the block diagonal elements in B^* is not positive semi-definite, we repeat Step (1) and (2).

After setting up the B^* matrix, we take its block diagonal to obtain the T matrix. For fixed B^* and T, we first draw i.i.d. samples of W^* from $N(0, T)$, and then pre-multiply them by $(B^*)^{-1}$ to get random samples of X. We remark that faithfulness is not necessarily guaranteed by the current sampling procedure and quantifying the deviation from the faithfulness assumption is beyond the scope of this paper.

5.1.2 PERFORMANCE UNDER DIFFERENT SETTINGS

We examine the performance of our algorithm in terms of three error measures: (a) the true positive rate (TPR) and (b) the false positive rate (FPR) for the skeleton and (c) the structural Hamming distance (SHD) for the pattern. In short, TPR is the ratio of # (correctly identified edge) over total number of edges, FPR is the ratio of # (incorrectly identified edge) over total number of gaps and SHD is the number of legitimate operations needed to change the current pattern to the true one, where legitimate operations are: (a) add or delete an edge and (b) insert, delete or reverse an edge orientation. In principle, a large TPR, a small FPR and a small SHD indicate good performance.

In our simulation, we change three parameters p (the number of vertices), n (sample size) and N (expected number of adjacent vertices) as follows:

- $p \in \{10, 40, 80\}$,
- $n \in \{100, 300, 1000, 3000, 10000, 30000\}$,
- $N \in \{2, 5\}$.

For each (p, N) combination, we first generate 25 random chain graphs. We then generate a random Gaussian distribution based on each graph and draw an identically independently distributed (i.i.d.) sample of size n from this distribution for each possible n. For each sample, three different significance levels ($\alpha = 0.005,\ 0.01$ or 0.05) are used to perform the hypothesis tests. We then compare the results to access the influence of the significance testing level on the performance of our algorithms. A separation tree is obtained through the following 'one step elimination' procedure:

1. We start from a complete UIG over all p vertices;
2. We test zero partial correlation for each element of the sample concentration matrix at the chosen significance level α and delete an edge if the corresponding test doesn't reject the null hypothesis;
3. An UIG is obtained after Step 2 and its junction tree is computed and used as the separation tree in the algorithms.

The plots of the error measures are given in Fig. 8, 9 and 10. From the plots, we see that: (a) our algorithms yield better results on sparse graphs ($N = 2$) than on dense graphs ($N = 5$); (b) the TPR increases with sample size while the SHD decreases; (c) the behavior of FPR is largely regulated by the significance level α used in the individual tests and has no clear dependence on the sample size (Note that FPRs and their variations in the middle columns of Fig. 8, 9 and 10 are very small since the vertical axes have very small scales); (d) large significance level α(=0.05) typically yields large TPR, FPR and SHD while the advantage in terms of a larger TPR (compared to $\alpha = 0.005$ or 0.01) fades out as the sample size increases and the disadvantage in terms of a larger SHD becomes much worse; (e) accuracy in terms of TPR and SHD based on $\alpha = 0.005$ or $\alpha = 0.01$ is very close while choosing $\alpha = 0.005$ does yield a consistently (albeit slightly) lower FPR across all the settings in the current simulation. Such empirical evidence suggests that in order to account for the multiple testing problem, we can choose a small value (say $\alpha = 0.005$ or 0.01 for the current example) for the significance level of individual tests. However, the optimal value for a desired overall error rate may depend on the sample size and the sparsity of the underlying graph.

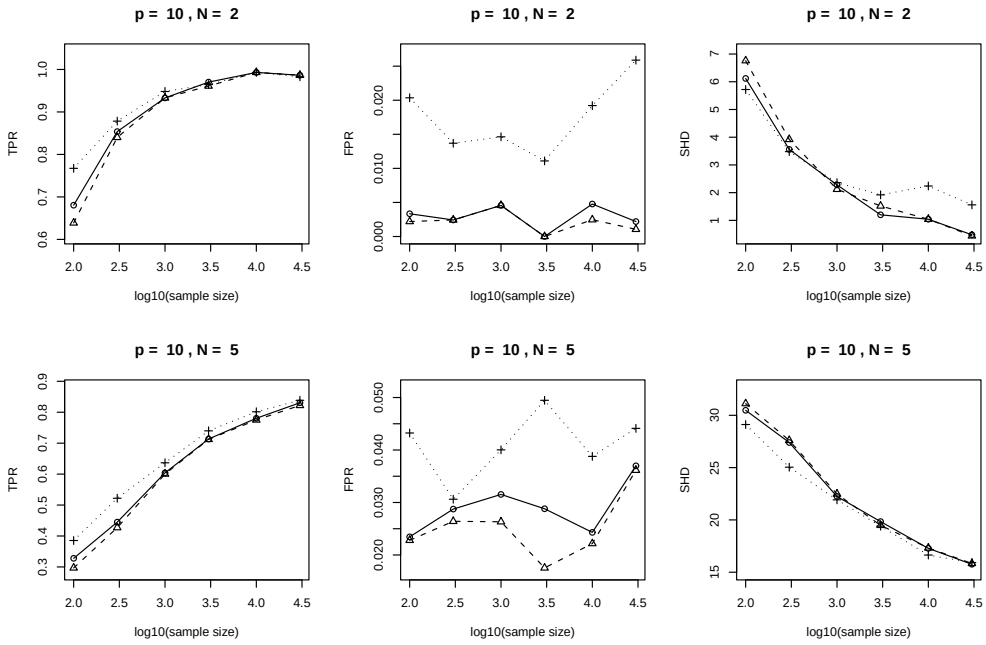

Figure 8: Error measures of the algorithms for randomly generated Gaussian chain graph models: average over 25 repetitions with 10 variables. The two rows correspond to $N = 2$ and $N = 5$ cases and the three columns give three error measures: TPR, FPR and SHD in each setting respectively. In each plot, the solid/dashed/dotted lines correspond to significance levels $\alpha = 0.01/0.005/0.05$.

Finally, we look at how our method scales with the sample size, which is not analyzed explicitly in Section 4. The average running times vs. the sample sizes are plotted in Fig. 11. It can be seen that: (a) the average run time scales approximately linearly with $\log(\text{sample size})$; and (b) the scaling constant depends on the sparsity of the graph. The simulations were run on an Intel Core Duo 1.83GHz CPU.

5.2 Learning the ALARM Network

As we have pointed out in Section 1, Bayesian networks are special cases of chain graphs. It is of interest to see whether our general algorithms still work well when the data are actually generated from a Bayesian network. For this purpose, in this subsection, we perform simulation studies on both Gaussian and discrete case for the ALARM network in Fig. 12 and compare our algorithms for general chain graphs with those specifically designed for Bayesian networks. The network was first proposed in Beinlich et al. (1989) as a medical diagnostic network.

5.2.1 THE GAUSSIAN CASE

In the Gaussian case, for each run of the simulation, we repeat the following steps:

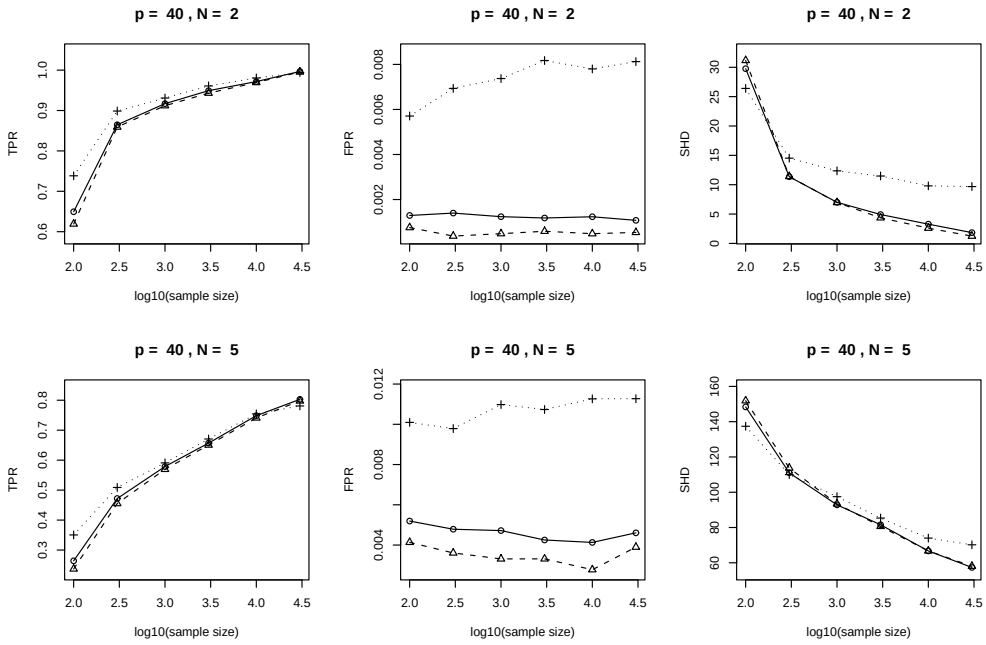

Figure 9: Error measures of the algorithms for randomly generated Gaussian chain graph models: average over 25 repetitions with 40 variables. Display setup is the same as in Fig. 8.

1. A Gaussian distribution on the network is generated using a recursive linear regression model, whose coefficients are random samples from the uniform distribution on $(-1.5,-0.5)\cup(0.5,1.5)$ and residuals are random samples from $N(0,1)$.

2. A sample of size n is generated from the distribution obtained at step 1.

3. We run the LCD algorithms, the DAG learning algorithms proposed in Xie et al. (2006) and the PC algorithm implemented in the R package `pcalg` (Kalisch and Bühlmann, 2007) all with several different choices of the significance level α. The one step elimination procedure described in Section 5.1.2 was used to construct the separation trees for the LCD and DAG methods.

4. We record the number of extra edges (FP), the number of missing edges (FN) and the structural Hamming distance (SHD) compared with the true pattern for all the three learned patterns.

We performed 100 runs for each sample size $n \in \{1000, 2000, 5000, 10000\}$. For each sample, we allow three different significance levels $\alpha \in \{0.05, 0.01, 0.005\}$ for all the three methods. Table 1 documents the averages and standard errors (in parentheses) from the 100 runs for each method-parameter-sample size combination.

As shown in Table 1, compared with the DAG method (Xie et al., 2006), the LCD method consistently yields a smaller number of false positives and the differences in false negatives are consistently smaller than two on recovering the skeleton of the network. The SHDs obtained from

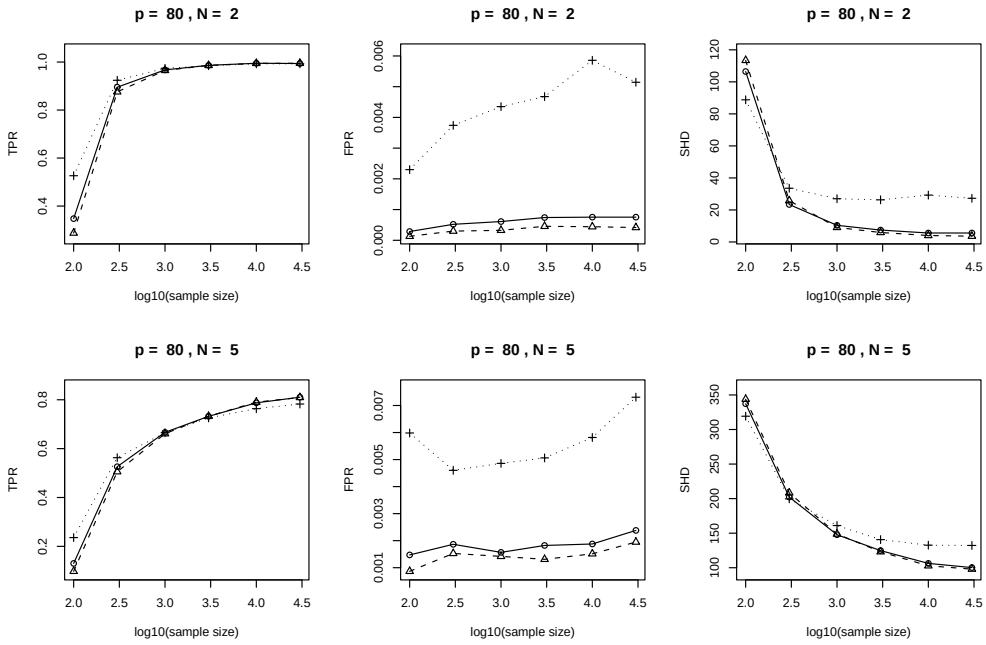

Figure 10: Error measures of the algorithms for randomly generated Gaussian chain graph models: average over 25 repetitions with 80 variables. Display setup is the same as in Fig. 8.

our algorithms are usually comparable to those from the DAG method when $\alpha = 0.05$ and the difference is usually less than five when $\alpha = 0.01$ or 0.005. Moreover, we remark that as sample size grows, the power of the significance test increases, which leads to better performance of the LCD method as in the case of other hypothesis testing based methods. However, from Table 1, we find that the LCD performance increases more rapidly in terms of SHD. One plausible reason is that in Algorithm 2, we identify complex arrows by rejecting conditional independence hypotheses rather than direct manipulation as in the algorithms specific for DAG and hence have some extra benefit in terms of accuracy as the power of the test becomes greater.

Finally, the LCD method consistently outperforms the PC algorithm in all three error measures. Such simulation results confirm that our method is reliable when we do not know the information that the underlying graph is a DAG, which is usually untestable from data.

5.2.2 THE DISCRETE CASE

In this section, a similar simulation study with discrete data sampled from the ALARM network is performed. The variables in the network are allowed to have two to four levels. For each run of the simulation, we repeat the following steps:

1. For each variable X_i and fixed configuration pa_i of its parents, we define the conditional probability $P(X_i = j|pa_i) = r_j / \sum_{k=1}^{L} r_k$, where L is the number of levels of X_i and $\{r_1, \cdots, r_L\}$ are random numbers from the Uniform(0,1) distribution.

2. A sample of size n is generated from the above distribution.

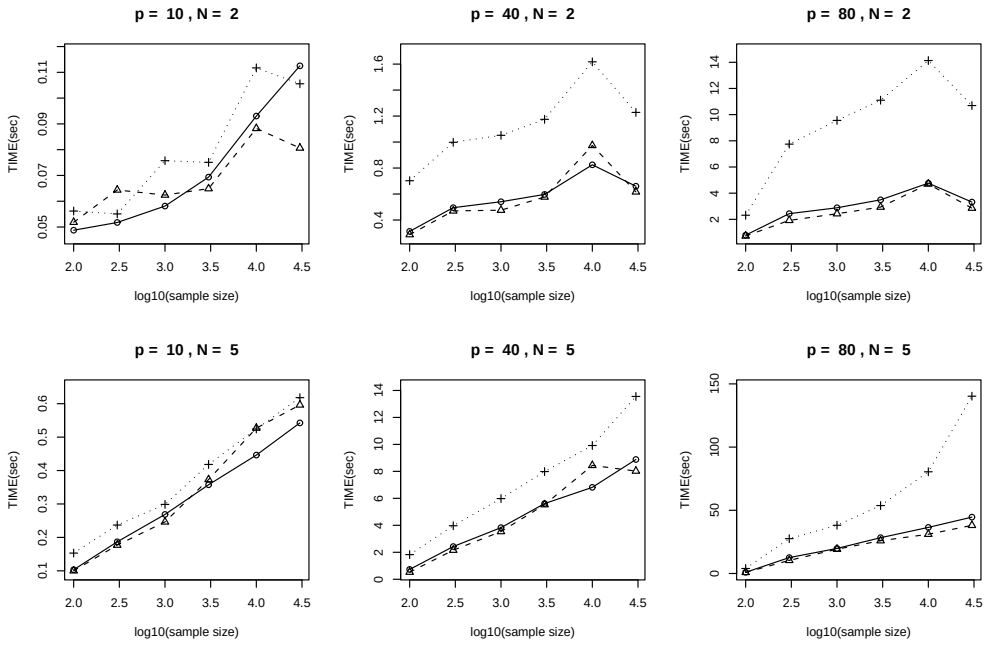

Figure 11: Running times of the algorithms on randomly generated Gaussian chain graph models: average over 25 repetitions. The two rows correspond to $N = 2$ and 5 cases and the three columns represent $p = 10,\ 40$ and 80 respectively. In each plot, the solid/dashed/dotted lines correspond to significance levels $\alpha = 0.01/0.005/0.05$.

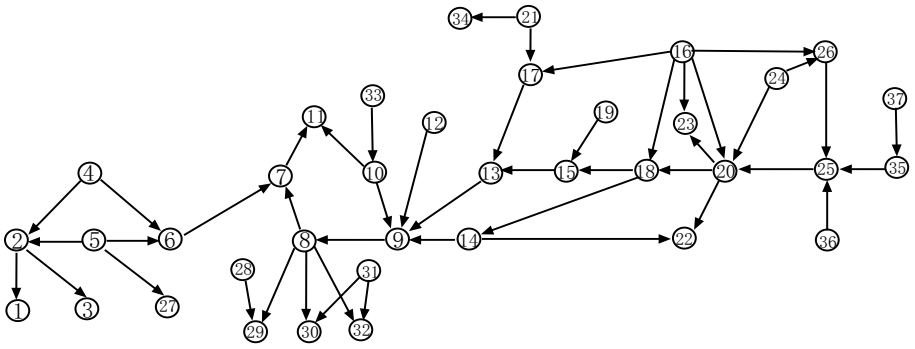

Figure 12: The ALARM network.

3. We run three algorithms designed specifically for DAG that have been shown to have a good performance: MMHC (Max-Min Hill Climbing: Tsamardinos et al., 2006), REC (Recursive: Xie and Geng, 2008) and SC (Sparse Candidate: Friedman et al., 1999) with several different choice of parameters. We also perform the LCD learning algorithm with different choices of the significance level. For the LCD method, a grow-shrink Markov blanket selection is

performed on the data to learn the UIG and the junction tree of the UIG is supplied as the separation tree for the algorithm.

4. For each algorithm, we recorded the FP, FN and SHD of the recovered pattern under each choice of the learning parameter.

We performed 100 runs for each of the four different sample sizes $n \in \{1000, 2000, 5000, 10000\}$, and in each run, we allow the following choices of the learning parameters:

Alg (Level α)	$n = 1000$	$n = 2000$	$n = 5000$	$n = 10000$
MMHC	(0.27, 7.77, 34.0)	(0.16, 5.15, 27.9)	(0.08, 2.61, 20.6)	(0.03, 1.53, 16.0)

Table 2: Simulation results for discrete samples from the ALARM network. Averages and standard errors for (FP, FN, SHD) from 100 runs.

- For MMHC, REC and LCD, we allow three different significance levels $\alpha \in \{0.05, 0.01, 0.005\}$; and
- For SC, we allow the learning parameters to be either 5 or 10.

The means and standard errors from the 100 runs of all the four learning methods are summarized in Table 2. It can be seen that REC could yield the best result when the learning parameter is appropriately chosen. However, all the other methods are more robust against the choice of learning parameters. For the LCD method, all the three error measures: FP, FN and SHD are consistently comparable to those of methods specifically designed for DAG. Moreover, as in the Gaussian case, the power of the tests used in the LCD method grows as the sample size become larger, which makes the LCD method even more competitive, especially in terms of SHD. For example, when the sample size reaches 10000, the LCD method with $\alpha = 0.01$ or 0.005 outperforms the sparse candidate method with parameters 5 or 10.

6. Discussion

In this paper, we presented a computationally feasible method for structural learning of chain graph models. The method can be used to facilitate the investigation of both response-explanatory and symmetric association relations among a set of variables simultaneously within the framework of chain graph models, a merit not shared by either Bayesian networks or Markov networks.

Simulation studies illustrate that our method yields good results in a variety of situations, especially when the underlying graph is sparse. On the other hand, the results also reveal that the power of the significance test has an important influence on the performance of our method. With fixed number of samples, one can expect a better accuracy if we replace the asymptotic test used in our implementation with an exact test. However, there is a trade-off between accuracy and computational time.

The results in this paper also raised a number of interesting questions for future research. We briefly comment on some of those questions here. First, the separation tree plays a key role in Algorithms 1 and 2. Although the construction of separation trees has been discussed in Xie et al. (2006) and Section 3.5 here, we believe that there is room for further improvements. Second, we have applied hypothesis testing for the detection of local separators in Algorithm 1 and also in complex arrow determination in Algorithm 2. It shall be interesting to see whether there exists some alternative approach, preferably not based on hypothesis testing, to serve the same purpose here. A theoretical analysis of the effect of multiple testing on the overall error rate of the procedure is also important. In addition, it is a common practice to incorporate prior information about the order of the variables in graphical modelling. Therefore, incorporation of such information into our algorithms is worth investigation. Finally, our approach might be extendible to the structural learning of chain graph of alternative Markov properties, for example, AMP chain graphs (Andersson et al., 2001) and multiple regression chain graphs (Cox and Wermuth, 1996).

An R language package `lcd` that implements our algorithms is available on the first author's website: `www.stanford.edu/~zongming/software.html`.

Acknowledgments

The authors would like to thank two referees for their valuable suggestions and comments which improve the presentation of the previous version of the paper. We would also like to thank Professor John Chambers and Xiangrui Meng for their help on the simulation study. This research was supported by NSFC (10771007, 10431010, 10721403), 863 Project of China (2007AA01Z437), MSRA and MOE-Microsoft Key Laboratory of Statistics and Information Technology of Peking University. The first author was also supported in part by grants NSF DMS 0505303 and NIH EB R01 EB001988.

Appendix A. Proofs of Theoretical Results

In this part, we give proofs to theorems and propositions. We first give a definition and several lemmas that are to be used in later proofs.

Definition 7 *Let $\mathcal{T}$ be a separation tree for a CG $\mathcal{G}$ with the node set $\mathcal{C} = \{C_1, \cdots, C_H\}$. For any two vertices u and v in $\mathcal{G}$, the* distance between u and v in the tree $\mathcal{T}$ *is defined by*

$$d(u,v) = \min_{C_i \ni u, C_j \ni v} d(C_i, C_j),$$

where $d(C_i, C_j)$ is the distance between nodes C_i and C_j in $\mathcal{T}$. We call C_i and C_j minimizers *for u and v if they minimize the distance $d(C_i, C_j)$.*

Lemma 8 *Let ρ be a route from u to v in a chain graph $\mathcal{G}$, and W the set of all vertices on ρ (W may or may not contain the two end vertices). Suppose that ρ is intervented by $S \subset V$. If $W \subset S$, ρ is also intervented by W and any vertex set containing W.*

Proof Since ρ is intervented by S and $W \subset S$, there must be a non head-to-head section σ of ρ that is hit by S and actually every non head-to-head section of ρ is hit by S. Thus, σ is also hit by W and any vertex set containing W. Hence, ρ is intervented. ■

Lemma 9 *Let $\mathcal{T}$ be a separation tree for a chain graph over vertex set V and K a separator of $\mathcal{T}$ which separates $\mathcal{T}$ into two subtrees $\mathcal{T}_1$ and $\mathcal{T}_2$ with variable sets V_1 and V_2. Suppose that $u \in V_1 \backslash K$, $v \in V_2 \backslash K$ and ρ is a route from u to v in $\mathcal{G}$. Let W denote the set of all vertices on ρ (W may or may not contain the two end vertices). Then ρ is intervented by $W \cap K$ and by any vertex set containing $W \cap K$.*

Proof Since $u \in V_1 \backslash K$ and $v \in V_2 \backslash K$, there must be a sequence from s (may be u) to y (may be v) in $\rho = (u, \cdots, s, t, \cdots, x, y, \cdots, v)$ such that $s \in V_1 \backslash K$, $y \in V_2 \backslash K$ and all vertices from t to x in this sequence are contained in K. Otherwise, every vertex of ρ is either in $V_1 \backslash K$ or in $V_2 \backslash K$. This implies that there exists $w \in V_1 \backslash K$ and $z \in V_2 \backslash K$ on ρ that are adjacent, which is contradictory to the fact that $\langle V_1 \backslash K, V_2 \backslash K | K \rangle_{\mathcal{G}}^{sep}$. Without loss of generality, we can suppose that y is the first vertex (from the left) of ρ that is not in V_1.

Let ρ' be the sub-route of the sequence $(s, t, \cdots, x, y)$, and W' be the vertex set of ρ' excluding s and y. Since $W' \subset K$, we know from Lemma 8 that there is at least one non head-to-head section

(w.r.t. ρ') on ρ' and every non head-to-head section of ρ' is hit by W'. We are to show that there is at least one non head-to-head section of ρ that is hit by K and hence $W \cap K$ as well as any set containing $W \cap K$.

The only problem arises when ρ' is part of a head-to-head section of ρ. Otherwise, there is some non head-to-head section of ρ' that is (part of) a non head-to-head section of ρ.

Thus, we suppose that the head-to-head section of ρ is

$$s' \to s" - \cdots - s - t - \cdots - x - y - \cdots - y" \leftarrow y'.$$

By our assumption on y, we know that $s' \in V_1$. If $s' \in K$, then the non head-to-head section containing s' is hit by K. If $s' \in V_1 \backslash K$ and $y' \in K$, then the non head-to-head section containing y' gives the result. If $s' \in V_1 \backslash K$ and $y' \in V_1 \backslash K$, then we can consider the sub-route starting from y'. This is legitimate since every non head-to-head section of that sub-route is also non head-to-head w.r.t. ρ. Hence, we need only consider the case that $s' \in V_1 \backslash K$ and $y' \in V_2 \backslash K$. In this case, let t' be the last (from left) vertex in this section that is adjacent to s' and x' the first vertex after t' in this section that is adjacent to y'. Since chain graphs cannot have directed pseudocycles, we know that $s' \to t'$ and $y' \to x'$. Then we have $s' \not\perp\!\!\!\perp y' | K$, which is contradictory to the property of separation trees that $\langle V_1 \backslash K, V_2 \backslash K | K \rangle_{\mathcal{G}}^{sep}$. This completes our proof. ■

Lemma 10 *Let u and v be two non adjacent vertices in a chain graph $\mathcal{G}$ and ρ a route from u to v in $\mathcal{T}$. If ρ is not contained in $\mathrm{An}(u) \cup \mathrm{An}(v)$, then ρ is intervented by any subset S of $\mathrm{An}(u) \cup \mathrm{An}(v)$.*

Proof Since ρ is not contained in $\mathrm{An}(u) \cup \mathrm{An}(v)$, there exist four vertices s, t, x and y, such that $\rho = (u, \cdots, s, t, \cdots, x, y, \cdots, v)$, with $\{s, y\} \subset \mathrm{An}(u) \cup \mathrm{An}(v)$ and $\{t, \cdots, x\} \cap [\mathrm{An}(u) \cup \mathrm{An}(v)] = \emptyset$. Then we have $s \to t$ and $x \leftarrow y$, since otherwise t and/or x must be in $\mathrm{An}(u) \cup \mathrm{An}(v)$. Thus, there exists at least one head-to-head section between s and y on ρ such that it is not hit by any subset of $\mathrm{An}(u) \cup \mathrm{An}(v)$. Hence, ρ is intervented by any subset S of $\mathrm{An}(u) \cup \mathrm{An}(v)$. ■

Lemma 11 *Let $\mathcal{T}$ be a separation tree for a chain graph $\mathcal{G}$ over V and C a node of $\mathcal{T}$. Let u and v be two vertices in C which are non adjacent in $\mathcal{G}$. If u and v are not contained simultaneously in any separator connected to C, then there exists a subset S of C which c-separates u and v in $\mathcal{G}$.*

Proof Define

$$S = [\mathrm{An}(u) \cup \mathrm{An}(v)] \cap [C \backslash \{u, v\}].$$

We show below that $\langle u, v | S \rangle_{\mathcal{G}}^{sep}$.

To this end, let ρ be any fixed route from u to v in $\mathcal{G}$. If ρ is not contained in $\mathrm{An}(u) \cup \mathrm{An}(v)$, by Lemma 10, ρ is intervented by S. Otherwise, we divide the problem into the following six possible situations:

1. $u - \cdots - u' \leftarrow x$, $x \neq v$, $x \in C$, where $u - \cdots - u'$ means the first (from left) section of ρ that contains u;
2. $u - \cdots - u' \to x - \cdots - x' \to y$, $x \neq v$, $x \in C$;

3. $u - \cdots - u' \to x - \cdots - x' \leftarrow y$, $x \neq v$, $x \in C$, $y \in C$;

4. $u - \cdots - u' \to x - \cdots - x' \leftarrow y$, $x \neq v$, $x \in C$, $y \notin C$;

5. $u - u' - \cdots - v' - v$, $u - u' - \cdots - v' \to v$ or $u - u' - \cdots - v' \leftarrow v$;

6. $u - \cdots - u' \to x$ or $u - \cdots - u' \leftarrow x$, $x \notin C$.

We prove the desired result situation by situation.

For situation 1, we have that $x \in \mathrm{An}(u)$, which, together with $x \in C$ implies that $x \in S$. The non head-to-head section containing x is hit by S, and ρ is thus intervented.

For situation 2, since $x \in \mathrm{An}(u) \cup \mathrm{An}(v)$ and $x \notin \mathrm{An}(u)$, we have $x \in \mathrm{An}(v)$. Together with $x \in C$, this gives $x \in S$ and the non head-to-head section containing x is hit by S.

For situation 3, since chain graphs do not admit directed pseudocycles, we know that $x \notin \mathrm{An}(u)$ and $y \neq v$. Similar to situation 2, we have $x \in \mathrm{An}(v)$ and hence $y \in \mathrm{An}(v)$. The non head-to-head section containing y is hit by S.

For situation 4, suppose that C' is one of the nodes on $\mathcal{T}$ that contains y. Consider first the case when v belongs to the separator K connected to C and the next node on the path from C to C' on $\mathcal{T}$. By our assumption, $u \notin K$. We divide the problem into the following three cases:

(i) $\{u, \cdots, u'\} \cap S \neq \emptyset$: $u - \cdots - u'$ is hit by S and ρ is hence intervented;

(ii) $\{u, \cdots, u'\} \cap S = \emptyset, \{x, \cdots, x'\} \cap S = \emptyset$: the head-to-head section $x - \cdots - x'$ is not hit by S and ρ is intervented;

(iii) $\{u, \cdots, u'\} \cap S = \emptyset, \{x, \cdots, x'\} \cap S \neq \emptyset$: there must exist some $x^* \in \{x, \cdots, x'\}$ such that $x^* \in C \cap \mathrm{An}(v)$ and $x^* \neq v$. Since $\{u, \cdots, u'\} \cap S = \emptyset$ and $u \perp\!\!\!\perp y | K$, there should be no complex in the induced subgraph of $(u, \cdots, u', x, \cdots, x', y)$. Otherwise, there exists some $u^* \in \{u, \cdots, u'\}$, such that (u^*, y) is an edge on $\left(\mathcal{G}_{\mathrm{An}(u,y,K)}\right)^m$, which implies $u \not\perp\!\!\!\perp y | K$ since $\{u, \cdots, u'\} \cap K = \emptyset$. However, this requires that there is some $u^{**} \in \{u, \cdots, u'\}$ such that (u^{**}, y) is an edge on $\mathcal{G}$, which again implies that $u \not\perp\!\!\!\perp y | K$. Hence, this case can never happen.

Next, we consider the case that $v \notin K$. The assumption that $\{x, \cdots, x'\} \subset \mathrm{An}(v)$ implies that there exists at least one $' \to'$ on the sub-route l' of ρ from y to v. Consider the rightmost one of such arrows, there is no further $' \leftarrow'$ closer to the right end v than it is. Otherwise, any vertex w between them satisfies $w \in \mathrm{An}(u)$ and $w \in \mathrm{de}(v)$, which is contradictory to the fact that $v \in \mathrm{de}(u)$ here. Thus, this case reduces to one of the situations 1, 5 and 6 with u replaced by v.

For situation 5, since u and v are non adjacent, we know that $v' \neq u$ and $u' \neq v$. If $\{u', \cdots, v'\} \cap S = \emptyset$, then $\{u', \cdots, v'\} \cap C \subset \{u, v\}$. We can eliminate vertices from the left such that $\{u', \cdots, v'\} \cap C \subset \{v\}$. This will not influence our result since any non head-to-head section of the sub-route is (part of) a non head-to-head section of ρ. Since $u' \neq v$ and $\{u', \cdots, v'\} \cap C \subset \{v\}$, we have $u' \notin C$. Suppose that $u' \in C'$ and K is the separator related to C and the next node on the path from C to C' on $\mathcal{T}$. Then $u \in K, v \notin K$ and $u' \perp\!\!\!\perp v | K$. However, since $\{u', \cdots, v'\} \cap C \subset \{v\}$, we have $\{u, \cdots, u'\} \cap K = \emptyset$, which is impossible. Hence $\{u', \cdots, v'\} \cap S \neq \emptyset$ and ρ is intervented.

For situation 6, consider first the case that $u - \cdots - u' \leftarrow x$. If $\{u, \cdots, u'\} \cap S \neq \emptyset$, then ρ is intervented by S. Otherwise, suppose that $x \in C'$ and K is the separator connected to C and the next node on the path from C to C' in $\mathcal{T}$. If $v \in K$, then $u \notin K$ and $\{u, \cdots, u'\} \cap K \subset \{v\}$. If $\{u, \cdots, u'\} \cap K = \{v\}$, then it reduces to situation 5. If $\{u, \cdots, u'\} \cap K = \emptyset$, then $u \not\perp\!\!\!\perp x | K$, which is

contradictory to the definition of separation tree. If $v \notin K$, then by the above argument, we must have $u \in K$. Consider the sub-route of ρ starting with x. It is legitimate to do so since any non head-to-head section of the sub-route is also non head-to-head in ρ. By Lemma 9, at least one non head-to-head section is hit by $W \cap K$ where W is the vertex set of the sub-route excluding the two end vertices. We know that $W \cap K \subset S \cup \{u,v\}$. If the non head-to-head section is hit at u or v, we can consider the further sub-route starting at that point and it is again legitimate by the same reason. Finally, we can reduce to the case where $W \cap K \subset S$. Thus, ρ is intervented by S. This also completes the proof of situation 4. For the other case in this situation, all the argument is the same up to the point where $v \notin K$ and $u \in K$. We can consider reversing the vertex sequence, then with u replaced by v, it must be in one of the situations 1 to 4, the second case in situation 6 or the first case in situation 6 with $u \notin K$. This complete the proof of the lemma. ■

Proof of Theorem 3. The sufficiency of condition 1 is given by Lemma 9. The sufficiencies of conditions 2 and 3 are trivial by the definition of c-separation.

Now we show the necessity part of the theorem. If $d(u,v) > 0$, by Lemma 9, any separator K on the path from minimizers C_i to C_j c-separates u and v. If $d(u,v) = 0$, we consider the following two possible cases: (1) u and v are not contained simultaneously in any separator connected to C for some node C on $\mathcal{T}$ containing both u and v; (2) otherwise. For the first case, Lemma 11 shows that there exists some $S' \subset C$ that c-separates u and v. Otherwise, since $\langle u,v|\mathrm{bd}_{\mathcal{G}}(u) \cup \mathrm{bd}_{\mathcal{G}}(v)\rangle_{\mathcal{G}}^{sep}$, $\mathrm{bd}_{\mathcal{G}}(u) \subset \bigcup_{u\in C} C$ and $\mathrm{bd}_{\mathcal{G}}(v) \subset \bigcup_{v\in C} C$, we know that at least one of the conditions 2 and 3 holds.

Proof of Proposition 4. We verify Proposition 4 by contradiction. Let us suppose that u and v are parents of a complex $\kappa = (u, w_1, \cdots, w_k, v), k \geq 1$ in $\mathcal{T}$ and that for any node C on $\mathcal{T}$, $\{u,v\} \cap C \neq \{u,v\}$. Now suppose that $u \in C_1$, $v \in C_2$ and K is the separator related to C_1 and the next node on the path from C_1 to C_2 on $\mathcal{T}$. If $u \notin K$ and $v \notin K$, we must have that $\{w_1, \cdots, w_k\} \cap K \neq \emptyset$. This implies that $u \not\perp\!\!\!\perp v|K$, which is contrary to the definition of separation trees. Hence, without loss of generality, we may suppose that $u \in K$, and this enables us to go one node closer to C_2 on the path. Then after finite steps, we will consider two adjacent nodes on $\mathcal{T}$. Repeating the above argument ensures that $\{u,v\}$ belongs to one of these two nodes.

Appendix B. Proofs for Correctness of the Algorithms

Before proving the correctness of the algorithms, we need several more lemmas.

Lemma 12 *Suppose that u and v are two adjacent vertices in $\mathcal{G}$, then for any separation tree $\mathcal{T}$ for $\mathcal{G}$, there exists a node C in $\mathcal{T}$ which contains both u and v.*

Proof If not, then there exists a separator K on $\mathcal{T}$, such that $u \in V_1 \backslash K$ and $v \in V_2 \backslash K$ where V_i denotes the variable set of the subtree $\mathcal{T}_i$ induced by removing the edge attached by the separator S, for $i = 1$ and 2. This implies $u \perp\!\!\!\perp v|K$, which is impossible. ■

Lemma 13 *Any arrow oriented in line 5 of Algorithm 2 is correct in the sense that it is an arrow with the same orientation in $\mathcal{G}$.*

Proof We prove the lemma by induction. If we don't orient any arrow in line 5, then the lemma holds trivially. Otherwise, suppose $u \to w$ is the first arrow we orient by considering the ordered triple $\langle u, v, w \rangle$, then we show that it cannot be $u - w$ or $u \leftarrow w$ in $\mathcal{G}$. If it is $u - w$ in $\mathcal{G}$, then by Lemma 11, if u and v are not in any separator simultaneously, there exists some $S_{uv} \subset C_h$ such that $u \perp\!\!\!\perp v | S_{uv}$ and $w \in S_{uv}$. Otherwise, $u \perp\!\!\!\perp v | \mathrm{bd}_{\mathcal{G}}(u) \cup \mathrm{bd}_{\mathcal{G}}(v)$, and we know that $w \in \mathrm{bd}_{\mathcal{G}}(u) \cup \mathrm{bd}_{\mathcal{G}}(v) \subset \mathrm{bd}_{\mathcal{G}'}(u) \cup \mathrm{bd}_{\mathcal{G}'}(v)$. Thus we won't orient it as $u \to w$. A similar argument holds for the case when $u \leftarrow w$ in $\mathcal{G}$.

Now suppose that the k-th arrow we orient is correct, let's consider the $k+1$-th. Suppose it's $u' \to w'$ by considering the order triple $\langle u', v', w' \rangle$. Then the above argument holds exactly with u, v and w substituted by u', v' and w'. However, for here, the claim that $\mathrm{bd}_{\mathcal{G}}(u') \cup \mathrm{bd}_{\mathcal{G}}(v') \subset \mathrm{bd}_{\mathcal{G}'}(u') \cup \mathrm{bd}_{\mathcal{G}'}(v')$ holds by the induction assumption. ■

Lemma 14 *Suppose that $\mathcal{H}$ is a graph, if we disorient any non-complex arrow in $\mathcal{H}$, the pattern of $\mathcal{H}$ does not change.*

Proof First, we note that we will not add or delete edge in $\mathcal{H}$, so the skeleton of $\mathcal{H}$ does not change.

Second, we only disorient non-complex arrows, and hence those complexes in $\mathcal{H}$ before disorientation remain complexes after disorientation since the subgraph induced by any complex does not change.

Finally, we show that there will not be new complex. If there appears a new complex, say $u \to w_1 - \cdots, -w_l \leftarrow v$, we must have $l \geq 2$. Since it was not a complex before disorientation, one of the lines in $w_1 - \cdots - w_l$ must be the arrow disoriented. Suppose we have $w_i \to w_{i+1}$ before disorientation, then $w_i \to w_{i+1} - \cdots - w_l \leftarrow v$ was a complex before disorientation. Hence, the disoriented arrow $w_i \to w_{i+1}$ was a complex arrow, which contradicts our assumption. ■

Correctness of Algorithm 1. On the one hand, by Studený (1997, Lemma 3.2), we know that for any chain graph $\mathcal{G}$, there is an edge between two vertices u and v if and only if $u \not\perp\!\!\!\perp v | S$ for any subset S of V. Thus, line 6 of Algorithm only deletes those edges that cannot appear in the true skeleton. So do lines 14 and 19.

On the other hand, if u and v are not adjacent in $\mathcal{G}$, by Theorem 3, it must be under one of the three possible conditions. If it is in condition 1, we will never connect them since we do not connect any vertex pair that is never contained in any node simultaneously. If it is in condition 2, then we will disconnect them in line 6 and line 14. Finally, if it is in condition 3, then either $u \perp\!\!\!\perp v | \mathrm{bd}_{\mathcal{G}}(u)$ or $u \perp\!\!\!\perp v | \mathrm{bd}_{\mathcal{G}}(v)$. By our previous discussion, we know that before starting line 17, we have $\mathrm{bd}_{\mathcal{G}}(u) \subset \mathrm{ne}_{\mathcal{G}'}(u)$ and $\mathrm{bd}_{\mathcal{G}}(v) \subset \mathrm{ne}_{\mathcal{G}'}(v)$ for the $\mathcal{G}'$ at that moment. Thus, we will disconnect u and v in line 19.

Correctness of Algorithm 2. By Proposition 4, Lemma 12 and the correctness of Algorithm 1, we know that every ordered vertex triple $\langle u, v, w \rangle$ in $\mathcal{G}$ with $u \to w$ a complex arrow and v the parent of (one of) the corresponding complex(es) is considered in line 4 of Algorithm 2. If the triple $\langle u, v, w \rangle$ is really in this situation, then we know that $u \not\perp\!\!\!\perp v | S_{uv} \cup \{w\}$, and hence we orient $u - w$ as $u \to w$. Moreover, Lemma 13 prevents us from orienting $u - w$ as $w \to u$ during the execution of Algorithm 2. This proves that we will orient every complex arrow right before starting line 9 in Algorithm 2.

Then by Lemma 13, the $\mathcal{G}^*$ before starting line 9 is a hybrid graph with the same pattern as $\mathcal{G}$. Thus Lemma 14 guarantees that we obtain the pattern of $\mathcal{G}$ after line 9.

Correctness of Algorithm 3. First of all, we show that any conditional independence relation represented by $\mathcal{D}$ is also represented by $\mathcal{G}$. This is straightforward by noting the following two facts:

1. assuming positivity, both DAG models and chain graph models are closed subset of graphoids under 5 axioms, see Pearl (1988) and Studený and Bouckaert (2001);

2. any conditional independence relation used in constructing $\mathcal{D}$ is represented by $\mathcal{G}$.

Then by Xie et al. (2006, Theorem 2), the $\mathcal{T}$ in line 2 is a separation tree of $\mathcal{D}$. With the block vertices substituted, by the definition of separation trees, the output $\mathcal{T}$ of Algorithm 3 is a separation tree of $\mathcal{G}$.

Correctness of Algorithm 4. Xie et al. (2006, Theorem 3) guarantees the correctness of Algorithm 4.
